Message from the Program Chairs <i>Karim Ali and Guido Salvaneschi</i>	0:ix
Message from the Artifact Evaluation Chairs <i>Stefan Winter and Hernan Luis Ponce de Leon</i>	0:xi
Foreword by the President of AITO <i>Eric Jul</i>	0:xiii
List of Authors	0:xv

Regular Papers

Designing Asynchronous Multiparty Protocols with Crash-Stop Failures <i>Adam D. Barwell, Ping Hou, Nobuko Yoshida, and Fangyi Zhou</i>	1:1–1:30
Nested Pure Operation-Based CRDTs <i>Jim Bauwens and Elisa Gonzalez Boix</i>	2:1–2:26
Multi-Graded Featherweight Java <i>Riccardo Bianchini, Francesco Dagnino, Paola Giannini, and Elena Zucca</i>	3:1–3:27
Hoogle \star : Constants and λ -abstractions in Petri-net-based Synthesis using Symbolic Execution <i>Henrique Botelho Guerra, João F. Ferreira, and João Costa Seco</i>	4:1–4:28
Modular Abstract Definitional Interpreters for WebAssembly <i>Katharina Brandl, Sebastian Erdweg, Sven Keidel, and Nils Hansen</i>	5:1–5:28
Dynamically Updatable Multiparty Session Protocols: Generating Concurrent Go Code from Unbounded Protocols <i>David Castro-Perez and Nobuko Yoshida</i>	6:1–6:30
Modular Compilation for Higher-Order Functional Choreographies <i>Luís Cruz-Filipe, Eva Graversen, Lovro Lugović, Fabrizio Montesi, and Marco Peressotti</i>	7:1–7:37
Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It... <i>Jan de Muijnck-Hughes and Wim Vanderbauwhede</i>	8:1–8:28
VeriFx: Correct Replicated Data Types for the Masses <i>Kevin De Porre, Carla Ferreira, and Elisa Gonzalez Boix</i>	9:1–9:45
On Leveraging Tests to Infer Nullable Annotations <i>Jens Dietrich, David J. Pearce, and Mahin Chandramohan</i>	10:1–10:25
super -Charging Object-Oriented Programming Through Precise Typing of Open Recursion <i>Andong Fan and Lionel Parreaux</i>	11:1–11:28

LoRe: A Programming Model for Verifiably Safe Local-First Software (Extended Abstract) <i>Julian Haas, Ragnar Mogk, Elena Yanakieva, Annette Bieniusa, and Mira Mezini</i>	12:1–12:15
Dynamic Determinacy Race Detection for Task-Parallel Programs with Promises <i>Feiyang Jin, Lechen Yu, Tiago Cogumbreiro, Jun Shirako, and Vivek Sarkar</i>	13:1–13:30
Algebraic Replicated Data Types: Programming Secure Local-First Software <i>Christian Kuessner, Ragnar Mogk, Anna-Katharina Wickert, and Mira Mezini</i> ...	14:1–14:33
Behavioural Types for Local-First Software <i>Roland Kuhn, Hernán Melgratti, and Emilio Tuosto</i>	15:1–15:28
Constraint Based Compiler Optimization for Energy Harvesting Applications <i>Yannan Li and Chao Wang</i>	16:1–16:29
Restrictable Variants: A Simple and Practical Alternative to Extensible Variants <i>Magnus Madsen, Jonathan Lindegaard Starup, and Matthew Lutze</i>	17:1–17:27
Programming with Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism <i>Magnus Madsen and Jaco van de Pol</i>	18:1–18:27
Exact Separation Logic: Towards Bridging the Gap Between Verification and Bug-Finding <i>Petar Maksimović, Caroline Cronjäger, Andreas Lööw, Julian Sutherland, and Philippa Gardner</i>	19:1–19:27
Morpheus: Automated Safety Verification of Data-Dependent Parser Combinator Programs <i>Ashish Mishra and Suresh Jagannathan</i>	20:1–20:27
Automata Learning with an Incomplete Teacher <i>Mark Moeller, Thomas Wiener, Alaia Solko-Breslin, Caleb Koch, Nate Foster, and Alexandra Silva</i>	21:1–21:30
Modular Verification of State-Based CRDTs in Separation Logic <i>Abel Nieto, Arnaud Daby-Seesaram, Léon Gondelman, Amin Timany, and Lars Birkedal</i>	22:1–22:27
Information Flow Analysis for Detecting Non-Determinism in Blockchain <i>Luca Olivieri, Luca Negrini, Vincenzo Arceri, Fabio Tagliaferro, Pietro Ferrara, Agostino Cortesi, and Fausto Spoto</i>	23:1–23:25
Toward Tool-Independent Summaries for Symbolic Execution <i>Frederico Ramos, Nuno Sabino, Pedro Adão, David A. Naumann, and José Fragoso Santos</i>	24:1–24:29
A Direct-Style Effect Notation for Sequential and Parallel Programs <i>David Richter, Timon Böhler, Pascal Weisenburger, and Mira Mezini</i>	25:1–25:22
SINATRA: Stateful Instantaneous Updates for Commercial Browsers Through Multi-Version eXecution <i>Ugnius Rumsevicius, Siddhanth Venkateshwaran, Ellen Kidane, and Luís Pina</i> ...	26:1–26:29

An Efficient Vectorized Hash Table for Batch Computations <i>Hesam Shahrokhi and Amir Shaikhha</i>	27:1–27:27
Hinted Dictionaries: Efficient Functional Ordered Sets and Maps <i>Amir Shaikhha, Mahdi Ghorbani, and Hesam Shahrokhi</i>	28:1–28:30
Semantics for Noninterference with Interaction Trees <i>Lucas Silver, Paul He, Ethan Cecchetti, Andrew K. Hirsch, and Steve Zdancewic</i>	29:1–29:29
Interaction Tree Specifications: A Framework for Specifying Recursive, Effectful Computations That Supports Auto-Active Verification <i>Lucas Silver, Eddy Westbrook, Matthew Yacavone, and Ryan Scott</i>	30:1–30:26
Breaking the Negative Cycle: Exploring the Design Space of Stratification for First-Class Datalog Constraints <i>Jonathan Lindegaard Starup, Magnus Madsen, and Ondřej Lhoták</i>	31:1–31:28
Asynchronous Multiparty Session Type Implementability is Decidable – Lessons Learned from Message Sequence Charts <i>Felix Stutz</i>	32:1–32:31
ConDRust: Scalable Deterministic Concurrency from Verifiable Rust Programs <i>Felix Suchert, Lisza Zeidler, Jeronimo Castrillon, and Sebastian Ertel</i>	33:1–33:39
Dependent Merges and First-Class Environments <i>Jinhao Tan and Bruno C. d. S. Oliveira</i>	34:1–34:32
Synthesis-Aided Crash Consistency for Storage Systems <i>Jacob Van Geffen, Xi Wang, Emina Torlak, and James Bornholt</i>	35:1–35:26
Synthesizing Conjunctive Queries for Code Search <i>Chengpeng Wang, Peisen Yao, Wensheng Tang, Gang Fan, and Charles Zhang</i> ...	36:1–36:30
Do Machine Learning Models Produce TypeScript Types That Type Check? <i>Ming-Ho Yee and Arjun Guha</i>	37:1–37:28

Experience Papers

Building Code Transpilers for Domain-Specific Languages Using Program Synthesis <i>Sahil Bhatia, Sumer Kohli, Sanjit A. Seshia, and Alvin Cheung</i>	38:1–38:30
Rust for Morello: Always-On Memory Safety, Even in Unsafe Code <i>Sarah Harris, Simon Cooksey, Michael Vollmer, and Mark Batty</i>	39:1–39:27
On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage <i>João Mota, Marco Giunti, and António Ravara</i>	40:1–40:29

Pearls/Brave New Ideas

The Dolorem Pattern: Growing a Language Through Compile-Time Function Execution <i>Simon Henniger and Nada Amin</i>	41:1–41:27
--	------------

Synthetic Behavioural Typing: Sound, Regular Multiparty Sessions via Implicit Local Types	
<i>Sung-Shik Jongmans and Francisco Ferreira</i>	42:1–42:30
On the Rise of Modern Software Documentation	
<i>Marco Raglianti, Csaba Nagy, Roberto Minelli, Bin Lin, and Michele Lanza</i>	43:1–43:24
Python Type Hints Are Turing Complete	
<i>Ori Roth</i>	44:1–44:15

■ Message from the Program Chairs

Started in 1987, ECOOP is Europe's oldest programming conference, welcoming papers on all practical and theoretical investigations of programming languages, systems and environment providing innovative solutions to real problems as well as evaluations of existing solutions. Papers were submitted to one of four categories: *Research* for papers that advance the state of the art in programming; *Reproduction* for empirical evaluations that reconstructs a published experiment in a different context in order to validate the results of that earlier work; *Experience* for applications of known techniques in practice; and *Pearl* for papers that either explain a known idea in an elegant way or unconventional papers introducing ideas that may take some time to substantiate. ECOOP is a selective venue, with acceptance, by tradition, capped at 25% of all submissions and re-submissions. The chairs thank the Program Committee: B. Hermann, C. Omar, E. Söderberg, G. Agha, R. Baghdadi, S. Chiba, A. Craik, W. De Meuter, A. F. Donaldson, S. J. Gay, J. Gibbons, T. Hosking, A. Igarashi, M. Luján, A. Milanova, A. Möller, K. Ostermann, T. Petricek, A. Potanin, T. Schrijvers, M. Serrano, T. Sotiropoulos, P. Thiemann, E. Tosch, V. T. Vasconcelos, Y. Wang, S. Wehr, T. Wrigstad, and C. Zhang. This year, we continued a number of innovations that were first introduced in 2022:

- **Multiple rounds.** ECOOP has two main rounds of submissions per year (Dec 1 and Mar 1). Each round supports both minor and major revisions. Major revisions are handled in the next round (either the same year or the next) by the same reviewers.
- **No format or length restrictions.** In order to reduce friction for authors, papers can come in any format and at any length. This applies to submissions. Final versions must abide by the publisher's requirements.
- **Artifacts and Papers together.** Every submitted paper can be accompanied with an artifact, submitted a few days after the paper. Both submissions are evaluated in parallel by overlapping committees as members of the artifact evaluation committee were invited to served on the conference review committee.
- **Journal First/Last.** Papers can be submitted either one of three associated journals and be invited to present at the meeting. Furthermore, some accepted papers can be forward to journals.

Overall, we found that most of these innovations to have worked well. We hope that future chairs will continue to experiment with more, and perhaps, different innovations that will enrich the ECOOP community further.

■ Message from the Artifact Evaluation Chairs

ECOOP has a long-standing tradition of offering artifact evaluation dating back to 2013. Following the process introduced in 2022, the artifact evaluation involved every single paper submission to ECOOP 2023, rather than just accepted papers, and happened in parallel with the paper review process. Besides providing feedback on the artifacts irrespective of paper acceptance, evaluation results were made available to the technical PC. Artifact submissions could, thus, provide more insights on the technical contributions described in the papers and help to improve the overall review process.

To handle the high review load that such a process entails, we recruited a large artifact evaluation committee that included a total of 51 artifact reviewers. The submission deadlines for artifacts were just 10 days after the paper deadlines for both submission rounds. We received a total of 45 submissions (20 for R1 and 25 for R2). After a kick-the-tires review and author response phase, during which authors had the opportunity to clarify or address technical issues with their submissions, each submitted artifact was reviewed by three committee members, leading to an overall review load of around 3 artifact reviews per committee member.

Following the positive experience with adopting ACM's artifact badges for ECOOP 2021 and 2022, we adopted the same badging policies for ECOOP 2023. The artifact evaluation committee positively evaluated 38 submissions (15/23 for R1/R2) as *functional* or *reusable*, out of which 22 belong to papers to appear in the technical program of ECOOP 2023. 4 submitted artifacts that did not pass the bar for the *functional* and *reusable* badges in R1 were found eligible for the *available* badge, 2 of which are associated with papers accepted for presentation at ECOOP 2023.

In order to streamline the artifact review process and to decouple artifact from paper review aspects, we asked authors to submit documentation of explicit *claims* in a pre-specified format that the artifact evaluation committee checked the artifacts against. At the same time, the PC could assess the *importance of these claims* for the submitted papers as a frame of reference for the strength of support for the paper that an artifact can provide. This separation greatly facilitated the artifact evaluation committee's discussions regarding which badges to award.

The smooth and thorough artifact evaluation process would have not been possible without the members of the artifact evaluation committee, who handled the artifact review workload and contributed to the technical PC discussions with great dedication. We would like to thank them for their valuable work and the inspiring discussions. We would also like to thank the ECOOP 2023 program committee chairs Karim Ali and Guido Salvaneschi for the pleasant and productive interactions over the coordination of the paper and artifact review processes.

■ Foreword by the President of AITO

Welcome to ECOOP 2023, which this time will be held in the “well-known European city of Seattle”. Why outside Europe? Well, ECOOP traditionally has had many contributors and participants from other parts of the world and so ECOOP every once in a while has been held outside Europe. In 1990, ECOOP was co-located with OOPSLA in Ottawa, Canada, and in 2012, ECOOP was co-located with PLDI, LCTES, and ISMM in Beijing, China. This year, we are co-locating with ISSTA at the University of Washington main campus beautifully located by Lake Washington and with splendid views of the Cascade Mountains and Mount Rainier. The ECOOP 2023 team along with the ISSTA team has done a great job of putting together a great program for the conferences – a huge thanks to them and to all others that have contributed.

I am looking forward to two excellent conferences with lots of great papers, personal interaction, excellent keynotes, including talks by the two 2023 Dahl-Nygaard Prize Winners. Enjoy the conference, and Seattle.

Eric Jul
AITO President

Abstract

Session types provide a typing discipline for message-passing systems. However, most session type approaches assume an ideal world: one in which everything is reliable and without failures. Yet this is in stark contrast with distributed systems in the real world. To address this limitation, we introduce TEATRINO, a code generation toolchain that utilises asynchronous *multiparty session types* (MPST) with *crash-stop* semantics to support failure handling protocols.

We augment asynchronous MPST and processes with *crash handling* branches. Our approach requires no user-level syntax extensions for global types and features a formalisation of global semantics, which captures complex behaviours induced by crashed/crash handling processes. The sound and complete correspondence between global and local type semantics guarantees deadlock-freedom, protocol conformance, and liveness of typed processes in the presence of crashes.

Our theory is implemented in the toolchain TEATRINO, which provides *correctness by construction*. TEATRINO extends the SCRIBBLE multiparty protocol language to generate protocol-conforming SCALA code, using the EFFPI concurrent programming library. We extend both SCRIBBLE and EFFPI to support *crash-stop* behaviour. We demonstrate the feasibility of our methodology and evaluate TEATRINO with examples extended from both session type and distributed systems literature.

1 Introduction

Background. As distributed programming grows increasingly prevalent, significant research effort has been devoted to improve the reliability of distributed systems. A key aspect of this research focuses on studying *unreliability* (or, more specifically, failures). Modelling unreliability and failures enables a distributed system to be designed to be more tolerant of failures, and thus more resilient.

In pursuit of methods to achieve safety in distributed communication systems, *session types* [19] provide a lightweight, type system–based approach to message-passing concurrency. In particular, *Multiparty Session Types* (MPST) [20] facilitate the specification and verification of communication between message-passing processes in concurrent and distributed systems. The typing discipline prevents common communication-based errors, e.g. deadlocks and communication mismatches [21, 37]. On the practical side, MPST have been implemented in various mainstream programming languages [7, 10, 11, 22, 24, 25, 28, 30], which facilitates their applications in real-world programs.

Nevertheless, the challenge to account for unreliability and failures persists for session types: most session type systems assume that both participants and message transmissions are *reliable* without failures. In a real-world setting, however, participants may crash, communications channels may fail, and messages may be lost. The lack of failure modelling in session type theories creates a barrier to their applications to large-scale distributed systems.

Recent works [3, 26, 27, 33, 42] close the gap of failure modelling in session types with various techniques. [42] introduces *failure suspicion*, where a participant may suspect their communication partner has failed, and act accordingly. [33] introduces *reliability annotations* at type level, and fall back to a given *default* value in case of failures. [26] proposes a framework of *affine* multiparty session types, where a session can terminate prematurely, e.g. in case of failures. [3] integrates *crash-stop failures*, where a generalised type system validates safety and liveness properties with model checking; [27] takes a similar approach, modelling more kinds of failures in a session type system, e.g. message losses, reordering, and delays.

While steady advancements are made on the theoretical side, the implementations of those enhanced session type theories seem to lag behind. Barring the approaches in [26, 42], the aforementioned approaches [3, 27, 33] do not provide session type API support for programming languages.¹ To bring the benefits of the theoretical developments into real-world distributed programming, a gap remains to be filled on the implementation side.

This Paper. We introduce a *top-down* methodology for designing asynchronous multiparty protocols with crash-stop failures:

- (1) We use an extended asynchronous MPST theory, which models *crash-stop* failures, and show that the usual session type guarantees remain valid, i.e. communication safety, deadlock-freedom, and liveness;
- (2) We present a toolchain for implementing asynchronous multiparty protocols, under our new asynchronous MPST theory, in SCALA, using the EFFPI concurrency library [38].

The top-down design methodology comes from the original MPST theory [20], where the design of multiparty protocols begins with a given *global* type (top), and implementations rely on *local* types (bottom) obtained from the global type. The global and local types reflect the

¹ [3] provides a prototype implementation, utilising the mCRL2 model checker [5], for verifying type-level properties, instead of a library for general use.

global and local communication behaviours respectively. Well-typed implementations that conform to a global type are guaranteed to be *correct by construction*, enjoying full guarantees (safety, deadlock-freedom, liveness) from the theory. This remains the predominant approach for implementing MPST theories, and is also followed by some aforementioned systems [26, 42].

We model *crash-stop* failures [6, §2.2], i.e. a process may fail arbitrarily and cease to interact with others. This model is simple and expressive, and has been adopted by other approaches [3, 27]. Using global types in our design for handling failures in multiparty protocols presents two distinct advantages:

- (1) global types provide a simple, high-level means to both specify a protocol abstractly and automatically derive local types; and,
- (2) desirable behavioural properties such as communication safety, deadlock-freedom, and liveness are guaranteed by construction.

In contrast to the *synchronous* semantics in [3], we model an *asynchronous* semantics, where messages are buffered whilst in transit. We focus on asynchronous systems since most communication in the real distributed world is asynchronous. In [27], although the authors develop a generic typing system incorporating asynchronous semantics, their approach results in the type-level properties becoming undecidable [27, §4.4]. With global types, we restore the decidability at a minor cost to expressivity.

To address the gap on the practical side, we present a code generator toolchain, TEATRINO, to implement our MPST theory. Our toolchain takes an asynchronous multiparty protocol as input, using the protocol description language SCRIBBLE [43], and generates SCALA code using the EFFPI [38] concurrency library as output.

The SCRIBBLE Language [43] is designed for describing multiparty communication protocols, and is closely connected to MPST theory (cf. [31]). This language enables a programmatic approach for expressing global types and designing multiparty protocols. The EFFPI concurrency library [38] offers an embedded Domain Specific Language (DSL) that provides a simple actor-based API. The library offers both type-level and value-level constructs for processes and channels. Notably, the type-level constructs reflect the behaviour of programs (i.e. processes) and can be used as specifications. Our code generation technique, as well as the EFFPI library itself, utilises the type system features introduced in SCALA 3, including match types and dependent function types, to encode local types in EFFPI. This approach enables us to specify and verify program behaviour at the type level, resulting in a more powerful and flexible method for handling concurrency.

By extending SCRIBBLE and EFFPI to support *crash detection and handling*, our toolchain TEATRINO provides a lightweight way for developers to take advantage of our theory, bridging the gap on the practical side. We evaluate the expressivity and feasibility of TEATRINO with examples incorporating crash handling behaviour, extended from session type literature.

Outline. We begin with an overview of our methodology in § 2. We introduce an asynchronous multiparty session calculus in § 3 with semantics of crashing and crash handling. We introduce an extended theory of asynchronous multiparty session types with semantic modelling of crash-stop failures in § 4. We present a typing system for the multiparty session calculus in § 5. We introduce TEATRINO, a code generation toolchain that implements our theory in § 6, demonstrating how our approach is applied in the SCALA programming language. We evaluate our toolchain with examples from both session type and distributed systems literature in § 7. We discuss related work in § 8 and conclude in § 9. Full proofs, auxiliary material, and more details of TEATRINO can be found in the full version of the paper [2]. Additionally, our toolchain and examples used in our evaluation are available on [GitHub](#).

■ **Figure 1** Top-down View of MPST with Crash.

2 Overview

In this section, we give an overview of our methodology for designing asynchronous multiparty protocols with crash-stop failures, and demonstrate our code generation toolchain, TEATRINO.

Asynchronous Multiparty Protocols with Crash-Stop Failures. We follow a standard top-down design approach enabling *correctness by construction*, but enrich asynchronous MPST with crash-stop semantics. As depicted in Fig. 1, we formalise (asynchronous) multiparty protocols with crash-stop failures as global types with *crash handling branches* (*crash*). These are projected into local types, which may similarly contain crash handling branches (*crash*). The projected local types are then used to type-check processes (also with crash handling branches (*crash*)) that are written in a session calculus. As an example, we consider a simple *distributed logging* scenario, which is inspired by the logging-management protocol [26], but extended with a third participant.

The Simpler Logging protocol consists of a *logger* (**L**) that controls the logging services, an *interface* (**I**) that provides communications between logger and client, and a *client* (**C**) that requires logging services via interface. Initially, **L** sends a heartbeat message *trigger* to **I**. Then **C** sends a command to **L** to read the logs (*read*). When a *read* request is sent, it is forwarded to **L**, and **L** responds with a *report*, which is then forwarded onto **C**. Assuming all participants (logger, interface, and client) are reliable, i.e. without any failures or crashes, this logging behaviour can be represented by the *global type* G_0 :

$$G_0 = \mathbf{L} \rightarrow \mathbf{I} : \text{trigger} . \mathbf{C} \rightarrow \mathbf{I} : \text{read} . \mathbf{I} \rightarrow \mathbf{L} : \text{read} . \mathbf{L} \rightarrow \mathbf{I} : \text{report}(\text{log}) . \mathbf{I} \rightarrow \mathbf{C} : \text{report}(\text{log}) . \text{end} \quad (1)$$

Here, G_0 is a specification of the Simpler Logging protocol between multiple roles from a global perspective.

In the real distributed world, all participants in the Simpler Logging system may fail. Ergo, we need to model protocols with failures or crashes and handling behaviour, e.g. should the client fail after the logging has started, the interface will inform the logger to stop and exit. We follow [6, §2.2] to model a *crash-stop* semantics, where we assume that roles can crash *at any time* unless assumed *reliable* (never crash). For simplicity, we assume **I** and **L** to be reliable. The above logging behaviour, incorporating crash-stop failures, can be represented by extending G_0 with a branch handling a crash of **C**:

$$G = \mathbf{L} \rightarrow \mathbf{I} : \text{trigger} . \mathbf{C} \rightarrow \mathbf{I} : \left\{ \begin{array}{l} \text{read} . \mathbf{I} \rightarrow \mathbf{L} : \text{read} . \mathbf{L} \rightarrow \mathbf{I} : \text{report}(\text{log}) . \mathbf{I} \rightarrow \mathbf{C} : \text{report}(\text{log}) . \text{end} \\ \text{crash} . \mathbf{I} \rightarrow \mathbf{L} : \text{fatal} . \text{end} \end{array} \right\} \quad (2)$$

We model crash detection on receiving roles: when **I** is waiting to receive a message from **C**, the receiving role **I** is able to detect whether **C** has crashed. Since crashes are detected only by the receiving role, we do not require a crash handling branch on the communication step between **I** and **C** – nor do we require them on any interaction between **L** and **I** (since we are assuming that **L** and **I** are reliable).

■ **Figure 2** Workflow of TEATRINO.

Following the MPST top-down methodology, a global type is then *projected* onto *local types*, which describe communications from the perspective of a single role. In our unreliable Simpler Logging example, G is projected onto three local types (one for each role C, L, I):

$$T_C = I \oplus \text{read}.I \& \text{report}(\log).\text{end} \quad T_L = I \oplus \text{trigger}.I \& \left\{ \begin{array}{l} \text{read}.I \oplus \text{report}(\log).\text{end} \\ \text{fatal}.\text{end} \end{array} \right\}$$

$$T_I = L \& \text{trigger}.C \& \left\{ \begin{array}{l} \text{read}.L \oplus \text{read}.L \& \text{report}(\log).C \oplus \text{report}(\log).\text{end} \\ \text{crash}.L \oplus \text{fatal}.\text{end} \end{array} \right\}$$

Here, T_I states that I first receives a trigger message from L ; then I either expects a **read** request from C , or detects the crash of C and handles it (in **crash**) by sending the **fatal** message to notify L . We add additional crash modelling and introduce a **stop** type for crashed endpoints. We show the operational correspondence between global and local type semantics, and demonstrate that a projectable global type always produces a safe, deadlock-free, and live typing context.

The next step in this top-down methodology is to use local types to type-check processes P_i executed by role p_i in our session calculus. For example, T_I can be used to type check I that executes the process:

$$L? \text{trigger} . \sum \left\{ \begin{array}{l} C? \text{read}.L! \text{read}.L? \text{report}(x).C! \text{report}(x).0 \\ C? \text{crash}.L! \text{fatal}.0 \end{array} \right\}$$

In our operational semantics (§3), we allow active processes executed by unreliable roles to crash *arbitrarily*. Therefore, the role executing the crashed process also crashes, and is assigned the local type **stop**. To ensure that a communicating process is type-safe even in presence of crashes, we require that its typing context satisfies a *safety property* accounting for possible crashes (Def. 13), which is preserved by projection. Additional semantics surrounding crashes adds subtleties even in standard results. We prove subject reduction and session fidelity results accounting for crashes and sets of reliable roles.

Code Generation Toolchain: Teatrino. To complement the theory, we present a code generation toolchain, TEATRINO, that generates protocol-conforming SCALA code from a multiparty protocol. We show the workflow diagram of our toolchain in Fig. 2. TEATRINO takes a SCRIBBLE protocol (Protocol.scr) and generates executable code (Protocol.scala) conforming to that protocol, which the programmer can integrate with existing code (Final.scala).

TEATRINO implements our session type theory to handle global types expressed using the SCRIBBLE protocol description language [43], a programmer-friendly way for describing multiparty protocols. We extend the syntax of SCRIBBLE slightly to include constructs for **crash** recovery branches and reliable roles.

The generated SCALA code utilises the EFFPI concurrency library [38]. EFFPI is an embedded domain specific language in SCALA 3 that offers a simple Actor-based API for concurrency. Our code generation technique, as well the EFFPI library itself, leverages the type system features introduced in SCALA 3, e.g. match types and dependent function types, to encode local types in EFFPI. We extend EFFPI to support crash detection and handling.

As a brief introduction to EFFPI, the concurrency library provides types for processes and channels. For processes, an output process type `Out[A, B]` describes a process that uses a channel of type `A` to send a value of type `B`, and an input process type `In[A, B, C]` describes a process that uses a channel of type `A` to receive a value of type `B`, and pass it to a continuation type `C`. Process types can be sequentially composed by the `>>>` operator. For channels, `Chan[X]` describes a channel that can be used communicate values of type `X`. More specifically, the usage of a channel can be reflected at the type level, using the types `InChan[X]/OutChan[X]` for input/output channels.

```

1 type I[C0 <: InChan[Trigger], C1 <: OutChan[Fatal],
2     C2 <: InChan[Read], C3 <: InChan[Report], C4 <: OutChan[Report]]
3 = InErr[C0, Trigger,
4     (X <: Read) =>
5     Out[C3,Read] >>> In[C4, Report, (Y <: Log) => Out[C5, Report]],
6     (Err <: Throwable) => Out[C2,Fatal]
7 ]

```

■ **Figure 3** EFFPI Type for T_I .

As a sneak peek of the code we generate, in Fig. 3, we show the generated EFFPI representation for the projected local type T_I from the Simpler Logging example. Readers may be surprised by the difference between T_I and the generated EFFPI type `I`. This is because the process types need their respective channel types, namely the type variables `C0`, `C1`, *etc.* bounded by `InChan[...]` and `OutChan[...]`. We explain the details of code generation in §6.2, and describe an interesting challenge posed by the channel generation procedure in §6.3.

For crash handling behaviour, we introduce a new type `InErr`, whose last argument specifies a continuation type to follow in case of a crash. Line 3 in Fig. 3 shows the crash handling behaviour: sending a message of type `Fatal`, which reflects the `crash` branch in the local type T_I . We give more details of the generated code in §6.2.

Code generated by TEATRINO is executable, protocol-conforming, and can be specialised by the programmer to integrate with existing code. We evaluate our toolchain on examples taken from both MPST and distributed programming literature in §7. Moreover, we extend each example with crash handling behaviour to define unreliable variants. We demonstrate that, with TEATRINO, code generation takes negligible time, and all potential crashes are accompanied with crash handlers.

3 Crash-Stop Asynchronous Multiparty Session Calculus

In this section, we formalise the syntax and operational semantics of our asynchronous multiparty session calculus with process failures and crash detection.

Syntax. Our asynchronous multiparty session calculus models processes that may crash arbitrarily. Our formalisation is based on [16] – but in addition, follows the *fail-stop* model in [6, §2.7], where processes may crash and never recover, and process failures can be detected by failure detectors [6, §2.6.2] [8] when attempting to receive messages.

We give the syntax of processes in Fig. 4. In our calculus, we assume that there are basic expressions e (e.g. `true`, `false`, $7 + 11$) that are assigned basic types B (e.g. `int`, `bool`). We write $e \downarrow v$ to denote an expression e evaluates to a value v (e.g. $(7 < 11) \downarrow \text{true}$, $(1 + 1) \downarrow 2$).

$P, Q ::=$ $\sum_{i \in I} \mathbf{p}^? \mathbf{m}_i(x_i).P_i$ $\mathbf{p}! \mathbf{m}(e).P \quad (\text{where } \mathbf{m} \neq \text{crash})$ $\text{if } e \text{ then } P \text{ else } Q$ X $\mu X.P$ $\mathbf{0}$ ζ	Processes <i>external choice</i> <i>output</i> <i>conditional</i> <i>variable</i> <i>recursion</i> <i>inaction</i> <i>crashed</i>	$\mathcal{M} ::=$ $\mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h$ $\mathcal{M} \mid \mathcal{M}$ $h ::=$ ϵ \emptyset $(\mathbf{p}, \mathbf{m}(v))$ $h \cdot h$	Sessions <i>participant</i> <i>parallel</i> Queues <i>empty</i> <i>unavailable</i> <i>message</i> <i>concatenation</i>
---	---	--	---

■ **Figure 4** Syntax of sessions, processes, and queues. Noticeable changes w.r.t. standard session calculus [16] are highlighted.

A process, ranged over by P, Q , is a communication agent within a session. An *output* process $\mathbf{p}! \mathbf{m}(e).P$ sends a message to another role \mathbf{p} in the session, where the message is labelled \mathbf{m} , and carries a payload expression e , then the process continues as P . An *external choice (input)* process $\sum_{i \in I} \mathbf{p}^? \mathbf{m}_i(x_i).P_i$ receives a message from another role \mathbf{p} in the session, among a finite set of indexes I , if the message is labelled \mathbf{m}_i , then the payload would be received as x_i , and process continues as P_i . Note that our calculus uses *crash* as a special message label denoting that a participant (role) has crashed. Such a label cannot be sent by any process, but a process can implement crash detection and handling by receiving it. Consequently, an output process *cannot* send a *crash* message (side condition $\mathbf{m} \neq \text{crash}$), whereas an input process may include a *crash handling branch* of the form $\text{crash}.P'$ meaning that P' is executed when the sending role has crashed. A *conditional* process $\text{if } e \text{ then } P \text{ else } Q$ continues as either P or Q depending on the evaluation of e . We allow *recursion* at the process level using $\mu X.P$ and X , and we require process recursion variables to be guarded by an input or an output action; we consider a recursion process structurally congruent to its unfolding $\mu X.P \equiv P\{\mu X.P/X\}$. Finally, we write $\mathbf{0}$ for an *inactive* process, representing a successful termination; and ζ for a *crashed* process, representing a termination due to failure.

An *incoming queue*², ranged over by h, h' , is a sequence of messages tagged with their origin. We write ϵ for an *empty* queue; \emptyset for an *unavailable* queue; and $(\mathbf{p}, \mathbf{m}(v))$ for a message sent from \mathbf{p} , labelled \mathbf{m} , and containing a payload value v . We write $h_1 \cdot h_2$ to denote the concatenation of two queues h_1 and h_2 . When describing incoming queues, we consider two messages from different origins as swappable: $h_1 \cdot (\mathbf{q}_1, \mathbf{m}_1(v_1)) \cdot (\mathbf{q}_2, \mathbf{m}_2(v_2)) \cdot h_2 \equiv h_1 \cdot (\mathbf{q}_2, \mathbf{m}_2(v_2)) \cdot (\mathbf{q}_1, \mathbf{m}_1(v_1)) \cdot h_2$ whenever $\mathbf{q}_1 \neq \mathbf{q}_2$. Moreover, we consider concatenation (\cdot) as associative, and the empty queue ϵ as the identity element for concatenation.

A session, ranged over by $\mathcal{M}, \mathcal{M}'$, consists of processes and their respective incoming queue, indexed by their roles. A single entry for a role \mathbf{p} is denoted $\mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h$, where P is the process for \mathbf{p} and h is the incoming queue. Entries are composed together in parallel as $\mathcal{M} \mid \mathcal{M}'$, where the roles in \mathcal{M} and \mathcal{M}' are disjoint. We consider parallel composition as commutative and associative, with $\mathbf{p} \triangleleft \mathbf{0} \mid \mathbf{p} \triangleleft \epsilon$ as a neutral element of the operator. We write $\prod_{i \in I} (\mathbf{p}_i \triangleleft P_i \mid \mathbf{p}_i \triangleleft h_i)$ for the parallel composition of multiple entries in a set.

Operational Semantics. Operational Semantics of our session calculus is given in Def. 1, using a standard *structural congruence* \equiv defined in [16]. Our semantics parameterises on a (possibly empty) set of *reliable* roles \mathcal{R} , which are assumed to *never crash*.

² In [16], the queues are outgoing instead of incoming. We use incoming queues to model our crashing semantics more easily.

[R- \downarrow]	$\mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathcal{M} \rightarrow_{\mathcal{R}} \mathbf{p} \triangleleft \downarrow \mid \mathbf{p} \triangleleft \emptyset \mid \mathcal{M}$	$(P \neq \mathbf{0}, \mathbf{p} \notin \mathcal{R})$
[R-SEND]	$\mathbf{p} \triangleleft \mathbf{q}!m(e).P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft Q \mid \mathbf{q} \triangleleft h_{\mathbf{q}} \mid \mathcal{M}$ $\rightarrow \mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft Q \mid \mathbf{q} \triangleleft h_{\mathbf{q}} \cdot (\mathbf{p}, m(v)) \mid \mathcal{M}$	$(e \downarrow v, h_{\mathbf{q}} \neq \emptyset)$
[R-SEND- \downarrow]	$\mathbf{p} \triangleleft \mathbf{q}!m(e).P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft \downarrow \mid \mathbf{q} \triangleleft \emptyset \mid \mathcal{M} \rightarrow \mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft \downarrow \mid \mathbf{q} \triangleleft \emptyset \mid \mathcal{M}$	
[R-RCV]	$\mathbf{p} \triangleleft \sum_{i \in I} \mathbf{q}^?m_i(x_i).P_i \mid \mathbf{p} \triangleleft (\mathbf{q}, m_k(v)) \cdot h_{\mathbf{p}} \mid \mathcal{M} \rightarrow \mathbf{p} \triangleleft P_k\{v/x_k\} \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathcal{M}$	$(k \in I)$
[R-RCV- \emptyset]	$\mathbf{p} \triangleleft \sum_{i \in I} \mathbf{q}^?m_i(x_i).P_i \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft \downarrow \mid \mathbf{q} \triangleleft \emptyset \mid \mathcal{M}$ $\rightarrow \mathbf{p} \triangleleft P_k \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathbf{q} \triangleleft \downarrow \mid \mathbf{q} \triangleleft \emptyset \mid \mathcal{M}$	$(k \in I, m_k = \text{crash}, \nexists m, v : (\mathbf{q}, m(v)) \in h_{\mathbf{p}})$
[R-COND-T]	$\mathbf{p} \triangleleft \text{if } e \text{ then } P \text{ else } Q \mid \mathbf{p} \triangleleft h \mid \mathcal{M} \rightarrow \mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h \mid \mathcal{M}$	$(e \downarrow \text{true})$
[R-COND-F]	$\mathbf{p} \triangleleft \text{if } e \text{ then } P \text{ else } Q \mid \mathbf{p} \triangleleft h \mid \mathcal{M} \rightarrow \mathbf{p} \triangleleft Q \mid \mathbf{p} \triangleleft h \mid \mathcal{M}$	$(e \downarrow \text{false})$
[R-STRUCT]	$\mathcal{M}_1 \equiv \mathcal{M}'_1 \text{ and } \mathcal{M}'_1 \rightarrow \mathcal{M}'_2 \text{ and } \mathcal{M}'_2 \equiv \mathcal{M}_2 \implies \mathcal{M}_1 \rightarrow \mathcal{M}_2$	

■ **Figure 5** Reduction relation on sessions with crash-stop failures.

► **Definition 1** (Session Reductions). *Session reduction $\rightarrow_{\mathcal{R}}$ is inductively defined by the rules in Fig. 5, parameterised by a fixed set \mathcal{R} of reliable roles. We write \rightarrow when \mathcal{R} is insignificant. We write $\rightarrow_{\mathcal{R}}^*$ (resp. \rightarrow^*) for the reflexive and transitive closure of $\rightarrow_{\mathcal{R}}$ (resp. \rightarrow).*

Our operational semantics retains the basic rules in [16], but also includes (highlighted) rules for crash-stop failures and crash handling, adapted from [3]. Rules [R-SEND] and [R-RCV] model ordinary message delivery and reception: an output process located at \mathbf{p} sending to \mathbf{q} appends a message to the incoming queue of \mathbf{q} ; and an input process located at \mathbf{p} receiving from \mathbf{q} consumes the first message from the incoming queue. Rules [R-COND-T] and [R-COND-F] model conditionals; and rule [R-STRUCT] permits reductions up to structural congruence.

With regard to crashes and related behaviour, rule [R- \downarrow] models process crashes: an active ($P \neq \mathbf{0}$) process located at an unreliable role ($\mathbf{p} \notin \mathcal{R}$) may reduce to a crashed process $\mathbf{p} \triangleleft \downarrow$, with its incoming queue becoming unavailable $\mathbf{p} \triangleleft \emptyset$. Rule [R-SEND- \downarrow] models a message delivery to a crashed role (and thus an unavailable queue), and the message becomes lost and would not be added to the queue. Rule [R-RCV- \emptyset] models crash detection, which activates as a “last resort”: an input process at \mathbf{p} receiving from \mathbf{q} would first attempt find a message from \mathbf{q} in the incoming queue, which engages the usual rule [R-RCV]; if none exists and \mathbf{q} has crashed ($\mathbf{q} \triangleleft \downarrow$), then the crash handling branch in the input process at \mathbf{p} can activate. We draw attention to the interesting fact that [R-RCV] may engage even if \mathbf{q} has crashed, in cases where a message from \mathbf{q} in the incoming queue may be consumed. We now illustrate our operational semantics of sessions with an example.

► **Example 2.** Consider the session $\mathcal{M} = \mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft \epsilon \mid \mathbf{q} \triangleleft Q \mid \mathbf{q} \triangleleft \epsilon$, where $P = \mathbf{q}!m(\text{“abc”}). \sum \left\{ \mathbf{q}^?m'(x).\mathbf{0} \right\}$ and $Q = \sum \left\{ \mathbf{p}^?m(x).\mathbf{p}!m'(42).\mathbf{0} \right\}$. In this session, the process Q for \mathbf{q} receives a message sent from \mathbf{p} to \mathbf{q} ; the process P for \mathbf{p} sends a message from \mathbf{p} to \mathbf{q} , and then receives a message sent from \mathbf{q} to \mathbf{p} . Let each role be unreliable, i.e. $\mathcal{R} = \emptyset$, and P crash before sending. We have $\mathcal{M} \rightarrow_{\emptyset} \mathbf{p} \triangleleft \downarrow \mid \mathbf{p} \triangleleft \emptyset \mid \mathbf{q} \triangleleft Q \mid \mathbf{q} \triangleleft \epsilon \rightarrow \mathbf{p} \triangleleft \downarrow \mid \mathbf{p} \triangleleft \emptyset \mid \mathbf{q} \triangleleft \mathbf{0} \mid \mathbf{q} \triangleleft \epsilon$. We observe that when the output process P located at an unreliable role \mathbf{p} crashes (by [R- \downarrow]), the resulting entry for \mathbf{p} is a crashed process ($\mathbf{p} \triangleleft \downarrow$) with an unavailable queue ($\mathbf{p} \triangleleft \emptyset$). Subsequently, the input process Q located at \mathbf{q} can detect and handle the crash by [R-RCV- \emptyset] via its crash handling branch.

4 Asynchronous Multiparty Session Types with Crash-Stop Semantics

In this section, we present our asynchronous multiparty session types with crash-stop semantics. We give an overview of global and local types with crashes in §4.1, including syntax, projection, subtyping, *etc.*; our key additions to the classic theory are *crash handling branches* in both global and local types, and a special local type `stop` to denote crashed processes. We give a Labelled Transition System (LTS) semantics to both global types (§4.2) and configurations (i.e. a collection of local types and point-to-point communication queues, §4.3). We discuss alternative design options of modelling crash-stop failures in §4.4. We relate the two semantics in §4.5, and show that a configuration obtained via projection is safe, deadlock-free, and live in §4.6.

4.1 Global and Local Types with Crash-Stop Failures

The top-down methodology begins with *global types* to provide an overview of the communication between a number of *roles* (p, q, s, t, \dots), belonging to a (fixed) set \mathcal{R} . At the other end, we use *local types* to describe how a *single* role communicates with other roles from a local perspective, and they are obtained via *projection* from a global type. We give the syntax of both global and local types in Fig. 6, which are similar to syntax used in [3, 37].

Global Types. Global Types are ranged over G, G', G_i, \dots , and describe the behaviour for all roles from a bird's eye view. The syntax shown in `shade` are *runtime* syntax, which are not used for describing a system at design-time, but for describing the state of a system during execution. The labels m are taken from a fixed set of all labels \mathcal{M} , and basic types B (types for payloads) from a fixed set of all basic types \mathcal{B} .

We explain each construct in the syntax of global types: a transmission, denoted $p \rightarrow q^\dagger: \{m_i(B_i).G_i\}_{i \in I}$, represents a message from role p to role q (with possible crash annotations), with labels m_i , payload types B_i , and continuations G_i , where i is taken from an index set I . We require that the index set be non-empty ($I \neq \emptyset$), labels m_i be pair-wise distinct, and self receptions be excluded (i.e. $p \neq q$), as standard in session type works. Additionally, we require that the special `crash` label (explained later) not be the only label in a transmission, i.e. $\{m_i \mid i \in I\} \neq \{\text{crash}\}$. A transmission en route $p^\dagger \leftrightarrow q:j \{m_i(B_i).G_i\}_{i \in I}$ is a runtime construct representing a message m_j (index j) sent by p , and yet to be received by q . Recursive types are represented via $\mu t.G$ and t , where contractive requirements apply [34, §21.8]. The type `end` describes a terminated type (omitted where unambiguous).

To model crashes and crash handling, we use crash annotations `⚡` and crash handling branches: a *crash annotation* `⚡`, a new addition in this work, marks a *crashed* role (only used in the *runtime syntax*), and we omit annotations for live roles, i.e. p is a live role, $p^{\text{⚡}}$ is

a crashed role, and p^\dagger represents a possibly crashed role, namely either p or p^\dagger . We use a special label `crash` for handling crashes: this continuation denotes the protocol to follow when the sender of a message is detected to have crashed by the receiver. The special label acts as a “pseudo-message”: when a sender role crashes, the receiver can select the pseudo-message to enter crash handling. We write $\text{roles}(G)$ (resp. $\text{roles}^\dagger(G)$) for the set of *active* (resp. *crashed*) roles in a global type G , *excluding* (resp. *consisting only of*) those with a crash annotation \dagger .

Local Types. Local Types are ranged over S, T, U, \dots , and describe the behaviour of a single role. An internal choice (selection) (or an external choice (branching)), denoted $p \oplus \{m_i(B_i).T_i\}_{i \in I}$ (or $p \& \{m_i(B_i).T_i\}_{i \in I}$), indicates that the *current* role is to *send* to (or *receive* from) the role p . Similarly to global types, we require pairwise-distinct, non-empty labels. Moreover, we require that the `crash` label not appear in *internal* choices, reflecting that a `crash` pseudo-message can never be sent; and that singleton `crash` labels not permitted in external choices. The type `end` indicates a *successful* termination (omitted where unambiguous), and recursive types follow a similar fashion to global types. We use a new *runtime* type `stop` to denote crashes.

Subtyping. Subtyping relation \leq on local types will be used in §4.5 to relate global and local type semantics. Our subtyping relation is mostly standard [37, Def. 2.5], except for an extra rule for `stop` and additional requirements to support crash handling branch in external choices.

Projection. Projection gives the local type of a participating role in a global type, defined as a *partial* function that takes a global type G and a role p , and returns a local type, given by Def. 3.

► **Definition 3** (Global Type Projection). *The projection of a global type G onto a role p , with respect to a set of reliable roles \mathcal{R} , written $G \upharpoonright_{\mathcal{R}} p$, is:*

$$\begin{aligned}
 (q \rightarrow r^\dagger : \{m_i(B_i).G_i\}_{i \in I}) \upharpoonright_{\mathcal{R}} p &= \begin{cases} r \oplus \{m_i(B_i).(G_i \upharpoonright_{\mathcal{R}} p)\}_{i \in \{j \in I \mid m_j \neq \text{crash}\}} & \text{if } p = q \\ q \& \{m_i(B_i).(G_i \upharpoonright_{\mathcal{R}} p)\}_{i \in I} & \text{if } p = r, \text{ and } q \notin \mathcal{R} \text{ implies } \\ & \exists k \in I : m_k = \text{crash} \\ \prod_{i \in I} G_i \upharpoonright_{\mathcal{R}} p & \text{if } p \neq q, \text{ and } p \neq r \end{cases} \\
 (q^\dagger \rightsquigarrow r : \{m_i(B_i).G_i\}_{i \in I}) \upharpoonright_{\mathcal{R}} p &= \begin{cases} G_j \upharpoonright_{\mathcal{R}} p & \text{if } p = q \\ q \& \{m_i(B_i).(G_i \upharpoonright_{\mathcal{R}} p)\}_{i \in I} & \text{if } p = r, \text{ and } q \notin \mathcal{R} \text{ implies } \\ & \exists k \in I : m_k = \text{crash} \\ \prod_{i \in I} G_i \upharpoonright_{\mathcal{R}} p & \text{if } p \neq q, \text{ and } p \neq r \end{cases} \\
 (\mu t. G) \upharpoonright_{\mathcal{R}} p &= \begin{cases} \mu t.(G \upharpoonright_{\mathcal{R}} p) & \text{if } p \in G \text{ or } \text{fv}(\mu t. G) \neq \emptyset \\ \text{end} & \text{otherwise} \end{cases} \quad \begin{matrix} t \upharpoonright_{\mathcal{R}} p = t \\ \text{end} \upharpoonright_{\mathcal{R}} p = \text{end} \end{matrix}
 \end{aligned}$$

where \prod is the merge operator for local types (full merging):

$$\begin{aligned}
 & p \& \{m_i(B_i).S'_i\}_{i \in I} \prod p \& \{m_j(B_j).T'_j\}_{j \in J} \\
 = & p \& \{m_k(B_k).(S'_k \prod T'_k)\}_{k \in I \cap J} \& p \& \{m_i(B_i).S'_i\}_{i \in I \setminus J} \& p \& \{m_j(B_j).T'_j\}_{j \in J \setminus I} \\
 & p \oplus \{m_i(B_i).S'_i\}_{i \in I} \prod p \oplus \{m_i(B_i).T'_i\}_{i \in I} = p \oplus \{m_i(B_i).(S'_i \prod T'_i)\}_{i \in I} \\
 & \mu t. S \prod \mu t. T = \mu t.(S \prod T) \quad t \prod t = t \quad \text{end} \prod \text{end} = \text{end}
 \end{aligned}$$

We parameterise our theory on a (fixed) set of *reliable* roles \mathcal{R} , i.e. roles assumed to *never crash*: if $\mathcal{R} = \emptyset$, every role is unreliable and susceptible to crash; if $\text{roles}(G) \subseteq \mathcal{R}$, every role in G is reliable, and we simulate the results from the original MPST theory without crashes. We base our definition of projection on [37], but include more (highlighted) cases to account for reliable roles, `crash` branches, and runtime global types.

When projecting a transmission from q to r , we remove the **crash** label from the internal choice at q , reflecting our model that a **crash** pseudo-message cannot be sent. Dually, we require a **crash** label to be present in the external choice at r – unless the sender role q is assumed to be reliable. Our definition of projection enforces that transmissions, whenever an unreliable role is the sender ($q \notin \mathcal{R}$), *must include* a crash handling branch ($\exists k \in I : m_k = \text{crash}$). This requirement ensures that the receiving role r can *always* handle crashes whenever it happens, so that processes are not stuck when crashes occur. We explain how these requirements help us achieve various properties by projection in §4.6. The rest of the rules are taken from the literature [37,40], without much modification.

4.2 Crash-Stop Semantics of Global Types

We now give a Labelled Transition System (LTS) semantics to global types, with crash-stop semantics. To this end, we first introduce some auxiliary definitions. We define the transition labels in Def. 4, which are also used in the LTS semantics of configurations (later in §4.3).

► **Definition 4** (Transition Labels). *Let α be a transition label of the form:*

$$\alpha ::= \begin{array}{l|l} p\&q:m(B) & (p \text{ receives } m(B) \text{ from } q) \\ \hline p\downarrow & (p \text{ crashes}) \end{array} \quad \left| \quad \begin{array}{l|l} p\oplus q:m(B) & (p \text{ sends } m(B) \text{ to } q) \\ \hline p\odot q & (p \text{ detects the crash of } q) \end{array}$$

The subject of a transition label, written $\text{subj}(\alpha)$, is defined as:

$$\text{subj}(p\&q:m(B)) = \text{subj}(p\oplus q:m(B)) = \text{subj}(p\downarrow) = \text{subj}(p\odot q) = p.$$

The labels $p\oplus q:m(B)$ and $p\&q:m(B)$ describe sending and receiving actions respectively. The crash of p is denoted by the label $p\downarrow$, and the detection of a crash by label $p\odot q$: we model crash detection at *reception*, the label contains a *detecting* role p and a *crashed* role q .

We define an operator to *remove* a role from a global type in Def. 5: the intuition is to remove any interaction of a crashed role from the given global type. When a role has crashed, we attach a *crashed annotation*, and remove infeasible actions, e.g. when the sender and receiver of a transmission have both crashed. The removal operator is a partial function that takes a global type G and a live role r ($r \in \text{roles}(G)$) and gives a global type $G\downarrow r$.

► **Definition 5** (Role Removal). *The removal of a live role p in a global type G , written $G\downarrow p$, is defined as follows:*

$$\begin{aligned} (p \rightarrow q : \{m_i(B_i).G_i\}_{i \in I})\downarrow r &= \begin{cases} p\downarrow \rightsquigarrow q:j \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p = r \text{ and } \exists j \in I : m_j = \text{crash} \\ p \rightarrow q\downarrow : \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } q = r \\ p \rightarrow q : \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p \neq r \text{ and } q \neq r \end{cases} \\ (p \rightsquigarrow q : j \{m_i(B_i).G_i\}_{i \in I})\downarrow r &= \begin{cases} p\downarrow \rightsquigarrow q:j \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p = r \\ G_j\downarrow r & \text{if } q = r \\ p \rightsquigarrow q : j \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p \neq r \text{ and } q \neq r \end{cases} \\ (p \rightarrow q\downarrow : \{m_i(B_i).G_i\}_{i \in I})\downarrow r &= \begin{cases} G_j\downarrow r & \text{if } p = r \text{ and } \exists j \in I : m_j = \text{crash} \\ p \rightarrow q\downarrow : \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p \neq r \text{ and } q \neq r \end{cases} \\ (p\downarrow \rightsquigarrow q : j \{m_i(B_i).G_i\}_{i \in I})\downarrow r &= \begin{cases} G_j\downarrow r & \text{if } q = r \\ p\downarrow \rightsquigarrow q : j \{m_i(B_i).(G_i\downarrow r)\}_{i \in I} & \text{if } p \neq r \text{ and } q \neq r \end{cases} \\ (\mu t.G)\downarrow r &= \begin{cases} \mu t.(G\downarrow r) & \text{if } \text{fv}(\mu t.G) \neq \emptyset \text{ or } \text{roles}(G\downarrow r) \neq \emptyset \\ \text{end} & \text{otherwise} \end{cases} \\ t\downarrow r &= t & \text{end}\downarrow r &= \text{end} \end{aligned}$$

For simple cases, the removal of a role $G\downarrow r$ attaches crash annotations \downarrow on all occurrences of the removed role r throughout global type G inductively.

$$\begin{array}{c}
 \frac{\mathbf{p} \notin \mathcal{R} \quad \mathbf{p} \in \text{roles}(G) \quad G \neq \mu\mathbf{t}.G'}{\langle \mathcal{C}; G \rangle \xrightarrow{\mathbf{p}^\ddagger} \langle \mathcal{C} \cup \{\mathbf{p}\}; G \downarrow \mathbf{p} \rangle} \text{ [GR-}\ddagger\text{]} \quad \frac{\langle \mathcal{C}; G\{\mu\mathbf{t}.G/\mathbf{t}\} \rangle \xrightarrow{\alpha} \langle \mathcal{C}'; G' \rangle}{\langle \mathcal{C}; \mu\mathbf{t}.G \rangle \xrightarrow{\alpha} \langle \mathcal{C}'; G' \rangle} \text{ [GR-}\mu\text{]} \\

 \frac{\forall i \in I : \langle \mathcal{C}; G'_i \rangle \xrightarrow{\alpha} \langle \mathcal{C}'; G''_i \rangle \quad \text{subj}(\alpha) \neq \mathbf{q}}{\langle \mathcal{C}; \mathbf{p}^\dagger \rightsquigarrow \mathbf{q}; j \{ \mathbf{m}_i(B_i).G'_i \}_{i \in I} \rangle \xrightarrow{\alpha} \langle \mathcal{C}'; \mathbf{p}^\dagger \rightsquigarrow \mathbf{q}; j \{ \mathbf{m}_i(B_i).G''_i \}_{i \in I} \rangle} \text{ [GR-Ctx-II]}
 \end{array}$$

■ **Figure 7** Global Type Reduction Rules.

We draw attention to some interesting cases: when we remove the sender role \mathbf{p} from a transmission prefix $\mathbf{p} \rightarrow \mathbf{q}$, the result is a “pseudo-transmission” en route prefix $\mathbf{p}^\ddagger \rightsquigarrow \mathbf{q}; j$ where $\mathbf{m}_j = \text{crash}$. This enables the receiver \mathbf{q} to “receive” the special crash after the crash of \mathbf{p} , hence triggering the crash handling branch. Recall that our definition of projection requires that a crash handling branch be present whenever a crash may occur ($\mathbf{q} \notin \mathcal{R}$).

When we remove the sender role \mathbf{p} from a transmission en route prefix $\mathbf{p} \rightsquigarrow \mathbf{q}; j$, the result *retains* the index j that was selected by \mathbf{p} , instead of the index associated with crash handling. This is crucial to our crash modelling: when a role crashes, the messages that the role *has sent* to other roles are still available. We discuss alternative models later in § 4.4.

In other cases, where removing the role \mathbf{r} would render a transmission (regardless of being en route or not) meaningless, e.g. both sender and receiver have crashed, we simply remove the prefix entirely.

We now give an LTS semantics to a global type G , by defining the semantics with a tuple $\langle \mathcal{C}; G \rangle$, where \mathcal{C} is a set of *crashed* roles. The transition system is parameterised by reliability assumptions, in the form of a fixed set of reliable roles \mathcal{R} . When unambiguous, we write G as an abbreviation of $\langle \emptyset; G \rangle$. We define the reduction rules of global types in Def. 6.

► **Definition 6** (Global Type Reductions). *The global type (annotated with a set of crashed roles \mathcal{C}) transition relation $\xrightarrow{\alpha} \mathcal{R}$ is inductively defined by the rules in Fig. 7, parameterised by a fixed set \mathcal{R} of reliable roles. We write $\langle \mathcal{C}; G \rangle \rightarrow \mathcal{R} \langle \mathcal{C}'; G' \rangle$ if there exists α such that $\langle \mathcal{C}; G \rangle \xrightarrow{\alpha} \mathcal{R} \langle \mathcal{C}'; G' \rangle$; we write $\langle \mathcal{C}; G \rangle \rightarrow \mathcal{R}$ if there exists \mathcal{C}', G' , and α such that $\langle \mathcal{C}; G \rangle \xrightarrow{\alpha} \mathcal{R} \langle \mathcal{C}'; G' \rangle$, and $\rightarrow \mathcal{R}^*$ for the transitive and reflexive closure of $\rightarrow \mathcal{R}$.*

Rules [GR- \oplus] and [GR- $\&$] model sending and receiving messages respectively, as are standard in existing works [13]. We add an (highlighted) extra condition that the message exchanged not be a pseudo-message carrying the crash label. [GR- μ] is a standard rule handling recursion.

We introduce (highlighted) rules to account for crash and consequential behaviour. Rule [GR- \ddagger] models crashes, where a live ($\mathbf{p} \in \text{roles}(G)$), but unreliable ($\mathbf{p} \notin \mathcal{R}$) role \mathbf{p} may crash. The crashed role \mathbf{p} is added into the set of crashed roles ($\mathcal{C} \cup \{\mathbf{p}\}$), and removed from the global type, resulting in a global type $G \downarrow \mathbf{p}$. Rule [GR- \circ] is for *crash detection*, where a

live role q may detect that p has crashed at reception, and then continues with the crash handling continuation labelled `crash`. This rule only applies when the message en route is a pseudo-message, since otherwise a message rests in the queue of the receiver and can be received despite the crash of the sender (cf. $[\text{GR-}\&]$). Rule $[\text{GR-}\&^{\dagger}]$ models the orphaning of a message sent from a live role p to a crashed role q . Similar to the requirement in $[\text{GR-}\oplus]$, we add the side condition that the message sent is not a pseudo-message.

Finally, rules $[\text{GR-CTX-I}]$ and $[\text{GR-CTX-II}]$ allow non-interfering reductions of (intermediate) global types under prefix, provided that all of the continuations can be reduced by that label.

► **Remark 7 (Necessity of \mathcal{C} in Semantics).** While we can obtain the set of crashed roles in any global type G via $\text{roles}^{\dagger}(G)$, we need a separate \mathcal{C} for bookkeeping purposes. To illustrate, let $G = p \rightarrow q: \{m.\text{end}, \text{crash.end}\}$; we can have the following reductions:

$$\langle \emptyset; G \rangle \xrightarrow{q^{\dagger}} \langle \{q\}; p \rightarrow q^{\dagger}: \{m.\text{end}, \text{crash.end}\} \rangle \xrightarrow{p \oplus q: m} \langle \{q\}; \text{end} \rangle$$

While we can deduce q is a crashed role in the interim global type, the same information cannot be recovered from the final global type `end`.

4.3 Crash-Stop Semantics of Configurations

After giving semantics to global types, we now give an LTS semantics to *configurations*, i.e. a collection of local types and communication queues across roles. We first give a definition of configurations in Def. 8, followed by their reduction rules in Def. 9.

► **Definition 8 (Configurations).** A configuration is a tuple $\Gamma; \Delta$, where Γ is a typing context, denoting a partial mapping from roles to local types, defined as: $\Gamma ::= \emptyset \mid \Gamma, p \triangleright T$. We write $\Gamma[p \mapsto T]$ for updates: $\Gamma[p \mapsto T](p) = T$ and $\Gamma[p \mapsto T](q) = \Gamma(q)$ (where $p \neq q$).

A queue, denoted τ , is either a (possibly empty) sequence of messages $M_1 \cdot M_2 \cdots M_n$, or unavailable \circ . We write ϵ for an empty queue, and $M \cdot \tau'$ for a non-empty queue with message M at the beginning. A queue message M is of form $m(B)$, denoting a message with label m and payload B . We sometimes omit B when the payload is not of specific interest.

We write Δ to denote a queue environment, a collection of peer-to-peer queues. A queue from p to q at Δ is denoted $\Delta(p, q)$. We define updates $\Delta[p, q \mapsto \tau]$ similarly. We write Δ_{\emptyset} for an empty queue environment, where $\Delta_{\emptyset}(p, q) = \epsilon$ for any p and q in the domain.

We write $\tau' \cdot M$ to append a message M at the end of a queue τ' : the message is appended to the sequence when τ' is available, or discarded when τ' is unavailable (i.e. $\circ \cdot M = \circ$). Additionally, we write $\Delta[\cdot, q \mapsto \circ]$ for making all the queues to q unavailable: i.e. $\Delta[p_1, q \mapsto \circ][p_2, q \mapsto \circ] \cdots [p_n, q \mapsto \circ]$.

We give an LTS semantics of configurations in Def. 9. Similar to that of global types, we model the semantics of configurations in an asynchronous (a.k.a. message passing) fashion, using a queue environment to represent the communication queues among all roles.

► **Definition 9 (Configuration Semantics).** The configuration transition relation $\xrightarrow{\alpha}$ is defined in Fig. 8. We write $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$ iff $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$ for some Γ' and Δ' . We define two reductions \rightarrow and $\rightarrow_{\mathcal{R}}$ (where \mathcal{R} is a fixed set of reliable roles) as follows:

- We write $\Gamma; \Delta \rightarrow \Gamma'; \Delta'$ for $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$ with $\alpha \in \{p \& q: m(B), p \oplus q: m(B), p \circ q\}$. We write $\Gamma; \Delta \rightarrow$ iff $\Gamma; \Delta \rightarrow \Gamma'; \Delta'$ for some $\Gamma'; \Delta'$, and $\Gamma; \Delta \not\rightarrow$ for its negation, and \rightarrow^* for the reflexive and transitive closure of \rightarrow ;
- We write $\Gamma; \Delta \rightarrow_{\mathcal{R}} \Gamma'; \Delta'$ for $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$ with $\alpha \notin \{r^{\dagger} \mid r \in \mathcal{R}\}$. We write $\Gamma; \Delta \rightarrow_{\mathcal{R}}$ iff $\Gamma; \Delta \rightarrow_{\mathcal{R}} \Gamma'; \Delta'$ for some $\Gamma'; \Delta'$, and $\Gamma; \Delta \not\rightarrow_{\mathcal{R}}$ for its negation. We define $\rightarrow_{\mathcal{R}}^*$ as the reflexive and transitive closure of $\rightarrow_{\mathcal{R}}$.

$$\begin{array}{c}
\frac{\Gamma(\mathbf{p}) = \mathbf{q} \oplus \{\mathbf{m}_i(B_i).T_i\}_{i \in I} \quad k \in I}{\Gamma; \Delta \xrightarrow{\mathbf{p} \oplus \mathbf{q}; \mathbf{m}_k(B_k)} \Gamma[\mathbf{p} \mapsto T_k]; \Delta[\mathbf{p}, \mathbf{q} \mapsto \Delta(\mathbf{p}, \mathbf{q}) \cdot \mathbf{m}_k(B_k)]} \text{[}\Gamma\text{-}\oplus\text{]} \\
\frac{\Gamma(\mathbf{p}) = \mathbf{q} \& \{\mathbf{m}_i(B_i).T_i\}_{i \in I} \quad k \in I \quad \mathbf{m}' = \mathbf{m}_k \quad B' = B_k \quad \Delta(\mathbf{q}, \mathbf{p}) = \mathbf{m}'(B') \cdot \tau' \neq \emptyset}{\Gamma; \Delta \xrightarrow{\mathbf{p} \& \mathbf{q}; \mathbf{m}_k(B_k)} \Gamma[\mathbf{p} \mapsto T_k]; \Delta[\mathbf{q}, \mathbf{p} \mapsto \tau']} \text{[}\Gamma\text{-}\&\text{]} \\
\frac{\Gamma(\mathbf{p}) = \mu t. T \quad \Gamma[\mathbf{p} \mapsto T\{\mu t. T/t\}]; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'}{\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'} \text{[}\Gamma\text{-}\mu\text{]} \quad \frac{\Gamma(\mathbf{p}) \neq \text{end} \quad \Gamma(\mathbf{p}) \neq \text{stop}}{\Gamma; \Delta \xrightarrow{\mathbf{p} \ddagger} \Gamma[\mathbf{p} \mapsto \text{stop}]; \Delta[\cdot, \mathbf{p} \mapsto \emptyset]} \text{[}\Gamma\text{-}\ddagger\text{]} \\
\frac{\Gamma(\mathbf{q}) = \mathbf{p} \& \{\mathbf{m}_i(B_i).T_i\}_{i \in I} \quad \Gamma(\mathbf{p}) = \text{stop} \quad k \in I \quad \mathbf{m}_k = \text{crash} \quad \Delta(\mathbf{p}, \mathbf{q}) = \epsilon}{\Gamma; \Delta \xrightarrow{\mathbf{q} \odot \mathbf{p}} \Gamma[\mathbf{q} \mapsto T_k]; \Delta} \text{[}\Gamma\text{-}\odot\text{]}
\end{array}$$

■ **Figure 8** Configuration Semantics.

We first explain the standard rules: rule $[\Gamma\text{-}\oplus]$ (resp. $[\Gamma\text{-}\&]$) says that a role can perform an output (resp. input) transition by appending (resp. consuming) a message at the corresponding queue. Recall that whenever a queue is unavailable, the resulting queue remains unavailable after appending ($\emptyset \cdot M = \emptyset$). Therefore, the rule $[\Gamma\text{-}\oplus]$ covers delivery to both crashed and live roles, whereas two separate rules are used in modelling global type semantics ($[\text{GR}\text{-}\oplus]$ and $[\text{GR}\text{-}\ddagger\text{m}]$). We also include a standard rule $[\Gamma\text{-}\mu]$ for recursive types.

The key innovations are the (highlighted) rules modelling crashes and crash detection: by rule $[\Gamma\text{-}\ddagger]$, a role \mathbf{p} may crash and become **stop** at any time (unless it is already **ended** or **stopped**). All of \mathbf{p} 's receiving queues become unavailable \emptyset , so that future messages to \mathbf{p} would be discarded. Rule $[\Gamma\text{-}\odot]$ models crash detection and handling: if \mathbf{p} is crashed and stopped, another role \mathbf{q} attempting to receive from \mathbf{p} can then take its **crash** handling branch. However, this rule only applies when the corresponding queue is empty: it is still possible to receive messages sent before crashing via $[\Gamma\text{-}\&]$.

4.4 Alternative Modellings for Crash-Stop Failures

Before we dive into the relation between two semantics, let us have a short digression to discuss our modelling choices and alternatives. In this work, we mostly follow the assumptions laid out in [3], where a crash is detected at reception. However, they opt to use a synchronous (rendez-vous) semantics, whereas we give an asynchronous (message passing) semantics, which entails interesting scenarios that would not arise in a synchronous semantics.

Specifically, consider the case where a role \mathbf{p} sends a message to \mathbf{q} , and then \mathbf{p} crashes after sending, but before \mathbf{q} receives the message. The situation does not arise under a synchronous semantics, since sending and receiving actions are combined into a single transmission action.

Intuitively, there are two possibilities to handle this scenario. The questions are whether the message sent immediately before crashing is deliverable to \mathbf{q} , and consequentially, at what time does \mathbf{q} detect the crash of \mathbf{p} .

In our semantics (Figs. 7 and 8), we opt to answer the first question in positive: we argue that this model is more consistent with our “passive” crash detection design. For example, if a role \mathbf{p} never receives from another role \mathbf{q} , then \mathbf{p} does not need to react in the event of \mathbf{q} 's crash. Following a similar line of reasoning, if the message sent by \mathbf{p} arrives in the receiving queue of \mathbf{q} , then \mathbf{q} should be able to receive the message, without triggering a crash detection (although it may be triggered later). As a consequence, we require in $[\Gamma\text{-}\odot]$ that the queue $\Delta(\mathbf{p}, \mathbf{q})$ be empty, to reflect the idea that crash detection should be a “last resort”.

For an alternative model, we can opt to detect the crash after crash has occurred. This is possibly better modelled with using outgoing queues (cf. [12]), instead of incoming queues in the semantics presented. Practically, this may be the scenario that a TCP connection is closed (or reset) when a peer has crashed, and the content in the queue is lost. It is worth noting that this kind of alternative model will not affect our main theoretical results: the operational correspondence between global and local type semantics, and furthermore, global type properties guaranteed by projection.

4.5 Relating Global Type and Configuration Semantics

We have given LTS semantics for both global types (Def. 6) and configurations (Def. 9), we now relate these two semantics with the help of the projection operator \uparrow (Def. 3).

We associate configurations $\Gamma; \Delta$ with global types G (as annotated with a set of crashed roles \mathcal{C}) by projection, written $\Gamma; \Delta \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}; G \rangle$. Naturally, there are two components of the association: (1) the local types in Γ need to correspond to the projections of the global type G and the set of crashed roles \mathcal{C} ; and (2) the queues in Δ corresponds to the transmissions en route in the global type G and also the set of crashed roles \mathcal{C} .

► **Definition 10** (Association of Global Types and Configurations). *A configuration $\Gamma; \Delta$ is associated with a (well-annotated w.r.t. \mathcal{R}) global type $\langle \mathcal{C}; G \rangle$, written $\Gamma; \Delta \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}; G \rangle$, iff*

1. Γ can be split into disjoint (possibly empty) sub-contexts $\Gamma = \Gamma_G, \Gamma_{\mathcal{C}}, \Gamma_{\text{end}}$ where:
 - (A1) Γ_G contains projections of G : $\text{dom}(\Gamma_G) = \text{roles}(G)$, and $\forall \mathbf{p} \in \text{dom}(\Gamma_G) : \Gamma(\mathbf{p}) \leq G \uparrow_{\mathcal{R}} \mathbf{p}$;
 - (A2) $\Gamma_{\mathcal{C}}$ contains crashed roles: $\text{dom}(\Gamma_{\mathcal{C}}) = \mathcal{C}$, and $\forall \mathbf{p} \in \text{dom}(\Gamma_{\mathcal{C}}) : \Gamma(\mathbf{p}) = \text{stop}$;
 - (A3) Γ_{end} contains only end endpoints: $\forall \mathbf{p} \in \Gamma_{\text{end}} : \Gamma(\mathbf{p}) = \text{end}$.
2. (A4) Δ is associated with global type $\langle \mathcal{C}; G \rangle$, given as follows:
 - i. Receiving queues for a role is unavailable if and only if it has crashed: $\forall \mathbf{q} : \mathbf{q} \in \mathcal{C} \iff \Delta(\cdot, \mathbf{q}) = \emptyset$;
 - ii. If $G = \text{end}$ or $G = \mu \mathbf{t}. G'$, then queues between all roles are empty (except receiving queue for crashed roles): $\forall \mathbf{p}, \mathbf{q} : \mathbf{q} \notin \mathcal{C} \implies \Delta(\mathbf{p}, \mathbf{q}) = \epsilon$;
 - iii. If $G = \mathbf{p} \rightarrow \mathbf{q}^{\dagger} : \{m_i(B_i).G'_i\}_{i \in I}$, or $G = \mathbf{p}^{\dagger} \rightsquigarrow \mathbf{q} : j \{m_i(B_i).G'_i\}_{i \in I}$ with $m_j = \text{crash}$ (i.e. a pseudo-message is en route), then
 - (i) if \mathbf{q} is live, then the queue from \mathbf{p} to \mathbf{q} is empty: $\mathbf{q}^{\dagger} \neq \mathbf{q}^{\ddagger} \implies \Delta(\mathbf{p}, \mathbf{q}) = \epsilon$, and
 - (ii) $\forall i \in I : \Delta$ is associated with $\langle \mathcal{C}; G'_i \rangle$;
 - iv. If $G = \mathbf{p}^{\dagger} \rightsquigarrow \mathbf{q} : j \{m_i(B_i).G'_i\}_{i \in I}$ with $m_j \neq \text{crash}$, then
 - (i) the queue from \mathbf{p} to \mathbf{q} begins with the message $m_j(B_j) : \Delta(\mathbf{p}, \mathbf{q}) = m_j(B_j) \cdot \tau$;
 - (ii) $\forall i \in I : \text{removing the message from the head of the queue, } \Delta[\mathbf{p}, \mathbf{q} \mapsto \tau]$ is associated with $\langle \mathcal{C}; G'_i \rangle$.

We write $\Gamma \sqsubseteq_{\mathcal{R}} G$ as an abbreviation of $\Gamma; \Delta_{\emptyset} \sqsubseteq_{\mathcal{R}} \langle \emptyset; G \rangle$. We sometimes say Γ (resp. Δ) is associated with $\langle \mathcal{C}; G \rangle$ for stating Item 1 (resp. Item 2) is satisfied.

We demonstrate the relation between the two semantics via association, by showing two main theorems: all possible reductions of a configuration have a corresponding action in reductions of the associated global type (Thm. 11); and the reducibility of a global type is the same as its associated configuration (Thm. 12).

► **Theorem 11** (Completeness of Association). *Given associated global type G and configuration $\Gamma; \Delta : \Gamma; \Delta \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}; G \rangle$. If $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$, where $\alpha \neq \mathbf{p}^{\ddagger}$ for all $\mathbf{p} \in \mathcal{R}$, then there exists $\langle \mathcal{C}'; G' \rangle$ such that $\Gamma'; \Delta' \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}'; G' \rangle$ and $\langle \mathcal{C}; G \rangle \xrightarrow{\alpha}_{\mathcal{R}} \langle \mathcal{C}'; G' \rangle$.*

► **Theorem 12** (Soundness of Association). *Given associated global type G and configuration $\Gamma; \Delta: \Gamma; \Delta \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}; G \rangle$. If $\langle \mathcal{C}; G \rangle \rightarrow_{\mathcal{R}}$, then there exists $\Gamma'; \Delta'$, α and $\langle \mathcal{C}'; G' \rangle$, such that $\langle \mathcal{C}; G \rangle \xrightarrow{\alpha}_{\mathcal{R}} \langle \mathcal{C}'; G' \rangle$, $\Gamma'; \Delta' \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}'; G' \rangle$, and $\Gamma; \Delta \xrightarrow{\alpha} \Gamma'; \Delta'$.*

By Thms. 11 and 12, we obtain, as a corollary, that a global type G is in operational correspondence with the typing context $\Gamma = \{\mathbf{p} \triangleright G \upharpoonright_{\mathcal{R}} \mathbf{p}\}_{\mathbf{p} \in \text{roles}(G)}$, which contains the projections of all roles in G .

4.6 Properties Guaranteed by Projection

A key benefit of our top-down approach of multiparty protocol design is that desirable properties are guaranteed by the methodology. As a consequence, processes following the local types obtained from projections are correct *by construction*. In this subsection, we focus on three properties: *communication safety*, *deadlock-freedom*, and *liveness*, and show that the three properties are guaranteed from configurations associated with global types.

Communication Safety. We begin by defining communication safety for configurations (Def. 13). We focus on two safety requirements:

- (i) each role must be able to handle any message that may end up in their receiving queue (so that there are no label mismatches); and
- (ii) each receiver must be able to handle the potential crash of the sender, unless the sender is reliable.

► **Definition 13** (Configuration Safety). *Given a fixed set of reliable roles \mathcal{R} , we say that φ is an \mathcal{R} -safety property of configurations iff, whenever $\varphi(\Gamma; \Delta)$, we have:*

[S- $\oplus \&$] $\Gamma(\mathbf{q}) = \mathbf{p} \& \{m_i(B_i).S'_i\}_{i \in I}$ and $\Delta(\mathbf{p}, \mathbf{q}) \neq \emptyset$ and $\Delta(\mathbf{p}, \mathbf{q}) \neq \epsilon$ implies $\Gamma; \Delta \xrightarrow{\mathbf{q} \& \mathbf{p}: m'(B')}$;

[S- $\& \&$] $\Gamma(\mathbf{p}) = \text{stop}$ and $\Gamma(\mathbf{q}) = \mathbf{p} \& \{m_i(S_i).S'_i\}_{i \in I}$ and $\Delta(\mathbf{p}, \mathbf{q}) = \epsilon$ implies $\Gamma; \Delta \xrightarrow{\mathbf{q} \oplus \mathbf{p}}$;

[S- μ] $\Gamma(\mathbf{p}) = \mu t.S$ implies $\varphi(\Gamma[\mathbf{p} \mapsto S\{\mu t.S/t\}]; \Delta)$;

[S- \rightarrow_i] $\Gamma; \Delta \rightarrow_{\mathcal{R}} \Gamma'; \Delta'$ implies $\varphi(\Gamma'; \Delta')$.

We say $\Gamma; \Delta$ is \mathcal{R} -safe, if $\varphi(\Gamma; \Delta)$ holds for some \mathcal{R} -safety property φ .

We use a coinductive view of the safety property [35], where the predicate of \mathcal{R} -safe configurations is the largest \mathcal{R} -safety property, by taking the union of all safety properties φ . For a configuration $\Gamma; \Delta$ to be \mathcal{R} -safe, it has to satisfy all clauses defined in Def. 13.

By clause [S- $\oplus \&$], whenever a role \mathbf{q} receives from another role \mathbf{p} , and a message is present in the queue, the receiving action must be possible for some label m' . Clause [S- $\& \&$] states that if a role \mathbf{q} receives from a crashed role \mathbf{p} , and there is nothing in the queue, then \mathbf{q} must have a *crash* branch, and a crash detection action can be fired. (Note that [S- $\oplus \&$] applies when the queue is non-empty, despite the crash of sender \mathbf{p} .) Finally, clause [S- μ] extends the previous clauses by unfolding any recursive entries; and clause [S- \rightarrow_i] states that any configuration $\Gamma'; \Delta'$ which $\Gamma; \Delta$ transitions to must also be \mathcal{R} -safe. By using transition $\rightarrow_{\mathcal{R}}$, we ignore crash transitions $\mathbf{p} \not\rightarrow$ for any reliable role $\mathbf{p} \in \mathcal{R}$.

► **Example 14.** Recall the local types $T_{\mathbf{C}}$, $T_{\mathbf{L}}$, and $T_{\mathbf{I}}$ of the Simpler Logging example in § 2. The configuration $\Gamma; \Delta$, where $\Gamma = \mathbf{C} \triangleright T_{\mathbf{C}}, \mathbf{L} \triangleright T_{\mathbf{L}}, \mathbf{I} \triangleright T_{\mathbf{I}}$ and $\Delta = \Delta_{\emptyset}$, is $\{\mathbf{L}, \mathbf{I}\}$ -safe. This can be verified by checking its reductions. For example, in the case where \mathbf{C} crashes immediately, we have: $\Gamma; \Delta \xrightarrow{\mathbf{C} \not\rightarrow} \Gamma[\mathbf{C} \mapsto \text{stop}]; \Delta[\cdot, \mathbf{C} \mapsto \emptyset] \xrightarrow{*} \Gamma[\mathbf{C} \mapsto \text{stop}][\mathbf{L} \mapsto \text{end}][\mathbf{I} \mapsto \text{end}]; \Delta[\cdot, \mathbf{C} \mapsto \emptyset]$ and each reductum satisfies all clauses of Def. 13.

Deadlock-Freedom. The property of deadlock-freedom, sometimes also known as progress, describes whether a configuration can keep reducing unless it is a terminal configuration. We give its formal definition in Def. 15.

► **Definition 15** (Configuration Deadlock-Freedom). *Given a set of reliable roles \mathcal{R} , we say that a configuration $\Gamma; \Delta$ is \mathcal{R} -deadlock-free iff:*

1. $\Gamma; \Delta$ is \mathcal{R} -safe; and,
2. If $\Gamma; \Delta$ can reduce to a configuration $\Gamma'; \Delta'$ without further reductions: $\Gamma; \Delta \rightarrow_{\mathcal{R}}^* \Gamma'; \Delta' \not\rightarrow_{\mathcal{R}}$, then:
 - a. Γ' can be split into two disjoint contexts, one with only **end** entries, and one with only **stop** entries: $\Gamma' = \Gamma'_{\text{end}}; \Gamma'_{\text{z}}$, where $\text{dom}(\Gamma'_{\text{end}}) = \{\mathbf{p} \mid \Gamma'(\mathbf{p}) = \text{end}\}$ and $\text{dom}(\Gamma'_{\text{z}}) = \{\mathbf{p} \mid \Gamma'(\mathbf{p}) = \text{stop}\}$; and,
 - b. Δ' is empty for all pairs of roles, except for the receiving queues of crashed roles, which are unavailable: $\forall \mathbf{p}, \mathbf{q} : \Delta'(\cdot, \mathbf{q}) = \emptyset$ if $\Gamma'(\mathbf{q}) = \text{stop}$, and $\Delta'(\mathbf{p}, \mathbf{q}) = \epsilon$, otherwise.

It is worth noting that a (safe) configuration that reduces infinitely satisfies deadlock-freedom, as Item 2 in the premise does not hold. Otherwise, whenever a terminal configuration is reached, it must satisfy Item 2a that all local types in the typing context be terminated (either successfully **end**, or crashed **stop**), and Item 2b that all queues be empty (unless unavailable due to crash). As a consequence, a deadlock-free configuration $\Gamma; \Delta$ either does not stop reducing, or terminates in a stable configuration.

Liveness. The property of liveness describes that every pending output/external choice is eventually triggered by means of a message transmission or crash detection. Our liveness property is based on *fairness*, which guarantees that every enabled message transmission, including crash detection, is performed successfully. We give the definitions of non-crashing, fair, and live paths of configurations respectively in Def. 16, and use these paths to formalise the liveness for configurations in Def. 17.

► **Definition 16** (Non-crashing, Fair, Live Paths). *A non-crashing path is a possibly infinite sequence of configurations $(\Gamma_n; \Delta_n)_{n \in N}$, where $N = \{0, 1, 2, \dots\}$ is a set of consecutive natural numbers, and $\forall n \in N, \Gamma_n; \Delta_n \rightarrow \Gamma_{n+1}; \Delta_{n+1}$. We say that a non-crashing path $(\Gamma_n; \Delta_n)_{n \in N}$ is fair iff, $\forall n \in N$:*

- (F1) $\Gamma_n; \Delta_n \xrightarrow{\mathbf{p} \oplus \mathbf{q}; \mathbf{m}(B)} \Gamma_{k+1}; \Delta_{k+1}$ implies $\exists k, \mathbf{m}', B'$ such that $n \leq k \in N$ and $\Gamma_k; \Delta_k \xrightarrow{\mathbf{p} \oplus \mathbf{q}; \mathbf{m}'(B')} \Gamma_{k+1}; \Delta_{k+1}$;
- (F2) $\Gamma_n; \Delta_n \xrightarrow{\mathbf{p} \& \mathbf{q}; \mathbf{m}(B)} \Gamma_{k+1}; \Delta_{k+1}$ implies $\exists k$ such that $n \leq k \in N$ and $\Gamma_k; \Delta_k \xrightarrow{\mathbf{p} \& \mathbf{q}; \mathbf{m}(B)} \Gamma_{k+1}; \Delta_{k+1}$;
- (F3) $\Gamma_n; \Delta_n \xrightarrow{\mathbf{p} \odot \mathbf{q}} \Gamma_{k+1}; \Delta_{k+1}$ implies $\exists k$ such that $n \leq k \in N$ and $\Gamma_k; \Delta_k \xrightarrow{\mathbf{p} \odot \mathbf{q}} \Gamma_{k+1}; \Delta_{k+1}$.

We say that a non-crashing path $(\Gamma_n; \Delta_n)_{n \in N}$ is live iff, $\forall n \in N$:

- (L1) $\Delta_n(\mathbf{p}, \mathbf{q}) = \mathbf{m}(B) \cdot \tau \neq \emptyset$ and $\mathbf{m} \neq \text{crash}$ implies $\exists k$ such that $n \leq k \in N$ and $\Gamma_k; \Delta_k \xrightarrow{\mathbf{q} \& \mathbf{p}; \mathbf{m}(B)} \Gamma_{k+1}; \Delta_{k+1}$;
- (L2) $\Gamma_n(\mathbf{p}) = \mathbf{q} \& \{ \mathbf{m}_i(B_i) \cdot T_i \}_{i \in I}$ implies $\exists k, \mathbf{m}', B'$ such that $n \leq k \in N$ and $\Gamma_k; \Delta_k \xrightarrow{\mathbf{p} \& \mathbf{q}; \mathbf{m}'(B')} \Gamma_{k+1}; \Delta_{k+1}$ or $\Gamma_k; \Delta_k \xrightarrow{\mathbf{p} \odot \mathbf{q}} \Gamma_{k+1}; \Delta_{k+1}$.

A non-crash path is a (possibly infinite) sequence of reductions of a configuration without crashes. A non-crash path is fair if along the path, every internal choice eventually sends a message (F1), every external choice eventually receives a message (F2), and every crash detection is eventually performed (F3). A non-crashing path is live if along the path, every non-crash message in the queue is eventually consumed (L1), and every hanging external choice eventually consumes a message or performs a crash detection (L2).

 \end{array}$$

■ **Figure 9** Typing rules for queues, processes, and sessions.

► **Definition 17** (Configuration Liveness). *Given a set of reliable roles \mathcal{R} , we say that a configuration $\Gamma; \Delta$ is \mathcal{R} -live iff:*

1. $\Gamma; \Delta$ is \mathcal{R} -safe; and,
2. $\Gamma; \Delta \rightarrow_{\mathcal{R}}^* \Gamma'; \Delta'$ implies all non-crashing paths starting with $\Gamma'; \Delta'$ that are fair are also live.

A configuration $\Gamma; \Delta$ is \mathcal{R} -live when it is \mathcal{R} -safe and any reductum of $\Gamma; \Delta$ (via transition $\rightarrow_{\mathcal{R}}^*$) consistently leads to a live path if it is fair.

Properties by Projection. We conclude by showing the guarantee of safety, deadlock-freedom, and liveness in configurations associated with global types in Lem. 18. Furthermore, as a corollary, Thm. 19 demonstrates that a typing context projected from a global type (without runtime constructs) is inherently safe, deadlock-free, and live by construction.

► **Lemma 18.** *If $\Gamma; \Delta \sqsubseteq_{\mathcal{R}} \langle \mathcal{C}; G \rangle$, then $\Gamma; \Delta$ is \mathcal{R} -safe, \mathcal{R} -deadlock-free, and \mathcal{R} -live.*

► **Theorem 19** (Safety, Deadlock-Freedom, and Liveness by Projection). *Let G be a global type without runtime constructs, and \mathcal{R} be a set of reliable roles. If Γ is a typing context associated with the global type $G: \Gamma \sqsubseteq_{\mathcal{R}} G$, then $\Gamma; \Delta_{\emptyset}$ is \mathcal{R} -safe, \mathcal{R} -deadlock-free, and \mathcal{R} -live.*

5 Typing System with Crash-Stop Semantics

In this section, we present a type system for our asynchronous multiparty session calculus. Our typing system is extended from the one in [16] with crash-stop failures. We introduce the typing rules in § 5.1, and show various properties of typed sessions: subject reduction, session fidelity, deadlock-freedom, and liveness in § 5.2.

5.1 Typing Rules

Our type system uses three kinds of typing judgements: (1) for processes; (2) for queues; and (3) for sessions, and is defined inductively by the typing rules in Fig. 9. Typing judgments for processes are of form $\Theta \vdash P : T$, where Θ is a typing context for variables, defined as $\Theta ::= \emptyset \mid \Theta, x : B \mid \Theta, X : T$.

With regard to queues, we use judgments of the form $\vdash h : \delta$, where we use δ to denote a partially applied queue lookup function. We write $\delta = \Delta(-, \mathbf{p})$ to describe the incoming queue for a role \mathbf{p} , as a partially applied function $\delta = \Delta(-, \mathbf{p})$ such that $\delta(\mathbf{q}) = \Delta(\mathbf{q}, \mathbf{p})$. We write $\delta_1 \cdot \delta_2$ to denote the point-wise application of concatenation. For empty queues (ϵ), unavailable queues (\emptyset), and queue concatenations (\cdot), we simply lift the process-level queue constructs to type-level counterparts. For a singleton message $(\mathbf{q}, \mathbf{m}(v))$, the appropriate partial queue δ would be a singleton of $\mathbf{m}(B)$ (where B is the type of v) for \mathbf{q} , and an empty queue (ϵ) for any other role.

Finally, we use judgments of the form $\langle \mathbf{C}; G \rangle \vdash \mathcal{M}$ for sessions. We use a global type-guided judgment, effectively asserting that all participants in the session respect the prescribed global type, as is the case in [15]. As **highlighted**, the global type with crashed roles $\langle \mathbf{C}; G \rangle$ must have some associated configuration $\Gamma; \Delta$, used to type the processes and the queues respectively. Moreover, all the entries in the configuration must be present in the session.

Most rules in Fig. 9 assign the corresponding session type according to the behaviour of the process. For example, (**highlighted**) rule $[\text{T-}\emptyset]$ assigns the unavailable queue type \emptyset to a unavailable queue \emptyset ; rules $[\text{T-OUT}]$ and $[\text{T-EXT}]$ assign internal and external choice types to input and output processes; (**highlighted**) rule $[\text{T-}\dagger]$ (resp. $[\text{T-}\mathbf{0}]$) assigns the crash termination **stop** (resp. successful termination **end**) to a crashed process \dagger (resp. inactive process $\mathbf{0}$).

► **Example 20.** Consider the process that acts as the role \mathbf{C} in our Simpler Logging example (§2 and Ex. 14): $P_{\mathbf{C}} = \mathbf{I!read.I?report}(x).\mathbf{0}$, and a message queue $h_{\mathbf{C}} = \epsilon$. Process $P_{\mathbf{C}}$ has the type $T_{\mathbf{C}}$, and queue $h_{\mathbf{C}}$ has the type ϵ , which can be verified in the standard way. If we follow a crash reduction, e.g. by the rule $[\text{R-}\dagger]$, the session evolves as $\mathbf{C} \triangleleft P_{\mathbf{C}} \mid \mathbf{C} \triangleleft h_{\mathbf{C}} \rightarrow_{\mathcal{R}} \mathbf{C} \triangleleft \dagger \mid \mathbf{C} \triangleleft \emptyset$, where, by $[\text{T-}\dagger]$, $P_{\mathbf{C}}$ is typed by **stop**, and $h_{\mathbf{C}}$ is typed by \emptyset .

5.2 Properties of Typed Sessions

We present the main properties of typed sessions: *subject reduction* (Thm. 21), *session fidelity* (Thm. 22), *deadlock-freedom* (Thm. 24), and *liveness* (Thm. 26).

Subject reduction states that well-typedness of sessions are preserved by reduction. In other words, a session governed by a global type continues to be governed by a global type.

► **Theorem 21 (Subject Reduction).** *If $\langle \mathbf{C}; G \rangle \vdash \mathcal{M}$ and $\mathcal{M} \rightarrow_{\mathcal{R}} \mathcal{M}'$, then either $\langle \mathbf{C}; G \rangle \vdash \mathcal{M}'$, or there exists $\langle \mathbf{C}'; G' \rangle$ such that $\langle \mathbf{C}; G \rangle \rightarrow_{\mathcal{R}} \langle \mathbf{C}'; G' \rangle$ and $\langle \mathbf{C}'; G' \rangle \vdash \mathcal{M}'$.*

Session fidelity states the opposite implication with regard to subject reduction: sessions respect the progress of the governing global type.

► **Theorem 22 (Session Fidelity).** *If $\langle \mathbf{C}; G \rangle \vdash \mathcal{M}$ and $\langle \mathbf{C}; G \rangle \rightarrow_{\mathcal{R}}$, then there exists \mathcal{M}' and $\langle \mathbf{C}'; G' \rangle$ such that $\langle \mathbf{C}; G \rangle \rightarrow_{\mathcal{R}} \langle \mathbf{C}'; G' \rangle$, $\mathcal{M} \rightarrow_{\mathcal{R}^*} \mathcal{M}'$ and $\langle \mathbf{C}'; G' \rangle \vdash \mathcal{M}'$.*

Session *deadlock-freedom* means that the “successful” termination of a session may include crashed processes and their respective unavailable incoming queues – but reliable roles (which cannot crash) can only successfully terminate by reaching inactive processes with empty incoming queues. We formalise the definition of deadlock-free sessions in Def. 23 and show that a well-typed session is deadlock-free in Thm. 24.

► **Definition 23 (Deadlock-Free Sessions).** *A session \mathcal{M} is deadlock-free iff $\mathcal{M} \rightarrow_{\mathcal{R}^*} \mathcal{M}' \not\rightarrow_{\mathcal{R}}$ implies either $\mathcal{M}' \equiv \mathbf{p} \triangleleft \mathbf{0} \mid \mathbf{p} \triangleleft \epsilon$, or $\mathcal{M}' \equiv \mathbf{p} \triangleleft \dagger \mid \mathbf{p} \triangleleft \emptyset$.*

► **Theorem 24 (Session Deadlock-Freedom).** *If $\langle \mathbf{C}; G \rangle \vdash \mathcal{M}$, then \mathcal{M} is deadlock-free.*

```

1 global protocol SimpleLogger(role U, reliable role L)
2 { rec t0 { choice at U { write(String) from U to L;
3     continue t0; }
4     or { read from U to L;
5     report(Log) from L to U;
6     continue t0; }
7     or { crash from U to L; } } }

```

■ **Figure 10** A Simple Logger protocol in SCRIBBLE.

Finally, we show that well-typed sessions guarantee the property of *liveness*: a session is *live* when all its input processes will be performed eventually, and all its queued messages will be consumed eventually. We formalise the definition of live sessions in Def. 25 and conclude by showing that a well-typed session is live in Thm. 26.

► **Definition 25** (Live Sessions). *A session \mathcal{M} is live iff $\mathcal{M} \rightarrow_{\mathcal{R}^*} \mathcal{M}' \equiv \mathbf{p} \triangleleft P \mid \mathbf{p} \triangleleft h_{\mathbf{p}} \mid \mathcal{M}''$ implies:*

1. if $h_{\mathbf{p}} = (\mathbf{q}, \mathbf{m}(v)) \cdot h'_{\mathbf{p}}$, then $\exists P', \mathcal{M}''' : \mathcal{M}' \rightarrow_{\mathcal{R}^*} \mathbf{p} \triangleleft P' \mid \mathbf{p} \triangleleft h'_{\mathbf{p}} \mid \mathcal{M}'''$; and
2. if $P = \sum_{i \in I} \mathbf{q}^? \mathbf{m}_i(x_i).P_i$, then $\exists k \in I, w, h'_p, \mathcal{M}''' : \mathcal{M}' \rightarrow_{\mathcal{R}^*} \mathbf{p} \triangleleft P_k \{w/x_k\} \mid \mathbf{p} \triangleleft h'_p \mid \mathcal{M}'''$.

► **Theorem 26** (Session Liveness). *If $\langle \mathcal{C}; G \rangle \vdash \mathcal{M}$, then \mathcal{M} is live.*

6 Teatrino: Generating Scala Programs from Protocols

In this section, we present our toolchain TEATRINO that implements our extended MPST theory with crash-stop failures. TEATRINO processes protocols represented in the SCRIBBLE protocol description language, and generates protocol-conforming Scala code that uses the EFFPI concurrency library. A user specifies a multiparty protocol in SCRIBBLE as input, introduced in §6.1. We show the style of our generated code in §6.2, and how a developer can use the generated code to implement multiparty protocols. As mentioned in §2, generating channels for each process and type poses an interesting challenge, explained in §6.3.

6.1 Specifying a Multiparty Protocol in Scribble

The SCRIBBLE Language [43] is a multiparty protocol description language that relates closely to MPST theory (cf. [31]), and provides a programmatic way to express global types. As an example, Fig. 10 describes the following global type of a simple distributed logging protocol:

$$G = \mu t_0. \mathbf{u} \rightarrow \mathbf{l} : \{ \text{write}(\text{str}).t_0, \text{read}.\mathbf{l} \rightarrow \mathbf{u} : \text{report}(\text{Log}).t_0, \text{crash}.\text{end} \}.$$

The global type is described by a SCRIBBLE `global protocol`, with roles declared on Line 1. A transmission in the global type (e.g. $\mathbf{u} \rightarrow \mathbf{l} : \{ \dots \}$) is in the form of an interaction statement (e.g. \dots `from U to L`), except that choice (i.e. with an index set $|I| > 1$) must be marked explicitly by a `choice` construct (Line 2). Recursions and type variables in the global types are in the forms of `rec` and `continue` statements, respectively.

In order to express our new theory, we need two extensions to the language:

- (1) a reserved label `crash` to mark crash handling branches (cf. the special label `crash` in the theory), e.g. on Line 7; and
- (2) a `reliable` keyword to mark the reliable roles in the protocol (cf. the reliable role set \mathcal{R} in the theory). Roles are assumed unreliable unless declared using the `reliable` keyword, e.g. L on Line 1.

6.2 Generating Scala Code from Scribble Protocols

The Effpi Concurrency Library. [38] provides an embedded Domain Specific Language (DSL) offering a simple actor-based API. The library utilises advanced type system features in Scala 3, and provides both type-level and value-level constructs for processes and channels. In particular, the type-level constructs reflect the behaviour of programs (i.e. processes), and thus can be used as specifications. Following this intuition, we generate process types that reflect local types from our theory, as well as a tentative process implementing that type (by providing some default values where necessary).

Generated Code. To illustrate our approach, we continue with the Simple Logger example from § 6.1, and show the generated code in Fig. 11. The generated code can be divided into five sections:

- (i) label and payload declarations,
- (ii) recursion variable declarations,
- (iii) local type declarations,
- (iv) role-implementing functions, and
- (v) an entry point.

Sections (i) and (ii) contain boilerplate code, where we generate type declarations for various constructs needed for expressing local types and processes. We draw attention to the *key* sections (iii) and (iv), where we generate a representation of local types for each role, as well as a tentative process inhabiting that type.

Local Types and Effpi Types. We postpone the discussion about channels in EFFPI to § 6.3. For now, we compare the generated EFFPI type and the projected local type, and also give a quick primer³ on EFFPI constructs. The projected local types of the roles **u** and **l** are shown as follows:

$$\begin{aligned} G \upharpoonright_{\{1\}} \mathbf{u} &= \mu t_0. \mathbf{l} \oplus \{ \text{write}(\text{str}).t_0, \text{read}.\mathbf{l} \& \text{report}(\text{Log}).t_0 \} \\ G \upharpoonright_{\{1\}} \mathbf{l} &= \mu t_0. \mathbf{u} \& \{ \text{write}(\text{str}).t_0, \text{read}.\mathbf{u} \oplus \text{report}(\text{Log}).t_0, \text{crash}.\text{end} \} \end{aligned}$$

The local types are recursive, and the EFFPI type implements recursion with `Rec[RecT0, ...]` and `Loop[RecT0]`, using the recursion variable `RecT0` declared in section (ii).

For role **u**, The inner local type is a sending type towards role **l**, and we use an EFFPI process output type `Out[A, B]`, which describes a process that uses a channel of type **A** to send a value of type **B**. For each branch, we use a separate output type, and connect it to the type of the continuation using a sequential composition operator (`>>:`). The different branches are then composed together using a union type (`|`) from the SCALA 3 type system.

Recall that the role **l** is declared `reliable`, and thus the reception labelled `report` from **l** at **u** does not need to contain a crash handler. We use an EFFPI process input type `In[A, B, C]`, which describes a process that uses a channel of type **A** to receive a value of type **B**, and uses the received value in a continuation of type **C**.

For role **l**, the reception type is more complex for two reasons:

- (1) role **u** is unreliable, necessitating crash handling; and
- (2) the reception contains branching behaviour (cf. the reception **u** being a singleton), with labels `write` and `read`.

³ A more detailed description of constructs can be found in [39].

```

1 // (i) label and payload declarations
2 case class Log() // payload type
3 case class Read() // label types
4 case class Report(x : Log)
5 case class Write(x : String)
6 // (ii) recursion variable declarations
7 sealed abstract class RecT0[A]() extends RecVar[A]("RecT0")
8 case object RecT0 extends RecT0[Unit]
9 // (iii) local type declarations
10 type U[C0 <: OutChan[Read | Write], C1 <: InChan[Report]] =
11   Rec[RecT0,
12     ( (Out[C0, Read] >>: In[C1, Report, (x0 : Report) => Loop[RecT0]]
13       | (Out[C0, Write] >>: Loop[RecT0]) ) ]
14
15 type L[C0 <: InChan[Read | Write], C1 <: OutChan[Report]] =
16   Rec[RecT0,
17     InErr[C0, Read | Write, (x0 : Read | Write) => L0[x0.type, C1],
18           (err : Throwable) => PNil]]
19
20 type L0[X0 <: Read | Write, C1 <: OutChan[Report]] <: Process =
21   X0 match { case Read => Out[C1, Report] >>: Loop[RecT0]
22             case Write => Loop[RecT0] }
23 // (iv) role-implementing functions
24 def u(c0 : OutChan[Read | Write],
25     c1 : InChan[Report]) : U[c0.type, c1.type] = {
26   rec(RecT0) {
27     val x0 = 0
28     if (x0 == 0) {
29       send(c0, new Read()) >> receive(c1) {(x1 : Report) => loop(RecT0) }
30     } else {
31       send(c0, new Write("")) >> loop(RecT0)
32     } } }
33
34 def l(c0 : InChan[Read | Write],
35     c1 : OutChan[Report]) : L[c0.type, c1.type] =
36   rec(RecT0) {
37     receiveErr(c0)((x0 : Read | Write) => l0(x0, c1),
38                 (err : Throwable) => nil) }
39
40 def l0(x : Read | Write, c1 : OutChan[Report]) : L0[x.type, c1.type] =
41   x match { case y : Read => send(c1, new Report(new Log())) >> loop(RecT0)
42           case y : Write => loop(RecT0) }
43 // (v) an entry point (main object)
44 object Main {
45   def main() : Unit = {
46     var c0 = Channel[Read | Write]()
47     var c1 = Channel[Report]()
48     eval(par(u(c0, c1), l(c0, c1)))
49   } }

```

■ **Figure 11** Generated SCALA code for the Simple Logger protocol in Fig. 10.

For (1), we extend EFFPI with a variant of the input process type `InErr[A, B, C, D]`, where `D` is the type of continuation in case of a crash. For (2), the payload type is first received as an union (Line 17), and then `matched` to select the correct continuation according to the type (Line 21).

From Types To Implementations. Since EFFPI type-level and value-level constructs are closely related, we can easily generate the processes from the processes types. Namely, by matching the type `Out[...]` with the process `send(...)`; the type `In[...]` with the process `receive(...)` `{... => ...}`; and similarly for other constructs. Whilst executable, the generated code represents a skeleton implementation, and the programmer is expected to alter the code according to their requirements.

We also introduce a new crash handling receive process `receiveErr`, to match the new `InErr` type. Process crashes are modelled by (caught) exceptions and errors in role-implementing functions, and crash detection is achieved via timeouts. Timeouts are set by the programmer in an (implicit) argument to each `receiveErr` call.

Finally, the entry point (main object) in section (v) composes the role-implementing functions together with `par` construct in EFFPI, and connects the processes with channels.

6.3 Generating Effpi Channels from Scribble Protocols

As previously mentioned, EFFPI processes use *channels* to communicate, and the type of the channel is reflected in the type of the process. However, our local types do not have any channels; instead, they contain a partner role with which to communicate. This poses an interesting challenge, and we explain the channel generation procedure in this section.

We draw attention to the generated code in Fig. 11 again, where we now focus on the parameters `C0` in the generated types `U` and `L`. In the type `U`, the channel type `C0` needs to be a subtype of `OutChan[Read | Write]` (Line 10), and we see the channel is used in the output processes types, e.g. `Out[C0, Read]` (Line 12, note that output channels subtyping is covariant on the payload type). Dually, in the type `L`, the channel type `C0` needs to be a subtype of `InChan[Read | Write]` (Line 15), and we see the channel is used in the input process type, i.e. `InErr[C0, Read | Write, ..., ...]` (Line 17).

Similarly, a channel `c0` is needed in the role-implementing functions `u` and `l` as arguments, and the channel is used in processes `send(c0, ...)` and `receiveErr(c0) ...`. Finally, in the entry point, we create a bidirectional channel `c0 = Channel[Read | Write]()` (Line 46), and pass it as an argument to the role-implementing functions `u` and `l` (Line 48), so that the channel can be used to link two role-implementing processes together for communication.

Generating the channels correctly is crucial to the correctness of our approach, but non-trivial since channels are implicit in the protocols. In order to do so, a simple approach is to traverse each interaction in the global protocol, and assign a channel to each accordingly.

This simple approach would work for the example we show in Fig. 10; however, it would not yield the correct result when *merging* occurs during projection, which we explain using an example. For clarity and convenience, we use *annotated* global and local types, where we assign an identifier for each interaction to signify the channel to use, and consider the following global type: $G = p \xrightarrow{0} q: \left\{ \text{left.} p \xrightarrow{1} r: \text{left.end}, \text{right.} p \xrightarrow{2} r: \text{right.end} \right\}$.

The global type describes a simple protocol, where role `p` selects a label `left` or `right` to `q`, and `q` passes on the same label to `r`. As a result, the projection on `r` (assuming all roles reliable) should be a reception from `q` with branches labelled `left` or `right`, i.e. $p \&^{1,2} \{ \text{left.end}, \text{right.end} \}$. Here, we notice that the interaction between `q` and `r` should take place on a single channel, instead of two separate channels annotated 1 and 2.

■ **Table 1** Overview of All Variants for Each Example.

Name	Var.	\mathcal{R}	Comms.	Crash Branches	Max Cont. Len.
PingPong $\mathcal{R} = \{p, q\}$	(a)	\mathcal{R}	2	0	4
	(b)	\emptyset	2	2	4
Adder $\mathcal{R} = \{p, q\}$	(c)	\mathcal{R}	5	0	6
	(d)	\emptyset	5	5	6
TwoBuyer $\mathcal{R} = \{p, q, r\}$	(e)	\mathcal{R}	7	0	8
	(f)	$\{r\}$	18	6	12
OAuth $\mathcal{R} = \{c, a, s\}$	(g)	\mathcal{R}	12	0	11
	(h)	$\{s, a\}$	21	8	11
	(i)	$\{s\}$	26	13	11
	(j)	\emptyset	30	28	11
TravelAgency $\mathcal{R} = \{c, a, s\}$	(k)	\mathcal{R}	8	0	6
	(l)	$\{a, s\}$	9	3	6
	(m)	$\{a\}$	9	4	6
DistLogger $\mathcal{R} = \{l, c, i\}$	(n)	\mathcal{R}	10	0	7
	(o)	$\{i, c\}$	15	2	7
	(p)	$\{i\}$	16	4	7
CircBreaker $\mathcal{R} = \{s, a, r\}$	(q)	\mathcal{R}	18	0	10
	(r)	$\{a, s\}$	24	3	10
	(s)	$\{a, s\}$	23	3	11

When *merging* behaviour occurs during projection, we need to use the same channel in those interactions to achieve the correct behaviour. After traversing the global type to annotate each interaction, we merge annotations involved in merges during projection.

7 Evaluation

We evaluate our toolchain TEATRINO from two perspectives: *expressivity* and *feasibility*. For expressivity, we use examples from session type literature, and extend them to include crash handling behaviour using two patterns: failover and graceful failure. For feasibility, we show that our tool generates SCALA code within negligible time.

We note that we do *not* evaluate the performance of the generated code. The generated code uses the EFFPI concurrency library to implement protocols, and any performance indication would depend and reflect on the performance of EFFPI, instead of TEATRINO.

Expressivity. We evaluate our approach with examples in session type literature: PingPong, Adder, TwoBuyer [21], OAuth [32], TravelAgency [23], DistLogger [26], and CircBreaker [26]. Notably, the last two are inspired by real-world patterns in distributed computing.

We begin with the *fully reliable* version of the examples, and extend them to include crash handling behaviour. Recall that our extended theory subsumes the original theory, when all roles are assumed *reliable*. Therefore, the fully reliable versions can act both as a sanity check, to ensure the code generation does not exclude good protocols in the original theory, and as a baseline to compare against.

To add crash handling behaviour, we employ two patterns: *failover* and *graceful failure*. In the former scenario, a crashed role has its functions taken over by another role, acting as a substitute to the crashed role [3]. In the latter scenario, the protocol is terminated peacefully, possibly involving additional messages for notification purposes. Using the example from §2, the fully reliable protocol in Eq. (1) is extended to one with graceful failure in Eq. (2).

■ **Figure 12** Average Generation Times for All Variants in Table 1.

We show a summary of the examples in Table 1. For each example, we give the set of all roles \mathcal{R} and vary the set of reliable roles (\mathcal{R}). Each variant is given an identifier (Var.), and each example always has a fully reliable variant where $\mathcal{R} = \mathcal{R}$. We give the number of communication interactions (Comms.), the number of `crash` branches added (Crash Branches), and the length of the longest continuation (Max Cont. Len.) in the given global type.

The largest of our examples in terms of concrete interactions is `OAuth`, with Variant (i) having 26 interactions and (j) having 30 interactions. This represents a $2.17\times$ and $2.5\times$ increase over the size of the original protocol, and is a consequence of the confluence of two factors: the graceful failure pattern, and low degree of branching in the protocol itself. The `TwoBuyer` Variant (f) represents the greatest increase ($2.57\times$) in interactions, a result of implementing the failover pattern. The `CircBreaker` variants are also notable in that they are large in terms of both interactions and branching degree – both affect generation times.

Feasibility. In order to demonstrate the feasibility of our tool `TEATRINO`, we give generation times using our prototype for all protocol variants and examples, plotted in Fig. 12. We show that `TEATRINO` is able to complete the code generation within milliseconds, which does not pose any major overhead for a developer.

In addition to total generation times, we report measurements for three main constituent phases of `TEATRINO`: parsing, `EffpiIR` generation, and code generation. `EffpiIR` generation projects and transforms a parsed global type into an intermediate representation, which is then used to generate concrete `SCALA` code.

For all variants, the code generation phase is the most expensive phase. This is likely a consequence of traversing the given `EffpiIR` representation of a protocol twice – once for local type declarations and once for role-implementing functions.

8 Related Work

We summarise related work on both theory and implementations of session types with failure handling, as well as other MPST implementations targeting `SCALA` without failures.

We first discuss closest related work [3, 27, 33, 42], where multiparty session types are extended to model crashes or failures. Both [33] and [27] are exclusively theoretical.

[33] proposes an MPST framework to model fine-grained unreliability: each transmission in a global type is parameterised by a reliability annotation, which can be one of unreliable (sender/receiver can crash, and messages can be lost), weakly reliable (sender/receiver can crash, messages are not lost), or reliable (no crashes or message losses). [42] utilises MPST as a guidance for fault-tolerant distributed system with recovery mechanisms. Their framework includes various features, such as sub-sessions, event-driven programming, dynamic role assignments, and, most importantly, failure handling. [3] develops a theory of multiparty

session types with crash-stop failures: they model crash-stop failures in the semantics of processes and session types, where the type system uses a model checker to validate type safety. [27] follow a similar framework to [3]: they model an asynchronous semantics, and support more patterns of failure, including message losses, delays, reordering, as well as link failures and network partitioning. However, their typing system suffers from its genericity, when type-level properties become undecidable [27, §4.4].

Other session type works on modelling failures can be briefly categorised into two: using affine types or exceptions [14, 26, 29], and using coordinators or supervision [1, 41]. The former adapts session types to an *affine* representation, in which endpoints may cease prematurely; the latter, instead, are usually reliant on one or more *reliable* processes that *coordinate* in the event of failure. The works [1, 29, 41] are limited to theory.

[29] first proposes the affine approach to failure handling. Their extension is primarily comprised of a *cancel operator*, which is semantically similar to our crash construct: it represents a process that has terminated early. [14] presents a concurrent λ -calculus based on [29], with asynchronous session-typed communication and exception handling, and implements their approach as parts of the LINKS language. [26] proposes a framework of *affine* multiparty session types, and provides an implementation of affine MPST in the RUST programming language. They utilise the affine type system and `Result` types of RUST, so that the type system enforces that failures are handled.

Coordinator model approaches [1, 41] often incorporate *interrupt blocks* (or similar constructs) to model crashes and failure handling. [1] extends the standard MPST syntax with *optional blocks*, representing regions of a protocol that are susceptible to communication failures. In their approach, if a process P expects a value from an optional block which fails, then a *default value* is provided to P , so P can continue running. This ensures termination and deadlock-freedom. Although this approach does not feature an explicit reliable coordinator process, we describe it here due to the inherent coordination required for multiple processes to start and end an optional block. [41] similarly extends the standard global type syntax with a *try-handle* construct, which is facilitated by the presence of a reliable coordinator process, and via a construct to specify reliable processes. When the coordinator detects a failure, it broadcasts notifications to all remaining live processes; then, the protocol proceeds according to the failure handling continuation specified as part of the try-handle construct.

Other related MPST implementations include [9, 17, 18]. [18] designs a framework for MPST-guided, safe actor programming. Whilst the MPST protocol does not include any failure handling, the actors may fail or raise exceptions, which are handled in a similar way to what we summarise as the affine technique. [9] revisits API generation techniques in SCALA for MPST. In addition to the traditional local type/automata-based code generation [22, 36], they propose a new technique based on sets of pomsets, utilising SCALA 3 match types [4]. [17] presents CHORAL, a programming language for choreographies (multiparty protocols). CHORAL supports the handling of *local exceptions* in choreographies, which can be used to program reliable channels over unreliable networks, supervision mechanisms, *etc.* for fallible communication. They utilise automatic retries to implement channel APIs.

9 Conclusion and Future Work

To overcome the challenge of accounting for failure handling in distributed systems using session types, we propose TEATRINO, a code generation toolchain. It is built on asynchronous MPST with crash-stop semantics, enabling the implementation of multiparty protocols that are resilient to failures. Desirable global type properties such as deadlock-freedom, protocol

conformance, and liveness are preserved by construction in typed processes, even in the presence of crashes. Our toolchain TEATRINO, extends SCRIBBLE and EFFPI to support crash detection and handling, providing developers with a lightweight way to leverage our theory. The evaluation of TEATRINO demonstrates that it can generate SCALA code with minimal overhead, which is made possible by the guarantees provided by our theory.

This work is a new step towards modelling and handling real-world failures using session types, bridging the gap between their theory and applications. As future work, we plan to study different crash models (e.g. crash-recover) and failures of other components (e.g. link failures). These further steps will contribute to our long-term objective of modelling and type-checking well-known consensus algorithms used in large-scale distributed systems.

Nested Pure Operation-Based CRDTs

Abstract

Modern distributed applications increasingly replicate data to guarantee high availability and optimal user experience. Conflict-free Replicated Data Types (CRDTs) are a family of data types specially designed for highly available systems that guarantee some form of eventual consistency. Designing CRDTs is very difficult because it requires devising designs that guarantee convergence in the presence of conflicting operations. Even though design patterns and structured frameworks have emerged to aid developers with this problem, they mostly focus on statically structured data; nesting and dynamically changing the structure of a CRDT remains to be an open issue.

This paper explores support for nested CRDTs in a structured and systematic way. To this end, we define an approach for building nested CRDTs based on the work of pure operation-based CRDTs, resulting in *nested pure operation-based CRDTs*. We add constructs to control the nesting of CRDTs into a pure operation-based CRDT framework and show how several well-known CRDT designs can be defined in our framework. We provide an implementation of nested pure operation-based CRDTs as an extension to the Flec, an existing TypeScript-based framework for pure operation-based CRDTs. We validate our approach, 1) by implementing a portfolio of nested data structures, 2) by implementing and verifying our approach in the VeriF_x language, and 3) by implementing a real-world application scenario and comparing its network usage against an implementation in the closest related work, Automerger. We show that the framework is general enough to nest well-known CRDT designs like maps and lists, and its performance in terms of network traffic is comparable to the state of the art.

1 Introduction

To ease the development of geo-distributed applications, much research has studied the concept of *replicated data types* (RDTs). An RDT exposes to programmers an interface akin to that of a sequential data type while incorporating mechanisms to keep data consistent across replicas [9, 22, 14]. Conflict-Free Replicated Data Types [22, 21, 19] (CRDTs) are the most well-known family of replicated data types. CRDTs guarantee strong eventual consistency (SEC) [22] that adds to eventual consistency the guarantee of *state convergence*, i.e. if two replicas of the data type have received the same updates, they will be in the same state. This implies that replicas converge without synchronisation or conflicts because they reach the same state as soon as they have observed the same operations.

2:2 Nested Pure Operation-Based CRDTs

Designing new RDTs that guarantee convergence is a complex task. Only for data types for which all operations commute (e.g., counters), one can easily construct a CRDT (since regardless of the ordering in which operations are applied, the resulting state will be equivalent). A common approach to designing CRDTs is to use causal ordering for non-concurrent operations and handle conflicts between non-commutative concurrent operations [19, 13, 3]. Many current designs handle those conflicts in an ad-hoc way crafted for each data type, often relying on specific meta-data to track causality and relations. For example, some CRDT designs (e.g., OR-Set) use *tombstones* to ensure that removal operations commute [22]. However, for many CRDT types, this meta-data grows unboundedly. Moreover, it is very difficult to modify existing designs (e.g., add operations to the data type, or modify the design to work with different networking assumptions). Pure operation-based CRDTs [3] aim to solve those issues and propose an approach for building operation-based CRDTs based on a Partial Ordered Log (PO-Log) of operations. The approach exposes causal information from the underlying communication middleware which can be used to enable the removal of redundant meta-data. While pure operation-based CRDTs provide a structured framework to build CRDTs, it is designed to build CRDTs for flat data structures.

In this work, we focus on the issues raised by composing CRDTs, e.g., when CRDTs are nested or more than one CRDT is combined into a new one. Composing CRDTs is non-trivial, as the convergence property of a CRDT design is made to hold for a *single* CRDT but does not necessarily hold when several CRDTs are composed into a new one. Recent work has explored what concurrency semantics can be utilised for composing designs [19] and several specific implementations exist [15, 16, 18]. Existing approaches, however, mainly follow a state-based design, in which any information on applied operations is lost during the merging process. This may result in non-sensible designs for nested CRDTs and hampers the development of CRDTs where the operation history needs to be used to improve the merging algorithm. For example, recent work [25] explores the design of a distributed file system CRDT that uses nested structures for storing filesystem metadata. They argue that to properly support authentication primitives, all semantically related authentication information needs to be combined and considered in the merging semantics.

Operation-based techniques, on the other hand, are better suited for replicating nested data structures as information on applied operations can be used to determine the optimal ordering for concurrent operations. In the context of nested structures, this means that it is less complex to relate different operations or even separate them when deciding what nested semantics for non-commutative concurrent operations are needed. To the best of our knowledge, no uniform (structured) approach exists for designing and implementing nested CRDTs, where CRDT designers can easily coordinate the interaction between nested structures, as part of the concurrency semantics of the replicated structure. In this paper, we introduce a general approach to nesting and composing pure operation-based CRDTs and propose a framework for implementing pure operation-based nested CRDTs. For this, we extend the pure operation-based CRDT framework [3] with support for nested CRDT structures. We implement our approach by extending an existing pure operation-based CRDT framework written in TypeScript called Flec [5], where we develop a portfolio of nested data structures. We demonstrate the correctness of our approach using a VeriFy implementation where we verify that the structures always remain strong eventually consistent. Finally, we implement a distributed file system based on Vanakieva et al. [25] to assess the performance of our approach in comparison to a state-of-the-art JSON CRDT implementation, Automerge [15].

To summarise, we introduce the following contributions:

- A general approach for the design and implementation of nested CRDTs, building on the work of pure operation-based CRDTs.
- A full-fledged TypeScript implementation of our approach which includes a portfolio of existing and novel pure operation-based CRDTs.
- A validation of the correctness of our nested pure operation-based framework and a portfolio of CRDTs built on this framework.
- A performance evaluation showing that our approach has reduced network usage when compared to Automerge [15].

2 Background

In this section, we provide the necessary background to understand the contributions of this work. Baquero et al. [2] introduced the pure operation-based framework for designing CRDTs in a structured way while avoiding performance issues related to the unbound growth of meta-data. They build on the idea of relying on Reliable Causal Broadcast [8] (RCB) middleware to ensure causal ordering for non-concurrent operations (along with reliable delivery) [22, 2]. Instead of manually encoding causality information as meta-data to operations, the framework exposes causality information stored within the RCB middleware to CRDT implementors. More concretely, the framework employs a partially ordered log of operations (PO-Log) constructed with the causality information of the underlying RCB middleware. The state of the data structure can be computed by observing this log, and the log can be compacted to ensure that memory does not grow unboundedly. Figure 1 shows an example of a PO-Log of an Add-Wins (AW-Set) set replica (in a system of three replicas). It contains four add operations, which form the state $\{A, B, C\}$, depicted in grey. Three of these operations include causality information from the underlying RCB middleware, i.e. they carry a vector clock.

Algorithm 1 shows the distributed algorithm describing the interaction between the RCB middleware and the pure operation-based CRDT framework. Each replica contains has a particular state (s_i for replica i), representing its PO-Log. The *operation*(o) method is called by client applications (e.g. by a CRDT implementation using the pure operation-based framework) when an operation o should be applied. It ensures that operations are broadcasted to other replicas and annotated with a logical timestamp on delivery (t in the algorithm description). It does this by invoking the *broadcast* method from the RCB layer, which broadcasts the operation with the associated timestamp meta-data to all other replicas. On delivery of these operations (and after all causal dependencies are met), the RCB layer will invoke the *deliver*(t, o) method from the pure operation-based framework, where the log (s_i) will be modified if needed.

■ **Figure 1** The internal state of an AW-Set. One operation is causally stable, and as such does not contain a timestamp. Together, the operations form the state $\{A, B, C\}$.

2:4 Nested Pure Operation-Based CRDTs

The framework introduces the concept of *causal redundancy* to keep the log compact. The idea is that a particular operation may make existing operations in the log redundant, or that the arriving operation may be redundant itself. Rules for this can be defined by using two binary redundancy relations, \mathbf{R} and \mathbf{R}_- . \mathbf{R}_- defines whether an arriving operation makes existing entries in the log redundant, and \mathbf{R} defines if a newly arriving operation should be stored in the log. The definitions for these relations need to be provided by the concrete CRDT implementation. The framework can also determine when operations are *causally stable*, i.e., they have been observed on all replicas, and trim causal information for their log entries. Since new operations can never be concurrent with causally stable operations, their causal meta-data (such as timestamps) is thus no longer needed. The RCB layer can determine causal stability by comparing the vector clocks of incoming messages and decide whether a particular timestamp must have been observed by all nodes. Whenever a particular timestamp is causally stable, the `stable` function will be invoked by the RCB layer, and the framework will compact stable operations that are returned by the `stabilize` function. It does this by replacing (removing) the associated timestamp with the bottom (null) element. This can also be seen in Figure 1, where the `add(A)` operation has been stripped from causality information. Similarly to the redundancy relations, the `stabilize` function has to be provided by any CRDT implementation built on the framework.

■ **Algorithm 1** (Simplified) distributed algorithm for a replica i showing the interaction between the RCB middleware and the pure op-based CRDT framework.

```

state:  $s_i := \emptyset$ 
on  $operation_i(o)$  :
  |  $broadcast_i(o)$ 
on  $deliver_i(t, o)$  :
  |  $s_i := (s_i \setminus \{(t', o') \mid (t', o') \in s_i \cdot (t', o') \mathbf{R}_-(t, o)\}) \cup \{(t, o) \mid (t, o) \not\mathbf{R} s_i\}$ 
on  $stable_i(t)$  :
  |  $stabilize_i(t, s_i)[(\perp, o)/(t, o)]$ 

```

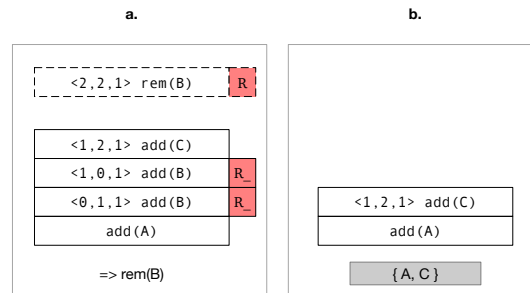

Table 1 shows the implementation for an AW-Set CRDT in the pure operation-based framework. The table is grouped as follows: (1) functions that are used by the framework and that dictate the interaction between new operations and entries in the log, and (2) procedures that can be invoked by the user for state serialisation or mutations.

The \mathbf{R} relation for the add-wins set defines that the `clear` and `remove` operations will never be stored in the log. \mathbf{R}_- , on the other hand, defines that an arriving operation o will make any stored operations (in the log) redundant if and only if the stored operation o' causally happened before the arriving operation (i.e. $t' < t$) and the arriving operation is acting on the same set element, or the arriving operation is a `clear` (i.e., which removes all happened-before elements). For example, a `remove(X)` will make a previous `add(X)` redundant; and a `clear` operation will remove all previous log entries. The combination of both rules ensures that `add` operations will always 'win' from concurrent operations. The implementation of `stabilize` defines that all causally stable operations will be stripped from their timestamps (to preserve memory consumption). Additionally, the log will only contain distinct `add` operations at any point in time. To query the state, a map function can extract each element from these operations (as shown in the `toList` function) and serialise it into an actual set data structure.

Figure 2 illustrates the internal state and the PO-Log of the AW-Set depicted in Figure 1 after receiving a `remove(B)` operation (depicted in the a. box) and after the operation has been applied (depicted in the b. box). Initially, the log consists of an operation which is

■ **Table 1** Semantics for the add-wins pure-op set, based on the approach in [3].

Pure	$(t, o) \mathbf{R} s = \text{op}(o) = (\text{clear} \vee \text{remove})$ $(t', o') \mathbf{R}_- (t, o) = t' < t \wedge (\text{op}(o) = \text{clear} \vee \text{arg}(o) = \text{arg}(o'))$ $\text{stabilize}(t, s) = s$
User	$\text{toList}(s) = \{v \mid (_, [\text{op}=\text{add}, \text{arg}=v]) \in s\}$ $\text{add}(e) = \text{operation}([\text{op}=\text{add}, \text{arg}=e])$ $\text{remove}(e) = \text{operation}([\text{op}=\text{remove}, \text{arg}=e])$

■ **Figure 2** The internal states of an AW-Set, after receiving a remove (rem) operation, and after the operation has been applied.

causally stable (the **add(a)**), and three other operations which are not yet stable. Looking at the vector clocks, we can observe that the log has two concurrent operations, both of which add element B. When the arriving **remove(B)** is checked against these stored operations, both previous **add(B)** operations will be marked as redundant by the **R₋** relation (as the operations have the same key, and are causal predecessors). Additionally, the arriving operation itself is immediately marked as redundant by the **R** relation of the AW-Set semantics (all **remove** and **clear** operations are immediately redundant) and as such, it will not be added to the log. The box denoted by *b*. shows the final result of applying **remove(B)**: no entries for adding element B remain, and the removal operation itself was not added to the log. Thus, the replica state becomes $\{A, C\}$.

3 Nesting Pure Operation-Based CRDTs

Currently, it is not possible to reason about nested structures within the pure operation-based CRDT framework. Redundancy relations only work on a flat level, and any logic to traverse hierarchical/nested structures would have to be manually bolted on top of the framework in an ad-hoc way.

As there is no native support for this functionality, nested designs built with the current framework require developers to store nested operations in a flattened form in the main log. To evaluate and apply the contents of the log, developers would need to either fully combine the logic of the nested and main top-level CRDT or encode the nested CRDT semantics in the query functions. In the former case, the redundancy relations and query functions would have to manage all concurrency rules for all needed nested strategies. This greatly complicates the design of such structures and makes them more prone to errors. In the latter case, only the query functions would need to be touched, but they would have to implement all redundancy logic from scratch. A programmer could delegate operations to separate components for the nested CRDTs, but in the end, this implies a reimplementaion of the delivery of operations in the query function logic while this should be kept in the framework.

In this work, we propose a novel nested pure operation-based CRDT framework that enables the systematic construction of nested data structures building on the ideas of Baquero et al [2]. We explore a framework that allows developers to combine and nest existing pure operation-based CRDTs and provides constructs for the development of novel CRDTs. In particular, we focus on designs where nested structures can dynamically change at runtime, i.e., data structures that grow and shrink during the lifetime of an application, such as maps and lists, where values can be CRDTs. Our approach offers developers novel framework constructs to define the relationship between parent and child CRDT. The framework then handles all replication aspects regarding the delivery of operations in the data-structure hierarchy, ensuring that causal ordering is respected and that nested children are recursively reset when needed. In the following section, we will focus on the CRDT framework level and detail our extensions to pure operation-based CRDTs to support nesting.

3.1 Extending the Pure Operation-Based Framework

In this work, we model a nested data structure as a nested hierarchy where children can be identified by a particular key and deeply nested children by an absolute path (list of keys) relative to the topmost data structure (the root CRDT). To support nested data structures, we introduce three extensions to the pure operation-based framework:

- An internal data structure to keep track of nested CRDTs (i.e., the *children* of a CRDT).
- An update propagation mechanism for nested CRDTs that delivers the applied operations ensuring that the concurrency semantics of parent data structures are upheld.
- A reset mechanism for nested CRDT operations that ensures that the concurrency semantics of children's data structures are upheld.

Each of these extensions is essential to ensure the correctness of replicated data types. In the following sections, we elaborate on them and motivate why they are needed.

3.1.1 Keeping Track of Nested Data Structures

Objects or data structures that have nested children typically refer to children by some key. Our approach assumes that children have a unique identifier by which they can be accessed (i.e., queried and updated). As nested children can also contain other nested elements, an absolute path can be constructed to identify a particular nested data structure, starting from the root (top-most) data structure.

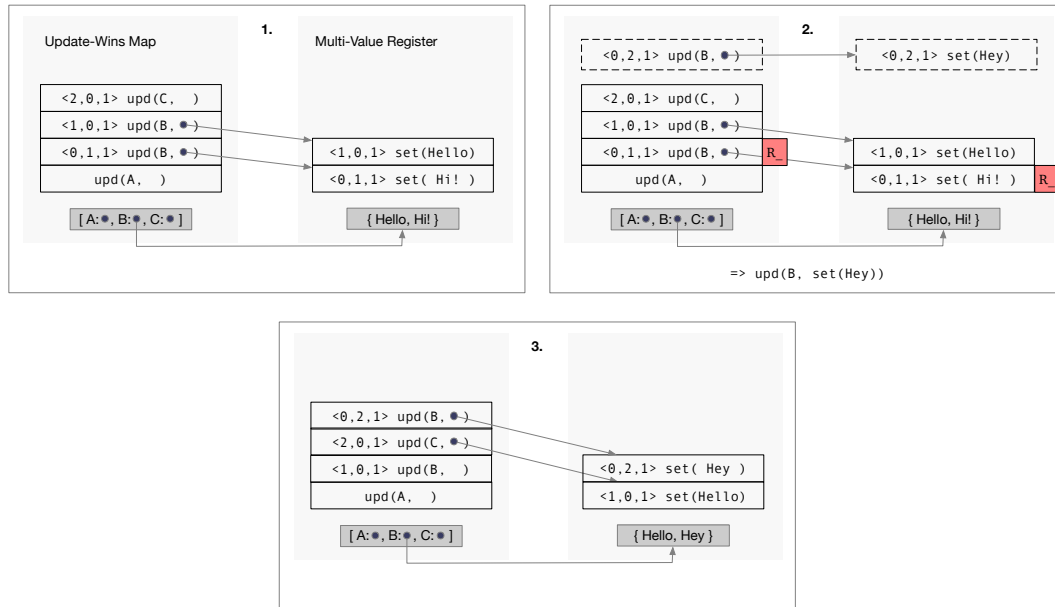

At the implementation level, a CRDT developer can decide in what manner key lookup works by providing an implementation of a particular handler function (`getChild`) that is used for lookup. The framework then provides a mechanism that allows absolute paths on a replicated structure to identify nested data structures that need to be queried or updated.

3.1.2 Updating Individual Nested CRDTs

When an operation needs to be applied to a nested child, the concurrency semantics of parent data structures must be upheld. Operations cannot just be immediately applied to the nested structure alone, as concurrent operations can be applied to the parent node which affects the key which points to the nested structure. For example, with a hash map, an entry could be concurrently updated, while it is being removed.

In our approach, when an update is applied to a particular child element, we will first issue special update operations to every parent node. These update operations signal the parent CRDTs that a nested operation is going to be applied and that it should be compared to

existing log entries using redundancy relations. For example, when building an update-wins replicated hash map, it is important to ensure that update operations win over remove operations (on the same key). At times, the update operation itself may be immediately redundant, and as such, there is no need to propagate the operation further to a nested child.

■ **Figure 3** Three stages of the internal state of a hash-map with update-wins semantics containing nested Multi-Value registers: 1) initial state, 2) arrival of an update (upd) operation, and 3) final state after applying the operation.

To illustrate how an update is applied in our approach, consider Figure 3 showing a hash map with update-wins semantics containing nested Multi-Value registers in three different stages. A Multi-Value register (MV-Register) [22] is a replicated register that, when faced with concurrent updates, will store all concurrent values. Updates that (causally) follow will replace previous values. This is in contrast to other replicated registers, for example, the Last-Writer-Wins (LWW) CRDT register [22] that always keeps a single value. When faced with concurrent updates, an LWW-Register will use an arbitrary method for picking a single update (such as picking the update from the replica with the highest network id). The first box (denoted by 1) shows the internal state and the PO-Log for the hash map and the register associated with the key 'B'. As explained, every update applied to the nested register has an associated update in the parent log. In this case, two concurrent updates were applied to the nested register, resulting in the state $\{Hello, Hi!\}$.

The second box shows the state when an `update(B, set(Hey))` is applied to the hash map. This update has a timestamp $\langle 0, 2, 1 \rangle$ which is concurrent with some operations $\langle 2, 0, 1 \rangle, \langle 1, 0, 1 \rangle$, but causally follows others $\langle 0, 1, 1 \rangle, \dots$. The update itself is applied to the hash map, making one of the existing update entries redundant, i.e., the one with vector clock $\langle 0, 1, 1 \rangle$, as it concerns the same key and has a non-concurrent timestamp. As the update operation itself is not redundant, its nested operation can be applied to the nested register. The `set(Hey)` is then applied to the nested register, making also one set operation redundant in the register, i.e., the one with vector clock $\langle 0, 1, 1 \rangle$. Note that there is another pair of concurrent operations in both the map and register that will not be made redundant, and thus are kept in the log. The third box shows the state and the log after applying `update(B, set(Hey))` resulting in the updated state $\{Hello, Hey\}$.

3.1.3 Maintaining Consistency of Children by Targeted Causal Resets

Applying redundancy checks on update operations ensures that the concurrency semantics of parents are upheld. However, they do not ensure that the concurrency semantics of children are upheld. In fact, the update mechanism ensures that redundancy relations are respected at each level of the CRDT, but these redundancy checks never cross hierarchical boundaries. This is problematic if a particular key is removed, but the remove operation is concurrent with one or more, but not all, previously applied operations (for example, remove operation c is concurrent with b , operation b is concurrent with a , but operation c causally follows operation a). This means that a key and associated child cannot be removed completely, as the child received some redundant operations (by the removal, e.g., operation a) and others that are not redundant (e.g., operation b).

To solve this issue, we introduce a novel nested redundancy relation R_n that allows nested children to be reset to a particular logical timestamp (inclusive or exclusive of concurrent operations). Using this relation, redundancy rules can be implemented that define hierarchical relations between log entries.

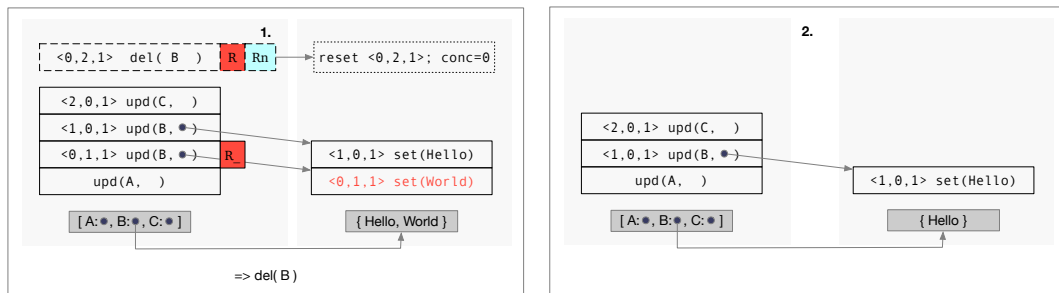

Figure 4 Example of a nested redundancy relation that selectively resets nested children, triggered by the deletion of a key. As the arriving delete (del) operation is concurrent with an update (upd) that arrived earlier, the nested child needs to be partially reset.

Figure 4 illustrates the use of the R_n relation in an update-wins hash map containing nested Multi-Value registers. The first box (denoted by 1) shows the internal state and the PO-Log for the hash map, and the register associated with the key 'B' when a $\text{delete}(B)$ operation arrives. As this operation is concurrent with one of the earlier updates in the map, and the map follows update-wins semantics, the key itself cannot be removed. The entry with a preceding vector clock $\langle 0,1,1 \rangle$, however, will be marked redundant by the existing R relation. At this point, the register associated with key B has partially redundant data, and as such needs to be updated to respect the remove operation. To this end, the R_n relation can be used to reset all operations *in the nested register* that are previous to the delete operation. In the case of the example, the set of the value 'Hi' (denoted in red in the figure) will be made redundant and removed from the register log. The second box shows the state and the log after applying the $\text{delete}(B)$ operation in which all redundant operations are removed from the entire hierarchy, and the state of the register is updated to $\{\text{Hello}\}$.

In the following section, we provide a more formal specification of our approach and extensions to the pure operation-based framework and describe example implementations for update-wins and delete-wins hash maps.

3.2 Formalised Semantics for Extended Functionality

We now describe our approach as an extension of the formal model of a pure operation-based CRDTs framework (cf. Section 2). Algorithm 2 describes the distributed algorithm for our novel nested pure operation-based framework specifying the interaction between the RCB middleware and the framework. The original Algorithm 1 used the i variable to denote a particular replica. In our extended model, Algorithm 2 compounds this with a list variable p , which denotes the path to the CRDT, relative to its parent. The top-most data structure is denoted as $root$. For example, $\{root, bob, favourite_colours\}$ could be a path that refers to a `favourite_colours` object associated with the key 'bob' in a map.

Compared to the original pure operation-based design, Algorithm 2 features new primitives for broadcasting and delivering nested operations:

- **broadcast_nested $_{i,p}(o)$** : broadcasts nested operations ensuring that the operation will be delivered to all replicas (reliably and in causal order). In our design, a broadcast can only be triggered from the top-most data structure, as such p will always be $root$.
- **deliver_nested $_{i,p}(t, o)$** : called when an operation o is delivered (e.g. after it was previously broadcasted) on a replica i at path p with causal clock t .
- **nested_operation $_i(p, o)$** : called when a nested operation o needs to be applied at path p .

Recall from Section 3.1.2 that when an operation is applied to a nested child, at each level of the parent hierarchy an `update` operation needs to be applied so that all redundancy rules can be activated. In the algorithm, the implementation of `nested_operation` ensures that an operation is packaged in an `update` operation and broadcasted using `broadcast_nested`. These broadcasted operations are received by the top-level data structure ($root$) using `deliver_nested`. `deliver_nested` will then try to deliver the operation to the child data structure specified by the path. At each level of the path, it will apply the `update` operation, check if the operation is not redundant, and if not, recursively descend into the hierarchy until the path only consists of one final child. It will then apply the actual operation to the last nested data structure using the non-nested `deliver` callback. Our approach extends the original `deliver` function with our novel nested redundancy relation: an implementation can use R_n to select what timestamps should become redundant for which nested children. Children are then (recursively) reset using the `reset` function, which takes a timestamp t and a variable $conc$ that denotes whether the reset is exclusive (only entries that happened-before) or exclusive (including all concurrent entries).

In the following section, we explore how an actual nested CRDT can be built using our proposed extensions.

3.3 Nested Pure Operation-Based Maps

In this section, we illustrate our framework by describing the design of two novel nested map CRDTs: an update-wins map (UW-Map) and a remove-wins map (RW-Map).

Table 2 shows the semantics for the update-wins map (UW-Map) in our pure operation-based framework which were informally described in the examples in Section 3.1. The design of the UW-Map CRDT is inspired by the add-wins Set CRDT [3, 4], with some modifications to take care of its nested nature [19]. The R relation for the UW-Map defines that `delete` operations will never be stored in the log (i.e., they are immediately redundant). They will, however, make any existing operation in the log redundant if they happened before (R_-). This ensures that keys can be deleted. Note that the R_- relation also makes `update` operations with the same key that happened before be redundant. This makes the data

■ **Algorithm 2** Distributed algorithm (for a replica i) showing the interaction between the RCB middleware and the pure operation-based CRDT framework.

```

state:  $s_{i,p} := \emptyset$ 
state:  $children_{i,p}$ 
on  $operation_i(o)$  :
  |  $broadcast_{i,root}(o)$ 
on  $nested\_operation_i(p, o)$  :
  |  $broadcast\_nested_{i,root}(update(p, o))$ 
on  $deliver\_nested_{i,p}(t, update((child, \emptyset), o))$  :
  |  $deliver_{i,p}(t, update(child))$ 
  |  $deliver_{n,child}(t, o)$  if  $(t, update(child)) \not\mathcal{R} s_{i,p}$ 
on  $deliver\_nested_{i,p}(t, update((child, p), o))$  if  $p \neq \emptyset$  :
  |  $deliver_{i,p}(t, update(child))$ 
  |  $deliver\_nested_{n,child}(t, update(p, o))$  if
  |  $(t, update(child)) \not\mathcal{R} s_{i,p}$ 
on  $deliver_i(t, o)$  :
  |  $s_{i,p} := (s_{i,p} \setminus \{(t', o') \mid \forall (t', o') \in s_{i,p} \cdot (t', o') \mathcal{R}_\perp (t, o)\}) \cup \{(t, o) \mid (t, o) \not\mathcal{R} s_{i,p}\}$ 
  |  $reset_{i,child}(t, 0) \mid \forall child \in children_{i,p} \cdot (child, 0) \mathcal{R}_n (t, o)$ 
  |  $reset_{i,child}(t, 1) \mid \forall child \in children_{i,p} \cdot (child, 1) \mathcal{R}_n (t, o)$ 
on  $stable_{i,p}(t)$  :
  |  $s_{i,p} := stabilize_{i,p}(t, s_{i,p})[(\perp, o)/(t, o)]$ 
  |  $stable_{i,child}(t) \mid \forall child \in children_{i,p}$ 
on  $reset_{i,p}(t, conc)$  :
  |  $s_{i,p} := s_{i,p} \setminus \{(t', o') \mid \forall (t', o') \in s_{i,p} \cdot ((t' \prec t) \vee (conc \neq 0 \wedge t' \parallel_c t))\}$ 
  |  $reset_{i,child}(t, conc) \mid \forall child \in children_{i,p}$ 

```

structure a bit more efficient. Finally, the R_n relation for UW-Map defines that all nested operations that happened before any delete need to be recursively reset (i.e. removed). As this remove should be exclusive, i.e., no concurrent entries should be removed, we additionally encode that $conc$ should be zero.

■ **Table 2** Update-wins pure operation-based map, with support for nested CRDTs.

Framework	$(t, o) \mathcal{R} s = op(o) = \text{delete}$ $(t', o') \mathcal{R}_\perp (t, o) = t' \prec t \wedge \text{arg}(o) = \text{arg}(o')$ $(child, conc) \mathcal{R}_n (t, o) = conc = 0 \wedge op(o) = \text{delete} \wedge \text{arg}(o) = child$ $stabilize(t, s) = s$
User	$update(p, o) = nested_operation([op=update, arg=[p, o]])$ $delete(c) = operation([op=delete, arg=e])$

An alternative to update-wins is ensuring that delete operations are ordered after concurrent updates, leading to a map with remove-wins semantics. Note that there are different ways to implement a CRDT from a sequential data type as there is no one solution for dealing with concurrent updates. Nevertheless, it is important to offer different variants to the end-user, as some concurrent semantics may be preferred over others in particular applications.

Table 3 shows the implementation of such a remove-wins map (RW-Map) in our framework. It is structured similarly to the AW-Map but has some additional complexity as the log needs to retain all delete operations until they are causally stable. The R_n relation encodes that all previous or concurrent nested updates need to be removed (to ensure remove-wins semantics).

■ **Table 3** Remove-wins pure operation-based map, with support for nested CRDTs.

Framework	$(t, o) \mathbb{R}_s$	$= \text{op}(o) = \text{update}$ $\wedge (\exists (t', o') \in s \cdot \text{arg}(o) = \text{arg}(o') \wedge \text{op}(o') = \text{delete} \wedge t \parallel_c t')$
	$(t', o') \mathbb{R}_\perp (t, o)$	$= t' \prec t \wedge \text{arg}(o) = \text{arg}(o') \wedge \text{op}(o) = \text{delete}$
	$(\text{child}, \text{conc}) \mathbb{R}_n (t, o)$	$= \text{op}(o) = \text{delete} \wedge \text{arg}(o) = \text{child}$
	$\text{stabilize}(t, s)$	$= s$
User	$\text{update}(p, o)$	$= \text{nested_operation}([\text{op}=\text{update}, \text{arg}=[p, o]])$
	$\text{delete}(c)$	$= \text{operation}([\text{op}=\text{delete}, \text{arg}=c])$

In this design of an RW-Map, in theory, `update` operations do not need to be stored in the log as these updates are stored in the nested children. However, only the last update operation for a particular child is kept (since previous update operations are removed from the log as they are redundant) As such, storing the `update` operations in the log can be useful to check if a particular child has a value, without having to query the nested children. When storing these entries poses a problem memory-wise, they can trivially be removed with no impact on the behaviour of the data type.

The implementation of these map CRDTs demonstrates that supporting nested structures can be tackled in a structured and easy way. Our framework handles all logic related to nesting and update propagation, aiming to provide an easy-to-use interface. Additionally, hierarchical redundancy rules can be encoded using the \mathbb{R}_n relation, ensuring that concurrency semantics are upheld at any level.

3.4 Discussion

We believe that our approach simplifies the design of replicated nested CRDTs, and with it, we aim to reduce their implementation complexity. With the presented methodology, one can think of every CRDT with nesting support as a flat CRDT, which needs to support one additional operation, namely `update`. For example, a map is similar to a set of keys with an associated value. In a set, we can add and remove keys. Using some rules we can make the set add-wins or remove-wins, and with a bit of extra work, we can define how an `update` operation could be ordered against concurrent add and remove. This could be the core design of a Map. Our framework will make sure that every nested operation, e.g. a nested operation to a child of the map, is first represented as an `update` operation for the parent CRDT. The parent CRDT (e.g. the map) does not need to know anything about the nested content of this update, it is simply trying to make sure that this update will be properly ordered between the additions and removals of keys. This alone, however, is not enough to ensure convergence, i.e. that the algorithm is functional and correct. Depending on the arrival order of an update in combination with other concurrent operations, the associated nested operation may have been applied to some replicas and not to others. To ensure that the nested state converges, the algorithm sometimes might need to apply some cleanup procedures, which is precisely where the nested redundancy relation comes into play. In Section 5.1 we formally prove that this is the case for our approach and our implemented designs.

4 Implementation

We implemented our novel nested pure operation-based approach in Flec [5, 6], an extensible programming framework and middleware for CRDTs written in TypeScript. Flec incorporates the concepts of ambient-oriented programming [10, 12], to discover and communicate with

replicas in a distributed dynamic network. Since it has support for pure operation-based CRDTs and RCB for causal delivery, Flec is the ideal platform for implementing our approach. In this section, we describe the extensions and modifications to Flec that are required to support nested pure operation-based CRDTs.

4.1 Nesting in Flec

To support the implementation of pure operation-based CRDTs, Flec provides an open framework with the following operations:

- **isPrecedingOperationRedundant** and **isConcurrentOperationRedundant**: encode the $\mathbf{R}__$ (or R_0, R_1) binary relation(s) defining if existing log entries become redundant by a new operation. Alternatively, **isRedundantByOperation** unifies both methods.
- **isArrivingOperationRedundant**: Encodes the \mathbf{R} binary relation (i.e., is a new operation redundant by an already existing log entry).
- **onLogEntryStable**: performs an action when an operation becomes stable.
- **onRemoveLogEntry**: performs an action when a particular item is removed from the log (for example if it was marked redundant by **isRedundantByOperation**).
- **onAddLogEntry**: performs an action when a new operation arrives in the log.

To build an actual CRDT data type, developers have to implement these methods, following the semantics of the datatype. While **onLogEntryStable**, **onRemoveLogEntry**, and **onAddLogEntry** are not required to implement the CRDT semantics, they can help optimise a pure operation-based CRDT to use a native data structure for causally stable entries. The log, entries, and optional native data compacted structures can be queried using the following methods:

- **getLog**: gets all current log entries.
- **getState**: gets all current log entries, the compact native state, and the current logical timestamp for the replica.
- **getConcurrentEntries**: gets all concurrent log entries for an operation.

In this work, we extend the framework with the following new hooks and operations to implement nested pure operation-based designs:

- **setChildInitialiser**: is a method that will be used to initialise new children, using child-specific constructs (e.g. if you want children to be AW-Sets, the initialiser will return a new AW-Set).
- **doesChildNeedReset**: encodes the \mathbf{R}_n binary relation (i.e., from what timestamps do children need a partial reset).
- **performNestedOp**: performs a nested operation and broadcasts it to other replicas.
- **addChild**: register a CRDT as a child to a parent, for a particular key.
- **resolveChild**: override the default internal child bookkeeping and instruct the framework on how to resolve a particular child CRDT based on a name (this will disable **addChild**).

4.2 Implementing Nested CRDTs in Flec

We now illustrate the extended Flec by means of the RW-Map CRDT described in Table 3. Listing 1 and Listing 2 show the core of the implementation of RW-Map CRDT in Flec. Lines 4 to 8 in Listing 1 define the CRDT constructor, which is used to initialise the **values** property that contains all nested children. Additionally, an initialiser can be specified that sets the initial (start) value for children. For example, if a map with a nested AW-Set is needed, the initializer will initialize a new AW-Set CRDT. Lines 14–16 in Listing 1 show the

update function which can be used to apply nested operations on children (by CRDT client code). Any operation on a child is indicated by specifying a particular path, and the update to be applied. Using `performNestedOp` this operation will be propagated to the child and all replicas. The actual semantics can be seen in Listing 2 which shows the implementation of the redundancy relations and children referencing.

■ **Listing 1** The implementation of an RW-Map in Flec, using the described extensions (A).

```

1  export class RRWMap extends PureOpCRDT<MapOps> {
2    values: Map<string, NestedCRDT>;
3
4    constructor(initializer: () => NestedCRDT) {
5      super();
6      this.values = new Map();
7
8      this.setChildInitialiser(initializer);
9    }
10   ...
11   // User functions
12   ...
13
14   public update(path, ...args) {
15     this.performNestedOp("update", path, args);
16   }
17 }

```

Lines 20 to 22 in Listing 2 show the implementation of the `resolveChild` method which allows the underlying Flec framework to reference children, stored in the `values` property. The rest of the listing shows how the RW-Map implements redundancy relations to achieve remove-wins semantics: the RW-Map provides an implementation for `isPrecedingOperationRedundant` to implement the R_{-} relation: any operation in the log is redundant if it has happened before a newly arriving operation, and if they are acting upon the same child. It also implements `isArrivingOperationRedundant` to define the R relation: any arriving update is not applied if a concurrent delete is stored in the log. Finally, by providing an implementation for `doesChildNeedReset` we specify that when a delete arrives for a particular child, the child will be reset. The `reset_concurrent` flag is set to true to indicate that even concurrent updates to the child should become redundant.

■ **Listing 2** The implementation of an RW-Map in Flec, using the described extensions (B).

```

1  protected isPrecedingOperationRedundant(existing: MapEntry, arriving
2    : MapEntry, isRedundant: boolean) {
3    return arriving.isDelete() && existing.hasSameArgAs(arriving);
4  }
5
6  protected isArrivingOperationRedundant(arriving: MapEntry) {
7    const concurrentDeletes = this.getConcurrentEntries(arriving).
8      filter(e => e.entry.isDelete() && e.entry.hasSameArgAs(
9        arriving));
10   return concurrentDeletes.length > 1;
11 }
12
13 protected doesChildNeedReset(child, arriving: MapEntry) {
14   return {
15     condition      : arriving.isDelete() && arriving.args[0] ==
16       child,
17     reset_concurrent: true
18   };
19 }
20
21 // Resolve child CRDTs
22 protected resolveChild(name: string) {
23   return this.values.get(name);
24 }

```

5 Validation

To validate our work, we conduct three experiments. First, verify the correctness of our proposed framework and nested pure op-based maps. Secondly, we implement the concepts in a real programming framework and finally, we compare it to another framework featuring similar concepts.

5.1 Verification with VeriFx

In order to verify our approach, we have re-implemented the core of our nested pure operation-based CRDTs in VeriFx [11]. VeriFx is a programming language for replicated data types with automated proof capabilities that allow users to implement replicated data types in a high-level language and express correctness properties that are verified automatically. VeriFx internally uses an SMT theorem prover to search for counterexamples for each property that needs to be upheld. It also enables the transpilation of the data types to mainstream languages (e.g. Scala and JavaScript).

Correctness means that strong eventually consistent data types can be built with the framework and that they exhibit the *strong convergence* property which requires that replicas need to have received the same operations to be in the same state (regardless of the order in which the operations have been received). Shapiro et al. showed in [22] that operation-based CRDTs guarantee strong convergence if all concurrent operations commute. In our case, this implies checking the effects of all redundancy relations. Proving the correctness is, however, slightly trickier in our case, as we are dealing with a recursive design. SMT solvers, such as Z3 used by VeriFx, do not deal well with recursive and nested data structures, as they might not be able to find a solution in a finite time. To verify our approach, we thus combine VeriFx proofs with structural induction, which limits the recursion depth needed to verify our design:

- Base case: we implemented a 'perfect' resettable pure operation-based CRDT in VeriFx that can model both a flat CRDT or a CRDT containing children. The CRDT logs all operations in a single flattened log (e.g., one log for all potentially nested structures). Items in the log can be reset by a parent when requested. No redundancy rules are applied. This design ensures that we can represent a 'correct' nested structure (in terms of SMT assumptions) without needing a recursive model. We use a VeriFx proof to ensure convergence of this 'perfect' CRDT.
- Induction step: a particular nested CRDT can be implemented on top of our VeriFx implementation and set to use perfect nestable CRDTs as children. With this approach, VeriFx can then be used to prove that our approach is correct for one level of nesting, for all pairs of operations.

By combining the base case and induction step, we prove using structural induction that our framework remains correct for any nestable structure.

7            && (e.t.before(t2) || e.t.concurrent(t2))
8              ))) =>: {
9      map.delete(t1, k1).delete(t2, k2) == map.delete(t2, k2).delete
10     (t1, k1)
11   }
12 }

```

As an example, Listings 3, 4, and 5 show the VeriF_x proof logic that was used to check the behaviour of concurrent operations on an update-wins map implemented with our framework. We define that any pair of correct operations that are concurrent and applied to a correct state should commute. The operations and state are correct if the operations (causally) follow or are concurrent with all other operations that were applied previously to the state (e.g. everything in the log). For this definition, we assume the usage of RCB (which is the case with the pure operation-based CRDT framework), so that we know that everything in the log must be concurrent or happened-before. In other words, the logic encodes the correctness properties that should always hold in our framework, i.e. that if all operations on the map commute and the nested operations are applied to correct CRDTs (in our case, all nested operations are applied to a 'perfect' CRDT), that the map is correct.

We use the automatic VeriF_x prover to verify these properties hold given the implemented designs. Internally, the VeriF_x SMT engine will look for valid solutions that satisfy the negation of our definitions, it will search for any case where the correctness properties are violated. Since no counterexamples (valid solutions for the negation of properties) were found after exhausting all search options, we can then constitute that our framework model is valid according to the correctness properties.

■ **Table 4** Implemented nested CRDT types.

CRDT	Semantics
UW-Map	Update-wins map where values can be CRDTs. Update win from concurrent deletes.
RW-Map	Remove-wins map where values can be CRDTs. Deletes win from concurrent updates.
RW-Map (mod)	Modular version of the remove-wins map that allows more efficient memory usage.
AW-Map	A variant of the update-wins Map where keys are managed by an add-wins set.
AW-Set	An add-wins set where values can be CRDTs.
DW-List	A delete-wins linked list where elements can be CRDTs.
ImmutableCRDT	A map with immutable keys, which behaves similarly to structs in C.

Using this approach, we have verified our map designs, validating both the concurrency semantics of our proposed CRDTs and proving that our novel framework functions correctly. The benefit of our verification approach is that to validate the correctness of any nestable CRDT (built on our framework), one only needs to encode proofs for the operations on a flat level. All needed nesting aspects of the proof will automatically be inherited from our VeriFx implementation. The full source code for our VeriFx implementation, including proofs and implemented models, is included as an artifact.

5.2 Portfolio of Nested CRDTs in Flec

To show the flexibility and applicability of our approach, we have implemented several commonly used data structures as novel nested pure operation-based CRDTs in Flec, summarised in Table 4. As shown in the previous section, we have map implementations with update-wins and remove-wins semantics. Maps form the basis for many other data structures and thus are essential to any replication framework. They have been verified using their VeriFx-based implementations and have been used in more complex data structures since.

We have implemented two other maps: one modified map (based on the remove-wins map) that optimises some structures to have better memory resource usage, and another map where keys are managed by an add-wins set. Finally, we have a delete-wins list that can be used to store values in sequential order. Similarly to other sequential replicated structures such as RGAs [13], a linked list is used internally.

The source code for the update-wins map, remove-wins map and delete-wins list implementations can be found as part of the included artifact.

5.3 Use-Case: A Mixed CRDT-Based Distributed Filesystem

To validate our approach in a real-world application scenario, we implemented a distributed file system based on the work of [25] in our Flec implementation. This application is also used later in Section 5.4 to compare our approach to state-of-art.

Flec does not only support pure operation-based CRDTs, it has many general-purpose constructs for building any replicated data type. As such, it comes with a portfolio of (non-pure-op) general CRDTs. While our extensions to Flec were focused on pure operation-based CRDTs, part of the nesting support we added can also be used in conjunction with general non-pure operation-based CRDTs to develop real-world applications.

When composing (traditional) CRDTs, operations on a (parent) root node typically trigger several operations that will be applied to internal (nested) CRDTs. For a single operation, these sub-operations need to be applied atomically, they cannot be viewed as independent and should not automatically replicate to nested children of replicated CRDTs. This is in contrast with our main approach where an update is applied via a particular sub-path. To ensure compatibility with this approach in the framework, nested children can detect the context in which operations are applied. If a nested CRDT has a parent, and an operation is applied directly from that parent (and not via a nested update), the operation will not be broadcasted to other replicas. Instead, it is assumed that the (top-)parent operation will be broadcasted, resulting in the same nested update path on other replicas.

We now discuss the overall data structures and operations of the distributed file system. Listings 6–8 in the appendix show the core of the implementation. It has been modified to hide some minor boilerplate code, type definitions, and a lot of operation handling code, but it contains the essentials. Listing 6 shows the main body of the `DistributedFS` class, which implements the core functionality of the CRDT. By extending the `SimpleCRDT` class it automatically inherits all the distribution and CRDT functionality from Flec (along with our extensions). Lines 5-21 define the required data structures for the distributed file system that keep track of metadata for files, groups and users. To this end, we define three maps, and each map on its own contains records (in the form of `ImmutableCRDT`) containing other CRDTs for storing the metadata of particular files, groups and users. For example, the `files` data structure is defined using an RW-Map and contains filesystem meta-data related to access rights, ownership, and data content. The data types we use for the registers (`AccessRightF`, `UserID`, ...) are basic types constructed from primitive types such as numbers or strings and can be stored directly in the registers. `AccessRightF` is a numerical value that we index as a bit-vector to store our permission flags (similar to POSIX systems). We provide an additional TypeScript class, `AccessRight`, that provides a high-level abstraction to this bit-vector, but concretely we store numerical values in the CRDT register. Lines 24-28 define the `onLoaded` method which associates the aforementioned three maps with their parent CRDT. In line 30, the `setHandler` method defines all operation handlers which implement the semantics of the CRDT.

Listing 7 shows the implementation of the `CreateFile` operation in more detail. Listing 8 shows code that exposes some of the CRDT API to the local user, for performing some basic actions which are used by the `test` method in Listing 9 to show local usage of the file system functionality. Flec will ensure that all operations are properly replicated and distributed. In general, most of the code is similar to that of sequential data structures, and the API is not much more complex. This is in line with the goal of our framework: an easy-to-use interface for building CRDTs where developers can immediately benefit from a middleware that does all the heavy lifting.

5.4 Evaluation of Network Traffic in Comparison With Automerge

To compare our approach with state of the art, we implemented the same distributed filesystem in Automerge v1.0.1 [15] and evaluated the differences in network traffic between our Flec implementation and the Automerge implementation.

It is not possible to select the individual concurrency semantics for nested objects with Automerge, as is possible with our extension to Flec. As such, the implementation has a slight difference in concurrency semantics when compared to the original design [25] and our implementation. For example, while the distributed filesystem (DFS) specification describes update-wins concurrency semantics for the user list, the Automerge implementation uses remove-wins concurrency semantics. Functionality-wise, it has the same features. In fact, in our implementations, both the Automerge and Flec versions have the same API.

2:18 Nested Pure Operation-Based CRDTs

Automerge itself does not provide a network layer but instead provides an API that allows you to query (Automerge) documents for changes, and if any changes exist, you can propagate these over any networking channel that your application depends on. On the receiving end, you can insert these changes back into Automerge, which can merge the received information in the local state. Automerge itself uses a state-based approach, where only the required changes (deltas) are propagated instead of the full state, to conserve network bandwidth.

■ **Figure 5** Network traffic (in bytes/op) originating from the source node for both Automerge and Flec. In every operation, a file is created and written.

■ **Figure 6** Total cumulative networking traffic (in bytes/op) from all nodes for Automerge. In every operation, a file is created and written.

For the experiments, we used a virtual network for both Automerge and Flec, which allows us to reproduce benchmarks and results with little non-determinism. We set up a system with 5 nodes (ad-hoc, peer-to-peer), and issue a thousand operations per experiment.

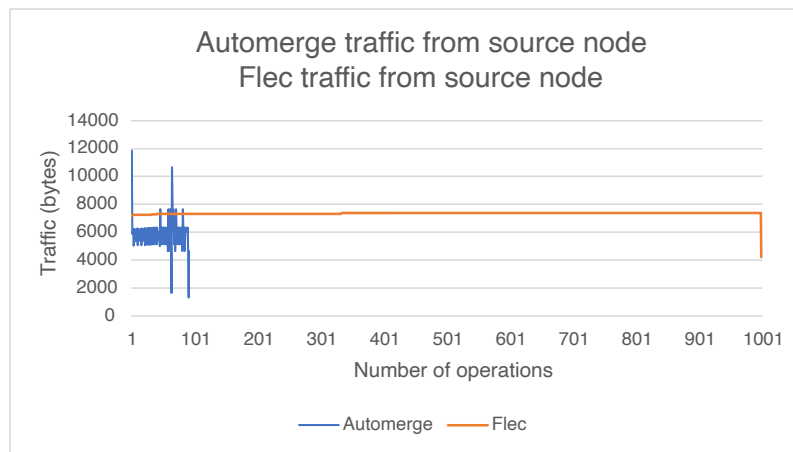

5.4.1 Experiment A: File Creation and Writing

For the first benchmark, each operation exists out of file creation and file modification. We applied these operations a thousand times to a deployed distributed file system, once using the Flec implementation and once with the Automerge implementation.

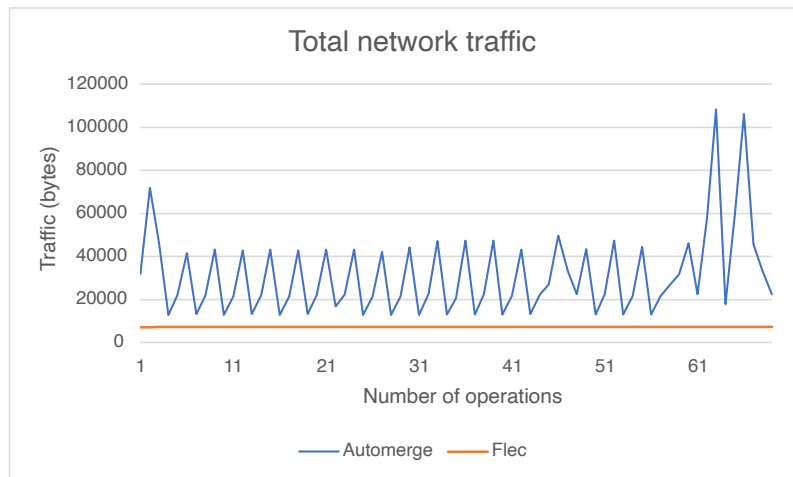

Figure 5 shows the network traffic originating from the source node (the node where the operations are applied), for both implementations. As both our approach and Automerge share the essential updates, the results are fairly stable and linear. Automerge will always send small updates containing the state delta (which means the newly modified file) and our extension to Flec sends the operations itself. While Automerge uses a binary representation for the update payload, the payload itself is still heavier than the non-optimized JSON payload used in Flec.

The visualisation hides some essential information, however. Automerge uses an additional protocol that allows replicas to propagate updates among each other. This means that not only the source node will share information, but also other nodes that received the new updates if they believe that other replicas may be missing information. Figure 6 highlights the additional traffic, showing that it makes up a significant portion of the total network traffic. In Flec updates are only sent directly from a source node to a destination node, and as such, there is no additional network usage.

5.4.2 Experiment B: User, Group, and File Creation, and Configuration

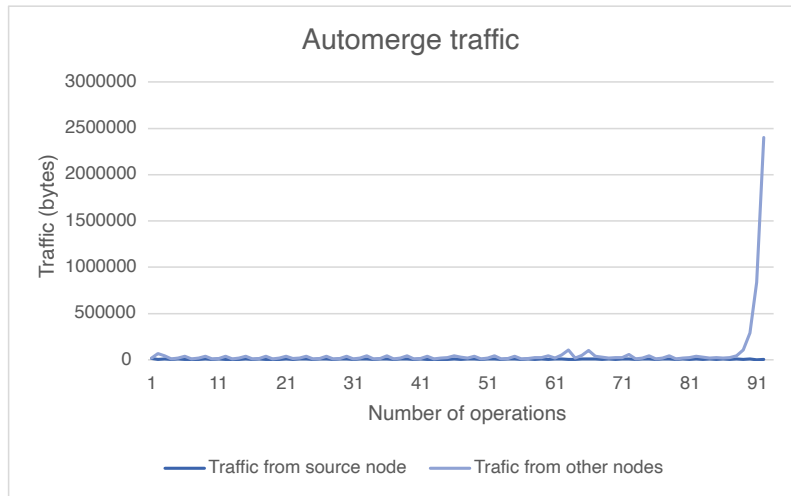

■ **Figure 7** Network traffic (in bytes/op) originating from the source node for both Automerge and Flec. Every operation creates a new user, a new group, and a new file. The user is added to the group, and the file is created with the new user as the owner. Finally, the file is written.

■ **Figure 8** Total network traffic (in bytes/op) for both Automerge and Flec. Every operation creates a new user, a new group, and a new file. The user is added to the group, and the file is created with the new user as the owner. Finally, the file is written.

For the second experiment, in each operation, we create a new user, and a new user group, add the user to the new group, create a new file (with the new user as owner), and write to this file. This extra complexity leads to some interesting results. As seen in Figure 7 the

■ **Figure 9** Total network traffic for Automerge for the previous experiment, highlighting an issue with exponential growth after a certain number of operations.

Automerge measurements stop at around ~ 100 operations. This is because the additional gossip traffic starts growing exponentially (see Figure 9) and causes the entire system to halt. We are not exactly certain what causes this problem, but we did not observe this issue with the previous experiment, only when we applied more complex operations. We believe that this is not correct behaviour from Automerge but have not been able to identify the root cause of the bug yet. The behaviour is consistent and reappears with each run. To be able to evaluate this example anyway, we will only focus on the initial measurements before the exponential explosion. Based on Figure 7 we can see that Automerge has a lower network overhead on the source node when compared to Flec. When looking at the total traffic, however (Figure 8), we can see that Automerge still utilizes more bandwidth. The reason for this is that as we are sending many operations, other replicas start propagating updates as well, resulting in the source node itself sending fewer updates (as it is relieved from work).

5.4.3 Experimental Evaluation: Conclusion

With this experimental evaluation, we showed that our approach is comparable to state-of-the-art CRDT frameworks, even though Flec and our extensions have not yet been optimised for non-experimental use. While additional optimisations can be applied to the pure operation-based CRDT framework and our nested framework extension, these results are promising and show that our approach is viable in real-world scenarios.

We now discuss some of the potential threats to the validity of our experimental evaluation and why our benchmark methodology and conclusions are not invalidated by these threats.

- T: The number of replicas used in our benchmarks (5) is potentially too low.
- The results of the experiments show that this number is fair, as it allows us to observe interesting differences between both benchmarked platforms. For example, in Figure 6., we can see that the total traffic generated by Automerge in experiment A quickly exceeds the traffic of our approach, but we can still compare results in a reasonable way.
- T: The chosen experiments are not realistic.
- The operations are tailored to induce complicated internal behaviour of the replicated data type, which we expect to also occur doing normal and realistic tasks. Of course, in a realistic setting such operations may not be applied repeatedly, but in the context

of our evaluation we wanted to evaluate behaviour under repeated, continual usage while testing many different parts of the CRDT framework as well. However, the total amount of operations used in the benchmarks could be achieved over a small period in a real deployment, and therefore it is important that a distributed filesystem system can handle such load. The operations used aim to use nesting to its full extent, in a realistic application case (a distributed file system). We, therefore, believe that the benchmarks are suitable for evaluating our approach.

- T: The benchmarks only compare results with one other related work.
- While comparing with extra platforms could improve the evaluation, we do not believe that this invalidates or diminishes our results. Automerge is a state-of-the-art framework for replicated data structures, with a lot of usages, and therefore a proper framework to compare against and evaluate whether our proposed approach has viability.

6 Related Work

The bulk of research in replicated data types has focused on devising a portfolio of conflict-free data structures such as counters, sets, and linked lists [22, 24, 20, 7, 21, 19]. However, the composition and nesting of CRDT have drawn little attention so far. The composition of replicated structures is possible in a few frameworks like Automerge [15] and Lasp [17]. While Automerge allows programmers to arbitrarily nest linked lists and maps in a document, it doesn't allow for much flexibility regarding the actual merging semantics. Lasp supports functional transformations over existing CRDTs provided in the language, which allows a composition to some extent. However, when the current portfolio of CRDTs falls short in those frameworks, developers need to design the desired nested data structure from scratch. This requires rethinking the data structure completely such that all operations commute and manually implement conflict resolution for concurrent non-commutative operations, which is hard and error-prone [22, 15, 1].

Weidner et al. [23] explore ways to compose and de-compose pure operation-based CRDTs. They introduce techniques for creating novel CRDTs based on existing (de-composed) CRDTs *with a static structure*. They do not aim to provide a solution for creating general nested data structures, but instead, propose constructs to define the semi-direct product of op-based CRDTs. This means that instead of nesting and maintaining individual semantics, novel semantics are introduced to create a combination of several CRDTs, leading to an entirely new, non-nested CRDT. In our approach, nested data structures can change dynamically during runtime, using maps, lists, and sets.

Preguiça in [19] explains several possible nesting semantics for operation-based CRDTs. To support a wide variety of CRDTs as nested values in different settings, it will be necessary for the CRDTs to be able to partially reset themselves to an initial state before a particular timestamp. Typically, this means that this reset has to be recursive and that nested sub-CRDTs will need to be reset as well. Without a disciplined approach, combining ad-hoc CRDTs will be hard. The benefit of using a log-based approach, which we are proposing, is that such recursive resets can be supported at the framework level, in a unified way, without needing to modify the semantics of CRDTs.

Operation-based and state-based CRDTs are two approaches to guarantee SEC that share an equivalence to some extent. While both approaches can be emulated as each other [22], it depends on the application or system in use which approach might be more suitable. It is typically a tradeoff choice, between waiting for the right moment to make a state merge, or rather propagating operations continuously. It should be possible to emulate our approach

(and pure operation-based CRDTs in general) as a state-based design, but making it efficient might be problematic as one would need to keep track of extra meta-data related to the applied operations (in order to maintain individual semantics between nested components). This information comes for free in an operation-based CRDT approach; as the operations themselves are directly propagated.

7 Conclusion

Conflict-Free Replicated Data Types (CRDTs) are useful programming tools to replicate data in a distributed system as they guarantee that eventually, all replicas end up in the same state. In this paper, we explore a structured approach for designing nested CRDTs based on the ideas of pure operation-based CRDTs. We propose a novel framework for building nested pure operation-based CRDTs and show how several common nested data structures can be designed and modelled in the framework. We validate our approach by extending an existing pure operation-based framework written in TypeScript, Flec, to include support for nested pure operation-based CRDTs and implement a portfolio of commonly nested data structures. This portfolio includes novel add-wins and remove-wins pure operation-based CRDTs, implemented following our framework. Additionally, we demonstrate the flexibility of the framework by implementing a distributed filesystem model using these techniques. We used an SMT-based implementation to verify the correctness of our approach. Finally, showed that our approach produces competitive results compared to Automerge, a state-of-the-art framework.

A DFS Code Listings

This appendix contains code listings with portions from our distributed filesystem test implementation. A legend for the used types can be found in Table 5.

■ **Table 5** Legend for the TypeScript classes and types used in the DFS implementation.

Class / Type	Description
RWWMap	Nested Remove-Wins Map CRDT.
RUWMap	Nested Update-Wins Map CRDT.
ImmutableCRDT	ImmutableCRDT map. Nested CRDT map that works as a C struct.
Register<T>	LLW-Register CRDT, containing a primitive value of type T.
AccessRightF	Alias of the 'Number' type, represents a bit vector with access flags.
AccessRight	Abstraction over AccessRightF, never stores in a CRDT, just used for easy modification of the access right bit vectors.
SimpleCRDT	Abstract CRDT class in Flec, for creating operation-based CRDTs.
GroupID / UserID / FileID	Aliases for strings that represent UUIDs.

■ **Listing 6** The general structure of the DFS nested CRDT, highlighting the main nested children that contain the filesystem meta-data.

```

1 export class DistributedFS extends SimpleCRDT<FSOperation> {
2   handler: FSOperation;
3   ...
4
5   files = new RRWMap(t => new ImmutableCRDT({
6     access_right_owner: new Register<AccessRightF>(),
7     access_right_group: new Register<AccessRightF>(),
8     access_right_other: new Register<AccessRightF>(),
9     file_owner: new Register<UserID>(),
10    file_group: new Register<GroupID>(),
11    file_data: new Register<string>()
12  }));
13
14  groups = new RRWMap(t => new ImmutableCRDT({
15    group_users: new AWSet(), // must be RW
16    created: new Register<flag>()
17  }));
18
19  users = new RUWMap(t => new ImmutableCRDT({
20    is_admin: new Register<flag>()
21  }));
22  ...
23
24  onLoaded() {
25    this.addChild("files", this.files);
26    this.addChild("users", this.users);
27    this.addChild("groups", this.groups);
28  }
29
30  setHandler() {
31    const me = this;
32    this.handler = {
33
34      ChangeOwner(userId: UserID, newOwnerId: UserID, fileId: NodeID
        ) { ... },

```

```

35     ChangeGroup(userId: UserID, newGroupId: GroupID, fileId:
        NodeID) { ... },
36     ChangeOwnerPermission(userId: UserID, newPerm: AR, fileId:
        NodeID) { ... },
37     ChangeGroupPermission(userId: UserID, newPerm: AR, fileId:
        NodeID) { ... },
38     ChangeOtherPermission(userId: UserID, newPerm: AR, fileId:
        NodeID) { ... },
39     ...
40     CreateUser(with_admin_rights: boolean, id: string) { /* ... */
        },
41     CreateGroup() { /* ... */ },
42     AssignUserToGroup(authorId: UserID, groupId: GroupID, userId:
        UserID) { ... },
43     CreateFile(userId: UserID, groupId: GroupID, fileId: NodeID) {
        ... see listing below ... },
44     WriteFile(userId: UserID, fileId: NodeID) { ... },
45     ...
46     update(key: string) { }
47 }
48 }
49 }

```

■ **Listing 7** Structure of the operation handling code for the DFS. Included is the code for the CreateFile callback, which can either be invoked locally or as a result of a replicated operation.

```

1  setHandler() {
2      const me = this;
3
4      this.handler = {
5          ...
6
7          CreateFile(userId: UserID, groupId: GroupID, fileId: NodeID) {
8              const user = me.users.lookup(userId) as any;
9              const group = me.groups.lookup(groupId) as any;
10
11             if (group && user && group.group_users.contains(userId)) {
12                 console.log("adding file");
13
14                 me.files.update([{ key: fileId, op: "update" },
15                                 { key: "file_owner", op: "write" }], userId);
16                 me.files.update([{ key: fileId, op: "update" },
17                                 { key: "file_group", op: "write" }], groupId);

Abstract

Resource-aware type systems statically approximate not only the expected result type of a program, but also the way external resources are used, e.g., how many times the value of a variable is needed. We extend the type system of Featherweight Java to be resource-aware, parametrically on an arbitrary *grade algebra* modeling a specific usage of resources. We prove that this type system is *sound* with respect to a resource-aware version of reduction, that is, a well-typed program has a reduction sequence which does not get stuck due to resource consumption. Moreover, we show that the available grades can be *heterogeneous*, that is, obtained by combining grades of different kinds, via a minimal collection of homomorphisms from one kind to another. Finally, we show how grade algebras and homomorphisms can be specified as Java classes, so that grade annotations in types can be written in the language itself.

1 Introduction

Recently, a considerable amount of research [25, 7, 2, 14, 15, 23, 8, 11] has been devoted to type systems allowing reasoning about resource usage. In *(type-and-)coeffect systems*, the typing judgment takes the shape $x_1 :_{r_1} T_1, \dots, x_n :_{r_n} T_n \vdash e : T$, where the *coeffect (grade)* r_i models how variable x_i is used in e . For instance, coeffects of shape $r ::= 0 \mid 1 \mid \omega$ trace when a variable is either not used, or used at most once, or used in an unrestricted way, respectively. In this way, functions, e.g., $\lambda x:\text{int}.5$, $\lambda x:\text{int}.x$, and $\lambda x:\text{int}.x + x$, which have the same type in the simply-typed lambda calculus, can be distinguished by adding coeffect annotations: $\lambda x:\text{int}[0].5$, $\lambda x:\text{int}[1].x$, and $\lambda x:\text{int}[\omega].x + x$. Other examples are exact usage (coeffects are natural numbers), and privacy levels. *Graded modal types* go further, by decorating types themselves with grades, in order to specify how *the result of an expression* should be used. In the different proposals in literature, grades have a similar algebraic structure, basically a semiring specifying *sum* $+$, *multiplication* \cdot , and 0 and 1 constants, and some kind of order relation. Here, we will assume a variant of this notion called *grade algebra*.

Resource-aware typing has been exploited in a fully-fledged programming language in Granule [23], a functional language equipped with graded modal types, hence allowing the programmer to write function declarations similar to those above. In Granule, different

kinds of coeffacts can be used at the same time, including naturals for exact usage, privacy levels, intervals, infinity, and products of coeffacts; however, available grades are fixed in the language. The initial objective of the work presented here was to study a similar support for Java-like languages, by introducing, in a variant of Featherweight Java (FJ) [19], types decorated with grades. Moreover, we wanted these grades to be taken, parametrically, in an arbitrary grade algebra; even more, we did not want this grade algebra to be fixed as in Granule, but to be extendable by the programmer with user-defined grades, by relying on the inheritance mechanism of OO languages. In the quest for such goals, we came up with several ideas which are novel, to our knowledge, with respect to the literature on resource-aware type systems, as detailed in the outline of contributions given below.

Resource-aware parametric FJ reduction. Given a resource-aware type system, we would like to prove that typing overapproximates the use of resources. However, resource usage is not modeled in standard operational semantics; for this reason, [8] proposed an instrumented operational semantics¹ and proved a soundness theorem showing correct accounting of resource usage. Inspired by this work, we define a *resource-aware semantics* for FJ, parametric on an arbitrary grade algebra, which tracks how much each available resource is consumed at each step, and is stuck when the needed amount of a resource is not available. Differently from [8], the semantics is given *independently* from the type system, as is the standard approach in calculi. That is, the aim is also to provide a simple purely semantic model which takes into account usage of resources. The resource-aware reduction is sound with respect to the standard reduction, but clearly not complete, since a reduction step allowed in the standard semantics could be impossible due to resource consumption.

Graded FJ. After defining the resource-aware calculus, we define the resource-aware type system. That is, types are decorated with grades, allowing the programmer to specify how a variable, a field or the result of a method should be used, e.g., how many times. Our approach is novel with respect to that generally used in the literature on graded modal types. Notably, in such works the production of types is $T ::= \dots \mid T^r$, that is, grade decorations can be arbitrarily nested. Correspondingly, the syntax includes an explicit *box* construct, which transforms a term of type T into a term of type T^r , through a *promotion* rule which multiplies the context with r , and a corresponding unboxing mechanism. Here, we prefer a much lighter approach, likely more convenient for Java-like languages, where the syntax of terms is not affected. The production for types is $T ::= C^r$, that is, all types (here only class names) are (once) graded; in contexts, types are non-graded, and grades are used as coeffacts, leading to a judgment of shape $x_1 :_{r_1} C_1, \dots, x_n :_{r_n} C_n \vdash e : C^r$. Finally, since there is no boxing/unboxing, there is no explicit promotion rule, but different grades can be assigned to an expression, assuming different coeffact contexts. We prove a soundness theorem, stating that the graded type system overapproximates resource usage, hence guaranteeing soundness, and, as a consequence, completeness with respect to standard reduction for well-typed programs.

Combining grades. The next matter is how to make the language *multi-graded*, in the sense that the programmer can use grades of different kinds, e.g., both natural numbers and privacy levels. This poses the problem of defining the result when grades of different kinds should

¹ Subsequently the model of [8] was used, in [21], to trace reference counting for uniqueness.

be combined by the type system. This issue has been considered in the Granule language [23], where, however, the available kinds of grades are fixed, hence can be combined in an ad-hoc way. We would like to have much more flexibility, that is, to allow the programmer to define grades to be added to those already available, very much in the same way a Java programmer can define her/his own class of exceptions. To this end, we define a construction which, given a family of grade algebras and a family of homomorphisms, leads to a unique grade algebra of *heterogeneous grades*. This allows a modular approach, in the sense that the developed meta-theory, including the proof of results, applies to this case as well.

Grades as Java expressions. Finally, we consider the issue of providing linguistic support to specify the desired grade algebras and homomorphisms. Of course this could be done by using an ad-hoc configuration language. However, we believe an interesting solution is that the grade annotations could be written themselves in Java, again analogously to what happens with exceptions. We describe how Java classes corresponding to grade algebras and homomorphisms could be written, providing some examples.

A preliminary step towards the results described in the current paper is [3], which proposes a first version of the type system with only coefficients (types are not graded), and a rudimentary version of the construction described above where combining coefficients of different kinds leads to the trivial coefficient.

In Section 2 we formally define grade algebras and related notions. In Section 3 we define the parametric resource-aware reduction for FJ, and in Section 4 the parametric resource-aware type system, proving its soundness. Section 5 defines the construction of the grade algebra of heterogeneous grades, and Section 6 illustrates how to express grade algebras and homomorphisms in Java. Finally, Section 7 surveys related work and Section 8 summarizes the contributions, and outlines future work. Omitted proofs can be found in [4].

2 Algebraic preliminaries

In this section we introduce the algebraic structures we will use throughout the paper. The core of our work is *grades*, namely, annotations in the code expressing how or how much resources are used by the program. As we will see, we need some operations to properly combine grades in the resource-aware semantics and in the typing rules, hence we will assume grades to form an algebraic structure called *grade algebra* defined below.

► **Definition 1** (Grade algebra). *A grade algebra is a tuple $R = \langle |R|, \preceq, +, \cdot, \mathbf{0}, \mathbf{1} \rangle$ such that:*

- $\langle |R|, \preceq \rangle$ is a partially ordered set;
 - $\langle |R|, +, \mathbf{0} \rangle$ is a commutative monoid;
 - $\langle |R|, \cdot, \mathbf{1} \rangle$ is a monoid;
- and the following axioms are satisfied:
- $r \cdot (s + t) = r \cdot s + r \cdot t$ and $(s + t) \cdot r = s \cdot r + t \cdot r$, for all $r, s, t \in |R|$;
 - $r \cdot \mathbf{0} = \mathbf{0}$ and $\mathbf{0} \cdot r = \mathbf{0}$, for all $r \in |R|$;
 - if $r \preceq r'$ and $s \preceq s'$ then $r + s \preceq r' + s'$ and $r \cdot s \preceq r' \cdot s'$, for all $r, r', s, s' \in |R|$;
 - $\mathbf{0} \preceq r$, for all $r \in |R|$.

Essentially, a grade algebra is an ordered semiring, that is, a semiring together with a partial order relation on its carrier which makes addition and multiplication monotonic with respect to it. We further require the zero of the semiring to be the least element of the partial order. Our definition is a slight variant of others proposed in literature [7, 15, 22, 2, 14, 1, 23, 8, 27]. In particular, the partial order models overapproximation in

the usage of resources, and allows flexibility, for instance we can have different usage in the branches of an if-then-else construct. The fact that the zero is the least element means that, in particular, overapproximation can add unused variables, making the calculus *affine*.

► **Example 2.**

1. The semiring $\mathbf{Nat} = \langle \mathbb{N}, \leq, +, \cdot, 0, 1 \rangle$ of natural numbers with the natural order and usual arithmetic operations is a grade algebra.
2. The *affinity* grade algebra $\langle \{0, 1, \infty\}, \leq, +, \cdot, 0, 1 \rangle$ is obtained from the previous one by identifying all natural numbers greater than 1.
3. The trivial semiring \mathbf{Triv} , whose carrier is a singleton set $|\mathbf{Triv}| = \{\infty\}$, the partial order is the equality, addition and multiplication are defined in the trivial way and $\mathbf{0}_{\mathbf{Triv}} = \mathbf{1}_{\mathbf{Triv}} = \infty$, is a grade algebra.
4. The semiring $\mathbf{R}_{\geq 0}^{\infty} = \langle [0, \infty], \leq, +, \cdot, 0, 1 \rangle$ of extended non-negative real numbers with usual order and operations, extended to ∞ in the expected way, is a grade algebra.
5. A distributive lattice $\mathbf{L} = \langle |\mathbf{L}|, \leq, \vee, \wedge, \perp, \top \rangle$, where \vee and \wedge denote join and meet operations and \perp and \top the bottom and the top element, respectively, is a grade algebra.
6. Given grade algebras $R = \langle |R|, \preceq_R, +_R, \cdot_R, \mathbf{0}_R, \mathbf{1}_R \rangle$ and $S = \langle |S|, \preceq_S, +_S, \cdot_S, \mathbf{0}_S, \mathbf{1}_S \rangle$, the *product* $R \times S = \langle \{ \langle r, s \rangle \mid r \in |R| \wedge s \in |S| \}, \preceq, +, \cdot, \langle \mathbf{0}_R, \mathbf{0}_S \rangle, \langle \mathbf{1}_R, \mathbf{1}_S \rangle \rangle$, where operations are the pairwise application of the operations for R and S , is a grade algebra.
7. Given a grade algebra $R = \langle |R|, \preceq_R, +_R, \cdot_R, \mathbf{0}_R, \mathbf{1}_R \rangle$, as in [23] we define $\mathbf{Ext} R = \langle |R| + \{\infty\}, \preceq, +, \cdot, \mathbf{0}_R, \mathbf{1}_R \rangle$ where \preceq extends \preceq_R by adding $r \preceq \infty$ for all $r \in |\mathbf{Ext} R|$ and $+$ and \cdot extend $+_R$ and \cdot_R by $r + \infty = \infty + r = \infty$, for all $r \in |\mathbf{Ext} R|$, and $r \cdot \infty = \infty \cdot r = \infty$, for all $r \in |\mathbf{Ext} R|$ with $r \neq \mathbf{0}_R$, and $\mathbf{0}_R \cdot \infty = \infty \cdot \mathbf{0}_R = \mathbf{0}_R$. Then, $\mathbf{Ext} R$ is a grade algebra.

A homomorphism of grade algebras $f: R \rightarrow S$ is a monotone function $f: \langle |R|, \preceq_R \rangle \rightarrow \langle |S|, \preceq_S \rangle$ between the underlying partial orders, which preserves the semiring structure, that is, satisfies the following equations:

- $f(\mathbf{0}_R) = \mathbf{0}_S$ and $f(r +_R s) = f(r) +_S f(s)$, for all $r, s \in |R|$;
- $f(\mathbf{1}_R) = \mathbf{1}_S$ and $f(r \cdot_R s) = f(r) \cdot_S f(s)$, for all $r, s \in |R|$.

Grade algebras and their homomorphisms form a category denoted by \mathbf{GrAlg} .

Consider a grade algebra R . Then, we can define functions $\zeta_R: |R| \rightarrow |\mathbf{Triv}|$ and $\iota_R: |\mathbf{Nat}| \rightarrow |R|$ as follows:

$$\zeta_R(r) = \infty \quad \iota_R(m) = \begin{cases} \mathbf{0}_R & \text{if } m = 0 \\ \iota_R(n) +_R \mathbf{1}_R & \text{if } m = n + 1 \end{cases}$$

Roughly, ζ_R maps every element of R to ∞ , while ι_R maps a natural number n to the sum in R of n copies of $\mathbf{1}_R$. We can easily check that both these functions give rise to homomorphisms $\zeta_R: R \rightarrow \mathbf{Triv}$ and $\iota_R: \mathbf{Nat} \rightarrow R$. This is straightforward for ζ_R , while for ι_R follows by arithmetic induction. Then, we can prove the following result.

► **Proposition 3.** *The following facts hold:*

1. \mathbf{Nat} is the initial object in \mathbf{GrAlg} ;
2. \mathbf{Triv} is the terminal object in \mathbf{GrAlg} .

Another kind of objects we will work with are maps assigning grades to variables. These inherit a nice algebraic structure from the one of the underlying grade algebra.

Assume a grade algebra $R = \langle |R|, \preceq, +, \cdot, \mathbf{0}, \mathbf{1} \rangle$ and a set X . The set of functions from X to $|R|$ carries a partially ordered commutative monoid structure given by the pointwise extension of the additive structure of R . That is, given $\gamma, \gamma': X \rightarrow |R|$, we define $\gamma \preceq \gamma'$

iff, for all $x \in X$, $\gamma(x) \preceq \gamma'(x)$, and $(\gamma + \gamma')(x) = \gamma(x) + \gamma'(x)$ and $\hat{\mathbf{0}}(x) = \mathbf{0}$, for all $x \in X$. Moreover, we can define a *scalar multiplication*, combining elements of $|R|$ and a function $\gamma: X \rightarrow |R|$; indeed, we set $(r \cdot \gamma)(x) = r \cdot \gamma(x)$, for all $r \in |R|$ and $x \in X$. It is easy to see that this operation turns the partially ordered commutative monoid of functions from X to $|R|$ into a partially ordered R -module.

The *support* of a function $\gamma: X \rightarrow |R|$ is the set $\mathbf{S}(\gamma) = \{x \in X \mid \gamma(x) \neq \mathbf{0}\}$. Denote by R^X the set of functions $\gamma: X \rightarrow |R|$ with finite support. The partial order and operations defined above can be safely restricted to R^X , noting that $\mathbf{S}(\hat{\mathbf{0}}) = \emptyset$, $\mathbf{S}(\gamma + \gamma') \subseteq \mathbf{S}(\gamma) \cup \mathbf{S}(\gamma')$ and $\mathbf{S}(r \cdot \gamma) \subseteq \mathbf{S}(\gamma)$. Therefore, R^X carries a partially ordered R -module structure as well.

As we will see in Section 4, *coeffect contexts* are (representations of) functions in R^X , with X set of variables. The fact that coeffect contexts form a module has been firstly noted in [22, 27], and fully formalized in [5], which also shows a *non-structural* example. That is, a module different from R^X described above, used in the present paper and mostly in the literature, is needed, where operations on coeffect contexts are not pointwise.

3 Resource-aware semantics

Standard operational models do not say anything about resources used by the computation. To address this problem, we follow an approach similar to that in [8], that is, we define an *instrumented* semantics which keeps track of resource usage, hence, in particular, it gets stuck if some needed resource is insufficient. However, unlike [8], the definition of our resource-aware semantics, though parameterized on a grade algebra, is given *independently* of the graded type system, as is the standard approach in calculi; in the next section, we will show how the graded type system actually overapproximates resource usage, hence guarantees soundness. As will be detailed in the following, the resource-aware semantics is non-deterministic, in the sense that, when a resource is needed, it can be consumed in different ways; hence, soundness is *soundness-may*, meaning that there is a reduction which does not get stuck because of standard typing errors or resource consumption.

Reference calculus. The calculus is a variant of FJ [19]. The syntax is reported in the top section of Figure 1. We write es as a metavariable for e_1, \dots, e_n , $n \geq 0$, and analogously for other sequences. We assume *variables* x, y, z, \dots , *class names* C, D , *field names* f , and *method names* m . Types are distinct from class names to mean that they could be extended to include other types, e.g., primitive types. In addition to the standard FJ constructs, we have a block expression, consisting of a local variable declaration, and a body.

The semantics is defined differently from the original one; that is, reduction is defined on *configurations* $e|\rho$, where ρ is an *environment*, a finite map from variables into values. In this way, variable occurrences are replaced one at a time by their value in the environment, rather than once and for all. This definition can be easily shown to be equivalent to the original one, and is convenient for our aims since, in this presentation, free variables in an expression can be naturally seen as *resources* which are consumed each time a variable occurrence is *used* (replaced by its value) during execution. In other words, this semantics can be naturally *instrumented* by adding grades expressing the “cost” of resource consumption, as we will do in Figure 2. Apart from that, the rules are straightforward; only note that, in rules (INVK) and (BLOCK), parameters (including **this**) and local variable are renamed to fresh variables, to avoid clashes. Single contextual rules are given, rather than defining evaluation contexts, to be uniform with the instrumented version, where this presentation is more convenient.

■ **Figure 1** Syntax and standard reduction.

To be concise, the class table is abstractly modeled as follows, omitting its (standard) syntax:

- $\text{fields}(C)$ gives, for each class C , the sequence $T_1 f_1; \dots T_n f_n$; of its fields, assumed to have distinct names, with their types;
- $\text{mbody}(C, m)$ gives, for each method m of class C , its parameters and body.

Instrumented reduction. This reduction uses *grades*, ranged over by r, s, t , assumed to form a grade algebra, specifying a *partial order* \preceq , a *sum* $+$, a *multiplication* \cdot , and constants $\mathbf{0}$ and $\mathbf{1}$, satisfying some axioms, as detailed in Definition 1 of Section 2.

In order to keep track of usage of resources, parametrically on a given grade algebra, we *instrument* reduction as follows.

- The environment associates, to each resource (variable), besides its value, a grade modeling its *allowed usage*.

- Moreover, the reduction relation is *graded*, that is, indexed by a grade r , meaning that it aims at producing a value to be used (at most) r times, or, in more general (non-quantitative) terms, to be used (at most) with grade r .
- The grade of a variable in the environment decreases, each time the variable is used, of the amount specified in the reduction grade².
- Of course, this can only happen if the current grade of the variable *can* be reduced of such an amount; otherwise the reduction is stuck.

Before giving the formal definition, we show some simple examples of reductions, considering the grade algebra of naturals of Example 2(1), tracking how many times a resource is used.

► **Example 4.** Assume the following classes:

```
class A {}
class Pair {A first; A second}
```

We write v_{pair} as an abbreviation for $\text{new Pair}(\text{new A}(), \text{new A}())$.

```
{A a = [new A()]4; {Pair p = [new Pair(a, a)]2; new Pair(p.first, p.second)}}|∅ →1
{Pair p = [new Pair(a, a)]2; new Pair(p.first, p.second)}|a ↦ ⟨new A(), 4⟩ →1
{Pair p = [new Pair(new A(), a)]2; new Pair(p.first, p.second)}|a ↦ ⟨new A(), 2⟩ →1
{Pair p = [new Pair(new A(), new A())]2; new Pair(p.first, p.second)}|a ↦ ⟨new A(), 0⟩ →1
new Pair(p.first, p.second)|a ↦ ⟨new A(), 0⟩, p ↦ ⟨vpair, 2⟩ →1
new Pair(vpair.first, p.second)|a ↦ ⟨new A(), 0⟩, p ↦ ⟨vpair, 1⟩ →1
new Pair(new A(), p.second)|a ↦ ⟨new A(), 0⟩, p ↦ ⟨vpair, 1⟩ →1
new Pair(new A(), vpair.second)|a ↦ ⟨new A(), 0⟩, p ↦ ⟨vpair, 0⟩ →1
vpair|a ↦ ⟨new A(), 0⟩, p ↦ ⟨vpair, 0⟩
```

In the example, the top-level reduction is graded 1, meaning that a single value is produced. Subterms are annotated with the grade of their reduction. For instance, the outer initialization expression is annotated 4, meaning that its result can be used (at most) 4 times. To lighten the notation, in this example we omit the index 1. A local variable introduced in a block is added³ as another available resource in the environment, with the value and the grade of its initialization expression; for instance, the outer local variable is added with grade 4. When evaluating the inner initialization expression, which is reduced with grade 2, each time the variable a is used its grade in the environment is decremented by 2.

It is important to notice that the annotations in subterms are *not* type annotations. Except those in arguments of constructor invocation, explained below, annotations are only needed to ensure that reduction of a subterm happens at each step with the same grade, see the formal definition below. We plan to investigate in future work a big-step formulation which would not need such an artifice. In the example above, we have chosen for the reduction of subterms the minimum grade allowing to perform the top-level reduction. We could have chosen any greater grade; instead, with a strictly lower grade, the reduction would be stuck.

As anticipated, in a constructor invocation $\text{new } C([e_1]_{r_1}, \dots, [e_n]_{r_n})$, the annotation r_i plays a special role: intuitively, it specifies that the object to be constructed should contain r_i copies of that field. Formally, this is reflected by the reduction grade of the subterm e_i , which must be exactly $r \cdot r_i$, if r is the reduction grade of the object, specifying how many copies of it the reduction is constructing. Correspondingly, an access to the field can be used (at most) $r \cdot r_i$ times. This is illustrated by the following variant of the previous example.

² More precisely, the reduction grade acts as a lower bound for this amount, see comment to rule (VAR).

³ Modulo renaming to avoid clashes, omitted in the example for simplicity.

► **Example 5.** Consider the term

$$\{A \ a = [\text{new } A()]_4; \{\text{Pair } p = [\text{new } \text{Pair}(a, a)]_2; \text{new } \text{Pair}([\text{p.first}]_2, p.\text{second})\}\}$$

As highlighted in grey, the first argument of the constructor invocation which is the body of the inner block is now annotated with 2, meaning that the resulting object should have “two copies” of the field. As a consequence, the expression `p.first` should be reduced with grade 2, as shown below, where $v_{\text{pair}} = \text{new } \text{Pair}(\text{new } A(), \text{new } A())$, the first four reduction steps are as in Example 4 and we explicitly write some annotations 1 for clarity

$$\begin{aligned} & \{A \ a = [\text{new } A()]_4; \{\text{Pair } p = [\text{new } \text{Pair}([a]_1, a)]_2; \text{new } \text{Pair}([\text{p}]_1.\text{first}]_2, p.\text{second})\}\} | \emptyset \rightarrow_1^* \\ & \text{new } \text{Pair}([\text{p}]_1.\text{first}]_2, p.\text{second}) | a \mapsto \langle \text{new } A(), 0 \rangle, p \mapsto \langle v_{\text{pair}}, 2 \rangle \rightarrow_1 \\ & \text{new } \text{Pair}([v_{\text{pair}}]_1.\text{first}]_2, p.\text{second}) | a \mapsto \langle \text{new } A(), 0 \rangle, p \mapsto \langle v_{\text{pair}}, 1 \rangle \quad \text{STUCK} \end{aligned}$$

Reduction of the subterm in grey, aiming at constructing a value (`new A()`) which can be used twice, is stuck, since we cannot obtain two copies of `new A()` from the field `first` of the object v_{pair} . If we choose, instead, to reduce the occurrence of `p` to be used twice, then we get the following reduction, where again we omit steps which are as before:

$$\begin{aligned} & \{A \ a = [\text{new } A()]_4; \{\text{Pair } p = [\text{new } \text{Pair}([a]_1, a)]_2; \text{new } \text{Pair}([\text{p}]_2.\text{first}]_2, p.\text{second})\}\} | \emptyset \rightarrow_1^* \\ & \text{new } \text{Pair}([\text{p}]_2.\text{first}]_2, p.\text{second}) | a \mapsto \langle \text{new } A(), 0 \rangle, p \mapsto \langle v_{\text{pair}}, 2 \rangle \rightarrow_1 \\ & \text{new } \text{Pair}([v_{\text{pair}}]_2.\text{first}]_2, p.\text{second}) | a \mapsto \langle \text{new } A(), 0 \rangle, p \mapsto \langle v_{\text{pair}}, 0 \rangle \rightarrow_1 \\ & \text{new } \text{Pair}(\text{new } A()]_2, p.\text{second}) | a \mapsto \langle \text{new } A(), 0 \rangle, p \mapsto \langle v_{\text{pair}}, 0 \rangle \quad \text{STUCK} \end{aligned}$$

In this case, the reduction is stuck since we consumed all the available copies of `p` to produce two copies of the field `first`, so now we cannot reduce `p.second`. To obtain a non-stuck reduction, we should choose to reduce the initialization expression of `p` with index 3, hence that of `a` with index 6. To complete the construction of the `Pair`, that is, to get a non-stuck reduction, we should have 3 copies of `p` and therefore 6 copies of `a`.

The formal definition of the instrumented semantics is given in Figure 2. To make the notation lighter, we use the same metavariables of the standard semantics in Figure 1. As explained above, reduction is defined on annotated terms. Notably, in each construct, the subterms which are reduced in contextual rules are annotated, so that their reduction always happens with a fixed grade.

In rule (VAR), which is the key rule where resources are consumed, a variable occurrence is replaced by the associated value in the environment, and its grade s decreases to s' , burning a non-zero amount r' of resources which has to be at least the reduction grade. The side condition $r' + s' \preceq s$ ensures that the initial grade of the variable suffices to cover both the consumed grade and the residual grade. To show why the amount of resource consumption should be non-zero, consider, e.g., the following variant of Example 4:

$$\{A \ a = [\text{new } A()]_4; \{\text{Pair } p = [\text{new } \text{Pair}(a, a)]_0; \text{new } \text{Pair}(a, a)\}\} | \emptyset$$

The local variable `p` is never used in the body of the block, so it makes sense for its initialization expression to be reduced with grade 0, since execution needs no copies of the result. Yet, the expression *needs to be reduced*, and to produce its useless result two copies of `a` are consumed; in a sense, they are wasted. However, such resource usage is tracked, whereas it would be lost if decrementing by 0. Removing the non-zero requirement would lead to a variant of resource-aware reduction where usage of resource which are useless to construct the final result is not tracked.

In rule (FIELD-ACCESS), the reduction grade should be (overapproximated by) the multiplication of the grade of the receiver with that of the field (constructor argument). Indeed, the former specifies how many copies of the object we have and the latter how many copies

$$\begin{aligned}
e &::= x \mid [e]_r \cdot f \mid \mathbf{new} C([e_1]_{r_1}, \dots, [e_n]_{r_n}) \mid && \text{(annotated) expression} \\

\end{aligned}$$

■ **Figure 2** Instrumented reduction.

of the field each of such objects has; thus, their product provides an upper bound to the grade of the resulting value. Note that, in this way, some reductions could be *forbidden*. For instance, taking the grade algebra of naturals, an access to a field whose value can be used 3 times, of an object reduced with grade 2, can be reduced with grade (at most) 6. Another more significant example is given in the following, taking the grade algebra of *privacy levels*.

Rule (INVK) adds each method parameter, including **this**, as available resource in the environment, modulo renaming with a fresh variable to avoid clashes. The associated value and grade are that of the corresponding argument. Rule (BLOCK) is exactly analogous, apart that only one variable is added.

Coming to contextual rules, the reduction grade of the subterm is that of the corresponding annotation, so that all steps happen with a fixed grade. The only exception is rule (NEW-CTX), where, symmetrically to rule (FIELD-ACCESS), the reduction grade for subterms should be the multiplication of the reduction grade of the object with the annotation of the field (constructor argument), capturing the intuition that the latter specifies the grade of the field for a single copy of the object. For instance, taking the grade algebra of naturals, to obtain an object which can be used twice, with a field which can be used 3 times, the value of such field should be an object which can be used 6 times.

Note that, besides the standard typing errors such as looking for a missing method or field, reduction graded r can get stuck since either rule (VAR) cannot be applied since the side conditions do not hold, or rule (FIELD-ACCESS) cannot be applied since the side condition $s \preceq r \cdot r_i$ does not hold. Informally, either some resource (variable) is exhausted, that is, can no longer be replaced by its value, or some field of some object cannot be extracted. It is also important to note that the instrumented reduction is non-deterministic, due to rule (VAR).

In the grade algebra used in the previous example, grades model *how many times* resources are used. However, grades can also model a non-quantitative⁴ knowledge, that is, track possible *modes* in which a resource can be used, or, in other words, possible *constraints* on how it could be used. A typical example of this situation are *privacy levels*, which can be formalized similarly to what is done in [1], as described below.

► **Example 6.** Starting from any distributive semilattice lattice L , like in Example 2(5), define $L_0 = \langle |L_0|, \leq_0, \vee_0, \wedge_0, 0, \top \rangle$, where $|L_0| = |L| + \{0\}$ with $0 \leq_0 x$, $x \vee_0 0 = 0 \vee_0 x = x$ and $x \wedge_0 0 = 0 \wedge_0 x = 0$, for all $x \in |L|$; on elements of $|L|$ the order and the operations are those of L . That is, we assume that the privacy levels form a distributive semilattice with order representing “decreasing privacy”, and we add a grade 0 modeling “non-used”. The simplest instance consists of just two privacy levels, that is, $0 \preceq \text{private} \preceq \text{public}$. Sum is the join, meaning that we obtain a privacy level which is less restrictive than both: for instance, a variable which is used as `public` in a subterm, and as `private` in another, is overall used as `public`. Multiplication is the meet, meaning that we obtain a privacy level which is more restrictive than both: for instance, an access to a field whose value has been obtained in `public` mode, of an object reduced in `private` mode, is reduced in `private` mode⁵. Note that exactly the same structure could be used to model, e.g., rather than privacy levels, modifiers `readonly` and `mutable` in an imperative setting, corresponding to forbid field assignment and no restrictions, respectively. The following examples illustrates the use of such grade algebra. We write `priv` and `pub` for short, and classes `A` and `Pair` are as in the previous examples.

1. Let $e_1 = \{A\ y = [\text{new } A()]_{\text{pub}}; \{A\ x = [y]_{\text{priv}}; x\}\}$ and p_- be either `pub` or `priv`, e_1 starting with the empty environment reduces with grade `private` as follows:

$$\begin{aligned}
e_1|\emptyset &\xrightarrow{\text{priv}} \{A\ x = [y]_{\text{priv}}; x\}|y \mapsto \langle \text{new } A(), \text{pub} \rangle \text{ with (BLOCK)} \\
&\xrightarrow{\text{priv}} \{A\ x = [\text{new } A()]_{\text{priv}}; x\}|y \mapsto \langle \text{new } A(), p_- \rangle \text{ with (BLOCK-CTX) and} \\
&\quad y|y \mapsto \langle \text{new } A(), \text{pub} \rangle \xrightarrow{\text{priv}} \text{new } A()|y \mapsto \langle \text{new } A(), p_- \rangle \\
&\xrightarrow{\text{priv}} x|y \mapsto \langle \text{new } A(), p_- \rangle, x \mapsto \langle \text{new } A(), \text{priv} \rangle \text{ with (BLOCK)} \\
&\xrightarrow{\text{priv}} \text{new } A()|y \mapsto \langle \text{new } A(), p_- \rangle, x \mapsto \langle \text{new } A(), \text{priv} \rangle \text{ with (VAR)}
\end{aligned}$$

Instead reduction with grade `public` would be stuck since `pub` $\not\preceq$ `priv` and so

$$x|y \mapsto \langle \text{new } A(), p_- \rangle, x \mapsto \langle \text{new } A(), \text{priv} \rangle \not\rightarrow_{\text{pub}}$$

Also the reduction of $e_2 = \{A\ y = [\text{new } A()]_{\text{priv}}; \{A\ x = [y]_{\text{pub}}; x\}\}$ with grade `private`

$$\begin{aligned}
e_2|\emptyset &\xrightarrow{\text{priv}} \{A\ x = [y]_{\text{pub}}; x\}|y \mapsto \langle \text{new } A(), \text{priv} \rangle \text{ with (BLOCK)} \\
&\not\rightarrow_{\text{priv}}
\end{aligned}$$

would be stuck since $y|y \mapsto \langle \text{new } A(), \text{priv} \rangle \not\rightarrow_{\text{pub}}$. Note that both e_1 and e_2 reduce to `new A()` with the semantics of Figure 1.

⁴ Such kind of applications are called *informational* in [1].

⁵ As in *viewpoint adaptation* [13], where permission to a field access can be restricted based on the permission to the base object.

2. Let $e_3 = \{A\ x = [\text{new } A()]_{\text{pub}}; \text{new Pair}([x]_{\text{pub}}, [x]_{\text{priv}})\}$, e_3 starting with the empty environment reduces with grade **public** as follows:

$$\begin{aligned}
e_3|\emptyset &\rightarrow_{\text{pub}} \text{new Pair}([x]_{\text{pub}}, [x]_{\text{priv}})|x \mapsto \langle \text{new } A(), \text{pub} \rangle \text{ with (BLOCK)} \\
&\rightarrow_{\text{pub}} \text{new Pair}([\text{new } A()]_{\text{pub}}, [x]_{\text{priv}})|x \mapsto \langle \text{new } A(), \text{p}_- \rangle \text{ with (NEW-CTX) and} \\
&\quad x|x \mapsto \langle \text{new } A(), \text{pub} \rangle \rightarrow_{\text{pub}} \text{new } A()|x \mapsto \langle \text{new } A(), \text{p}_- \rangle \\
&\rightarrow_{\text{pub}} \text{new Pair}([\text{new } A()]_{\text{pub}}, [\text{new } A()]_{\text{priv}})|x \mapsto \langle \text{new } A(), \text{p}_- \rangle \text{ with (NEW-CTX) and} \\
&\quad x|x \mapsto \langle \text{new } A(), \text{p}_- \rangle \rightarrow_{\text{priv}} \text{new } A()|x \mapsto \langle \text{new } A(), \text{p}_- \rangle
\end{aligned}$$

It is easy to see that also $e_3|\emptyset \rightarrow_{\text{priv}}^* \text{new Pair}([\text{new } A()]_{\text{pub}}, [\text{new } A()]_{\text{priv}})|x \mapsto \langle \text{new } A(), \text{p}_- \rangle$. So we have

$$[e_3]_r.f|\emptyset \rightarrow_s^* [\text{new Pair}([\text{new } A()]_{\text{pub}}, [\text{new } A()]_{\text{priv}})]_r.f|x \mapsto \langle \text{new } A(), \text{p}_- \rangle$$

where f can be either **first** or **second** and r and s can be either **pub** or **priv**. Now, the reductions of grade **priv** accessing either **first** or **second** produce the value of the fields

$$[\text{new Pair}([\text{new } A()]_{\text{pub}}, [\text{new } A()]_{\text{priv}})]_r.f|_ \rightarrow_{\text{priv}} \text{new } A()|_$$

However, looking at the reductions of grade **pub**, only

$$[\text{new Pair}([\text{new } A()]_{\text{pub}}, [\text{new } A()]_{\text{priv}})]_{\text{pub}}.\text{first}|_ \rightarrow_{\text{pub}} \text{new } A()|_$$

is not stuck. That is, we produce a value that can be used as **public** only if we get a **public** field of a **public** object, whereas any value can be used as **private**.

We now state some simple properties of the semantics we will use to prove type soundness. The former establishes that reduction does not remove variables from the environment, the latter states that we can always decrease the grade of a reduction step.

► **Proposition 7.** *If $e|\rho \rightarrow_r e'|\rho'$ then $\text{dom}(\rho) \subseteq \text{dom}(\rho')$ and for all $x \in \text{dom}(\rho)$, $\rho(x) = \langle v, r \rangle$ implies $\rho'(x) = \langle v, s \rangle$ with $s \preceq r$.*

► **Proposition 8.** *If $e|\rho \rightarrow_r e'|\rho'$ and $s \preceq r$ then $e|\rho \rightarrow_s e'|\rho'$.*

We expect the instrumented reduction to be *sound* with respect to the standard reduction, in the sense that by erasing annotations from an instrumented reduction sequence we get a standard reduction sequence. This is formally stated below.

For any e expression, let us denote by $[e]$ the expression obtained by erasing annotations, defined in the obvious way, and analogously for environments, where grades associated to variables are removed as well.

► **Proposition 9** (Soundness of instrumented semantics).

If $e|\rho \rightarrow_r e'|\rho'$, then $[e]||[\rho] \rightarrow [e']||[\rho']$.

The converse does not hold, since a configuration could be annotated in a way that makes it stuck; notably, some resource (variable) could be exhausted or some field of an object could not be extracted. The graded type system in the next section will generate annotations which ensure soundness, hence also completeness with respect to the standard reduction.

4 Graded Featherweight Java

Types (class names) are annotated with *grades*, as shown in Figure 3.

As anticipated at the end of Section 2, a *coefficient context*, of shape $\gamma = x_1 : r_1, \dots, x_n : r_n$, where order is immaterial and $x_i \neq x_j$ for $i \neq j$, represents a map from variables to grades (called *coeffects* when used in this position) where only a finite number of variables have

3:12 Multi-Graded Featherweight Java

e	$::= x \mid e.f \mid \mathbf{new} C(es) \mid e.m(es) \mid \{T x = e; e'\}$	expression
T	$::= C^r$	(graded) type
v	$::= \mathbf{new} C(vs)$	value

■ **Figure 3** Syntax with grades.

non-zero coeffect. A (*type-and-coeffect*) *context*, of shape $\Gamma = x_1 :_{r_1} C_1, \dots, x_n :_{r_n} C_n$, with analogous conventions, represents the pair of the standard type context $x_1 : C_1 \dots, x_n : C_n$, and the coeffect context $x_1 : r_1, \dots, x_n : r_n$. We write $\mathbf{dom}(\Gamma)$ for $\{x_1, \dots, x_n\}$.

As customary in type-and-coeffect systems, in typing rules contexts are combined by means of some operations, which are, in turn, defined in terms of the corresponding operations on coeffects (grades). More precisely, we define:

- a partial order \preceq

$$\begin{aligned} \emptyset &\preceq \emptyset \\ x :_s C, \Gamma &\preceq x :_r C, \Delta && \text{if } s \preceq r \text{ and } \Gamma \preceq \Delta \\ \Gamma &\preceq x :_r C, \Delta && \text{if } x \notin \mathbf{dom}(\Gamma) \text{ and } \Gamma \preceq \Delta \end{aligned}$$

- a sum $+$

$$\begin{aligned} \emptyset + \Gamma &= \Gamma \\ (x :_s C, \Gamma) + (x :_r C, \Delta) &= x :_{s+r} C, (\Gamma + \Delta) \\ (x :_s C, \Gamma) + \Delta &= x :_s C, (\Gamma + \Delta) && \text{if } x \notin \mathbf{dom}(\Delta) \end{aligned}$$

- a scalar multiplication \cdot

$$s \cdot \emptyset = \emptyset \qquad s \cdot (x :_r C, \Gamma) = x :_{s \cdot r} C, (s \cdot \Gamma)$$

As the reader may notice, these operations on type-and-coeffect contexts can be equivalently defined by lifting the corresponding operations on coeffect contexts, which are the pointwise extension of those on coeffects, to handle types as well. In this step, the addition becomes partial since a variable in the domain of both contexts is required to have the same type.

The type system relies on the type information extracted from the class table, which, again to be concise, is abstractly modeled as follows:

- the subtyping relation \leq on class names is the reflexive and transitive closure of the **extends** relation
- $\mathbf{mtype}(C, m)$ gives, for each method m of class C , its enriched method type, where the types of the parameters and of **this** have coeffect annotations.

Moreover, $\mathbf{fields}(C)$ gives now a sequence $C_1^{r_1} f_1; \dots, C_n^{r_n} f_n;$, meaning that, to construct an object of type C , we need to provide, for each $i \in 1..n$, a value with a grade at least r_i .

The subtyping relation on graded types is defined as follows:

$$C^r \leq D^s \text{ iff } C \leq D \text{ and } s \preceq r$$

That is, a graded type is a subtype of another if the class is a heir class and the grade is more constraining. For instance, taking the affinity grade algebra of Example 2(2), an invocation of a method with return type C^ω can be used in a context where a type C^1 is required, e.g., to initialize a C^1 variable.

The typing judgment has shape $\Gamma \vdash e : T \rightsquigarrow e'$, where Γ is a type-and-coeffect context, and e' is an annotated expression, as defined in Figure 2. That is, typechecking generates annotations in code such that evaluation cannot get stuck, as will be formally expressed and proved in the following.

$$\begin{array}{c}
\text{(T-SUB)} \quad \frac{\Gamma \vdash e : T \rightsquigarrow e' \quad \Gamma \preceq \Gamma'}{\Gamma' \vdash e : T' \rightsquigarrow e' \quad T \leq T'} \quad \text{(T-VAR)} \quad \frac{}{x :_r C \vdash x : C^r \rightsquigarrow x} \quad r \neq \mathbf{0} \\
\text{(T-FIELD-ACCESS)} \quad \frac{\Gamma \vdash e : C^r \rightsquigarrow e'}{\Gamma \vdash e.f_i : C_i^{r \cdot r_i} \rightsquigarrow [e']_{r \cdot r_i}} \quad \text{fields}(C) = C_1^{r_1} f_1; \dots C_n^{r_n} f_n; \\
\text{(T-NEW)} \quad \frac{\Gamma_i \vdash e_i : C_i^{r \cdot r_i} \rightsquigarrow e'_i \quad \forall i \in 1..n}{\Gamma_1 + \dots + \Gamma_n \vdash \mathbf{new} C(e_1, \dots, e_n) : C^r \rightsquigarrow \mathbf{new} C([e'_1]_{r_1}, \dots, [e'_n]_{r_n})} \quad \text{fields}(C) = C_1^{r_1} f_1; \dots C_n^{r_n} f_n; \\
\text{(T-INVK)} \quad \frac{\Gamma_0 \vdash e_0 : C^{r_0} \rightsquigarrow e'_0 \quad \Gamma_i \vdash e_i : C_i^{r_i} \rightsquigarrow e'_i \quad \forall i \in 1..n}{\Gamma_0 + \dots + \Gamma_n \vdash e_0.m(e_1, \dots, e_n) : T \rightsquigarrow [e'_0]_{r_0}.m([e'_1]_{r_1}, \dots, [e'_n]_{r_n})} \quad \text{mtype}(C, m) = r_0, C_1^{r_1} \dots C_n^{r_n} \rightarrow T \\
\text{(T-BLOCK)} \quad \frac{\Gamma_1 \vdash e_1 : C^r \rightsquigarrow e'_1 \quad \Gamma_2, x :_r C \vdash e_2 : T \rightsquigarrow e'_2}{\Gamma_1 + \Gamma_2 \vdash \{C^r x = e_1; e_2\} : T \rightsquigarrow \{C x = [e'_1]_r; e'_2\}} \\
\text{(T-ENV)} \quad \frac{\vdash v_i : C_i^{r_i} \rightsquigarrow v'_i \quad \forall i \in 1..n}{\Gamma \vdash \rho \rightsquigarrow \rho'} \quad \begin{array}{l} \Gamma = x_1 :_{r_1} C_1, \dots, x_n :_{r_n} C_n \\ \rho = x_1 \mapsto \langle v_1, r_1 \rangle, \dots, x_n \mapsto \langle v_n, r_n \rangle \\ \rho' = x_1 \mapsto \langle v'_1, r_1 \rangle, \dots, x_n \mapsto \langle v'_n, r_n \rangle \end{array} \\
\text{(T-CONF)} \quad \frac{\Delta \vdash e : T \rightsquigarrow e' \quad \Gamma \vdash \rho \rightsquigarrow \rho'}{\Gamma \vdash e|\rho : T \rightsquigarrow e'|\rho'} \quad \Delta \preceq \Gamma
\end{array}$$

■ **Figure 4** Graded type system.

In a well-typed class table, method bodies are expected to conform to method types. That is, $\text{mtype}(C, m)$ and $\text{mbody}(C, m)$ should be either both undefined or both defined with the same number of parameters. In the latter case, the method body should be well-typed with respect to the method type, notably by typechecking the method body we should get coeffects which are (overapproximated by) those specified in the annotations. Formally, if $\text{mbody}(C, m) = \langle x_1 \dots x_n, e \rangle$, and $\text{mtype}(C, m) = r_0, C_1^{r_1} \dots C_n^{r_n} \rightarrow T$, then the following condition must hold:

$$\text{(T-METH)} \quad \mathbf{this} :_{r_0} C, x_1 :_{r_1} C_1, \dots, x_n :_{r_n} C_n \vdash e : T \rightsquigarrow e'$$

Moreover, we assume the standard coherence conditions on the class table with respect to inheritance. That is, if $C \leq D$, then $\text{fields}(D)$ is a prefix of $\text{fields}(C)$ and, if $\text{mtype}(C, m) = r_0, C_1^{r_1} \dots C_n^{r_n} \rightarrow T$, then $\text{mtype}(D, m) = r_0, C_1^{r_1} \dots C_n^{r_n} \rightarrow T'$ with $T' \leq T$.

In Figure 4, we describe the typing rules, which are *parameterized* on the underlying grade algebra.

In rule (T-SUB), both the coeffect context and the (graded) type can be made more general. This means that, on one hand, variables can get less constraining coeffects. For instance, assuming again affinity coeffects, an expression which can be typechecked assuming to use a given variable at most once (coeffect 1) can be typechecked as well with no constraints (coeffect ω). On the other hand, recalling that grades are contravariant in types, an expression can get a more constraining grade. For instance, an expression of grade ω can be used where a grade 1 is required.

If we take $r = \mathbf{1}$, then rule (T-VAR) is analogous to the standard rule for variable in coeffect systems, where the coeffect context is the map where the given variable is used once, and no other is used. Here, more generally, the variable can get an arbitrary grade r , provided that it gets the same grade in the context. However, the use of the variable cannot be just discarded, as expressed by the side condition $r \neq \mathbf{0}$.

In rule (T-FIELD-ACCESS), the grade of the field is multiplied by the grade of the receiver. As already mentioned, this is a form of *viewpoint adaptation* [13]. For instance, using affinity grades, a field graded ω of an object graded 1 can be used at most once.

3:14 Multi-Graded Featherweight Java

In rule (T-NEW), analogously to rule (T-VAR), the constructor invocation can get an arbitrary grade r , provided that the grades of the fields are multiplied by the same grade. Coeffects of the subterms are summed, as customary in type-and-coeffect systems.

In rule (T-INVK), the coeffects of the arguments are summed as well. The rule uses the function `mtype` on the class table, which, given a class name and a method name, returns its parameter and return (graded) types. For the implicit parameter `this` only the grade is specified. Note that the grades of the parameters are used in two different ways: as (part of) types, when typechecking the arguments; as coeffects, when typechecking the method body.

In rule (T-BLOCK), the coeffects of the initialization expression are summed with those of the body, excluding the local variable. Analogously to method parameters, the grade of the local variable is both used as (part of) type, when typechecking the initialization expression, and as coeffect, when typechecking the body.

Finally, we have straightforward rules for typing environments and configurations. Values in the environment are assumed to be closed, since we are in a call-by-value calculus. Also note that, in the judgment for environments and configurations, since no subsumption rule is available, variables in the context are exactly those in the domain of the environment, which are a superset of those used in the expression.

► **Example 10.** We show a simple example illustrating the use of graded types, assuming affinity grades. We write in square brackets the grade of the implicit `this` parameter. The class `Pair` declares three versions of the getter for the `first` field, which differ for the grade of the result: either 0, meaning that the result of the method *cannot* be used, or 1, meaning it can be used at most once, or ω , meaning it can be used with no constraints. Note that the first version, clearly useless in a functional calculus, could make sense adding effects, e.g. in an imperative calculus, playing a role similar to that of `void`.

```
class Pair { A1 first; A1 second;
  A0 getFirstZero() [1]{this.first}
  A1 getFirstAffine() [1]{this.first}
  Aω getFirst() [1]{this.first}
}
```

The coeffect of `this` is 1 in all versions, and it is actually used once in the bodies. The occurrence of `this` in the bodies can get any non-zero grade thanks to rule (T-VAR), and fields are graded 1, meaning that a field access does not affect the grade of the receiver, hence the three bodies can get any non-zero grade as well, so they are well-typed with respect to the grade in the method return type.

In the client code below, a call of the getter is assigned to a local variable of the same grade, which is then used consistently with such grade.

```
Pair1 p = ...
{A0 a = p.getFirstZero(); new Pair(new A(),new A())}
{A1 a = p.getFirstAffine(); new Pair(a,new A())}
{Aω a = p.getFirst(); new Pair(a,a)}
```

The following blocks are, instead, ill-typed, for two different reasons.

```
{A1 a = p.getFirst(); new Pair(a,a)}
{Aω a = p.getFirstAffine(); new Pair(a,a)}
```

In the first one, the initialization is correct, by subsumption, since we use an expression of a less constrained grade. However, the variable is then used in a way which is not compatible with its grade. In the second one, instead, the variable is used consistently with its grade, but the initialization is ill-typed, since we use an expression of a more constrained grade.

Finally, note that the coefficient of `this` could be safely changed to be ω in the three methods, providing an overapproximated information; in this case, however, the three invocations in the client code would be wrong, since the receiver `p` is required to be used at most once.

► **Example 11.** Consider the following source (that is, non-annotated) version of the expression in Example 5.

```
{Apublic y = new A(); {Aprivate x = y; x}}
```

The `private` variable `x` is initialized with the `public` expression/variable `y`. The block expression has type A^{private} as the following type derivation shows.

$$\text{(T-BLOCK)} \frac{\text{(T-NEW)} \frac{}{\vdash \text{new A}() : A^{\text{pub}}} \mathcal{D}}{\vdash \{A^{\text{pub}} y = \text{new A}(); \{A^{\text{priv}} x = y; x\}\} : A^{\text{priv}}}$$

where \mathcal{D} is the following derivation

$$\text{(T-BLOCK)} \frac{\text{(T-SUB)} \frac{\text{(T-VAR)} \frac{}{y :_{\text{pub}} A \vdash y : A^{\text{pub}}}}{y :_{\text{pub}} A \vdash y : A^{\text{priv}}} \quad \text{(T-VAR)} \frac{}{y :_{\text{pub}} A, x :_{\text{priv}} A \vdash x : A^{\text{priv}}}}{y :_{\text{pub}} A \vdash \{A^{\text{priv}} x = y; x\} : A^{\text{priv}}}}$$

On the other hand, initializing a `public` variable with a `private` expression as in

```
{Aprivate y = new A(); {Apublic x = y; x}}
```

is not possible, as expected, since $y :_{\text{priv}} A \not\vdash y : A^{\text{pub}}$.

Consider now the class `Pair` with a `private` field and a `public` one.

```
class B { Apublic f1; Aprivate f2; }
```

The expression e

```
{Apublic x = new A(); new B(x, x)}
```

can be given type $\text{Pair}^{\text{public}}$ as follows:

$$\text{(T-BLOCK)} \frac{\text{(T-NEW)} \frac{}{\vdash \text{new A}() : A^{\text{pub}}} \quad \text{(T-NEW)} \frac{\text{(T-VAR)} \frac{\text{(T-VAR)} \frac{}{x :_{\text{pub}} A \vdash x : A^{\text{pub}}} \quad \text{(T-SUB)} \frac{}{x :_{\text{pub}} A \vdash x : A^{\text{priv}}}}{x :_{\text{pub}} A \vdash \text{new Pair}(x, x) : \text{Pair}^{\text{pub}}}}{x :_{\text{pub}} A \vdash \text{new Pair}(x, x) : \text{Pair}^{\text{pub}}}}{\vdash \{A^{\text{pub}} x = \text{new A}(); \text{new Pair}(x, x)\} : \text{Pair}^{\text{pub}}}}$$

By (T-SUB) we can also derive $\vdash e : \text{Pair}^{\text{priv}}$ and so we get

$$\text{(T-FIELD)} \frac{\vdash e : \text{Pair}^{\text{priv}}}{\vdash e.\text{first} : A^{\text{priv}}} \quad \text{(T-FIELD)} \frac{\vdash e : \text{Pair}^{\text{pub}}}{\vdash e.\text{second} : A^{\text{priv}}}$$

that is, accessing a `public` field of a `private` expression we get a `private` result as well as accessing a `private` field of a `public` expression.

Also note that the following expression e'

```
{Aprivate x = new A(); new B(x, x)}
```

can be given only type $\text{Pair}^{\text{private}}$ by

$$\text{(T-BLOCK)} \frac{\text{(T-NEW)} \frac{}{\vdash \text{new A}() : A^{\text{priv}}} \quad \text{(T-NEW)} \frac{\text{(T-VAR)} \frac{}{x :_{\text{priv}} A \vdash x : A^{\text{priv}}} \quad \text{(T-VAR)} \frac{}{x :_{\text{priv}} A \vdash x : A^{\text{priv}}}}{x :_{\text{priv}} A \vdash \text{new Pair}(x, x) : \text{Pair}^{\text{priv}}}}{x :_{\text{priv}} A \vdash \text{new Pair}(x, x) : \text{Pair}^{\text{priv}}}}$$

We cannot derive $\vdash e' : \text{Pair}^{\text{pub}}$, since the grade of `first` is `public` and (T-NEW) would require $x :_{\text{priv}} A \vdash x : A^{\text{pub}\cdot\text{pub}}$, which does not hold.

3:16 Multi-Graded Featherweight Java

$$\begin{array}{c}

\end{array}$$

■ **Figure 5** Graded type system for annotated syntax.

Resource-aware soundness. We state that the graded type system is sound with respect to the resource-aware semantics. In other words, the graded type system prevents both standard typing errors, such as invoking a missing field or method, and resource-usage errors, such as requiring a resource which is exhausted (cannot be used in the needed way).

In order to state and prove a soundness theorem, we need to introduce a (straightforward) typing judgment \vdash_a for annotated expressions, environments and configurations. The typing rules are reported in Figure 5.

Recall that $[_]$ denotes erasing annotations. It is easy to see that an annotated expression is well-typed if and only if it is produced by the type system:

► **Proposition 12.** $\Gamma \vdash e : T \rightsquigarrow e'$ if and only if $[e'] = e$ and $\Gamma \vdash_a e' : T$.

A similar property holds for environments and configurations.

The main result is the following resource-aware progress theorem.

► **Theorem 13 (Resource-aware progress).** If $\Gamma \vdash_a e | \rho : C^r$ then either e is a value or $e | \rho \rightarrow_r e' | \rho'$ and $\Gamma' \vdash_a e' | \rho' : C^r$ with $\text{dom}(\Gamma) \subseteq \text{dom}(\Gamma')$ and $\Gamma' \preceq \Gamma, \Delta$.

When reduction is non-deterministic, we can distinguish two flavours of soundness, *soundness-must* meaning that no computation can be stuck, and *soundness-may*, meaning that at least one computation is not stuck. The terminology of *may* and *must* properties is very general and comes originally from [12]; the specific names *soundness-may* and *soundness-must* were introduced in [10, 9] in the context of big-step semantics. In our case, graded reduction is non-deterministic since, as discussed before, the rule (VAR) could be instantiated in different ways, possibly consuming the resource more than necessary. However, we expect that, for a well-typed configuration, there is at least one computation which is not stuck, hence a *soundness-may* result. *Soundness-may* can be proved by a theorem like the one above, which can be seen as a *subject-reduction-may* result, including standard progress. In our case, if the configuration is well-typed, that is, annotations have been generated by the type system, *there is a step* which leads, in turn, to a well-typed configuration. More in detail, the type is preserved, resources initially available may have reduced grades, and other available resources may be added.

Theorem 13 is proved as a special case of the following more general result, which makes explicit the invariant needed to carry out the induction. Indeed, by looking at the reduction rules, we can see that computational ones either add new variables to the environment or reduce the grade of a variable of some amount that depends on the grade of the reduction. In the latter case, the amount can be arbitrarily chosen with the only restrictions that it is non zero and at least the grade of the reduction. However, to prove progress, we not only have to prove that a reduction can be done, but, if the reduction is done in a context, say evaluating the argument of a constructor, then after such reduction we still have enough resources to go on with the reduction, that is, to evaluate the rest of the context (the other arguments of the constructor). This means that the resulting environment has enough resources to type the whole context (the constructor call). For this reason, in the statement of the theorem that follows, we add to the assumption of Theorem 13 a typing context Θ that would contain the information on the amount of resources that we want to preserve during the reduction (see Item 4 of the theorem). This allows us to choose the appropriate grade to be kept when reducing a variable and to reconstruct a typing derivation when using contextual reduction rules. For the expression at the top level, as we see from the proof of Theorem 13, Θ is simply $\mathbf{0}$ for all variables in the typing context in which the expression is typed.

► **Theorem 14.** *If $\Delta \vdash_a e : C^r$ and $\Gamma \vdash_a \rho$ and $\Delta + \Theta \preceq \Gamma$ and $\text{dom}(\Delta) \subseteq \text{dom}(\Theta)$ and e is not a value, then there are $e', \rho', \Delta', \Gamma'$ and Θ' such that*

1. $e|\rho \rightarrow_r e'|\rho'$ and
2. $\Delta' \vdash_a e' : C^r$ with $\Delta' \preceq \Delta, \Theta'$ and
3. $\Gamma' \vdash_a \rho'$ with $\Gamma' \preceq \Gamma, \Theta'$ and
4. $\Delta' + \Theta' \preceq \Gamma'$.

Finally, the following corollary states both subject-reduction for the standard semantics, that is, type and coeffects are preserved, and completeness of the instrumented semantics, that is, for well-typed configurations, every reduction step in the usual semantics can be simulated by an appropriate step in the instrumented semantics.

► **Corollary 15 (Subject reduction).** *If $\Gamma_1 \vdash e_1|\rho_1 : C^r \rightsquigarrow e'_1|\rho'_1$ and $e_1|\rho_1 \rightarrow e_2|\rho_2$, then $\Gamma_2 \vdash e_2|\rho_2 : C^r \rightsquigarrow e'_2|\rho'_2$ with $\text{dom}(\Gamma_1) \subseteq \text{dom}(\Gamma_2)$ and $\Gamma_2 \preceq \Gamma_1, \Delta$, and $e'_1|\rho'_1 \rightarrow_r e'_2|\rho'_2$.*

Proof. By Proposition 12 we get $\Gamma_1 \vdash_a e'_1|\rho'_1 : C^r$ and, by Theorem 13, $e'_1|\rho'_1 \rightarrow_r e'_2|\rho'_2$ and $\Gamma_2 \vdash_a e'_2|\rho'_2 : C^r$ with $\text{dom}(\Gamma_1) \subseteq \text{dom}(\Gamma_2)$ and $\Gamma_2 \preceq \Gamma_1, \Delta$. By Proposition 12, we get $\Gamma_2 \vdash [e'_2]|\rho'_2 : C^r \rightsquigarrow e_2|\rho_2$ and by Proposition 9, we get $e_1|\rho_1 \rightarrow [e'_2]|\rho'_2$. By the determinism of the standard semantics we have $[e'_2] = e_2$ and $[\rho'_2] = \rho_2$, hence the thesis. ◀

5 Combining grades

As we have seen, each grade algebra encodes a specific notion of resource usage. However, a program may need different notions of usage for different resources or different pieces of code (e.g., different classes). Hence, one needs to use several grade algebras at the same time, that is, a family $(H_k)_{k \in \mathcal{K}}$ of grade algebras⁶ indexed over a set \mathcal{K} of *grade kinds*. We assume grade kinds to always include \mathbf{N} and \mathbf{T} , with $H_{\mathbf{N}}$ and $H_{\mathbf{T}}$ the grade algebras of natural numbers and trivial, respectively, as in Example 2, since they play a special role, as will be shown.

⁶ H stands for “heterogeneous”.

- **Example 16.** Assume to use, in a program, grade kinds \mathbf{N} , \mathbf{A} , \mathbf{P} , \mathbf{PP} , \mathbf{AP} , and \mathbf{T} , where:
- $H_{\mathbf{A}}$ is the affinity grade algebra, as in Example 2(3).
 - $H_{\mathbf{P}}$ and $H_{\mathbf{PP}}$ are two different instantiations of the grade algebra of privacy levels, as in Example 6; namely, in $H_{\mathbf{P}}$ there are only two privacy levels `public` and `private`, whereas in $H_{\mathbf{PP}}$ we have privacy levels `a`, `b`, `c`, `d`, with $a \preceq b \preceq d$ and $a \preceq c \preceq d$.
 - Finally, $H_{\mathbf{AP}}$ is $H_{\mathbf{A}} \times H_{\mathbf{P}}$, as in Example 2(7), tracking simultaneously affinity and privacy.
- We want to make grades of all such kinds simultaneously available to the programmer. In order to achieve this, we should specify how to *combine* grades of different kinds through their distinctive operators; for instance, an object with grade of kind k could have a field with grade of kind μ , hence a field access should be graded by their multiplication.

In other words, we need to construct, starting from the family $(H_k)_{k \in \mathcal{K}}$, a single grade algebra of *heterogeneous grades*. In this way, the meta-theory developed in previous sections for an arbitrary grade algebra applies also to the case when several grade algebras are used at the same time. Note that this construction is necessary since we do not want available grades to be fixed, as in [23]; rather, the programmer should be allowed to define grades for a specific application, using some linguistic support which could be the language itself, as will be described in Section 6.

Direct refinement. The obvious approach is to define heterogeneous grades as pairs $\langle k, r \rangle$ where $k \in \mathcal{K}$, and $r \in H_k$. Concerning operators, in previous work, handling coefficients rather than grades, [3] we took the simplest choice, that is, combining (by either sum or product) grades of different kinds always returns $\langle \infty, \mathbf{T} \rangle$, meaning, in a sense, that we “do not know” how the combination should be done. The only exception are grades of kind \mathbf{N} ; indeed, since the corresponding grade algebra is initial, we know that, for any kind k , there is a unique grade homomorphism ι_k from \mathbf{Nat} to H_k , hence, to combine $\langle n, \mathbf{N} \rangle$ with $\langle r, k \rangle$, we can map n into a grade of kind k through such homomorphism, and then use the operator of kind k . In this paper, we generalize this idea, by allowing the programmer to specify, for each pair of kinds k and μ , a uniquely determined kind $k \oplus \mu$ and two uniquely determined grade homomorphisms $\text{lh}_{\kappa, \mu}^H : H_{\kappa} \rightarrow H_{\kappa \oplus \mu}$, and $\text{rh}_{\kappa, \mu}^H : H_{\mu} \rightarrow H_{\kappa \oplus \mu}$. In this way, to combine $\langle \kappa, r \rangle$ and $\langle \mu, s \rangle$, we can map both in grades of kind $k \oplus \mu$, and then use the operator of kind $k \oplus \mu$.

The operator \oplus and the family of unique homomorphisms, one for each pair of kinds, can be specified by the programmer, in a minimal and easy to check way, by defining a (*direct*) *refinement relation* \sqsubset^1 , as defined below, and a family of grade homomorphisms $H_{\kappa, \mu} : H_{\kappa} \rightarrow H_{\mu}$, indexed over pairs $\kappa \sqsubset^1 \mu$.

Given a relation \Rightarrow on kinds, a *path* from k_0 to k_n is a sequence $k_0 \dots k_n$ such as $k_i \Rightarrow k_{i+1}$, for all $i \in 1..n - 1$. We say that μ is an *ancestor* of κ if there is a path from κ to μ .

Then, a (*direct*) *refinement relation* is a relation \sqsubset^1 on $\mathcal{K} \setminus \{\mathbf{N}, \mathbf{T}\}$ such as the following conditions hold:

1. for each κ, μ , there exists at most one path from κ to μ
2. for each κ, μ with a common ancestor, there is a *least* common ancestor, denoted $\kappa \oplus \mu$; that is, such that, for any common ancestor ν , ν is an ancestor of $k \oplus \mu$.

Note that, thanks to requirement (1), requirement (2) means that the unique path, e.g., from κ to ν , consists of a unique path from κ to $k \oplus \mu$, and then a unique path from $k \oplus \mu$ to ν .

Given a direct refinement relation \sqsubset^1 , we can derive the following structure on \mathcal{K} :

- \sqsubset^1 can be extended to a partial order \sqsubseteq on \mathcal{K} , by taking the reflexive and transitive closure of \sqsubset^1 and adding $\mathbf{N} \sqsubseteq \kappa \sqsubseteq \mathbf{T}$ for all $\kappa \in \mathcal{K}$.
- \oplus can be extended to all pairs, by defining $\kappa \oplus \mu = \mathbf{T}$ if κ and μ have no common ancestor.

■ **Figure 6** Direct refinement diagram.

Altogether, we obtain an instance of a structure called *grade signature*, as will be detailed in Definition 18. Moreover, given a \sqsubset^1 -family of homomorphisms:

- they can be extended, by composition⁷, to all pairs of grades $\langle \kappa, \mu \rangle \in \mathcal{K} \setminus \{\mathbf{N}, \mathbf{T}\}$ such that there is a path from κ to μ ; since this path is unique, the resulting homomorphism is uniquely defined
- for each kind κ , we add the unique homomorphisms from \mathbf{Nat} and to \mathbf{Triv} .

Altogether, besides a grade algebra for each kind, we get a grade homomorphism for each pair $\langle \kappa, \mu \rangle$ such that $\kappa \sqsubseteq \mu$. That is, we obtain an instance of a structure called *heterogeneous grade algebra*, as will be detailed in Definition 19.

Thus, as desired, combining grades of kinds $\langle \kappa, r \rangle$ and $\langle \mu, s \rangle$ can be defined by mapping both r and s into grades of kind $\kappa \oplus \mu$, and then the operator of kind $\kappa \oplus \mu$ is applied.

The fact that in this way we actually obtain a grade algebra, that is, all required axioms are satisfied, is proved in the next subsection on the more general case of an arbitrary grade signature and heterogeneous grade algebra.

Note the special role played by the grade kinds \mathbf{N} and \mathbf{T} , with their corresponding grade algebras. The former turns out to be the minimal kind required in a grade signature (Definition 18); this is important since the zero and one of the resulting grade algebra (hence the zero and one used in the type system) will be those of this kind. The latter, as shown above, is used as default common ancestor for pairs of kinds which do not have one.

► **Example 17.** Coming back to our example, a programmer could define the direct refinement relation and the corresponding homomorphisms as follows:

- $\mathbf{PP} \sqsubset^1 \mathbf{P}$, and the homomorphism maps, e.g., \mathbf{a} , \mathbf{b} , and \mathbf{c} into **private** and \mathbf{d} into **public**
- $\mathbf{AP} \sqsubset^1 \mathbf{A}$, and $\mathbf{AP} \sqsubset^1 \mathbf{P}$, and the homomorphisms are the projections.

Thus, for instance, the grade $\langle \mathbf{AP}, \langle \omega, \mathbf{private} \rangle \rangle$, meaning that we can use the resource an arbitrary number of times in **private** mode, and $\langle \mathbf{PP}, \mathbf{d} \rangle$, meaning that we can use the resource in **d** mode, gives **private**. Indeed, both grades are mapped into the grade algebra of privacy levels $0 \preceq \mathbf{private} \preceq \mathbf{public}$; for the former, the information about the affinity is lost, whereas for the second the privacy level \mathbf{d} is mapped into **public**; finally, we get **private** = **private** · **public**.

The direct refinement relation is pictorially shown in Figure 6. Dotted arrows denote (some of) the order relations added for \mathbf{N} and \mathbf{T} .

Note that specifying the grade signature and the heterogeneous grade algebra indirectly, by means of the direct refinement relation and the corresponding homomorphisms, has a fundamental advantage: the semantic check that, for each κ, μ , we can map grades of grade κ into grades of kind μ in a unique way (that is, there is at most one homomorphism), which would require checking the equivalence of function definitions, is replaced by the checks (1)

⁷ Note that in this way we obtain, in particular, all the identities.

and (2) in the definition of direct refinement, which are purely syntactic and can be easily implemented in a type system (a simple stronger condition is to impose that each kind has a unique parent in the direct refinement relation, as it is for single inheritance).

In Section 6, we will see how to express both grade algebras and homomorphisms in Java; roughly, both will be represented by classes implementing a suitable generic interface.

A general construction. We provide a construction that, starting from a family of grade algebras with a suitable structure, yields a unique grade algebra summarising the whole family. As a consequence, the meta-theory developed in previous sections for a single grade algebra applies also to the case when several grade algebras are used at the same time.

To develop this construction, we use simple and standard categorical tools, referring to [20, 26] for more details. Given a category \mathcal{C} , we denote by \mathcal{C}_0 the collection of objects in \mathcal{C} and we say that \mathcal{C} is *small* when \mathcal{C}_0 is a set. Recall that any partially ordered set $\mathcal{P} = \langle \mathcal{P}_0, \sqsubseteq \rangle$ can be seen as a small category where objects are the elements of \mathcal{P}_0 and, for all $x, y \in \mathcal{P}_0$, there is an arrow $x \rightarrow y$ iff $x \sqsubseteq y$; hence, for every pair of objects in \mathcal{P}_0 , there is at most one arrow between them, and the only isomorphisms are the identities.

► **Definition 18.** A grade signature \mathcal{S} is a partially ordered set with finite suprema, that is, it consists of the following data:

- a partially ordered set $\langle \mathcal{S}_0, \sqsubseteq \rangle$;
- a function $\oplus: \mathcal{S}_0 \times \mathcal{S}_0 \rightarrow \mathcal{S}_0$ monotone in both arguments and such that for all $\kappa, \mu, \nu \in \mathcal{S}_0$, $\kappa \oplus \mu \sqsubseteq \nu$ iff $\kappa \sqsubseteq \nu$ and $\mu \sqsubseteq \nu$;
- a distinguished object $I \in \mathcal{S}_0$ such that $I \sqsubseteq \kappa$, for all $\kappa \in \mathcal{S}_0$.

Intuitively, objects in \mathcal{S} represent the *kinds* of grades one wants to work with, while the arrows, namely, the order relation, model a refinement between such kinds: $\kappa \sqsubseteq \mu$ means that the kind κ is *more specific* than the kind μ . The operation \oplus combines two kinds to produce the most specific kind generalising both. Finally, the kind I is the most specific one.

It is easy to check that the following properties hold for all $\kappa, \mu, \nu \in \mathcal{S}_0$:

$$\begin{aligned} (\kappa \oplus \mu) \oplus \nu &= \kappa \oplus (\mu \oplus \nu) & \kappa \oplus \kappa &= \kappa \\ \kappa \oplus \mu &= \mu \oplus \kappa & \kappa \oplus I &= \kappa \end{aligned}$$

namely, $\langle \mathcal{S}_0, \oplus, I \rangle$ is a commutative idempotent monoid.

► **Definition 19.** A heterogeneous grade algebra over the grade signature \mathcal{S} is just a functor $H: \mathcal{S} \rightarrow \mathit{GrAlg}$. That is, it consists of a grade algebra $H(\kappa)$, written also H_κ , for every kind $\kappa \in \mathcal{S}_0$, and a grade algebra homomorphism $H_{\kappa, \mu}: H_\kappa \rightarrow H_\mu$ for every arrow $\kappa \sqsubseteq \mu$, respecting composition and identities⁸, that is, $\kappa \sqsubseteq \mu \sqsubseteq \nu$ implies $H_{\kappa, \nu} = H_{\mu, \nu} \circ H_{\kappa, \mu}$ and $H_{\kappa, \kappa} = \text{id}_{H_\kappa}$.

Essentially, the homomorphisms $H_{\kappa, \mu}$ realise the refinement $\kappa \sqsubseteq \mu$, transforming grades of kind κ into grades of kind μ , preserving the grade algebra structure.

Observe that the arrows $I \sqsubseteq \kappa$ and $\kappa \sqsubseteq \kappa \oplus \mu$ and $\mu \sqsubseteq \kappa \oplus \mu$ in \mathcal{S} give rise to the following grade algebra homomorphisms:

$$\text{in}_\kappa^H = H_{I, \kappa}: H_I \rightarrow H_\kappa \quad \text{lh}_{\kappa, \mu}^H = H_{\kappa, \kappa \oplus \mu}: H_\kappa \rightarrow H_{\kappa \oplus \mu} \quad \text{rh}_{\kappa, \mu}^H = H_{\mu, \kappa \oplus \mu}: H_\mu \rightarrow H_{\kappa \oplus \mu}$$

⁸ The notation $H_{\kappa, \mu}$ makes sense, since between κ and μ there is at most one arrow.

which provide us with a way to map grades of kind I into grades of any other kind, and grades of kind κ and μ into grades of their composition $\kappa \oplus \mu$. By functoriality of H and using the commutative idempotent monoid structure of \mathcal{S} , we get the following equalities hold in the category \mathcal{GrAlg} , ensuring consistency of such transformations:

$$\text{lh}_{\kappa \oplus \mu, \nu}^H \circ \text{lh}_{\kappa, \mu}^H = \text{lh}_{\kappa, \mu \oplus \nu}^H \quad (1)$$

$$\text{rh}_{\kappa \oplus \mu, \nu}^H \circ \text{lh}_{\kappa, \mu}^H = \text{rh}_{\kappa, \mu \oplus \nu}^H \circ \text{lh}_{\mu, \nu}^H \quad (2)$$

$$\text{lh}_{\kappa, \mu}^H = \text{rh}_{\mu, \kappa}^H \quad (3)$$

$$\text{lh}_{\kappa, \kappa}^H = \text{id}_{H_\kappa} \quad (4)$$

$$\text{lh}_{\kappa, I}^H = \text{id}_{H_\kappa} \quad (5)$$

$$\text{rh}_{\kappa, I}^H = \text{in}_\kappa^H \quad (6)$$

In the following, we will show how to turn a heterogeneous grade algebra into a single grade algebra. The procedure we will describe is based on a general construction due to Grothendieck [17] defined on indexed categories.

Let us assume a grade signature \mathcal{S} and a heterogeneous grade algebra $H: \mathcal{S} \rightarrow \mathcal{GrAlg}$. We consider the following set:

$$|G(H)| = \{\langle \kappa, r \rangle \mid \kappa \in \mathcal{S}_0, r \in |H_\kappa|\}$$

That is, elements of $G(H)$ will be *kinded grades*, namely, pairs of a kind κ and a grade of that kind. Note that this is indeed a set because \mathcal{S} is small, that is, \mathcal{S}_0 is a set. Then, we define a binary relation \preceq_H on $|G(H)|$ as follows:

$$\langle \kappa, r \rangle \preceq_H \langle \mu, s \rangle \quad \text{iff} \quad \kappa \sqsubseteq \mu \quad \text{and} \quad H_{\kappa, \mu}(r) \preceq_\mu s$$

that is, the kind κ must be more specific than the kind μ and, transforming r by $H_{\kappa, \mu}$, we obtain a grade of kind μ which is smaller than s . These data define a partially ordered set as the following proposition shows.

► **Proposition 20.** $\langle |G(H)|, \preceq_H \rangle$ is a partially ordered set.

The additive structure is given by a binary operation $+_H: |G(H)| \times |G(H)| \rightarrow |G(H)|$ and an element $\mathbf{0}_H$ in $|G(H)|$ defined as follows:

$$\langle \kappa, r \rangle +_H \langle \mu, s \rangle = \langle \kappa \oplus \mu, \text{lh}_{\kappa, \mu}^H(r) +_{\kappa \oplus \mu} \text{rh}_{\kappa, \mu}^H(s) \rangle \quad \mathbf{0}_H = \langle I, \mathbf{0}_I \rangle$$

That is, the addition of $\langle \kappa, r \rangle$ and $\langle \mu, s \rangle$ is performed by first mapping r and s in the most specific kind generalising both κ and μ , namely $\kappa \oplus \mu$, and then by summing them in the grade algebra over that kind. The zero element is just the zero of the most specific kind.

► **Proposition 21.** $\langle |G(H)|, \preceq_H, +_H, \mathbf{0}_H \rangle$ is an ordered commutative monoid.

► **Proposition 22.** $\mathbf{0}_H \preceq_H \langle \kappa, r \rangle$ for every $\langle \kappa, r \rangle \in |G(H)|$.

Similarly, the multiplicative structure is given by a binary operation $\cdot_H: |G(H)| \times |G(H)| \rightarrow |G(H)|$ and an element $\mathbf{1}_H$ in $|G(H)|$ defined as follows:

$$\langle \kappa, r \rangle \cdot_H \langle \mu, s \rangle = \begin{cases} \langle \kappa \oplus \mu, \text{lh}_{\kappa, \mu}^H(r) \cdot_{\kappa \oplus \mu} \text{rh}_{\kappa, \mu}^H(s) \rangle & \langle \kappa, r \rangle \neq \mathbf{0}_H \quad \text{and} \quad \langle \mu, s \rangle \neq \mathbf{0}_H \\ \mathbf{0}_H & \text{otherwise} \end{cases} \quad \mathbf{1}_H = \langle I, \mathbf{1}_I \rangle$$

Notice that the definitions above follow almost the same pattern as additive operations, but we force that multiplying by $\mathbf{0}_H$ we get again $\mathbf{0}_H$, which is a key property of grade algebras.

► **Proposition 23.** $\langle |G(H)|, \preceq_H, \cdot_H, \mathbf{1}_H \rangle$ is an ordered monoid.

Altogether, we finally get the following result.

► **Theorem 24.** $G(H) = \langle |G(H)|, \preceq_H, +_H, \cdot_H, \mathbf{0}_H, \mathbf{1}_H \rangle$ is a grade algebra.

6 Grades as Java expressions

In Section 4 we described how a Java-like language could be equipped with *grades* decorating types, taken in an arbitrary grade algebra. Moreover, in Section 5, we have shown that such grade algebra could have been obtained by composing, in a specific way determined by providing a minimal collection of grade homomorphisms, different grade algebras corresponding to different ways to track usage of resources. In this section, we consider the issue of providing a linguistic support to this aim. This could be done by using an ad-hoc configuration language, however, we believe an interesting solution is that the grade annotations in types could be written themselves in Java.

The key idea is that grade annotations are Java expressions of (classes implementing) a predefined interface `Grade`, analogously to Java exceptions which are expressions of (subclasses of) `Exception`. Moreover, grade homomorphisms are user-defined as well. Namely, a user program can include:

- pairs of *grade classes* and *grade factory classes*, each one modeling a grade algebra desired for the specific application, with the factory class providing its constants
- *grade homomorphism classes*, each one modeling a homomorphism from a grade algebra (class) to another.

When typechecking code with grade annotations, the grades internally used by the type system are those obtained by combining all the declared grade algebras (classes) by means of the declared grade homomorphism classes, with the construction described in Section 5. Operations on grades in the same grade algebra (class) are derived from user-defined methods, as discussed more in detail below, whereas operations on heterogeneous grades are derived as in the construction in Section 5.

Grade and grade factory classes. They are classes implementing the following generic interfaces, respectively:

```
interface Grade<T extends Grade<T>> {
    boolean leq(T x);
    T sum(T x);
    T mult(T x);
}
interface GradeFactory<T extends Grade<T>>{
    T zero();
    T one();
}
```

Grade homomorphism classes. They are classes implementing the following generic interface:

```
interface GradeHom<T extends Grade<T>, R extends Grade<R>> {
    R apply(T x);
}
```

Examples of grade classes and grade homomorphism classes can be found in [4].

Typechecking could then be performed in two steps:

1. Code defining grades, which is assumed to be standard (that is, non-graded) Java code, is typechecked by the standard compiler.
2. Graded code (containing grade annotations written in Java) is typechecked accordingly to the graded type system in Figure 4, where the underlying grade algebra is obtained by composing, by the construction described in Section 5, the user-defined grade algebras through the user-defined grade homomorphisms. Each user-defined algebra has as carrier (set of grades) the Java values which are instances of the corresponding class, and the operations are computed by executing user-defined methods in such class. For instance, to compute the sum $v_1 + v_2$ of two grades which are values of a grade class, we evaluate $v_1.\text{sum}(v_2)$. Analogously to compute the result of a grade homomorphism.

For the whole process to work correctly, the following are responsibilities of the programmer:

- Grade classes, grade factory classes, and grade homomorphism classes should satisfy the axioms required for the structures they model, e.g., that the sum derived from `sum` methods is commutative and associative. The same happens, for instance, in Haskell, when one defines instances of `Functor` or `Monad`.
- Code defining grades should be *terminating*, since, as described above, the second typechecking step requires to *execute* code typechecked in the first step.
- Finally, the relation among grade classes implicitly defined by declaring grade homomorphism classes should actually be a direct refinement relation, that is, should satisfy the two requirements: (1) there exists at most one path between two grade classes, and (2) each two grade classes with a common ancestor have a *least* common ancestor. These are requirements easy to check, similarly to the check that inheritance is acyclic, or that there are no diamonds in multiple inheritance.

An interesting point is that implementations could use in a parametric way auxiliary tools, notably a termination checker to prevent divergence in methods implementing grade operations, and/or a verifier to ensure that they provide the required properties.

7 Related work

The two contributions which have been more inspiring for the work in this paper are the instrumented semantics proposed in [8] and the Granule language [23]. In [8], the authors develop GRAD, a graded dependent type system that includes functions, tensor products, additive sums, and a unit type. Moreover, they define an instrumented operational semantics which tracks usage of resources, and prove that the graded type system is sound with respect to such instrumented semantics. In this paper, we take the same approach to define a resource-aware semantics, parametric on an arbitrary grade algebra. However, differently from [8], where such semantics is defined on typed terms, with the only aim to show the role of the type system, the definition of our semantics is given *independently* from the type system, as is the standard approach in calculi. That is, the aim is also to provide a simple purely semantic model which takes into account usage of resources.

Granule [23] is a functional language equipped with graded modal types, where different kinds of grades can be used at the same time, including naturals for exact usage, security levels, intervals, infinity, and products of coeffects. We owe to Granule the idea of allowing different kinds of grades to coexist, and the overall objective to exploit graded modal types in a programming language. Concerning heterogeneous grades, in this paper we push forward the Granule approach, since we do not want this grade algebra to be fixed, but extendable

by the programmer with user-defined grades. To this aim we define the construction in Section 5. Concerning the design of a graded programming language, here we investigate the object-oriented rather than functional paradigm, taking some solutions which seem more adequate in that context, e.g., to have once-graded types and no boxing/unboxing. The design and implementation of a real Java-like language are not objectives of the current paper; however, we outline in Section 6 a possible interesting solution, where grade annotations are written in the language itself.

Coming more in general to resource-aware type systems, coeffects were first introduced by [24] and further analyzed by [25]. In particular, [25] develops a generic coeffect system which augments the simply-typed λ -calculus with context annotations indexed by *coeffect shapes*. The proposed framework is very abstract, and the authors focus only on two opposite instances: structural (per-variable) and flat (whole context) coeffects, identified by specific choices of context shapes.

Most of the subsequent literature on coeffects focuses on structural ones, for which there is a clear algebraic description in terms of semirings. This was first noticed by [7], who developed a framework for structural coeffects for a functional language. This approach is inspired by a generalization of the exponential modality of linear logic, see, e.g., [6]. That is, the distinction between linear and unrestricted variables of linear systems is generalized to have variables decorated by coeffects, or *grades*, that determine how much they can be used. In this setting, many advances have been made to combine coeffects with other programming features, such as computational effects [14, 23, 11], dependent types [2, 8, 22], and polymorphism [1]. Other graded type systems are explored in [2, 15, 1], also combining effects and coeffects [14, 23]. In all these papers, the process of tracking usage through grades is a powerful method of instrumenting type systems with analyses of irrelevance and linearity that have practical benefits like erasure of irrelevant terms (resulting in speed-up) and compiler optimizations (such as in-place update).

As already mentioned, [22] and [27] observed that contexts in a structural coeffect system form a module over the semiring of grades, even though they do not use this structure in its full generality, restricting themselves to free modules, that is, to structural coeffect systems. Recently, [5] shows a significant non-structural instance, namely, a coeffect system to track sharing in the imperative paradigm.

8 Conclusion

The contributions of the paper can be summarized as follows:

- Resource-aware extension of FJ reduction, parametric on an arbitrary grade algebra.
- Resource-aware extension of the type system, proved to ensure soundness-may of the resource-aware semantics.
- Formal construction which, given grades of different kinds and grade transformations corresponding to a refinement relation among kinds (formally, a functor over a grade signature), provides a grade algebra of *heterogeneous grades*.
- Notion of *direct refinement* allowing a minimal and easy to check way to specify the above functor.
- Outline of a Java extension where grades are user-defined, and grade annotations are written in the language itself.

As already noted, the key novel ideas in the contributions above are mostly independent from the language. So, a first natural direction for future work is to explore their incarnation in another paradigm, e.g., the functional one. That would include the definition of a parametric

resource-aware reduction independent from types, the design of a type system with once-graded types, and possibly the design of user-defined grades in a functional language, e.g., in Haskell by relying on the typeclass feature. Though the overall approach should still apply, we expect the investigation to be significant due to the specific features of the paradigm.

The resource-aware operational semantics defined in this paper requires *annotations* in subterms, with the only aim to fix their reduction grade in the reduction of the enclosing term. As mentioned in Section 3, adopting a big-step style would clearly remove the need of such technical artifice; only annotations in constructor subterms should be kept, since they express a true constraint on the semantics. Thus, a very interesting alternative to be studied is a big-step version of resource-aware semantics, allowing a more abstract and clean presentation. With this choice, we should employ, to prove soundness-may, the techniques recently introduced in [10, 9].

Coming back to Java-like languages, the FJ language considered in the paper does not include imperative features. Adding mutable memory leads to many significant research directions. First, besides the model presented in this paper, and in general in literature, where “using a resource” means “replacing a variable with its value”, another view is possible where the resource is the memory and “using” means “interacting with the memory”. Moreover, we would like to investigate more in detail how to express by grade algebras forms of usages which are typical of the imperative paradigm, such as the `readonly` modifier, and, more in general, *capabilities* [18, 16].

Abstract

Type-directed component-based program synthesis is the task of automatically building a function with applications of available components and whose type matches a given goal type. Existing approaches to component-based synthesis, based on classical proof search, cannot deal with large sets of components. Recently, HOOGLE+, a component-based synthesizer for Haskell, overcomes this issue by reducing the search problem to a Petri-net reachability problem. However, HOOGLE+ cannot synthesize constants nor λ -abstractions, which limits the problems that it can solve.

We present HOOGLE \star , an extension to HOOGLE+ that brings constants and λ -abstractions to the search space, in two independent steps. First, we introduce the notion of *wildcard* component, a component that matches all types. This enables the algorithm to produce *incomplete functions*, i.e., functions containing occurrences of the wildcard component. Second, we complete those functions, by replacing each occurrence with constants or custom-defined λ -abstractions. We have chosen to find constants by means of an inference algorithm: we present a new unification algorithm based on symbolic execution that uses the input-output examples supplied by the user to compute substitutions for the occurrences of the wildcard.

When compared to HOOGLE+, HOOGLE \star can solve more kinds of problems, especially problems that require the generation of constants and λ -abstractions, without performance degradation.

1 Introduction

Program synthesis is the task of automatically building a program that fulfills a specification supplied by the user [12]. Specifications can vary from examples [31], sketches [36], to ontologies [4] and types [13]. In type-guided component-based program synthesis, users provide the type of the function to synthesize (the *query type*), and optionally, input-output examples. Each solution is composed of applications of functions from a given *component set*. A recent example is HOOGLE+ [14, 20], a state-of-the-art synthesizer for the Haskell programming language that successfully solves several real-world problems with large component sets. For example, given the query type $(a \rightarrow b) \rightarrow [a] \rightarrow b$, it can

synthesize the function `\x1 x2 -> x1 (GHC.List.head x2)`. Multiple solutions are filtered using input-output examples. Unlike most approaches to component-based synthesis, which are based on classical proof search, HOOGLE+ can deal with large sets of components, because it reduces synthesis to a Petri-net reachability problem, following the approach of SYPET [7], a component-based synthesizer for Java.

Challenges for constants and λ -abstractions. Despite the benefits of Petri-net-based approaches, they exclude constants and custom λ -abstractions from the search space, because Petri nets only synthesize solutions whose terms belong to the component set, and it is impossible to insert all constants and custom λ -abstractions in a finite set. We found several problems in StackOverflow that HOOGLE+ cannot solve because the solutions require constants or λ -abstractions to be synthesized. So, bringing both classes of terms to the search space will allow HOOGLE+ to solve more problems, making life easier for Haskell programmers.

Motivating example. As an example, suppose that we want to append the constant 0 to a list. We provide to HOOGLE+ the query type `[Int] -> [Int]` together with the example that maps the input `[1]`¹ to the output `[1, 0]`. A solution is as simple as `\x1 -> x1 ++ [0]`, however, HOOGLE+ is not able to synthesize it, because it requires the constant `[0]` to be synthesized. The same happens with custom λ -abstractions. Suppose that we want to map each element of a list of integers to its square. For example, given `[1, 2, 3]`, the output should be `[1, 4, 9]`. The query type is `[Int] -> [Int]`, and a solution is `\list -> map (\x -> x * x) list`. However, this solution cannot be synthesized by HOOGLE+ as λ -abstractions do not belong to the search space.

Our approach. In this work we propose and evaluate a solution to bring constants and λ -abstractions to the search space of HOOGLE+, following two independent steps. First, we add to the component set the *wildcard component*, a component that matches all types. The Petri net is then allowed to synthesize *incomplete functions*: functions that use that component, such as `\list -> map wildcard list`. In this example, the wildcard component appears where a function is expected; however, in general, it could appear in place of an integer, string, or any other type. The second step is to replace the occurrences of the wildcard component with constants or λ -abstractions. When the wildcard occurs in place of a constant, we use a unification algorithm based on symbolic execution, that uses the input-output examples provided by the user to infer the constant. When the wildcard occurs in place of a function, we synthesize a λ -abstraction, using a faster, bespoke synthesizer.

Contributions. In summary, our contributions are:

1. We develop a new unification algorithm for a subset of Haskell, that we use to replace the occurrences of the wildcard component with constants. The algorithm is generic enough for other uses, as explained in Section 8.
2. We present HOOGLE*, an extension of HOOGLE+, that synthesizes functions with constants and λ -abstractions. As shown in Section 5, it solves several problems that cannot be solved by the original HOOGLE+.

Document structure. Section 2 presents the background: Petri nets and HOOGLE+; Section 3 presents the unification algorithm; Section 4 describes the extension made to HOOGLE+; Section 5 evaluates HOOGLE*, by comparing it to HOOGLE+; Section 6 discusses the related work; Section 7 discusses the limitations of this work; and Section 8 summarizes the lessons learned and the future work.

2 Background

In this section, we describe Petri nets, HOOGLE+, and SYPET.

2.1 Petri nets

Petri nets are used by HOOGLE+ to represent the search space. In this section, we define relevant concepts of Petri nets and present examples.

► **Definition 1.** A *Petri net* is a tuple (P, T, E, W) , where P is the set of places, T is the set of transitions, $E \subseteq (P \times T) \cup (T \times P)$ is the set of edges between places and transitions and between transitions and places, and $W : E \rightarrow \mathbb{N}_0$ is a function that maps each edge to its weight. Each place in a Petri net can have zero or more tokens. A **marking** (also known as configuration) M of a Petri net $N = (P, T, E, W)$ is a function $P \rightarrow \mathbb{N}_0$ that maps each place to its number of tokens.

We represent places by drawing circles and transitions by drawing narrow rectangles. Edges are represented by arrows, and each natural number we write near each edge is its weight. For example, consider the Petri net in Figure 1. The places are P_1 , P_2 and P_3 , and the transitions are T_1 , T_2 and T_3 . The edge (P_2, T_2) has weight 2, and all the other edges have weight 1. The place P_1 has 2 tokens, whereas the remaining places have no tokens.

We explain next how transitions can change the marking of a Petri net, defining the concepts of enabled transition and firing a transition.

► **Definition 2.** We say that the transition t is **enabled** if and only if for each place p with an edge to t , the number of tokens is at least the weight of the edge (p, t) . We say that **firing an enabled transition** is changing the marking of the Petri net, consuming a certain number of tokens from each place that has an edge to the transition, and producing a certain number of tokens in each place with an edge from the transition, according to the weight of each edge.

■ **Figure 3** A Petri net for the component set $f:A \rightarrow C$, $g:B \rightarrow C \rightarrow D$, $h:D \rightarrow E$. The initial marking for the query type $A \rightarrow B \rightarrow E$.

In the example of Figure 1, T_1 is the only enabled transition. Firing T_1 produces the marking of Figure 2: one token was consumed in P_1 ($W(P_1, T_1) = 1$), and one token was produced P_2 ($W(T_1, P_2) = 1$).

The last concept about Petri nets that we introduce is a decision problem called reachability.

► **Definition 3.** Given a Petri net $N = (P, T, E, W)$, with marking M , and new marking M' , the **reachability problem for Petri nets** consists of assessing whether it is possible to reach M' starting at M and by firing a certain sequence of transitions. We say that M is the **initial marking**, M' is the **target marking**, and the **trace** is the sequence of fired transitions.

For example, consider the Petri net and marking M shown in Figure 1. A marking $\{P_1 \mapsto 0, P_2 \mapsto 0, P_3 \mapsto 1\}$ is reachable from M . A trace is $\langle T_1, T_1, T_2 \rangle$.

2.2 SyPet, Hoogle⁺ and Synthesis via Petri-net reachability

SYPET [7] is a scalable component-based synthesizer for Java and deals with large component sets by reducing the problem to a Petri-net reachability problem. HOOGLE⁺ [14] adapts this idea to the Haskell programming language, extending the approach to deal with parametric polymorphism, high-order functions, and typeclasses. In its latest version, it support input-output examples [20]. In this section, we explain how Petri nets can be used for synthesis, as well as an overview of SYPET, and the changes introduced by HOOGLE⁺.

Petri net construction. Generally speaking, SYPET starts with building a Petri net that models the component set, and then solves the reachability problem, using the resulting trace to synthesize functions. Given a component set C and a query type t , SYPET constructs the Petri net $N = (P, T, E', W)$, and the initial marking as follows.

1. The places in P are the parameter types and return types of the components in C .
2. The transitions in T are the components of C , i.e., $T = C$.
3. For each type t' , and component c , we have $(t', c) \in E$ with $W((t', c)) = m$ if and only if t' is the type of $m > 0$ parameters of c .
4. For each type t' , and component c , we have edge (c, t') if and only if t' is the return type of c .
5. For each place p that is the type of a parameter of the query type, we add a clone transition k where $W(p, k) = 1$ and $W(k, p) = 0$.
6. For each parameter type of the query type we put as many tokens as the number of arguments of the given type.

Figure 3 shows an example of a Petri net that models a synthesis problem.

Synthesizing a function from a trace. Once the Petri net is built, we solve a reachability problem, where the target marking has a single token in the place that represents the return type of the query type. Then, the resulting trace is used to synthesize the desired function. For instance, in Figure 3, the target marking would have a token in place `E`, and a trace is $\langle f, g, h \rangle$, from which the function $\backslash \text{arg1 arg2} \rightarrow h (g (f \text{ arg1}) \text{ arg2})$ is synthesized. However, synthesizing a function from a trace is not trivial, because a trace cannot distinguish between different tokens in the same place, and no notion of order of incoming edges is maintained. So, multiple functions may arise from a single trace. We do not explain how SYPET performs the reachability analysis and synthesis from traces, as it is not necessary to follow the rest of this paper; for more details, see Feng et al. [7].

Hoogle+. So far we have discussed the algorithm of SYPET, which only supports monomorphic types. However, most functions from the Haskell libraries have polymorphic types. Thus, HOOGLE+ [14] has to deal with polymorphic types, which introduce the following challenges, if we represent all the monomorphic types in the Petri net: there is no limit to the set of types that may arise (for example `[Char]`, `[[Char]]`, `[[[Char]]]`, etc.), and some components, such as `id :: a -> a`, create a transition for each place. Representing monomorphic types, even if we bound the set of types, leads to an intractable Petri net, so HOOGLE+ uses abstract types, representing sets of concrete, monomorphic types. For example, the abstract type τ is the set of all existing types, whereas `Maybe` $\tau = \{\text{Maybe } t : t \in \text{Type}\}$. The algorithm starts with the most abstract Petri net, containing only the place τ , which leads to ill-typed programs. Then, the type errors are used to refine the Petri net, introducing more concrete types. For more details, see Guo et al. [14].

3 Unification via Symbolic Execution

Petri nets allow the generation of functions with occurrences of the wildcard component. Our goal is to use HOOGLE+ to generate functions that may contain wildcards and then replace each wildcard occurrence with a constant or a custom λ -abstraction, matching the set of given input-output examples. For this purpose, we use a unification algorithm that, given a source expression with symbolic variables, and a target grounded expression, computes a substitution for the symbolic variables so that the first expression evaluates to the second expression. When a solution is found by HOOGLE+, we replace the occurrences of the wildcard with symbolic variables in the synthesized function, the parameters with the input of the input-output example, and unify the resulting expression with the output of the input-output example. Consider the example from Section 1, where constant `[0]` is appended to the input list. The query type is `[Int] -> [Int]`, and an example maps the input `[1]` to the output `[1, 0]`. The Petri net will generate $\backslash x1 \rightarrow x1 ++ \text{wildcard}$. We then replace the occurrences of `wildcard` with fresh symbols and unify `[1] ++ s1` with `[1, 0]`, where the algorithm substitutes the symbolic variable `s1` with the constant `[0]`, by inspecting the definition of `(++)`.

Requirements. The unification algorithm has the following requirements:

- The input of the unification algorithm is the function synthesized by the Petri net, as well as the input-output examples. As the algorithm inspects the definitions of the synthesized function, and of the applied components, it has to support enough language constructs to encode the component set of HOOGLE+, such as the case construct, algebraic data types, integers, or, at least naturals, ad-hoc polymorphism, function application, and λ -abstractions. Additionally, it has to support symbols both in place of constants and in place of functions.

e	$::=$	x	<i>(variable)</i>	
		$ $	s	<i>(symbolic variable)</i>
		$ $	$\lambda \bar{x}.e$	<i>(λ-abstraction)</i>
		$ $	$\mu \{\bar{e}\}$	<i>(polymorphic λ-abstraction)</i>
		$ $	$K \bar{e}$	<i>(data constructor)</i>
		$ $	case e of $\{\bar{a}\}$	<i>(case)</i>
		$ $	$e \bar{e}$	<i>(application)</i>
a	$::=$	$K \bar{x} \rightarrow e$	<i>(case alternative)</i>	

■ **Figure 4** Grammar of the supported language, λ_U .

- The unification algorithm does not need to support the occurrence of symbols, nor the application of functions or case constructs in the target expression, because this expression is always the output of an input-output example, simplifying the algorithm.

3.1 Syntax

Figure 4 presents the grammar of the language supported by the unification algorithm, which we call λ_U . Now, we discuss each construct, and present Example 4 and Example 5.

Variables play the same role as in λ -calculus, and are represented by x, x_i .

Symbolic variables denote unknown expressions and are represented by s, s_i . Symbolic variables can occur in place of functions or constants.

Abstractions have a sequence of variables (the parameters) and an expression that defines the abstraction. For example, the identity function can be encoded as $\lambda x . x$.

Polymorphic abstractions allow us to encode ad-hoc polymorphism, present in Haskell through typeclasses: each type provides an implementation for a given operation, which are chosen depending on the types of the arguments [33]. In λ_U , a polymorphic abstraction consists of a set of λ -abstractions, each one being a monomorphic variant.

Data constructors have a name and a sequence of arguments. As we do not have literals, this is the only way to represent data (natural numbers are represented using Peano numbers², such as $S (S Z)$), lists are represented using constructors *Cons* and *Nil*).

Case expressions have an expression (the *scrutinee*) and a sequence of alternatives. Each alternative has the name of a data constructor, a sequence of variables (one variable per constructor argument), and an expression. A case expression is of the form: **case** x **of** $\{Cons\ x_1\ x_2 \rightarrow Just\ x_1; Nil \rightarrow Nothing\}$. There are two differences with relation to case expressions in Haskell: we do not support guards and our alternatives only support variables after the data constructor (Haskell allows patterns such as **Just True**).

Applications have an expression and a sequence of expressions (the arguments). For example, $e\ e_1\ e_2$ denotes the application of e to the arguments e_1 and e_2 . Currying is not supported natively, and requires a specific encoding, as explained in Section 7.

► **Example 4.** Function map, applying a function f to a list l , can be encoded in λ_U as:

$$map = \lambda f\ l . \mathbf{case}\ l\ \mathbf{of}\ \{Nil \rightarrow Nil; Cons\ h\ t \rightarrow Cons\ (f\ h)\ (map\ f\ t)\}$$

² To be concise, we may write Arabic numbers as an abbreviation of the Peano representation.

► **Example 5.** We define the polymorphic abstraction eq , similar to the function `Data.Eq.(==)` from the Haskell standard library, which has two arguments, and returns *True* if and only if the arguments are equal. We define two versions: one for naturals and another for booleans: $eq = \mu \{eqN, eqB\}$.

$$\begin{aligned}
 eqN &= \lambda x_1 x_2 . \mathbf{case} x_1 \mathbf{of} \{Z \rightarrow \mathbf{case} x_2 \mathbf{of} \{Z \rightarrow True; S x_3 \rightarrow False\}; \\
 &\quad S x_3 \rightarrow \mathbf{case} x_2 \mathbf{of} \{Z \rightarrow False; S x_4 \rightarrow eq x_3 x_4\}\} \\
 eqB &= \lambda x_1 x_2 . \mathbf{case} x_1 \mathbf{of} \{False \rightarrow \mathbf{case} x_2 \mathbf{of} \{False \rightarrow True; True \rightarrow False\}; \\
 &\quad True \rightarrow \mathbf{case} x_2 \mathbf{of} \{False \rightarrow False; True \rightarrow True\}\}
 \end{aligned}$$

3.2 Inference rules

Now, we explain how the algorithm works by providing inference rules. First, we define the concept of map of substitutions, in Definition 6, and then, in Definition 7, we introduce a judgement that establishes the result of unifying two expressions. The inference rules can be used to derive judgements, and we provide different rules for different combinations of source and target expressions.

► **Definition 6.** A *map of substitutions* Σ is a mapping from symbolic variables to expressions (or applications of symbolic variables, when they occur in place of functions, as explained in Section 3.2.5). $\Sigma(s)$ denotes the value of s in map Σ , while $\Sigma[s \mapsto e]$ denotes the map Σ updated with the substitution of s with e . We write $[\]$ to denote the empty map, and $\text{dom}(\Sigma)$ to denote the set of symbolic variables that are substituted in Σ .

► **Definition 7.** The *judgement* $\Sigma \vdash e_{src} \equiv e_{tgt} \triangleright \Sigma'$, defined by the rules in Figure 5, denotes the relation where Σ' is the map of substitutions that results from unifying e_{src} and e_{tgt} , given the initial map Σ .

The rules shown in Figure 5 guarantee that for all resulting substitutions Σ' , we have $\text{eval}(\Sigma', e_{src}) = \text{eval}(\Sigma', e_{tgt})$, with $\Sigma \subseteq \Sigma'$. We validated this experimentally (a formal proof is left for future work). The evaluation function is defined in Algorithm 1. We need to use two maps Σ and Σ' because the first map represents the substitutions computed so far, and the second map represents the first one, eventually updated with new substitutions so that a substitution computed before is not discarded. So, we have $\Sigma \subseteq \Sigma'$. We will return to this topic when we address the rule for unifying data constructors, in Section 3.2.2. In the rest of this section, we present the syntax-directed rule system, which is summarized in Figure 5.

3.2.1 Unifying symbolic variables with expressions

We start with the simplest case: $\Sigma \vdash s \equiv e \triangleright \Sigma'$, in which the source expression is a symbolic variable s , and the target expression is any expression e . In this case, adding the substitution of s for e to the input map solves the problem, if s is not already assigned in the substitutions map computed so far, which is Σ (rule *SNAL*). When the symbolic variable s is already substituted in Σ , we try to unify e with $\Sigma(s)$ and add the new substitutions to the initial map (rule *SAL*).

► **Example 8.** We derive $[s_1 \mapsto s_2] \vdash s_1 \equiv False \triangleright [s_1 \mapsto s_2, s_2 \mapsto False]$.

$$\frac{s_1 \in [s_1 \mapsto s_2] \quad \frac{s_2 \notin \text{dom}([s_1 \mapsto s_2])}{[s_1 \mapsto s_2] \vdash [s_1 \mapsto s_2](s_1) \equiv False \triangleright [s_1 \mapsto s_2, s_2 \mapsto False]} \text{SNAL}}{[s_1 \mapsto s_2] \vdash s_1 \equiv False \triangleright [s_1 \mapsto s_2, s_2 \mapsto False]} \text{SAL}$$

s_1 cannot be assigned to *False* because it is already assigned to s_2 . So, we unified $\Sigma(s_1)$ with *False*.

■ **Algorithm 1** Function eval.

$$\begin{aligned}
\text{eval}(\Sigma, \lambda \bar{x} . b) &= \lambda \bar{x} . b & \text{eval}(\Sigma, \mu \{\overline{opts}\}) &= \mu \{\overline{opts}\} \\
\text{eval}(\Sigma, s) &= \begin{cases} s & \text{if } s \notin \text{dom}(\Sigma) \\ \text{eval}(\Sigma, e) & \text{if } \Sigma(s) = e \end{cases} \\
\text{eval}(\Sigma, K) &= K \\
\text{eval}(\Sigma, K e_1 \dots e_k) &= K \text{ eval}(\Sigma, e_1) \dots \text{eval}(\Sigma, e_k) \\
\text{eval}(\Sigma, f e_1 \dots e_k) &= \begin{cases} \text{eval}(\Sigma, b\{e'_1/x_1, \dots, e'_k/x_k\}) & \begin{array}{l} \text{if } \text{eval}(\Sigma, f) = \lambda x_1 \dots x_k . b \\ \text{where } e'_i = \text{eval}(\Sigma, e_i), \text{ for } i \in \{1, \dots, k\} \end{array} \\ \text{eval}(\Sigma, b\{e'_1/x_1, \dots, e'_k/x_k\}) & \begin{array}{l} \text{if } \text{eval}(\Sigma, f) = \mu \{\overline{opts}\}, \\ \lambda x_1 \dots x_k . b \in \overline{opts}, \text{ and} \\ \text{eval}(\Sigma, b\{e'_1/x_1, \dots, e'_k/x_k\}) \neq \text{error} \\ \text{where } e'_i = \text{eval}(\Sigma, e_i), \text{ for } i \in \{1, \dots, k\} \end{array} \\ \text{eval}(\Sigma, \Sigma(s e'_1 \dots e'_k)) & \begin{array}{l} \text{if } \text{eval}(\Sigma, f) = s \\ s e'_1 \dots e'_k \in \text{dom}(\Sigma) \\ \text{where } e'_i = \text{eval}(\Sigma, e_i), \text{ for } i \in \{1, \dots, k\} \end{array} \\ s e'_1 \dots e'_k & \begin{array}{l} \text{if } \text{eval}(\Sigma, f) = s \\ s e'_1 \dots e'_k \notin \text{dom}(\Sigma) \\ \text{where } e'_i = \text{eval}(\Sigma, e_i), \text{ for } i \in \{1, \dots, k\} \end{array} \end{cases} \\
\text{eval}(\Sigma, \text{case } scr \text{ of } \{\overline{alts}\}) &= \text{eval}(\Sigma, b\{e_1/x_1, \dots, e_k/x_k\}) & \begin{array}{l} \text{if } \text{eval}(\Sigma, scr) = K e_1 \dots e_k \\ \text{and } K x_1 \dots x_k \rightarrow b \in \overline{alts} \end{array} \\
\text{eval}(\Sigma, e) &= \text{error} & \text{otherwise}
\end{aligned}$$

We have said that the target expression should not contain symbols. However, internally, we need support for symbols in the target expression, due to the rule for case constructors, which is presented in Section 3.2.3. So, there are two more rules: *SNAR* and *SAR*, similar to the *SNAL* and *SAL*, with the difference that the symbolic variable is now the target expression.

3.2.2 Unifying data constructors

The rule *DC* is applied when both expressions are data constructors, with the same data constructor and the same number of arguments, and unifies each argument of the source data constructor with the corresponding argument in the target data constructor.

► **Example 9.** We derive $[] \vdash \text{Pair } s_1 s_2 \equiv \text{Pair } \text{True } \text{Nil} \triangleright [s_1 \mapsto \text{True}, s_2 \mapsto \text{Nil}]$.

$$\frac{\frac{s_1 \notin \text{dom}([\])}{[\] \vdash s_1 \equiv \text{True} \triangleright [s_1 \mapsto \text{True}]} \quad \frac{s_2 \notin \text{dom}([s_1 \mapsto \text{True}])}{[s_1 \mapsto \text{True}] \vdash s_2 \equiv \text{Nil} \triangleright [s_1 \mapsto \text{True}, s_2 \mapsto \text{Nil}]}}{[\] \vdash \text{Pair } s_1 s_2 \equiv \text{Pair } \text{True } \text{Nil} \triangleright [s_1 \mapsto \text{True}, s_2 \mapsto \text{Nil}]}$$

where the two top rules are *SNAL*, and the bottom rule is *DC*. Both expressions are data constructors with two arguments, and the constructor is the same, *Pair*. So, we unify s_1 with *True*, and the result is passed to the unification of s_2 with *Nil*. An important aspect is

$$\begin{array}{c}
\frac{s \notin \text{dom}(\Sigma)}{\Sigma \vdash s \equiv e \triangleright \Sigma[s \mapsto e]} \text{SNAL} \qquad \frac{e'_i = \text{eval}(\Sigma, e_i), i = 1, 2, \dots, k}{\Sigma \vdash s e_1 \dots e_k \equiv \text{dst} \triangleright \Sigma[s e'_1 \dots e'_k \mapsto \text{dst}]} \text{ASNA} \\
\\
\frac{s \notin \text{dom}(\Sigma)}{\Sigma \vdash e \equiv s \triangleright \Sigma[s \mapsto e]} \text{SNAR} \qquad \frac{e'_i = \text{eval}(\Sigma, e_i), i = 1, 2, \dots, k}{\Sigma \vdash s e_1 \dots e_k \equiv \text{dst} \triangleright \Sigma'} \text{ASA} \\
\\
\frac{s \in \text{dom}(\Sigma) \quad \Sigma \vdash \Sigma(s) \equiv e \triangleright \Sigma'}{\Sigma \vdash s \equiv e \triangleright \Sigma'} \text{SAL} \qquad \frac{s \in \text{dom}(\Sigma) \quad \Sigma \vdash e \equiv \Sigma(s) \triangleright \Sigma'}{\Sigma \vdash e \equiv s \triangleright \Sigma'} \text{SAR} \\
\\
\frac{\Sigma_0 \vdash e_1 \equiv f_1 \triangleright \Sigma_1 \quad \dots \quad \Sigma_{k-1} \vdash e_k \equiv f_k \triangleright \Sigma_k}{\Sigma_0 \vdash K e_1 \dots e_k \equiv K f_1 \dots f_k \triangleright \Sigma_k} \text{DC} \qquad \frac{\lambda x_1 \dots x_k . b \in \overline{\text{opts}}}{\Sigma \vdash (\lambda x_1 \dots x_k . b) e_1 \dots e_k \equiv e' \triangleright \Sigma'} \text{AP} \\
\\
\frac{\Sigma \vdash b\{s_1/x_1, \dots, s_k/x_k\} \equiv e' \triangleright \Sigma_0 \quad s_1, \dots, s_k \text{ fresh} \quad \Sigma_0 \vdash e_1 \equiv s_1 \triangleright \Sigma_1 \quad \dots \quad \Sigma_{k-1} \vdash e_k \equiv s_k \triangleright \Sigma_k}{\Sigma \vdash (\lambda x_1 \dots x_k . b) e_1 \dots e_k \equiv e' \triangleright \Sigma_k} \text{AL} \qquad \frac{K \bar{x} \rightarrow b \in \bar{a} \quad \Sigma \vdash \text{scr} \equiv K \bar{s} \triangleright \Sigma', \bar{s} \text{ fresh} \quad \Sigma' \vdash b\{\bar{s}/\bar{x}\} \equiv e \triangleright \Sigma''}{\Sigma \vdash \mathbf{case} \text{scr} \mathbf{of} \{\bar{a}\} \equiv e \triangleright \Sigma''} \text{C}
\end{array}$$

■ **Figure 5** Syntax-directed rule system that defines the judgement $\Sigma \vdash e_{src} \equiv e_{tgt} \triangleright \Sigma'$.

that the map that results from unifying e_1 with f_1 is passed as input to unify e_2 with f_2 , and so on, to preserve all substitutions and to avoid contradictions, which is illustrated in Example 10.

► **Example 10.** We want to unify *Pair s s* with *Pair True False*. Both expressions have the same data constructor and the same number of arguments, so let us apply the *DC* rule. First, we have to derive $[\] \vdash s \equiv \text{True} \triangleright [s \mapsto \text{True}]$, by using the rule *SNAL*. Second, we have to derive $[s \mapsto \text{True}] \vdash s \equiv \text{False} \triangleright \Sigma'$, for a certain Σ' . However, this is impossible because we are trying to unify s with *False*, and the unification of the first argument substituted s with *True*.

3.2.3 Unifying case expressions with expressions

When the source expression is a case construct, the rule *C* chooses a case alternative such that the *scrutinee* (*scr*) unifies with the selected data constructor. For example, if the case expression is **case** *expr of* $\{\text{Nothing} \rightarrow \text{False}, \text{Just } x \rightarrow x\}$, and supposing that we have chosen the first alternative, we have to ensure that *expr* unifies with *Nothing*. When the

data constructor has arguments (for instance, *Just* has one argument), we generate fresh symbols (which introduces the need to support symbolic variables in the target expression). This would be the case if we selected the second alternative: we would unify *expr* with *Just s*, where *s* is a fresh symbol. Finally, we unify the body of the alternative, *b*, with the target expression, substituting the variables of the alternative with the fresh symbols ($b\{\bar{s}/\bar{x}\}$). In rule *C* of Figure 5, \bar{s} denotes the sequence of fresh symbols, \bar{x} denotes the sequence of arguments of the data constructor, and $b\{\bar{s}/\bar{x}\}$ denotes the expression *b* in which each occurrence of $x_i \in \bar{x}$ is replaced with the corresponding symbol $s_i \in \bar{s}$.

► **Example 11.** We derive

$$[] \vdash \mathbf{case\ } s \mathbf{ of\ } \{Nothing \rightarrow False, Just\ x \rightarrow x\} \equiv True \triangleright [s \mapsto Just\ s_1, s_1 \mapsto True]$$

where s_1 is a fresh symbol, and *A* and *B* are derivation subtrees. The derivation applies *C*:

$$\frac{A \quad B \quad (Just\ x \rightarrow x) \in \{Nothing \rightarrow False, Just\ x \rightarrow x\}}{[] \vdash \mathbf{case\ } s \mathbf{ of\ } \{Nothing \rightarrow False, Just\ x \rightarrow x\} \equiv True \triangleright [s \mapsto Just\ s_1, s_1 \mapsto True]}$$

where *A* abbreviates

$$\frac{s \notin \text{dom}([])}{[] \vdash s \equiv Just\ s_1 \triangleright [s \mapsto Just\ s_1], s_1 \text{ fresh}} \text{SNAL}$$

and *B* abbreviates

$$\frac{s_1 \notin \text{dom}([s \mapsto Just\ s_1])}{[s \mapsto Just\ s_1] \vdash x\{s_1/x\} \equiv True \triangleright [s \mapsto Just\ s_1, s_1 \mapsto True]} \text{SNAL}$$

We choose the alternative *Just x → x*, unify *s* with *Just* instantiated with a fresh symbolic variable s_1 and then unify the body with the target expression. Note that the symbolic variable *s* is substituted with *Just s₁* and s_1 is substituted with *True*, so we have to evaluate *s*. We have $\text{eval}([s \mapsto Just\ s_1, s_1 \mapsto True], s) = Just\ True$, and substituting *s* with *Just True* solves the unification problem.

3.2.4 Unifying λ -abstraction applications with expressions

When the source expression is an application of a λ -abstraction, and the number of arguments is the same as the number of parameters, we apply *AL*, replacing the arguments of the application with fresh symbols in *b* and unifying this result, $b\{s_1/x_1, \dots, s_k/x_k\}$, with the target expression. The idea is to propagate the target expression to the arguments of the application: the unification will compute substitutions for the fresh symbols, and then we unify each argument with the corresponding fresh symbol.

► **Example 12.** We derive $[] \vdash (\lambda x\ y . x)\ s\ F \equiv T \triangleright [s_1 \mapsto T, s \mapsto s_1, s_2 \mapsto F]$, where s_1 and s_2 are fresh symbols, and *A*, *B* and *C* are derivation subtrees.

$$\frac{A \quad B \quad C}{[] \vdash (\lambda x\ y . x)\ s\ F \equiv T \triangleright [s_1 \mapsto T, s \mapsto s_1, s_2 \mapsto F]} \text{AL}$$

where *A*, *B*, and *C* abbreviate respectively

$$\frac{s_1 \notin \text{dom}([])}{[] \vdash x\{s_1/x, s_2/y\} \equiv T \triangleright [s_1 \mapsto T], s_1, s_2 \text{ fresh}} \text{SNAL}$$

$$\frac{s \notin \text{dom}([s_1 \mapsto T])}{[s_1 \mapsto T] \vdash s \equiv s_1 \triangleright [s_1 \mapsto T, s \mapsto s_1]} \text{SNAL}$$

$$\frac{s_2 \notin \text{dom}([s_1 \mapsto T, s \mapsto s_1])}{[s_1 \mapsto T, s \mapsto s_1] \vdash F \equiv s_2 \triangleright [s_1 \mapsto T, s \mapsto s_1, s_2 \mapsto F]} \text{SNAR}$$

The λ -abstraction has two parameters, and so we generate two symbols: s_1 and s_2 . The body of the λ -abstraction is x , and $x\{s_1/x, s_2/y\} = s_1$, which is unified with the target expression. Finally, we unify the arguments s and F with s_1 and s_2 .

3.2.5 Unifying applications of symbols with expressions

As stated in Section 3.1, a symbolic variable can occur in place of a function, however, instead of assigning it directly to expressions, which is out of the scope of this work, we assign applications of symbolic variables to expressions. This allows the generation of input-output examples for unknown functions and the detection of contradictions, which is relevant for HOOGLÉ \star , as described in Section 4. For instance, unifying $\text{map } s \text{ (Cons 1 (Cons 2 Nil))}$ with $\text{Cons 2 (Cons 3 Nil)}$ generates examples for the unknown function s : assigns s 1 to 2 and s 2 to 3. On the other hand, it will be impossible to unify $\text{map } s \text{ (Cons 1 (Cons 1 Nil))}$ with $\text{(Cons 1 (Cons 2 Nil))}$, because s 1 will be assigned to 1, and then to 2, which generates a contradiction.

We have two rules *ASNA* and *ASA*, very similar to the rules for symbols, shown in Section 3.2.1. We need to store the arguments $\bar{e} = e_1 e_2 \dots e_k$ in a form as reduced as possible (using eval) because we need to compare each argument for equality³, to check if an application is already assigned as in the following example.

► **Example 13.** We derive $[s \ 0 \mapsto 2, s \ 1 \mapsto 3] \vdash s \ ((\lambda x . 0) \ 1) \equiv 2 \triangleright [s \ 0 \mapsto 2, s \ 1 \mapsto 3]$.

$$\frac{0 = \text{eval}(\Sigma, s \ ((\lambda x . 0) \ 1)) \quad \Sigma(s \ 0) = 2 \quad \Sigma \vdash 2 \equiv 2 \triangleright \Sigma}{\Sigma \vdash s \ ((\lambda x . 0) \ 1) \equiv 2 \triangleright \Sigma} \text{ASA}$$

where $\Sigma = [s \ 0 \mapsto 2, s \ 1 \mapsto 3]$. We omit the derivation of $\Sigma \vdash 2 \equiv 2 \triangleright \Sigma$. This example shows the importance of evaluating the arguments before updates and lookups to the map of substitutions. Indeed, the application $s \ ((\lambda x . 0) \ 1)$ is not substituted in Σ , but $(\lambda x . 0) \ 1$ evaluates to 0, and $s \ 0$ is already substituted in Σ .

3.2.6 Unifying applications of polymorphic abstractions with expressions

When the source expression is an application of a polymorphic abstraction, we apply *AP*, which chooses a λ -abstraction from $\overline{\text{opts}}$ and then unifies the application of this λ -abstraction to the provided arguments with the target expression. However, we cannot just choose any λ -abstraction. For instance, if the arguments are lists, we cannot choose a function that expects booleans, as the unification will fail.

► **Example 14.** We derive that $[] \vdash \text{eq } s \ \text{False} \equiv \text{True} \triangleright [s \mapsto s_1, s_1 \mapsto \text{False}, s_2 \mapsto \text{False}]$ where polymorphic abstraction *eq* was defined in Example 5.

$$\frac{\text{eq}B \in \overline{\text{opts}} \quad [] \vdash \text{eq}B \ s \ \text{False} \equiv \text{True} \triangleright [s \mapsto s_1, s_1 \mapsto \text{False}, s_2 \mapsto \text{False}]}{[] \vdash \text{eq } s \ \text{False} \equiv \text{True} \triangleright [s \mapsto s_1, s_1 \mapsto \text{False}, s_2 \mapsto \text{False}]}$$

³ Rule *ASA* can be applied only if the arguments are comparable for equality, which require the arguments not to be abstractions.

where rule AP is applied, $\overline{opts} = \{eqN, eqB\}$ and the derivation of the second hypothesis is omitted. When applying rule AP , we cannot choose the λ -abstraction eqN , because the derivation of $[\] \vdash eqN \ s \ False \equiv True \triangleright [s \mapsto s_1, s_1 \mapsto False, s_2 \mapsto False]$ gets stuck, as the case expressions of eqN do not contain alternatives matching $True$ and $False$.

3.3 Lazyness

The inference rules are lazy. For instance, consider the application $(\lambda x y . x) e_1 e_2$ being unified with $target$. We first unify the body with arguments replaced with symbols $x\{s_1/x, s_2/y\}$ with $target$, and then unify e_1 with s_1 and e_2 with s_2 . As y is not used in the abstraction, s_2 will not be assigned, so the unification of e_2 with s_2 will simply assign the symbol to the expression, and e_2 is not reduced. Thus, in principle, the algorithm supports computations with conceptually infinite structures [18]. For instance, it can unify `take sym1 (repeat sym2)` with `[3, 3]`, replacing `sym1` with 2 and `sym2` with 3.

3.4 Implementation

The unification algorithm was implemented in Haskell and performs a depth-first search: it tries to apply the rules and backtracks if it fails. The heart of symbolic execution and backtracking in the algorithm is the rule for the case construct: it attempts each alternative until it succeeds. To prevent the algorithm from running forever, we limit the depth of the DFS. The algorithm returns a substitution if found; `Mismatch`, if no substitution was found after trying all the possible rules (never reaching the limit for rules); or `DepthReached` if the maximum number of rules was reached in at least one path and no solution was found. Although the algorithm implements a search, it is very fast in practice. We conjecture that this is because the branching factor is reduced. Functions that work with lists typically have case expressions with no more than two cases (*Nil* and *Cons*), and the *Nil* case tends to be a base case (a leaf, in the search tree).

4 Extension to Hoogle \star : Hoogle \star

In this section, we describe the implementation of `HOOGLE \star` ⁴, by explaining the two independent steps presented in Section 1. We start with the modifications to introduce the wildcard component in Section 4.1, and, in Section 4.2, we address how the occurrences of the wildcard component are replaced.

4.1 The wildcard component

The first step is to add a component that matches all types so that it can occur where an integer, a list, a function, etc., is expected. `HOOGLE+` requires the name and the type of each component, so we provided the name *wildcard* associated with the type `a`, which matches all types. With this extension, `HOOGLE+` can synthesize functions containing the wildcard such as `\arg1 -> map wildcard arg1`, in which the wildcard occurs in place of a function (the first parameter of `GHC.List.map` is a function) or `\arg1 -> arg1 ++ wildcard`, in which the wildcard occurs in place of a list (both parameters of `GHC.List.++` are lists).

⁴ The `HOOGLE \star` repository is available at https://github.com/sr-lab/hoogle_plus.

The component set of HOOGLE+ contains four constants (`[]`, `True`, `False`, and `Nothing`), which are not required in HOOGLE* because the unification algorithm is able to generate them. So, these constants are not present in the default component set of HOOGLE*.

4.2 Replacing occurrences of the wildcard component

■ **Algorithm 2** Overview of HOOGLE*.

```

1: procedure HOOGLE*(components, query, N, examples)
2:   parsedExamples ← parse examples to  $\lambda_U$ 
3:   petri ← build the Petri Net with components  $\cup$  {("wildcard", "a")}
4:   for  $i = 1, \dots, N$  do
5:     synth ← synthesize a function for query using petri
6:     if synth has wildcards then
7:       completions ← COMPLETE(synth, parsedExamples, components, query)
8:       PRINT(comp) for  $comp \in completions$ 
9:     else if synth respects examples then
10:      PRINT(synth)

```

Algorithm 2 shows an overview of HOOGLE*. It takes four parameters: *components*, the component set; *query*, the query type; *N*, the number of functions the Petri net should synthesize; and *examples*, the input-output examples. HOOGLE* starts by parsing each input-output example to a pair $(x_{i1} \dots x_{ik}, y_i)$, containing a sequence of k inputs and output in λ_U , and the Petri net is built, considering the wildcard component. Then the Petri net synthesizes N functions. The function COMPLETE then tries to replace the wildcards (Algorithm 3).

4.2.1 The Complete function

COMPLETE takes four parameters: f , the function generated by the Petri net, expressed in the Hoogle+ grammar; *examples*, the examples expressed in λ_U ; *components*, the component set; and *type*, the query type. It has three main steps, presented afterward.

Step 1: Convert to λ_U . COMPLETE starts by converting the function generated by the Petri net to λ_U , where each wildcard is replaced with a fresh symbolic variable. The variable f' denotes the function in λ_U , and *symbols* denotes the array of generated symbols.

Step 2: Unify. The next step is to call the unification algorithm with the examples. For each example, the application of f' to the inputs is unified with the output, which requires as many calls to the unification algorithm as the number of examples. The result of all unifications, Σ , contains symbolic variables assigned to constants for the wildcards occurring in place of constants, and input-output examples for the wildcards occurring in place of a function⁵.

Note that Σ respects all the examples because the unification of each example uses the result of the unification of the previous example.

⁵ It is not guaranteed that each symbol is assigned in Σ , which can happen if its value does not impact the result of the unification. For instance, unifying *head* (*Cons* s_1 s_2) with *target* assigns s_1 to *target*, but does not assign s_2 . In this case, the incomplete function is rejected.

■ **Algorithm 3** Function COMPLETE.

```

1: procedure COMPLETE( $f, examples, components, type$ )
2:    $f', symbols \leftarrow$  convert  $f$  to  $\lambda_U$ , replace wildcards with fresh symbols, and return it
3:    $\Sigma \leftarrow []$  ▷ unify pairs of applications to outputs of examples
4:   for  $((x_1, \dots, x_k), y) \in examples$  do
5:      $\Sigma \leftarrow$  UNIFY( $\Sigma, f' x_1 \dots x_k, y$ )
6:     if  $\Sigma = \text{ERROR}$  then
7:       return Error
8:    $p \leftarrow$  the length of  $symbols$  ▷ i.e., the number of wildcards to replace
9:   for  $i = 1, \dots, p$  do
10:    if  $\exists \bar{e} : symbols[i] \bar{e} \in \text{dom}(\Sigma)$  then ▷ if  $symbols[i]$  denotes a function
11:       $wildcardType \leftarrow$  get the type of the wildcard  $i$  in function  $f$ 
12:       $\lambda \leftarrow$  SYNTH-LAMBDA( $wildcardType, f', examples, components, symbols[i]$ )
13:       $fill[i] \leftarrow \lambda$ 
14:    else if  $symbols[i] \in \text{dom}(\Sigma)$  then ▷ if  $symbols[i]$  denotes a constant
15:       $val \leftarrow$  eval( $\Sigma, symbols[i]$ )
16:       $fill[i] \leftarrow$  convert  $val$  to Haskell notation
17:    $res \leftarrow \{\}$ 
18:   for  $(e_1, \dots, e_p) \in fill[1] \times \dots \times fill[p]$  do ▷ all combinations of expressions
19:      $res \leftarrow res \cup f'\{e_1/symbols[1], \dots, e_p/symbols[p]\}$  ▷ replace wildcards
20:   return  $res$  in the grammar of HOOGLE+

```

Step 3: Replacing wildcards. After the unification, each symbolic variable is replaced with a constant or a λ -abstraction. Each iteration of the loop starting at line 9 replaces a symbol, assigning the replacement (or replacements, if there is more than one alternative) to the corresponding entry in the array $fill$. It starts with a lookup in Σ to determine the type of the expected term:

- If there is an application of the symbol, $symbols[i]$, in Σ , the corresponding wildcard must be replaced with a function. In this case, SYNTH-LAMBDA (Algorithm 4, Section 4.2.2), is called to synthesize λ -abstractions, with the data type of the function, $wildcardType$. Note that this function returns a set of λ -abstractions, because it may find more than one function that has the specified type and respects the examples.
- If the symbol s is itself assigned in Σ , the corresponding wildcard should be replaced with a constant. In this case, $\Sigma(s)$ is the expression that replaces the wildcard. However, this expression must be evaluated, because it may contain occurrences of other symbols, as explained in Section 3.2.3. Additionally, we replace Peano numbers with Arabic numbers and *Cons/Nil* lists with Haskell-syntax lists.

At the end of the loop that starts in line 9, $fill$ has one entry for each wildcard, each one containing a set of alternative replacements. Then, in the loop starting at line 18 we compute all the combinations of replacements for each wildcard, through a cartesian product, and, for each combination, we replace the wildcards in f' , and add the resulting expression to res .

► **Example 15.** Recall the first example of Section 1. The Petri net is able to synthesize $\backslash x1 \rightarrow x1 ++ wildcard$. We start by converting both the generated function and the input-output examples to λ_U . The function corresponds to $\lambda x_1 . (++) x1 s_1$, the input of the example becomes *Cons 1 Nil*, and the output becomes *Cons 1 (Cons 0 Nil)*. The next step is to unify $(\lambda x_1 . (++) x1 s_1)(\text{Cons } 1 \text{ Nil})$ with *Cons 1 (Cons 0 Nil)*, to compute Σ . As a result, s_1 is assigned itself in Σ to an expression, so the expected term is a constant. We have $\text{eval}(\Sigma, s_1) = \text{Cons } 0 \text{ Nil}$, that corresponds to $[0]$ in Haskell notation. Finally, the wildcard is replaced with $[0]$, which produces the function $\backslash x1 \rightarrow x1 ++ [0]$.

Note the importance of having the unification algorithm supporting symbols in place of functions, described in detail in Section 3.2.5. On the one hand, it allows replacing multiple function wildcards, because they are replaced one at a time. For instance, suppose that there are two function wildcards to replace. When replacing the first wildcard, we pick a λ -abstraction and then apply the unification algorithm to the original function, with the new λ -abstraction replaced. In this case, the second symbol remains, but the unification algorithm is able to validate if the first wildcard is replaced correctly. If the algorithm could not support symbolic functions, we would have to pick all the λ -abstractions at once and try each possible combination, which would lead to a combinatorial explosion. On the other hand, supporting symbolic functions allows for saving time, because the algorithm can detect if no λ -abstraction can fill a specific wildcard. In those cases, HOOGLE \star does not waste time calling SYNTH-LAMBDA. Section 4.2.2 discusses in detail SYNTH-LAMBDA.

4.2.2 The synthesizer for λ -abstractions

■ **Algorithm 4** Function SYNTH-LAMBDA.

```

1: procedure SYNTH-LAMBDA(type, originalFun, examples, comps, symbol)
2:   lamComps  $\leftarrow$  remove Data.ByteString and high-order components from comps
3:    $y_i \leftarrow$  the i-th parameter of originalFun for  $i = 1, \dots, n$ 
4:    $x_i \leftarrow$  the i-th parameter of the  $\lambda$ -abstraction, for  $i = 1, \dots, k$ 
5:   leafs  $\leftarrow$   $\{y_1, \dots, y_n, x_1, \dots, x_k, s\}$ , s fresh
6:   exprs  $\leftarrow$  SYNTH-EXPR(type, leafs, lamComps, 0)
7:   res  $\leftarrow$   $\{\}$ 
8:   for  $e \in$  exprs do
9:     lambda  $\leftarrow$   $\lambda x_1 \dots x_k . e$ 
10:    lambda'  $\leftarrow$  REPLACE-SYMBOLS(originalFun, lambda, examples, symbol)
11:    if lambda'  $\neq$  ERROR and the type of lambda' matches type then
12:      res  $\leftarrow$  res  $\cup$   $\{lambda'\}$ 
13:  return res ▷ a list of many  $\lambda$ -abstractions with the specified type

```

The function SYNTH-LAMBDA computes a λ -abstraction that respects the input-output examples and has the specified type. We could call HOOGLE \star recursively, but we conjecture that it would lead to performance degradations, and a simpler, faster synthesizer is enough to synthesize λ -abstractions. On the one hand, it may be needed to synthesize λ -abstractions several times during a single HOOGLE+ query, but the paper that presented HOOGLE+ [14] has shown that for many problems, HOOGLE+ may take several seconds. Note that each query may require an unbounded number of synthesis of λ -abstractions because each one of the N incomplete functions may have an arbitrary number of wildcards in place of functions. On the other hand, from our experience with the Haskell programming language, λ -abstractions are simpler than other portions of code and use fewer components. So, we decided to build a faster, bespoke synthesizer that corresponds to the function SYNTH-LAMBDA.

Search space. The search space of SYNTH-LAMBDA is composed of applications of components from HOOGLE \star . To guarantee a faster synthesis, we exclude high-order functions, as well as the module **Data.ByteString** (that seems less common in λ -abstractions, from our experience as Haskell programmers), which leaves 54 popular components. The arguments of the applications can be the parameters of the λ -abstraction, parameters of the original function, symbols (to replace using the unification algorithm), and applications of components, with at

Algorithm 5 Function SYNTH-EXPR.

```

1: procedure SYNTH-EXPR(type, leafs, components, level)
2:   exprs  $\leftarrow$  {}
3:   for  $l \in \text{leafs}$  s.t. the type of  $l$  matches type do
4:     exprs  $\leftarrow$  exprs  $\cup$  { $l$ }
5:   if level < 2 then
6:     for comp  $\in$  components s.t. the return type of comp matches type do
7:       sign  $\leftarrow$  the signature of comp, with type variables replaced s.t. the return
       type matches type
8:       prms  $\leftarrow$  extract the types of the parameters from sign
9:        $p \leftarrow$  the number of parameters of comp
10:      args[ $i$ ]  $\leftarrow$  SYNTH-EXPR(prms[ $i$ ], leafs, components, level + 1) for  $i = 1, \dots, p$ 
11:      for  $(e_1, \dots, e_p) \in \text{args}[1] \times \dots \times \text{args}[p]$  do  $\triangleright$  all combinations of expressions
12:        exprs  $\leftarrow$  exprs  $\cup$  {comp  $e_1 \dots e_p$ }
13:   return exprs  $\triangleright$  a list of many expressions with the specified type

```

Algorithm 6 Function REPLACE-SYMBOLS.

```

1: procedure REPLACE-SYMBOLS(originalFun, lambda, examples, symbol)
2:   originalFun  $\leftarrow$  originalFun{lambda/symbol}
3:    $\Sigma \leftarrow []$ 
4:   for  $((x_1, \dots, x_k), y) \in \text{examples}$  do
5:      $\Sigma \leftarrow \text{UNIFY}(\Sigma, \text{originalFun } x_1 \dots x_k, y)$ 
6:     if  $\Sigma = \text{ERROR}$  then
7:       return ERROR
8:   for each symbolic variable  $s$  in lambda do
9:     val  $\leftarrow$  eval( $\Sigma, s$ )
10:    converted  $\leftarrow$  convert val to Haskell notation
11:    lambda  $\leftarrow$  lambda{converted/ $s$ }
12:   return lambda

```

most two levels, for performance reasons (e.g., in $\backslash x \rightarrow f (g x) (h x)$, the arguments of g and h cannot be applications, only variables, and constants). For example, if the Petri net synthesizes $\backslash \text{arg1} \rightarrow \text{map } \textit{wildcard} \text{ arg1}$, for the query type $[\text{Int}] \rightarrow [\text{Int}]$, the wildcard may be replaced with $\backslash x1 \rightarrow x1 + 2$, $\backslash x1 \rightarrow x1 * (\text{length } \text{arg1})$, etc., depending on the input-output examples provided by the user.

Implementation. SYNTH-LAMBDA (Algorithm 4), takes five parameters: *type*, the signature of the function to synthesize; *originalFun*, the original function generated by the Petri net, but with wildcards replaced with fresh symbols; *examples*, the input-output examples of the original function; *comps*, the component set; and *symbol*, the symbolic variable that the new λ -abstraction should replace in *originalFun*. It follows a generate-and-test approach: SYNTH-EXPR does a type-guided enumeration of λ -abstractions, and then REPLACE-SYMBOLS tests the original function with each new λ -abstraction in place of the corresponding symbol, and replace symbols if any. Finally, we check that the λ -abstraction has the specified type, because SYNTH-EXPR does not perform a *full* type-checking, and only uses types to prune the search, thus can return ill-typed expressions. At this stage, type classes are ignored, and we leave for future work the analysis of their impact on the algorithm and its performance.

SYNTH-EXPR (Algorithm 5) takes four parameters: *type*, the type of the expression to synthesize; *leafs*, the set that contains the parameters of the new λ -abstraction (x_1, \dots, x_n), the parameters of the original function (y_1, \dots, y_k), and a fresh symbol; *components*, the component set of HOOGLE \star excluding high-order functions and the `Data.ByteString` module; and the depth of applications, *level*. If *level* is equal or greater than 2, SYNTH-EXPR only returns the *leafs* whose type matches *type*, to ensure that the maximum level is not exceeded. Otherwise, it returns also the application of components whose return type matches *type*, and the arguments are synthesized by calling SYNTH-EXPR recursively. Note that we may have to replace type variables, which we do in line 7. For instance, if the component has type `a -> a` and *type* is `Int`, we replace `a` with `Int`.

REPLACE-SYMBOLS (Algorithm 6) takes four parameters: the original Hoogle+ function, *originalFun*; the new λ -abstraction, *lambda*; the input-output examples, *examples*; and the symbolic variable that *lambda* replaces. It starts by replacing *symbol* with *lambda* in the original function. Then, the unification algorithm is used as in the COMPLETE function: for each example, we unify the application of *originalFun* to the inputs of the example with the expected output. Finally, each symbol that belongs to λ is replaced with a *lookup* in Σ , as COMPLETE does. Note that every symbol in the new λ -abstraction must be a constant because the component set excludes high-order functions.

Example 16 illustrates the synthesis of wildcards in place of functions.

► **Example 16.** Recall the second example of Section 1. The Petri net is able to synthesize `\x1 -> map wildcard x1`, which corresponds to $\lambda x_1 . map\ s\ x_1$ in λ_U . The example is converted to λ_U , and the unification is performed, assigning applications of *s* (for instance, *s* 1 to 1), which informs that the expected term is a λ -abstraction. Then, we call SYNTH-LAMBDA, where *type* is `Int -> Int`, *originalFun* is $\lambda x_1 . map\ s\ x_1$, *examples* is $\{([1, 2, 3]), [1, 4, 9])\}$ and *symbol* is *s*. The *leafs* are the parameter of the original function (x_1), the parameter of the new λ -abstraction (y_1), and a fresh symbol. One of the generated λ -abstractions can be `\y1 -> (GHC.Num.*) y1 y1`. Then REPLACE-SYMBOLS unifies `(\x1 -> map (\y1 -> y1 * y1) x1) [1, 2, 3]` with `[1, 4, 9]`, which succeeds. Finally, we check that the function has type `Int -> Int`.

5 Evaluation

In this chapter we empirically evaluate HOOGLE \star , answering the following research questions:

RQ1 Can HOOGLE \star solve all the problems that HOOGLE+ solves, without performance degradation?

RQ2 Can HOOGLE \star solve more problems than HOOGLE+?

5.1 Evaluation Design

Benchmarks. We use two different sets of benchmarks. To answer RQ1, we use the first set of 44 benchmarks (Table 1) from the original paper of HOOGLE+ [14], which consists of only query types. To answer RQ2, we use the second set of 26 benchmarks (Table 2), which consists of a query types and input-output examples and requires the generation of constants or λ -abstractions⁶.

⁶ Most of those benchmarks were adapted from questions in StackOverflow because we could not use them directly (e.g., if a question used floats, we changed, when possible, to integers). We systematically searched StackOverflow for Haskell problems, excluding the ones that did not require the generation of

Experiments. We compare HOOGLE* to the original HOOGLE+ as described below, giving each benchmark a timeout of 60 seconds, in the first set of benchmarks, and 90 seconds in the second set.

1. We run both HOOGLE+ (twice, with and without the constants `True`, `False`, `Nothing` and `[]`) and HOOGLE* on the 44 original benchmarks measuring the number of synthesized solutions, and the time taken to synthesize the first solution. For each benchmark, we

constants and λ -abstractions, and problems exercising the same capabilities. We also excluded problems that could not be solved by Hoogle+, for other reasons than the absence of constants and λ -abstractions. To diversify the components used we searched for questions using specific components. No problem that we have excluded would be solved by Hoogle+.

■ **Table 2** Second set of 26 benchmarks.

ask both synthesizers to synthesize at most 10 solutions (parameter N in Algorithm 2). The goal is to understand the impact of the addition of the wildcard component, and the removal of the constant components.

- We run both HOOGLÉ \star and the version of HOOGLÉ $+$ that supports examples[20], on the 26 benchmarks, measuring also the time consumed replacing the occurrences of the wildcard, and we ask both synthesizers to synthesize at most 35 solutions⁷.

Experimental setup. We run the experiments on a laptop with an AMD 5600G, running at 3.9 GHz, with 6 cores and 16 GB of RAM. All the versions of HOOGLÉ $+$ and HOOGLÉ \star use only two cores. The operating system is Ubuntu 22.04.2 LTS, the version of stack is 2.9.1, and

⁷ This is a higher value than in the previous step, because many of the N functions synthesized by the Petri net may be rejected due to the test of input-output examples, and with a lower value of N , both synthesizers ended the search before the timeout, without finding any solution.

the version of GHC is 8.4.4. The component set used by both HOOGLE+ versions contains the following modules: `Data.Bool`, `Data.ByteString.Builder`, `Data.ByteString.Lazy`, `Data.Either`, `Data.Eq`, `Data.Function`, `Data.Int`, `Data.Maybe`, `Data.Ord`, `Data.Tuple`, `GHC.Char`, `GHC.List`, and `Text.Show`. The total number of components is 297. The component set used by HOOGLE \star is the same, except that we removed the constants `Data.Bool.True`, `Data.Bool.False`, `Data.Maybe.Nothing` and `[]`, and we added the wildcard component. Those constants can be synthesized by the unification algorithm, so the component set does not need to contain them.

5.2 Results

In this section, we discuss the results of the experiments performed to answer the research questions stated at the beginning of the Section 5.

Results of the first set of benchmarks. The results of the first set of benchmarks are presented in Table 3, which shows that HOOGLE \star solves two problems that HOOGLE+ could not solve (benchmarks 6 and 9), and HOOGLE+ one problem that HOOGLE \star could not solve (benchmark 35). We have not found significant differences in the synthesized solutions, and in most benchmarks, there are solutions in common.

HOOGLE \star tends to be faster at synthesizing the first solution and synthesizes more solutions. On average, HOOGLE \star synthesizes 2.95 solutions per benchmark and takes 3.92 seconds to synthesize the first solution. HOOGLE+ synthesizes 2.41 solutions and takes 5.58 seconds. This can be explained by the removal of the four constants: on average, HOOGLE+ without constants takes 3.37 seconds to synthesize the first solution, so, in average, it is faster than HOOGLE+ with constants and HOOGLE \star . Indeed, the removal of the constants leads to a smaller component set, however, the reason for that is not the number of components that were removed, but the kind of components. Note that in the Petri net encoding, constants correspond to nullary transitions, i.e., transitions that do not need tokens to fire, so they can fire at any moment, leading to a higher branching factor. Thus, the removal of a constant should have more impact than the removal of a function.

Results of the second set of benchmarks. The results of the second set of benchmarks are shown in Table 4. HOOGLE \star solves 22 out of 26 benchmarks, whereas HOOGLE+ solves only 3 (benchmarks 50, 52, and 62), which are all solved by HOOGLE \star . This happens because most benchmarks require constants and λ -abstractions to be synthesized, which HOOGLE+ is not able to do. The authors of HOOGLE+ [14] argue that the absence of λ -abstractions does not impact the completeness of the method, because terms with λ -abstractions can be replaced with a term in point-free style, using the combinators S, K and I. However, this requires adding a nullary version of each component to the component set, which the authors consider infeasible, and in practice, only a small subset is added. The component sets of each version of HOOGLE+ used in our evaluation contain the combinators S, K, and I (module `Data.Function`), but it was not enough to solve the problems that require λ -abstractions.

In the benchmarks that require the synthesis of constants, the time spent completing the functions is always lower than 20% of the total time. However, in the benchmarks that require the synthesis of λ -abstractions, the time spent completing the wildcards can reach more than 50% of the total time, as happens in benchmarks 53, 59, and 60. HOOGLE \star cannot solve benchmark 51, whose solution is `\arg1 arg2 -> filter (\x1 -> x1 'elem' arg2) arg1`, because it requires the Petri net to synthesize the incomplete function `\arg1 arg2 -> filter wildcard arg1`, which does not use `arg2`, and the Petri net always synthesizes functions that use all the parameters. It also fails to solve benchmark 68, which is very similar to 56, with the difference that

■ **Table 3** Results of the first set of benchmarks. For both synthesizers, we show the number of solutions and the total time to synthesize the first solution, in seconds, or - if no solution was produced within the timeout of 60 seconds.

the query type has a typeclass constraint, instead of a monomorphic type. The solution is `\arg1 -> filter (\p -> fst p == snd p) arg1`, however, the Petri net does not synthesize the incomplete function `\arg1 -> filter wildcard arg1` within the timeout (whereas it synthesizes when the type is monomorphic). Benchmark 69 uses real numbers, that are not supported by the unification algorithm, and benchmark 70 contains input-output examples with large constants, leading the unification to reach the maximum depth before finding valid assignments. Comparing the solutions synthesized for the benchmarks that HOOGLE+ solves, the solutions of HOOGLE* are simpler, using fewer components. For instance, in benchmark 52, HOOGLE+ synthesizes `\arg0 -> last (init (init arg0))`, whereas HOOGLE* synthesizes `\arg1 -> (!!)` `arg1 3`.

■ **Table 4** Results of the second set of benchmarks. This table shows, for both synthesizers, the time elapsed to synthesize the first solution, in seconds, as well as the number of solutions, and the time spent replacing symbols until the first solution is completed. The timeout is 90 seconds.

5.3 Answers to Research Questions

Given the results discussed in Section 5.2, we answer the two research questions as follows:

RQ1 The addition of the wildcard component did not lead to performance degradations.

Instead, the removal of constants resulted in performance improvements. From the original HOOGLE+ benchmarks, there is a single benchmark that HOOGLE+ solves and HOOGLE \star cannot solve within the timeout, but it solves two that HOOGLE+ does not solve.

RQ2 HOOGLE \star can solve many more new problems than HOOGLE+, especially when constants or λ -abstractions are required, which makes it able to solve new classes of problems.

We also found that in the cases that both synthesizers produce solutions, the solutions of HOOGLE \star are simpler, since they use fewer components.

6 Related Work

In this section, we compare our work to other research in program synthesis, unification, and symbolic execution. Most of the related work has been already presented in the HOOGLE+ original paper, so our focus is the work apart from this one.

6.1 Program Synthesis

Hoogle+ related work summary. The subjects most directly related to HOOGLE+ are type inhabitation and graph reachability. However, most of the related work on type inhabitation is based on classical proof search, such as AGDA [30], or produce solutions

that do not use all the arguments, such as DJINN [1]. In turn, the related work on graph reachability only supports functions with a single parameter, such as PROSPECTOR [25], or does not support polymorphism, such as SYPET [7]. When compared to other API search tools, such as HOOGLER [26], HOOGLER+ is able to synthesize applications of multiple components. Using statistical methods to improve the search, such as SLANG [34], the authors of HOOGLER+ conjecture that it is not effective in functional languages, due to the “high degree of compositionality”. There are also approaches to scalable proof search; however, the search space is restricted to names of parameters, functions, or fields [32], or does not support polymorphism, such as INSYNTH [15].

Synthesis from sketches. The idea of completing programs with holes, also known as sketches, has already been used in SKETCH [36] and ROSETTE [37], in which SAT/SMT solvers infer integer constants. However, in our work, a hole can be replaced with an expression of any algebraic type, or λ -abstractions. More recently, SMYTH [24], an evaluator-based program synthesizer, replaces holes with any expression, including case expressions, by performing a search guided by input-output examples. However, it inherits scalability issues from MYTH [31], the base of SMYTH, and the authors consider that HOOGLER+ “might also be incorporated into our approach in future work”. SCRYBE [27] extends the approach of SMYTH, with example propagation, and can solve more problems than SMYTH. However, we conjecture that the scalability issues remain, as the evaluation uses specific component sets for each test of at most 10 components [28], whereas the component set of HOOGLER+ has 291 components. GHC, a Haskell compiler, supports programs with missing expressions, suggesting valid fits [9]. However, constants are excluded (apart from already defined constants, such as `True`) and λ -abstractions. PROPR [10] uses this GHC feature to replace faulty sub-expressions on Haskell programs, and suggest constants, that, however, are limited to the ones contained in the program to repair.

Component-based synthesis. Apart from the related work of HOOGLER+, PETSy [38] performs a top-down enumerative search, instead of using a Petri net encoding. Its evaluation shows that, at least with 130 components, its performance is comparable to HOOGLER+. However, it does not synthesize constants. HECTARE [23], a new synthesizer for Haskell that uses a new graph data structure to represent the search space, has shown to be faster than HOOGLER+, but it does not support constants nor λ -abstractions.

6.2 Unification and Symbolic Execution

***E*-Unification.** Unification is a process that, given two expressions, tries to replace the symbols in both expressions, such that the resulting expressions are syntactically equal [2]. In our case, the goal is to make two expressions equal after evaluation. This leads us to *E*-Unification, in which the equality of terms is established by a set of equations *E*: two terms *s*, *t* are equal if and only if $s \approx t \in E$ [35]. There are several approaches to solving *E*-Unification [8, 6], but we have not found any formulation that could be directly applied to our context. The same can be stated about Huet’s algorithm [19], which solves the unification problem for typed λ -calculus, from which Haskell’s Core language is an extension [21].

Symbolic execution. Symbolic execution tools explore multiple paths of a program to find counterexamples for a given property [3] and the unification problem discussed in this article can be reduced to finding a counterexample for $e_{src} \neq e_{tgt}$. G2 [16] and G2Q [17] are two symbolic execution tools for Haskell, but they do not support symbolic variables in place of

functions, which is required for HOOGLE \star . NEBULA [22], built on top of G2, supports symbols in place of functions, and treats applications of symbolic variables in a way similar to our approach: it replaces the application with a fresh symbol denoting the return value. However, it does not fully evaluate the arguments, so it may treat two equivalent calls as different calls. NEBULA can prove the equivalence of Haskell programs, by combining symbolic execution and coinduction, whereas our algorithm only finds assignments to symbolic variables. However, it is one order of magnitude faster, which makes the difference in the performance of HOOGLE \star . SCV [29] uses symbolic execution to validate software contracts in Racket programs and supports symbols in place of functions, but instead of assigning applications of functions to expressions, it generates candidate functions. However, while our algorithm supports infinite structures, SCV does not, since Racket is a strict language.

7 Limitations

Using polymorphic abstractions, instead of the standard way of implementing typeclasses, dictionary passing [33], simplifies the algorithm, especially when the term that determines the version of the polymorphic function is a symbol. But, as a drawback, this approach requires that each time a new monomorphic variant of a polymorphic operation is provided, the existing code must be edited (the new implementation must be added to each occurrence of the corresponding polymorphic abstraction). However, since the component set is not expected to change, this does not impact the usage of HOOGLE \star .

Currying is not supported for practical reasons. Whenever a curried application is translated to λ_U , we need to replace it with a λ -abstraction: supposing that f takes n arguments, we rewrite $f e_1 \dots e_m$ as $\lambda x_{m+1} \dots x_n . f e_1 \dots e_m x_{m+1} \dots x_n$ (with $m < n$). Also, for practical reasons, data constructors are not treated as the left side of abstractions, which means that a data constructor cannot be used as a function directly.

Data is represented by data constructors, which simplifies the algorithm, because all operations can be written in λ_U and each value can be built incrementally, by choosing a branch of each case expression. For instance, if we had to use the constant representation of integers, the implementation of operators such as integer comparison could not be expressed in λ_U , and expressions such as $n1 \leq n2$ would have to be processed by an SMT solver. A drawback of this representation is that real numbers are not supported (benchmark 69), and, in some specific cases, large integers may lead to an intractable search (if it is required to iterate the whole structure). Unifying a symbol with a large number, which is the case of benchmark 47, simply requires the application of *SNAL* or *SAL*; however, unifying $s + 1$ with N (similar to what happens in benchmark 70) requires a depth greater than N , which, in the context of complex problems with large branching factors, may become intractable.

Allow unused parameters. The Petri net does not synthesize functions that do not use all parameters, but the wildcards could be replaced with expressions using the remaining parameters. For instance, HOOGLE \star cannot synthesize `\xs n -> filter (\x -> x < n) xs`, because `\xs n -> filter wildcard xs` does not use the parameter `n`.

Queries with typeclass constraints are not solved, as in benchmark 68, because the Petri net becomes significantly slower when there are typeclass constraints (typeclass constraints are treated as extra arguments of the type query).

Completeness, normal form, and soundness. We do not have a definition of normal form for the terms of λ_U , nor proofs of completeness and of the guarantees of the inference rules, stated in Section 3.2.

8 Conclusion

In this work we developed a unification algorithm for a subset of the Haskell programming language and extended HOOGLE+, which can now synthesize constants and λ -abstractions.

Unification algorithm. To evaluate HOOGLE*, we have encoded 92 functions from the Haskell standard library⁸ in λ_U , and our algorithm successfully replaced the occurrences of the wildcard component for constants. But it has other applications; for instance, it can be used to compute inverses (by unifying $f\ s_1 \dots s_k$ with the output, $s_1 \dots s_k$ will be assigned to the values of the arguments), or for software testing and verification, finding counterexamples (for instance, if a function f is expected to always return a positive number, we can unify the application of f to symbolic variables with 0, to search for inputs that eventually make the function return 0).

Hoogle*. HOOGLE* can solve more problems than the original HOOGLE+ as it successfully synthesizes constants and λ -abstractions, without performance degradation. As explained in Section 6, existing synthesizers do not synthesize constants and λ -abstractions, or do not have the scalability that Petri nets give to HOOGLE+. HOOGLE* can generate constants and λ -abstractions while maintaining the scalability of Petri nets. Although we extended HOOGLE+, the contributions are not exclusive to this synthesizer, as they can be applied to other Petri-net synthesizers, such as SYPET. As a program synthesizer, it can impact science and industry in different ways: discovering new algorithms, allowing end users to build programs, improving teaching or assisting programmers [11, 5].

Future work. The main lines of future work are: supporting the representation of real numbers, as well as large integers; allowing the Petri net to synthesize functions that do not use all parameters; improving the synthesis of queries involving typeclass constraints; providing notions of completeness, normal forms, and a proof of the guarantees claimed in Section 3.2; and incorporating typeclasses in the type-checker of SYNTH-EXPR.

Abstract

Even though static analyses can improve performance and secure programs against vulnerabilities, no static whole-program analyses exist for WebAssembly (Wasm) to date. Part of the reason is that Wasm has many complex language concerns, and it is not obvious how to adopt existing analysis frameworks for these features. This paper explores how *abstract definitional interpretation* can be used to develop sophisticated analyses for Wasm and other complex languages efficiently. In particular, we show that the semantics of Wasm can be decomposed into 19 language-independent components that abstract different aspects of Wasm. We have written a highly configurable definitional interpreter for full Wasm 1.0 in 1628 LOC against these components. Analysis developers can instantiate this interpreter with different value and effect abstractions to obtain abstract definitional interpreters that compute inter-procedural control and data-flow information. This way, we develop the first whole-program dead code, constant propagation, and taint analyses for Wasm, each in less than 210 LOC. We evaluate our analyses on 1458 Wasm binaries collected by others in the wild. Our implementation is based on a novel framework for definitional abstract interpretation in Scala that eliminates scalability issues of prior work.

1 Introduction

WebAssembly (Wasm) is a low-level programming language targeted at efficient and portable computation on the web [10]. Wasm modules are often used as a drop-in replacement for computation-intensive JavaScript libraries such as game engines [23, 10]. Wasm has also been designed with security in mind, but many security vulnerabilities reemerge in Wasm because OS-level routines must be provided as user code, which makes them susceptible to attacks [20], and because current compilers targeting Wasm lack protection mechanisms such as stack canaries [29]. While it is well-known that static program analyses can drive performance optimization, reduce binary size, and discover vulnerabilities, no static whole-program analyses exist for Wasm to date.

Wasm involves many complex and interacting language features that analyses have to model: operand stacks, call frames, jumps to scoped labels, function and global-variable tables, dynamically loaded modules, and module-owned linear memory to name a few. It is not obvious how to adopt existing analysis frameworks for these features, nor is it obvious how to develop a new analysis framework for these features. In this paper, we demonstrate that *abstract definitional interpretation* is capable of developing analyses for Wasm.

Abstract definitional interpretation was first proposed by Darais et al. [7] as an alternative to abstracting abstract machines [12]. The key idea is to define a generic definitional interpreter that is parametric in value and effect operations, such that it can be instantiated to form concrete as well as abstract interpreters. Keidel et. al. [14] refined this approach to isolate and permit modular reasoning about value and effect components [13]. However, it is unclear if abstract definitional interpretation scales to languages as complex as Wasm and if the resulting analyzers scale to real-world programs of considerable size. In this paper, we answer both of these questions affirmatively and explain how we developed three Wasm analyses in less than 210 LOC each.

The foundation of all our Wasm analyses is a generic definitional interpreter for Wasm, which we designed and implemented. An important contribution of this paper is to decompose the semantics of Wasm and map it to 12 value components and 7 effect components. Each component consists of an interface with a canonical concrete semantics and any number of abstract semantics. Since these components are language-independent, we only have to develop them once and can reuse them across languages and analyses. This way, we managed to develop a fully-fledged definitional interpreter for Wasm 1.0 and its module system in only 1628 lines of language-dependent code.

The generic interpreter is implemented against the interfaces of value and effect components, making the mapping from language concerns to components explicit. Analysis developers can derive abstract definitional Wasm interpreters by selecting an implementation for each component used by the generic interpreter. This makes analysis development modular: We can reuse components between analyses and refine individual components while reusing others unchanged. We demonstrate this modularity by deriving three abstract definitional interpreters from the generic Wasm interpreter: a context-insensitive dead code analysis based on an inter-procedural control-flow graph that we compute, a callsite-sensitive constant propagation analysis, and a callsite-sensitive taint analysis. Each of the three analyses is novel for Wasm, and each of them required less than 210 lines of Wasm-specific code:

	Generic interpreter	Dead code analysis	Constant analysis	Taint analysis
LoC	1628	130	156	209

Technically, our implementation is based on a new framework for definitional abstract interpretation in Scala. Our framework improves over the original DAI by Darais et al. [7] and Sturdy by Keidel et al. [13] to make definitional abstract interpreters scalable. Specifically, our framework exploits a simpler component design and eliminates the monadic transformer stack required by DAI and Sturdy. We show that our analyses scale to real-world programs by analyzing 1458 Wasm binaries collected by others in the wild. Since these binaries are not full applications, we also developed a most general client for Wasm that allows us to apply our whole-program analyses to individual modules soundly. On average, each of our analyses takes 5s per binary, and we find 14% of all instructions are dead code, 10% of all instructions could be replaced by constants, and 56% of all memory accesses are safe against tampering.

■ **Figure 1** Factorial in Wasm: Two concrete runs and an abstract run using a type-based domain.

In summary, we make the following contributions:

- We present the design of a modular analysis platform for Wasm (section 3).
- We decompose Wasm into 12 value components and 7 effect components and implement a generic interpreter against their interfaces (section 4).
- We modularly define 3 whole-program analyses that are novel for Wasm and provide a most general client for Wasm modules (section 5).
- We designed and implemented a new, scalable framework for abstract definitional interpreters in Scala and explain how it improves over prior work. We realized our modular analysis platform for Wasm on top of this framework (section 6).
- We validate the soundness, performance, and applicability of the Wasm analyses (section 7).

2 Introduction to WebAssembly and Problem Statement

Wasm is a low-level stack-based programming language with structured control flow. We illustrate the textual syntax and some of the core features of Wasm using an iterative factorial function in Figure 1 as an example. The leftmost column shows the code of the factorial function, whereas the other columns display the stack of the concrete and abstract executions of that code. Note that the local variable at index 0 refers to the function parameter and is used as an iteration counter, whereas the local variable at index 1 is an accumulator for the result of the factorial function.

We illustrate the concrete interpretation of the factorial function for arguments 1 and 4. Most Wasm operations interact with the operand stack whose contents we show in Figure 1 for each instruction. For example, `i64.const` and `local.get` push values to the stack, whereas `local.set` and `i64.le_u` pop values from the stack. For `param=1`, the `if` finds that the argument is less-equal than 1 and thus terminates. For `param=4`, the `if` goes to the else-branch, where we accumulate the factorial result, decrement the iteration counter, and jump to the beginning

of the loop. Jumps in Wasm are structured, which means they can only target enclosing blocks, indexed by distance. In our example, `br 1` jumps over the `if`-block and targets the loop. After a few more iterations, we will again reach the `then`-branch where the loop terminates.

To illustrate the abstract interpretation of Wasm, the two rightmost columns in Figure 1 show an abstract evaluation of the factorial function where values are approximated by their types and by concrete values if they are constant. The factorial function is called with type `i64` as argument, denoting any 64-bit integer. Each abstract evaluation must overapproximate both concrete evaluations. Hence the abstract interpreter analyzes both branches of the `if`-instruction and loop until reaching a fixed point. This type analysis can be used to derive a control-flow graph, but the value representation is configurable in our system. Later in this paper, we present Wasm analyses that use more precise value abstractions.

Wasm provides many other interesting features not shown in our illustrating example. For instance, in addition to normal function calls, there are also indirect function calls whose call target can be found in a function table. Functions can also be imported from other modules and Wasm code can invoke external functions provided by the runtime system. When Wasm runs in the browser, these external functions are JavaScript programs. Finally, each Wasm module can declare module-global variables and request a linear memory (i.e., a byte array) to store data.

Problem Statement

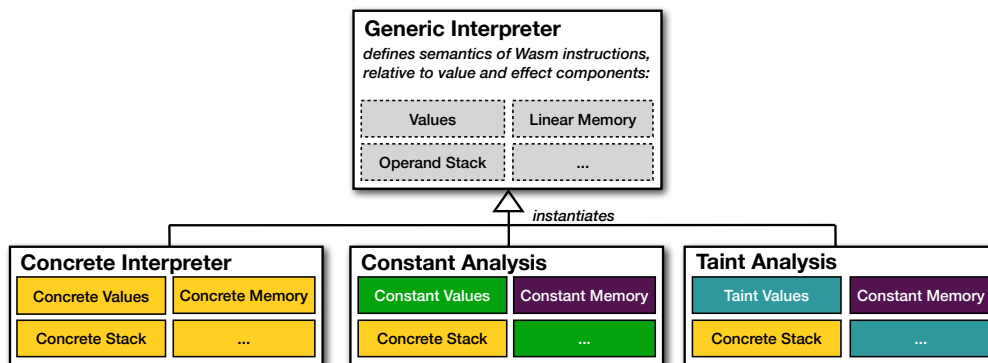

We want to develop abstract interpreters for Wasm that track data-flow and information-flow. This is a difficult challenge since the abstract interpreter has to deal with all of Wasm's concerns: the operand stack, call frames, global variables, linear memory, function tables, and structured jumps. Without modularity, all concerns have to be handled at once, complicating the initial development and hindering evolution.

For example, consider the semantics of indirect function calls which combines 5 Wasm concerns highlighted with italic font: The interpreter first pops the *numeric index* of the function from *operand stack* and uses it to search through the *function table* to find the function definition. If the table has a function definition of the correct type at the index, the interpreter invokes the function. In particular, the interpreter binds the function arguments on the operand stack to the function parameters on a newly created *call frame*. Finally, the interpreter processes the body of the function and afterwards pushes the return argument on the stack. There are also multiple edge cases which cause the function invocation to *fail*.

A naive monolithic analysis implementation may closely couple the semantics of indirect calls to specific abstractions for the function index, the operand stack, call frame, and failures. This coupling not only complicates the analysis implementation, it also makes it difficult to change the abstractions without also requiring changes to the abstract semantics of indirect calls. To solve this problem, we divide and conquer by modularizing the analysis implementation, which we discuss in the following section.

3 Modular Wasm Analyses in a Nutshell

In this section, we present the design of our modular analysis platform for Wasm. At the core of our platform is a generic definitional interpreter for Wasm. The generic interpreter describes the semantics of Wasm instructions and serves as a template to derive different Wasm analyses, as well as a concrete interpreter. The generic interpreter is parametric in its representation for values such as integers and floating point values. Furthermore, the generic interpreter is parametric in its representation of effects such as the linear memory or the

■ **Figure 2** We propose a modular Wasm analysis platform with a generic interpreter at its root.

```

trait GenericInterpreter[V, ExcV]:
  // Independent value components for abstract value type V
  val i32ops: IntegerOps[Int, V]
  val f64ops: FloatOps[Double, V]
  // Independent effect components
  val stack: OperandStack[V]
  type WasmExc[V] = (JumpTarget, List[V])
  val except: Except[WasmExc[V], ExcV]
  // Interpreter written against value and effect components
  def evalInst(inst: Inst): Unit = inst match
    case i32.Sub =>
      val v2 = stack.popOrFail(); val v1 = stack.popOrFail()
      stack.push(i32ops.sub(v1, v2))
    case f64.Abs =>
      val v = stack.popOrFail()
      stack.push(f64ops.abs(v))
    case Return =>
      val operands = stack.popNOrFail(currentReturnArity)
      except.throws((JumpTarget.Return, operands))

```

■ **Figure 3** Simplified generic interpreter that handles subtraction, absolutes, and function returns.

operand stack. Analyses instantiate the generic interpreter with different abstractions for values such as constants, taint flags, or types and with different abstraction for effects such as a constant memory abstraction. Similarly, the concrete interpreter instantiates the generic interpreter with concrete values and effects.

Our platform is modular along two dimensions. First, the generic interpreter defines the semantics for Wasm instructions once and for all; analyses simply reuse that semantics. Second, the values and effects required by the generic interpreter are decomposed into language-independent components, which can be defined language-independently and reused flexibly. Figure 2 illustrates the modularity of our platform. The generic interpreter sits on top and is instantiated to obtain concrete and abstract interpreters. It depends on various value and effect components that must be provided during instantiation. In Figure 2, the colors illustrate component reuse. While each interpreter uses a different value representation, the two abstract interpreters use the same component for linear memory and the operand stack. Since the shape of the operand stack is decidable in Wasm [10], this component is also shared with the concrete interpreter. In the remainder of this section, we illustrate how our analysis platform realizes the generic interpreter, its instances, and the components.

Generic interpreter

Figure 3 shows a simplified generic interpreter for Wasm. The generic interpreter does not refer to any specific concrete or abstract value representations. Instead, the interpreter abstracts over them with the value components `IntegerOps` for 32-bit integers and `FloatOps` for 64-bit floats. Value components are interfaces with any number of implementations, for example:

```

trait IntegerOps[B, V]:           // a type class for integer operations
  def integerLit(i: B): V         // - embeds base literals of type B into the value type V
  def sub(v1: V, v2: V): V       // - subtraction of two values
object ConcreteIntegerOps extends IntegerOps[Int, Int] {...}           // concrete semantics
object ConstantIntegerOps extends IntegerOps[Int, Topped[Int]] {...} // constant abstraction
object SignLongIntegerOps extends IntegerOps[Long, Sign] {...}       // sign abstraction

```

In addition to the value components, the simplified generic interpreter requests two components for effects: one for the mutable operand stack and one for exception handling. Like value components, effect components define an interface that can be implemented in various ways. The `OperandStack[V]` effect component provides `push`, `pop`, and `peek` operation for values of type `v`. The `Except` component provides operations for throwing and catching exceptions of type `WasmExc[V]`, consisting of a jump target and a list of operand values. In contrast to prior frameworks for abstract definitional interpretation, we distinguish value from effect components to improve the run-time performance of our analyses. Specifically, value components capture pure operations and do not contribute to the analysis state, whereas effect components maintain internal state that is part of the overall analysis state. This becomes relevant when joining computations or computing the fixpoint of an analysis.

The generic interpreter only relies on the interfaces of value and effect components. Based on these, the generic interpreter defines the semantics of Wasm instructions with the interpretation function `evalInst`. We only show a few selected cases. For integer subtraction, function `evalInst` pops two values from the stack, subtracts them, and pushes the result back on the stack. Note that most Wasm instructions are not overloaded, so it is easy to select the appropriate value component. For example, function `evalInst` delegates the instruction `f64.Abs` to the component `f64ops`, which handles 64-bit floating-point numbers. The operand stack is ubiquitous in the generic interpreter, but other effects are needed too. For example, function `evalInst` implements return instructions using exceptions that are caught at the function head. Exception handling is a standard way for implementing non-local control flow on the JVM, where our analyzers run. Exception handling also closely aligns with jumps and returns in Wasm: Due to the structured control flow of Wasm, all jumps (including returns) target a surrounding block. Similarly, exceptions interrupt execution and return to the closest surrounding exception handler.

Concrete interpreter

We can instantiate the generic interpreter for different value and effect components. In particular, we can derive a concrete Wasm interpreter by choosing the canonical concrete semantics for all components and lifting them to Wasm values. Specifically, we represent Wasm values using the corresponding number types of the JVM, because the definitional Wasm interpreter is implemented in Scala.

```

enum Value:
  case I32(i: Int); case I64(l: Long); case F32(f: Float); case F64(d: Double)

```

With this, we can instantiate the generic interpreter:

```
class ConcreteInterpreter extends GenericInterpreter[Value, WasmExc[Value]]:
  val i32ops = ... // lifts IntegerOps[Int, Int] to Value.I32
  val f64ops = ... // lifts FloatOps[Double, Double] to Value.F64
  val stack = new ConcreteOperandStack[Value]
  val except = new ConcreteExcept[WasmExc[Value]]
```

For values we lift the canonical concrete semantics to the `Value` type, for effects we select all required effect components directly from our library.

Abstract interpreter

We can derive abstract interpreters in the same manner. For example, let us build a type analysis that only distinguishes the type of each value:

```
enum Type:
  case I32; case I64; case F32; case F64; case Top
```

Wasm does not need `Top`, but we include it so `Type` forms a semi-lattice. We instantiate the generic interpreter using `Type` for values and join exceptions that jump to the same target:

```
type ExcByTarget = Map[JumpTarget, List[Type]]
class AbstractInterpreter extends GenericInterpreter[Type, ExcByTarget]:
  val i32ops = // lifts IntegerOps[Int, IntType] to Type.I32
  val f64ops = // lifts FloatOps[Double, DoubleType] to Type.F64
  val stack = new JoinableConcreteOperandStack[Type]
  val except = new JoinedExcept[WasmExc[Type], ExcByTarget]
```

Our platform provides language-independent type abstractions for various components. For the value components in Wasm, we lift these abstractions to the Wasm-specific abstraction `Type`. For the operand stack, we exploit that its shape is decidable for Wasm, which allows us to reuse the concrete operand stack (through subclassing). The abstract interpreter must join the contents of stacks at control-flow join points, but these stacks will have equal size. For exceptions, we select an abstract semantics that collects all possibly active exceptions in a set. Although not shown here, analyses can select a context-sensitivity and configure other aspects of the fixpoint algorithm, such as the iteration strategy or loop unrolling depth.

This example illustrates how our platform supports the modular development of Wasm analyses: by plugging together value and effect components and instantiating the generic interpreter. Moreover, individual components can be refined and replaced easily. But how can we decompose Wasm into value and effect components and define a generic interpreter for the full language?

4 Decomposing Language Concerns of WebAssembly

In this section, we propose a decomposition of Wasm that separates individual language concerns into components. We will then define a Wasm generic interpreter on top of these components. The generic interpreter only uses the interfaces of the components, while concrete and abstract interpreters instantiate the generic interpreter with selected implementations of the components. This way, the decomposition of Wasm into components enables analysis developers to compose full-fledged Wasm analyses modularly.

In the remainder of this section, we present our decomposition of Wasm and its mapping to value and effect components. For each component, we have implemented the canonical concrete semantics compatible with the Wasm specification. We show possible abstract semantics in section 5, where we construct data and information-flow analyses for Wasm.

4.1 Values

Wasm defines four different value types, namely integers and floats with 32 and 64 bits: `i32`, `i64`, `f32`, `f64`. In section 3, we already showed how some of the value components can be used to implement value operations generically, such as `IntegerOps` for implementing operations on integers. However, we omitted many details for illustration purpose. The goal of this subsection is to fill the gap and to introduce other value components we used for Wasm. Throughout this section, the type variable `v` stands for the abstract value type used by the generic interpreter.

Numeric operations

We decompose the numeric operations of Wasm into 6 value components. Besides components for the various arithmetic operations of the four value types, we use one component for equality testing, and one component for ordering comparisons of Wasm values:

```
val i32ops: IntegerOps[Int, V]           val f32ops: FloatOps[Float, V]
val i64ops: IntegerOps[Long, V]        val f64ops: FloatOps[Double, V]
val eqOps: EqOps[V, V]                 val orderingOps: OrderingOps[V, V]
```

The mapping from Wasm instructions to the respective components is straightforward, but it is not a one-to-one mapping; some instructions combine multiple operations from components:

```
def evalIntegerUnaryOperation(op: IUnop, v: V): V = op match
  case i64.Extend32S =>
    val shift = i64ops.integerLit(32)
    i64ops.shiftRight(i64ops.shiftLeft(v, shift), shift)
```

Also note that the validation of Wasm rejects comparisons on values of different type. Thus, when providing instances for `EqOps` and `OrderingOps`, it is sufficient to consider those cases where the operands have the same type.

Conversions

Wasm features many operations that convert between value types. For example, there are three operations converting from `i32` values to `f32` values, namely signed and unsigned conversions and byte reinterpretation. We use a single `Convert` interface for all conversions, but require 12 different instances of that component:

```
trait Convert[From, To, VFrom, VTo, Config]:
  def apply(from: VFrom, conf: Config): VTo

val convert_i32_i64: Convert[Int, Long, V, V, ..]
val convert_i32_f32: Convert[Int, Float, V, V, ..]
val convert_i32_f64: Convert[Int, Double, V, V, ..]
...
```

Note that the first two type parameters `From` and `To` of `Convert` are tags or phantom types: They are only used to describe the component. The actual values to be converted are of type `VFrom` and `VTo`, both of which we instantiate with `v` in the generic interpreter. Actual instances consider specific value representations for `VFrom` and `VTo`, and we lift these instances to operate on values `v` as described below. The `Config` parameter guides the conversion. For example, the following code handles the three different conversions of `i32` to `f32` values:

```
def evalConvertop(op: Convertop, v: V): V = op match
  case f32.ConvertSI32 => convert_i32_f32(v, Signed)
  case f32.ConvertUI32 => convert_i32_f32(v, Unsigned)
  case f32.ReinterpretI32 => convert_i32_f32(v, Raw)
```

The `Convert` interface can not only be used for numeric conversion operations. We use the same interface for operations that serialize and deserialize values into bytes. This is required to write values into Wasm's linear byte memory:

```
val encode: Convert[V, Seq[Byte], V, Bytes, ...]
val decode: Convert[Seq[Byte], V, Bytes, V, ...]

def evalInst(inst: Inst): Unit = inst match
  case i: StoreInst =>
    val v = stack.popOrFail()
    val bytes = encode(v, ...)
    ... // store bytes in memory
```

Branching

Concrete and abstract interpreters differ significantly when it comes to branching control flow, as required for conditional constructs. While the concrete interpreter will select exactly one branch to execute, abstract interpreters must analyze both branches unless they can statically decide if the branching condition is true or false. We capture branching with a value component that receives two continuations:

```
trait BoolBranching[B, R]:
  def boolBranch(v: B, thn: => R, els: => R): R
```

Implementations of this interface can select the type `B`, for which they can decide the branching. For example, we show the canonical concrete semantics that instantiates `B` with `Boolean` and a type semantics that uses `BooleanType`:

```
class ConcreteBranch[R] extends BoolBranching[Boolean, R]:
  def boolBranch(v: Boolean, thn: => R, els: => R): R = if (v) thn else els

class BoolTypeBranch[R](eff: EffectStack, j: Join[R]) extends BoolBranching[BooleanType, R]:
  def boolBranch(v: BooleanType, thn: => R, els: => R): R = eff.joinComputations(thn, els, j)
```

The concrete semantics simply uses the boolean condition to decide which branch to execute. In contrast, the type semantics must execute both branches and join their results and effects. Our platform provides a helper function `joinComputations` to achieve that, given the stack of effects (`EffectStack`) used by the abstract interpreter and an instance of type class `Join[R]`. In our implementation, these arguments are modeled as implicit parameters and resolved automatically. We explain how our framework joins effectful computations in section 6.

We use `boolBranch` for all conditional instructions: `select`, `brif`, and `if`. For example:

```
val branchOps: BooleanBranching[V, Unit]
def evalInst(inst: Inst): Unit = inst match
  case If(bt, thnInsts, elsInsts) =>
    val isZero = evalNumeric(i32.Eqz)
    branchOps.boolBranch(isZero, label(elsInsts), label(thnInsts))
```

We will explain the `label` function later in the context of jumps. For now it is sufficient to know that it executes a labeled block of code.

Lifting Value Components

Our platform provides language-independent concrete and abstract instances for all value components, such as the concrete `IntegerOps[Int, Int]` and the abstract `IntegerOps[Int, IntType]`. However, as shown above, generic interpreters usually require operations on some compound

5:10 Modular Abstract Definitional Interpreters for WebAssembly

type for values. To reuse the language-independent component instances, we must lift them to the Wasm-specific value type. To facilitate this, our platform provides lifting instances for all value components, which can be easily instantiated. For example, the following two definitions lift the concrete and type-based integer operations to Wasm values and types, respectively:

```
val i32opsValue: IntegerOps[Int, Value] =
  new LiftIntegerOps({case Value.I32(i) => i}, i => Value.I32(i))
val i32opsType: IntegerOps[Int, Type] =
  new LiftIntegerOps({case Type.I32 => IntType}, _ => Type.I32)
```

For an underlying value type U , `LiftIntegerOps` takes an extract function $v \Rightarrow U$ and an inject function $U \Rightarrow v$. With these, it wraps the operations of the underlying language-independent component instance, for example:

```
def sub(v1: V, v2: V): V = inject(underlying.sub(extract(v1), extract(v2)))
```

In our Wasm analyses, all value components are based on language-independent component instances that we lift.

4.2 Effects

Computations generally yield values and trigger effects. Wasm features many language concerns that are effectful. We capture these concerns in effect components. While value components are stateless, effect components contain internal state. This distinction is important when joining computations (as in the type-based `boolBranch`), because effect components must participate in the join (see section 6 for details). In this subsection, we present a decomposition of Wasm's effectful language concerns into effect components.

Operand Stack

Wasm programs interact with an operand stack. We capture this effect in a dedicated effect component:

```
trait OperandStack[V, MayJoin[_]]:
  def push(v: V): Unit
  def pop(): JOption[MayJoin, V]
  def popOrFail(): V = ...
  ...
```

Except for the `MayJoin` type parameter, this component provides a standard stack interface. The `MayJoin` parameter determines whether the component can yield an uncertain result for `pop`. For example, if an abstract stack semantics lost track of the stack's height, `pop` would yield an uncertain result that comprises alternative values or even a stack underflow. In contrast, a concrete stack semantics yields certain results only: either the stack's topmost value or no value if the stack is empty. Instances of `OperandStack` can declare which behavior they provide by choosing `NoJoin` or `WithJoin` for `MayJoin`:

```
enum MayJoin[A]:
  case NoJoin()
  case WithJoin(j: Join[A], eff: EffectStack)
```

Indeed, a concrete stack uses `NoJoin` whereas an abstract stack uses `WithJoin`. Given a `WithJoin[A]`, we can invoke `joinComputations` as shown above in the abstract branching semantics of subsection 4.1. Furthermore, `Join[A]` is used to join values of type `A`. `OperandStack` forwards the `MayJoin` parameter to `JOption`, a data type for joinable option values that we use to represent uncertain data. Since `JOption[NoJoin, A]` is isomorphic to the standard `Option[A]`, concrete operand stacks provide a standard stack interface.

Many of our effect components use a similar design to declare that operations may yield uncertain results in the abstract semantics. Indeed, the generic interpreter itself has a `MayJoin` parameter that it forwards to the required effect components. However, sometimes the generic interpreter can formulate more precise requirements. For Wasm, the language specification guarantees that the height of the stack is decidable at all times and that stack lookups must yield certain results. To this end, the generic Wasm interpreter requires a decidable operand stack, which internally selects `NoJoin` for `MayJoin`.

Indirect Calls and Function Tables

Wasm features indirect function calls via function indices, which really are plain `i32` values computed by the program. To evaluate an indirect function call, Wasm reads a function index from the stack, looks up the index in a function table, and invokes the found function:

```
def evalInst(inst: Inst): Unit = inst match
  case CallIndirect(typeIx) =>
    val funcIx = stack.popOrElseFail()
    val funV = funTable.getOrElse(funcIx, fail(UnboundFunctionIndex, ...))
    funOps.invokeFun(funV, invoke)
```

This code uses two additional components: an effect component `funTable` and a value component `funOps`. We model the function table as a generic `SymbolTable` component that maps symbols to entries:

```
trait SymbolTable[Symbol, V, MayJoin[_]]:
  def get(symbol: Symbol): JOption[MayJoin, V]
  def put(symbol: Symbol, newEntry: V): JOption[MayJoin, Unit]

val funTable: SymbolTable[FuncIx, FunV, MayJoin]
```

Note how the symbol table uses the same `MayJoin` pattern as the operand stack. However, lookups in the function table are not decidable in Wasm, so that abstract interpreters sometimes obtain an uncertain function. For example, our type analysis does not track the values of function indices and thus must consider all reachable functions as potential targets for indirect calls. This also is the reason why the function table contains `FunV` values rather than functions directly: We must be able to join function values. To abstract from the specific `FunV` representation, we use a generic value component `FunctionOps`:

```
trait FunctionOps[Fun, A, R, FunV]:
  def funValue(fun: Fun): FunV
  def invokeFun(v: FunV, a: A)(invoke: (Fun, A) => R): R

val funOps: FunctionOps[Function, FuncType, Unit, FunV]
```

Operation `funValue` lifts a function into a function value `FunV`. Operation `invokeFun` does the inverse: It extracts functions from a function value and applies the continuation `invoke` on each of them. Similar to `boolBranch`, abstract instances of `FunctionOps` join the result `R` of all functions.

Global Variables

Wasm features numerically indexed global variables that can be used to store values. We model global variables using the same `SymbolTable` component that we used for function tables. However, the resolution of global variables is decidable in Wasm and always yields a certain result. We incorporate this fact in the generic interpreter by requiring a decidable symbol table for global variables:

```
val globals: DecidableSymbolTable[Int, V]
```

5:12 Modular Abstract Definitional Interpreters for WebAssembly

Please note that in Wasm, each module has its own globals, function table, and memory, which can also be shared between modules. Our implementation takes this into account, but we decided to simplify the presentation of the code for the paper.

Local Variables

Each Wasm function can declare local variables, which we understand to include the function parameters. A function can read and write its local variables freely. We model local variables through a generic `CallFrame` component. Each call frame has a fixed size determined at construction by operation `inNewFrame`. In addition, a call frame can track auxiliary `Data` for each frame. For Wasm, we use the call frame to track the module instance of the currently executing function as well as its return arity:

```
trait CallFrame[Data, Var, V, MayJoin[_]]:
  def inNewFrame[A](d: Data, vs: Seq[(Var, V)])(f: => A): A
  def getFrameData: Data
  def getLocal(x: Int): JOption[MayJoin, V]
  def setLocal(x: Int, v: V): JOption[MayJoin, Unit]

val callFrame: DecidableCallFrame[(ModuleInst, Int), Int, V]
```

Note how both call frames and symbol tables map indices to values. However, call frames are scoped by function call and the previous call frame is restored when exiting a function. Operation `inNewFrame` takes care of this behavior, executing `f` in the new frame and restoring the previous frame after `f` finishes. This way, the generic interpreter can implement function invocations:

```
def invoke(fun: Function): Unit =
  val args = stack.popNOrFail(fun.params.size)
  val locals = args ++ fun.locals.map(num.defaultValue)
  val data = (module, fun.returnArity)
  callFrame.inNewFrame(data, locals)(enterFunction(fun))
```

Linear Memory

Wasm programs can load and store data from a growable linear memory. Technically, the linear memory is a byte array that is accessed using 32-bit integers as index. Wasm provides various instructions to load and store values of different types. In our generic interpreter, the following code handles load instructions using the memory effect component:

```
trait Memory[Addr, Bytes, Size, MayJoin[_]]:
  def read(addr: Addr, length: Int): JOption[MayJoin, Bytes]
  def write(addr: Addr, bytes: Bytes): JOption[MayJoin, Unit]

val memory: Memory[Addr, Bytes, Size, MayJoin]
def load(inst: LoadInst): Unit =
  val addr = effectiveAddr(inst.offset)
  val length = getBytesToRead(inst)
  val bytes = memory.read(addr, length).orElse(fail(MemoryAccessOutOfBounds, ...))
  stack.push(decode(bytes, inst))
```

We first compute the effective address to be loaded by adding a static offset to the base address, which is on the operand stack. We then determine the number of bytes to be loaded. We invoke the read operation of the memory effect component to obtain a byte sequence. Finally, we decode those bytes using the `decode` component discussed in subsection 4.1.

Jumps

Wasm features a limited form of jumps that abides by structured control flow, which means that jumps can only target enclosing blocks. Instead of using named labels, Wasm jumps declare the number of blocks to skip, that is, the block-distance between the jump and the target block. We model jumps through an effect component for exception handling:

```
trait Except[Exc, ExcV, MayJoin[_]]:
  def throws(ex: Exc): Nothing
  def tries[A](f: => A): JEither[MayJoin, A, ExcV]
```

The `Except` component is parametric in the underlying exception type `Exc` and the representation of exception values `ExcV`. Similar to `JOption` from above, operation `tries` yields a value of a joinable either data type, `JEither` for short. That is, `tries` either yields an `A` when `f` triggers no exception, or it yields an `ExcV`. Since abstract instances of `Except` may not be able to determine the exact behavior of `f`, the result of `tries` can be uncertain, which `JEither` encapsulates.

The generic interpreter uses exception handling to support jumps and returns:

```
type WasmExc[V] = (JumpTarget, List[V])
enum JumpTarget:
  case Jump(labelIndex: LabelIdx)
  case Return

val except: Except[WasmExc[V], ExcV, MayJoin]

def jump(labelIndex: LabelIdx): Unit =
  val returnArity: Int = labelStack.arityOf(labelIndex)
  val operands = stack.popNOrFail(returnArity)
  except.throws((JumpTarget.Jump(labelIndex), operands))

def label(returnArity: Int, insts: Seq[Inst]): Unit =
  labelStack.pushLabel(returnArity)
  val tried = except.tries(insts.foreach(evalInst))
  labelStack.popLabel()
  tried.either(identity) {
    case (JumpTarget.Jump(0), ops) => stack.pushN(ops)
    case (JumpTarget.Jump(ix), ops) => except.throws(WasmExc.Jump(ix - 1, ops))
    case (JumpTarget.Return, ops) => except.throws(WasmExc.Return(ops))
  }
```

Function `jump` takes the index of a label, looks up the return arity required by that label in an auxiliary data structure called `labelStack`, and triggers a `Jump` exception with the corresponding number of operands. `Jump` exceptions are handled by function `label`, which we use when entering a new block. This function first pushes the return arity of the label to the `labelStack` and then tries to run all instructions of the block. We use `either` to react to the result of that execution. If the block succeeds without exception, nothing has to be done (`identity`). However, if an exception was (possibly) thrown, we react accordingly. If the jump target has index 0, it targets the current label and we push the operands on the stack. Otherwise, we decrement the jump target index and escalate the exception. Return exceptions always escalate; they are handled by `enterFunction`.

Traps

Wasm programs can trigger unrecoverable errors, called traps. We model traps using the `Failure` effect.

```

trait Failure:
  def fail(kind: FailureKind, msg: String): Nothing

val failure: Failure

```

In contrast to exceptions, failures are unrecoverable and cannot be caught. While the canonical concrete semantics of `Failure` aborts the execution of a Wasm program, abstract interpreters must continue to explore execution paths that do not fail. That is, the abstract `fail` produces a set of potential `FailureKind` and throws a specific Scala failure exception. Furthermore, the failure join operation catches failure exceptions at branching points and continues to explore other branches. After all branches have been explored, the failure join operation rethrows the failure exception if one of the branches failed.

4.3 Summary

We have decomposed the analysis of Wasm into various language concerns. We implemented each of these concerns with 12 separate value components for numeric operations, conversions, and branching, and with 7 effect components for the operand stack, function and symbol tables, global and local variables, linear memory, jumps, and traps. Based on this decomposition, we have developed a generic interpreter for Wasm that is parametric in how the value and effect components are instantiated. The generic interpreter implements evaluation of Wasm code. The generic interpreter also implements the module system, manages exports, resolves imports, and performs module instantiation, which is used to initialize variables, function tables, and memories. In particular, we have implemented the canonical concrete semantics for all value and effect components and used those to derive a concrete Wasm interpreter. This concrete Wasm interpreter is a feature-complete and correct implementation of the Wasm 1.0 specification, as we detail in section 7.

The generic interpreter is not only parametric in the value and effect components, but also in the fixpoint algorithm. While the concrete interpreter can simply run a program until it terminates, abstract interpreters must widen analysis results to ensure termination. To this end, our generic interpreter is written in an open recursive style, giving control to the fixpoint algorithm in each recursive invocation. When instantiating the generic interpreter, we configure a generic fixpoint algorithm provided by our platform to select context-sensitivity and other aspects. We illustrate such configuration in the next section, where we build three whole-program Wasm analyses as instances of the generic interpreter.

5 Modularly Defined Analyses for Wasm

In the previous section, we have presented the key ingredients of our modular static analysis platform for Wasm: a Wasm semantics decomposed into value and effect components and a generic Wasm interpreter. In the present section, we demonstrate how our platform can be used to implement Wasm analyses modularly. To this end, we implement three Wasm analyses: a dead code analysis, a constant propagation analysis, and a taint analysis. We compose each analysis modularly from value and effect components that we use to instantiate the generic interpreter.

5.1 Type Analysis

As a baseline, we first describe an analysis with a type abstraction, which additionally identifies dead code. To this end, we must construct an inter-procedural control-flow graph (CFG) that allows us to identify unreachable instructions. Note that the construction of a precise interprocedural CFG is undecidable in general and approximation is required. In this subsection, we use a type analysis to approximate the behavior of the program.

Our platform provides a reusable singleton type `BaseType[T]` to represent type `T`, which we use to model our type analysis:

```
enum Type:
  case I32(i: BaseType[Int]); case I64(l: BaseType[Long]);
  case F32(f: BaseType[Float]); case F64(d: BaseType[Double]); case Top

type Addr = BaseType[Int]
type Bytes = BaseType[Seq[Byte]]
type Size = BaseType[Int]

type FuncIx = BaseType[Int]
type FunV = Powerset[FunctionInstance]
type ExcV = Map[JumpTarget, List[Type]]
```

The type analysis does not track memory access precisely: all reads yield a top value. Specifically, we represent addresses `Addr`, byte sequences `Bytes`, and memory size `Size` using their type. We also don't track function indices: Indirect function calls resolve to the set of all functions currently in the function table. For exceptions, we collect all active exceptions in a set. Based on these definitions, we select the following effect components:

```
val stack = new JoinableConcreteOperandStack[Type]
val memory = new TopMemory[MemoryAddr, Addr, Bytes, Size]
val globals = new JoinableConcreteSymbolTable[GlobalAddr, Type]
val funTable = new UpperBoundSymbolTable[TableAddr, FuncIx, FunV]
val callFrame = new JoinableConcreteCallFrame[FrameData, Int, Type]
val except = new JoinedExcept[WasmException[Value], ExcV]
val failure = new AFailureCollect
```

Note how we use decidable instances for the operand stack, call frames, and global variables, since all three concerns are statically decidable in Wasm. The memory yields top on every read, the function table yields all stored entries when queried. We use the `AFailureCollect` instance for abstract failures, which collects all possible failures of the analyzed program.

Finally, every analysis must configure the fixpoint algorithm used by our platform. Most importantly, we must select a context-sensitivity and iteration strategy. Our platform provides a combinator library for describing these aspects:

```
val phi = fix.log(controlFlowGraphLogger,
  fix.contextSensitive(fix.context.none,
    fix.filter(isFunOrLoop, fix.iter.innermost))
```

Combinator `fix.contextSensitive` determines the context-sensitivity of the type analysis. Specifically, the type analysis is context-insensitive, which means that all calls of the same function are joined. Combinator `fix.filter` applies the inner combinator only to instructions for which predicate holds. In this case, the filter combinator applies a specific iteration strategy to functions and loops, because these are the only Wasm constructs which can diverge and need to be iterated on. Combinator `fix.iter.innermost` iterates on the innermost strongly-connected components of the dependency graph of the abstract interpreter. Specifically, it iterates on the innermost of nested loops and the innermost of nested recursive function calls. Lastly, combinator `fix.log` calls a logger before and after every instruction. The logger in this case records an interprocedural control-flow graph, which we explain in the following paragraph.

CFG construction

Our platform uses big-step abstract interpretation, in which the control flow of analyzed programs is implicit. However, we can make the control flow explicit by observing the order in which instructions are executed by the abstract interpreter. To this end, we call function `fix.control` of our platform with mappings from Wasm instructions to CFG nodes:

```

val controlFlowGraphLogger = fix.control(config) {
  // called before interpreting an instruction
  case Enter(fun) => CfgEnter(fun)
  case Eval(c: Call, loc) => CfgCall(c, loc)
  case Eval(inst, loc) => CfgInstruction(inst, loc)
} {
  // called after interpreting an instruction
  case (Enter(fun), Exit(_)) => CfgExit(fun)
  case (Eval(c: Call, loc), _) => CfgCallReturn(c, loc)
}

```

Function `fix.control` returns a logger, that is called before and after each Wasm instruction. The logger adds instructions to basic blocks, adds control-flow edges between basic blocks, and adds call edges between call-site, entry, and exit points of functions.

For example, this code constructs the CFG shown on the right for a recursive factorial function, where dashed lines represent call-return edges. Of course, the CFG construction also scales to larger examples. The last line in the code above activates CFG logging for a given `analysis`. While our type analysis is context-insensitive, other analyses may exploit context-sensitive CFGs. But, as we show in section 7, even the simple type analysis already produces useful results and finds dead code in Wasm programs. Furthermore, the CFG can be used as a starting point for other analysis approaches.

5.2 Constant Propagation Analysis

We define a constant propagation analysis by refining the type analysis from above. In a constant propagation analysis, values are either a concrete value or `Top`:

```

enum Value:
  case I32(i: Topped[Int]);   case I64(l: Topped[Long]);
  case F32(f: Topped[Float]); case F64(d: Topped[Double]); case Top

type Addr = Topped[Int]
type Bytes = Seq[Topped[Byte]]
type Size = Topped[Int]

type FuncIx = Topped[Int]
type FunV = Powerset[FunctionInstance]
type ExcV = Map[JumpTarget, List[Type]]

```

Notably, the constant propagation analysis tracks constant memory addresses and bytes. That is, when writing a concrete value to a known address, we store the concrete byte encoding of the value. Conversely, when reading from a known address, if we find a concrete byte sequence, we decode it into a concrete value. This memory abstraction is certainly only a first step in developing sophisticated Wasm analyses, but our modular analysis platform allows us to refine it in future work. For function indices, we track their precise index if possible. Ideally, dereferencing a function index yields a single function that we can execute, but if the function index is `Top`, we obtain a set of all functions in the function table.

Compared to the type analysis, we only have to adapt two effect components, namely those that handle memory and function indices. We highlight the differences in blue font:

```

val stack = new JoinableConcreteOperandStack[Type]
val memory = new ConstantAddressMemory[MemoryAddr, Addr, Bytes, Size]
val globals = new JoinableConcreteSymbolTable[GlobalAddr, Type]
val funTable = new ConstantSymbolTable[TableAddr, FuncIx, FunV]
val callFrame = new JoinableConcreteCallFrame[FrameData, Int, Type]
val except = new JoinedExcept[WasmException[Value], ExcV]
val failure = new AFailureCollect

```

To increase the precision of the constant propagation analysis, we can choose a 1-callsite sensitive fixpoint algorithm. To this end, we log each function call with a call-site logger and use the most recent call site as a context:

```
val callSites = fix.context.callSites {
  case Eval(c: (Call | CallIndirect), _) => Some(c)
  case _ => None
}
val phi = fix.log(callSites,
  fix.log(controlFlowGraphLogger,
    fix.contextSensitive(callSites.callString(1),
      fix.filter(isFunOrLoop, fix.iter.innermost))))
```

Finally, we need to determine whether an instruction is constant in all execution paths. We can achieve this by observing the results of the abstract interpreter for each instruction. To this end, we implemented a logger that reads the relevant data from the operand stack before and after executing an instruction. In case an instruction is visited more than once (e.g., in a loop) the recorded values are joined. If the final result is constant, the instruction is constant across all execution paths. Our analysis platform allows us to add this functionality modularly:

```
val constants = new InstructionLogger { inst =>
  // log before execution of inst
  if (readsSingleValueFromStack(inst))
    Some(stack.peekOrFail())
  else if ...
} { inst =>
  // log after execution of inst
  if (writesSingleValueToStack(inst))
    Some(stack.peekOrFail())
  else if ...
}
```

5.3 Taint Analysis

As a last example, we define a taint analysis by refining the constant propagation analysis. The goal of the analysis is to detect tainted memory accesses, i.e., if a tainted value is used as memory address. As source for tainted values, we consider user input which results from calling host functions. To track taint, we tag a taint property to each value:

```
enum Value:
  case I32(i: Taint[Topped[Int]]); case I64(l: Taint[Topped[Long]]);
  case F32(f: Taint[Topped[Float]]); case F64(d: Taint[Topped[Double]]); case Top

type Addr = Topped[Int]           type FuncIx = Topped[Int]
type Bytes = Seq[Taint[Topped[Byte]]] type FunV = Topped[Powerset[FunctionInstance]]
type Size = Topped[Int]           type ExcV = Map[JumpTarget, List[Type]]
```

We omit the effect and fixpoint configuration of the taint analysis since it is identical to the constant propagation analysis.

To detect illegal memory access through tainted values, we add a new observer to the analysis. Note that we observe the values on the stack before they are cast to an address, which is why type `Addr` does not need a taint flag.

```
val tainting = new InstructionLogger { inst =>
  if (isLoadInst(inst)) {
    val addrV = stack.peekOrFail()
    if (addrV.isTainted) Some(Powerset(addrV)) else None
  }
}
```

We collect tainted addresses for each memory instruction. A memory instruction is safe if its set of tainted addresses is empty. Of course, we could track other sinks or sources for tainted values and expect to do so in future work.

5.4 Most General Client for Wasm Modules

Abstract definitional interpreters are whole-program analyses: Interpretation starts in the main function and subsequently explores all code reachable from there. However, Wasm programs are usually used as libraries within JavaScript applications. To apply our whole-program analyses to individual Wasm modules, we develop a most general client for Wasm.

Most general clients can be used to apply whole-program static analyses to library code [19]. A most general client approximates all valid usages of a given library, and it can be used as a single entry point for the analysis. We have developed a most general client for Wasm modules that exercises all interleavings of all exported functions in a loop:

```
def runMostGeneralClientLoop(modInst: ModuleInstance): Unit =
  effectStack.mapJoin(modInst.exportedFunctions) { case (funName, funIx) =>
    val fun = modInst.functions.getOrElse(funIx, fail(UnboundFunctionIndex, funIx.toString))
    val args = fun.funcType.params.map(typedTop).toList
    invokeExported(modInst, funName, args)
  }
  fixpoint(runMostGeneralClientLoop(modInst))
```

In each loop iteration, we run all exported functions in isolation and join their effects to update the analysis state. Our fixpoint algorithm iterates this loop until the analysis state is stable. The final analysis state soundly approximates all possible sequences of exported functions.

Note that a Wasm client can also write to exported tables and memory. Our most general client does not capture this behavior, which may cause the analysis result to be unsound for such clients. If the exported tables and memory are not edited externally, our approach obtains a sound analysis result for the library code.

6 A Scalable Framework for Abstract Definitional Interpretation

We designed and implemented a new framework for abstract definitional interpretation in Scala as open source.¹ In this section, we describe how our new framework improves over prior work and why that was necessary for scaling the approach to complex languages and real-world programs. There are two prior frameworks for abstract definitional interpretation: the original DAI in Racket by Darais et al. [7] and Sturdy in Haskell by Keidel et al. [13]. While we compare to both, we also implemented a complete generic definitional interpreter for Wasm in Sturdy and report on the lessons learned.

Component design

Abstract definitional interpretation has supported modularly defined components from the start. Already in DAI, the generic PCF interpreter used components for environments, stores, and allocation [7]. However, these components followed an ad-hoc design and did not share an interface between concrete and abstract semantics. Not only did this preclude modular reasoning about components, it also implies that we must use the non-determinism

¹ <https://gitlab.rlp.net/plmz/sturdy.scala>

monad to collect alternative analysis (sub-)results. For example, DAI features a function `isZero(v: V): Boolean` in the concrete semantics and `isZero(v: V): List[Boolean]` in the abstract semantics. Consequently, when the abstract semantics cannot decide if a value is zero it yields `List(true, false)` and all of the remaining analysis is run twice: once for `true` and once for `false`. Nested conditionals with uncertain conditions like this trigger an exponential blow-up that is unacceptable when scaling up.

Sturdy was designed to support the development of sound static analyses with compositional soundness proofs. For this reason, Sturdy introduced a design principle based on parametricity that ensures no details about the concrete or abstract semantics is leaked into the generic interpreter [14]. This design principle prohibits an operation `isZero` as in DAI. Instead, Sturdy provides a operation `ifZero(v: V, ifTrue: => R, ifFalse: => R): R`, where `ifTrue` and `ifFalse` are continuations. If both continuations must be run, Sturdy joins their results before moving on with the rest of the analysis. Sturdy uses a similar design for all operations that introduce uncertainty. For example, reading from a store is done by operation `read(a: Addr, ifFound: V => R, ifNotFound: => R): R`. We found the use of continuations in Sturdy excessive, making it harder to write and maintain the generic interpreter for Wasm. But can this be avoided?

In our framework, we have retained Sturdy’s design principles to permit modular reasoning about components. While our framework does not attempt to support formal proofs, modular reasoning reemerges in the form of modular soundness propositions that can be used during testing. However, we significantly reduce the amount of continuations needed by encapsulating uncertain results in dedicated auxiliary data types: `JOption` and `JEither`. These data types provide standard operations such as `getOrElse`, `map`, and `flatMap`. For the concrete semantics, these data types behave identical to the standard `Option` and `Either` types, but their abstract semantics can encode uncertainty such as `LeftOrRight(1, r)`. Besides reducing the number of continuations needed, these types significantly improve the readability of component interfaces. For example, reading from a store has the simple signature `read(a: Addr): JOption[MayJoin, V]`.

Eliminating the monadic transformer stack

Both DAI and Sturdy encode the generic interpreter in monadic style: The side effects triggered by the analyzed program are threaded through the monadic computation. And both frameworks use transformers to decompose effect handling into components. For example, in Figure 4 we show the transformer stacks used by DAI and Sturdy for a k-CFA analysis of PCF, as well as the transformer stack for our prototypical constant propagation analysis of Wasm implemented in Sturdy. This shows how the transformer stack grows considerably when analyzing complex languages.

Large transformer stacks are problematic because they impair the performance of the interpreter. Every monadic operation in the interpreter must traverse the entire transformer stack, slowing down interpretation considerably. Keidel et al. [13] measured this effect and showed that an interpreter on a transformer stack was 7756x slower than the same computation after exhaustive inlining of the entire stack. Thus, they argued that inlining allows us to enjoy modularity without regrets. While we concur in principle, this approach does not scale to complex languages unfortunately. For transformers stacks like the one for Wasm shown in Figure 4, the compiler exceeded 16 GB of memory while inlining and ultimately failed to compile the program. Since a 7756x slower analysis is not feasible, we must find an alternative design to support modularly defined components.

In our framework, we follow an object-oriented design in representing independent components. Rather than stacking all components and threading their effect through the computation, we let each component manage and manipulate its own internal state. As

5:20 Modular Abstract Definitional Interpreters for WebAssembly

```
// DAI: k-CFA analysis of PCF, 6 components
ReaderT (FailT (StateT (NondetT (CacheT (FinMap0 Power0) ID))))

// Sturdy: k-CFA analysis of PCF, 8 components
ValueT (ErrorT (EnvT (FixT (ComponentT (StackT (CacheT (CallSiteT (->))))))))

// Sturdy: constant propagation of Wasm, 15 components
ValueT (JumpTypesT (OperandStackT (ExceptT (StaticGlobalStateT
  (MemoryT (SerializeT (TableT (FrameT (LogErrorT
    (FixT (ComponentT (StackT (CacheT (ControlFlowT (->))))))))))))))
```

■ **Figure 4** Deep transformer stacks as required by DAI and Sturdy impair the performance of the analyzers.

usual in OO, the internal state is encapsulated in the component and hidden behind a public interface. For example, setting a global variable `globals.set(x, stack.popOrFail())` changes the internal state of `stack` and `globals`, which is observable through operations of the public interface, such as `globals.get`. Since components are not stacked, invoking a component's operation is a simple method call that does not involve any other components.

Only when joining effectful computations, all effect components must participate, each taking care of their own internal state. The generic interpreter defines an effect stack that determines the order in which effects are joined. For Wasm, we use the following effect stack:

```
val effectStack = EffectStack(List(
  stack, memory, globals, funTable, callFrame, except, failure))
```

Each abstract semantics of an effect component must implement `joinComputations(f)(g)`, which executes `f` and `g` on the current internal state and merges the two resulting states. We apply a common strategy to implement these joins:

1. Take a snapshot of the internal state.
2. Execute `f`, store the resulting state.
3. Restore the snapshot state.
4. Execute `g`, store the resulting state.
5. Join the two states in an effect-dependent manner.

Consider the following example program:

```
// locals before: 0 := 0; 1 := 10
(if (then (i32.const 25) (local.set 0)) (else (local.get 0) (local.set 1)))
// locals after: 0 := (25 ⊔ 0); 1 := (10 ⊔ 0)
```

The `then` branch produces a call frame that still maps `0 := 25` and `1 := 10` unchanged. The `else` branch must operate on a copy of the original call frame and produce `0 := 0` unchanged and `1 := 0`, ignoring the manipulations done in the `then` branch. Finally, we join the resulting call frames, obtaining the result shown above. In the next section, we show that analyses defined in our framework scale to real-world programs.

7 Evaluation

section 5 has already demonstrated how our approach enables the modular construction of Wasm analyses. In this section, we present empirical results that attest (i) the concrete interpreter is correct, (ii) the static analyses are sound with respect to the concrete interpreter, and (iii) the type, constant, and taint analyses yield relevant results.

Correctness of concrete interpreter

Establishing the correctness of the concrete interpreter is important, because the concrete interpreter provides ground truth for reasoning about the soundness of our analyses. Thus, any soundness result we may provide is only meaningful as long as the concrete interpreter itself is a true implementation of the Wasm specification. In particular, our analyses and the concrete interpreter share the generic interpreter, which must be correct. In fact, if there was a bug in the generic interpreter, this bug would *not* trigger a soundness violation, because the concrete interpreter would exhibit the same incorrect behavior. Therefore, establishing the correctness of the concrete interpreter is paramount.

To this end, we ran our concrete Wasm interpreter against the official test suite from the Wasm specification.² The test suite consists of 16481 assertions, testing the correct behaviour of the Wasm interpreter. This testing revealed several bugs in our implementation, all of which we fixed. For example, we found indexing errors in the linear memory and several subtle bugs concerning floating-point operations. Our concrete Wasm interpreter now passes the complete test suite.

Soundness of static analyses

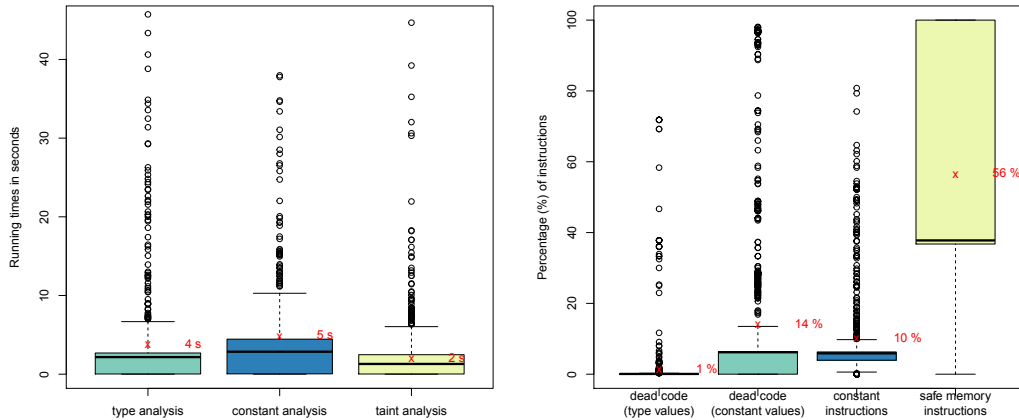

Only sound analyses can be used to inform program optimizations without jeopardizing the program's semantics. Since we want to conduct performance optimizations and reduce the size of Wasm binaries, we must ensure our analyses are sound. To this end, we tested soundness of our analyses against the concrete interpreter. Our platform allows us to implement soundness propositions for each value and effect component modularly. Value components implement an abstraction function that lifts the canonical concrete value representation into the abstract domain, using a partial order on the abstract domain to determine sound approximation. Effect components implement a soundness proposition that relates the internal state of the canonical effect implementation to their own internal state. That is, we not only check the final value computed by an analysis, but also the final state of the linear memory and other effect components. An analysis then simply composes the soundness propositions of its components.

We tested the soundness of our analyses against the concrete interpreter on the test suite from the Wasm specification. Specifically, we ran the analyses and the concrete interpreter simultaneously and tested analysis soundness after every single assertion. This uncovered several bugs. For example, we initially defined integer division $\text{Top} / \text{Top} = \text{Top}$, which neglects division-by-zero errors and should yield $\text{Top} \sqcup \text{fail}(\dots)$ instead. We were able to fix all soundness bugs, so that we are confident the abstract interpreters are sound with respect to the concrete interpreter.

Large-scale evaluation

To assess the applicability and performance of our analyses, we applied them to the programs collected by others in the WasmBench benchmark suite. WasmBench [11] contains 8461 unique Wasm binaries collected from various sources, including github, NPM, and by crawling websites. Out of these, we had to ignore 7003 binaries that failed to validate, 6354 of which due to unresolvable imports of modules not collected by the benchmark suite. Since WasmBench collects individual binaries rather than applications, we have no principled

² <https://github.com/WebAssembly/spec/>

■ **Figure 5** Running times in seconds (left) and analysis results in % of instructions (right) for analyzing each of the 1458 WasmBench binaries. The red cross indicates the mean time or percentage.

means of finding the right module. Another 607 binaries out of the 7003 were rejected due to invalid memory page size information. For each binary of the remaining 1458 binaries, we run our analyses using the most general client described in subsection 5.4, so that the analysis results soundly approximate any potential usage of the module.

We measured the running times after a warm-up phase. We cancelled analysis runs after 60 seconds, which yielded between 196 and 200 timeouts per analysis. This timeout was chosen for pragmatic reasons: To limit the overall time required to run the experiment, which finishes in a little over 7 hours. Figure 5 shows the running times of the successful analysis runs. On average, the type analysis finishes in 4s, the constant analysis in 5s, and the taint analysis in 2s. The taint analysis is faster because it does not construct a call graph. We note that 81% of all type and constant analysis runs finish in 10s or less (including those runs that timed out), as do 85% of all taint analysis runs.

Figure 5 shows the percentage of instructions our type-based dead code, constant-based dead code, constant propagation analysis, and taint analysis identified. We count an instruction as dead if it is unreachable or, in case of blocks and loops, if they are never targeted by a jump. Such dead instructions can be safely eliminated from a Wasm binary. This reduces the binary size and saves bandwidth if the binary is sent over the network. Unsurprisingly, our baseline type analysis cannot find much dead code. However, even a simple constant propagation analysis can already reduce binaries by 14% on average. Note that the dead code this analysis identified was missed by other compilers, as many of the binaries stem from deployed packages and websites. The constant analysis also identifies 10% of instructions as computing constant results. This excludes instructions like `i32.const` of course. Constant instructions can be replaced by such `const` instructions. Due to our modular architecture, analysis developers can focus on improving one aspect of the analysis at a time to increase the optimization potential further.

Finally, the goal of the taint analysis is to track the data flow of tainted values and detect if tainted values can reach critical program points. Our taint analysis defines user input and results of calling host functions as tainted and detects potential security risks if tainted values are used as memory addresses. Protecting the memory is important because many compilation schemes targeting Wasm use the memory to embed critical infrastructure of the source language’s runtime system [20]. For example, some runtime systems manage their own call stack in the memory, which thus is not protected from the user. If we can show that

■ **Figure 6** Comparing our approach to Binaryen, the industry standard for Wasm optimizations.

the user cannot access or and manipulate the memory shape, this means that the runtime system cannot be tampered with this way. Consequently, we consider a memory access to be safe if the analysis can guarantee that a tainted (user-influenced) value cannot be used as an address. On average, our analysis finds 56% of all memory accesses to be safe. Out of the 1458 Wasm binaries, our analysis shows 28% to be completely safe, meaning they only contain safe memory accesses. This analysis is fairly simple still and, for example, does not support any sanitization of tainted values, which should further improve the analysis results.

Comparison with the industry standard

While we compare to related work in the subsequent section, we thought it is important to validate our approach empirically in comparison to the industry standard. The de-facto industry standard for Wasm code optimization is Binaryen³, a C++ library that provides its own Wasm IR and implements about 100 optimization passes in its `wasm-opt` tool. This includes whole-program constant propagation and dead code optimizations, although the details and limits of the underlying analyses are not clearly documented. This begs the question: Can our approach compete with Binaryen, an industry standard for Wasm optimization developed by more than 140 contributors.

We answer this question quantitatively by running the optimizer of Binaryen on all WasmBench binaries that we successfully optimized. Binaryen transforms the Wasm code into its own IR, optimizes that IR, and translates it back into the Wasm binary format. We configured Binaryen using the `-oz` flag, which aggressively optimizes for code size. We compute the number of *eliminated instructions* by loading the original and the optimized module and subtracting their instruction counts. We then compare this number to our constant analysis, where each dead or constant instruction counts toward the *eliminated instructions*. Figure 6 shows the results of our experiment.

Our experiment clearly shows that our approach outperforms Binaryen in terms of precision, eliminating twice as many instructions on average. While further investigation is necessary to understand where exactly our approach wins compared to Binaryen, note that

³ <https://github.com/WebAssembly/binaryen>

we have built a generic framework for Wasm analyses. In particular, constant propagation is a simple abstract domain and we may expect far better precision by using intervals or even relational abstract domains. Our framework is designed to accommodate those future improvements. In terms of performance, Binaryen only takes 0.1s on average, where our callsite-sensitive constant propagation analysis takes 4.8s on average. This is to be expected, given that our analysis lies in a different complexity class.

One important threat to validity of this experiment is that our analyses do not actually rewrite Wasm binaries. Instead, we count the number of instructions that were detected as dead or constant. We believe this is fair, since dead instructions can be dropped for sure and the constant instructions can be removed by propagating the constant value. Actually, we penalizes our own approach because in `i32.const 1; i32.const 2; i32.add`, we only count the last instruction as eliminable, while Binaryen removes all three of them. We hope to integrate our analysis into a framework like Binaryen in future work to realize optimizations based on our analysis results.

8 Related Work

Our work investigates how to develop modular static analyses for Wasm using abstract definitional interpreters. We have already compared to prior approaches of abstract definitional interpreters in section 6 in detail. In this section, we discuss how our work relates to prior work on Wasm, x86 assembly, and JVM bytecode.

Stiévenart and Roover [28] designed the first static taint analysis *Wassail* for Wasm using a compositional approach. In particular, they analyze each function in isolation and compute a summary of the taint information of the following form:

```
function 8: stack: [10,11], globals: [g0;11], mem: g7
```

This example summary means that the Wasm function with id 8 may store the variables 10, 11 on stack, may store the variables g0, 11 as globals, and variable g7 in the linear memory. In a second step, they combine the summaries of multiple functions in bottom-up order of the call graph to compute the complete analysis result. While compositional analyses are known to scale better, they are also less precise than whole-program analyses. There are two places where our whole-program taint analysis is more precise than *Wassail*'s compositional taint analysis. First, *Wassail* does not resolve indirect calls precisely. In particular, an indirect call reads the function index from the stack, which is not approximated by *Wassail*. Instead, *Wassail* resolves an indirect call to all functions which have a matching type [2]. This may be especially imprecise for common function signatures such as `F64 -> F64`. In contrast, our constant taint analysis approximates the stack and is able to resolve indirect calls precisely in case the function index is a constant. Second, *Wassail* does not approximate the layout of Wasm's linear memory precisely. In particular, *Wassail* returns all taint variables stored in memory on every load instruction. In contrast, our constant taint analysis approximates the layout of Wasm's linear memory more precisely. Specifically, we have distinct read behavior for constant addresses and top addresses. Reading from a top address yields the memories upper bound, which is the default behavior for all reads in *wassail*, but constant addresses result in actual lookups. This increases the precision of load instructions with a constant address.

Wasp⁴ is a C++ library for performing simple static analyses on Wasm code. It offers methods to dump specific parts of a module (e.g., all functions) and to compute a function's call graph, control-flow graph, and data-flow graph. In contrast to our work, Wasp is not

⁴ <https://github.com/WebAssembly/wasp>

designed to implement more sophisticated analyses for Wasm but rather as a tool making it easy to work with Wasm modules. In particular, Wasp does not consider abstract domains to approximate values and thus, by and large, yields results equivalent to our type analysis. But, as our evaluation showed, even simple value domains such as constant propagation improve the precision of analyses significantly: The type analysis only found 1% of dead instructions on average, whereas we were able to prove 14% of instructions are dead using an abstract domain for constant propagation. This is out of reach for Wasp.

Wasabi [21] is a general purpose framework for implementing *dynamic* analyses for Wasm, which can be implemented using a high-level JavaScript API. The framework then instruments the Wasm binary to call these JavaScript analysis functions. Dynamic analyses are used in different contexts than static analyses. While analyses for security (e.g., a taint analyses) may be performed both statically and dynamically, compiler optimizations entail the use of a static analysis. Hence, the focus of their work is orthogonal to ours and explores a different part of the design space.

Watt et al. [34] developed two formal semantics for Wasm in the Isabelle and Coq proof assistants. These formal semantics can be used to prove properties about Wasm programs. However, these proofs require a high amount of manual effort and expertise in contrast to static analyses, which are automatized.

Static analysis of x86 assembly code [3, 6, 16] faces several challenges summarized in the PhD thesis of Kinder [15]. For example, unstructured control-flow with `goto`'s and long jumps with dynamic jump target complicate the construction of a control-flow graph [17, 24]. Furthermore, x86 programs store their code alongside the data during the execution, which makes it harder for static analyses to differentiate between them [33]. This also allows x86 programs to modify their own code during execution, which poses a severe challenge for static analyses [30]. In contrast, Wasm prevents these problems with a stricter language design. In particular, Wasm is statically-typed, features only structured control-flow and clearly separates between code and data, which makes it impossible for Wasm programs to modify their own code [10]. The stricter language design of Wasm lowers the bar for implementing static analyses and improves their precision compared to x86 analyses.

Many static analysis frameworks for Java target JVM bytecode [8, 4, 27], the assembly code that underlies the Java Virtual Machine [22]. However, JVM bytecode poses a challenge to static analyses, because of its implicit dataflow and due to the use of a stack. Vallee-rai and Hendren [32] solved this problem by compiling JVM byte code to *Jimple*, a simpler three-address code. Jimple is easier to analyze than JVM bytecode, because the addresses relieve from having to extract dataflow information from the stack. Since its inception, Jimple has become the defacto standard for analyzing JVM bytecode and is used by popular Java analysis frameworks such as Doop [25, 9] and Soot [31, 5, 1, 26]. In contrast, we show that abstract definitional interpretation can be used to analyze Wasm code directly, without requiring another intermediate representation, such as Jimple. This is a key advantage of abstract definitional interpretation.

Koren [18] presented an integrated development environment for Wasm that can be used to develop high-performance and latency-sensitive Wasm applications for the internet of things. Such an IDE would benefit from static analyses built with our modular platform, as static analyses can provide valuable feedback to the developer about low-level and hard to understand Wasm programs.

Lehmann et al. [20] and Stiévenart et al. [29] investigated the security risk of compiled Wasm programs. In particular, C applications compiled to Wasm reexperience security problems that are well known and fixed in the native C compiler. More specifically, the compiled C programs are vulnerable to stack and heap-based buffer overflow attacks. These vulnerabilities can be detected by static analyses for Wasm code.

9 Conclusion

In this work, we developed the first whole-program control and data-flow analyses for Wasm based on abstract interpretation. It is important that we understand how to analyze Wasm programs for enabling optimizations and to find bugs and vulnerabilities. Our analyses lay the foundation for that as they scale to real-world programs, where we find 14% of all Wasm instructions are dead code, 10% of all instructions can be replaced by constants, and 56% of all memory accesses are safe against tampering.

Our analyzers are based on two core contributions this paper makes. First, we present a decomposition of the Wasm semantics into 19 language-independent components that abstract different aspects of Wasm. This decomposition allowed us to develop static analyses modularly, which was essential for limiting the complexity of the implementation and the development effort. Second, we show how abstract definitional interpretation can be used to implement modularly defined static analyses for complex languages at scale. We explained how our new framework for abstract definitional interpretation eliminates the inefficiencies of prior frameworks, and why that was crucial for scaling to complex languages and real-world programs. The lessons learned for building abstract definitional Wasm interpreters can certainly be transferred.

Dynamically Updatable Multiparty Session Protocols

Generating Concurrent Go Code from Unbounded Protocols

Nobuko Yoshida ✉ 

University of Oxford, UK

Abstract

Multiparty Session Types (MPST) are a typing disciplines that guarantee the absence of deadlocks and communication errors in concurrent and distributed systems. However, existing MPST frameworks do not support protocols with *dynamic unbounded participants*, and cannot express many common programming patterns that require the introduction of new participants into a protocol. This poses a barrier for the adoption of MPST in languages that favour the creation of new participants (processes, lightweight threads, etc) that communicate via message passing, such as Go or Erlang.

This paper proposes *Dynamically Updatable Multiparty Session Protocols*, a new MPST theory (DMst) that supports protocols with an *unbounded* number of fresh participants, whose communication topologies are *dynamically updatable*. We prove that DMst guarantees deadlock-freedom and liveness. We implement a toolchain, GoScr (Go-Scribble), which generates Go implementations from DMst, ensuring **by construction**, that the different participants will only perform I/O actions that comply with a given protocol specification. We evaluate our toolchain by (1) implementing representative parallel and concurrent algorithms from existing benchmarks, textbooks and literature; (2) showing that GoScr does not introduce significant overheads compared to a naive implementation, for computationally expensive benchmarks; and (3) building three realistic protocols (dynamic task delegation, recursive Domain Name System, and a parallel Min-Max strategy) in GoScr that could not be represented with previous theories of session types.

1 Introduction

Multiparty Session Types. Multiparty Session Types (MPST) are typing disciplines that can guarantee the absence of deadlocks and communication errors in concurrent and distributed systems [21, 22]. MPST allow the specification of *global communication protocols (global types)* among a number of participants. The **projection** operation extracts the *local communication protocols (local types)*, from the point of view of each participant in the

system. Projection only succeeds when the protocol is absent of deadlocks and communication errors. These local types can then be used to typecheck processes [21], generate **correct by construction** code [25, 3], or monitor to detect communication errors at runtime [8].

However, MPST have a severe limitation: they cannot model protocols in which *new participants join the system*. Many important protocols rely on this. For example, Chord [54] is a popular protocol for distributed hash tables where participants join a ring, and relies on a stabilisation protocol to guarantee that each participant keeps up-to-date channels to their successors and predecessors. To model such scenarios using MPST, it would be necessary to *interleave* different sessions. But arbitrary session interleavings can lead to deadlocks, so it must be restricted [2, 5]. This not only rules out the use of MPST for many realistic scenarios, but also limits the applicability of MPST for languages that favour process creation and message passing, such as **Go**, which is the main motivation of our work.

Dynamic (Unbounded) Participants in Go. Go is a concurrent programming language designed in 2009 by Google, and it is increasingly popular among professional developers. According to a 2020 Stack Overflow survey, Go is used by 9.4% of developers, and it is the “third most wanted language” [52]. Go was also the 4th most active language in GitHub in 2020 [16], and it has been adopted in many large software systems such as Kubernetes [32], gRPC [18] and Docker [13]. Its main features are explicit communication primitives, namely *channels* and *goroutines* (lightweight threads), whose design comes from concurrent process calculi [20, 40, 41]. Unfortunately, a recent empirical study reveals that over 50% of Go concurrent bugs are caused by communication [56, 39, 61] (i.e., more than shared memory bugs). While Go includes a global *runtime* deadlock detector, it is neither adequate to verify applications with complex communication structures, nor can it detect deadlocks involving only a strict subset of a program’s goroutines (partial deadlocks) [37].

Figure 1 illustrates Go’s core concurrency constructs. It shows a server (Master) that processes client requests (Line 4), and sends responses back to the Client (Line 20). The Master breaks down the request into different subtasks and delegates them to different Worker goroutines (Lines 7–10). The Master then aggregates the Worker results (Lines 11–19). If the Master receives an error message, it will forward it to the Client and stop processing any new messages (Lines 16–19). This program uses a common Go computation pattern¹, the master-worker pattern, and the number of workers depends on a **runtime value**.

Unfortunately, there is a bug in the implementation in Figure 1. The implementation uses synchronous channels. Since the Master goroutine stops processing Worker responses after receiving the first error message, all other goroutines which have not sent their result or error messages will be **deadlocked**, as they will be stuck waiting for the Master to process their message. One might think that this error could be fixed by replacing the synchronous channels in the implementation with asynchronous (buffered) channels. Unfortunately, this approach leaves *orphan messages* which could introduce other concurrency bugs, e.g. the Master may need to clean up resources after receiving a response from the Workers.

This example demonstrates how even in simple programs, message passing can introduce concurrency bugs and channel leakage, violating **deadlock-freedom** and **liveness**. While, in simple programs, these concurrency bugs can be fixed with relative ease, identifying and fixing them is usually done during testing phase, which becomes increasingly harder as the complexity of the program and the number of goroutines increases. Unfortunately, standard MPST cannot model protocols such as Figure 1, since the number of participants is not fixed at the start, and depends on a run-time value.

```

1 func Worker(n int, resp chan int, err chan error) { ... } // Worker returns either result or error
2 func Master(reqCh chan int, respCh chan []int, cErrCh chan error) {
3   for {
4     ubound := <-reqCh // Receive request from Client
5     workerChs := make([]chan int, ubound) // Array to store worker result channels
6     errCh := make(chan error)
7     for i := 0; i < ubound; i++ { // n_workers depends on runtime value
8       workerChs[i] = make(chan int) // Create worker channel
9       go Worker(i+1, workerChs[i], errCh)
10    }
11    var res []int
12    for i := 0; i < ubound; i++ { // Aggregate worker results
13      select {
14        case sql := <-workerChs[i]: // Aggregate successful result
15          res = append(res, sql)
16        case err := <-errCh: // Some worker failed
17          cErrCh <- err // Propagate error and
18            return // stop processing any further messages
19      }
20    }
    respCh <- res // Send final result to client
  }
}

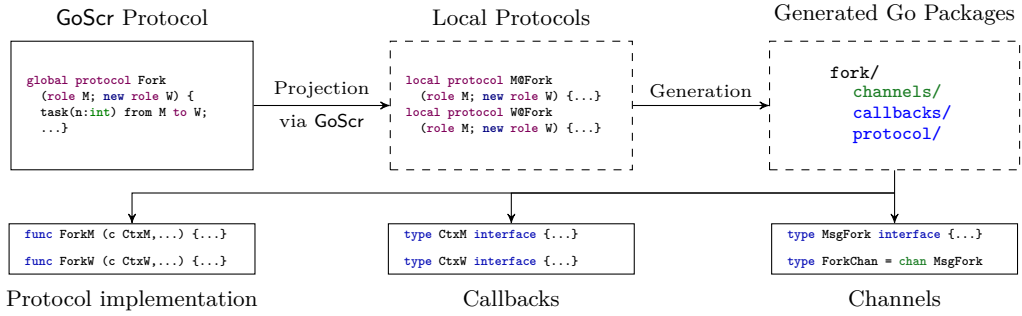

```

■ **Figure 1** Dynamic task delegation implementation in Go (unsafe).

Adding dynamic participants to MPST. This paper introduces *Dynamically Updatable Multiparty Session Types* (DMst), a new theory of MPST whose **novel feature** is to model protocols in which participants can join an already existing session (*dynamic participants*). DMst can guarantee *deadlock-freedom* and *liveness* (*partial-deadlock-freedom*) **by construction** in such protocols. We implement DMst as a tool, GoScr, which generates **correct by construction Go code**, and we evaluate it on a number of representative algorithms in Go, including a safe version of Figure 1 (see § 5.2(a)). While our target language is Go, DMst is not Go specific and a part of GoScr (GoScr protocols, projection and local protocols in Figure 2) is reusable for any language, as long as it supports (1) the creation of new participants (threads or processes) and (2) communication between participants.

Contributions. DMst overcomes several bottlenecks of existing theories on session types (A); and the two main lines of work (B,C) for static deadlock detection in Go:

(A) Dynamic Participants and Session Types. There are two main existing theoretical lines of work related to dynamic MPST. *Dynamic Multirole Session Types* (MRST) [9] enable a set of participants which belong to the same group (i.e. role) to join a multiparty session type. The roles are *fixed at the start*, and can only join at specific points in the protocol, e.g at the beginning of each protocol iteration. *Nested MPST* [7] model protocols with unbounded new participants. Neither MRST nor Nested MPST can represent DMst protocols (A-1) where participants join dynamically to recursive protocols, except at fixed points and with fixed roles (see Example 6). In addition, (A-2) our theory provides stronger guarantees than [7], while their global types are more complex, as they must be checked by a complex typing system. Hence a safe version of Figure 1 cannot be represented by [7, 9]. Both of [9, 7] are *only theoretical*, and lack any implementation or practical results. DMst’s global types are not only more expressive than those in [9, 7], but also simpler, thus DMst is more suitable for real language implementations. Other lines of work add session types to calculi that allow dynamic participants, or extend MPST to specify where can participants join in a protocol, e.g. [19, 57, 58, 30]. While these lines of work can add or replace participants to a system, these participants must act according to known, fixed roles. Therefore, these lines of work do not allow the specification of cyclic recursive topologies that change dynamically with the introduction of new participants.

■ **Figure 2** Overview of GoScr toolchain.

(B) Inference Approach. This approach verifies safety and liveness properties of Go programs, by using model-checking on their *inferred* concurrent behavioural types [47, 36, 37, 14]. The major limitations of this approach are: **(B-1)** there is a gap between properties of types and programs, i.e., there are cases where types satisfy liveness but programs do not, leading to *unsound* verification, and **(B-2)** it cannot verify infinitely spawning goroutines because either the theory is limited to bounded approximation [36] or a decidable set of types are limited to finite-control (i.e. no parallel processes inside loops) [37, 14].

(C) Go Code Generation. Another approach is the generation of Go code from *parameterised* multiparty session protocols [3]. However, the major limitation of [3] is that participants in a protocol still need to be **fixed** at the start of a session, so it cannot express and generate code for typical Go-style programs with goroutines – e.g. a safe version of Figure 1. There is a subtle, but important distinction between dynamic participants and parameterised roles: parameterised roles cannot depend on a run-time value that is exchanged in a message *that is part of the protocol*, because in parameterised MPST approaches, all of the participants must join the session at session initialisation, and are therefore fixed.

Our challenges are to overcome all these limitations with a scalable (implementable) MPST theory. In summary, this work solves bottlenecks of the existing MPST work by proposing a new theory, **DMst**, that allows the dynamic generation of an unbounded number of participants in recursive protocols, overcoming expressiveness issues in [9, 7] **(A)** and **(C)**; unsoundness **(B-1)**, but is not limited to a bounded analysis nor finite-control **(B-2)**.

Outline. § 2 presents an overview of the GoScr toolchain; § 3 presents **DMst**, multiparty session types extended with the ability to add unbounded participants dynamically during a protocol execution, and proves its deadlock-freedom (Theorem 23), orphan message freedom, and liveness (Theorem 29); § 4 describes the code generation process of GoScr, and how to use it to implement **DMst** protocols; § 5 first measures the runtime overhead of the GoScr backend, then demonstrate the expressiveness of **DMst**, comparing the expressiveness of GoScr to **(A)** [47, 36, 37, 14] and **(B)** [3] with a number of case studies. We also implement three use cases – dynamic task delegation, a recursive Domain Name System, a noughts and crosses game with Min-Max strategy – to demonstrate the applicability of GoScr; § 6 gives related work, and § 7 concludes with future work.

2 Overview of GoScr

GoScr follows a typical Multiparty Session Types workflow (see diagram on the right). In this workflow, the starting point is the definition of a *global protocol* (*global type* in MPST), which describes a structured sequence of interactions between a number of participants. From this global type, we extract automatically a number of *local protocols* (*local types*) that describe the interactions (i.e. send or receive actions) from the point of view of every participant in the protocol. This is done using the *projection* operation. If some participant is not projectable, then we raise an error, since the protocol is not well-formed and can lead to deadlocks or other communication errors. If the programmer provides a set of processes that behaves as prescribed by each of the local types, then the whole system is safe. We take a *code generation* approach, where we generate process code from their respective local types, providing safety guarantees *by construction*.

Adding Participants Dynamically. GoScr is a code generation tool which extends nuScr [48] with the theory of DMst, targeting the Go language. nuScr is a new implementation of Scribble [51], aimed at experimenting with extensions to core MPST. Figure 2 presents an overview of GoScr. We distinguish toolchain internals (dashed boxes) from tool inputs (solid boxes). Development starts by specifying a global protocol in GoScr [51, 23], a programmer-friendly protocol description language based on MPST [22, 44]. GoScr validates the well-formedness of the protocol, and produces a local type for each participant via *projection*. GoScr generates protocol implementations from these sets of local types. We provide an overview of the GoScr workflow using the dynamic recursive pipeline of Figure 3. Intuitively, this pipeline introduces a new participant after each iteration.

Global Protocol Specification. The first key novel feature of GoScr is the ability to *define* and *call* protocols (e.g. Line 1 in Figure 3) that may bring new participants to the protocol *dynamically*, specified by the `new` keyword in the signature. These calls can be recursive, allowing for an *unbounded* number of participants. Lines 1–14 declare `UPipe`, which requires only participant `m`, and introduces a new participant `w` dynamically. Protocol calls create any necessary new participants, as well as any necessary channels, before performing the interactions described by the called protocol. The second key novel feature of GoScr is the ability to *modify* a recursive protocol by *combining* (i.e. *interleaving*) its interactions with those of a protocol call. In our syntax, this is specified by *annotating* recursion variables with protocol calls. We call this **updatable recursion**, and an example of this can be found in Line 5. The meaning of such calls is as follows. Suppose that processes r_0 and r_1 are behaving as `m` and `w` (resp.) in `UPipe`. Just before the protocol jumps back to Line 2, process r_1 calls protocol `UPipe(r1)`. This means that r_1 will create a new participant r_2 , and r_1 will *delegate* to r_2 a session to act as `w` in `UPipe`, with r_1 acting as `m`. But at this point, r_1 should act as both `m` and `w`. To address this, r_1 will combine its interactions acting as `m` and `w`. The fact that r_1 needs to change its behaviour to act as *two* distinct roles in `UPipe` will be reflected in its **local protocol specification** (participant `w` in Figure 3).

6:6 Dynamically Updatable Multiparty Session Protocols

```

1 global protocol UPipe(role M;new role W){
2   rec X {
3     choice at M {
4       (Put:int) from M to W;
5       continue X with W calls UPipe(W);
6     } or {
7       (Quit:int) from M to W; }}}
8 local protocol M@UPipe(role M;new role W){
9   rec X {
10    choice at M {
11      (Put:int) to W;
12      continue X;
13    } or {
14      (Quit:int) to W; }}}

local protocol W@UPipe(role M;new role W){
1  choice at M {
2    (Put:int) from M;
3    invite UPipe(self; new W2);
4  }
5  rec X {
6    choice at M {
7      (Put:int) from M;
8      (Put:int) to W2;
9      continue X;
10   } or {
11     (Quit:int) from M;
12     (Quit:int) to W2;
13   }}
14 } or { (Quit:int) from M; }}

```

■ **Figure 3** Global and Local protocols for a dynamic recursive pipeline.

```

2 type Quit int
3 type Ctx_UPipe_W interface {
4   Recv_M_Put(v_2 Put)
5   Init_W_UPipe() Ctx_UPipe_W
6   ...
7   Recv_M_Quit(v_2 Quit)
8   Quit() }
9 func UPipeW(ctx Ctx_UPipe_W,
10 wg *sync.WaitGroup, chMW chan MsgUPipe){
11   defer wg.Done()
12   x_1 := <- chMW
13
14   switch v_2 := x_1.(type) {
15     case Put:
16       ctx.Recv_M_Put(v_2)
17       ch_W_W_1 := make(chan MsgUPipe, 1)
18       ctx_1 := ctx.Init_W_UPipe_Ctx()
19       wg.Add(1)
20       go UPipeW(ctx_1, wg, ch_W_W_1)
21     case Quit:
22       ctx.Recv_M_Quit(v_2)
23       ctx.End() }
24   }
25 }
26

```

■ **Figure 4** Implementation and context of role *W* in *UPipe* in Figure 3.

Local Protocol Specification. GoScr extracts local protocol specifications from global protocols using an operation called *projection*. Local protocols describe the structured sequence of interactions, from the point of view of a single participant. Figure 3 lists local protocols for *M* and *w*. Consider the point of view of the new participant *w* in protocol *UPipe* from Figure 3. *w* first receives an integer, either with label *Put* or *Quit* from *M*. If *w* receives *Quit*, then the protocol finishes. Otherwise, *w* performs a protocol call, bringing in a new participant *w2* to act as *w* in *UPipe*. In the subsequent interactions, from Line 5, *w* acts as both *M* (with respect to *w2*) and *w* (with respect to *M*). These lines (5 – 13) appear as a result of projecting Line 5 onto *w*. Notice that, if we have two participants, one acting as *M* and another one acting as *w*, this will generate a pipeline with an unbounded number of stages, until the first participant acting as *M* sends *Quit*. These kinds of protocols could not be represented in previous MPST theories and frameworks.

Program Logic. From local protocol specifications, GoScr generates the implementation of each role as a self-contained function. GoScr interleaves communication actions and the program logic. Communication actions in Go are a direct translation of those in local protocols: a send is a regular Go send, a receive is a regular Go receive, a choice is a type switch on a label, etc. Programmer inputs at this stage are, therefore, protocol specifications and program logic. We follow a *callback* approach similar to [42, 62] that guarantees correctness of communication *by construction*, unlike other approaches that required runtime *linearity* checks [3]. We discuss this approach in detail in §4. Figure 4 presents the code that

GoScr generates for w in UPipe . The generated implementation requires that the programmer implements the **context** interface Ctx_UPipe_W (Lines 3 – 8, Figure 4). This interface defines all the necessary callbacks to implement the program logic. Programmers can use any type definition to store a local state for each participant in the protocol, e.g.

```

1 type CtxW int // This type implements Ctx_UPipe_W, and stores the accumulated sum
2 func (c *CtxW) Recv_M_Put(v upipe.Put) { // upipe.Put is also an 'int'
3     *c += CtxW(v) }
4 ...

```

By using ctxW for implementing Ctx_UPipe_W , workers will store the sum of all the numbers that they receive, and forward their accumulated sum to the next participant. The generated code for w will signal when it has terminated (Line 11), and starts by receiving from m (Line 12). Depending on whether w receives Put or Quit , w continues with the corresponding branch (Line 14). If m sends Put , then w creates a new participant that also acts as w (with respect to the previous w). To create this participant, first a channel is created (Line 17), then a new context is created (Line 18), the participant count is increased to guarantee that execution does not end before all participants have ended (Line 19), and finally a new goroutine is created (Line 20). Otherwise, if m sends Quit , the callback for ending is called, a last callback to perform any necessary cleanup is called, and the participant ends (Lines 25 and 26).

As we show in Figure 2, from a global protocol specification GoScr produces an implementation of all of its participants. To run this generated implementation, programmers must provide the necessary types to represent protocol contexts and their required callbacks. Our code generation scheme statically ensures that implementations never lead to the errors described in § 1, i.e. there will be no **deadlocks** and **orphan messages**.

3 Dynamically Updatable Unbounded Multiparty Session Protocols

This section introduces the theory of *Dynamically Updatable Multiparty Session Types* (DMst) with examples, and proves that DMst satisfies deadlock-freedom and liveness. DMst is the formalism that underlies GoScr. To illustrate our theory, consider the dynamic pipeline of Figure 3. In this protocol, new participants are introduced into the protocol after each iteration. In DMst, we write this dynamic pipeline as follows:

$$\text{Pipe} = \lambda\langle p; \nu q \rangle. \mu t. (p \rightarrow q: \text{put}[\text{nat}]. (t \blacklozenge q \leftrightarrow \text{Pipe}(q))) + (p \rightarrow q: \text{quit}. \text{end})$$

This protocol definition requires two participants p and q . Participant q is annotated with ν to specify that it is introduced *dynamically* (a *dynamic participant*). Participant p is called a *parameter participant*. The body of the protocol specifies that it is a recursive protocol ($\mu t. \dots$), with recursion variable t , where p sends to q either put or quit . This is a choice (+), where each branch starts with $p \rightarrow q: \text{put}[\text{nat}]$ and $p \rightarrow q: \text{quit}$ respectively. If p sends put , then both participants enter a new iteration, but q *extends* the protocol by performing call to $\text{Pipe}(q \leftrightarrow \text{Pipe}(q))$ before entering the new iteration. Note that although the signature mentions two participants p and q , the call in the global type only needs to list the parameter participants. This protocol call effectively brings in a new participant to the protocol (e.g. r), creates and distributes the necessary additional channels, and extends the interactions of the protocol with those of $\text{Pipe}(q; r)$.

Introducing new interactions into an existing protocol requires to *interleave* them with the actions of this existing protocol. For example, the interactions of $\text{Pipe}(q; r)$ need to be interleaved with the remaining interactions of $\text{Pipe}(p; q)$. Our protocol specification allows two forms of interleavings: (a) sequencing all the interactions of a protocol call with the remaining interactions; and (b) alternating the actions of each iteration of two recursive protocols. We introduce a protocol construct \blacklozenge to specify the latter.

3.1 Global Types of DMst

The syntax of DMst global types (given in Definition 1) is an extension of the simplest version of MPST [60]. The novel added features are **highlighted**.

► **Definition 1** (DMst Global Types).

$$\gamma ::= \mathbf{p} \rightarrow \mathbf{q}:m[U] \mid \mathbf{p} \hookrightarrow x(\vec{\mathbf{q}}) \qquad G ::= \mathbf{end} \mid \gamma.G \mid \sum_{i \in I} G_i \mid \mu \mathbf{t}.G \mid \mathbf{t} \mid G \blacklozenge \vec{\gamma}$$

Prefixes (γ, γ', \dots) represent individual interactions between **participants**, also called **roles**², $(\mathbf{p}, \mathbf{q}, \mathbf{r}, \dots)$. There are two prefixes: messages and protocol calls. A **message** between \mathbf{p} and \mathbf{q} with **label** m and **payload type** U (e.g. `int`, `bool`, ...) is written $\mathbf{p} \rightarrow \mathbf{q}:m[U]$, or $\mathbf{p} \rightarrow \mathbf{q}:m$ whenever the payload is not relevant, e.g. when U is unit. We write $\mathbf{p} \hookrightarrow x(\vec{\mathbf{q}})$ to denote a **call** to protocol x by \mathbf{p} , with participants $\vec{\mathbf{q}} (= \mathbf{q}_1 \dots \mathbf{q}_n)$ (see **protocol definitions** below). A protocol call prefix will introduce the new interactions described by x .

Global types (G, G', \dots) denote global protocols among participants. The syntax of global types is mostly standard: **end** is **termination** and it is often omitted. \mathbf{t} denotes a **recursive variable**. **Choice** $\sum_{i \in I} G_i$ chooses any G_i , depending on the first action of each G_i (see Definition 3). **Recursive protocol** $\mu \mathbf{t}.G$ behaves as G , binding recursive variable \mathbf{t} to $\mu \mathbf{t}.G$. **Sequencing** $\gamma.G$ denotes the execution of a prefix γ , and a continuation G . The new construct $G \blacklozenge \vec{\gamma}$ denotes an **updatable protocol**, where G is extended with the interactions and participants introduced by $\vec{\gamma}$ (if any). When G is a recursive variable \mathbf{t} ($\mathbf{t} \blacklozenge \vec{\gamma}$), we often call these *updatable recursion*, or *updatable recursion variable*. We use updatable protocols to represent recursive protocols where subsequent iterations are extended with new message exchanges and/or participants. We will show in Example 6 how to use updatable recursion to represent the dynamic recursive pipeline of Figure 3.

Choice well-formedness. Standard MPST syntax only allows choices where a participant \mathbf{p} sends to another participant \mathbf{q} a distinct label in each branch. This means that \mathbf{p} and \mathbf{q} can use the label to distinguish each branch of the choice [21, 60]. DMst's syntax is more flexible, since branches can also be distinguished by distinct protocol calls. However, we still require that a single participant either sends a distinct label, or performs a distinct protocol call as the first interaction of each branch. We say that the choices that satisfy this condition are *directed*. Checking that choices are directed is necessary for well-formedness, but it is not sufficient. Protocol well-formedness is defined in a standard way later in Definition 15. To refer to the interaction that occurs in a branch, we use the *extended labels*.

► **Definition 2** (Extended Labels). We define extended labels, $\ell ::= m \mid i @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}})$, where $i @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}})$ identifies a protocol call as the i -th participant of x with participants $\vec{\mathbf{p}}; \vec{\mathbf{q}}$. We use participant index instead of name, since x may give different names to $\vec{\mathbf{p}}$ and $\vec{\mathbf{q}}$.

► **Definition 3** (Directed Choices). Then, we define **dc** (directed choice):

$$\mathbf{dc}(\mathbf{p}, \{\ell_i\}_{i \in I}, \sum_{i \in I} \gamma_i.G_i) = (\forall i \in I. \mathbf{inter}(\mathbf{p}, \ell_i, \gamma_i)) \text{ with all } \ell_i \neq \ell_j \text{ for } i \neq j$$

The predicate $\mathbf{inter}(\mathbf{p}, \ell_i, \gamma_i)$ states that γ_i is an interaction initiated by \mathbf{p} with extended label ℓ_i : $\mathbf{inter}(\mathbf{p}, i @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}}), \mathbf{p} \hookrightarrow x(\vec{\mathbf{q}}))$, if $i \leq \mathbf{size}(\vec{\mathbf{p}}\vec{\mathbf{q}})$, and $\mathbf{inter}(\mathbf{p}, m, \mathbf{p} \rightarrow \mathbf{q}:m[U])$.

² A participant plays a *role* in the protocol, and this role is determined by the structured sequence of interactions that are allowed by the global type.

Protocol definitions ($x = \lambda\langle\vec{q}; \nu\vec{r}\rangle.G$) associate a protocol name x with a global type G , given a sequence of parameter participants \vec{q} , and a sequence of *new* participants \vec{r} (where “ ν ” means “new” [41]) that join the protocol **dynamically** (we call these *dynamic participants*). Any participant occurring in G must be bound by \vec{q} or \vec{r} . Protocol call prefixes ($x\langle\vec{q}\rangle$) only specify the parameter participants, not the dynamic ones. To refer to the global type of a definition, we write $x\langle\vec{q}; \vec{r}\rangle$, with parameter participants \vec{q} , and dynamic participants \vec{r} .

► **Example 4** (Fibonacci). The following protocol represents the interactions of an unbounded series of participants, that together compute the Fibonacci sequence:

$$Fib = \lambda\langle s, f_1, f_2; \nu f_3 \rangle. f_1 \rightarrow f_3:F[int]. f_2 \rightarrow f_3:F[int]. f_3 \rightarrow s:NF[int]. f_3 \hookrightarrow Fib\langle s, f_2, f_3 \rangle.end$$

Fib defines a protocol that recursively creates new participants (f_3 in the global type) to compute the next element of the Fibonacci sequence after receiving the results from the previous two participants (f_1 and f_2). Participant s receives all the results. Intuitively, the implementation of f_3 starts by receiving from f_1 and f_2 , sends the new Fibonacci number to s , and then creates a new participant and continues with f_2 acting as f_1 , and f_3 as f_2 . The code generated by a similar protocol is shown later in Figure 5.

Protocol calls can also be used to represent recursive protocols that are augmented dynamically with new interactions and/or participants. To represent such protocols we use updatable recursion variables. Intuitively, subsequent iterations of a recursive protocol $\mu t.G$ that contains an updatable recursion variable $t \blacklozenge p \hookrightarrow x\langle\vec{q}\rangle$ will proceed as $\mu t.G$ combined with the global type defined by x . Global types are combined by interleaving their interactions.

► **Definition 5** (Combining Recursive Global Types). *Let $cont$ be a function that computes the set of final continuations, i.e. recursion variables or end , after executing all possible prefixes: $cont(\gamma.G) = cont(G)$, $cont(\mu t.G) = cont(G) \setminus \{t\}$, $cont(\sum_{i \in I} G_i) = \cup_{i \in I} cont(G_i)$, $cont(t) = \{t\}$, $cont(G \blacklozenge \gamma) = cont(G)$, $cont(end) = \{end\}$. We define*

$$(\mu t. \sum_{i \in I} G'_i) \blacklozenge (\mu t. \sum_{i \in I} G_i) = \mu t. \sum_{i \in I} (G'_i \blacklozenge_t G_i)$$

where $G' \blacklozenge_t G = [G/t]G'$ if $cont(G') = cont(G) = \{t\}$, $G' \blacklozenge_t G = [G/end]G'$ if $cont(G') = cont(G) = \{end\}$, and is undefined otherwise.

The composition operator takes two recursive protocols with the same branching structure, and combines each of the branches using $G' \blacklozenge_t G$. This operator simply appends the interactions of G after the interactions of G' by substituting either end or t by G . Both G and G' must finish with the same last continuation, either t or end . For example:

$$((\gamma_1. end) + (\gamma_2. t)) \blacklozenge_t ((\gamma_3. end) + (\gamma_4. t)) = (\gamma_1. \gamma_3. end) + (\gamma_2. \gamma_4. t),$$

but the following case is undefined: $((\gamma_1. end) + (\gamma_2. t)) \blacklozenge_t ((\gamma_3. end) + (\gamma_4. t'))$ (if $t \neq t'$)

► **Example 6** (Dynamic Recursive Pipeline). Consider again the dynamic pipeline of Figure 3:

$$Pipe = \lambda\langle p; \nu q \rangle. \mu t. (p \rightarrow q:put[nat]. (t \blacklozenge q \hookrightarrow Pipe\langle q \rangle)) + (p \rightarrow q:quit. end)$$

A set of processes that runs according to this specification would proceed as follows. The first iteration is the same as the first iteration of $Pipe$, but without updatable recursion. This is equivalent to the following global type:

$$G_0 = \mu t. (p \rightarrow q:put[nat]. t) + (p \rightarrow q:quit. end)$$

I.e. participant p would start by sending put or $quit$ to q , and q would receive this message. Subsequent iterations will *combine* G_0 , with the result of the protocol call $(Pipe\langle q \rangle)$. Given a fresh participant r , this is as follows:

$$\begin{aligned} G_1 &= G_0 \diamond \text{Pipe}(\mathbf{q}; \mathbf{r}) = G_0 \diamond (\mu \mathbf{t}. (\mathbf{q} \rightarrow \mathbf{r}: \text{put}[\text{nat}]. (\mathbf{t} \blacklozenge \mathbf{r} \hookrightarrow \text{Pipe}(\mathbf{r}))) + (\mathbf{q} \rightarrow \mathbf{r}: \text{quit}. \text{end})) \\ &= \mu \mathbf{t}. (\mathbf{p} \rightarrow \mathbf{q}: \text{put}[\text{nat}]. \mathbf{q} \rightarrow \mathbf{r}: \text{put}[\text{nat}]. (\mathbf{t} \blacklozenge \mathbf{r} \hookrightarrow \text{Pipe}(\mathbf{r}))) + (\mathbf{p} \rightarrow \mathbf{q}: \text{quit}. \mathbf{q} \rightarrow \mathbf{r}: \text{quit}. \text{end}) \end{aligned}$$

Note that \diamond plugs in the interactions of the first (second) branch of $\text{Pipe}(\mathbf{q}; \mathbf{r})$ after the first (resp. second) branch of G_0 . This has the effect that, after each iteration of the protocol, a new participant will join the pipeline, until the first participant sends message `quit`. Such protocols could not be represented in previous MPST extensions. See §6 for a discussion.

► **Example 7** (Dynamic Ring). DMst can also be used to model protocols, such a *dynamic ring*, in which participants join a recursive ring protocol. Such dynamic rings are at the core of some well-known protocols, such as Chord and its extensions. The protocol in DMst is as follows, omitting choices and payload types for simplicity:

$$\text{Ring} = \lambda \langle \mathbf{i}, \mathbf{p}; \nu \mathbf{q} \rangle. \mu \mathbf{t}. \mathbf{p} \rightarrow \mathbf{q}: \mathbf{N}. \mathbf{t} \blacklozenge (\mathbf{q} \rightarrow \mathbf{i}: \mathbf{N}. \mathbf{i} \hookrightarrow \text{Ring}(\mathbf{i}, \mathbf{q}))$$

The entrypoint is $\text{Ring}(\mathbf{p}, \mathbf{p}; \mathbf{q})$. Subsequent iterations would be combined with new protocol calls (e.g. $\text{Ring}(\mathbf{p}, \mathbf{q}; \mathbf{r})$), producing the following sequences of interactions:

$$G_0 = \mu \mathbf{t}. \mathbf{p} \rightarrow \mathbf{q}: \mathbf{N}. \mathbf{q} \rightarrow \mathbf{p}: \mathbf{N}. \mathbf{t} \quad G_1 = \mu \mathbf{t}. \mathbf{p} \rightarrow \mathbf{q}: \mathbf{N}. \mathbf{q} \rightarrow \mathbf{q}': \mathbf{N}. \mathbf{q}' \rightarrow \mathbf{p}: \mathbf{N}. \mathbf{t} \quad G_2 = \dots$$

3.2 Asynchronous Semantics of DMst Global Types

We guarantee the processes implementing all roles in a global type G indeed behave as G . To characterise the set of behaviours that are allowed by G , we define the semantics of global types as a Labelled State Transition System. The labels are the **observable actions**:

$$\alpha ::= \mathbf{pq}! \ell \mid \mathbf{pq}? \ell \mid \mathbf{pq} \nu i @ x(\vec{\mathbf{r}}; \vec{\mathbf{s}})$$

Observable $\mathbf{pq}! \ell$ is a **send** action from \mathbf{p} to \mathbf{q} with an *extended label* (either a label or a protocol call, see Definition 2). Action $\mathbf{pq}? \ell$ is **receive** and action $\mathbf{pq} \nu i @ x(\vec{\mathbf{r}}; \vec{\mathbf{s}})$ is **participant creation** which brings in \mathbf{q} as a new participant acting as the i -th role in the protocol specified by $x(\vec{\mathbf{r}}; \vec{\mathbf{s}})$. For simplicity, we sometimes write $\mathbf{pq} \nu \ell$ to refer to participant creation, assuming that ℓ is of the form $i @ x(\vec{\mathbf{r}}; \vec{\mathbf{s}})$, for some i , x , $\vec{\mathbf{r}}$ and $\vec{\mathbf{s}}$.

Extended Global Types. We extend the global types (Definition 1) with constructs that capture intermediate states of the execution of a protocol. Note that these intermediate states only appear as a result of applying the rules of the operational semantics, and these will not need to be written by users specifying full protocols. Since extended global types are a superset of Definition 1, we will use the same meta-variable G for both and, unless we specify otherwise, all global types from now on are considered to be extended.

$$\gamma ::= \dots \mid \mathbf{p} \rightarrow \mathbf{q}: \ell[U] \mid \mathbf{p} \rightsquigarrow \mathbf{q}: \ell[U] \mid \mathbf{p} \nu(\vec{\mathbf{r}}: [i, j] @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}})) \mid \triangleright[G]$$

Sending protocol call labels (e.g. $\mathbf{p} \rightarrow \mathbf{q}: i @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}})$) is a form of delegation that is used to perform protocol calls (see **Notations** below). $\mathbf{p} \rightsquigarrow \mathbf{q}: \ell[U]$ means \mathbf{p} has sent a message to \mathbf{q} , yet \mathbf{q} has not received it. $\mathbf{p} \nu(\vec{\mathbf{r}}: [i, j] @ x(\vec{\mathbf{p}}; \vec{\mathbf{q}}))$ represents that \mathbf{p} creates new participants $\vec{\mathbf{r}}$, acting as the i th to j th participants in x , and $\triangleright[G]$ is the nested protocol with global type G . Intuitively, a nested protocol prefix $\triangleright[G_0]. G_1$ is equivalent to sequencing G_0 and G_1 .

Notations. We use notations to break down protocol calls into the individual interactions. Suppose that $\vec{q} = (q_1, \dots, q_n)$ and $\vec{r} = (r_1, \dots, r_m)$. We define $\text{idx}(\mathbf{p}; \vec{q})$ as $\{i\}$, if $\mathbf{p} = q_i$ with $1 \leq i \leq n$, or the empty set $\{\}$ otherwise. We define the following shortcuts:

$$\begin{aligned} \mathbf{p} \rightarrow \vec{q}; \vec{i} @ x(\vec{q}; \vec{r}) &= \mathbf{p} \rightarrow q_1; i_1 @ x(\vec{q}; \vec{r}). \dots \mathbf{p} \rightarrow q_n; i_n @ x(\vec{q}; \vec{r}) \\ \mathbf{p} \text{ call } x(\vec{q}; \vec{r}) &= \mathbf{p} \nu(\vec{r} : [n+1, n+m] @ x(\vec{q}; \vec{r})). \mathbf{p} \rightarrow \vec{q} \setminus \{\mathbf{p}\}; ([1, n] \setminus \text{idx}(\mathbf{p}; \vec{q})) @ x(\vec{q}; \vec{r}) \end{aligned}$$

Notation $\mathbf{p} \rightarrow \vec{q}; \vec{i} @ x(\vec{q}; \vec{r})$ represents a sequence of messages from \mathbf{p} to each of the $q \in \vec{q}$ with the respective extended label. These are sometimes called **invitations** to x . Notation $\mathbf{p} \text{ call } x(\vec{q}; \vec{r})$ is a sequence of actions, where \mathbf{p} first creates \vec{r} , and then sends invitations to \vec{q} , excluding itself to avoid self-communication.

Global Type Equivalence and LTS. We define the erasure of updatable recursive variables as $|t \blacklozenge \gamma|_{t'} = t$ if $t = t'$; and $|t \blacklozenge \gamma|_{t'} = t \blacklozenge \gamma$ otherwise (other cases are homomorphic). The LTS is defined up to the equivalence: (1) $\mathbf{p} \nu(); G \equiv G$; (2) $\triangleright[\text{end}]. G \equiv G$; (3) $\mu t. G \equiv [\mu t. |G|_t / t] G$, and, assuming \vec{r} fresh, (4) $\mathbf{p} \hookrightarrow x(\vec{q}). G \equiv \mathbf{p} \text{ call } x(\vec{q}; \vec{r}). \triangleright[x(\vec{q}; \vec{r})]. G$, and (5) $G \blacklozenge (\vec{\gamma}. \mathbf{p} \hookrightarrow x(\vec{q})) \equiv \vec{\gamma}. \mathbf{p} \text{ call } x(\vec{q}; \vec{r}). (G \blacklozenge x(\vec{q}; \vec{r}))$. Rules (1) and (2) capture that finished prefixes (creating an empty list of participants, or a nested ended global type) can be skipped. Rule (3) is recursion unrolling. Similarly to Example 6, subsequent iterations of the protocol will combine the body of the recursion without updatable recursion variables, with the result of the protocol calls. By this rule, recursion will be updated by protocol calls, and after the first iteration, the protocol can continue as $\mu t. |G|_t$ (possibly combined with the result of a protocol call). Rule (4) expands the sequence of a protocol call and a global type, and rule (5) *updates* a global type by first executing the specified prefixes and then continuing with G combined with the result of the protocol call. We guarantee that new roles are globally fresh by adopting a Barendregt convention on all binders, i.e. each time we access a protocol definition x , we alpha-rename the participants bound by $\nu \vec{r}$ to avoid participant name clashes. Without it, consecutive protocol calls could incorrectly introduce repeated participant names.

► **Definition 8** (Active Participants). *The active participants of a global type (prefix), $\text{pt}(G)$ ($\text{pt}(\gamma)$), is the set of participants that can perform an action in the protocol (or prefix).*

$$\begin{aligned} \text{pt}(\mathbf{p} \rightarrow \mathbf{q}; \ell[U]) &= \{\mathbf{p}, \mathbf{q}\} & \text{pt}(\mathbf{p} \hookrightarrow x(\vec{q})) &= \{\mathbf{p}\} \cup \vec{q} & \text{pt}(\mathbf{p} \rightsquigarrow \mathbf{q}; \ell[U]) &= \{\mathbf{q}\} & \gamma. G &= \text{pt}(\gamma) \cup \text{pt}(G) \\ \text{pt}(\mathbf{p} \text{ call } x(\vec{q})) &= \{\mathbf{p}\} \cup \vec{q} & \text{pt}(\mathbf{p} \nu(\vec{r} : [i, j] @ x(\vec{p}; \vec{q}))) &= \{\mathbf{p}\} \cup \vec{r} & \text{pt}(\triangleright[G]) &= \text{pt}(G) \\ \text{pt}(\text{end}) &= \text{pt}(t) = \{\} & \text{pt}(\mu t. G) &= \text{pt}(G) & \text{pt}(\sum_{i \in I} G_i) &= \bigcup_{i \in I} \text{pt}(G_i) & \text{pt}(G \blacklozenge \gamma) &= \text{pt}(G) \cup \text{pt}(\gamma) \end{aligned}$$

► **Definition 9** (LTS for Global Types). Let the **subject** of an action denote the role that performs it: $\mathbf{p} = \text{subj}(\mathbf{p} \mathbf{q} ! \ell) = \text{subj}(\mathbf{p} \mathbf{q} ? \ell) = \text{subj}(\mathbf{p} \mathbf{q} \nu \ell)$. The LTS for G :

$$\begin{array}{c} \begin{array}{c} \text{[BR-A]} \\ \frac{\forall i \in I, G_i \xrightarrow{\alpha} G'_i}{\sum_{i \in I} G_i \xrightarrow{\alpha} \sum_{i \in I} G'_i} \end{array} \quad \begin{array}{c} \text{[BR-B]} \\ \frac{G_j \xrightarrow{\mathbf{p} \mathbf{q} ! \ell_j} G'_j \quad \text{dc}(\mathbf{p}, \{\ell_i\}_i, \sum_{i \in I} G_i)}{\sum_{i \in I} G_i \xrightarrow{\mathbf{p} \mathbf{q} ! \ell_j} G'_j} \end{array} \quad \begin{array}{c} \text{[NEST]} \\ \frac{G_1 \xrightarrow{\alpha} G_2}{\triangleright[G_1]. G \xrightarrow{\alpha} \triangleright[G_2]. G} \end{array} \\ \text{[NEW]} \quad \mathbf{p}(\mathbf{r}, \vec{r} : [i, j] @ x(\vec{q}; \vec{r}')). G \xrightarrow{\mathbf{p} \nu i @ x(\vec{q}; \vec{r}')} \mathbf{p}(\vec{r} : [i+1, j] @ x(\vec{q}; \vec{r}')). G \\ \text{[SEND]} \quad \mathbf{p} \rightarrow \mathbf{q}; \ell[U]. G \xrightarrow{\mathbf{p} \mathbf{q} ! \ell} \mathbf{p} \rightsquigarrow \mathbf{q}; \ell[U]. G \quad \text{[RECV]} \quad \mathbf{p} \rightsquigarrow \mathbf{q}; \ell[U]. G \xrightarrow{\mathbf{p} \mathbf{q} ? \ell} G \quad \text{[SEQ]} \quad \frac{G \xrightarrow{\alpha} G' \quad \text{subj}(\alpha) \notin \text{pt}(\gamma)}{\gamma. G \xrightarrow{\alpha} \gamma. G'} \end{array}$$

[BR-A] specifies that if an action can be taken in all branches of a choice, it can be taken before the choice is decided. The reason is that if an action can be taken in all branches, then it must be *independent* of the choice. [BR-B] states that if the sender of a choice does an action that selects branch j , then the choice transitions to this branch. [SEQ] states that

6:12 Dynamically Updatable Multiparty Session Protocols

an action can take place in a continuation, if the action does not involve the participants of the prefix. In the prefix transitions, [SEND] (resp. [RECV]) represents a send (resp. receive) action. [NEW] specifies that a new participant \mathbf{r} of the nested protocol is created, and [NEST] represents the execution of an action in the nested global type.

► **Example 10** (DMst Semantics). Consider the following protocol, cf. Example 6:

$$Pipe = \lambda\langle \mathbf{p}; \nu \mathbf{q} \rangle. \mu \mathbf{t}. G_0 \quad \text{with } G_0 = (\mathbf{p} \rightarrow \mathbf{q}; \text{put}[\text{nat}]. (\mathbf{t} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle)) + (\mathbf{p} \rightarrow \mathbf{q}; \text{quit}. \text{end})$$

First, assuming two initial participants (\mathbf{p} and \mathbf{q}), we unfold recursion using \equiv :

$$\mu \mathbf{t}. G_0 \equiv [\mu \mathbf{t}. |G_0|_{\mathbf{t}} / \mathbf{t}] G_0 = (\mathbf{p} \rightarrow \mathbf{q}; \text{put}[\text{nat}]. (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle)) + (\mathbf{p} \rightarrow \mathbf{q}; \text{quit}. \text{end})$$

There are two allowed actions: sending **put** and sending **quit**. By [BR-B] and [SEND],

$$[\mu \mathbf{t}. |G_0|_{\mathbf{t}} / \mathbf{t}] G_0 \xrightarrow{\mathbf{pq}! \text{put}} \mathbf{p} \rightsquigarrow \mathbf{q}; \text{put}[\text{nat}]. (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle)$$

There are now two actions accepted. First, we can use [RECV]:

$$\mathbf{p} \rightsquigarrow \mathbf{q}; \text{put}[\text{nat}]. (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle) \xrightarrow{\mathbf{qp}^? \text{put}} \mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle$$

To enable the second action, we use equivalences to unfold the updatable global type:

$$\begin{aligned} G_1 &= \mathbf{p} \rightsquigarrow \mathbf{q}; \text{put}[\text{nat}]. (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge \mathbf{q} \hookrightarrow Pipe\langle \mathbf{q} \rangle) \\ &\equiv \mathbf{p} \rightsquigarrow \mathbf{q}; \text{put}[\text{nat}]. \mathbf{q} \nu (\mathbf{r} : 2@Pipe(\mathbf{q}; \mathbf{r})). (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge Pipe(\mathbf{q}; \mathbf{r})) \end{aligned}$$

Note that \mathbf{p} is not in the set of active participants of the prefix, so \mathbf{p} can take a step, using repeated applications of [SEQ], in $(\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge Pipe(\mathbf{q}; \mathbf{r}))$.

$$\begin{aligned} \mu \mathbf{t}. G_2 &= (\mu \mathbf{t}. |G_0|_{\mathbf{t}} \blacklozenge Pipe(\mathbf{q}; \mathbf{r})) \\ &= \mu \mathbf{t}. (\mathbf{p} \rightarrow \mathbf{q}; \text{put}[\text{nat}]. \mathbf{q} \rightarrow \mathbf{r}; \text{put}[\text{nat}]. (\mathbf{t} \blacklozenge \mathbf{r} \hookrightarrow Pipe\langle \mathbf{r} \rangle)) + (\mathbf{p} \rightarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end}) \\ &\equiv (\mathbf{p} \rightarrow \mathbf{q}; \text{put}[\text{nat}]. \mathbf{q} \rightarrow \mathbf{r}; \text{put}[\text{nat}]. (\mu \mathbf{t}. |G_2|_{\mathbf{t}} \blacklozenge \mathbf{r} \hookrightarrow Pipe\langle \mathbf{r} \rangle)) + (\mathbf{p} \rightarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end}) \end{aligned}$$

Suppose that G_2 proceeds by \mathbf{p} sending **quit**: $\mu \mathbf{t}. G_2 \xrightarrow{\mathbf{pq}! \text{quit}} (\mathbf{p} \rightsquigarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end})$. Then, G_1 transitions to the following global type:

$$\mu \mathbf{t}. G_1 \xrightarrow{\mathbf{pq}! \text{quit}} \mathbf{p} \rightsquigarrow \mathbf{q}; \text{put}[\text{nat}]. \mathbf{q} \nu (\mathbf{r} : 2@Pipe(\mathbf{q}; \mathbf{r})). \mathbf{p} \rightsquigarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end}$$

After [SQ-A] and [RECV], the global type transitions to:

$$G_3 = \mathbf{q} \nu (\mathbf{r} : 2@Pipe(\mathbf{q}; \mathbf{r})). \mathbf{p} \rightsquigarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end}$$

With [SQ-A] and [NEW], the protocol transitions as follows:

$$G_3 \xrightarrow{\mathbf{qr} \nu 2@Pipe(\mathbf{q}; \mathbf{r})} \mathbf{p} \rightsquigarrow \mathbf{q}; \text{quit}. \mathbf{q} \rightarrow \mathbf{r}; \text{quit}. \text{end}$$

At this stage, \mathbf{r} is a new active participant of the protocol. The remaining global type can run to completion via a sequence of [RECV], [SEND], and finally [RECV].

3.3 Local Types

Local types describe the interactions of a protocol from the point of view of a single participant.

► **Definition 11** (DMst Local Types). Let $M ::= l[U] \mid L$. The syntax of local types is:

$$\pi ::= \mathbf{p}!M \mid \mathbf{p}?M \mid \nu(\vec{\mathbf{p}} : \vec{L}) \mid \triangleright[L] \quad L ::= \text{end} \mid \pi. L \mid \sum_{i \in I} L_i \mid \mu \mathbf{t}. L \mid \mathbf{t} \mid L \blacklozenge \vec{\pi}$$

Local type syntax differs from that of global types in the prefixes (π instead of γ). Local type prefixes are as follows: **send** $\mathbf{p}!M$, **receive** $\mathbf{p}?M$, **new participant creation** $\nu(\mathbf{p}_1 : L_1) \cdots (\mathbf{p}_n : L_n)$, and the **nested local type** $\triangleright[L]$. We lift the definitions of directed choices, updatable recursion erasure, and the composition operator from global types to local types. **Endpoint projection** takes a global type G and a participant \mathbf{r} , and produces the local type (the local interactions) of \mathbf{r} in G .

Similarly to global types, we introduce the notations for protocol calls. Assuming $\vec{\mathbf{q}} = \mathbf{q}_1, \dots, \mathbf{q}_n$ and $\vec{\mathbf{r}} = \mathbf{r}_1, \dots, \mathbf{r}_m$, we define these notations as follows:

$$\begin{aligned} \vec{\mathbf{q}}!i@x(\vec{\mathbf{q}}; \vec{\mathbf{r}}) &= \mathbf{q}_1!i_1@x(\vec{\mathbf{q}}; \vec{\mathbf{r}}). \dots \mathbf{q}_n!i_n@x(\vec{\mathbf{q}}; \vec{\mathbf{r}}) \\ \mathbf{p} \text{ call } x(\vec{\mathbf{q}}; \vec{\mathbf{r}}) &= \nu(\vec{\mathbf{r}} : [n+1, n+m]@x(\vec{\mathbf{q}}; \vec{\mathbf{r}})). \vec{\mathbf{q}} \setminus \mathbf{p}!([1, n] \setminus \text{idx}(\mathbf{p}; \vec{\mathbf{q}}))@x(\vec{\mathbf{q}}; \vec{\mathbf{r}}) \end{aligned}$$

► **Definition 12** (Prefix Projection). *Global type projection is defined in terms of prefix projection. Prefix projection is a partial function that takes a global prefix, and produces a possibly empty (ε) sequence of local prefixes. We give the two main rules:*

$$\begin{aligned} \mathbf{p} \rightarrow \mathbf{q}:l[U] \upharpoonright \mathbf{r} &= \begin{cases} \mathbf{q}!l[U] & \mathbf{p} = \mathbf{r} \neq \mathbf{q} \\ \mathbf{p}?l[U] & \mathbf{p} \neq \mathbf{r} = \mathbf{q} \\ \varepsilon & \mathbf{p}, \mathbf{r}, \mathbf{q} \text{ distinct} \end{cases} & \mathbf{p} \hookrightarrow x(\vec{\mathbf{q}}) \upharpoonright \mathbf{r} &= \begin{cases} \mathbf{p} \text{ call } x(\vec{\mathbf{q}}; \vec{\mathbf{r}}). \triangleright[i@x(\vec{\mathbf{q}}; \vec{\mathbf{r}})] & \mathbf{p} = \mathbf{r} \in_i \vec{\mathbf{q}} \\ \mathbf{p} \text{ call } x(\vec{\mathbf{q}}; \vec{\mathbf{r}}) & \mathbf{p} = \mathbf{r} \notin \vec{\mathbf{q}} \\ \mathbf{p}?i@x(\vec{\mathbf{q}}; \vec{\mathbf{r}}). \triangleright[i@x(\vec{\mathbf{q}}; \vec{\mathbf{r}})] & \mathbf{p} \neq \mathbf{r} \in \vec{\mathbf{q}} \\ \varepsilon & \mathbf{p} \neq \mathbf{r} \notin \vec{\mathbf{q}} \end{cases} \end{aligned}$$

$(\vec{\mathbf{r}} \text{ fresh})$

The projection of $\mathbf{p} \rightarrow \mathbf{q}:l[U]$ onto \mathbf{r} is a *send* if \mathbf{r} is \mathbf{p} , and a *receive* if \mathbf{r} is \mathbf{q} , an empty prefix if all roles are distinct, or undefined if $\mathbf{r} = \mathbf{p} = \mathbf{q}$. The projection of $\mathbf{p} \hookrightarrow x(\vec{\mathbf{q}})$ follows a similar pattern. If \mathbf{r} is \mathbf{p} , then the projected sequence of prefixes is the one that corresponds to making the protocol call, i.e. delegating channels and creating new participants. If \mathbf{r} is the i th participant in $\vec{\mathbf{q}}$, then \mathbf{r} also takes part in the protocol, so the prefixes correspond to the reception of the channel for acting as the i th participant in x , followed by the execution of the nested local type for this i th participant in x , $i@x(\vec{\mathbf{q}}; \vec{\mathbf{r}})$. If \mathbf{r} is both the protocol caller \mathbf{p} , and also takes part in it, then the prefix sequence is the sequence of prefixes for making the protocol call, followed by the nested local type for $i@x$. Note that a participant may call a protocol, and not take part in it. When this happens, the protocol caller simply distributes the necessary channels for executing the nested protocol, and then proceeds to the continuation, without entering the nested protocol.

► **Definition 13** (Projection and Merging). Projection is defined as follows:

$$\begin{aligned} \gamma.G \upharpoonright \mathbf{r} &= \gamma \upharpoonright \mathbf{r}. G \upharpoonright \mathbf{r} & \mathbf{t} \upharpoonright \mathbf{r} &= \mathbf{t} & G \blacklozenge \vec{\gamma} \upharpoonright \mathbf{r} &= \begin{cases} G \upharpoonright \mathbf{r} & (\text{if } \mathbf{r} \notin \vec{\gamma}) \\ G \upharpoonright \mathbf{r} \blacklozenge (\vec{\gamma} \upharpoonright \mathbf{r}) & (\text{if } \mathbf{r} \in \vec{\gamma}) \end{cases} \\ \mu\mathbf{t}.G \upharpoonright \mathbf{r} &= \begin{cases} \mu\mathbf{t}.G \upharpoonright \mathbf{r} & \mathbf{r} \in \text{pt}(G) \text{ or } \\ & \text{fv}(\mu\mathbf{t}.G) \neq \emptyset \\ \text{end} & \text{otherwise} \end{cases} & \sum_{i \in I} G_i \upharpoonright \mathbf{r} &= \begin{cases} \sum_{i \in I} (G_i \upharpoonright \mathbf{r}) & \text{dc}(\mathbf{p}, \vec{\ell}, \sum_{i \in I} G_i), \mathbf{r} = \mathbf{p} \\ \prod_{i \in I} (G_i \upharpoonright \mathbf{r}) & \text{dc}(\mathbf{p}, \vec{\ell}, \sum_{i \in I} G_i), \mathbf{r} \neq \mathbf{p} \end{cases} \end{aligned}$$

Projection is a partial function from global to local types. We lift the definition of directed choices (Definition 3, dc) to local types. We define $\prod_{i \in I} L_i$ as the *merging* operator:

$$\begin{aligned} (1) \quad L \sqcap L &= L & (2) \quad \mu\mathbf{t}.L_1 \sqcap \mu\mathbf{t}.L_2 &= \mu\mathbf{t}.(L_1 \sqcap L_2) \\ (3) \quad \sum_{i \in I} \mathbf{p}?\ell_i[U_i]. L_i \sqcap \sum_{j \in J} \mathbf{p}?\ell_j[U_j]. L'_j &= \\ & \sum_{k \in I \cap J} (\mathbf{p}?\ell_k[U_k]. L_k \sqcap L'_k) + \sum_{i \in I \setminus J} (\mathbf{p}?\ell_i[U_i]. L_i) + \sum_{j \in J \setminus I} (\mathbf{p}?\ell_j[U_j]. L'_j) \end{aligned}$$

The projection rules are standard [60], except the choice. A choice is only defined if it is directed. The projection of the participant that makes the choice is a local type choice of the projection of the branches. The projection for all other participants is the *merging* of the

projection of the branches. Local types can be merged in three cases: (1) they are the same, (2) they are recursive local types whose bodies can be merged, or (3) they become aware of which branch of the choice was taken (if necessary), by receive actions with distinct labels. Case (3) implies that both local types are choices with a receive prefix as the first action, where the continuations for the branches with the same labels can be merged.

It is standard in MPST to define *well-formedness* in terms of *projectability* [21]. This means that if a global type is projectable onto all of its roles, then it is well-formed and therefore live and deadlock-free. Unfortunately, the use of \blacklozenge means that this is not possible with DMst. E.g., the following global type is projectable, but it will get stuck:

$$\begin{aligned} Proto1 &= \lambda\langle \mathbf{p}; \nu \mathbf{r} \rangle. \mu \mathbf{t}. (\mathbf{r} \rightarrow \mathbf{p}:m_1. \text{end}) + (\mathbf{r} \rightarrow \mathbf{p}:m_2. \mathbf{t}) \\ IllFormed &= \lambda\langle \mathbf{p}; \nu \mathbf{q} \rangle. \mu \mathbf{t}. (\mathbf{p} \rightarrow \mathbf{q}:m_1. \text{end}) + (\mathbf{p} \rightarrow \mathbf{q}:m_2. \mathbf{t} \blacklozenge (\mathbf{p} \hookrightarrow Proto1 \langle \mathbf{p} \rangle)) \end{aligned}$$

Specifically, \mathbf{r} in *Proto1* will not become aware of the branch taken by \mathbf{p} in *IllFormed*, so after unfolding *IllFormed* once, we will obtain the following global type:

$$\mu \mathbf{t}. (\mathbf{p} \rightarrow \mathbf{q}:m_1. \mathbf{r} \rightarrow \mathbf{p}:m_1. \text{end}) + (\mathbf{p} \rightarrow \mathbf{q}:m_2. \mathbf{r} \rightarrow \mathbf{p}:m_2. \mathbf{t})$$

But this protocol would not be projectable. To avoid such cases, we define a necessary condition for well-formedness, the *safe protocol update* condition.

► **Definition 14** (Safe Protocol Update). *Suppose that $C[\]$ and $C'[\]$ are 1-hole global type contexts. A global type $\mu \mathbf{t}. C[\mathbf{t} \blacklozenge (\vec{\gamma}. \mathbf{p} \hookrightarrow x(\vec{\mathbf{q}}))]$ contains a safe update if its 1-unfolding is some $C'[G \blacklozenge (\vec{\gamma}. \mathbf{p} \hookrightarrow x(\vec{\mathbf{q}}))]$, such that given a sequence of fresh roles $\vec{\mathbf{r}}$, $G \blacklozenge x(\vec{\mathbf{q}}; \vec{\mathbf{r}})$ is projectable.*

► **Definition 15** (Projection and Well-Formed Global Types). *A global type G is projectable if its projection $G \upharpoonright \mathbf{r}$ is defined on all roles $\mathbf{r} \in G$. A global type is well formed iff it is projectable, and contains only safe protocol updates.*

► **Definition 16** (Projections of Protocol Definitions). *Assume a definition $x = \lambda\langle \vec{\mathbf{p}}; \nu \vec{\mathbf{p}}' \rangle. G$, with participants $\vec{\mathbf{p}} = (\mathbf{p}_1, \dots, \mathbf{p}_n)$ and with participants $\vec{\mathbf{p}}' = (\mathbf{p}_{n+1}, \dots, \mathbf{p}_m)$. The projections of x are the local protocol definitions that correspond to each of the participants in the protocol:*

$$1 @ x = \lambda\langle \vec{\mathbf{p}}; \nu \vec{\mathbf{p}}' \rangle. G \upharpoonright \mathbf{p}_1 \quad \dots \quad m @ x = \lambda\langle \vec{\mathbf{p}}; \nu \vec{\mathbf{p}}' \rangle. G \upharpoonright \mathbf{p}_m$$

► **Example 17** (Directed Choices and Merging). *BFib* computes the n -th Fibonacci number:

$$\begin{aligned} BFib &= \lambda\langle \mathbf{r}, \mathbf{f}_1, \mathbf{f}_2; \nu \mathbf{f}_3 \rangle. \mathbf{f}_1 \rightarrow \mathbf{f}_3: F[\text{int}]. \\ &\quad \mathbf{f}_2 \rightarrow \mathbf{f}_3: F[\text{int}]. ((\mathbf{f}_3 \rightarrow \mathbf{r}: \text{NF}[\text{int}]. \mathbf{f}_3 \rightarrow \mathbf{f}_2: \text{quit}. \text{end}) + (\mathbf{f}_3 \hookrightarrow BFib \langle \mathbf{r}, \mathbf{f}_2, \mathbf{f}_3 \rangle. \text{end})) \end{aligned}$$

This protocol is similar to that of Example 4, but instead of calling *BFib* indefinitely, the protocol offers a choice: \mathbf{f}_3 will either reply to \mathbf{r} with its Fibonacci number, or call *BFib* recursively to compute the next number. Participant \mathbf{f}_3 selects the branch of the protocol that is taken, and \mathbf{r} offers the two branches. The choice has a single sender, and both branches can be distinguished by the labels or protocol calls, so the choice is *directed* by \mathbf{f}_3 , with extended labels $\vec{\ell} = \text{NF}, i @ BFib(\mathbf{r}, \mathbf{f}_2, \mathbf{f}_3; \mathbf{f}_4)$. In a directed choice, one participant decides the branch. But how do the remaining participants *know* which branch was taken? Consider \mathbf{f}_1 in *BFib*. Its part in both branches of the protocol is the same, *end*, so we can project \mathbf{f}_1 in the choice as *end*. This is one of the cases of Definition 13: two local types can be merged if they are the same. But \mathbf{f}_2 's behaviour is different in each branch: $\mathbf{f}_3? \text{quit}. \text{end}$ and $\mathbf{f}_3? 2 @ BFib(\mathbf{r}, \mathbf{f}_2, \mathbf{f}_3; \mathbf{f}_4). \text{end}$ respectively. However, \mathbf{f}_2 is *aware* of the branch that was taken by receiving either label *quit* or protocol call label $2 @ BFib(\mathbf{r}, \mathbf{f}_2, \mathbf{f}_3; \mathbf{f}_4)$. This is case (3), as explained after Definition 13:

$$(\mathbf{f}_3?quit. end) \sqcap (\mathbf{f}_3?2@BFib(\mathbf{r}, \mathbf{f}_2, \mathbf{f}_3; \mathbf{f}_4). end) = (\mathbf{f}_3?quit. end) + (\mathbf{f}_3?2@BFib(\mathbf{r}, \mathbf{f}_2, \mathbf{f}_3; \mathbf{f}_4). end)$$

► **Example 18** (Projecting Pipeline). Consider again Example 6. We are projecting the first and second participants of x . The result of the syntactic projection is as follows:

$$\begin{aligned} x(\mathbf{p}; \mathbf{q}) &= \mu t. (\mathbf{p} \rightarrow \mathbf{q}; put[nat]. (t \blacklozenge \mathbf{q} \hookrightarrow x(\mathbf{q}))) + (\mathbf{p} \rightarrow \mathbf{q}; quit. end) \\ 1@x(\mathbf{p}; \mathbf{q}) &= \mu t. (\mathbf{q}!put[nat]. t) + (\mathbf{q}!put[nat]. end) \\ 2@x(\mathbf{p}; \mathbf{q}) &= \mu t. (\mathbf{p}?put[nat]. (t \blacklozenge (\text{call } x(\mathbf{q}; \mathbf{r}). \mathbf{q}?q1@x(\mathbf{q}; \mathbf{r}). \triangleright[1@x(\mathbf{q}; \mathbf{r}]))) + (\mathbf{p}?quit. end) \end{aligned}$$

3.4 Semantics of DMst Local Types and Correctness

The semantics for local types is defined for **local type configurations**. A configuration is a pair of *channel* and *participant* environments, $\langle \Delta ; \Theta \rangle$. The channel environment Δ contains the shared channels used for the asynchronous communication between each pair of participants, and the participant environment Θ is a set of the local types of all participants:

$$\Delta = \mathbf{p}_i \mathbf{q}_j :: \vec{w}_1, \dots, \mathbf{p}_k \mathbf{q}_l :: \vec{w}_n \quad \mathbf{w} ::= \ell[U] \quad \Theta = \{\mathbf{p}_1 :: L_1, \dots, \mathbf{q}_m :: L_m\}$$

\mathbf{w} denotes a *payload* of a message. We consider the channel and participant environments up to commutativity and associativity, since all entries must be disjoint. Channels \mathbf{pq} are channels of messages to \mathbf{p} from \mathbf{q} . We use $\Delta(\mathbf{pq})$ as notation for retrieving channel \mathbf{pq} , and $\Delta[\mathbf{pq} :: \vec{w}]$ for updating channel \mathbf{pq} with \vec{w} . Θ does not impose the ordering between the entries (like a set). We update the entry by writing $\Theta[\mathbf{p} :: L] = \mathbf{p} :: L, (\Theta \setminus \mathbf{p})$.

The semantics of configurations is defined by the LTS of local types and given in Definition 19, and it is defined up to local type equivalences, analogous to those of global types: (1) $\mu t.L \equiv \vec{\pi}. end$ if $L = t \blacklozenge \vec{\pi}$; (2) $[\mu t. |L|_t / t]L$ if $L \neq t \blacklozenge \vec{\pi}$, (3) $L \blacklozenge (\vec{\pi}. \pi) \equiv \vec{\pi}. \pi. L$, if $\pi \neq \triangleright[L']$, and (4) $L \blacklozenge (\vec{\pi}. \pi) \equiv \vec{\pi}. (L \blacklozenge L')$, if $\pi = \triangleright[L']$. The semantics of choices requires that they are directed. At the local type, all branches start with a send/receive prefix to/from the same participant \mathbf{p} . We use the predicate $dc(\mathbf{p}, \{\ell_i\}_i, \sum_{i \in I} \pi_i. L_i)$, and define it analogously to the predicate for global types.

► **Definition 19** (LTS for Local Types). The LTS for local types is defined as follows:

$$\begin{aligned} \text{[L-CONG]} \frac{\langle \Delta ; \mathbf{p} :: L \rangle \xrightarrow{\alpha} \langle \Delta' ; \Theta' \rangle}{\langle \Delta ; \mathbf{p} :: L, \Theta \rangle \xrightarrow{\alpha} \langle \Delta' ; \Theta', \Theta \rangle} \quad \text{[L-NEST]} \frac{\langle \Delta ; \mathbf{p} :: L' \rangle \xrightarrow{\alpha} \langle \Delta' ; \mathbf{p} :: L'', \Theta \rangle}{\langle \Delta ; \mathbf{p} :: \triangleright[L']. L \rangle \xrightarrow{\alpha} \langle \Delta' ; \mathbf{p} :: \triangleright[L'']. L, \Theta \rangle} \\ \text{[L-CHOICE]} \frac{j \in I \quad \langle \Delta ; \mathbf{p} :: L_j \rangle \xrightarrow{\alpha} \langle \Delta' ; \Theta \rangle \quad dc(\mathbf{q}, \vec{\ell}, \sum_{i \in I} L_i)}{\langle \Delta ; \mathbf{p} :: \sum_{i \in I} L_i \rangle \xrightarrow{\alpha} \langle \Delta' ; \Theta \rangle} \\ \text{[L-SEND]} \langle \Delta, \mathbf{qp} :: \vec{w} ; \mathbf{p} :: \mathbf{q}! \ell[U]. L \rangle \xrightarrow{\mathbf{pq}! \ell} \langle \Delta, \mathbf{qp} :: \vec{w} \cdot \ell[U] ; \mathbf{p} :: L \rangle \\ \text{[L-RECV]} \langle \Delta, \mathbf{pq} :: \ell[U] \cdot \vec{w} ; \mathbf{p} :: \mathbf{q}? \ell[U]. L \rangle \xrightarrow{\mathbf{pq}? \ell} \langle \Delta, \mathbf{pq} :: \vec{w} ; \mathbf{p} :: L \rangle \\ \text{[L-NEW]} \langle \Delta ; \mathbf{p} :: \nu(\mathbf{q}_i : L_i) \cdots (\mathbf{q}_j : L_j) \rangle \xrightarrow{\mathbf{pq}_i \nu L_i} \langle \Delta ; \mathbf{q}_i :: L_i, \mathbf{p} :: \nu(\mathbf{q}_{i+1} : L_{i+1}) \cdots (\mathbf{q}_j : L_j) \rangle \end{aligned}$$

[L-CONG] specifies a step by a participant in the configuration. [L-RECUR] unfolds recursion, and [L-CHOICE] selects one branch of a choice by performing a step into one of the continuations. In [L-CHOICE], only one action can take place in one branch, because the labels of all branches must be distinct for the choice to be directed. [L-SEND] executes a send prefix by enqueueing the label and the payload type into the channel of the receiver, [L-RECV] executes a receive prefix by dequeuing the label and payload type from the corresponding channel, [L-NEW] creates a new participant by composing its associated local type in parallel with the remainder

6:16 Dynamically Updatable Multiparty Session Protocols

of the local type environment, [L-NEST] performs a step into a nested local type. We allow the renaming of participants introduced by [L-NEW] to avoid participant name clashes. For simplicity, we assume that Δ always contains a (possibly empty) sequence of payloads for every pair of roles. For example, if \mathbf{pq} is not in Δ , we allow to match Δ with $\Delta, \mathbf{pq} :: \epsilon$.

We prove the correctness of DMst: (1) the global type semantics coincides with behaviours of local endpoints, a well-formed global type is (2) deadlock-free and (3) live. (1) together with (2) and (3) imply that the programs generated from local types projected from well-formed global types are deadlock-free and live.

We define **the projection of G** as $\llbracket G \rrbracket = \langle [] ; \mathbf{p} :: G \upharpoonright \mathbf{p}, \dots, \mathbf{q} :: G \upharpoonright \mathbf{q} \rangle$, for all $\mathbf{p}, \dots, \mathbf{q} \in \text{pt}(G)$. A configuration is a subtype of another if it contains the same participants and their local types are related under the standard subtyping relation [60], i.e., $\langle \Delta ; \Theta \rangle \leq \langle \Delta' ; \Theta' \rangle$ implies that $\Theta(\mathbf{p}) \leq \Theta'(\mathbf{p})$ for all \mathbf{p} .

► **Theorem 20** (Trace Equivalence). *If $\langle \Delta ; \Theta \rangle \leq \llbracket G \rrbracket$, then $\Gamma \vdash G \xrightarrow{\alpha^*} G'$ if and only if there exists $\langle \Delta' ; \Theta' \rangle$ such that $\langle \Delta ; \Theta \rangle \xrightarrow{\alpha^*} \langle \Delta' ; \Theta' \rangle$ and $\langle \Delta' ; \Theta' \rangle \leq \llbracket G' \rrbracket$.*

Proof. The full proof uses the extended projection, that produces both local types and the queue contents implicit in the intermediate forms. The core part of the proof is completed by induction on the derivations for the global and local type LTS, using the fact that if $G \equiv G'$, then $G \upharpoonright \mathbf{r} \equiv G' \upharpoonright \mathbf{r}$. ◀

A configuration $\langle \Delta ; \Theta \rangle$ is *final* if for all $\mathbf{pq} \in \text{dom}(\Delta)$, $\Delta(\mathbf{pq}) = \epsilon$, and for all $\mathbf{p} \in \text{dom}(\Theta)$, $\Theta(\mathbf{pq}) = \text{end}$. The configuration is in a *deadlock* if it cannot make progress and it is not final, i.e. the protocol has not ended, and all participants are stuck.

► **Definition 21** (Deadlock). $\langle \Delta ; \Theta \rangle$ is a *deadlock configuration* if there exists a sequence of actions α^* such that $\langle \Delta ; \Theta \rangle \xrightarrow{\alpha^*} \langle \Delta' ; \Theta' \rangle$, with $\langle \Delta' ; \Theta' \rangle$ not final and for all action α , $\langle \Delta' ; \Theta' \rangle \not\xrightarrow{\alpha}$.

► **Example 22** (Deadlock Configuration). A deadlock configuration is one in which the whole system can get stuck and cannot progress. A usual example of this is a configuration where all participants need to receive, but their messages have not been sent. We show below such configuration, where after one action, it reaches a receive cycle:

$$\begin{array}{l} \langle [\quad] ; \mathbf{p} :: \mathbf{q}!l[U]. \mathbf{q}?l[U]. L_1, \mathbf{q} :: \mathbf{r}?l[U]. L_2, \mathbf{r} :: \mathbf{p}?l[U]. L_3 \rangle \xrightarrow{\mathbf{pq}!l} \\ \langle [\mathbf{qp} :: l[U]] ; \mathbf{p} :: \mathbf{q}?l[U]. L_1, \mathbf{q} :: \mathbf{r}?l[U]. L_2, \mathbf{r} :: \mathbf{p}?l[U]. L_3 \rangle \not\xrightarrow{\alpha} \end{array}$$

► **Theorem 23** (Deadlock-Freedom). *If $\langle \Delta ; \Theta \rangle \leq \llbracket G \rrbracket$, then $\langle \Delta ; \Theta \rangle$ is deadlock-free.*

Proof. We show that either G is ended, or there is a step available for G , and use trace equivalence to conclude this for $\langle \Delta ; \Theta \rangle \leq \llbracket G \rrbracket$. ◀

Theorem 23 refers exclusively to the absence of *global* deadlocks, i.e. the whole system will never get stuck. But DMst also guarantees the absence of *local* deadlocks, i.e. that no participant in the system gets stuck. An example of such partial deadlocks is the usual *receive-cycle*, where a subset of participants are waiting forever, and can never make progress. DMst guarantees that this situation cannot happen. To prove this, we first show that DMst guarantees *orphan message freedom* [10], which means that all messages are eventually consumed without a type mismatch.

► **Definition 24** (Orphan Message). $\langle \Delta ; \Theta \rangle$ has an *orphan message* if there exists $\mathbf{w} \in \Delta(\mathbf{pq})$ but there exists no transition such that consumes it, i.e. there is no transition $\langle \Delta ; \Theta \rangle \xrightarrow{\alpha^*} \langle \Delta' ; \Theta' \rangle$ with $\mathbf{pq}?|\mathbf{w}| \in \alpha^*$.

► **Example 25** (Orphan Message). Orphan messages can occur whenever a send prefix is not coupled with the corresponding receive, thus leaving a message *hanging* in the corresponding buffer. For example, the following situation contains an orphan message:

$$\begin{aligned} & \langle [\quad] ; \mathbf{p} :: \mathbf{q}!l[U]. \mathbf{q}?l[U]. \text{end}, \mathbf{q} :: \mathbf{p}!l[U]. \text{end} \rangle \xrightarrow{\mathbf{pq}!l} \\ & \langle [\mathbf{qp} :: l[U]] ; \mathbf{p} :: \mathbf{q}?l[U]. \text{end}, \mathbf{q} :: \mathbf{p}!l[U]. \text{end} \rangle \xrightarrow{\mathbf{qp}!l \cdot \mathbf{pq}!l} \langle [\mathbf{qp} :: l[U]] ; \mathbf{p} :: \text{end}, \mathbf{q} :: \text{end} \rangle \end{aligned}$$

At the end of the execution, the configuration contains a non-empty buffer: $\mathbf{qp} :: l[U]$.

Another example of orphan messages is one in which the reduction gets stuck because of receiving a message of the wrong type or label, i.e. there is a reception error.

$$\begin{aligned} & \langle [\quad] ; \mathbf{p} :: \mathbf{q}!l[\text{int}]. \text{end}, \mathbf{q} :: \mathbf{p}?l[\text{bool}]. \text{end} \rangle \xrightarrow{\mathbf{pq}!l} \\ & \langle [\mathbf{qp} :: l[\text{int}]] ; \mathbf{p} :: \text{end}, \mathbf{q} :: \mathbf{p}?l[\text{bool}]. \text{end} \rangle \not\rightarrow \end{aligned}$$

In this case, reduction cannot continue, and the message $\mathbf{qp} :: l[\text{int}]$ cannot be consumed, because \mathbf{q} is expecting payload type bool .

Proving that DMst guarantees the absence of orphan messages relies on the absence of *blocked local types*. A blocked local type is a local type that contains a nested session that cannot terminate, followed by a non-empty continuation. For example, if $L = \triangleright[\mu\mathbf{t}.\mathbf{q}_2!l'[U']. \mathbf{t}]. \mathbf{p}?l[U]$, then L is blocked, because it will enter the nested protocol (with local type $\mu\mathbf{t}.\mathbf{q}_2!l'[U']. \mathbf{t}$), but it will never be able to continue executing $\mathbf{p}?l[U]$.

► **Definition 26** (Blocked Participant). A *blocked* local type is one that contains a continuation of the form $\triangleright[L_1]. L_2$, where: (a) L_1 is blocked, or (b) $L_2 \neq \text{end}$ and end is not reachable from L_1 .

► **Definition 27** (Liveness). We say that $\langle \Delta ; \Theta \rangle$ is *live*, if no participant is stuck. A participant \mathbf{p} is stuck in a configuration whenever it cannot progress, i.e. if $\Theta(\mathbf{p}) = L$ with $L \neq \text{end}$, but there is no trace $\langle \Delta ; \Theta \rangle \xrightarrow{\alpha^*} \langle \Delta' ; \Theta' \rangle$ with $\mathbf{p} = \text{subj}(\alpha)$ and $\alpha \in \alpha^*$.

► **Example 28** (Stuck Participant). The following configuration is *not live*, because even if \mathbf{p} and \mathbf{q} can continue interacting, \mathbf{r} and \mathbf{s} are stuck in a local receive cycle:

$$\begin{aligned} & \langle [\quad] ; \mathbf{p} :: \mu\mathbf{t}.\mathbf{q}!l[U]. \mathbf{t}, \mathbf{q} :: \mu\mathbf{t}.\mathbf{p}?l[U]. \mathbf{t}, \mathbf{r} :: \mathbf{s}?l[U]. L_3, \mathbf{s} :: \mathbf{r}?l[U]. L_4 \rangle \xrightarrow{\mathbf{pq}!l \cdot \mathbf{qp}!l} \\ & \langle [\quad] ; \mathbf{p} :: \mu\mathbf{t}.\mathbf{q}!l[U]. \mathbf{t}, \mathbf{q} :: \mu\mathbf{t}.\mathbf{p}?l[U]. \mathbf{t}, \mathbf{r} :: \mathbf{s}?l[U]. L_3, \mathbf{s} :: \mathbf{r}?l[U]. L_4 \rangle \xrightarrow{\alpha^*} \dots \end{aligned}$$

No possible trace can contain $\mathbf{rs}?l$ or $\mathbf{sr}?l$. Participants \mathbf{r} and \mathbf{s} are stuck. Note that, from Definition 19, only receive prefixes can get stuck, since send prefixes will always succeed.

► **Theorem 29** (Orphan Message Freedom and Liveness).

Suppose $\langle \Delta ; \Theta \rangle \leq \llbracket G \rrbracket$, such that Θ contains no blocked participants. Then $\langle \Delta ; \Theta \rangle$ is free of orphan messages and live.

Proof. Liveness is a straightforward consequence of orphan message freedom. The prefix of a local type can have two kinds of actions: outputs (sending data or invitations), or inputs (receiving data, or accepting invitations). Every input is coupled with an output by another participant (see Definition 13). Hence outputs can always be performed, in any state. To prove that inputs can always be consumed, we use trace equivalence. We show that any pending message can be received, since a step can only happen in a continuation if its subject is not in any of the previous prefixes, and it is always possible to end nested protocols, because they cannot be blocked. ◀

► **Proposition 30.** As a consequence of Theorems 23, 29 and 20, the global types of Example 10 are live and deadlock-free.

4 GoScr Code Generation

This section describes the GoScr toolchain. GoScr is an extension of nuScr [48], which is a new implementation of Scribble in OCaml. nuScr is designed with modularity and extensibility in mind, so that extensions of the core MPST theory [60] can be easily integrated.

GoScr Global Protocols. The syntax of GoScr global protocols is given in Definition 31.

► **Definition 31** (GoScr syntax).

$$\begin{aligned}
 P &::= \text{global protocol } x(\text{role } \mathbf{p}_1, \dots, \text{role } \mathbf{p}_n; \text{new role } \mathbf{q}_1, \dots, \text{role } \mathbf{q}_m) \{P^* G\} \\
 g &::= m[U] \text{ from } \mathbf{p} \text{ to } \mathbf{q} \mid \mathbf{p} \text{ calls } x(\mathbf{p}_1, \dots, \mathbf{p}_n) \\
 G &::= \text{choice at } \mathbf{p} \{G_1\} \text{ or } \dots \text{ or } \{G_n\} \mid g; G \mid \text{rec } \mathbf{t} \{G\} \mid \text{continue } \mathbf{t} \mid \text{end} \\
 &\quad \mid \text{continue } \mathbf{t} \text{ with } \{g_1; \dots; g_n; \mathbf{p} \text{ calls } x(\mathbf{p}_1, \dots, \mathbf{p}_n)\} \mid \text{do } x(\mathbf{p}_1, \dots, \mathbf{p}_n); G
 \end{aligned}$$

A GoScr module is a sequence of one or more **global** protocols. The last protocol definition is the entry point. The constructs of GoScr were chosen to mirror those defined in Definition 1: **global protocol** are protocol definitions ($x = \lambda\langle\vec{\mathbf{p}}; \nu\vec{\mathbf{q}}\rangle.G \dots$; **global protocol** can be used for protocol declarations with no new participants; **choice at p** defines directed choices from **p** to the receiver of the first interaction in the G_i ; **do** is a protocol call to a global protocol; and the rest of the constructs correspond to those of DMst. Protocol definitions in GoScr can start by defining other nested protocols, but this is simply a syntactic convenience, since we require every role in a nested protocol to be bound by the protocol signature.

Steps for Code Generation. The steps of code generation in GoScr are: (1) lifting all nested protocol definitions to the top-level; (2) obtaining the projections of all roles in all protocol definitions; (3) preprocessing local types to deal with instances of \blacklozenge (or **continue...with...** in GoScr); and, (4) translating the local types to Go functions, where communication is implemented using Go channels, interleaved with *callbacks* that will be used to implement the program logic.

Step (1) is straightforward. Step (2) is an implementation of Definition 13. Step (3) requires applying local type equivalences to unfold any updatable recursion. Step (4) traverses the local types, and generates on demand the necessary channels and callback interfaces. The type of the Go channels is an interface that represents the allowed payload types. Then, for each labelled message exchange: (1) we add a new type declaration for the label and payload type that implements the interface of allowed messages; (2) we search for a channel for the required endpoints, creating it if necessary; (3) we create the necessary callbacks before or after the interaction. The channels can be created either synchronous, or buffered with a user-specified size. Choosing synchronous channels is safe, since the traces accepted by using synchronous semantics is a subset of those accepted by our asynchronous semantics, which implies that the same safety properties will hold.

Go Code Generation. The Go code for each role and protocol is generated in `protocol/`. Communication is implemented using regular Go send/receive statements. There is no need to explicitly send message labels, since labels are encoded as type declarations. Protocol choices are encoded as type switches, either on the value returned from a previous callback (internal choices), or on the received value (external choices). We only generate implementations for branching choices that start with an explicit interaction.

```

1 func BFib_F2(ctx Ctx_BFib_F2, wg *sync.WaitGroup, ch_F2_F3, ch_F3_F2 chan MsgBFib) {
2     x := ctx.Send_F3_BFib_Fib2() // Callback to generate payload
3     ch_F3_F2 <- x // Send payload to F3
4     x_1 := <- ch_F2_F3 // External choice by from F3
5     switch v := x_1.(type) {
6     case End: // F3 chooses to finish the protocol
7         ctx.Recv_F3_BFib_End(v) // Callback for processing label End
8         ctx.End()
9         return
10    case Call_F1_BFib: // F3 sends the channel for acting as F1 in BFib
11        ctx_1 := ctx.Init_F1_BFib_Ctx() // Initialise context for F1 in BFib
12        BFib_F1(ctx_1, wg, v) // Run code for F1 in BFib with channel [v]
13        ctx.End_F1_BFib_Ctx(ctx_1) // Close context for F1 in BFib
14        ctx.End()
15        return
16    } }

```

■ **Figure 5** Implementation of role **F2** in protocol **BFib**.

Calling a nested protocol is implemented as regular Go function calls. `rec` constructs are generated as labelled `for` loops, where the body of the recursion is used to generate the body of the `for` loop, and recursive variables are translated as `continue` to the label of the corresponding variable. It is also possible to represent recursion using protocol calls. However, protocol calls would need to create the necessary channels and send them to any participant in the protocol, thus being less efficient than using `rec` and `for`.

4.1 Linearity and CFSM Code Generation

Program logic is defined through *callbacks*, similar to [42, 62], to avoid the *linearity* problem of previous Communicating Finite State Machine approaches (e.g. [3]). In a CFSM approach, code generation from a local protocol produces a series of interfaces that encode the protocol states. Each protocol state exposes *only* the permitted actions (e.g. send/receive), and returns the next state in the protocol. Programmers must use such states to implement their program logic. The linearity problem arises from the fact that nothing prevents programmers from mistakenly using the same protocol state again. For example, suppose that st_0, st_1, \dots , are protocol states that expose different send/recv actions. A programmer might (mistakenly) save state st_1 and perform its action twice in the implementation. In the Go code snippet below, st_1 is used both in Line 2 and Line 4, violating linearity:

```

1 st1 := st0.send_Msg_to_p(x)
2 st2 := st1.recv_Lbl_from_p(&z)
3 ...
4 stn := st1.recv_Lbl_from_p(&buffer) /* linearity error at st1 */

```

If participant p does not send any other message, then this implementation will **deadlock**. If p does send another message, this might cause a run-time error. A callback-based approach solves this problem *by construction*, since channels are not exposed to programmers [42, 62].

4.2 Example of Generated Go Code

Consider the following GoScr global type:

```

1 global protocol BFib(role Res, role F1, role F2; new role F3) {
2     Fib1(v:int) from F1 to F3; Fib2(v:int) from F2 to F3;
3     choice at F3 {
4         F3 calls BFib(Res, F2, F3);
5     } or {
6         Result(fib:int) from F3 to Res; End() from F3 to F2; }}

```

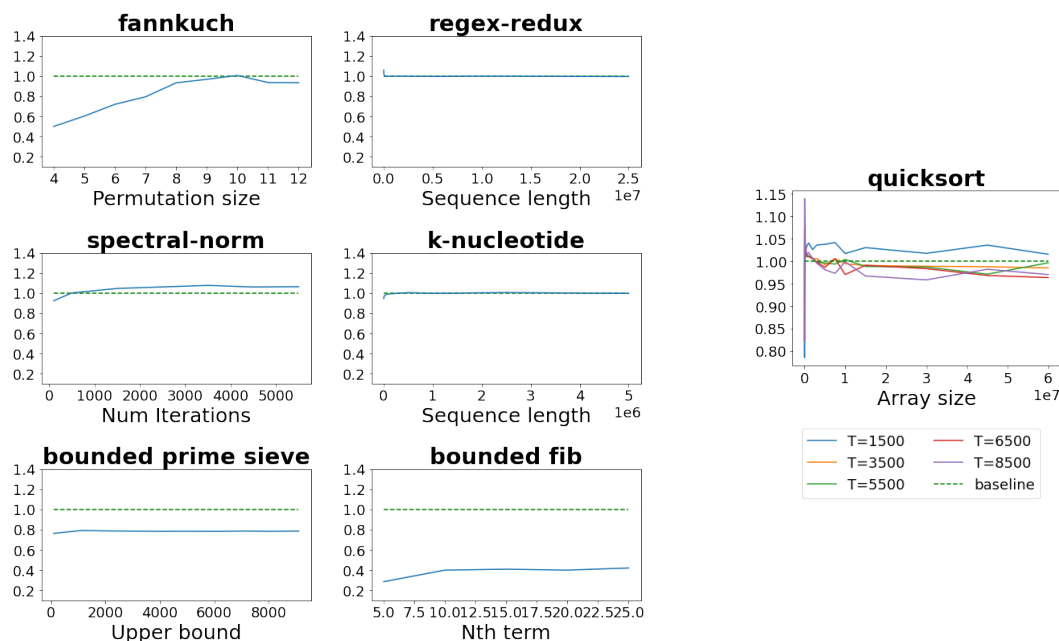

This is a *bounded* version of Example 4, that computes the Fibonacci sequence up to an upper bound. F_1 and F_2 send their respective $n - 2$ and $n - 1$ Fibonacci numbers to F_3 . Then, F_3 computes the n -th number, and makes a choice: compute the $n + 1$ number, or end the protocol. If F_3 decides to continue, then a recursive call to `BFib` happens. Otherwise, it sends the result to `Res`, and notifies F_2 that the protocol is ending. F_3 needs to notify F_2 , because depending on F_3 's decision, F_2 may need to forward its $n - 1$ number.

Figure 5 shows the code for F_2 in `BFib`. The parameters of `BFib_F2` are: `ctx` is the local state for F_2 ; `wg` is used to ensure that the main thread does not resume execution until all participants have finished executing; `ch_A_B` is the channel for communicating from B to A . The first interaction of F_2 is a message to F_3 . The payload for this message is generated in Line 2, it is sent in Line 3. Then, F_3 makes a choice: either it sends the result back to `Res` and sends `End` to F_2 to communicate the end of the protocol, or it calls `BFib` recursively. F_2 performs a type switch to check which branch it needs to take (Line 4). If the label it receives is `End` (Line 6), then F_2 processes this label and ends the protocol. Otherwise, F_2 receives an invitation as F_1 in `BFib` (Line 10); then F_2 initialises a new context for F_1 using the callback on Line 11; it calls `BFib_F1` with this new context, the waitgroup, and the received channel (Line 12); F_2 performs cleanup on the context for F_1 , gathering any necessary results from the call (Line 13); and, finally F_2 finishes.

Finally, `GoScr` generates the main protocol entrypoint, which creates the goroutines for F_1 , F_2 and F_3 , all the needed channels, and waits for the completion of the protocol.

Usability and GoScr Front-end. The tool requires the user to instantiate a large number of callbacks and interfaces to allow running a protocol. Since the `GoScr` methodology is top-down, the user must start by specifying a protocol. Therefore we expect an end-user to be aware of the callbacks and contexts that need to be instantiated. However, many of such instantiations are tedious, but straightforward, and can be automated in future work. We discuss this improvement in Section 7.

Deadlock Freedom and Liveness. Since the generated code follows the behaviour of the local types, it will satisfy both **deadlock freedom** and **liveness** (Theorems 23 and 29). Although the generated code satisfies these properties, whether the final code that is run also satisfies them depends on three requirements on the callbacks. These requirements are not checked by `GoScr`, and must be guaranteed by `GoScr` users. The three requirements that the callbacks must satisfy are: (1) callbacks must not have side-effects that interfere with other participants (e.g. using channels to add communication that is not accounted for in the protocol) (2) callbacks must be terminating, otherwise a participant may block before a necessary interaction, in a non-terminating callback; and, (3) callbacks must ensure that nested protocol calls that are not in tail position are terminating. Requirement (1) is to guarantee that programmers do not use local synchronisation mechanisms that are not accounted for in the protocol, and can cause blocking. Requirement (3) is to guarantee that any interaction after a nested protocol call is eventually performed. `GoScr` checks that local types are not blocked (Definition 26), so the code for nested calls that are not in tail position will always contain a path that ends the protocol. However, whether the actual code is terminating depends on the callback implementation that the users need to provide satisfying Requirement (3). Provided that these requirements are met, and assuming a fair scheduler, `GoScr` implementations will be deadlock free and live by construction. These requirements are not unique to our implementation. Similar requirements must be satisfied in other MPST code generation approaches.

■ **Figure 6** Execution time comparison (t_{base} / t_{GoScr}), CLBG and Quicksort.

5 Evaluation

We evaluate three aspects of GoScr: (1) the runtime overhead of the GoScr backend (§ 5.1); (2) the increased expressiveness with respect to related approaches (§ 5.3); and (3) the applicability of GoScr for building realistic protocols, by implementing dynamic task delegation, a Domain Name System, and a parallel Min-Max strategy. We show that for computation-intensive protocols, the runtime overhead of GoScr is negligible.

5.1 Runtime Overhead of GoScr

We use an Intel(R) Core(TM) i7-4770 CPU @ 3.40GHz processor with 4 physical cores, 16GB RAM, running Ubuntu 16.04.7 and Go version go1.15.11. We use Golang’s time package to measure execution times. There are two main sources of run-time overheads: (1) callbacks; and (2) type switches and assertions. Our approach is to compare GoScr implementations against baseline Go code. Baselines are taken from benchmarking repositories, and follow similar communication patterns to the GoScr implementations. The measured time includes session initialisation. We execute each benchmark for a minimum of 20 iterations and a minimum of 20 seconds. The standard deviation for computationally expensive benchmarks is less than 5%. Only the standard deviation of fibonacci and prime sieve with small inputs (< 10th term, bound < 2000) remain high, at 70%. This is because these benchmarks with very short execution times (in the order of nanoseconds) are highly dependent on the system (e.g. channel creation, goroutine scheduling, etc). Our benchmarks are mainly taken from the *Computer Language Benchmarks Game* [17], and we include a parallel Quicksort that showcases the handling unbalanced workloads. Figure 6 shows the execution time of the Go baseline relative to GoScr: t_{base} / t_{GoScr} (below $y = 1$ is a slowdown, above is a speedup).

```

1  global protocol DynTaskGen(role S;
2     new role W) {
3     choice at S {
4         Req(req: string) from S to W;
5         S calls DynTaskGen(S);
6         choice at W {
7             Resp(resp: string) from W to S;
8         } or {
9             Error(err: string) from W to S; }
10    } or {
11        LastReq(req: string) from S to W;
12        choice at W {
13            Resp(resp: string) from W to S;
14        } or {
15            Error(err: string) from W to S;
16        }}}
11 global protocol ClientServer(role C,
12     role S) {
13     rec REPEAT {
14         Req(req: string) from C to S;
15         S calls DynTaskGen(S);
16         choice at S {
17             Resp(resp: string) from S to C;
18             continue REPEAT;
19         } or {
20             Error(err: string) from S to C;
21             continue REPEAT;
22         }}}

```

■ **Figure 7** GoScr protocol for Dynamic Task Generation.

Computer Language Benchmarks Game (CLBG). CLBG [17] is a repository of programs used to compare the performance of different languages. We use four concurrent Go programs: (1) **fannkuch** counts the maximum number of flips for a permutation of length n ; (2) **regex** matches regex patterns in a DNA string; (3) **spect** (spectral-norm) calculates the greatest eigenvalue of a matrix; and (4) **k-nuc** (k-nucleotide) counts the occurrences of a molecule sequence in a DNA string. We selected these benchmarks out of [17] because they parallelise the work using goroutines and channels, following a similar scatter/gather approach that depends on runtime values, and they could not be accurately captured by previous MPST approaches. We use the CLBG implementations [17] as the Go baseline implementations, and we extracted the communication structure of the baseline implementations as GoScr protocols. A single execution for each of these protocols takes between 1 millisecond–10 seconds depending on the input size. Smaller input sizes imply smaller local computation times, and therefore, the overhead introduced by GoScr will be more significant. We can observe a slowdown of up to 50%, in **fannkuch**, for executions in the order of magnitude of milliseconds. However, as the workload increases, the difference in the execution time shrinks to the point of becoming negligible, as we can observe in Figure 6. The **regex** baseline has a high standard deviation, which explains the small peak for the first result of **regex**, since when the execution time is in the order of hundreds of microseconds, the non-deterministic scheduling of the goroutines can significantly affect the results. **spect** seems to show that for large enough values, the GoScr implementation performs better than its naively implemented counterpart. However, the real difference in the execution time is negligible, and it is explained by differences in the program structure, e.g. the baseline uses a single shared channel, whereas GoScr generates different channels for every new goroutine.

Microbenchmarks. Bounded fibonacci (**fibonacci**) shows, as expected, that the overhead of performing type switches and callbacks is relatively high when compared with a simple addition. The baseline runs in in 40% of the execution time of GoScr. Bounded prime sieve (**prime**) shows that, when the computation complexity increases slightly (modulus operation on a stream of values), then the GoScr version performs in about 80% the execution time of the baseline. In both cases, when we add more participants and interactions to the protocol (larger values on the x-axis) the overhead *remains constant, and does not increase*.

Unbalanced Workload. In *Parallel QuickSort* (`qsort`), workers either partition the array and spawn two new workers, or apply a sequential Quicksort, depending on a threshold size (T). The execution times are similar to the CLBG benchmarks (50 microseconds–2 seconds). We observe a negligible difference in the execution time for different threshold sizes, and a spike for small arrays due to the high standard deviation for array sizes under the threshold. GoScr execution times are in the range of 1.05 and 0.95 times the baseline.

5.2 Use Cases

We demonstrate the expressiveness of GoScr using three applications, all of which require dynamic participants, and could not be expressed by previous work [3, 37].

- (a) **Dynamic Task Generation:** We present a correct implementation of the program in Figure 1 using GoScr. It is a master-worker pattern with dynamic participants.
- (b) **Domain Name System (DNS) protocol:** We demonstrate how GoScr can be used to specify one of the core Internet protocols, modelling as dynamic participants the different DNS servers which may need to be contacted in order to resolve a host’s IP address.
- (c) **Noughts and Crosses with Min-Max [49]:** We implement a Min-Max strategy for the well-known two-player game of Noughts and Crosses to demonstrate the suitability of DMst to model a parallel Divide and Conquer paradigm.

Dynamic Task Generation. The aim of this program is to generate the first n square numbers by delegating the calculation of each square number to a different worker goroutine. The program uses a common computation in Go, the *master-worker pattern*, where goroutines dynamically divide and delegate part of their tasks to other goroutines, aggregating their partial results to produce the complete result. We highlighted in § 1 (Figure 1) how even in such a simple example, incorrect management of channels can lead to orphan messages and deadlocks. Figure 7 shows a GoScr protocol specification whose behaviour is a safe version of the program in Figure 1. Notice how the behaviour of the `select` statement in Figure 1 is represented as a choice. In Figure 7, the `ClientServer` protocol models the behaviour of the main loop of the program, where two roles, a client and a server, repeatedly exchange requests (Line 14) and responses (Line 17). The server may also communicate an error in the computation of the request to the client (Line 20). We model the master-worker pattern as a call to protocol `DynTaskGen` (Line 15). Every call to the protocol introduces a new worker (`w`), and the master (`s`) will delegate a task to each new worker (Lines 4,11). If there are more tasks to assign, it will assign those tasks to new workers through recursive calls to `DynTaskGen` (Line 5). Once it has assigned the final task (Line 11), it will traverse the protocol stack, aggregating the results from the different workers in reverse order (Lines 7,13). While computing their subtask, the workers may encounter an error which they will communicate back to the server (Lines 9, 15). As opposed to the original program in Figure 1, the server will continue aggregating all the results from the workers even after encountering an error in order to ensure that there are no orphan messages.

5.3 Expressiveness

We compare the expressiveness of GoScr against the parameterised `Scribble` [3] and the static analysis framework of Go [37]. For a reference purpose, we also list comparisons with **theory-only work** in [7, 9] (i.e., they are **not** implemented). See § 6 for more detailed comparison with [7, 9]. In Table 1, we present the protocols that we implemented and whether or how closely other approaches [37, 3] can represent them. All our DMst-based implementations introduce dynamic, possibly unbounded participants. All representable

■ **Table 1** Comparison of Expressiveness.

Dyn: Dynamic participants; Unb: Unbounded participants; Inv: Choice through invitations

protocols (✓) by DMst in Table 1 are deadlock-free and live. For protocols which can be modified and re-implemented with [37] or [3], we use ○. Protocol 3 cannot be captured by any of the previous work, since it requires the dynamic introduction of participants to a recursive protocol. [3, 37] could only precisely model Protocols 12 and 13, as they create all the participants at the start. In Protocols 8, 10 and 11, the goroutines are spawned and assigned tasks dynamically, but [3, 37] can model them by initialising all goroutines at the start. We write △ to represent such changes to protocol structure. Three use cases (Protocols 13–15) discussed in § 5.2, could not be expressed by [3, 37]. In summary, DMst is more expressive than [3, 37], and capture more closely the typical Go programming style.

6 Related Work

There are a vast amount of studies of session types [27, 15, 1]. Due to the space limitations, we only compare with the most closely related work on multiparty session types (MPST).

Binary Session Types. While Scalas et al. [50] prove that the MPST processes can be mimicked by linearly typed processes with a continuation-passing style translation, in general, it is not possible to guarantee deadlock-freedom for more than two interleaved binary session processes unless one uses additional sophisticated means such as a global causal analysis on channels (e.g. [12, 4, 5]), graph-connectivity analysis with extensions on fork primitives [29], and event-driven constructs [57, 24, 34]. GV, a linear functional language with binary session types, can guarantee deadlock freedom by relying on linear typing [58]. However, linear typing prevents cyclic topologies that change dynamically, since this would require a participant to drop their communication channels when new participants join, as in Example 7. There are further substantial differences with our approach. First, GV is an end-point calculus, whereas DMst’s global types are *global specifications*, from which we can extract endpoint Go code (GoScr). Secondly, while both GV and DMst support similar programming patterns (e.g. pipeline and tree-like topologies, and channel passing), there are two major differences. Both GV and GoScr support sending effectful functions over channels (e.g. using `chan func()` type in Go, and passing a generated protocol implementation), GV’s type system would guarantee deadlock-freedom, but in Go, it would depend on how the function is used (requirements 1-3 in Section 4).

Code Generation and Multiparty Session Types. We follow the standard MPST top-down *specification-guided* methodology to guarantee **safety and liveness properties by construction using code generation**, extending an extensible toolchain, nuScr [48]. Safety by construction via code generation is a common approach in MPST. Scribble is a language/tool [51, 48] used for generating APIs for safely implementing distributed systems written in the end-point programming language that are guaranteed to conform to a protocol, and are therefore deadlock-free [25]. This approach has been applied to several languages, e.g. Scala [50, 57], Java [33], F# [43], Go [3], TypeScript [42], F \star [62] and Rust [35, 6]. A later extension of [25] proposed *explicit connection actions* as part of the Scribble protocol [26], which is also recently applied to domain-specific language in [19]. This construction specifies the point in the protocol where the different participants join, but the role of these participants must be statically known. Hence it does not allow the unbounded participants to change the protocol topology, as DMst does. *Parameterised multiparty session types* extend MPST with a parametric number of participants [11]. One example is the work by Castro-Perez et al. [3], discussed it in § 1. *Pabble* [46, 45] is another parameterised extension of Scribble used for generating safe by construction C+MPI code. Zhou et al. [62] formalised and implemented an extension of MPST with *refinement types*, which can specify constraints in the messages. Their backend targets F \star , and follows a similar callback approach to the one in this paper. Miu et al. [42] define an extension of MPST for web programming in TypeScript that uses the callback approach. Unlike DMst, the participants in all these approaches are fixed from the start of the protocol. Viering et al. [57] present a theory and implementation of MPST aimed at programming correct fault-tolerant distributed systems that supports the dynamic replacement of participants in a protocol. In their work, the replacement of participants must happen within some known roles, and their global types do not allow to extend the current protocol interactions with those of new participants. Viering et al. [57] use event handlers in their code generation, which allows safe session interleaving. Instead, we use an operator to *combine* global types in a way that does not introduce deadlocks. All previous work, unlike DMst, does not support dynamically growing protocols with an unbounded number of participants such as Example 6. Jacobs et al. [30] extend GV, a binary session typed calculus with multiparty session types. The calculus allows the introduction of new participants, but the protocols themselves are restricted to a fixed set of participants. Their use of linearity prevents the definition of recursive dynamic topologies, unlike DMst.

Dynamic Multiparty Session Types. Dynamic multirole session types (MRST) enable a set of participants which belong to the same group (i.e. role) to join a multiparty session type [9]. The major limitations are: (a) all the roles are fixed at the start (b) participants can only join at specific points in the protocol: (1) at the beginning of each iteration of a recursive protocol; or (2) at particular points marked with explicit barriers and locks. We list a number of protocols that cannot be represented using MRST in Table 1. In contrast, DMst allows any arbitrary role to join at any nested session call. A nested session call is a form of delegation, which is not supported by MRST. Therefore, a protocol such as a dynamically growing pipeline (e.g. Fibonacci in Example 4) cannot be represented by [9] either, since it would require participants to evolve their behaviour through channel passing. Nested multiparty session types [7] allow multiparty protocols with unbounded, dynamic participants. However, [7] cannot represent *recursive* protocols that are *updated* with new dynamic participants. Hence the main example of this paper, Example 6, is not representable in [7]. Moreover, nested multiparty session types cannot prove liveness (our Theorem 29), except for non-recursive protocols. Arbitrary session interleaving in [7] can introduce orphan

messages. DMst has proven deadlock-freedom and liveness clearly identifying the conditions (Definition 26). This limitation is stated in [7, Proposition 3], i.e. a protocol that violates liveness will be accepted in [7], but not in DMst. Additionally, the theory of DMst has a number of differences that make it better suited for implementing than nested MPST: (a) DMst’s choices are more flexible than those in nested MPST, since DMst can also depend on protocol calls; (b) the semantics of nested MPST is synchronous, while DMst is asynchronous; (c) nested MPST does not prove trace equivalence between global types and local type configurations; (d) The syntax of DMst’s global types are simpler than those in nested MPST, but more expressive – this is because in nested MPST, protocol definitions are part of the global type syntax, which requires the use of a kinding relation for checking well-formedness. Nested MPST protocols do not allow the occurrence of free roles, and are therefore equivalent to DMst’s global types with just top-level protocol definitions, which avoids the kinding relation for checking well-formedness. Due to our simpler but more expressive treatment, DMst is more suitable for real language implementations.

Verification of Go Programs. Our work aims at providing *correctness by construction*. The comparison with the previous code generation approach in Go [3] can be found in (C) in § 1 and **Expressiveness** in § 5.3. All of the previous work is limited to *bounded* participants. The following are several recent lines of work on *a posteriori* verification of message passing in existing Go programs. All of them use *whole-program* techniques, and support only the built-in Go channel *primitives* (i.e., intra-process messaging); none of them, however, support a dynamic, unbounded number of participants. Gobra is an automated tool for the modular verification of Go programs, based on separation logic [59]. Gobra is aimed at the functional verification of Go programs, whereas our approach focuses on communication safety. GoScr is fully automated, and aimed at building live and deadlock-free communicating systems by construction. In contrast, Gobra is aimed at the verification of annotated Go code, and it requires a high amount of invariant annotations.

Ng and Yoshida [47] extract graph-based protocol specifications [38] from Go programs that are checked for deadlock-freedom; Stadtmüller et al. [53] extract regex-based protocol specifications [55], checked for deadlock-freedom. Both approaches work only for programs restricted to *synchronous* Go channels; the former also requires all goroutines to be spawned before any communication among them occurs, and the latter has limited support for branching behaviours. Lange et al. [36, 37] (already compared in (B) in § 1 and **Expressiveness** in § 5.3) statically infer channel communication patterns from Go programs as *behavioural types*, that are checked for liveness properties. This was recently extended to analyse shared memory concurrency [14]. Like previous work, their tool is also limited to verify finite controlled programs, it is best-effort only due to the imprecision of the inference, and the verification times (and timeouts) preclude practical checking on the fly during programming. Liu et al. [39] present a tool that detects blocking misuse-of-channel bugs in Go and produces bug fixes for Go programs. Unlike DMst, Liu et al. [39] focuses only on practice, and does not formalise nor guarantee communication safety, deadlock-freedom nor liveness. Moreover their tool produces both false positive and false negative errors.

7 Conclusion and Future Work

GoScr is the first implementation of multiparty session types with dynamic, unbounded participants, from which we generate Go code with unbounded participants that is, *by construction*, deadlock-free and live. GoScr focuses on correctness (Theorems 20, 23 and

29), and it is strictly more expressive than previous Go verification frameworks (see § 1, Table 1, § 6). Furthermore, we observe that whenever the computation time is large with respect to the communication time, the performance overhead becomes negligible. GoScr is therefore suitable for implementing systems where correctness is prioritised, or systems where the computation times dominate over communication. Currently, DMst does not allow a participant to communicate with an unbounded number of participants during protocol execution. This is a limitation of the Go code generation, which we plan to address in future work. We are also considering extending our back-end to use event-handlers in the style of Viering et al. [57], and allow the arbitrary parallel composition of global types instead of our combination operator. We are also planning to extend the back-end to disparate transports (e.g. using TCP instead of Go channels), thus allowing the implementation of distributed systems. The main challenge of this is integrating delegation, as it is required by protocol invitations, in these disparate transports. Finally, to simplify usability, we plan to extend the protocol specification with annotations to guide code generation, so we can automatically generate trivial callback/context instantiation. We plan to draw inspiration for such annotations from *choreographies*, e.g [31].

Abstract

Choreographic programming is a paradigm for concurrent and distributed software, whereby descriptions of the intended communications (choreographies) are automatically compiled into distributed code with strong safety and liveness properties (e.g., deadlock-freedom).

Recent efforts tried to combine the theories of choreographic programming and higher-order functional programming, in order to integrate the benefits of the former with the modularity of the latter. However, they do not offer a satisfactory theory of compilation compared to the literature, because of important syntactic and semantic shortcomings: compilation is not modular (editing a part might require recompiling everything) and the generated code can perform unexpected global synchronisations.

In this paper, we find that these shortcomings are not mere coincidences. Rather, they stem from genuine new challenges posed by the integration of choreographies and functions: knowing which participants are involved in a choreography becomes nontrivial, and divergence in applications requires rethinking how to prove the semantic correctness of compilation.

We present a novel theory of compilation for functional choreographies that overcomes these challenges, based on types and a careful design of the semantics of choreographies and distributed code. The result: a modular notion of compilation, which produces code that is deadlock-free and correct (it operationally corresponds to its source choreography).

■ **Figure 1** Choreographic programming: the communication and computation behaviour of a system is defined in a choreography, which is then projected (compiled) to deadlock-free distributed code (adapted from [17]).

1 Introduction

Functional and choreographic programming

Higher-order functional programming is a popular paradigm, which allows programmers to write modular code with strong guarantees through types. However, when dealing with concurrent and distributed programs, functional programming still requires developers to manually write a separate program for each participant, using send and receive actions to communicate data. This makes it easy to write programs that deadlock, or perform in other unexpected ways [22].

Choreographic programming (Figure 1) is a simple and powerful method to produce distributed code that does what it is supposed to do [23, 21, 18]. In this paradigm, programs are choreographies: structured compositions of the intended communications and computations that participants should perform, given from a joint perspective. A communication is expressed in some variation of the communication term from security protocol notation, Alice \rightarrow Bob : M , which reads “Alice communicates the message M to Bob” [26]. Given a choreography, a compiler produces executable distributed code. In the theory of choreographies, this compilation is called Endpoint Projection (EPP) [1]. A correct EPP has the powerful consequence of guaranteeing deadlock-freedom “for free”: it is syntactically impossible to specify mismatched communication actions in choreographies, so the resulting distributed code cannot get stuck (deadlock-freedom by design) [2].

Recently, there have been two attempts at developing theories that combine the paradigms of choreographic and functional programming, in the hope of reaping the benefits of both [18, 6]. Finding an adequate notion of EPP in this setting has been an issue. In [6] the λ -calculus is extended with choreographic primitives for communications, yielding a simple yet expressive model called Chor λ , but no EPP is presented. In [18] an EPP is given for a choreographic language that extends a standard imperative choreographic language with primitives for abstraction and application (for higher-order composition). However, this theory comes at two important costs when compared to the expected properties of choreographic programming [24]. First, EPP is not modular: changing a part of a choreography that involves only some participants can change also the code projected for other participants. This means

that updating a choreography requires reprojecting and redeploying the entire system, which is not necessary in previous work. Second, participants perform more synchronisations than those written in the choreography. This breaks the design principle that all communications are made syntactically manifest in choreographies.

These issues are not consequences of careless work. Rather, we find that they are both caused by a novel challenge that arises precisely from the combination of functional and choreographic programming – explained in the next paragraph. The aim of this work is to develop a new theory that overcomes this challenge.

The problem

When projecting a choreography to a participant, say *Alice*, the parts of the choreography not involving *Alice* should be ignored [1, 24]. Doing this is simple with traditional imperative choreographies, which are essentially sequences of commands $(c_1; c_2; \dots)$. For each command: if the participant that we are projecting for is involved, we return some (appropriate) code; otherwise, we just skip the command and go to the next. For example, given the choreography $\text{Carol} \rightarrow \text{Bob} : M; \text{Alice} \rightarrow \text{Bob} : M'$, a standard EPP would produce for *Alice* only the code to execute the second command (a send action towards *Bob*).

In a higher-order functional setting, checking if a participant is “involved” in a choreographic term is not an easy syntactic check anymore. Consider a choreography C that takes another choreography x as parameter, runs it, and communicates the result from *Alice* to *Bob*. Since x can be an arbitrary choreography, the participants involved in C are known only after x is instantiated. This is the technical issue that makes defining EPP for functional choreographies nontrivial. In [18], the proposed solution sacrifices modularity: every function application is projected to all participants, who then have to perform a global system synchronisation for every function call.

This work

We define a notion of EPP for $\text{Chor}\lambda$, capitalising on the design of its type system and semantics.

We start our development by focusing on the finite fragment $\text{Chor}\lambda$, i.e., without recursion. First, we introduce a target language for representing distributed code: a distributed λ -calculus, which consists of well-known terms extended with primitives for sending and receiving messages. Then, we use this language to define a modular EPP for (finite) $\text{Chor}\lambda$. The key insight for achieving modularity is the inclusion of a no-op term in the target language, which is the projection of any choreographic term in which a participant is not involved. In this way, if some choreographic subterm does not involve a participant p , it is projected as no-op. And if this term is later edited without involving p , then the projection for p remains no-op and does not need to be recompiled. This is explained in detail in Example 6.

The rule for generating no-ops benefits from the careful design of the rule for typing abstractions in $\text{Chor}\lambda$. This is not an accident: in [6] this particular rule was claimed to be designed with the future development of a suitable EPP in mind, but this was not substantiated. In this paper we show that our EPP satisfies the expected operational correspondence between choreographies and their projections (Theorems 25 and 26). As a consequence, projections of choreographies cannot deadlock.

Furthermore, we define a type system for the target language based on standard techniques, and show that well-typed choreographies are projected onto well-typed target terms whose types are projections of the source choreographic types (Proposition 10). This result is

relevant for applicability: knowing the type of projected functions lets programmers compose them in larger projects through APIs under the control of the programmer, as is commonly done with projected code [15, 17].

A unique feature of $\text{Chor}\lambda$ is that conditionals can use whole choreographies as conditions, and in particular ones that return distributed data structures – data structures that compose data residing at different participants. For the first time, our EPP leverages this feature to offer a new method for capturing *knowledge of choice* – distributed agreement regarding choices between alternative choreographic behaviours [4]. Specifically, we can statically guarantee that two (or more) participants will agree on the instantiation of a sum type (representing alternative choices) solely by performing independent local checks. When this is used in a conditional, it means that all participants are guaranteed to make the same choice at runtime. This gives a simpler alternative to existing verification methods for distributed choices [21]. We call types used in this way *distributed choice types*.

Lastly, we extend our development to the full language of $\text{Chor}\lambda$, including recursion. Recursion allows for divergent behaviour, which gives an interesting problem: a divergent term does not necessarily involve all participants, so generalising the operational correspondence between choreographies and their projections requires allowing choreographies to perform actions involving participants that are not blocked by divergent computations. The semantics of $\text{Chor}\lambda$ include rules for performing reductions out of order, which again were designed with the future development of EPP in mind. We show that these rules are adequate to generalise our results.

Contribution

We define the first notion of EPP for a functional choreographic programming language that is modular and does not add extra communications. This necessitates using not only the information contained in the syntactic structure of a choreography, but also the one contained in the typing derivation that accompanies it. These sources of information give a number of cases for projection that need to be designed carefully, in order to distinguish correctly when a process is potentially involved in the realisation of part of a choreography. We show that EPP satisfies the usual operational correspondence property between choreographies and their projections. Our development also proves two unsubstantiated claims from [6]: that the typing system of $\text{Chor}\lambda$ is expressive enough to support a modular notion of EPP, and that the semantics of $\text{Chor}\lambda$ capture how distributed participants behave in the presence of divergence. Furthermore, we check the practical applicability of our theory by using it to project the model of the Extensible Authentication Protocol (EAP) [28] given in [6], a nontrivial choreography that makes use of higher-order composition, distributed data structures, and distributed choice types.

We anticipate that our developments on the theory of higher-order choreographies will allow higher-order functions to be added to implementations of existing choreographic and similar languages. We discuss this in Section 7.

Structure

We provide a review of the main features of recursion-free $\text{Chor}\lambda$ in Section 2. In Section 3 we describe the local endpoint language $\text{Chor}\lambda$ is projected to and how to project a choreography. We reintroduce recursion into $\text{Chor}\lambda$ and introduce it to our endpoint language in Section 4. An example of a realistic use case (the Extensible Authentication Protocol) projected using our method can be seen in Section 5. Related work is given in Section 6. Conclusions are presented in Section 7. Full definitions and proofs of results for the full language of $\text{Chor}\lambda$ can be found in Appendix A.

2 Background

In this section, we recap the theory of the choreographic λ -calculus (Chor λ) without recursion, from [6]. Chor λ extends the simply typed λ -calculus [5] with primitives that make distribution and communication syntactically manifest.

System model

Chor λ is used to model systems of independent processes, which can interact by synchronous communication. Each process has a name, and knows the names of the other processes in the network. There are two kinds of messages that can be exchanged: *values* are results of computations; and *selection labels* are special constants used to implement agreement on choices about alternative distributed behaviour.

Syntax

The syntax of Chor λ is given by the following grammar

$$\begin{aligned} M &::= V \mid M M \mid \mathbf{case} M \mathbf{of} \mathbf{Inl} x \Rightarrow M; \mathbf{Inr} x \Rightarrow M \mid \mathbf{select}_{\mathbf{p},\mathbf{p}} l M \\ V &::= x \mid \lambda x : T.M \mid \mathbf{Inl} V \mid \mathbf{Inr} V \mid \mathbf{fst} \mid \mathbf{snd} \mid \mathbf{Pair} V V \mid ()@_{\mathbf{p}} \mid \mathbf{com}_{\mathbf{p},\mathbf{p}} \\ T &::= T \rightarrow_{\rho} T \mid T + T \mid T \times T \mid ()@_{\mathbf{p}} \end{aligned}$$

where M is a choreography, V is a value, T is a type, x is a variable, l is a label, \mathbf{p} is a process name, and ρ is a set of process names.

Terms are located at processes, to reflect distribution. For example, the value $()@_{\mathbf{A}}$ reads “the unit value at \mathbf{A} ”. Types are annotated with process names, as well. In the typing rules of Chor λ (shown later), term $()@_{\mathbf{A}}$ has the type $()@_{\mathbf{A}}$, read “the unit type at \mathbf{A} ”. In our examples, for simplicity, we assume the presence of primitives for integer values and an integer type $\mathbf{Int}@_{\mathbf{p}}$ (“an integer at \mathbf{p} ”) – the formal treatment of these are straightforward and similar to that of units.

Abstraction $\lambda x : T.M$, variable x and application MM are as in the standard (simply typed) λ -calculus. Sums and products are constructed, respectively, by using **Inl/Inr** and **Pair**. They are deconstructed in the usual way, respectively with **case** and **fst/snd**. The constructors can take only values as arguments, but this does not restrict expressivity (cf. [6]).

The primitives $\mathbf{com}_{\mathbf{p},\mathbf{q}}$ and $\mathbf{select}_{\mathbf{p},\mathbf{q}} l M$ (where \mathbf{p} and \mathbf{q} are process names) model communications of, respectively, values and selection labels. A *communication* term $\mathbf{com}_{\mathbf{p},\mathbf{q}}$ acts as a function that takes a value at the process named \mathbf{p} and returns the same value at the process named \mathbf{q} . In a *selection* term $\mathbf{select}_{\mathbf{p},\mathbf{q}} l M$, instead, \mathbf{p} informs \mathbf{q} that it has selected the label l before continuing as M . Selections choreographically represent the communication of an internal choice made by \mathbf{p} to \mathbf{q} . As we shall see in our definition of EPP, they play a key role in establishing agreement among processes regarding what behaviour they should enact together.

Selections are standard in choreographic languages and should not to be confused with the distributed choice types that we anticipated in the introduction (these will be illustrated later, in the next section). The former used to implement agreement on choices, whereas the latter are used to codify the information that an agreement has been reached and can thus be used without requiring communication. We will touch on this topic later, in Example 15 and Section 5.

A key feature of $\text{Chor}\lambda$ is distributed data structures. For example, $\mathbf{Pair} ()@p ()@q$ is a distributed pair where the first element resides at p and the second at q . Types record the distribution of values across processes: if p occurs in the type given to V then part of V will be located at p . A function may involve more processes than those listed in the types of its input and output, so the type of abstractions $T \rightarrow_{\rho} T'$ has the extra ingredient ρ , which denotes the processes that may participate in the computation of the function besides those occurring in T or T' . We simply write $T \rightarrow T'$ in place of $T \rightarrow_{\emptyset} T'$. For example, if Alice wants to communicate an integer to Bob directly (without intermediaries), she can use a choreography of type $\text{Int}@Alice \rightarrow \text{Int}@Bob$; however, if the communication might go through a proxy, then she can use a choreography of type $\text{Int}@Alice \rightarrow_{\{\text{Proxy}\}} \text{Int}@Bob$. The information given by ρ gives control on what processes may participate in choreographies taken as arguments. As we show in Section 3, this information is essential to achieve a modular EPP.

We write $\text{fv}(M)$ for the set of free variables in a term M , and $\text{pn}(T)$ and $\text{pn}(M)$ for the set of process names mentioned in respectively a type T and a choreography M . A choreography is *closed* if it has no free variables. Our key results apply to closed choreographies.

► **Example 1** (Remote Function [6]). The following choreography models a distributed computation in which a client, C sends an integer val to a server S and a local function fun located at S is applied to val before the result gets returned to C . The choreography is parametrised on both fun and val .

```
 $\lambda fun : \text{Int}@S \rightarrow_{\emptyset} \text{Int}@S. \lambda val : \text{Int}@C. \mathbf{com}_{S,C} (fun (\mathbf{com}_{C,S} val))$ 
```

Typing

Choreographies are typed with judgements of the form $\Theta; \Gamma \vdash M : T$, where Θ is the set of process names that can be used for typing M and Γ is a function assigning types to variables. We recall a few key typing rules from [6]. Our rules use the notation $\text{pn}(T)$ for the process names that appear in the type T .

$$\frac{\text{pn}(T) = \{p\} \quad \{p, q\} \subseteq \Theta}{\Theta; \Gamma \vdash \mathbf{com}_{p,q} : T \rightarrow_{\emptyset} T[p := q]} \text{[TCOM]}$$

$$\frac{\Theta; \Gamma \vdash N : T \rightarrow_{\rho} T' \quad \Theta; \Gamma \vdash M : T}{\Theta; \Gamma \vdash N M : T'} \text{[TAPP]}$$

$$\frac{\Theta'; \Gamma, x : T \vdash M : T' \quad \rho \cup \text{pn}(T) \cup \text{pn}(T') = \Theta' \subseteq \Theta}{\Theta; \Gamma \vdash \lambda x : T.M : T \rightarrow_{\rho} T'} \text{[TABS]}$$

A communication is typed as a function from any type T located entirely at the sender p to the same type moved to the receiver, as long as both process names are in Θ . Application and abstraction are typed similarly to simply-typed λ -calculus, extended with ρ and Θ (whose consistency is checked in rule TABS). Note that ρ and Θ in rule TABS are not necessarily minimal, and it is possible to type, e.g., $\{p, q\}; \emptyset \vdash \lambda x : \text{Int}@p.x : \text{Int}@p \rightarrow_{\{q\}} \text{Int}@p$. A minimal ρ would consist of those processes that appear either in M or in the types of the free variables of M according to Γ .

► **Example 2.** Let h be the function $\lambda x : \text{Int}@Alice. \mathbf{com}_{\text{Proxy}, \text{Bob}} (\mathbf{com}_{\text{Alice}, \text{Proxy}} x)$, which communicates an integer from Alice to Bob by passing through an intermediary Proxy. Then, $\{Alice, Bob, Proxy\}; \emptyset \vdash h : \text{Int}@Alice \rightarrow_{\{\text{Proxy}\}} \text{Int}@Bob$. For any term M , the composition

h M is well-typed if M has type $\text{Int}@Alice$, denoting that the evaluation of M will yield an integer at Alice. By contrast, h $5@Bob$ is ill-typed because of wrong data locality (the argument is not at the process expected by h).

Semantics

$\text{Chor}\lambda$ comes with an operational semantics given in terms of labelled reductions. Reduction labels are used to keep track of which processes interact in a reduction, which is going to be important for our development. We illustrate this with the two key rules below.

$$\frac{}{\lambda x : T.M \ V \xrightarrow{\emptyset} M[x := V]} \text{[APPABS]} \quad \frac{\text{fv}(V) = \emptyset}{\mathbf{com}_{q,p} \ V \xrightarrow{\{q,p\}} V[q \mapsto p]} \text{[COM]}$$

Rule APPABS is the standard application rule of call-by-value λ -calculus – annotated with an empty set, which indicates that no synchronisation is taking place. Rule COM, instead, implements a communication by “moving” the communicated value from the sender to the receiver (through a substitution). Thus, for example, $\mathbf{com}_{\text{Alice},\text{Bob}} 3@Alice \xrightarrow{\{\text{Alice},\text{Bob}\}} 3@Bob$. Since it makes no sense to communicate a variable whose value is stored at the sender rather than the value itself, we require that the communicated value has no free variables. Communicating a free variable would cause problems for $\text{Chor}\lambda$'s type system, since it would require changing the type of the variable in the environment.

Reductions are labelled with the processes synchronising in them, but this only becomes relevant information in Section 4.

3 Endpoint Projection (EPP) for finite $\text{Chor}\lambda$

In this section we develop a theory of EPP for finite $\text{Chor}\lambda$.

3.1 Process Language

We write implementations of choreographies in a distributed λ -calculus, which we call process language. Processes run in parallel, each with its own behaviour, and can interact by message passing.

Syntax

The syntax of process behaviours is given by the following grammar

$$\begin{aligned} B &::= L \mid B \ B \mid \mathbf{case} \ B \ \mathbf{of} \ \mathbf{Inl} \ x \Rightarrow B; \ \mathbf{Inr} \ x \Rightarrow B \mid \oplus_p \ l \ B \\ &\quad \mid \&_p \{l_1 : B_1, \dots, l_n : B_n\} \\ L &::= x \mid \lambda x : T.B \mid \mathbf{Inl} \ L \mid \mathbf{Inr} \ L \mid \mathbf{fst} \mid \mathbf{snd} \mid \mathbf{Pair} \ L \ L \mid () \mid \mathbf{recv}_p \mid \mathbf{send}_p \mid \perp \\ T &::= T \rightarrow T \mid T + T \mid T \times T \mid () \mid \perp \end{aligned}$$

where B is a behaviour, L is a local value, and T is a local type.

The terms from the λ -calculus are standard. Pairs and sums work as described for $\text{Chor}\lambda$, but note that now they are completely local (as usual) because there are no process name annotations anymore.

The terms for message passing are the local counterparts of choreographic communication terms. Selections are implemented by the *offer* branching term $\&_p \{l_1 : B_1, \dots, l_n : B_n\}$, which offers a number of different ways it can continue for another process p to choose from,

$$\begin{array}{c}
\frac{\Sigma; \Gamma \vdash B : T}{\Sigma; \Gamma \vdash \oplus_p l B : T} [\text{NTCHOR}] \quad \frac{\Sigma; \Gamma \vdash B_i : T \text{ for } 1 \leq i \leq n}{\Sigma; \Gamma \vdash \&_p \{l_1 : B_1, \dots, l_n : B_n\} : T} [\text{NTOFF}] \\
\frac{}{\Sigma; \Gamma \vdash \mathbf{send}_p : T \rightarrow \perp} [\text{NTSEND}] \quad \frac{}{\Sigma; \Gamma \vdash \mathbf{recv}_p : \perp \rightarrow T} [\text{NTRECV}] \\
\frac{}{\Sigma; \Gamma \vdash \perp : \perp} [\text{NTBOTM}] \quad \frac{\Sigma; \Gamma \vdash B : \perp \quad \Sigma; \Gamma \vdash B' : \perp}{\Sigma; \Gamma \vdash B B' : \perp} [\text{NTAPP2}]
\end{array}$$

■ **Figure 2** Typing rules for behaviours (selected rules).

and the *choice* term $\oplus_p l B$, which directs p to continue as the behaviour labelled l . Likewise, value communication is divided into a *send* to p action, \mathbf{send}_p , and a *receive* from p action, \mathbf{recv}_p .

We also add the no-op term mentioned in the introduction, \perp , and its type, \perp . A term \perp represents a terminated behaviour with no result. This term is used in the semantics of send and receive: locally, \mathbf{send}_p acts as a function that can take any input and returns \perp , and \mathbf{recv}_p a function that given \perp returns some value. More interestingly, \perp also plays an important role wrt modularity in our notion of EPP, which we will discuss later in our presentation of projection. All types but \perp are standard (as in $\text{Chor}\lambda$, but without process name annotations).

A system of running processes is called a *network*.

► **Definition 3.** A network \mathcal{N} is a finite map from a set of process names to behaviours.

Given two networks \mathcal{N} and \mathcal{N}' with disjoint domains, their parallel composition $\mathcal{N} \mid \mathcal{N}'$ maps each process name to the behaviour in the network defining the process. Any network is equivalent to a parallel composition of networks with singleton domains, so we write $p_1[B_1] \mid \dots \mid p_n[B_n]$ for the network where each process p_i has behaviour B_i [24].

► **Example 4.** Consider the choreography $\mathbf{com}_{B,C} (\mathbf{com}_{A,B} ()@A)$. A correct implementation is the network $A[\mathbf{send}_B ()] \mid B[\mathbf{send}_C (\mathbf{recv}_A \perp)] \mid C[\mathbf{recv}_B \perp]$.

Typing

Behaviours are typed with judgements of the form $\Gamma \vdash B : T$. The typing rules are the local counterparts of those in $\text{Chor}\lambda$, obtained by removing Θ and process names in types. We add the \perp type for terms that can result in \perp . Figure 2 displays representative typing rules to deal with \perp and communications.

Semantics

The semantics of networks is given as a labelled transition system. Figure 3 displays some representative transition rules.

Labels for network transitions have the form τ_P , where P ranges over sets of one or two process names. Rule NPRO annotates an internal transition by a process with its name, and rule NPAR lifts transitions in parallel compositions.

The transition axioms for send and receive are typical of process calculi with early semantics. Send and receive transitions are matched in rule NCOM to perform a communication. The label $\tau_{p,q}$ denotes an internal move (τ) and manifests the names of processes that contribute to performing it (p and q). We treat the subscript p, q as an unordered set that consists of the two process names.

$$\begin{array}{c}
\frac{fv(L) = \emptyset}{\text{send}_p L \xrightarrow{\text{send}_p L} \perp} \text{[NSEND]} \quad \frac{}{\text{rcv}_p \perp \xrightarrow{\text{rcv}_p L} L} \text{[NRECV]} \\
\frac{B_1 \xrightarrow{\text{send}_q L} B'_1 \quad B_2 \xrightarrow{\text{rcv}_p L} B'_2}{p[B_1] \mid q[B_2] \xrightarrow{\tau_{p,q}} p[B'_1] \mid q[B'_2]} \text{[NCOM]} \\
\frac{}{\oplus_p l B \xrightarrow{\oplus_p l} B} \text{[NCHO]} \quad \frac{}{\&_p \{\ell_1 : B_1, \dots, \ell_n : B_n\} \xrightarrow{\&_p \ell_i} B_i} \text{[NOFF]} \\
\frac{B_1 \xrightarrow{\oplus_q \ell} B'_1 \quad B_2 \xrightarrow{\&_p \ell} B'_2}{p[B_1] \mid q[B_2] \xrightarrow{\tau_{p,q}} p[B'_1] \mid q[B'_2]} \text{[NSEL]} \\
\frac{}{(\lambda x : T.B) L \xrightarrow{\tau} B[x := L]} \text{[NABSAPP]} \quad \frac{}{\perp \perp \xrightarrow{\tau} \perp} \text{[NBOTM]} \\
\frac{B \xrightarrow{\tau} B'}{p[B] \xrightarrow{\tau_p} p[B']} \text{[NPRO]} \quad \frac{\mathcal{N} \xrightarrow{\tau_p} \mathcal{N}''}{\mathcal{N} \mid \mathcal{N}' \xrightarrow{\tau_p} \mathcal{N}'' \mid \mathcal{N}'} \text{[NPAR]}
\end{array}$$

■ **Figure 3** Network semantics (representative rules).

The P-annotations in labels enable the formulation of the next lemma, which we use in some of our proofs to focus on the processes involved in a transition. The proof of this result and others for the full Chor λ language are provided in Appendix A.

► **Lemma 5.** *For any p and \mathcal{N} , if $\mathcal{N} \xrightarrow{\tau_p} \mathcal{N}'$ and $p \notin P$ then $\mathcal{N}(p) = \mathcal{N}'(p)$.*

Most of the other rules follow the same intuition and are otherwise standard. The exception is rule NBOTM, which garbage collects \perp terms. We discuss the role of this rule in Example 9, after having presented our notion of EPP.

3.2 Endpoint Projection (EPP)

We now move to defining the endpoint projection (EPP) of a choreography M for an individual process p , assuming that M is well-typed; that is, $\Theta; \Gamma \vdash M : T$ for some Θ , Γ , and T . The definition of EPP formally depends on this typing derivation, but to keep notation simple we write just $\llbracket M \rrbracket_p$ for the projection of M on p and refer to the type T associated to M in the specific derivation we are looking at as $\text{type}(M)$.

Projection translates each choreographic term to a corresponding local behaviour. For example, a communication term $\mathbf{com}_{p,q}$ is projected to a send action for the sender p and a receive action for the receiver q .

Abstraction presents a novel challenge compared to previous, non-functional choreographic languages. We discuss it in the next example, which also illustrates the importance of \perp in our theory of EPP.

► **Example 6.** Let $M = \lambda x : \text{Int}@p.M'$ for some M' , and consider the issue of defining its projection on a process q different than p , $\llbracket M \rrbracket_q$. Since EPP is usually defined inductively on the structure of the choreography, this definition should not depend on the context that M is used in.

The standard principle for EPP found in the literature is to ignore the parts that do not mention the process we are currently projecting to. Following this principle, we should omit the initial abstraction (λx) of M in the implementation of q .

7:10 Modular Compilation for Higher-Order Functional Choreographies

For example, for $M = \lambda x : \text{Int}@p.2@q$, we could design EPP such that $\llbracket M \rrbracket_q = 2$. This works when M is used in an application as $(\lambda x : \text{Int}@p.2@q) 1@p$, where $\llbracket M \rrbracket_q = 2$ is still reasonable (since q has nothing to do with the argument).

Unfortunately, this standard approach is not robust in the case of functional choreographies: even if q is not mentioned in the type of x in $\lambda x : \text{Int}@p$, in general it could still participate in the context that produces the value that x is going to be replaced with. For example, let $M'' = (\lambda x : \text{Int}@p.\text{com}_{q,p} 2@q) (\text{com}_{q,p} 1@q)$, which expresses a sequence of communications between q and p (first of 1 and then of 2, in order). If we insist on excluding the abstraction from the projection on q , then we obtain $\llbracket M'' \rrbracket_q = (\text{send}_p 2) (\text{send}_p 1)$. This is wrong, because it would send 2 before 1. Therefore, we cannot just skip abstractions that do not involve the process we are projecting on. In this case, a correct implementation of q in M'' would be $(\lambda x : \perp.\text{send}_p 2) (\text{send}_p 1)$. Our process language is carefully designed to make terms like this normalise gracefully: after executing $\text{send}_p 1$ the righthandside is \perp , thus allowing for the application to be resolved and for the second send action to be executed.

Sometimes, however, abstractions should be skipped. For example, if M is $\lambda x : \text{Int}@p.1@p$, then $\llbracket M \rrbracket_q$ should clearly be \perp . The alternative, $\lambda x : \perp.\perp$, would break modularity of EPP because the structure of $\llbracket M \rrbracket_q$ would depend on the internal behaviour of p . To solve this issue, we take the approach of skipping an abstraction like $\lambda x : T.M'$ only if both T and M' do not mention the process that we are projecting on. Type information is therefore key to our EPP, in addition to the usual syntactic checks, which is why we have made the EPP dependent on a typing derivation.

We will come back to \perp and its companion rule NBOTM in Example 9. J

In order to define EPP precisely, we need a few additional ingredients.

Projecting a term M requires knowing the processes involved in its type. As our EPP takes an entire typing derivation of M as input, the type is implicitly given in the derivation provided to EPP. So we write without ambiguity $\text{pn}(\text{type}(M))$ for this set of process names.

The second ingredient concerns knowledge of choice. When projecting a conditional **case** M of **Inl** $x \Rightarrow M'$; **Inr** $y \Rightarrow M''$, processes not occurring in M cannot know what branch of the choreography is chosen; therefore, the projections of M' and M'' must be combined in a uniquely-defined behaviour. We thus define a partial *merge* operator (\sqcup), adapted from [1, 8, 19], whose key property is

$$\&\{l_i : B_i\}_{i \in I} \sqcup \&\{l_j : B'_j\}_{j \in J} = \&\{l_k : B_k \sqcup B'_k\}_{k \in I \cap J} \cup \{l_i : B_i\}_{i \in I \setminus J} \cup \{l_j : B'_j\}_{j \in J \setminus I}$$

and which is homomorphically defined for the remaining constructs (see Appendix A for the full definition). The idea is that a process not in M must either perform the same actions in M' and M'' (so the choice does not matter) or receive an appropriate selection to know which branch has been chosen. Merging of incompatible behaviours is undefined.

► **Example 7.** Consider the choreography

$$C = \text{case Inl } ()@p \text{ of Inl } x \Rightarrow \text{select}_{p,q} \text{ left } 0@q; \text{ Inr } y \Rightarrow \text{select}_{p,q} \text{ right } 1@q.$$

Using merging, its projection on process q is $\llbracket C \rrbracket_q = \&_p\{\text{left} : 0, \text{right} : 1\}$. J

► **Definition 8.** The EPP of a choreography M on a specific process p ($\llbracket M \rrbracket_p$) is defined by the rules in Figure 4. The EPP of a choreography ($\llbracket M \rrbracket$) is the parallel composition of the EPPs on its processes: $\llbracket M \rrbracket = \prod_{p \in \text{pn}(M)} p \llbracket M \rrbracket_p$.

Intuitively, projecting a choreography on a process that is not involved in it returns a \perp . In general, however, a choreography may involve processes not mentioned in its type. This explains the first clause for projecting an application: even if p does not appear in the type of

Choreographies

$$\begin{aligned}
\llbracket M \ N \rrbracket_{\mathfrak{p}} &= \begin{cases} \llbracket M \rrbracket_{\mathfrak{p}} \ \llbracket N \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(M)) \text{ or } \mathfrak{p} \in \text{pn}(M) \cap \text{pn}(N) \\ \llbracket M \rrbracket_{\mathfrak{p}} & \text{if } \llbracket N \rrbracket_{\mathfrak{p}} = \perp \\ \llbracket N \rrbracket_{\mathfrak{p}} & \text{otherwise} \end{cases} \\
\llbracket \lambda x : T.M \rrbracket_{\mathfrak{p}} &= \begin{cases} \lambda x : \llbracket T \rrbracket_{\mathfrak{p}} . \llbracket M \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(\lambda x : T.M)) \\ \perp & \text{otherwise} \end{cases} \\
\llbracket \text{case } M \text{ of } \mathbf{Inl} \ x \Rightarrow N; \mathbf{Inr} \ x' \Rightarrow N' \rrbracket_{\mathfrak{p}} &= \\
&\begin{cases} \text{case } \llbracket M \rrbracket_{\mathfrak{p}} \text{ of } \mathbf{Inl} \ x \Rightarrow \llbracket N \rrbracket_{\mathfrak{p}}; \mathbf{Inr} \ x' \Rightarrow \llbracket N' \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(M)) \\ \llbracket M \rrbracket_{\mathfrak{p}} & \text{if } \llbracket N \rrbracket_{\mathfrak{p}} = \llbracket N' \rrbracket_{\mathfrak{p}} = \perp \\ \llbracket N \rrbracket_{\mathfrak{p}} \sqcup \llbracket N' \rrbracket_{\mathfrak{p}} & \text{if } \llbracket M \rrbracket_{\mathfrak{p}} = \perp \\ (\lambda x'' : \perp . \llbracket N \rrbracket_{\mathfrak{p}} \sqcup \llbracket N' \rrbracket_{\mathfrak{p}}) \ \llbracket M \rrbracket_{\mathfrak{p}} & \text{otherwise, for some} \\ & \quad x'' \notin \text{fv}(N) \cup \text{fv}(N') \end{cases} \\
\llbracket \mathbf{Inl} \ V \rrbracket_{\mathfrak{p}} &= \begin{cases} \mathbf{Inl} \ \llbracket V \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(\mathbf{Inl} \ V)) \\ \perp & \text{otherwise} \end{cases} \quad \llbracket \mathbf{fst} \rrbracket_{\mathfrak{p}} = \begin{cases} \mathbf{fst} & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(\mathbf{fst})) \\ \perp & \text{otherwise} \end{cases} \\
\llbracket \text{select}_{\mathfrak{q}, \mathfrak{q}'} \ l \ M \rrbracket_{\mathfrak{p}} &= \begin{cases} \oplus_{\mathfrak{q}'} \ l \ \llbracket M \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} = \mathfrak{q} \neq \mathfrak{q}' \\ \&_{\mathfrak{q}} \{l : \llbracket M \rrbracket_{\mathfrak{p}}\} & \text{if } \mathfrak{p} = \mathfrak{q}' \neq \mathfrak{q} \\ \llbracket M \rrbracket_{\mathfrak{p}} & \text{otherwise} \end{cases} \\
\llbracket \text{com}_{\mathfrak{q}, \mathfrak{q}'} \rrbracket_{\mathfrak{p}} &= \begin{cases} \lambda x : \llbracket T \rrbracket_{\mathfrak{p}} . x & \text{if } \mathfrak{p} = \mathfrak{q} = \mathfrak{q}' \text{ and } \text{type}(\text{com}_{\mathfrak{q}, \mathfrak{q}'}) = T \rightarrow_{\emptyset} T' \\ \text{send}_{\mathfrak{q}'} & \text{if } \mathfrak{p} = \mathfrak{q} \neq \mathfrak{q}' \\ \text{recv}_{\mathfrak{q}} & \text{if } \mathfrak{p} = \mathfrak{q}' \neq \mathfrak{q} \\ \perp & \text{otherwise} \end{cases} \\
\llbracket () @ \mathfrak{q} \rrbracket_{\mathfrak{p}} &= \begin{cases} () & \text{if } \mathfrak{q} = \mathfrak{p} \\ \perp & \text{otherwise} \end{cases} \quad \llbracket x \rrbracket_{\mathfrak{p}} = \begin{cases} x & \text{if } \mathfrak{p} \in \text{pn}(\text{type}(x)) \\ \perp & \text{otherwise} \end{cases}
\end{aligned}$$

Types

$$\begin{aligned}
\llbracket () @ \mathfrak{q} \rrbracket_{\mathfrak{p}} &= \begin{cases} () & \text{if } \mathfrak{q} = \mathfrak{p} \\ \perp & \text{otherwise} \end{cases} \quad \llbracket T \times T' \rrbracket_{\mathfrak{p}} = \begin{cases} \llbracket T \rrbracket_{\mathfrak{p}} \times \llbracket T' \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \text{pn}(T \times T') \\ \perp & \text{otherwise} \end{cases} \\
\llbracket T \rightarrow_{\rho} T' \rrbracket_{\mathfrak{p}} &= \begin{cases} \llbracket T \rrbracket_{\mathfrak{p}} \rightarrow \llbracket T' \rrbracket_{\mathfrak{p}} & \text{if } \mathfrak{p} \in \rho \cup \text{pn}(T) \cup \text{pn}(T') \\ \perp & \text{otherwise} \end{cases}
\end{aligned}$$

■ **Figure 4** Projecting a choreography in Chor λ onto a process – when cases overlap, the first one takes precedence (representative rules).

M , it may participate in interactions in M . Vice versa, a process can appear in the type of a choreography without appearing in the choreography itself. The difference between a process appearing in a choreography or its type becomes important when we look at the projection of **case** M of **lnl** $x \Rightarrow N$; **lnr** $x' \Rightarrow N'$. Here, \mathfrak{p} appearing in the type of M indicates that \mathfrak{p} will, at the end of the computation of M , know what branch will be chosen; therefore, the projection on \mathfrak{p} is a **case**. However, it is possible that \mathfrak{p} is involved in the computation of the condition M without knowing the final choice, e.g., if $M = \mathbf{com}_{\mathfrak{p},\mathfrak{q}} M'$. In this case, the projection on \mathfrak{p} is not a **case** but still needs code to participate in the implementation of M correctly. If \mathfrak{p} is involved in the branches as well, then we need to project code for them too: we inject an abstraction in order to maintain the correct order of computation (M before N and N') and make the resulting process well typed (since \mathfrak{p} does not appear in the type of M , that type will be projected to \perp).

The projection of abstraction illustrates the necessity of the ρ annotation on abstraction types. For example, consider an application of a communication via a proxy ($\lambda x : \text{Int}@_{\mathfrak{p}} \rightarrow_{\{\mathfrak{r}\}} \text{Int}@_{\mathfrak{q}}.x \text{ } 3@_{\mathfrak{p}} \text{ } (\lambda y : \text{Int}@_{\mathfrak{p}}.\mathbf{com}_{\mathfrak{r},\mathfrak{q}} \mathbf{com}_{\mathfrak{p},\mathfrak{r}} y)$). Without the annotation $\{\mathfrak{r}\}$ in subterm ($\lambda x : \text{Int}@_{\mathfrak{p}} \rightarrow_{\{\mathfrak{r}\}} \text{Int}@_{\mathfrak{q}}.x \text{ } 3@_{\mathfrak{p}} \text{ } (\lambda y : \text{Int}@_{\mathfrak{p}}.\mathbf{com}_{\mathfrak{r},\mathfrak{q}} \mathbf{com}_{\mathfrak{p},\mathfrak{r}} y)$), the projection of this subterm on \mathfrak{r} would just be \perp , which is wrong for the overall application since \mathfrak{r} will actually be involved.

Selections and communications follow the intuition given before, with one interesting detail: self-selections are ignored, and self-communications are projected to the identity function. This is different from previous works, where self-communication is not allowed – here we lift this restriction.

Likewise, projecting a type T yields \perp at any process not used in T .

► **Example 9.** Let $M = (\mathbf{com}_{\mathfrak{p},\mathfrak{q}} (\lambda x : \text{Int}@_{\mathfrak{p}}.3@_{\mathfrak{p}})) (\mathbf{com}_{\mathfrak{p},\mathfrak{q}} 5@_{\mathfrak{p}})$, where a function and a value are both sent from \mathfrak{p} to \mathfrak{q} before being applied at \mathfrak{q} . The implementation of \mathfrak{q} is $\llbracket M \rrbracket_{\mathfrak{q}} = (\mathbf{recv}_{\mathfrak{p}} \perp) (\mathbf{recv}_{\mathfrak{p}} \perp)$, whose execution is straightforward. At \mathfrak{p} , however, we have that $\llbracket M \rrbracket_{\mathfrak{p}} = (\mathbf{send}_{\mathfrak{q}}(\lambda x : \text{Int}.3)) (\mathbf{send}_{\mathfrak{q}} 5)$, which after executing the two send actions becomes $\perp \perp$. After executing its two communications, the choreography M becomes $M' = (\lambda x : \text{Int}@_{\mathfrak{q}}.3@_{\mathfrak{q}}) 5@_{\mathfrak{q}}$. M' is located entirely at \mathfrak{q} , and therefore $\llbracket M' \rrbracket_{\mathfrak{p}} = \perp$, which is different than the $\perp \perp$ reached by $\llbracket M \rrbracket_{\mathfrak{p}}$. We therefore need a way to make the application $\perp \perp$ become \perp . Rule NBTM serves this purpose. The fact that this is not possible with two units is the key semantic difference between \perp and $()$. J

► **Proposition 10.** *Let M be a closed choreography. If $\Theta; \Gamma \vdash M : T$, then for any process \mathfrak{p} appearing in M , we have that $\llbracket \Gamma \rrbracket \vdash \llbracket M \rrbracket_{\mathfrak{p}} : \llbracket T \rrbracket_{\mathfrak{p}}$, where $\llbracket \Gamma \rrbracket$ are defined by applying EPP to all types occurring Γ .*

► **Example 11.** Let M be the remote function choreography in Example 1. Its projections on \mathfrak{C} and \mathfrak{S} are as follows.

$$\llbracket M \rrbracket_{\mathfrak{C}} = \lambda f : \perp. \lambda val : \text{Int}. \mathbf{recv}_{\mathfrak{S}} (\mathbf{send}_{\mathfrak{S}} val)$$

$$\llbracket M \rrbracket_{\mathfrak{S}} = \lambda f : (\text{Int} \rightarrow \text{Int}). \lambda val : \perp. \mathbf{send}_{\mathfrak{C}} (f (\mathbf{recv}_{\mathfrak{C}} \perp))$$

This example illustrates the key features discussed in the text: projection of communications as two dual actions; and the way function applications are projected when the process does not appear in the function's type. J

We describe what we consider modularity of EPP, formally defined in Definition 12. Modular projection means that for any context $C[\]$ the projection of $C[M]$ at \mathfrak{p} will be the same for any M which does not involve \mathfrak{p} . The definition of context is as expected and can be found in Appendix A. Modularity is typical (and expected) of EPP, because the projection of \mathfrak{p} should not be generating junk code based on the behaviour of other processes.

► **Definition 12** (Modularity of EPP). *An EPP $\llbracket - \rrbracket$ is called modular if $\llbracket C[M] \rrbracket_{\mathfrak{p}} = \llbracket C[N] \rrbracket_{\mathfrak{p}}$ for any process \mathfrak{p} , context $C[\]$, and choreographies M and N such that $\Theta; \Gamma \vdash M : T$ and $\Theta; \Gamma \vdash N : T$ with $\mathfrak{p} \notin \Theta$.*

Modularity ensures that if we modify part of a choreography in which a process \mathfrak{p} is not involved, we do not need to recompile the projection of the choreography onto \mathfrak{p} because this projection is unaffected. In general, the strong equality requirement could be relaxed to allow for some extra local actions that do not change the observable behaviour of a process, e.g., adding “empty” applications like $\lambda x. \perp : \perp$. This would yield some extra flexibility to deal with cases such as the one seen in Example 6, so long as the interactions with other processes and return value at \mathfrak{p} do not change. However, this design would come at some costs: an increase in complexity due to the addition of a suitable notion of behavioural equivalence; a potential loss in efficiency, since processes might gain unnecessary reductions in their projections; and a potential leak of information, since the local code projected on a process would reveal some information about the behaviours of other processes.

The following proposition, Proposition 14, shows that our EPP is modular.

► **Lemma 13.** *Given a choreography M , if $\Theta; \Gamma \vdash M : T$ and $\mathfrak{p} \notin \Theta$ then $\llbracket M \rrbracket_{\mathfrak{p}} = \perp$.*

Proof. Follows from $\mathfrak{p} \notin \Theta$ implying $\mathfrak{p} \notin \text{pn}(T) \cup \text{pn}(M)$ and induction on the derivation of $\llbracket M \rrbracket_{\mathfrak{p}}$. ◀

► **Proposition 14.** *The EPP $\llbracket - \rrbracket$ given in Definition 8 is modular.*

Proof. Follows from Lemma 13 and observing that the projection of any context always treats \perp the same. ◀

► **Example 15** (Distributed choice types). Now that we can project a choreography, we return to the idea of distributed choice types from the introduction. Consider a choreography

$$M = \lambda x : \text{Bool}@(\mathfrak{p}, \mathfrak{q}). \text{case } x \text{ of } \mathbf{Inl } y \Rightarrow \mathbf{comp}_{\mathfrak{p}, \mathfrak{q}} 3 @ \mathfrak{p}; \mathbf{Inr } y \Rightarrow 5 @ \mathfrak{q}$$

Here $\text{Bool}@(\mathfrak{p}, \mathfrak{q})$ is equivalent to the type $(()@_{\mathfrak{p}} \times ()@_{\mathfrak{q}}) + (()@_{\mathfrak{p}} \times ()@_{\mathfrak{q}})$, and in general we can encode a “distributed boolean” as

$$\text{Bool}@_{\vec{\mathfrak{p}}} = (()@_{\mathfrak{p}_1} \times \cdots \times ()@_{\mathfrak{p}_n}) + (()@_{\mathfrak{p}_1} \times \cdots \times ()@_{\mathfrak{p}_n})$$

We can use distributed booleans to codify distributed choices, in this case by having both \mathfrak{p} and \mathfrak{q} be able to make local choice without interacting but still guaranteeing that they choose their respective behaviours correctly.

Specifically, when we project M we get two local choices made at \mathfrak{p} and \mathfrak{q} , both of which are guaranteed to make the same choice. First we have the projections

$$\llbracket M \rrbracket_{\mathfrak{p}} = \lambda x : (() \times \perp) + (() \times \perp). \text{case } x \text{ of } \mathbf{Inl } y \Rightarrow \mathbf{send}_{\mathfrak{q}} 3; \mathbf{Inr } y \Rightarrow \perp$$

and

$$\llbracket M \rrbracket_{\mathfrak{q}} = \lambda x : (\perp \times ()) + (\perp \times []). \text{case } x \text{ of } \mathbf{Inl } y \Rightarrow \mathbf{recv}_{\mathfrak{p}} \perp; \mathbf{Inr } y \Rightarrow 5$$

For these processes to be deadlock-free when put in parallel, we need both of them to make the same choice. Thankfully, the distributed boolean type ensures that x will always be instantiated as either $\mathbf{Inl} (\mathbf{Pair} ()@_{\mathfrak{p}} ()@_{\mathfrak{q}})$ or $\mathbf{Inr} (\mathbf{Pair} ()@_{\mathfrak{p}} ()@_{\mathfrak{q}})$. From the projection we get $\llbracket \mathbf{Inl} (\mathbf{Pair} ()@_{\mathfrak{p}} ()@_{\mathfrak{q}}) \rrbracket_{\mathfrak{p}} = \mathbf{Inl} (\mathbf{Pair} () \perp)$ and $\llbracket \mathbf{Inl} (\mathbf{Pair} ()@_{\mathfrak{p}} ()@_{\mathfrak{q}}) \rrbracket_{\mathfrak{q}} = \mathbf{Inl} (\mathbf{Pair} \perp ())$,

7:14 Modular Compilation for Higher-Order Functional Choreographies

and similar for the **Inr** case. We therefore know that $\text{Chor}\lambda$'s distributed choice works as intended when projected. As we shall see in Section 5, one use for this technique is to have different processes independently agree on the size of a distributed list.

Note that if we tried to model a distributed boolean as $(\text{()@p} + \text{()@p}) \times (\text{()@q} + \text{()@q})$, it would not be useful to represent a distributed choice because it would allow the processes to make different choices. (Also, M would obviously not be well-typed, as a condition must have a sum type.)

We now show that there is a close correspondence between the executions of choreographies and of their projections. Intuitively, this correspondence states that a choreography can execute an action if, and only if, its projection can execute the same action, and both transition to new terms in the same relation. Technically, we need to be more precise: if a choreography M reduces by rule **CASE**, then the result has fewer branches than the network obtained by performing the corresponding reduction in the projection of M . (This is a standard issue with choreographic conditionals [24].)

In order to capture this, we define a partial order \sqsupseteq that relates a behaviour to a version with fewer branches: $B \sqsupseteq B'$ iff $B \sqcup B' = B$. Intuitively, if $B \sqsupseteq B'$, then B offers the same or more branches than B' (also in subterms). This notion extends to networks by defining $\mathcal{N} \sqsupseteq \mathcal{N}'$ to mean that, for any process \mathfrak{p} , $\mathcal{N}(\mathfrak{p}) \sqsupseteq \mathcal{N}'(\mathfrak{p})$. Example 16 shows the necessity of \sqsupseteq in order to get a meaningful notion of operational correspondence between choreographies and their projection.

► **Example 16.** Consider again the choreography from Example 7,

$$C = \mathbf{case} \text{ Inl } (\text{()@p} \text{ of } \text{Inl } x \Rightarrow \mathbf{select}_{\mathfrak{p},\mathfrak{q}} \text{ left } 0\text{@q}; \text{Inr } y \Rightarrow \mathbf{select}_{\mathfrak{p},\mathfrak{q}} \text{ right } 1\text{@q}),$$

and its projection B on \mathfrak{q} , $B = \llbracket C \rrbracket_{\mathfrak{q}} = \&_{\mathfrak{p}}\{\text{left} : 0, \text{right} : 1\}$.

When entering the **case**, C reduces to $C' = \mathbf{select}_{\mathfrak{p},\mathfrak{q}} \text{ left } 0\text{@q}$, but \mathfrak{q} is not involved in this action and its behaviour remains B , which is not $\llbracket C' \rrbracket_{\mathfrak{q}}$. However, $\&_{\mathfrak{p}}\{\text{left} : 0, \text{right} : 1\} \sqcup \&_{\mathfrak{p}}\{\text{left} : 0\} = \&_{\mathfrak{p}}\{\text{left} : 0, \text{right} : 1\}$, so $B \sqsupseteq \llbracket C' \rrbracket_{\mathfrak{q}}$.

In addition to \sqsupseteq , we need to equate behaviours that differ only by applications to \perp like P and $(\lambda x : \perp.P) \perp$ introduced by the projection of applications.

► **Definition 17.** We define \equiv as the least equivalence relation on behaviours that is closed under context and $P \equiv (\lambda x : \perp.P) \perp$ for any behaviour P . We write $\mathcal{N} \equiv \mathcal{N}'$ for the pointwise extension of \equiv to networks (i.e., $\Pi_{\mathfrak{p}}\mathfrak{p}[P_{\mathfrak{p}}] \equiv \Pi_{\mathfrak{p}}\mathfrak{p}[P'_{\mathfrak{p}}]$ iff $P_{\mathfrak{p}} \equiv P'_{\mathfrak{p}}$ for all \mathfrak{p} s) and $\mathcal{N} \sqsupseteq \mathcal{N}'$ if there is a network \mathcal{N}'' such that $\mathcal{N} \sqsupseteq \mathcal{N}''$ and $\mathcal{N}'' \equiv \mathcal{N}'$.

We can finally show that the EPP of a choreography can do all that (completeness) and only what (soundness) the choreography does. Here \rightarrow^* denotes a sequence of transitions with any labels, and \rightarrow^+ a nonempty such sequence.

► **Theorem 18 (Completeness).** Given a closed choreography M , if $M \xrightarrow{P} M'$, $\Theta; \Gamma \vdash M : T$, and $\llbracket M \rrbracket$ is defined, then there exist networks \mathcal{N} and M'' such that: $\llbracket M \rrbracket \rightarrow^+ \mathcal{N}$; $M' \rightarrow^* M''$; and $\mathcal{N} \sqsupseteq \llbracket M'' \rrbracket$.

► **Theorem 19 (Soundness).** Given a closed choreography M , if $\Theta; \Gamma \vdash M : T$ and $\llbracket M \rrbracket \rightarrow^* \mathcal{N}$ for some network \mathcal{N} , then there exist a choreography M' , and a network \mathcal{N}' such that: $M \rightarrow^* M'$; $\mathcal{N} \rightarrow^* \mathcal{N}'$; and $\mathcal{N}' \sqsupseteq \llbracket M' \rrbracket$.

Since we have no recursion and only require that the choreography and projection eventually get to the same state, we can prove soundness and correctness without needing the out-of-order semantics usually required in choreographic languages [24].

From Theorems 18 and 19 and the type preservation and progress results from [6], we obtain deadlock-freedom: the EPP of a well-typed closed choreography can continue to reduce until all processes contain only local values.

► **Corollary 20** (Deadlock-freedom). *Given a closed choreography M , if $\Theta; \Gamma \vdash M : T$ then: whenever $\llbracket M \rrbracket \rightarrow^* \mathcal{N}$ for some network \mathcal{N} , either there exists \mathfrak{p} and \mathcal{N}' such that $\mathcal{N} \xrightarrow{\tau} \mathcal{N}'$ or $\mathcal{N} = \prod_{\mathfrak{p} \in \text{pn}(M)} \mathfrak{p}[L_{\mathfrak{p}}]$.*

4 Recursion

So far we have worked with a recursion-free subset of $\text{Chor}\lambda$. In this section, we extend our development to the full language presented of $\text{Chor}\lambda$, which includes recursive definitions [6]. As we will see, recursion is technically challenging because of the introduction of divergence.

4.1 Definitions

Choreographies

Recursion in $\text{Chor}\lambda$ is achieved by named functions (f) parametrised on process names. We use D to range over mappings of parametrised functions names to choreographies (the bodies of the functions). To execute a choreography M containing calls to named functions, the choreography must be associated with a mapping D that contains all the named functions called by M . The grammar of choreographies is extended with $M ::= \dots \mid f(\vec{\mathfrak{p}})$. A function call $f(\vec{\mathfrak{p}})$ invokes f by instantiating its parameters with the process names $\vec{\mathfrak{p}}$, which evaluates to the body of the function. In a function call or definition, parameters must be distinct. Semantically, we add D as an annotation to the reduction relation for choreographies and use the following rule to evaluate functions. Labels in $\text{Chor}\lambda$ with recursion are extended to the form ℓ, \mathfrak{P} , where the new ingredient ℓ can be either τ or λ . The need for ℓ is explained later.

$$\frac{D(f(\vec{\mathfrak{p}})) = M}{f(\vec{\mathfrak{p}}) \xrightarrow{\tau, \emptyset}_D M[\vec{\mathfrak{p}} \mapsto \vec{\mathfrak{p}}]} \text{ [DEF]}$$

To type recursive choreographies, we introduce recursive type variables ranged over by t . These are defined in a collection Σ , which contains type equations of the form $t@_{\vec{\mathfrak{p}}} = T$ – the elements of $\vec{\mathfrak{p}}$ must be distinct. The grammar of types is extended with parametrised variables: $T ::= \dots \mid t@_{\vec{\mathfrak{p}}}$. Essentially, assuming the presence of an equation $t@_{\vec{\mathfrak{p}'}} = T$, $t@_{\vec{\mathfrak{p}}}$ can be unfolded into $T[\vec{\mathfrak{p}} := \vec{\mathfrak{p}}]$. Typing judgements are then of the form $\Theta; \Sigma; \Gamma \vdash M : T$, where Γ may now also contain type assignments for recursive functions of the form $f(\vec{\mathfrak{p}}) : T$.

$$\frac{\Theta; \Sigma; \Gamma \vdash M : t@_{\vec{\mathfrak{p}}} \quad t@_{\vec{\mathfrak{p}}} =_{\Sigma} T \quad \vec{\mathfrak{p}} \subseteq \Theta \quad \|\vec{\mathfrak{p}}\| = \|\vec{\mathfrak{p}}'\| \quad \vec{\mathfrak{p}}' \text{ distinct}}{\Theta; \Sigma; \Gamma \vdash M : T[\vec{\mathfrak{p}} := \vec{\mathfrak{p}}']} \text{ [TEQ]}$$

We also write $\Theta; \Sigma; \Gamma \vdash D$ to denote that each function in D can be typed accordingly to its type in Γ .

► **Example 21** (Remote Map). With recursive functions, we can write more complex choreographies that call themselves and each other. Let `remoteFunction(C, S)` be defined as the choreography in Example 1. We use it to define a function `remoteMap(C, S)`, where a

7:16 Modular Compilation for Higher-Order Functional Choreographies

server S applies a function to not just one value, but instead to each element of a stream communicated from a client C . Then S returns the results, which C gathers into a list with the standard `cons` function used to construct a new list.

```
remoteMap(C, S) = λfun : Int@S → Int@S. λlist : [Int]@C.
  case list of
  Inl x ⇒ selectC,S stop ()@C;
  Inr x ⇒ selectC,S again
    cons(C) (remoteFunction(C, S) fun (fst x)) (remoteMap(C, S) fun (snd x))
```

Here, $[Int]@C$ is defined as $[Int]@C = ()@C + (Int@C \times [Int]@C)$, representing a list of integers. In general, we write $[t]@(p_1, \dots, p_n)$ to mean the type satisfying $[t]@(p_1, \dots, p_n) = (()@p_1 \times \dots \times ()@p_n) + (t@(p_1, \dots, p_n) \times [t]@(p_1, \dots, p_n))$.

► **Example 22** (Diffie-Hellman [6]). We recall the choreography for the Diffie-Hellman key exchange protocol [13], which allows two processes to agree on a shared secret key without assuming secrecy of communications. Again, we use the primitive type `Int`.

To define this protocol, we use the local function `modPow(R)` of the type

$$\text{modPow}(R) : \text{Int}@R \rightarrow \text{Int}@R \rightarrow \text{Int}@R \rightarrow \text{Int}@R$$

which computes powers with a given modulo. Given `modPow(R)`, we can implement Diffie-Hellman as the following choreography:

```
diffieHellman(P, Q) =
  λpsk : Int@P. λqsk : Int@Q. λpsg : Int@P.
  λqsg : Int@Q. λpsp : Int@P. λqsp : Int@Q.
  pair (modPow(P) psg (comQ,P (modPow(Q) qsg qsk qsp)) psp)
    (modPow(Q) qsg (comP,Q (modPow(P) psg psk psp)) qsp)
```

Given the individual secret keys (psk and qsk) and a previously publicly agreed upon shared prime modulus and base ($psg = qsg, psp = qsp$), the participants exchange their locally-computed public keys in order to arrive at a shared key that can be used to encrypt all further communication. This means `diffieHellman(P, Q)` has the type:

$$\text{Int}@P \rightarrow \text{Int}@Q \rightarrow \text{Int}@P \rightarrow \text{Int}@Q \rightarrow \text{Int}@P \rightarrow \text{Int}@Q \rightarrow \text{Int}@P \times \text{Int}@Q$$

and represents the shared key as a pair of equal keys, one for each participant.

The choreography then takes a shared key as its parameter and produces a pair of unidirectional channels that wrap the communication primitive with the necessary encryption based on the key:

```
makeSecureChannels(P, Q) = λkey : Int@P × Int@Q.
  Pair (λval : String@P. (dec(Q) (snd key) (comP,Q (enc(P) (fst key) val))))
    (λval : String@Q. (dec(P) (fst key) (comQ,P (enc(Q) (snd key) val))))
```

Here `enc` and `dec` are local function for encoding and decoding values based on keys.

The fact that this choreography returns a pair of channels can also be seen from its type:

$$(\text{Int}@P \times \text{Int}@Q) \rightarrow ((\text{String}@P \rightarrow \text{String}@Q) \times (\text{String}@Q \rightarrow \text{String}@P))$$

Using the channels is as easy as using `com` itself and amounts to a function application.

Process language

To implement recursive functions in Chor λ , we also add recursive functions to our process language: $B ::= \dots \mid f(\vec{p})$. They have the same syntax as in choreographies, being parametric on the names of any other processes our process may interact with as part of the function. Local function names are associated with their definition by a function \mathbb{D} , which works the same as D in the choreographic setting. Furthermore, we add a transition rule to the process language similar to rule DEF for choreographies.

Endpoint Projection

We respectively project function calls, type variables, and function definitions as follows.

$$\begin{aligned} \llbracket f(\vec{p}) \rrbracket_{\mathbf{p}} &= \begin{cases} f_i(\mathbf{p}_1, \dots, \mathbf{p}_{i-1}, \mathbf{p}_{i+1}, \dots, \mathbf{p}_n) & \text{if } \vec{p} = \mathbf{p}_1, \dots, \mathbf{p}_{i-1}, \mathbf{p}, \mathbf{p}_{i+1}, \dots, \mathbf{p}_n \\ \perp & \text{otherwise} \end{cases} \\ \llbracket t@{\vec{p}} \rrbracket_{\mathbf{p}} &= \begin{cases} t_i & \text{if } \vec{p} = \mathbf{p}_1, \dots, \mathbf{p}_{i-1}, \mathbf{p}, \mathbf{p}_{i+1}, \dots, \mathbf{p}_n \\ \perp & \text{otherwise} \end{cases} \\ \llbracket D \rrbracket &= \{f_i(\mathbf{p}_1, \dots, \mathbf{p}_{i-1}, \mathbf{p}_{i+1}, \dots, \mathbf{p}_n) \mapsto \llbracket M \rrbracket_{\mathbf{p}_i} \mid D(f(\mathbf{p}_1, \dots, \mathbf{p}_n)) = M\} \end{aligned}$$

Each named function gets projected to a different named function for each process in its list of parameters, with the projected environment now treating each of these as separate functions parametric on the remaining involved processes. These parameters are needed to implement interactions. Each process can enter a named function independently. Thus, for example, if $D(f(\mathbf{p}, \mathbf{q})) = M$ we get $\llbracket D \rrbracket (f_1(\mathbf{q})) = \llbracket M \rrbracket_{\mathbf{p}}$ and $\llbracket D \rrbracket (f_2(\mathbf{p})) = \llbracket M \rrbracket_{\mathbf{q}}$.

On the other hand, projection of recursive types does not need to consider other processes than the one we are projecting on, since local types never mention any processes. Σ is otherwise projected similarly to D . For example, if $t@(\mathbf{p}, \mathbf{q}) = T \in \Sigma$ then $t_1 = \llbracket T \rrbracket_{\mathbf{p}} \in \llbracket \Sigma \rrbracket$ and $t_2 = \llbracket T \rrbracket_{\mathbf{q}} \in \llbracket \Sigma \rrbracket$.

$$\llbracket \Sigma \rrbracket = \{t_i = \llbracket T \rrbracket_{\mathbf{p}_i} \mid t@(\mathbf{p}_1, \dots, \mathbf{p}_n) = T \in \Sigma\}$$

► **Example 23** (Projecting Example 21). Projecting the choreography in Example 21 yields the processes `remoteMap1` (for the client) and `remoteMap2` (for the server) below. The bodies of `remoteFunction1` and `remoteFunction2` are the terms in Example 11.

```
remoteMap1(S) = λfun : ⊥. λlist : [Int].
  case list of
    Inl x ⇒ ⊕S stop ();
    Inr x ⇒ ⊕S again
      cons1 (remoteFunction1(S) ⊥ (fst x)) (remoteMap1(S) ⊥ (snd x))
remoteMap2(C) = λfun : Int → Int. λlist : ⊥.
  &C{stop : ⊥, again : (remoteFunction2(C) fun ⊥) (remoteMap2(C) fun ⊥)}
```

► **Example 24** (Projecting Example 22). Projecting our choreographies `diffieHellman(P, Q)` and `makeSecureChannels(P, Q)` for process P yields the following behaviours.

```
\llbracket D(diffieHellman(P, Q)) \rrbracket1 (Q) = λpsk : Int. λqsk : ⊥. λpsg : Int. λqsg : ⊥. λpsp : Int. λqsp : ⊥.
  pair (modPow1 psg (recvQ ⊥)) psp
    (sendQ (modPow1 psg psk psp))
```

$$\begin{aligned} \llbracket D(\text{makeSecureChannels}(P, Q)) \rrbracket_1(Q) &= \lambda key : \text{Int} \times \perp. \\ \mathbf{Pair} (\lambda val : \text{String}. ((\mathbf{snd} \ key) (\mathbf{send}_Q (\mathbf{encrypt}_1 (\mathbf{fst} \ key) \ val)))) \\ (\lambda val : \perp. (\mathbf{decrypt}_1 (\mathbf{fst} \ key) (\mathbf{recv}_Q (\mathbf{snd} \ key)))) \end{aligned}$$

Note the way function calls such as $\text{modPow}(P)$ in the choreography get projected to modPow_1 on P , since they are treated as degenerate choreographies (they have only one process) and P is the first and only process involved. Conversely, $\text{modPow}(Q)$ on P gets projected as \perp since it is located entirely at a different process.

4.2 Out-of-order execution

In the presence of recursion, getting a correspondence between a process and choreographic language becomes much more challenging. In our results for $\text{Chor}\lambda$ without recursion, we relied on the fact that a choreography would eventually reduce to a value. This is no longer true as choreographies can now diverge, and worse they can diverge at one process without diverging at another. Let, for example, $M = (\lambda x : \text{Int}@p. \mathbf{fst} (\mathbf{Pair} \ 5@q \ x)) \ f(p)$. Assume that $D(f(p_1)) = M'$, where M' diverges. Then the reduction rules that we have seen so far would not allow x to be instantiated. However, $\llbracket f(p) \rrbracket_q = \perp$, so $\llbracket M \rrbracket_q$ can reduce to 5 . Therefore, we need a way to let M copy the reduction of $\mathbf{fst} (\mathbf{Pair} \ 5@q \ x)$ to $5@q$. In [6], we included corresponding reduction rules for $\text{Chor}\lambda$ to deal with this kind of issues. These rules are all type preserving and avoid creating situations where processes disagree on which communication should be performed first [6]. These rules were unnecessary to deal with the recursion-free fragment, so we introduce them now.

Rule INABS below addresses situations as in the previous example.

$$\frac{M \xrightarrow{\ell, P}_D M'}{\lambda x : T.M \xrightarrow{\lambda, P}_D \lambda x : T.M'} \text{ [INABS]} \quad \frac{M \xrightarrow{\ell, R}_D M' \quad \ell = \lambda \Rightarrow P \cap \text{pn}(N) = \emptyset}{M \ N \xrightarrow{\tau, P}_D M' \ N} \text{ [APP1]}$$

Rule APP1 use the ℓ -component in reduction labels to identify whether a reduction is performed under an abstraction ($\ell = \lambda$) or not ($\ell = \tau$). We need this distinction to prevent interactions under an abstraction performed by processes involved in the righthandside of an application. This restriction serves to avoid breaking causal dependencies between communications. Consider the choreography $(\lambda x : \text{Int}@p. \mathbf{com}_{q,p} \ 4@q) (\mathbf{com}_{q,p} \ 5@q)$, where the righthandside communication should be performed first – without the restriction, this would not be guaranteed. Reductions under abstractions additionally necessitates a new safety condition on rule APPABS , ensuring that the free variables of V are distinct from the bound variables of M to avoid problems with scope.

Our modification allows the choreography $M = (\lambda x : \text{Int}@q. \mathbf{fst} (\mathbf{Pair} \ 5@q \ x)) \ f(p, q)$ to reduce to $M' = (\lambda x : \text{Int}@p_2. 5@q) \ f(p, q)$. Thus, the projections of M on p and q must be able to reduce to the projections of M' . For p this is easy, since $\llbracket M \rrbracket_p = \llbracket M' \rrbracket_p = \perp \ f_1(q)$. For q , however, we need $\llbracket M \rrbracket_q = (\lambda x : \text{Int}. \mathbf{fst} (\mathbf{Pair} \ \perp \ x)) \ f_2(p)$ to reduce to $\llbracket M' \rrbracket_q = (\lambda x : \text{Int}. \perp) \ f_2(p)$, which requires the process language to have similar out-of-order semantics. We therefore add an equivalent rule NINABS and modify rule NAPP1 similarly to rule APP1 .

In the network, rather than checking for interacting processes, we do not allow communication actions (\mathbf{send} , \mathbf{recv} , \oplus , $\&$) from inside an abstraction. The reduction labels for the process language are thus simpler (τ or λ), since we do not need to track process names involved in actions.

Similar problems appear with applications that have divergent subterms on the lefthand-side, like $f(q) ((\lambda x : \text{Int}@p. 4@q) \ 3@p)$, and are treated similarly (the corresponding reduction rules are given in the appendix).

$$\begin{array}{c}
\frac{x \notin \text{fv}(M')}{((\lambda x : T.M) N) M' \rightsquigarrow (\lambda x : T.(M M')) N} \text{ [R-ABS R]} \\
\frac{x, x' \notin \text{fv}(M) \quad \text{spn}(M) \cap \text{pn}(N) = \emptyset}{M (\text{case } N \text{ of } \text{Inl } x \Rightarrow M_1; \text{Inr } x' \Rightarrow M_2) \rightsquigarrow \text{case } N \text{ of } \text{Inl } x \Rightarrow (M M_1); \text{Inr } x' \Rightarrow (M M_2)} \text{ [R-CASE L]} \\
\frac{\text{spn}(M) \cap \text{pn}(N) = \emptyset}{M (\text{select}_{q,p} l N) \rightsquigarrow \text{select}_{q,p} l (M N)} \text{ [R-SELL]} \\
\frac{y \text{ fresh for } M}{\lambda x : T.M \rightsquigarrow \lambda y : T.M[x := y]} \text{ [R-ALPH]}
\end{array}$$

■ **Figure 5** Rewriting of Chor λ (representative rules).

$$\begin{array}{c}
\frac{\text{pn}(B) = \emptyset}{B (\&_p \{l_1 : B_1, \dots, l_n : B_n\}) \rightsquigarrow \&_p \{l_1 : B B_1, \dots, l_n : B B_n\}} \text{ [LR-OFFL]} \\
\frac{\text{pn}(B') = \emptyset}{B' (\oplus_p l B) \rightsquigarrow \oplus_p l (B' B)} \text{ [LR-CHOL]} \quad \frac{}{\perp \perp \rightsquigarrow \perp} \text{ [LR-BOTM]}
\end{array}$$

■ **Figure 6** Rewriting of behaviours (representative rules).

Dealing with recursive functions in nested applications requires another addition to the semantics of Chor λ . Consider the choreography $M = ((\lambda x : \text{Int}@p.\lambda y : \text{Int}@q.3@p) f(p)) 4@q$. We have $\llbracket M \rrbracket_q = ((\lambda x : \perp.\lambda y : \text{Int}.\perp) \perp) 4$, which can reduce to \perp in two steps. Reducing M accordingly requires being able to instantiate y as $4@q$ even if $f(p)$ diverges. For this, and other cases of functions whose divergence blocks actions, Chor λ has a set of rewriting rules (see Figure 5). In our example, M can be rewritten as $(\lambda x : \text{Int}@p.(\lambda y : \text{Int}@q.3@p 4@q)) f(p)$ by using rule R-ABS R, which can reduce to $(\lambda x : \text{Int}@p.3@p) f(p)$ as needed. In the rewriting rules that move a subterm in a lefthandside further in, the synchronising processes of the subterm, $\text{spn}(M)$, is used to prevent rewritings that would change the order of communications. To use the rewritings in the semantics we add the rule

$$\frac{M \rightsquigarrow^* N \quad N \xrightarrow{\tau, P} M'}{M \xrightarrow{\tau, P}_D M'} \text{ [STR]}$$

As before, equivalent rules must be added to the semantics of our process language (see Figure 6), and the reduction relation is closed under these rewritings. This allows $\llbracket M \rrbracket_p = ((\lambda x : \text{Int}.\lambda y : \perp.3) f_1()) \perp$ to be rewritten to $(\lambda x : \text{Int}.\lambda y : \perp.3 \perp) f_1()$, which can reduce to $(\lambda x : \text{Int}.3) f_1()$.

4.3 Properties

Thanks to the extensions discussed in this section, our results can be generalised to the full language of Chor λ with recursion.

► **Theorem 25 (Completeness).** *Given a closed choreography M , if $M \xrightarrow{\tau, P}_D M'$ and $\Theta; \Sigma; \Gamma \vdash M : T$ and $\llbracket M \rrbracket$ is defined, then there exist networks \mathcal{N} and M'' such that: $\llbracket M \rrbracket \rightarrow_{\llbracket D \rrbracket}^+ \mathcal{N}$; $M' \rightarrow^* M''$; and $\mathcal{N} \cong \llbracket M'' \rrbracket$.*

► **Theorem 26** (Soundness). *Given a closed choreography M , if $\Theta; \Gamma \vdash M : T$ and $\llbracket M \rrbracket \rightarrow^* \mathcal{N}$ for some network \mathcal{N} , then there exist a choreography M' , and a network \mathcal{N}' such that: $M \rightarrow_D^* M'$; $\mathcal{N} \rightarrow^* \mathcal{N}'$; and $\mathcal{N}' \cong \llbracket M' \rrbracket$.*

From Theorems 25 and 26 and the type preservation and progress results from [6], we get the following corollary about deadlock-freedom. Specifically, the EPP of a well-typed closed choreography can keep reducing until all processes contain only local values (which denotes termination).

► **Corollary 27** (Deadlock-freedom). *Given a closed choreography M and a function environment D containing all the functions of M , if $\Theta; \Sigma; \Gamma \vdash M : T$ and $\Theta; \Sigma; \Gamma \vdash D$, then: whenever $\llbracket M \rrbracket \rightarrow_{[D]}^* \mathcal{N}$ for some network \mathcal{N} , either there exists P and \mathcal{N}' such that $\mathcal{N} \xrightarrow{Tp}_{[D]} \mathcal{N}'$ or $\mathcal{N} = \prod_{p \in \text{pn}(M)} p[L_p]$.*

We also show that adding recursion does not stop our projection being modular.

► **Proposition 28.** *The EPP $\llbracket - \rrbracket$ given in Definition 8 and extended with the equations in Section 4.1 is modular.*

Proof. The only change to the projection of choreographies is adding the projection of $f(\vec{p})$, for which Lemma 13 still holds. Since no new contexts have been added, projection is then still modular. ◀

5 EAP

We now use our theory of EPP to obtain an implementation of the core of the Extensible Authentication Protocol (EAP) [28], which was modelled as a choreography in [6]. EAP is a widely-employed link-layer protocol that defines an authentication framework allowing a peer P to authenticate with a backend authentication server S , with the communication passing through an authenticator A that acts as an access point for the network.

The framework provides a core protocol parametrised over a set of authentication methods (either predefined or custom vendor-specific ones), modelled as individual choreographies with type $\text{AuthMethod}@(\mathcal{P}, \mathcal{A}, \mathcal{S}) = \text{String}@S \rightarrow_{\{\mathcal{P}, \mathcal{A}\}} \text{Bool}@S$.

For reasons of modularity, it is desirable that the core of the protocol be written in a way that does not assume any particular authentication method. The $\text{eap}(\mathcal{P}, \mathcal{A}, \mathcal{S})$ choreography does exactly that by leveraging higher-order composition of choreographies:

```
eap(P, A, S) = λmethods : [AuthMethod]@(P, A, S).
  eapAuth(P, A, S) (eapIdentity(P, A, S) "Auth request"@S) methods

eapAuth(P, A, S) = λid : String@S. λmethods : [AuthMethod]@(P, A, S).
  if empty(P, A, S) methods then
    eapFailure(P, A, S) "Try again later"@S
  else
    if (fst methods) id then
      selectS,P ok (selectS,A ok (eapSuccess(P, A, S) "Welcome"@S))
    else
      selectS,P ko (selectS,A ko (eapAuth(P, A, S) id (snd methods)))
```

For the sake of simplicity, we have left out the definitions of a couple of helper choreographies that are referenced in the example:

```
eapIdentity(P, A, S) : String@S →\{P,A\}} String@S
```

$$\begin{aligned} \text{empty}(P, A, S) &: [\text{AuthMethod}]@(\text{P}, \text{A}, \text{S}) \rightarrow \text{Bool}@(\text{P}, \text{A}, \text{S}) \\ \text{eapSuccess}(P, A, S) &: \text{String}@S \rightarrow (\text{String}@P \times \text{String}@A) \\ \text{eapFailure}(P, A, S) &: \text{String}@S \rightarrow (\text{String}@P \times \text{String}@A) \end{aligned}$$

First, $\text{eap}(P, A, S)$ fetches the client's identity using $\text{eapIdentity}(P, A, S)$, a function which exchanges the necessary EAP packets and delivers the client's identity to the server. Once the identity is known, $\text{eapAuth}(P, A, S)$ is invoked in order to try the list of authentication methods until one succeeds, or the list is exhausted and authentication fails.

EAP is parametric on a list of choreographies called *methods*. We use the notation for lists in $[\text{AuthMethod}]@(\text{P}, \text{A}, \text{S})$ as described in Example 21, as well as the **if** M **then** M' **else** M'' construct which is just syntactic sugar for the previously described **case** M **of** $\text{Inl } x \Rightarrow M'$; $\text{Inr } x \Rightarrow M''$. Each authentication method can be an arbitrarily-complex choreography with its own communication structures that can involve all three involved processes, and it implements a particular authentication method on top of EAP.

The function $\text{empty}(P, A, S)$ is used to determine whether the list of methods is empty. Recall the distributed boolean from Example 15, and note how we now use the same idea to minimise unnecessary communication while still guaranteeing that every process has the necessary information. The return type of this function, $\text{Bool}@(\text{P}, \text{A}, \text{S})$, denotes that the function uniformly returns either true ($\text{Inl } ()$) or false ($\text{Inr } ()$) at all of P , A , and S . That is, the result is guaranteed to be the same at these three processes. Since agreement is guaranteed, each process can locally check its own value without having to perform any selections. This is in contrast to the return type of each authentication method, $\text{Bool}@S$, meaning that only the server S has the authority of determining whether the authentication method was successful or not.

Finally, depending on the outcome of the authentication, an appropriate EAP packet is delivered by using either $\text{eapSuccess}(P, A, S)$ or $\text{eapFailure}(P, A, S)$ to indicate the result to the client.

```
eap1(A, S) = λmethods : [AuthMethod].
  eapAuth1(A, S) (eapIdentity1(A, S) ⊥) methods

eap2(P, S) = λmethods : [AuthMethod].
  eapAuth2(P, S) (eapIdentity2(P, S) ⊥) methods

eap3(P, A) = λmethods : [AuthMethod].
  eapAuth3(P, A) (eapIdentity3(P, A) "Auth request") methods
```

It is interesting to look at the projections of $\text{eapAuth}(P, A, S)$ for each of the three participants, which follow below. For the purposes of projection, we desugar the if-then-else construct.

```
eapAuth1(A, S) = λid : ⊥. λmethods : [AuthMethod].
  case empty1(A, S) methods of
    Inl _ ⇒ eapFailure1(A, S) ⊥
    Inr _ ⇒ &S {ok : eapSuccess1(A, S) ⊥
              ko : eapAuth1(A, S) ⊥ (snd methods)}

eapAuth2(P, S) = λid : ⊥. λmethods : [AuthMethod].
  case empty2(P, S) methods of
    Inl _ ⇒ eapFailure2(P, S) ⊥
    Inr _ ⇒ &S {ok : (eapSuccess2(P, S) ⊥)
              ko : (eapAuth2(P, S) ⊥ (snd methods))}
```

```

eapAuth3(P, A) = λid : String. λmethods : [AuthMethod].
  case empty3(P, A) methods of
    Inl _ ⇒ eapFailure3(P, A) "Try again later"
    Inr _ ⇒ case (fst methods) id of
      Inl _ ⇒ ⊕P ok (⊕A ok (eapSuccess3(P, A) "Welcome"))
      Inr _ ⇒ ⊕P ko (⊕A ko (eapAuth3(P, A) id (snd methods)))

```

Note that the implementation of the check `empty(P, A, S) methods` at each process is completely local, i.e., it does not perform communications. This is possible because all processes have access to the same list. Afterwards however, only the server `S` is capable of determining whether the authentication method was successful or not, and has to communicate that result to the other two participants by means of selections.

6 Related Work

We already discussed the most related work on choreographic programming and EPP in Section 1. In this section, we discuss some technical aspects of our development in the context of previous work more in detail.

In our process language, the terms for communication actions (send, receive, selection, and branching) are adaptations to the functional setting of standard primitives from traditional imperative choreographic programming [8, 10, 21] and the local language of multiparty session types (choreographies without computation) [20, 19, 3]. A similar adaptation was carried out in [27] for the different setting of multi-threading (their primitives are not based on process names, but shared channels). Modelling a network as a map from process names to programs was previously done in [9, 24]. The idea of reporting the names of the involved processes in transition labels comes from [2, 19, 9, 24].

The first attempt at adding higher-order composition to choreographies goes back to [11], for a choreographic language that cannot express data nor computation (it is an abstract specification language). The approach in [11] adopts centralised coordination: resolving a choreographic application ($M M'$ in $\text{Chor}\lambda$, with M' involving more than one process) requires that the programmer picks a process as central coordinator, which then orchestrates the other processes with multicasts. This coordination effectively acts as a barrier, so processes cannot perform their own local computations independently of each other when higher-order composition is involved. Ten years after [11], another attempt at a notion of EPP for higher-order choreographies was proposed in [18]. The language in [18] is more expressive, i.e., it supports expressing computation at processes. However, this feature came at a cost: it is even more centralised than [11]. In particular, every application in a choreography requires that all processes generated by projection go through a global barrier that involves the entire system. The global barrier is modelled as a middleware in the semantics of the language, and involves even processes that do not contribute at all to the function or its arguments. Because processes need to participate also in the resolution of applications that do not involve them, the notion of EPP in [18] is not modular.

In contrast to [11] and [18], $\text{Chor}\lambda$ presents no “hidden” barriers: coordination among processes is left to the programmer of the choreography, and EPP inserts no hidden synchronisations. Our EPP thus generates more concurrent and faithful implementations. It is also the first modular EPP for functional choreographic programming: changing the behaviours of some processes in a choreography requires re-running EPP only for those processes. This is important for the application of choreographic programming to DevOps (continuous integration and deployment), library management, and modularity in general.

Another related line of work is that on multitier programming and its progenitor calculus, Lambda 5 [25]. Similarly to Chor λ , Lambda 5 and multitier languages have data types with locations [29]. However, they are used very differently. In choreographic languages (thus Chor λ), programs have a “global” point of view and express how multiple processes interact with each other. By contrast, in multitier programming programs have the usual “local” point of view of a single process but they can nest (local) code that is supposed to be executed remotely. The reader interested in a detailed comparison of choreographic and multitier programming can consult [17], which presents algorithms for translating choreographies to multitier programs and vice versa. The correctness of these algorithms has never been proven, because they use an informally-specified fragment of Choral as a representative choreographic language. We conjecture that the introduction of an EPP for Chor λ could be the basis for a future comparison of the compilations for choreographic programs (in terms of Chor λ) and multitier programs (in terms of Lambda 5).

To the best of our knowledge, no other work supports distributed choice types. The nearest feature is presented in [21], where choreographic conditionals for a first-order calculus can be conjunctions of local conditions at different processes. These conditions must be checked to be consistent by means of separate proofs given in a Hoare-like logic. Our syntax is more general, since conditions can be choreographies, and our EPP requires no such additional proofs. However, using a Hoare logic in [21] gives some interesting flexibility, in that agreement does not need to be encoded as distributed sum types. In the future, it could be interesting to integrate the two approaches such that agreement could be proved by using a logic and then made manifest to EPP through our distributed choice types.

7 Conclusion and Future Work

We have presented a new theory of compilation for higher-order functional choreographies, which introduces modularity and decentralisation.

Our development validates the design of Chor λ [6], but it also reveals that in the case without recursion it can be significantly simplified: reduction rules for out-of-order execution were not necessary until we had to deal with divergence. In particular, we have shown that the fragment of Chor λ without recursion can be modelled by simple semantics and still achieve the standard deadlock-freedom by design property. However, once recursion is added, a more sophisticated semantics allowing for out-of-order execution is required. This stems from the structure of a functional choreography being different than traditional imperative choreographies.

Our study fills a knowledge gap that is relevant for the future implementations and applications of choreographic languages. An ad-hoc distributed implementation of higher-order choreographies exists already in the Choral programming language [16]. However, Choral is a large object-oriented language that extends Java, meaning that it is not practical to formally study and prove the standard results expected of a choreographic language. We have been able to prove these results – correspondence between choreography and projected distributed implementation (Theorems 25 and 26) and deadlock-freedom (Corollary 27) – because Chor λ captures the essence of higher-order choreographic composition in a small language based on the λ -calculus. Our EPP is largely consistent with the implementation of the Choral compiler, but there are two key differences, both caused by Chor λ being based on the λ -calculus. First, since Choral is an object-oriented language, not every expression needs to return a value even if the result of the expression is located elsewhere as in **send**; therefore, Choral does not need a \perp construct. Second, Choral does not have distributed choice types and instead restricts all conditions to be local (at one process). Thus, our distributed choice types could form the basis for an interesting extension of Choral.

Aside from Choral, existing choreographic programming languages either have no higher-order constructs (e.g., Scribble [30], a language based on multiparty session types [19]), or have the compilation of their higher-order constructs lack modularity and decentralisation (e.g., Pirouette [18]). Our results provide a foundation for adding mechanisms for higher-order composition to other choreographic and similar languages with modular compilation.

Future Work

Synchronous communication is widely adopted in theories of processes and is usually implemented in practice by using acknowledgements. A potential extension of $\text{Chor}\lambda$ is adding support for asynchronous communication, which is usually achieved by adding message queues and choreographic terms to represent partially-executed communications [12, 7, 14, 24].

Another potential extension of $\text{Chor}\lambda$, our process language, and our theory of EPP would be to enable abstraction over process names, that is, extending the syntax such that values can be the names of processes to be acted upon. This could, for example, enable the modelling of choreographies with dynamic topologies, where processes discover whom they have to interact with at runtime.

A Full definitions and proofs

► **Definition 29** (Free Variables). *Given a choreography M , the free variables of M , $\text{fv}(M)$ are defined as:*

$$\begin{aligned}
\text{fv}(N \ N') &= \text{fv}(N) \cup \text{fv}(N') & \text{fv}(\mathbf{select}_{q,p} \ l \ M) &= \text{fv}(M) \\
\text{fv}(x) &= x & \text{fv}(\lambda x : T.N) &= \text{fv}(N) \setminus \{x\} \\
\text{fv}(()@p) &= \emptyset & \text{fv}(\mathbf{com}_{q,p}) &= \emptyset \\
\text{fv}(f(\vec{p})) &= \emptyset & \text{fv}(\mathbf{Pair} \ V \ V') &= \text{fv}(V) \cup \text{fv}(V') \\
\text{fv}(\mathbf{case} \ N \ \mathbf{of} \ \mathbf{Inl} \ x \Rightarrow M; \ \mathbf{Inr} \ y \Rightarrow M') &= \text{fv}(N) \cup (\text{fv}(M) \setminus \{x\}) \cup (\text{fv}(M') \setminus \{y\}) \\
\text{fv}(\mathbf{fst}) &= \text{fv}(\mathbf{snd}) = \emptyset & \text{fv}(\mathbf{Inl} \ V) &= \text{fv}(\mathbf{Inr} \ V) = \text{fv}(V)
\end{aligned}$$

► **Definition 30** (Bound Variables). *Given a choreography M , the bound variables of M , $\text{bv}(M)$ are defined as:*

$$\begin{aligned}
\text{bv}(N \ N') &= \text{bv}(N) \cup \text{bv}(N') & \text{bv}(\mathbf{select}_{q,p} \ l \ M) &= \text{bv}(M) \\
\text{bv}(x) &= \emptyset & \text{bv}(\lambda x : T.N) &= \text{bv}(N) \cup \{x\} \\
\text{bv}(()@p) &= \emptyset & \text{bv}(\mathbf{com}_{q,p}) &= \emptyset \\
\text{bv}(f(\vec{p})) &= \emptyset & \text{bv}(\mathbf{Pair} \ V \ V') &= \text{bv}(V) \cup \text{bv}(V') \\
\text{bv}(\mathbf{case} \ N \ \mathbf{of} \ \mathbf{Inl} \ x \Rightarrow M; \ \mathbf{Inr} \ y \Rightarrow M') &= \text{bv}(N) \cup \text{bv}(M) \cup \{x\} \cup (\text{bv}(M') \cup \{y\}) \\
\text{bv}(\mathbf{fst}) &= \text{bv}(\mathbf{snd}) = \emptyset & \text{bv}(\mathbf{Inl} \ V) &= \text{bv}(\mathbf{Inr} \ V) = \text{bv}(V)
\end{aligned}$$

► **Definition 31** (Process names of a type). *The process names of a type T , $\text{pn}(T)$, are defined as follows.*

$$\begin{aligned}
\text{pn}(t@R) &= \vec{R} & \text{pn}(T \rightarrow_{\rho} T') &= \text{pn}(T) \cup \text{pn}(T') \cup \rho \\
\text{pn}(()@R) &= \{R\} & \text{pn}(T + T') &= \text{pn}(T \times T') = \text{pn}(T) \cup \text{pn}(T')
\end{aligned}$$

► **Definition 32** (Process names of a choreography). *The process names of a choreography M , $\text{pn}(M)$, are defined as follows.*

$$\begin{aligned}
\text{pn}(M \ N) &= \text{pn}(M) \cup \text{pn}(N) \\
\text{pn}(\mathbf{select}_{p,q} \ l \ M) &= \{p, q\} \cup \text{pn}(M) \\
\text{pn}(x) &= \emptyset \\
\text{pn}(\mathbf{case} \ M \ \mathbf{of} \ \mathbf{Inl} \ x \Rightarrow N; \ \mathbf{Inr} \ y \Rightarrow N') &= \text{pn}(M) \cup \text{pn}(N) \cup \text{pn}(N') \\
\text{pn}(\lambda x : T.M) &= \text{pn}(T) \cup \text{pn}(M) \\
\text{pn}(\mathbf{Inl} \ V) &= (\text{pn} \ \mathbf{Inr} \ V) = \text{pn}(V)
\end{aligned}$$

$$\begin{array}{c}

\end{array}$$

■ **Figure 7** Full set of typing rules for Chor λ .

$$\begin{aligned}
\text{pn}(\mathbf{Pair} V V') &= \text{pn}(V) \cup \text{pn}(V') \\
\text{pn}(\mathbf{fst}) &= \text{pn}(\mathbf{snd}) = \emptyset \\
\text{pn}(\mathbf{com}_{\mathbf{p}, \mathbf{q}}) &= \{\mathbf{p}, \mathbf{q}\}
\end{aligned}$$

► **Definition 33.** We define the set of synchronising processes of a choreography M , $\text{spn}(M)$, by recursion on the structure of M :

$$\begin{aligned}
\text{spn}(\mathbf{com}_{S,R}) &= \{S, R\}, \text{spn}(\mathbf{select}_{S,R} l M) = \{S, R\} \cup \text{spn}(M), \\
\text{spn}(f(\vec{R})) &= \vec{R}, \text{ and homomorphically on all other cases.}
\end{aligned}$$

► **Definition 34** (Merging). Given two behaviours B and B' , $B \sqcup B'$ is defined as follows.

$$\begin{aligned}
B_1 B_2 \sqcup B'_1 B'_2 &= (B_1 \sqcup B'_1) (B_2 \sqcup B'_2) \\
\mathbf{case} B_1 \mathbf{ of} \mathbf{Inl} x \Rightarrow B_2; \mathbf{Inr} y \Rightarrow B_3 \sqcup \mathbf{case} B'_1 \mathbf{ of} \mathbf{Inl} x \Rightarrow B'_2; \mathbf{Inr} y \Rightarrow B'_3 &= \\
\mathbf{case} (B_1 \sqcup B'_1) \mathbf{ of} \mathbf{Inl} x \Rightarrow (B_2 \sqcup B'_2); \mathbf{Inr} y \Rightarrow (B_3 \sqcup B'_3) & \\
\oplus_{\mathbf{p}} l B \sqcup \oplus_{\mathbf{p}} l B' &= \oplus_{\mathbf{p}} l (B \sqcup B') \\
\&\{\ell_i : B_i\}_{i \in I} \sqcup \&\{\ell_j : B'_j\}_{j \in J} &\{\{\ell_k : B_k \sqcup B'_k\}_{k \in I \cup J} \cup \{\ell_i : B_i\}_{i \in I \setminus J} \cup \{\ell_j : B'_j\}_{j \in J \setminus I}\} & \\
x \sqcup x = x \quad \lambda x : T. B \sqcup \lambda x : T. B' &= \lambda x : T. (B \sqcup B')
\end{aligned}$$

$$\begin{array}{c}
 \frac{\text{fv}(V) \cap \text{bv}(M) = \emptyset}{\lambda x : T.M \ V \xrightarrow{\tau, \emptyset}_D M[x := V]} \text{[APPABS]} \quad \frac{M \xrightarrow{\ell, P}_D M'}{\lambda x : T.M \xrightarrow{\lambda, P}_D \lambda x : T.M'} \text{[INABS]} \\

Proof of Lemma 5. Straightforward from the network semantics. \blacktriangleleft

► **Lemma 36.** *Given a value V , if $\Theta; \Sigma; \Gamma \vdash V : T$ and $\llbracket V \rrbracket$ is defined then for any process p in $\text{pn}(V)$, $\llbracket V \rrbracket_p = L$.*

Proof. Straightforward from the projection rules. \blacktriangleleft

► **Lemma 37.** *Given a type T , for any process $p \notin \text{pn}(T)$, $\llbracket T \rrbracket_p = \perp$.*

Proof. Straightforward from induction on T . \blacktriangleleft

► **Lemma 38.** *Given a value V , for any process $p \notin \text{pn}(\text{type}(V))$, if $\llbracket V \rrbracket_p$ is defined then $\llbracket V \rrbracket_p = \perp$.*

Proof. Follows from Lemmas 36 and 37 and the projection rules. \blacktriangleleft

► **Lemma 39.** *If $M \rightsquigarrow M'$ and $M \xrightarrow{\tau, P}_D M''$ and $\llbracket M \rrbracket$ is defined then $M' \xrightarrow{\tau, P}_D M'''$ such that $M'' \rightsquigarrow^* M'''$*

Proof. Follows from case analysis on $M \rightsquigarrow M'$. \blacktriangleleft

► **Lemma 40.** *If $M \rightsquigarrow M'$ then for any process p , $\llbracket M \rrbracket_p \rightsquigarrow \cup \xrightarrow{\tau}^* B$ such that $B \equiv \llbracket M' \rrbracket_p$*

Proof. Follows from case analysis on $M \rightsquigarrow M'$. \blacktriangleleft

Proof of Theorem 25. We prove this by structural induction on $M \xrightarrow{\tau, P}_D M'$.

- Assume $M = \lambda x : T.N V$ and $M' = N[x := V]$. Then for any process $p \in \text{pn}(\text{type}(\lambda x : T.N))$, we have $\llbracket M \rrbracket_p = (\lambda x : \llbracket T \rrbracket_p . \llbracket N \rrbracket_p) \llbracket V \rrbracket_p$ and $\llbracket M' \rrbracket_p = \llbracket N \rrbracket_p[x := \llbracket V \rrbracket_p]$, and for any $p' \notin \text{pn}(\text{type}(\lambda x : T.N))$, we have $p' \notin \text{pn}(\text{type}(V))$ and therefore $\llbracket M \rrbracket_{p'} = \llbracket M' \rrbracket_{p'} = \perp$. We therefore get $p[\llbracket M \rrbracket_p] \xrightarrow{\tau}_{[D]} \llbracket M' \rrbracket_p$ for all $p \in \text{pn}(\text{type}(\lambda x : T.N))$ and define $\mathcal{N} = \prod_{p \in \text{pn}(\text{type}(\lambda x : T.N))} p[\llbracket M' \rrbracket_p] \mid \prod_{p' \notin \text{pn}(\text{type}(\lambda x : T.N))} p'[\perp]$ and the result follows.
- Assume $M = N M''$, $M' = N' M''$, and $N \xrightarrow{\tau, P}_D N'$. Then for any process $p \in \text{pn}(\text{type}(N))$, $\llbracket M \rrbracket_p = \llbracket N \rrbracket_p \llbracket M'' \rrbracket_p$ and $\llbracket M' \rrbracket_p = \llbracket N' \rrbracket_p \llbracket M'' \rrbracket_p$. For any process p' such that $\llbracket N \rrbracket_{p'} = \llbracket M'' \rrbracket_{p'} = \perp$, by induction we have $\llbracket N' \rrbracket_{p'} = \perp$, and therefore $\llbracket M \rrbracket_{p'} = \llbracket M' \rrbracket_{p'} = \perp$. For any other process p'' such that $\llbracket N \rrbracket_{p''} = \perp$, by induction we get $\llbracket N' \rrbracket_{p''} = \perp$ and therefore $\llbracket M \rrbracket_{p''} = \llbracket M' \rrbracket_{p''} = \llbracket M'' \rrbracket_{p''}$. For any other process p''' such that $\llbracket M'' \rrbracket_{p'''} = \perp$, we get $\llbracket M \rrbracket_{p'''} = \llbracket N \rrbracket_{p'''} = \perp$ and $\llbracket M' \rrbracket_{p'''} = \llbracket N' \rrbracket_{p'''} = \perp$. And by induction $\llbracket N \rrbracket \xrightarrow{*_D} \mathcal{N}_N$ and $N' \xrightarrow{*_D} N''$ for $\mathcal{N}_N \equiv \llbracket N'' \rrbracket$. For any process p we therefore get $\llbracket N \rrbracket_p \xrightarrow{\mu_0}_{[D]} \xrightarrow{\mu_1}_{[D]} \dots B_p$ for $B_p \equiv \llbracket N'' \rrbracket_p$ for some sequences of transitions $\xrightarrow{\mu_0}_{[D]} \xrightarrow{\mu_1}_{[D]} \dots$, and from the network semantics we get

$$\llbracket M \rrbracket \rightarrow^* \left(\prod_{p \in \text{pn}(\text{type}(N)) \cup (\text{pn}(N) \cap \text{pn}(M''))} p[B_p \llbracket M'' \rrbracket_p] \mid \prod_{\llbracket N \rrbracket_{p'} = \llbracket M'' \rrbracket_{p'} = \perp} p'[\perp] \right) \mid \left(\prod_{\llbracket M \rrbracket_{p''} = \llbracket M'' \rrbracket_{p''}} p''[\llbracket M'' \rrbracket_{p''}] \mid \prod_{\llbracket M \rrbracket_{p'''} = \llbracket N \rrbracket_{p'''}} p''[B_{p''}] \right) = \mathcal{N}$$

and $M' \rightarrow^* N'' M$. And since $\llbracket N \rrbracket \xrightarrow{*_D} \mathcal{N}'$ and $\llbracket N' \rrbracket \xrightarrow{*_D} \mathcal{N}'_N$, we know these sequences of transitions can synchronise when necessary, and if $\llbracket N \rrbracket_{p'''} \neq \llbracket N' \rrbracket_{p'''} = \perp$ then we can do the extra application to get rid of this unit.

- Assume $M = V N$, $M' = V N'$, and $N \xrightarrow{\tau, P}_D N'$. Then for any process $\mathfrak{p} \in \text{pn}(\text{type}(V))$, $\llbracket M \rrbracket_{\mathfrak{p}} = \llbracket V \rrbracket_{\mathfrak{p}} \llbracket N \rrbracket_{\mathfrak{p}}$ and $\llbracket M' \rrbracket_{\mathfrak{p}} = \llbracket V \rrbracket_{\mathfrak{p}} \llbracket N' \rrbracket_{\mathfrak{p}}$. Since V is a value, for any process $\mathfrak{p}' \notin \text{pn}(\text{type}(V))$, we have $\llbracket V \rrbracket_{\mathfrak{p}'} = \perp$ and so for any process \mathfrak{p}' such that $\llbracket V \rrbracket_{\mathfrak{p}'} = \llbracket N \rrbracket_{\mathfrak{p}'} = \perp$, by induction we get $\llbracket N' \rrbracket_{\mathfrak{p}'} = \perp$ and therefore $\llbracket M \rrbracket_{\mathfrak{p}'} = \llbracket M' \rrbracket_{\mathfrak{p}'} = \perp$. For any other process \mathfrak{p}'' such that $\llbracket V \rrbracket_{\mathfrak{p}''} = \perp$, we have $\llbracket M \rrbracket_{\mathfrak{p}''} = \llbracket N \rrbracket_{\mathfrak{p}''}$ and $\llbracket M' \rrbracket_{\mathfrak{p}''} = \llbracket N' \rrbracket_{\mathfrak{p}''}$. By induction, $\llbracket N \rrbracket \xrightarrow{*_D} \mathcal{N}_N$ and $N' \xrightarrow{*_D} \mathcal{N}'$ for $\mathcal{N}' \sqsupseteq \llbracket N'' \rrbracket$. For any process \mathfrak{p} we therefore get $\llbracket N \rrbracket_{\mathfrak{p}} \xrightarrow{\mu_0}_{[D](\mathfrak{p})} \xrightarrow{\mu_1}_{[D](\mathfrak{p})} \dots B_{\mathfrak{p}}$ for $B_{\mathfrak{p}} \sqsupseteq \llbracket N'' \rrbracket_{\mathfrak{p}}$ for some sequences of transitions $\xrightarrow{\mu_0}_{[D](\mathfrak{p})} \xrightarrow{\mu_1}_{[D](\mathfrak{p})} \dots$ and from the network semantics we get

$$\llbracket M \rrbracket \xrightarrow{*} \prod_{\mathfrak{p} \in \text{pn}(\text{type}(N))} \mathfrak{p}[\llbracket V \rrbracket_{\mathfrak{p}} B_{\mathfrak{p}}] \mid \prod_{\mathfrak{p}' \notin \text{pn}(\text{type}(N))} \mathfrak{p}'[B_{\mathfrak{p}'}] = \mathcal{N}$$

and

$$M' \xrightarrow{*} V N''$$

and the result follows.

- Assume $M = M'' N$, $M' = M'' N'$, $N \xrightarrow{\tau, P}_D N'$, and $\text{pn}(M) \cap P = \emptyset$. Then for any $\mathfrak{p} \in P$, $\text{pn}(\llbracket M'' \rrbracket_{\mathfrak{p}}) \cap P = \emptyset$ and the result follows from induction and using rule NAPP3.
- Assume $M = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N'; \mathbf{Inr} x' \Rightarrow N''$, $M' = \mathbf{case} M'' \mathbf{ of} \mathbf{Inl} x \Rightarrow N'; \mathbf{Inr} x' \Rightarrow N''$, and $N \xrightarrow{\tau, P}_D M''$. Then for any process \mathfrak{p} such that $\mathfrak{p} \in \text{pn}(\text{type}(N))$, we have projections $\llbracket M \rrbracket_{\mathfrak{p}} = \mathbf{case} \llbracket N \rrbracket_{\mathfrak{p}} \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N' \rrbracket_{\mathfrak{p}}; \mathbf{Inr} x' \Rightarrow \llbracket N'' \rrbracket_{\mathfrak{p}}$ and $\llbracket M' \rrbracket_{\mathfrak{p}} = \mathbf{case} \llbracket M'' \rrbracket_{\mathfrak{p}} \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N' \rrbracket_{\mathfrak{p}}; \mathbf{Inr} x' \Rightarrow \llbracket N'' \rrbracket_{\mathfrak{p}}$. For any other process \mathfrak{p}' such that $\llbracket N \rrbracket_{\mathfrak{p}'} = \llbracket N' \rrbracket_{\mathfrak{p}'} = \llbracket N'' \rrbracket_{\mathfrak{p}'} = \perp$, by induction we get $\llbracket M'' \rrbracket_{\mathfrak{p}'} = \perp$, and therefore $\llbracket M \rrbracket_{\mathfrak{p}'} = \llbracket M' \rrbracket_{\mathfrak{p}'} = \perp$. For any other process \mathfrak{p}'' such that $\llbracket N \rrbracket_{\mathfrak{p}''} = \perp$, we get $\llbracket M \rrbracket_{\mathfrak{p}''} = \llbracket M' \rrbracket_{\mathfrak{p}''} = \llbracket N' \rrbracket_{\mathfrak{p}''} \sqcup \llbracket N'' \rrbracket_{\mathfrak{p}''}$. For any other processes \mathfrak{p}''' such that $\llbracket N' \rrbracket_{\mathfrak{p}'''} = \llbracket N'' \rrbracket_{\mathfrak{p}'''} = \perp$, we have $\llbracket M \rrbracket_{\mathfrak{p}'''} = \llbracket N \rrbracket_{\mathfrak{p}'''} = \llbracket M' \rrbracket_{\mathfrak{p}'''} = \llbracket M'' \rrbracket_{\mathfrak{p}'''}$. For any other process \mathfrak{p}'''' , we have $\llbracket M \rrbracket_{\mathfrak{p}''''} = (\lambda x : \perp. \llbracket N' \rrbracket_{\mathfrak{p}''''} \sqcup \llbracket N'' \rrbracket_{\mathfrak{p}''''}) \llbracket N \rrbracket_{\mathfrak{p}''''}$ and $\llbracket M' \rrbracket_{\mathfrak{p}''''} = (\lambda x. \llbracket N' \rrbracket_{\mathfrak{p}''''} \sqcup \llbracket N'' \rrbracket_{\mathfrak{p}''''}) \llbracket M'' \rrbracket_{\mathfrak{p}''''}$ for $x \notin \text{fv}(N') \cup \text{fv}(N'')$. The rest follows by simple induction similar to the second case.
- Assume $M = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N_1; \mathbf{Inr} x' \Rightarrow N_2$, $M' = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N'_1; \mathbf{Inr} x' \Rightarrow N'_2$, $N_1 \xrightarrow{\tau, P}_D N'_1$, $N_2 \xrightarrow{\tau, P}_D N'_2$, and $P \cap \text{pn}(N) = \emptyset$. Then for any process \mathfrak{p} such that $\mathfrak{p} \in \text{pn}(\text{type}(N))$, we have $\llbracket M \rrbracket_{\mathfrak{p}} = \mathbf{case} \llbracket N \rrbracket_{\mathfrak{p}} \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N_1 \rrbracket_{\mathfrak{p}}; \mathbf{Inr} x' \Rightarrow \llbracket N_2 \rrbracket_{\mathfrak{p}}$. For any other process \mathfrak{p}' such that $\llbracket N \rrbracket_{\mathfrak{p}'} = \llbracket N_1 \rrbracket_{\mathfrak{p}'} = \llbracket N_2 \rrbracket_{\mathfrak{p}'} = \perp$, by induction we get $\llbracket N'_1 \rrbracket_{\mathfrak{p}'} = \llbracket N'_2 \rrbracket_{\mathfrak{p}'} = \perp$, and therefore $\llbracket M \rrbracket_{\mathfrak{p}'} = \llbracket M' \rrbracket_{\mathfrak{p}'} = \perp$. For any other process \mathfrak{p}'' such that $\llbracket N \rrbracket_{\mathfrak{p}''} = \perp$, we get $\llbracket M \rrbracket_{\mathfrak{p}''} = \llbracket N_1 \rrbracket_{\mathfrak{p}''} \sqcup \llbracket N_2 \rrbracket_{\mathfrak{p}''}$. For any other processes \mathfrak{p}''' such that $\llbracket N_1 \rrbracket_{\mathfrak{p}'''} = \llbracket N_2 \rrbracket_{\mathfrak{p}'''} = \perp$, we have $\llbracket M \rrbracket_{\mathfrak{p}'''} = \llbracket N \rrbracket_{\mathfrak{p}'''}$. For any other process \mathfrak{p}'''' , we have $\llbracket M \rrbracket_{\mathfrak{p}''''} = (\lambda x : \perp. \llbracket N_1 \rrbracket_{\mathfrak{p}''''} \sqcup \llbracket N_2 \rrbracket_{\mathfrak{p}''''}) \llbracket N \rrbracket_{\mathfrak{p}''''}$. If $\llbracket N'_1 \rrbracket_{\mathfrak{p}} \sqcup \llbracket N'_2 \rrbracket_{\mathfrak{p}}$ is defined for all \mathfrak{p} then the result follows from induction. Otherwise we have M_1 and M_2 such that $N'_1 \xrightarrow{\tau, P}_D M_1$ and $N'_2 \xrightarrow{\tau, P}_D M_2$ and $\llbracket M_1 \rrbracket_{\mathfrak{p}} \sqcup \llbracket M_2 \rrbracket_{\mathfrak{p}}$ for all \mathfrak{p} , and the result follows from induction on these transitions.
- Assume $M = \mathbf{case} \mathbf{Inl} V \mathbf{ of} \mathbf{Inl} x \Rightarrow N; \mathbf{Inr} x' \Rightarrow N'$ and $M' = N[x := V]$. Then for any process $\mathfrak{p} \in \text{pn}(\text{type}(\mathbf{Inl} V))$, we have $\llbracket M \rrbracket_{\mathfrak{p}} = \mathbf{case} \mathbf{Inl} \llbracket V \rrbracket_{\mathfrak{p}} \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N \rrbracket_{\mathfrak{p}}; \mathbf{Inr} x' \Rightarrow \llbracket N' \rrbracket_{\mathfrak{p}}$ and $\llbracket M' \rrbracket_{\mathfrak{p}} = \llbracket N[x := \llbracket V \rrbracket_{\mathfrak{p}}] \rrbracket_{\mathfrak{p}}$. By Lemma 38, $\llbracket N[x := \llbracket V \rrbracket_{\mathfrak{p}}] \rrbracket_{\mathfrak{p}} = \llbracket N \rrbracket_{\mathfrak{p}}[x := \llbracket V \rrbracket_{\mathfrak{p}}]$. For any other process $\mathfrak{p}' \notin \text{pn}(\text{type}(\mathbf{Inl} V))$, $\llbracket \mathbf{Inl} V \rrbracket_{\mathfrak{p}'} = \perp$, and therefore $\llbracket M \rrbracket_{\mathfrak{p}'} = \llbracket N \rrbracket_{\mathfrak{p}'} \sqcup \llbracket N' \rrbracket_{\mathfrak{p}'} \sqsupset \llbracket N \rrbracket_{\mathfrak{p}'} = \llbracket M' \rrbracket_{\mathfrak{p}'}$. The result follows.
- Assume $M = \mathbf{case} \mathbf{Inr} V \mathbf{ of} \mathbf{Inl} x \Rightarrow N; \mathbf{Inr} x' \Rightarrow N'$ and $M' = N'[x' := V]$. This case is similar to the previous.
- Assume $M = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N_1; \mathbf{Inr} x' \Rightarrow N_2$, $M' = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N'_1; \mathbf{Inr} x' \Rightarrow N'_2$, $N_1 \xrightarrow{P}_D N'_1$, $N_2 \xrightarrow{P}_D N'_2$, and $P \cap \text{pn}(N) = \emptyset$. This case is similar to case four.

- Assume $M = \mathbf{com}_{q,p}V$ and $M' = V[q := p]$ and $\text{fv}(V) = \emptyset$. Then if $q \neq p$, $\llbracket M \rrbracket_p = \mathbf{recv}_q \perp$, $\llbracket M' \rrbracket_p = \llbracket V[q := p] \rrbracket_p = \llbracket V \rrbracket_p[q := p]$ since $\text{pn}(\text{type}(V)) = q$, $\llbracket M \rrbracket_q = \mathbf{send}_p \llbracket V \rrbracket_q$, $\llbracket M' \rrbracket_q = \perp$, and for any $p' \notin \{q, p\}$, $\llbracket M \rrbracket_{p'} = \llbracket M' \rrbracket_{p'} = \perp$. We therefore get $\llbracket M \rrbracket_p \xrightarrow{\mathbf{recv}_q \llbracket V \rrbracket_q[q := p]}_{[D]} \llbracket M' \rrbracket_p$, $\llbracket M \rrbracket_q \xrightarrow{\mathbf{send}_p \llbracket V \rrbracket_q}_{[D]} \llbracket M' \rrbracket_q$, and $\llbracket M \rrbracket_{p'} = \llbracket M' \rrbracket_{p'}$. We define $\mathcal{N} = \mathcal{N}' = \llbracket M' \rrbracket$ and the result follows. If $q = p$, then $\llbracket M \rrbracket_p = (\lambda x.x) \llbracket V \rrbracket_p$ and $\llbracket M' \rrbracket_p = \llbracket V \rrbracket_p$ and $\mathcal{N} = \mathcal{N}' = \llbracket M' \rrbracket$ and the result follows.
- Assume $M = \mathbf{select}_{q,p} l M'$. Then $\llbracket M \rrbracket_q = \oplus_p l \llbracket M' \rrbracket_q$, $\llbracket M \rrbracket_p = \&\{l : \llbracket M' \rrbracket_p\}$, and for any $p' \notin \{q, p\}$, $\llbracket M \rrbracket_{p'} = \llbracket M' \rrbracket_{p'}$. We therefore get $\llbracket M \rrbracket \xrightarrow{\tau_{p,q}}_{[D]} \llbracket M \rrbracket \setminus \{p, q\} \mid p[\llbracket M' \rrbracket_p] \mid q[\llbracket M' \rrbracket_q]$ and the result follows.
- Assume $M = \mathbf{select}_{q,p} l N$, $M' = \mathbf{select}_{q,p} l N'$, $N \xrightarrow{\tau, P}_D N'$, and $P \cap \{q, p\} = \emptyset$. Then $\llbracket M \rrbracket_q = \oplus_p l \llbracket N \rrbracket_q$, $\llbracket M' \rrbracket_q = \oplus_p l \llbracket N' \rrbracket_q$, $\llbracket M \rrbracket_p = \&\{l : \llbracket N \rrbracket_p\}$, $\llbracket M' \rrbracket_p = \&\{l : \llbracket N' \rrbracket_p\}$, and for any $p' \notin \{q, p\}$, $\llbracket M \rrbracket_{p'} = \llbracket N \rrbracket_{p'}$ and $\llbracket M' \rrbracket_{p'} = \llbracket N' \rrbracket_{p'}$. The result follows from induction and using rules NOFF2 and NCHO2.
- Assume $M = \mathbf{fst Pair} V V'$ and $M' = V$. Then for any process $p \in \text{pn}(\text{type}(\mathbf{Pair} M' V'))$, $\llbracket M \rrbracket_p = \mathbf{fst Pair} \llbracket M' \rrbracket_p \llbracket V' \rrbracket_p$ and for any other process $p' \notin \text{pn}(\text{type}(\mathbf{Pair} M' V'))$, we have $\llbracket M \rrbracket_{p'} = \perp$ and $\llbracket M' \rrbracket_{p'} = \perp$. We define $\mathcal{N} = \mathcal{N}' = \llbracket M' \rrbracket$ and the result follows.
- Assume $M = \mathbf{snd Pair} V V'$ and $M' = V'$. Then the case is similar to the previous.
- Assume $M = f(\vec{p})$ and $M' = D(f(\vec{p}'))[\vec{p}' := \vec{p}]$. Then the result follows from the definition of $[D]$.
- Assume there exists N such that $M \rightsquigarrow N$ and $N \xrightarrow{\tau, P}_D M'$. Then the result follows from induction and Lemma 40. ◀

A.2 Proof of Theorem 26

► **Definition 41.** Given a network $\mathcal{N} = \prod_{p \in \rho} p[B_p]$, we have $\mathcal{N} \setminus \rho' = \prod_{p \in (\rho \setminus \rho')} p[B_p]$

► **Lemma 42.** For any process p and network \mathcal{N} , if $\mathcal{N} \xrightarrow{\tau, P} \mathcal{N}'$ and $p \notin P$ then $\mathcal{N}(p) = \mathcal{N}'(p)$.

Proof. Straightforward from the network semantics. ◀

► **Lemma 43.** For any set of processes P and network \mathcal{N} , if $\mathcal{N} \xrightarrow{\tau, P'} \mathcal{N}'$ and $P \cap P' = \emptyset$ then $\mathcal{N} \setminus P \xrightarrow{\tau, P'} \mathcal{N}' \setminus P$.

Proof. Straightforward from the network semantics. ◀

► **Lemma 44.** If $\llbracket M \rrbracket_p \rightsquigarrow B$ then there exists M' such that $M \rightsquigarrow M'$ and $B \equiv \llbracket M' \rrbracket_p$

Proof. Follows from case analysis on $\llbracket M \rrbracket_p \rightsquigarrow B$ keeping in mind that $\llbracket M \rrbracket_p$ cannot be $\perp \perp$. ◀

Proof of Theorem 26. If $\llbracket M \rrbracket \xrightarrow{*_D} \mathcal{N}$ uses rule NSTR then this follows from Lemma 44. Otherwise we prove this by structural induction on M .

- Assume $M = N_1 N_2$. Then for any process $p \in \text{pn}(\text{type}(N_1)) \cup (\text{pn}(N_1) \cap \text{pn}(N_2))$, $\llbracket M \rrbracket_p = \llbracket N_1 \rrbracket_p \llbracket N_2 \rrbracket_p$, for any process p' such that $\llbracket N_1 \rrbracket_{p'} = \llbracket N_2 \rrbracket_{p'} = \perp$, we have $\llbracket M \rrbracket_{p'} = \perp$. For any other process p'' such that $\llbracket N_1 \rrbracket_{p''} = \perp$, $\llbracket M \rrbracket_{p''} = \llbracket N_2 \rrbracket_{p''}$. For any other process p''' such that $\llbracket N_2 \rrbracket_{p'''} = \perp$, we get $\llbracket M \rrbracket_{p'''} = \llbracket N_1 \rrbracket_{p'''}$. We then have 2 cases.
 - Assume $N_2 = V$. Then $\llbracket N_2 \rrbracket_p = L$ by Lemma 36, and for any p' such that $p' \notin \text{pn}(\text{type}(N_2)) \subseteq \text{pn}(\text{type}(N_1))$, by Lemma 38, $\llbracket N_2 \rrbracket_{p'} = \perp$ and therefore $\llbracket M \rrbracket_{p'} = \llbracket N_1 \rrbracket_{p'}$, and we have 5 cases.

* Assume $N_1 = \lambda x : T.N_3$. Then for any process $\mathfrak{p} \in \text{pn}(\text{type}(N_1))$, $\llbracket N_1 \rrbracket_{\mathfrak{p}} = \lambda x : \llbracket T \rrbracket_{\mathfrak{p}} . \llbracket N_3 \rrbracket_{\mathfrak{p}}$. And for any process $\mathfrak{p}' \notin \text{pn}(\text{type}(N_1))$, $\llbracket N_1 \rrbracket_{\mathfrak{p}'} = \perp$. We have two cases, using either rule NABSAPP or rules NINABS and NAPP1.

If we use rule NABSAPP, then there exists \mathfrak{p}'' such that $\mathfrak{P} = \mathfrak{p}''$ and $\mathfrak{p}'' \in \text{pn}(\text{type}(N_1))$. We then get $\llbracket M \rrbracket \xrightarrow{\tau, \mathfrak{P}}_{[D]} \mathcal{M} = \llbracket M \rrbracket \setminus \{\mathfrak{p}''\} \mid \mathfrak{p}''[\llbracket N_3 \rrbracket_{\mathfrak{p}''} [x := \llbracket N_2 \rrbracket_{\mathfrak{p}''}]]$. Since $\mathcal{M} \rightarrow^* \llbracket N_3 [x := N_2] \rrbracket$ and the remaining transitions in $\llbracket M \rrbracket \rightarrow^*_{[D]} \mathcal{N}$ take place in N_3 , the result follows from using rule NABSAPP in every process in $\text{pn}(\text{type}(N_1))$ and induction.

If we use rules NINABS and NAPP1 then there exists \mathfrak{p}'' such that $\mathfrak{P} = \mathfrak{p}''$ and $\llbracket N_3 \rrbracket_{\mathfrak{p}''} \xrightarrow{\mu} B$ and

$$\llbracket M \rrbracket \xrightarrow{\mu}_{[D]} \llbracket M \rrbracket \setminus \{\mathfrak{p}''\} \mid \mathfrak{p}''[\lambda x. B \llbracket N_2 \rrbracket_{\mathfrak{p}''}] \rightarrow^*_{[D]} \mathcal{N}$$

By induction, $N_3 \rightarrow^*_D N'_3$ and $(\llbracket N_3 \rrbracket \setminus \{\mathfrak{p}''\} \mid \mathfrak{p}''[B] \rightarrow_{\mathbb{D}} \mathcal{N}'')$ such that $\llbracket N_3 \rrbracket \supseteq \mathcal{N}''$, and we define $M' = \lambda x : T.N'_3 N_2$ and

$$\mathcal{N}' = (\mathcal{N} \setminus \text{pn}(\text{type}(N_1))) \mid \prod_{\mathfrak{p} \in \text{pn}(\text{type}(N_3))} \mathfrak{p}[(\lambda x. \mathcal{N}''(\mathfrak{p})) \llbracket N_2 \rrbracket_{\mathfrak{p}''}]$$

and the result follows by using rules INABS, APP1, NINABS, and NAPP1 and induction.

* Assume $N_1 = \mathbf{com}_{\mathfrak{q}, \mathfrak{p}}$. Then if $\mathfrak{q} \neq \mathfrak{p}$, $\llbracket M \rrbracket_{\mathfrak{q}} = \mathbf{send}_{\mathfrak{p}} \llbracket N_2 \rrbracket_{\mathfrak{q}}$, $\llbracket M \rrbracket_{\mathfrak{p}} = \mathbf{recv}_{\mathfrak{p}} \perp$, and for $\mathfrak{p}' \notin \{\mathfrak{q}, \mathfrak{p}\}$, $\llbracket N_1 \rrbracket_{\mathfrak{p}'} = \perp = \llbracket M \rrbracket_{\mathfrak{p}'}$, and therefore $\mathfrak{P} = \mathfrak{q}, \mathfrak{p}$, and if $\mathfrak{q} = \mathfrak{p}$ then $\llbracket N_1 \rrbracket_{\mathfrak{p}} = \lambda x. x$.

If $\mathfrak{P} = \mathfrak{q}, \mathfrak{p}$ then $\mathcal{N} = \llbracket M \rrbracket \setminus \{\mathfrak{q}, \mathfrak{p}\} \mid \mathfrak{q}[\perp] \mid \mathfrak{p}[\llbracket N_2 \rrbracket_{\mathfrak{q}} [\mathfrak{q} := \mathfrak{p}]]$. Because $\llbracket N_2 \rrbracket_{\mathfrak{p}} = \perp$ and $\llbracket N_2 \rrbracket_{\mathfrak{q}} = V$, $N_2 = V$. Therefore $M \xrightarrow{P}_D V[\mathfrak{q} := \mathfrak{p}]$ and the result follows.

If $\mathfrak{P} = \mathfrak{p}$ then $\mathfrak{q} = \mathfrak{p}$, $\mathcal{N} = \llbracket M \rrbracket \setminus \{\mathfrak{p}\} \mid \mathfrak{p}[\llbracket N_2 \rrbracket_{\mathfrak{p}}]$ and the rest is similar to above.

* Assume $N_1 = \mathbf{fst}$. Then $N_2 = \mathbf{Pair} V V'$ and for any process $\mathfrak{p} \in \text{pn}(\text{type}(\mathbf{Pair} V V'))$, $\llbracket M \rrbracket_{\mathfrak{p}} = \mathbf{fst} \mathbf{Pair} \llbracket V \rrbracket_{\mathfrak{p}} \llbracket V' \rrbracket_{\mathfrak{p}}$ and for any other process $\mathfrak{p}' \notin \text{pn}(\text{type}(\mathbf{Pair} V V'))$, by Lemma 38 we have $\llbracket M \rrbracket_{\mathfrak{p}'} = \llbracket N_1 \rrbracket_{\mathfrak{p}'} = \perp$, and therefore $\llbracket M \rrbracket_{\mathfrak{p}'} \rightarrow$.

If $\mathfrak{P} = \mathfrak{p} \in \text{pn}(\text{type}(\mathbf{Pair} V V'))$ then $\mathcal{N} = \llbracket M \rrbracket \setminus \{\mathfrak{p}\} \mid \mathfrak{p}[\llbracket V \rrbracket_{\mathfrak{p}}]$ and $M \xrightarrow{P}_D V$. The result follows by use of rule NPROJ1 and Lemma 38.

* Assume $N_1 = \mathbf{snd}$. This case is similar to the previous.

* Otherwise, $N_1 \neq V$ and either $\llbracket M \rrbracket \xrightarrow{\tau}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$ or $\llbracket M \rrbracket \xrightarrow{\tau, \mathfrak{a}}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$.

If $\llbracket M \rrbracket \xrightarrow{\tau}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$ then either $\llbracket N_1 \rrbracket_{\mathfrak{p}} \xrightarrow{\tau} B$ and $\mathfrak{p} \in \text{pn}(\text{type}(N_1))$, $\mathcal{M} = \llbracket M \rrbracket \setminus \{\mathfrak{p}\} \mid \mathfrak{p}[B \llbracket N_2 \rrbracket_{\mathfrak{p}}]$. We therefore have $\llbracket N_1 \rrbracket \xrightarrow{\tau}_{\mathfrak{p}} \llbracket N_1 \rrbracket \setminus \{\mathfrak{p}\} \mid \mathfrak{p}[B]$, and by induction, $N_1 \rightarrow^*_D N'_1$ such that $\llbracket N_1 \rrbracket \setminus \{\mathfrak{p}\} \mid \mathfrak{p}[B] \rightarrow^* \mathcal{N}'_1 \supseteq \llbracket N'_1 \rrbracket$. Since all these transitions can be propagated past N_2 in the network and $\llbracket N_2 \rrbracket_{\mathfrak{p}'}$ in any process \mathfrak{p}' involved, we get the result for $M' = N'_1 N_2$.

If $\llbracket M \rrbracket \xrightarrow{\tau, \mathfrak{a}}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$ then the case is similar.

– If $N_2 \neq V$ then we have 2 cases.

* If $\llbracket M \rrbracket \xrightarrow{\tau}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$ then either $\llbracket N_1 \rrbracket_{\mathfrak{p}} \xrightarrow{\tau} B$ or $\llbracket N_2 \rrbracket_{\mathfrak{p}} \xrightarrow{\tau} B$ and the case is similar to the previous.

* If $\llbracket M \rrbracket \xrightarrow{\tau, \mathfrak{a}}_{[D]} \mathcal{M} \rightarrow^*_{[D]} \mathcal{N}$ then there exists L such that either $\llbracket N_1 \rrbracket_{\mathfrak{q}} \xrightarrow{\mathbf{send}_{\mathfrak{p}} L} B_{\mathfrak{q}}$ or $\llbracket N_2 \rrbracket_{\mathfrak{q}} \xrightarrow{\mathbf{send}_{\mathfrak{p}} L} B_{\mathfrak{q}}$ and $\llbracket N_1 \rrbracket_{\mathfrak{p}} \xrightarrow{\mathbf{recv}_{\mathfrak{q}} L[\mathfrak{q} := \mathfrak{p}]} B_{\mathfrak{p}}$ or $\llbracket N_2 \rrbracket_{\mathfrak{p}} \xrightarrow{\mathbf{recv}_{\mathfrak{q}} L[\mathfrak{q} := \mathfrak{p}]} B_{\mathfrak{p}}$.

If $\llbracket N_1 \rrbracket_{\mathfrak{q}} \xrightarrow{\mathbf{send}_{\mathfrak{p}} L} B_{\mathfrak{q}}$ then $\llbracket N_1 \rrbracket_{\mathfrak{q}} \neq L'$ and therefore $\llbracket N_1 \rrbracket_{\mathfrak{p}} \xrightarrow{\mathbf{recv}_{\mathfrak{q}} L[\mathfrak{q} := \mathfrak{p}]} B_{\mathfrak{p}}$ and the

case is similar to the previous. If $\llbracket N_2 \rrbracket_q \xrightarrow{\text{send}_p L} B_q$ then $\llbracket N_1 \rrbracket_q = L'$, and therefore $\llbracket N_2 \rrbracket_p \xrightarrow{\text{recv}_q L[q:=p]} B_p$ and the case is similar to the previous.

- Assume $M = \mathbf{case} N \mathbf{ of} \mathbf{Inl} x \Rightarrow N'; \mathbf{Inr} x' \Rightarrow N''$. Then for any process $p \in \text{pn}(\text{type}(N))$, $\llbracket M \rrbracket_p = \mathbf{case} \llbracket N \rrbracket_p \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N' \rrbracket_p; \mathbf{Inr} x' \Rightarrow \llbracket N'' \rrbracket_p$. And for any other process $p' \notin \text{pn}(\text{type}(N))$, $\llbracket M \rrbracket_{p'} = (\lambda x. \llbracket N' \rrbracket_{p'} \sqcup \llbracket N'' \rrbracket_{p'}) \llbracket N \rrbracket_{p'}$. We know that $\llbracket M \rrbracket \xrightarrow{\tau_p}_{\llbracket D \rrbracket} \mathcal{M} \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}$ and we have three cases.
 - Assume $P = p \in \text{pn}(\text{type}(N))$. Then we have three cases.
 - * Assume $N = \mathbf{Inl} V$. Then $\llbracket N \rrbracket_p = \mathbf{Inl} \llbracket V \rrbracket_p$ and $\mathcal{M} = \llbracket M \rrbracket \setminus \{p\} \mid p[\llbracket N' \rrbracket_p[x := \llbracket V \rrbracket_p]]_p$. We define $M'' = N'$ and the transitions used in $\mathcal{M} \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}$ can be used on M'' . By induction, since $\llbracket N' \rrbracket_{p'} \sqsupseteq \llbracket N' \rrbracket_{p'} \sqcup \llbracket N'' \rrbracket_{p'}$ the result follows from using rules NABSAPP and NCASEL.
 - * Assume $N = \mathbf{Inr} V$. Then the case is similar to the previous.
 - * Otherwise, we use either rule NCASE or rule NCASE2. If we use rule NCASE, we have a transition $\llbracket N \rrbracket_p \xrightarrow{\tau} B$ such that

$$M = \llbracket M \rrbracket \setminus \{p\} \mid p[\mathbf{case} B \mathbf{ of} \mathbf{Inl} x \Rightarrow \llbracket N' \rrbracket_p; \mathbf{Inr} x' \Rightarrow \llbracket N'' \rrbracket_p]$$

and the result follows from induction similar to the last application case.

If we use rule NCASE2 then $\llbracket N' \rrbracket_p \xrightarrow{\tau}_{\llbracket D \rrbracket} B$ and $\llbracket N'' \rrbracket_p \xrightarrow{\tau}_{\llbracket D \rrbracket} B$. If $\llbracket N' \rrbracket_p \xrightarrow{\tau}_{\llbracket D \rrbracket} B$ then by induction, $N' \rightarrow_{\llbracket D \rrbracket}^* N'''$ and $\llbracket N' \rrbracket \setminus \{p\} \mid p[B] \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}''$ such that $\mathcal{N}'' \sqsupseteq \llbracket N''' \rrbracket$ and $N'' \rightarrow_{\llbracket D \rrbracket}^* N''''$ and $\llbracket N'' \rrbracket \setminus \{p\} \mid p[B] \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}'''$ such that $\mathcal{N}''' \sqsupseteq \llbracket N'''' \rrbracket$. Since N' and N'' are mergeable on other processes, the result follows from using rule INCASE.

- Assume $P = p \notin \text{pn}(\text{type}(N))$. Then we have three cases.
 - * Assume $N = \mathbf{Inl} V$. Then $\llbracket N \rrbracket_p = \perp$ and $\mathcal{M} = \llbracket M \rrbracket \setminus \{p\} \mid p[\llbracket N' \rrbracket_p \sqcup \llbracket N'' \rrbracket_p]$. We define $M' = N'$ and the result follows.
 - * Assume $N = \mathbf{Inr} V$. Then the case is similar to the previous.
 - * Otherwise, $\llbracket N \rrbracket_p \neq L$ and we therefore have $\llbracket N \rrbracket_p \xrightarrow{\tau} B$ and $\mathcal{M} = \llbracket M \rrbracket \setminus \{p\} \mid p[(\lambda x. \llbracket N' \rrbracket_p \sqcup \llbracket N'' \rrbracket_p) B]$. We therefore have $\llbracket N \rrbracket \xrightarrow{\tau_p}_{\llbracket D \rrbracket} \llbracket N \rrbracket \setminus \{p\} \mid p[B]$, and by induction, $N \rightarrow_{\llbracket D \rrbracket} N'''$ such that $\llbracket N \rrbracket \setminus \{p\} \mid p[B] \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}'''$ for $\mathcal{N}''' \sqsupseteq \llbracket N''' \rrbracket$. Since all these transitions can be propagated past N_2 in the network and the conditional or $(\lambda x. \llbracket N' \rrbracket_{p'} \sqcup \llbracket N'' \rrbracket_{p'})$ in any other process p' involved, we get the result for $M' = \mathbf{case} N''' \mathbf{ of} \mathbf{Inl} x \Rightarrow N'; \mathbf{Inr} x' \Rightarrow N''$.
- Assume $P = q, p$. Then the logic is similar to the third subcases of the previous two cases.
- Assume $M = \mathbf{select}_{q,p} \ell N$. This is similar to the $N_1 = \mathbf{com}_{q,p}$ case above.
- Assume $M = f(p_1, \dots, p_n)$. Then

$$\llbracket M \rrbracket = \prod_{i=1}^n p_i[f_i(p_1, \dots, p_{i-1}, p_{i+1}, \dots, p_n)] \mid \prod_{p \notin \{p_1, \dots, p_n\}} p[\perp]$$

We therefore have some process p such that $P = p$ and $(\llbracket M \rrbracket \setminus p_i \mid p_i[\llbracket D \rrbracket(f_i(\vec{p}))][\vec{p}' := p_1, \dots, p_{i-1}, p_{i+1}, \dots, p_n]] \rightarrow_{\llbracket D \rrbracket}^* \mathcal{N}$. We then define the required choreography $M'' = D(f(p'_1, \dots, p'_n))[\vec{p}' := p_1, \dots, p_n]$ and network

$$\mathcal{N} = \llbracket M'' \rrbracket = \prod_{i=1}^n p_i[\llbracket D \rrbracket(f_i(\vec{p}))][\vec{p}' := p_1, \dots, p_{i-1}, p_{i+1}, \dots, p_n] \mid \prod_{p \notin \{p_1, \dots, p_n\}} p[\perp]$$

and the result follows from induction. ◀

Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

Jan de Muijnck-Hughes

Wim Vanderbauwhede  

University of Glasgow, UK

Abstract

Quantitative Type-Systems support fine-grained reasoning about term usage in our *programming languages*. Hardware Design Languages are another style of language in which quantitative typing would be beneficial. When wiring components together we must ensure that there are no unused ports, dangling wires, or accidental fan-ins and fan-outs. Although many wire usage checks are detectable using static analysis tools, such as Verilator, quantitative typing supports making these extrinsic checks an intrinsic aspect of the type-system. With quantitative typing of bound terms, we can provide design-time checks that all wires and ports have been used, and ensure that all wiring decisions are explicitly made, and are neither implicit nor accidental.

We showcase the use of quantitative types in hardware design languages by detailing how we can retrofit quantitative types onto SystemVerilog netlists, and the impact that such a quantitative type-system has when creating designs. Netlists are gate-level descriptions of hardware that are produced as the result of synthesis, and it is from these netlists that hardware is generated (fabless or fabbed). First, we present a simple structural type-system for a featherweight version of SystemVerilog netlists that demonstrates how we can type netlists using standard structural techniques, and what it means for netlists to be type-safe but still lead to ill-wired designs. We then detail how to retrofit the language with quantitative types, make the type-system sub-structural, and detail how our new type-safety result ensures that wires and ports are used once.

Our ideas have been proven both practically and formally by realising our work in Idris2, through which we can construct a verified language implementation that can type-check existing designs. From this work we can look to promote quantitative typing back up the synthesis chain to a more comprehensive hardware description language; and to help develop new and better hardware description languages with quantitative typing.

1 Introduction

Quantitative Type System (*QTS*) support fine-grained reasoning about term usage in our *programming languages*, such that we can control precisely how many times a bounded term can be used. We are even starting to see *QTSs* being introduced into general purpose programming languages, for example: Linear Haskell [7], Idris2 [10], and Granule [33]. Issues around term usage are, however, not limited to programming languages.

Widely used Hardware Description Languages (*HDLs*) capture not only how hardware designs behave but also how they are physically structured. SystemVerilog is a leading industry standard *HDL* that supports the modelling, verification, and fabrication of hardware designs [14, 23]. Within SystemVerilog a hardware design consists of a high-level structural description of hardware in which modules represent physical units of design, are connected with wires, and each module contains descriptions of the modules behaviour. These behavioural descriptions describe how values are either initially placed on a wire, modified, or distributed through other channels. From this behavioural description, the design is *verified* (tested) to ensure that it behaves as intended. Verification happens using a mixture of static analysis tooling (to externally analyse the design), and testbench creation (in the same language) that is then simulated. Once the design has been verified, a *synthesis* tool converts the high-level description into a gate-level netlist; depending on the complexity of the described design, synthesis can take hours to complete. Netlists sit at the end of the synthesis process that takes high-level hardware designs and generates a single description from which hardware is then generated for fabrication or deployed in fabless environments. These netlist descriptions are also written in SystemVerilog, and the low-level gates offered can differ per hardware platform.

Term usage within *HDLs* is, unfortunately, different to that seen in general purpose programming languages. Bounded terms represent, quite literally, a physical resource that is to be used. Figure 1 presents several illustrative valid hardware designs as specified in Verilog, a subset of SystemVerilog. Each module has an explicit *header* (also known as a portgroup) that details the module’s interface with the outside world. Portgroups detail the typed ports in the interface and the direction that signals can flow through each port. Within modules, we can connect ports to logic gates (or other synthesisable terms), introduce internal wiring, and make direct assignments between ports. Now let us focus on the wiring in our illustrative examples: Figure 1a presents a valid repeated use of a wire; Figure 1b presents a potentially invalid fan-in in which the two inputting wires are negated and wired into the outputting port; Figure 1c presents bit-vector indexing that requires repeated term usage; and Figure 1d presents use of an intermediate variable to reroute part of a bit-vector, and that the bit-vector’s last port is not used. All these examples are structurally valid designs yet the wiring decisions (if a wire is to be used or not, and how often it is to be used) are not always explicit. Existing tools, such as *Verilator*¹, support *external* static analyses of hardware designs that includes reasoning about wire usage. Such static analyses can detect, amongst other things, if wires are unused, and if outputting ports are driven by multiple wires. If such wiring issues are not resolved they could physically damage the hardware and produce ill-behaved hardware.

An issue arising from using external tooling is that their checks are external to the design being captured, thus allowing a *time-of-check time-of-use* issue to exist between when a design is checked and when a design is used. With the rising popularity of *QTS* we must ask ourselves: Can quantitative reasoning about term usage also be applied to *HDLs*? With such quantitative reasoning we can start to embed wire usage constraints directly into our *HDL*’s type-system, such that our external checks (using external tools) now become an intrinsic aspect of the language design itself. By using a more expressive quantitative type-system we can ensure that any and all wiring decisions are explicit, and that ill-wired designs cannot be expressed as they are ruled out by the type-system as ill-typed designs.

1.1 Contributions

Existing efforts in developing calculi for verifying hardware designs in Verilog-like languages have not sought to reason about quantitative wire usage [28, 31, 26]. Leaning on the idea of *featherweight* languages [21, 36, 34, 24] we have explored a type-based approach to reasoning about linear wire usage for *netlists* using Quantitative Type Theory (*QTT*) [4]. By capturing a valid subset of Verilog we can type existing designs to ensure that all wires are used exactly once, and showcase our approach. Moreover, we now have a foundation for future work that can investigate ways in which the calculi can be extended up the synthesis chain *formally* (inline with the formal specification); and *safely* (such that known properties of the specification still hold).

Specifically, our contributions are:

- We provide a formal unrestricted type-system (*CIRCUITS*) for Verilog netlists, and introduce notions of type-(un)safety based on denotational semantics relating to graph topology.
- We provide a formal restricted type-system (*CIRQTS*) that is resource-oriented, and detail how it provides fine-grained resource tracking for wires and ports without the need for user annotations. Using *CIRQTS* we ensure that wire and ports can only be connected to once and we detail how we can supply new Verilog primitives that support explicit weakening of a wire’s linearity safely. This weakening enables modelling of existing valid designs, and ensure wiring decisions are explicitly made.
- We put theory into practice by building a mechanised verified implementation of *CIRCUITS* and *CIRQTS* in Idris2 such that we can type-check existing valid Verilog netlists (modulo implementation restrictions and technology mapping) to detect wire usage violations. The implementation of *CIRCUITS* and *CIRQTS* has been made freely available online, and can also be found in the accompanying supplementary material.

With *CIRCUITS* and *CIRQTS* we have developed a better understanding of how to: fundamentally type wiring in Verilog; and produce a type-system that makes wiring safer. Moreover, with *CIRQTS* we have also begun to understand what impact linear wire usage has on circuit design. Although we can reason linearly about wire usage, we have found that

sometimes linear usage is too restrictive and dependent on the intended behaviour of the design. It remains an open question over how best we can weaken linearity in more nuanced ways needed for hardware design.

1.2 Outline

Section 2 details a formal abstract syntax for Verilog netlists that our two type-systems type. Our unrestricted netlist language (CIRCUITS) is formally presented in Section 3, and the linearly wired variant (CIRQTS) in Section 4. For both calculi we detail their *wire-safety*, our approach to type-safety as an interpretation to a graph, and how CIRCUITS is wire unsafe but CIRQTS is not. With linear wiring, wire endpoints and ports, cannot be reused. We detail in Section 5 new *easy-to-add* primitives to Verilog (as primitive gates), that support valid weakening of linearity to allow wires to be split and combined. Section 6 details how we have mechanised our realisation of both languages in Idris2, and Section 7 discusses the results of using CIRQTS for designing netlists. From our experimentation we discuss the efficacy of our approach in Section 7. We end by relating our contributions to the wider world in Section 8.

2 A Syntax for Netlists

Figure 2 presents the shared abstract syntax for CIRCUITS and CIRQTS. Both languages abstract over a subset of Verilog’s concrete syntax required for gate-level modelling. The syntax is unremarkable, which highlights the simplicity that accompanies netlist language design.

$$\begin{aligned}
 n : \mathbb{N} &::= \text{Natural Numbers} \\
 d : \mathcal{D} &::= \text{I} \mid \text{O} \mid \text{IO} \\
 i : \mathcal{I} &::= \text{Logic} \mid [i ; n] \\
 g &::= \text{mux2}(e, e, e, e) \mid b(e, e, e), b \in \{\text{and, or, } \dots\} \mid u(e, e), u \in \{\text{not, } \dots\} \\
 e &::= \varphi \mid \text{port } i \text{ d as } \varphi \text{ in } e \mid \text{gate } g \text{ as } \varphi \text{ in } e \mid \text{wire } i \text{ as } \varphi \text{ in } e \mid \text{assign } e \leftarrow e \text{ in } e \\
 &\quad \mid \text{stop} \mid (\text{index } e \ n) \mid (\text{cast } e \ f) \mid (\text{readFrom } e) \mid (\text{writeTo } e)
 \end{aligned}$$

■ **Figure 2** Abstract Syntax for CIRCUITS and CIRQTS.

We restrict our modelling to simple synthesisable datatypes (\mathcal{I}) as seen in Verilog: 4-state logic bits and their aggregation into bit-vectors. The set of supported gates (g) is indicative, as many netlists are dependent on the technology (gates) as supported by the underlying hardware. For our investigation we explored two input multiplexers, binary logic gates, and unary logic gates, as this presents an expressive enough set of gates to create interesting designs. Although we do not consider gates with n-ary outputs, such as demultiplexers, our setting does support them as we shall see in Section 4.2. Whilst this language seems overly restrictive when compared to state-of-the-art *HDLs*, the syntax and type-system can be extended to deal with n-ary gate syntax, and new primitive gates added.

Most notable from Figure 2 is that the top-level module header is implicit, and sequencing (recall that Verilog is imperative) of statements is realised as continuations on desired sub-terms. Circuit designs represent a single module with a predefined set of ports (supporting uni-directional and bi-directional signals), as such we can represent the module header as a series of bespoke let-bindings that introduce bound terms (with variables being represented

by φ) into the corresponding scope. Declarations for gates and internal wires follow this same pattern, as does the direct assignment (connection) of ports and wires which is supported by the assign statement. Verilog also supports anonymous gate declarations, to keep our minimal calculi small we have purposefully not incorporated them into the syntax but note their addition is straightforward. Finally, the `stop` expression indicates the end of the netlist specification.

The final set of expressions are required to capture type-safe wiring of ports and wires to gates. Naturally, bit-vectors can be indexed to access individual wires in the vector. We do not support slicing as it can be elaborated/synthesised into our core syntax. The remaining expressions are however, not explicit in Verilog’s concrete syntax. Nonetheless, they can be inserted automatically through syntax elaboration.

The first of these hidden expressions supports the insertion of bi-directional ports into gates. Gates only have ports that are inputting or outputting, but bound ports may be bi-directional. `Cast`, like `index`, is an in-place operation on ports and endpoints, that supports transformation of the given direction to supplied direction f .

The final two expressions relate to inserting internal wires into declared gates. Verilog’s concrete syntax does not discriminate between ports and wire endpoints. We thus introduce two projection terms to support such access, one that supports reading from a channel, and the other to support writing to a channel.

We end this section with Figure 3 that illustrates how Figure 1d is encoded in the shared syntax.

```
port Logic O as c in
port Logic I as ab in
wire Logic as temp
  in assign (writeTo temp) ← (index ab 0)
  in gate and (c, (readFrom temp), (index ab 1)) as ga
in stop
```

■ **Figure 3** Figure 1d in the shared Syntax.

3 A Structural Type-System

The abstract syntax from Section 2 helps direct well-formed netlists through its syntactical structure. Nonetheless, a type-system will categorically ensure that the netlists are *well-formed*. This section introduces a simple, yet *flawed*, type-system for CIRCUITS in which term usage is unrestricted, but nonetheless respects how netlists are typed. Practically speaking, the flaw allows uncontrolled fan-ins and fan-outs to be inserted unchecked into the design, and for ports and channels to be left dangling (unused). Section 4 details how quantitative wire usage ensures that ports and channels are used exactly once.

3.1 Types and Contexts

Figure 4 details the (unsurprising) set of types and typing context for CIRCUITS. Ports types (\mathcal{P}) are parameterised by how signals flow from ports, together with the port’s shape as captured by the given datatype. Similarly, wire types (\mathcal{W}) are parameterised by the wire’s shape, the provided datatype. Further, gates are given their own type (\mathcal{G}), and the unit type ($\mathbb{1}$) signifies the end of a design.

$$t : \text{TYPE} ::= \mathcal{P}(i, d) \mid \mathcal{W}(i) \mid \mathcal{G} \mid \mathbb{1}$$

$$\Gamma ::= \emptyset \mid \Gamma + x : t$$

■ **Figure 4** Types and Contexts for CIRCUITS.

3.2 Typing Rules

Figure 5 details the typing rules for CIRCUITS. The introduction rules for natural numbers and datatypes are not presented and are implicitly given in Figure 2. Much like the rest of the definition of CIRCUITS, the rules are for the most part unsurprising and follow standard norms. Rule STOP introduces the unit type, signalling the end of the design. Rules MUX, BIN, & UN type gates and, as in Verilog itself, gates present their output ports then their input ports such that all ports have the same type, which for netlists will be: `Logic`. The Rules PORT, WIRE, & GATE adapt the standard presentation for let-bindings in which the body is extended with the introduced variable. Direct assignment (Rule ASSIGN) of an output port to an input port happens if they both have the same shape i.e. datatype. Indexing vector-shaped ports (Rule INDEX) returns a single port from the array with the shape of the contained elements, and the same signal flow. Further, a compile-time bounds check is required to ensure safe vector-indexing.

Gates and direct assignment only support ports with flow input or output. Casting (Rule CAST) supports safe transformation of a bidirectional port to either an input or output, which we formally express as follows:

► **Definition 1** (Valid Casting of Directions). *Given $a, b : \mathcal{D}$ the safe transformation of flow a to b , which we denote as $\text{ValidCast}(a, b)$, is:*

$\text{ValidCast}(a, b)$	I	O	IO
I	×	×	×
O	×	×	×
IO	✓	✓	×

We have purposefully presented a *strict* interpretation of casting, and do not include the *identity* cast. During the mechanised elaboration of terms (Section 6), we wished to ensure that casts are only inserted if the cast would change the direction. Inclusion of the identity cast would not weaken our result.

The final two rules, Rules READ & WRITE detail how a wire's endpoints are accessed by projection. It is here that the typing rules become somewhat counter-intuitive. Intuition tells us that projecting a wire to *read its contents* would return an outputting port, and conversely *writing to a wire* would require its inputting port. Instead we have swapped the directions: reading gives an input; writing gives an output. Such a swap supports the *natural* typing rules when checking gates and direct assignments. That is, by swapping the expected flow of information during projection we do not need to check if a port marked output will go to an input and vice-versa. Checking for direction equality thus simplifies the typing rules, and checking, for CIRCUITS.

$$\begin{array}{c}
\text{VAR} \frac{\varphi : t \in \Gamma}{\Gamma \vdash \varphi : t} \qquad \text{STOP} \frac{}{\Gamma \vdash \text{stop} : \mathbb{1}} \\
\\
\text{MUX} \frac{\Gamma \vdash o : \mathcal{P}(\text{Logic}, \text{O}) \quad \Gamma \vdash c : \mathcal{P}(\text{Logic}, \text{l}) \quad \Gamma \vdash a : \mathcal{P}(\text{Logic}, \text{l}) \quad \Gamma \vdash b : \mathcal{P}(\text{Logic}, \text{l})}{\Gamma \vdash \text{mux2}(o, c, a, b) : \mathcal{G}} \\
\\
\text{BIN} \frac{\Gamma \vdash o : \mathcal{P}(\text{Logic}, \text{O}) \quad \Gamma \vdash x : \mathcal{P}(\text{Logic}, \text{l}) \quad \Gamma \vdash y : \mathcal{P}(\text{Logic}, \text{l}) \quad b \in \{\text{and}, \text{or}, \dots\}}{\Gamma \vdash b(o, x, y) : \mathcal{G}} \\
\\
\text{UN} \frac{\Gamma \vdash o : \mathcal{P}(\text{Logic}, \text{O}) \quad \Gamma \vdash i : \mathcal{P}(\text{Logic}, \text{l}) \quad u \in \{\text{not}, \dots\}}{\Gamma \vdash u(o, i) : \mathcal{G}} \\
\\

\end{array}$$

■ **Figure 5** Simple Typing Rules for CIRCUITS.

3.3 Wire-(Un)Safety

As programming languages are computational it makes sense to reason about their type-safety using their operational semantics: How they compute! Standard syntactic approaches require that we describe how terms reduce (progress) during operation, and prove that once a value is reached that the types have been preserved (preservation). *HDLs* on the other hand, not only describe how signals flow across wires, but also the structure of the circuit itself. At the level of netlists, *HDLs* are not computational languages and there is no reduction of terms. We must, therefore be concerned with a design's physical structure rather than its behaviour. As such we will reason about our type system's correctness based on its *wire-safety*, that is how well the design has been wired together, as opposed to how the design behaves. Specifically, we will use a denotational approach in which we use the circuit design as the instructions to

construct a graph, and assess the design’s wire-safety using the constructed graph’s topology. We stress that these results provide assurances over how circuits are wired and not how they behave. Behavioural safety requires more work [22, 28].

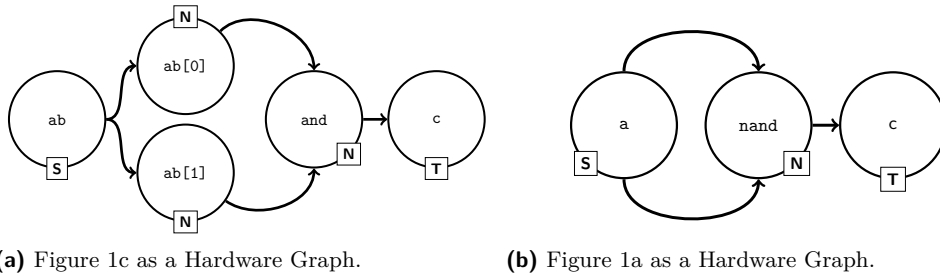

We remark that our denotational approach to wire-safety is inspired by the use of definitional interpreters [38, 37] to prove type-soundness [3]. We elide technical details, highlighting the main results only, and remark that the accompanying artefact (which provides a mechanisation of our contributions, see Section 6) contains the full details.

As a reminder, the “safety” result we present here is purposefully unsafe to capture how a structural type-system does not provide guarantees over the sub-structural property that is wire-safety. The next section Section 4 describes a more (type) safe way to determine wire-safety.

3.3.1 Graphs for Hardware

Digital circuits (netlists) are *just* multigraphs. Leaf vertices map to a netlist’s inputting and outputting ports, and internal vertices represent logic gates. Wires too can be represented by pairs of internal vertices (one for each endpoint, with a single edge to connect the two), and edges in our graph model wiring between ports, channels, and gates. To better reason about our graph’s topology we categorise leaf vertices as being sources (S ; output ports), targets (T ; input ports), or unknown (U ; bidirectional ports). Internal nodes (N) capture gates, casting, and projection of wires. Figure 6 shows how Figures 1a and 1c can be viewed as a hardware graph, and that the edges represent the wiring between ports, gates, and wires. More formally we can describe such graphs as:

► **Definition 2** (Hardware Graph). *Let $H = \langle vs, es \rangle$ be a directed multigraph where vs is a set of vertices, and es is a list of edges. Vertices in H will be labelled with an element of $\{S, T, U, N\}$.*

■ **Figure 6** Example Hardware Graphs for CIRCUITS.

To reason about wire usage we need to define what it means for our hardware graph to be wired. We can determine the expected degree a vertex has directly from its categorisation: source vertices will have zero incoming edges, and zero or more outgoing edges; leaf vertices will have zero or more incoming edges, and zero outgoing edges; bi-directional vertices will have zero or more incoming or outgoing edges; and internal vertices will have zero or more incoming or outgoing edges. Using $\text{deg}^+(v, es)$ and $\text{deg}^-(v, es)$ to calculate the out and in degrees for a vertex v from a given list of edges es , we can compare the given degrees with the expected degrees. If the relations hold then the circuit has been wired. We formally present this definition as:

► **Definition 3** (A Wired Hardware Graph). *Let $H = \langle vs, es \rangle$ be our hardware graph, the wiring of H is well-formed, $C(H)$, if:*

$$\forall v \in vs \begin{cases} S & \text{deg}^+(S, es) \geq 0 \wedge \text{deg}^-(S, es) \equiv 0 \\ T & \text{deg}^+(T, es) \equiv 0 \wedge \text{deg}^-(T, es) \geq 0 \\ U & \text{deg}^+(U, es) \geq 0 \vee \text{deg}^-(U, es) \geq 0 \\ N & \text{deg}^+(N, es) \geq 0 \wedge \text{deg}^-(N, es) \geq 0 \end{cases}$$

Interpretation of terms will result in either: an error related to binding; a hardware graph; a vertex; the empty value (\perp) of the empty type. Port definitions are interpreted into leaf vertices following the port's direction, whereas gates, wires, and casts interpret into internal nodes. The end of a specification is interpreted into the empty type. Port usages, and channel projection, inserts edges into the graph. We can also strengthen the interpretation by making it type-directed (represented by $\llbracket t \rrbracket_T$), where terms from CIRCUITS are mapped to hardware graph concepts.

Formally we can denote the act of interpretation as follows:

► **Definition 4** (Interpretation). *Let Σ_i be an interpretation environment and $H_i = \langle vs, es \rangle$ be a Hardware Graph. We denote the interpretation of CIRCUITS specification $(\Gamma \vdash e : t)$ as:*

$$(\Sigma, H_i) \llbracket e \rrbracket ::= \text{Error} \mid \text{Done}(H_o, v : \llbracket t \rrbracket_T)$$

where H_o is the resulting hardware graph.

The interpretation environment (Σ) stores the result of interpretation for bound terms and is passed around as an input to interpretation explicitly. The accumulator graph (H) carries the resulting graph as we traverse sub-terms. Here subscripts i and o denote an inputting and resulting value. We cannot *just* return a complete graph for each interpretation step as not all terms return a graph. Take ports, for example, they return a vertex when interpreted during the construction of edges, and `stop` returns the empty value.

More information about the interpretation can be found in the accompanying artefact which contains the mechanisation (Section 6) of CIRCUITS.

3.3.2 Well-Typed Circuits are Valid Hardware Graphs

With this high-level description of interpretation we can detail our strong interpretation soundness result, which is our wire-safety result.

► **Theorem 5** (Strong Interpretation Soundness).

$$\frac{\emptyset \vdash e : \mathbb{1} \quad \llbracket e \rrbracket = \text{Done}(\Sigma, H, v)}{\Sigma \equiv \emptyset \quad v \equiv \perp \quad C(H)}$$

Strong interpretation soundness states that interpretation of a closed specification will result in a valid wired hardware graph. A weak soundness result would be that we can construct *just* a valid hardware graph.

3.3.3 Proof Sketch

Our soundness proof needs to ensure that our interpretation will result in a valid hardware graph. We can structure our proof using Siek's "three easy lemmas" [41] but adapted for interpretation as seen with existing work [3] and adapted to build hardware graphs. Siek's

8:10 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

approach requires that we divide the proof into three sub-lemmas that, when combined, cover all aspects of the interpretation process: 1) interpreting primitives; 2) ensuring that variables are well-scoped; and 3) that doing interpretation will produce a value.

The first lemma deals with typing primitives.

► **Lemma 6 (Primitives).** *Well-typed primitives are not stuck and will interpret correctly.*

Proof. By induction on typing derivations. ◀

The only primitive term in `CIRCUITS` is `stop`, the rest contain interpretable sub-terms. The term `stop` will always interpret.

The next lemma addresses environment lookups. As in existing work [3] we must first define a consistency relation (\vDash) between typing contexts and interpretation environments. Such a relation ensures that as the typing context grows, so will the interpretation environment.

► **Definition 7 (Consistent Interpretation Environments).**

$$\frac{\text{EMPTYENV}}{\emptyset \vDash \emptyset} \qquad \frac{\text{EXTENDENV} \quad \Gamma \vDash \Sigma}{\Gamma + \varphi : t \vDash \Sigma + (\varphi, v : \llbracket t \rrbracket_T)}$$

Using our consistency relation (\vDash) we can describe well-scoped environment lookups. When given an interpretation environment that is consistent with a typing context, we can map bound variables within the typing context to their equivalent bindings in the corresponding interpretation environment. Thus when given a well-scoped variable $\varphi \in \Gamma$ such that φ has type t , then there is a value $(v : \llbracket t \rrbracket_T)$ in the interpretation environment bound to φ .

► **Lemma 8 (Lookup).** *Well-typed interpretation environment lookups are not stuck and will interpret correctly.*

$$\frac{\Gamma \vDash \Sigma \quad \varphi : t \in \Gamma \quad x \equiv \llbracket t \rrbracket_T}{(\varphi, v) \in \Sigma \quad v : x}$$

Proof. By structural induction over the interpretation environment. ◀

As environment lookups are guided by the typing-context, interpretation will succeed because all references to bound terms exist. Otherwise lookup will fail.

The final lemma, which we provide here, details interpretation.

► **Lemma 9 (Interpretation).** *If the interpretation returns a result then the result is a valid hardware graph.*

$$\frac{\Gamma \vdash e : t \quad \Gamma \vDash \Sigma \quad (\Sigma, H_i) \llbracket e \rrbracket ::= (\text{Done } res)}{res = (H_o, v) \quad v : t' \quad t' \equiv \llbracket t \rrbracket_T}$$

Proof. By induction on typing derivations. ◀

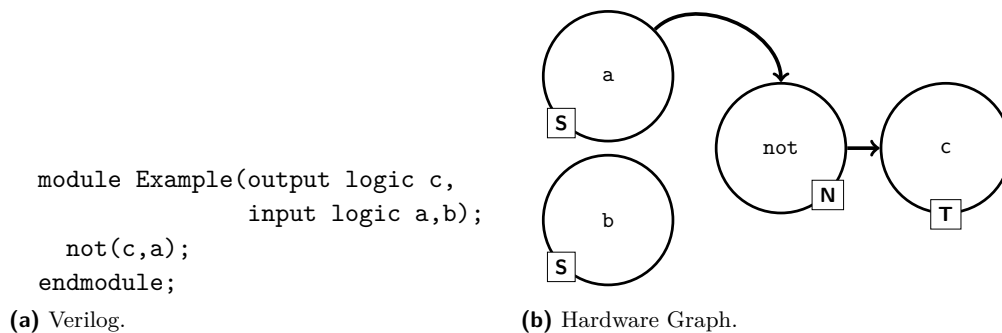

We know that within definitional interpreters the strong soundness property [3] corresponds to the classic strong soundness property used in proving type soundness [47]. With our final lemma we can show that well-typed `CIRCUITS` specifications *will* construct correctly wired hardware graphs, if not an error will occur. Interpretation will finish when the term `stop` is reached. The consistency relation ensures that the typing contexts and interpretation environment remain consistent as we step across binders.

We only check the strong soundness result after the interpretation process has finished. Sub-terms return components of a hardware graph, and not a complete graph itself, we need to ensure that the soundness result is applied to a whole specification.

3.4 Towards True Wire-Safety

Our definition of a wire-safety, and thus safety of `CIRCUITS` type-system, is not one that leads to designs that are inherently *safely wired*: Designs in which wires are used once, and wire usage is clear. The type-system for `CIRCUITS` is not sub-structural, and will admit designs in which ports (and wires) are left dangling or partially used. We know this because our definition for wiredness ($C(H)$) is too loosely specified. We can show this by changing the definition of $C(H)$ to one where the expected degree of leaf nodes is *greater than zero to equal to one*. Such a change now invalidates various graphs in which ports and wires were left dangling, and were once admitted by `CIRCUITS` type-system.

Consider, for example, the netlist and its corresponding hardware graph in Figure 7. The netlist has a dangling input `b`. It is unclear from the immediate context if `b` is supposed to be dangling or included in the design; gates in Verilog are n-ary. The change in definition of $C(H)$ supports identification of ill-wired designs, as the expected out degree of for `b` is one but its given degree is zero.

■ **Figure 7** Example Netlist with Ambiguous Wiring.

Changing the definition of $C(H)$ is still, however, not enough to get safe designs. We need to reason about bidirectional ports, remember that bit-vectors can be indexed, ensure that channel endpoints are accessed once, and that gates are only wired into once. We need a sub-structural type-system to reason about wire/port usage. We will show this in the next section, and provide a better definition of what it means for a hardware graph to be *well-wired*.

4 A Sub-Structural Type-System

The illustrative designs from Figure 1 are not linear in their bound term usage. There are repeated variables, dangling wires, and parts of bit-vectors left unused. Trying to fit *wire usage constraints* into existing quantitative systems is hard. Generally speaking, *QTSs* such as Atkey’s *QTT* [4], and those based around linear logic [45, 44] and graded semirings [33], are designed to reason about term usage within general purpose programming languages. Specifically, linear systems require that bounded terms are used *exactly once*; affine systems require that bounded terms are used *at most once*; graded systems require that bounded terms are used *at most n-times*; and *QTT* allows bounded terms to be used linearly, and unbounded terms have unrestricted usage. *None-One-Tonne* systems do not have a fine grained usage modality. *HDLs* capture circuit behaviour as well as structure.

A key design challenge when *linearising* `CIRCUITS` type-system is to know what *usage* means for *HDLs*, as bounded terms do not have singular usage. Within `CIRCUITS` wires have two endpoints that are used in separate locations, and bit-vector shaped wires/ports can

be indexed in strange and wonderful ways. Roughly, projection of endpoints and indexing implies that each sub-term may be partially used in a design and type-checking needs to take this into account. Further, while ports/wire have bounded usage, gates are unbounded. It is not clear how *QTT* and Granule can be co-opted to encode these domain specific usages as part of a semiring structure. Our approach to the type-system for CIRQTS must be different, for now.

4.1 Types and Usages

Figure 8 details the additional infrastructure required to make CIRCUITS linear. Inspiration is taken from *QTT* to base our system of usages (Figure 8a) on the *none-one-tonne* semiring. Things are free until used, and some things will always be free to use i.e. unbounded usage. In practice, however, this can be distilled to the ordinary boolean semiring as our usage requirements are more conservative and constrained, and we make no link between compile time and runtime quantities as *QTT* is used in practice [10].

$$R ::= 0 \mid 1 \mid \omega \quad \begin{array}{l} i : \mathcal{I} \quad ::= \text{Logic} \\ u : \text{USAGE}_D(i) \quad ::= R \\ \text{Init}_D(u) \quad ::= 1 \end{array} \left| \begin{array}{l} [i; n] \\ \{u_j : \text{USAGE}_D(i)^{j \in 1..n}\} \\ \{\text{Init}_D(u_j)^{j \in 1..n}\} \end{array} \right.$$

(a) Usages.

(b) DataTypes.

$$\begin{array}{l} t : \text{TYPE} \quad ::= \mathcal{P}(i, d) \\ u : \text{USAGE}_T(t) \quad ::= \text{USAGE}_D(i) \\ \text{Init}_T(u) \quad ::= \text{Init}_D(i) \end{array} \left| \begin{array}{l} \mathcal{W}(i) \\ (\text{USAGE}_D(i), \text{USAGE}_D(i)) \\ (\text{Init}_D(i), \text{Init}_D(i)) \end{array} \right| \left. \begin{array}{l} \mathcal{G} \mid \mathbb{1} \\ \omega \mid \omega \\ \omega \mid \omega \end{array} \right.$$

(c) Types.

$$\Gamma ::= \emptyset \mid \Gamma + (\varphi : t, u : \text{USAGE}_T(t)) \mid \Gamma \pm (\varphi : t, u : \text{USAGE}_T(t)) \quad \Gamma_i \vdash e : t \dashv \Gamma_o$$

(d) Contexts.

(e) Judgements.

■ **Figure 8** Types and Contexts for CIRQTS.

Figure 8b presents how we capture datatype usage. Recall that the types for ports and channels are indexed by a datatype. The shape of a port/wire's datatype will direct the usage we need to track. Logic-shaped ports and channels will have a single wire to use, and bit-vectors an array of elements to use. Bit-vectors are, however, multidimensional and the usages should reflect that when indexing bit-vectors. When initialising usages for datatypes we set them to be free.

Figure 8c presents how we specify usages for bindable types. Ports will have to keep track of their usage based on the usage of the datatype they are indexed by, and wires will have a pair of usages (one for each endpoint). Gates (and unit) will be left unrestricted as their use is unrestricted. The syntax for CIRCUITS/CIRQTS enforces that **stop** can only be used once. For newly introduced ports and wires, their initial usage will be free.

Figure 8d details how we situate our usages in the type-system. Following existing work [46] we must annotate our typing context to keep track of the usage of bounded terms. Given the different shapes of our boundable types, we cannot use linear algebra to capture usage updates. Instead we take a simpler approach by envisaging our types (and type-system)

as a stateful resource in which the usage of bound term is a state. Specifically not only can our context be extended, but we can also update the state of a bound term's resource: its usage.

We differ from standard linear typing approaches by not relying on context splitting. Rather our judgement formation (Figure 8e), and typing rules, are more algorithmic. Successfully typing a term will may result in a new updated context. This mirrors the algorithmic presentation of the Linear Lambda Calculus (*LLC*) [45, Figure 1-6].

4.2 New Syntax for Indexing

$$\begin{aligned} (\text{index } e \ n) &\rightarrow (\text{index } \varphi_p \ \{n_i^{i \in 1..m}\}) \\ (\text{readFrom } e) &\rightarrow (\text{readFrom } \varphi_c) \mid (\text{readFromAt } \varphi_c \ \text{id}x) \\ (\text{writeTo } e) &\rightarrow (\text{writeTo } \varphi_c) \mid (\text{writeToAt } \varphi_c \ \text{id}x) \end{aligned}$$

■ **Figure 9** Syntax Changes required for CIRQTS.

We can now start to describe the typing rules for CIRQTS as presented in Figure 10. We must first realise, however, that the abstract syntax (Figure 2) is too expressive. The trouble stems from n-dimensional indexing of bit-vectors. Type-checking each (sub)term in our stateful typing updates the states held within the typing context. How do we know which sub-usage of the bit-vector for which bound term in the typing-context needs to be updated? Indexing a one-dimensional bit-vector is simple, but for deeper indexing (i.e. indexing a projection or an index of an index) updating the state is impossible. We need the location within the context. Thus, we must flatten nested indices to a single term, and have separate terms for when wire endpoints are also projected. This transformation step occurs during elaboration, and Figure 9 presents the replacement terms required. How we can adapt the type-system to support nested indexing is not clear.

4.3 Typing Rules

Figure 10 presents the salient typing rules for CIRQTS. Missing are the rules for the *write* projection as they mirror the rules for the *read* projection. The presented rules are not too dissimilar from those in Figure 5. For each rule we reason, using custom predicates, about the state of the usage resource for each binder, or expect context transitions to enforce our linear wiring property.

Rule VAR ensures that bound variables are only used *if* they are completely free; ruling out use of partially used variables that have been used through indexing. Such a predicate means that once a port/wire has been indexed it can only be used through indexing.

Rule STOP describes the end conditions for each bound term's usage, as dictated by the $\text{CanStop}(t, u)$ predicate that requires that all bound terms must be totally used. That is all ports and wires must be used for the design to type-check. How we define $\text{CanStop}(t, u)$ impacts on what it means for a design to be *totally used*. Verilator, for example, does not require output ports to be fully used in its static analysis. That is, Verilator is affine for outputs but linear for inputs, whereas CIRQTS is linear for all wires/ports. We stress that the termination conditions for CIRQTS are not closed for debate. Rather it supports discussing the conditions under which ports and wires are said to be sufficiently used. Verilator's termination choice, for example, can be replicated by requiring that $\text{CanStop}(t, u)$ requires inputting ports and wire endpoints be used.

8:14 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

$$\begin{array}{c}

\end{array}$$

■ **Figure 10** Typing Rules for CIRQTS.

The rules for gates (Rules MUX, BIN, & UN), casting (Rule CAST), and assignment (Rule ASSIGN) shows how the linearity checking can be propagated *silently* through the type-system. Key to Rules CAST, MUX, BIN, & UN operation is that the premises for ports updates the stateful typing-context. A port can only be used if it is either a variable (Rule VAR) or is the result of indexing a port, or a projection of a wire. Threading the updated state left-to-right along the typing rules ensures that ports cannot be reused, as each sub-term uses the latest version of the context possible.

Terms that introduce binders (Rules PORTS, WIRES, & GATE) are not complicated, and extend the typing-context with a new variable binding with a default usage state.

The final rules deal with indexing ports, and channel projection. Rule INDEX becomes a variant of Rule VAR in which the typing conditions require that instead of the referenced port being completely free, the port must be free at the specified index. Importantly, the return type in Rule INDEX is not the inner type of φ_p but is, instead, the type of element at the end of the presented index. The rules for projection also follow on from Rule VAR in that they resolve references. Whereas Rule READ acts on a port entirely, Rule READAT adapts the structure for Rule INDEX but the usage resource associated with the wire's input endpoint is analysed/updated. Writing to a wire (rules not shown) mirrors those for reading but affect the other resource.

4.4 Wire-Safety

Our approach to reasoning about wire-safety in CIRQTS does not differ much from Section 3.3. The core differences relate to how Hardware Graphs are defined, and what it means for a Hardware Graph to be well wired. We highlight the key differences in approach.

To better reason about our graph's topology we extend the definition of Hardware Graph from Definition 2 and label each vertex with its expected in/out degree. More formally:

► **Definition 10** (Hardware Graph). *Let $H = \langle vs, es \rangle$ be a directed multigraph graph where vs is a partitioned set of vertices, and es a list of edges. Vertices in H are labelled with their minimum in/out degree, and are defined as $v^{o,i}$ where: o is the expected out-degree; i the expected in-degree; and the shape of each v is taken from $\{S^{(n,0)}, T^{(0,n)}, U^{(n,n)}, N(n,m)^{(n,m)}\}$.*

Like the previous definition of a hardware graph we must define what it means for such a graph to be wired. Again, we do so by checking that the expected degrees for each vertex must match the degrees as calculated from the set of edges. Our previous definition, however, is too permissive. Must refine our definition to ensure that the given degrees will match the expected degrees. Moreover, we must ensure that bi-directional ports are used in one direction only, thus we require an exclusive disjunction ($\underline{\vee}$) between the calculated in/out degrees and the expected degrees. Formally we present his definition as:

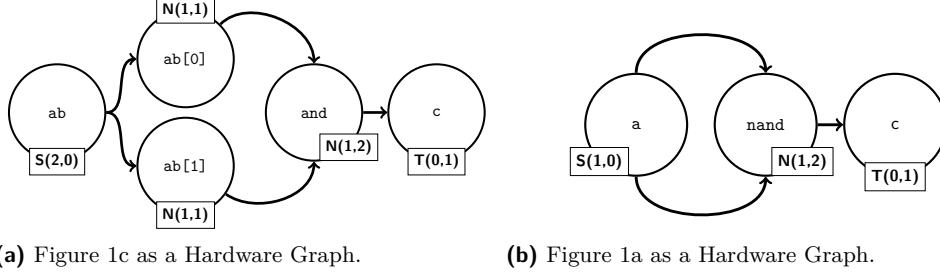

► **Definition 11** (Well-Wired Hardware Graph). *Let $H = \langle vs, es \rangle$ be our hardware graph, the wiring of H is well-formed, $\mathcal{W}(H)$, if $\forall v^{(o,i)} \in vs$:*

$$v^{(o,i)} \left\{ \begin{array}{l} S^{(o,0)} \quad \text{deg}^+(S^{(o,0)}, es) \equiv o \wedge \text{deg}^-(S^{(o,0)}, es) \equiv 0 \\ T^{(0,i)} \quad \text{deg}^+(T^{(0,i)}, es) \equiv 0 \wedge \text{deg}^-(T^{(0,i)}, es) \equiv i \\ U^{(o,i)} \quad \text{deg}^+(U^{(o,i)}, es) \equiv o \wedge \text{deg}^-(U^{(o,i)}, es) \equiv 0 \\ \underline{\vee} \\ \text{deg}^+(U^{(o,i)}, es) \equiv 0 \wedge \text{deg}^-(U^{(o,i)}, es) \equiv i \\ N^{(o,i)} \quad \text{deg}^+(N^{(o,i)}, es) \equiv o \wedge \text{deg}^-(N^{(o,i)}, es) \equiv i \end{array} \right.$$

Figure 11 shows how Figures 1a and 1c can be viewed using the amended hardware graph. With the new hardware graph definition correspondences (Figure 11a) and discrepancies (Figure 11b) can be seen between the expected and given degrees for the vertices in each example. This demonstrates the ability of our new hardware graph definition to more accurately reason about wiring. If we compare these graphs with those in Figure 6 we can better see the accuracy. Both Figure 11a and Figure 6a presents graphs in which there are

8:16 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

no discrepancies. Figure 11b, however, now shows a discrepancy for vertex a in which its expected out degree is one but its given out degree is two, this was not seen in Figure 6b as there is insufficient information to decide.

(a) Figure 1c as a Hardware Graph.

(b) Figure 1a as a Hardware Graph.

■ **Figure 11** Example Hardware Graphs for CIRQTS.

Interpretation of Verliog to hardware graphs is as before, however, to reason more accurately about bit-vector wiring we calculate the degree of a vertex based on the size of its datatype. The shape logic has size one, and bit-vectors have the size of its element multiplied by the size of the bit-vector. We also need to take into account that type-checking will alter the state associated with bound types. Thus, we must return both the accumulated hardware graph (H_o) and the resulting interpretation environment (Σ_o).

► **Definition 12** (Interpretation). *Let Σ_i be an interpretation environment and $H_i = \langle vs, ws \rangle$ be a Hardware Graph. We denote the interpretation of a CIRQTS design ($\Gamma_i \vdash e : t \dashv \Gamma_o$) as:*

$$(\Sigma_i, H_i) \llbracket e \rrbracket ::= \text{Error} \mid \text{Done}(\Sigma_o, H_o, v : \llbracket t \rrbracket_T)$$

where Σ_o and H_o are the updated environment and resulting hardware graph.

With this new interpretation definition we must also update our interpretation soundness result accordingly.

► **Theorem 13** (Strong Interpretation Soundness).

$$\frac{\emptyset \vdash e : \mathbb{1} \quad \llbracket e \rrbracket = \text{Done}(\Sigma, H, v)}{\Sigma \equiv \emptyset \quad v \equiv \perp \quad \mathcal{W}(H)}$$

and also the final lemma which details interpretation.

► **Lemma 14** (Interpretation). *Interpretation of a design is not stuck and will return a result containing a valid hardware graph.*

$$\frac{\Gamma_i \vdash e : t \dashv \Gamma_o \quad \Gamma_i \models \Sigma_i \quad (\Sigma_i, H_i) \llbracket e \rrbracket ::= (\text{Done } res)}{res = (\Sigma_o, H_o, v) \quad \Gamma_o \models \Sigma_o \quad v : t' \quad t' \equiv \llbracket t \rrbracket_T}$$

Note that we also require a consistency relation on outgoing typing contexts and interpretation environments, as well as the inputting ones. This is required, as stepping through each sub-term modifies the type-level state, and returns a new interpretation environment. Further we need to extend the consistency relation to account for context updates.

► **Definition 15** (Consistent Interpretation Environments under Context Updates).

$$\frac{\text{UPDATEENV} \quad \Gamma \models \Sigma}{\Gamma \pm \varphi : t \models \Sigma \pm (\varphi, v : \llbracket t \rrbracket_T)}$$

With these revised definitions we can now reason about the type system of CIRQTS and its linearity guarantees. The proof that well-typed designs are well-wired hardware graphs does not change from the simply-typed proof sketch in Section 3.3.

An interesting aspect of our formulation, is that we can use the same wire-safety result defined here to show that designs with CIRCUITS specification will be unsafe as the resulting hardware graphs are not linearly wired.

Unfortunately, we are still not done. CIRQTS is too restrictive in its approach to linear wiring. Our type-system, as it stands, will rule out valid designs by removing the ability to fan-out and fan-in when it is benign to do so. Verilog designs require that we can split and join wires together i.e. weaken linearity. The next section discusses how we can extend the *syntax* to support this.

5 Weakening Linearity for Free with new Gates

Figure 12a presents a variant of Figure 1a with many potential linear violations, specifically that the use of `a` is non-linear and that `b` is unused. From this example it is, however, unclear what the designer’s intended wiring was. What was accidental: the repeated use of `a`, or specification of `b` as an input? The linearity encoded within the type-system for CIRQTS is too restrictive. There will be valid cases, for example driving n-ary logic gates with the same input (Figures 1a and 12a), in which we need to weaken linearity to support valid designs. At the same time though, we need to report accidental dangling and repeated wiring.

	<pre>module Example0(output logic c, input logic a);</pre>
<pre>module Example0(output logic c, input logic a,b);</pre>	<pre> wire logic temp0, temp1; split(temp0, temp1, a); nand(c, temp0, temp1);</pre>
<pre> nand(c, a, a);</pre>	<pre>endmodule;</pre>
<pre>endmodule;</pre>	<pre>endmodule;</pre>
(a) Unclear usage.	(b) Clear usage.

■ **Figure 12** Example showing unclear usage violation, and new syntax to make usage explicit.

Figure 13 presents two new gate primitives that support wire duplication (splitting), and wire joining (collection). With these new primitives designers must now *explicitly* state when wires are to be duplicated (i.e. split) and when they are merged (i.e. drive the same output). Presenting them as primitives addresses issues of backwards compatibility as the SystemVerilog standard [23] supports new gate primitives to be introduced: No new syntax changes are required! More so, our wire-safety result from Section 4.4 need not change either.

With the addition of these new primitives we can use internal wiring to rewrite Figure 12a as Figure 12b if the duplication was required, and if not replace an `a` with the `b`. Again we stress that the implicit wiring decision (duplication) is now an explicit one. Figure 14 illustrate this further by comparing the resulting hardware graph and circuit diagrams for Figure 12b.

6 Mechanisation and Realisation in a Dependently-Typed Language

We have mechanised the implementations of CIRCUITS and CIRQTS using Idris2 [10, 9], a general purpose dependently-typed language. Leveraging Idris2’s support for dependent types we can provide both a verifiable *practical* type-checker for each language, but also formally

8:18 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

$e ::= \dots \mid \text{collect}(e, e, e) \mid \text{split}(e, e, e)$

(a) Syntax.

$$\text{COLLECT} \frac{\Gamma_1 \vdash o : \mathcal{P}(\text{Logic}, O) \dashv \Gamma_2 \quad \Gamma_2 \vdash i_a : \mathcal{P}(\text{Logic}, I) \dashv \Gamma_3 \quad \Gamma_3 \vdash i_b : \mathcal{P}(\text{Logic}, I) \dashv \Gamma_4}{\Gamma_1 \vdash \text{collect}(o, i_a, i_b) : \mathcal{G} \dashv \Gamma_4}$$

$$\text{SPLIT} \frac{\Gamma_1 \vdash o_a : \mathcal{P}(\text{Logic}, O) \dashv \Gamma_2 \quad \Gamma_2 \vdash o_b : \mathcal{P}(\text{Logic}, O) \dashv \Gamma_3 \quad \Gamma_3 \vdash i : \mathcal{P}(\text{Logic}, I) \dashv \Gamma_4}{\Gamma_1 \vdash \text{split}(o_a, o_b, i) : \mathcal{G} \dashv \Gamma_4}$$

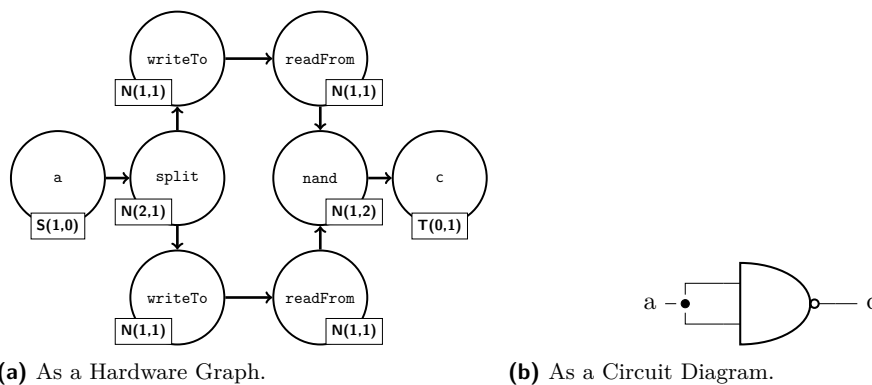

(b) Typing Rules.

```
primitive collect ( output logic o, input logic a, b);
  assign o = a;
  assign o = b;
endprimitive;
```

```
primitive split ( output logic a, b, input logic i);
  assign a = i;
  assign b = i;
endprimitive;
```

(c) Verilog Primitives.

■ **Figure 13** New Primitive Gates to Safely “Weaken” Linearity.

■ **Figure 14** Figure 12b as a Hardware Graph and Circuit Diagram.

reason about wire-safety. Thus, our implementations primarily support the type-checking of netlists (modulo syntax restrictions from Section 2) written in Verilog. With CIRCUITS we can check if it is valid Verilog, with CIRQTS we can check if the netlists are linearly wired. Further, for both type-checkers we incorporated a soundness check (modelled on the type-safety result from CIRQTS) to show which designs accepted by CIRCUITS are in-fact *wire unsafe*.

Both CIRCUITS and CIRQTS have been realised as intrinsically well-typed well-scoped Embedded Domain Specification Languages (*EDSLs*) within Idris2 using well documented techniques [27, 2, 29, 25]. The terms, types, and usages for our languages translate directly into standard dependently (and non-dependently) typed data structures. Reading of valid Verilog netlists comes from a frontend Domain Specification Language (*DSL*) coupled with an elaborator (also known as the type, scope, and usage checker) to construct intrinsically typed terms.

There are three interesting aspects with our approach to the mechanisation: relation between soundness check and our formal proof; intrinsic linearity checking; and error reporting.

Existing work has demonstrated how *well-typed* definitional interpreters can be realised within dependently-typed languages [40, 35] to provide a mechanised runtime. We borrow this approach to not only reason about our type-safety result (wire-safety) as code (i.e. its mechanisation) but make the proof an integral aspect of our tool’s operation.

The core *EDSLs* representing CIRQTS are intrinsically typed both structurally and sub-structurally. Our approach is inspired by *Leftover Typing* [1] in which variable usage updates a type-level state iff a variable is “free” to be used. We use a bespoke list quantifier (presented in Figure 15) paired with a generic update datatype and decision procedure (Figure 16) to provide a type-safe updating of the typing context respective to the predicate being asserted. The type-level constraints that act on variables, that enable our linearity, are instances of these decidable constructs.

<pre> data Elem : (p : type -> Type) -> (x : type) -> (xs : List type) -> Type where Here : (prfSame : x = y) -> (prfSat : p y) -> Elem p x (y::xs) There : (rest : Elem p x xs) -> Elem p x (y::xs) </pre>	<pre> isElemSat : DecEq type => (f : (x : type) -> DecInfo (n x) (p x)) -> (x : type) -> (xs : List type) -> DecInfo (ElemNot n p x xs) (Elem p x xs) </pre>
<p>(a) Decidable Predicate.</p>	<p>(b) Decision Procedure.</p>

■ **Figure 15** Quantification over Lists.

The standard decidable predicate (*Dec*) for decision procedures is lossy when reporting errors, such that it is impossible to know at runtime why the procedure failed. Such predicates are analogous to the *Maybe* datatype. We need an *Either* equivalent to help report useful information when a decidable procedure fails: *Dec* needs to be decidedly informative. Constructive negation is an interesting area of research that supports positive information to be used when reporting errors [5]. Inspired by constructive negation we have used *DecInfo*, which is similar to the definition for decidable but is further indexed by a type that carries showable error messages as well as proofs of contradiction. We see this in the type signature for *isElemSat* in Figure 15, where *ElemNot* records why the procedure failed and requires an informative decision procedure: empty list, or element does not satisfy

8:20 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

```

data Update : (o,n : type -> Type)
  -> (use : (x : type) -> (prf0 : o x) -> (y : type) -> (prfN : n y) -> Type)
  -> (old : List type) -> (prf : Elem o x old)
  -> (new : List type)
  -> Type

where
  UHere : {0 u : (x : type) -> (p0 : o x) -> (y : type) -> (pN : n y) -> Type}
    -> (use : u x pX y pY)
        -> Update o n u (x::xs) (Here Refl pX)
            (y::xs)
  UThere : (rest : Update o n u xs l ys)
    -> Update o n u (x::xs) (There l) (x::ys)

(a) Instructions.

update : (use : {x : type} -> (prf0 : o x) -> (y : type ** prfN : n y ** u x prf0 y prfN))
  -> (old : List type)
  -> (prf : Elem o x old)
  -> (new ** Update o n u old prf new)

(b) Procedure.

```

■ **Figure 16** Safe List Updating.

the provided predicate. Sadly `DecInfo` is not truly positive as it carries a *proof of void*. Making it *positively negative*, that is using only positive information to represent proofs and refutations, is ongoing work.

Using `Idris2` to construct our proof-of-concept type-checkers demonstrates the power of mechanising our proofs in a practical general purpose language that supports dependent types.

7 Evaluation

We investigated the efficacy of `CIRCUITS` and `CIRQTS` through creation of an illustrative testbench. The testbench was designed to illustrate how well-known circuits can contain implicit wiring decisions (checked against `CIRCUITS`), and that by using `CIRQTS` we can make the wiring explicit. Other examples chosen were inspired by various online Verilog tutorials and sought to test the ability of our type-systems to type-check existing designs (`CIRCUITS`) and to reason about quantitative wire usage for those designs (`CIRQTS`). The well-known designs chosen were flip flops, full and half adders, and gate-level multiplexers. We provided normal and linear variants of these well-known designs, and Table 1 presents salient modelling information comparing the two variants.

■ **Table 1** Salient Modelling Information for Core Netlists used during Benchmarking.

Netlist	Non-Linear				Linear			
	Inputs	Outputs	Wires	Gates	Inputs	Outputs	Wires	Gates
FlipFlopD	2	2	3	5	2	2	11	9
FullAdder	3	2	3	5	3	2	11	9
HalfAdder	2	2	0	2	2	2	4	4
Mux21	3	1	3	4	3	1	5	5

All examples presented were checked against: `CIRCUITS`, `CIRQTS`, and `Verilator`. We performed these checks for two reasons. First, we wanted to show that designs that were admitted by `CIRCUITS` but failed the soundness checker, then failed to type check using

CIRQTS, and that valid linear designs could also be checked using CIRCUITS. Second, Verilator is a well-known open source static analysis and simulation tool for SystemVerilog. Comparison against Verilator provides a validation step that CIRQTS is comparable to existing tooling and that, unlike commercial static analysis tools, can be incorporated into our supplied artefact due to its small installation footprint and permissive licence.

For all examples, we found that type-checking time was negligible, and comparable to Verilator, whether an error was found or not. From this experimentation we made the following observations.

We can Retrofit Linear Types onto Verilog NetLists

The gate-level syntax is the last intermediate representation before fabrication (or deployment to an FPGA). For this subset of Verilog chosen for our featherweight language, we have been successful in introducing linear wirings. From this subset the challenge will be how to promote linearity to the remainder of Verilog, and of course SystemVerilog.

Verbosely Made Implicit Wirings Explicit

The new primitives presented in Section 5 support valid weakening of linearity, specifically splitting and joining of wires. Such weakening, however, comes at the cost of design verbosity. Compare in Figure 17, for example, the implementations of a half-adder in both CIRCUITS and CIRQTS. For each wire split, or joined, new wires must be presented.

<pre> module Example(output logic sum, carry ,input logic a b); wire logic a1,a2,b1,b2; module Example(output logic sum, carry ,input logic a b); xor g1(sum,a,b); and g2(carry,a,b); endmodule; (a) CIRCUITS. </pre>	<pre> module Example(output logic sum, carry ,input logic a b); wire logic a1,a2,b1,b2; split sa(a1,a2,a); split sb(b1,b2,b); xor g1(sum,a1,b1); and g2(carry,a2,b2); endmodule; (b) CIRQTS. </pre>
--	---

■ **Figure 17** Half-Adder in both CIRCUITS and CIRQTS.

Although in the linear setting such redundant wires can be optimised away, their addition to the language makes it verbose. If we are to introduce such linear restrictions elsewhere in SystemVerilog, that is for synthesisable terms, the end user will be presented with a *needlessly* verbose language. Thus raising the question of how best to retrofit existing *HDLs* with quantitative types such that linearity does not get in the way. Perhaps we should not take this approach, and instead look at providing annotations as seen in other extensions to Verilog [48].

Some Ports are Linear but Some are More Linear Than Others

One aspect we found interesting is that CIRQTS performs more finegrained resource tracking for inputting n-dimensional bit-vectors when compared to Verilator. Although Verilator can identify unused inputs in designs, for logic and bit-vectors, it does not consistently report

8:22 Wiring Circuits Is Easy as $\{0, 1, \omega\}$, or Is It...

unused inputs for n-dimensional bit-vectors. Consider, for example, the following illustrative netlists presented in Figure 18. The netlist within Figure 18a *is* caught by Verilator as the output port (`out`) is not fully used. The netlist within Figure 18b *is not* caught by Verilator even though the input port (`bc`) is not fully used.

```
module Example(output logic[1:0][1:0] out, input logic a,b);  
  
    and n1(out[0][1],a,b);  
  
endmodule;
```

(a) Caught by Verilator.

```
module Example(output logic out, input logic[1:0][1:0] bc);  
  
    and n1(out, bc[0][1], bc[1][0]);  
  
endmodule;
```

(b) Not Caught by Verilator.

■ **Figure 18** Illustrative Netlists with sparsely used input and output ports.

We noted the potential discrepancy in Section 4.3 when discussing the stopping condition, that is when and how we check for linear usage. Such difference is because unused signals can be safely removed from the design. Specifically, inputting ports can be left unused if they are never connected to anything else in the entire design, and module outputs need to be driven as they could potentially be used later in the design to drive another part of the design.

Such differences in granularity of reporting between CIRQTS and Verilator does raise interesting questions about the semantics (veracity) of linear wiring. Whilst outputting ports must be linear in usage, inputting ports are affine. Linear usage restrictions are incredibly restrictive, terms must be used exactly once. In certain circuit designs it is okay to leave the input of a circuit dangling. Perhaps our quantitative type-system requires fine-tuning to ensure that we are affine for inputs, but linear for outputs, or even gradations to specify how much a signal must be used as seen in Granule? Although we could also extend our syntax to support “noops” primitives that *consumes* purposefully dangling wires. . . . That being said, such allowed dangling is very much a *behavioural aspect* that requires more information that we do not presently give in the type-system about the intended behaviour being realised. Our use of quantitative typing is purely structural and not behavioural. More descriptive behavioural typing is required, and that is a different kettle of fish entirely.

8 Related Work

Section 4 discussed the limitations of modelling linear wiring in existing *QTS*, and mentioned that Verilator performs an extrinsic graph-based check. This section looks to the wider world of *HDL* design and verification, and where our work resides.

8.1 Formal Models of Verilog

There have been several attempts at verifying the *behaviour* of Verilog designs [28, 31, 26]. Many of these works are limited by looking at the behaviour of modules in isolation and not their composition. CIRQTS complements these attempts by providing *a* formal account for wiring. Integrating our type-system into existing behavioural semantics would be advantageous.

8.2 BlueSpecVerilog

Verilog-like languages view hardware in the traditional sense of wiring up boxes/gates that communicate concurrently. BlueSpecVerilog (*BSV*) [32] takes a different route by allowing designers to take a slightly higher-level view of hardware and describe circuits as atomic actions on stateful elements i.e. registers. *BSV* builds upon SystemVerilog with strong types and known techniques lifted from the well-known functional language Haskell. Kami and Kôika are two rule-based hardware description languages that capture core behavioural semantics of *BSV* [11, 8]. Both languages are presented as *EDSLs* written in the Coq Theorem Prover. Our approach to wire-safety can compliment existing work relating to *BSV* by enforcing wiring decisions to be explicit rather than implicit. How our work intersects practically is an area for future investigation.

8.3 High-Level Synthesis

Similar to the realisation of Kami and Kôika, High-Level Synthesis (*HLS*) typically approaches hardware design as *EDSLs* in high-level languages such as Haskell and Scala that are then synthesised into hardware descriptions i.e. netlists. Popular *HDLs* that take this approach are PyRTL [13], Lava [20], Chisel [6], Delite [43], ReWrire [39], and Clash [42]. By embedding their work in an existing general-purpose language these languages can take full advantage of the host language’s eco-system to provide guarantees about program composition and behaviour. For instance *Wire Sorts* [12] is an extension to PyRTL to reason about wirings. Many of the approaches described here model circuit level designs as combinators, and treat hardware components as functions that can be translated directly to SystemVerilog. Our work intersects through provision of a means to account for how wires are generated and used in the synthesised designs.

More interestingly are *HDLs* embedded in languages that are *QTS* aware e.g. Haskell. It will be interesting to see how Linear Haskell can be used by the Lava and Clash to enforce linear wiring.

8.4 Cava

Coq + Lava (*Cava*) is an industrial research project² that looks at providing an *easy to verify HDL* for “network-style” low level circuits, rather than higher level processor designs as seen in *BSV*. *Cava* primarily looks to verify circuit behaviour. Much like Kami and Kôika, *Cava* is an *EDSL* in the Coq Theorem Prover. Interestingly, *Cava* and CIRCUITS/CIRQTS share similarities in that they both describe netlists. We differ in that *Cava* syntax is not verilog-like when representing wiring but ours is.

8.5 Formal Models for High-Level Synthesis

We end our discussion of related work by looking at theoretical models for hardware. The *Geometry of Synthesis* series [16, 19, 17, 15, 18] looks at leveraging *Geometry of Interaction* style interpretation as a way to better understand the behavioural and structural aspects of hardware design. Especially, they target a *HLS* combined with category theory to better tell the synthesis story. Fortunately, existing work (Section 8.1) has looked at the synthesis story for Verilog. We have not explored these stories to include *QTS*, we have short-circuited this story by jumping straight to the end. That being said we are, however, interested in exploring how our *QTS* can be included.

9 Conclusion

CIRQTS demonstrates that quantitative typing, specifically, the idea of linearity, is not just for general purpose programming languages. We can use *fancy types* to be reason about hardware design. With Verilog being so integral to hardware design, our efforts at formal verification (through typing) of the language itself has helped move existing extrinsic checks (as performed by static analyses and simulation, and also caught during synthesis) directly into the type-system, and become an integral part of the language itself. With the correct type-system, errors that were once caught late in the design process will now be caught earlier helping to increase design productivity and enhance the trustworthiness of developed designs.

A question remains though over what precise usage restrictions should be applied to hardware terms, and presented to the system designer. Is it the case that all terms should be restricted equally, or that some terms be restricted less equally than others? Moreover, we have not required designers to annotate their designs. Would it be better to extend/embed Verilog with linear annotations? If such restrictions are given, would some form of gradations *a la* Granule on terms be better for specifying usage? These are all exciting open areas of investigation.

A secondary area of interest is where we place usage information in CIRQTS. We have used usage *annotations* on binders, as is common in *QTS*. An alternative approach would be to index types directly with their usage, rather than as usage annotations on binders. We think this is an equally valid approach but will require further investigation over soundness and suitability.

Regardless, we have demonstrated how to *retrofit* a sub-structural type-system onto existing syntax modulo minor syntax elaboration. Retrofitting means that we do not need new languages that existing designs must be ported to. However, looking at what syntax changes are needed to make Verilog more conducive to linear wiring, or new primitives, is also a worthy area of future investigation. Our retrofitting approach also opens up future work on what else needs changing (in the type-system) when bringing quantitative typing back up the synthesis to higher-levels of abstraction. A key aspect of which will be design composition in the face of modules and interfaces, and the quasi-dependently-typed parameterisation of modules and interfaces.

Finally, within Idris2 the none-one-tonne rig [30] provides a distinction between code available at runtime ($1, \omega$) and its usage, and code only available at compiletime (0). We have used elements of *QTT* to reason about wire usage, but not their movement through the *fourth dimension*: time. Whereas we think of a program's journey as going first through the compiletime and then the runtime, SystemVerilog is a language where designs will journey through many more "times": design, testing, simulation, synthesis, placement & routing, and execution. A fascinating area of investigation would be to see if *QTT*, or *QTT*-like structures, can help to better reason about terms as they traverse through the many times of SystemVerilog. Can terms be stratified according to *when* in time they are expected to be? We hope so!

Abstract

Distributed systems adopt weak consistency to ensure high availability and low latency, but state convergence is hard to guarantee due to conflicts. Experts carefully design replicated data types (RDTs) that resemble sequential data types and embed conflict resolution mechanisms that ensure convergence. Designing RDTs is challenging as their correctness depends on subtleties such as the ordering of concurrent operations. Currently, researchers manually verify RDTs, either by paper proofs or using proof assistants. Unfortunately, paper proofs are subject to reasoning flaws and mechanized proofs verify a formalization instead of a real-world implementation. Furthermore, writing mechanized proofs is reserved for verification experts and is extremely time-consuming. To simplify the design, implementation, and verification of RDTs, we propose VeriFx, a specialized programming language for RDTs with *automated* proof capabilities. VeriFx lets programmers implement RDTs atop functional collections and express correctness properties that are verified automatically. Verified RDTs can be transpiled to mainstream languages (currently Scala and JavaScript). VeriFx provides libraries for implementing and verifying Conflict-free Replicated Data Types (CRDTs) and Operational Transformation (OT) functions. These libraries implement the general execution model of those approaches and define their correctness properties. We use the libraries to implement and verify an extensive portfolio of 51 CRDTs, 16 of which are used in industrial databases, and reproduce a study on the correctness of OT functions.

1 Introduction

Replication is essential to modern distributed systems as it enables fast access times and improves the system's overall scalability, availability, and fault tolerance. When data is replicated across machines, replicas must be kept consistent to some extent. When facing network partitions, replicas cannot remain consistent while also accepting reads and writes, a consequence of the CAP theorem [17, 18, 39]. Programmers thus face a trade-off between

consistency and availability. Keeping replicas strongly consistent induces high latencies, poor scalability, and reduced availability since updates must be coordinated, e.g. using a consensus algorithm. By relaxing the consistency guarantees, latencies can be reduced and the overall availability improved, but users may observe temporary inconsistencies between replicas.

Distributed systems increasingly adopt weak consistency models. However, concurrent operations may lead to conflicts which must be solved in order to guarantee state convergence. Consider the case of collaborative text editors. When a user edits a document, the operation is immediately applied on the local replica and propagated asynchronously to other replicas. Since concurrent edits are applied in different orders at different replicas, states can diverge.

To ensure convergence, Ellis and Gibbs [25] proposed a technique called Operational Transformation (OT) that modifies incoming operations against previously executed concurrent operations such that the modified operation preserves the intended effect. Much work focused on designing OT functions for collaborative text editing [25, 34, 64, 69, 72], but most tombstone-free transformation functions (some with mechanized proofs) are wrong [34, 49, 62].

Since conflict resolution is hard [2, 41, 68], researchers now focus on designing replicated data types (RDTs) that serve as building blocks for the development of highly available distributed systems. Such RDTs resemble sequential data types (e.g. counters, sets) but include conflict resolution strategies that guarantee convergence.

Conflict-free Replicated Data Types (CRDTs) [68] are a widely adopted family of RDTs that leverage mathematical properties (such as commutative operations) to avoid conflicts by design. However, designing new RDTs is difficult [42] and even seasoned researchers miss subtle corner cases for basic data structures such as maps [40]. Currently, researchers and practitioners propose new or improved RDT designs [2, 8, 14, 19, 38, 41, 66–68] and include a formal specification or pseudo code of the RDT with a manual proof of convergence, mostly paper proofs. Unfortunately, paper proofs are subject to reasoning flaws.

To avoid the pitfalls of paper proofs, Zeller et al. [79], Gomes et al. [27], and Nieto et al. [59] propose formal frameworks to verify the correctness of CRDTs using proof assistants. However, these frameworks use abstract specifications that are disconnected from actual implementations (e.g. Akka’s CRDT implementations in Scala). Hence, a particular implementation may be flawed, even if the specification was proven to be correct.

While interactive proofs are more convincing (as the proof logic is machine-checked), they require significant programmer intervention which is time-consuming and reserved to experts [45, 60]. Recent works try to automate (part of) the verification process of CRDTs. Nagar and Jagannathan [56] automatically verify CRDTs under different consistency models but require a first-order logic specification of the CRDT’s operations that is cumbersome and error-prone. Liu et al. [54] extend Liquid Haskell [75] to verify CRDTs but significant parts need to be proven manually due to the way how Liquid Haskell encodes user-defined functions in SMT. For example, their Map CRDT required more than 1000 lines of proof code. We conclude that developing RDTs is reserved for experts in distribution and verification.

To simplify the development of RDTs, we propose VeriFx, a specialized functional object-oriented programming language for designing, implementing, and *automatically* verifying RDTs. The main challenge behind VeriFx’s design consists in striking a good balance between expressiveness and automated verification. We designed VeriFx to support familiar, high-level language constructs that are suited to implement RDTs, without breaking automated verification. To *implement* RDTs, VeriFx provides extensive functional collections including tuples, sets, maps, vectors, and lists. These collections are immutable which is said to be desirable for the implementation of RDTs and their integration in distributed systems [30]. To *verify* RDT implementations, VeriFx features a novel proof construct that enables

programmers to express correctness properties. For each proof, VeriFx automatically derives proof obligations and discharges them using SMT solvers. This is possible because VeriFx efficiently encodes all functional collections and their operations using the Combinatory Array Logic [23] for SMT solvers, which is decidable. This enables VeriFx to automatically verify complex RDTs built atop these collections. VeriFx provides libraries that ease the implementation and verification of CRDT and OT data types. Internally, these libraries use the proof construct to define the necessary correctness properties. Verified RDTs can be transpiled to one of the supported target languages (currently Scala and JavaScript).

VeriFx is reminiscent of existing object-oriented languages (like Scala) and demonstrates that it is possible to automatically verify real-world RDT implementations without requiring separate specifications. This avoids mismatches between the implementation and the specification and simplifies software maintenance. We argue that the ability to implement RDTs and automatically verify them in the *same* language allows programmers to catch mistakes early during the development process.

To demonstrate the applicability of VeriFx, we implemented and *automatically* verified 51 CRDTs, including well-known CRDTs [2, 8, 14, 40, 66, 67] and new variants. 50 of these CRDTs were verified in a matter of seconds and one could not be verified due to its recursive nature. The CRDTs we verified feature highly optimized designs and many are used in industrial databases such as Riak [12], Cassandra [73], and AntidoteDB [1]. We also applied VeriFx to OT and verified *all* transformation functions described by Imine et al. [34] and some unpublished designs [33].

In summary, we make the following contributions:

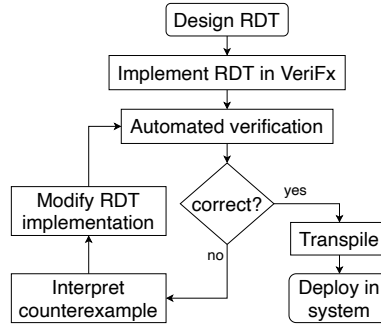

- VeriFx, the first high-level programming language that enables programmers to implement RDTs by composing functional collections, express correctness properties about those RDTs within the same language, and automatically verify those properties. The novelty consists of carefully crafting the language such that every language construct is efficiently encoded without breaking automated verification.
- We devise VeriFx libraries that simplify the implementation of CRDT and OT data types and automatically verify the necessary correctness properties.
- We give the first fully automated and mechanized proofs for 51 CRDTs, including the state-based and operation-based CRDTs proposed by Shapiro et al. [67], delta state-based CRDTs proposed by Almeida et al. [2], pure op-based CRDTs proposed by Baquero et al. [8], and many more. To the best of our knowledge, this is the most extensive treatment of verified RDTs to date. Prior efforts [27, 54, 59, 79] verified only a few CRDTs due to the labour-intensive nature of the verification process.
- We reproduce the study of Imine et al. [34] regarding the verification of OT functions.

2 Motivation

To motivate the need for a language with automated proof capabilities, consider a distributed system in Scala with replicated data on top of Akka's highly-available distributed key-value store [52]. The store provides built-in CRDTs, e.g. sets, counters, etc. However, our system requires a Two-Phase Set (2PSet) CRDT [67] that is not provided by Akka. We thus need to implement it and verify our implementation.

For the implementation, we can take the specification from Shapiro et al. [67]. For the verification, we typically need a complete formalization of the implementation and its correctness properties which can then be proven manually using proof assistants. The resulting interactive proofs are complex and require considerable expertise. For example, Nieto et al. [59]'s implementation of a 2PSet in OCaml is only 25 LoC but its specification in Coq is 80 LoC and requires an additional 73 LoC to verify.

Alternatively, programmers could resort to Liu et al. [54]’s extension of Liquid Haskell that automates part of the verification process. However, non-trivial RDTs still require significant manual proof efforts: 200+ LoC for a replicated set and 1000+ LoC for a map [54]. Thus, we cannot reasonably assume that programmers have the time nor the skills to manually verify their implementation [45,60].

■ **Figure 1** Envisioned workflow.

We argue that verification needs to be fully automatic to be accessible to non-experts. Figure 1 shows the workflow for developing RDTs using VeriFx, our novel language with a syntax reminiscent of Scala. Programmers start from a new or existing RDT design and implement it in VeriFx which verifies the implementation automatically without requiring a separate formalization. If the implementation is not correct, VeriFx returns a counterexample in which the replicas diverge. After interpreting the counterexample, the programmer needs to fix the RDT implementation and verify it again. This iterative process repeats until the implementation is correct. Verified RDT implementations can be transpiled to a mainstream language (e.g. Scala) and deployed in an actual system.

Our envisioned workflow verifies RDT implementations before deployment. Moreover, our workflow benefits from a feedback loop allowing programmers to correct implementations based on concrete counterexamples. In contrast, traditional verification techniques such as interactive theorem provers do not provide such feedback; when programmers fail to verify a property, they do not know if the implementation is flawed or if the chosen proof strategy is not suited. Similarly, Liquid Haskell [75] may fail to verify a property and raise a type error without providing additional information as to why the refinement type is not met. Next, we illustrate each step of our workflow by means of an existing 2PSet design in which VeriFx uncovered a bug. The corrected version was then transpiled to Scala, and deployed on Akka.

2.1 Design and Implementation

Specification 1 shows the design of the 2PSet CRDT taken from Shapiro et al. [67] unaltered. The 2PSet is a state-based CRDT whose state (the A and R sets) thus forms a join semilattice, i.e. a partial order \leq_v with a least upper bound (LUB) \sqcup_v for all states. Elements are added to the 2PSet by adding them to the A set and removed by *adding* them to the R set. An element is in the 2PSet if it is in A and not in R . Hence, removed elements can never be added again. Replicas are merged by computing the LUB of their states, which in this case is the union of their respective A and R sets.

The `compare(S, T)` operation checks if $S \leq_v T$ and is used to define state equivalence [68]: $S \equiv T \iff S \leq_v T \wedge T \leq_v S$. Since state equivalence is defined in terms of \leq_v on the lattice, replicas may be considered equivalent even though they are not identical. This is relevant

■ Specification 1 2PSet CRDT

taken from Shapiro et al. [67].

```

1: payload set  $A$ , set  $R$ 
2:   initial  $\emptyset, \emptyset$ 
3: query lookup (element  $e$ ) : boolean  $b$ 
4:   let  $b = (e \in A \wedge e \notin R)$ 
5: update add (element  $e$ )
6:    $A := A \cup \{e\}$ 
7: update remove (element  $e$ )
8:   pre lookup( $e$ )
9:    $R := R \cup \{e\}$ 
10: compare ( $S, T$ ) : boolean  $b$ 
11:   let  $b = (S.A \subseteq T.A \vee S.R \subseteq T.R)$ 
12: merge ( $S, T$ ) : payload  $U$ 
13:   let  $U.A = S.A \cup T.A$ 
14:   let  $U.R = S.R \cup T.R$ 

```

■ Listing 1 2PSet implementation in VeriF_x.

```

1 class TwoPSet[V](added: Set[V], removed: Set[V])
2   extends CvRDT[TwoPSet[V]] {
3   def lookup(element: V) =
4     this.added.contains(element) &&
5     !this.removed.contains(element)
6   def add(element: V) =
7     new TwoPSet(this.added.add(element), this.removed)
8   def remove(element: V) =
9     new TwoPSet(this.added, this.removed.add(element))
10  def compare(that: TwoPSet[V]) =
11    this.added.subsetOf(that.added) ||
12    this.removed.subsetOf(that.removed)
13  def merge(that: TwoPSet[V]) =
14    new TwoPSet(this.added.union(that.added),
15               this.removed.union(that.removed))
16  }

```

for CRDTs that keep additional information. For example, CRDTs often use a Lamport clock [43] together with unique replica identifiers to generate globally unique IDs. Every replica identifier is different and is not part of the lattice even though it is part of the state.

Listing 1 shows the implementation of the 2PSet CRDT in VeriF_x, which is a straightforward translation of Specification 1. The `TwoPSet` class is polymorphic in the type of values it stores. It defines the `added` and `removed` fields which correspond to the A and R sets respectively. The `add` and `remove` methods return an updated copy of the state. The class extends the `CvRDT` trait¹ provided by VeriF_x's CRDT library (explained in Section 5.1). This trait requires the class to implement the `compare` and `merge` methods.

2.2 Verification

We now verify our 2PSet implementation in VeriF_x. State-based CRDTs guarantee convergence if the merge function is idempotent, commutative, and associative [68]. VeriF_x provides several `CvRDTProof` traits which encode these correctness conditions (explained later in Section 5.1). To verify the `TwoPSet`, we define a `TwoPSetProof` object that extends the `CvRDTProof1` trait (where 1 is the rank). The trait takes as argument the type constructor of the CRDT we want to verify (i.e. `TwoPSet`):

```
object TwoPSetProof extends CvRDTProof1[TwoPSet]
```

The `TwoPSetProof` object inherits automated correctness proofs for the polymorphic `TwoPSet` CRDT. When executing this object, VeriF_x will automatically try to verify those proofs. In this case, VeriF_x proves that the `TwoPSet` guarantees convergence (independent of the type of elements it holds), according to the notion of state equivalence that is derived from `compare`. However, VeriF_x warns the user that the proof for state equivalence fails, which means that the derived notion of equivalence does not correspond to structural equality. As explained before, this may be normal in some CRDT designs but it requires further investigation.

VeriF_x provides the following counterexample for the equivalence proof:

```
enum V { v }
val s: TwoPSet[V] = TwoPSet({v}, {})
val t: TwoPSet[V] = TwoPSet({v}, {v})
```

¹ VeriF_x traits can declare abstract methods and fields, and provide default implementations for methods.

■ **Listing 2** Transpiled 2PSet in Scala.

```

1 case class TwoPSet[V](added: Set[V], removed: Set[V])
  extends CvRDT[TwoPSet[V]] { // CvRDT trait provided
  by our CRDT library is also compiled to Scala
2 def lookup(element: V) = this.added.contains(element) &&
  !this.removed.contains(element)
3
4 def add(element: V): TwoPSet[V] =
  TwoPSet[V](this.added + element, this.removed)
5
6 def remove(element: V): TwoPSet[V] =
  TwoPSet[V](this.added, this.removed + element)
7
8 def compare(that: TwoPSet[V]): Boolean =
  this.added.subsetOf(that.added) &&
  this.removed.subsetOf(that.removed)
9
10
11 def merge(that: TwoPSet[V]): TwoPSet[V] =
12   TwoPSet[V](this.added.union(that.added),
13             this.removed.union(that.removed)) }

```

■ **Listing 3** Modified 2PSet implementation for integration with Akka’s distributed key-value store.

```

1 @SerialVersionUID(1L)
2 case class TwoPSet[V](
3   added: Set[V], removed: Set[V])
  extends CvRDT[TwoPSet[V]] with
  ReplicatedData with Serializable {
4   type T = TwoPSet[V]
5   // The remainder of the implementation
  is unchanged
6 }

```

The counterexample defines an enumeration V containing a single value v . It then defines two instances s and t of a `TwoPSet[V]` that are considered equivalent $s \equiv t$ (according to the definition of `compare`) but are not structurally equivalent $s \neq t$. These two instances should indeed not be considered equivalent since $v \in s$ but $v \notin t$ according to `lookup`. Looking back at Spec. 1, we notice that the original specification of `compare` from Shapiro et al. [67] defines replica s to be smaller or equal to replica t iff $s.A \subseteq t.A$ or $s.R \subseteq t.R$. Since $s.A = t.A$ it follows that $s \leq_v t \wedge t \leq_v s$ and thus they are considered equal ($s \equiv t$) without even considering the removed elements (i.e. the R sets). Based on this counterexample, we modify `compare` to consider both the A sets and the R sets:

```

def compare(that: TwoPSet[V]) =
  this.added.subsetOf(that.added) && this.removed.subsetOf(that.removed)

```

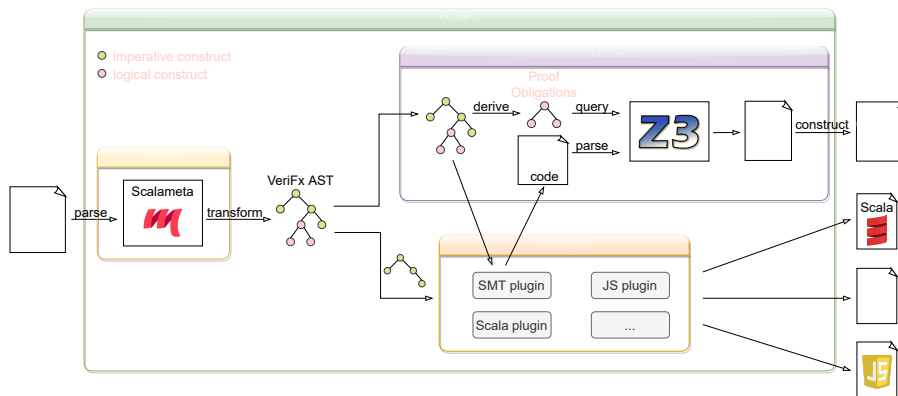

We verify the implementation again and VeriFx proves that this modified implementation still guarantees convergence and that the definition of equality that is derived from `compare` now corresponds to structural equality, i.e. $s \equiv t \iff s = t$.

This example showcases the importance of automated verification as it detected an error in the specification that would have percolated to the implementation. We completed the verification of the 2PSet CRDT in VeriFx without providing any verification-specific code.

2.3 Deployment

The final step in our workflow consists of automatically transpiling the CRDT implementation from VeriFx to Scala and integrating the CRDT in our distributed application which uses Akka’s distributed key-value store. Listing 2 shows the transpiled implementation of the 2PSet in Scala. To store the RDT in Akka’s distributed key-value store, we need to perform two manual modifications which are shown in Listing 3. First, the RDT must extend Akka’s `ReplicatedData` trait (Line 3) which requires at least the definition of a type member T corresponding to the actual type of the CRDT (Line 4) and a `merge` method for CRDTs of that type (which we already have). Second, the RDT must be serializable. For simplicity, we use Java’s built-in serializer². Hence, it suffices to extend the `Serializable` trait (Line 3) and to annotate the class with a serial version (Line 1). After applying these modifications, our verified `TwoPSet` can be stored in Akka’s distributed key-value store and will automatically be replicated across the cluster and be kept eventually consistent.

² In production it is safer and more efficient to implement a custom serializer [53], e.g. with Protobuf [28].

■ **Figure 2** VeriFx’s plugin architecture.

3 The VeriFx Language

The goal of this work is to build a familiar high-level programming language that is suited to implement RDTs and *automatically* verify them. The main challenge is to efficiently encode every feature of the language without breaking automatic verification. The result of this exercise is VeriFx, a functional object-oriented programming language with Scala-like syntax and a type system that resembles Featherweight Generic Java [32]. VeriFx features a novel proof construct to express correctness properties about programs. For every proof construct a proof obligation is derived that is discharged automatically by an SMT solver (cf. Section 4).

VeriFx advocates for the object-oriented programming paradigm as it is widespread across programmers and fits the conceptual representation of replicated data as “shared” objects. The functional aspect of VeriFx, in particular its immutable collections, makes it suitable for implementing and integrating RDTs in distributed systems, as argued by Helland [30].

The remainder of this section is organized in three parts. First, we give an overview of VeriFx’s architecture. Second, we define its syntax. Third, we describe its functional collections. VeriFx’s type system is described in Appendix A.

3.1 Overall Architecture

Figure 2 provides an overview of VeriFx’s architecture. VeriFx programs consist of imperative code and proof code (i.e. logic statements). VeriFx uses Scala Meta [65] to parse VeriFx source code into an AST representing the program. This is possible because every piece of VeriFx code is valid Scala syntax (but not necessarily semantically correct).

The AST representing a VeriFx program can be verified or transpiled to other languages. Transpilation is done by the compiler which features *compiler plugins*. These plugins dictate the compilation of the AST to the target language. Currently, VeriFx comes with compiler plugins for Scala, JavaScript, and SMT-LIB [74], a standardized language for SMT solvers. Support for other languages can be added by implementing a compiler plugin for them.

To verify the proofs that are defined by a VeriFx program, the verifier derives the necessary proof obligations from the AST. VeriFx then compiles the program to SMT-LIB and automatically discharges the proof obligations using the Z3 SMT solver [22]. For every proof, the outcome is: *accepted*, *rejected*, or *unknown*. Accepted means that the property holds, rejected means that a counterexample was found for which the property does not hold, and unknown means that the property could not be verified within a certain time

■ **Figure 3** VeriF_x syntax. The metavariable C ranges over class names; O ranges over object names; I ranges over trait names; E ranges over enumeration names; K ranges over constructor names of enumerations; T , P and Q range over types; X and Y range over type variables; v ranges over field names; x and y range over parameter and variable names; m ranges over method names; p ranges over proof names; and e ranges over expressions. An overline, e.g. \overline{X} , denotes zero or more. A dashed overline, e.g. $\overline{\overline{X}}$, denotes one or more.

frame (which is configurable). When a proof is rejected by Z3, VeriF_x constructs a high-level counterexample that consists of concrete assignments of values to variables that violate the given property. Note that VeriF_x can automatically verify application-specific properties because it derives the proof obligations from the program itself.

3.2 Syntax

Figure 3 defines the syntax of VeriF_x. VeriF_x programs consist of one or more statements which can be the definition of an object O , a class $C \langle \overline{X} \rangle$, a trait $I \langle \overline{X} \rangle$, or an enumeration $E \langle \overline{X} \rangle$. Objects, classes, enumerations, and traits can be polymorphic and inherit from a single trait (except enumerations). Objects define zero or more methods and proofs. Classes contain zero or more fields and (polymorphic) methods. Traits can declare values and methods that need to be provided by concrete classes extending the trait, and define (polymorphic) methods and proofs. Traits can express upper bounds on their type parameters to restrict possible extensions. Enumerations define one or more constructors, each containing zero or more fields. Programmers can deconstruct enumerations by pattern matching on them.

Unique to VeriF_x is its proof construct which is defined by a name and a (well-typed) boolean expression that expresses the property that must be verified. A proof is accepted if its body always evaluates to true, otherwise it is rejected; when rejected, VeriF_x provides a concrete counterexample for which the property does not hold. Proofs can be polymorphic, allowing properties to be proved for all possible type instantiations. Polymorphic proofs are useful to prove that a polymorphic RDT converges independent of its type of values.

VeriF_x supports a variety of expressions, including literal values, arithmetic \oplus and boolean operations \otimes , negation, field accesses, and method calls, variable definitions, if tests, anonymous functions and function calls, class and enum instantiations, pattern matching, quantified formulas, and logical implication. Functions are *first-class* and take at least one argument. Nullary functions can be expressed as constants.

Single inheritance is supported from traits to foster code re-use but some restrictions are imposed. E.g, the arguments of a class method need to be concrete (cannot be of a trait type) because proofs about these methods require reasoning about all subtypes but these may not necessarily be known at compile time. In contrast, enumerations are supported because their constructors are fixed and known at compile time.

■ **Figure 4** An overview of VeriFx’s built-in functional collections.

3.3 Functional Collections

VeriFx features built-in collections for tuples, sets, maps, vectors, and lists. Every operation of these collections are verifiable and can be arbitrarily composed to build custom RDTs. All collections are immutable, “mutators” thus return an updated copy of the object. Figure 4 provides an overview of the interface exposed by these collections, which is heavily inspired by functional programming.

Sets. Support the typical set operations and can be mapped over or filtered using user-provided functions. The `forall` and `exists` methods check if a given predicate holds for all (respectively for at least one) element of the set.

Maps. Associate keys to values. Support adding key-value pairs, removing keys, and fetching the value associated with a key. The `keys` (resp. `values`) method returns a set containing all keys (resp. values) in the map. The `bijective` method checks if there is a one-to-one correspondence between keys and values. Maps support well-known functional operations; `zip` returns a map of tuples containing only the keys that are present in both maps and stores their values in a tuple; `combine` returns a map containing *all* entries from both maps, using a user-provided function `f` to combine values that are present in both maps.

Vectors. Represent a sequence of elements that are indexed from 0 to `size-1`. Elements can be written to a certain index which will overwrite the existing value at that index. One can append a value to the vector which will write that value at index `size`, thereby, making the vector grow. Like sets and maps, programmers can map functions over vectors, zip vectors, and check predicates for all or for one element of a vector.

Lists. Represent a sequence of elements in a linked list. Unlike vectors, `insert` does not overwrite the existing value at that index. Instead, the existing value at that index and all subsequent values are moved one position to the right. Elements can also be deleted from a list, making the list shrink.

$$\begin{array}{l}
T ::= \text{int} \mid \text{string} \mid \text{bool} \qquad G ::= \text{adt } A(\overline{X})\{K(\overline{v} : \overline{T})\} \qquad C ::= \text{const } x \ T \quad R ::= \text{assert } e \\
\mid \text{Array}(\overline{T}, T) \mid A(\overline{T}) \mid S(\overline{T}) \quad e ::= e[\overline{e}] \mid e[\overline{e}] := e \mid \lambda(\overline{x} : \overline{T}).e \quad D ::= \text{sort } S \ i \quad H ::= \text{check}() \\
F ::= \text{fun } f(\overline{X})(\overline{x} : \overline{T}) : T = e \qquad \mid \forall(\overline{x} : \overline{T}).e \mid \exists(\overline{x} : \overline{T}).e \mid \dots
\end{array}$$

■ **Figure 5** Core SMT syntax. The metavariable S ranges over user-declared sorts; A ranges over names of algebraic data types (ADTs); K ranges over ADT constructor names; X ranges over type variables; v ranges over field names; f ranges over function names; T ranges over types; x ranges over variable names; e ranges over expressions; and i ranges over integers.

4 Automated Verification

VeriF_x leverages SMT solvers to enable automated verification. Such solvers try to (automatically) determine whether or not a given formula is satisfiable. Modern SMT solvers support various specialized theories (for bit vectors, arrays, etc.) and are very powerful if care is taken to encode programs efficiently using these theories. However, SMT-LIB [74], the language of SMT solvers, is low-level and is not meant to be used directly by programmers to verify high-level programs. Instead, semi-automatic program verification usually involves implementing the program in an Intermediate Verification Language (IVL) which internally compiles to SMT-LIB to discharge the proof obligations using an appropriate SMT solver. IVLs like Dafny [44], Spec# [11], and Why3 [26] are designed to be general-purpose but this breaks automated verification since programmers need to specify preconditions and postconditions on methods, loop invariants, etc.

VeriF_x can be seen as a specialized high-level IVL that was carefully designed such that every feature has an efficient SMT encoding; leaving out features that break automated verification. For example, VeriF_x does not support traditional loop statements but instead provides higher-order operations (map, filter, etc.) on top of its functional collections. The resulting language is surprisingly expressive given its automated verification capabilities.

The remainder of this section shows how VeriF_x compiles programs to SMT and derives proof obligations that can be discharged automatically by SMT solvers. Afterward, we explain how VeriF_x leverages a specialized theory of arrays to efficiently encode its functional collections. These encodings are key to our approach because they enable fully automated verification of RDTs built atop VeriF_x's functional collections. VeriF_x's encodings significantly differ from related work such as Why3 [26] and Liquid Haskell [75] which encode higher-order operations like map, and filter, recursively which hampers automated verification.

Appendix C.4 exemplifies VeriF_x's compilation rules using a concrete example.

4.1 Core SMT

The semantics of VeriF_x are defined using translation functions from VeriF_x to Core SMT, a reduced version of SMT that suffices to verify VeriF_x programs. Figure 5 defines the syntax of Core SMT. Valid types include integers, strings, booleans, arrays, ADTs $A(\overline{T})$, and user-declared sorts $S(\overline{T})$. Arrays are *total* and map values of the key types to a value of the element type. Arrays can be multidimensional and map several keys to a value.

Core SMT programs consist of one or more statements which can be the declaration of a constant or sort³, assertions, the definition of a function or ADT, or a call to check. Constant declarations take a name and a type. Sort declarations take a name and a non-negative number i representing their arity, i.e. how many type parameters the sort takes.

³ The literature on SMT solvers uses the term “sort” to refer to types and type constructors.

Declared constants and sorts are *uninterpreted* and the SMT solver is free to assign any valid interpretation. Assertions are boolean formulas that constrain the possible interpretations of the program, e.g. `assert age >= 18`.

Function definitions consist of a name f , optional type parameters \overline{X} , formal parameters $\overline{x} : \overline{T}$, a return type T , and a body containing an expression e . Valid expressions include array accesses $e[\tilde{e}]$, array updates $e[\tilde{e}] := e$, anonymous functions, quantified formulas (the full list of expressions is shown in Appendix B). Updating an array returns a modified copy of the array. Note that arrays are total and that anonymous functions define an array. For example, $\lambda(x : \text{int}, y : \text{int}).x + y$ defines an `Array<int, int, int>` that maps two integers to their sum. As arrays are first-class values in SMT, it follows that lambdas are also first-class.

ADT definitions consist of a name A , optional type parameters \overline{X} , and one or more constructors. A constructor has a name K and optionally defines fields with name v and type T . Constructors are called like regular functions and return an instance of the data type.

The decision procedure (`check`) checks the satisfiability of the SMT program. If the program's assertions are satisfiable, `check` returns a concrete model, i.e. an interpretation of the constants and sorts that satisfies the assertions. A property p can be proven by showing that the negation $\neg p$ is unsatisfiable, i.e. that no counterexample exists.

Note that our Core SMT language includes lambdas and polymorphic functions which are not part of SMT-LIB v2.6. Nevertheless, they are described in the preliminary proposal for SMT-LIB v3.0 [35] and Z3 already supports lambdas. For the time being, VeriF_x monomorphizes polymorphic functions when they are compiled to Core SMT. For example, given a polymorphic identity function `id<X> :: X -> X`, VeriF_x creates a monomorphic version `id_int :: int -> int` when encountering a call to `id` with an integer argument.

4.2 Compiling VeriF_x to SMT

Similar to Dafny in [44], we describe the semantics of VeriF_x by means of translation functions that compile VeriF_x to Core SMT. Types are translated by the $\llbracket \cdot \rrbracket_t$ function:

$$\begin{aligned} \llbracket \text{bool} \rrbracket_t &= \text{bool} & \llbracket \text{int} \rrbracket_t &= \text{int} & \llbracket \text{string} \rrbracket_t &= \text{string} \\ \llbracket C(\overline{T}) \rrbracket_t &= C(\llbracket \overline{T} \rrbracket_t) & \llbracket E(\overline{T}) \rrbracket_t &= E(\llbracket \overline{T} \rrbracket_t) & \llbracket \overline{T} \rightarrow P \rrbracket_t &= \text{Array}(\llbracket \overline{T} \rrbracket_t, \llbracket P \rrbracket_t) \end{aligned}$$

Primitive types are translated to the corresponding primitive type in Core SMT. Class types and enumeration types keep the same type name and their type arguments are translated recursively $\llbracket \overline{T} \rrbracket_t$. Functions are encoded as arrays from the argument types to the return type. Trait types do not exist in the compiled SMT program because traits are compiled away by VeriF_x, i.e. only the types of the classes that implement the trait exist in the SMT program.

We now take a look at the translation function $\text{def}[\llbracket \cdot \rrbracket]$ which compiles VeriF_x's main constructs: enumerations, classes, and objects. Enumerations are encoded as ADTs:

$$\text{def}[\llbracket \text{enum } E(\overline{X}) \{ K(\overline{v} : \overline{T}) \} \rrbracket] = \text{adt } E(\overline{X}) \{ K(\overline{v} : \llbracket \overline{T} \rrbracket_t) \}$$

For every enumeration an ADT is constructed with the same name, type parameters, and constructors. The types of the fields are translated recursively.

Classes are encoded as ADTs with one constructor and class methods become functions:

$$\begin{aligned} \text{def}[\llbracket \text{class } C(\overline{X}) (\overline{v} : \overline{T}) \{ \overline{M} \} \text{ extends } I(\overline{P}) \rrbracket] &= \\ &\text{adt } C(\overline{X}) \{ K(\overline{v} : \llbracket \overline{T} \rrbracket_t) \} ; \text{method}[\llbracket C, \overline{X}, M \rrbracket] ; \text{method}[\llbracket C, \overline{X}, M'[\overline{P}/\overline{Y}] \rrbracket] \\ &\text{where } K = \text{str_concat}(C, \text{"_ctor"}) \text{ and } I \text{ is defined as } \text{trait } I(\overline{Y}) \{ \overline{M}' ; \dots \} \\ \text{method}[\llbracket C, \overline{X}, \text{def } m(\overline{Y}) (\overline{x} : \overline{T}) : T_r = e \rrbracket] &= \text{fun } f(\overline{X}, \overline{Y})(\text{this} : C(\overline{X}), \overline{x} : \llbracket \overline{T} \rrbracket_t) : \llbracket T_r \rrbracket_t = \llbracket e \rrbracket \\ &\text{where } f = \text{str_concat}(C, \text{"_"} , m) \end{aligned}$$

The ADT keeps the name of the class and its type parameters, and defines one constructor containing the class' fields. Since the name of the constructor must differ from the ADT's name, the compiler defines a unique name K which is the name of the class followed by “_ctor”. Class methods \bar{M} are compiled to regular functions by function $method[\bar{\cdot}]$. Further, a class inherits all concrete methods \bar{M}' defined by its super trait that are not overridden. This entails substituting the trait's type parameters \bar{Y} by the concrete type arguments \bar{P} defined by the class. As such, traits are compiled away and do not exist in the transpiled SMT program.

For every method, a function is created with a unique name f that is the name of the class followed by an underscore and the name of the method. In the argument list, the body, and the return type of a method, programmers can refer to type parameters of the class and type parameters of the method. Therefore, the compiled SMT function takes both the class' type parameters \bar{X} and the method's type parameters \bar{Y} . Without loss of generality we assume that a method's type parameters do not override the class' type parameters which can be achieved through α -conversion. The method's parameters become parameters of the function. In addition, the function takes an additional parameter *this* referring to the receiver of the method call which should be of the class' type. The types of the parameters and the return type are translated using function $[\bar{\cdot}]_t$. The body of the method must be a well-typed expression. Expressions are translated by the $[\bar{\cdot}]$ function:

$$\begin{array}{lll}
[x] & = & x \\
[\text{val } x : T = e_1 \text{ in } e_2] & = & \text{let } x = [e_1] \text{ in } [e_2] \\
[(x : \bar{T}) \Rightarrow e] & = & \lambda(x : [\bar{T}]_t). [e] \\
[e_1(\bar{e}_2)] & = & [e_1][[\bar{e}_2]] \\
[\text{new } C(\bar{T})(\bar{e})] & = & C'([\bar{T}]_t)([e]) \\
& \text{where } C' = \text{str_concat}(C, \text{"_ctor"}) & \text{and } \bar{P} \cap \bar{T} = \emptyset
\end{array}
\qquad
\begin{array}{ll}
[\text{new } K(\bar{T})(\bar{e})] & = & K([\bar{T}]_t)([e]) \\
[e.v] & = & [e].v \\
[e_1.m(\bar{T})(\bar{e})] & = & m'([\bar{P}]_t, [\bar{T}]_t)([e_1], [e]) \\
& \text{where } \text{typeof}(e_1) = C(\bar{P}) & \\
& \text{and } m' = \text{str_concat}(C, \text{"_"}, m) &
\end{array}$$

Primitive values, variable references, and parameter references remain unchanged in Core SMT. The definition of an immutable variable is translated to a let expression. Anonymous functions remain anonymous functions in Core SMT, the type of the parameters and the body are compiled recursively. Remember that anonymous functions in SMT define (multidimensional) arrays from one or more arguments to the function's return value. Hence, function calls are translated to array accesses. To instantiate a class or ADT, the compiler calls the data type's constructor function. For classes, the constructor's name is the name of the class followed by “_ctor”. To access a field, the compiler translates the expression and accesses the field on the translated expression. To invoke a method m on an object e_1 the compiler calls the corresponding function m' which by convention is the name of the class followed by an underscore and the name of the method. Recall that the function takes both the class' type arguments \bar{T} and the method's type arguments \bar{P} as well as an additional argument e_1 which is the receiver of the call. The complete set of compilation rules for expressions is provided in Appendix C.1 as part of the additional material.

Objects are singletons that can define methods and proofs, and are compiled as follows:

$$\begin{array}{l}
\text{def}[\text{object } O \text{ extends } I(\bar{T}) \{ \bar{M}; \bar{R} \}] = \\
\text{def}[\text{class } O'() \{ \bar{M} \} \text{ extends } I(\bar{T})]; \text{const } O O'; \text{assert } O == O'(); \text{def}[\bar{R}]
\end{array}$$

The object is compiled to a regular class with a fresh name O' . Then, a single instance of that class is created and assigned to a constant named after the object O . The proofs defined by the object are compiled to functions. This translation is the subject of the next section.

4.3 Deriving Proof Obligations

We previously verified a 2PSet CRDT using VeriF_x's CRDT library which internally uses our novel proof construct to define the necessary correctness properties (discussed in Section 5). However, programmers can also define custom proofs, for instance to verify data invariants.

We now explain how proof obligations are derived from user-defined proofs in VeriF_x programs. Proofs are compiled to regular functions without arguments. While, the name and type parameters remain unchanged, the body of the proof is compiled and becomes the function's body. Proofs always return a boolean since the body is a logical formula whose satisfiability must be checked.

$$\text{def } \llbracket \text{proof } p \langle \bar{X} \rangle \{ e \} \rrbracket = \text{fun } p \langle \bar{X} \rangle () : \text{bool} = \llbracket e \rrbracket$$

To check if the property described by a proof holds, the negation of the proof must be unsatisfiable – if no counterexample exists it constitutes a proof that the property is correct. A (polymorphic) proof called p with zero or more type parameters i is checked as follows:

$$\text{prove}(p, i) = \text{sort } S_1 \ 0 ; \dots ; \text{sort } S_i \ 0 ; \text{assert } \neg p \langle S_1, \dots, S_i \rangle () ; \text{check}() == \text{UNSAT}$$

For every type parameter, an *uninterpreted* sort is declared. Then, the proof function is called with those sorts as type arguments and we check that the negation is unsatisfiable. If the negation is unsatisfiable, the (polymorphic) proof holds for all possible instantiations of its type parameters. The underlying SMT solver can generate an actual proof which could be reconstructed by proof assistants as shown by Böhme et al. [15], Böhme and Weber [16].

4.4 Encoding Functional Collections Efficiently in SMT

Some IVLs feature collections with rich APIs (e.g. Why3 [26]) but encode operations on these collections recursively. Traditional SMT solvers fail to verify recursive definitions automatically because they require inductive proofs, which is beyond the capabilities of most solvers. However, many SMT solvers support specialized array theories. A key insight of this paper consists of efficiently encoding the collections and their operations using the Combinatory Array Logic (CAL) [23] which is decidable. As a result, VeriF_x can automatically verify RDTs that are built by arbitrary compositions of functional collections. Next, we describe the encoding of sets using this array logic, while maps are described in Appendix C.3.

Set Encoding. Sets are encoded as arrays from the element type to a boolean type that indicates whether the element is in the set:

$$\llbracket \text{Set } \langle T \rangle \rrbracket_t = \text{Array}(\llbracket T \rrbracket_t, \text{bool})$$

An empty set corresponds to an array containing false for every element. We can create such an array by defining a lambda that ignores its argument and always returns false:

$$\llbracket \text{new Set } \langle T \rangle () \rrbracket = \lambda(x : \llbracket T \rrbracket_t). \text{false}$$

Operations on sets are compiled as follows:

$$\begin{aligned} \llbracket e_1.add(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] := \text{true} & \llbracket e_1.remove(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] := \text{false} \\ \llbracket e_1.filter(e_2) \rrbracket &= \lambda(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x] & \llbracket e_1.contains(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] \\ \text{where } \text{typeof}(e_1) &= \text{Set} \langle T \rangle \wedge \text{typeof}(e_2) = T \rightarrow \text{bool} & & \\ \llbracket e_1.map(e_2) \rrbracket &= \lambda(y : \llbracket P \rrbracket_t). \exists(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x] = y & & \\ \text{where } \text{typeof}(e_1) &= \text{Set} \langle T \rangle \wedge \text{typeof}(e_2) = T \rightarrow P & & \end{aligned}$$

An element e_2 is added to a set e_1 by setting the entry for e_2 in the array that results from transforming e_1 to true. Similarly, an element is removed by changing its entry in the array to false. An element is in the set if its entry is true. A set e_1 containing elements of type

T can be filtered such that only the elements that fulfil a given predicate $e_2 : T \rightarrow \text{bool}$ are retained. Calls to *filter* are compiled to a lambda that defines a set (i.e. an array from elements to booleans) containing only the elements x that are in the original set e_1 (i.e. $\llbracket e_1 \rrbracket [x]$) and fulfil predicate e_2 (i.e. $\llbracket e_2 \rrbracket [x]$). Similarly, a function $e_2 : T \rightarrow P$ can be mapped over a set e_1 of T s, yielding a set of P s. Calls to *map* are compiled to a lambda that defines a set containing elements y of type $\llbracket P \rrbracket_t$ such that an element x exists that is in the original set e_1 (i.e. $\llbracket e_1 \rrbracket [x]$) and maps to y (i.e. $\llbracket e_2 \rrbracket [x] = y$). The remaining methods are described in Appendix C.2 as part of the additional material.

5 Implementing and Verifying Replicated Data Types

VeriF_x aims to simplify the development of correct RDTs by integrating automated verification capabilities in the language. Based on our experience implementing RDTs, we noticed that RDTs need to fulfill specific correctness properties that are well-defined for each RDT family. Therefore, VeriF_x features built-in libraries for the development and automated verification of two well-known RDT families: CRDTs [68] and OT [25]. These libraries are written in VeriF_x and define proofs that encode the necessary correctness properties such that programmers do not need to redefine these proofs for every RDT they implement.

This section discusses the aforementioned libraries. For each library, we formally define the correctness properties that must be verified for that specific RDT family. Section 5.1 describes the implementation of a general execution model for CRDTs and its verification library in VeriF_x. Next, Section 5.2 presents a library for implementing RDTs using OT and verifying the transformation functions. VeriF_x is not limited to these families of RDTs; programmers can build custom libraries for implementing and verifying other abstractions or families of RDTs. Last, Section 5.3 explains how to encode common assumptions such as causal delivery in VeriF_x since the CRDT and OT libraries do not make specific assumptions.

5.1 CRDT Library

CRDTs guarantee *strong eventual consistency* (SEC), a consistency model that strengthens eventual consistency with the *strong convergence* property which requires replicas that received the same updates, possibly in a different order, to be in the same state. VeriF_x's CRDT library supports all CRDT families: state-based [68], delta state-based [2], op-based [68], and pure op-based CRDTs [8]. The remainder explains how our library supports each family.

5.1.1 State-based CRDTs

State-based CRDTs (CvRDTs for short) periodically broadcast their state to all replicas and merge incoming states by computing the least upper bound (LUB) of the incoming state and their own state. Shapiro et al. [68] showed that CvRDTs converge if the merge function \sqcup_v is idempotent, commutative, and associative. We define these properties based on their work:

Idempotent: $\forall x \in \Sigma : \text{reachable}(x) \implies x \equiv x \sqcup_v x$

Commutative: $\forall x, y \in \Sigma : \text{reachable}(x) \wedge \text{reachable}(y) \wedge \text{compatible}(x, y) \implies (x \sqcup_v y \equiv y \sqcup_v x) \wedge \text{reachable}(x \sqcup_v y)$

Associative: $\forall x, y, z \in \Sigma : \text{reachable}(x) \wedge \text{reachable}(y) \wedge \text{reachable}(z) \wedge \text{compatible}(x, y) \wedge \text{compatible}(x, z) \wedge \text{compatible}(y, z) \implies ((x \sqcup_v y) \sqcup_v z \equiv x \sqcup_v (y \sqcup_v z)) \wedge \text{reachable}((x \sqcup_v y) \sqcup_v z)$

■ **Listing 4** Trait for the implementation of CvRDTs in VeriF_x.

```

1 trait CvRDT[T <: CvRDT[T]] {
2   def merge(that: T): T
3   def compare(that: T): Boolean
4   def reachable(): Boolean = true
5   def compatible(that: T): Boolean =
6     true
7   def equals(that: T): Boolean = {
8     this.asInstanceOf[T].compare(that)
9     &&
10    that.compare(this.asInstanceOf[T])
11  }

```

■ **Listing 5** Trait for the verification of CvRDTs in VeriF_x. The arrow function =>: implements logical implication.

```

1 trait CvRDTProof[T <: CvRDT[T]] {
2   proof mergeIdempotent {
3     forall (x: T) { x.reachable() => x.merge(x).equals(x) } }
4   proof mergeCommutative {
5     forall (x: T, y: T) {
6       (x.reachable() && y.reachable() && x.compatible(y)) =>
7       (x.merge(y).equals(y.merge(x)) &&
8        x.merge(y).reachable())}
9   proof mergeAssociative {
10    forall (x: T, y: T, z: T) {
11      (x.reachable() && y.reachable() && z.reachable() &&
12       x.compatible(y) && x.compatible(z) && y.compatible(z))
13      => (x.merge(y).merge(z).equals(x.merge(y.merge(z))) &&
14         x.merge(y).merge(z).reachable()) } }
15  proof equalityCheck {
16    forall (x: T, y: T) { x.equals(y) == (x == y) } } }

```

Σ denotes the set of all states. A state is *reachable* if it can be reached starting from the initial state and applying only supported operations. Two states are *compatible* if they represent different replicas of the same CRDT object⁴. As explained in Section 2.1, Shapiro et al. [68] define state equivalence in terms of \leq_v on the lattice: $S \leq_v T \wedge T \leq_v S \implies S \equiv T$.

VeriF_x's CRDT library provides traits for the implementation and verification of CvRDTs, shown in Listings 4 and 5 respectively. Listing 4 shows the `CvRDT` trait that was used in Listing 1 to implement the `TwoPSet` CRDT. Every state-based CRDT that extends the `CvRDT` trait must provide a type argument which is the actual type of the CRDT and provide an implementation for the `merge` and `compare` methods. By default, all states are considered reachable and compatible, and state equivalence is defined in terms of `compare`. These methods can be overridden by the concrete CRDT that implements the trait.

Listing 5 shows the `CvRDTProof` trait used to verify CvRDT implementations. This trait defines one type parameter `T` that must be a CvRDT type and defines proofs to check that its merge function adheres to the aforementioned properties (i.e. is idempotent, commutative, and associative). It also defines an additional proof, `equalityCheck`, that checks that the notion of state equivalence that, by default, relies on structural equality (i.e., the default implementation of the `equals` method computes structural equality). However, programmers can override the `equals` method to use another notion of state equivalence if needed.

Objects can extend the `CvRDTProof` trait to inherit automated correctness proofs for the given CRDT type. Note that the trait's type parameter `T` expects a concrete CvRDT type (e.g. `PNCOUNTER`) and will not work for polymorphic CvRDTs (e.g. `ORSet`) because those are type constructors. Instead, the CRDT library provides additional `CvRDTProof1`, `CvRDTProof2`, and `CvRDTProof3` traits to verify polymorphic CvRDTs that expect 1, 2, or 3 type arguments respectively. For example, the `TwoPSet[V]` from Section 2 is polymorphic in the type of values it stores; the `TwoPSetProof` object thus extended the `CvRDTProof1` trait because the `TwoPSet` expects one type argument.

5.1.2 Delta state-based CRDTs

Delta state-based CRDTs are a family of state-based CRDTs that exchange only the changes to the state (called deltas) instead of the full state in order to reduce the amount of data that is sent. Mutator operations return a delta which is joined into the replica's local state, propagated to the other replicas, and eventually joined into the state of all replicas.

⁴ The `compatible` predicate can be used to encode certain assumptions. For example, replicas have unique identifiers which enables them to generate unique tags.

VeriF_x's CRDT library provides a `DeltaCRDT` trait that specializes the `CvRDT` trait and can be used to implement delta state-based CRDTs. When extending `DeltaCRDT` traits, programmers must implement a `merge` method that joins delta states into the local state.

To verify delta state-based CRDTs, programmers can reuse the `CvRDTProof` trait since delta state-based CRDTs are essentially state-based CRDTs. As shown in Listing 5, the `CvRDTProof` trait verifies that the `merge` is idempotent, commutative, and associative **for all** valid states. This valid states contain all valid delta states as they are a subset of the full state.

5.1.3 Op-based CRDTs

Op-based CRDTs (`CmRDTs` for short) execute update operations in two phases, called *prepare* and *effect*. The prepare phase executes locally at the source replica (only if its source precondition holds) and prepares a message to be broadcast⁵ to all replicas (including itself). The effect phase applies such incoming messages and updates the state (only if its downstream precondition holds, otherwise the message is ignored).

Shapiro et al. [68] and Gomes et al. [27] have shown that `CmRDTs` guarantee SEC if all concurrent operations commute. Hence, for any `CmRDT` it suffices to show that all pairs of concurrent operations commute. Formally, for any operation o_1 that is enabled by some reachable replica state s_1 (i.e. o_1 's source precondition holds in s_1) and any operation o_2 that is enabled by some reachable replica state s_2 , if these operations can be concurrent, and s_1 , s_2 , and s_3 are compatible replica states, then we must show that on any reachable replica state s_3 the operations commute and the intermediate and resulting states are reachable:

$$\begin{aligned} & \forall s_1, s_2, s_3 \in \Sigma, \forall o_1, o_2 \in \Sigma \rightarrow \Sigma : \text{reachable}(s_1) \wedge \text{reachable}(s_2) \wedge \text{reachable}(s_3) \wedge \\ & \quad \text{enabledSrc}(o_1, s_1) \wedge \text{enabledSrc}(o_2, s_2) \wedge \text{canConcur}(o_1, o_2) \wedge \\ & \quad \text{compatible}(s_1, s_2) \wedge \text{compatible}(s_1, s_3) \wedge \text{compatible}(s_2, s_3) \\ & \implies o_2 \cdot o_1 \cdot s_3 \equiv o_1 \cdot o_2 \cdot s_3 \wedge \text{reachable}(o_1 \cdot s_3) \wedge \text{reachable}(o_2 \cdot s_3) \wedge \text{reachable}(o_1 \cdot o_2 \cdot s_3) \end{aligned}$$

We use the notation $o \cdot s$ to denote the application of an operation o on state s if its downstream precondition holds, otherwise, it returns the state unchanged.

Listing 6 shows the `CmRDT` trait that must be extended by op-based CRDTs with concrete type arguments for the supported operations, exchanged messages, and the CRDT type itself. A CRDT that extends the `CmRDT` trait must implement the `prepare` and `effect` methods. The `tryEffect` method has a default implementation that applies the operation if its downstream precondition holds, otherwise, it returns the state unchanged. By default, we assume all states are reachable, all operations are enabled at the source and downstream, all operations can occur concurrently, and all states are compatible. For most `CmRDTs` these settings do not need to be altered but some `CmRDTs` have other assumptions which can be encoded by overriding the appropriate method. For example, in an OR-Set [67] it is not possible to delete tags added concurrently; this can be encoded by overriding `canConcur`.

Similar to state-based CRDTs, our CRDT library provides a `CmRDTProof` trait and several versions to verify op-based CRDTs. These traits define a general proof of correctness that checks that all operations commute based on the previously described formula.

5.1.4 Pure op-based CRDTs

Pure op-based CRDTs are a family of op-based CRDTs that exchange only the operations instead of data-type specific messages. The effect phase stores incoming operations in a partially ordered log of (concurrent) operations. Queries are computed against the log and

⁵ While some `CmRDT` do not require causal delivery, the overall model assumes reliable causal broadcast.

■ **Listing 6** Polymorphic CmRDT trait to implement op-based CRDTs in VeriFx.

```

1  trait CmRDT[Op, Msg, T <: CmRDT[Op, Msg, T]] {
2    def prepare(op: Op): Msg
3    def effect(msg: Msg): T
4    def tryEffect(msg: Msg): T = if (this.enabledDown(msg)) this.effect(msg) else this.asInstanceOf[T]
5    def reachable(): Boolean = true // by default all states are considered reachable
6    def canConcur(x: Msg, y: Msg): Boolean = true // all ops can occur concurrently
7    def compatible(that: T): Boolean = true // all states are compatible
8    def enabledSrc(op: Op): Boolean = true // no source preconditions by default
9    def enabledDown(msg: Msg): Boolean = true // no downstream preconditions by default
10   def equals(that: T): Boolean = this == that
11 }

```

operations do not need to commute. Data-type specific redundancy relations dictate which operations to store in the log and when to remove operations from the log. VeriFx’s CRDT library provides a `PureOpBasedCRDT` trait which is a specialization of the `CmRDT` trait for implementing pure op-based CRDTs. The implementing CRDT inherits the prepare and effect phase (the same for all pure op-based CRDTs) and only needs to implement the redundancy relations. Since pure op-based CRDTs are essentially operation-based CRDTs, programmers can reuse the `CmRDTProof` traits to verify pure op-based CRDT implementations.

5.2 OT Library

The Operational Transformation (OT) [25] approach applies operations locally and propagates them asynchronously to the other replicas. Incoming operations are transformed against previously executed concurrent operations such that the modified operation preserves the intended effect. Operations are functions from state to state: $Op : \Sigma \rightarrow \Sigma$ and are transformed using a transformation function $T : Op \times Op \rightarrow Op$. Thus, $T(o_1, o_2)$ denotes the operation that results from transforming o_1 against a previously executed concurrent operation o_2 . Suleiman et al. [70] and Sun et al. [72] proved that replicas eventually converge if the transformation function satisfies two properties: TP_1 and TP_2 . Property TP_1 states that any two enabled concurrent operations o_i and o_j must commute after transforming them:

$$\forall o_i, o_j \in Op, \forall s \in \Sigma : \text{enabled}(o_i, s) \wedge \text{enabled}(o_j, s) \wedge \text{canConcur}(o_i, o_j) \\ \implies T(o_j, o_i)(o_i(s)) = T(o_i, o_j)(o_j(s))$$

Property TP_2 states that given three enabled concurrent operations o_i , o_j , and o_k , the transformation of o_k does not depend on the order of the transformation of operations o_i and o_j :

$$\forall o_i, o_j, o_k \in Op, \forall s \in \Sigma : \text{enabled}(o_i, s) \wedge \text{enabled}(o_j, s) \wedge \text{enabled}(o_k, s) \wedge \text{canConcur}(o_i, o_j) \wedge \\ \text{canConcur}(o_j, o_k) \wedge \text{canConcur}(o_i, o_k) \implies T(T(o_k, o_i), T(o_j, o_i)) = T(T(o_k, o_j), T(o_i, o_j))$$

Note that properties TP_1 and TP_2 only need to hold for states in which the operations can be generated, represented by the relation $\text{enabled} : Op \times \Sigma \rightarrow \mathbb{B}$, and only if the two operations can occur concurrently, represented by the relation $\text{canConcur} : Op \times Op \rightarrow \mathbb{B}$.

VeriFx provides a library for implementing and verifying RDTs that use operational transformations. Programmers can build custom RDTs by extending the `OT` trait shown in Listing 7. Every RDT that extends the `OT` trait must provide concrete type arguments for the state and operations, and implement the `transform` and `apply` methods. The `transform` method transforms an incoming operation against a previously executed concurrent operation. The `apply` method applies an operation on the state. By extending this trait, the RDT inherits proofs for TP_1 and TP_2 . By default, these proofs assume that operations are always enabled and that all operations can occur concurrently. If this is not the case, the RDT can override the `enabled` and `canConcur` methods respectively.

■ **Listing 7** Polymorphic OT trait to implement and verify RDTs using operational transformation.

```

1 trait OT[State, Op] {
2   def transform(x: Op, y: Op): Op
3   def apply(state: State, op: Op): State
4   def enabled(op: Op, state: State): Boolean = true
5   def canConcur(x: Op, y: Op): Boolean = true
6   proof TP1 {
7     forall (opI: Op, opJ: Op, st: State) {
8       (this.enabled(opI, st) && this.enabled(opJ, st) && this.canConcur(opI, opJ)) => {
9         this.apply(this.apply(st, opI), this.transform(opJ, opI)) ==
10        this.apply(this.apply(st, opJ), this.transform(opI, opJ)) } } }
11  proof TP2 {
12    forall (opI: Op, opJ: Op, opK: Op, st: State) {
13      (this.enabled(opI, st) && this.enabled(opJ, st) && this.enabled(opK, st) &&
14       this.canConcur(opI, opJ) && this.canConcur(opJ, opK) && this.canConcur(opI, opK)) => {
15        this.transform(this.transform(opK, opI), this.transform(opJ, opI)) ==
16        this.transform(this.transform(opK, opJ), this.transform(opI, opJ)) } } } }

```

Although VeriFx supports the general execution model of OT, most transformation functions described by the literature were specifically designed for collaborative text editing. They model text documents as a sequence of characters and operations insert or delete characters at a given position in the document. Every paper thus describes four transformations functions, one for every pair of operations: insert-insert, insert-delete, delete-insert, delete-delete.

Likewise, VeriFx’s OT library provides a `ListOT` trait that models the state as a list of values and supports insertions and deletions. RDTs extending the `ListOT` trait need to implement four methods (`Tii`, `Tid`, `Tdi`, `Tdd`) corresponding to the transformation functions for transforming insertions against insertions (`Tii`), insertions against deletions (`Tid`), deletions against insertions (`Tdi`), and deletions against deletions (`Tdd`). The trait provides a default implementation of `transform` that dispatches to the corresponding transformation function based on the type of operations, and a default implementation of `apply` that inserts or deletes a value from the underlying list.

5.3 Encoding RDT-Specific Assumptions

Some RDTs (most notably op-based CRDTs) assume causal delivery of operations but VeriFx and its CRDT and OT libraries do not make any assumptions. In VeriFx, assumptions must either be guaranteed by the RDT’s implementation or be explicitly encoded in the proofs.

We now show, using the OR-Set CRDT [67], how to encode RDT-specific assumptions. The OR-Set CRDT assumes that 1) replicas can generate globally unique tags, and 2) add and remove operations of the same element are delivered in causal order. These assumptions imply that replicas cannot add a tag and concurrently remove the same tag. The first assumption can be guaranteed by the RDT implementation if every replica has a unique ID that is combined with a local counter that increases monotonically to generate unique tags. The latter assumption about causal delivery can be explicitly encoded in the proof. One could also model the underlying causal communication protocols in VeriFx to remove this assumption.

Listing 8 shows an excerpt from the implementation of the OR-Set CRDT. It overrides the `compatible` predicate (Line 7) to encode the fact that replicas have unique IDs, and overrides the `canConcur` predicate (Line 8 to 16) such that the proof does not consider `add` and `remove` operations if the tag generated by `add` is contained in the set of tags that are removed (because causal delivery precludes `remove` from having observed that tag). This example shows how to encode specific assumptions but, in practice, many RDT implementations do not require any assumptions. Only 7 out of the 51 verified CRDTs (cf. Section 6.1) required assumptions, all of which are related to causal delivery and logical timestamps.

■ **Listing 8** Excerpt from the implementation of the OR-Set CRDT [67].

```

1 class Tag[ID](replica: ID, counter: Int)
2 enum SetOp[V, ID] { Add(e: V) | Remove(e: V) }
3 enum SetMsg[V, ID] { AddMsg(e: V, tag: Tag[ID]) | RemoveMsg(e: V, tags: Set[Tag[ID]]) }
4 class ORSet[V, ID](id: ID, counter: Int, elements: Map[V, Set[Tag[ID]]])
5   extends CmRDT[SetOp[V, ID], SetMsg[V, ID], ORSet[V, ID]] {
6   // ...
7   override def compatible(that: ORSet[V, ID]) = this.id != that.id
8   override def canConcur(x: SetMsg[V, ID], y: SetMsg[V, ID]) = x match {
9     case AddMsg(_, tag) => y match {
10      case AddMsg(_, _) => true
11      case RemoveMsg(_, tags) => !tags.contains(tag) // tag cannot be in tags because of causal delivery
12    }
13    case RemoveMsg(_, tags) => y match {
14      case AddMsg(_, tag) => !tags.contains(tag) // tag cannot be in tags because of causal delivery
15      case RemoveMsg(_, _) => true
16  } } }

```

6 Evaluation

We now evaluate the applicability of VeriF_x to implement and verify RDTs. Our evaluation is twofold. First, we implement and verify numerous CRDTs taken from literature as well as some new variants⁶. Also, we verify well-known OT functions and some unpublished designs.

All experiments reported were conducted on AWS using an m5.xlarge VM with 4 virtual CPUs and 16 GiB of RAM. All benchmarks are implemented using JMH [61], a benchmarking library for the JVM. We configured JMH to execute 20 warmup iterations followed by 20 measurement iterations for every benchmark. To avoid run-to-run variance JMH repeats every benchmark in 3 fresh JVM forks, yielding a total of 60 samples per benchmark.

We do not conduct a performance evaluation for the transpiled RDT implementations as the transpilation merely changes the syntax to Scala or JavaScript but does not modify the RDT’s design. Thus, the transpilation step does not affect the RDT’s performance.

6.1 Verifying Conflict-free Replicated Data Types

We implemented and verified an extensive portfolio comprising 51 CRDTs, coming from literature [2, 8, 14, 40, 66, 67], open source projects [9], and industrial databases [1, 12, 52]. To the best of our knowledge, we are the first to mechanically verify all CRDTs from Shapiro et al. [67], all delta state-based CRDTs from Almeida et al. [2], all pure op-based CRDTs from Baquero et al. [8], and the map CRDT from Kleppmann [40].

Table 1 summarizes the verification results, including the average verification time and code size of each CRDT. When applicable, we mention which CRDTs are used in industrial databases. VeriF_x was able to verify all implemented CRDTs except the Replicated Growable Array (RGA) [67] due to the recursive nature of the insertion algorithm (cf. Section 7). We found three issues: 1) the Two-Phase Set CRDT (described in Section 2) converges but is not functionally correct, 2) the original Map CRDT proposed by Kleppmann [40] diverges as VeriF_x found the same counterexample as described in their technical report, and 3) the Molli, Weiss, Skaf (MWS) Set is incomplete. We now describe the implementation and verification of the Map CRDTs from [40], while Appendix E discusses the MWS Set.

⁶ All implementations and proofs are provided as supplementary material in this submission.

■ **Table 1** Verification results for CRDTs implemented and verified in VeriF_x. S = state-based, D = delta state-based, O = op-based, P = pure op-based CRDT. ⊙ = timeout, @ = adaptation of an existing CRDT, ⊕ = incomplete definition. The database column includes databases that are known to use these CRDTs. Some delta state-based CRDTs use a dot kernel abstraction that is not counted in the LoC, this is indicated in the LoC column with an asterisk.

6.1.1 Map CRDTs

Kleppmann [40] describes the implementation of a Map CRDT which he believed to be “obviously correct” only to find out it contains a bug that causes divergence after spending hours trying to verify it. He then tweeted the buggy pseudo code of the Map CRDT and challenged his 29400 followers (mainly software engineers) to find the bug. Only one person managed to manually identify the bug and one other person came close (at the time, both were Ph.D. students specialized in RDTs). Kleppmann later tweeted a variation on the algorithm: “Here is a variant of the algorithm that is correct (I believe)”.

We used VeriFx to implement and *automatically* verify both the buggy Map CRDT and the corrected Map CRDT, which had not been formally verified. The full implementation and verification of the buggy map CRDT is explained in Appendix D. We now present the key takeaways from our experience implementing and verifying these map CRDTs.

Implementation. The implementation of the map CRDTs mainly consisted of translating the mathematical specifications to VeriFx. We introduced slight changes to the design to improve efficiency. For example, the specification keeps a set of triples where each triple holds a key, a value, and a timestamp. Since every key appears at most in one triple, our implementation uses a dictionary to efficiently map keys to their value and timestamp.

Verification. After implementing the buggy map CRDT, we proceeded to its automated verification but VeriFx generated invalid counterexamples. For instance, one in which two distinct replicas generated the same timestamp. This is not possible because the design assumes that replicas have unique IDs and combines them with Lamport clocks [43] to generate unique timestamps. However, VeriFx does not know this assumption nor does it know the relation between a replica’s clock and the values it observed. In practice, other CRDTs make similar *implicit* assumptions which is the reason they are complex and difficult to get right. VeriFx helped us to explicitly encode all assumptions as it kept returning invalid counterexamples which helped us find and formulate the missing assumptions. Listing 11 in Appendix D.3 shows the encoding of these assumptions.

Counterexample. After explicitly defining all assumptions, VeriFx found a valid counterexample for the buggy map CRDT that is equivalent to the one found manually by Nair [40]. It consists of a corner case in which the `Put` and `Delete` operations do not commute and thus may cause replicas to diverge. We detail the counterexample in Appendix D.3.

Corrected Map CRDT. After finding the counterexample for the buggy map CRDT, we also verified the corrected map CRDT from Kleppmann [40]. This did not require additional efforts since we already distilled all assumptions for the buggy map CRDT. VeriFx automatically proved that the corrected design indeed guarantees convergence, which to the best of our knowledge, is the first mechanical proof of correctness for this CRDT.

As shown in Table 1, the verification times for the buggy and corrected map CRDTs are slightly higher compared to the other CRDTs we verified, but are still very fast for a fully automated verification approach. The higher times come from the fact that these CRDTs are too complex to directly prove convergence of all operation pairs. Hence, we use a subproof for every operation pair. The total verification time is the sum of the times of the subproofs.

6.1.2 Conclusion

Based on Table 1, we conclude that VeriFx is suited to verify CRDT implementations since all were verified mechanically and fully automatically in a matter of seconds. To the best of our knowledge, this is the most extensive portfolio of verified RDTs to date. It is representative of real-world use cases as it includes several CRDTs used in industrial databases.

■ **Table 2** Verification results of OT functions in VeriF_x.

Transformation Function	LoC	Props		Time	
		TP_1	TP_2	TP_1	TP_2
Ellis and Gibbs [25]	84	✗	✗	115 s	29 s
Ressel et al. [64]	78	✓	✗	68 s	30 s
Sun et al. [72]	68	✗	✗	321 s	13 s

■ **Listing 9** Excerpt from the implementation of Imine et al. [34]’s functions.

```

1  enum Op { Ins(p: Int, ip: Int, c: Int) |
      Del(p: Int) | Id() }
2  object Imine extends ListOT[Int, Op] {
3    def Tii(x: Ins, y: Ins) = {
4      val p1 = x.p; val ip1 = x.ip; val c1 = x.c
5      val p2 = y.p; val ip2 = y.ip; val c2 = y.c
6      if (p1 < p2) x
7      else if (p1 > p2) new Ins(p1 + 1, ip1, c1)
8      else if (ip1 < ip2) x
9      else if (ip1 > ip2) new Ins(p1+1, ip1, c1)
10     else if (c1 < c2) x
11     else if (c1 > c2) new Ins(p1+1, ip1, c1)
12     else new Id() }
13   def Tid(x: Ins, y: Del) =
14     if (x.p > y.p) new Ins(x.p - 1, x.ip, x.c)
15     else x
16   def Tdi(x: Del, y: Ins) =
17     if (x.p < y.p) x else new Del(x.p + 1)
18   def Tdd(x: Del, y: Del) = if (x.p < y.p) x
19     else if (x.p > y.p) new Del(x.p - 1)
20     else new Id() }

```

Overall, the main challenge to building such an extensive portfolio consisted of finding and encoding the correct assumptions. Those assumptions were usually gradually discovered as VeriF_x returned counterexamples that cannot occur in practice, which indicates that one or more assumptions are missing. In particular, counterexamples were crucial for verifying the Map CRDTs from [40]. These are the designs that took the longest to implement and verify and they required an afternoon of work.

6.2 Verifying Operational Transformation

We now show that VeriF_x is general enough to verify other distributed abstractions such as Operational Transformation (OT). We implemented all transformation functions for collaborative text editing defined by Imine et al. [34] and verified TP_1 and TP_2 in VeriF_x.

Table 2 summarizes the verification results. For each transformation function, the table shows the code size, whether or not it satisfies TP_1 and TP_2 , and the average verification time. As shown in the table, the functions proposed by Ellis and Gibbs [25], Sun et al. [72], and Suleiman et al. [69] do not satisfy TP_1 nor TP_2 . Ressel et al. [64]’s functions satisfy TP_1 but not TP_2 . These results confirm prior findings by Imine et al. [34]. VeriF_x also found that the functions proposed by Imine et al. [34] do not satisfy TP_2 , which confirms the findings of Li and Li [49] and Oster et al. [62]. That same counterexample also invalidates the transformation functions of Suleiman for TP_2 . Imine et al. [34] wrongly proved Suleiman’s functions [69] correct, but VeriF_x found counterexamples for both properties (the counterexample for TP_1 was manually found in [63]). We believe that the specification defined in Imine et al. [34] may have missed those counterexamples due to a wrong encoding of assumptions. Finally, in a private communication, Imine [33] asked us to verify (unpublished) OT designs for replicated registers and stacks. Out of the three register designs verified in VeriF_x, only one is correct for both TP_1 and TP_2 . Regarding the stack design, it guarantees TP_2 but not TP_1 . VeriF_x provided meaningful counterexamples for each incorrect design.

To exemplify our approach to verifying OT, we now describe the implementation and verification of Imine et al. [34]’s transformation functions in VeriF_x, which are shown in Listing 9. The enumeration `Op` on Line 1 defines the three supported operations:

- `Ins(p, ip, c)` represents the insertion of character c^7 at position `p`. Initially, `c` was inserted at position `ip`. Transformations may change `p` but leave `ip` untouched.
- `Del(p)` represents the deletion of the character at position `p`.
- `Id()` acts as a no-op (to which operations may be transformed).

Object `Imine` extends the `ListOT` trait and implements the transformation functions (`Tii`, `Tid`, `Tdi`, `Tdd`) required for collaborative text editing (cf. Section 5.2). The implementation of these transformation functions is a straightforward translation from their description by Imine et al. [34]. The resulting object inherits automated proofs for TP_1 and TP_2 . When running these proofs, VeriFx reports that the transformation functions guarantee TP_1 but not TP_2 .

Based on the results shown in Table 2, we conclude that VeriFx is suited to verify other RDT families such as OT. Due to the number of cases that have to be considered, the verification times are longer than for CRDTs but are still acceptable for static verification [21].

7 Discussion

We now discuss the main design decisions behind VeriFx, its limitations and trade-offs.

Traits. For simplicity, VeriFx only supports single inheritance from traits. However, it could be extended to support multiple inheritance. Traits are not meant for subtyping because subtyping complicates verification as every subtype needs to be verified but these might not be known at compile time. Hence, class fields, method parameters, etc. cannot be of a trait type. Programmers can, however, define enumerations as these have a fixed number of constructors, which are known at compile time. Note that traits can define type parameters with upper type bounds. The type checker uses these bounds to ensure that every extending class or trait is well-typed. The compiled SMT program does not contain traits as they are compiled away (cf. Section 4.2). Proofs, classes, and methods cannot have bounds on type parameters because the compiler does not know all subtypes.

Functional collections. VeriFx encodes higher-order operations on collections (e.g. `map`, `filter`) using arrays, which are treated as function spaces in the Combinatory Array Logic (CAL) [23]. Hence, anonymous functions (lambdas) merely define arrays that are first-class. SMT solvers can efficiently reason about VeriFx’s functional collections because CAL is decidable. However, some operations are encoded using universal or existential quantifiers which may hamper decidability. In practice, VeriFx can verify RDTs involving complex functional operations. Unfortunately, VeriFx’s collections do not yet provide aggregation methods (e.g. `fold` and `reduce`) because this is beyond the capabilities of CAL. These restrictions may soon be lifted as SMT-LIB v3 [35] preliminary plans incorporate new theories that include aggregation functions such as `fold`.

Trade-off between expressiveness and verifiability. All constructs in VeriFx were carefully designed to have efficient SMT encoding. Overall, general loop constructs cannot be verified automatically as those require inductive proofs. A key insight of VeriFx is that *implicit* loop constructs (e.g. `map`, etc.) enable the automatic verification of an extensive portfolio of RDTs. Even though the language does not provide general loop constructs, programmers can define recursive methods. While VeriFx will not prove facts about (unbounded) recursive methods out-of-the-box, programmers can still verify these implementations by explicitly defining inductive proofs. This requires devising a suitable induction hypothesis and defining two proofs: one for the base case, and another for the induction step. Then, VeriFx can verify both proofs. This approach has been used to verify nested CRDT designs [13].

⁷ We represent characters using integers that correspond to their ASCII code.

8 Related Work

We focus our comparison of related work on verification languages and approaches for verifying RDTs, invariants in distributed systems, and operational transformation.

Verification languages. Verification languages can be classified into three categories: interactive, auto-active, and automated [45]. Interactive languages include proof assistants like Coq and Isabelle/HOL in which programmers define theorems and prove them manually using proof tactics. Although automation tactics exist, proving complex theorems requires considerable manual proof efforts. Vazou et al. [76] introduce the idea of refinement reflection in Liquid Haskell [75], where user-defined functions are reflected in a decidable fragment of SMT logic and can be used in refinement types to express correctness properties. Similarly, in VeriFx *every* construct of the language and its collections are reflected in SMT logic such that arbitrary VeriFx programs can be reflected in the logic. However, VeriFx enables *automated* verification of user-defined correctness properties whereas, Liquid Haskell requires programmers to express correctness properties using refinement types and *manually* write proofs as Haskell functions. Moreover, VeriFx offers an iterative process where incorrect designs are improved based on the counterexamples, whereas Liquid Haskell only raises a type error. Auto-active verification languages like Dafny [44] and Spec# [11] verify programs based on annotations provided by the programmer (e.g. preconditions, postconditions, loop invariants). Intermediate verification languages (IVLs) like Boogie [10] and Why3 [26] automate the proof task by generating verification conditions (VCs) from source code and discharging them using one or more SMT solvers. IVLs are not meant to be used by programmers directly. Instead, programs written in some verification language (e.g. Dafny, Spec#) are translated to an IVL to verify the VCs. Regarding automated verification, the work by Kaki and Jagannathan [37] integrated an automated verification framework in a refinement type system. Programmers write relational specifications that define structural relations for the RDT at hand and express correctness properties as refinement types atop operations. However, writing relational specifications for advanced data types is non-trivial and can be rather verbose, as noted by the authors themselves. In contrast, VeriFx does not require separate specifications.

Verifying SEC for RDTs. Burckhardt et al. [20] propose a formal framework that enables the specification and verification of RDTs. Attiya et al. [5] use a variation on this framework to provide specifications of replicated lists and prove the correctness of an existing text editing protocol. Gomes et al. [27] and Zeller et al. [79] propose formal frameworks in the Isabelle/HOL theorem prover to mechanically verify SEC for CRDTs. In contrast to VeriFx, Gomes et al. [27] only consider operation-based CRDTs but model the underlying network to reason about causal delivery of messages. Nieto et al. [59] developed libraries to implement and verify op-based CRDTs in separation logic. Their approach requires programmers to write Coq specifications atop the provided libraries and manually prove correctness. Liu et al. [54] extend Liquid Haskell with typeclass refinements and use them to prove SEC for some of their own CRDTs. While simple proofs can be discharged automatically by the underlying SMT solver, advanced CRDTs also require significant proof efforts (as discussed in Section 2). All the aforementioned verification techniques require significant effort and expertise whereas, VeriFx fully automatically verified 51 well-known CRDTs. Liang and Feng [51] propose a new correctness criterion for CRDTs that extends SEC with functional correctness and enables manual verification of CRDT implementations and client programs using them. They mainly focus on functional correctness and provide paper proofs rather than automated verification. Wang et al. [77]

propose replication-aware linearizability, a criterion that enables sequential reasoning to prove the correctness of CRDT implementations. The CRDTs were manually encoded in the Boogie verification tool to prove correctness. Those encodings are non-trivial and differ from real-world CRDT implementations. Nagar and Jagannathan [56] developed a proof rule that is parametrized by the consistency model and automatically checks convergence for CRDTs. Unfortunately, their framework introduces imprecision and may reject correct CRDTs. Moreover, their framework requires a first-order logic specification of the CRDT. In contrast, VeriFx can verify high-level CRDT implementations instead of specifications. Finally, Jagadeesan and Riely [36] introduce a notion of validity for RDTs and manually prove it for some CRDTs. We do not consider validity in this work.

Verifying applications invariants. Some work has focused on verifying application invariants under weak consistency. Bailis et al. [6] introduce invariant confluent operations that maintain application invariants, even without coordination. Whittaker and Hellerstein [78] devise a decision procedure for invariant confluence that can be checked automatically. Other work has focused on verifying invariants for RDTs [7, 29, 57, 58, 80]. Soteria [57] verifies program invariants for state-based RDTs. Repliss [80] verifies program invariants for applications that are built on top of their CRDT library. CISE [29, 58] proposes a proof rule to check that a chosen consistency level for operations preserves the application invariants. IPA [7] detects invariant-breaking operations and proposes changes to the operations in order to preserve the invariants. All these approaches assume that the underlying RDT is correct, while VeriFx enables programmers to verify that this is the case. This paper does not consider RDTs with mixed consistency levels as [24, 31, 46–48, 50, 55, 81, 82].

Verifying operational transformation functions. Ellis and Gibbs [25] first proposed an algorithm for OT together with a set of transformation functions. Several works [70, 72] showed that integration algorithms like adOPTed [64], SOCT2 [70], and GOTO [71] guarantee convergence iff the transformation functions satisfy the TP_1 and TP_2 properties. Ellis and Gibbs [25]’s functions do not satisfy these properties [64, 70, 72] and, over the years, several functions were proposed [64, 69, 72]. Imine et al. [34] used SPIKE, an automated theorem prover, to verify the correctness of these functions and found counterexamples for all of them, except for Suleiman et al. [69]’s functions. As shown in Section 6.2, we reproduced their study and generated similar counterexamples. Imine et al. [34] proposed a simpler set of functions which later was found to also violate TP_2 [49, 62]. VeriFx also found this counterexample.

9 Conclusion

To support the development of correct RDTs, we propose VeriFx, a high-level programming language powerful enough to implement RDTs as CRDTs and OT, and verify them automatically without requiring annotations or programmer intervention. Our approach enables programmers to implement RDTs, and express and verify correctness properties, all within the *same* language. This avoids gaps between the implementation and verification. VeriFx high-level counterexamples enable programmers to iteratively improve their implementation. Once verified, RDTs can be transpiled to mainstream languages, e.g. Scala and JavaScript.

VeriFx shows that automated verification based on SMT solving can verify real-world RDT implementations with minimal programmer intervention. This work accounts for the most extensive portfolio of mechanically verified RDTs to date, including 51 CRDTs and 9 OT designs. All were verified in a matter of seconds or minutes and with minimal effort.

In this work, we focused on verifying correctness properties in the domain of RDTs. In future work, we would like to explore the applicability of VeriF_x to other domains.

A VeriFx's Type System

We now present VeriFx's type system. An environment Γ is a partial and finite mapping from variables to types. A type environment Δ is a finite set of type variables. VeriFx's type system consists of a judgment for type wellformedness $\Delta \vdash T$ ok which says that type T is well-formed in context Δ , and a judgment for typing $\Delta; \Gamma \vdash e : T$ which says that in context Δ and environment Γ , the expression e is of type T . We abbreviate $\Delta \vdash T_1$ ok, \dots , $\Delta \vdash T_n$ ok to $\Delta \vdash \bar{T}$ ok, and $\Delta; \Gamma \vdash e_1 : T_1, \dots, \Delta; \Gamma \vdash e_n : T_n$ to $\Delta; \Gamma \vdash \bar{e} : \bar{T}$.

Below we define well-formed types:

$$\begin{array}{c}
\frac{}{\Delta \vdash \text{string ok}} \text{ (WF-STRING)} \quad \frac{}{\Delta \vdash \text{bool ok}} \text{ (WF-BOOL)} \quad \frac{}{\Delta \vdash \text{int ok}} \text{ (WF-INT)} \\
\\
\frac{\Delta \vdash \overline{T} \text{ ok} \quad \text{class } C \langle \overline{X} \rangle (\dots) \{ \dots \} \quad \text{or class } C \langle \overline{X} \rangle (\dots) \text{ extends } I \langle \dots \rangle \{ \dots \}}{\Delta \vdash C \langle \overline{T} \rangle \text{ ok}} \text{ (WF-CLASS)} \\
\\
\frac{\Delta \vdash \overline{T} \text{ ok} \quad \overline{T} <: \overline{P} \quad \text{trait } I \langle \overline{X} <: \overline{P} \rangle \{ \dots \} \quad \text{or trait } I \langle \overline{X} <: \overline{P} \rangle \text{ extends } I \langle \dots \rangle \{ \dots \}}{\Delta \vdash I \langle \overline{T} \rangle \text{ ok}} \text{ (WF-TRAIT)} \\
\\
\frac{\Delta \vdash \overline{T} \text{ ok} \quad \text{enum } E \langle \overline{X} \rangle \{ \dots \}}{\Delta \vdash E \langle \overline{T} \rangle \text{ ok}} \text{ (WF-ENUM)} \quad \frac{X \in \Delta}{\Delta \vdash X \text{ ok}} \text{ (WF-TVAR)}
\end{array}$$

Primitive types are always well-formed. A type variable X is valid if it is in scope: $X \in \Delta$, i.e. the surrounding method or class defined the type parameter. Class types and enumeration types are valid if a corresponding class or enumeration definition exists and all type arguments are well-formed.

We now define a few auxiliary definitions which are needed for the typing rules. The *fields* function takes a class type and returns its fields and their types:

$$\frac{\text{class } C \langle \overline{X} \rangle (\overline{v} : \overline{T}) \{ \overline{M} \} \quad \text{or class } C \langle \overline{X} \rangle (\overline{v} : \overline{T}) \text{ extends } I \langle \overline{Q} \rangle \{ \overline{M} \}}{\text{fields}(C \langle \overline{P} \rangle) = [\overline{P}/\overline{X}] \overline{v} : \overline{T}} \text{ (F-CLASS)}$$

The *ftypes* function takes an enumeration type and the name of one of its constructors and returns the type of the fields of that constructor.

$$\frac{\text{enum } E \langle \overline{X} \rangle \{ K(\overline{v} : \overline{T}), \dots \}}{\text{ftypes}(E \langle \overline{P} \rangle, K) = [\overline{P}/\overline{X}] \overline{T}} \text{ (FT-ENUM)}$$

The *mtype* function takes the name of a method and the type of a class, and returns the actual type signature of the method. If the method is not found in the class (MT-CLASS-REC rule) it is looked up in the hierarchy of super traits by the MT-TRAIT rules. For polymorphic methods, the returned type signature is polymorphic:

$$\frac{\text{class } C \langle \overline{X} \rangle (\dots) \{ \overline{M} \} \quad \text{or class } C \langle \overline{X} \rangle (\dots) \text{ extends } I \langle \overline{Q} \rangle \{ \overline{M} \} \quad \text{def } m \langle \overline{Y} \rangle (\overline{x} : \overline{T}) : T = e \in \overline{M}}{\text{mtype}(m, C \langle \overline{P} \rangle) = [\overline{P}/\overline{X}] (\langle \overline{Y} \rangle \overline{T} \rightarrow T)} \text{ (MT-CLASS)}$$

$$\frac{\text{class } C \langle \overline{X} \rangle (\dots) \text{ extends } I \langle \overline{Q} \rangle \{ \overline{M} \} \quad \text{def } m \langle \overline{Y} \rangle (\overline{x} : \overline{T}) : T = e \notin \overline{M}}{\text{mtype}(m, C \langle \overline{P} \rangle) = \text{mtype}(m, I \langle \overline{Q} \rangle)} \text{ (MT-CLASS-REC)}$$

$$\frac{\text{trait } I \langle \overline{X} <: \overline{T}' \rangle \{ \overline{M} \} \quad \text{or trait } I \langle \overline{X} <: \overline{T}' \rangle \text{ extends } I' \langle \dots \rangle \{ \overline{M} \} \quad \text{def } m \langle \overline{Y} \rangle (\overline{x} : \overline{T}) : T = e \in \overline{M}}{\text{mtype}(m, I \langle \overline{P} \rangle) = [\overline{P}/\overline{X}] (\langle \overline{Y} \rangle \overline{T} \rightarrow T)} \text{ (MT-TRAIT)}$$

$$\frac{\text{trait } I \langle \overline{X} <: \overline{T}' \rangle \{ \overline{M} \} \quad \text{or trait } I \langle \overline{X} <: \overline{T}' \rangle \text{ extends } I' \langle \overline{P} \rangle \{ \overline{M} \} \quad \text{def } m \langle \overline{Y} \rangle (\overline{x} : \overline{T}) : T = e \notin \overline{M}}{\text{mtype}(m, I \langle \overline{P} \rangle) = \text{mtype}(m, I' \langle \overline{P} \rangle)} \text{ (MT-TRAIT-REC)}$$

Similarly, we assume that there are functions $valNames(I(\overline{P}))$ and $declaredMethods(I(\overline{P}))$ that return all fields, respectively all methods, declared by a trait (and its super traits). The $ctors$ function takes an enumeration type and returns the names of its constructors.

$$\frac{\text{enum } E \langle \overline{X} \rangle \{ K(\overline{x} : \overline{T}) \}}{ctors(E \langle \overline{P} \rangle) = \overline{K}} \text{ (C-ENUM)}$$

Figure 6 shows the typing rules for expressions. Most rules are a simplification of Featherweight Generic Java [32] without subtyping. Quantified formulas are boolean expressions if their body also types to a boolean expression in the environment that is extended with the quantified variables (T-UNI and T-EXI rules). The logical implication is a well-typed boolean expression if both the antecedent and the consequent are boolean expressions (T-IMPL rule).

Classes are well-formed if the types of the fields are well-formed and all its methods are well-formed (T-CLASS1 rule). If the class extends a trait, it must also implement all fields and methods declared by the hierarchy of super traits (T-CLASS2 rule). The typing rules for trait definitions and object definitions can be defined similarly.

When instantiating an enumeration through one of its constructors $\text{new } K \langle \overline{P} \rangle (\overline{e})$, the provided arguments \overline{e} need to match the types of the constructors' fields, and the result effectively is an object of the enumeration type $E \langle \overline{P} \rangle$.

Programmers can pattern match on enumerations but the cases must be exhaustive, i.e. every constructor must be matched by at least one case. If all cases are of type T , then the resulting pattern match expression is also of type T .

Finally, the body of a proof must be a well-typed boolean expression.

B Core SMT Expressions

We will now discuss the expressions that are supported by Core SMT. Those expressions are common to most SMT solvers, except lambdas which, as mentioned before, are described by the preliminary proposal for SMT-LIB v3.0 and are only implemented by some SMT solvers such as Z3 [22].

Figure 7 provides an overview of all Core SMT expressions. The simplest expressions are literal values representing integers, strings, and booleans. Core SMT supports the typical arithmetic operators ($+$, $-$, $*$, $/$) and boolean operators (\wedge , \vee , and negation \neg) as well as universal and existential quantification, and logical implication. Immutable variables are defined by let bindings. Pattern matching is supported but the cases must be exhaustive. For example, when pattern matching against an algebraic data type every constructor must be handled. Core SMT supports two types of patterns: constructor patterns $n(\overline{n})$ that match a specific ADT constructor n and binds names to its fields \overline{n} , and wildcard patterns that match anything and give it a name n . References v refer to variables that are in scope, e.g. function parameters or variables introduced by let binding or pattern matching. If statements are supported but an else branch is mandatory and both branches must evaluate to the same sort. Functions can be called and type arguments can be provided explicitly to disambiguate polymorphic functions. For example, we defined an ADT $\text{Option} \langle T \rangle$ with two constructors `Some` and `None`. When calling the `None` constructor we need to explicitly provide a type argument since it cannot be inferred from the call, e.g. `None(int)()`. Finally, fields of an ADT can be accessed by their name. Arrays and lambdas were already discussed in Section 4.1.

$$\begin{array}{c}
\frac{}{\Delta; \Gamma \vdash \text{num} : \text{int}} \text{(T-NUM)} \quad \frac{}{\Delta; \Gamma \vdash \text{str} : \text{string}} \text{(T-STR)} \quad \frac{}{\Delta; \Gamma \vdash \text{true} : \text{bool}} \text{(T-TRUE)} \\
\frac{}{\Delta; \Gamma \vdash \text{false} : \text{bool}} \text{(T-FALSE)} \quad \frac{x \in \text{dom}(\Gamma)}{\Delta; \Gamma \vdash x : \Gamma(x)} \text{(T-VAR)} \quad \frac{\Delta; \Gamma \vdash e : \text{bool}}{\Delta; \Gamma \vdash !e : \text{bool}} \text{(T-NEG)} \\

■ **Figure 7** All Core SMT expressions.

C Compiler Semantics

We now discuss the compiler semantics that was not discussed in the main body of the paper. First, we provide all compilation rules for expressions in Appendix C.1. Then, we provide all compilation rules for sets and maps in Appendices C.2 and C.3 respectively.

C.1 Compiling Expressions

Figure 8 shows the compilation rules for expressions. The operands of binary operators \oplus are compiled recursively. A negated expression is compiled to the negation of the compiled expression. For if statements, the condition, and both branches are compiled recursively. In VeriF_x, **this** can be used inside the body of a method to refer to the current object. The reference is compiled to a similar *this* reference in Core SMT which refers to the *this* parameter which is always the first parameter of any method (cf. compilation of class methods in Section 4.2). We explained how to compile the remaining expressions in Section 4.2.

Figure 9 shows the compilation rules for logic expressions which in VeriF_x can only occur within the body of proofs. For quantified formulas the types of the variables \tilde{T} and the formula e are compiled. For logical implications, the antecedent and the consequent are compiled recursively.

Finally, pattern match expressions are compiled to similar pattern match expressions in Core SMT (shown in Figure 10). To this end, every pattern is compiled recursively. Core SMT supports two types of patterns: constructor patterns $n_1(\overline{n_2})$ that match an algebraic data type constructor n_1 and bind its fields to the provided names $\overline{n_2}$, and wildcard patterns n that match any value and give it a name n . Every VeriF_x pattern is compiled into the corresponding Core SMT pattern. The first pattern, $n_1(\overline{n_2})$, matches an ADT constructor n_1 and binds its fields to $\overline{n_2}$. It is compiled to an equivalent constructor pattern in Core SMT. The other two patterns match any expression and are compiled to an equivalent wildcard pattern in Core SMT.

C.2 Compiling Sets

In Section 4.4 we explained how basic set operations (**add**, **remove**, **contains**) and some advanced operations (**filter**, **map**) are compiled to Core SMT. Now, we explain how the remaining operations on sets are compiled. Figure 11 shows the compilation rules for

$\llbracket x \rrbracket$	$= x$
$\llbracket e_1 \oplus e_2 \rrbracket$	$= \llbracket e_1 \rrbracket \oplus \llbracket e_2 \rrbracket$
$\llbracket !e \rrbracket$	$= \neg \llbracket e \rrbracket$
$\llbracket \text{val } x : T = e_1 \text{ in } e_2 \rrbracket$	$= \text{let } x = \llbracket e_1 \rrbracket \text{ in } \llbracket e_2 \rrbracket$
$\llbracket \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \rrbracket$	$= \text{if } (\llbracket e_1 \rrbracket, \llbracket e_2 \rrbracket, \llbracket e_3 \rrbracket)$
$\llbracket (\bar{x} : \bar{T}) \Rightarrow e \rrbracket$	$= \lambda(\bar{x} : \llbracket \bar{T} \rrbracket_t) . \llbracket e \rrbracket$
$\llbracket e_1(\bar{e}_2) \rrbracket$	$= \llbracket e_1 \rrbracket[\llbracket \bar{e}_2 \rrbracket]$
$\llbracket \text{new Set } \langle T \rangle () \rrbracket$	$= \lambda(x : \llbracket T \rrbracket_t) . \text{false}$
$\llbracket \text{new Map } \langle T, P \rangle () \rrbracket$	$= \lambda(x : \llbracket T \rrbracket_t) . \text{None}(\llbracket P \rrbracket_t)()$
$\llbracket \text{new } C \langle \bar{T} \rangle (\bar{e}) \rrbracket$	$= C'(\llbracket \bar{T} \rrbracket_t)(\llbracket \bar{e} \rrbracket)$
	where $C' = \text{str_concat}(C, \text{"_ctor"})$
$\llbracket \text{new } K \langle \bar{T} \rangle (\bar{e}) \rrbracket$	$= K(\llbracket \bar{T} \rrbracket_t)(\llbracket \bar{e} \rrbracket)$
$\llbracket e.v \rrbracket$	$= \llbracket e \rrbracket.v$
$\llbracket e_1.m \langle \bar{T} \rangle (\bar{e}) \rrbracket$	$= m'(\llbracket \bar{P} \rrbracket_t, \llbracket \bar{T} \rrbracket_t)(\llbracket e_1 \rrbracket, \llbracket \bar{e} \rrbracket)$
	where $\text{typeof}(e_1) = C(\bar{P})$
	and $m' = \text{str_concat}(C, \text{"_"}, m)$ and $\bar{P} \cap \bar{T} = \emptyset$

■ **Figure 8** Compiling expressions.

$\llbracket \text{forall } (\bar{x} : \bar{T}) . e \rrbracket$	$= \forall(\bar{x} : \llbracket \bar{T} \rrbracket_t) . \llbracket e \rrbracket$
$\llbracket \text{exists } (\bar{x} : \bar{T}) . e \rrbracket$	$= \exists(\bar{x} : \llbracket \bar{T} \rrbracket_t) . \llbracket e \rrbracket$
$\llbracket e_1 \Longrightarrow e_2 \rrbracket$	$= \llbracket e_1 \rrbracket \Longrightarrow \llbracket e_2 \rrbracket$

■ **Figure 9** Compiling logical expressions.

operations over sets. The union of two sets e_1 and e_2 is compiled to a lambda which defines an array of elements x of type $\llbracket T \rrbracket_t$ containing only elements that are in at least one of the two sets, i.e. $\llbracket e_1 \rrbracket[x] \vee \llbracket e_2 \rrbracket[x]$. Similarly, the intersection of two sets e_1 and e_2 is compiled to a lambda which defines an array containing only elements that are in both sets, i.e. $\llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x]$. For set difference, the lambda defines an array containing only elements that are in e_1 and not in e_2 . A set e_1 is a subset of e_2 iff all elements from e_1 are also in e_2 . A set e is non-empty if an element x exists that is in the set, i.e. $\llbracket e \rrbracket[x]$. A set e is empty if all elements x are not in the set. A predicate $e_2 : T \rightarrow \text{bool}$ holds for all elements of a set e_1 if for every element x that is in the set the predicate is true, i.e. $\llbracket e_1 \rrbracket[x] \Longrightarrow \llbracket e_2 \rrbracket[x]$. A predicate $e_2 : T \rightarrow \text{bool}$ holds for at least one element of a set e_1 if there exists an element x that is in the set and for which the predicate holds, i.e. $\llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x]$.

C.3 Compiling Maps

Maps are encoded as arrays from the key type to an optional value:

$$\llbracket \text{Map } \langle T, P \rangle \rrbracket_t = \text{Array}(\llbracket T \rrbracket_t, \text{Option}(\llbracket P \rrbracket_t))$$

Optional values indicate the presence or absence of a value for a certain key. The option type is defined as an ADT with two constructors: `Some(value)` which holds a value and `None()` indicating the absence of a value. An empty map corresponds to an array containing `None()` for every key and is created by a lambda that returns `None()` for every key:

$$\begin{aligned}
 \llbracket e \text{ match } \{ \text{case } r \Rightarrow e_c \} \rrbracket &= \text{match}(\llbracket e \rrbracket, \text{pat}[\llbracket \text{case } r \Rightarrow e_c \rrbracket]) \\
 \text{pat}[\llbracket \text{case } K(\bar{x}) \Rightarrow e \rrbracket] &= \text{case}(K(\bar{x}), \llbracket e \rrbracket) \\
 \text{pat}[\llbracket \text{case } x \Rightarrow e \rrbracket] &= \text{case}(x, \llbracket e \rrbracket) \\
 \text{pat}[\llbracket \text{case } _ \Rightarrow e \rrbracket] &= \text{case}(_, \llbracket e \rrbracket)
 \end{aligned}$$

■ **Figure 10** Compiling pattern match expressions.

$$\begin{aligned}
 \llbracket e_1.\text{add}(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] := \text{true} \\
 \llbracket e_1.\text{remove}(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] := \text{false} \\
 \llbracket e_1.\text{contains}(e_2) \rrbracket &= \llbracket e_1 \rrbracket[\llbracket e_2 \rrbracket] \\
 \llbracket e_1.\text{filter}(e_2) \rrbracket &= \lambda(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x] \quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{map}(e_2) \rrbracket &= \lambda(y : \llbracket P \rrbracket_t). \exists(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x] = y \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \wedge \text{typeof}(e_2) = T \rightarrow P \\
 \llbracket e_1.\text{union}(e_2) \rrbracket &= \lambda(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \vee \llbracket e_2 \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \wedge \text{typeof}(e_2) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{intersect}(e_2) \rrbracket &= \lambda(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_2 \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \wedge \text{typeof}(e_2) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{diff}(e_2) \rrbracket &= \lambda(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \neg \llbracket e_2 \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \wedge \text{typeof}(e_2) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{subsetOf}(e_2) \rrbracket &= \forall(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \implies \llbracket e_2 \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \wedge \text{typeof}(e_2) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{nonEmpty}() \rrbracket &= \exists(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \quad \text{where } \text{typeof}(e) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{isEmpty}() \rrbracket &= \forall(x : \llbracket T \rrbracket_t). \neg \llbracket e_1 \rrbracket[x] \quad \text{where } \text{typeof}(e) = \text{Set}\langle T \rangle \\
 \llbracket e_1.\text{forall}(e_p) \rrbracket &= \forall(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \implies \llbracket e_p \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \text{ and } \text{typeof}(e_p) = T \rightarrow \text{bool} \\
 \llbracket e_1.\text{exists}(e_p) \rrbracket &= \exists(x : \llbracket T \rrbracket_t). \llbracket e_1 \rrbracket[x] \wedge \llbracket e_p \rrbracket[x] \\
 &\quad \text{where } \text{typeof}(e_1) = \text{Set}\langle T \rangle \text{ and } \text{typeof}(e_p) = T \rightarrow \text{bool}
 \end{aligned}$$

■ **Figure 11** Compiling set operations.

$$\llbracket \text{new Map} \langle T, P \rangle () \rrbracket = \lambda(x : \llbracket T \rrbracket_t). \text{None}(\llbracket P \rrbracket_t)()$$

Operations on maps are compiled as follows:

$$\begin{aligned}
 \text{map}[\llbracket e_m.\text{add}(e_k, e_v) \rrbracket] &= \llbracket e_m \rrbracket[\llbracket e_k \rrbracket] := \text{Some}(\llbracket e_v \rrbracket) \\
 \text{map}[\llbracket e_m.\text{remove}(e_k) \rrbracket] &= \llbracket e_m \rrbracket[\llbracket e_k \rrbracket] := \text{None}(\llbracket V \rrbracket_t)() \\
 \text{map}[\llbracket e_m.\text{contains}(e_k) \rrbracket] &= \llbracket e_m \rrbracket[\llbracket e_k \rrbracket] \neq \text{None}(\llbracket V \rrbracket_t)() \\
 \text{map}[\llbracket e_m.\text{get}(e_k) \rrbracket] &= \llbracket e_m \rrbracket[\llbracket e_k \rrbracket].\text{value} \\
 \text{map}[\llbracket e_m.\text{getOrElse}(e_k, e_v) \rrbracket] &= \text{if}(\llbracket e_m \rrbracket[\llbracket e_k \rrbracket] = \text{None}(\llbracket V \rrbracket_t)(), \llbracket e_v \rrbracket, \llbracket e_m \rrbracket[\llbracket e_k \rrbracket].\text{value})
 \end{aligned}$$

A key-value pair $e_k \mapsto e_v$ is added to a map e_m by updating the entry for the compiled key $\llbracket e_k \rrbracket$ in the compiled array $\llbracket e_m \rrbracket$ with the compiled value, $\text{Some}(\llbracket e_v \rrbracket)$. A key e_k is removed from a map e_m by updating the corresponding entry to $\text{None}(\llbracket V \rrbracket_t)()$, thereby indicating the absence of a value. Note that None is polymorphic but the type parameter cannot be inferred from the arguments; it is thus passed explicitly. A key e_k is present in a map e_m if the value that is associated to the key is not $\text{None}(\llbracket V \rrbracket_t)()$. The `get` method fetches the value that is associated to a key e_k in a map e_m . To this end, the compiled key $\llbracket e_k \rrbracket$ is accessed in the compiled map $\llbracket e_m \rrbracket$ and the value it holds is then fetched by accessing the `value` field of

the `Some` constructor. Even though the entry that is read from the array is an option type (i.e. a `None` or a `Some`) we can access the `value` field because the interpretation of `value` is underspecified in SMT. If the entry is a `None`, the SMT solver can assign any interpretation to the `value` field. Hence, the `get` method on maps should only be called if the key is known to be present in the map, e.g. after calling `contains`. VeriF_x also features a safe variant, called `getOrElse`, which returns a default value if the key is not present.

Next, we explain how to encode the advanced map operations. Figure 12 defines the SMT encoding for all advanced map operations. The `keys` method on maps returns a set containing only the keys that are present in the map. Calls to `keys` on a map e_m of type $\text{Map} \langle K, V \rangle$ are compiled to a lambda which defines a set of keys k of the compiled key type $\llbracket K \rrbracket_t$ such that a key is present in the set iff it is present in the compiled map: $\llbracket e_m \rrbracket [k] \neq \text{None}(\llbracket V \rrbracket_t)()$. A predicate e_p of type $(K, V) \rightarrow \text{bool}$ holds for all elements of a map e_m of type $\text{Map} \langle K, V \rangle$ iff it holds for every key k that is present in the map and its associated value:

$$\underbrace{\llbracket e_m \rrbracket [k] \neq \text{None}(\llbracket V \rrbracket_t)()}_{e_m.\text{contains}(k)} \implies \underbrace{\llbracket e_p \rrbracket [k, \llbracket e_m \rrbracket [k].\text{value}]}_{e_p(k, e_m.\text{get}(k))}$$

Similarly, the `values` method returns a set with all values of the map. To this end, it defines an array containing all values for which at least one key exists that maps to that value.

A predicate e_p of type $(K, V) \rightarrow \text{bool}$ holds for at least one element of a map e_m of type $\text{Map} \langle K, V \rangle$ iff there exists a key k with associated value v that is present in the map and for which the predicate holds. Mapping a function e_f over the key-value pairs of a map e_m is encoded as a lambda that defines an array containing only the keys that are present in the compiled map $\llbracket e_m \rrbracket$ and whose values are the result of applying e_f on the original value, i.e. $\text{Some}(\llbracket e_f \rrbracket [k, \llbracket e_m \rrbracket [k].\text{value}])$. The `mapValues` method is similar except that it applies the provided function only on the value. A map e_m can be filtered using a predicate e_p such that the resulting map only contains key-value pairs that fulfill the predicate. Calls to `filter` are encoded as a lambda that defines an array containing only the key-value pairs that are in the compiled map:

$$\text{if} \left(\underbrace{\llbracket e_m \rrbracket [k] \neq \text{None}(\llbracket V \rrbracket_t)()}_{\text{in original map}} \wedge \underbrace{\llbracket e_p \rrbracket [k, \llbracket e_m \rrbracket [k].\text{value}]}_{\text{predicate holds}}, \right. \\ \left. \underbrace{\text{Some}(\llbracket e_m \rrbracket [k].\text{value})}_{\text{then keep the value}}, \underbrace{\text{None}(\llbracket V \rrbracket_t)()}_{\text{else not in the map}} \right)$$

To zip two maps e_{m_1} and e_{m_2} the compiler creates a lambda that defines an array containing only the keys that are present in both maps and the value is a tuple holding the corresponding values from both maps:

$$\text{Some}(\text{Tuple_ctor}(\llbracket e_{m_1} \rrbracket [k].\text{value}, \llbracket e_{m_2} \rrbracket [k].\text{value}))$$

To combine two maps e_{m_1} and e_{m_2} with a function e_f the compiler creates a lambda that defines an array containing all the keys from e_{m_1} and e_{m_2} . If a key is present in both maps their values are combined using the provided function e_f :

$$\text{Some}(\llbracket e_f \rrbracket [\llbracket e_{m_1} \rrbracket [k].\text{value}, \llbracket e_{m_2} \rrbracket [k].\text{value}])$$

If a key-value pair is present in only one of the maps it is also present in the new map. If a key is not present in e_{m_1} neither in e_{m_2} then it is also not present in the resulting map.

Vectors and Lists. The encoding of sets and maps is very useful to build new data structures in VeriF_x without having to encode them manually in SMT. For example, vectors and lists are implemented on top of maps. Internally, they map indices between 0 and $\text{size} - 1$

$$\begin{aligned}
\text{map}[e_m.\text{keys}()] &= \lambda(x : \llbracket K \rrbracket_t). \llbracket e_m \rrbracket [x] \neq \text{None}(\llbracket V \rrbracket_t)() \\
&\text{ where } \text{typeof}(e_m) = \text{Map}\langle K, V \rangle \\
\text{map}[e_m.\text{values}()] &= \lambda(x : \llbracket V \rrbracket_t). \exists(k : \llbracket K \rrbracket_t). \llbracket e_m \rrbracket [k] = \text{Some}(x) \\
&\text{ where } \text{typeof}(e_m) = \text{Map}\langle K, V \rangle \\
\text{map}[e_m.\text{bijective}()] &= \forall(k_1 : \llbracket K \rrbracket_t, k_2 : \llbracket K \rrbracket_t). \\
&\quad (k_1 \neq k_2 \wedge \llbracket e_m \rrbracket [k_1] \neq \text{None}(\llbracket V \rrbracket_t)() \wedge \llbracket e_m \rrbracket [k_2] \neq \text{None}(\llbracket V \rrbracket_t)()) \\
&\quad \implies \llbracket e_m \rrbracket [k_1] \neq \llbracket e_m \rrbracket [k_2] \\
&\text{ where } \text{typeof}(e_m) = \text{Map}\langle K, V \rangle \\
\text{map}[e_m.\text{forall}(e_p)] &= \forall(x : \llbracket K \rrbracket_t). \llbracket e_m \rrbracket [x] \neq \text{None}(\llbracket V \rrbracket_t)() \implies \llbracket e_p \rrbracket [x, \llbracket e_m \rrbracket [x].\text{value}] \\
&\text{ where } \text{typeof}(e_m) = \text{Map}\langle K, V \rangle \text{ and } \text{typeof}(e_p) = (K, V) \rightarrow \text{bool} \\

&\text{ where } \text{typeof}(e_{m_1}) = \text{Map}\langle K, V \rangle \text{ and } \text{typeof}(e_{m_2}) = \text{Map}\langle K, V \rangle \text{ and } \text{typeof}(e_f) = (V, V) \rightarrow V \\
\text{map}[e_m.\text{toSet}()] &= \lambda(x : \text{Tuple}\langle \llbracket K \rrbracket_t, \llbracket V \rrbracket_t \rangle). \llbracket e_m \rrbracket [x.\text{fst}] = \text{Some}(x.\text{snd}) \\
&\text{ where } \text{typeof}(e_m) = \text{Map}\langle K, V \rangle
\end{aligned}$$

■ **Figure 12** Compiling advanced map operations.

to their value, and provide a traditional interface on top (cf. Figure 4). Note that this encoding of vectors and lists on top of maps is only used when verifying proofs in SMT; when compiling to a target language (e.g. Scala or JavaScript), VeriF_x leverages the language’s built-in vector and list data structures.

C.4 Compilation Example

Figure 13 shows a concrete example of a polymorphic set implemented in VeriF_x and its compiled code in Core SMT. The *MSet* class defines a type parameter *V* corresponding to the type of elements it holds. It also contains one field *set* of type *Set*⟨*V*⟩ and defines a polymorphic method *map* that takes a function $f : V \rightarrow W$ and returns a new *MSet* that results from applying *f* on every element. The compiled Core SMT code defines an ADT *MSet* with one type parameter *V* and one constructor *MSet_ctor*. The constructor defines one field *set* of sort *Array*⟨*V*, *bool*⟩ which is the compiled sort for sets. In addition, a polymorphic *MSet_map* function is defined which takes two type parameters *V* and *W*

```

class MSet[V] (set: Set[V]) {
  def map[W] (f: V => W): MSet[W] =
    new MSet(this.set.map(f))
}

adt MSet⟨V⟩ { MSet_ctor(set : Array⟨V, bool⟩) }
fun MSet_map⟨V, W⟩(this : MSet⟨V⟩,
                  f : Array⟨V, W⟩) : MSet⟨W⟩ =
  MSet_ctor(
    λ(y : W).∃(x : V).this.set[x] ∧ f[x] = y)

```

(a) A polymorphic class in VeriF_x. (b) Compiled Core SMT code.

■ **Figure 13** Example of a polymorphic class in VeriF_x and the compiled Core SMT code.

which correspond to *MSet*'s type parameter and *map*'s type parameter respectively. The function takes two arguments, the object that receives the call and the function *f*. The function's body calls the *MSet* constructor with the result of mapping *f* over the set.

D Implementation and Verification of the Buggy Map CRDT

Section 6.1.1 reported on our experience implementing and verifying the buggy and corrected map CRDTs proposed by Kleppmann [40]. In this appendix, we explain the implementation and verification of the *buggy* map CRDT in detail using code examples. We also discuss the counterexample found by VeriF_x.

■ **Specification 2** The buggy map CRDT algorithm, taken from [40].

```

on initialisation do
  values := {}
end on

on request to read value for key k do
  if ∃t, v. (t, k, v) ∈ values then return v else return null
end on

on request to set key k to value v do
  t := newTimestamp()                                     ▷ globally unique, e.g. Lamport timestamp
  broadcast (set, t, k, v) by causal broadcast (including to self)
end on

on delivering (set, t, k, v) by causal broadcast do
  previous := {(t', k', v') ∈ values | k' = k}
  if previous = {} ∨ ∀(t', k', v') ∈ previous. t' < t then
    values := (values \ previous) ∪ {(t, k, v)}
  end if
end on

on request to delete key k do
  if ∃t, v. (t, k, v) ∈ values then
    broadcast (delete, t) by causal broadcast (including to self)
  end if
end on

on delivering (delete, t) by causal broadcast do
  values := {(t', k', v') ∈ values | t' ≠ t}
end on

```

D.1 Original Specification

The buggy map CRDT is a replicated dictionary storing key-value pairs where the values are regular values (i.e. no nested CRDTs). Specification 2 shows the specification of the buggy map CRDT. It defines a **read** operation to fetch the value associated with a certain

■ **Listing 10** Excerpt from the implementation of the buggy map CRDT in VeriF_x.

```

1  enum MapOp[K, V] { Put(k: K, v: V) | Delete(k: K) }
2  enum MapMsg[K, V] {
3    PutMsg(t: Clock, k: K, v: V) |
4    DeleteMsg(t: Clock, k: K) |
5    NopMsg()
6  }
7  class KMap[K, V](clock: Clock, values: Map[K, Tuple[Clock, V]])
8    extends CmRDT[MapOp[K, V], MapMsg[K, V], KMap[K, V]] {
9    def contains(k: K): Boolean = this.values.contains(k)
10   def get(k: K): V = this.values.get(k).snd
11
12   // Prepare phase for the "put" operation
13   // "put" corresponds to the "set" operation in the specification
14   def preparePut(k: K, v: V) = {
15     val t = this.clock
16     new PutMsg(t, k, v)
17   }
18   // Effect phase for incoming "put" messages
19   def put(t: Clock, k: K, v: V) = {
20     val newClock = this.clock.sync(t)
21     if (!this.values.contains(k) ||
22         this.values.get(k).fst.smaller(t))
23       new KMap(newClock, this.values.add(k, new Tuple(t, v)))
24     else
25       new KMap(newClock, this.values)
26   }
27
28   // Prepare phase for the "delete" operation
29   def prepareDelete(k: K) = {
30     if (this.values.contains(k)) {
31       val t = this.values.get(k).fst
32       new DeleteMsg[K, V](t, k)
33     }
34     else
35       new NopMsg[K, V]()
36   }
37   // Effect phase for incoming "delete" messages
38   def delete(t: Clock, k: K) = {
39     if (this.values.contains(k) && this.values.get(k).fst == t)
40       new KMap(this.clock, this.values.remove(k))
41     else
42       new KMap(this.clock, this.values)
43   }
44
45   override def equals(that: KMap[K, V]) =
46     this.values == that.values
47 }

```

key, and two update operations: `set` and `delete` which assign a value to a key, respectively, delete a certain key. Every operation consists of two parts, a prepare phase (denoted “on request”) that prepares a message to be broadcast to every replica (including itself), and an effect phase (denoted “on delivering”) that applies the incoming message. We briefly explain both update operations:

`set(k, v)`. When preparing a `set` operation that assigns a value v to a key k , the replica generates a new and globally unique timestamp t and broadcasts a `(set, t, k, v)` message. When receiving such a message, the replica checks if it already stores a value for this key. If this is not the case, or if the previous value has a smaller timestamp $t' < t$, then it assigns the incoming value v to the key k , thereby, overriding any previous value. On the other hand, if the previous value has a bigger timestamp, then the incoming `set` message is ignored and the previous value is kept.

`delete(k)`. When preparing a `delete` operation that deletes a key k , the replica fetches the timestamp t at which that key was inserted and broadcasts a `(delete, t)` message. Note that the key itself is not added to the message because `set` always inserts a single key with a unique timestamp, hence, the timestamp t uniquely identifies the key. When receiving a `(delete, t)` message, the replica removes the key that was inserted at timestamp t (if it is still present).

D.2 Implementation in VeriFx

Listing 10 shows the implementation of the buggy map CRDT in VeriFx. Every replica (i.e. every instance of the `KMap` class) maintains a local Lamport clock (consisting of a counter and a replica identifier) and keeps a dictionary that maps keys to timestamped values (i.e. a tuple containing a timestamp and a value). This implementation strategy is slightly different from Spec. 2 but more efficient because a dictionary allows for constant-time lookup, insertion, and deletion. We also extended the `DeleteMsg` such that it not only contains the timestamp t but also the key to be deleted (Line 4). This allows for an efficient implementation of `delete` since the replica knows which key to delete and does not have to loop over the map to find the key whose value has timestamp t .

We override equality - which by default is structural equality - because replicas have different Lamport clocks [43] as our implementation of the clocks keeps a unique replica identifier. Hence, two replicas are considered equal if they have the same values, independent of their clocks. We also renamed the `set` operation to `put`. The remainder of the implementation is a straightforward translation from the specification.

D.3 Verification in VeriFx

After implementing the buggy map CRDT in VeriFx we proceeded to the verification of the map. As explained in Section 6.1.1, VeriFx returned invalid counterexamples because it is not aware of the CRDT’s assumptions which are *implicit* in the design. For instance, VeriFx does not know that replicas have unique IDs nor does it know the relation between a replica’s clock and the values it observed. We need to encode these assumptions explicitly such that VeriFx does not consider cases that cannot occur in practice. To this end, we override the `reachable` and `compatible` predicates (cf. Section 5.1). The former defines which states are reachable (i.e. valid), while the latter defines which replicas are compatible.

Listing 11 shows the implementation of the `reachable` and `compatible` predicates. First, we define a state to be reachable iff every value has a unique timestamp (Line 3 to 6) and all values have a timestamp whose count is smaller than the replica’s local clock (Line 10).

■ Listing 11 Encoding the assumptions of the Map CRDT in VeriF_x.

```

1  override def reachable(): Boolean = {
2    // every value must have a unique timestamp
3    !(exists(k1: K, k2: K) {
4      k1 != k2 &&
5      this.values.get(k1).fst == this.values.get(k2).fst
6    }) &&
7    // All the values in the map must have a timestamp < than our local clock
8    // (since we sync our clock on incoming updates)
9    this.values.values().forall((entry: Tuple[Clock, V]) =>
10   entry.fst.counter < this.clock.counter)
11  }
12  private def noValueFromFuture(r1: KMap[K, V], r2: KMap[K, V]) {
13    r1.values.values().forall((entry: Tuple[Clock, V]) => {
14      val t = entry.fst
15      (t.replica == r2.clock.replica) =>:
16      (t.counter < r2.clock.counter)
17    })
18  }
19  override def compatible(that: KMap[K, V]) = {
20    // replicas have unique IDs
21    (this.clock.replica != that.clock.replica) &&
22    // we have no value from the future of the other replica
23    this.noValueFromFuture(this, that) &&
24    // the other did not observe a value from our future
25    this.noValueFromFuture(that, this) &&
26    // unique timestamps
27    !(exists(k1: K, k2: K) {
28      k1 != k2 && this.values.get(k1).fst == that.values.get(k2).fst
29    }) &&
30    // replicas cannot store different values for the same key and timestamp
31    !(exists(k: K) {
32      val thisTuple = this.values.get(k)
33      val thisTimestamp = thisTuple.fst
34      val thisValue = thisTuple.snd
35      val thatTuple = that.values.get(k)
36      val thatTimestamp = thatTuple.fst
37      val thatValue = thatTuple.snd
38      (thisTimestamp == thatTimestamp) && (thisValue != thatValue)
39    })
40  }

```

```

enum V { v0 | v2 }
enum K { k1 }
val s1 = KMap(Clock(1, 1), Map())
val s2 = KMap(Clock(2, 9), Map(k1 -> (Clock(4, 2), v2)))
val s3 = KMap(Clock(3, 3), Map(k1 -> (Clock(4, 2), v2)))
val x = Put(k1, v0) // operation generated by s1
// The prepare phase will broadcast the following message:
// s1.preparePut(k1, v0) = PutMsg(Clock(1, 1), k1, v0)
val y = Delete(k1) // operation generated by s2
// s2.prepareDelete(k1) = DeleteMsg(Clock(4, 2), k1)

```

(a) Simplified counterexample returned by VeriF_x.

(b) Visualization of the counterexample returned by VeriF_x.

■ **Figure 14** Counterexample for the buggy Map CRDT, found by VeriF_x.

The latter property follows from the fact that the dictionary is constructed by successive insertions and every insertion synchronizes the replica's clock with the timestamp of the inserted element.

Second, we define two replicas to be compatible iff:

- they have unique IDs (Line 21),
- they did not observe values with a timestamp that is bigger than the current clock of the replica that inserted that value (Line 23 to 25) because that would mean that some replica observed a value from the future of the origin replica which is not possible,
- they do not have the same timestamp for different keys (Line 27 to 29) because every insertion inserts a single key with a unique timestamp,
- for every key k for which they store the same timestamp t they also store the same value v (Line 31 to 39) because every timestamp uniquely identifies one insertion: $\text{PutMsg}(t, k, v)$.

Clearly, the above assumptions are not straightforward and are in fact implicit in the original specification, but are nevertheless vital to the correctness of the algorithm. In practice, many CRDTs make similar implicit assumptions which is the reason they are complex and difficult to get right.

Counterexample. After defining all assumptions described above, VeriF_x found a valid counterexample which is shown in Figure 14a. We simplified the counterexample by renaming the keys and values and removing those that do not affect the outcome. The counterexample is equivalent to the one that was found manually by Nair (cf. [40]). It consists of a corner case in which the `Put` and `Delete` operations do not commute and thus may cause replicas to diverge.

Recall that a counterexample is a mapping from variables (defined by the proof) to values that break the proof. In this case, the `CmRDTProof2` trait (cf. Section 5.1) that was used to check commutativity of the operations, defines three variables `s1`, `s2`, and `s3` representing

the state of the replicas, and two variables $x = \text{Put}(k_1, v_0)$ and $y = \text{Delete}(k_1)$ representing concurrent operations that were generated by replica s_1 and s_2 respectively. These replicas first prepare a message for the operations (respectively, $\text{PutMsg}(\text{Clock}(1, 1), k_1, v_0)$) and $\text{DeleteMsg}(\text{Clock}(4, 2), k_1)$) and broadcast those messages to every replica. Every replica receives these messages, possibly in a different order, and applies them.

Depending on the order in which replica s_3 applies the operations, the outcome is different. This is visualized in Figure 14b. If s_3 first processes the $\text{DeleteMsg}(\text{Clock}(4, 2), k_1)$ message then key k_1 is gone because the stored timestamp matches the timestamp that was requested to delete. Afterwards, when processing the $\text{PutMsg}(\text{Clock}(1, 1), k_1, v_0)$ message, the replica will add key k_1 with value v_0 . When applying the operations the other way around, the outcome is different because the $\text{PutMsg}(\text{Clock}(1, 1), k_1, v_0)$ message is ignored since its timestamp is smaller than the timestamp s_3 currently stores for that key: $\text{Clock}(1, 1) < \text{Clock}(4, 2)$. Later, when processing the $\text{DeleteMsg}(\text{Clock}(4, 2), k_1)$ message, s_3 effectively deletes key k_1 because the timestamp matches the one that is stored. Thus, after the first execution, the resulting state contains key k_1 , whereas, after the second execution, k_1 is not present in the map. This explains the divergence bug.

E Verification of the MWS Set

Specification 3 describes the MWS Set, which associates a count to every element. An element is considered in the set if its count is strictly positive. `remove` decreases the element's count, while `add` increments the count by the amount that is needed to make it positive (or by 1 if it is already positive). Listing 12 shows the implementation of the MWS Set in VeriF_x as a polymorphic class that extends the `CmRDT` trait (cf. Section 5.1.3). The type arguments passed to `CmRDT` correspond to the supported operations (`SetOps`), the messages that are exchanged (`SetMsgs`), and the CRDT type itself (`MWSSet`). The `SetOp` enumeration defines two types of operations: `Add(e)` and `Remove(e)`.

The `MWSSet` class has a field, called `elements`, that maps elements to their count (Line 3). Like all op-based CRDTs, the `MWSSet` implements two methods: `prepare` and `effect`. The `prepare` method pattern matches on the operation and delegates it to the corresponding source method which prepares a `SetMsg` to be broadcast to all replicas. The class overrides the `enabledSrc` method to implement the source precondition on `remove`, as defined by Spec. 3. When replicas receive incoming messages, they are processed by the `effect` method which delegates them to the corresponding downstream method which performs the actual update. For example, the `removeDownstream` method processes incoming `RmvMsgs` by decreasing some count k' by 1. Unfortunately, k' is undefined in Spec. 3.

We believe that k' is either defined by the source replica and included in the propagated message (Spec. 4), or, k' is defined as the element's count at the downstream replica (Spec. 5). We implemented both possibilities in VeriF_x (Listings 13 and 14) and verified them to find out which one, if any, is correct. To this end, the companion object of the `MWSSet` class (cf. Line 26 in Listing 12) extends the `CmRDTProof1` trait (cf. Section 5.1.3), passing along three type arguments: the type of operations `SetOp`, the type of messages being exchanged `SetMsg`, and the CRDT type constructor `MWSSet`. The object extends the `CmRDTProof1` trait since the `MWSSet` class is polymorphic and expects one type argument. When executing the proof inherited by the companion object, VeriF_x automatically proves that the possibility implemented by Listing 14 is correct and that the one of Listing 13 is wrong. We thus successfully completed the MWS Set implementation using VeriF_x's integrated verification capabilities.

On Leveraging Tests to Infer Nullable Annotations

Jens Dietrich

Abstract

Issues related to the dereferencing of null pointers are a pervasive and widely studied problem, and numerous static analyses have been proposed for this purpose. These are typically based on dataflow analysis, and take advantage of annotations indicating whether a type is nullable or not. The presence of such annotations can significantly improve the accuracy of null checkers. However, most code found in the wild is not annotated, and tools must fall back on default assumptions, leading to both false positives and false negatives. Manually annotating code is a laborious task and requires deep knowledge of how a program interacts with clients and components.

We propose to infer nullable annotations from an analysis of existing test cases. For this purpose, we execute instrumented tests and capture nullable API interactions. Those recorded interactions are then refined (sanitised and propagated) in order to improve their precision and recall. We evaluate our approach on seven projects from the spring ecosystems and two google projects which have been extensively manually annotated with thousands of `@Nullable` annotations. We find that our approach has a high precision, and can find around half of the existing `@Nullable` annotations. This suggests that the method proposed is useful to mechanise a significant part of the very labour-intensive annotation task.

1 Introduction

Null-pointer related issues are one of the most common sources of program crashes. Much research has focused on this issue, including: eliminating the problems of `null` in new language designs [55, 48, 51, 58]; mitigating the impact of `null` in existing programs [23, 66, 5, 19]; and, developing alternatives for languages stuck with `null` [20, 29, 67].

More recently, several industrial-strength static analyses have been developed to operate at scale, such as *infer* / *nullsafe* [1, 19] and *nullaway* [5]. Such tools employ some form of dataflow analysis and take advantage of an extended type system that distinguishes in some way between nullable and nonnull types [23]. Here, a nonnull type is considered a subtype of a nullable type, and this relationship enables checkers to identify illegal assignments pointing to potential runtime issues. In Java, the standard annotation mechanism can be

10:2 On Leveraging Tests to Infer Nullable Annotations

used to define such custom *pluggable* types [9]. For instance, using an annotation defined in JSR305 (i.e., the `javax.annotation` namespace), we can distinguish between the two types `Nullable String` and `Nonnull String`, with `Nonnull String` being a subtype of `Nullable String`. In a perfect world, developers would annotate all methods and fields, allowing static checkers to perform analyses with high recall and precision. Not surprisingly, this hasn't happened. Annotating code is generally a complex problem [13], and recent developer discussions reflect this. For instance, for *commons-lang* the issue LANG-1598 has been open since 14 August 20.¹ In a comment on this issue one developer commented “Agreed this idea, but it is a HUGE work if we want to add `NotNull` and `Nullable` to all public functions in *commons-lang*.” A similar comment can be found in a discussion on adding null-safety annotations to *spring boot* (“it may well be a lot of work”).²

Null-related annotations form part of a contract between the provider and consumer of an API. For instance, consider a library that provides some class `Foo` with a method `String foo()`. Adding an annotation may change this to `Nullable String foo()`. This alters the contract with downstream clients which may have assumed the return was not nullable. Technically this change weakens the postcondition, thus violating Liskov's Substitution Principle (LSP) [41].³ This may therefore cause breaking changes, forcing clients to refactor, for instance, by guarding call sites to protect against null pointer exceptions. Such a change may imply the downstream client was using the API incorrectly (i.e. by assuming `null` could not be returned). As such, one might argue the downstream client is simply at fault here and this change helps expose this. But, such situations arise commonly and oftentimes for legitimate reasons: perhaps the downstream client uses the API in such a way that, in fact, `null` can never be returned; or, the method in question only returns `null` in very rare circumstances which weren't triggered despite extensive testing by the downstream client. Regardless, developers must gauge the impact of such decisions carefully when modifying APIs. This illustrates the complexity of the task, and suggests that it is laborious and therefore expensive to add nullability-related annotations to projects.

Null checkers deal with missing annotations by using defaults to fill in the blanks. Those assumptions have a direct impact on recall and precision. The question arises whether suitable annotations can be inferred by other means.⁴ Indeed, some simple analyses could be used here in principle, such as harvesting existing runtime contract checks. Using such checks is increasingly common as programmers opt to implement defensive APIs in order to reduce maintenance costs [17]. This includes the use of contract APIs such as *guava's Preconditions*⁵, *commons-lang3's Validate*⁶, *spring's Assert*⁷ and the standard library `Objects::requireNonNull` protocol which all include non-null checks. Such an analysis could boost the accuracy of static null checkers that integrate with the compiler, as those contract APIs are defined in libraries that are usually outside the scope of the analysis performed by static checkers. However, exploiting the call sites of such methods is of limited benefit as those checks would only establish that a reference *must not be null*.

¹ Open as of 20 October 22, see <https://issues.apache.org/jira/browse/LANG-1598>

² <https://github.com/spring-projects/spring-boot/issues/10712>

³ LSP was formulated for safe subtyping, but can be applied in this context if we consider evolution as replacement

⁴ Other here means not using the same technique used by static checkers. One could argue that if a static dataflow analysis was used to infer annotations, then that should be integrated into the checker in the first place

⁵ <https://guava.dev/releases/21.0/api/docs/com/google/common/base/Preconditions.html>

⁶ <https://commons.apache.org/proper/commons-lang/apidocs/org/apache/commons/lang3/Validate.html>

⁷ <https://docs.spring.io/spring-framework/docs/current/javadoc-api/org/springframework/util/Assert.html>

It is much more beneficial for static checkers to annotate code indicating that a reference *may be null* (i.e., “*is nullable*”). The reason is that many static checkers use the *non-null-by-default* assumption that was suggested by Chalin and James after studying real-world systems and finding the vast majority of reference type declarations are not null, making this a sensible choice to reduce the annotation burden for developers [14]. They also point out that this is consistent with default choices in some other languages. The *checkerframework* and *infer* nullness checkers are based on this assumption, whilst some other null checkers such as the one embedded in the Eclipse IDE can be configured as such. Sometime, this is formalised. For instance, the *spring framework* makes the use of the *non-null-by-default* assumption explicit by defining and using two package annotations⁸ `@NonNullApi` and `@NonNullFields` in `org.springframework.lang`, with the following semantics (`@NonNullApi`, similar for `@NonNullFields` for fields): “*A common Spring annotation to declare that parameters and return values are to be considered as non-nullable by default for a given package*”.⁹

Using dynamic techniques is a suitable approach to observe nullability, and can be combined with static analyses to improve accuracy. Such hybrid techniques consisting of a dynamic pre-analysis feeding into a static analysis have been used very successfully in other areas of program analysis [7, 31]. A common reason to use those approaches is to boost recall [65].

In this paper, we explore this idea of inferring nullable annotations from test executions. This is based on the assumption that tests are a good (although imperfect) representation of the intended semantics of a program. We then refine those annotations by means of various static analyses in order to reduce the number of both false positives and false negatives.

Our analysis is *sound* in the sense that it will not infer or add `@NonNull` to a method or field where it may become inconsistent with the runtime behaviour of the program. It is *conservative* in the sense that it will never retract `@Nullable` annotations added by developers.

This paper makes the following contributions:

1. **a dynamic analysis** to capture nullable API interactions representing potential `@Nullable` annotations (“nullability issues”) from program executions,
2. **a set of static analyses (“sanitisation”)** to identify false positives
3. **a static analysis (“propagation”)** to infer additional nullability issues from existing issues
4. **a method to mechanically add the annotations inferred** into projects by manipulating the respective abstract syntax trees (ASTs)
5. **an experiment** evaluating how the annotations we infer compare to existing `@Nullable` annotations of seven projects in the spring framework ecosystem and two additional google projects, containing some of the most widely used components in the Java ecosystem
6. **an open source implementation** of the methods and algorithms proposed, available from <https://github.com/jensdietrich/null-annotation-inference>

These contributions directly relate to concrete research questions which we study in the context of evaluation experiments in Section 7.

Our approach meets the expectations of engineers for tools with high precision [6, 59], and has clear economic benefits – it can partially automate the expensive task of manually annotating code. At the time of writing, some of the results produced by our tool have already been adapted into *spring* and *guava*.

⁸ I.e., annotation used in `package-info.java`

⁹ <https://docs.spring.io/spring-framework/docs/current/javadoc-api/org/springframework/lang/NonNullApi.html>

10:4 On Leveraging Tests to Infer Nullable Annotations

The paper is organised as follows. Starting with the introduction in this section, we provide a high-level overview of our approach in Section 2. This is followed by a more detailed discussion of the major steps of our method: the capture of potential nullability issues from the execution of instrumented tests (Section 3), the removal of likely false positives through *sanitisation* (Section 4), and inference of additional issues to address false negatives through *propagation* (Section 5). We then briefly discuss a utility to inject the annotations our tool infers back into programs in Section 6, and present evaluation experiments in Section 7. This includes the formulation of four research questions in Section 7.3. Finally, we discuss related work in Section 8, and finish with a brief conclusion in Section 9.

2 Approach

Our approach consists of the following steps and the construction of a respective processing pipeline:

1. **Capture:** The execution of an instrumented program and the recording of *nullability issues*, i.e. uses of `null` in method parameters, returns and fields.
2. **Refinement:** The refinement of nullability issues captured using several light-weight static analyses.
 - a. **Sanitisation:** The identification and removal of nullability issues captured that may not be suitable to infer `@Nullable` annotations to be added to the program, therefore eliminating potential false positives.
 - b. **LSP Propagation:** The inference of additional nullability issues to comply with Liskov’s Substitution Principle [41], therefore addressing potential false negatives.
3. **Annotation:** the mechanical injection of captured and inferred annotations into projects.

These steps are described in detail in the following sections.

3 Capture

3.1 Driver Selection

A dynamic analysis can be used to observe an executing program, and to record when `null` is used in APIs that can then be annotated. The question arises which driver to use to exercise the program. One option is to use existing tests, assuming they are representative of the expected and intended program behaviour.

If libraries are analysed there is another option – to use the tests of *downstream clients*. This approach has been shown to be promising recently to identify breaking changes in evolving libraries [46]. The advantage is that clients can be identified mechanically using an analysis of dependency graphs exposed by package managers and the respective repositories.¹⁰ However, this raises the question which clients to use. Using an open world assumption to include all visible clients (i.e., excluding clients not in public repositories) is practically impossible given the high number of projects using commodity libraries like the ones we have in our dataset. There is no established criteria of how to select *representative* clients.

¹⁰Note that this requires the analysis of incoming dependencies, which is not as straightforward as the analysis of outgoing dependencies (which can simply use the maven dependency plugin) and requires some manual analysis, web site scraping or use of third-party repository snapshots such as *libraries.io*

In principle, synthesised tests [53, 28] could also be used. However, they expose *possible*, but not necessarily *intended* program behaviour. Using synthesised tests would therefore likely result in too many `@Nullable` annotations being inferred. We note that some manually written tests may have the same issue. We will address this in Section 4.2.

In the approach presented here we opted to use only a project’s own tests for generating actual annotations.

3.2 Instrumentation

In order to instrument tests, Java agents were implemented to record uses of `null` in APIs during the execution of tests. These agents can be deployed by modifying the (Maven or Gradle) build script of the project under analysis. The agents intercept code executions using the following six rules which check for occurrence of null references during program execution, and record those occurrences:

ARG at method entries, parameter values are checked for `null`

RET at method exits, return values are checked for `null`

FL1 at constructor (`<init>`) exits, reflection is used to check non-static fields for `null`

FL2 at non-static field writes (i.e. the `putfield` bytecode instruction), the value to be set is checked for `null`

SFL1 at class initialiser (`<clinit>`) exits, reflection is used to check static fields for `null`

SFL2 at static field writes (i.e. the `putstatic` bytecode instruction), the value to be set is checked for `null`

We have implemented agents implementing those rules using a combination of *asm* [11] and *bytebuddy* [70]. If `null` is encountered, *nullability issues* are created and made persistent (written to disk).

Instrumentation can be restricted to certain (project-specific) packages, a system variable is used to set a package prefix for this purpose. This is to filter out relevant issues early as the amount of data collected is significant (see results in Table 2, column 3).

3.3 Capturing Context

A nullability issue is identified by the position of the nullable API element (return type or argument index), and the coordinates (class name, method name, descriptor) of the respective method or field. We are also interested to capture and record the execution context for several reasons:

1. to record sufficient information providing provenance about the execution, sufficient for an engineer who has to decide whether to add a `@Nullable` annotation or not
2. related to the previous item, the number of contexts in which a nullable issue has been observed may itself serve as a quality indicator for the issue – more observed contexts provide some support for this being an issue (instead of a single tests triggering “unintended” program behaviour)
3. to distinguish issues detected by running a project’s own tests from issues detected by running client tests
4. to facilitate the sanitisation of issues, with some sanitisation techniques analysing the execution context.

In order to achieve this, we record the stack during capture. From the stack, we can then infer the *trigger*, i.e. the test method leading to the issue. The following algorithm is used to remove noise from the captured stack and identify the trigger:

10:6 On Leveraging Tests to Infer Nullable Annotations

1. the invocation of `java.lang.Thread::getStackTrace` triggering the stacktrace capture is removed from the stacktrace
2. all elements related to the instrumentation are removed
3. elements related to test processing (*surefire*, *junit*), reflection and other JDK-internal functionality are removed based on the package names of the respective classes owning those methods ¹¹
4. the last element in the stacktrace is set to be the trigger

3.4 Example

Listing 1 shows an issue captured running a test in *spring-core* and serialized using JSON. The test (trigger) is `ConcurrentReferenceHashMapTests::shouldGetSize`, it uses the `Map::put` API implemented in `ConcurrentReferenceHashMap`, which leads to `put` returning `null`.

■ **Listing 1** A serialised nullability issue captured in *spring-core* (for better readability `org.springframework.util` is replaced by `$$`).

```
1 {
2   "className": "$$.ConcurrentReferenceHashMap",
3   "methodName": "put",
4   "descriptor": "(Ljava/lang/Object;Ljava/lang/Object;Z)Ljava/lang/Object;",
5   "kind": "RETURN_VALUE",
6   "argsIndex": -1,
7   "stacktrace": [
8     "$$.ConcurrentReferenceHashMap::put:282",
9     "$$.ConcurrentReferenceHashMap::put:271",
10    "$$.ConcurrentReferenceHashMapTests::shouldGetSize:331"
11  ]
12 }
```

3.5 Deduplication

When issues are captured, it is common that several versions of the same issue are being reported. For instance, there might be two nullability issues reported for the return type of the same method in the same class, but triggered by different tests, and therefore with different stack traces. Throughout the paper, only deduplicated (aggregated) issue counts are reported unless mentioned otherwise. The raw issues might still be of interest as they differ with respect to their provenance, which might be important for a developer reviewing issues.

3.6 Limitations

Our approach does not support generic types. For instance, consider a method returning `List<String>`. In order to establish that the list may contain `Nullable` strings the analysis would need to traverse the object graph of the list object using reflection or some similar method, in order to check that some elements of the list are (or in general some referenced objects associated with the type parameters) are nullable. This is generally not scalable.

Secondly, there are dynamic programming techniques that may bypass the instrumentation. This is in particular the case if reflective field access is used, either directly using reflection, or via deserialisation. This is a known problem, however, reflective field access is rare in practice [65].

¹¹ More specifically, we consider methods in packages starting with the following prefixes as noise: `java.lang.reflect.`, `org.apache.maven.surefire`, `org.junit.`, `junit.`, `jdk.internal`.

4 Sanitisation

4.1 Scope Sanitisation

When exercising code using instrumented tests, potential issues are captured and recorded for all classes including classes defined in dependencies, system and project classes. By setting project-specific namespace (package) prefixes, the analysis can be restricted to project-defined classes only as discussed in Section 3.2. However, this still does not distinguish between classes used at runtime (in Maven and Gradle, this is referred to as the *main* scope), and classes only to be used during testing (the *test* scope). Engineers may not see the need to annotate test code, and a static null checker would usually be configured to ignore test code as its purpose is to predict runtime behaviour such as potential null dereferences resulting in runtime exception.

The analysis to filter out classes not defined in main scope is straightforward: scopes are encoded in the project directory structure if build systems like Maven and Gradle are used. Those build systems and the associated project structures are the defacto-standards used in Java projects [2]. For instance, *spring* uses Gradle, and the compiled classes in main scope can be found in `build/classes/java/main`. The main scope sanitiser simply removes issues in classes not found in this folder.

4.2 Negative Test Sanitisation

The code in Listing 2 from the *spring-core* project is an example of a defensive API practice in `org.springframework.util.Assert`. A runtime exception is used to signal a violated pre-condition, a null parameter in this case. The exception (`IllegalArgumentException`) is thrown in the `Assert::notNull` utility method. While a null pointer exception is also a runtime exception, throwing an `IllegalArgumentException` here is more meaningful as this is (expected to be) thrown by the application, not by the JVM, and clearly communicates to clients that this is a problem caused by how an API is used, as opposed to an exception caused by a bug within the library.

■ **Listing 2** A defensive API in *spring-core*, `org.springframework.util.Assert::isInstanceOf`.

```
1 public static void isInstanceOf(Class<?> type, @Nullable Object obj, String message) {
2     assertNotNull(type, "Type to check against must not be null");
3     ..
4 }
```

This contract is then tested in `org.springframework.util.AssertTests::isInstanceOfWithNullType`, shown in Listing 3.

■ **Listing 3** Testing a defensive API in *spring-core* with JUnit5.

```
1 @Test void isInstanceOfWithNullType() {
2     assertThrows(IllegalArgumentException.class, () -> Assert.isInstanceOf(
3         null, "foo", "enigma")
4     ).withMessageContaining(..);
5 }
```

We refer to such tests as *negative tests* – i.e. tests that exercise abnormal and unintended but possible behaviour, and use an exception or error as the test oracle for this purpose. Features often used to implement such tests are the `assertThrows` method in JUnit5, and the `expected` attribute of the `@Test` annotation in JUnit4.

Including such tests (as drivers) is likely to result in false positives – nulls are passed to the test to trigger defense mechanisms, such as runtime checks. We therefore excluded issues triggered by such tests. This is done by a lightweight ASM-based static analysis that checks

10:8 On Leveraging Tests to Infer Nullable Annotations

for the annotations and call sites indicating the presence of an exception oracle and produces a list of negative tests, and a second analysis that cross-references the context information captured while recording issues against this list, and removes issues triggered by negative tests.

The analysis checks for the above-mentioned negative test patterns in JUnit4 and JUnit5, and a similar pattern in the popular *assertj* library. We also check for call sites for the JUnit4 and JUnit5 `fail` methods in `try` blocks, usually indicating that tests pass if they enter the corresponding `catch` block. Finally, the analysis looks for call sites of methods in `com.google.common.testing.NullPointerTester`. This is a utility that uses reflection to call methods with null for parameters not marked as nullable, expecting a NPE or an `UnsupportedOperationException` being thrown. This may be considered as over-fitting as *guava* is also part of our data set used for evaluation. However, like JUnit, *guava* is a widely used utility library, which warrants supporting this features in a generic tool.

4.3 Shaded Dependency Sanitisation

Shading is a common practice where library classes and often entire package or even libraries are inlined, i.e. copied into the project and relocated into new name spaces. A common use case is to avoid classpath conflicts when multiple versions of the same class are (expected to be) present in a project [69].

For instance, the return type of `org.springframework.asm.ClassVisitor::visitMethod` is not annotated as nullable. The problem here is that *spring-core* also defines several subclasses of this class overriding the method (including `SimpleAnnotationMetadataReadingVisitor`, package name omitted for brevity), which mark the return type as nullable. Reading this as pluggable types with the non-null by default assumption, with `@Nullable MethodVisitor` being a subtype of `MethodVisitor`, this violates Liskov's substitution principle [41] as the postcondition of a non-null return value is weakened in the overriding method. The reason that engineers wont add the annotation is that this class originates from a shaded dependency.¹² This is usually not done manually, but automated using build plugins such as Maven's *shade plugin*¹³. The respective section of the Gradle build script for *spring-core* is shown in Listing 4.

■ **Listing 4** Shading spec in *spring-corespring-core.gradle*.

```
1 task cglibRepackJar(type: ShadowJar) {
2   archiveBaseName.set('spring-cglib-repack')
3   archiveVersion.set(cglibVersion)
4   configurations = [project.configurations.cglib]
5   relocate 'net.sf.cglib', 'org.springframework.cglib'
6   relocate 'org.objectweb.asm', 'org.springframework.asm'
7 }
```

This makes adding `@Nullable` annotations for those classes unattractive – any developer effort to add them is wasted as the source code is replaced during each build, and modern projects are rebuilt often, sometimes multiple times a day. A possible solution would be to add annotations during code generation at build time, but to the best of our knowledge, there are no suitable tools or meta programming techniques readily available to engineers that could be used for this purpose.

Another option would be to add the annotation to the respective method provided by the shaded library, however, engineers are usually not in a position to make such a change.

A sanitiser to take this into account takes a list of packages corresponding to shaded classes as input, and removes issues detected within those classes.

¹² See <https://github.com/spring-projects/spring-framework/pull/28852> for discussion

¹³ <https://maven.apache.org/plugins/maven-shade-plugin/>

4.4 Deprecation Sanitisation

The final sanitiser removes issues collected from deprecated (i.e., annotated with `@java.lang.Deprecated`) fields, methods or classes. The rationale is that given the significant cost of annotating code, engineers might be reluctant to add annotations to code scheduled for removal, and will consider the inference of such annotations less useful. Such a sanitiser can be implemented with a straightforward byte code analysis as `@Deprecated` annotations are retained in byte code. We used *asm* for this purpose in our implementation.

5 Propagation

Annotating an API with `@Nullable` annotations changes the expectations and guarantees of the API contract with clients. In terms of Liskov’s Substitution principle (LSP), adding `@Nullable` to a method (i.e., to the type it returns) weakens its postconditions if we consider `@NonNull` to be the baseline. To preserve LSP, a non-null return type must not be made nullable in a overriding method.

For nullable arguments, the direction changes: while overriding a method making arguments nullable complies to LSP as expectations (for callers) are weakened, nullable arguments must not be made non-null in overridden methods. If we assume `@NonNull` to be the default, this implies that `@Nullable` should also be applied to the arguments of the overriding method. However, the standard Java language semantics only supports covariant return types (e.g., methods can be overridden using a more specific return type), while for argument types invariance is used. Different null checkers and other languages use a variety of approaches here [13] and it is not completely clear what the canonical approach should be. Therefore, in our proof-of-concept implementation, LSP propagation can be customised to propagate nullability for arguments, or not, with propagation being the default strategy.

Listing 5 illustrates our approach. Assume we have annotated `B::foo` using observations from instrumented test runs. Then we also have to add `@Nullable` to the return type of the overridden method `A::foo`, and (if argument propagation is enabled) to the sole argument of the overriding method `C::foo`.

Listing 5 Propagation of `@Nullable` to Sub- and Supertypes.

```
1 public class A {
2     public @Nullable Object foo (Object arg) ;
3 }
4 public class B extends A {
5     public @Nullable Object foo (@Nullable Object arg) ;
6 }
7 public class C extends B {
8     public Object foo (@Nullable Object arg) ;
9 }
```

LSP propagation is implemented using a lightweight ASM-based analysis that extracts overrides relationships from compiled classes, and cross-references with with captured issues, creating new issues. For provenance, references to the original parent issues leading to inferred issues are captured as well and stored alongside the (JSON-serialised) inferred issues as a *parent* attribute.

5.1 Limitations

There is a limitation to hierarchy-based propagation – subtype relationships may extend across libraries, and we may infer nullable annotations for classes that are not in the scope of the analysis, and cannot be refactored. While project owners know super types (and can use methods like opening issues or creating pull requests for projects we don’t control), they

10:10 On Leveraging Tests to Infer Nullable Annotations

are not in control of subtypes in an open world, and rely that downstream projects would eventually pick up those annotations through notifications from some static analyses tools checking for those issues.

5.2 Sanitisation vs Propagation Fixpoint

Sanitisation and propagation have opposite effects. Preferably, an algorithm used to refine the initially collected nullability issues would reach a unique fix point where the future application of sanitisation and propagation would not change the set of refined nullability issues. However, such a fixpoint does not exist. Consider for instance a scenario where a shaded class has a method that is overridden and has a nullable return type in the overriding method. Then LSP propagation suggests to also add this to the return of the overridden method in the super class (to avoid weakening the post conditions), while sanitisation suggests not to refactor the shaded class. This is the issue we have observed in *spring-core* and discussed in Section 4.3.

6 Annotation Injection

We implemented a tool to inject the inferred annotations into projects, using the following steps:

1. compilation units are parsed into ASTs using the *javaparser* API [62]
2. for each nullable issue, the respective method arguments, returns or fields are annotated by adding nodes representing the `@Nullable` annotation to the respective AST
3. after the AST for a compilation unit is processed, it is written out as a Java source code file
4. if necessary, the respective import for the nullable annotation type used is added to the `pom.xml` project file

The tool has been evaluated using standard JUnit unit tests, and by round-tripping (removing and then reinserting existing annotations) the spring projects studied.

There are different annotation libraries available defining nullable annotations, and static checkers often support multiple such annotations. For this reason, the annotator tool supports pluggable annotations. This abstraction is implemented as a `NullableAnnotationProvider` service, implementations provide the nullable type and package names, and the coordinates of an Maven artifact providing the respective annotation. The default implementation is based on JSR305. Alternative providers can be deployed using the standard Java service loader mechanism.

7 Evaluation

Our evaluation is based on a study of some of the popular real-world projects which have been manually null-annotated by project members. We compare those existing annotations with the annotations captured and inferred by our method, and check those two sets for consistency. This is done by measuring *precision* and *recall*. Informally, those measures represent the ratio of inferred annotations to existing annotations, and the percentage of existing annotations our method is able to infer. More precisely, given a set of existing nullable annotations *Existing* and a set of annotations inferred using our method *Inferred*, we define the following metrics:

$$\begin{aligned}
TP &:= Existing \cap Inferred \\
FP &:= Inferred \setminus Existing \\
FN &:= Existing \setminus Inferred \\
precision &:= |TP| / (|TP| + |FP|) \\
recall &:= |TP| / (|TP| + |FN|)
\end{aligned}$$

Those are standard definitions, however, they need to be used with caution here. The concepts suggest that the existing annotations are *the ground truth*. This hinges on two assumptions:

1. The existing annotations are complete.
2. The project test cases provide enough coverage to exercise all possible nullable behaviour.

The first assumption means that all existing nullable annotations our method fails to infer are in fact false positives. This might not be true as the annotations may not be complete, and we explore this issue further in Section 7.8. Therefore, the precision reported needs to be understood as the *lower precision bound (lpb)* in the sense of false positive detection. The second assumption means that all existing issues our tool cannot detect are false negatives. While this is correct in some sense, it does not necessarily indicate a weakness of our method as such, rather than an issue of the quality of input data, i.e. the quality of tests.

Existing annotations are extracted by using a simple byte code analysis (noting that common nullable annotation use runtime retention), we are looking for `@Nullable` annotations in any package to account for the multiple annotation providers. We also support two semantically closely related annotations defined in widely used utility libraries or tools, *guava's* `@ParametricNullness` and *findbug's* `@CheckForNull`.

7.1 Dataset

The data set we use in our study consists of seven projects (modules) from the *spring framework* ecosystem, plus two additional google projects. Those projects were located by searching the Maven repository for projects using libraries providing `@Nullable` annotations, and the selecting projects that actually use a significant number of those annotations. The reason that we chose this method was that we wanted to use existing annotations as (an approximation of) the ground truth to evaluate the inferred annotations. We were particularly looking for projects backed by large engineering teams and well-resourced organisations, assuming that this would result in high-quality annotations.

Spring is the dominating framework for enterprise computing in Java [68], it is supported by a large developer community, is almost 20 years old and keeps on maintaining and innovating its code base. What makes those projects particularly suitable for evaluation is the fact that they have been manually annotated with `@Nullable` annotations. Spring defines its own annotation for this purpose in *spring-core*¹⁴. The amount of annotations found in those projects is extensive, see Section 7.4 for details. Spring uses gradle as build system.

Spring is organised in modules, projects with their own build scripts producing independent deployable binaries. We selected seven projects with different characteristics in particular with respect to how APIs are provided or consumed: *core*, *beans* and *context* are foundational projects for the spring framework overall, with few dependencies. *orm* and *oxm* are middleware

¹⁴ Defined in in `org.springframework.lang`

10:12 On Leveraging Tests to Infer Nullable Annotations

■ **Table 1** project summary, reporting the number of Java, Kotlin and Groovy source code files for both main and test scope, and branch coverage.

program	version	main			test			coverage
		java	kotlin	groovy	java	kotlin	groovy	
s.-beans	5.3.22	301	2	1	126	4	0	60%
s.-context	5.3.22	640	5	0	483	7	2	63%
s.-core	5.3.22	499	1	0	214	14	0	66%
s.-orm	5.3.22	72	0	0	32	0	0	39%
s.-oxm	5.3.22	31	0	0	19	0	0	58%
s.-web	5.3.22	653	1	0	268	5	0	18%
s.-webmvc	5.3.22	368	3	0	225	5	0	39%
guava	31.1	619	0	0	502	0	0	70%
error-prone	2.18.0	745	0	0	1,222	0	0	73%

components for applications to interact with XML data and relational databases, and integrate with existing frameworks for this purpose like *hibernate*, *jpa* and *jaxb*. Finally, *web* is a utility library for web programming (including an HTTP client), and *webmvc* is a comprehensive application framework based on the model-view-controller design pattern [30].

We also include two additional non-spring programs to demonstrate the generality of the method proposed, and avoid over-fitting for spring. Those are *guava* and *error-prone*, both by google. *Guava* is a very popular utility library, whereas *error-prone* is a code analysis utility, similar to *findbugs*. Those two projects use Maven as build system, and have a modular structure, with some modules only containing tests, test tools or annotations. We analysed nullability for the *errorprone/core* and *guava/guava* modules, respectively.

Table 1 provides an overview of the data set used together with some metrics, broken down by scope as discussed in Section 4.1. While those projects predominately contain Java classes, they also contain a smaller amount of Kotlin and Groovy code. Most of this are tests, and as the capture is based on bytecode instrumentation, those tests are still being used as drivers for the dynamic analysis. The table also contains some coverage data.¹⁵ This provides some indication that the projects detected are well tested, and provide reasonable drivers for a dynamic analysis. The coverage data compares favourably to the coverage observed for typical Java programs [18].

7.2 Capture

For the dynamic analysis, we used the agents described in Section 3. With those agents deployed in the build scripts, ground truth extraction is a matter of running the projects builds using the test targets. The agents collect large amounts of data. For instance, the raw uncompressed size of the nullability issue file collected is 19.96 GB for *spring-context*, 4.11 GB for *guava* and 3.57 GB for *error-prone* (see also Table 2). To avoid memory leaks caused by instrumentation, agents dump data frequently, and after test execution using a shutdown hook.

Not unexpectedly, the presence of the agents significantly prolongs the build times – to around one hour for *spring* and 16 hours for *guava*¹⁶. Profiling reveals that stack capture and IO are performance bottlenecks.

¹⁵Branch coverage is reported, calculated using the *jacoco* coverage tool integrated into the IntelliJ IDEA 2022.2 (Ultimate Edition) IDE, and reporting the values aggregated by IntelliJ for the respective packages

¹⁶Builds were run on a MacBook Pro (16-inch, 2021) with Apple M1 Pro, and OpenJDK 11.0.11

We argue that this is acceptable as this is an one-off effort, i.e. this is not designed to be integrated into standard builds.

7.3 Research Questions

We break down the evaluation into a number of research questions. RQ1 compares the possible nullable annotations collected from instrumented test runs with existing annotations. RQ2 and RQ3 assess the utility of the refinements (sanitisation and propagation) performed on the nullability issues collected to improve recall and precision. Finally, in RQ4 we assess the interaction between sanitisation and propagation.

RQ1 How does nullability observed during test execution compare to existing `@Nullable` annotations?

RQ2 Can sanitisation techniques improve the precision of `@Nullable` annotation inference?

RQ3 Can propagation improve the recall of `@Nullable` annotation inference?

RQ4 Does the repeated application of sanitisation and propagation reach a fixpoint?

Results will be reported in Tables for each RQ, and we will summarise the distribution of recall and lower precision bound values across our dataset at the end of Section 7.7 in Figures 1 (for lpb) and 2 (for recall).

7.4 How does nullability observed during test execution compare to existing `@Nullable` annotations ? [RQ1]

The data to answer this RQ are presented in Table 2. Column 2 (ex) contains the number of `@Nullable` annotations found in the respective program (existing `@Nullable` annotations are extracted and also represented as *extracted issues* to facilitate comparison), column 3 (obs) shows the number of `@Nullable` issues observed during the execution of instrumented tests, corresponding to inferred `@Nullable` annotations. The number of observed issues is surprisingly large, but often, multiple nullability issues are reported for the same field, method parameter or method return. To take this into account, we also report the aggregated issues resulting from deduplication as discussed in Section 3.5 in column 4 (agg), and the aggregation ratio (agg/obs) in column 5. This demonstrates that deduplication is very effective. I.e., nullability reported for a given field, method return or parameter is usually supported by different tests, resulting in different contexts. We see this as a strength of our methods as each context provides independent support for the nullability that is being detected. Finally, we report recall and lower precision bound (r,lpb) in column 6. Both are around 50% with two notable exceptions – the significantly lower recall for *spring-core*, and the significantly lower precision for *spring-context* and *error-prone*.

These results suggests that inferring nullability issues dynamically by only observing tests is not sufficient, and further refinement of those results by means of additional analyses is needed.

7.5 Can sanitisation techniques improve the precision of `@Nullable` annotation inference ? [RQ2]

The various sanitisation techniques discussed in Section 4 address potential false positives. To evaluate their impact, we applied the sanitisers to the observed nullability issues for each program in the data set, and report the number of aggregated inferred nullability issues after sanitisation. We also report the results of applying all sanitisers. The absolute numbers are reported in Table 3, the recall / precision metrics are reported in Table 4.

error-prone	1,736	1,736	1,337	1,736	1,736	1,337

■ **Table 4** RQ2b – recall and lower precision bound (r,lpb) w.r.t. existing annotations after applying sanitisers (D – deprecation, M – main scope, N – negative tests, S – shading).

program	r,lpb(D)	r,lpb(M)	r,lpb(N)	r,lpb(S)	r,lpb(all)
s.-beans	0.52,0.52	0.54,0.91	0.52,0.53	0.54,0.52	0.50,0.95
s.-context	0.48,0.12	0.49,0.90	0.48,0.12	0.49,0.12	0.47,0.94
s.-core	0.50,0.67	0.52,0.78	0.49,0.72	0.52,0.70	0.47,0.92
s.-orm	0.47,0.63	0.47,0.92	0.45,0.63	0.47,0.63	0.45,0.93
s.-oxm	0.54,0.70	0.54,0.92	0.54,0.70	0.54,0.70	0.54,0.92
s.-web	0.43,0.54	0.45,0.85	0.44,0.57	0.45,0.55	0.42,0.90
s.-webmvc	0.68,0.41	0.69,0.92	0.68,0.42	0.69,0.41	0.67,0.92
guava	0.48,0.40	0.48,0.48	0.48,0.56	0.48,0.39	0.48,0.77
error-prone	0.39,0.11	0.39,0.15	0.39,0.11	0.39,0.11	0.39,0.15

The results suggest that most sanitisers have only a minor impact on precision and, sometimes, those improvements come at the price of slight drops in recall. However, one sanitiser stands out: by focusing on classes in the main scope, the precision can be improved dramatically. This suggests that our instrumented tests pick up a lot of nullability in test classes or other test-scoped classes supporting tests.

After applying all sanitisation techniques, we observe a very high lower precision bound of 0.9 or better for all *spring* programs, with some minor drops in recall. The lower precision bound for *guava* is still fairly high, but surprisingly low for *error-prone*, to be discussed below. Balancing precision and recall is a common issue when designing program analyses, but we believe that the focus should be on precision as developers have little tolerance for false alerts. For instance, it has been reported that “Google developers have a strong bias to ignore static analysis, and any false positives or poor reporting give them a justification for inaction.” [59].

■ **Table 5** Annotated vs annotatable program elements, in the last column the number of annotatable elements of type `java.lang.Void` is reported.

program	annotated	annotatable	annotation ratio	Void usage
s.-beans	1,290	5,230	0.25	0
s.-context	1,435	8,849	0.16	0
s.-core	1,510	10,628	0.14	0
s.-orm	377	1,676	0.22	0
s.-oxm	84	467	0.18	0
s.-web	2,025	13,658	0.15	6
s.-webmvc	1,437	8,317	0.17	1
guava	3,964	25,472	0.16	2
error-prone	507	22,669	0.02	958

To investigate the low lower precision bound we observed for *error-prone* further, we conducted an additional experiment where we calculated the *annotation ratio*. For this purpose, we counted the existing `@Nullable` annotations, and the number of program elements that can be annotated, i.e. fields, method parameters and return types for non-synthetic methods and fields whose type is not a primitive type. The results are displayed in Table 5. This show that the annotation ratio for *error-prone* is by on order of a magnitude lower than for the other programs. Therefore, many of the potential false positives are likely to be true positives, and the existing annotations are not suitable to act as a ground truth here. To investigate the matter further, we looked for patterns amongst the potential false positives detected. One pattern stands out – the frequent use of `java.lang.Void` as method parameter and return type. The respective numbers are shown in Table 5, column 5. The use of `Void` in *error-prone* is unusually high. `Void` has an interesting semantics – this class cannot be instantiated, i.e. *it must be null*, and is therefore always nullable by definition. However, in *error-prone*, the respective method returns and parameters are not annotated as `@Nullable`. Interestingly, this is in violation of one of *error-prone*'s own rule *VoidMissingNullable* (“The type `Void` is not annotated `@Nullable`”) ¹⁷. I.e., *error-prone* is not *dog-fooding* [32] here. *Error-prone* has recently opened an issue to address this ¹⁸. We also note that the *nullaway* checker treats `Void` as nullable ¹⁹, and the *checkerframework* declares `@Nullable` as default for `Void` using a meta annotation ²⁰.

We rerun the recall and precision calculation against a ground truth that interprets `Void` as nullable, and for *error-prone* as expected the result change significantly to a recall of 0.72 and a lower precision bound of 0.79.

After performing sanitisation, we also investigated the context depth, i.e. the size of the stack traces recorded. Without sanitisation this data would be distorted by issues discovered in testing scope, leading to very low context depth. For each aggregated issue equivalence class modulo the deduplication relationship (see Section 3.5), we computed the lowest context depth for all issues in the respective equivalence class, and then counted aggregated issues by this depth. The results are reported in Table 6.

10:16 On Leveraging Tests to Infer Nullable Annotations

■ **Table 6** Observed and sanitised issues by context depths.

program	all	2	3	4	5	6	7	8	9	10	>10
s.-beans	687	167	109	64	58	46	35	24	22	39	123
s.-context	718	197	122	76	58	52	25	26	22	11	129
s.-core	780	266	165	105	63	37	32	23	21	10	58
s.-orm	184	23	28	20	18	14	24	2	3	3	49
s.-oxm	49	35	4	1	7	0	0	0	0	0	2
s.-web	941	305	258	149	77	52	10	8	2	9	71
s.-webmvc	1,048	329	195	212	117	50	32	12	9	10	82
guava	2,464	972	606	399	163	122	37	20	13	11	121
error-prone	1,337	8	23	56	4	26	4	8	6	2	1,200

■ **Table 7** RQ3a – effect of propagation, aggregated issue counts and recall / lower precision bound for sanitised issues (s), sanitised and then propagated issues (sp) and sanitised, propagated and re-sanitised issues (sps).

program	s	sp	r,sps	r,lpb(s)	r,lpb(sp)	r,lpb(sps)
s.-beans	687	693	693	0.50,0.95	0.51,0.95	0.51,0.95
s.-context	718	736	736	0.47,0.94	0.48,0.94	0.48,0.94
s.-core	780	791	788	0.47,0.92	0.48,0.91	0.48,0.92
s.-orm	184	184	184	0.45,0.93	0.45,0.93	0.45,0.93
s.-oxm	49	49	49	0.54,0.92	0.54,0.92	0.54,0.92
s.-web	941	949	949	0.42,0.90	0.42,0.90	0.42,0.90
s.-webmvc	1,048	1,059	1,059	0.67,0.92	0.68,0.92	0.68,0.92
guava	2,464	2,503	2,503	0.48,0.77	0.49,0.77	0.49,0.77
error-prone	1,337	1,361	1,361	0.39,0.15	0.43,0.16	0.43,0.16

The results suggest that there are some issues revealed by trivial tests (e.g., tests directly invoking functions with `null` parameters). However, a significant number of issues is revealed by more complex behaviour with deep calling contexts. We consider this to be a strengths of the analysis being presented. Note that the context depths are not inflated by boiler-plate code as the stack traces are cleaned during capture (see Section 3.3).

7.6 Can propagation improve the recall of @Nullable annotation inference ? [RQ3]

Next, we applied propagation to the sanitised nullability issues (using all sanitisers). This can discover additional nullability issues not observable during testing, and therefore improve recall. The results are reported in Table 7. Those results suggests that propagation does not significantly change the quality of the analysis. We observe minor improvements in recall for only four programs in our dataset.

As already discussed in Section 7.5, the results for *error-prone* are heavily impacted by the fact that `Void` is not annotated as nullable. If we consider it as implicitly annotated as nullable, and extend the ground truth used to compare the inferred annotations accordingly, the results change to a recall of 0.73 and a lower precision bound of 0.79. We therefore observe a small increase of the recall for *error-prone* as the result of propagation.

■ **Table 8** RQ3b – number of propagated issues and recall / lower precision bound of propagated issues by type (F – field, P – method parameters, R – method return types).

program	prop(F)	prop(P)	prop(R)	r,lpb(F)	r,lpb(P)	r,lpb(R)
s.-beans	205	279	209	0.81,1.00	0.41,0.90	0.47,0.97
s.-context	308	220	208	0.80,0.98	0.34,0.91	0.41,0.90
s.-core	125	422	241	0.80,1.00	0.43,0.86	0.46,0.97
s.-orm	111	38	35	0.90,1.00	0.21,0.76	0.26,0.89
s.-oxm	35	12	2	0.70,1.00	0.45,0.83	0.00,0.00
s.-web	308	438	203	0.72,0.94	0.36,0.87	0.33,0.91
s.-webmvc	373	319	367	0.95,1.00	0.52,0.87	0.63,0.88
guava	353	1,474	676	0.88,0.98	0.42,0.68	0.48,0.87
error-prone	77	700	584	0.80,0.10	0.47,0.11	0.40,0.23

7.7 Does the repeated application of sanitisation and propagation reach a fixpoint ? [RQ4]

Propagation can introduce new annotations which would otherwise be sanitised, and the process generally does not converge against a fix point. An example was already discussed in Section 5.2. However, it is still a relevant question to study and quantify whether we come close to a fix point, and whether it is common for programs not to reach such a fix point. Therefore, we investigated whether this is a significant observable effect by applying sanitisation to the propagated inferred annotations. This had almost no effect, with only a very few issues in *spring-core* being re-sanitised, the respective data is reported in the columns labelled *sp*s (*sanitised-propagated-sanitised*) in Table 7.

Since propagation is the last step of our inference pipeline (capture-sanitise-propagate), we also report a breakdown of nullability issues by program element annotated, as shown in Table 8. What stands out is that for fields both recall and precision of inferring nullability is better than average.

Figures 1 and 2 show the distribution of lpb and recall values across the dataset after each step discussed.

7.8 False False Positives

Despite the generally high precision our approach achieves, it is not perfect. The question arises whether this is caused by false positives. This relates to the fact that our baseline – the existing `@Nullable` annotations, only (under-)approximates the ground truth. In particular, it is unclear whether it is complete. If it was not, some of the false positives our analysis produces would actually be true positives. Sometimes additional analyses can reveal patterns where developers missed annotations that should have been added by some heuristics, an example is the `Void` analysis for *error-prone* discussed in Section 7.5. If no such pattern can be identified, there is another way to find out – add additional annotations inferred by our tool to the respective project(s) via pull requests.

The number of annotations to be added is still relatively large, and given the importance spring has in the developer ecosystem, it can be expected that project owners are generally reluctant to accept pull requests from newcomers. Pull requests have also experienced some amount of inflation recently (partially caused by bots creating pull requests), and therefore processing is delayed.²¹

²¹There were 164 open pull requests on 20 October 2022, <https://github.com/spring-projects/spring-framework/pulls?q=is%3Aopen>

■ **Figure 1** Lower precision bound distribution across the dataset after each step: capture, applying the various sanitisers (san-*), propagation, propagation followed by re-sanitisation (sps), and special handling of Void in *errorprone*.

We have submitted two pull requests with different outcomes: PR1 ²² has resulted in a @Nullable annotation inferred being added ²³. PR2 ²⁴ was rejected, but the developers refined the test the inference is based on ²⁵.

While PR1 and PR2 have resulted in different outcomes, they both have revealed issues in *spring*, and after rerunning the analysis after the action taking by developers in response to the PRs, precision would increase in both cases. Adding an inferred annotation clearly shows that some false positives are actually true positive. Refining the tests has a similar effect – the semantics of tests is sometimes at odds with what is considered intended behaviour, and our tools exposes this. After the test is fixed, the false positive disappears as the tool can no longer infer it.

Our tools has also led to the re-annotation of some classes in *guava* ²⁶.

7.9 Comparison with Purely Static Inference

Houdini [25] infers annotations using the Esc/Java checker. The platform has been deprecated and replaced by other tools, and there is no implementation available. Houdini still uses “pseudo-annotation“ using special markup. This approach is also highly unscalable. The authors report that “*the running time on the 36,000-line Cobalt program was 62 hours*”. For comparison, the version of *spring-core* used in the evaluation experiments alone contains over 146,000 lines of Java code, and checkers rarely scale linearly. For comparison, our analysis generally scales. The bottleneck of our method is the capture, and while this is expensive it generally scales as discussed in Section 7.2.

We contacted the authors of several tools [21, 35, 34] and succeeded in using *jasaddj-nonnullinference* [21] to analyse some programs, and compare results.²⁷ The tool has been maintained until 2015, and based on advice by the authors, we selected some older programs buildable with Java 1.7. The builds had to be heavily customised in order to deal with broken dependencies, details are described in the artefact. The comparison is not straightforward as *jasaddj* infers `@Nonnull` annotations, whereas our method infers `@Nullable`.

The results are shown in Table 9. The *annotatable* column shows the total number of fields, method return and parameters with nullable types. The `@Nonnull` column show the number of annotations inferred by *jasaddj*, and the `@Nullable` columns shows the number of annotations our approach infers. We also report the intersection between both sets in the last column. Both approaches annotate less than half of all annotatable elements. It

²⁷ <https://bitbucket.org/jastadd/jastaddj-nonnullinference>

■ **Table 9** Comparing our approach with JastAddJ NonNull inference.

program	annotatable	@Nonnull	@Nullable	Intersection
commons-lang-3.0	4,647	1,480	1,041	633
commons-cli-3.1	2,724	1,179	65	17
commons-io-2.5	2,241	1,012	326	184
commons-math-3.0	9,404	3,208	270	50

is not clear how to interpret the set complement for both tools. If we interpret everything not `@Nonnull` annotated by *jasaddj* as `@Nullable`, then *jasaddj* has a low precision. The intersection column suggests that there are a significant number of cases where the tools produce inconsistent results. Given the low number of false positive we observe with our tool, it is likely that *jasaddj* produces false positives here.

However, this is not really surprising given that tools like *jasaddj* have been designed to analyse program (as opposed to libraries), where all method calls and field access is known. Our method however is designed for an open world where API interactions from unknown clients have to be considered, and test cases act as proxies for those clients.

8 Related Work

Much work exists on the problem of eliminating null dereferences, of which the vast majority focuses on static checking. Nevertheless, a number of empirical studies exist which are relevant here. The early work of Chalin *et al.* empirically studied the ratio of parameter, return and field declarations which are intended to be non-null, concluding 2/3 are [13, 14]. Another early work was that of Li *et al.* who sampled hundreds of real-world bugs from two large open source projects [40]. They found (amongst other things) null dereferences are the most prevalent of memory-related bugs.

Kimura *et al.* argued that “*it is generally felt that a method returning null is costly to maintain*” [37]. Their study of several open source projects examined whether statements returning `null` or checks against `null` were modified more frequently than others and they observed a difference for the former (but not the latter). Furthermore, they found occurrences of developers replacing statements returning `null` with alternatives (e.g. Null Objects [29] or exceptions) suggesting a desire to move away from using `null` like this. Osman *et al.* also investigated null checks across a large number of open source programs [52]. They found the most common reason developers insert null checks is for method returns and, furthermore, that this is most often to signal errors. The follow-up work of Leuenberger *et al.* investigated the nullability of method returns in Apache Lucene (a widely-used search library) [39]. For each method call site (either internally within Lucene or externally across clients), they identified whether the method return was checked against `null` before being dereferenced (i.e. as this indicates whether the caller expected it could return `null` or not). They confirmed that most methods are expected to return non-null values. However, they also found that external clients were more likely to check a method against `null`, suggesting clients employ defensive behaviour (e.g. when documentation is missing, etc).

8.1 Migration

Dietrich *et al.* harvested lightweight contracts, such as `@Nonnull` and `@Nullable` annotations, from real-world code bases [17]. Unfortunately, they found such annotations are rarely used in practice and that, instead, throwing `IllegalArgumentException` and (to a lesser extent) use of Java `assert` remain predominant. This suggests a key problem faced by all tools for checking non-null annotations (such as those above) is that of annotating existing code bases.

Brotherston *et al.* aimed to simplify migration of existing code bases to use non-null annotations [10]. Their goal is to enable incremental migration of existing code bases to use non-null annotations. Here, developers begin by annotating the most important parts of their system and then slowly widen the net until, eventually, everything is covered. Their approach follows gradual typing [61] and divides programs into the *checked* and *unchecked* portions, such that null dereferences cannot occur in the former. To achieve this, runtime checks are added to unchecked code to prevent exceptions occurring within checked code (i.e. by forcing exceptions at the boundary between them). Such an approach is complementary to our work, and the two could be used together. For example, one might start by inferring annotations using our technique and, subsequently, shift to a gradual typing approach to manage parts where inferred annotations were insufficiently strong, or otherwise require manual intervention. Estep *et al.* further apply ideas of gradual typing to static analysis, using null-pointer analysis as an example [22]. They argue gradual null-pointer analysis hits a “sweet spot” by mixing static and dynamic analysis as needed. A key question they consider is “*why it is better to fail at runtime when passing a null value as a non-null annotated argument, instead of just relying on the upcoming null-pointer exception*”. In essence, they provide two answers: (1) for languages such as C, null dereferences lead to undefined behaviour and, hence, catching them in a controlled fashion is critical; (2) for others, such as Java, it is generally better practice to catch errors as early as possible. Neito *et al.* also take inspiration from gradual typing by considering *blame* across language interop boundaries [50]. In particular, when null-safe languages (e.g. Scala or Kotlin) interact with unsafe languages (e.g. Java), problems can arise.

Houdini statically infers a range of annotations (including non-null) for Java programs [25]. The tool works by generating a large number of candidate annotations and using an existing (modular) checker to eliminate spurious ones. Ekman *et al.* also developed a tool for inferring non-null annotations which could identify roughly 70% of dereferences as safe [21]. Hubert *et al.* formalised an inference tool for non-null annotations based on pointer analysis [35, 34], whilst Spoto developed a similar system arguing it is faster and more precise in practice [63]. XYLEM employs a backwards analysis to find null dereferences [49]. Whilst it doesn’t (strictly speaking) infer annotations, it could be modified to do so. Bouaziz *et al.* also propose a backwards analysis to infer *necessary field conditions* on objects (e.g. that a field is non-null) [8]. This approach is *demand driven* in the sense that fields are marked non-null only if this is necessary to prohibit a null dereference being reported elsewhere.

Finally, inference tools have been developed for pluggable type systems [26, 27, 15, 16]. However, such tools typically cannot account for null checks in conditionals making them relatively imprecise in this context.

8.2 Static Checking

Many tools for statically checking non-null annotations have been proposed. Typically, they differ from traditional type checkers by operating *flow-sensitively* to account for conditional null checks. They also assume non-null annotations have already been added to programs. NULLAWAY provides a nice example here, since it was developed by Uber for static non-null checking at scale [5]. The key requirement was that it could run on all builds, rather than just at code review time (as for a previous tool they used). Their tool is flow-sensitive, but often takes an “optimistic” view (i.e. is unsound). Their reasoning is that sound (i.e. pessimistic) tools produce too many false positives. NULLAWAY does not soundly handle initialisation (see below); likewise, for external (unannotated) code it assumes all interactions are safe. Despite this, they found no cases where unsoundness lead to actual bugs across a 30-day

10:22 On Leveraging Tests to Infer Nullable Annotations

period of usage on a real-world code base. Indeed, this corroborates the earlier findings of Ayewah and Pugh who argued many null dereferences reported by tools do not actually materialise as bugs in practice [4]. As another example, *Eradicate* is part of Facebook Infer [1, 19, 12] and, in many ways, is similar to NULLAWAY.

A number of other tools have been developed which can be used for static `@NonNull` checking, such as FindBugs [33], ESC/Java [24], JastAdd [21], JACK [45] and more [56, 44]. Almost all of these employ flow-sensitive analysis, and many are unsound in various ways (e.g. support for initialisation). Indeed, the initialisation problem has proved so challenging that a large number of works are devoted almost exclusively to its solution [23, 36, 57, 66, 64, 60, 42, 43, 38]. Roughly speaking, the issue is that fields of reference type are assigned a default value of `null` and, thus, every `@NonNull` field initially holds `null` (and this is observable [66]). In our approach we check nullability at the end of object construction. This method is unsound only if super constructors allow access to fields defined in subclasses. We think that this is a rare programming pattern, and note that our approach while aiming for high recall, does not guarantee soundness anyway as it is based on a dynamic analysis.

Finally, so-called “pluggable type systems” [9] allow optional type systems to be layered on existing languages, thus allowing them to evolve independently [26, 27, 15, 3, 16, 47]. The *checkers framework* provides a prominent example which heavily influenced JSR308 (included in Java 8) [54]. A key advantage of this tool over others is the ability to support for flow-sensitive type systems (a.k.a. *flow typing* [55]). Indeed, without this feature checking non-null types is largely impractical [3].

9 Conclusion

We have presented a hybrid analysis pipeline that can be used to capture and refine nullability issues and mechanically inject inferred `@Nullable` annotations into Java programs. Our experiments on some of the most widely used Java commodity libraries demonstrates that this approach is suitable for real-world programs, and that the inferred annotations are consistent with annotations manually added by engineers. In particular, our approach has high precision, and there is evidence from pull requests we have initiated that this precision is potentially higher as our analysis is able to discover missing annotations in the already nullable-annotated programs we have used for evaluation.

Mechanising this process addresses a major issues in real-world projects: the lack of null annotations. Such annotations are part of the program semantics, and generally the annotation process requires deep understanding by project owners and contributors. However, the workload of adding such annotations is significant, and the lack of annotations compromises the utility of static checkers. We have argued that the semantics of which types are nullable and not is already at least partially encoded in existing test cases, and our pipeline exploits this idea of leveraging tests.

The tool has been open sourced and is available from <https://github.com/jensdietrich/null-annotation-inference>.

super-Charging Object-Oriented Programming Through Precise Typing of Open Recursion

Abstract

We present a new variation of object-oriented programming built around three simple and orthogonal constructs: *classes* for storing object state, *interfaces* for expressing object types, and *mixins* for reusing and overriding implementations. We show that the latter can be made uniquely expressive by leveraging a novel feature that we call *precisely-typed open recursion*. This feature uses “this” and “super” annotations to express the requirements of any given partial method implementation on the types of respectively the current object and the inherited definitions. Crucially, the fact that mixins do *not* introduce types nor subtyping relationships means they can be composed even when the overriding and overridden methods have incomparable types. Together with advanced type inference and structural typing support provided by the MLscript programming language, we show that this enables an elegant and powerful solution to the Expression Problem.

1 Introduction

Every object-oriented programming (OOP) developer regularly uses the **super** keyword to access overridden definitions from inherited classes. Yet, this keyword has received relatively little attention in previous OOP literature and has been conspicuously absent from most previous research, with few exceptions [17]. This may be due to the assumption that **super**-calls can be resolved statically and are thus a mere syntactic convenience that is easily desugared into traditional core OOP features [2]. In this paper, we propose to challenge this assumption: noting that **super** is in fact *late-bound* in mixin-composition systems,¹ we describe an OOP approach which assigns *precise types* to **super**-calls to reflect the “open” nature of this late binding. Consider the following prototypical `Point` example class:

```
class Point(x: Int, y: Int)
```

¹ **super** is bound at the time the mixin method where it appears is composed into a class, which can happen as late as runtime in many mixin-composition languages.

11:2 super-Charging Object-Oriented Programming

This class simply defines two coordinates `x` and `y` as immutable fields.

Suppose we want to define a comparison function that works on points. We place this definition in a *mixin* declaration, for reasons that shall soon become clear:

```
mixin ComparePoint {  
  fun compare(lhs: Point, rhs: Point): Bool =  
    lhs.x == rhs.x and lhs.y == rhs.y }
```

Now suppose we want to compare colored points, but we would like colored comparison to be generally specified, so that it can be directly reused with other things than points. This can be done using the following combination of interface and mixin (`Base` is a type parameter):

```
interface Colored { color: String }  
  
mixin CompareColored[Base] {  
  super: { compare: (Base, Base) → Bool }  
  fun compare(lhs: Base & Colored, rhs: Base & Colored): Bool =  
    super.compare(lhs, rhs) && lhs.color.equals(rhs.color) }
```

We define an interface specifying that a `Colored` object should contain a `color` method or field of type `String`. We also define the `CompareColored` mixin, which implements a comparison method *based on* an assumed existing comparison method, inherited from an unknown parent implementation and referred to through **super**. The `Base` type parameter denotes the type compared by that unknown parent implementation; it is needed in order to leave the mixin *open-ended*, i.e., to allow mixing it with arbitrary parent implementations. Notice that the type of `compare` in `CompareColored` is *different* from the one specified in the **super** annotation, and is in particular not a subtype of it: the version defined in `CompareColored` takes parameters of *more precise* type `Base & Colored`, where `&` is an intersection type constructor, meaning that each parameter should be *both* a `Base` *and* a `Colored`. This difference is a crucial ingredient in our precisely-typed open recursion approach.

We now define `ColoredPoint` and place its comparison implementation in a module:²

```
class ColoredPoint(x: Int, y: Int, color: String)  
  extends Point(x, y) implements Colored  
  
module CompareColoredPoint extends ComparePoint, CompareColored[Point]
```

`CompareColoredPoint` did not need to define its own comparison method – that method was *composed automatically* by inheriting from the `ComparePoint` and `CompareColored` mixins, the latter using the correct `Point` base type argument. Note that mixins on the right override those on the left. The signature of `CompareColoredPoint`'s `compare` method, which allows passing in colored points, is:

```
CompareColoredPoint.compare: (Point & Colored, Point & Colored) → Bool
```

which is *not* a subtype of `ComparePoint`'s `compare` method. This is fine because mixins in our approach do not introduce types, and there is thus no subtyping relationship between `CompareColoredPoint` and `ComparePoint`, which is reminiscent of Cook et al. famous assertion that *inheritance is not subtyping* [7].

² A module declares a class with a singleton instance, similar to Scala's **object**.

Now imagine we want to deal with “*nested*” objects, which are objects that may optionally have a parent.³ We can similarly define a comparison mixin for nested objects as follows:

```
interface Nested[A] { parent: Option[A] }

mixin CompareNested[Base, Final] {
  super: { compare: (Base, Base) → Bool }
  this: { compare: (Final, Final) → Bool }

  fun compare(lhs: Base & Nested[Final], rhs: Base & Nested[Final]): Bool =
    super.compare(lhs, rhs) &&
    if lhs.parent is Some(p)
      then rhs.parent is Some(q) and this.compare(p, q)
      else rhs.parent is None
}
```

In this variant, we additionally use a **this** refinement, which specifies the *eventual* types of the methods the current object should support, after all inheritance and overriding is performed. The reason we use **this** and not **super** in the recursive **this.compare(p, q)** call is that we should take into account that *p* and *q* *themselves* may be nested points!

Finally, it is possible to compare points that are *both* nested *and* colored by directly composing the corresponding implementations:

```
class MyPoint(x: Int, y: Int, color: String, parent: Option[MyPoint])
  extends Point implements Colored, Nested[MyPoint]

module CompareMyPoint extends ComparePoint, CompareColored[Point],
  CompareNested[Point & Colored, MyPoint]
```

Or alternatively, in a different order:

```
module CompareMyPoint extends ComparePoint, CompareNested[Point, MyPoint],
  CompareColored[Point & Nested[MyPoint]]
```

Mixin composition order is meaningful because it determines overriding order; moreover, in our approach, the types of methods may change through overriding – here, notice how we pass different type arguments to `CompareColored` and `CompareNested` in each version.

To support this idea of precisely-typed mixin composition, we present the **SuperOOP** system, a simple yet uniquely expressive core description of OOP built around three orthogonal concepts: *classes* for storing object state, *interfaces* for expressing object types, and *mixins* for reusing and overriding implementations.⁴ Notably, we only support inheriting from interfaces and mixins, not from classes.⁵ We show that these simple, orthogonal concepts are sufficient to explain the usual features of object-oriented programming languages, including those with complicated multiple-inheritance disciplines, like Scala’s trait composition approach.

We also describe how the ideas of SuperOOP can be integrated into MLscript, a nascent ML-inspired programming language with structural types and advanced type inference, based on the recently proposed MLstruct type system [26]. Using this approach, all the types can

³ `Option[A]` is defined as the usual algebraic data type, with cases `Some[A](value: A)` and `None`.

⁴ Such separation of concerns was already proposed by previous authors, such as Bettini et al. [2] and Damiani et al. [8], but the systems they developed did not support overriding and open recursion, which is the *raison d’être* of our approach.

⁵ We see in Section 4.1 that the `Point` class inheritance example seen above can be desugared into our core λ^{super} calculus through interface inheritance and without requiring class inheritance.

11:4 super-Charging Object-Oriented Programming

be inferred automatically as long as they do not involve first-class polymorphism (which requires explicit annotations). For instance, in MLscript, the `CompareColored` mixin shown above could also be written as the more lightweight:

```
mixin CompareColored {  
  fun compare(lhs, rhs) =  
    super.compare(lhs, rhs) && lhs.color.equals(rhs.color) }
```

for which our compiler infers the following *mixin signature*:

```
mixin CompareColored:  $\forall$  'A1 'A2 'B . {  
  super: { compare: ('A1, 'A2)  $\rightarrow$  Bool }  
  compare: ('A1 & {color: {equals: 'B  $\rightarrow$  Bool}}, 'A2 & {color: 'B})  $\rightarrow$  Bool }
```

Our specific contributions are summarized as follows:

- We explain the general ideas of SuperOOP in the context of the structurally-typed MLscript programming language, and how it allows solving interesting problems simply and elegantly, including the Expression Problem and derivatives (Section 2). SuperOOP mixins improve on the state of the art by allowing precise typing of open recursion, which to the best of our knowledge was never proposed before.
- We formalize the core concepts of SuperOOP, including its precisely-typed mixin inheritance mechanism, in a declarative type system called λ^{super} . We use big-step semantics to closely reflect a real implementation and prove the soundness of λ^{super} through the preservation and coverage properties (Section 3).
- We discuss the expressiveness and limitations of the presented design of SuperOOP as well as its implementation. We present several important approaches from previous literature on the topic of inheritance and the Expression Problem, and explain how these approaches compare to SuperOOP in detail (Section 4).
- We provide an implementation of MLscript/SuperOOP which demonstrates how type inference can be used to type check concise mixin and class definitions. Both the open-source version and the archived artifact with documentation are available. A demo of this implementation is included in the supplementary material of this paper.⁶

2 Motivation

In this section, we introduce a motivating example in MLscript “**super-charged**” by our OOP approach in more detail.

The Expression Problem and Extensible Variants

In modular programming, the *Expression Problem* (EP) describes the dilemma posed by the modular extension for both data types and their operations in object-oriented and functional programming. There are many ways of tackling this problem, but one of the most straightforward is to rely on some notion of *extensible variants*, as done by Garrigue [16] with OCaml’s polymorphic variants. The general idea of extensible variants is that they are similar to algebraic data types (a.k.a. variants) except that one is able to specify which data type cases are allowed in a given type, and moreover one is able to add new data type cases after the fact.

⁶ The demo is also available at: <https://hkust-taco.github.io/superoop/>.

MLscript supports a simple form of extensible variants implemented through *subtyping and structural types*. In this section, we see how the combination of this feature and SuperOOP's precise typing of open recursion can achieve what we believe is one of the simplest and cleanest solutions to the expression problem so far.

A Quick Look at MLscript

We first take a quick look at MLscript's basic language features that enable a form of extensible variants and serve as key ingredients in our solution to the Expression Problem.

Basic data type classes. Consider the following MLscript class definitions which encode a very minimal expression language that we will later extend in several directions.

```
class Lit(value: Int)
class Add[T](lhs: T, rhs: T)
```

The `Lit` class represents integer literals and the `Add` class represents addition. Note that the types of `Add`'s value parameter are polymorphic, meaning that they can be chosen arbitrarily. We will see that the ability to leave the types of subexpressions open is crucial to the extensibility of our approach.

Union types. Based on these class definitions, we can construct types such as:

```
type LitOrAddLit = Lit | Add[Lit]
```

where `|` is called a *union type* constructor. `LitOrAddLit` represents the type of an expression that is *either* an integer literal *or* an addition between two integer literals.

Equirecursive types. More interestingly, we can define the type of arbitrary expressions in our little language as:

```
type SimpleExpr = Lit | Add[SimpleExpr]
```

Notice that this type is *equirecursive*, meaning that `SimpleExpr` is *equivalent* to its unrolling `Lit | Add[SimpleExpr]`. This is quite convenient in the context of structural typing, and it allows us to have subtyping relationships (denoted as ' $\tau_1 <: \tau_2$ ', meaning that τ_1 is a subtype of τ_2) such as `LitOrAddLit <: SimpleExpr`. An equivalent way of specifying `SimpleExpr` without having to introduce a type declaration is through MLscript's `'as'` binder (similar to `'as'` in languages like OCaml), as in `'Lit | Add['a] as 'a'` (where `'as'` has least precedence).

Evaluation. To use values in our small expression language, we define an `eval` recursive function:

```
fun eval(e) = if e is
  Lit(n)      then n
  Add(lhs, rhs) then eval(lhs) + eval(rhs)
```

This function uses MLscript's syntax for pattern matching, which extends the traditional `if-then-else` syntactic form with multi-way-`if`-style functionality and destructuring through an `'is'` keyword [25]. The type of this function is inferred by MLscript to be:

```
eval: (Lit | Add['a] as 'a) → Int
```

11:6 super-Charging Object-Oriented Programming

Default cases and constructor difference. It is quite instructive to consider what happens when default cases are used in MLscript, as in:

```
fun eval2(e) =
  if e is
    Lit(n)          then n
    Add(lhs, rhs)  then eval2(lhs) + eval2(rhs)
  else e
```

In this case, the type inferred is

```
eval2: (Lit | Add['a] | 'b\Lit\Add as 'a) → (Int | 'b)
```

Above, ‘\’ is a *constructor difference* type operator,⁷ which is used to *remove* concrete class type constructors from a given type (here ‘b’). This type operator applies incrementally, as its left-hand side becomes concretely known upon type instantiation. For instance, after instantiating the type variable ‘b’ to, say, `Add[Int] | Bool` in the type above, ‘b\Lit\Add’ becomes `(Add[Int] | Bool)\Lit\Add`, which is equivalent to just `Bool`. Since all negative occurrences of ‘b’ (here there is only one) are subject to this constructor difference, passing values for ‘b’ which are of the `Lit` or `Add` forms is effectively prevented, which ensures type safety⁸ [26]. On the other hand, any other type constructor is allowed, for example, we could call `eval2(true)`, with inferred result type `Int | Bool`.

Open Recursion in MLscript with SuperOOP Mixins

Now let us consider putting our original evaluation function inside of a *mixin*, in order to enable future extensions. To make the recursion of evaluation *open*, we now recurse through method calls of the form ‘`this.eval`’ (here ‘`this`’ is the class instance to be late-bound) instead of a direct `eval` recursive function call:

```
mixin EvalBase {
  fun eval(e) = if e is
    Lit(n)          then n
    Add(lhs, rhs)  then this.eval(lhs) + this.eval(rhs) }
```

The type signature inferred for that mixin definition is the following:

```
mixin EvalBase: ∀ 'A. {
  this: { eval: ('A) → Int }
  eval: (Lit | Add['A]) → Int
}
```

Above, ‘A’ is a *mixin-level* type variable,⁹ meaning that it must be instantiated to a specific type each time the mixin is inherited as part of a class. Since mixins do *not* introduce types on their own, `EvalBase` cannot be used as a type. Using `EvalBase` as a type would be a

⁷ Constructor difference is not a primitive construct of MLscript’s underlying type system, MLstruct [26]. Type $A \setminus B$ is encoded in that type system as $A \ \& \ \sim\#B$, where $\&$ is the *type intersection* operator, \sim is the *type negation* operator, and $\#B$ represents the *nominal identity* of class B, i.e., its raw type constructor without any fields or type parameters attached.

⁸ Perhaps counter-intuitively, we do not need to restrict the positive occurrences of ‘b’, as they are always effectively unrestricted due to covariance. Consider a function of type $(\text{'b}\setminus\text{Lit}\setminus\text{Add}) \rightarrow \text{'b}$. Substituting `Mul | Lit | Add` for ‘b’ results in $((\text{Mul} \mid \text{Lit} \mid \text{Add})\setminus\text{Lit}\setminus\text{Add}) \rightarrow (\text{Mul} \mid \text{Lit} \mid \text{Add})$, which is equivalent to $\text{Mul} \rightarrow (\text{Mul} \mid \text{Lit} \mid \text{Add})$. This is a supertype of $\text{Mul} \rightarrow \text{Mul}$, which we could have obtained from substituting `Mul` for ‘b’ in the first place, so this type would have been reachable even after a “properly restricted” substitution of ‘b’. In other words, it does not make much sense to restrict the positive occurrence of ‘b’ and there is no practical need for it.

⁹ We use uppercase names for *mixin-level* type variables and lowercase names for *function-level* ones.

problem because there would be no definite type to replace 'A with in the signature of its `eval` method – so we would not know how to type expressions such as `x.eval` when `x` has type `EvalBase`. Note that 'A can even be instantiated to *several incomparable types* within a single class, if `EvalBase` is inherited several times.

What is interesting here is that MLscript infers a **this** type refinement (also called *self type*), which specifies what the type of **this** should be for the mixin to be well-typed. Here, **this** represents the final object obtained from the future mixin composition. Crucially, notice that the type of `eval` is *no longer recursive* – indeed, it no longer contains a recursive ‘**as**’ binder. This is because we have *opened* the recursion, and the type that is inferred for `eval` *precisely* specifies what this partial definition accomplishes: it examines the top level of an expression and when that expression is an `Add`, it calls `eval` open-recursively through **this** with the corresponding subexpressions, expecting integer results from that recursive call.

Opening recursion in this way allows us to adapt the interpretation of this partially-specified recursive function, as we shall see shortly.

Closing back. We can immediately tie the knot and obtain an equivalent implementation to the original recursive function `eval` by defining a class that only inherits from `EvalBase`:

```
class SimpleLang extends EvalBase
```

whose inferred type signature is:

```
class SimpleLang: {
  eval: (Lit | Add['a] as 'a) → Int
}
```

Something important happened here: by creating the class `SimpleLang` from the previous mixin, we effectively *tie the recursive knot* for the corresponding method. That is, to type check `SimpleLang`, MLscript constrains the “open” polymorphic type variable 'A associated with `eval` in `EvalBase` and instantiates it to the correct type to make the overall mixin composition type check. More specifically, remember that `eval` as defined in `EvalBase` was given type $(\text{Lit} \mid \text{Add}['A]) \rightarrow \text{Int}$ *assuming* that **this** had type $\{ \text{eval}: ('A) \rightarrow \text{Int} \}$. Here, we know that the type of **this** is `SimpleLang` and that `SimpleLang`'s `eval` implementation is the one inherited from `EvalBase`. So when constraining types to make the subtyping relation $\text{SimpleLang} <: \{ \text{eval}: ('A) \rightarrow \text{Int} \}$ hold, this leads to constraining $(\text{Lit} \mid \text{Add}['A]) \rightarrow \text{Int} <: ('A) \rightarrow \text{Int}$, which in turn leads to the constraint $'A <: (\text{Lit} \mid \text{Add}['A])$. So MLscript instantiates the type variable 'A to the principal solution, i.e the recursive type $(\text{Lit} \mid \text{Add}['a]) \text{ as } 'a$, which satisfies this recursive constraint.

Extending the operations. Now consider extending our code for a new expression pretty-printing method:

```
mixin PrettyBase {
  fun print(e) = if e is
    Lit(n)          then toString(n)
    Add(lhs, rhs)  then this.print(lhs) ++ "+" ++ this.print(rhs) }
```

Mixin `PrettyBase` defines a `print` method for `Lit` and `Add`. Its inferred type is analogous to that of `EvalBase`. This demonstrates that we can extend the operations performed on our simple language, which is one of the extensibility directions considered by the Expression Problem.

11:8 super-Charging Object-Oriented Programming

Extending the data types. Next, consider another direction of code extension – defining a *new expression constructor*. We here define a negation expression type `Neg`:

```
class Neg[T](expr: T)
```

Now, the obvious question is how to extend arbitrary existing operations to this new data type constructor in a way that is as general and modular as possible.

super-charging OOP with Polymorphic Mixins

As noticed by Garrigue [16], it is often useful to define components that extend *yet unknown* base implementations, so that the same components can be applied to different base implementations, and so that in general we can merge independently-defined languages together. This is possible to do in MLscript by defining mixins that make use of **this** and **super**, as in the following example:

```
mixin EvalNeg {  
  fun eval(e) =  
    if e is Neg(d) then 0 - this.eval(d)  
    else super.eval(e)  
}
```

which can be written more concisely using the following syntax sugar:

```
mixin EvalNeg { fun eval(override Neg(d)) = 0 - this.eval(d) }
```

We can include this partial `Neg`-handling recursion step as part of any previously-defined base implementation, such as our previous `EvalBase`. We get the following inferred type for `EvalNeg`, which precisely describes this property:

```
mixin EvalNeg:  $\forall$  'A 'B 'R . {  
  this: { eval: 'A  $\rightarrow$  Int }  
  super: { eval: 'B  $\rightarrow$  'R }  
  eval: (Neg['A] | 'B \ Neg)  $\rightarrow$  (Int | 'R)  
}
```

We can see that the type signature of our mixin now includes a **super** refinement *in addition* to the **this** refinement. This is the key to enabling polymorphic extension: when composing such a mixin later on, MLscript will match up this **super** requirement with whatever implementation is provided by the previous mixin implementations in the chain of mixin composition. Recursive knots will only be tied when the mixin is composed as part of a class.

The `PrettyNeg` extension for pretty-printing is defined analogously.

Tying the knot again. Finally, we can compose everything together as part of a new class:

```
class Lang extends EvalBase, EvalNeg, PrettyBase, PrettyNeg
```

And here is the type signature inferred for this definition:

```
class Lang: {  
  eval: (Lit | Add['a] | Neg['a] as 'a)  $\rightarrow$  Int  
  print: (Lit | Add['a] | Neg['a] as 'a)  $\rightarrow$  Str  
}
```

Again, what happens here is important to consider. We are now tying the knot with respect to *both* **this** and **super** in all the mixins making up the mixin inheritance stack. More specifically, we start by making sure that the member types provided by the first mixin `EvalBase` satisfy the **super** requirement of the second mixin `EvalNeg`, then we compute new member types based on `EvalNeg`'s contributions, before checking that the resulting type

satisfies the **super** requirement of the next mixin in line, `PrettyBase`, etc. This results in the inferred recursive types above, which precisely characterize what shapes of data that `Lang`'s `eval` and `print` methods can handle.

Polymorphic extensibility. To demonstrate that our `EvalNeg` component is truly generic over the existing implementation it is to be merged upon, we can define yet another mixin that adds a new `Mul` language feature:

```
class Mul[T](lhs: T, rhs: T)
mixin EvalMul { fun eval(override Mul(l, r)) = this.eval(l) * this.eval(r) }
```

And then we compose all of these mixins together in two possible orders (the order determines which of `Neg` and `Mul` will be matched first):

```
class LangNegMul extends EvalBase, EvalNeg, EvalMul
class LangMulNeg extends EvalBase, EvalMul, EvalNeg
```

In both cases, the inferred signature is equivalent:

```
class LangNegMul: { eval: (Lit | Add['a'] | Neg['a'] | Mul['a'] as 'a) → Int }
```

Pattern-Matching All the Way

To conclude this motivating example, we exemplify a capability of our system that most solutions to the expression problem lack, with the notable exception of polymorphic variants (see Section 4.3): the ability of *pattern matching deeply inside subexpressions*, which enables the definition of optimization passes.

For instance, below we define an `EvalNegNeg` optimization which shortcuts the evaluation of double negations, directly evaluating the doubly-negated expression instead:

```
mixin EvalNegNeg { fun eval(override Neg(Neg(d))) = this.eval(d) }
```

of inferred type:

```
mixin EvalNegNeg: ∀ 'A 'B 'C 'D . {
  super: {eval: (Neg['A'] | 'B) → 'C}
  this: {eval: 'D → 'C}
  fun eval: (Neg[Neg['D']] | 'A \ Neg | 'B \ Neg) → 'C
}
```

This type deserves some explanation. The parameter type of `eval` is `'Neg[Neg['D']] | 'A \ Neg | 'B \ Neg`, which describes the fact that:

- `eval` accepts either an instance of `Neg` or, failing that, a `'B` that is *not* a `Neg`;
- If the argument *is* a `Neg`, then its type argument must itself be either a `Neg` or an `'A` that is not a `Neg`;
- If that nested type argument is a `Neg`, then its type argument must be `'D`. Since this type argument is passed to `this.eval`, we get the **this** refinement `{eval: 'D → 'C}`.
- In case either the `eval` argument is not a `Neg` (so the argument is a `'B`) or the `eval` argument is a `Neg['A']` where `'A` is not a `Neg`, evaluation falls back to a **super** call, which is translated into the **super** refinement `{eval: (Neg['A'] | 'B) → 'C}`.

This mixin can be merged onto any mixin stack to obtain the desired effect; for example:¹⁰

```
class Lang extends EvalBase, EvalNeg, EvalMul, EvalNegNeg
```

¹⁰In this case, it is important to mix in `EvalNegNeg` *after* `EvalNeg` in the inheritance stack, so that the optimization semantics override the base semantics, and not the other way around. This is a fundamental property of optimization passes: their composition order matters.

3 A Core Language for SuperOOP

In this section, we present an explicitly-typed core language that captures the core object-oriented concepts of SuperOOP, leaving type inference aside. We first informally present the key innovation of SuperOOP's object-oriented type system and then define λ^{super} , a minimal declarative and explicitly-polymorphic calculus.

3.1 SuperOOP Core Concepts

The core concepts of SuperOOP can be summarized as follows.

Interfaces, mixins, and classes. Interfaces, mixins, and classes are three orthogonal building blocks that model OOP in our system. *Interfaces* define a set of method signatures. For an object conforming to an interface, it should support all the methods specified in that interface. Contrary to classes and mixins, which in our core language have no types, we associate each interface with its own type. *Mixins* provide *implementations* for methods. *Classes*, finally, implement interfaces by a set of parameters, which represent the *state* of the object, and a linear composition of mixins.

Interface inheritance. As in most OOP languages, existing interfaces can be extended with additional methods through interface inheritance. A child interface may inherit from several parent interfaces (i.e., we support *multiple inheritance* of interfaces). Moreover, a child interface may override parent method signatures with *refined* signatures, as determined by the subtyping relation. As an example, consider the following interface composition:

```
interface I1 { a: S }; interface I2 { a: T }; interface I3 extends I1, I2
```

Method `a`'s signature in the composed interface `I3` is the *intersection* of the inherited signatures, i.e. `S & T`. Intersection types enable precise multiple interface inheritance, since they are used as greatest lower bounds of the inherited type signatures, which also makes the composed interface a subtype of all inherited interfaces.

Mixin composition. SuperOOP mixins are compositional and reusable building blocks to construct classes. They provide partial method implementations that, when composed together, are checked to satisfy the interface that the class is meant to conform to. A mixin composition is simply a list of mixins. Each mixin in a mixin composition *overrides* not only method implementations but also method *types* inherited from previous mixins. So the type of a method may change along the mixin composition, but the type system ensures that the typing assumptions made by each implementation (in the form of `this` and `super` refinements) are satisfied. This also explains why mixins are not considered types (unlike, e.g., Scala traits): the fact that a mixin is present in the inheritance clause of a class does *not* imply that the resulting object will offer methods with types comparable to the ones provided by the mixin.

Precisely-Typed Open Recursion. A crucial feature of OOP, *open recursion* is the ability for a method to invoke itself or another method via a late-bound `this` instance, which may lead to evaluating overriding implementations. In most OOP languages with inheritance, the type of `this` is the current class's type. In these languages, method invocations on `this` are safe because overriding implementations from subclasses can only refine the types of overridden methods. By contrast, in SuperOOP, methods are overridden regardless of types,

Names, types, and terms	
<i>Class name</i>	C
<i>Mixin name</i>	M, N
<i>Interface name</i>	I, J
<i>Field name</i>	m, p
<i>Type</i>	$S, T, U, V ::= X, Y \mid I[\overline{T}] \mid S \rightarrow T \mid \forall X. T \mid S \& T \mid \mathbf{Object}$

<i>Top-level definition</i>	$\mathcal{D} ::=$
<i>Interface</i>	$I[\overline{X}] \triangleleft J[\overline{T}] \mathcal{R}$
<i>Mixin</i>	$\mid M[\overline{X}]_T^{\mathcal{R}} \mathcal{I}$
<i>Class</i>	$\mid C[\overline{X}](\overline{m : \overline{T}}) \triangleleft I[\overline{T}], \overline{M[\overline{T}]}$
<i>Program</i>	$\mathcal{P} ::= \overline{\mathcal{D}}; e$

■ **Figure 1** Syntax of $\lambda^{\mathbf{super}}$.

and the actual type of **this** is only decided when the mixin composition is finalized as part of a class definition. Therefore, a precise type specification for **this** is necessary for open recursive calls in mixin methods. Importantly, **this** type refinement can be polymorphic at the mixin level, being instantiated at mixin composition time (i.e., upon being used as part of a class definition). Such polymorphism allows for later extensions to the shapes of data types that a method may be made to work on, as described in Section 2.

3.2 Formal Syntax

We now introduce the $\lambda^{\mathbf{super}}$ calculus, a formalization of SuperOOP. The design of this calculus is inspired by Featherweight Generic Java [19] and Pathless Scala [20]. Throughout our formalization, we use the notation $\overline{E}_i^{i \in n..m}$ to denote the repetition of syntax form E_i with index i from n to m . We use \overline{E} as a shorthand when i is not necessary for disambiguation. Moreover, we use $[T/X]$ to denote the conventional capture-avoiding substitution of a list of type parameters \overline{X} (which can possibly be empty) to \overline{T} . In definitions of metafunctions, we use \emptyset as a default vacuous result.

The syntax of $\lambda^{\mathbf{super}}$ is presented in Figure 1. Meta-variables S, T, U, V range over types, which include type variables, interfaces with a list of type arguments, arrow types, universally quantified types, intersection types, and the top type **Object**. For terms e , there are term variables x and y . **this** and **super** are akin to term variables with special treatment. We have standard explicitly-typed lambda abstractions and term applications, as well as type abstraction and type application terms. Method invocation and access to object fields share a single syntax: we consider access to object fields as method invocation. Objects are created with a **new** keyword with term and type arguments supplied.

$\boxed{S <: T}$	S-REFL $\frac{}{T <: T}$	S-TOP $\frac{}{T <: \text{Object}}$	S-INTERFACE $\frac{S \in \text{parents}(I[\overline{T}])}{I[\overline{T}] <: S}$	S-INV $\frac{S <: T \quad T <: S}{I[S] <: I[\overline{T}]}$

	S-ARROW $\frac{S_2 <: S_1 \quad T_1 <: T_2}{S_1 \rightarrow T_1 <: S_2 \rightarrow T_2}$	S-FORALL $\frac{S <: T}{\forall X. S <: \forall X. T}$		

■ **Figure 2** Declarative subtyping.

The top-level definitions of λ^{super} are interfaces, mixins, and classes. Every interface $I[\overline{X}]$ has a type parameter list $[\overline{X}]$, a structural refinement \mathcal{R} , and inherits multiple parent interfaces $J[\overline{T}]$. A structural refinement \mathcal{R} contains a list of method signatures $m : T$ that specify methods' names and types. Mixins, parametrized by type parameters, provide method implementations \mathcal{I} . Crucially, each mixin has a structural refinement \mathcal{R} attached to **super** and a type T for **this** for precise typing of open recursion. Finally, a class has a class-level type parameter list, immutable object fields, an interface it implements, and a mixin composition $M[\overline{T}]$ that provides method implementations. A program consists in a list of top-level definitions and a term that accesses them. For all top-level definitions, we require the standard well-formedness conditions that all names are uniquely defined and no class transitively inherits itself. In later rules, we assume terms' access to the underlying top-level definitions.

3.3 Static Semantics

We present the static semantics of λ^{super} which includes a declarative subtyping, term typing, and well-formedness check of top-level definitions.

Declarative subtyping. Figure 2 shows the declarative subtyping of λ^{super} . Most rules are unsurprising. Rule S-INTERFACE describes that an interface is a subtype of its parent interfaces. Auxiliary function $\text{parents}(I[\overline{T}])$ (defined in the extended version) returns the list of parent interfaces. For simplicity, we consider that interfaces are *invariant* in their type parameters (rule S-INV). A universally quantified type is a subtype of another universally quantified type only when they are quantifying the same type variable.

Term typing. Figure 3 lists the typing rule of terms. $\Gamma \vdash e : T$ is the term typing relation. A typing context Γ maps term variables to types, **super** to a structural refinement, and **this** to a type. The typing rules for term variables (T-VAR), lambda and type abstractions (T-ABS and T-TABS), term and type applications (T-APP and T-TAPP), as well as the subsumption rule (T-SUB), are standard. Note that since **super** is not bound to a type (but to a structural refinement) in typing contexts, **super** itself will never be assigned a type, which matches the usual semantics of **super** that it should only receive method call messages but not be passed around. The typing of method invocations is separated into two cases. If the receiver is a term (other than **super**) that has a type, we look up the method signature

$$\begin{array}{c}
\text{Typing context} \quad \Gamma ::= \epsilon \mid \Gamma, x : T \mid \Gamma, \mathbf{super} : \mathcal{R} \mid \Gamma, \mathbf{this} : T \\
\\
\boxed{\Gamma \vdash e : T} \quad \begin{array}{c} \text{T-VAR} \\ \Gamma(x) = T \\ \hline \Gamma \vdash x : T \end{array} \quad \begin{array}{c} \text{T-THIS} \\ \Gamma(\mathbf{this}) = T \\ \hline \Gamma \vdash \mathbf{this} : T \end{array} \quad \begin{array}{c} \text{T-ABS} \\ \Gamma, x : S \vdash e : T \\ \hline \Gamma \vdash \lambda x : S. e : S \rightarrow T \end{array} \quad \begin{array}{c} \text{T-TABS} \\ \Gamma \vdash e : T \\ \hline \Gamma \vdash \Lambda X. e : \forall X. T \end{array} \\
\\
\begin{array}{c} \text{T-APP} \\ \Gamma \vdash e_1 : S \rightarrow T \quad \Gamma \vdash e_2 : S \\ \hline \Gamma \vdash e_1 e_2 : T \end{array} \quad \begin{array}{c} \text{T-TAPP} \\ \Gamma \vdash e : \forall X. S \\ \hline \Gamma \vdash e T : [T/X]S \end{array} \quad \begin{array}{c} \text{T-ACCESS} \\ \Gamma \vdash e : T \quad \text{mtype}(m, T) = S \\ \hline \Gamma \vdash e.m : S \end{array} \\
\\
\begin{array}{c} \text{T-SUPER} \\ \Gamma(\mathbf{super}) = \mathcal{R} \\ \text{mrefn}(m, \mathcal{R}) = S \\ \hline \Gamma \vdash \mathbf{super}.m : S \end{array} \quad \begin{array}{c} \text{T-NEW} \\ \text{vparams}(C[\overline{T}]) = \overline{m_i : U_i^{i \in 1..n}} \\ \Gamma \vdash e_i : \overline{U_i^{i \in 1..n}} \quad \text{ctype}(C[\overline{T}]) = V \\ \hline \Gamma \vdash \mathbf{new } C[\overline{T}](\overline{e_i^{i \in 1..n}}) : V \end{array} \quad \begin{array}{c} \text{T-SUB} \\ \Gamma \vdash e : S \\ S <: T \\ \hline \Gamma \vdash e : T \end{array}
\end{array}$$

Given that interface I is defined as $I[\overline{X}] \triangleleft J[\overline{U}] \mathcal{R}$:

$$\begin{array}{l}
\text{mtype}(m, I[\overline{T}]) = \begin{cases} [\overline{T/X}]S & \text{if } (m : S) \in \mathcal{R} \\ S & \text{if } m \notin \mathcal{R} \text{ and } \text{mtype}(m, \&[\overline{T/X}]J[\overline{U}]) = S \end{cases} \\
\text{mtype}(m, S \& T) = \begin{cases} U \& V & \text{if } \text{mtype}(m, S) = U \text{ and } \text{mtype}(m, T) = V \\ U & \text{if } \text{mtype}(m, S) = U \text{ and } \text{mtype}(m, T) = \emptyset \\ V & \text{if } \text{mtype}(m, S) = \emptyset \text{ and } \text{mtype}(m, T) = V \end{cases} \\
\text{mtype}(m, T) = \emptyset \text{ otherwise}
\end{array}$$

■ **Figure 3** Term typing.

in the receiver's type. Function $\text{mtype}(m, T)$ computes method m 's signature from type T . Otherwise, if the receiver is **super**, we directly read the method type from its associated structural refinement using function $\text{mrefn}(m, \mathcal{R})$ (defined in the extended version). To type class instantiation (T-NEW), we check that all constructor arguments match the types of the class fields returned by function $\text{vparams}(C[\overline{T}])$, and the object has interface type $\text{ctype}(C[\overline{T}])$ of the class (vparams and ctype are defined in the extended version).

The design of mtype basically follows that of Pathless Scala [20]. When a method signature is present in an interface, we directly return it. Otherwise, we search parent interfaces by calling mtype with the *intersection* of all parent interfaces (denoted as $\&J[\overline{U}]$). Note that nullary intersection is **Object**. To compute a method signature from an intersection type, we recursively consider both sides of the intersection. When both types define the method, we take the intersection of corresponding results.

Well-formedness of top-level definitions. Figure 4 shows the well-formedness check of mixins, classes, and interfaces. We put name lookup results of those structures as premises in the rules. The first premises of rules in Figure 4 are the case.

11:14 super-Charging Object-Oriented Programming

$$\begin{array}{c}
\boxed{M \text{ ok}} \quad \frac{\text{MIXINCHECK} \quad M[\overline{X}]_T^{\mathcal{R}} \{ \overline{m : S = e} \} \quad \forall (m : S = e) \in M. \text{ this} : T, \text{ super} : \mathcal{R} \vdash e : S}{M \text{ ok}} \\
\\
\boxed{I \text{ ok}} \quad \frac{\text{INTERFACECHECK} \quad I[\overline{X}] \triangleleft J[\overline{T}] \{ \overline{m : S} \} \quad \overline{J \text{ ok}} \quad \forall (m : S) \in I. \text{ mtype}(m, \&\mathcal{J}[\overline{T}]) = \emptyset \text{ or } \begin{cases} \text{mtype}(m, \&\mathcal{J}[\overline{T}]) = U \\ S <: U \end{cases}}{I \text{ ok}} \\
\\
\boxed{C \text{ ok}} \quad \frac{\text{CLASSCHECK} \quad C[\overline{X}](\overline{p : T}) \triangleleft I[\overline{U}], \overline{M_i[\overline{U}]}^{i \in n..1} \quad \begin{array}{l} I \text{ ok} \quad \overline{M_i \text{ ok}} \quad \overline{M_i} \Rightarrow \overline{C} \quad \forall m \in \text{mnames}(I[\overline{U}]). \begin{cases} \text{mtype}(m, I[\overline{U}]) = S \\ \text{search}(m, 0, C) = V \\ V <: S \end{cases} \end{array}}{C \text{ ok}} \\
\\
\boxed{M_i \Rightarrow C} \quad \frac{\text{INHERITCHECK} \quad C[\overline{X}](\overline{p : U'}) \triangleleft I[\overline{U}], \overline{M_i[\overline{V}]}^{i \in n..1} \quad M_i[\overline{Y}]_T^{\mathcal{R}} \mathcal{I} \quad I[\overline{U}] <: [\overline{V/Y}]T \quad \forall (m : S) \in \mathcal{R}. \begin{cases} \text{search}(m, (i+1), C) = S' \\ S' <: [\overline{V/Y}]S \end{cases}}{M_i \Rightarrow C}
\end{array}$$

■ **Figure 4** Well-formedness check of top-level definitions and mixin inheritance check.

Well-formed mixins. To check a mixin ($M \text{ ok}$), we check that every method implementation can be typed at its signature with precise types of **this** and **super** in the context.¹¹

Well-formed interfaces. An interface is well-formed ($I \text{ ok}$) when its parent interfaces are all well-formed. A method signature should either be newly introduced (in this case, $\text{mtype}(m, \&\mathcal{J}[\overline{T}]) = \emptyset$), or have a subtype of the intersection of all m 's signatures in parents (i.e., $\text{mtype}(m, \&\mathcal{J}[\overline{T}]) = U$).

Well-formed classes. Class well-formedness check ($C \text{ ok}$) considers the following aspects:

1. The implemented interface and each mixin in the mixin composition are well-formed.
2. Open-recursive calls via **this** in the mixin composition are safe: the class type is a subtype of each mixin's **this** type annotation.
3. The mixin composition is correct: each mixin's structural refinement on **super** is satisfied.
4. The interface is satisfied: the class has all methods (and fields, as we uniformly treat fields and methods) required, and their signatures conform to the interface.

¹¹ Note that we bind **this** to a type while **super** to a structural refinement in each mixin. For **super**, the parent mixin in the composition hierarchy does *not* define an object type. It is therefore enough to give **super** a structural method refinement to tell what types the overridden methods should have. On the other hand, **this** is late-bound to the receiver object that has a type, can be passed around, and receive method invocation messages. Hence **this** is annotated with a type, and the annotated type should be a supertype of the later defined class's type.

Given that class C is defined as $C[\overline{X}](\overline{m_j : T_j}) \triangleleft I[\overline{S}], \overline{M_i[\overline{S}]}^{i \in n..1}$,
and mixin M_i is defined as $M_i[\overline{Y}]_V^R \mathcal{I}$:

$$\begin{aligned} \text{search}(m_j, 0, C) &= \begin{cases} T_j & \text{if } m_j : T_j \in \overline{m_j : T_j} \\ U & \text{if } m_j \notin \overline{m_j : T_j} \text{ and } \text{search}(m_j, 1, C) = U \end{cases} \\ \text{search}(m, i, C) &= \begin{cases} [\overline{S/\overline{Y}}]U & \text{if } 0 < i \leq n \text{ and } (m : U = e) \in \mathcal{I} \\ U & \text{if } 0 < i \leq n \text{ and } m \notin \mathcal{I} \text{ and } \text{search}(m, (i + 1), C) = U \end{cases} \\ \text{search}(m, i, C) &= \emptyset \text{ otherwise} \end{aligned}$$

■ **Figure 5** Method implementation type search function.

For 1., I **ok** checks the interface, and \overline{M} **ok** checks each mixin. Relation $M_i \Rightarrow C$ implements mixin inheritance check which deals with 2. and 3.. It checks if the inheritance of the i -th mixin in class C 's mixin composition is correct. Note that the index i here ranges in $n..1$ (as $\overline{M_i[\overline{S}]}^{i \in n..1}$), which means syntactically, the *rightmost* mixin in the mixin composition is the *first* one. Rule INHERITCHECK guarantees that, first, **this** type of the i -th mixin should be a *supertype* of the interface that the class conforms to, which satisfies 2.. Second, for each method m 's signature in the structural refinement of **super**, the parent mixin composition provides a compatible implementation. Specifically, the type of m 's implementation provided by mixins ranging in $n..(i + 1)$ (computed by $\text{search}(m, (i + 1), C)$, defined in Figure 5 and explained later) should be a *subtype* of the i -th mixin's **super** refinement on m , which satisfies 3.. To satisfy 4., for each method name m defined in the interface (computed by mnames , defined in the extended version), its implementation type provided by the class fields or mixin composition (computed by $\text{search}(m, 0, C)$) should be compatible with the signature specified by the interface (computed by mtype).

Method implementation type search. Figure 5 defines function $\text{search}(m, i, C)$ to search implementation type of m provided by fields or mixins ranging in $n..i$. When $i = 0$, it searches class fields for the method name m . If m is not implemented by fields, the search continues with the first mixin ($i = 1$). For the i -th mixin, the search directly returns the method signature if m is implemented in this mixin. Otherwise, it continues with the parent mixin (indexed $(i + 1)$). The search returns \emptyset if i exceeds the length of class C 's mixin composition ($i > n$), which means m is not implemented in the class, and the search fails.

3.4 Dynamic Semantics

Figure 6 lists the syntax of values, results, and runtime contexts, and lists the evaluation rules that produce values (the rules that produce runtime errors are omitted and can be found in the extended version). The big-step evaluation judgment $\Xi \vdash e \Downarrow r$ denotes that term e evaluates to result r under runtime context Ξ . The result of evaluation may be a normal value or an error. Values are either *closures* or *objects*. A runtime context Ξ binds values to term variables and a *configured object* to **this**. A configured object $\{i \star C[\overline{T}](\overline{v})\}$ is a pair of an object and a natural number i called the *search index*. This index directs the search for method implementation in the object fields and mixin composition at runtime. The evaluation rules for variables and term applications are standard. For type applications, while we use type substitution in the semantics, this will be no-op at runtime, as all generic types are erasable – only class tags are used at runtime, which are concrete types that need

■ **Figure 6** Big-step operational semantics producing values.

no substitution. Note that evaluation of **this** is to simply read the configured object from the context and return a plain object (i.e., with no search index). Class instantiations produce objects. Lambda and type abstractions are evaluated to closures. Note that $\lambda^{\mathbf{super}}$ would not need a value restriction [32] even if we added imperative effects to it, because it does not evaluate under polymorphic abstractions. This is different from the real MLscript language, which does need a value restriction as it uses ML-style polymorphism.

Method invocation and access to fields. Proper modeling of method invocation and access to fields are of our particular interest. The following procedure explains the overall idea:

1. When the receiver is a term (modulo **super**), we first evaluate the term to an object and search through the object's fields for the method implementation (E-ACCESS).
2. If the invoking method is not provided by any object field, we traverse the mixin composition of the class (E-ARGMISS).

$$\begin{array}{c}
\boxed{v : T} \\

■ **Figure 7** Value typing of closures.

3. If the invoking method is provided as an object field, we return the value bound to the field (E-ARGHIT).
4. If the invoking method is not implemented by the i -th mixin, we search the next mixin in the composition hierarchy (E-SUPERMISS). Helper function $\text{methods}(i, C[\overline{S}](\overline{v}))$ (defined in the extended version) returns all method implementations of the i -th mixin.
5. If the invoking method is implemented by the i -th mixin, we evaluate the method body with \mathbf{this} bound to the configured object where the search index points to the parent mixin (E-SUPERHIT).

3.5 Metatheory

We now develop the metatheory of $\lambda^{\mathbf{super}}$. We follow Ernst et al.'s approach to prove type soundness of our big-step style semantics.

Value typing. Our metatheory focuses on *strong* soundness, that is, we need to type values to ensure that the evaluation result keeps the type. Value typing rules of closures are listed in Figure 7. Rule VT-ABS1 types lambda abstraction body under a typing context Γ with the term variable bound to the input type and \mathbf{super} refined by a structural refinement \mathcal{R} . Here we perform two consistency checks. First, the typing context should be consistent with the runtime context ($\Gamma \models \Xi$, rules are listed in the extended version), i.e., each term variable is bound to a value that matches the variable's type in the typing context. Second, to guarantee that calls to super implementations are always safe, the structural refinement \mathcal{R} giving precise types to calls on \mathbf{super} in the closure body should be *consistent* with the configured object in the closure's context. Relation $\mathcal{R} \models \{i \star C[\overline{S}](\overline{v})\}$ implements the second consistency check, which examines each method signature's compatibility with the method implementation type provided by the configured object. The remaining rules (in the extended version) that type objects and closures with no binding to \mathbf{this} in the context are non-surprising.

Soundness. We finally show the soundness results of our formal calculus. The complete proofs can be found in the extended version. For a program \mathcal{P} , we denote its top-level definitions as $\overline{\mathcal{D}}_{\mathcal{P}}$ and the associated term as $e_{\mathcal{P}}$. The preservation lemma is stated below:

► **Lemma 1** (Preservation). *If $\overline{\mathcal{D}}_{\mathcal{P}} \text{ ok}$ and $\epsilon \vdash e_{\mathcal{P}} : T$ and $\epsilon \vdash e_{\mathcal{P}} \Downarrow r$ then $r = \mathbf{val} \ v$ and $v : T$.*

We define the *finite evaluation* relation [9] here to augment our big-step semantics with fuel.

11:18 super-Charging Object-Oriented Programming

► **Definition 2** (Finite evaluation). Define an evaluation relation $\Xi \vdash e \Downarrow_k r^+$ (where $r^+ ::= r \mid \text{kill}$, and k is the step-counting index, i.e. fuel) with evaluation rules copied from $\Xi \vdash e \Downarrow r$. For each rule, \Downarrow in the conclusion is replaced by \Downarrow_k , and \Downarrow in premises is replaced by \Downarrow_{k-1} . Also, propagate timeout result of subderivations (the corresponding rules are listed in the extended version). Finally, add the following axiom:

$$\begin{array}{l} E\text{-TIMEOUT} \\ \Xi \vdash e \Downarrow_0 \text{kill} \end{array}$$

The soundness theorem of our calculus follows from the preservation lemma that rules out errors when evaluation terminates and the coverage lemma that ensures our evaluation rules with finite fuel always produce a result.

► **Lemma 3** (Coverage). For all n, Ξ , and e , there exists an r^+ such that $\Xi \vdash e \Downarrow_n r^+$.

► **Definition 4** (Expression divergence). e diverges \triangleq For all $n, \epsilon \vdash e \Downarrow_n \text{kill}$.

► **Theorem 5** (Soundness). If $\overline{\mathcal{D}_{\mathcal{P}} \text{ok}}$ and $\epsilon \vdash e_{\mathcal{P}} : T$ then (1) $\epsilon \vdash e_{\mathcal{P}} \Downarrow \text{val } v$ and $v : T$, or (2) $e_{\mathcal{P}}$ diverges.

4 Discussion and Related Work

We now discuss the expressiveness, limitations, and implementation of SuperOOP as presented in this paper, and we compare our approach to related work.

4.1 Expressiveness and Limitations

Thanks to the clear separation of concerns between the orthogonal concepts of interfaces, mixins, and classes, and thanks to the flexibility of mixins, SuperOOP not only captures standard OOP features but can also be used to explain existing advanced OOP models.

Desugaring traditional classes. A classic OOP class is desugared into three SuperOOP core language components: (a) a core-language class for its fields; (b) a core-language mixin for its implementations; and (c) a core-language interface for its method signatures. Although our core language does not directly support class inheritance, this feature can easily be desugared into SuperOOP. For example, recall `ColoredPoint` from Section 1, which inherited from class `Point`. This class hierarchy can be desugared to SuperOOP as:

```
interface IPoint { x: Int; y: Int }
class Point(x: Int, y: Int) implements IPoint

interface IColoredPoint extends IPoint, Colored
class ColoredPoint(x: Int, y: Int, color: Color) implements IColoredPoint
```

Multiple inheritance and linearization. Languages that support multiple inheritance usually have a *linearization* mechanism that determines the order of inherited parent classes, traits, or mixins. The underlying assumption is that each parent can only be inherited at most once, so if a parent transitively occurs more than once in an inheritance clause, the linearization mechanism removes all but its first occurrence. Consequently, linearization affects the semantics of method resolution and **super**-calls. For example, Scala uses linearization for its multiple trait inheritance system [22]. The linearization of a Scala class definition of the form `class C extends B0, B1, ..., Bn` starts with `B0`'s linearization and appends to it the

linearization of B_1 save for those traits that are already in the constructed linearization of B_0 , etc. Several languages such as Python adopt the influential C3 linearization algorithm [1]. Although SuperOOP does not natively support multiple class inheritance, we can still apply any linearization algorithms used by existing languages and desugar the result using core SuperOOP classes, interfaces, and mixins. On the other hand, in SuperOOP, one can inherit a given mixin an arbitrary number of times at different positions in the mixin inheritance stack. The resolution of method invocations simply follows the order of inherited mixins, which do not necessarily need to be linearized. So SuperOOP’s approach is more general.

We show an example encoding of Scala multiple trait inheritance in SuperOOP in the extended version of this paper.

Mixin parameters. Mixin parameters are a powerful extension to the core SuperOOP language presented in this paper. They for instance allow one to define flexible and efficient streaming processing abstractions that are composed through mixins, as in the following:

```
module MyPipeline extends
  Map(x => x + 1),
  Filter(x => x % 2 == 0),
  Map(x => x * 2)
```

We use *two* instances of `Map` in the mixin composition above, showing that using **this** refinements to encode mixin parameters would not be sufficient, as each of these two `Map` instances needs to be given a *different* argument. Mixin parameters are implemented in MLscript/SuperOOP, but we omitted this extension from λ^{super} for simplicity.

Member access control. We have not yet modeled in the core language nor implemented any notions of encapsulation and visibility, such as the **private** and **protected** modifiers. We expect that modeling these features should be straightforward, as their design is mostly orthogonal to the features of SuperOOP.

4.2 Implementation of SuperOOP in MLscript

We now briefly describe our implementation and possible alternative implementation strategies.

Compilation to JavaScript. MLscript currently compiles to JavaScript, which supports classes as first-class entities. This means it is possible to define mixins directly, by using functions. For instance, the `EvalNeg` and `EvalMul` mixins and the `LangNegMul` class mentioned in Section 2 are essentially compiled into the following JavaScript code:

```
function mkEvalNeg(base) {
  return class EvalNeg extends base {
    eval(e) {
      if (e instanceof Neg) return 0 - this.eval(e.expr)
      else return super.eval(e) } }
}
function mkEvalMul(base) {
  return class EvalMul extends base {
    eval(e) {
      if (e instanceof Mul) return this.eval(e.lhs) * this.eval(e.rhs)
      else return super.eval(e) } }
}
class LangNegMul extends mkEvalMul(mkEvalNeg(EvalBase))
```

11:20 super-Charging Object-Oriented Programming

One side effect of this straightforward implementation is that mixins in MLscript can be inherited an arbitrary number of times and that no inheritance linearization is needed. MLscript *classes*, on the other hand, follow the usual single-inheritance hierarchy discipline, which is useful for type checking pattern matching and inferring simple types for it.

Compilation to other targets. We are also considering adding alternative compilation backends to MLscript, such as backend compilers targeting WebAssembly and the Java Virtual Machine. In that context, we can still follow the general JavaScript-based semantics described above, but we will make sure to evaluate the mixin functions at compilation time, to guarantee optimal performance and simple compilation. Super calls would then be resolved statically, allowing for efficient target code. Therefore, our approach to mixin composition should offer better performance than alternative solutions to the expression problem which rely on closure compositions and thus require virtual dispatch, like the approach of Garrigue [16]. However, we reserve a rigorous performance evaluation for future work.

Separate compilation. An aspect of the Expression Problem as originally stated is that it should be possible to compile each extension separately before putting them all together. We can essentially achieve this even in the static compiler scenario by separately compiling method *implementations* and composing classes whose methods simply forward to these pre-compiled implementations. This is more or less the approach used by Scala for traits, which was shown to be practical in real-world scenarios.

Case studies. In the extended version of this paper, we provide case studies of MLscript/SuperOOP that include a modular evaluator of extended lambda calculus, as described by Garrigue [16], and a simple “regions” DSL developed by Sun et al. [31]. These case studies showcase the flexibility of SuperOOP polymorphic mixins, the ability to handle mutually-recursive functions across different mixins, interpret complex data types, and optimize domain-specific languages via built-in nested pattern matching. Additionally, thanks to MLscript’s powerful principal type inference [26], those case studies type check without the help of a single type annotation.

4.3 Solutions to the Expression Problem

There is a sea of work in extensible programming that address the Expression Problem, based on techniques such as polymorphic variants [15] in OCaml, recursive modules [21] in ML, and new programming paradigms [4, 23] like Compositional Programming [34]. We survey a few of them by showing their solutions to the Expression Problem and discuss various design tradeoffs with respect to the approach of SuperOOP.

Polymorphic Variants. The *polymorphic variant* (PV) solution [16] probably comes closest to our approach. Open recursion there is implemented by way of an explicit parameter for recursive calls, and by manually tying the recursive knots. For example, one defines an open-recursive base implementation of evaluation on two expression data types as follows:

```
let eval_base eval_rec = function
  | 'Lit(n) → n
  | 'Add(e1, e2) → eval_rec e1 + eval_rec e2
(* val eval_base :
  ('a → int) → [< 'Add of 'a * 'a | 'Lit of int ] → int *)
```

PVs differ from traditional variants or *algebraic data types* (ADTs) in that PVs allow the use of arbitrary constructors without a corresponding data type definition; they can be thought of as ADTs that are “not fully specified” and thus allow further extension. In the example above, two constructors ‘Lit and ‘Add are introduced. Function `eval_base` takes a first parameter `eval_rec` for open-recursive calls and the expression to evaluate as a second parameter. Parameter `eval_rec` accepts expressions with type ‘a, and the expression is required to have type [`< ‘Add of 'a * 'a | ‘Lit of int`], which allows either an ‘Add expression containing nested subexpressions of type ‘a, or a ‘Lit instance with an integer payload. Extending this base evaluator with new operations is done by composing it inside new functions. To extend the supported expression forms, one defines another evaluation implementation that works, e.g., on negations:

```
let eval_ext eval_rec = function
  'Neg(e) → 0 - eval_rec e
(* val eval_ext : ('a → int) → [< ‘Neg of 'a ] → int *)
```

Finally, one needs to tie both implementations together:

```
type 'a expr_base = ['Lit of int | ‘Add of 'a * 'a]
type 'a expr_ext = ['Neg of 'a]
let rec eval = function
  | #expr_base as x → eval_base eval x
  | #expr_ext as x → eval_ext eval x
(* val eval :
  ([< ‘Add of 'a * 'a | ‘Lit of int | ‘Neg of 'a ] as 'a) → int *)
```

Function `eval` dispatches the evaluation of the base and extended data types to the two evaluation sub-implementations, and it ties the recursive knots by passing itself as the entry point of the recursion. Note that `eval` has an inferred recursive type that accepts an expression recursively constructed by the three variants. Compared with our solution, from a programming style perspective, one programs with polymorphic variants in a functional way, while SuperOOP adopts a more object-oriented style. More importantly, polymorphic variants suffer from several practical drawbacks, including loss of polymorphism and approximated typing of pattern matching [5]. Those drawbacks can be fixed by embracing “proper” implicit subtyping as in MLscript [26]. In particular, we argue that union types are simpler than row polymorphism, which imperfectly emulates subtyping through unification [26].

OCaml’s Object System. In OCaml class definitions, one can annotate “self” with a type signature and define “super” explicitly in a way that superficially looks similar to SuperOOP. One may be tempted to try and encode precise typing of open recursion in OCaml, to enable extensible programming with classes. However, this does not work due to OCaml’s use of unification and its lack of subtyping: the self and super types are *unified* with the object type being defined, and thus all three must exactly coincide. By contrast, SuperOOP mixins allows *different* self and super types and allows overriding methods with *different* types, which is crucial for our technique. We discuss this in more detail in the extended version.

Featherweight Generic Go. Go is a popular programming language developed by Google. Featherweight Go (FG) and its generic version Featherweight Generic Go (FGG) proposed by Griesemer et al. [18] are formal developments of Go with the goal of helping “get polymorphism right”. FGG provides a solution to the Expression Problem based on generics and covariant matching of method receiver type refinements, as in:

```
func (e Plus(type a Evaluator)) Eval() int {
  return e.left.Eval() + e.right.Eval()
}
```

11:22 super-Charging Object-Oriented Programming

Method `Eval` is generic in type variable `'a'` which is upper-bounded by interface `Evaler`. Once dissociated from the quantification of `a`, the receiver type of the method is `Plus(a)`, the type of a `Plus` instance with subexpressions of type `'a'`. To extend the supported operations in the encoded language, one may define a similar pretty-printing method. Finally, one combines the interfaces for different interpretations together in a final expression type:

```
type Expr interface {
    Evaler
    Stringer
}
```

Type `Expr` composes two operations together, so it implements both of `Evaler` and `Stringer` (an interface for stringification). One can build and use such expressions as follows:

```
var e Expr = Plus(Expr){Lit{1}, Lit{2}}
var result Int = e.Eval()
var pretty string = e.String()
```

While this allows FGg to solve the Expression Problem, the features that enable this solution are not part of the Go team's current design for generics [18]. Moreover, the inspection of data structures only happens at the *outermost* level. If one wants to deeply transform an expression instance, that is, to inspect its inner structure and, for example, perform optimizations on it, one would have to make an additional method to delegate the inspection semantics itself. This approach, called *delegated method patterns* in Sun et al.'s work [31], is non-modular in FGg as it requires adding a new method for each inner structure inspection and to implement this method for each constructor of the data type, even those constructors that should otherwise fall into a default case of the encoded pattern matching.

Object Algebras. *Object Algebras* are a well-known object-oriented approach to solve the Expression Problem [23]. The key to this solution is an abstract factory called *object algebra interface*, which contains data type constructor signatures, leaving their interpretation unspecified. An object algebra interface for expressions could be, in Scala syntax:

```
trait ExpAlg[Exp] {
    def Lit: Int => Exp
    def Add: (Exp, Exp) => Exp
}
```

Trait `ExpAlg` specifies two data type constructors, and it is parameterized by type parameter `Exp` that indicates the interpretation of expression data types. We can implement evaluation on expressions by implementing the object algebra interface:

```
trait IEval { def eval: Int }
trait Eval extends ExpAlg[IEval] {
    def Lit = n => new IEval { def eval = n }
    def Add = (e1, e2) => new IEval { def eval = e1.eval + e2.eval }
}
```

Trait `Eval` is an object algebra which implements `ExpAlg` with the type parameter instantiated to `IEval`. Trait `IEval` indicates that expressions can be evaluated to integers. To extend the language with new operations, we may simply define a new interpretation type and a corresponding object algebra interface implementation. On the other hand, for new data type extensions, we inherit the object algebra interface and the old implementation:

```

trait NegAlg[Exp] extends ExpAlg[Exp] {
  def Neg: Exp => Exp
}
trait EvalNeg extends NegAlg[IEval] with Eval {
  def Neg = (e) => new IEval { def eval = 0 - e.eval }
}

```

We can now define an expression instance and instantiate the language:

```

trait exp[Exp](f: NegAlg[Exp]) {
  f.Add(f.Lit(1), f.Neg(f.Lit(-1)))
}
object eval extends EvalNeg
println(exp(eval).eval)

```

In trait `exp`, the data type constructors are accessed through the input object algebra `f`. With different implementations of the object algebra interface passed in, the expression will be interpreted in different ways. However, as noticed by Zhang et al. [34], one needs to create an expression instance for each data type interpretation, and there is no built-in approach to composing interpretations in different object algebras. Moreover, as data type constructors are specified through type *signatures* in object algebra interfaces, there is no way to have an inspectable representation of language instances without a complete definition of abstract syntax, blocking useful extensions such as modular transformations and optimizations.

Compositional Programming. *Compositional programming* [34] (implemented in the *CP* language) is a novel programming paradigm that features modularity. It supports a *merge operator* as the introduction term for intersection types. At the type level, the intersection type operator composes interfaces. At the term level, the merge operator composes *first-class traits* that contain data and operations. Similarly to Object Algebras, in Compositional Programming, a *compositional interface* specifies data type signatures, leaving their interpretation unspecified, and concrete interpretations are defined in first-class traits:

```

type ExpSig<Exp> = {
  Lit : Int → Exp;
  Add : Exp → Exp → Exp;
};
type Eval = { eval : Int };
evalNum = trait implements ExpSig<Eval> => {
  (Lit n).eval = n;
  (Add e1 e2).eval = e1.eval + e2.eval;
};

```

Trait `evalNum` implements the compositional interface `ExpSig<Eval>` which specifies that `Lit` and `Add` support an evaluation method. Similarly, one can implement a pretty-printing operation by adding another concrete interpretation. To extend the expression language with new data types, one extends the compositional interface and implements new operations in derived traits. Finally, everything is tied together with the merge operator as shown below:

```

type NegSig<Exp> extends ExpSig<Exp> = {
  Neg : Exp → Exp → Exp;
};
evalNeg = trait implements NegSig<Eval> inherits evalNum => {
  (Neg e).eval = 0 - e.eval;
};

```

```

exp Exp = trait [self : NegSig<Exp>] => {
  test = new Neg (new Add (new Lit 1) (new Lit 2));
};
// Assume pretty-printing of expression is analogously defined
e = new evalNeg ,, printNeg ,, exp @(Eval & Print);

```

Trait `exp` contains an example expression. The `self` type annotation in square brackets enables the trait body to access the three data type constructors. With the merge operator, trait instance `e` is composed of traits that contain different expression interpretations and the test trait. Note that trait `Exp` is passed with an intersection type argument `Eval & Print`, meaning the expression language supports both evaluation and pretty-printing.

In recent follow-up work on Compositional Programming by Sun et al. [31], different aspects of domain-specific language embedding are investigated, including the two-direction extensibility of language constructs and their interpretations, transformations and optimizations on language instances, etc. Since Compositional Programming does not natively support nested pattern matching (unlike our approach), deep inspection of data is only possible via the delegated method pattern (discussed above in the paragraph on `Go`), which is “not as convenient”, as the authors put it. We also argue that this does *not* work well for defining *optimizations* in a modular way. Indeed, optimizations are fundamentally order-sensitive, and encoding them in terms of CP’s unordered patterns requires non-local transformations of the involved pattern matching structures. For instance, one cannot *independently* define optimizations for evaluating `Neg(Neg(e))` as `e` and `Neg(Lit(n))` as `Lit(0 - n)`, whereas doing so in `MLscript/SuperOOP` is straightforward.

Approaches lacking type safety. It is much easier to solve the Expression Problem if one no longer cares about catching composition errors at compilation time. Zenger and Odersky [33] propose to use exception-throwing default cases in base implementations and to override these cases in further extensions, which relies on the programmer *remembering* to override all default cases and to pass only supported expression forms to the various methods in the program. Similar to `SuperOOP`, in a method that defines the interpretation of extended data types and overrides the base interpretation, they delegate the interpretation of base data types to the overridden method using `super`. While just as flexible as `SuperOOP`, this approach is fundamentally unsafe and error-prone. Going further, at the other end of the spectrum, approaches such as monkey-patching and Julia-style multiple dispatch allow completely dynamic updates of base implementations, which trivially supports extension but is anti-modular, as reasoning about the well-foundedness of method calls on given argument types requires global knowledge of all extension points in the program and libraries.

4.4 Modeling Inheritance and Reuse

In this subsection, we discuss previous work related to modeling inheritance and code reuse.

In their seminal *Inheritance Is Not Subtyping* paper, Cook et al. [7] introduced the crucial idea that inheritance could be unrestrained if it was decoupled from the subtyping relationship. However, they do not provide a specific source language in which to realize their ideas and only describe an imagined typed encoding of it, without an obvious way of connecting that encoding back to a hypothetical source language.

Bracha and Cook [3] describe both a Smalltalk-style approach and a CLOS-style multiple inheritance approach for modeling single inheritance and `super`. The paper uses a notion of implementation “deltas” Δ , which are not first-class and only used for explanation. In our approach, this notion of deltas exists as a first-class entity which we call *mixins*. Bracha and

Cook describe mixins as a form of *abstraction* (over an unknown base class), and linearization as *application* (wiring in all the base classes), by analogy with the classical lambda calculus concepts. In our approach, abstraction is similarly done through **super** and application is done through **extends**, but we do not require linearization and allow mixins to be inherited an arbitrary number of times. While Bracha and Cook leverage the notion that subtyping is not inheritance and allow the types of methods to change, they do not support the idea of precise **this** and **super** annotations and thus cannot precisely type open recursion.

The concept of “mixin” described by Flatt et al. [13, 14, 12] is related to ours, but conceptually different. While they do model **super**, their mixins necessarily conform to interfaces and are thus constrained to specific method signatures, preventing SuperOOP-style modular programming. The authors discuss the possibility of solving the EP with modules and their mixins in later work [11], but without proposing a static typing model.

Schärli et al. [29] study and discuss many perceived problems with mixin composition. They suggest that *traits* are a better unit of abstraction. We agree that traits are useful for architecting OOP code in the large, but argue that mixins are independently useful: abstract (i.e., open-ended) base classes are specifically what unlocks the expressiveness of mixin inheritance and our new solution to the Expression Problem. We believe that mixins should be conceptualized as pure *whitebox implementation* bundles (the implementation itself being the API) by contrast with interfaces, which hide implementation detail, and traits, which enable a form of well-behaved (associative and commutative) multiple inheritance, and that all three could have a place in an OO programmer’s toolkit.

The idea of separating reusable components from types was previously embraced by Bettini et al. [2], who argue that the role of *units of reuse* and the role of *types* are competing, as also observed by Cook et al. [7] and Snyder [30]. The semantics of Bettini et al.’s trait systems are similar to Schärli et al.’s but provide additional flexibility, in that traits are composed with explicit operations on methods such as renaming and exclusion to resolve conflict. A similar idea is used by Damiani et al. [8] in their design of a language enabling both trait reuse and *deltas* of classes, in the context of Software Product Line Engineering.

Type classes as in languages like Haskell [27] and Scala [24] also provide *data abstraction* and powerful parametrization and extensibility [6]. SuperOOP’s **super** is a way of *nesting* interpretations the same way one can design dependent type class instances. Any class hierarchy encoded solely with **super** refinements in SuperOOP translates straightforwardly to classic type classes. However, type classes *per se* are not enough for modular code reuse with recursive data structures, as that requires open recursion. Explicit encodings of open recursion can be implemented in Haskell and Scala, but these would live outside of the type class definitions and are orthogonal to type classes. By contrast, SuperOOP directly provides precisely-typed open recursion via **this** refinements in mixins.

5 Conclusion and Future Work

We presented a new approach to OOP which cleanly separates the concerns of *state*, *implementations*, and *interfaces* into the orthogonal constructs of *classes*, *mixins*, and *interfaces*. We showed that a refined typing of mixins allows for a new and powerful solution to the expression problem. Finally, we presented an implementation in MLscript, leveraging its flexible type inference capabilities to enable annotation-free modular programming. The main item of future work we would like to look into is the *deep* composition of mixin *families*, reminiscent of Delta-Oriented Programming [28, 8] but with precisely-typed open recursion.

Abstract

Local-first software manages and processes private data locally while still enabling collaboration between multiple parties connected via partially unreliable networks. Such software typically involves interactions with users and the execution environment (the outside world). The unpredictability of such interactions paired with their decentralized nature make reasoning about the correctness of local-first software a challenging endeavor. Yet, existing solutions to develop local-first software do not provide support for automated safety guarantees and instead expect developers to reason about concurrent interactions in an environment with unreliable network conditions.

We propose *LoRe*, a programming model and compiler that automatically verifies developer-supplied safety properties for local-first applications. *LoRe* combines the declarative data flow of reactive programming with static analysis and verification techniques to precisely determine concurrent interactions that violate safety invariants and to selectively employ strong consistency through coordination where required. We propose a formalized proof principle and demonstrate how to automate the process in a prototype implementation that outputs verified executable code. Our evaluation shows that *LoRe* simplifies the development of safe local-first software when compared to state-of-the-art approaches and that verification times are acceptable.

1 Introduction

Applications that enable multiple parties connected via partially unreliable networks to collaboratively process data prevail today. An illustrative example is a distributed calendar application with services to add or modify appointments, where a user may maintain multiple calendars on different devices, may share calendars with other users, back them up in a cloud; calendars must be accessible to users in a variety of scenarios, including offline periods, e.g., while traveling – yet, planning appointments may require coordination between multiple parties. The calendar application is representative for other collaborative data-driven software such as group collaboration tools, digital (cross-organizational) supply chains, multiplayer online gaming, and more.

The dominating software architecture for such applications is centralized: data is collected, managed, and processed centrally in data centers, while devices on the edge of the communication infrastructure serve primarily as interfaces to users and the outside world. This architecture simplifies the software running on edge devices since concerns like consistent data changes to ensure safety properties are managed centrally. However, this comes with issues including loss of control over data ownership and privacy, insufficient offline availability, poor latency, inefficient use of communication infrastructure, and waste of (powerful) computing resources on the edge.

To address these issues, local-first principles for software development have been formulated [17], calling for moving data management and processing to edge devices instead of confining the data to clouds. But for programming approaches that implement these principles to be viable alternatives to the centralized approach, they must support automatically verifiable safety guarantees to counter for the simplifying assumptions afforded by a centralized approach. Unfortunately, existing approaches to programming local-first applications such as *Yjs* [31] or *Automerge*¹ do not provide such guarantees. They use *conflict-free replicated data types (CRDTs)* [34] to store the parts of their state that is shared across devices and rely on callbacks for modeling and managing state that changes in both time and space. The unpredictability of the interactions triggered by the outside world, concurrently at different devices, paired with the absence of a central authority and the prevailing implicit dependencies in current callback-centred programming models, makes such reasoning without automated support a challenging, error-prone endeavour.

To close this gap, we propose a programming model for local-first applications that features explicit safety properties and automatically enforces them. The model has three core building blocks: *reactives*, *invariants*, and *interactions*. *Reactives* express values that change in time, but also in space by being replicated over multiple devices. *Invariants* are formula in first-order logic specifying safety properties that must hold at all times when the application interacts with the outside world, or values of reactives are observable. *Interactions* interface to the outside world and encapsulate changes to all reactives affected by interactions with it (state directly changed by the interactions, device-local values derived from the changed state, and shared state at remote devices). We use automatic verification with invariants as verification obligations to identify interactions that need coordination across devices, for which the compiler generates the coordination protocol; all other interactions become visible in causal order. This way, the compiler makes an application-specific availability-safety trade-off.

¹ <https://automerge.org/>

In summary, we make the following contributions²:

1. A programming model for local-first applications with verified safety properties (Section 2), called LoRe. While individual elements of the model, e.g., CRDTs or reactivities, are not novel, they are repurposed, combined, and extended in a unique way to systematically address specific needs of local-first applications with regard to ensuring safety properties.
2. A formal definition of the model including a formal notion of invariant preservation and confluence for interactions, and a modular verification that invariants are never violated. In particular, our model enables invariants that reason about the sequential behaviour of the program. In case of potential invariant violation due to concurrent execution, LoRe automatically adds the necessary coordination logic (see the extended version of this work²).
3. A verifying compiler³ that translates LoRe programs to Viper [28] for automated verification and to Scala for the application logic including synthesized synchronization to guarantee the specified safety invariants (Section 3).
4. An evaluation of LoRe in two case studies (Section 4). Our evaluation validates two claims we make about the programming model proposed, (a) It facilitates the development of safe local-first software, and (b) it enables an efficient and modular verification of safety properties. It further shows that the additional safety properties offered by our model do not come with prohibitive costs in terms of verification effort and time.

2 LoRe in a Nutshell

We introduce the concepts of LoRe along the example of a distributed calendar for tracking work meetings and vacation days. LoRe is an external DSL that compiles to Scala (for execution) and Viper IR [28] (for verification); its syntax is inspired by both. A LoRe program defines a distributed application that runs on multiple physical or virtual devices.⁴ Listing 1 shows a simplified implementation of the calendar example application in LoRe. As any LoRe program, it consists of replicated state (`Source` reactivities in Lines 2-3), local values derived from them (`Derived` reactivities in Lines 5-6), interactions (Lines 8-15), and invariants (Lines 20-23).

2.1 Reactives

Reactivities are the composition units in a LoRe program. We distinguish two types of them: *source* and *derived* reactivities, declared by the keywords `Source` and `Derived`, respectively. Source reactivities are values that are directly changed through interactions. Their state is modeled as *conflict-free replicated data types* (CRDTs) [34, 32] and is replicated between the different devices collaborating on the application. Derived reactivities represent local values that are automatically computed by the system from the values of other reactivities (source or derived). Changes to source reactivities automatically (a) trigger updates of derived reactivities and (b) cause devices to asynchronously send update messages to the other devices, which then merge the changes into their local state. Together, local propagations and asynchronous

² This is a short version of this work. The extended version is available at: <https://doi.org/10.48550/arXiv.2304.07133>.

³ The source code of our prototype implementation is available at <https://github.com/stg-tud/LoRe>.

⁴ We assume that every device is running the same application code (i.e., the same binary), and different types of devices (such as client and server) are modeled by limiting them to execute a subset of the defined interactions.

■ **Listing 1** The distributed calendar application.

```

1  type Calendar = ASet[Appointment]
2  val work: Source[Calendar] = Source(ASet())
3  val vacation: Source[Calendar] = Source(ASet())
4
5  val all_appointments: Derived[Set[Appointment]] = Derived{ work.
      toSet.union(vacation.toSet) }
6  val remaining_vacation: Derived[Int] = Derived{ 30 - sumDays(vacation.
      toSet) }
7
8  val add_appointment : Unit = Interaction[Calendar][Appointment]
9      .requires{ cal => a => get_start(a) < get_end(a) }
10     .requires{ cal => a => !(a in cal.toSet)}
11     .executes{ cal => a => cal.add(a) }
12     .ensures { cal => a => a in cal.toSet }
13  val add_vacation : Unit = add_appointment.modifies(vacation)
14     .requires{ cal => a => remaining_vacation - a.days >= 0}
15  val add_work      : Unit = add_appointment.modifies(work)
16
17  UI.display(all_appointments, remaining_vacation)
18  UI.vacationDialog.onConfirm{a => add_vacation.apply(a)}
19
20  invariant forall a: Appointment ::
21      a in all_appointments ==> get_start(a) < get_end(a)
22
23  invariant remaining_vacation >= 0

```

cross-device update messages ensure that users always have a consistent view of the overall application state. All reactivities are statically declared in the program source code. LoRe then statically extracts knowledge about the data flow for modular verification and to minimize the proof goals (cf. Sec 3.1). We discuss the technical implications of static reactivities in Section 6.

Listing 1 shows two source reactivities, `work` and `vacation` (Line 2 and 3), each modeling a calendar as a set of appointments. The work calendar tracks work meetings, while the vacation calendar contains registered vacation days. When defining a source reactive, programmers have to choose a CRDT for the reactive’s internal state. LoRe offers a selection of pre-defined CRDTs including various standard data types such as sets, counters, registers and lists. Further data types can be supported by providing a Viper specification for that data type. In this case, an *add-wins-set* (a set CRDT where additions have precedence over concurrent deletions) is selected for both source reactivities. Appointments from both calendars are tracked in the `all_appointments` derived reactive (Line 5), while the `remaining_vacation` reactive (Line 6) tracks the number of remaining vacation days.

2.2 Interactions

Changes to the state of the system, e.g., adding appointments to a calendar, happen through explicit *interactions*. Each interaction has two sets of type parameters: the types of source reactivities that it modifies and the types of parameters that are provided when the interaction is applied. For example, the `add_appointment` interaction in Line 8 modifies a reactive of type `Calendar` and takes a parameter of type `Appointment`. The semantics of an interaction `I` are defined in four parts: (1) `requires` (Line 9) defines the preconditions that must hold for `I` to be executed, (2) `executes` (Line 11) defines the changes to source reactivities, (3) `ensures` (Line 12) defines the postconditions that must hold at the end of `I`’s execution, (4) `modifies`

■ **Figure 1** Concurrent execution of interactions may cause invariant violations. In this example, device D_1 adds a vacation of 20 days to the calendar, while D_2 concurrently adds a vacation of 12 days. Given a total amount of 30 available vacation days, this leads to a negative amount of remaining vacation once the devices synchronize.

(Line 13) defines the source reactivities that I changes. The parameters of `requires`, `executes`, and `ensures` are functions that take the modified reactivities and the interaction parameters as input (`cal` is of type `Calendar` and `a` is of type `Appointment`). The splitting of the definition of interactions in four parts allows for modularization and reuse. For instance, `add_appointment` is only a partial specification of an interaction, missing the `modifies` specification. Both `add_work` (Line 15) and `add_vacation` (Line 13) specify complete interactions by adding `modifies` to `add_appointment`; they are independent interactions that differ only in their `modifies` set.

Interactions encapsulate reactions to input from the outside world (e.g., the callback in Line 18 that is triggered by the UI and applies the arguments to `add_vacation`). Applying an interaction checks the preconditions, and – if they are fulfilled – computes and applies the changes to the source reactivities, and propagates them to derived reactivities – all in a “transactional” way in the sense that all changes to affected reactivities become observable at-once (“atomically”). Only source reactivities are replicated between devices, while derived reactivities are computed by each device individually. LoRe guarantees that executing interactions does not invalidate neither postconditions nor invariants.

2.3 Invariants and Conflicts

LoRe expects the developer to use *invariants*, introduced with the keyword `invariant`, to specify application properties that should always hold. Invariants are first-order logic assertions given to a verifier based on the Viper verification infrastructure [28]. Invariants can help uncover programming bugs and reveal where the eventually-consistent replication based on CRDTs could lead to safety problems.

For illustration, consider the invariants for the calendar application in Lines 20 and 23. The invariant in Line 20 requires that all appointments must start before they end. Notice, how the invariant can be defined without knowing the amount of calendars and the actual structure of the data-flow graph by simply referring to the `all_appointments` reactive. This invariant represents a form of input validation, and is directly ensured by `add_appointment` interactions because the precondition on the arguments requires the added appointment to start before it ends (Line 9). In absence of this precondition, the LoRe compiler would reject the program and report a safety error due to a possible invariant violation. The invariant in Line 23 requires that employees do not take more vacation days than available to them. Again, this is locally enforced by the precondition of the `add_vacation` interaction, which ensures that new entries do not exceed the remaining vacation days. But there is nothing stopping two devices from concurrently adding vacation entries, which in sum violates the invariant. Figure 1 illustrates such a situation: A user plans a vacation of 20 days on the mobile phone (device D_1) and later schedules a 12-day vacation on a desktop (device D_2), at a time when D_1 was offline. Thus, both interactions happened concurrently and after merging the states the calendar contains a total of 32 days of vacation, violating the `remaining_vacation` invariant.

■ **Figure 2** Overview of LoRe’s automated compilation and verification procedure.

This example illustrates a conflict between (concurrent) execution of interactions – in this case, two executions of the `add_vacation` Interaction must be coordinated (synchronized) in order to avoid invariant violations. The LoRe compiler reports conflicting interactions to the developer and automatically synthesizes the required coordination code for the execution of such interactions (see Section 3.3). In a local-first setting, it is of paramount importance to minimize the required coordination to allow offline availability. Reporting of conflicts due to invariants helps developers to explore different situations and make informed decisions about the safety guarantees of their program. When they find that their program requires too much synchronization, they can lower the guarantees by adapting their invariants.

3 Implementation

Figure 2 depicts the architecture of LoRe’s verifying compiler. The input to the compiler is a program with its specifications expressed by the invariants, e.g., the program in Listing 1. The output consists of the conflicting interactions and a safe executable program. We use the Viper program verifier to reason about invariant violations and possible conflicts between interactions. We employ an analysis of the data-flow graph to minimize proof obligations to those invariant pairs that may actually conflict.

The rest of this section describes the pipeline from Figure 2 in detail – from left to right, top to bottom.

3.1 Graph Analysis

Checking all pairs of interactions for confluence would result in an exponential amount of proof obligations. To avoid this, we employ a graph analysis to quickly detect pairs of interactions that cannot conflict, because they change completely separate parts of the data-flow graph. For illustration, consider the `add_work` interaction. It modifies the `work` reactive, and – transitively – `all_appointments`. Hence, the reachable reactivities are $\{work, all_appointments\}$ and only the first but not the second invariant in Listing 1 overlaps. Thus, neither the `remaining_vacation` reactive, nor the invariant on this reactive will be part of the proof obligation for the `add_work` interaction.

3.2 Automated Verification

We use Viper to classify each interaction into one of the following three categories: 1) *Non-preserving* interactions can violate invariants during execution and are reported as bugs to the developer. 2) *Invariant-preserving* interactions preserve an invariant when executed on a single device but can violate an invariant in the presence of concurrent interactions by other devices. 3) *Invariant-confluent* [4] interactions can be executed concurrently without ever violating an invariant. Whenever two interactions in the second category must not

be executed concurrently to each other, they are *conflicting* and have to be coordinated to ensure invariant-safety. Using the proofs, we can precisely determine the sets of conflicting interactions and automatically synthesize coordination procedures which ensure safety at runtime while limiting the synchronization points to the necessary cases.

3.3 Synchronization at Runtime

Our compiler generates an executable application by converting the data-flow graph to a distributed REScala program [26, 27]. REScala supports all reactive features we require and integrates well with our CRDT-based replication, but has no mechanism for synchronization. LoRe’s formal synchronization semantics (see the extended version of this work²) could be implemented using any existing form of coordination, such as a central server, a distributed ledger, a consensus algorithm, or a distributed locking protocol. Which choice is suitable, depends on the target application, network size, and the reliability of the chosen transport layer. We use a simple distributed locking protocol for our implementation: Each interaction has an associated lock (represented as a simple token). Whenever a device wants to execute an interaction, it acquires the tokens of all conflicting interactions. If multiple devices request the same token concurrently, the token is given to the device with the lowest ID that requested it. This ensures deadlock freedom; fairness is left for future work. After performing the interaction, the resulting state changes are synchronized with the other devices and the tokens are made available again. Timeouts ensure that whenever a device crashes or becomes unavailable for a longer period of time, its currently owned tokens are released and any unfinished interactions by the device are aborted.

4 Evaluation

Our evaluation aims to validate two claims about LoRe’s programming model:

- C1:** It facilitates the development of safe local-first software.
- C2:** It enables an efficient and modular verification of safety properties.

We base our validation on two case studies. First, we implemented the standard TPC-C benchmark [36] as a local-first application in LoRe. This case study enables comparing LoRe’s model with traditional database-centered development of data processing software and showcasing the benefits of LoRe’s verifiable safety guarantees on standard *consistency conditions*. Second, we implemented the running calendar example (Section 2) using Yjs [31]. This case study allows comparing LoRe with an existing framework for local-first applications that we consider a representative of the state-of-the-art.

4.1 Does LoRe facilitate the development of safe local-first software?

4.1.1 Local-first TPC-C

TPC-C models an order fulfillment system with multiple warehouses in different districts, consisting of five *database transactions* alongside twelve *consistency conditions*. We implemented TPC-C in LoRe by mapping database tables to source reactivities and derived database values to derived reactivities. Each database transaction was modelled as a LoRe interaction.

While modelling the application using reactivities might require some adaption from developers not familiar with data-flow programming, we found that using derived reactivities led to a more concise and less error-prone design when compared to storing derived values in separate tables. For example, instead of storing the year to date (YTD) value of each TPC-C district in a separate table and updating it each time the payment history changes,

■ **Listing 2** Defining source and derived variables in Yjs.

```

1  const ydoc = new Y.Doc()
2  let work = ydoc.getMap('work');
3  let vacation = ydoc.getMap('
4      vacation');
5  let all_appointments;
6  let remaining_vacation = 30;
7  work.observe(ymapEvent => {
8      all_appointments = getMap(work,
9          vacation);
10 })
11 vacation.observe(ymapEvent => {
12     let days_total = getTotalVacDays
13         (vacation);
14     remaining_vacation = 30 -
15         daysTotal;
16     all_appointments = getMap(work,
17         vacation);
18 })

```

■ **Listing 3** Adding appointments in Yjs.

```

1  function addAppointment(calendar,
2      appointment) {
3      if(appointment.start <
4          appointment.end){
5          calendar.set(appointment.id,
6              appointment);
7      }
8  }
9  function addVacation(appointment)
10 {
11     let days =
12         appointment.getDays();
13     if(remainingVacation < days){
14         console.log("Sorry, no
15             vacation left!");
16     }
17     else{
18         addAppointment(vacation,
19             appointment)
20     }
21 }

```

we can model the district YTD as a derived reactive. Following this approach automatically guarantees 9 out of 12 consistency conditions of TPC-C that express consistency requirements between multiple related tables. We were able to phrase the remaining 3 conditions as invariants by directly translating the natural language formulations into logical specifications. To prove them, we additionally needed to specify pre- and postconditions of interactions corresponding to transactions. Other than that, LoRe relieves the TPC-C developer from any considerations of transaction interleavings that could potentially violate the conditions as well as from implementing the synchronization logic, both tedious and error-prone processes.

4.1.2 Yjs-based Calendar

We now compare the LoRe implementation of the distributed calendar to an implementation using the state of the art local-first framework Yjs [31]. Like other solutions for local-first software, Yjs uses a library of CRDTs (usually maps, sets, sequences / arrays, and counters) composed into nested trees – called a *documents* – used to model domain objects.

Source and Derived Variables. For illustration, consider Listing 2, showing how one could implement the domain model of the calendar application. Lines 2 and 3 initialize two CRDTs for the work and vacation calendar. Yjs has no abstraction for derived values and only provides callbacks for reacting to value changes, e.g., Lines 7-15 declare callback methods that update the derived variables in case the Yjs document changes.

Safety Guarantees. Using callbacks to model and manage complex state that changes both in time and in space has issues. It requires that developers programmatically update the derived values once the sources get updated, via local interactions or on receiving updates from other devices, with no guarantees that they do so consistently. It yields a complex control-flow and requires intricate knowledge of the execution semantics to ensure atomicity of updates, let alone to enforce application-level safety properties. Frameworks like Yjs do not offer support for application invariants and thus force developers to integrate custom safety measures at each possible source of safety violations.

■ **Table 1** Seconds to verify combinations of interactions and invariants of the two example applications. Each entry represents the mean verification time over 5 runs with the deviation shown in parentheses.

Distributed Calendar			
Interaction	Invariant		
	1	2	
Add vacation	3.32 (± 0.05)	2.97 (± 0.03)	
Remove vacation	3.28 (± 0.06)	3.00 (± 0.02)	
Change vacation	3.32 (± 0.05)	3.04 (± 0.03)	
Add work	3.31 (± 0.04)	–	
Remove work	3.30 (± 0.06)	–	
Change work	3.34 (± 0.06)	–	
TPC-C			
Interaction	Consistency Condition		
	3	5	7
New Order	45.4 (± 63.69)	7.63 (± 0.11)	14.49 (± 7.31)
Delivery	5.78 (± 0.03)	5.74 (± 0.07)	5.76 (± 0.09)

In summary, while the replication capabilities of systems like Yjs are valuable for local-first applications, these systems still require the developer to do state management manually. The prevailing use of callbacks and implicit dependencies makes reasoning about the code challenging for both developers and automatic analyses. In contrast, LoRe allows declarative definitions of derived values, with positive effects on reasoning [33, 10]. Moreover, LoRe integrates application invariants as explicit language constructs, which allows for a modular specification and verification and relieves developers from having to consider every involved interaction whenever the specification changes.

4.2 Does LoRe enable efficient and modular verification of safety properties?

To empirically evaluate the performance of LoRe’s verifier, we quantify how long it takes to verify different combinations of interactions and invariants of our two case studies. The results are shown in Table 1. The calendar example has two additional types of interactions, which we have not shown in Section 2: removing and changing calendar entries. This leads to a total of 6 interactions (3 per calendar reactive). For TPC-C we only had to verify consistency conditions 3, 5, and 7 because the others were already ensured by the respective derived reactivities. The benchmarks were performed on a desktop PC with an AMD Ryzen 7 5700G CPU and 32 GB RAM using Viper’s *silicon* verification backend (release v.23.01) [37].

Results. In summary, every interaction/invariant combination in our case studies could be verified in less than a minute. Verification times differed depending mainly on the complexity and length of the interactions and invariants under consideration. Differences become apparent especially when looking at the results for TPC-C. Proofs involving the *New Order* interaction, which is the most “write-heavy” interaction of TPC-C that changes many source reactivities at once, generally took longer to verify than others. For *New Order*, we also observe a much higher deviation of up to 64 seconds which we assume to be caused

by internal Z3 heuristics⁵. When interpreting the results, it is important to note that each interaction/invariant combination has to be verified only once and independently of other combinations. Large-scale applications can be verified step-by-step by splitting them into smaller pieces. Furthermore, we limit the need for verification to potential conflicts that we derive from the reactive data-flow graph. Programmers can add new functionality to the application (i.e., specify interactions) and only have to reason about the properties of that new functionality (i.e., specify its invariants) and the system ensures global safety – at only the cost of the amount of overlap with existing functionality. This allows for an incremental development style, where only certain parts of programs have to be (re-)verified, when they have been changed or added.

5 Related Work

Our work relates to three areas: distributed datatypes, formal reasoning, and language-based approaches. Sections below relate work from each area to respective aspects of our approach.

5.1 Consistency Through Distributed Data Types

Conflict-Free Replicated Datatypes (CRDTs) [34, 32] are a building block for constructing systems and applications that guarantee eventual consistency. CRDTs are used in distributed database systems such as *Riak* [18] and *AntidoteDB* [1]. These databases make it possible to construct applications that behave under mixed consistency, but unlike our approach, they leave reasoning about application guarantees to the programmer. Several works [12, 30] propose frameworks for formally verifying the correctness of CRDTs, while others [16, 20] focus on synthesizing correct-by construction CRDTs from specifications.

De Porre et al. [9, 8] suggest *strong eventually consistent replicated objects (SECROs)* relying on a replication protocol that tries to find a valid total order of all operations. Similar to LoRe, *SECROs* [9, 8] and *Hamsaz* [14] extend upon the eventually consistent replication of CRDTs by automatically choosing the right consistency level based on application invariants. Both approaches tie consistency and safety properties to specific datatypes/objects. This is not sufficient to guarantee end-to-end correctness of an entire local-first application - consistency bugs can still manifest in derived information (e.g., in the user interface).

5.2 Automated Reasoning about Consistency Levels

Our formalization is in part inspired by the work of Balegas et al. [6, 7] on *Indigo*. The work introduces a database middleware consisting of transactions and invariants to determine the ideal consistency level – called *explicit consistency*. They build on the notion of *invariant-confluence* for transactions that cannot harm an invariant which was first introduced by Bailis et al. [4]. While they work on a database level, we show how to integrate this reasoning approach into a programming language. An important difference between our *invariant-confluence* and the one by Balegas et al. [6] is that our approach also verifies local preservation of invariants, whereas their reasoning principle assumes invariants to always hold in a local context. In a more recent work called *IPA*, Balegas et al. [5] propose a static analysis technique that aims at automatically repairing transaction/invariant conflicts without adding synchronization between devices. We consider this latter work complementary to ours.

⁵ These could likely be improved by annotating quantifiers in invariants and pre-/postconditions with hand-crafted trigger expressions [28].

Whittaker and Hellerstein [38] also build on the idea of invariant-confluence and extend it to the concept of *segmented invariant-confluence*. Under segmented invariant-confluence, programs are separated into segments that can operate without coordination and coordination only happens in between the segments. The idea is similar to our definition of *conflicting interactions*, however, their procedure cannot suggest a suitable program segmentation, but requires developers to supply them.

The *SIEVE* framework [22] builds on the previous work on *Red/Blue-Consistency* [23] and uses invariants and program annotations to infer where a Java program can safely operate under CRDT-based replication (*blue*) and where strong consistency is necessary (*red*). They do so by relying on a combination of static and dynamic analysis techniques. Compared to *SIEVE*, our formal reasoning does not require any form of dynamic analysis. *Blazes* [2] is another analysis framework that uses programmer supplied specifications to determine where synchronization is necessary to ensure eventual consistency. Contrary to *Blazes*, LoRe ensures that programs are “by design” at least eventually consistent, while also allowing the expression and analysis of programs that need stronger consistency. *Q9* [15] is a bounded symbolic execution system, which identifies invariant violations caused by weak consistency guarantees. Similar to our work, *Q9* can determine where exactly stronger consistency guarantees are needed to maintain certain application invariants. However, its verification technique is bound by the number of possible concurrent operations. LoRe can provide guarantees for an unlimited amount of devices with an unlimited amount of concurrent operations.

5.3 Language Abstractions for Data Consistency

We categorize language-based approaches based on how they achieve consistency and on the level of programmer involvement.

Manual Choice of Consistency Levels. Li et al. [23] propose *RedBlue Consistency* where programmers manually label their operations to be either blue (eventually consistent) or red (strongly consistent). In MixT [25], programmers annotate classes with different consistency levels and the system uses an information-flow type system to ensure that the requested guarantees are maintained. However, this still requires expert knowledge about each consistency level, and wrong choices can violate the intended program semantics. Other approaches [29, 19] expect programmers to choose between *consistency* and *availability*, again leaving the reasoning duty about consistency levels to the programmer. Compared to LoRe, languages in this category place higher burden on programmers: They decide which operation needs which consistency level, a non-trivial and error-prone selection.

Automatically Deriving Consistency from Application Invariants. *CAROL* [21] uses CRDTs to replicate data and features a refinement typing discipline for expressing safety properties similar to our *invariants*. Carol makes use of pre-defined datatypes with *consistency guards* used by the type system to check for invariant violations. The compatibility of datatype operations and consistency guards is verified ahead of time using an algorithm for the Z3 SMT solver. This approach hides much of the complexity from the programmer, but the abstraction breaks once functionality that is not covered by a pre-defined datatype is needed. Unlike Carol, LoRe does not rely on predefined consistency guards, but allows the expression of safety properties as arbitrary logical formulae. Additionally, *CAROL* only checks the concurrent interactions of a program for invariant violations, whereas LoRe verifies the overall application including non-distributed parts. Sivaramakrishnan et al. [35] propose *QUELEA*, a declarative language for programming on top of eventually consistent datastores. It features a contract-language to express application-level invariants and automatically

generates coordination strategies in cases where invariants could be violated by concurrent operations. *QUELEA*'s contract-language requires programmers to express the desired properties using low-level visibility relations, which can be challenging to get right for non-experts. LoRe avoids this intermediate reasoning and automatically derives the right level of consistency for satisfying high-level safety invariants to enable end-to-end correctness.

Automating Consistency by Prescribing the Programming Model. Languages in this category seek to automate consistency decisions by prescribing a certain programming model such that certain consistency problems are impossible to occur. In *Lasp* [24], programmers model the data flow of their applications using combinator functions on CRDTs. Programs written in *Lasp* always provide eventual consistency but contrary to LoRe, *Lasp* does not allow arbitrary compositions of distributed datatypes. *Bloom* [3] provides programmers with ways to write programs that are *logically monotonic* and therefore offer automatic eventual consistency. Both *Lasp* and *Bloom*, however, are not meant to formulate programs that need stronger consistency guarantees. LoRe is similar to *Lasp* and *Bloom* in the sense that we also prescribe a specific – reactive – programming style. However, our programming model is less restrictive and allows arbitrary compositions of distributed datatypes. This is enabled by leveraging the composability properties of reactive data-flow graphs. Secondly, LoRe provides a principled way to express hybrid consistency applications with guarantees stronger than eventual consistency. Drechsler et al. [11] and Mogk et al. [26, 27] also use a reactive programming model similar to ours to automate consistency in presence of multi-threading respectively of a distributed execution setting. However, they do not support a hybrid consistency model. Drechsler et al. [11] enable strong consistency (serializability) only, while Mogk et al. [26, 27] support only eventual consistency.

6 Conclusion and Future Work

In this paper, we proposed LoRe, a language for local-first software with verified safety guarantees. *LoRe* combines the declarative data flow of reactive programming with static analysis and verification techniques to precisely determine concurrent interactions that could violate programmer-specified safety properties. We presented a formal definition of the programming model and a modular verification that detects concurrent executions that may violate application invariants. In case of invariant violation due to concurrent execution, LoRe automatically enforces the necessary amount of coordination. LoRe's verifying compiler translates LoRe programs to Viper [28] for automated verification and to Scala for the application logic including synthesized synchronization to guarantee the specified safety invariants. An evaluation of LoRe's programming model in two case studies confirms that it facilitates the development of safe local-first applications and enables efficient and modular automated reasoning about an application's safety properties. Our evaluation shows that verification times are acceptable and that the verification effort required from developers is reasonable.

In the future, it would be desirable to integrate existing libraries of verified CRDTs [12] or even solutions that allow ad-hoc verification of CRDT-like datatypes [30, 20]. This would enable us to support a wider range of data types or even allow programmers to use custom distributed datatypes, which can be verified to be eventually consistent. Furthermore, our current data-flow analysis is limited to static data-flow graphs. While static reasoning about dynamic graphs is impossible in the general case, most applications make systematic use of dynamic dependencies, and we believe it would be feasible to support common cases.

Abstract

Much of the past work on dynamic data-race and determinacy-race detection algorithms for task parallelism has focused on structured parallelism with fork-join constructs and, more recently, with future constructs. This paper addresses the problem of dynamic detection of data-races and determinacy-races in task-parallel programs with *promises*, which are more general than fork-join constructs and futures. The motivation for our work is twofold. First, promises have now become a mainstream synchronization construct, with their inclusion in multiple languages, including C++, JavaScript, and Java. Second, past work on dynamic data-race and determinacy-race detection for task-parallel programs does not apply to programs with promises, thereby identifying a vital need for this work.

This paper makes multiple contributions. First, we introduce a featherweight programming language that captures the semantics of task-parallel programs with promises and provides a basis for formally defining *determinacy* using our semantics. This definition subsumes functional determinacy (same output for same input) and structural determinacy (same computation graph for same input). The main theoretical result shows that the absence of data races is sufficient to guarantee determinacy with both properties. We are unaware of any prior work that established this result for task-parallel programs with promises. Next, we introduce a new Dynamic Race Detector for Promises that we call DRDP. DRDP is the first known race detection algorithm that executes a task-parallel program sequentially without requiring the serial-projection property; this is a critical requirement since programs with promises do not satisfy the serial-projection property in general. Finally, the paper includes experimental results obtained from an implementation of DRDP. The results show that, with some important optimizations introduced in our work, the space and time overheads of DRDP are comparable to those of more restrictive race detection algorithms from past work. To the best of our knowledge, DRDP is the first determinacy race detector for task-parallel programs with promises.

1 Introduction

In recent years, promises have been incorporated as a general synchronization construct into multiple mainstream languages, including C++ [17], Java [28], and JavaScript [27]. A promise is a wrapper for a data payload that is initially empty. It typically has two operations which we refer to as `set` and `get`. Each `get` operation blocks until the promise receives a value for its payload; multiple `get` operations may be performed on the same promise from multiple tasks, and they all return the same value. Figure 1 shows the usage: an `async` task sets the promise at line 5, and the main task gets the promise at line 9.

A promise with a set payload is referred to as a *fulfilled promise*. Following standard conventions, we assume that promises obey the single-assignment policy, where an invocation of `set` on a fulfilled promise (i.e., a second assignment) will induce a runtime error. Compared to futures [20], promises generalize the semantics for synchronization in that a promise need not be bound to the return value of a specific task; instead, any task can choose to perform a `set` operation on a given promise. Promises support arbitrary point-to-point synchronization wherein one or more tasks can await the arrival of a payload for which the producer task is not known in advance. However, it has been observed that the convenience of this generality may also be accompanied by the increasing complexity of dynamic analysis for bug detection in parallel programs [42].

As with any source of parallelism, accesses to shared memory locations must be correctly ordered to avoid *determinacy races* [15], defined as race conditions causing non-determinism. A determinacy race often results from a *data race* [26,31], which occurs when two concurrent memory accesses operate on the same memory location and at least one of them is a write. A key result in our paper is that the absence of data races is sufficient to guarantee determinacy for task-parallel programs with promises; in contrast, this property does not hold for programs that use mutual exclusion constructs such as locks or transactions.

For dynamic race detectors, enumerating all possible inputs is usually intractable; therefore, they are typically *per-input* or *per-schedule* race detectors. Per-input race detectors report all potential races for a given input by covering all possible thread schedules [15,30,31,35,43–45], whereas per-schedule race detectors only cover the observed schedule when analyzing a program’s execution [1,16,33]. However, prior work related to dynamic determinacy race detection has some major limitations:

1. None of these race detectors support promises.
2. No formal definition of “determinacy” is provided. For example, in the SP-Bags paper [15], the authors state “[determinacy race]... may cause the program to behave nondeterministically. That is, different runs of the same program may produce different behaviors”. However, no formal definition was provided for what is meant by “different behaviors.”
3. It has been observed in some past work (e.g., [7, 31, 35]) that for certain classes of task-parallel programs, data-race freedom leads to determinacy but no formal proof was given for this observation.

In this paper, we introduce a featherweight programming language that captures the semantics of Task-Parallel Programs with Promises (TP3) and use it as a basis for formally defining determinacy, along with a proof that data-race freedom implies both structural and functional determinacy for TP3. We also designed and implemented a race detector for TP3. A major obstacle is that the tasks issuing `get/set` operations on a given promise cannot be identified in advance. As a result, TP3 do not satisfy the *serial-projection* property [32], i.e., the property that a sequential execution of the program with all parallel constructs removed is guaranteed to be a legal execution of the original parallel program. This feature is utilized by a number of dynamic race detectors [4, 15, 30, 35, 37]. Without this property, the sequential execution of a parallel program may be blocked by a `get` operation. To address this and other challenges, we extended the Habanero-C/C++ library [8] to enable correct single-worker execution of such programs via cooperative task switching. However, keeping track of happens-before relationships also becomes more challenging in the presence of task switching. Efficient data structures used previously [4, 15, 30, 35, 37] rely on the serial-projection property to maintain happens-before information correctly and cannot directly be used for programs with promises.

In summary, the key contributions of this paper are as follows:

1. A formalization of determinacy for TP3 using a featherweight programming language (Section 2).
2. A proof that TP3 are guaranteed to be determinate in the absence of data races (Section 3).
3. A new dynamic race detection algorithm for TP3 called Determinacy Race Detector for Promises (DRDP, Section 4). To the best of our knowledge, this is the first precise and efficient per-input race detector for TP3.
4. An implementation of DRDP on top of the Habanero-C/C++ library and its evaluation on a set of benchmarks using promises (Section 5). The results show that, with some essential optimizations introduced in our work, the space and time overheads of DRDP are comparable to those of more restrictive race detection algorithms from past work.

2 A Featherweight Language for Task-Parallel Programs with Promises

In this section, we introduce a featherweight language that features task parallelism and promises to establish determinacy. Our language is Turing-complete. We do not include functions and types because we aim to use this core language to prove properties of dynamic program executions that are possible from a given static program, rather than using this language for static program analysis.

Program	P	::=	$s ; P \mid \text{return}$	
Statement	s	::=	m $\mid \text{async}\{P\}$ (create asynchronous task) $\mid x \leftarrow \text{new_promise}$ $\mid x.\text{set}$ $\mid x.\text{get}$ $\mid x \leftarrow e$ $\mid \text{while } (0 \neq \text{load } y) \{P\}$	
Memory Operation	m	::=	$y \leftarrow \text{alloc}$ $\mid x \leftarrow \text{load } y$ $\mid \text{store } e \text{ to } y$	
Expression	e	::=	x (local variable) $\mid y$ (local variable that saves shared variable name) $\mid c$ (integer constant) $\mid e_1 + e_2$	
Runtime value	k	::=	$c \mid r \mid p$	

■ **Figure 2** Syntax of the core language.

2.1 Language Syntax

Figure 2 lists the syntax of our language. A program consists of a sequence of statements terminated by a `return`. A single statement can be task creation (`async`)¹, a memory operation (`alloc`, `load`, and `store`), a promise operation (`new_promise`, `set`, `get`), a local variable assignment (`x ← e`), or a conditional loop (`while`). We use symbols x and y to denote local variables within a specific task, along with an LLVM-style syntax and convention.

The language syntax introduces two types of variables: local variables and shared variables. Each task has a set of scoped local variables which must satisfy the single-assignment rule; apart from local variables, tasks may also access shared variables using memory operations. In fact, the only way for two tasks² to share data is via memory operations.

Shared variables are modeled as a global map (i.e., *memory*), in which each instance has a unique name assigned during its allocation; this name serves as a *reference* for operating on the corresponding shared variable. Statement `y ← alloc` allocates a new shared variable, with its reference saved into y . Statement `x ← load y` retrieves a shared variable’s content using the reference in local variable y and saves the retrieved content into another local variable x . Likewise, statement `store e to y` locates a shared variable using the reference in y and updates the shared variable’s content with value e .

Statement `x ← e` initializes single-assignment local variable x with the value e . According to the syntax, e could be an integer, a local variable, or a sum of two expressions. Statement `async{P}` spawns a concurrent task to execute the body P . Statement `while (0 ≠ load y) {P}` will continuously execute the loop body P until the condition no longer holds. Statement `x ← new_promise` creates a new promise, and saves a reference to the promise in local variable x . Statement `x.set` signals promise x , and statement `x.get` blocks until a task issues a `set` operation on promise x . To simplify the presentation, we eschew the data payload of promises, thus only offering synchronization functionality. Communicating data through a promise is still possible, but must be encoded using additional shared variables.

¹ We do not include join operations like `finish` and `sync` in our language, since they can be modeled using sets of promises.

² For convenience, the main program is considered to be a root task.

2.2 Runtime State

The runtime state σ of our language is a pair $\sigma = (M, G)$, where M maps shared variables into runtime values, and a *computation graph* G . We denote a map M as $\{r_1 : k_1, r_2 : k_2, \dots, r_n : k_n\}$. We use the notation $M[r := k]$ to extend M . We define computation graphs G inductively using the rules in Figure 3.

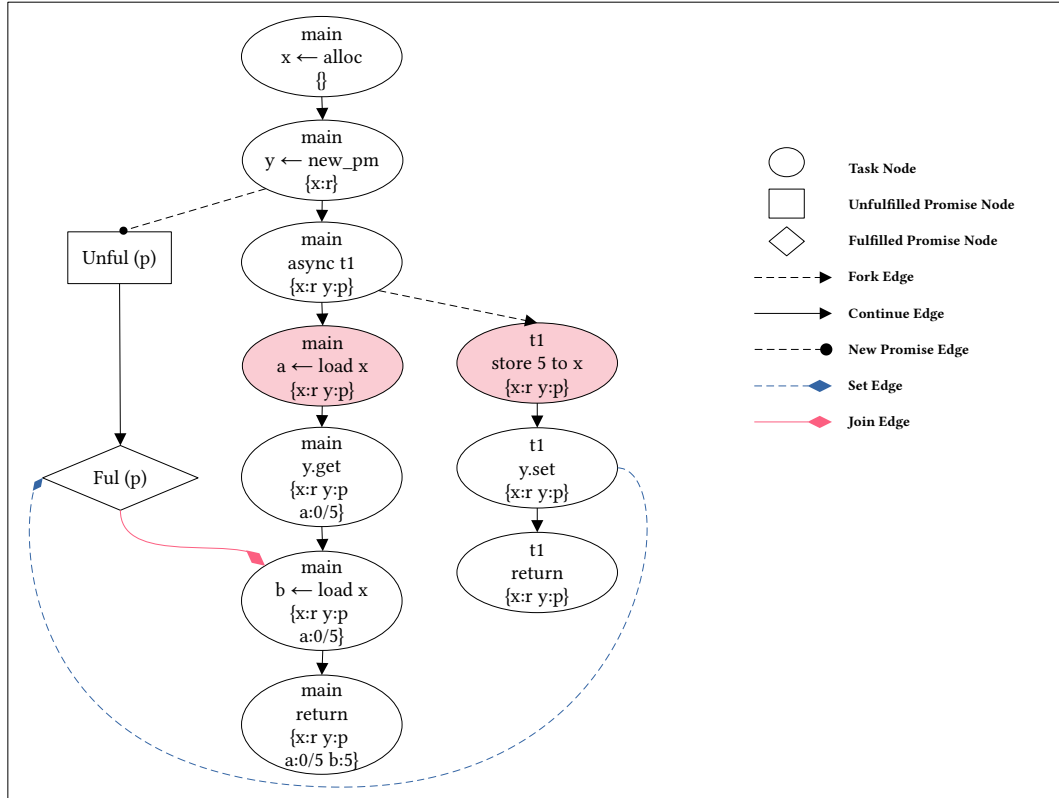

$n ::= t \mid \text{Unful}(p) \mid \text{Ful}(p)$	Runtime nodes
$t ::= [f, P, L]$	Task nodes
$G ::= t$	
$\mid G + t_1 \xrightarrow{\text{cont}} t_2$	Continue edges
$\mid G + t_2 \xleftarrow{\text{fork}} t_1 \xrightarrow{\text{cont}} t_3$	Fork edges
$\mid G + \text{Unful}(p) \xleftarrow{\text{np}} t_1 \xrightarrow{\text{cont}} t_2$	New promise edges
$\mid G + \text{Unful}(p) \xrightarrow{\text{cont}} \text{Ful}(p) \xleftarrow{\text{set}} t_1 \xrightarrow{\text{cont}} t_2$	Set edges
$\mid G + t_1 \xrightarrow{\text{cont}} t_2 \xleftarrow{\text{join}} \text{Ful}(p)$	Join edges
$\text{R-NAT} \frac{}{c \Downarrow_{t_{mem}} c}$	
$\text{R-ADD} \frac{e_1 \Downarrow_{t_{mem}} c_1 \quad e_2 \Downarrow_{t_{mem}} c_2}{e_1 + e_2 \Downarrow_{t_{mem}} c_1 + c_2}$	
$\text{R-VAR} \frac{}{x \Downarrow_{t_{mem}} t_{mem}[x]}$	

■ **Figure 3** Computation graph and reduction rule.

In a computation graph G , nodes represent the states of tasks and promises across time, and edges represent happens-before relations. There are three types of nodes in a computation graph: a *task node* t , an unfulfilled promise $\text{Unful}(p)$, and fulfilled promise $\text{Ful}(p)$. A task node t is a triple that includes a task name f , a program P to execute, and a map L representing the task's local variables. We define three helper functions to obtain the content of a task node t : t_{tid} , t_{code} , and t_{mem} , which return the task name ($t.f$), the program ($t.P$), and the local variable map ($t.L$), respectively.

The base case of a computation graph is a task node t . Notation $G + t_1 \xrightarrow{\text{cont}} t_2$ depicts a computation graph acquired by adding a new continue edge from t_1 to t_2 on top of the original graph G . Notation $G + t_2 \xleftarrow{\text{fork}} t_1 \xrightarrow{\text{cont}} t_3$ captures the semantics of task creation: node t_1 issues the task creation, node t_2 represents the child task, and node t_3 represents the continuation after spawning t_2 . Since t_2 and t_3 may happen in parallel, there exists no path between the two nodes. Notation $G + \text{Unful}(p) \xleftarrow{\text{np}} t_1 \xrightarrow{\text{cont}} t_2$ represents the semantics of promise creation. Node $\text{Unful}(p)$ represents the spawned instance of promise and t_2 represents the continuation after promise creation. Notation $G + \text{Unful}(p) \xrightarrow{\text{cont}} \text{Ful}(p) \xleftarrow{\text{set}} t_1 \xrightarrow{\text{cont}} t_2$ depicts an invocation of **set** issued by node t_1 . Node $\text{Ful}(p)$ represents the fulfilled promise after the **set**, and t_2 represents the task state upon the **set** operation. Finally, Notation $G + t_1 \xrightarrow{\text{cont}} t_2 \xleftarrow{\text{join}} \text{Ful}(p)$ signifies a **get** operation. Node t_1 issues the synchronization, while node t_2 observes the synchronization.

Example. The corresponding computation graph of the example program in Figure 1 is shown in Figure 4. Note that there is a determinacy race between line 4 and line 8 in the program. In different executions, variable a can be either 0 or 5. The race is also reflected in the computation graph, as no path connects the two nodes in red. On the other hand, the store in line 4 happens before the load on line 10 because of the `get` operation in line 9; the final value of variable b will always be five, regardless of the actual task schedule.

■ **Figure 4** Associated computation graph of Figure 1.

Leveraging the formal definition in Figure 3, we formalize the happens-before relation between two task nodes and memory accesses performed by task nodes.

► **Definition 1** (Happens-before). We say node v precedes or happens before node u if and only if one directed path from v to u exists in the computation graph. We denote the happens-before relation as $v \rightsquigarrow u$. We use $v \not\rightsquigarrow u$ to indicate that there exists no path from u to v .

► **Definition 2** (May-happen-in-parallel). Node v may happen in parallel with node u , denoted by $v \parallel u$, iff $u \not\rightsquigarrow v$ and $v \not\rightsquigarrow u$.

► **Definition 3** (Read and Write). A task node t reads from a shared variable r if 1). $t_{code} = \{x \leftarrow \text{load } y ; P\}$, $t_{mem}[y] = r$, or 2). $t_{code} = \{\text{while } (0 \neq \text{load } y) \{P'\} ; P\}$, $t_{mem}[y] = r$. A task node t writes to a shared variable r if $t_{code} = \{\text{store } x \text{ to } y ; P\}$ and $t_{mem}[y] = r$. Node t accesses a shared variable r if node t reads from or writes to r .

- (1) G-ASYNC $\frac{t_{code} = \text{async}\{P'\}; P \quad g \text{ does not occur in } G \quad t_{tid} = f}{(M, G) \rightarrow (M, G + [g, P', t_{mem}] \xleftarrow{\text{fork}} t \xrightarrow{\text{cont}} [f, P, t_{mem}])}$
- (2) G-ALLOC $\frac{t_{code} = y \leftarrow \text{alloc}; P \quad r \notin M \quad t_{tid} = f}{(M, G) \rightarrow (M[r := 0], G + t \xrightarrow{\text{cont}} [f, P, t_{mem}[y := r]])}$
- (3) G-LOAD $\frac{t_{code} = x \leftarrow \text{load } y; P \quad t_{mem}[y] = r \quad M[r] = k \quad t_{tid} = f}{(M, G) \rightarrow (M, G + t \xrightarrow{\text{cont}} [f, P, t_{mem}[x := k]])}$
- (4) G-STORE $\frac{t_{code} = \text{store } e \text{ to } y; P \quad e \Downarrow_{t_{mem}} k \quad t_{mem}[y] = r \quad t_{tid} = f}{(M, G) \rightarrow (M[r := k], G + t \xrightarrow{\text{cont}} [f, P, t_{mem}])}$
- (5) G-PROMISE $\frac{t_{code} = x \leftarrow \text{new_promise}; P \quad \text{Unful}(p) \notin G \quad t_{tid} = f}{(M, G) \rightarrow (M, G + \text{Unful}(p) \xleftarrow{\text{np}} t \xrightarrow{\text{cont}} [f, P, t_{mem}[x := p]])}$
- (6) G-SET $\frac{t_{code} = x.\text{set}; P \quad t_{mem}[x] = p \quad \text{Unful}(p) \text{ no outgoing edges in } G \quad t_{tid} = f}{(M, G) \rightarrow (M, G + \text{Unful}(p) \xrightarrow{\text{cont}} \text{Ful}(p) \xleftarrow{\text{set}} t \xrightarrow{\text{cont}} [f, P, t_{mem}])}$
- (7) G-GET $\frac{t_{code} = x.\text{get}; P \quad t_{mem}[x] = p \quad \text{Ful}(p) \in G \quad t_{tid} = f}{(M, G) \rightarrow (M, G + t \xrightarrow{\text{cont}} [f, P, t_{mem}] \xleftarrow{\text{join}} \text{Ful}(p))}$
- (8) G-ASSIGN $\frac{t_{code} = x \leftarrow e; P \quad e \Downarrow_{t_{mem}} k \quad t_{tid} = f}{(M, G) \rightarrow (M, G + t \xrightarrow{\text{cont}} [f, P, t_{mem}[x := k]])}$
- (9) G-WHILE-1 $\frac{t_{code} = \text{while } (0 \neq \text{load } y) \{P'\}; P \quad M[t_{mem}[y]] = 0 \quad t_{tid} = f}{(M, G) \rightarrow (M, G + t \xrightarrow{\text{cont}} [f, P, t_{mem}])}$
- (10) G-WHILE-2 $\frac{t_{code} = \text{while } (0 \neq \text{load } y) \{P'\}; P \quad M[t_{mem}[y]] \neq 0 \quad t_{tid} = f}{(M, G) \rightarrow (M, G + t \xrightarrow{\text{cont}} [f, P'; \text{while } (0 \neq \text{load } y) \{P'\}; P, t_{mem}])}$

■ **Figure 5** Small-step semantics.

2.3 Small-step Operational Semantics

We introduce the small-step operational semantics, denoted by $\sigma \rightarrow \sigma'$, in Figure 5. Spawning a task g with `async` creates a new node for the child task, which inherits the local memory of the parent task f (Rule 1). Memory allocation creates a new shared variable r , initializes it with 0, and assigns its name r to y in the local memory (Rule 2). A load retrieves the content of shared variable r from the shared memory M . A store writes the value e to shared variable r (variable name r is stored in local variable y). Creating a promise adds a new node that marks promise p as unfulfilled (Rule 5). Our semantics only allows a single `set` per promise; thus, a pre-condition of Rule 6 is to ensure that promise p is unfulfilled. Getting a promise links the fulfilled promise $\text{Ful}(p)$ to the continuation node $[f, P, t_{mem}]$, thus adding a

happens-before relation from the `set` to the `get` (Rule 7). Assignment extends local memory with a new variable x , which has the value of evaluating expression e (Rule 8). Rules 9 and 10 handle a while loop in a standard way.

Let $\text{root}(P)$ denotes runtime state $(m, [main, P, l])$: a runtime state that holds the initial memory m and the initial computation graph with a single vertex $[main, P, l]$, where l is the local memory for the single vertex. When it is clear from the context we may say P to signify the runtime state $\text{root}(P)$. Let notation $P \Downarrow \sigma$ be defined as $\text{root}(P) \rightarrow^* \sigma$ and $\sigma \not\Downarrow \sigma'$ for any σ' .

We use a naming convention that gives *unique* and *consistent* name to each variable in the operational semantics. “unique” means whenever a new task, variable, or promise is being created, it will be given a unique name that does not yet exist in σ ; “consistent” means the name is the same name that other program runs will have when creating this new task, variable or promise.

3 Proof of Determinism

In this section, we show that determinacy-race freedom implies determinism for programs in our featherweight language. Our proof structure is adapted from prior work on Concurrent Collection (CnC) [6, Theorem 1]. CnC applies a single-assignment policy on all shared variables (called *data collections* in CnC) to assure determinism. An important distinction between this work and [6] is that our formalism expresses both promises and shared memory, whereas [6] only expresses a construct akin to promises. Our proof utilizes the property of determinacy-race freedom to show that the shared memory and the computation graph will be determinate for a given input (the initial program state $\text{root}(P)$).

► **Definition 4** (Determinacy Race and Determinacy-Race Freedom). A *determinacy race* is a triple (r, t_1, t_2) ; it happens on a shared variable r if and only if two task nodes t_1 and t_2 access r , at least one of them conducts a write, and $t_1 \parallel t_2$. A computation graph G is *determinacy-race-free* if and only if for any task nodes t_1, t_2 in G , there is no determinacy race (r, t_1, t_2) for any shared variable r . A program P is *determinacy-race-free* if for any G and M such that $P \rightarrow^* (M, G)$, G is determinacy-race-free.

We define an ordering \leq on runtime states such that $\sigma \leq \sigma'$ if and only if $\text{dom}(\sigma.M) \subseteq \text{dom}(\sigma'.M)$ and $\sigma.G$ is a subgraph of $\sigma'.G$. Next, we establish the necessary lemmas to prove our main result: if $P \Downarrow \sigma$ and $P \Downarrow \sigma'$, then $\sigma = \sigma'$.

► **Lemma 5** (Monotonicity). *If $\sigma \rightarrow \sigma'$, then $\sigma \leq \sigma'$*

Proof. The proof follows by case analysis on the derivation of $\sigma \rightarrow \sigma'$. Let $\sigma = (M, G)$. The key insight is that nodes and edges are only added to G ; nodes and edges are never removed. Similarly, the domain of M either grows or remains the same. We omit the proof details. ◀

We use $\sigma \rightarrow_v \sigma'$ to denote that executing node v triggers the state transition.

► **Lemma 6** (Independence). *Let $\sigma \rightarrow_v \sigma'$, $\sigma \rightarrow_u \sigma''$ and $\sigma' \neq \sigma''$. We have $v \parallel u$.*

Proof. If $v \rightsquigarrow u$ or $u \rightsquigarrow v$, we can only derive either σ' or σ'' from σ , but not both. ◀

The next Lemma proves what we call strong local confluence. This property essentially implies that from the same program state σ , if there exists more than one choice to proceed, those different choices will eventually proceed to the same state σ_c . The proof also reveals why determinacy-race freedom is necessary for this property.

► **Lemma 7** (Strong Local Confluence). *Let P be determinacy-race-free and $P \rightarrow^* \sigma$. If $\sigma \rightarrow_v \sigma'$ and $\sigma \rightarrow_u \sigma''$, then there exists σ_c, i, j such that $\sigma' \rightarrow^i \sigma_c$, $\sigma'' \rightarrow^j \sigma_c$, $i \leq 1$ and $j \leq 1$.*

Proof. If $v = u$, we have $\sigma' = \sigma''$; in this case $\sigma_c = \sigma'$, $i = 0, j = 0$. If $v \neq u$, we claim $\sigma' \rightarrow_u \sigma_c, \sigma'' \rightarrow_v \sigma_c, i = 1, j = 1$. To prove the claim, we do a case analysis on the rule used to derive $\sigma \rightarrow_v \sigma'$.

- (3) G-LOAD: We know $v_{code} = x \leftarrow \text{load } y; P'$ and $v_{mem}[y] = r$ and $M[r] = k$. We have $\sigma'.G = \sigma.G + v \xrightarrow{cont} [v_{tid}, v_{mem}[x := k], P']$, $\sigma'.M = \sigma.M$. Let us do a case analysis of the rule used to derive $\sigma \rightarrow_u \sigma''$.
 1. G-ALLOC: We know $u_{code} = y' \leftarrow \text{alloc}; P''$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}[y' := r'], P'']$, $\sigma''.M = \sigma.M[r' := 0]$. Because our naming system is unique, we have $r' \neq r$. We can pick σ_c such that $\sigma_c.M = \sigma''.M$, $\sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}[x := k], P']$. It is clear that $\sigma'' \rightarrow_v \sigma_c$. It is also true that $\sigma' \rightarrow_u \sigma_c$ because our naming system is consistent among different execution. In this case, $i = 1, j = 1$.
 2. G-LOAD: $u_{code} = x' \leftarrow \text{load } y'; P''$ and $u_{mem}[y'] = r'$ and $M[r'] = k'$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}[x' := k'], P'']$, $\sigma''.M = \sigma.M$. In this case, it is fine that $r' = r$ because concurrent reads on the same memory location are allowed. We can pick σ_c such that $\sigma_c.M = \sigma''.M$, $\sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}[x := k], P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 3. G-STORE: We know $u_{code} = \text{store } e' \text{ to } y'; P''$ and $e' \Downarrow k'$ and $u_{mem}[y'] = r'$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}, P'']$, $\sigma''.M = \sigma.M[r' := k']$. If $r' = r$, this is a determinacy race by Definition 4 and Lemma 6. Because $r' \neq r$, we can pick σ_c such that $\sigma_c.M = \sigma''.M$, $\sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}[x := k], P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 4. Any other rules: we omit the details for other rules because the proof is similar to the above cases.
- (4) G-STORE: We know $v_{code} = \text{store } e \text{ to } y; P'$ and $e \Downarrow k$ and $v_{mem}[y] = r$. We have $\sigma'.G = \sigma.G + v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$, $\sigma'.M = \sigma.M[r := k]$. Let us do a case analysis of the rule used to derive $\sigma \rightarrow_u \sigma''$.
 1. G-STORE: We know $u_{code} = \text{store } e' \text{ to } y'; P''$ and $e' \Downarrow k'$ and $u_{mem}[y'] = r'$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}, P'']$, $\sigma''.M = \sigma.M[r' := k']$. If $r' = r$, this is a determinacy race by Definition 4 and Lemma 6. Because $r' \neq r$, we can pick σ_c such that $\sigma_c.M = \sigma''.M[r := k]$, $\sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 2. G-WHILE-*: We know $u_{code} = \text{while } (0 \neq \text{load } y') \{P'''\}; P''$ and $u_{mem}[y'] = r'$. If $r' = r$, this is a determinacy race by Definition 4 and Lemma 6. Because $r' \neq r$, we can pick σ_c such that $\sigma_c.M = \sigma''.M[r := k]$, $\sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 3. Any other rules: we omit the details for other rules because the proof is similar to the above cases.
- (6) G-SET: we know $v_{code} = x.\text{set}; P'$ and $v_{mem}[x] = p$ and $\text{Unful}(p)$ has no outgoing edge. We have $\sigma'.G = \sigma.G + \text{Unful}(p) \xrightarrow{cont} \text{Ful}(p) \xleftarrow{set} v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$, $\sigma'.M = \sigma.M$. Let us do a case analysis of the rule used to derive $\sigma \rightarrow_u \sigma''$.
 1. G-Set: we know $u_{code} = x'.\text{set}; P''$ and $u_{mem}[x'] = p'$ and $\text{Unful}(p')$ has no outgoing edge. We have $\sigma''.G = \sigma.G + \text{Unful}(p') \xrightarrow{cont} \text{Ful}(p') \xleftarrow{set} u \xrightarrow{cont} [u_{tid}, u_{mem}, P'']$, $\sigma''.M = \sigma.M$. If $p = p'$, this violates the single set policy for promises. Because $p \neq p'$, we can pick σ_c such that $\sigma_c.M = \sigma''.M$, $\sigma_c.G = \sigma''.G + \text{Unful}(p) \xrightarrow{cont} \text{Ful}(p) \xleftarrow{set} v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.

13:10 Dynamic Determinacy Race Detection for Task-Parallel Programs with Promises

2. G-GET: we know $u_{code} = x'.get ; P''$ and $u_{mem}[x'] = p'$ and $Ful(p') \in G$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}, P''] \xleftarrow{join} Ful(p'), \sigma''.M = \sigma.M$. In this case, we must have $p \neq p'$ because otherwise, we cannot make the step $\sigma \rightarrow_u \sigma'$ until v is executed. We can pick σ_c such that $\sigma_c.M = \sigma''.M, \sigma_c.G = \sigma''.G + Unful(p) \xrightarrow{cont} Ful(p) \xleftarrow{set} v \xrightarrow{cont} [v_{tid}, v_{mem}, P']$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 3. Any other rules: we omit the details for other rules because the proof is similar to the above cases.
- (7) G-GET: we know $v_{code} = x.get ; P'$ and $v_{mem}[x] = p$ and $Ful(p) \in G$. We have $\sigma'.G = \sigma.G + v \xrightarrow{cont} [v_{tid}, v_{mem}, P'] \xleftarrow{join} Ful(p), \sigma'.M = \sigma.M$. Let us do a case analysis of the rule used to derive $\sigma \rightarrow_u \sigma''$.
1. G-GET: we know $u_{code} = x'.get ; P''$ and $u_{mem}[x'] = p'$ and $Ful(p') \in G$. We have $\sigma''.G = \sigma.G + u \xrightarrow{cont} [u_{tid}, u_{mem}, P''] \xleftarrow{join} Ful(p'), \sigma''.M = \sigma.M$. In this case, it is fine if $p = p'$ because concurrent `get` operations performed on the same promise is allowed. We can pick σ_c such that $\sigma_c.M = \sigma''.M, \sigma_c.G = \sigma''.G + v \xrightarrow{cont} [v_{tid}, v_{mem}, P'] \xleftarrow{join} Ful(p)$. It is clear that $\sigma' \rightarrow_u \sigma_c$ and $\sigma'' \rightarrow_v \sigma_c$. In this case, $i = 1, j = 1$.
 2. Any other rules: we omit the details for other rules because the proof is similar to the above cases.
- Any other rules v and u could execute: we omit the details for other rules because the proof is similar to the above cases. ◀

► **Lemma 8** (Strong One-Sided Confluence). *Let P be determinacy-race-free and $P \rightarrow^* \sigma$. If $\sigma \rightarrow \sigma', \sigma \rightarrow^m \sigma''$, where $1 \leq m$, then there exist σ_c, i, j such that $\sigma' \rightarrow^i \sigma_c, \sigma'' \rightarrow^j \sigma_c, i \leq m$ and $j \leq 1$.*

Proof. We prove it by inducting on m .

Base case: $m = 1$. Proved by Lemma 7.

Induction step: suppose $\sigma \rightarrow^m \sigma'' \rightarrow \sigma'''$. By our induction hypothesis, the lemma holds for m . We have σ'_c, i', j' such that $\sigma' \rightarrow^{i'} \sigma'_c$ and $\sigma'' \rightarrow^{j'} \sigma'_c$ and $i' \leq m$ and $j' \leq 1$. We want to prove the lemma holds for $m + 1$. There are two cases based on the value of j' :

1. $j' = 0$. In this case, $\sigma'_c = \sigma''$. We pick $\sigma_c = \sigma''', i = i' + 1, j = 0$. Because $i' \leq m$, we have $i \leq m + 1$, which obeys the lemma.
2. $j' = 1$. In this case, we have $\sigma'' \rightarrow \sigma'''$ and $\sigma'' \rightarrow \sigma'_c$. By Lemma 7, there exist σ_d, a, b such that $\sigma''' \rightarrow^a \sigma_d$ and $\sigma'_c \rightarrow^b \sigma_d$ and $a \leq 1$ and $b \leq 1$. So we also have $\sigma' \rightarrow^{i'} \sigma'_c \rightarrow^b \sigma_d$. As a result, we pick $\sigma_c = \sigma_d, i = i' + b, j = a$. This is fine because $i = i' + b \leq m + 1$ and $j = a \leq 1$. ◀

► **Lemma 9** (Strong Confluence). *Let P be determinacy-race-free and $P \rightarrow^* \sigma$. If $\sigma \rightarrow^n \sigma', \sigma \rightarrow^m \sigma''$, where $1 \leq m, 1 \leq n$, then there exist σ_c, i, j such that $\sigma' \rightarrow^i \sigma_c, \sigma'' \rightarrow^j \sigma_c, i \leq m$ and $j \leq n$.*

Proof. We prove it by inducting on n .

Base case: $n = 1$. Proved by Lemma 8.

Induction step: suppose $\sigma \rightarrow^n \sigma' \rightarrow \sigma'''$. By our induction hypothesis, the lemma holds for n . We have σ'_c, i', j' such that $\sigma' \rightarrow^{i'} \sigma'_c$ and $\sigma'' \rightarrow^{j'} \sigma'_c$ and $i' \leq m$ and $j' \leq n$. We want to prove the lemma holds for $n + 1$. There are two cases based on the value of i' :

1. $i' = 0$. In this case, $\sigma' = \sigma'_c$. We pick $\sigma_c = \sigma''', i = 0, j = j' + 1$. Because $j' \leq n$, we have $j \leq n + 1$, which obeys the lemma.

2. $i' \geq 1$. In this case, we have $\sigma' \rightarrow \sigma'''$ and $\sigma' \rightarrow^{i'} \sigma'_c$. By Lemma 8, there exist σ_d, a, b such that $\sigma''' \rightarrow^a \sigma_d$ and $\sigma'_c \rightarrow^b \sigma_d$ and $a \leq i'$ and $b \leq 1$. So we also have $\sigma'' \rightarrow^{j'} \sigma'_c \rightarrow^b \sigma_d$. As a result, we pick $\sigma_c = \sigma_d, i = a, j = j' + b$. This is fine because $i = a \leq i' \leq m$ and $j = j' + b \leq n + 1$. ◀

► **Lemma 10** (Confluence). *Let P be determinacy-race-free and $P \rightarrow^* \sigma$. If $\sigma \rightarrow^* \sigma'$ and $\sigma \rightarrow^* \sigma''$, then there exists σ_c such that $\sigma' \rightarrow^* \sigma_c$ and $\sigma'' \rightarrow^* \sigma_c$.*

Proof. Implied by Lemma 9 ◀

With Lemma 10, we are ready to present our main theorem. Notice that we do not assume deadlock freedom for the program P . The notation $P \Downarrow \sigma$ is defined as P cannot make further progress; some `get` operations never resume after blocking because no task elects to set the required promises. However, our main theorem reveals that even if deadlock(s) exists in a determinacy-race-free program P , any execution of P will still reach the same final state (same shared memory, same computation graph).

► **Theorem 11** (Determinism). *Let P be determinacy-race-free. If $P \Downarrow \sigma$ and $P \Downarrow \sigma'$, then $\sigma = \sigma'$.*

Proof. By Lemma 10, we have σ_c such that $\sigma \rightarrow^* \sigma_c$ and $\sigma' \rightarrow^* \sigma_c$. Given that neither σ nor σ' can proceed, we must have $\sigma = \sigma' = \sigma_c$. ◀

4 DRDP Race Detection Algorithm

Race detection for parallel programs has evolved with the development of parallel programming models. The widely-used ThreadSanitizer [33] and other vector-clock-based race detectors [16, 21] work well for multithreaded programs with lock-based synchronization. More recently, task-based parallel programming models have gained popularity for developing parallel programs intended to be determinate, i.e., these programs are always expected to compute the same results when given the same inputs. The work to be carried out is decomposed into a large number of user-defined fine-grained tasks, and dependencies among tasks are specified using join operations/futures/promises rather than locks. Task-parallel programs execute on a group of *worker* threads, with the actual schedule of tasks on worker threads determined adaptively and automatically by a runtime system. Although vector-clock-based race detectors can be applied to task-parallel programs at the worker-thread level, such an approach may also exhibit false negative results. For two tasks executing on the same worker thread, a vector-clock-based race detector may enforce a happens-before relation between them, and then fail to identify potential data races³. On the other hand, it is not practical to use such race detectors by treating each task as a thread. Task-parallel programs may create millions of tasks at runtime, making it intractable to store associated vector clocks of spawned tasks in the memory space. Other researchers have also made similar observations about the limitations of using the vector clock approach for task parallelism [29, 44, 45].

Per-input dynamic race detectors designed for task parallelism can usually be classified by the task-parallel constructs they support. Different task-parallel constructs impose different structural constraints on the computation graphs generated by programs, and the determinacy race detection problem becomes more challenging as the computation

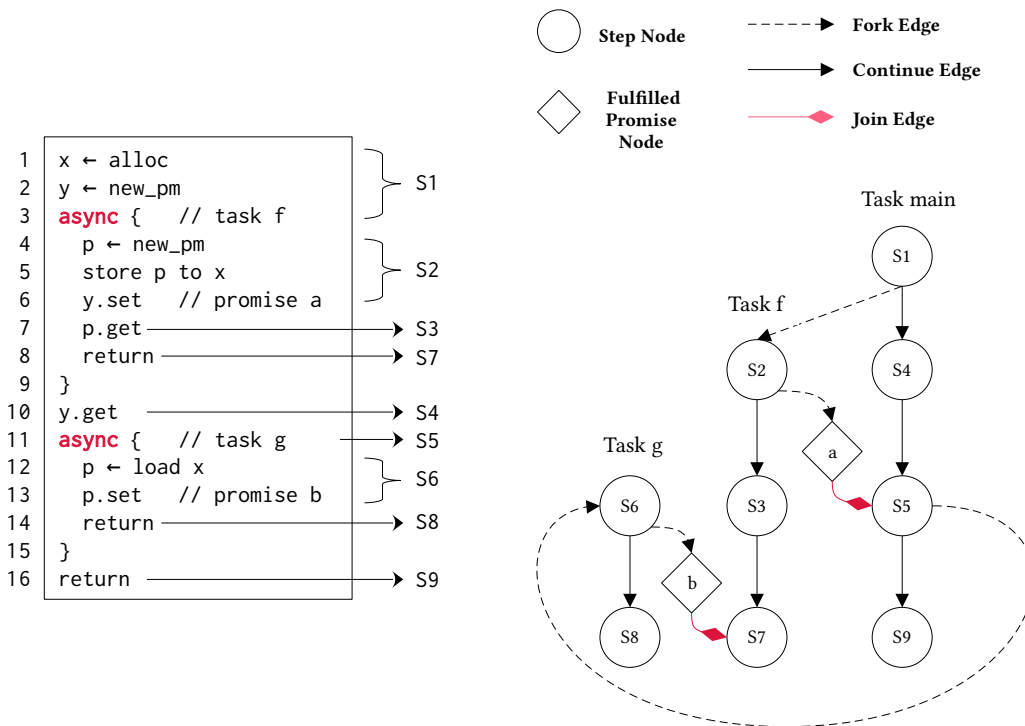

³ ThreadSanitizer limits the vector clock size to 256 [11], and can also exhibit false negatives for programs with larger numbers of threads.

13:12 Dynamic Determinacy Race Detection for Task-Parallel Programs with Promises

graphs become more general [4, 15, 26, 30, 31]. For example, SP-Bags is a race detection algorithm designed for spawn-sync task-parallel programs which only generate fully strict computation graphs [15]. ESP-Bags is an extension of SP-Bags that can support the more general terminally strict computation graphs [30] generated by async-finish task parallelism. More recent algorithms have been introduced for task-parallel programs with futures, one as an extension to async-finish constructs [35] and others as an extension to spawn-sync constructs [37, 43].

In this section, we introduce DRDP, a dynamic determinacy race detector taking task parallelism and promises into account. DRDP is based on our theoretical conclusion in Section 3. For better time and memory efficiency, we make two revisions to the notation of computation graph. Such changes do not affect the precision of race detection.

- We introduce *step nodes* to replace task nodes. A step node is a sequence of statements without task creation, `set`, or `get` except the last statement. For example, node *s1* in Figure 6 is a step node ending with a task creation.
- We simplify the computation graph construction related to promises. Every promise has only one corresponding node in the computation graph (see promises *a* and *b* in Figure 6), created when the `set` happens.

■ **Figure 6** Example program and its computation graph.

As with other dynamic race detectors, DRDP consists of 1). a *reachability data structure* that keeps track of the happens-before relationship and 2). a *shadow memory* that records access history for every memory location. We first introduce our reachability structure, which is built on-the-fly as the program executes.

4.1 DRDP Reachability Data Structures

The reachability data structure of DRDP is adapted from previous work [31, 35] on async-finish task parallelism (but no support for promise). The statement “finish { s }” causes the current task to execute the body s and wait for all spawned tasks, including transitively created tasks within the finish statement.

We leverage *Dynamic Program Structure Tree* (DPST) [31] to encode happens-before relations created by async-finish parallelism efficiently. Figure 7 shows an instance of DPST associated with the example program in Figure 6. DPST resembles the computation graph by nature. Each leaf node in the DPST represents a step node. Each internal node in the DPST is either an `async` or a `finish` node, denoting an instance of such construct in the program. Node $A1$ in Figure 7 represents the `async` in line 3 of the example program and $A3$ represents the one in line 11. The other two `async` nodes, $A2$ and $A4$, represent the `promise set` in lines 6 and 13.

■ **Figure 7** DPST and set information for the example program.

For any two step nodes s_i, s_j in a DPST, their happens-before relation (\rightsquigarrow) can be determined by examining the children of their least common ancestor (LCA). Assume s_i is to the left of s_j in the DPST. Among all children of the two node’s LCA (denoted as $lca(s_i, s_j)$), a node V (denoted as $lca_lc(s_i, s_j)$) must exist such that V is a ’s ancestor or a itself. If V is not an `async` node, $a \rightsquigarrow b$; otherwise, $a \parallel b$.

As an example, in Figure 7, step nodes $s1$ and $s2$ have the root R as their LCA. The node V , in this case, is $s1$ itself because $s1$ is a child of R . Since $s1$ is a step node, DPST will report $s1 \rightsquigarrow s2$, which is confirmed by the path from $s1$ to $s2$ in Figure 6.

Limitation of DPST. DPST may report incorrect happens-before relationships when naively applied to programs with promises. Let us consider step nodes $s2$ and $s6$ in Figure 7. Their LCA is R , and among R ’s children, the one that is $s2$ ’s ancestor is $A1$. The DPST-based happens-before check will decide that $s2 \parallel s6$. However, Figure 6 clearly shows a path from $s2$ to $s6$, so the happens-before check returns an incorrect result. The reason is that DPST does not consider synchronization semantics brought by promises.

Thus, we need to maintain additional information for those happens-before relations incurred by promises. We refer to those promise join edges in a computation graph as *non-tree joins* (nt) because DPST does not store them. For other task joins kept by DPST, we call them *tree joins*. The problem turns into how to store these non-tree joins efficiently.

Inspired by previous work [35], we use disjoint sets [12] to effectively save non-tree joins information. Tasks synchronized by tree joins will be grouped into the same set. Each set will maintain its non-tree joins, plus the lowest ancestor with at least one non-tree join, which we refer to as the *least-significant ancestor* (LSA). How do we use and maintain set, non-tree joins, and LSAs will be introduced in Section 4.3.

DRDP Example. From a high-level perspective, DRDP checks happens-before relations in two stages. It first carries out the DPST-based happens-before check. If the happens-before check returns that the two steps may happen in parallel, DRDP conducts an additional graph traversal on the computation graph. The graph traversal loops through non-tree joins and LSAs to see if the two steps are ordered by non-tree joins.

We now explain how DRDP can find out $s2 \rightsquigarrow s6$ by the information in Figure 7. DRDP first checks DPST and finds $lca_lc(s2, s6)$ is an `async` node, so it continues with the graph traversal. Because $s6$ is in task g and task g is in set 2, DRDP examines the column `nt` of set 2. In this case, we do not have any non-tree join for set 2. Finally, DRDP checks the column `lsa` of set 2, realizes set 2's `lsa` is the main task, and the main task has a non-tree join from task a . Now, DRDP knows $a \rightsquigarrow s6$. The goal becomes deciding if $s2 \rightsquigarrow a$. DRDP inspects DPST and finds $lca_lc(s2, a)$ is a step node, which indicates $s2 \rightsquigarrow a$. Now DRDP can conclude $s2 \rightsquigarrow s6$.

4.2 DRDP Task Scheduling and Shadow Memory

Existing race detectors [4, 15, 30, 35, 37] that execute programs sequentially usually rely on the *serial-projection property*, which ensures that there is a legal scheduling strategy that executes a parallel program sequentially without any blocking. Crucially, however, programs with promises do not enjoy the serial-projection property.

As a solution, our runtime follows a depth-first execution order and switches to task T 's parent task recursively when T is blocked. As soon as some other task S sets the promise that T is waiting on, the worker thread will suspend task S and resume the execution of task T . If the fulfilled promise P enables more than one task, we execute these enabled tasks in the same order as they were placed in the waiting queue for promise P . The worker switches back to task S after all tasks previously blocked on promise P are finished. If a deadlock exists in the program, our race detector works up to the point of deadlock.

Shadow memory also needs careful design due to possible blockings. For each memory location, we save the last step node that writes to it, plus a read list that records all step nodes reading from the memory location after the last write. When a write occurs, if no race is found with the recorded historical accesses, we empty the reader list and save the current step node as the last write. When a read occurs, if no race is found with the last write, we add it to the reader list.

4.3 Algorithm

DRDP algorithm is presented in Figure 8 and Figure 9. Figure 8 explains how we maintain the reachability structure and the shadow memory, which happens per instruction of the program being executed; Figure 9 defines procedure *PRECEDE* for happens-before check. When encountering a read or write to memory location M , DRDP will do race checks as in lines 40 - 44 and lines 45 - 55; if the function reports a race, it means a race exists between current access and previous access to M .

The built-in function $run_eager(U)$ suspends the execution of current task T and starts executing task U . For tasks returning from blocking, run_eager will resume their execution from the first statement after blocking.

Now we briefly explain each callback executed by DRDP.

Task creation: When a task is created, we initialize some information and create a disjoint set. The worker then starts executing the task until finished or blocked.

Task termination: We set the task state from active to finished.

<pre> // Task creation: // task T creates task U 1 S_U = new set_info(U) 2 set[U.id] = S_U 3 U.state = ACTIVE 4 U.parent = T.id 5 6 S_T = set[T.id] 7 if S_T.nt.isEmpty() then 8 S_U.lsa = S_T.lsa 9 else 10 S_U.lsa = lsa_info(T.id, S_T.nt) 11 end 12 run_eager(U) </pre> <hr/> <pre> // Task termination: // task T terminates 13 T.state = FINISHED </pre> <hr/> <pre> // Promise set: // task T sets promise P 14 P.setter_task_id = T.id 15 P.empty_task_id = (new task()).id 16 foreach task X waiting on P do 17 run_eager(X) 18 end </pre> <hr/> <pre> // Promise get: // task T gets promise P 19 if P.satisfied == false then 20 T.state = BLOCKED 21 run_eager(T.parent) 22 end 23 x = new nt_info(P.empty_task_id) 24 S_T = set[T.id] 25 S_T.nt = S_T.nt ∪ x </pre>	<pre> // Finish end: // Finish F ends in task T 26 S_T = set[T.id] 27 foreach task X in F do 28 S_X = set[X.id] 30 nt = S_T.nt ∪ S_X.nt 32 lsa = S_T.lsa 34 S_T = Union(S_T, S_X) 36 S_T.nt = nt 38 S_T.lsa = lsa 39 end </pre> <hr/> <pre> // Read check: // step s reads from memory_location M 40 w = M.writer 41 if PRECEDE(w, s) == false then 42 report race 43 end 44 M.reader_list = M.reader_list + s </pre> <hr/> <pre> // Write check: // step s writes to memory_location M 45 w = M.writer 46 if PRECEDE(w, s) == false then 47 report race 48 end 49 foreach r in M.reader_list do 50 if PRECEDE(r, s) == false then 51 report race 52 end 53 end 54 M.reader_list = {} 55 M.writer = s </pre>
--	--

■ **Figure 8** DRDP algorithm parts that maintain data structures and shadow memory.

Promise set: We create an empty task, and if any task is enabled, the worker will begin to execute enabled tasks. The worker will go back to the current task sometime in the future.

Promise get: If the promise is not yet set, we block the current task and switch to its parent recursively; if the promise is set, we add its empty task to the current set's nt.

Finish end: This happens at the end of a finish statement. The finish's owner task will merge all spawned tasks in the finish by keeping its original LSA plus unionizing the tasks and non-tree joins (*nt*) from the merged sets.

Read check: If current step *s* reads from memory location *M*, we first check race against *M*'s *writer*. If no race is reported, we directly add *s* to the *reader_list*.

Write check: If current step *s* writes to memory location *M*, we check race against *M*'s *writer* and all recorded steps in *M*'s *reader_list*. If no race is reported, we clear the *reader_list* and update *M*'s *writer* to be the current step.

Reachability query: Figure 9 elucidates how we perform reachability checks in DRDP. Given two step nodes *a, b*, we first examine if *a* precedes *b* by inspecting DPST. If *lca_lc(a, b)* is not an **async** node, we return true; this is reflected in lines 3-5. Next, we check if the previous task is still active starting from line 7. If *a*'s task is still active, either *b* is *a*'s

descendant, or a 's task sets the promise that b depends on; both cases indicate $a \rightsquigarrow b$. The remaining code in Figure 9 conducts a breadth-first search on the computation graph based on fields nt and lsa . Lines 23-39 search through non-tree joins. Lines 41 to 57 search through lsa 's non-tree joins. We return false if there are no more step nodes to search.

► **Theorem 12.** *DRDP's race detection algorithm is sound and precise. For a program P , if no execution with input ψ has any determinacy race, DRDP will not report any race (sound). For a program P , if any execution with input ψ has a determinacy race, DRDP will report the race (precise).*

Proof. To relate the theoretical result given by Theorem 11, the input ψ here refers to the initial program state $\text{root}(P)$. The proof is presented in Appendix A. ◀

► **Theorem 13.** *Given a parallel program consisting of $async$, $finish$ and $promise$ that runs in time T_1 on one worker. Assume it creates P promises and Q $async$ tasks. Let H be the height of DPST at the end of the execution, and m be the number of non-tree joins. DRDP can be implemented to check this program for determinacy races in $O(T_1 * Q * H * m * \alpha(T_1, P + Q))$ time, where α is the inverse Ackermann function.*

Proof. For a single run of PRECEDE, it could take up to $O(H * m * \alpha(T_1, P + Q))$ in the worst case if it checks all non-tree joins, and each check contains one DPST traversal plus a disjoint set operation. The maximum count of disjoint sets is $(P + Q)$ because we create one set for each task and one set for each empty task.

The PRECEDE routine may be called Q times for each shadow memory location access. This is because the reader list for a single memory location can be as large as size Q if we save all the tasks. We have at most T_1 shared memory access; thus, with DRDP checking races, the original program can be finished in $O(T_1 * Q * H * m * \alpha(T_1, P + Q))$ time. ◀

4.4 Optimizations

We introduce two optimization techniques used for DRDP. The impacts of these optimizations are respectively evaluated in Sections 5.5 and 5.6.

4.4.1 Adaptive Selection of Graph Traversal Order

A complete computation graph traversal can become necessary without restricted graph structures that enable fast encoding and checking reachability. To accelerate this part, how to traverse all non-tree joins and lsa is the key. We optimize the graph traversal in two ways: first, rather than conducting a depth-first search starting from the current node, we apply a breadth-first search instead; second, when iterating through non-tree joins, we start from the latest join to the oldest. The impact of the proper selection of these two choices is evaluated in Section 5.5.

4.4.2 Redundant Check Elimination

A single step node may access the same memory location multiple times. This may introduce a substantial amount of unnecessary duplicate checks. We present the performance improvement by skipping these redundant checks in Section 5.6. Here we introduce our approach based on the polyhedral model, a powerful linear algebraic framework for affine program analysis, transformations, and code generation.

```

Input: step nodes a, b
1 Procedure PRECEDE(a, b)
2    $S_B = \text{set}[b.task\_id]$ 
3   if  $lca\_lc(a, b).type \neq ASYNC$  then
4     | return true
5   end
6
7   if  $task[a.task\_id].state == ACTIVE$  then
8     | return true
9   end
10
11  // breadth-first search the computation graph via nt and lsa
12   $visited = \text{set}()$ 
13   $nt - steps = \text{deque}()$ 
14   $lsa - sets = \text{deque}()$ 
15  foreach  $t$  in  $S_B.nt$  do
16    |  $nt - steps.push\_back(task[t.task\_id].last\_step\_node)$ 
17  end
18
19  if  $S_B.lsa \neq NULL$  then
20    |  $lsa - sets.push\_back(S_B.lsa)$ 
21  end
22
23  while true do
24    | while  $nt - steps.size > 0$  do
25      |  $step = nt - steps.pop\_front()$ 
26      | if  $lca\_lc(a, step).type \neq ASYNC$  then
27        | return true
28      | end
29
30      |  $visited.insert(step.task\_id)$ 
31      |  $S_{step} = \text{set}[step.task\_id]$ 
32      | foreach  $t$  in  $S_{step}.nt$  do
33        | | if  $t.task\_id$  not in  $visited$  then
34          | | |  $nt - steps.push\_back(task[t.task\_id].last\_step\_node)$ 
35          | | |  $visited.insert(t.task\_id)$ 
36        | | end
37      | end
38
39      |  $add\ S_{step}.lsa\ \text{to}\ lsa - sets\ \text{if\ exists}$ 
40    | end
41
42    | while  $lsa - sets.size > 0$  do
43      |  $lsa = lsa - sets.pop\_front()$ 
44      |  $S_{lsa} = \text{set}[lsa.task\_id]$ 
45      |  $add\ S_{lsa}.lsa\ \text{to}\ lsa - sets\ \text{if\ exists}$ 
46      | foreach  $t$  in  $lsa.nts$  do
47        | |  $taskt = task[t.task\_id]$ 
48        | | if  $taskt.id$  in  $visited$  then
49          | | | Continue
50        | | end
51        | | if  $lca\_lc(a, taskt.last\_step\_node) \neq ASYNC$  then
52          | | | return true
53        | | end
54        | |  $add\ set[taskt.id].nt\ \text{to}\ nt - steps$ 
55        | |  $add\ set[taskt.id].lsa\ \text{to}\ lsa - sets\ \text{if\ exists}$ 
56        | |  $visited.insert(taskt.id)$ 
57      | end
58    | end
59
60    | if  $nt - steps.size == 0$  then
61      | return false
62    | end
63  end

```

■ **Figure 9** Reachability Check.

<pre> 1 /* Input code */ 2 for(int i = 0; i < n; i++) 3 for(int j = 0; j < m; j++) 4 for(int k = 0; k < l; k++) 5 S: C[i, j] += A[i, k] * B[k, j]; </pre>	<pre> 1 /* Code to scan written elements */ 2 /* 3 if (l >= 1) 4 for (int c1 = 0; c1 < n; c1 += 1) 5 for (int c2 = 0; c2 < m; c2 += 1) 6 write(C[c1, c2]); </pre>	<pre> 1 /* Code to scan read elements */ 2 if (l >= 1) 3 for (int c1 = 0; c1 < n; c1 += 1) 4 for (int c2 = 0; c2 < m; c2 += 1) 5 read(C[c1, c2]); 6 if (m >= 1) 7 for (int c1 = 0; c1 < n; c1 += 1) 8 for (int c2 = 0; c2 < l; c2 += 1) 9 read(A[c1, c2]); 10 if (n >= 1) 11 for (int c1 = 0; c1 < l; c1 += 1) 12 for (int c2 = 0; c2 < m; c2 += 1) 13 read(B[c1, c2]); </pre>
--	--	--

■ **Figure 10** Matmul input (left), loops to scan written elements (center), and read elements (right).

When the code region of interest are composed of *affine loops* – i.e., their loop bounds and array accesses are affine combinations of symbolic constants and outer loop iterators, that region is converted into SCoP format [3]. This format precisely specifies the set of read/written elements in the region via affine mapping representation. As an example shown in Figure 10, the SCoP representation of matmul after delinearization [18] is:

$$\begin{aligned}
 \text{Domain}_S &= \{S(i, j, k) \mid 0 \leq i < n \wedge 0 \leq j < m \wedge 0 \leq k < l\} \\
 \text{Write}_S &= \{S(i, j, k) \rightarrow C[i, j]\} \\
 \text{Read}_S &= \{S(i, j, k) \rightarrow C[i, j]; S(i, j, k) \rightarrow A[i, k]; S(i, j, k) \rightarrow B[k, j]\}
 \end{aligned}$$

Domain_S is the iteration space of statement S while Write_S and Read_S are respectively the mappings from statement instance $S(i, j, k)$ to the written and read elements of arrays A, B, C. The set of elements that are written/read by statement S is computed as the projection of Domain_S via $\text{Write}_S/\text{Read}_S$ mapping.

$$\begin{aligned}
 \text{Write}_S(\text{Domain}_S) &= \{C[i, j] \mid 0 \leq i < n \wedge 0 \leq j < m\} \\
 \text{Read}_S(\text{Domain}_S) &= \{C[i, j] \mid 0 \leq i < n \wedge 0 \leq j < m; A[i, k] \mid 0 \leq i < n \wedge 0 \leq k < l; \\
 &\quad B[k, j] \mid 0 \leq k < l \wedge 0 \leq j < m\}
 \end{aligned}$$

Using the above written & read element sets, as with the abstract memory layout [34] as scanning order, the loop nests that scan all the written and read elements are generated by the polyhedral code generation method [2].

$$\begin{aligned}
 \text{Layout} &= \{C[c_1, c_2] \rightarrow (0, c_1, c_2); A[c_1, c_2] \rightarrow (1, c_1, c_2); B[c_1, c_2] \rightarrow (2, c_1, c_2); \} \\
 \text{Code}_{\text{write}} &= \text{codegen}(\text{Layout} \cdot \text{Write}_S(\text{Domain}_S)) \\
 \text{Code}_{\text{read}} &= \text{codegen}(\text{Layout} \cdot \text{Read}_S(\text{Domain}_S))
 \end{aligned}$$

This polyhedral optimization phase has been implemented as a source-to-source transformation tool using PET [40] and ISL [39], integrated in the overall LLVM-based instrumentation pass (Section 5.1). The LLVM transformation pass first identifies the SCoP-convertible code regions and outputs them as sequential C code with SCoP annotations. Given SCoP region, the polyhedral phase computes the exact sets of read/written array elements and generates the loops that scan all elements only once. Finally, the output scanning loops are fed back to the LLVM instrumentation as the optimized code after array-based redundant check elimination. The code fragments generated by our polyhedral phase are shown in Figure 10 (center and right).

5 Evaluation

In this section, we evaluate a prototype implementation of the DRDP algorithm to address the following research questions:

1. Correctness (Section 5.2). How does DRDP compare with state-of-the-art data race detectors with respect to false positives and false negatives?
2. Performance (Section 5.4). How does DRDP perform in practice, and how does its time and space performance depend on dynamic characteristics of task-parallel programs with promises (DPST height, number of reads/writes, number of join operations, number of tasks created)?
3. What is the impact of graph traversal order on performance? (Section 5.5).
4. What is the impact of redundant check elimination on performance? (Section 5.6).

5.1 DRDP Implementation

We have implemented DRDP in a prototype race detector for task-parallel programs written in Habanero-C/C++ Library (HCLIB). Notice that any parallel program with promises that exhibits a determinacy race in the HCLIB version will also exhibit the race if rewritten with C++ promises. Our prototype can be downloaded here⁴, which includes

- a) an LLVM transform pass for instrumentation, and
- b) a C++ library for dynamic analysis.

The instrumentation pass is executed along with LLVM. When compiling a task-parallel program using the Clang/LLVM compiler, the instrumentation pass will inject a call into the dynamic analysis library after each read and write operation. The library also adds hooks into runtime to capture the invocations of HCLIB constructs (async, finish, promise). The library applies a direct-mapping shadow memory implementation [46]. A contiguous memory region shadows the entire address space, and each memory location’s shadow memory cell can be efficiently located using pointer arithmetic.

5.2 Correctness Evaluation

DataRaceBench [24] is a micro-benchmark suite designed to gauge the effectiveness of OpenMP data race detectors. In the latest 1.4.0 version, there are 181 C/C++ micro-benchmarks that cover the majority of OpenMP constructs. We leveraged DataRaceBench to conduct a correctness evaluation for DRDP. We found that micro-benchmarks using OpenMP tasking constructs can be transformed into equivalent HCLIB programs, and task dependencies specified by the `depend` clause can be achieved using promises. Therefore, we picked up all C/C++ micro-benchmarks containing the `depend` clause except DRB135 and DRB136. These two micro-benchmarks combine mutexes with the `depend` clause, which go beyond the set of programs captured by TP3 and also do not satisfy the determinacy property of TP3.

The evaluation results for these micro-benchmarks are shown in Table 1. The “yes/no” suffix in the benchmark name indicates whether the benchmark has a known data race. For short, we refer to these two groups of benchmarks as *yes-benchmarks* and *no-benchmarks*. The evaluation results are described using four terms in Table 1. FP and FN stand for *false positive* and *false negative*, respectively. A false-positive result means the race detector

⁴ <https://github.com/FeiyangJin/hclib/tree/ecoop>

reports false alarms on a no-benchmark. A false-negative result means the race detector misses potential races on a yes-benchmark. The other two terms, TP and TN, stand for *true positive* and *true negative*. TP/TN indicates that the race detector generates the expected result on a yes-benchmark/no-benchmark.

Evaluation results are shown for five state-of-the-art data-race detection tools, followed by our work (DRDP). The results for the five other tools were downloaded from the DataRaceBench GitHub repository [25] and evaluated on the OpenMP versions of the micro-benchmarks; these results were obtained in 2021 by the authors of DataRaceBench. All five tools were evaluated with the number of worker threads set to 8. Among the five tools, Intel Inspector [21], ThreadSanitizer [33], and ROMP [19] are dynamic race detectors, while Coderrect [36] and LLOV [5] are static race detectors. The DRDP results were obtained by converting the OpenMP benchmarks to HCLIB task-parallel programs with promises. From the results, we observe that DRDP is the only tool that does not report any false-positive or false-negative results for these benchmarks.

We were unable to identify the root cause of false-positive and false-negative results for ROMP and Intel Inspector since their papers did not provide sufficient information on how their dynamic analysis supports the `depend` clause. For ThreadSanitizer, the documentation states that it applies a fixed-size shadow cell to each memory location. When the shadow cell is full, ThreadSanitizer will randomly discard a recorded memory access to reserve space for the latest one. As a result, ThreadSanitizer may miss data races if one of the involved memory accesses has been discarded from the shadow cell thereby leading to false negatives. For Coderrect and LLOV, it appears that their support for tasking constructs and the `depend` clause is still under development which may explain the false-negative results. We would also expect false-positive results from these static analysis tools, when evaluated on larger benchmarks.

Apart from these converted micro-benchmarks from DataRaceBench, we also wrote some additional tests to check DRDP’s implementation. All converted micro-benchmarks and additional tests are included in our code repository.

■ **Table 1** Correctness evaluation results on DataRaceBench.

Benchmarks	Has Race?	Intel Inspector	ThreadSanitizer	ROMP	Coderrect	LLOV	DRDP

5.3 Performance Evaluation Benchmarks and Setup

Since we could not easily locate an existing set of performance benchmarks for task-parallel programs using promises, we assembled a suite of seven benchmarks from other benchmark sets as follows. We did not convert the program with the largest lines of code for each set.

⁴ <https://github.com/LLNL/dataracebench/wiki/Tool-Evaluation-Dashboard>

We first converted the future-based `matmul`, `sort` and `strassen` (shared by Kastors) programs from [43] (originally from the Rodinia suite [9]) to use promises. Next, we examined the Kastors benchmark suite [41] for OpenMP task dependencies and converted two (`sparselu`, `poisson`) to use promises instead to implement the same dependencies. Finally, we converted two task-parallel OpenMP programs from the BOTS benchmark suite (`health`, `knapsack`) [14]. We only convert two because race detection on pure task-parallel programs has been widely studied before.

The summary of each benchmark is as follows:

- **matmul**: multiplies two matrices of size $2048 * 2048$ with base case size $64 * 64$.
- **sort**: sorts an array of size 10000000.
- **strassen**: multiplies two matrices of size $2048 * 2048$ by Strassen algorithm.
- **poisson**: solves the Poisson equation (aka jacobi iteration) on the unit square. The parameters we have are 8192,128,3 for matrix size, block size and number of iterations.
- **sparselu**: computes the LU decomposition of a sparse matrix. The parameters we have are 128 and 32 for matrix size and submatrix size.
- **knapsack**: calculates the solution of the knapsack problem with 40 items as input.
- **health**: simulates the Colombian health care system. We estimate the running time for the small model input file given in the source.

The evaluation was conducted on a single-node AMD server machine consisting of a 12-core Ryzen9 3900X running at 3.8GHZ with 128GB memory. All benchmarks were compiled using `-O3` optimizations by Clang/LLVM 14.0.0 running on Ubuntu 18.04.05. We report each benchmark’s mean execution time and memory usage of 5 runs for *base* and *rd* configurations. “base” is the program running time without race detection; “rd” is the one with full race detection. The standard deviations for both configurations are within 5%.

5.4 Performance Evaluation Results

The results of our evaluation are shown in Table 2; the corresponding time overheads are in Figure 11. The first four columns show the running time in seconds and memory usage in GB, for the two configurations mentioned above. The next column “H” shows the height of DPST. Columns “Check Write” and “Check Read” are the numbers of shared memory access conducted for write and read. The following two columns, “Tree Join” and “NT Join”, are the numbers of tree and non-tree joins in the programs. Finally, column “Task” contains the number of dynamic tasks created during program execution.

■ **Table 2** DRDP performance and statistics.

Bench	Base Time	RD Time	Base Mem	RD Mem	H	Check Write	Check Read	Tree Join	NT Join	Task
health	1.51	31.99	0.45	11.64	5	49554260	84975199	2253510	0	2253511
knapsack	1.61	8.00	0.38	4.40	37	3939935	19699117	1969965	0	1969966
matmul	2.52	51.84	0.06	13.44	7	134231771	268477586	28086	0	28087
sort	0.99	40.95	0.18	4.91	15	207671935	261760850	118205	0	118206
strassen	1.37	39.97	0.20	26.12	12	123772570	243307611	29182	16380	45563
sparselu	2.46	69.01	0.04	16.70	4	187379732	362287128	12416	357760	195521
poisson	1.56	71.92	0.80	20.09	4	251658242	654802935	0	122870	106497

From the experiment statistics, we can make several observations. First, the sum of joins for `sparselu` and `poisson` surpasses the number of tasks; the reason is that each task may set and get more than one promise. This pattern is not achievable by pure task-parallel

programs. Even the future construct cannot produce more synchronization than the task number because creating a future requires creating a new task (who is responsible for setting the future). Moreover, from Table 2 and Figure 11, the race detection time overheads increase with the complexity of the parallelism pattern of the programs. Strassen, sparselu and poisson, with relatively high overheads, use promises without restrictions. The computation graphs created by the three are much more complex than the others, which is reflected by the number of non-tree joins generated.

■ **Figure 11** DRDP time overhead.

5.5 Performance Optimization: Graph Traversal Order

The motivation for selection between depth-first search (dfs) and breadth-first search (bfs) is summarized in Table 3, which shows traversal counts by different combinations of graph order (dfs vs. bfs) and iterating order through non-tree joins (back-to-front vs. front-to-back). Our optimization is extremely helpful: we always get the smallest values for columns “Max Task Visited” and “Average Task Visited” when doing bfs on the computation graph and iterating non-tree joins back-to-front. The rows with these two choices are marked in yellow in Table 3. The column “Max Task Visited” records the max number of tasks traversed in any run of the reachability check. The column “Average Task Visited” is the average number of tasks visited for each reachability check that does the graph traversal part. We picked bfs and back-to-front approach in our race detector and evaluated all benchmarks on them.

5.6 Performance Optimization: Redundant Check Elimination

Another crucial observation is that duplicate read and write checks in the same step are the bottlenecks for four benchmarks (matmul, strassen sparselu and poisson). The results in Section 5.4 included the optimized performance for these four benchmarks. In this section, we study the performance impact of the Redundant Check Elimination optimization for these four benchmarks; currently this optimization had no impact on the remaining three benchmarks evaluated in Section 5.4 because they would need interprocedural analysis across recursive calls, which is currently not performed by our optimizing compiler.

■ **Table 3** Graph traversal order comparison.

Bench	Graph Order	Input	NT Order	Min Visited Task	Max Visited Task	Average Visited Task
strassen	dfs	512 16	back to front	1	2	1.43
strassen	dfs	512 16	front to back	1	337	11.04
strassen	bfs	512 16	back to front	1	1	1.00
strassen	bfs	512 16	front to back	1	4	1.13
sparselu	dfs	32 8	back to front	1	544	8.85
sparselu	dfs	32 8	front to back	1	544	65.72
sparselu	bfs	32 8	back to front	1	2	1.07
sparselu	bfs	32 8	front to back	1	17	6.08
poisson	dfs	2048 128 3	back to front	1	32	9.54
poisson	dfs	2048 128 3	front to back	1	32	9.54
poisson	bfs	2048 128 3	back to front	1	6	2.84
poisson	bfs	2048 128 3	front to back	1	6	2.84

We record runtime statistics for these programs with or without reducing redundant checks. To measure the time overhead and memory usage, we have to re-evaluate these benchmarks on a different machine with enough memory. We present the outcomes in Table 4. The parentheses after some data show the increase/decrease percentage.

■ **Table 4** Performance comparison for reducing redundant checks.

Bench	Reduce Checks	RD Time	RD Mem	Input	Reachability Check	Write Check	Read Check
matmul	No	118.95 (+1038%)	74.77 (+3805%)	1024	1.57E+07 (+0%)	1.68E+07 (+0%)	2.15E+09 (+6299%)
matmul	Yes	10.45	1.91	1024	1.57E+07	1.68E+07	3.36E+07
strassen	No	19.73 (+233%)	12.88 (+584%)	512 16	1.94E+08 (+496%)	4.10E+06 (-47%)	7.74E+07 (+408%)
strassen	Yes	5.93	1.88	512 16	3.26E+07	7.77E+06	1.52E+07
poisson	No	214.85 (+135%)	37.87 (+129%)	7424 128 3	1.93E+09 (+84%)	2.07E+08 (-0.02%)	1.36E+09 (+154%)
poisson	Yes	91.49	16.56	7424 128 3	1.05E+09	2.07E+08	5.38E+08
sparselu	No	1137.68 (+918%)	382.37 (+2189%)	128 32	9.94E+08 (+84%)	5.86E+09 (+3029%)	1.20E+10 (+3219%)
sparselu	Yes	111.74	16.70	128 32	5.41E+08	1.87E+08	3.62E+08

All four benchmarks (matmul, strassen, poisson and sparselu) are matrix-based. As explained in Section 4.4.2, a considerable amount of redundant read checks can be eliminated in such cases. After the transformation, as shown in Table 4, the running time increases by 135% to 1038% when comparing the optimized version with the unoptimized version.

5.7 Comparison with ThreadSanitizer

Directly evaluating other tools on our benchmarks will typically generate false positives because they do not consider synchronization constraints imposed by promises. Nevertheless, given the widespread use of ThreadSanitizer in practice, we decided to evaluate it on one of our benchmarks (matmul), which is the only one for which ThreadSanitizer was able to complete successfully and that too with a smaller input. We set “report_bugs=0, ignore_uninstrumented_modules=1” for ThreadSanitizer to ensure that it ignores uninstrumented code and does not print a race report.

The issue we encountered is that ThreadSanitizer crashes on large inputs for our promise-based applications. The error messages from these crashes report a stack overflow. Most likely, it was caused by the fixed-size stack ThreadSanitizer set⁵, especially since all of our benchmarks use recursion. We use a smaller input size (128 x 128 for the matmul benchmark) instead to perform the evaluation.

⁵ https://github.com/llvm/llvm-project/blob/2e999b7dd1934a44d38c3a753460f1e5a217e9a5/compiler-rt/lib/tsan/rtl/tsan_platform_posix.cpp#L53

■ **Table 5** Performance comparison between DRDP and ThreadSanitizer.

Tool	Threads	Time Overhead	Memory Overhead	Time (ms)	Memory (MB)
ThreadSanitizer	4	20.26×	34.91×	45.8	180.49
Baseline	4	1.00×	1.00×	2.3	5.17
DRDP	1	6.10×	33.65×	17.6	166.31
Baseline	1	1.00×	1.00×	2.9	4.94

This benchmark generates 7 tasks at runtime for the given input size, so we reasonably chose to execute it with 4 worker threads for the ThreadSanitizer case. From the results in Table 5, we can see that when the input size is small DRDP has a better time performance and a similar memory performance compared with ThreadSanitizer. This is even though the ThreadSanitizer execution uses 4 threads, and the DRDP execution uses 1 thread. (The Baseline measurements were obtained on the same original version of the benchmark, but with 4 threads and 1 thread respectively.)

6 Related Work

The concept of determinacy was introduced by Karp and Miller in the late 1960s [23]. More recently, Dennis et al. reviewed this past work and introduced the concepts of structural and functional determinism [13]. Related work on the Habanero-Java programming model [7] classified task-parallel programs into seven categories where each category satisfies or does not satisfy certain properties, such as data race freedom, deadlock-freedom or determinism. The paper observed that for some parallel constructs, data race freedom implies determinacy but no proof was given for that claim. Concurrent Collection (CnC) is a dataflow-based coordination language, which was proved to be determinate [6]. Data-race free GPU programs that use barriers for synchronization have been proven to be determinate [10], though the programming model is data parallel rather than task parallel. Similarly, programs designed for heterogeneous systems can achieve portability (same input, same result regardless of the specific backend used) if data-race free [22].

There has been a long history of dynamic determinacy race detection algorithms and tools based on vector clocks [16, 21, 33]. A major advantage of the vector clock approach is that it can be applied to parallel programs with arbitrary parallel constructs, including locks and transactions (say). However, its major limitation when applied to task-parallel programs is that it can only provide guarantees on a per-schedule (rather than per-input) basis since it is not practical for vector clock sizes to be proportional to the number of active tasks.

The serial projection property has been used in past work to perform per-input race detection via sequential execution for restricted classes of task-parallel programs [4, 30]. These algorithms take advantage of the structural property of computation graphs for fork-join programs, but they do not support the arbitrary computation graphs that can be generated by task-parallel programs with promises. Surendran and Sarkar also leveraged the serial projection property to devise the first per-input dynamic race detector for task-parallel programs with futures [35]. The futureRD race detector from Utterback et al. [37] supports a restricted class of futures: it does not allow multiple `get` operations on a future handle. In contrast to previous algorithms, DRDP can support general blocking operations in task-parallel programs with promises. It also illustrates how dynamic race detection can be performed via sequential execution for task-parallel programs that do not satisfy the serial projection property.

Labeling techniques have also been used in past work on race detection for task parallelism. This approach enables reachability checking between two nodes by comparing two labels. Mellor-Crummey introduced the Offset-Span [26] algorithm as one such approach, in which the length of the label attached to each task can grow as large as the depth of nested fork structures. The SP-Bags [15] structure devised by Feng and Leiserson, and the ESP-Bags [30] introduced by Raman et al. are also examples of using labeling to record happens-before relationships.

More recently, there have been some new results on performing per-input dynamic race detection when executing programs in parallel instead of sequentially. In 2012, Raman et al. introduced the DPST data structure [31], which runs in parallel and efficiently tracks happens-before relationships of async-finish constructs. An application of DPST targets task parallelism in OpenMP has been proposed [45]. Utterback et al. [38] proposed an asymptotically optimized parallel race detection algorithm for fork-join programs. More recently, Xu et al. [43] introduced the first known parallel dynamic race detector for task-parallel programs with futures. However, none of these prior works support per-input determinacy race detection of task-parallel programs with promises.

7 Conclusions

In this paper, we addressed the problem of dynamic detection of data-races and determinacy-races in Task-Parallel Programs with Promises (TP3), which support more flexible synchronization patterns than fork-join constructs and futures. We first introduced a featherweight programming language that captures the semantics of TP3 and provides a basis for formally defining determinacy using our semantics. This definition subsumes functional determinacy (same output for same input) and structural determinacy (same computation graph for same input). We also introduced DRDP, the first-known per-input dynamic determinacy race detector algorithm for TP3, and demonstrated that it is practical to implement. To the best of our knowledge, DRDP is the first race detector that executes a task-parallel program sequentially without requiring the serial-projection property, which is a critical requirement for TP3 in general. The execution time slowdowns are all under 50×, which is comparable to overheads incurred by other dynamic race detection and debugging tools used in practice. The results also highlighted the impact of two important optimizations, traversal order and redundant check elimination, in obtaining these results. Opportunities for future work include exploring static and dynamic optimizations to further reduce the overheads in our implementation of the DRDP, as well as extensions to support determinacy race detection for promise-like constructs used in heterogeneous parallelism (e.g., CUDA graph) and in distributed-memory parallelism (e.g., MPI_Request).

A Proof

► **Lemma 14.** *Non-tree joins (nt) and least-significant ancestor (lsa) maintain happens-before relationships correctly, given the routines in Figure 8.*

Proof. For a task T in the disjoint-set D , there are two conditions we may update D 's nt according to Figure 8.

- Lines 19 to 25: when task T gets a promise, we add the empty task created by the promise setter to D 's nt. In this way, we create dependency from step nodes (those before the set operation) in the setter task to the remaining step nodes in T .
- Line 26 to 38: when finish F ends in task T , we merge all non-tree joins from merged tasks. The merged tasks are essentially descendants of T and we keep those non-tree joins in D 's nt.

For a task T in the disjoint-set D , there are two conditions we may update D 's lsa according to Figure 8.

- Lines 1 to 12: when task T is created, if the parent has non-tree joins, we set D 's lsa to be the parent. Otherwise, we set D 's lsa to be the lsa of parent. This obeys the definition of lsa (the lowest ancestor that has non-tree joins).
- Line 26 to 38: when finish F ends in task T , we keep T 's lsa and ignore merged tasks' lsa. This is valid because merged tasks are essentially descendants of T , so for any merged task, its lsa is either T , T 's lsa or one of T 's descendants. In all cases, the nt and lsa of D already cover the information. ◀

► **Theorem 15.** *If DRDP does not report any determinacy race during an execution of program P with input ψ , then no execution of P with ψ will have a write-write race on any memory location r .*

Proof. Consider an execution δ of a program P with input ψ in which DRDP is enabled and does not report any determinacy race.

Suppose that a write-write race, χ , occurs on a memory location r in some execution δ' of P with ψ . Let W_1 and W_2 denote the two steps that write to r resulting in the race in δ' . Note that the execution δ' does not have any race until χ occurs. Without loss of generality, assume W_1 writes to r first and W_2 writes to r later in δ . We will prove by contradiction that DRDP must report the race in δ . There are two cases:

1. There are no writes to r between W_1 and W_2 in δ .

When W_1 occurs in δ' , Figure 8 lines 45 - 55 check all readers in reader list and last writer of r to see if any can execute in parallel with W_1 . Because χ is the first determinacy race in δ' , no race will be reported when W_1 occurs. We then save W_1 as the last writer to r in δ' .

When W_1 occurs in δ , because no determinacy race occurs yet, we then save W_1 as the last writer to r in δ .

When W_2 occurs in δ , we will run $PRECEDE(W_1, W_2)$ to check if $W_1 \rightsquigarrow W_2$. In δ' , $PRECEDE(W_1, W_2)$ returns false. In δ , $PRECEDE(W_1, W_2)$ returns true. We are going to show it is impossible in δ that true was returned.

In Algorithm 9, we may return true in four places: lines 4, 8, 26, and 51.

Line 4 cannot be executed in δ because DPST is the same across all executions without determinacy race. When W_2 happens, the related DPST parts that were previously generated are the same across δ, δ' . As a result, in δ , DRDP cannot return true at line 4. Line 8 cannot be executed in δ . This line only returns true if the task W_1 in is still active in δ at this point. This means either W_2 is W_1 's descendant or W_1 's task has set a promise that W_2 's task needs. Both conditions cannot be true because in δ' we have $W_1 \parallel W_2$.

Lines 26 and 51 cannot be executed in δ . We may return in these two lines if we find a path from W_1 to W_2 in a graph traversal over the computation graph. The validity is proved in Lemma 14.

2. There are writes to r by steps $W_i \dots W_j$ between W_1 and W_2 in δ .

In δ' , the happens-before relationship must be $W_1 \rightsquigarrow W_i \rightsquigarrow W_{i+1} \rightsquigarrow \dots W_{j-1} \rightsquigarrow W_j$ because χ is the first race in δ' . As $W_1 \parallel W_2$, we have $W_j \parallel W_2$, so W_j and W_2 is also a pair of write that leads to a race. Because the related computation graph parts are the same across data-race free execution, the same happens-before relationship exists in δ . When W_2 occurs in δ , the shadow memory has W_j as the last writer. We will run $PRECEDE(W_j, W_2)$ to check if $W_j \rightsquigarrow W_2$. In δ , $PRECEDE(W_j, W_2)$ cannot return true, which can be proved similarly as part 1. This is a contradiction with the statement DRDP does not report any race in δ . ◀

► **Theorem 16.** *If DRDP does not report any data race during an execution of program P with input ψ , then no execution of P with ψ will have a read-write determinacy race on any memory location r .*

Proof. Consider an execution δ of a program P with input ψ in which DRDP is enabled and does not report any determinacy race.

Suppose that a read-write race, χ , occurs on a memory location r in some execution δ' of P with ψ . Let R_1 and W_1 denote the two steps that read and write r resulting in the race in δ' . Because this is a read-write data race, R_1 occurs before W_1 in δ' . Note that the execution δ' does not have any race until χ occurs. We will prove by contradiction that DRDP must report the race in δ . There are two cases:

1. R_1 executes before W_1 in δ .
 - a. There are no writes of r between R_1 and W_1 in δ .
When R_1 occurs in δ , we check race with the last write. We then save R_1 to the reader list of r in δ .
When W_1 occurs in δ , we will run $PRECEDE(R_1, W_1)$ to check if $R_1 \rightsquigarrow W_1$. The call returns true in δ . This is impossible. The reasoning is similar to Theorem 15 part 1.
 - b. There are writes of r by steps $W_i \dots W_j$ between R_1 and W_1 in δ .
Theorem 15 states that if there is a write-write race in the program P , DRDP will always report it. This means if there exists a race in any pair of writers in $W_i \dots W_j, W_1$, DRDP must find it. Because in δ execution, DRDP does not report any write-write race, we must have $W_i \rightsquigarrow W_{i+1} \rightsquigarrow \dots \rightsquigarrow W_{j-1} \rightsquigarrow W_j \rightsquigarrow W_1$. This relationship is the same in δ' .
As a result, we can conclude in δ' , we have $R_1 \parallel W_i$, otherwise there cannot be a race between R_1 and W_1 in δ' . In δ , when W_i occurs, DRDP must report the race. The reasoning is similar to part a. This is a contradiction with the statement that DRDP does not report any race in δ .
2. W_1 executes before R_1 in δ .
 - a. There are no writes of r between W_1 and R_1 in δ .
The proof is similar to Theorem 15 part 1. We omit the details.
 - b. There are writes of r by steps $W_i \dots W_j$ between W_1 and R_1 in δ .
The proof is similar to Theorem 15 part 2. We omit the details. ◀

► **Theorem 17.** *If DRDP does not report any determinacy race during an execution of program P with input ψ , then no execution of P with ψ will have a write-read determinacy race on any memory location r .*

Proof. We omit the proof because it is similar to proof for Theorem 16. ◀

► **Theorem 18.** *If DRDP reports a determinacy race on r during an execution of program P with input ψ , then at least one execution of P with ψ will have this determinacy race on r .*

Proof. In Algorithm 9, we may return true in four places: lines 4, 8, 26, and 51. If DRDP reports a write-write race or a read-write race or a write-read race, we know none of the lines is executed. The validity of the check is explained in Theorem 15 part 1.

From the definition of determinacy race and the fact DRDP reports a race, we know at least one execution of program P will show the race. ◀

► **Theorem 19.** *The race detection algorithm described in Figure 8 and 9 is sound and precise.*

Proof. Theorem 15,16,17 show that the algorithm is sound for a given input. Theorem 18 proves that the algorithm is precise for a given input. ◀

Algebraic Replicated Data Types: Programming Secure Local-First Software

Abstract

This paper is about programming support for local-first applications that manage private data locally, but still synchronize data between multiple devices. Typical use cases are synchronizing settings and data, and collaboration between multiple users. Such applications must preserve the privacy and integrity of the user's data without impeding or interrupting the user's normal workflow – even when the device is offline or has a flaky network connection.

From the programming perspective, availability along with privacy and security concerns pose significant challenges, for which developers have to learn and use specialized solutions such as *conflict-free replicated data types* (CRDTs) or APIs for centralized data stores. This work relieves developers from this complexity by enabling the direct and automatic use of algebraic data types – which developers already use to express the business logic of the application – for synchronization and collaboration. Moreover, we use this approach to provide end-to-end encryption and authentication between multiple replicas (using a shared secret), that is suitable for a coordination-free setting. Overall, our approach combines all the following advantages: it (1) allows developers to design custom data types, (2) provides data privacy and integrity when using untrusted intermediaries, (3) is coordination free, (4) guarantees eventual consistency by construction (i.e., independent of developer errors), (5) does not cause indefinite growth of metadata, (6) has sufficiently efficient implementations for the local-first setting.

1 Introduction

Today, the dominant software architecture for distributed applications is centralized. This is true for a wide variety of application types, such as single user applications deployed on multiple devices (e.g., calendars, notes, email, etc.), software that enables multi-party collaboration (e.g., shared calendars, document editors, business workflows, etc.), and software for autonomous systems with remote control and interactions (e.g., home automation and autonomous vehicles). Data is collected, managed, and processed in the cloud. Devices at the edge – owned by individuals and companies – serve merely as gateways to the cloud. Such an architecture has strengths, but also several weaknesses: It causes undue lost control over data ownership and privacy, lack of offline availability, poor latency, inefficient use of communication infrastructure, and waste of powerful computing resources on the edge.

To address these issues, local-first software design principles [25] call for “data confidentiality and privacy by default” and “ultimate ownership and control” by the user – both to be achieved by moving data storage and processing to the edge. However, developing local-first applications is challenging. Crucially, suitable existing mechanisms for efficient decentralized data management, specifically *coordination-free replicated data types (CRDTs)* [52], were invented for the geo-replicated database setting, which differs significantly from the local-first setting.

First, each local-first application has its own unique application-specific data model, designed by developers to encode domain knowledge. Developers have to figure out how to map application-specific data models to CRDTs, which are only available “off-the-shelf” in the form of databases [50] or libraries with a fixed API [24, 37]. Designing application state based on a fixed set operations is known to cause application design issues [11], because it requires translation between the application domain model and the fixed set of operations.

Second, in a local-first setting, a diverse set of networks is used for state synchronization. But general off-the-self CRDTs are designed for the geo-replicated database setting. The assumed network has mostly available direct connections between replicas, i.e., systems are designed to deal with seconds or minutes of latency between data centers. In contrast, local-first replicas (on user devices) have varied network conditions, ranging from always online devices, to personal computers that are turned off when unused, to mobile devices that only synchronize data when connected to a Wi-Fi network. In such a setting, we cannot assume direct connections between devices. Notably, this implies that connection oriented security protocols (e.g., TLS) are not applicable. A common solution for such indirect communication are cloud servers that act as intermediaries, i.e., as post offices that store, manage, and forward messages – further complicating the network model.

Third, the geo-replicated and the local-first settings have different security assumptions. Local-first applications often process personal data, with better data privacy and security being a selling point to users of local-first software. Existing security efforts for CRDTs in the geo-replicated setting [4] do not apply, due to weak attacker models and reliance on encrypted direct connections. Specifically, communication over untrusted intermediaries must not jeopardize the principles of local-first software, i.e., intermediaries must be unable to inspect or modify application data.

To fill the gaps, we propose *algebraic replicated data types (ARDTs)* – algebraic data types (ADT) that provide, by construction, provably consistent decentralized data management. ARDTs are delivered as a library that integrates seamlessly with existing language support for function composition and algebraic data types. Behind the scenes, ARDTs combine the theory of consistency as logical monotonicity (CALM theorem) [12] with delta replication [2]

for efficient and correct synchronization. Moreover, ARDTs also offer an encryption layer for efficient synchronization over untrusted intermediaries. Overall, ARDTs provide the ease of development of traditional applications, the privacy advantages of local-first, with the data sharing advantages of clouds – independent of the underlying network. We evaluate the proposed ARDT-based design of local-first applications on a case study and with micro-benchmarks. The results show that (a) typical local-first applications can be implemented with negligible performance overhead compared to existing data synchronization and UI rendering costs, and (b) encryption comes with minimal computational costs and with predictable, reasonable storage overhead on intermediaries.

In summary, our contributions are:

- A critical analysis of the state-of-the-art in developing local-first applications (Section 2).
- Use of standard ADTs suitable for application design for replication the realm of local-first software (Section 3).
- A novel synchronization-free authenticated encryption scheme, itself provided as an algebraic replicated data type (Section 4). As part of designing the encryption scheme, we contribute a systematic analysis of the suitability of existing encryption primitives for decentralized synchronization protocols (Section 5).
- An implementation of our proposal as an embedding into Scala along with a systematic empirical evaluation (Section 6).

2 State of the Art and Problem Statement

Below, we discuss two families of existing approaches, which are relevant for our work: (a) dedicated systems for collaborative workflows and (b) approaches to replicated data types employed in geo-replicated data stores. We briefly introduce relevant and missing features with respect to developing secure local-first software. We also introduce existing building blocks for distributed systems programming, which we adopt and combine to exploit their advantages in our setting.

2.1 Systems for Distributed Workflows

There are two kinds of systems for distributed workflows. The first kind has automated handling of conflicts at the price of centralized coordination; prominent examples are Google Docs or Firefox Sync. The other kind has flexible replication that does not rely on centralization; the most prominent example is Git, which allows for replication via different intermediaries including specialized ones like GitHub, or general ones like email. Similarly, systems like Syncthing and Resilio Sync enable peer-to-peer file synchronization in an arbitrary network topology, and even support encrypted intermediaries. But Git, Syncthing, and Resilio Sync require manual user intervention for conflict resolution.

We aim for combining flexible and secure data synchronization à la Git with automated conflict resolution à la Google Docs. Crucially, we aim to offer this combination to general-purpose programs with unconstrained types of data. This is unlike the above solutions, which target specific use cases and specific types of data. For example, Google Docs builds on research around operational transform [54] to enable efficient synchronization specifically for text documents. Such specialized solutions are infeasible for arbitrary local-first applications from different domains. Adapting existing solutions would require developers to become experts and understand the underlying assumptions and data models, or otherwise risk to introduce errors into an adaptation.

2.2 Replicated Data Types in Geo-replicated Data Stores

Another class of solutions that are relevant for our purposes are those developed to enable availability in geo-replicated data stores in the presence of network partitions – a scenario that bears some superficial similarity with local-first software. In particular, the solution from this context that is most relevant to the development of local-first applications are conflict-free replicated data types (CRDTs) [52]. CRDTs are data types, whose API consists of a fixed set of query and update operators, which satisfy the condition that two replicas that know of the same updates return the same result for all queries (also known as *eventual consistency*). This property is key in supporting coordination-free synchronization. CRDTs are typically built into a replicated data store with specific assumptions about the underlying network for efficiency (e.g., availability of reliable causal broadcast, trustworthiness of the involved servers).

The assumptions built into the design of off-the-shelf CRDTs limits their applicability to local-first software development. First, application developers are left with not much choice but to express their application design using the fixed APIs of existing CRDTs. A similar approach – object-relational mappings in database-centric software – is known to be a leaky abstraction, requiring frequent security relevant changes, and does not work well together with language-based tooling [11]. Second, local-first software operates in varied network scenarios for which there is no “one size fits all” solution to handle network communication. Thus, some CRDT runtimes allow developers to provide a custom message dissemination system that is specific to their needs. However, for two common network scenarios – using a cloud provider to store and forward messages, and using epidemic routing in an ad-hoc network – messages are not secure by default. Adding security burdens developers with ensuring correct and efficient encryption of messages, a task that requires expert knowledge of both the CRDT implementation and the network dissemination scheme to accomplish correctly and efficiently.

To recap, local-first applications have multiple new challenging concerns including design of the application state with replication-awareness, efficient dissemination of messages given the target network topology, and security of exchanged data, considering that messages may be stored for a long time before delivery. Each of these concerns needs both, system-level expert knowledge and application-specific insight. It is too much to ask of application developers to become experts in all of these fields. Thus, we must make expert implementations of system-level concerns such as state synchronization, message dissemination over physical networks, and security, available in a reusable and composable manner to application developers.

2.3 Building Blocks for Algebraic Replicated Data Types

Our solution builds on insights from previous research, but makes them reusable and combinable by application developers.

CALM and lattices. The first result we exploit is the *consistency as logical monotonicity* (CALM) theorem [21]. It states that consistency is possible without coordination if and only if all replicas only add to (i.e., monotonically increase) but never invalidate prior results. Existing solutions using replicated data types generally require all operations to prove (or pray for) a correctness property related to monotonicity. For example, state-based CRDTs require all operators to monotonically increase the state according to a specified order, and operation-based CRDTs require all operators to commute with one another. However, as we want to enable developers to define their own synchronization-free replicated data types

including new operations, it would be too easy for them to accidentally introduce consistency bugs (i.e., design operations that are not eventually consistent). A constructive way to enable consistency by-design, is to restrict available programming support to monotonic functions [12]. But such an approach may be too restrictive and does not integrate well into general-purpose languages.

Our solution is based on join semi-lattices – a set of states (i.e., a data type) with an associative, commutative, and idempotent *merge function*. In practical terms, associativity ensures that states can be combined before transmission, commutativity tolerates disordered arrivals of messages, and idempotence handles duplicated transmissions. Any (merge) function \sqcup with the above three properties provides monotonicity in the sense above, because it implies an order on states: $s_1 \leq s_2$ if and only if $s_1 \sqcup s_2 = s_2$. Lattices have been used to reason about correctness of CRDTs since their beginning [52], but our approach makes states and merge functions directly available as building blocks for application developers.

Delta replication. We use delta replication [2] to separate efficient message dissemination from the application logic. Delta replication is a variant on state-based replicated data type design, where monotonic changes are expressed as a delta to prior state. The overall application state results by merging all deltas (according to the lattice merge). The application logic is free to generate deltas however it wants, and the message dissemination algorithm is free to optimize the transmission of deltas for the specific networking platform.

Note that not every combination of lattice semantics and message dissemination provides causal consistency (only eventual consistency). However, causal consistency always comes at the cost of waiting for messages to arrive, and most local-first applications do not require causal consistency. It is well understood how to add causal delivery to any message dissemination scheme, and doing so is compatible with our results.

But delta replication does not tell how to add encryption transparently, i.e., without having to adapt all existing message dissemination implementations (of which, each application may have its own). In general, message dissemination in a local-first setting needs to consider many application- and environment-specific interwoven concerns in addition to security. Such concerns include causal delivery, importance of messages to the application logic, and messages that become obsolete because of newer state changes. While we focus on security, our approach is designed to be parametric over the dissemination strategy for deltas, and thus enables customization.

Authenticated encryption with associated data. Local-first applications require confidentiality – the guarantee that application private data can not be accessed by unauthorized parties – and integrity – the guarantee that neither private data nor communication metadata (the associated data) can be tampered with by an attacker. These guarantees are provided by *authenticated encryption with associated data* (AEAD) [44], a family of cryptographic solutions based on symmetric-key cryptography, where only trusted parties (in our case replicas) have access to a single shared key. AEAD is well studied and widely used, e.g., in TLS 1.3 [43]. But each use of a cryptographic construction in a new field requires to carefully select concrete implementations of cryptographic functions and to ensure that they are executed with suitable parameters. The local-first setting is no exception in this respect. Specifically, in local-first applications, an unknown number of replicas need to encrypt and decrypt data using a single shared key. Widely available AEAD functions require a globally unique number (nonce) as an input for each operation using the same key. Guaranteeing global uniqueness requires coordination, which we need to avoid in the local-first setting.

■ **Figure 1** Architecture overview.

3 Algebraic Replicated Data Types

The architecture of our solution is structured in three layers depicted as colored areas in Figure 1. The layer on the left concerns algebraic replicated data types (ARDTs), which are used to model the application logic. The layer on the right concerns message dissemination over physical networks; this includes sending messages (serialized deltas) and applying a merge function to recombine received deltas into the full application state. Finally, the middle layer concerns encrypted replication (encrypted ARDTs – encARDTs). We provide a library with implementations of each layer. It includes ARDTs for common data types such as set and map, different encARDT implementations with different performance versus metadata tradeoffs, and implementations for message dissemination over TCP, Websockets, WebRTC, and disruption tolerant networks (DTNs). We expect that developers want to design new ARDTs specific for their application logic. In doing so, they can freely combine different implementations of each layer to address specific application needs. This section presents how developers design their own ARDTs and configure it to use a message dissemination module. Section 4 and Section 5 elaborate on encrypted ARDTs.

3.1 Programming and Replicating ARDTs

An ARDT is an (immutable) algebraic data type (ADT) of the host language (Scala in our case) plus a set of associated operators. The ADT values represent the (lattice) state of the ARDT. The values represent application data and, depending on the used lattice, may also include metadata for automatic merging. Operators are functions/methods that operate on an ARDT’s state. Operators may (i) just read the ARDT state to produce a value used by the application, or (ii) produce a delta that describes the desired changes to the current state. A delta is technically an instance of the ARDT, but it must first be merged into the current state to become meaningful in the context of the application.

For illustration, assume that we want to implement a local-first social media application to be used by a group of friends in a peer-to-peer network to share messages, comments, likes, and dislikes. The ARDT in Figure 2 models the state and operators of such an application¹. The `SocialMedia` type (Line 1) is defined as a product type with named components (a case class in Scala). `SocialMedia` wraps a `Map` (Scala’s built-in dictionary type) of IDs to values of type `SocialPost` (Line 6 – type parameters are in square brackets). A social post uses the built-in type `Set` for comments, two `Counters` for likes and dislikes, and a `LWW` (last-writer-wins) register for the post and comment contents. The `LWW` register is a built-in ARDT provided by our library that can be set to a new value, with the implication that all replicas will show the newest value according to a real-time clock. `Counter` is an ARDT defined in Figure 3.

¹ All code examples in the paper use Scala 3 syntax.

```

1 case class SocialMedia(sm: Map[ID, SocialPost]):
2   def like(post: ID, replica: ReplicaID): SocialMedia =
3     val increment = sm(post).likes.inc(replica)
4     SocialMedia(Map(post -> SocialPost(likes = increment)))
5
6 case class SocialPost(message: LWW[String], comments:
   Set[LWW[String]], likes: Counter, dislikes: Counter)

```

■ **Figure 2** Compositional design of the social media ARDTs.

```

7 case class Counter(c: Map[ReplicaID, Int]):
8   def value: Int = c.values.sum
9   def inc(id: ReplicaID): Counter =
10    Counter(Map(id -> (c.getOrElse(id, 0) + 1)))
11
12 object Counter: // object for static methods
13   def zero: Counter = Counter(Map.empty)

```

■ **Figure 3** The state and operators of a counter ARDT.

The operators of ARDTs implement their application logic. While `Counter` (Line 7) and `SocialMedia` (Line 1) are both wrappers around a `Map`, their operators make the difference. Each `Int` stored in the `Map` of the `Counter` ARDT represents an individual amount contributed by the specific `ReplicaID`. This is expressed by the `value` operator (Line 8). A zero counter is expressed by the empty map (Line 13). Like other immutable data structures, operators that modify ARDTs return a new state, e.g., `inc` (Line 9) increases a counter by returning a new counter. But for ARDTs it is sufficient to return a *delta* – the changed parts of the state – the rest is managed automatically by applying the merge function. For instance, `inc` (Line 9) returns only the entry with the increased values; unchanged entries in the `Map` are omitted. The `like` operator of the `SocialMedia` ARDT in Line 2, while being a bit more complex, follows the same pattern. To “like” the post with the given `ID`, it computes the increment of the likes counter (Line 3) and returns a new delta of the `SocialMedia` state, which contains only the changed `ID` and defines only the likes component² of the social post (Line 4). Returning deltas is preferable, because it is more efficient to send and merge smaller values. But since merging is idempotent, developers could also return full states without impacting behavior.

In the examples so far we assumed that a merge function for our ARDTs exist. This is indeed the case, because all built-in types we used have merge functions provided off-the-shelf by our library, and the user-defined ADTs (`SocialMedia`, `SocialPost`, and `Counter`) have their merge function automatically generated. For example, the merge functions for `Counter` and `SocialMedia` keep all entries of both maps and (recursively) merge the values that have the same key; and the merge function of the `SocialPost` merges each component individually. See Subsection 3.2 for the precise definition of these merge functions. In general, the availability of a merge function for a type `S` (e.g., `Counter` or `SocialMedia`) is modeled by the type class `Lattice[S]` below.

```

14 trait Lattice[S] { def merge(left: S, right: S): S }

```

² The syntax that looks like an assignment in Line 4 is a named parameter, and we assume that this constructor sets all other components to “empty” values (not shown in the example for brevity). The `->` operator constructs a key-value pair.

```

15 class MessageDissemination[S]:
16   def send(delta: S): Unit
17   def recombine(using Lattice[S]): S

```

■ **Figure 4** Example message dissemination module.

```

18 val smd = new MessageDissemination[SocialMedia]
19 val current: SocialMedia = smd.recombine
20 val delta: SocialMedia = current.like(myPost, replicaID)
21 smd.send(delta)
22 val updated: SocialMedia = smd.recombine

```

■ **Figure 5** Using and replicating the social media ARDT.

Specifically, we say that S is the state of an ARDT, when there exists a correct instance of `Lattice[S]`; an instance is correct if its merge function is associative, commutative, and idempotent. The correctness of the merge function is the only requirement for eventual consistency in our system, and we do not want to burden developers with its definition. Thus, our library comes with a broad range of built-in ARDTs (with state, operators, and merge function). Moreover, correct instances of `Lattice` for standard data structures, user-defined product types, and the compositions of all of the above, are automatically generated. The system produces a compilation error if no lattice instance for a custom type can be generated. In other words, eventual consistency is always guaranteed automatically.

We put ARDTs into action by composing them with a concrete message dissemination module. The API of the message dissemination module is shown in Figure 4. It allows to send and recombine a replicated state of type S (Line 15)³. The `send` method (Line 16) sends a delta message of type S . The `recombine` method (Line 17) merges all received delta messages into a full state of type S , which requires a `Lattice[S]`. The `using` keyword (Line 17) asks the compiler to provide such an instance automatically if available, or report a compilation error. Figure 5 shows how to use and replicate the social media platform. Line 18 creates a `MessageDissemination` named `smd`. We access the current state of social media (`current`) using `recombine` (Line 19). To like a post named `myPost`, we first apply the like operator on `current` to compute the delta state.⁴ Once we send delta (Line 21), the like is merged into the rest of social media, and we can access the full `updated` state by calling `recombine` (Line 22).

3.2 Lattice Composition

By design, the correctness of both the operators and the distributed consistency of ARDTs rely exclusively on their state forming a lattice, i.e., on having a correct merge function. We provide ready-to-use `Lattice` instances for a range of data types such as last-writer-wins registers, multi-version registers, and lists (RGA). We have implemented those based on existing schemes for state-based CRDTs [51, 2]. On top, our library supports automatic generation of merge functions for compound data types including associative maps, pairs, tuples, optional values, and user-defined case classes (generally all product types), given their

³ This supports multiple ARDTs by composing them into a single type S .

⁴ Note that while delta is of type `SocialMedia`, it only contains that single like.

```

23 given Lattice[Int] with
24   def merge(left: Int, right: Int): Int = max(left, right)

```

■ **Figure 6** Lattice instance for integers using their maximum.

```

25 given [A]: Lattice[Set[A]] with
26   def merge(left: Set[A], right: Set[A]): Set[A] = left union
      right
27
28 case class LWW[A](time: Time, value: A)
29 given [A]: Lattice[LWW[A]] with
30   def merge(left: LWW[A], right: LWW[A]): LWW[A] =
31     if right.time < left.time then left else right

```

■ **Figure 7** Set and last-writer-wins lattice.

constituents are ARDTs (i.e., have a lattice instance)⁵. For example, `SocialPost`'s merge is automatically generated from its constituent types, `Set`, `Counter`, `LWW`. The generation is recursive with pre-defined ARDTs (e.g., `LWW`) being the recursion anchors.

The generation for product types exploits the canonical representation of a compound data type as a function (e.g., a key-value map is a function from keys to values). The merge of two functions l and r is a new function f that merges the result of applying l and r ($f(x) = \text{merge}(l(x), r(x))$). Sum types (i.e., types representing alternatives such as colors: red, green, blue) either use built-in lattice instances, or use an explicitly specified order of the cases (e.g., $\text{red} < \text{green} < \text{blue}$) and merging returns the larger case.

In the following, we elaborate on how concrete lattice instances are defined for different ARDTs starting with the recursion anchors and ending with automatic derivation of instances for compound data types.

3.2.1 Provided and Custom Lattice Instances

We provide ready-to-use lattice instances for primitive data types and for common CRDTs. For example, the code in Figure 6 implements lattice instances for integers. The `given` keyword defines an unnamed instance of `Lattice[Int]`. The `with` keyword states that the following is the implementation of the `Lattice` methods, in this case, the implementation of `merge` as the application of the `max` function. This definition uses Scala's support for implicit values to seamlessly integrate ARDTs into the rest of the language. Methods can access an instance with the `using` keyword (as seen in the `recombine` method from Figure 4); the developer does not need to explicitly provide the instance, when the method is called.

Figure 7 shows lattice instances for sets and last-writer-wins registers. Merging sets is delegated to the existing `union` method on sets. `LWW` is a custom type, whose state associates a unique timestamp and a value. Its merge function makes an arbitrary but deterministic decision – it selects the state with the larger timestamp and ignores the other one.

We do not expect developers to define their own merge functions. It is possible to do so, by providing custom lattice instances, but carries the risk of an incorrect implementation. Instead, our library provides support to automatically derive lattice instances for custom ADTs, as elaborated in the following sections.

⁵ This is not unlike Haskell's support for deriving instances of type classes for compound data structures.

```

32 given [K, V](using Lattice[V]): Lattice[Map[K, V]] with
33   def merge(left: Map[K, V], right: Map[K, V]) =
34     left.merged(right){
35       case ((id, v1), (_, v2)) => (id, Lattice[V].merge(v1, v2))
36     }

```

■ Figure 8 Map lattice.

3.2.2 Derived Lattice Instances

Deriving lattices for a compound type makes use of lattices of its component types. Technically, this is represented as `given` instances that take other instances as parameters. In the following, we present how to derive lattices for generic map and product types. The appendix includes proofs of their correctness by showing that the respective merge functions are commutative, associative, and idempotent.

The map lattice. Figure 8 states how any `Map[K, V]` has a lattice instance, if its values `V` also have a lattice instance. Specifically, the `using` keyword states that to create the lattice instance for the map we require a `Lattice[V]` where `V` is the type of values stored in the map. The merge function (Line 33) for a map delegates to the built-in `merged` function of `Map` (Line 34). The built-in `merged` function does not automatically handle the case when a key is assigned to value in both the left and the right map and requires a custom function to handle such conflicts. We implement this function to delegate to the merge function of the value type provided by `Lattice[V]` (Line 35). We prove correctness of this merge function in Appendix A.1.

The product lattice. We support automatic generation of lattices for any product type whose elements themselves have lattice instances. In Scala, product types include tuples and case classes. Consider the exemplary case class `MyData` in the first line of the code snippet below, and an explicit definition of the automatically generated lattice instance in the second line.

```

37 case class MyData(a: A, b: B)
38 given Lattice[MyData] = Lattice.derived[MyData]

```

The `derived` method generates a lattice instance for any product type `S`. Its implementation is shown in Figure 16 (in the Appendix). At a high-level of abstraction, a lattice instance for a product is generated as follows. (i) Acquire lattice instances for each component of the product. (ii) Define the merge function for two instances of the product type (a left and a right one) to (iii) take each component of the left product and merge it with the corresponding component of the right product and (iv) return the results wrapped in a new instance of the product.

We give the full technical details of the implementation in Appendix A.2. We prove correctness of the merge function for arbitrary products in Appendix A.3.

3.3 Qualitative Assessment of Design Features

We recap key advantages and limitations of our approach to defining and using ARDTs.

Reused implementations. When designing a new ARDT, expert developers can reuse any existing data structure, as long as they can define a merge function. For instance, the `Map` data structure in our social media ARDT is a highly optimized implementation from the Scala standard library. But developers are not limited to the options in our library and are free to choose an implementation that best suits their needs. For instance, there are multiple implementation strategies for sets to choose from, including sorted trees and hash-based solutions. The decision about the particular data type to use for representing the state of custom ARDTs is decoupled from and does not affect consistency management. Our approach enables to reuse existing off-the-shelf CRDTs by providing a suitable lattice instance. State-based CRDTs have a correct merge function, which we can and have directly used for this purpose. Operation-based CRDTs can be systematically converted to state-based CRDTs [52], thus they can be reused, too.

Unified consistency management. The CALM theorem [21] implies that monotonicity is a necessary requirement for consistency without coordination. To achieve monotonicity, existing state-based CRDT implementations [52] require that operators return a state that is larger than the original one (with respect to a pre-defined order of all possible states) and operation-based CRDTs require operators to be commutative. In contrast, our approach automatically enforces monotonicity of operators by merging their delta result with the current state. Thus, application developers do not need to reason about consistency when designing operators. The potential for introducing consistency bugs is limited to custom merge functions, which we assume to be designed by experts.

To illustrate the positive effects of this, consider again the `Counter` ARDT in the social media application. We only have to ensure that operators implement the intended application semantics, but we are always guaranteed consistent results. That is, the developer may make a mistake and the increment operator does not increment the value of the counter, as it is supposed to do. But it is guaranteed that the operator exhibits the same (erroneous) behavior on all replicas. This is in contrast to classic CRDTs, where an incorrect operator may lead to different states on different replicas. Due to unified consistency, distributed correctness boils down to correctness of a single replica, i.e., we get along with local reasoning, which simplifies development and testing.

Finally, since correctness relies exclusively on the properties of the merge functions, reasoning about consistency and ensuring it automatically is greatly simplified. An indication for this are the proofs (in the Appendix) for generated merge functions presented in Subsubsection 3.2.2. First, they are of manageable size. Second and more importantly, one can prove the correctness of individual merge functions independently of other merge functions and operators, because they do not rely on any global assumptions. Correctness for all composed data types then follows automatically from the individual proofs.

Versatile message dissemination. Local-first applications may run on diverse communication infrastructures, especially when considering various potential intermediaries ranging from a centralized server, to a shared network disk, to passing data along multiple ad-hoc Wi-Fi connections, to storing messages on a USB drive and sending the latter via physical mail.⁶ Even though concrete strategies for message dissemination are not a focus of our

⁶ Networks, where messages are not exchanged directly, but rather stored and forwarded until they are eventually received, are called delay-tolerant networks (DTN) [5]). They are actively developed and researched to enable resilient communication [53, 48, 5, 6], a highly relevant area for local-first software.

contributions, our assumptions about message dissemination are explicitly designed to admit many different such strategies. Moreover, the separation of message dissemination from ARDTs enables independent improvement of separate concerns. Specifically, in Section 4, we thoroughly explore secure communication that works in any setting. On the other side of the spectrum, in Section 6, we also explore possible optimizations of message dissemination in less challenging environments such as a central server.

Limitations. According to the CALM theorem [21], coordination-free consistent replication schemes can only express algorithms that do not require consensus. This is true for ARDTs, too. Even though we support arbitrary code to express operators, the deltas produced by operators are merged back into the current state, which enforces that the actual change to the state is monotonic. For example, a decrement operation on the counter ARDT (Figure 3) could produce a delta that decrements one of the integer values in the counter. However, because merging integers (Figure 6) returns the maximum, such a delta has no effect when merged into the current value.

4 Encrypting ARDTs

The design of ARDTs is motivated by the need for a flexible encryption mechanism suited for local-first applications. In particular, encryption should be independent of the message dissemination mechanism to provide the same guarantees in any network scenario. Moreover, the encryption should enable efficient storage of encrypted data on untrusted intermediaries.

Our solution provides encryption as a special kind of ARDTs, called *encrypting ARDTs* (encARDTs in the middle of Figure 1). EncARDTs are normal ARDTs for all purposes – they can be replicated using any message dissemination mechanism, and they can be parts of composed ARDTs. EncARDTs provide encryption via their operators, specifically, they implement the message dissemination API (send and recombine) where sending encrypts and recombine decrypts the state.

For example, a naive implementation of an encARDT is shown in Figure 9. Line 41 defines the state of the encARDT as a set of encrypted values. For encryption, we rely on *authenticated encryption with associated data* (AEAD) to ensure confidentiality of the state and integrity of both the state and the metadata. There are multiple encryption primitives that provide AEAD, and we elaborate on the challenge of correct use of AEAD in a coordination-free setting in Section 5. For now, we assume that there exists a suitable AEAD module with the following interface.

```
39 def encrypt[S, A](data: S, meta: A, key: Secret): AEAD[S, A]
40 def decrypt[S, A](aead: AEAD[S, A], key: Secret): Option[(S, A)]
```

The naive encARDT in Figure 9 stores values of type AEAD. We generally refer to encrypted states as *messages* to distinguish them from the state of the encARDT itself. The send operator (Line 42) adds new messages into the encARDT, by using the `encrypt` method of the AEAD module, and producing a delta containing the message. This delta is handled as usual, i.e., it is merged into the current state using the automatically derived merge function. The recombine operator (Line 44) reconstructs the plaintext ARDT state of type `S`. To do so, all messages are processed by the `decrypt` method (Line 45), whose return value for authentication failures makes `flatMap` discard that message. The successfully decrypted messages are merged pairwise using the lattice of the plaintext ARDT `Lattice[S]`.

```

41 case class Naive[S](messages: Set[AEAD[S, Unit]]):
42   def send(data: S, key: Secret, rID: ReplicaID): Naive[S] =
43     Naive(Set(encrypt(data, (), key)))
44   def recombine(key: Secret)(using Lattice[S]): Option[S] =
45     messages.flatMap(aead => decrypt(aead, key)).map(_.data)
46     .reduceOption(Lattice[S].merge)

```

■ **Figure 9** Naive encARDT stores all states.

```

47 case class Subsuming[S](messages: Set[AEAD[S, Version]]):
48   def version: Version = messages.map(_.metadata)
49     .reduceOption(Lattice.merge[Version])
50     .getOrElse(Version.zero)
51   def send(data: S, key: Secret, replicaID: ReplicaID) =
52     val cause = version merge version.inc(replicaID)
53     Set(encrypt(recombine(key) merge data, cause, key))
54
55 given [S]: Lattice[Subsuming[S]] with
56   def merge(left: Subsuming[S], right: Subsuming[S]): Subsuming[S] =
57     val combined = left union right
58     combined.filterNot(s =>
59       combined.exists(o => s.metadata < o.metadata))
60
61 extension [S] (c: Subsuming[S])

```

■ **Figure 10** Subsuming encARDT based on version data.

Consistency of the naive encARDT directly follows from the automatic construction of the merge function, because we only ever add new messages. However, storing all messages forever is a naive solution, because the state grows indefinitely. Yet, the naive encARDT represents the realistic case where an intermediary has no further information about encrypted messages. The following sections describe how to fix the indefinite growth of required space by using associated metadata.

4.1 Pruning Subsumed States

The naive encARDT stores messages even if they are no longer relevant. As an example why this is problematic, consider the counter ARDT. The counter stores an integer per replica ID, each time a counter is incremented we store the new value and no longer need the old value for that replica ID. In such cases, we say that the old state is *subsumed* by the new state. Formally, a state s' subsumes another state s , if s' contains all updates of s , i.e., $s \sqcup s' = s'$ (where \sqcup is the merge function).

The *subsuming encARDT* attaches logical timestamps [28] in the form of *version vectors* [10] to messages as associated metadata. Version vector metadata provides an order \leq on encrypted states $e(s)$ that implies subsumption: $e(s) \leq e(s') \implies s \sqcup s' = s'$. This allows intermediaries to remove subsumed messages without inspecting their contents. Figure 10 shows the implementation of the subsuming encARDT, whose messages include the `Version` as associated metadata for the encrypted states. A version vector is semantically a counter CRDT, and `Version` uses the implementation from Figure 3, but is renamed to reflect its use within the subsuming encARDT.

```

63 case class Dotted[S](messages: Set[AEAD[S, (Dot, Set[Dot])]]):
64   def send(data: S, key: Secret, replicaID: ReplicaID) =
65     val cont = messages.flatMap(aead => decrypt(aead, key))
66     val sub = cont.filter(s =>
67       Lattice[S].merge(s.data, data) == data)
68       .flatMap(s => dotsIn(s.metadata)).toSet
69     Set(encrypt(data, (Dots.next(replicaID), sub), key))

```

■ **Figure 11** Dotted encARDT – precise subsumption.

The operators of the subsuming encARDT automatically add the correct metadata to messages. The helper method `version` (Line 48) merges all currently stored versions, thus returning the upper bound of all versions. The `send` operator increments the upper bound of versions (Line 52), implying that the new message subsumes all existing messages, but is not subsumed by any of them. To ensure this is true, the delta state to be send (`data` in Line 53) is merged with all current values in the encARDT, thus producing a full state that does contain all others. The `recombine` operator is the same as for the naive encARDT in Figure 9, hence not shown.

An explicit lattice instance implements subsumption as part of the merge function (Line 55). After computing the union of the sets of encrypted states (Line 57), the merge keeps only the states that are not subsumed by another state (Line 58); formally the kept states are $\{e(s) \mid \nexists e(s') : e(s) < e(s')\}$.

For an intuition to how a subsuming encARDT behaves, consider that a message subsumes all messages that are currently stored in the encARDT, and the merge function removes all subsumed messages. Thus, each time a replica sends a message, only that message (containing all deltas) is stored. However, when multiple untrusted intermediaries synchronize between each other, each may store multiple incomparable messages (generated by different replicas), and merging will keep all of these messages until a trusted replica decrypts and merges them.

In Appendix A.5, we prove that the subsuming encARDT is transparent, i.e., sending and recombining behaves as if we just merge states without encryption, and without removing them based on subsumption metadata. This proof includes correctness of the custom merge function (associative, commutative, idempotent).

4.2 Pruning Encrypted Deltas

With the subsuming encARDT, we lose the advantages of delta replication, because it combines all deltas into a single state when sending a message. To address the problem, *dotted encARDT* in Figure 11 store precise per-delta subsumption information in the metadata. Specifically, the metadata contains (a) a globally unique logical timestamp for the message, called a *dot* [40], and (b) the set of dots that the message subsumes. The `send` operator computes the set of messages currently contained (`cont` in Line 65) in the dotted encARDT. For each contained message, it uses the merge function (Line 67) to check if it is subsumed by the new message. Subsumption is transitive, thus the new subsumption info combines all dots in the metadata of all subsumed messages (`sub` in Line 68). Finally, the message containing only the delta (`data`) and subsumption info is returned (Line 69). The other methods (including the merge function) of the dotted encARDT are the same as for the subsuming encARDT, thus are not shown.

With dotted encARDTs, intermediaries still cannot decide if two concurrent messages from different trusted replicas subsume one another, but the messages are potentially much smaller compared to the subsuming encARDT. However, dotted encARDTs require more metadata, thus use more space when no concurrent messages occur. See Section 6 for an empirical evaluation, but keep in mind that the best choice is highly dependent on the used ARDTs and application behavior. It is possible to use different encARDTs for different ARDTs in the application, thus providing maximum flexibility. Correctness proofs for the dotted encARDTs are analogous to the subsuming encARDT, because using a more precise notion of subsumption only strengthens the preconditions of the proof.

4.3 Security Assessment

We have presented three different encARDT strategies that cover different points in the design space. Assuming that only trusted replicas know the shared secret, and that AEAD protects data confidentiality and authenticity of the contained messages, all encARDTs prevent the following attacks. Intermediaries cannot tamper with the order of data, because recombination is order independent. Replay attacks using duplicated messages also have no effect, since merging is idempotent. Intermediaries can forge new messages using incorrect keys, but these are ignored when decrypting. The only way for intermediaries to interfere is to selectively stop disseminating messages to (some or all) replicas – this is not worse than the scenario where the intermediary did not exist.

Encrypted communication may still leak information, e.g., the size of messages, and who sends which message at what time. In addition, different encARDTs have different tradeoffs. The naive encARDT leaks no metadata, but stores unneeded messages. The dotted encARDT is as precise as possible, but also leaks precise subsumption metadata. Subsuming encARDTs are in the middle. They leak the order of messages, which can be learned anyway by an attacker that can observe the overall network (a common threat model), while still enabling to remove unneeded messages.

Leaking metadata is considered as unproblematic when synchronizing rich data such as texts and images, because the contained data is not deducible by the order in which modifications happened. But it can be problematic for certain simple ARDTs, e.g., in the case of Counter (Figure 3), which has a single operation, one can deduce the current values by learning the number of messages. But these issues are not unique to our solution, and countermeasures exist [20, 56]. Moreover, because encARDTs do not require a central entity, it becomes easier to apply countermeasures. For example, one can split messages over multiple intermediaries (hence, no single intermediary may learn all metadata), or can use randomized routing such as TOR [13], because ARDTs are resilient against unreliable message delivery.

5 Coordination-free Encrypted ARDTs

The discussion in the previous section leaves out one open challenge: AEAD primitives require each call to the encrypt method to use a globally unique number (nonce). In general, ensuring global uniqueness of something requires coordination, which contradicts our goal to support coordination-free synchronization. Thus, the open question is how to guarantee global uniqueness while practically avoiding coordination. To answer this question, we are the first to analyze multiple stochastic methods of selecting unique numbers for their suitability for the local-first setting.

	Java	Web	libsodium	Tink
AES-GCM	•	•	•	•
AES-GCM-SIV				•
ChaCha20-Poly1305	•		•	•
XChaCha20-Poly1305			•	•

■ **Figure 12** Overview of supported AEAD modes in various environments.

5.1 The Study Setup

Existing solutions vary in different respects: their availability, the number of replicas that are securely supported, the number of operations that can be executed without coordination. The goal of our analysis is to delimit the chances for conflicts within common security standards.

We considered the following AEAD constructions: AES-GCM, AES-GCM-SIV, and (X)ChaCha20-Poly1305. Figure 12 shows their availability in the Java Cryptography Architecture⁷, Web Cryptography API⁸, libsodium⁹, and Tink¹⁰. All libraries support AES-GCM due to its use in the TLS specification [43]. The more modern AEAD construction ChaCha20-Poly1305 was introduced in TLS 1.3 [43] and is currently also supported by all libraries except Web Cryptography API. XChaCha20-Poly1305 [3] is an adaption of ChaCha20-Poly1305 with a larger nonce-size and proven to be at least as secure [7]; while not yet standardized by IETF, it is supported by libsodium and Tink [3]. AES-GCM-SIV [19] (implemented only in Tink) claims resistance to nonce reuse; it is also not standardized.

In summary, the best available options are:

AES-GCM Use a 64 bit random ID per replica and 32 bit replica specific counter as nonces.

Supports up to 92,000 replicas, communicating once per second for 132 years.

XChaCha20-Poly1305 Use fully random 192 bit nonces. Supports 2^{32} replicas for communicating once per millisecond for 8900 years.

Our implementation defaults to XChaCha20-Poly1305, because it allows to completely hide the use of nonces from the developer. In the following, we elaborate on how we reached the conclusion that the above solutions are the best available options.

5.2 Coordination-free Generation of Nonces for AEAD

To encrypt and authenticate a message, AEAD schemes generally require three inputs: the message, the encryption key, and a *nonce* [45]. A nonce is a **number** that must only be used **once** together with the same key. If a nonce is used multiple times, then encryption schemes leak information about the plaintext, e.g., in AES, an attacker learns the bitwise exclusive-or of messages [31]. The Nonce misuse has led to severe real-world attacks, e.g., on TLS [9] and WPA2 [57]. The issue is that the decision on how to choose nonces is left to the developer, and, unfortunately, previous research on crypto misuses has shown that developers struggle with secure choices for crypto APIs [27, 36, 41]. This is not surprising, considering that libraries like the Web Cryptography API do not even document that nonces should be unique. Ensuring uniqueness is a classical coordination problem. Thus, we discuss how to select unique nonces without coordination, while staying within generally accepted levels of certainty for the provided confidentiality.

⁸ <https://www.w3.org/TR/WebCryptoAPI/>

⁹ <https://libsodium.org/>

¹⁰ <https://developers.google.com/tink>

5.2.1 Selecting Nonces by Space Partitioning

A textbook approach to ensure uniqueness of nonces is using a strictly monotonic counter [14]. This is the case for AEAD algorithms in TLS 1.3 [43]. Using a single counter for all replicas is not possible without coordination, since this is a prime example of mutual exclusion. An adaption of the counter approach is to partition the nonce space into multiple ranges, each exclusive to a single replica. This strategy requires coordination only once per replica. Fixed ranges are a good choice for a set of devices provided by a single authority (a single user or company). In large groups of loosely cooperating devices, however, deterministic coordination of non-overlapping nonce ranges is infeasible. An alternative approach is *cryptographically secure pseudorandom number generation* (CSPRNG).

Using replica IDs for partitioning. Certain ARDTs such as the counter (Figure 3) already require replica-specific IDs for their behavior. Therefore, it seems intuitive to reuse the replica ID to partition the space of nonces. If the chance of collisions of any two replica IDs is small enough to be negligible, this is a secure choice. In general, to ensure uniqueness, typical examples for replica-IDs are randomly generated UUIDs (as seen in automerge¹¹), or a hash of a replica-specific public-key [24], with the size of such identifiers usually being 128 bits [29]. Unfortunately, this size is too large for use with popular AEAD constructions. For example, the NIST specification for AES-GCM recommends that implementations should restrict their nonce lengths in AES-GCM to 96 bits [14]. Thus, direct use of replica IDs to partition the nonce space is not possible.

Using small random replica-specific numbers for partitioning. Instead of using the replica ID, we can generate short replica-specific numbers using a CSPRNG, but this leaves us with a probability of collisions of replica-specific numbers, thus a collision of nonces. According to the NIST specification, the probability that a nonce is reused for a given key must be less or equal to 2^{-32} [14]. Considering the birthday paradox [49], there is a surprisingly high probability that two replicas choose the same replica-specific number. With a 64-bit long replica-specific number, we can have 92,000 replicas before the collision probability reaches over 2^{-32} . Assuming 92,000 replicas are sufficient, and given the explicit 96-bit nonces of AES-GCM, a 64-bit replica-specific number leaves room for 32-bit replica-specific counters. This provides $2^{32} \approx 4.3 \times 10^9$ messages to each replica. Assuming that a replica encrypts one message per second, the counter could be used for 136 years, before requiring coordination to select a new shared secret. This is a realistic choice for local-first applications, when only AES-GCM is available.

5.2.2 Selecting Fully Random Nonces

A fully coordination-free approach to nonce generation is to rely on a CSPRNG to generate a new random nonce for each message. Literature warns against random nonces in some cases [9]. For example, nonces in TLS (using AES-GCM) consist of 32-bit part specific to the sender and connection, and a 64-bit part to ensure uniqueness [46]. With 64-bit random nonces the collision probability after encrypting $2^{28} \approx 2.7 \times 10^8$ (three hundred million) messages would be around 0.2 % and for $2^{32} \approx 4.3 \times 10^9$ messages around 39 % [9].

¹¹<https://github.com/automerger/automerger>

For using 96-bit random nonces with AES-GCM, the libsodium documentation recommends against it [30], while the documentation of Tink recommends it for “most uses” [17]. Specifically, Tink guarantees that AES-GCM with random nonces can be used for at least $2^{32} \approx 4.3 \times 10^9$ messages, while keeping the attack probability smaller than 2^{-32} [17].

This, however, is a global message limit, i.e., counting all messages encrypted by all replicas using the same key. The only way to enforce this limit without coordination is to restrict the number of distinct messages to $\frac{2^{32}}{n}$, where n is the maximum number of replicas that can use a single key. Thus, further limiting the number of encrypted messages. Assuming 1024 as an upper bound on the number of replicas, this leaves $\frac{2^{32}}{1024} = 2^{22} \approx 4.2 \times 10^6$ messages to each replica. Or, in other words, 7 weeks of coordination-free operation using one outbound message per second for each replica. Moreover, enforcing a limit on the number of replicas also requires coordination.

Fortunately, random nonces become practical with the very large nonce sizes supported by XChaCha20-Poly1305 [3]. The use of 192-bit nonces allows $2^{80} (\approx 10^{24})$ messages to be encrypted with a nonce collision probability of 2^{-32} [3]. Putting this in context: If every possible of the 2^{32} IPv4 devices is encrypting messages at the rate of one message per *millisecond*, this leaves us with over 8900 years before we must rotate keys. Therefore, with random nonces, we only recommend XChaCha20-Poly1305.

5.2.3 Nonce Misuse-resistant AEAD Schemes

Nonce misuse-resistant authenticated encryption schemes, such as AES-GCM-SIV [19], aim to be secure even when a nonce is reused for the same key with a different message. Thus, in theory, they are good candidates for use with shared, long-lived keys. But these schemes also do have bounds on the number of messages that can be safely sent [22]. Moreover, they are not yet standardized and fully scrutinized, and, as discussed in Figure 12, an implementation of AES-GCM-SIV is not widely available; thus, we can not give clear recommendations.

6 Evaluation

In our interim qualitative assessments, our focus was on design considerations in Section 3 (e.g., reusability, flexibility, correctness) and security guarantees in Section 4 and Section 5. The question remains: What is the cost of the properties of our approach featured in the qualitative assessments. To assess this cost, we empirically evaluate our approach along the following research questions:

- RQ1: Is the performance of ARDTs – including encryption – good enough for use in local-first applications?
- RQ2: Are the space requirements of ARDTs using intermediaries acceptable?

We use two methods to explore each of these questions: A concrete case study that makes specific choices about the used ARDTs and a set of microbenchmarks that explore encARDTs more generally to uncover their behavior in multiple dimensions, in particular the overhead caused by encryption and intermediaries. The implementation is part of the REScala project, and all implementations and benchmarks – in addition to further case studies that explore different scenarios – can be found on the project website¹². The case study evaluated here runs on the JVM (using a JavaFX UI) due to the generally better availability of tooling for

¹²<https://www.rescala-lang.com>

empirical evaluation, but our approach works for both the JVM and on the Web platform (integrating with various Scala-based Web UI frameworks). Unless otherwise noted, we use the following hardware and software setup for this evaluation.

CPU 2015 Intel Core i7-6700HQ (laptop CPUs are the most common for local-first software).

OS Arch Linux (Linux 5.16.16).

JRE We use the Java runtime OpenJDK 17.0.3.

Microbenchmarks For performance microbenchmarks, we use JMH¹³ the standard Java benchmarking tool. The time measurements we conduct have very stable runtime behavior, with a maximum relative error of 3%, thus we do not show error bars.

Libraries AEAD implementations are provided by Tink 1.6.1¹⁴, which uses hardware acceleration for AES variants, but not for XChaCha20-Poly1305. To serialize states, we use jsoniter-scala¹⁵ (the arguably fastest JSON serializer available on the JVM¹⁶).

6.1 Case Study

We implement the popular to-do list example as a JavaFX GUI application. The application manages a list of to-dos, and the user may add entries containing arbitrary text, mark to-dos as completed, change their text, or delete to-dos completely. Its correctness and consistency properties are: added to-dos remain until deleted, and all users see the same to-dos in the same order. The interactions and properties of the case study touch on most of the complexity in the design space of local-first applications. Furthermore, the state of the to-do list – a potentially ordered set of changeable entries – is complex enough to demonstrate the need for composed data types.

We experienced no limitations in implementing the to-do list application with ARDTs and encARDTs. The prototype makes heavy use of the composability of ARDTs. Concretely, the to-do list uses an add-wins last-writer-wins map for its primary state. This is a composition out of a tombstone-free add-wins set [8] and a last-writer-wins register. When two users edit the same to-do entry, a deterministic decision keeps one of the edits and the other is discarded. Changes to the primary state are normally triggered by the UI library (e.g., a button click handler), but the UI is replaced by our benchmark infrastructure. The handlers for each change are similar to the example in Figure 5. Each handler uses a corresponding operator on the to-do entries (the add-wins-last-writer-wins map) to compute the delta of the new application state. The delta is passed to the `send` operator of the dotted encARDT, and the operator computes its own delta that is in turn passed to the message dissemination implementation (a custom one for benchmarking the transferred data). In addition, there is a notification API (not discussed in the paper) in the message dissemination module that executes a handler whenever a change happens (caused locally or remotely), which triggers the UI to update and show the new state.

To answer our research questions, we run a deterministic simulation of the to-do list. Our simulation uses a single intermediary and simulates a total of one million operations that add, modify, and remove to-do entries (see Subsection 6.2 for a discussion of concurrent operations and multiple intermediaries). A million operations correspond to about 11 days of usage, with an interaction per second. We include serialization, encryption, and other application logic in the simulation. We omit physical network, storing the state on disk, or rendering the

¹³<https://openjdk.java.net/projects/code-tools/jmh/>

¹⁴<https://developers.google.com/tink>

¹⁵<https://github.com/plokhotnyuk/jsoniter-scala>

¹⁶<https://plokhotnyuk.github.io/jsoniter-scala/>

graphical UI, as their performance is not part of our contributions. The simulation follows a randomly generated trace of operations: adding to-dos, marking to-dos as completed, and deleting batches of the 30 oldest to-dos. To-dos are added and completed individually, but deleted in batches to reflect the expected usage of the application, which has a “remove all completed to-dos” button, but no methods of batch insertion or completion.

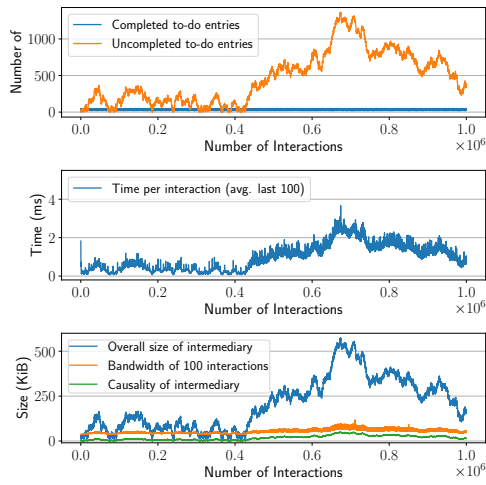

The top plot of Figure 13 shows the runtime behavior of the simulation. The x-axis represents abstract time as the number of executed interactions and the graphs show the respective state of the application, i.e., the number of open and completed to-do entries.

RQ1. Time overhead is presented in Figure 13 (middle plot). It shows the runtime per interaction (measured in batches of 100 interactions). This time includes executing the operator locally, merging it into the local state, serializing then encrypting and sending the delta, merging the encrypted delta into the encARDTs thus computing subsumption, and replicating the encARDTs to the intermediary. The spike in the beginning is due to the warm-up of the JVM. Otherwise, the overall runtime is proportional to the size of the current application state, because tasks – such as merging the add-wins-map, computing subsumption for existing deltas, and the application logic – linearly depend on the number of to-do entries. We believe that staying within 3 ms per operation is reasonable. While further optimizations are certainly possible, there is no indication that our core architecture has prohibitive costs for local-first applications.

RQ2. Space overhead is presented in Figure 13 (bottom). Note that we show the accumulated bandwidth of 100 interactions (i.e., 100 deltas), because the size would otherwise not be visible at the scale of the figure. In summary, we observe that the total data stored at the intermediary has a linear relation to the actual size of the application state and grows and shrinks accordingly. We want to point out that neither the state, nor the causality metadata increases over time. While encARDTs require that we store information about subsumed deltas indefinitely (the set of subsumed dots), it is stored as efficient ranges that only grow with the number of replicas, concurrent operations, and current size of the data set, but not with the number of total interactions over time. The data transferred (used bandwidth) between the replica and the intermediary remains mostly constant because transfer time depends on the size of deltas, which are largely unaffected by the size of the application state. The slight increase in bandwidth is because each removal delta includes causality information in the encARDT that grows with the amount of currently non-removed entries. We show the difference to using a trusted intermediary (i.e., no encARDT) in Appendix A.6, which requires less space due to the impact of encrypted deltas discussed in Subsection 6.2. In conclusion, we consider the size demand and required bandwidth of ARDTs adequate for the local-first scenario.

6.2 Microbenchmarks

We perform microbenchmarks to acquire data points that the case study does not exhibit. Specifically, we investigate the isolated overhead of encryption as well as the effect of concurrent operations (e.g., due to multiple intermediaries) on the required storage size. We use the same add-wins last-writer-wins map (AWLWWMap) that was used for the to-do list case study. Yet, the results are independent from the concrete choice of ARDT, because for the microbenchmarks only the serialized size of the state matters, which we give explicitly.

■ **Figure 13** To-do list case study measurement results.

■ **Figure 14** Encryption vs. serialization time for AWLWMap states of 256 KB.

■ **Figure 15** State size when storing concurrent encrypted messages.

RQ1: Time overhead of encARDTs. We measure how long it takes to prepare the serialized bytes compared to the time for encrypting those bytes via an encARDT. The results in Figure 14 show the difference (encryption time vs. serialization time) for different AEAD schemes, and for a payload of 256 KiB (1,000 to-do entries). Hardware accelerated AES has an overhead of a fraction of a millisecond. XChaCha20-Poly1305 is designed to be efficiently implemented in software [3], thus should be considered for systems where no hardware accelerated encryption is available. Even if it does not benefit from hardware acceleration it has an overhead of less than 3 ms.

To put these numbers into context, consider the relative sizes of operations. The full state of a to-do list with 1000 to-do entries serializes into a 256 KiB state. The dotted encARDT requires an additional 0.16 ms for encryption. The serialization of the state alone takes 0.67 ms. Sending data over the network has expected latencies of 0.1~100 ms. Receiving and processing the data on the other replica and displaying the result adds a minimum of 7~33 ms due to typical refresh rates of monitors. In summary, we consider the time overhead of encARDTs to be negligible compared to all other parts of the synchronization process.

RQ2: Space overhead of encARDTs. Intermediaries cannot merge states that are created concurrently by different replicas, due to the limitations of the plaintext metadata. The overhead depends on the encARDT and the number concurrent operations. Figure 15 shows the space requirement of storing 1 to 4 concurrent updates using a subsuming encARDT (left) and a dotted encARDT (right). The base size of the stored ARDT is an AWLWMap with 96 (+1 to +4 added) entries requiring about 14 KiB. Any trusted replica (in blue) can always merge any received updates, thus the total stored size does not grow noticeably.

For the intermediary, however, we observe that the size of subsuming encARDT (left subfigure) grows linearly with each concurrent update. We expected this result as each update contains the full state to be stored, and the timestamps of the four updates are incomparable, because each full state differs in exactly one item, thus they do not subsume each other. For the dotted encARDT (right subfigure), the stored state is larger than the state of the trusted replica, because each delta is stored separately, which introduces a constant overhead per

delta. However, each concurrent update only marginally increases the state size to store the single additional delta. Note that the number of concurrent operations is typically limited by the number intermediaries, because once a replica is connected to an intermediary the next operations of the replica will merge and subsume concurrent operations.

In general, storing only deltas at intermediaries has a fixed overhead, but avoids large storage increases for concurrent updates. Which strategy is more suitable depends on how reliable connections are, and how many intermediaries are part of the system, because both unreliability and more intermediaries introduce more concurrency. In summary, we believe that a wide range of potential use cases are covered by the presented encARDTs. If other behavior is required, new variants of encARDTs with different subsumption strategies can be used.

7 Related Work

Programming methods for local-first software. Two popular general-purpose CRDT implementations that can be integrated into applications are `automerger`¹⁷ (loosely based on a paper by Kleppmann et al. [24]) and `Yjs`¹⁸ [37]. Both libraries are based on the operation-based variant of CRDTs. They run in the same process as the application and provide the latter with an API to update and query a single JSON document (a nested tree structure). The intended way to use the API is to have developers convert their application state into the JSON structure, with no further customization of available operations.

`REScala` [34] provides programming support for local-first applications. It integrates off-the-shelf CRDTs with functional reactive programming, the latter being a very common approach to UI and thus local-first applications. The rationale for the integration is that reactive applications are practically not limited by the monotonicity restriction of CRDTs, because user interactions are monotonic by nature: Users can only press, click, and touch keys and buttons and not “unpress” a prior action. However, `REScala` assumes that the developer provides CRDTs with suitable operations, and does not consider encryption [33, 35].

Similar to our work, other systems for local-first software consider message dissemination as an orthogonal concern that depends on the concrete network environment. `Yjs`, and `automerger`, provide default implementations to be ready to use, while `REScala` defers to `ScalaLoc` [58] – a library that abstracts over communication implementations. None of the approaches considers network security beyond encrypted direct connections. Almeida et al. and Enes et al. [2, 15] show how to achieve causal consistency for delta CRDTs independently of the underlying network. This is done by providing an additional layer on top of another message dissemination algorithm. While they do not consider security, their approach is similar in that they separate different concerns in the message dissemination.

Security in replicated systems. Prego et al. [39] survey CRDTs in the geo-distributed setting and point out the need for future research on security. They observe that replicas are vulnerable to harmful operations of other replicas, and that authentication and encryption between replicas is insufficient in the geo-distributed setting. This is because the trusted entities in that setting are the clients (end users) that issue operations to a replica (in the cloud). They conclude that end-to-end security between clients is (nearly) impossible in the existing architecture, and argue for “moving computations to the edge”. Moving computation to the edge, while replicating state in the cloud, is exactly what ARDTs enable.

¹⁷<https://github.com/automerger/automerger>

¹⁸<https://github.com/yjs/yjs>

Barbosa et al. [4] implement an approach that keeps the client/replica split while proving some guarantees to clients. The clients use customized solutions from the space of homomorphic encryption to secure their data before storing it in a distributed database (AntidoteDB [50]), which then handles replication. This approach has the major shortcoming that all the cryptographic constructions are specific to individual CRDTs. Moreover, they only target *honest-but-curious* adversaries, which is an assumption where the attacker is bound to service-level agreements, and only interested in secretly extracting information (i.e., a cloud service provider hosting the database). Crucially, this entails that an adversarial provider could modify data, because operations cannot be authenticated.

High-level cryptographic APIs. We do believe that encARDTs offer an advantage even when used with simple direct connections. Security is often treated as an afterthought, and it has been shown that leaving this task of using crypto solutions to application developers often leads to insecure systems [16, 38]. The correct usage of cryptographic components is challenging in general [36], with 84 % of Apache projects containing cryptographic misuses [41]. Especially developers of end-user applications seem to have a hard time, with more than 95 % of android applications that use a cryptographic API using it incorrectly [27]. High-level abstractions with built-in cryptographic features are considered as an effective solution to support developers with writing secure software [1, 18, 32]. With encARDTs, we bring high-level cryptographic APIs to local-first applications, thus reducing the potential for misuse. In addition, encARDTs define encryption of data structures, not encryption of connections, which is better suited to the flexible dynamic connections of local-first applications.

Identities and attackers. Security and authentication of our approach require a shared secret between trusted parties. If secrets are shared with untrusted parties, our approach does not provide additional guarantees. Sanjuan et al. [47] and Kleppmann [23] investigate settings where other replicas are not trusted. They argue that CRDTs are well suited to detect Byzantine faults at the eventual consistency layer. Specifically, by including cryptographic hashes of the causal history of each change, it is possible to discard and detect messages from misbehaving replicas. We believe that these solutions also apply to ARDTs due to their similarity to CRDTs. However, even when using these solutions an attacker may still execute consistent but undesirable actions, and is able to read the system state.

To prevent undesirable actions, we need a way to manage and enforce access policies over time. EncARDTs use a shared secret to define the current set of trusted replicas, and it is possible to rotate this key to change the set of trusted replicas. Rault et al. [42] propose how to manage access control itself as a CRDT, thus answering the question of who should have access to the shared secret. Truong et al. [55] discuss authentication of the log of operations in an RDT, which allows replicas to identify and attribute tampering carried out by replicas with full access. Kollmann et al. [26] propose a solution to compress such authentication information within a snapshot of an RDT. This also allows them to keep the exact history of changes hidden from newly joined replicas by leveraging coordination-free authentication of snapshots. We believe that these approaches could be adapted for the use with ARDTs.

8 Conclusions and Future Work

Local-first applications address several weaknesses of a centralized software architecture. But designing applications with consistent replication is challenging for application developers, because it requires expertise in several system-level concerns such as consistency, networking,

and security protocols. Existing solutions such as CRDTs provide consistency “out-of-the-box”, but have several shortcomings otherwise. First, they do not integrate well into the application design process: Application developers have to map application-specific data models to CRDTs, which are only available “off-the-shelf” in the form of databases [50] or libraries with a fixed API [24, 37]. Designing application state based on a fixed set of operations is known to cause design issues [11]. Second, off-the-shelf systems do not support heterogeneous network environments, and authenticity and confidentiality is considered as an afterthought at best.

The foundation of our solution to the above gaps is an approach for systematic, modular, and extensible design of algebraic replicated data types (ARDTs). The approach provides the same guarantees as CRDTs, but as a modular and extensible library that embraces algebraic data types, which are widely used to model application state. This approach facilitates the integration of ARDTs into existing programming models and existing network runtimes. Further, our solution provides confidentiality and authenticity by design. Specifically, we presented a family of encrypting ARDTs for different network requirements. Each such encARDT wraps around the data of an ARDT and secures the data independently of how messages are disseminated, with specific support to transmit data over untrusted intermediaries. Using our encARDTs, the application data is authenticated and encrypted, while retaining coordination freedom and preventing common misuses of cryptographic primitives. A significant partial result of the above is, that while current AEAD schemes theoretically require coordination due to the uniqueness constraint on the nonces, it is possible to avoid coordination for long enough to make them applicable in a coordination-free setting. Specifically, this result applies to all other approaches for local-first software that could adapt our techniques to encrypt and authenticate their network communication.

Our evaluation shows that we can implement typical local-first applications efficiently and that any ARDT can be securely disseminated. The performance overhead is only a small fraction of the existing dissemination cost. The additional storage requirement is limited by the amount of concurrent changes in the worst case and can be minimized further by including more precise metadata. Moreover, the storage requirement does not increase indefinitely, as ARDTs makes it possible to remove data that is no longer needed by the application logic. Together, the results of the experiments show that it is feasible to use the proposed solution in practice.

A remaining issue – common to all encrypted synchronization techniques – is that it needs to leak metadata to enable efficient dissemination of messages. However, because our approach is resilient to poor network conditions including reordering, delay, and duplication of messages, we believe that many common mitigation techniques can be applied without impeding normal operations. Such mitigations include sending fake data to make metadata less usable, or routing data on multiple intermediaries such that no single one has a full view of the system. We may also be able to apply concepts from homomorphic encryption or secure enclaves to enable intermediaries to learn which states subsume each other, without gaining any further insight into the exact metadata of each message.

Finally, it is noteworthy that besides solving the practical problem of ensuring the integrity and authenticity of replicated state in the presence of untrusted replicas, encARDTs also represent the novel concept of RDT-based implementations of what would classically be seen as a (network) protocol. An encARDT addresses protocol concerns such as transparency of encrypting and decrypting transferred data, which messages are important (and must be retransmitted), and which ones have been superseded by newer messages. Crucially, these concerns are separated from concrete issues concerning physical networks such as message

losses, retries and retransmission delays, or splitting large packages. These concerns are specific to each communication platform and are handled by concrete message dissemination modules. As a future expansion on this concept it could be possible to implement other concerns of network protocols as ARDTs. A concrete example is message delivery in causal order, which can be achieved by attaching ordering information to each message [2]. Such an ARDT would wrap another ARDT, similar to how an encARDT works, but use its operator to present a state merged in causal order (temporarily ignoring messages that were received out of order).

A Appendix

A.1 Map Merge is Correct

Proof. Given that K is the set of all keys (replica ids), x_k is a lookup of key k in map x that returns 0 if the key is not present, $\{k \rightarrow v\}_{k \in K}$ constructs a new map that associates the key k to the value v , that m_0 is a correct merge function for the values stored in the map, and $m(x, y) = \{k \rightarrow m_0(x_k, y_k)\}_{k \in K}$ is the implementation of the merge function. All three proofs are calculations that first expand the definition of m , then use the respective property of the m_0 function, and finally use the reverse definition of m (except in the idempotence case which is already done).

$$\begin{aligned}
 \text{Commutative: } m(x, y) &= \{k \rightarrow m_0(x_k, y_k)\}_{k \in K} \\
 &= \{k \rightarrow m_0(y_k, x_k)\}_{k \in K} = m(y, x)
 \end{aligned} \tag{1}$$

$$\begin{aligned}
 \text{Associative: } m(m(x, y), z) &= \{k \rightarrow m_0(m_0(x_k, y_k), z_k)\}_{k \in K} \\
 &= \{k \rightarrow m_0(x_k, m_0(y_k, z_k))\}_{k \in K} = m(x, m(y, z))
 \end{aligned} \tag{2}$$

$$\begin{aligned}
 \text{Idempotent: } m(x, x) &= \{k \rightarrow m_0(x_k, x_k)\}_{k \in K} \\
 &= \{k \rightarrow x_k\}_{k \in K} = x
 \end{aligned} \tag{3}$$

A.2 Derived Product Merge Implementation

We elaborate on the technical details of the implementation of method `derived` in Figure 16. The method is marked `inline` to make use of compile-time meta programming, which we use to acquire lattice instances of the individual components of the product, specifically, the `summonAll` method used later. The `using` keyword asks the compiler to provide a product mirror (named `pm`) for the product type `S` to allow inspection of the components of `S`.

The `summonAll` method in Line 72, similar to the `using` keyword, “summons” instances provided by the given keyword based on their types. Specifically, the type we request are the component types (`pm.MirroredElemTypes`) of our product mapped to the `Lattice` type. As an example, the component types of our `MyData` class returns the type `(A, B)` and mapping

that onto the lattice type results in the type (`Lattice[A]`, `Lattice[B]`) which is the type for which we “summon” the instances. The result is a tuple of typed lattice instances, but we throw away all type information (Line 73) and rely on the fact that all used products have the same component type at the same structural position.

Having computed lattice instances of the components, we create a new instance of the lattice trait (Line 74). The merge function of that instance (defined in Line 75) uses the `pm.fromProduct` helper to generically create a new instance of the result product `S` (e.g., a new instance of our `MyData` class) in Line 76. The parameter to `pm.fromProduct` essentially assigns each component at index `i` (`productElement` in Line 76) the result of using merge function `i` to merge the left and right components at position `i`.

The technical challenges of generating merge functions for arbitrary products are mostly related to practical concerns in the programming language.

A.3 Derived Product Merge is Correct

Proof. Given that K is the set of product indices (this would be the field names of a case class), x_k is a lookup of index k in product x , the syntax $\{k \rightarrow v\}_{k \in K}$ constructs a new product of correct type that associates the index k to the value v , each component type at index k has a merge function m_k , and $m(x, y) = \{k \rightarrow m_k(x_k, y_k)\}_{k \in K}$ is the implementation of the merge function for the product. We show that m is commutative, associative, and idempotent. All three proofs are calculations that first expand the definition of m , then use the respective property of the component merge functions, and finally use the reverse definition of m (except in the idempotence case which is already done).

$$\begin{aligned} \text{Commutative: } m(x, y) &= \{k \rightarrow m_k(x_k, y_k)\}_{k \in K} \\ &= \{k \rightarrow m_k(y_k, x_k)\}_{k \in K} = m(y, x) \end{aligned} \tag{4}$$

$$\begin{aligned} \text{Associative: } m(m(x, y), z) &= \{k \rightarrow m_k(m_k(x_k, y_k), z_k)\}_{k \in K} \\ &= \{k \rightarrow m_k(x_k, m_k(y_k, z_k))\}_{k \in K} = m(x, m(y, z)) \end{aligned} \tag{5}$$

$$\begin{aligned} \text{Idempotent: } m(x, x) &= \{k \rightarrow m_k(x_k, x_k)\}_{k \in K} \\ &= \{k \rightarrow x_k\}_{k \in K} = x \end{aligned} \tag{6}$$

◀

A.4 Naive encARDT is Transparent

Proof. We show that for any subset of states $c \subset S$ sending (encrypting) and recombining (decrypting and merging) the set c is equivalent to merging the set c directly. This uses the secret key k , the merge function m_S for states in S , the merge function $m_e = \text{union}$ of the encARDT, the encrypt e_k and decrypt d_k function with $d_k(e_k(s)) = s$, the send function $\text{send}_k(s) = \{e_k(s)\}$, and the recombine function $\text{rec}_k(c) = m_S(\{d_k(s) \mid s \in c\})$. The proof is done by expanding the above definitions (highlighted in blue) when appropriate.

$$\begin{aligned}
& \text{rec}_k(m_e(\{\text{send}_k(s')|s' \in c\})) \\
&= m_S(\{d_k(s)|s \in m_e(\{\text{send}_k(s')|s' \in c\})\}) \quad \text{def of rec} \\
&= m_S(\{d_k(s)|s \in m_e(\{\{e_k(s')\}|s' \in c\})\}) \quad \text{def of send} \\
&= m_S(\{d_k(s)|s \in \{e_k(s')|s' \in c\}\}) \quad \text{def of } m_e \tag{7} \\
&= m_S(\{d_k(e_k(s))|s \in c\}) \quad \text{simplify set ops} \\
&= m_S(\{s|s \in c\}) \quad \text{def of } e_k \text{ and } d_k \\
&= m_S(c)
\end{aligned}$$

◀

A.5 Subsuming encARDT is Transparent

Proof. Given a secret key k , a subset of states $c \subset S$, individual states s, x, y, z , a merge function m_S for states in S , associated data for each state a_s where $a_x \leq a_y$ if $m_S(x, y) = y$, the filter function $f(c) = \{x \in c | \nexists y \in c : a_x < a_y\}$, the merge function $m_e(c) = f(\bigcup(c))$ of the encARDT, the encrypt e_k the decrypt d_k function with $d_k(e_k(s)) = s$, the current encrypted states c_e , the send function $\text{send}_k(c_e, s) = \{e_k(m_S(\text{rec}_k(c_e), s))\}$, and the recombine function $\text{rec}_k(c_e) = m_S(\{d_k(s)|s \in c_e\})$.

It holds that filtering distributes over union $f(p \cup q) = f(f(p) \cup q)$, because all elements of $f(p)$ are larger or equal to all elements in p , so filtering them out first does not change the result of $f(p \cup q)$.

Filter distributes over decryption, i.e., $\{d_k(s)|s \in f(c)\} = f(\{d_k(s)|s \in c\})$, because filtering is defined on associated data which is also available in the encrypted state.

It holds that filtering is subsumed by merging $m_S(f(c)) = m_S(c)$, because for each removed element $r \in p \setminus f(p)$ it is subsumed by one of the remaining elements $q \in f(p)$ thus merging it again makes no difference $m_S(r, p) = p$.

We first show that the merge function of the encARDT m_e is associative, idempotent, and commutative. Note, that up until now, we have proven a slightly stronger version of idempotence that requires less calculation, but we can not do so here, because the filtering function does not provide the stronger guarantee that $f(a) = a$, thus we only have $m(x, x) = f(x)$. Instead of strong idempotence, we prove that $m(m(x, y), y) = m(x, y)$, that is, merging y multiple times still makes no difference, but we must merge at least once.

$$\text{Commutative: } m_e(x, y) = f(x \cup y) = f(y \cup x) = m_e(y, x) \tag{8}$$

$$\begin{aligned}
\text{Associative: } m_e(m_e(x, y), z) &= f(f(x \cup y) \cup z) = f(x \cup y \cup z) \\
&= f(x \cup f(y \cup z)) = m_e(x, m_e(y, z))
\end{aligned} \tag{9}$$

$$\begin{aligned}
\text{Idempotent: } m_e(m_e(x, y), y) &= f(f(x \cup y) \cup y) = f(x \cup y \cup y) \\
&= f(x \cup y) = m_e(x, y)
\end{aligned} \tag{10}$$

Finally, transparency of the subsuming encARDT, i.e., that receiving a set of send and filtered states is equivalent to merging those states directly. The applied definitions are listed and the changes highlighted in blue.

$$\begin{aligned}
& \text{rec}_k(m_e(\{\text{send}_k(c_e, s') | s' \in c\})) \\
&= m_S(\{d_k(s) | s \in m_e(\{\text{send}_k(c_e, s') | s' \in c\})\}) && \text{def of rec} \\
&= m_S(\{d_k(s) | s \in m_e(\{\{e_k(m_S(\text{rec}_k(c_e), s'))\} | s' \in c\})\}) && \text{def of send} \\
&= m_S(\{d_k(s) | s \in f(\{e_k(m_S(\text{rec}_k(c_e), s')) | s' \in c\})\}) && \text{def of } m_e \\
&= m_S(f(\{d_k(s) | s \in \{e_k(m_S(\text{rec}_k(c_e), s')) | s' \in c\}\})) && \text{filter distributes} \\
&= m_S(f(\{d_k(e_k(m_S(\text{rec}_k(c_e), s')) | s' \in c\})) && \text{simplify set ops} \\
&= m_S(f(\{m_S(\text{rec}_k(c_e), s') | s' \in c\})) && \text{def of } e_k \text{ and } d_k \\
&= m_S(\{m_S(\text{rec}_k(c_e), s') | s' \in c\}) && \text{filter subsumed} \\
&= m_S(\text{rec}_k(c_e), m_S(c)) && \text{merge properties} \\
&= m_S(m_S(\{d_k(e_k(s)) | e_k(s) \in c_e\}), m_S(c)) && \text{def of rec} \\
&= m_S(m_S(\{s | e_k(s) \in c_e\}), m_S(c)) && \text{decrypted} \\
&= m_S(\{s | e_k(s) \in c_e\} \cup c) && \text{merge properties}
\end{aligned} \tag{11}$$

◀

A.6 Case Study with Trusted Intermediary

Figure 17 shows the benchmark results for the to-do list case study when we trust the intermediaries and do not use an encARDT. The overall trends are similar, both the time per interaction and the size stored on the intermediary have a linear correlation to the current number of to-do entries. This is because those costs are inherent to the ARDT of the to-do list. There are notable differences. First, the overall runtime when using encARDTs is better (each interaction is faster), because merging the encARDT on the intermediary (i.e., pruning subsumed deltas) is faster than merging the to-do list on the intermediary (i.e., merging the two add-wins-last-writer-wins maps). The encryption overhead is negligible compared to that cost. Second, the overall size of the stored data on the trusted intermediary is smaller, because storing individual encrypted deltas requires more space as discussed in Subsection 6.2. Third, the client does not have to transmit any additional causality information and also does not create subsuming deltas that would reduce the overall size of an encARDT, but lead to larger deltas in some cases. This leads to a nearly constant bandwidth use, with small variations for the random difference between the relative amount of added, completed, and removed to-dos, as well as differences in to-do description lengths.

■ **Figure 17** To-do list case study measurement results with trusted intermediary.

Behavioural Types for Local-First Software

Abstract

Peer-to-peer systems are the most resilient form of distributed computing, but the design of robust protocols for their coordination is difficult. This makes it hard to specify and reason about global behaviour of such systems.

This paper presents *swarm protocols* to specify such systems from a *global* viewpoint. Swarm protocols are projected to *machines*, that is *local* specifications of peers. We take inspiration from behavioural types with a key difference: peers communicate through an event notification mechanism rather than through point-to-point message passing. Our goal is to adhere to the principles of *local-first software* where network devices collaborate on a common task while retaining full autonomy: every participating device can locally make progress at all times, not encumbered by unavailability of other devices or network connections. This coordination-free approach leads to inconsistencies that may emerge during computations. Our main result shows that under suitable well-formedness conditions for swarm protocols consistency is eventually recovered and the locally observable behaviour of conforming machines will eventually match the global specification.

Our model elaborates on the Actyx industrial platform and provides the basis for tool support: we sketch an implemented prototype which proves this work a viable step towards reasoning about local-first and peer-to-peer software systems.

1 Introduction

Fully decentralised systems like peer-to-peer (P2P) networks are notoriously hard to design and analyse. A main challenge is to coordinate components so that the composed system exhibits the expected behaviour. As all decisions in such a system are made locally based on the available partial knowledge, the main problem is to specify which information is transferred to whom and when and how to interpret it, i.e. protocol design. The example we observed with Actyx is implemented in factory shop floor coordination, which is mission-critical: logistics robots compete for transport orders to move goods between machines and warehouses¹. For familiarity, we use taxi rides instead which are of the same shape.

► **Example 1.1** (Our running example). The fleet of a taxi company organises rides within a town using a P2P network. The main goal is to provide any registered passenger who requests a ride with some offers from taxis willing to perform the desired transportation; the passenger may pick one offer based on price and estimated time of arrival – followed by tracking the pickup, ride, and arrival – or cancel the ride. At the end of the trip the accounting office provides a receipt for the journey or cancellation. Note how there is some level of trust between the parties involved; we will treat this as a non-adversarial setting.

The structure of the expected interaction between the different peers (classified by *roles*) can be informally illustrated with the following diagram involving a passenger role P, a taxi role T, and an accounting office role as O.

When a passenger needs a ride (state 1 in the diagram above), they open an auction by executing a **Request**. Then, any taxi with capacity can proceed with an **Offer**. In this description, we do not make any assumption about the number of instances playing each role; in fact, we expect to have many taxis playing role T and hence many offers. The passenger ends the auction by using **Select** to pick a winner; note that we do not capture which taxi won the contract, instead we assume that only the winning taxi will perform actions after state 3 (we could model one selected branch per taxi and replicate states 3–6, but this only makes the example larger without additional insight).

The second phase starts with a race in state 3: the taxi begins the ride invoking **Arrive** while the passenger loses patience and uses the **Cancel** command to back out. The office will create a receipt in either case, but we must settle the dispute whether a ride happened. ─

The classic solution to such a problem would use a central database to present an up-to-date view of the respective data each participant is allowed to see. This solution avoids conflicts, maintains invariants, and steers the whole process by virtue of there being only one source of truth – one of the **Arrive** or **Cancel** commands would happen first and the

¹ This use-case has been implemented and is used in factories based on the Actyx Pond library, which uses the same event log replication mechanism as described in this article but does not model the interaction of differently shaped machines nor does it provide formal verification of the protocol. For a different factory the implementation and deployment is ongoing using the theory presented herein – developers report greater confidence and productivity than with established approaches. The main difficulty in factory logistics is reasoning about transient network partitions of mobile participants. Note that orchestrating the movement of goods on the shop floor is most critical for a factory’s success!

other would be rejected. It is well-known (cf. the CAP [16] and FLP [14] results) that such a solution suffers from unavailability if the system model includes network partitions, since either the database is localised and may be unreachable, or it is distributed and may need to reject requests to maintain consistency. With the advent of *conflict-free replicated data types (CRDTs)* [33] a different solution came into view: instead of avoiding conflicts through coordination, CRDTs provide a data model of such a structure that is conflict-free by construction. CRDTs facilitate that by demanding a join semi-lattice for the data structure, i.e. that there is a merge function that given two differently evolved states will compute a new state that represents the sum of all operations that were done to either input. Applied to Example 1.1 this would typically be achieved by systematically preferring either side of the choice at state 3, e.g. “cancellation always wins” (cf. the *add-wins set* CRDT). This illustrates that CRDTs are not well-suited for capturing and fairly resolving conflicts such as the one in our example. Nevertheless, the increasing research focus on coordination-free systems inspired the formulation of *local-first software* [25] in which all participants in a distributed system maintain full autonomy and control over their data. Besides the focus on agency and ownership, local-first principles can also be used to build software that is fully available and maximally resilient [26], where each participant can independently make decisions that are globally valid.

We propose a new way of approaching local-first software based on embracing conflict, recognising it, and finally reconciling it to reach eventual consensus [38]. Our model builds upon the middleware developed at Actyx [1], which provides a reliable durable pub-sub mechanism for event logs as well as a coordination-free total order of all events. A distributed system in our model is realised by a set of participants, dubbed *machines*, that can exhibit discordant behaviour and interact by broadcasting and reacting to *events*. Events are generated locally in response to the execution of *commands*, added to the *local log* and then propagated to other participants, to be merged into the log local at the recipient. We assume that events propagate asynchronously and that there is no traditional mechanism for coordination (like consensus or central nodes): machines liaise with each other purely on the basis of the events spreading in the system. We refer to such systems as *swarms*.

Each machine in a swarm implementing the scenario in Example 1.1 plays a role, i.e. it subscribes to a defined subset of event types and applies an assigned logic to interpret those. Depending on its local state (which it computes from its local log), any machine may decide to execute a command. For instance, a machine playing the role P may execute **Request**, which generates new events containing details of the request. Such events are appended to the local log of the machine and then propagated asynchronously to other machines that have subscribed to such events, e.g. the machines corresponding to taxis. After receiving such events, a taxi updates its local state and decides whether to place an offer for the ride. In such case, it executes **Offer**, which generates the events describing the offer, appends them to local log and propagates them to the rest of the system. The interaction described in Example 1.1 may proceed to completion in this way. Our swarms protocols specify the intended communications in an ideal run of the protocol, assuming that different sessions are independent from each other – we therefore do not represent sessions in our syntax.

Noteworthy, our computational model does not preclude the execution of conflicting commands. For instance, the race in state 3 of Example 1.1 allows two machines to generate their respective events and propagate them through the system. When receiving such events, each machine will be in charge of detecting and properly resolving the conflict. This is achieved by using the total order between events – interpreted as manifestation of (logical) time: the earliest event emitted after a choice decides which branch is taken (events from a

losing branch are ignored). Note that we do not assume knowledge of when the event log is complete, i.e. a machine cannot detect whether an event is globally the earliest after a choice; thus, computed local states may transiently diverge. As soon as events up to and including a given choice are fully replicated across the swarm, all machines will agree upon which branch is taken (i.e. we achieve *eventual consensus* [38]).

The fact that events are processed only by subscribers makes the resolution of choices subtle. Assume that the accounting office incorrectly subscribes to the cancellation event but not to the arrival one. In the presence of a conflicting choice, it may incorrectly conclude that the ride was cancelled even when all other roles understand that the ride took place. We rely on a typing discipline for ruling out such inconsistencies. We follow a top-down approach featuring *swarm protocols*, namely abstractions similar to the diagram in Example 1.1 that – akin to global types [19, 20] – formalise a description of the expected protocol from a *global* viewpoint. A projection operation can automatically generate local specifications of each role formally defined as *machines* (cf. Section 2.3). Our typing discipline establishes sufficient conditions – *well-formedness* of swarm protocols – to guarantee that well-typed systems will resolve conflicting choices consistently once information has sufficiently spread to participants. This and the fact that swarm protocols fully abstract away from the number of instances enacting a role are distinguished features of our approach.

Main contributions. We develop a behavioural typing discipline for local-first software tailored to a formal operational model distilled from a real middleware. More specifically:

1. We introduce an operational model for distributed computation based on replication of event logs to drive the behaviour of machines (Section 2). We do not assume log stability but combine speculative computation with a “rewind” mechanism à la *time warp machine* [22]: a conflict is resolved by backtracking and re-execution along the right path.
2. We define a novel behavioural type approach (Section 4) in which swarm protocols are specified in terms of the information injected into a heterogeneous swarm through the actions performed by participants of specific roles. Swarm protocols enjoy a lightweight syntax and simple operational semantics; they are deadlock-free and communication-safe; yet they are expressive enough for modelling complex protocols.
3. We define well-formedness conditions for swarm protocols (Definition 6.7) and a projection operation to derive local machine specifications (Section 5). These ensure eventual consistency between local observations and globally specified behaviour (Theorem 7.14 and Corollary 7.15), which is non-trivial due to the absence of any infrastructure coordination, non-homogeneous event subscriptions across roles, and the ability to implement a role with an arbitrary positive number of replicas.
4. We apply our approach to the TypeScript language and Actyx middleware in the form of a runtime library and a tool for checking protocol well-formedness and conformance, as well as a stochastic simulation tool exploring possible executions.

Assumptions. We work under the following assumptions (cf. Section 9 for extensions):

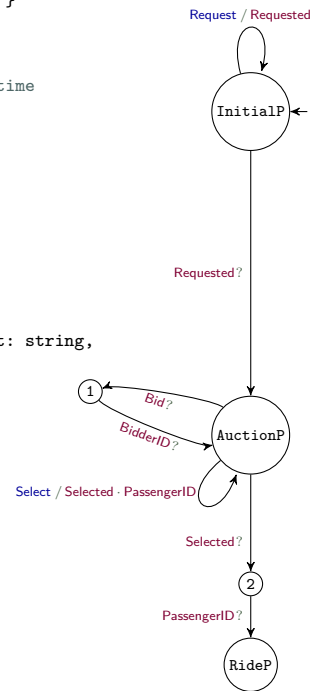

- *collaborative setting*: we consider P2P participants to not be malicious or adversarial;
- *pure effects*: effects performed by machines can be reverted or compensated;
- *reliable pub-sub mechanism*: events (incl. metadata) are neither forged nor lost;
- *session encoding*: machines only receive events pertaining to their session.

Structure. We present the semantics of machines and of log shipping in Section 2. An overview of the accompanying tooling is in Section 3. Swarm protocols are introduced in Section 4 and their local projection onto machines in Section 5. We define well-formed

```

1 // analogous for other events; "type" property matches type name (checked by tool)
2 type Requested = { type: 'Requested'; pickup: string; dest: string }
3 type Events = Requested | Bid | BidderID | Selected | ...
4
5 /** Initial state for role P */
6 @proto('taxiRide') // decorator injects inferred protocol into runtime
7 export class InitialP extends State<Events> {
8   constructor(public id: string) { super() }
9   execRequest(pickup: string, dest: string) {
10    return this.events({ type: 'Requested', pickup, dest })
11  }
12  onRequested(ev: Requested) {
13    return new AuctionP(this.id, ev.pickup, ev.dest, [])
14  }
15 }
16 @proto('taxiRide')
17 export class AuctionP extends State<Events> {
18   constructor(public id: string, public pickup: string, public dest: string,
19     public bids: BidData[]) { super() }
20   onBid(ev1: Bid, ev2: BidderID) {
21     const [ price, time ] = ev1
22     this.bids.push({ price, time, bidderID: ev2.id })
23     return this
24   }
25   execSelect(taxiId: string) {
26     return this.events({ type: 'Selected', taxiID },
27       { type: 'PassengerID', id: this.id })
28   }
29   onSelected(ev: Selected, id: PassengerID) {
30     return new RideP(this.id, ev.taxiID)
31   }
32 }
33 @proto('taxiRide')
34 export class RideP extends State<Events> { ... }

```

swarm protocols in Section 6 and study eventual correctness in Section 7. Related works are discussed in Section 8 and Section 9 yields final remarks together with possible generalisations and future work.

2 Asymmetric Replicated State Machines

Our model hinges on three ingredients: machines, event emission and consumption, and logging. The behaviour of a machine is captured by a finite-state automaton as described in Section 2.1. In Section 2.2 we show how machines may offer *commands* that, upon execution, emit events as well as how machines consume (typed) events stored in their *local log*. Such events are immediately stored in the local log of the emitting machine and later asynchronously shipped to the other machines as described in Section 2.3.

2.1 From TypeScript to automata

We formalise (and elaborate on) the computational model realised in the middleware of Actyx by offering a new library for writing endpoint code. Like the Actyx SDK, we use the TypeScript language. Our API focuses on a concise but well-structured expression of finite-state machines for interpreting the current state of distributed computation.

We illustrate this by considering the implementation of the request and auction part of our running taxi example from the passenger's point of view, with the TypeScript code given in Listing 1. For the purposes of this section – all details, including runtime evaluation, are given in Section 3 – it suffices to know that each state of a machine is represented by a

■ **Table 1** Notation for machines.

Notation:	State computation:
$\vdash e : \mathbf{t}$: event e is of type \mathbf{t} $src(e)$: identity of the machine generating e l : event log (seq. without repetition) \mathbf{l} : event log type (sequence of types) \mathbf{c} / \mathbf{l} : command \mathbf{c} emits log type \mathbf{l} $\mathbf{t}?$: consumption of event of type \mathbf{t} \mathbf{M} : machine (labelled transition system)	Let q_0 be the initial state of \mathbf{M} and $\mathbf{M}[q]$ be machine \mathbf{M} with initial state changed to q : $\delta(\mathbf{M}, \epsilon) = q_0$ $\delta(\mathbf{M}, e \cdot l) = \begin{cases} \delta(\mathbf{M}[q], l) & \text{if } \vdash e : \mathbf{t}, q_0 \xrightarrow{\mathbf{t}^?} q \text{ in } \mathbf{M} \\ \delta(\mathbf{M}, l) & \text{otherwise} \end{cases}$

TypeScript class, with methods for command invocation whose name is prefixed with “**exec**”, and event handler methods to compute the next state (names prefixed with “**on**”). The types of the event handler method arguments are significant, as are the return types of command methods. Listing 1 also depicts the finite-state automaton corresponding to the snippet, as inferred by the `machine-check` build tool (cf. Section 3.2):

- states `InitialP`, `AuctionP`, and `RideP` of the automaton respectively correspond to the classes in the snippet with the same name;
- states 1 and 2 of the automaton correspond to the implicit states interspersed between the events specified as arguments to the event handler methods `onBid` and `onSelected`;
- command methods correspond to self-loops in the automaton, labelled with the command name and the resulting event log type, such as `Request / Requested` in state `InitialP`;
- event handlers correspond to transitions or sequences thereof, where each transition is labelled with an event type, such as `Requested?` from state `InitialP`.

The correspondence sketched above is the basis for our formalisation of swarms and it is at the heart of the library `machine-runner` introduced in Section 3.

Note that in the automaton we abstract away from payloads, considering only the types of events. We also ignore internal computations not involving event emission/consumption (e.g. the computation of the constructor arguments for state `AuctionP` is immaterial).

2.2 Commands execution and events consumption

A machine can be thought of as the proxy of an agent (algorithm or human) that processes the information in the local log, comes to conclusions, and makes decisions which may lead to the invocation of an enabled command. For instance, in state `AuctionP`, the machine in Section 2.1 enables the passenger to execute the command `Select` triggering the emission of a log like `selected · passengerid`. This sequence of events is added to the local event log making the machine move to state 2 first by consuming the event `selected` and then to state `RideP` by consuming the event `passengerid`. This is why the inferred machine state diagram records commands as self-loops while only event consumption may induce state changes.

The automata representation of machines discussed in Section 2.1 allows us to limit technicalities in defining the behaviour of machines. We illustrate the notation given in Table 1 by abstracting the above example: a machine \mathbf{M} enabling command \mathbf{c} will upon invoking that command emit a sequence of events $e_1 \cdot e_2 \cdot \dots = l$ (called a log); the events are decidable typed as $\vdash e_i : \mathbf{t}_i$, with $\mathbf{t}_1 \cdot \mathbf{t}_2 \cdot \dots = \mathbf{l}$ being the log type associated with \mathbf{c} . We only consider deterministic machines, i.e. the labels of event transitions $\mathbf{t}?$ are pairwise distinct.

For the purpose of enabling commands a machine \mathbf{M} with log l is implicitly in a state denoted $\delta(\mathbf{M}, l)$. The determinism of \mathbf{M} ensures that there is a unique such state. $\delta(\mathbf{M}, l)$ is a *transition function* defined by adapting the standard transition function of finite-state automata. Starting with the initial state of \mathbf{M} we inductively remove the oldest event, say e ,

■ **Figure 1** Events sliced by their source: each event starts out at the machine where it is emitted. Logs are disseminated such that the recipient (like machine M_C) holds a prefix of each of the source slices, which is a partial view of the global log. The recipient’s local log is ordered like the global log. Eventually every event arrives at all machines, filling the transient gaps that may have existed.

and check it against the outgoing transitions of the current state: if M has a transition with label t ? and e has type t we transition to its target state, otherwise the event e is dropped; in either case we repeat this step until the log is empty.

It is important to note that a command may be invoked only if it is enabled in the state reached after fully processing the local log. Also, emitted events are *appended* to the local log of the machine they originate at. This ensures causality preservation since the new events are ordered *after* all events previously known by this machine.

2.3 Swarms and log-shipping

The last piece of our computational model is the mechanism for disseminating event logs among the machines of a swarm. This mechanism affects the behaviour of a recipient: as described in Section 2.2, the local log contains more events, leading to a new current state being computed, which in turn may change the set of available commands.

Our goal is eventual consensus between machines, in particular different replicas of the same machine must reach the same state when consuming the same events. According to the definition of the state transition function in Table 1, this can be achieved only if the events are ordered in the same way in the local logs. We address this by enforcing a total order between events, without requiring coordination between machines. As discussed in the previous section this total order preserves causality. Note that the ordering of events that are not yet locally known is arbitrary but well-defined, and to capture this concept we introduce the notion of a global log. Figure 1 illustrates the dissemination of logs, where each event begins in the local log of the emitting machine and simultaneously takes its place in the virtual global log based on the total order. We model log-shipping as a machine enlarging its local log with events from the global log; in practice, events flow from the local log of a machine to another machine’s local log. The precise algorithm for selecting the source and destination is not relevant to our theory. Due to the uncoordinated total order, it may happen that an incoming event is sorted into the middle of a local log, which can alter the interpretation of all subsequent events and affect the computation of the current state.

For example, consider the case in our running example in which the passenger selects the taxi at the same time that another taxi places a new bid. If the passenger’s selection is ordered before the bid, a later inspection of the log may reveal that the passenger selected suboptimally, but the selection still remains in effect and the bid is ignored. (In a system based on a central database the “bid” transaction would be rejected instead.) On the other hand, if the event *selected* were placed in between *bid* and *bidderid*, it would be ignored once the logs are replicated. In this case there are two reasonable paths forward: honouring the passenger’s previous wish would require a *compensating action* of executing the same selection again, or the selection could be redone including the new bid, possibly leading to a different outcome – this workflow choice needs to be made by the application designer.

■ **Table 2** Swarm semantics: coinductively unfold machines to inductively build up logs.

<p>Notation:</p> <p>\mathbf{S} : a list of pairs (\mathbf{M}_i, l_i)</p> <p>(\mathbf{S}, l) : a system (machines with local logs paired with a global log)</p> <p>κ : set of command invocations $\mathbf{c} / \mathbf{1}$</p> <p>$\implies = \longrightarrow^*$ where $\longrightarrow = \xrightarrow{\tau} \cup \bigcup_{\mathbf{c}, \mathbf{1}} \xrightarrow{\mathbf{c} / \mathbf{1}}$</p>	<p>Log merging:</p> <p>Let \sqsubseteq be the sublog relation of Definition 2.1:</p> $l_1 \bowtie l_2 = \{l \mid l \subseteq l_1 \cup l_2 \text{ and } l_1 \sqsubseteq l \text{ and } l_2 \sqsubseteq l\}$ <p>Machine step:</p> <p>If $\delta(\mathbf{M}, l)$ has a self-loop with label $\mathbf{c} / \mathbf{1}$ and $\vdash l' : \mathbf{1}$ then $(\mathbf{M}, l) \xrightarrow{\mathbf{c} / \mathbf{1}} (\mathbf{M}, l \cdot l')$.</p>
<p>Operational semantics:</p> $\frac{\mathbf{S}(i) = (\mathbf{M}, l_i) \quad (\mathbf{M}, l_i) \xrightarrow{\mathbf{c} / \mathbf{1}} (\mathbf{M}, l'_i) \quad \text{src}(l'_i \setminus l_i) = \{i\} \quad l' \in l \bowtie l'_i}{(\mathbf{S}, l) \xrightarrow{\mathbf{c} / \mathbf{1}} (\mathbf{S}[i \mapsto (\mathbf{M}, l'_i)], l')} \text{[LOCAL]}$ $\frac{\mathbf{S}(i) = (\mathbf{M}, l_i) \quad l_i \sqsubseteq l'_i \sqsubseteq l \quad l_i \subset l'_i}{(\mathbf{S}, l) \xrightarrow{\tau} (\mathbf{S}[i \mapsto (\mathbf{M}, l'_i)], l)} \text{[PROP]}$	

2.4 Formalisation

A *swarm* (of size n) is a pair (\mathbf{S}, l) where \mathbf{S} maps indices $1 \leq i \leq n$ to machines and their local log, i.e. $\mathbf{S}(i) = (\mathbf{M}_i, l_i)$ and l is the global log. It is convenient to let $(\mathbf{M}_1, l_1) \mid \dots \mid (\mathbf{M}_n, l_n) \mid l$ denote the swarm (\mathbf{S}, l) such that $\mathbf{S}(i) = (\mathbf{M}_i, l_i)$ for $1 \leq i \leq n$. A swarm $(\mathbf{M}_1, l_1) \mid \dots \mid (\mathbf{M}_n, l_n) \mid l$ is *coherent* when the local log l_i of each machine \mathbf{M}_i is made of events actually emitted in \mathbf{S} in the order in which they appear in the global log.

► **Definition 2.1** (Sublogs and coherence). *A log $l = e_1 \dots e_n$ induces a total order $<_l$ on its elements as follows: $e_i <_l e_j \iff i < j$. The sublog relation on logs \sqsubseteq demands an order-preserving and downward-complete morphism from l_1 into l_2 . Formally, $l_1 \sqsubseteq l_2$ if*

1. *all events of l_1 appear in l_2 ($l_1 \subseteq l_2$) in the same order ($<_{l_1} \subseteq <_{l_2}$); and*
2. *the per-source partitions of l_1 are prefixes of the corresponding partitions of l_2 , i.e. for all $e_1 \in l_1, e_2 \in l_2$ from a given src , $e_2 <_{l_2} e_1$ implies $e_2 \in l_1$.*

A swarm $(\mathbf{M}_1, l_1) \mid \dots \mid (\mathbf{M}_n, l_n) \mid l$ is coherent if $\bigcup_{1 \leq i \leq n} l_i = l$ and $l_i \sqsubseteq l$ for $1 \leq i \leq n$.

The operational semantics of swarms accounts for the construction of the global log, i.e. the total order defined over generated events. To model that this assignment is non-deterministic we rely on the merge operator $_ \bowtie _$ defined in Table 2 to combine two logs that may share events. This operator generates all possible logs that contain the events from both original logs while maintaining their input order.

The operational semantics is given by the rules LOCAL and PROP in Table 2. They respectively formalise the effects of command execution described in Section 2.2 and the non-deterministic log-shipping mechanism illustrated in Section 2.3. Recall that a machine \mathbf{M} with a log l is implicitly in state $\delta(\mathbf{M}, l)$. We can hence define the relation $(\mathbf{M}, l) \xrightarrow{\mathbf{c} / \mathbf{1}} (\mathbf{M}, l \cdot l')$ holding when the state $\delta(\mathbf{M}, l)$ enables the command $\mathbf{c} / \mathbf{1}$ and l' has type $\mathbf{1}$. The type of a log $\mathbf{1}$ is the sequence of the types of its events. We write $\vdash l : \mathbf{1}$ when l has type $\mathbf{1}$; this is decidable since the typing of events (cf. Table 1) is decidable.

Rule LOCAL describes the invocation of the command \mathbf{c} enabled at the i -th machine of the swarm (\mathbf{S}, l) . In addition to updating the local log of the i -th machine to l'_i , which extends l_i with the events generated by \mathbf{c} , the rule also updates the global log. The new global log now

includes the events generated by the i -th machine, assigning their place in the total order by picking one of the possible orders generated by the merge operator defined in Table 2. Rule PROP defines event log propagation between machines. The idea is to non-deterministically select a machine whose local log is a strict sublog of the global log, identify a larger sublog $l'_i \sqsubseteq l$, and transfer events to the machine by assigning l'_i as its new local log.

Note that our formalisation acts on the logs which grow by appending newly generated events. These features play an important role in the realisation of the local-first principle and permit to formally represent the conflicts discussed in Section 1.

Let \Longrightarrow be the reflexive and transitive closure of the operational semantics relation (cf. Table 2). The following properties hold on coherent swarms.

- **Lemma 2.2** (Coherence preservation and eventual consistency). *Given a coherent swarm $(S, l) = (M_1, l_1) \mid \dots \mid (M_n, l_n) \mid l$ then*
- coherence preservation: $(S, l) \xrightarrow{\alpha} (S', l')$ implies that (S', l') is coherent
 - eventual consistency: $(S, l) \Longrightarrow (M_1, l) \mid \dots \mid (M_n, l) \mid l$.

3 Tool support

Our theoretical development is accompanied by a set of software tools that support the implementation of swarms as a composition of type-checked TypeScript machines [30] and runs them based on the Actyx middleware [1]. The ecosystem is depicted in Figure 2.

3.1 Execution of compiled machines

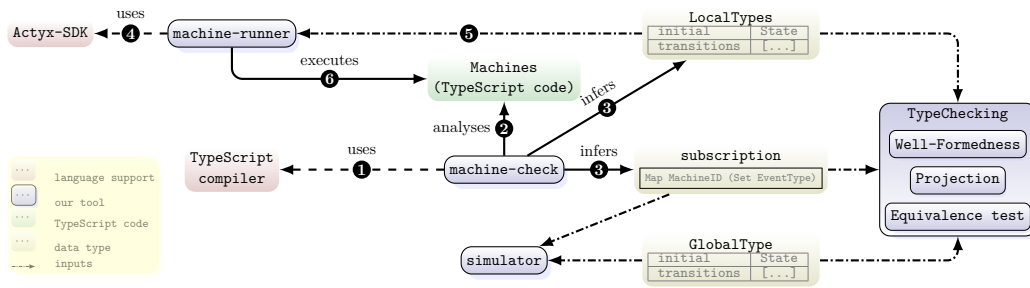

The `machine-runner` library uses the Actyx SDK (cf. arrow ④ in Figure 2) to drive machines written in TypeScript; more precisely, it employs ⑤ local types to interpret incoming events and execute ⑥ the corresponding machine logic. The declaration of a machine revolves around the event types that it can handle. Referring back to Listing 1, we show the `Requested` event type on line 2 as an example: using a property called `type` to hold a string of singleton type (here: `'Requested'`) is a customary way to express a *tagged union* in TypeScript, as shown on line 3.

Every machine state is represented by a class that derives from the `State` base class (or *prototype* in JavaScript terms) provided by the `machine-runner` library. This serves both as a marker for machine states and to carry the type parameter constraining all emitted events to a common type: the inherited `this.events` function used for example on line 28 is a utility for helping TypeScript to correctly capture the tuple type `[Selected, PassengerID]` (instead of the otherwise inferred array type `Events[]`) and assert that each of the event types conforms to type `Events`.

A program using the passenger’s machine would start by constructing the initial state using for example `new InitialP('myID')`. Together with a suitable set of Actyx event tags (like `'ride:12345'` to tag this particular taxi ride protocol session) and a state change callback (see below). This initial state is then passed to the library’s `runMachine` function. This will set up a subscription for events with those tags using the Actyx SDK, where Actyx will first deliver all historic events already locally known and then switch to live mode.

Whenever an event is received, it is slated for consumption by the appropriate event handler method; to this end the handler method for the event’s type is dynamically looked up in the JavaScript object underlying the state’s class. If that method takes only a single argument then the event is immediately consumed by calling the method, which returns the next state of the machine. Otherwise, the event is enqueued, awaiting the receipt of the following required event type etc. until the desired event sequence is complete and

15:10 Behavioural Types for Local-First Software

■ **Figure 2** Tool ecosystem.

the method can be invoked with all arguments. During this whole process, whenever the incoming event type does not have a matching handler or is not of the next required type in an argument list, the event is discarded as detailed in Section 2.2.

Whenever the machine state changes (i.e. when $\delta(M, l)$ computes a new value), the new state is passed to a function that the application passed to `runMachine` earlier – this scheme is termed a *callback* in TypeScript (note that this language implements an imperative style with mutable bindings). This could update a user interface or trigger an algorithm to compute reactions. The state’s command methods can therein be used to construct adequate event payloads for enabled commands, which would then be stored in Actyx using an SDK function and come back via the event subscriptions – now with metadata – to be applied to the current state and eventually trigger another invocation of the callback.

3.2 Enforcing typing at run-time

Readers versed in TypeScript may have noticed that we glossed over a difficulty here: TypeScript types are fully erased at runtime, meaning that the `machine-runner` code will not be able to find the event handler method by using the event type, and it will also not know how many arguments that method takes and what its types are. Therefore, the first responsibility of the `machine-check` build tool is to analyse ② the TypeScript code and ascertain that all event types are declared such that they can be recognised at runtime on their `type` property – the handler method’s name can then be constructed by prefixing the value of this property with `'on'`. The second responsibility is to extract the function signatures of all event handlers, check that each handler’s name corresponds to the name of its first argument type, and then construct a per-state mapping from first event type to the list of following events (possibly empty). This information is made available to `runMachine` by decorating [37] the user-written state class: the `@proto` decorator transforms the class definition as it is loaded by the JavaScript VM, overriding the `reactions` method inherited from the `State` prototype. To do that, the implementation of the `proto` function needs to access the `machine-check`’s extraction results. This is done by importing ⑤ a source module generated by `machine-check` that contains all protocol information in JSON format [36].

While the aforementioned duties of `machine-check` are crucial for `machine-runner`’s operation, the more interesting function of this build tool relates to the inference of local types and subscriptions (arrows ③ in Figure 2) as well as initiating the type-checking process on swarm protocols. To this end, the TypeScript compiler is used ① as a library to obtain ② a fully typed AST representation of the user program. Since we are only interested in machines, our entry points are `State` subclasses that are marked as initial states by a documentation

comment starting with “Initial state for role”, as is shown on line 5 of Listing 1. This comment serves the secondary purpose of naming the role this machine aspires to play (P for passenger in this example). The `@proto` decorator on line 6 not only has its runtime duties as explained above, it also carries in its argument the name of the swarm protocol that provides the context for the role name – we discuss both concepts in detail in the following sections; `machine-check` expects to find the definition of the swarm protocol in a correspondingly named file in JSON format. Finally, `machine-check` assembles the lists of command and event handler methods by inspecting (arrow ⑤) a state class’s method names and signatures and follows up with recursively processing the result types of event handlers in the same fashion. Any event type seen in an event handler argument list is automatically added to the subscription set of the machine (needed for the projection as explained in Section 5).

3.3 Type-checking, simulation and more

As a result of the analysis described above `machine-check` has assembled the following pieces for each machine definition within the user program: swarm protocol, role name, subscriptions, states, and transitions. Each such tuple is then passed – again in JSON format – to the `typechecking` tool, our third artifact contribution, written in Haskell. This tool first checks that the provided swarm protocol and subscription are well-formed (according to the rules presented in Section 6), computes the projection for the given role, and finally checks the inferred machine type for equivalence to the projection result (where state names are immaterial).

We provide a tool written in Haskell for the simulation of the formal operational semantics of the model. For a given protocol and subscription, the tool computes the projections and simulates the execution of swarms consisting of machines according to those projections. It supports both exhaustive and random generation of traces up to a given length. The tool has been used for checking claims and results about our running example.

The aforementioned tools are detailed in [28]. Through an example project, the accompanying paper also demonstrates the use of the inferred machine type to generically render a machine UI. Besides showing the current state of the computation, the UI gives the user the possibility to interact with machines by invoking enabled commands, where command arguments are gathered using automatically generated HTML forms.

4 Swarm protocols

A *swarm protocol* (hereafter also called *protocol* for short) describes the intended overarching event log structure realised by a swarm of machines; it corresponds to a global type in the terminology of session types, with our machines playing a similar role to local types. The protocol captures the overall communication structure as well as the details relevant for implementing it with machines. As it is customary with behavioural types, swarm protocols rely on an idealised environment where all communication is infallible and instantaneous. The link to the realisation in terms of machines is given in the following section by way of a projection operation.

When defining the syntax of swarm protocols, we follow the approach initiated in [7] that avoids fixing a syntactic representation of recursion and simplifies later treatment by instead using infinite regular trees. A swarm protocols is a possible infinite, *regular* term coinductively generated by the grammar in Table 3. A term is regular if it consists of finitely many *distinct* subterms. The language generated by the coinductive grammar is thus finitely representable either using the so-called “ μ notation” [31] or as solutions of finite sets of equations [9]. The

■ **Table 3** Swarm protocols: traverse a coinductive type to inductively build up an event log.

<p>Swarm protocol syntax: Regular terms generated by:</p> $\mathbf{G} ::= \sum_{i \in I} \mathbf{c}_i @ \mathbf{R}_i \langle \mathbf{l}_i \rangle . \mathbf{G}_i \mid \mathbf{0}$ <p>\mathbf{R}_i : role $\mathbf{c}, \mathbf{l}, l$: as for machines</p>	<p>State computation:</p> $\mathbf{G} \xrightarrow{\mathbf{c}_j / \mathbf{l}_j} \mathbf{G}_j \iff \mathbf{G} = \sum_{i \in I} \mathbf{c}_i @ \mathbf{R}_i \langle \mathbf{l}_i \rangle . \mathbf{G}_i \text{ and } j \in I$ $\delta(\mathbf{G}, l) = \begin{cases} \mathbf{G} & \text{if } l = \epsilon \\ \delta(\mathbf{G}', l'') & \text{if } \mathbf{G} \xrightarrow{\mathbf{c}/\mathbf{l}} \mathbf{G}' \text{ and } \vdash l' : \mathbf{l} \text{ and } l = l' \cdot l'' \\ \perp & \text{otherwise} \end{cases}$

interested reader is referred to [9] for a comprehensive treatment. Intuitively, the protocol progresses by some role \mathbf{R}_i invoking command \mathbf{c}_i , appending a non-empty event sequence of type \mathbf{l}_i to the global log and continuing as protocol \mathbf{G}_i . As discussed at the end of Section 2.4, the resolution of the choice specified in a swarm protocol is not coordinated among the instances of the roles involved in the choice (i.e. there is no unique selector). In fact, instances of different roles involved in the choice may enable commands at the same time as well as different instances of the same role may enable different commands (recall that each machine tracks a separate local log and event replication is asynchronous). This is in contrast to most other behavioural type systems hitherto, which do not permit such race conditions.

► **Definition 4.1** (Determinism). *A protocol $\mathbf{G} = \sum_{i \in I} \mathbf{c}_i @ \mathbf{R}_i \langle \mathbf{l}_i \rangle . \mathbf{G}_i$ is log-deterministic if the event types $\mathbf{l}_i[0]$ are pairwise different and all \mathbf{G}_i are log-deterministic. \mathbf{G} is command-deterministic if the tuples $(\mathbf{c}_i, \mathbf{R}_i)$ are pairwise different and all \mathbf{G}_i are command-deterministic. \mathbf{G} is deterministic if it is log-deterministic and command-deterministic.*

Hereafter we only consider deterministic swarm protocols. Note that determinism is evidently decidable on swarm protocols due to the regularity constraint.

► **Example 4.2** (Taxi service). The swarm protocol for the scenario in Example 1.1 is

$$\begin{aligned} \mathbf{G} &= \text{Request}@P \langle \text{Requested} \rangle . \mathbf{G}_{\text{auction}} \\ \mathbf{G}_{\text{auction}} &= \text{Offer}@T \langle \text{Bid} \cdot \text{BidderID} \rangle . \mathbf{G}_{\text{auction}} + \text{Select}@P \langle \text{Selected} \cdot \text{PassengerID} \rangle . \mathbf{G}_{\text{choose}} \\ \mathbf{G}_{\text{choose}} &= \text{Arrive}@T \langle \text{Arrived} \rangle . \text{Start}@P \langle \text{Started} \rangle . \mathbf{G}_{\text{ride}} + \text{Cancel}@P \langle \text{Cancelled} \rangle . \text{Receipt}@O \langle \text{Receipt} \rangle . \mathbf{0} \\ \mathbf{G}_{\text{ride}} &= \text{Record}@T \langle \text{Path} \rangle . \mathbf{G}_{\text{ride}} + \text{Finish}@P \langle \text{Finished} \cdot \text{Rating} \rangle . \text{Receipt}@O \langle \text{Receipt} \rangle . \mathbf{0} \end{aligned}$$

The structure in terms of commands and roles is straightforwardly induced from Example 1.1, with event log types filled in according to further requirements. The event type **BidderID** represents identifying information illustrating that not all events are of interest to all roles (e.g., the office does not need to know all bidders, it only needs to know which taxi was **Selected**). It is straightforward to check that \mathbf{G} is both log- and command-deterministic. ◻

Mirroring the formulation of machines we ascribe operational semantics to a swarm protocol via the generation and processing of an event log. The main difference in state computation is that swarm protocols generate and consume logs instead of events, as illustrated with the **Offer**, **Select**, and **Finish** commands in the example above.

The state reached by a swarm protocol \mathbf{G} after processing a log l is computed using an extension of the transition function δ as defined in Table 3. Analogously to the definition for machines, the transition function $\delta(\mathbf{G}, l)$ returns the continuation of the swarm protocol \mathbf{G} after processing the entire log l . We stress that δ is a partial function on swarm protocols, it is undefined when log l cannot be generated according to \mathbf{G} (unlike the definition of δ on machines, which is a total function since it just discharges unrecognised events). Note also that δ is well-defined over log-deterministic swarm protocols because a log in a branch cannot appear as a prefix of the logs of the remaining branches of the choice.

The operational semantics of a swarm protocol is defined as a labelled transition system given by rule [G-CMD] in Table 3. This rule states that a swarm protocol \mathbf{G} with log l enables command c , upon whose invocation the log is extended with fresh events l' of type $\mathbf{1}$ before possibly allowing another command to be invoked. The freshness of the events in l' can e.g. be guaranteed by the inclusion of node ID and logical timestamp.

► **Example 4.3** (Idealised taxi service). Consider the protocol from Example 4.2, starting out with (\mathbf{G}, ϵ) . After invoking the **Request** command our log contains *requested* and we reach state $\mathbf{G}_{\text{Auction}}$. Two bids later the passenger makes their selection, leading us to

$$\delta(\mathbf{G}, \text{requested} \cdot \text{bid}_A \cdot \text{bidderid}_A \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{selected} \cdot \text{passengerid}) = \mathbf{G}_{\text{choose}}$$

with $\mathbf{G}_{\text{choose}}$ offering two options: either the passenger invokes **Cancel** or the taxi **Arrives**. ◻

5 Projection

For the definition of our projection operation it is convenient to introduce a textual presentation of machines equivalent to the automata-based presentation used so far. Let κ denote a finite function mapping commands to non-empty log types; we allow ourselves to treat κ as set (the graph of function κ) and e.g. write $c / \mathbf{1} \in \kappa$ for $\kappa(c) = \mathbf{1}$ or else write $\{c_1 / \mathbf{1}_1, \dots, c_h / \mathbf{1}_h\}$ for the function κ mapping c_i to $\mathbf{1}_i$ for each $i \in \{1, \dots, h\}$. t_i ranges over event types.

Similarly to swarm protocols, the textual presentation of our machines is a regular term² of the following coinductive grammar:

$$\mathbf{M} ::=^{\text{co}} \kappa \cdot [t_1?M_1 \ \& \ \dots \ \& \ t_n?M_n] \quad (1)$$

and we abbreviate $\kappa \cdot [t_1?M_1 \ \& \ \dots \ \& \ t_n?M_n]$ as $\kappa \cdot \mathbf{0}$ when $n = 0$ and as $t_1?M_1 \ \& \ \dots \ \& \ t_n?M_n$ when κ is the empty map. We also write $\&_{1 \leq i \leq n} \mathbf{1}_i?M_i$ in place of $t_1?M_1 \ \& \ \dots \ \& \ t_n?M_n$.

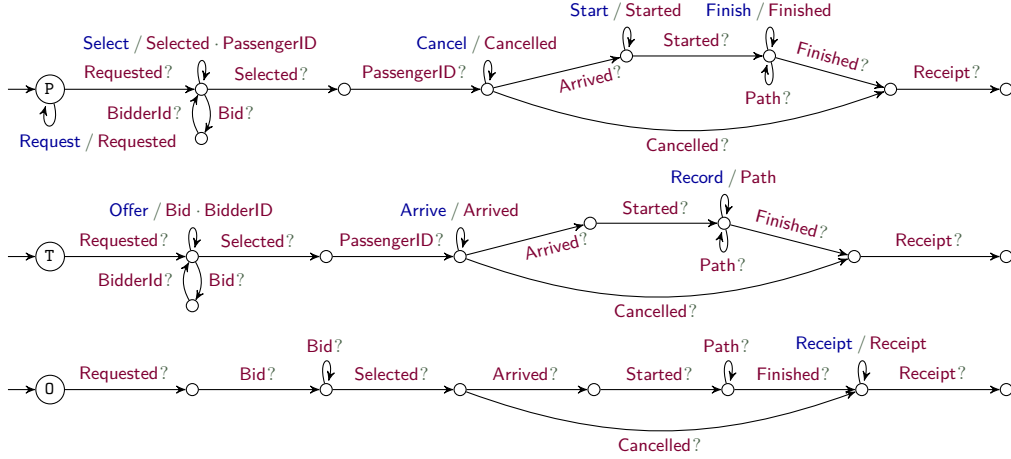

In turning our attention to projection operations we first note that the responsibility for driving the protocol forward is distributed across the participants: each transition in the swarm protocol is labelled with one role that may trigger it by invoking the command. Each machine plays one role, whose machine specification is obtained by the projection operation $\mathbf{G} \downarrow_{\mathbf{R}}$. Note that multiple machines may implement the same role.

One could define $\mathbf{G} \downarrow_{\mathbf{R}}$ such that each transition in \mathbf{G} produces a series of event transitions in the machine plus a command invocation on the originating state if the role matches.

$$\left(\sum_{i \in I} c_i @_{\mathbf{R}_i} \langle \mathbf{1}_i \rangle \cdot \mathbf{G}_i \right) \downarrow_{\mathbf{R}} = \kappa \cdot [\&_{i \in I} \mathbf{1}_i? \mathbf{G}_i \downarrow_{\mathbf{R}}] \quad \text{where} \quad \kappa = \{(c_i / \mathbf{1}_i) \mid \mathbf{R}_i = \mathbf{R} \text{ and } i \in I\}$$

² The correspondence between these regular terms and finite-state automata yields exactly the presentation of machines in terms of finite-state automata that we have adopted so far.

15:14 Behavioural Types for Local-First Software

■ **Figure 3** Projection of Example 4.2 on P, T, and O as automata.

Albeit simple, this projection scheme generates unnecessarily large machines in all but the most trivial cases. More crucially, forcing each machine to process all events is undesirable for reasons of security and efficiency. It would be highly desirable to allow some information to be kept secret from certain roles (like `passengerID` in Example 4.2), and it would be most efficient if every role processed just enough information to correctly enable and disable command invocations. We therefore define a more appealing construction.

Our projections are based on the notion of whether a machine shall process a certain type of event. Formally, the projection operation is parameterised by a *subscription*, namely a map σ assigning to each role the set of event types that it reacts to. Given a set of log types E , let $filter(_, E)$ be a function transforming a log type, retaining only the event types in E while preserving their relative order. Intuitively, subscriptions correspond to topics in a publish–subscribe framework whereby processes declare which kinds of messages they are interested in receiving.

► **Definition 5.1** (Projection). *Given a swarm protocol G and a subscription σ , the projection of G over a role R with respect to σ , written $G \downarrow_R^\sigma$, is defined as follows:*

$$\left(\sum_{i \in I} c_i @ R_i \langle \mathbf{1}_i \rangle \cdot G_i \right) \downarrow_R^\sigma = \{ c_i / \mathbf{1}_i \mid R_i = R \text{ and } i \in I \} \cdot [\&_{j \in J} filter(\mathbf{1}_j, \sigma(R)) ? (G_j \downarrow_R^\sigma)]$$

where $J = \{ i \in I \mid filter(\mathbf{1}_i, \sigma(R)) \neq \epsilon \}$.

Notice that we omit the projection of a branch when a role R is not subscribed to any of the event types emitted by the command that selects that branch. We opted for this simplification of the formalism because our well-formedness conditions (cf. Section 6) ensure that if a role is involved in the continuation it will subscribe to the the first event in the branch. Further, note that this pruning applies to branches in isolation, later states reachable by other paths remain part of the projection.

► **Example 5.2.** Let σ be such that $\sigma(P)$ consists of all the event types in the protocol G defined in Example 4.2. The projections of G are in Figure 3. ┘

6 Well-formedness

We now focus on the *well-formedness* conditions of our swarm protocols. As is standard in behavioural types, sufficient conditions are established on global specifications that guarantee relevant properties on projections such as deadlock or lock freedom and absence of orphan messages. The properties of interest to us are quite different from those common in standard settings since we aim to guarantee that eventual consensus is reached even when some of the participants make choices that are discordant due to their incomplete view on the global log. The idea is that transitory deviations are *tolerated* provided that consistency is eventually recovered, which happens once information has sufficiently spread within the swarm. For instance, a taxi in our running example may keep bidding for a passenger's auction after the passenger has made their selection as long as the selection event has not yet been received. This temporary inconsistency is recognised and resolved once the events have propagated to the deviating taxi and the passenger, respectively.

Realising swarms with this property is not straightforward. The rest of this section illustrates the problems arising in our setting with a few examples. For each problem we identify sufficient conditions on our swarm protocols that rule out the problem for coordination issues in realistic scenarios based on our running example). These conditions culminate in our definition of *well-formedness* (cf. Definition 6.7).

6.1 On causality and propagation

The first problem we look at is related to how a command is disabled once it has been invoked. In our setting, this boils down to fine tuning the registration of roles to event types. For example, if a command c should be enabled only after another, say c' has been executed, then the role executing c' should be subscribed to some event type emitted in response to the execution of c . Another example is that a command can stay perpetually enabled if the role executing it is oblivious of all resulting events (cf. [27]).

Another class of problems is caused by the fact that events propagate asynchronously within a swarm and that an emission of multiple events is not guaranteed to reach all other machines as one atomic transmission (cf. [27]) This anomaly may be excluded by a runtime system that never applies the [PROP] rule to a strict subset of the event log emitted by a single command, i.e. it treats the log from each command invocation as an atomic unit. We chose to not restrict the way in which a runtime system should propagate events between network sites because we consider it important that implementations be free to optimise their strategy in different ways (e.g. for latency, bandwidth, efficiency, or consistency).

We define the *active* roles of a swarm protocol G as those that can select one of the branches in the top-level choice of G and – given a subscription σ – the *roles* of G as those that can invoke commands or are subscribed to events in G . Formally,

$$\begin{aligned} \text{active}\left(\sum_{i \in I} c_i @ R_i \langle \mathbf{1}_i \rangle . G_i\right) &= \{R_i \mid i \in I\} \\ \text{roles}\left(\sum_{i \in I} c_i @ R_i \langle \mathbf{1}_i \rangle . G_i, \sigma\right) &= \bigcup_{i \in I} (\{R \in \text{dom } \sigma \mid R_i = R \vee \mathbf{1}_i \cap \sigma(R) \neq \emptyset\} \cup \text{roles}(G_i, \sigma)) \end{aligned}$$

(note that the latter is a coinductive definition). With this notation we define the following sufficient condition for avoiding the aforementioned problems.

► **Definition 6.1** (Causal consistency). *A swarm protocol $\sum_{i \in I} c_i @ R_i \langle \mathbf{1}_i \rangle . G_i$ is causal-consistent in a subscription σ if for all $i \in I$*

1. $\mathbf{1}_i \cap \sigma(\mathbf{R}_i) \neq \emptyset$, and
2. $\mathbf{R} \in \text{active}(\mathbf{G}_i)$ implies $\mathbf{1}_i \cap \sigma(\mathbf{R}) \neq \emptyset$ and for all $\mathbf{R}' \in \text{roles}(\mathbf{G}_i, \sigma)$, $\mathbf{1}_i \cap \sigma(\mathbf{R}') \subseteq \mathbf{1}_i \cap \sigma(\mathbf{R})$

Condition (1) requires that the role that performs one of the commands c_i should observe some of the corresponding emitted events $\mathbf{1}_i$. This simple mechanism ensures that repeated command invocation can only occur where foreseen in the swarm protocol. Condition (2) ensures the adequate tracking of causality for subsequent command invocations. The first part ensures that the immediately following command must wait for the enabling transition to occur, while the second part guarantees the ordering of the subsequent command's generated events after all events from the preceding command that are observed by some role in the further evolution of the protocol.

► **Example 6.2.** The protocol of the running example \mathbf{G} in Example 4.2 is causal-consistent for the subscription σ in Example 5.2. In fact, the commands generate logs that start with pairwise-different event types. Hence, the conditions straightforwardly hold for roles P and T, which observe every event. For O, we observe that they only execute the command `receipt`; which should be performed after `Cancelled` or `Finished`, which are also observed by O. ─

6.2 On distributed choices

The next anomaly we study is caused by the fact that our model permits multiple roles to be active at the same time without coordination – this property is essential for perfect availability as demanded by local-first cooperation. Such behaviour would be ruled out in all the global type systems we are aware of. Our strategy for coping with the inevitably arising conflicts is that we permit machines to make inconsistent local decisions but reconcile those once the corresponding events have propagated to all relevant parties (e.g., the office in our example can make a choice inconsistent with the decisions taken by other participants as shown in see [27]). We fix this by requiring *determinacy*.

► **Definition 6.3** (Determinacy). A swarm protocol $\mathbf{G} = \sum_{i \in I} c_i @ \mathbf{R}_i \langle \mathbf{1}_i \rangle$. \mathbf{G}_i is determinate for subscription σ if it is causal-consistent and $\mathbf{R} \in \text{roles}(\mathbf{G}_i, \sigma)$ implies $\mathbf{1}_i[0] \in \sigma(\mathbf{R})$ for $i \in I$.

This definition of determinacy is prompted by our determinism rule (Definition 4.1): we identify a branch by the first event type of its emitted log. Note that a role involved in one branch but not in another may invoke commands that are later invalidated without that role being able to recognise this situation; we will explore mechanisms for compensating such errors in future work, which may require strengthening the rule above.

► **Example 6.4.** The swarm protocol \mathbf{G} in Example 4.2 is determinate for the subscription σ in Example 5.2. ─

6.3 On interference

Events emitted by the losing parties to a conflict should be ignored in order to let every machine eventually agree on each choice. Each machine must locally be able to ignore such events, which means that it would be problematic to confuse a machine by emitting such a branch-choosing event in another context (e.g. while proceeding along a sibling branch which this machine does not follow). We avoid this confusion by requiring that any branch of a swarm protocol is communicated using a dedicated event type, i.e. that event type cannot be emitted by any other command. We formulate this notion in terms of the set *subterms*(\mathbf{G}) of all subterms (incl. indirect) of a swarm protocol \mathbf{G} . Recall that this set is finite because our swarm protocols are regular.

In what follows we write $events(\mathbf{G})$ and $guards(\mathbf{G})$ respectively for the sets of all event types and the ones that identify branches; formally, if $\mathbf{G} = \sum_{i \in I} \mathbf{c}_i @ \mathbf{R}_i \langle \mathbf{1}_i \rangle . \mathbf{G}_i$ then

$$events(\mathbf{G}) = \bigcup_{i \in I} \left(events(\mathbf{G}_i) \cup \bigcup_j \mathbf{1}_i[j] \right) \quad \text{and} \quad guards(\mathbf{G}) = \bigcup_{i \in I} (\{\mathbf{1}_i[0]\} \cup guards(\mathbf{G}_i))$$

(observe that $events(\mathbf{0}) = guards(\mathbf{0}) = \emptyset$ and that these coinductively defined sets correspond to computable greatest fixpoint since swarm protocols are regular trees).

A swarm protocol \mathbf{G} is *invariant under event type* \mathbf{t} if either (i) \mathbf{t} does not appear in \mathbf{G} , i.e. $\mathbf{t} \notin events(\mathbf{G})$ or (ii) it only appears as part of the same choice, i.e. there is a unique $\mathbf{G}' \in subterms(\mathbf{G})$ such that $\mathbf{G}' \xrightarrow{\mathbf{c}/\mathbf{1}}$ and $\mathbf{t} \in \mathbf{1}$.

► **Definition 6.5** (Confusion-freeness). *A swarm protocol \mathbf{G} is confusion-free if \mathbf{G} is invariant for all event types in $guards(\mathbf{G})$.*

► **Example 6.6.** It is easy to check that the protocol of the running example \mathbf{G} in Example 4.2 is invariant for all types. The only type appearing in two guards is **Receipt**; however, the occurrences are associated to the same subterm. Hence, the protocol is confusion-free. ◻

6.4 Putting the pieces together

With this, we can finally state our *well-formedness* condition.

► **Definition 6.7** (Well-formedness). *A swarm protocol $\mathbf{G} = \sum_{i \in I} \mathbf{c}_i @ \mathbf{R}_i \langle \mathbf{1}_i \rangle . \mathbf{G}_i$ is well-formed with respect to a subscription σ (σ -WF for short) if*

1. \mathbf{G} is causal-consistent, determinate, and confusion-free; and
2. \mathbf{G}_i is σ -WF for all $i \in I$;

Note that well-formedness is defined coinductively and decidable on swarm protocols.

► **Example 6.8.** Examples 6.2, 6.4, and 6.6 imply that the protocol \mathbf{G} in Example 4.2 is well-formed with respect to the subscription σ given in Example 5.2. ◻

Projection preserves determinism in well-formed protocols:

► **Proposition 6.9.** *Let \mathbf{G} and σ respectively be a swarm protocol and a subscription. If \mathbf{G} is σ -WF then $\mathbf{G} \downarrow_{\mathbf{R}}^{\sigma}$ is deterministic for all \mathbf{R} .*

Well-formed swarm protocols guarantee that local machines reach eventual consensus [38] on each choice, as we show next. However, anomalies (cf. [27]) occur at system level:

- Machines could have commands enabled that would be disabled if the model were synchronous; this may lead to the emission of events that need to be ignored later.
- Events are ignored according to their type only, therefore even after full propagation of the events in the global log a machine may process events stemming from the anomalous invocation of a command.

We note that the first anomaly above is inherent to local-first architecture requirements.

The second anomaly can be avoided by a runtime system that tracks full causality information. We chose to not require full causality tracking since it imposes additional storage, communication, and computation requirements on the implementation. Our weaker causality model supports deployment on less capable hardware where needed.

7 Correct Realisations of swarm protocols

We now turn our attention to the formal characterisation of *correct implementations* of swarm protocols. As discussed in the previous sections, we deviate from the usual expected properties of mainstream (multiparty) session types, such as communication safety, session fidelity, and progress (i.e., absence of deadlocks or its variants). We first note that there are no communication mismatches in our model because every machine simply ignores unexpected or unwanted events (recall the definition of δ in Section 2.1). Session fidelity instead advocates implementations that behave as described by their types, which customarily means that the states of all components are always aligned with the global state of the protocol. Contrastingly, we aim to tolerate deviations provided that all machines eventually agree on the state of the execution of the protocol. In our setting, an implementation may be correct even if machines temporarily diverge, executing different branches of the protocol; this is quite expected if we allow independent decisions taken based on incomplete views of the global state. Consequently, correct implementations may perform sequences of commands – and hence generate logs – that are different from those derived from the corresponding protocol. In such cases, we still expect machines to be able to eventually agree on an interpretation of the log that matches one possible execution of the specification.

We tackle this problem by first defining the relevant events of an execution, namely those that are part of the *effective log*. Based on this, we establish an equivalence relation on logs that allows us to characterise the logs that can be produced by an execution of a swarm protocol's realisation as a swarm. Armed with these tools we then state that all correct realisations produce valid effective logs and that all swarm protocol executions have corresponding swarms that realise them.

7.1 Eventual fidelity

We start by introducing some machinery for making precise the notion of correct implementation of a swarm protocol.

Roughly, one may think that (\mathbf{S}, ϵ) is a faithful implementation of a swarm protocol \mathbf{G} if it produces only global logs that can be generated by \mathbf{G} . However, this notion is too strong for our setting; in fact, we appeal to a weaker notion of fidelity such that for any global log l produced by (\mathbf{S}, ϵ) , i.e. $(\mathbf{S}, \epsilon) \Longrightarrow (\mathbf{S}, l)$, there is a *related* log l' that \mathbf{G} admits, i.e. $(\mathbf{G}, \epsilon) \Longrightarrow (\mathbf{G}, l')$. We postpone for a moment the formal definition of the expected relation between logs, and convey some intuitions in the following example.

► **Example 7.1.** Consider the swarm protocol \mathbf{G} in Example 4.2, and the swarm $(\mathbf{P}, \epsilon) \mid (\mathbf{T}, \epsilon) \mid (\mathbf{0}, \epsilon) \mid (\mathbf{T}, \epsilon) \mid \epsilon$ having three taxis dubbed A , B , and C . The swarm can produce the global log

$$l_{\text{auc}} = \text{requested} \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{bid}_A \cdot \text{bidderid}_A \cdot \text{selected} \cdot \text{bid}_C \cdot \text{bidderid}_C \cdot \text{passengerid}$$

Contrastingly, \mathbf{G} cannot generate such log; in fact, the protocol continuation after generating the prefix $l_1 = \text{requested} \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{bid}_A \cdot \text{bidderid}_A$ is $\delta(\mathbf{G}, l_{\text{auc}}) = \mathbf{G}_{\text{Bid}}$; hence, log l_1 can only grow by appending $\text{bid}_C \cdot \text{bidderid}_C$ or $\text{selected} \cdot \text{passengerid}$. In the second case, we obtain the log $l_2 = \text{requested} \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{bid}_A \cdot \text{bidderid}_A \cdot \text{selected} \cdot \text{passengerid}$. Remarkably, all the machines discard the events bid_C and bidderid_C when processing l_{auc} , i.e., they behave as if they were processing l_2 . In fact, $\delta(\mathbf{P}, l_{\text{auc}}) = \delta(\mathbf{P}, l_2)$, $\delta(\mathbf{T}, l_{\text{auc}}) = \delta(\mathbf{T}, l_2)$ and $\delta(\mathbf{0}, l_{\text{auc}}) = \delta(\mathbf{0}, l_2)$. \lrcorner

As highlighted by the previous example, despite the actual log generated by the swarm differing from the logs generated by the protocol, all the machines are able to consistently discard those ill-generated events after complete propagation. In other words, the states of the machines in the swarm depend only on a subset of the events in the log. We characterise such subset via a type, called *effective type*. Intuitively, the effective type of a log is the type of the sublog containing all those events that are effectively relevant to the machines in the swarm. Given a protocol G and a subscription σ , we expect an implementation to process only those events which some role has been subscribed to; consequently, our notion of *effective type* is relative to a subscription. However, the effective type of a log is not just the projection of its type with respect to the image of the subscription σ . This is illustrated in the following example.

► **Example 7.2** (Effective type and projection). The type of the log l_{auc} in Example 7.1 is

$$l_{\text{auc}} = \text{Requested} \cdot \text{Bid} \cdot \text{BidderID} \cdot \text{Bid} \cdot \text{BidderID} \cdot \text{Selected} \cdot \text{Bid} \cdot \text{BidderID} \cdot \text{PassengerID}$$

which differs from the type of l_2 which is $\text{Requested} \cdot \text{Bid} \cdot \text{BidderID} \cdot \text{Bid} \cdot \text{BidderID} \cdot \text{Selected} \cdot \text{PassengerID}$. Let us consider a subscription σ such that $\sigma(P) \supseteq \{\text{Requested}, \text{Bid}, \text{BidderID}, \text{Selected}, \text{PassengerID}\}$. Then, if we just keep the sublog of l_{auc} containing all types for which at least one role has been subscribed to, then we obtain exactly l_{auc} , which does not reflect the type of the sublog that is effectively processed by the machines. For this reason, the effective type depends also on the protocol being implemented. \lrcorner

► **Definition 7.3** (Effective type). *The effective type of a log l with respect to a swarm protocol G and a subscription σ , written $\mathbb{T}_\sigma(l, G) = \mathbb{T}_\sigma(l, G, \epsilon)$, is defined as follows*

$$\mathbb{T}_\sigma(\epsilon, G, \mathbf{1}) = \epsilon \quad (2)$$

$$\mathbb{T}_\sigma(e \cdot l, G, \epsilon) = \mathbf{t} \cdot \mathbb{T}_\sigma(l, G', \mathbf{1}') \quad \text{if } \vdash e : \mathbf{t}, \mathbf{t} \in \sigma(\text{roles}(G, \sigma)), G \xrightarrow{c/\mathbf{t} \cdot \mathbf{1}} G', \text{ and } \mathbf{1}' = \text{filter}(\mathbf{1}, \sigma(\text{active}(G'))) \quad (3)$$

$$\mathbb{T}_\sigma(e \cdot l, G, \mathbf{t} \cdot \mathbf{1}) = \mathbf{t} \cdot \mathbb{T}_\sigma(l, G, \mathbf{1}) \quad \text{if } \vdash e : \mathbf{t} \quad (4)$$

$$\mathbb{T}_\sigma(e \cdot l, G, \mathbf{1}) = \mathbb{T}_\sigma(l, G, \mathbf{1}) \quad \text{otherwise} \quad (5)$$

As expected, the effective type of an empty log is the empty log type. The effective type of a non-empty log keeps track of those events that match the type of a log that can be generated by the protocol (and discards all ill-ordered events). Hence, the effective type of $e \cdot l$ with respect to G records the type \mathbf{t} of the first event e only if it has a type that is expected by the protocol (namely at least one of the roles in the protocol is subscribed to that type). According to case (3), a protocol G expects some event whose type \mathbf{t} coincides with the guard of one of its branches and at least one role is subscribed to \mathbf{t} . In such case, the effective type of the remaining log l is processed first by consuming events of type $\mathbf{1}'$ (rule (4)), which is the sequence of the remaining types generated by the branch that are observed by the *active* roles in the continuation G' , followed by considering the continuation G' . We remark here that only the types of events that are relevant for active roles are reflected in the effective type (more details are given in Section 7.2.1). Note that the types that are not observed are just disregarded from the effective type as per (5). We have that $\mathbb{T}_\sigma(l, G)$ is a well-defined function over deterministic swarm protocols because log-determinism (Definition 4.1) ensures that at most one branch of G can match the event type \mathbf{t} of the event e .

► **Example 7.4.** Let G_{auction} and G_{choose} the swarm protocol in Example 4.2. We have

$$G_{\text{auction}} \xrightarrow{\text{Offer}@\mathbf{T}(\text{Bid} \cdot \text{BidderID})} G_{\text{auction}} \quad (6) \quad G_{\text{auction}} \xrightarrow{\text{Select}@\mathbf{T}(\text{Selected} \cdot \text{PassengerID})} G_{\text{choose}} \quad (7)$$

15:20 Behavioural Types for Local-First Software

Let us compute the effective type of the log $l = \text{bid}_A \cdot \text{bidderid}_A \cdot \text{rating} \cdot l'$ on $\mathbf{G}_{\text{auction}}$ using a subscription σ for which \mathbf{P} , \mathbf{T} and \mathbf{O} are subscribed to all events but rating . We have

$$\begin{aligned} \mathbb{T}_\sigma(l, \mathbf{G}_{\text{auction}}) &= \mathbf{Bid} \cdot \mathbb{T}_\sigma(\text{bidderid}_A \cdot \text{rating} \cdot l', \mathbf{G}_{\text{auction}}, \mathbf{BidderID}) \\ &= \mathbf{Bid} \cdot \mathbf{BidderID} \cdot \mathbb{T}_\sigma(\text{rating} \cdot l', \mathbf{G}_{\text{auction}}, \epsilon) \\ &= \mathbf{Bid} \cdot \mathbf{BidderID} \cdot \mathbb{T}_\sigma(l', \mathbf{G}_{\text{auction}}, \epsilon) \end{aligned}$$

where the first equality holds by (3) since $\mathbf{Bid} \in \sigma(\mathbf{T})$ and (6), the second equality holds by (4) since $\vdash \text{bidderid}_A : \mathbf{BidderID}$, and the third equation holds by (5) since by hypothesis $\text{rating} \notin \sigma(\mathbf{P}) \cup \sigma(\mathbf{T}) \cup \sigma(\mathbf{O})$. If $l' = \epsilon$ then $\mathbb{T}_\sigma(l, \mathbf{G}_{\text{auction}}) = \mathbf{Bid} \cdot \mathbf{BidderID}$ by (2).

Suppose instead that $l' = \text{selected} \cdot \text{passengerid} \cdot \text{bid}_B \cdot \text{bidderid}_B$. Then, similarly to the first two equations above (using (7)), we have

$$\mathbb{T}_\sigma(l', \mathbf{G}_{\text{auction}}, \epsilon) = \mathbf{Selected} \cdot \mathbf{PassengerID} \cdot \mathbb{T}_\sigma(\text{bid}_B \cdot \text{bidderid}_B, \mathbf{G}_{\text{choose}}, \epsilon)$$

And, by (4), $\mathbb{T}_\sigma(\text{bid}_B \cdot \text{bidderid}_B, \mathbf{G}_{\text{choose}}, \epsilon) = \mathbb{T}_\sigma(\epsilon, \mathbf{G}_{\text{choose}}, \epsilon) = \epsilon$. \lrcorner

The relation between logs of an implementation with those of a specification that we need is the equivalence induced by the equality of their effective types.

► **Definition 7.5** (Log equivalence). *Two logs l and l' are equivalent with respect to a swarm protocol \mathbf{G} and a subscription σ , written $l \equiv_{\mathbf{G}, \sigma} l'$, if they have the same effective type with respect to \mathbf{G} and σ , i.e., $\mathbb{T}_\sigma(l, \mathbf{G}) = \mathbb{T}_\sigma(l', \mathbf{G})$.*

Then, the notion of correct implementation is simply stated as follows.

► **Definition 7.6** (Eventual fidelity). *A swarm (\mathbf{S}, ϵ) is eventually faithful to a swarm protocol \mathbf{G} and a subscription σ if $(\mathbf{S}, \epsilon) \implies (\mathbf{S}, l)$ implies $(\mathbf{G}, \epsilon) \implies (\mathbf{G}, l')$ and $l \equiv_{\mathbf{G}, \sigma} l'$ for a log l' .*

7.2 Implementation correctness by projection

Our projection operation yields an effective procedure for obtaining correct implementations out of well-formed swarm protocols which we call *realisations*.

► **Definition 7.7** (Realisation). *Let \mathbf{G} be a swarm protocol and σ be a subscription. A realisation (of size n) of \mathbf{G} with respect to σ , shortened as (σ, \mathbf{G}) -realisation, is a swarm (\mathbf{S}, ϵ) of size n such that, for each $1 \leq i \leq n$, there exists a role $\mathbf{R} \in \text{roles}(\mathbf{G}, \sigma)$ such that $\mathbf{S}(i) = (\mathbf{G} \downarrow_{\mathbf{R}}^\sigma, \epsilon)$. A realisation \mathbf{S} is complete if for all $\mathbf{R} \in \text{roles}(\mathbf{G}, \sigma)$ there exists $1 \leq i \leq n$ such that $\mathbf{S}(i) = (\mathbf{G} \downarrow_{\mathbf{R}}^\sigma, \epsilon)$; we call partial a realisation which is not complete.*

Remarkably, the number of machines in a realisation is not related to the number of roles in the corresponding swarm protocol. Indeed, Definition 7.7 simply requires that each machine in the swarm plays one of the roles in the swarm protocol. Concretely, we may have several components implementing the same role (i.e., the role is replicated) as well as roles without a corresponding machine, that is partial realisations.

► **Example 7.8** (Realisations). The swarm protocol in Example 4.2 would typically be realised by one machine for the passenger $\mathbf{G} \downarrow_{\mathbf{P}}^\sigma$, several taxis running the machine $\mathbf{G} \downarrow_{\mathbf{T}}^\sigma$, and at least one accounting office running $\mathbf{G} \downarrow_{\mathbf{O}}^\sigma$. A partial realisation could be one without an accounting office, in which case no machine can generate **receipt** events. \lrcorner

The rest of this section is devoted to showing that realisations (either complete or partial) are eventually faithful if they are obtained by projecting well-formed swarm protocols.

7.2.1 Projections and effective types

We first establish a correspondence between the behaviour of a single projection and that of the respective protocol. In particular, we show that effective types provide an accurate abstraction of the information contained in a log that is relevant for a role. Concretely, the next result states that a projection enables a command after processing a log l only when the protocol enables the same command after producing an equivalent log l' .

► **Lemma 7.9.** *If G is a σ -WF swarm protocol and $(\delta(G \downarrow_R^\sigma, l)) \downarrow_{c/1}$ then there exists $l' \equiv_{G,\sigma} l$ such that $(G, \epsilon) \Longrightarrow (G, l')$ and $\delta(G, l') \xrightarrow{c/1} G'$.*

Apparently equivalent logs are indistinguishable for a machine, i.e., $l \equiv_{G,\sigma} l'$ implies $\delta(G \downarrow_R^\sigma, l) = \delta(G \downarrow_R^\sigma, l')$. However this might not be the case if logs do not include all the events generated by the same command as shown in the next example.

► **Example 7.10.** Consider the swarm protocol $G = c@R\langle a \cdot b \rangle . d@S\langle c \rangle . 0$ with $\sigma = \{R \mapsto \{a, b\}, S \mapsto \{a, c\}\}$. If $\vdash a : a$ and $\vdash b : b$ then $\mathbb{T}_\sigma(a, G) = a$ and $\mathbb{T}_\sigma(a \cdot b, G) = a$; in fact the first equation holds by definition and the second holds because $b \notin \sigma(\text{active}(d@S\langle c \rangle . 0')) = \sigma(S) = \{a, c\}$. Therefore, $a \equiv_{G,\sigma} a \cdot b$. Now take the projection of G over R with respect to σ , i.e., $M_R = G \downarrow_R^\sigma = a?b?(d@S\langle c \rangle . 0 \downarrow_R^\sigma) = a?b?0$. Clearly $\delta(M_R, a \cdot b) \neq \delta(M_R, a)$. ◻

Two considerations on Example 7.10 are worthwhile. On the one hand, while $a \cdot b$ has all the events produced by the execution of the command c , the log consisting of just the event a does not. Since we assume that all events are eventually propagated, our technical development in the next section will disregard incomplete (global) logs. On the other hand, one may wonder about the fact that effective types do not collect information of events that are not observed by active roles. This is essential to account for the fact that a realisation may interject events. For instance, a realisation may actually generate a log of type $a \cdot c \cdot b$ because a machine that implements the role S may perform the command d as soon as it processes an event of type a ; hence the generated event can precede the one of type b in the consolidated log. If our notion of log equivalence were fine enough to distinguish logs of type $a \cdot c \cdot b$ from $a \cdot b \cdot c$ then we would rule out implementations behaving as above, which is not what we want because the interaction does not violate the protocol.

7.2.2 Characterisation of the logs admitted by a protocol

We now provide a characterisation of the logs that can be generated by a realisation of a well-formed swarm protocol. To do this we have to take into account for the possible reordering and the spurious events that can be generated by machines that faithfully implement a protocol. Intuitively, we may think that a realisation generates logs that correspond to the combination of several executions of the protocol, which might share a common prefix. Consider again the swarm protocol G in Example 4.2. As discussed in Example 7.1, we expect realisations to be able to generate logs such as l_{auc} of this example. Note that such log can be generated by merging, among others, two different reductions of G , e.g. $(G, \epsilon) \Longrightarrow (G, \text{requested} \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{bid}_A \cdot \text{bidderid}_A \cdot \text{selected} \cdot \text{passengerid})$ and $(G, \epsilon) \Longrightarrow (G, \text{requested} \cdot \text{bid}_B \cdot \text{bidderid}_B \cdot \text{bid}_C \cdot \text{bidderid}_C)$. Note that the reductions share events (accounting for an scenario in which the computation has diverged). Intuitively, two runs can be combined either if they produce disjoint logs or they share events that come from a common execution prefix (as in the previous example). Formally, two runs $(G, \epsilon) \Longrightarrow (G, l_i)$ with $i = 1, 2$ are *consistent* if there exist logs $l, l'_1 \cap l'_2 = \emptyset$, such that $l_i = l \cdot l'_i$ and $(G, \epsilon) \Longrightarrow (G, l) \Longrightarrow (G, l \cdot l'_i)$

for $i = 1, 2$. The notion of consistency is lifted to sets of runs $\{(\mathbf{G}, \epsilon) \Longrightarrow (\mathbf{G}, l_i)\}_{1 \leq i \leq k}$, by requiring pair-wise consistency. We write l_i^j for the sequence of events produced by the j -th step in the reduction i , i.e., $(\mathbf{G}, \epsilon) \Longrightarrow^{j-1} (\mathbf{G}, l_i^j) \xrightarrow{c/1} (\mathbf{G}, l_i^j \cdot l_i^j) \Longrightarrow (\mathbf{G}, l_i)$.

► **Definition 7.11** (Admissible log). *A log l is admissible for a σ -WF protocol \mathbf{G} if there are consistent runs $\{(\mathbf{G}, \epsilon) \Longrightarrow (\mathbf{G}, l_i)\}_{1 \leq i \leq k}$ and a log $l' \in (\bowtie_{1 \leq i \leq k} l_i)$ with $l' \equiv_{\mathbf{G}, \sigma} l = \bigcup_{1 \leq i \leq k} l_i$, and for all $1 \leq i \leq k$ and $l_i^j \sqsubseteq l$ for all events l_i^j produced by the j -th step in reduction i .*

Remarkably, admissible logs are not just those that can be obtained by merging several logs l_i ; it may be the case that l is admissible but $l \notin (\bowtie_{1 \leq i \leq k} l_i)$. In fact the notion is weaker and accounts for the possible reorderings of events that do not change the effective type of the log. Consider the protocol in Example 7.10 and its complete realisation consisting of two machines. As previously discussed, that realisation may generate a log of type $a \cdot c \cdot b$. With a single run of the protocol, i.e. by fixing $k = 1$ and taking $(\mathbf{G}, \epsilon) \xrightarrow{c/a \cdot b} (\mathbf{G}, a \cdot b) \xrightarrow{d/c} (\mathbf{G}, l_1)$ with $l_1 = a \cdot b \cdot c$, we can conclude that $a \cdot c \cdot b$ is generated by some realisation. Note that $\bowtie_{1 \leq i \leq 1} l_i = \{l_1\} = \{a \cdot b \cdot c\}$. Hence, $l' \in \bowtie_{1 \leq i \leq 1} l_i$ iff $l' = a \cdot b \cdot c$ and $\mathbb{T}_\sigma(l', \mathbf{G}) = a \cdot c$. Then, the log $a \cdot c \cdot b$ is equivalent (i.e., it has the same effective type), and moreover it has the same elements and preserves the relative order between events generated by the same command (i.e., a precedes b). Hence, we conclude that the protocol admits the log $a \cdot c \cdot b$. On the contrary, the last condition $l_i^j \sqsubseteq l$ about the preservation of the relative order of events generated by the same command bans logs such as $b \cdot a \cdot c$.

Next lemma ensures that any admissible log of a well-formed protocol is equivalent to a log obtained by the sequential execution of the protocol. Namely, despite a log may contain events produced by conflicting decisions, its effective type corresponds to a sequential run.

► **Lemma 7.12.** *If l is admissible for a σ -WF swarm protocol \mathbf{G} then there exists a log l' such that $(\mathbf{G}, \epsilon) \Longrightarrow (\mathbf{G}, l')$ and $l \equiv_{\mathbf{G}, \sigma} l'$.*

Moreover, if we extend an admissible log with events generated by the execution of command enabled over a partial view of the global log, then we obtain an admissible log. This property is instrumental for our main result in the following section (Theorem 7.14).

► **Lemma 7.13.** *Let l_1 and $l_2 \subseteq l_1$ be admissible logs for a σ -WF swarm protocol \mathbf{G} . If $(\mathbf{G}, l_2) \xrightarrow{c/1} (\mathbf{G}, l_2 \cdot l_3)$ and $l \in l_1 \bowtie (l_2 \cdot l_3)$ then l is admissible for \mathbf{G} .*

7.2.3 Realisations are faithful

Our key result shows that realisations of well-formed protocols only generate admissible logs.

► **Theorem 7.14.** *Let (\mathbf{S}, ϵ) be a realisation of a σ -WF swarm protocol \mathbf{G} . If $(\mathbf{S}, \epsilon) \Longrightarrow (\mathbf{S}', l)$ then l is admissible for \mathbf{G} .*

Since every admissible log is equivalent to a log generated by the protocol (Lemma 7.12), we conclude that any realisation of a well-formed swarm protocol is eventually faithful (i.e., correct). Note that this implies that all realisations of a well-formed swarm protocol exhibit eventual consensus [38] regarding which branch is taken in its choices (concretely, there is a $\xrightarrow{\tau}$ step after which all machines take the same branch in their state computation).

► **Corollary 7.15.** *Every realisation of size n of a σ -WF swarm protocol \mathbf{G} is eventually faithful with respect to \mathbf{G} and σ .*

The above result is independent from the number of replicas that implement each role; it also holds for partial realisations (i.e., when some roles are absent).

7.3 Implementation completeness

Differently from common session type systems, the behaviour of a complete realisation (i.e., one in which every role is implemented) is complete with respect to the protocol, in the sense that every reduction of the protocol can be mimicked by the realisation. This derives from the fact that non-determinism in our model arises from the execution of external commands but not because of the abstraction of internal (and customary deterministic) choices. Firstly, we note that logs that are generated sequentially according to the protocol drives the machines to the corresponding states.

► **Lemma 7.16.** *If G is σ -WF swarm protocol and $(G, \epsilon) \Longrightarrow (G, l)$ then $\delta(G \downarrow_R^\sigma, l) = \delta(G, l) \downarrow_R^\sigma$ for all $R \in \text{roles}(G, \sigma)$.*

Moreover, Proposition 7.17 below states that a complete realisation is able to generate the logs that are generated by the protocol (the result is obtained by using previous result and by propagating all events to all replicas right after a machine performs a command).

► **Proposition 7.17.** *Let (S, ϵ) be a complete realisation of size n of the σ -WF swarm protocol G . If $(G, \epsilon) \Longrightarrow (G, l)$ then there is a swarm S' such that $(S, \epsilon) \Longrightarrow (S', l)$.*

8 Related work

It is widely accepted that solutions to distributed coordination problems strongly depend on the adopted computation model [15, 21, 2]. Our proposal is grounded on the principles of *local-first cooperation* [26, 25]. Key to this architecture is the *autonomy* of each participating node within a swarm. Autonomy allows each node to make progress independently of network connections, availability of other nodes, or delay in the communications. Our target model features specific hues that distinguish it from other behavioural types systems. In our case, distributed heterogeneous components interact asynchronously by emitting and consuming *events* according to a role specified in a given protocol (such as passenger and the taxi in our running example). More precisely, events are the side effects of commands non-deterministically executed by components; events are locally logged by each of the components and asynchronously spread through the swarm. Crucially, we do not make any assumption on the relative speed of communications and simply require that logs *eventually* agree on the order of events [4]. This liberal setting permits inconsistencies: components may take discordant decisions which compromise the execution of the protocol and exhibit behaviour precluded in strongly consistent models. Our approach lies within methods related to data replication, which are notoriously complex. In fact, standard techniques have to trade-off among availability, consistency, and partition tolerance [16]. Several techniques have been proposed, such as conflict-free replicated data types [34], cloud types [5], consistency contracts [35], invariants [18, 24, 3], linearizability [40], and operational models for applications such as GSP [6, 17]. An original facet of our approach is that we use behavioural types to discipline data replication in order to eventually reach consistency. We focus on the consequences that arise from the ability of each node to take decisions based exclusively on *local information*.

Our proposal is inspired by the choreographic framework introduced in the seminal work on *multiparty session types* [19, 20]. However, the peculiarities of our execution model as well as on the properties that we target require a radical change in the definition of well-established notions of global types, such as projections and well-formedness. The main originality of our approach is that components speculatively proceed along several (possibly inconsistent)

branches of distributed choices provided that an agreement is eventually reached. Intuitively, this is attained by disregarding all executions bar one when the local logs “consolidate”, namely when relevant events have propagated to all relevant components. As far as we are aware of, multiple selectors are forbidden in the well-formedness conditions of most behavioural type systems [21]. A slight weakening of this condition is given in [23] but the conditions there still reject the protocol in Example 1.1. Noteworthy, we divert from the research path of behavioral types with respect to the properties we are after. We aim to guarantee that projections of global specifications yield realisations of swarms that eventually reach a consistent view of the distributed execution, even in presence of transitory inconsistencies. This is in contrast with behavioural type systems designed to attain (dead)lock freedom or some notions of progress (see [21] and [10] for a recent account on the binary case).

Secondly, our behavioural specifications completely abstract over the number of instances enacting a role. This is often not the case for multiparty session types. Parametric multiparty session types have been considered in [41, 11, 12] and more recently in [8, 23]. These proposals aim to capture the fact that roles in a protocol are “connected” to form a topology that can be generalised (e.g. parameterising a ring topology by its size). These behavioural type systems therefore require to explicitly handle the parameters of the protocol. Our specifications are instead completely oblivious of such parameters. To the best of our knowledge, multiparty session types have focused on point-to-point, message-passing communication model, even to deal with highly dynamic scenarios, as those involving robot coordination [29].

9 Final Remarks

We proposed rather unconventional behavioural types deviating from point-to-point, message-passing communication, which is a common practice (see e.g. [13, 39, 21]). Components in our setting interact via a shared distributed log built without any further coordination mechanism. More precisely, each component keeps a local, possibly partial and inconsistent view of the global log. Based on that view alone a component may perform an action with immediate effect on its local state; those effects are then propagated asynchronously to the rest of the system. This implies that components can perform globally invalid actions (as long as they are locally valid), but we require every component be able to recognise these and eventually behave as if only valid actions were performed. Technically this means that we renounce established properties like *session fidelity* to guarantee instead that systems eventually agree without dedicated coordination (our typing discipline guarantees deadlock-freedom, though).

Our target applications intrinsically involve sets of components whose number is statically unknown: components may dynamically join and leave the execution of an interaction. A reference application domain is factory logistics where all the assumptions listed at the end of Section 1 apply: collaborative components act in a trustworthy setting, compensations are specified for irreversible actions, and the underlying communication infrastructure is controlled by the business owner. The collaborative assumption, while commonplace in the literature on behavioural types, may be unrealistic in some domains. Extension to adversarial settings will for example require enforcing that machines cannot violate causality when emitting events, i.e. they cannot artificially truncate their local log to undo an earlier choice via an event that they maliciously sort before it. This can be achieved by requiring them to cryptographically sign their logs, allowing other nodes to prove illicit behaviour; similarly, machines joining later would be required to sign recent events before being allowed to emit.

Common practice in behavioural types is to describe protocols in terms of the roles that components may play. Unlike most behavioural types, ours are agnostic to the number of instances playing each role. We assume that any role in any swarm protocol can be replicated

as many times as needed. This choice also impacts the interpretation of choices. In standard approaches, every choice is assigned to a single role implemented by a single component responsible for coordinating the decision. This is problematic when the implementation of a role can be replicated, even more when the states of the replicas may be misaligned: different components may decide differently. Consequently, choices in our swarm protocols are intended to be resolved distributedly among components that may implement different roles. Our solution is based on speculative computation: different choices can proceed concurrently until components are able to agree (by inspecting their local state) on the branch that has been selected based on a total order for all events (implemented for example using Lamport timestamps and unique node identifiers).

Our computational model gives an abstract description of Actyx infrastructure [1], in which machines are actually implemented as programs in `TypeScript`: the machines presented here play the role of local types that describe the intended behaviour of each component.

Subscriptions can be seen as a minimum requirement for which events need to be available to each participant in a swarm protocol. This directly translates to which events need to (or shall) be sent to a swarm member participating in a given protocol session. Swarm members not partaking in the session do not need to see any of the events (e.g. other passengers), so the middleware should not send them there (this can be elevated to a security guarantee if needed). Our system does not cause additional information to be sent, it is minimal within the constraints of our well-formedness conditions (which are sufficient but not necessary, so there is some room for further improvement).

Determining a suitable subscription could be hard in general. We conjecture that the swarm protocol itself could be used to infer a suitable “minimal” registration enforcing well-formedness to be suggested to designers. Such subscription could then manually be refined, provided that well-formedness is preserved. Moreover, we may envision programmers specifying just the relevant information that needs to be transmitted and then automatically infer the events needed for coordinating choices (pretty much in the style of the communication of labels in session types).

An underlying assumption about speculative execution is that the effects of performing invalid actions can be discarded. In other words, invalid actions have no consequences. In several situations this may be unacceptable. Swarm protocols could be used to systematically identify such situations – e.g. by noting when corresponding events are disregarded by machines – and enable principled treatment at the application level. We plan to study suitable extensions for our projections that automatically inject the required behaviour for executing amending actions. Alternatively, we will explore monitoring approaches equipped with sanitisers responsible for compensation.

We have only partly addressed failures in our model: while we do model transient inability to receive (which would inhibit the event propagation transition [PROP]) or to operate (i.e. inhibit command invocation [LOCAL]), we do not model permanent inability to send. In the presence of a stop failure a machine could communicate the first event of a choice but then fail in propagating all the expected following events resulting from the command invocation, in which case the system could get stuck. A fix for this issue could be to only proceed with an external choice once all specified events are present in the local log, allowing the swarm to permanently discard a choice made by a failing machine; this could be expressed by ingesting logs instead of single events in the definition of machine semantics.

Another worthwhile extension, hinted at in Section 2.3, is to achieve a per-choice notion of non-interference if the first event of a choice not only decided which branch to take but also from which source machine to consume the rest of the choice’s events. This would

further strengthen the failure handling sketched above by making sure that inputs from failing machines are consistently discarded. Characterising the precise guarantees that derive from such a scheme will be an interesting topic for further study.

Constraint Based Compiler Optimization for Energy Harvesting Applications

Yannan Li¹ ✉

Abstract

We propose a method for optimizing the energy efficiency of software code running on small computing devices in the Internet of Things (IoT) that are powered exclusively by electricity harvested from ambient energy in the environment. Due to the weak and unstable nature of the energy source, it is challenging for developers to manually optimize the software code to deal with mismatch between the intermittent power supply and the computation demand. Our method overcomes the challenge by using a combination of three techniques. First, we use static program analysis to automatically identify opportunities for *precomputation*, i.e., computation that may be performed ahead of time as opposed to just in time. Second, we optimize the precomputation policy, i.e., a way to split and reorder steps of a computation task in the original software to match the intermittent power supply while satisfying a variety of system requirements; this is accomplished by formulating energy optimization as a constraint satisfiability problem and then solving the problem using an off-the-shelf SMT solver. Third, we use a state-of-the-art compiler platform (LLVM) to automate the program transformation to ensure that the optimized software code is correct by construction. We have evaluated our method on a large number of benchmark programs, which are C programs implementing secure communication protocols that are popular for energy-harvesting IoT devices. Our experimental results show that the method is efficient in optimizing all benchmark programs. Furthermore, the optimized programs significantly outperform the original programs in terms of energy efficiency and latency, and the overall improvement ranges from 2.3X to 36.7X.

1 Introduction

Energy harvesting is an environment-friendly technology that converts ambient energy in the environment such as sunlight, RF emission, and vibration into electricity [41, 38, 7, 33, 35, 32, 48]. When being used to power small computing devices in the Internet of Things (IoT), it avoids a main problem in the deployment of IoT at scale, which is the need to frequently change batteries [12]. Due to this reason, energy harvesting has been increasingly used in real-world deployment of IoT devices [44, 26]. However, due to the weak and unstable nature of the energy source, it is often challenging for developers to manually optimize the software code running on these IoT devices, to deal with problems caused by *mismatch* between the intermittent power supply and the often unpredictable computation demand.

■ **Figure 1** Using precomputation to reduce the energy needed by the (online) computation task.

Consider an IoT device powered by electricity harvested from sunlight as an example. During the day time, there may be significantly more harvested electricity than the combined total of what can be stored in the supercapacitor of the device, and what can be consumed by the software code running on the device. During the night time, however, the electricity stored in the supercapacitor may be significantly less than what is needed by the software code running on the device. In this context, an important research question is whether the *mismatch between supply and demand* can be avoided, or at the very least mitigated by rewriting the original software in such a way that, while the functionality of the software remains the same, the overall energy efficiency is improved. Prior work [4, 5, 47] has demonstrated the feasibility of this approach, based on two observations made for typical energy-harvesting IoT devices.

The first observation is that, since the software on an IoT device only runs from time to time, rather than continuously, the device may be idle when ambient energy in the environment is abundant (e.g., sunlight during the day time) and yet the supercapacitor used to store the harvested electricity is full. In such a case, the *freely available* energy in the environment cannot be utilized. The second observation is that, in such an IoT device, the most common computation tasks are collecting sensor data from time to time, and encrypting these sensor data before sending them to some remote servers, e.g., servers in the cloud. Thus, the most time-consuming and energy-consuming part of the computation is the execution of the secure communication protocol. While the sensor data may have to be collected *just in time*, a significant part of the secure communication protocol (e.g., computing security tokens needed for encrypting the sensor data) may be executed *ahead of time*. This leads to the idea of leveraging the *precomputation* opportunities to utilize the *freely-available* ambient energy in the environment.

Figure 1 illustrates how to optimize a computation task that must be executed during the night time, when ambient energy is not available. While the original program (P) has to execute the entire computation task during the night time using electricity stored in the supercapacitor, the optimized program (P') executes a significant part of the task during the day time, by harvesting the freely-available ambient energy that otherwise would have to be wasted due to the storage limit of the supercapacitor. In some sense, the precomputation performed during the day time transforms the solar energy to a digital form, called *coupons*, and stores them in the non-volatile memory of the IoT device. During the night time, these coupons are used to lower the energy cost of the remaining part of the computation task.

■ **Figure 2** The overall flow of our constraint based method for energy optimization.

There are two main benefits. The first one is reduction in latency for the online computation part, since a significant portion of the computation task has been completed ahead of time. The second one is increase in the number of computation tasks that can be completed by the device. As a concrete example, Suslowicz et al. [47] show that, for a popular secure communication protocol based on *one-time pad (OTP)* [45], using precomputed OTPs for sensor data encryption reduces the energy cost of the online computation to 5% of the original energy cost needed for AES-OFB. Since the energy used to precompute OTPs is free, the overall energy reduction is close to 18 times (18X). To understand what this means, consider an IoT device that must complete 20 tasks during the day time and 20 tasks during the night time, but the electricity stored in the supercapacitor is only enough to support the completion of 2 tasks during the night time. Without precomputation, the device may be able to complete 20 tasks during the day time and only 2 tasks during the night time. By leveraging the coupons precomputed during the day time, the same device is able to complete 20 tasks and 20 partial tasks during the day time and finish off these 20 partial tasks during the night time.

However, to obtain the aforementioned benefits of precomputation, the current state of the art [4, 5, 47] requires a domain expert to optimize the software code manually, which is not only labor intensive but also error prone. Furthermore, the domain expert must be familiar with both the functionality of the software code and the energy characteristics of the hardware platform. The domain expert must also consider all of the system requirements while making the trade-off between energy reduction and increase in storage cost. In addition, manual optimization does not respond well to frequent software updates in practice: if the original software code is updated due to a bug fix or a security patch, there will be no easy way to update the manually-optimized software code.

To solve these problems, we propose a fully automated method for optimizing the energy efficiency of software running on energy-harvesting IoT devices. Toward this end, we must overcome three technical challenges. The first challenge is to identify the precomputation opportunities from the original software code automatically. The second challenge is to optimize the precomputation policy by exploiting the *energy-storage* trade-off and deciding which part of the computation task should be precomputed and which part of the computation task should be computed just in time. The third challenge is to automatically transform the software code to implement the energy optimization policy.

Figure 2 shows the overall flow of our method, which builds upon the state-of-the-art LLVM compiler platform [29]. Given the original program, our method takes three steps to produce the optimized program. In the first step, our method conducts a static analysis of the original program to identify precomputation opportunities, which are captured by *preSet* – the set of instructions in the program that may be computed ahead of time. In the second step, our method computes an optimal subset of *preSet* based on a variety of system

requirements, to minimize the energy cost while satisfying all requirements, including the storage limit of non-volatile memory used to save precomputation results. In the third step, our method leverages the LLVM compiler to generate the optimized program that has the ability to load the precomputation results from non-volatile memory and leverage them to speed up the just-in-time (online) computation part of the task. Finally, we evaluate the performance of the optimized programs on a popular hardware platform (MSP430 [24]) for energy-harvesting applications.

At the center of our method is a constraint based technique for optimizing the precomputation policy. The policy captures a solution to the complex optimization problem. The optimization problem is complex for several reasons. First, just because an instruction may be precomputed does not mean it is beneficial to precompute it, since precomputing does not always reduce energy cost; there is a trade-off between the cost of storing a precomputed coupon and the benefit of avoiding computing it directly. Second, decisions on *which instructions to precompute* cannot be made in isolation, since many of these instructions are dependent on each other; the precomputation policy has to consider all of the intra- and inter-procedural control- and data-flow dependencies in the program. Third, the size of the non-volatile memory used to store the precomputed coupons may not grow monotonically with the number of precomputed instructions, and furthermore, not all intermediate computation results in the program need to be stored as coupons in non-volatile memory. We will use concrete examples in Section 2 to illustrate these challenges and our proposed solution to overcome these challenges.

To demonstrate the effectiveness of our method, we have implemented and evaluated it on a large number of benchmark programs. Our implementation builds upon the LLVM compiler [29] and the Z3 SMT solver [11]. Specifically, we use LLVM to parse the original software code (written in the C language), conduct static program analysis, and generate the optimized software code; we use Z3 to solve the constraint satisfiability problems formulated by our method. Our tool was evaluated on 26 benchmark programs, which are C programs implementing popular secure communication protocols for IoT devices; in total, they have 31,113 lines of C code (LoC). The LoC of each program ranges from 339 to 1,572. Our target hardware platform is MSP430 [24], a family of ultra-low-power microcontroller units (MCUs) popular for energy-harvesting IoT applications.

Our experimental results are promising. In terms of the efficiency of our method, the experimental evaluation shows that all of the benchmark programs can be optimized by our tool quickly, and the optimization time is always limited to a few seconds. In terms of the effectiveness of our method, the experimental evaluation shows that all of the optimized programs significantly outperform the original programs in terms of energy efficiency and latency. Specifically, reduction in the overall energy cost ranges from 2.3X to 36.7X.

To summarize, this paper makes the following contributions:

- We propose a compiler based technique for automatically identifying precomputation opportunities in the software code using static analysis and then exploiting these opportunities using a semantic-preserving program transformation.
- We formulate energy optimization as a constraint satisfiability problem and solve the problem using an off-the-shelf SMT solver; this approach is not only flexible but also efficient in minimizing the energy cost while satisfying a variety of system requirements.
- We implement the method using a state-of-the-art compiler (LLVM) and a popular hardware platform (MSP430) for energy-harvesting applications, and demonstrate the effectiveness on a large number of benchmark programs.

2 Background

We review the technical background, including the characteristics of the hardware platform (MSP430) and an example software program to motivate our approach.

2.1 The Hardware Platform

MSP430 is a family of microcontroller units (MCUs) based on a 16-bit RISC instruction set architecture. Due to our focus on energy-harvesting applications, we are concerned with a subset of MSP430 MCUs that have the main memory partitioned into the volatile part and the non-volatile part. Depending on the application, data may be stored either in volatile memory or in non-volatile memory. These MCUs have a large number of configuration parameters, including sixteen nominal frequencies in the range 0.06 MHz to 16 MHz. For example, they may run in a low-power mode at the clock frequency of 1 MHz and the supply voltage of 1.8V, or in a high-performance mode at the clock frequency of 16 MHz and the supply voltage of 2.9V.

Since MSP430 MCUs are designed for low-power applications, they have no instruction cache or data cache. Unlike high-end CPUs widely used in servers and desktops, which routinely use advanced frequency or voltage scaling techniques, low-power MCUs such as MSP430 have significantly simpler energy models: fluctuations in power consumption are primarily due to the dynamics in supply voltage and clock speed. In fact, power consumption may be modeled using a non-linear function derived by empirically measuring the impact of varying voltage supplies and clock speeds on the power consumption of real hardware for all possible MCU configurations [2].

Accurate compile-time analysis for energy prediction [10, 3] is well studied topic for transiently powered computing systems [2], where software developers need to know the worst-case energy cost of a computation task, to maximize the software's utilization of the electricity harvested from the environment and to ensure timely checkpointing of the program state before loss of power. The accuracy of such compile-time analysis techniques have come close to direct hardware emulation. While direct hardware emulation [20, 8] offers the highest possible accuracy due to the direct measurement on target hardware, it does not offer the level of convenience and automation desired at the early stages of software development.

In this work, we evaluate our proposed method using MSPSim [15, 39], which is a popular compile-time analysis tool for MSP430. Specifically, we use MSPSim to compute and then compare the latency and energy cost of all benchmark programs, before and after our constraint-based optimization. MSPSim allows the developer to tag a piece of the software code for which energy consumption will be estimated. It does this by first generating the assembly code for MSP430, and then analyzing the assembly code to compute the number of MCU cycles needed to execute each basic block. Then, it estimates the energy consumption of each basic block based on the empirically derived energy model, the supply voltage, and the clock speed of the device.

At a high level, the energy consumption depends on the supply voltage as well as the electrical current for a given resistance of the MCU, the latter of which in turn depends on the supply voltage and the clock speed. For more details on the energy model used in such compile-time analysis tools, refer to Ahmed et al. [2].

```

1  __interrupt void ISR(void) {
2      if (msg_ready) {
3          wots(msg, pub_key, sig);
4          //Send the pair <pub_key,sig> to verifier;
5      }
6  }
7  void wots(MSG msg, KEY pub_key, SIG sig) {
8      gen_key(priv_key, pub_key);
9      sign(msg, priv_key, sig);
10 }

```

■ **Figure 3** An example program that invokes the W-OTS routine when `msg` is ready. Here, `msg_ready` and `msg` are global variables updated by other functions not presented in this figure. For `wots()`, `msg` is the input while `pub_key` and `sig` are the output. For `gen_key()`, both `priv_key` and `pub_key` are the output. For `sign()`, `msg` and `priv_key` are the input while `sig` is the output.

2.2 The Software Program

Figure 3 shows the program, where `ISR` stands for the interrupt service routine. Assume that the routine is triggered periodically by a timer. Whenever the input data stored in `msg` is ready, the subroutine `wots()` is invoked (Line 3). It implements a hash-based cryptographic primitive called the *Winternitz* one-time signature (W-OTS [40]). Here, `msg` is the input, while `pub_key` and `sig` are the output. After generating the output, the device sends the pair (`pub_key,sig`) to a verifier on a remote server (Line 4).

Let us take a closer look at the routine `wots()` defined in Lines 7-10, which consists of two subroutines. The subroutine `gen_key()` is invoked first, which returns a fresh pair of the private key `priv_key` and the public key `pub_key` as output. Then, the subroutine `sign()` is invoked, which takes `msg` and `priv_key` as input and returns the signature `sig` as output.

Since the input `msg` may be sensor data generated *just in time*, in the context of our work, it is called an *online* input. Furthermore, any output or intermediate variable that is control- or data-dependent on the *online* input must be computed *just in time*. In contrast, results that do not depend on the *online* input may be computed *ahead of time*.

2.2.1 The Original Program

Figure 4 shows the definitions of the two subroutines invoked by `wots()`. The subroutine `sign()` in Line 7 takes `msg` and `priv_key` as input and returns `sig` as output. While `msg` is an *online* input, `priv_key` is computed by the subroutine `gen_key()`. In this sense, `sign()` depends on `gen_key()`.

The subroutine `gen_key()` does not have any input, and thus does not depend on any other subroutine. More importantly, it does not depend on any *online* input. Thus, `gen_key()` may be executed ahead of time, e.g., whenever ambient energy is available to the harvester. It means that both `priv_key` and `pub_key` may be computed ahead of time. These precomputed keys may be saved to non-volatile memory as *coupons*, and later used by `sign()` to encrypt the *online* input `msg`.

Although the subroutine `sign()` partially depends on the *online* input `msg`, and thus cannot be executed ahead of time *in its entirety*, a significant part of the function body can still be executed ahead of time. Specifically, the subroutine `gen_random()` does not depend on the *online* input at all, and the subroutine `memcpy()` depends only on `rand` computed by `gen_random()`; thus, both subroutines can be computed ahead of time.

```

1  gen_key(priv_key, pub_key) {
2      gen_random(priv_key, PRIV_KEY_SIZE);
3      sha256_init(&keyHash);
4      sha256_update(&keyHash, priv_key, PRIV_KEY_SIZE);
5      sha256_final(&keyHash, pub_key);
6  }
7  sign(msg, priv_key, sig) {
8      gen_random(rand, SHA_BLK_SIZE);
9      memcpy(sig, rand, SHA_BLK_SIZE);
10     message_digest(digest_bits, sig, msg);
11     gen_sig(sig, priv_key, digest_bits);
12 }

```

■ **Figure 4** Definitions of the subroutines used by the W-OTS routine.

```

1  wots_precom(msg, pub_key, sig) {
2      gen_key(priv_key, pub_key);
3      //NVM-Store <priv_key, pub_key> to coupon pool;
4      sign_precom(msg, priv_key, sig);
5  }
6  wots_online(msg, pub_key, sig) {
7      //NVM-Load <priv_key, pub_key> from coupon pool;
8      sign_online(msg, priv_key, sig);
9  }
10 gen_key(priv_key, pub_key) {
11     gen_random(priv_key, PRIV_KEY_SIZE);
12     sha256_init(&keyHash);
13     sha256_update(&keyHash, priv_key, PRIV_KEY_SIZE);
14     sha256_final(&keyHash, pub_key);
15 }
16 sign_precom(msg, priv_key, sig) {
17     gen_random(rand, SHA_BLK_SIZE);
18     memcpy(sig, rand, SHA_BLK_SIZE);
19     //NVM-Store <sig> to coupon pool;
20 }
21 sign_online(msg, priv_key, sig) {
22     //NVM-Load <sig> from coupon pool;
23     message_digest(digest_bits, sig, msg);
24     gen_sig(sig, priv_key, digest_bits);
25 }

```

■ **Figure 5** Conceptually, the program may be divided into two parts (*precom* and *online*).

If we continue this analysis by going down the chain of function calls, we may identify more precomputation opportunities, e.g., instructions inside subroutines `message_digest()` and `gen_sig()`. In our proposed method, this process of systematically identifying these precomputation opportunities is automated, based on static program analysis techniques.

2.2.2 Dividing into Two Parts

Based on the precomputation opportunities identified by static program analysis, the original program may be divided into two parts: the precomputation (*precom*) part and the online computation (*online*) part, as shown by Figure 5.

Specifically, top-level routine `wots()` is divided into `wots_precom()` and `wots_online()`. The subroutine `wots_precom()` may be invoked ahead of time, since it does not depend on the *online* input `msg` at all. After invoking `gen_key()` to compute the public and private keys, denoted `priv_key` and `pub_key`, it stores them in non-volatile memory (Line 3). Then, it invokes `sign_precom()` defined in Line 16, to compute the signature `sig`, before storing it in non-volatile memory (Line 19).

The subroutine `wots_online()` must be invoked just in time, since it depends on the *online* input `msg`. This subroutine first loads the precomputed keys `priv_key` and `pub_key` from non-volatile memory (Line 7) and then invokes `sign_online()` defined in Line 21. Inside `sign_online()`, the precomputed signature `sig` is loaded from non-volatile memory (Line 22) and then used together with `msg` and `priv_key` to compute the final version of the signature `sig` (Lines 23-24).

According to our experimental evaluation (presented in Section 7), on low-power devices such as MSP430, this kind of precomputation can reduce the energy cost of running W-OTS to 42.89% of the original cost. In other words, it is more than 2.3X reduction. Thus, with the same amount of electricity used to run the original W-OTS program once, now, we can run the optimized W-OTS program 2.3 times.

2.2.3 Challenges in Optimization

Just because an instruction may be precomputed (i.e., it does not depend on any *online* input) does not mean that it is beneficial to do so, since precomputation does not always reduce the energy cost. Depending on the hardware platform, it is possible for the cost of storing and retrieving the precomputed result to outweigh the benefit.

For example, in Line 18 of Figure 5, if we choose to precompute `memcpy()` inside the subroutine `sign()`, the energy cost of loading the precomputed coupon `sig` from non-volatile memory may be slightly higher than the energy needed to execute `memcpy()` directly. If that is the case, precomputation should be avoided.

In general, whether precomputation is beneficial or not depends on both the software and the hardware. Consider the characteristics of volatile and non-volatile memory used in MSP430FR5969 [24] as an example. According to the hardware data-sheet, at the clock frequency of 8 MHz, the energy per clock cycle is 0.33 nJ for volatile memory, but is 0.42 nJ for non-volatile memory. This kind of information must be considered during optimization.

Furthermore, decisions on which instructions to precompute cannot be made in isolation, since many of these instructions are dependent on each other according to the control and data flows of the program. Therefore, we must consider all of the intra- and inter-procedural control- and data-flow dependencies in the program while performing the optimization.

These are the reasons why we propose the constraint based method. By first formulating it as a constraint satisfiability problem and then solving the problem using an off-the-shelf SMT solver, we are able to optimally partition the program into the precomputation part and the online computation part, while satisfying a variety of requirements coming from the hardware platform as well as the software program.

2.2.4 The Optimized Program

To keep the size of the optimized program small, we do not actually divide the program into two parts as shown by Figure 5. Instead, we keep the two parts in a single program, and try to retain the original control and data flows of the program as much as possible.

Figure 6 illustrates our method by showing the optimized program for the original program in Figure 4. Our method adds two parameters, `precom_flag` and `online_flag`, to represent the following three use cases:

- When $\langle \text{precom_flag}, \text{online_flag} \rangle = \langle \text{true}, \text{false} \rangle$, it does precomputation.
- When $\langle \text{precom_flag}, \text{online_flag} \rangle = \langle \text{false}, \text{true} \rangle$, it does online computation.
- When $\langle \text{precom_flag}, \text{online_flag} \rangle = \langle \text{true}, \text{true} \rangle$, it acts as the original program.

```

1  wots_trans(msg, pub_key, sig, precom_flag, online_flag) {
2    if (precom_flag == true)
3      gen_key(priv_key, pub_key);
4    if (!online_flag)
5      //NVM-Store <priv_key, pub_key> to coupon pool;
6    if (!precom_flag)
7      //NVM-Load <priv_key, pub_key> from coupon pool;
8    sign_trans(msg, priv_key, sig, precom_flag, online_flag);
9  }
10 sign_trans(msg, priv_key, sig, precom_flag, online_flag) {
11   if (precom_flag == true) {
12     gen_random(rand, SHA_BLK_SIZE);
13     memcpy(sig, rand, SHA_BLK_SIZE);
14   }
15   if (!online_flag)
16     //NVM-Store <sig> to coupon pool;
17   if (!precom_flag)
18     //NVM-Load <sig> from coupon pool;
19   if (online_flag == true) {
20     message_digest(digest_bits, sig, msg);
21     gen_sig(sig, priv_key, digest_bits);
22   }
23 }

```

■ **Figure 6** Merging the two parts into a single optimized W-OTS routine.

```

1  __interrupt void ISR(void) {
2    if (!msg_ready) {
3      if (ambient_energy_available)
4        wots_trans(NULL, pub_key, sig, true, false); //precom (part 1)
5    }
6    else {
7      if (!ambient_energy_available)
8        wots_trans(msg, pub_key, sig, false, true); //online (part 2)
9      else
10       wots_trans(msg, pub_key, sig, true, true); //combined (part 1 + part 2)
11     //Send the pair <pub_key,sig> to verifier;
12   }
13 }

```

■ **Figure 7** Different scenarios for invoking the optimized W-OTS routine.

Compared to the original program in Figure 4, the only difference in Figure 6 is the addition of two flags as input parameters of some of the subroutines, together with the if-conditions that indicate whether a code block should be executed during the precomputation step or during the online computation step.

Figure 7 shows how the optimized program may be invoked by the interrupt service routine. Unlike what is shown in Figure 3, here, precomputation is performed when `msg` is not available but ambient energy is available (Line 4). When `msg` is available, it depends on whether ambient energy is still available. If ambient energy is not available, then online computation is performed (Line 8). However, if ambient energy is available, operations that access non-volatile memory will be skipped, which makes `wots_trans()` behaves exactly the same as the original program (Line 10).

3 Overview of Our Method

We first present our top-level procedure and then outline the main technical challenges.

3.1 The Top-Level Procedure

Algorithm 1 shows our top-level procedure. The input consists of the original program (P), the *online* input (OI) of the program, and the system constraint (C). The output is the optimized program (P').

■ **Algorithm 1** The top-level procedure of our method.

```

input : original program  $P$ , online input  $OI$ , system constraint  $C$ 
output : optimized program  $P'$ 
1  $PDG \leftarrow \text{ConstructPDG}(P)$ ;
2  $preSet \leftarrow \text{IdentifyPreSet}(P, PDG, OI)$ ;
3  $preSet^* \leftarrow \text{OptimizePreSet}(preSet, PDG, C)$ ;
4  $P' \leftarrow \text{Transform}(P, PDG, preSet^*)$ ;
5 return  $P'$ 

```

For the running example in Figure 3, where the entry function is `wots()`, the online input is $OI = \{\text{msg}\}$, since `msg` is the only input value that must be ready at run time. C consists of a set of platform-dependent requirements, e.g., the size of non-volatile memory used to store coupons must be limited to ≤ 256 KB.

In Algorithm 1, our method first constructs a program dependency graph (PDG) for the program P . Then, our method uses the PDG and the set of variables in the *online* input OI to compute $preSet$, which is the set of instructions in P that may be precomputed. Next, it computes $preSet^*$, which is a subset of $preSet$ that represents the optimal solution to the constraint satisfiability problem. Finally, our method transforms the program P to a new program P' based on the information stored in both PDG and $preSet^*$.

Before presenting the detailed algorithms inside the subroutines `IdentifyPreSet()`, `OptimizePreSet()` and `Transform()`, we point out the main technical challenges.

3.2 The Technical Challenges

The first challenge, related to the subroutine `IdentifyPreSet()`, is the complex nature of the program dependency analysis. In Figures 3 and 4, for example, we observe that the subroutine `sign()` depends on `gen_key()`; furthermore, the subroutine `gen_sig()` invoked by `sign()` depends on `gen_key()`. It means that we must consider not only dependencies of instructions within each subroutine, but also dependencies between subroutines.

Moreover, since we aim to transform individual functions of the original program without changing the overall function call structure, each function must be analyzed in all of its calling contexts, to figure out how the function body should be optimized. In Figure 4, for example, it means that since `gen_random()` is called by both `gen_key()` and `sign()`, we must consider both calling contexts.

The second challenge, related to the subroutine `OptimizePreSet()`, is optimizing the precomputation policy while satisfying a variety of system constraints. Given $preSet$ (which is the set of instructions that may be computed), we need to identify a proper subset. For the MSP430 family of microcontroller units, a limiting factor may be the capacity of non-volatile

memory, only part of which may be dedicated to coupon storage. In general, this is a non-linear optimization problem, e.g., the storage cost may not increase linearly, or even monotonically, as more instructions are added to the precomputation set.

In Figure 4, for example, the cost of precomputing only Lines 2-4 is $size(\text{priv_key}) + size(\text{keyHash})$, where $size()$ denotes the size of non-volatile memory for storing the value. However, the cost of precomputing Lines 2-5 is $size(\text{priv_key}) + size(\text{pub_key})$, because keyHash no longer needs to be stored in non-volatile memory. Since $size(\text{pub_key})$ is much smaller than $size(\text{keyHash})$ in the W-OTS example, this means that precomputing one more line actually decreases the overall storage cost.

The third challenge, related to the subroutine `Transform()`, is the difficulty in preserving functional equivalence while allowing the program to change its execution order and data flow. For example, if we want to precompute Line 2 and Line 8 in Figure 4, we must modify the program to ensure that the original execution order (Line l_3 executed before Line l_8) changes to the new execution order (l_8 executed before l_3); at the same time, we must ensure that the original data flow $\text{priv_key}(l_2) - l_3, l_4, l_5 - l_8$ changes to $\text{priv_key}(l_2) - l_8 - l_3, l_4, l_5$. While doing so for this particular example may seem easy, in general, maintaining functional equivalence during such program transformation can be challenging.

4 Identifying the Precomputation Set

In this section, we present our method for computing $preSet$, as shown in Algorithm 2. It takes the program P , the program dependency graph PDG , and the *online* input OI as parameters, and return $preSet$ as output.

Algorithm 2 The subroutine `IdentifyPreSet` (P, PDG, OI).

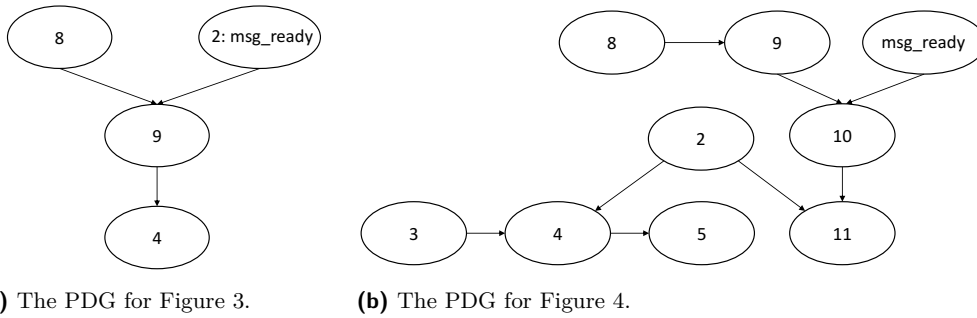

```

1 Let  $pred(inst)$  be a predecessor node of instruction  $inst$  in the  $PDG$ 
2  $preSet \leftarrow \{\text{elementary instructions in } P\} \cup (\{\text{input parameters of } P\} \setminus OI)$ 
3 while  $\exists inst \in preSet$  and  $pred(inst) \notin preSet$  do
4   | remove  $inst$  from  $preSet$ 
5 end
6 return  $preSet$ 

```

Recall that $preSet$ is the set of instructions in P that may be computed ahead of time. Internally, our method computes $preSet$ in two steps. The first step is identifying the interprocedural dependencies related to the online input OI . These dependencies will be captured by function such as $pred(inst)$, $preds(inst)$, and $succs(inst)$, which returns the predecessor, set of predecessors, and set of successors of an instruction $inst$, respectively. The second step is leveraging these dependencies to compute the instructions in $preSet$.

In Algorithm 2, initially, $preSet$ consists of all the *elementary instructions* and input parameters of P , except for the ones in OI . Variables in OI are excluded because they are the *online* variables. Here, an *elementary instruction* means that during our analysis the instruction will be treated as a whole. First, non-function-call instructions are elementary instructions. Second, when an instruction invokes a function call, whether it is elementary depends on how many times the function is called. If the function is called only once, it is not treated as an elementary instruction; instead, we enter the function body to try to identify more precomputation opportunities. But if the function is called from multiple sites, we treat each call as an elementary instruction, meaning that we do not enter the function body

■ **Figure 8** The program dependency graphs (PDGs) of the example W-OTS program. Here, each node represents an instruction, and the number is the instruction’s line number in the program.

to explore further. This is a reasonable compromise since, when a function is called from multiple sites, the function body often implements some basic computation, e.g., generating a random number, and there is no need to split it further.

4.1 Inter-Procedural Dependencies

To identify the maximum set of instructions in *PreSet* using Algorithm 2, we need the dependencies associated with the online input *OI*. These dependencies are more complex than what are typically available in the compiler. For example, by default, LLVM provides the control- and data-dependencies between instructions only within each function. However, we need to know dependencies not only within each function, but also between functions.

To identify inter-procedural dependencies, we first compute a PDG for each function, together with a call graph that represents the *caller-callee* relations of all functions in the program. We also extend LLVM to add the ability to determine whether a function call may change the content of a function parameter passed by reference or the value of a global variable. This is accomplished by traversing paths in the call graph and analyzing all of the functions involved in the path.

Next, we analyze the inter-procedural dependencies in a bottom-up fashion, according to the function call graph. Consider the example of the following two functions: `fun1(arg1)` and `fun2(arg2, arg3)`, where the input parameter `arg1` of `fun1()` depends on the output parameter `arg2` of `fun2()`. Assume that `arg3` is also an output parameter of `fun2()`.

Assume that inside the function `fun2()` there is an instruction *I* that computes the value of `arg2`. Furthermore, inside `fun1()` there is an instruction *I'* that computes the value of `arg1`. While all intra-procedural dependencies may be computed in isolation, we must combine them to identify the inter-procedural dependencies, such as the dependency between *I'* of `fun1()` and *I* of `fun2()`.

Figure 8 shows a more concrete example, where the PDGs are constructed for the code snippets in Figures 3 and 4. Consider the edge $2 \rightarrow 11$ in Figure 8 (b), which represents the dependency between the instruction at Line 2 and the instruction at Line 11 of the program in Figure 4. It means the input parameter `priv_key` used by `sign()` at Line 11 comes from the output parameter `priv_key` of `gen_key()` at Line 2.

With the inter-procedural dependencies, we can define the notion of a *predecessor*, denoted by *pred()*. For example, in Figure 8 (b), due to the edge $2 \rightarrow 11$, we say that the instruction at Line 2 is a predecessor of the instruction at Line 11 inside the program shown by Figure 4.

4.2 Iteratively Computing *preSet*

Using the notion of a *predecessor* of an instruction *inst*, denoted $pred(inst)$, our method computes the *preSet* according to the while-loop in Algorithm 2.

It starts with all elementary instructions and input parameters that are not in *OI*. Then, it removes any instruction (*inst*) that has a predecessor $pred(inst)$ not in *preSet*. There are two possible reasons why $pred(inst)$ is not in *preSet*: either it is in *OI*, or during the previous iteration, it has been removed from *preSet*. Thus, it is a fixed-point computation.

The correctness of the fixed-point computation can be understood as follows: By definition, the instruction *inst* depends on its predecessor $pred(inst)$. If $pred(inst) \notin preSet$, meaning the predecessor instruction cannot be precomputed, then the instruction *inst* itself cannot be precomputed either.

As an example, consider the instructions of W-OTS in Figure 4. For ease of presentation, we use l_i to represent the instruction at Line *i*, and we treat all instructions in this program as elementary instructions. Initially, we have $preSet = \{l_2 - l_5, l_8 - l_{11}\}$.

Next, we check if any of these instructions should be removed, based on the *predecessor* relation shown in Figure 8. The instruction l_{10} should be removed, since its predecessor (`msg_ready`) is not in *preSet*. Thus, we remove l_{10} from *preSet*.

The removal of l_{10} leads to the removal of l_{11} during the next iteration, since l_{10} is the predecessor of l_{11} . If l_{11} cannot be precomputed, then l_{10} cannot be precomputed either.

Thus, in the end, we have $preSet = \{l_2 - l_5, l_8 - l_9\}$.

► **Theorem 1.** *Our method for computing *preSet* is sound in that, for all $inst \in preSet$, there is guarantee that the instruction (*inst*) can indeed be computed ahead of time.*

Proof. An instruction *inst* remains in *preSet* only if all of its predecessors are also in *preSet*. As long as the inter-procedural dependencies represented by the PDGs are an over-approximation of the actual dependencies, the *preSet* is guaranteed to be an under-approximation of the set of instructions that may be computed ahead of time.

The reason why it is an under-approximation because $pred(inst)$ is an over-approximation of the predecessors. Whenever $pred(inst) \notin preSet$, Algorithm 2 removes *inst* from *preSet*.

The reason why $pred(inst)$ is an over-approximation is due to the nature of PDG-based analysis techniques. Refer to Horwitz et al. [22] and Reps et al. [42] for more information. ◀

4.2.1 Handling Loops

Similar to all other PDG-based analysis techniques [22, 42], our method has no problem in handling software code with loops. In most of the practical cases, computing the *predecessor* is straightforward. For example, the function call `sign()` at Line 9 in Figure 3 requires `msg` and `priv_key` to be available. These dependencies are due to data flow represented by the *definition-use* correspondence.

However, there are cases where definitions and uses do not have one-to-one mapping. For example, in Figure 9, the variable `i` used at Line 7 may be defined at either Line 2 or Line 5. In the context of data-flow analysis, the definition at Line 5 does not *kill* the definition at Line 2. Therefore, it may or may not be necessary to precompute Line 3-6 in order to precompute Line 7, for example, if `CNT[len-1] != 0xff`.

Since our method is designed to be sound, to ensure that the optimized program is correct for all input values, it is allowed to *first* over-approximate the predecessor relation, and *then* conservatively assume that an instruction can be precomputed *only if* all of its predecessors can be precomputed.

```

1 void increment_CNT(BYTE *CNT, int len){
2     int i = len;
3     while ((i > 0) && (CNT[i-1] == 0xff)){
4         CNT[i-1] = 0;
5         i--;
6     }
7     if (i) {
8         CNT[i-1]++;
9     }
10 }

```

■ **Figure 9** Code snippet taken from the benchmark program named AES-CTR.

5 Optimizing the Precomputation Set

While all instructions in $preSet$ have been identified at this moment, it may not be beneficial to compute all of them ahead of time. In this section, we present our method for computing an optimal subset $preSet^* \subseteq preSet$. This is implemented in $OptimizePreSet(preSet, PDG, C)$, where C is the system constraint. Besides the characteristics of the hardware platform, such as the size of non-volatile memory, it also includes the characteristics of the software program, such as how often the encrypted sensor data must be transmitted to the remote server.

5.1 The Motivation

We use an example to illustrate the complex nature of the optimization problem, which in turn motivates our development of the constraint based solution.

Consider the W-OTS program in Figure 4 and its PDGs in Figure 8 (b). According to Algorithm 2, $preSet = \{l_2 - l_5, l_8 - l_9\}$. Since these instructions do not depend on the *online* input `msg`, in theory, they may be precomputed *as many times as possible*. However, due to the storage capacity, in practice, the number has to be bounded.

Let \mathcal{S}_i be a subset of $preSet$, called a precomputation choice, and m_i be the maximum number of times that \mathcal{S}_i may be precomputed. Since each time \mathcal{S}_i produces an intermediate result, or *coupon*, we also call m_i the *coupon count* (number of copies of this particular coupon). Let $NVM(\mathcal{S}_i)$ be the storage cost for this coupon, and \maxNVM be the storage capacity of the entire device. We use the maximal allowed NVM size to avoid the potential risk of running out of NVM. One precomputation choice for the running example is represented by $\mathcal{S}_1 = \{l_2\}$, where $m_1 \leq \maxNVM/NVM(\mathcal{S}_1)$. That is, the coupon count m_1 is bounded only by the storage capacity.

Below are some other precomputation choices:

$$\begin{aligned} \mathcal{S}_2 &= \{l_2 - l_5, l_8\}, \text{ where } m_2 \leq \maxNVM/NVM(\mathcal{S}_2) \\ \mathcal{S}_3 &= \{l_2 - l_5, l_8 - l_9\}, \text{ where } m_3 \leq \maxNVM/NVM(\mathcal{S}_3) \\ &\dots \end{aligned}$$

Let $n = |preSet|$, the number of precomputation choices is $\sum_{i=1}^n \binom{n}{i}$. Since it causes combinatorial explosion, we cannot afford to enumerate them to decide which one is optimal.

The number of precomputation choices can be even higher than $\sum_{i=1}^n \binom{n}{i}$. For example, when $\mathcal{S}_{4a} = \{l_2 - l_5\}$ and $\mathcal{S}_{4b} = \{l_2 - l_5, l_8 - l_9\}$, if we allow the coupon counts m_{4a} and m_{4b} to have different values, they would be bounded only by the constraint $m_{4a} \times NVM(\mathcal{S}_{4a}) + m_{4b} \times NVM(\mathcal{S}_{4b}) \leq \maxNVM$. This leads to another combinatorial explosion.

While making a precomputation choice, we cannot consider instructions in isolation, since they may be dependent on each other. For example, precomputing one instruction may require precomputing another instruction. Recall that in the example program shown in Figure 4, we cannot precompute l_5 without precomputing l_4 , because there is dependency from l_4 to l_5 . In other words, $l_4 = \text{pred}(l_5)$.

All these challenges motivate us to define the constraint satisfiability problem, which allows us to consider all of the selected instructions as a whole, together with a variety of system constraints. Specifically, it allows us to consider the coupon count (m_i) and the coupon size $\text{NVM}(\mathcal{S}_i)$ for each subset $\mathcal{S}_i \subseteq \text{preSet}$, together with system constraints such as the capacity of non-volatile memory used to store coupons computed by different instructions, and the inter-procedural dependencies between these chosen instructions.

5.2 The Problem Statement

Our goal is to compute the optimal subset, denoted $\mathcal{S}^* \subseteq \text{preSet}$, that satisfies the system constraint. For ease of presentation, assume that \mathcal{S} represents a precomputation choice, while $V(\mathcal{S})$ represents the value (or benefit) of precomputing \mathcal{S} , and $C(\mathcal{S})$ represents the cost of precomputing \mathcal{S} . The optimization problem is defined formally as follows:

$$\mathcal{S}^* = \underset{\mathcal{S} \subseteq \text{preSet}}{\text{argmax}} V(\mathcal{S}) \quad \text{subject to} \quad C(\mathcal{S}) \leq \text{maxNVM} \quad (5.2)$$

In other words, the optimal subset is the subset \mathcal{S} that maximize the value $V(\mathcal{S})$ while keeping the cost $C(\mathcal{S})$ under control. Recall that explicitly enumerating solutions would lead to combinatorial explosion. Thus, we encode them symbolically using a set of logical constraints and solve these constraints using an off-the-shelf SMT solver.

One advantage of the *constraint based approach* is flexibility in modeling various tradeoffs. While it is easy to compute the coupon size or the coupon count individually, finding the right combination may be hard due to the fact that they are inter-dependent.

Another advantage of our approach is flexibility in modeling the chain of influence; that is, precomputing one instruction (e.g., l_4 of `gen_key` in Figure 4) may require precomputing another instruction (e.g., l_3).

Yet another advantage is the ability to bound the total cost of storing coupons from different instructions. As mentioned earlier, precomputing more instructions may not always increase the storage cost. In Figure 4, if we precompute $l_3 - l_4$ but not l_5 , we need to store both `pub_key` and `keyHash`, the latter of which is an array of 108 bytes; but if we precompute $l_3 - l_5$, we only need to store `pub_key`, which is an array of 32 bytes.

5.3 Defining the Value and Cost Functions

First, we define the energy saving (*value*) and storage overhead (*cost*).

5.3.1 Value

Since the value of precomputing one instruction may depend on which other instructions are precomputed, we can only define it based on which other instructions are chosen. Since an instruction *inst* may be precomputed only if all its *predecessors* are precomputed, we define the value of precomputing *inst* based on the predecessor relation.

16:16 Constraint Based Compiler Optimization for Energy Harvesting Applications

Let \mathcal{S} be the set of chosen instructions, and $v(inst \mid \mathcal{S})$ be the *value* of precomputing $inst$ in the presence of \mathcal{S} . We have

$$v(inst \mid \mathcal{S}) = \begin{cases} E(inst) & \text{if } preds(inst) \subseteq \mathcal{S} \\ -\infty & \text{otherwise} \end{cases}$$

Here, $E(inst)$ is the energy saved by precomputing $inst$, and $preds(inst)$ is the set of all predecessors of $inst$ in the PDG. We use the large value $-\infty$ to avoid precomputing $inst$ before all of its predecessors in $preds(inst)$ are precomputed.

With the values of precomputing individual instructions, we define the *value* of precomputing the entire set \mathcal{S} as follows:

$$V(\mathcal{S}) = \sum_{inst \in \mathcal{S}} v(inst \mid \mathcal{S}).$$

For the example in Figures 4 and 8 (b), we have $V(\{l_2\}) = E(l_2)$. We also have $V(\{l_2, l_5\}) = -\infty$ since l_5 cannot be selected when its predecessors $l_3 - l_4$ are not selected.

5.3.2 Cost

Unlike the value $v(inst)$, which depends only on the predecessors of $inst$, the cost of precomputing $inst$ depends also on its *successors* in the PDG.

Let \mathcal{S} be the set of chosen instructions, and $c(inst \mid \mathcal{S})$ be the *cost* of precomputing $inst$ in the presence of \mathcal{S} . In Figure 4, for instance, we have

$$c(l_3 \mid \mathcal{S}) = \begin{cases} 0 & \text{if } l_4, l_5 \in \mathcal{S} \\ \text{NVM}(\text{keyHash}) & \text{otherwise} \end{cases}$$

and

$$c(l_4 \mid \mathcal{S}) = \begin{cases} 0 & \text{if } l_2, l_3 \in \mathcal{S} \\ +\infty & \text{otherwise} \end{cases}$$

That is, if $l_3 - l_5$ are selected, we do not need to store `keyHash`; but if $l_4 - l_5$ are not selected, we need to store `keyHash`. Thus, the cost of precomputing l_3 depends on if $(l_4 - l_5)$ are selected. Here, the large value $+\infty$ is used to avoid selecting instructions whose predecessors in the PDG are not selected.

With the costs of precomputing individual instructions, we define the cost of precomputing the entire set \mathcal{S} as follows:

$$C(\mathcal{S}) = \sum_{inst \in \mathcal{S}} c(inst \mid \mathcal{S}).$$

5.4 Symbolic Encoding of the Constraints

We construct an SMT formula $\Psi = \Phi_{Dep} \wedge \Phi_{Value} \wedge \Phi_{Cost}$, where the subformula Φ_{Dep} captures the dependencies that we have computed in the previous section, Φ_{Value} captures the value constraint, and Φ_{Cost} captures the cost constraint. Thus, a satisfying assignment to Ψ corresponds to $\mathcal{S}^* \subseteq preSet$.

5.4.1 Dependency Constraint

Φ_{Dep} encodes the dependency relations captured by edges of the inter-procedural PDG. Specifically, for each dependency edge (n_1, n_2) , we add a Boolean constraint $(\neg n_2 \vee n_1)$, where n_1 and n_2 are Boolean variables indicating whether these nodes are precomputed, and the constraint means that, if n_2 is true, then n_1 must also be true. Therefore, n_2 being precomputed implies that n_1 is also precomputed. Then, all these individual constraints are conjoined to form Φ_{Dep} . As an example, consider the PDG in Figure 8 (b): the dependency constraints include $(\neg l_4 \vee l_3) \wedge (\neg l_4 \vee l_2) \wedge (\neg l_5 \vee l_4) \wedge (\neg l_9 \vee l_8)$.

5.4.2 Value Constraint

Φ_{Value} encodes the value of precomputing each instruction. Since Φ_{Dep} already guarantees that an instruction is precomputed only if all its predecessors (as in the PDG) are precomputed, the encoding becomes straightforward. That is, if $inst$ is selected, then $v(inst) = E(inst)$; otherwise $v(inst) = 0$. The total value of precomputing the set of instructions in $preSet$ is simply the sum of all the individual values. In Figure 4, the value of precomputing each instruction l_i , where $i = 2, 3, \dots, 5, 8, 9$, would be $v(l_i) = (l_i ? E(l_i) : 0)$ and the total would be $V(\mathcal{S}) = \sum v(l_i)$.

5.4.3 Cost Constraint

Φ_{Cost} encodes the cost of precomputing the chosen instructions. Recall that the cost of precomputing $inst$ depends on not only if its predecessors are precomputed but also if its successors are precomputed. Since Φ_{Dep} guarantees to select the predecessors whenever $inst$ is selected, here we only need to deal with the set of successors, denoted $succs(inst)$.

In general, precomputing $inst$ increases storage cost only when its result (coupon) is used by some of the successors in the online computation step; otherwise, there is no need to save the coupon. For example, the cost of precomputing l_3 in Figure 4 is zero if instructions in $succs(l_3) = \{l_4, l_5\}$ are also precomputed.

For the entire program shown in Figure 4, the cost constraint would be

$$\begin{aligned} & (c(l_2) = (\neg l_2 \vee l_3 \wedge l_4 \wedge l_5 \wedge l_{send}) ? 0 : \text{NVM}[\text{priv_key}]) \wedge \\ & (c(l_3) = (\neg l_3 \vee l_4) ? 0 : \text{NVM}[\text{keyHash}]) \wedge \\ & (c(l_4) = (\neg l_4 \vee l_5) ? 0 : \text{NVM}[\text{keyHash}]) \wedge \\ & (c(l_5) = \neg l_5 ? 0 : \text{NVM}[\text{pub_key}]) \wedge \\ & (c(l_8) = (\neg l_8 \vee l_9) ? 0 : \text{NVM}[\text{rand}]) \wedge \\ & (c(l_9) = \neg l_9 ? 0 : \text{NVM}[\text{sig}]) \\ & (C(\mathcal{S}) = c(l_2) + c(l_3) + c(l_4) + c(l_5) + c(l_8) + c(l_9)) \wedge \\ & (C(\mathcal{S}) \leq \text{maxNVM}) \end{aligned}$$

With proper definitions of the cost and value functions, our constraint based method can also handle other optimization metrics.

5.5 Solving the Constraints

After constructing the entire SMT formula Ψ , we solve it using the Z3 SMT solver [11]. Specifically, we use Z3's `optimize` interface iteratively to search for the optimal solution. This is done by insisting that the total value $V(\mathcal{S})$ shown in Equation (5.2) is greater than a given constant value; then, we find the maximum constant by gradually increasing the value of the constant as long as Z3 can still find a satisfying solution.

6 Transforming the Program

We now explain the subroutine $\text{Transform}(P, PDG, preSet^*)$, which transforms the original program P to a new program P' to implement $preSet^*$. Recall that in Figure 6, we gave an example of such a transformed program for W-OTS. There are two important properties of the program P' : (1) it retains the overall function call structure in P and (2) it changes the body of each function to implement both the precomputation and online computation steps.

6.1 The Terminology

For each function f in the program P , we must separate the precomputation instructions from the online computation instructions. This leads to a partition of the program to segments, $\{S_1, \tilde{S}_2, S_3, \tilde{S}_4, \dots\}$, where S_i represents a precomputation segment and \tilde{S}_j represents an online computation segment. A *segment* is a maximal set of instructions that may execute continuously during precomputation or online computation.

Consider an example program $P = \{S_1, \tilde{S}_2, S_3, \tilde{S}_4\}$ whose original execution order is $S_1 \rightarrow \tilde{S}_2 \rightarrow S_3 \rightarrow \tilde{S}_4$. In the transformed program P' , however, the execution order must be changed to $S_1 \rightarrow S_3 \rightarrow \tilde{S}_2 \rightarrow \tilde{S}_4$. In general, changes in the execution order lead to changes in the data flow.

Before discussing changes in the data flow, we define the terminology.

- Let $def(x)$ be an instruction that defines the value of variable x , and $use(x)$ be an instruction that uses the value. The two instructions may form a *def-use* pair.
- Given two segments S_i and \tilde{S}_j , where $def(x) \in S_i$ and $use(x) \in \tilde{S}_j$, we represent the data-flow edge (or def-use pair) as $\langle S_i, \tilde{S}_j \rangle(x)$.
- Let $Val[x, S_i]$ denote the value of x at the end of executing the segment S_i .
- A variable x is *live* at a program location p if its value is used before it is defined again along *some* path from p to the program exit.

6.2 The Problem

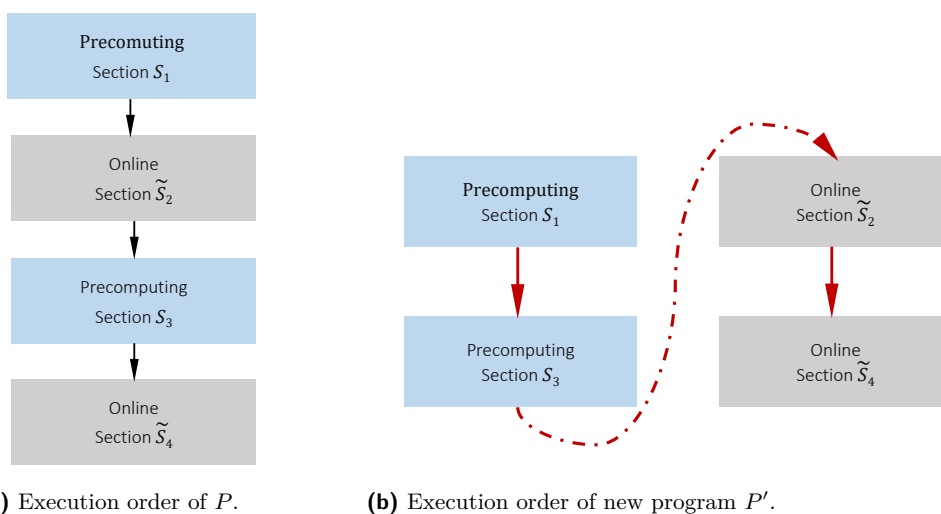

Now, we show an example where changes in the execution order bring unexpected changes of the data flow.

► **Example 6.1.** In program $P = \{S_1, \tilde{S}_2, S_3, \tilde{S}_4\}$, assume that $def_1(x) \in S_1$, $def_2(x) \in \tilde{S}_2$, $use(x) \in \tilde{S}_4$. Due to the execution order, the def-use chain contains only $def_2(x)$ and $use(x)$, meaning the value of x used in \tilde{S}_4 should be from $def_2(x)$.

In the original execution order $S_1 \rightarrow \tilde{S}_2 \rightarrow S_3 \rightarrow \tilde{S}_4$, the value $Val[x, S_3]$ comes from $def_2(x)$, and the variable x is live in S_3 , since $Val[x, S_3]$ will be used in \tilde{S}_4 .

In the new program, however, since the execution order is changed to $S_1 \rightarrow S_3 \rightarrow \tilde{S}_2 \rightarrow \tilde{S}_4$, without our intervention, the value $Val[x, S_3]$ would come from $def_1(x)$, and the variable x would *no longer* be live in S_3 . Such unexpected changes of the data flow may change the semantics of the program. This is illustrated by Figure 10.

In general, it can be challenging to preserve the data flow while allowing change of the execution order. While the technique of *checkpointing* has been used in intermittent computing systems [32, 48, 35], it cannot solve our problem because checkpointing does not involve splitting a program into two parts and then executing the two parts in an interleaved order. For the program in Example 6.1, specifically, checkpointing techniques would have failed to preserve the data flow.

■ **Figure 10** Difference in execution order means P and P' are no longer functionally equivalent.

To understand why checkpointing would fail, consider the fact that variable x is *live* at the end of \tilde{S}_2 , at the end of S_3 , and at the start of \tilde{S}_4 . Checkpointing would insert $\text{nvm_ST}(Val[x, \tilde{S}_2])$ at the end of \tilde{S}_2 and insert $\text{nvm_ST}(Val[x, S_3])$ at the end of S_3 . It would also insert $\text{nvm_LD}(Val[x, \tilde{S}_2])$ and $\text{nvm_LD}(Val[x, S_3])$ at the start of \tilde{S}_4 .

When executing P' ($S_1 \rightarrow S_3 \rightarrow \tilde{S}_2 \rightarrow \tilde{S}_4$), $\text{nvm_LD}(Val[x, S_3])$ would over-write $\text{nvm_LD}(Val[x, \tilde{S}_2])$; thus, the value of x used in \tilde{S}_4 would be $Val(x, S_3) = \text{def}_1(x)$. However, in the original program, the value of x used in \tilde{S}_4 is $\text{def}_2(x)$.

The fundamental reason why *checkpointing* techniques are ill-suited for our project is that the *liveness* property of a program variable, which forms the theoretical foundation of checkpointing techniques, is not preserved by the split of a program into the precomputation and online computation parts. Thus, instead of relying on the *liveness* property, our method relies on the *def-use* relations.

6.3 The Baseline Method

We first present the baseline method using the *def-use* relations, and then present the optimized method in the next subsection.

Since we treat each segment as an atomic unit during transformation, we only need to consider the *def-use* relations between segments. Thus, whenever two segments have *def-use* relations, there can only be three scenarios:

- (I) $\langle S_i, S_j \rangle$, meaning both are precomputation segments;
- (II) $\langle S_i, \tilde{S}_j \rangle$, meaning S_i is a precomputation and \tilde{S}_j is an online computation; and
- (III) $\langle \tilde{S}_i, \tilde{S}_j \rangle$, meaning both are online computation segments.

The fourth scenario, $\langle \tilde{S}_i, S_j \rangle$, is impossible due to our method for computing *preSet*.

In other words, a *use* in a precomputation segment always comes from a *definition* in a precomputation segment, whereas a *use* in an online computation segment may come from a *definition* in a precomputation or an online computation segment.

Furthermore, it suffices to handle only type (II) case $\langle S_i, \tilde{S}_j \rangle$, because for the other two cases, the value *can be* propagated directly between the two segments of the same type.

To maintain the *def-use* chains between precomputation and online computation segments in the type (II) case, we must insert nvm_LD and nvm_ST instructions at the proper *def* and *use* locations.

Thus, our baseline method can be summarized as follows: For each data-flow edge $\langle S_i, \tilde{S}_j \rangle(x)$, we insert $\text{nvm_ST}(Val[x, S_i])$ at the end of S_i , and insert $\text{nvm_LD}(Val[x, S_i])$ at the start of \tilde{S}_j .

Recall the scenario shown in Example 6.1, where the *def-use* chain contains only $\text{def}_2(x)$ and $\text{use}(x)$. According to our baseline method, no NVM operation needs to be added, since the *def-use* is of the type (III). The value of x used in \tilde{S}_4 comes directly from $\text{def}_2(x)$.

6.4 The Optimized Method

Now, we present an optimization to avoid *redundant* NVM operations inserted by the baseline method. To understand why some of the NVM operations inserted by our baseline method may be redundant, consider the following example.

► **Example 6.2.** In $\{S_1, \tilde{S}_2, S_3, \tilde{S}_4\}$, assume that $\text{def}(x) \in S_1$, $\text{use}_1(x) \in \tilde{S}_2$, $\text{use}_2(x) \in \tilde{S}_4$, and the *def-use* chain contains both $\text{def}(x)\text{-use}_1(x)$ and $\text{def}(x)\text{-use}_2(x)$. Our baseline method would insert

- $\text{nvm_ST}(Val[x, S_1])$ after S_1 (twice);
- $\text{nvm_LD}(Val[x, S_1])$ before \tilde{S}_2 ;
- $\text{nvm_LD}(Val[x, S_1])$ before \tilde{S}_4 .

However, executing $\text{nvm_LD}(Val[x, S_1])$ before \tilde{S}_4 is redundant because the value of x can be propagated directly from \tilde{S}_2 .

To avoid the redundant operations, we should insert nvm_LD of a $\text{def}(x)$ at the start of the earliest online computation segment where $\text{def}(x)$ is available. For the program in Example 6.2, the earliest segment is \tilde{S}_2 , which means we should insert $\text{nvm_LD}(Val[x, S_1])$ right before \tilde{S}_2 .

Thus, our optimized method can be summarized as follows: For each data-flow edge $\langle S_i, \tilde{S}_j \rangle(x)$ that we have not inserted $\text{nvm_ST}(Val[x, S_i])$ after S_i , insert $\text{nvm_ST}(Val[x, S_i])$ after S_i and insert $\text{nvm_LD}(Val[x, S_i])$ before \tilde{S}_{i+1} .

To understand the benefit of this optimization, let us compare the data flows of the following two programs. If, for example, in the original program, $Val[x, S_i]$ is available (and not killed) in the range

$$\text{end}[S_i] \rightarrow \tilde{S}_{i+1} \rightarrow S_{i+2} \rightarrow \tilde{S}_{i+3} \rightarrow \dots \quad (1)$$

and in the transformed program, $Val[x, S_i]$ is available (and not killed) in the range

$$\text{end}[S_i] \rightarrow S_{i+2} \rightarrow S_{i+4} \rightarrow S_{i+6} \rightarrow \dots \quad (2)$$

and $\text{nvm_LD } Val[x, S_i]$ has been inserted before \tilde{S}_{i+1} in the transformed program, the loaded value will also be available in the entire range

$$\tilde{S}_{i+1} \rightarrow \tilde{S}_{i+3} \rightarrow \tilde{S}_{i+5} \rightarrow \tilde{S}_{i+7} \rightarrow \dots \quad (3)$$

Therefore, we can avoid the other (redundant) nvm_LD operations before $\tilde{S}_{i+3} \dots \tilde{S}_{i+7}$.

6.5 The Transformation Algorithm

To sum up, our optimized method for transforming each function f of the original program based on preSet^* is presented in Algorithm 3.

Our method first partitions the instructions in function f to precomputation segments $\{S_i\}$ and online computation segments $\{\tilde{S}_j\}$. Next, it inserts *if-condition* to each segment using the two flags, to differentiate the three use cases. Finally, for each data-flow edge

■ **Algorithm 3** Transforming a function f in program P based on $preSet^*$.

```

1 Partition  $f$  into segments  $\{S_i\}$  and segments  $\{\tilde{S}_j\}$ ;
2 Add if-condition to each segment using precom_flag and online_flag;
3 foreach data-flow edge denoted  $\langle S_i, \tilde{S}_j \rangle(x)$  do
4   | if there is no nvm_ST(Val[x, Si]) after segment  $S_i$  then
5   |   | Add nvm_ST(Val[x, Si]) after  $S_i$ ;
6   |   | Add nvm_LD(Val[x, Si]) before  $\tilde{S}_{i+1}$ ;
7   | end
8 end

```

$\langle S_i, \tilde{S}_j \rangle(x)$, it insert NVM operations to store the value of variable x computed in S_i (the coupon) at the end of segment S_i .

While in the baseline method, the coupon is loaded from NVM at the start of \tilde{S}_j , in the optimized method, it is loaded at the start of the online computation segment \tilde{S}_{i+1} . Loading the coupon earlier provides the opportunity to eliminate many redundant NVM operations.

7 Experiments

We have implemented our method in a software tool, named COUPONMAKER, which builds upon the LLVM compiler platform [29] and the Z3 SMT solver [11]. We leverage LLVM to parse the C code of the original program, conduct inter-procedural dependency analysis and implement the semantic-preserving transformation. We use Z3 to solve the constraint satisfiability subproblems. In total, our implementation adds 1,852 lines of C++ code.

Our tool generates the LLVM bit-code of the optimized program as output, which in turn is compiled to machine code for the MSP430 MCU. To evaluate the performance of the optimized program, we use the cycle-accurate emulator MSPSim [39]. Specifically, we use MSPSim to compute the latency and energy consumption of the optimized program, and compare them with the latency and energy consumption of the original program.

7.1 Benchmarks

We evaluated COUPONMAKER on 26 benchmark programs, which are C programs implementing lightweight cryptographic protocols. In total, they have 31,113 lines of C code. Table 1 shows the statistics, where Columns 1-3 show the name, category, and source of each program, and Column 4 shows the number of lines of code (LoC).

The benchmark programs fall into two groups. The first group consists of programs that compute one-time signatures (W-OTS and Lamport) and the second group consists of programs that implement block-ciphers (e.g., AES and Camellia). A one-time signature scheme allows a message to be signed using a fresh key pair. Since any fresh key pair may work for any message, it is possible to precompute many key pairs and store them as coupons for future use. A block cipher divides a message into fixed-size blocks and then encrypts each block. For example, AES-CTR encrypts each block by first encrypting a counter value and then XOR-ing it with the plaintext to generate the ciphertext. The precomputing function is responsible for encrypting the counter value. Since there are multiple blocks, different counter values need to be encrypted. For each of the eight block-cipher programs, we also configure it in three different modes, marked by suffixes -OFB, -CFB, and -CTR, respectively.

■ **Table 1** Statistics of the benchmark programs.

Name	Category	Source	LoC
W-OTS	One-time signature	Merkle signature [40]	1,062
Lamport	One-time signature	Lamport signature[28]	339
AES	Block cipher	OpenSSL[37]	1,572
Camellia	Block cipher	OpenSSL[37]	708
DES	Block cipher	avr-crypto-lib[6]	1,277
Blowfish	Block cipher	OpenSSL[30]	1,112
skipjack	Block cipher	avr-crypto-lib[6]	475
GOST	Block cipher	OpenSSL[37]	357
SEED	Block cipher	OpenSSL[30]	476
CAST128	Block cipher	OpenSSL[31]	963

Our experiments were conducted on a computer with 2 GHz Intel Core i5 CPU and 16 GB memory. These experiments were designed to answer the following questions:

- Is COUPONMAKER efficient in optimizing the benchmark programs?
- Are the optimized programs better than the original programs in terms of both energy efficiency and latency?

7.2 Performance of the Optimization Tool

Table 2 shows the results of evaluating the optimization tool. Column 1 shows the benchmark name. Column 2 shows the total running time in seconds. Column 3 shows the size of *preSet*, which is the set of instructions that may be precomputed. Columns 4-5 compare the size of the original and optimized programs, where the size is measured in the number of bytes of the LLVM bit-code. Columns 6-8 show the details of the coupons stored in non-volatile memory, including the number of coupons, and the total bytes, and whether the coupons may be precomputed multiple times (copies).

Specifically, ∞ in the last column means the coupons may be precomputed an unlimited number of times, while 1 means they may be precomputed only once.

For programs that compute one-time signatures (W-OTS and Lamport), a theoretically unbounded number of signatures (coupons) may be precomputed. For block-cipher programs in the -OFB mode, the ciphertext of the first block may also be precomputed as many times as possible (after the first block becomes available), and in the -CNT mode, the counter *CNT* may be incremented as many times as possible and then pre-encrypted for future use.

For block-cipher programs in the -CFB mode, however, precomputation can only be done once per block, i.e., after the current block arrives.

The results show that our method is able to analyze, optimize, and transform all benchmark programs quickly. The total running time is limited to a few seconds. Moreover, the size of the program before and after optimization changes moderately. Furthermore, the number and size of precomputed coupons are significant for all programs.

7.3 Performance of the Optimized Programs

Table 3 shows the result of evaluating the performance of the optimized programs. These results were obtained using the MSPSim tool for MSP430FR599x [24]. Since MSPSim requires the programs to be executed under concrete test inputs, for one-time signature programs (W-OTS and Lamport), we obtain the test inputs by signing a fixed-length message; for block-cipher programs, we obtain the test inputs by encrypting sensor data that represent a sequence of temperature measurements.

■ **Table 2** Performance of the analysis tool COUPONMAKER.

Name	Time (s)	PreSet Size	Program Size		Coupon Size		
			orig.	opti.	num	bytes	copies
W-OTS	5.26	1,632	16,116	21,704	3	1,152	∞

GOST-OFB	2.79	596	12,508	17,504	1	8	∞
GOST-CFB	3.16	596	12,492	17,484	1	8	1
GOST-CTR	3.01	844	12,952	17,984	1	8	∞
SEED-OFB	2.67	196	31,120	36,384	1	8	∞
SEED-CFB	2.68	196	31,100	36,368	1	8	1
SEED-CTR	3.11	340	31,564	36,852	1	8	∞
CAST128-OFB	2.49	352	46,628	51,748	1	8	∞
CAST128-CFB	2.74	352	46,608	51,732	1	8	1
CAST128-CTR	3.00	396	47,064	52,228	1	8	∞

In the result table, Column 1 shows the benchmark name. Column 2 shows the energy (μJ) consumed by the original program. Columns 3-4 show the energy (μJ) consumed by the optimized program, which is divided into the precomputing and online steps. Recall that in energy-harvesting applications, energy reported in the $E(\text{pre})$ column is considered to be free. Thus, the ratio in Column 5 represents the actual performance improvement.

The results show that the optimized programs significantly outperform the original programs in terms of energy efficiency. The improvement ranges from 2.3X to 36.7X. We also compared the latency of the original and optimized programs and observed a similar improvement; we omit the result table due to space limit. Overall, these results show that our method is effective in reducing the latency and energy cost.

7.4 Impact of the Precomputation Policy

Finally, we evaluate the impact of precomputation policy by computing the energy saving per unit use of non-volatile memory storage, measured by $qf = (E(\text{ori}) - E(\text{on})) / \text{Size}(\text{coupon})$, where qf stands for quality factor. The results are shown in Figure 11, where the x -axis is the index of the array of benchmark programs and the y -axis is the quality factors (qf) achieved by the baseline and optimized methods for program transformation (Section 6).

In this figure, blue bars (*optimal*) correspond to the optimized precomputation policy (preSet^*), while orange bars (*baseline*) corresponds to the initial precomputation policy (preSet). Here, a higher qf value corresponds to a better result. Overall, the optimized precomputation policy leads to significantly better results.

■ **Table 3** Evaluating reduction in energy cost on MSP430.

Name	Original Program	Optimized Program		Improvement
	$E(ori)$	free $E(pre)$	$E(on)$	$E(ori)/E(on)$
W-OTS	115565.43	56114.99	49576.70	2.3X
Lamport	355.91	287.31	82.71	4.3X
AES-OFB	89.06	87.96	4.85	18.4X

skipjack-OFB	26.16	25.20	5.42	4.8X
skipjack-CFB	29.33	25.20	8.58	3.4X
skipjack-CTR	26.73	26.06	5.71	4.7X
GOST-OFB	29.10	29.01	2.59	11.3X
GOST-CFB	29.83	29.01	3.32	9.0X
GOST-CTR	29.65	29.61	2.62	11.3X
SEED-OFB	20.32	19.21	4.85	4.2X
SEED-CFB	21.92	19.21	6.45	3.4X
SEED-CTR	20.49	17.64	3.22	6.4X
CAST128-OFB	164.89	161.86	16.89	9.8X
CAST128-CFB	170.24	161.86	22.24	7.7X
CAST128-CTR	165.95	163.05	16.99	9.8X

For W-OTS, qf (optimal) is also significantly higher than qf (baseline). However, the qf values for W-OTS are not included in the figure, to avoid making the rest of the bar chart less readable. This is because W-OTS takes several orders-of-magnitude more clock cycles than the other programs, and thus has a much higher qf value.

8 Related Work

While prior work has shown the feasibility of optimizing energy-harvesting applications using precomputation [47], optimization is performed manually; to the best of our knowledge, this is the first automated optimization method. Compared to Suslowicz et al. [47], in particular, our method can complete all of the optimization work with comparable performance. Moreover, our method can support additional constraints for optimization, which the manual method cannot deal with easily. Since our method is designed to preserve the original program semantics, it is not meant for scenarios where the underlying algorithms are intended to be rewritten according to some mathematical rules [4, 5] – automation for such transformation is beyond the scope of this work.

Our method differs from the large number of intermittent computing techniques aimed to improve general-purpose systems with a strong and yet unstable power supply; these techniques [43, 35, 32, 48] focus on recovering from power loss using *checkpointing*, avoiding the costly register accesses, or reducing the cost for loop-heavy programs [18, 17]. There are also techniques for robustly supporting peripherals [46, 36]. However, none of them considers the scenario where ambient energy source is ample but the computing device is idle, let alone leveraging precomputation to reduce the energy cost.

■ **Figure 11** The impact of the precomputation policy on performance improvement. Here, baseline corresponds to *preSet* and optimal corresponds to *preSet**.

There are also techniques for programming transiently-powered computers with both volatile and non-volatile memory, for example, by leveraging the application’s memory access patterns to manually optimize data placement [9, 32, 34], or mapping of code sections to either volatile or non-volatile memory [25] based on where the optimal energy consumption could be achieved. There are also efficient checkpointing techniques [21, 1] for CPUs with fully non-volatile main memory. However, none of them focuses on automated program optimization based on precomputation.

Constraint solving based techniques are widely used for program verification, repair and optimization. For example, they have been used to debug concurrent software [27, 23] and optimize the quality of embedded software [13]. They have also been used to mitigate side-channel vulnerabilities [49, 19, 52, 50], including power side-channel leaks [54, 51]. However, power side-channel mitigation focuses on eliminating *tiny fluctuations* in power consumption that are also *secret-dependent* [14], instead of reducing the power consumption itself.

While our focus in this work is on optimizing software for energy-harvesting applications, the underlying ideas may be applied to other applications of similar nature, e.g., precomputation for Trusted Authority (TA) in the context of multi-party computation (multi-party learning and predicting[53, 16]). Since the application domain is significantly different, to deal with software used in such applications, our LLVM based implementation may need to be updated accordingly – we leave this for future work.

9 Conclusion

We have presented a constraint based method for optimizing the energy efficiency of software code running on devices powered by electricity harvested from the environment. Our method is sound and fully automated. It relies on static program analysis to identify instructions that may be precomputed, constraint solving to compute an optimal subset, and compiler transformation to generate the new software code. Our experimental evaluation on a large number of benchmark programs shows that the proposed method can handle all of the benchmark programs quickly, and the optimized programs significantly outperform the original programs in terms of both energy efficiency and latency.

Abstract

We propose restrictable variants as a simple and practical alternative to extensible variants. Restrictable variants combine nominal and structural typing: a restrictable variant is an algebraic data type indexed by a type-level set formula that captures its set of active labels. We introduce new pattern-matching constructs that allows programmers to write functions that only match on a subset of variants, i.e., pattern-matches may be non-exhaustive. We then present a type system for restrictable variants which ensures that such non-exhaustive matches cannot get stuck at runtime.

An essential feature of restrictable variants is that the type system can capture structure-preserving transformations: specifically the introduction and elimination of variants. This property is important for writing reusable functions, yet many row-based extensible variant systems lack it.

In this paper, we present a calculus with restrictable variants, two partial pattern-matching constructs, and a type system that ensures progress and preservation. The type system extends Hindley-Milner with restrictable variants and supports type inference with an extension of Algorithm W with Boolean unification. We implement restrictable variants as an extension of the Flix programming language and conduct a few case studies to illustrate their practical usefulness.

1 Introduction

“Perfection is achieved, not when there is nothing more to add, but when there is nothing left to take away.”
– Antoine de Saint-Exupéry

In functional programming, algebraic data types and pattern matching have been hugely successful. So successful that many non-functional mainstream programming languages, including Kotlin and Rust have also adopted them. While algebraic data types, i.e. sum and variant types, are widely used, their cousins *extensible variants* and *extensible records* are far less available. Extensible variants and records, based on row-polymorphic type systems, have been known for several decades [11, 16, 37]. Yet one has to look far to find usable implementations. OCaml does not support extensible records, but does support a form of extensible variants as a “language extension”, but this implementation is far less powerful than simple row-polymorphic systems. PureScript supports extensible records, but not extensible variants.¹ Elm had support for extensible records, but this feature was removed.² We speculate that there are at least a few reasons for this lack of support: (i) lack of real (or perceived) use cases, (ii) implementation difficulty, and (iii) hitting the “right” expressiveness.

17:2 Restrictable Variants

To expand on (iii), we believe we have identified a major practical weakness in existing row-based extensible variant systems. We illustrate the problem with an example: In a compiler pipeline, we can view each compiler phase as a function, and the whole compiler as the composition of these functions. For example, we might have:

```
let compile = ... >> typecheck >> lambdalift >> codegen
```

where `>>` is forward function composition. The `lambdalift` phase performs closure conversion and lambda lifting which is required before we can generate machine code. Concretely, we can imagine that the `lambdalift` function replaces `Lambda` expressions with `Closure` expressions in the abstract syntax tree. We say that `lambdalift` *introduces* the `Closure` variant and *eliminates* the `Lambda` variant. Importantly, we must run `lambdalift` before we can run `codegen`.

As compiler writers, it would be very useful if we could type check the abstract syntax trees produced by `lambdalift`. That is, we would like to write:

```
let compile = ... >> typecheck >> lambdalift >> typecheck >> codegen
```

This requires us to extend the `typecheck` function to handle `Closure` expressions, but that is simple; type checking them is similar to type checking lambdas.

We might think that the above scenario can be programmed with row-based extensible variants, but, unfortunately, this is not the case. The problem is the following: The `codegen` phase *cannot* handle abstract syntax trees unless they have been closure-converted and lambda-lifted, i.e. unless the `Lambda` expression has been eliminated. But after the second call to `typecheck`, a row-based system loses the knowledge that the `Lambda` variant has been eliminated, hence the above program does not type check.

We call this phenomenon the *co-domain problem* for extensible variants:

The Co-Domain Problem: Type systems with extensible variants based on row polymorphism are unable to precisely capture the *introduction* and *elimination* of variants in pattern-matches. (We expand on the details in Section 5.)

To overcome this issue, we propose *restrictable variants*. A restrictable variant is a sum type indexed by a type-level set formula that over-approximates the “active” set of labels of the sum. We can think of a restrictable variant as a form of refinement type [10, 36] where the type-level index refines the possible labels of an expression of that type. In this way, restrictable variants combine nominal and structural typing. With restrictable variants, programmers can write *one* data type definition and reuse it in different contexts. This is in contrast to the standard functional programming approach of writing multiple, but similar, data types definitions or using a purely structural type system.

In this paper, we introduce restrictable variants and a new partial pattern-matching construct which comes in two flavors: `choose` and `choose*`. The `choose` expression permits a non-exhaustive pattern-match on a restrictable variant where only some variants are handled. The `choose*` expression goes further and enables programmers to write structure-preserving transformations which are captured at the type level. Specifically, we can precisely capture the *introduction* or *elimination* of variants. This overcomes the co-domain problem that was outlined above. We propose a type system for restrictable variants which is an extension of Hindley-Milner, supports complete type inference, and ensures that programs with partial pattern-matches (i.e. with `choose` and `choose*`) cannot get stuck.

We compare the expressiveness of restrictable variants to other existing systems, including row-based extensible variants [11, 16, 33, 37], row theories [30], occurrence typing [7], and relational nullable types [25]. We find that many of these systems are significantly more expressive (and sometimes more complex) than restrictable variants, yet most cannot express

the simple programming patterns that we use in our case studies. We think that restrictable variants (like row-based systems) have simple types that will be understandable by ordinary programmers and which will work well in practice. It is also our hope that restrictable variants can serve as inspiration for new and more sophisticated type systems that can handle the use cases we present.

The ideas in this paper are simple, but as far as we can tell, they have not yet been explored in the literature, and we believe they solve real problems. While we present *restrictable variants* as an alternative to *extensible variants*, we have found that it is natural to combine restrictable variants with *extensible records* (a point we return to in Section 6).

We implement restrictable variants as an extension of the Flix programming language. We discuss how the implementation supports complete type inference as a natural extension of Algorithm W. The two key ideas are: (i) a type rule, for the `choose*` expression, which relates the type-level index of the “input” (scrutinee expression) to the “output” (result expression), and (ii) a formulation of the type rule as a *set equation* which is solvable by Boolean unification in the algebra of sets.

We use the implementation to conduct a case study of a few programs that use restrictable variants. The first case study models Boolean formulas and is used as a running example throughout the paper. The second case study combines the `Option`, `List`, and `Nel` (non-empty list) data types into one restrictable variant. The third case study shows how to combine restrictable variants with extensible records. The case studies demonstrate that programming with restrictable variants is simple and valuable.

In summary, the contributions of this paper are:

- **(Restrictable Variants)** We present *restrictable variants*: a simple alternative to extensible variants. Restrictable variants offer a new point in the design space with different trade-offs from existing systems. Moreover, restrictable variants solve the function composition problem for row-based extensible variants.
- **(Type System)** We present a type system for restrictable variants. We prove the standard progress and preservation theorems. The type system ensures that a program with partial pattern-matches (the `choose` and `choose*` expressions) cannot get stuck.
- **(Implementation)** We implement restrictable variants as an extension of the Flix programming language. We discuss how the type system supports type inference via an extension of Algorithm W with Boolean unification.
- **(Expressiveness)** We compare the expressiveness of restrictable variants to other systems. We observe that restrictable variants are simple, yet they support reasonable use cases that cannot be handled by many other systems, in particular those based on row polymorphism.
- **(Case Study)** We present a case study of a few programs that use restrictable variants. The case study shows that (a) restrictable variants are useful and (b) capture real-world programming patterns.

This paper is organized as follows: In Section 2 we present restrictable variants and motivate their use with several examples. In Section 3 we present a type system for restrictable variants based on type-level set formulas. In Section 4 we discuss our implementation of restrictable variants and show how to implement type inference. In Section 5 we compare the expressiveness of restrictable variants to other systems, including row-based extensible variants. In Section 6 we present a case study on the use of restrictable variants. In Section 7 we present related work and in Section 8 we conclude the paper.

2 Motivation

We motivate restrictable variants with several examples. We begin with a simple example to build intuition. Next, we move on to a more realistic example of modeling Boolean formulas, which we use as a running example throughout the rest of the paper. We show many types, but, of course, the point is that they can be inferred. All examples are runnable in our extension of Flix.

► **Example 1 (Restrictable Variant).** We can define a *restrictable variant* data type:

```
enum Color[s] {
  case Red
  case Green
  case Blue
}
```

The `Color` type is *indexed* by a type variable `s` that ranges over the *labels* of the algebraic data type. The labels of the `Color` data type are: `Red`, `Green`, and `Blue`. The index is a set formula that captures which variants of the data type may be present. For example:

$$\text{Color}\{\{\}\} = \emptyset \quad \text{Color}\{\{\text{Red}, \text{Blue}\}\} = \{\text{Red}, \text{Blue}\} \quad \text{Color}[\text{Green}^c] = \{\text{Red}, \text{Blue}\}$$

We can also have richer indices where a free variable is involved. For example:

$$\text{Color}[s - \text{Red}] \subseteq \{\text{Green}, \text{Blue}\} \quad \{\text{Green}, \text{Blue}\} \subseteq \text{Color}[(s - \text{Red}) + (s^c)] \subseteq \{\text{Red}, \text{Green}, \text{Blue}\}$$

where s is a free variable. In full generality, the index is a *type-level set formula* whose valuations capture which variants of the data type may be present. As the examples show, there are many equivalent set formulas. For example, Green^c is equivalent to the set $\{\text{Red}, \text{Blue}\}$. The set formulas may also contain variables, a fact that becomes important when we consider pattern-matches on restrictable variants.

We can write a function that only operates on some colors of a restrictable variant:

```
def isWarm(c: Color[{Red, Blue}]): Bool = choose c {
  case Red => true
  case Blue => false
}
```

Here the type of `isWarm`, which can be fully inferred, captures that the function can accept any color which is either `Red` or `Blue`. Specifically, the type system ensures that it is a compile-time type error to call `isWarm` with the color `Green`.

This example demonstrates a key feature of the proposed type system: We can write pattern-matches that are non-exhaustive and have the type system ensure that a function like `isWarm` is never invoked with a value that is not handled.

With some intuition in place, we now move on to our running example: a restrictable variant that models Boolean formulas. We use Boolean formulas since they are well-known and they are sufficient to illustrate several key features of our system. We want to stress that the following ideas scale to more complex data types, e.g. abstract syntax trees, as we shall discuss in Section 6.

A remark on notation: In Flix source code we shall write $\neg s$ for S^c , $s_1 + s_2$ for $S_1 \cup S_2$, and $s_1 \& s_2$ for $S_1 \cap S_2$. We use these symbols because they are in ASCII and are reminiscent of the bitwise operators. In the formal treatment of the calculus and its type system (Section 3), we will use the standard math symbols.

► **Example 2 (Variant Restriction).** We can define a restrictable variant for Boolean formulas:

```
enum Expr[s] {
  case Var(Int32)
  case Cst(Bool)
  case Not(Expr[s])
  case Or(Expr[s], Expr[s])
  case And(Expr[s], Expr[s])
  case Xor(Expr[s], Expr[s])
}
```

We can write a function which reduces *closed* terms to a Boolean constant:

```
def eval(e: Expr[~Var]): Bool =
  choose e {
    // Var case omitted: We can only evaluate closed terms.
    case Cst(b)      => b
    case Not(x)      => not eval(x)
    case Or(x, y)    => eval(x) or eval(y)
    case And(x, y)   => eval(x) and eval(y)
    case Xor(x, y)   => eval(x) != eval(y)
  }
```

The evaluator itself is straightforward. We simply pattern-match on each case and implement the semantics directly. What is interesting is that we cannot evaluate an open term (i.e. a formula with variables in it), hence we simply omit the `Var` case from the pattern-match. The type system then infers that the `eval` function can be passed any Boolean expression as long as it does not use the `Var` variant. This is captured by the type `Expr[~Var]` which is equivalent to `Expr[~{Cst, Not, Or, And, Xor}]`.

► **Example 3 (Variant Elimination).** We can also write a Boolean formula simplifier which eliminates the `Xor` term by translation:

```
def simplify(e: Expr[s]): Expr[~Xor] =
  choose e {
    case Var(x)      => Var(x)
    case Cst(b)      => Cst(b)
    case Not(x)      => Not(simplify(x))
    case Or(x, y)    => Or(simplify(x), simplify(y))
    case And(x, y)   => And(simplify(x), simplify(y))
    case Xor(x, y)   =>
      let x1 = simplify(x);
      let y1 = simplify(y);
      Or(And(x1, Not(y1)), And(Not(x1), y1))
  }
```

The simplifier is also straightforward. The return type of the `simplify` function now excludes the possibility that the returned value can contain a `Xor` variant. This is captured by the type `Expr[~Xor]` which is equivalent to `Expr[~{Var, Cst, Not, Or, And}]`.

The unfortunate weakness of the simplifier is that if we know that the input cannot contain any variables (e.g. the `Var` variant) then this information is lost in the output. For example, if we have a closed Boolean formula, *we cannot simplify it and then evaluate it* because the return type of `simplify` includes the `Var` variant in its type. We lost the knowledge that the term was closed!

17:6 Restrictable Variants

The fundamental issue is that in `simplify` we have lost the relation between the type-level index in the argument type (i.e., `Expr[s]`) and the result type (i.e., `Expr[~Xor]`). To overcome this, we introduce the `choose*` construct. The `choose*` construct allows us to maintain a relation between the input type and the output type, as the following example shows:

► **Example 4 (Structure-Preserving Map)**. We can use the `choose*` construct to write a structure-preserving map function:

```
def map(f: Int32 -> Int32, e: Expr[s]): Expr[s] =
  choose* e {
    case Var(x)      => Var(f(x))
    case Cst(b)      => Cst(b)
    case Not(x)      => Not(map(f, x))
    case Or(x, y)    => Or(map(f, x), map(f, y))
    case And(x, y)   => And(map(f, x), map(f, y))
    case Xor(x, y)   => Xor(map(f, x), map(f, y))
  }
```

The `map` function applies a function $f : \text{Int32} \rightarrow \text{Int32}$ to every variable in the given expression. What is essential is that the argument type is `Expr[s]` and the result type is `Expr[s]` which means that information about the “active” variants in the input is preserved in the output.

► **Example 5 (Simplify – Revisited)**. Recall that the original version of `simplify` used `choose` and had the signature:

```
def simplify(e: Expr[s]): Expr[~Xor] = ...
```

If we change the implementation to use `choose*` we instead get the more precise signature:

```
def simplify(e: Expr[s]): Expr[(s - Xor) + {Not, And, Or}]
```

which captures that `simplify` will return an expression that may contain the `Not`, `Or`, `And` variants plus the `Cst` and `Var` variants, if the input contains them. We might have hoped the return type would simply be `Expr[(s - Xor)]`, but the type system cannot exclude the `Not`, `Or`, `And` variants because they are introduced by elimination of `Xor`. Fortunately, the signature of `simplify` is strong enough to capture the two important properties we care about:

- The `Var` variant can only occur in the output if it occurs in the input.
- The `Xor` variant is eliminated, i.e. cannot occur in the output.

Consequently, if the input is a closed formula (i.e. lacks the `Var` variant) then after simplification *it will still be closed* and we can evaluate it.

With the updated `simplify`, we can write a function:

```
let run = simplify >> eval
```

which is inferred to have the type `Expr[s - Var] → Bool` where the closedness requirement is propagated “backwards” through the (forward) function composition operator `>>`.

► **Example 6 (Substitution)**. We can also write a substitution function that replaces each variable in a Boolean formula with a value from an environment:

```
def subst(m: Map[Int32, Bool], e: Expr[s]): Expr[(s - Var) + Cst] =
  choose* e {
    case Var(x)      => Cst(Map.getWithDefault(x, false, m))
    case Cst(b)      => Cst(b)
    case Not(x)      => Not(subst(m, x))
    case Or(x, y)    => Or(subst(m, x), subst(m, y))
    case And(x, y)   => And(subst(m, x), subst(m, y))
    case Xor(x, y)   => Xor(subst(m, x), subst(m, y))
  }
```

We define the `subst` function to operate on all Boolean expressions. The return type of `subst` is the same as the input type (*sans* `Var`), but may potentially contain the `Cst` variant. The reason is that the type system is not sufficiently expressive to capture that the `Cst` variant can only occur if *either* the `Var` *or* the `Cst` variants are present in the input. This “loss of precision” only affects the `Cst` variant. For example, we still know that if the input cannot contain the `Xor` variant then neither can the output.

► **Example 7 (Function Composition).** Imagine that we have a fast evaluator, but it only supports the `Cst`, `Not`, `And`, and `Or` variants. We can capture this with the signature:

```
def fasteval(e: Expr[s & {Cst, Not, And, Or}]): Bool = ...
```

We can *compose* the `simplify`, `subst`, and `fasteval` functions as follows:

```
let fastrun = m -> simplify >> subst(m) >> fasteval
```

The (inferred) type of `fastrun` is:

$$\text{fastrun} : \forall s. \text{Map}[\text{Int32}, \text{Bool}] \rightarrow \text{Expr}[s] \rightarrow \text{Bool}$$

i.e., given an environment and a Boolean expression it computes a primitive `Bool`.

What is essential is that the function types of `simplify`, `subst`, and `fasteval` *compose* in a way that preserves the information that `simplify` eliminates the `Xor` variant and `subst` eliminates the `Var` variant, hence the final call to `fasteval` is valid. Looking at the types:

$$\begin{aligned} \text{simplify} &: \forall s_1. \text{Expr}[s_1] \rightarrow \text{Expr}[s_1 - \text{Xor} + \{\text{Not}, \text{And}, \text{Or}\}] \\ \text{subst}(m) &: \forall s_2. \text{Expr}[s_2] \rightarrow \text{Expr}[(s_2 - \text{Var}) + \text{Cst}] \\ \text{fasteval} &: \forall s_3. \text{Expr}[s_3 \& \{\text{Cst}, \text{Not}, \text{And}, \text{Or}\}] \rightarrow \text{Bool} \end{aligned}$$

We see that when we apply the output of `simplify` as the input to `subst(m)`, we get the type:

$$\text{Expr}[(((s_1 - \text{Xor} + \{\text{Not}, \text{And}, \text{Or}\})) - \text{Var}) + \text{Cst}]$$

This type is compatible with the input type of `fasteval` because the *set equation*:

$$(((s_1 - \text{Xor} + \{\text{Not}, \text{And}, \text{Or}\})) - \text{Var}) + \text{Cst} = s_3 \& \{\text{Cst}, \text{Not}, \text{And}, \text{Or}\}$$

has a solution. Specifically, it has the most-general unifier:

$$\{s_3 \mapsto s_1 + \{\text{Cst}, \text{Not}, \text{And}, \text{Or}\}\}$$

where s_1 and s_2 are implicitly mapped to themselves. This solution can be found by Boolean unification. Thus, in summary, we are able to infer that `fastrun` has the type $\forall s. \text{Map}[\text{Int32}, \text{Bool}] \rightarrow \text{Expr}[s] \rightarrow \text{Bool}$ which means that it works for any Boolean formula.

As we shall discuss in Section 5, the power of our system is this ability to track the *introduction* and *elimination* of variants *through function composition*. Notably, several other existing systems lack this property, including row-based extensible variants. The key issue is that a row polymorphic system is unable to precisely relate the input type of a (partial) pattern-match to its output type. Thus we lose track of the fact that `simplify` eliminates the `Xor` variant and hence we cannot call `fasteval`. We call this phenomenon the “co-domain” problem for extensible variants since these type systems lack the ability to relate the domain of a (partial) pattern-match (i.e. its input type) to its co-domain (i.e. its output type).

In our experience and based on the case studies (Section 6), we find it important to stress how important this property is for reusability. In a compiler, we want to write the `subst` function *once* and for the *entire* abstract syntax tree. However, if the `subst` function loses information about what variants can be returned in its output, then its utility is hampered, as most compiler phases only operate on a subset of the entire abstract syntax tree.

2.1 Summary

We conclude with a summary of the properties of the proposed system:

- **(Property I)** Restrictable variants are sum types indexed by a type-level set formula that over-approximates the “active” set of labels of the sum. Programmers can use restrictable variants to write *one* data type definition that is reusable in many different contexts.
- **(Property II)** The `choose` construct enables programmers to write non-exhaustive pattern-matches on restrictable variants handling only the relevant cases. The `choose*` construct enables a form of refinement typing where the result type of a non-exhaustive pattern-match is related to its input type.
- **(Property III)** Functions on restrictable variants *compose* under introduction and elimination of labels; i.e., a sequence of introductions and eliminations does not lose information at the type level.
- **(Property IV)** The type system ensures that the non-exhaustive `choose` or `choose*` constructs cannot get stuck at runtime. The type system extends Hindley-Milner and supports complete type inference.
- **(Property V)** Restrictable variants are a natural generalization of algebraic data types and are simple to implement.

3 Restrictable Variants

We now present $\lambda_{\text{var}}^{\text{res}}$: a minimal lambda calculus with restrictable variants. We present its syntax and semantics, then its type system, and finally its meta theoretic properties. The $\lambda_{\text{var}}^{\text{res}}$ calculus and its type system are mostly standard; the novelties are the `choose` and `choose*` constructs and the use of *set formulas* in the type system.

3.1 Syntax and Semantics

We begin with a discussion of the syntax and semantics of the $\lambda_{\text{var}}^{\text{res}}$ calculus.

Syntax

The syntax of the $\lambda_{\text{var}}^{\text{res}}$ calculus (cf. Figure 1a) includes the standard lambda calculus constructs: variables, constants, lambda abstractions, and function applications. The `let`-expression allows polymorphic generalization, as is standard in Hindley-Milner. We include the `if-then-else` expression to illustrate how the type system merges information. We require that every $\lambda_{\text{var}}^{\text{res}}$ program comes with a map $\Sigma : \text{Enum} \rightarrow \text{Label} \rightarrow \text{Scheme}$ of declared variants.

The raison d’être is the `choose $e \{\bar{\eta}\}$` and `choose* $e \{\bar{\eta}\}$` expressions. In both expressions, e is the match expression and $\bar{\eta}$ is a sequence of match cases. A match case is of the form `case $\mathcal{E}.\ell(x) \Rightarrow e$` where \mathcal{E} is the enum that the label ℓ belongs to, x is the match variable, and e is the match expression body. As shown, we prefix all labels with the enum they come from; i.e., we write “Color.Red” and not just “Red”. Recall that both `choose` expressions are needed, since `choose` allows expression bodies to have an arbitrary type, whereas `choose*` requires that the expression bodies have the same type as the match expression (modulo the type-level

--	---

■ **Figure 2** Evaluation Rules of $\lambda_{\text{var}}^{\text{res}}$.

indices). We construct a variant value with the $\mathcal{E}.\ell(e)$ expression, e.g. “Color.Red()” where $()$ is the unit value. The $\mathbf{choose} \ e \ \{\bar{\eta}\}$ and $\mathbf{choose}^* e \ \{\bar{\eta}\}$ expressions are akin to pattern-matches, except there are no wildcards, tuple patterns, or nested patterns. Importantly, the **choose** and **choose*** expressions do not have to be exhaustive.

The $\mathbf{open} \ e$ expression is not part of the surface syntax, and is present only during evaluation. Semantically, $\mathbf{open} \ e$ is equivalent to e . Its purpose is explained in Section 3.2.

Semantics

The semantics of $\lambda_{\text{var}}^{\text{res}}$ is a call-by-value operational semantics for the lambda calculus. Figure 2 shows the evaluation rules of $\lambda_{\text{var}}^{\text{res}}$ which are standard except for (E-OPEN), (E-CHOOSE), and (E-CHOOSE- \star). We write $e[x \mapsto v]$ for the capture avoiding substitution of $x \mapsto v$ into e . The congruence rules, prefixed with C, enforce a left-to-right evaluation order. The (E-OPEN) rule reduces a tagged value $\mathcal{E}.\ell(v)$ to itself. The (E-CHOOSE) evaluation rule captures that if we evaluate a tagged value $\mathcal{E}.\ell(v)$ for some value v then we look for a case $\mathbf{case} \ \mathcal{E}.\ell(x) \Rightarrow e$ in the pattern-match. If found, we evaluate the case body, i.e. we step to $e[x \mapsto v]$. The (E-CHOOSE- \star) is very similar, but it instead steps to $\mathbf{open} \ e[x \mapsto v]$.

How $\lambda_{\text{var}}^{\text{res}}$ Programs “Get Stuck”

We briefly illustrate how $\lambda_{\text{var}}^{\text{res}}$ programs may get stuck during evaluation. The obvious reason is when `true` or `false` is applied as a function, or when a lambda expression is used as a condition in an if-then-else. The more interesting case is when a `choose` or `choose*` expression is applied to a variant for which there is no case:

```
choose Green {
  case Red => true
  case Blue => false
}
```

The type system will reject such programs.

3.2 Type System

We now describe the type system of $\lambda_{\text{var}}^{\text{res}}$: its types, type rules, and meta-theory.

Mono Types and Poly Types (Type Schemes)

The types of $\lambda_{\text{var}}^{\text{res}}$ are separated into mono types (τ) and type schemes (σ). The mono types include type variables α , the base types `Unit` and `Bool`, function types $\tau \rightarrow \tau$, and variant types $\mathcal{E}[\varphi]$ which consist of an enum symbol \mathcal{E} indexed by a type-level Boolean set formula φ . The language of formulas, for a given variant type \mathcal{E} , consists of the empty set \emptyset , a singleton set with one label $\{\mathcal{E}.l\}$, Boolean variables β , the complement of a formula φ^c , the union of two formulas $\varphi \cup \varphi$, and the intersection of two formulas $\varphi \cap \varphi$. We write $A - B$ for set difference which is equivalent to $A \cap B^c$. We also write $A <: B$ as an alias for the constraint $A - B = \emptyset$ (i.e. $A <: B \Leftrightarrow A \cap B^c = \emptyset$). Note that the complement of a set is well-defined, since a variant type is declared to have a fixed finite set of labels (which forms the universe).

In principle, to ensure that it always clear what the universe of labels is, we should always index each set formula with its associated variant type \mathcal{E} symbol, e.g. we should write $\varphi_{\mathcal{E}}$. However, we typically omit the enum name when it is clear from the context.

We write $\text{ftv}(\varphi)$ for the variables in φ . A *valuation* ν for a formula φ is an assignment of concrete sets of labels to all of the variables in $\text{ftv}(\varphi)$. In this way, we can view a set formula as a function from concrete sets to a concrete set. Two set formulas φ_1 and φ_2 are *equivalent* (written $\varphi_1 \equiv_{\mathbb{B}} \varphi_2$) if they describe the same function. That is, if $\forall \nu. \nu(\varphi_1) = \nu(\varphi_2)$ where ν must be a valuation of both φ_1 and φ_2 .

Type schemes σ extend types by quantification over type variables α and Boolean variables β . That is, a type scheme is of the form $\forall \bar{\gamma}. \tau$, where $\bar{\gamma}$ is a vector of type variables and Boolean variables. Figure 1b shows the types and type schemes of $\lambda_{\text{var}}^{\text{res}}$.

We define type equivalence as the smallest relation $\equiv_{\mathbb{B}}$ ³ such that:

- $\tau \equiv_{\mathbb{B}} \tau$.
- If $\tau_1 \equiv_{\mathbb{B}} \tau'_1$ and $\tau_2 \equiv_{\mathbb{B}} \tau'_2$ then $\tau_1 \rightarrow \tau_2 \equiv_{\mathbb{B}} \tau'_1 \rightarrow \tau'_2$.
- If $\varphi \equiv_{\mathbb{B}} \varphi'$, then $\mathcal{E}[\varphi] \equiv_{\mathbb{B}} \mathcal{E}[\varphi']$.

For example, we have that $\text{Color}[\{\text{Red}\}^c] \equiv_{\mathbb{B}} \text{Color}[\{\text{Green}, \text{Blue}\}]$. Two types, with set formulas in them, do not have to share the same variables (or even share the same number of variables) to be equivalent. For example: $\text{Color}[\{\text{Green}\}] \equiv_{\mathbb{B}} \text{Color}[(\beta \cap \{\text{Green}\}) \cup \{\text{Green}\}]$.

We define substitutions $S : (\text{TypeVar} \cup \text{BoolVar} \rightarrow \text{Type})$ as assignment of type variables to types and Boolean variables to Boolean formulas. We say the type τ is an instance of type scheme σ , written $\sigma \sqsubseteq \tau$, if $\sigma = \forall \bar{\gamma}. \tau'$ and there exists a type substitution S such

³ We overload the $\equiv_{\mathbb{B}}$ symbol to stand for both Boolean equivalence and type equivalence.

that $\text{dom}(S) = \bar{\gamma}$ and $S(\tau') = \tau$. Moreover, we define a context Γ as a map of bindings $x : \sigma$, and $\text{ftv}(\sigma)$ to be the type variables that occur free in σ , and $\text{ftv}(\Gamma)$ as the union of all free type variables in its range. We also define the generalization of a type $\text{gen}(\Gamma, \tau)$ as $\forall \alpha_1, \dots, \forall \alpha_n. \forall \beta_1, \dots, \forall \beta_n. \tau$ where $\{\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_n\} = \text{ftv}(\tau) \setminus \text{ftv}(\Gamma)$.

Variant Declarations

As stated earlier, we require every restrictable variant to be declared. Specifically, we assume that there is a set of enum symbols $Enum$ and map $\Sigma : Enum \rightarrow Label \rightarrow Scheme^4$ which assigns a type scheme to every constructor (label) of the type. We require that the type schemes are of one of the two following forms⁵:

1. $\Sigma(\mathcal{E}.l) = \forall \beta. \tau \rightarrow \mathcal{E}[\beta]$ $\text{ftv}(\tau) = \emptyset$
2. $\Sigma(\mathcal{E}.l) = \forall \beta. \mathcal{E}[\beta] \rightarrow \mathcal{E}[\beta]$

These requirements ensure that:

- A constructor is applied to a simple type (e.g. $\Sigma(\text{Color.Red}) = \forall \beta. \text{Unit} \rightarrow \text{Color}[\beta]$), or
- A constructor is applied to the same variant type, but with the *same* type-level index (e.g. $\Sigma(\text{Expr.Not}) = \forall \beta. \text{Expr}[\beta] \rightarrow \text{Expr}[\beta]$).
- The type scheme of a constructor is always polymorphic function type over β whose result type is of the form $\mathcal{E}[\beta]$.

And that the following lemma holds:

► **Lemma 8** (LABEL-INSTANTIATION). *If two instantiations of the same label type scheme share the same result type then they must share the same argument type.*

$$\Sigma(\mathcal{E}.l) \sqsubseteq \tau_1 \rightarrow \mathcal{E}[\varphi] \quad \wedge \quad \Sigma(\mathcal{E}.l) \sqsubseteq \tau_2 \rightarrow \mathcal{E}[\varphi] \quad \Longrightarrow \quad \tau_1 = \tau_2$$

Intuitively, the result type of an instantiated label type scheme uniquely determines its argument type. The idea is that if we know that $\text{Not}(e) : \text{Expr}[\{\text{Cst}, \text{Not}\}]$ then know that the type of e is also $\text{Expr}[\{\text{Cst}, \text{Not}\}]$. In other words, the type-level index of a restrictable variant also applies to its constituents. This fact is used to show preservation.

Type Rules

Figure 3 shows the declarative type rules of $\lambda_{\text{var}}^{\text{res}}$. A declarative typing judgment is of the form $\Gamma \vdash e : \tau$. As is standard, the context $\Gamma : Var \leftrightarrow Scheme$ is a partial function from variables to type schemes. Most of the type rules are standard.

The (T-EQ) rule states that if an expression e can be typed as τ_1 , that type can be replaced by any equivalent type $\tau_2 \equiv_{\mathbb{B}} \tau_1$. The (T-VAR) rule is the standard Hindley-Milner instantiation rule. It states that if the assumption $x : \sigma$ is in the context, then we can *instantiate* σ to a specific type τ , and conclude $x : \tau$. The (T-LET) rule is the standard Hindley-Milner generalization rule. The rule states that if we can type e_1 as τ_1 under the environment Γ then we may *generalize* the type τ_1 to a type scheme σ , and type e_2 under an extended environment with $x : \sigma$.

The (T-TAG) rule states that we can type a tag expression $\mathcal{E}.l(e)$ with the type $\mathcal{E}[\varphi \cup \{\mathcal{E}.l\}]$ where the type-level formula φ is obtained by instantiating the type scheme associated with the label $\mathcal{E}.l$ to $\tau \rightarrow \mathcal{E}[\varphi \cup \{\mathcal{E}.l\}]$. The reason that the label is not part of the scheme is that we do not want to assume the occurrence of the label when the scheme is used in (T-CHOOSE) and (T-CHOOSE- \star).

⁴ In the implementation the Σ map is simply constructed from the `enum` declarations in the program.

⁵ The calculus does not have tuples, but the extension to tuples and polymorphic enums is straightforward. They are supported in the implementation.

$$\frac{\eta_i = \text{case } \mathcal{E}.l_i(x_i) \Rightarrow e_i \quad \Gamma, x_i : \tau_i \vdash e_i : \mathcal{E}[\varphi_i^{\text{out}}] \quad \Gamma \vdash e : \mathcal{E}[\varphi_{\text{in}}] \quad \Sigma(\mathcal{E}.l_i) \sqsubseteq \tau_i \rightarrow \mathcal{E}[\varphi_{\text{in}}] \quad \varphi_{\text{in}} <: \bigcup_i \{\mathcal{E}.l_i\} \quad (\varphi_{\text{in}} \cap (\bigcup_i (\varphi_i^{\text{out}} \cap \{\mathcal{E}.l_i\}))) \cup \bigcup_i (\varphi_i^{\text{out}} - \{\mathcal{E}.l_i\}) <: \varphi_{\text{out}}}{\Gamma \vdash \text{choose}^* e \{ \bar{\eta} \} : \mathcal{E}[\varphi_{\text{out}}]} \quad (\text{T-CHOOSE-}\star)$$

$$\text{gen}(\Gamma, \tau) = \forall \bar{\alpha}. \tau \text{ where } \bar{\alpha} = \text{ftv}(\tau) \setminus \text{ftv}(\Gamma)$$

■ **Figure 3** Type Rules for $\lambda_{\text{var}}^{\text{res}}$.

The (T-OPEN) rule allows tagged values to be typed with additional labels. Essentially, the (T-OPEN) rule enables a form of weakening, which is necessary for the proof of preservation, without having to introduce general sub-typing into the system, since that would break type inference (recall that the surface language does not have `open e` expressions).

The (T-CHOOSE) rule states that a `choose` expression of the form `choose e { $\bar{\eta}$ }`, where $\eta_i = \text{case } \mathcal{E}.l_i(x_i) \Rightarrow e_i$, can be typed as τ_{out} , if the scrutinee e has the type $\mathcal{E}[\varphi_{\text{in}}]$, each tag's type scheme can be instantiated to $\tau_i^{\text{in}} \rightarrow \mathcal{E}[\varphi_{\text{in}}]$, φ_{in} is less than the union of the handled tags $\mathcal{E}.l_i$, if each result e_i has the type τ_{out} under an environment where x_i has type τ_i . This rule expresses the standard `match` typing conditions, but allows non-exhaustive matches as long as the type of e ensures that the value of e will be handled. In this rule we see why the scheme of labels do not include their tag. If it was included, then φ_{in} would *have* to include the label of the case.

The (T-CHOOSE- \star) is similar to the (T-CHOOSE) rule but with two major differences: First, the type of each result e_i must be of the form $\mathcal{E}[\varphi_i^{\text{out}}]$, and second, a side-condition is posed relating the input and output. The side-condition requires the output φ_{out} to be greater than a union of two set formulas: The first formula represents the set of labels *maintained* in φ_{in} ; i.e. the labels in the type of the cases that matches the label of the case and also exists in φ_{in} . The second formula represents the set of labels *introduced* by each case; i.e. the labels in the type of the cases that does not match the label of the case.

We explain the additional side-condition in the (T-CHOOSE- \star) rule with an example. Assume that we have the program below on the left and we assign the case expressions the types on the right:

<pre> choose* c { case Red => Red case Green => Blue case Blue => Green } </pre>	$\varphi_1^{\text{out}} = \text{Red}$ $\varphi_2^{\text{out}} = \text{Blue}$ $\varphi_3^{\text{out}} = \text{Green}$
--	--

If we instantiate the additional side-constraint (T-CHOOSE- \star), we get:

$$(\varphi_{\text{in}} \cap (\text{R} \cap \text{R}) \cup (\text{G} \cap \text{B}) \cup (\text{B} \cap \text{G})) \cup (\text{R} - \text{R}) \cup (\text{G} - \text{B}) \cup (\text{B} - \text{G}) <: \varphi_{\text{out}} \quad (1)$$

where we have highlighted the two parts of the outer union. This simplifies to:

$$(\varphi_{\text{in}} \cap \text{R}) \cup (\text{G} \cup \text{B}) <: \varphi_{\text{out}} \quad (2)$$

That is, the result may contain Blue and Green, but whether it contains Red is dependent on whether the input contains Red.

If, instead of $\varphi_2^{\text{out}} = \{\text{Blue}\}$, we had assumed $\varphi_2^{\text{out}} = \{\text{Blue}\} \cup \beta$ then we get:

$$(\varphi_{\text{in}} \cap (\text{Red} \cup (\text{Green} \cap \beta))) \cup (\text{Green} \cup \text{Blue}) \cup (\beta - \text{Green}) <: \varphi_{\text{out}} \quad (3)$$

This is sensible because if we later learn that $\beta = \text{Yellow}$ (i.e. the second case could return Blue or Yellow) then the above type reduces to:

$$(\varphi_{\text{in}} \cap \text{Red}) \cup (\text{Green} \cup \text{Blue} \cup \text{Yellow}) <: \varphi_{\text{out}} \quad (4)$$

3.3 Uninhabited Types

The type system of $\lambda_{\text{var}}^{\text{res}}$ admits programs that have uninhabited types. For example:

```

def f(c) =
  choose c { case Red   => ... }; // c must have type Color[s]
  choose c { case Green => ... } // where s <: {Red}

```

Here, the two pattern-matches give rise to the constraints $s <: \{\text{Red}\}$ and $s <: \{\text{Green}\}$. Thus, the type of the formal parameter c is $\text{Color}\{\{\}\}$ which is uninhabited. However, this is not a problem; it simply means we cannot call f .

3.4 Meta Theory

The meta theory for the type system is fairly straightforward. We want to ensure that programs which use `choose` and `choose*` cannot get stuck. In other words, we want to prove the standard progress and preservation theorems.

We begin with the canonical forms lemma extended with typing inversion. The lemma shows that the index of a tagged value over-approximates its label:

► **Lemma 9** (CANONICAL-TAG). *If a value is typed with an enum type then the value must be a label of that enum and the enum index includes the label of the value.*

If $\vdash v : \mathcal{E}[\varphi]$ then for some ℓ, v', τ_1 , and φ' it holds that:

1. $v = \mathcal{E}.\ell(v')$
2. $\vdash v' : \tau_1$

17:14 Restrictable Variants

3. $\varphi \equiv_{\mathbb{B}} \varphi' \cup \{\mathcal{E}.l\}$
4. $\Sigma(\mathcal{E}.l) \sqsubseteq \tau_1 \rightarrow \mathcal{E}[\varphi' \cup \{\mathcal{E}.l\}]$

Another key lemma shows that the `open e` expression enables a form of subtyping (which is used to prove preservation of `choose*`):

► **Lemma 10** (OPEN-TAG). *If a value can be typed as an enum with some index then it can also be typed with a super set of that index.*

If $\vdash \mathcal{E}.l(v) : \mathcal{E}[\varphi]$ then $\vdash \mathcal{E}.l(v) : \mathcal{E}[\varphi \cup \varphi']$.

► **Theorem 11** (PROGRESS). *For any closed, well-typed expression then either it is a value or it can evaluate to another expression.*

If $\vdash e : \tau$ then $e \in \text{Val}$ or $e \rightsquigarrow e'$.

► **Theorem 12** (PRESERVATION). *If a closed well-typed expression can take a step then the new expression can also be typed with the original type.*

If $\vdash e : \tau$ and $e \rightsquigarrow e'$, then $\vdash e' : \tau$.

The proofs are available in the extended version of the paper.

3.5 Type Inference

We can support type inference for $\lambda_{\text{var}}^{\text{res}}$ with a suitable extension of Algorithm W [8, 28] with Boolean unification on set formulas [27]. We can use the type rules from the declarative type system of Figure 3 to systematically obtain a collection of type inference rules. The declarative system uses a typing judgment of the form $\Gamma \vdash e : \tau$, the type inference system extends this to $\Gamma \vdash e : \tau; S$ where S is a substitution. Here the type environment Γ and the expression e can be seen as the input to the type inference algorithm and τ and S as the output. We omit the actual inference rules, but they mostly concern a lot of administration around the careful use of substitutions and the composition of substitutions. As is standard, equalities in the declarative system become unification queries in the inference system.

We solve unification queries on types in the standard way, but when we reach two Boolean set formulas we use Boolean unification to solve the queries. Specifically, we rely on the Successive Variable Elimination (SVE) algorithm [27]. The most interesting aspect is how we translate set formula constraints, in the declarative type rules, into unification queries. This however – by *design* – turns out to be straightforward. Given the (T-CHOOSE) type rule:

$$\frac{\eta_i = \text{case } \mathcal{E}.l_i(x_i) \Rightarrow e_i \quad \Gamma \vdash e : \mathcal{E}[\varphi_{\text{in}}] \quad \boxed{\varphi_{\text{in}} <: \bigcup_i \{\mathcal{E}.l_i\}}}{\Gamma, x_i : \tau_i \vdash e_i : \tau_{\text{out}} \quad \Sigma(\mathcal{E}.l_i) \sqsubseteq \tau_i \rightarrow \mathcal{E}[\varphi_{\text{in}}]} \quad \text{(T-CHOOSE)} \quad \Gamma \vdash \text{choose } e \{\eta\} : \tau_{\text{out}}$$

The interesting part is to translate what is shown in the gray box. Recall that this is the part of the constraint which ensures that the input is upper-bounded by the labels that occur in the pattern-match. We translate this constraint to the Boolean unification query:

$$\varphi_{\text{in}} \cap \left(\bigcup_i \{\mathcal{E}.l_i\} \right)^c \stackrel{?}{=} \emptyset$$

whose most-general unifier will capture exactly the above property. Similarly, we can translate the additional side-condition in (T-CHOOSE- \star) as a unification problem on set formulas.

At the time of writing, the type inference machinery works (c.f. Section 4), but sometimes the substitutions computed by SVE can be very large. Large substitutions lead to large formulas which leads to slow inference. Fortunately, we have good reason to believe that the situation can be improved. We know from the case studies (c.f. Section 6) that most functions have small types (i.e. small formulas). Hence the challenge is to compute them. We think that this should be possible with a more sophisticated implementation of SVE that exploits Boolean technology, such as BDDs or ZDDs [1, 29].

3.6 Subtyping

The type system does not have explicit support for subtyping, but instead, like row-based systems, relies on parametric polymorphism [16, 37]. For example, the if-then-else expression:

```
if (true) then Red else Blue
```

is typable because we can assign the types:

$$\Gamma \vdash \text{Red} : \text{Color}[\{\text{Red}, \text{Blue}\} \cup s] \quad \text{and} \quad \Gamma \vdash \text{Blue} : \text{Color}[\{\text{Blue}, \text{Red}\} \cup s]$$

for some type variable s . We could probably extend the type system with subtyping, but then we would likely lose principal type inference.

3.7 A Few Practical Aspects

We conclude with a discussion of a few practical issues.

- When should a programmer use `choose` or `choose*`? A programmer should use `choose` when he or she wants to partially pattern-match on a subset of labels, but the result can be of any type. On the other hand, a programmer should reach for `choose*` when he or she wants to partially pattern-match on a restrictable variant and the result is *the same restrictable variant*. In this case, `choose*` is preferable because it is structure-preserving; relating the “input” labels to the “output” labels.
- Would it be possible to have one “universal” type that holds all possible variants? Yes, in the limit one could define a single gigantic restrictable variant with all possible labels and then use that type everywhere in the program. In practice, this would probably be cumbersome and confusing. For example, it would seem pointless to merge the `Color` and `Expr` restrictable variants, even though one could conceptually do so.

4 Implementation

We have implemented the $\lambda_{\text{var}}^{\text{es}}$ calculus as an extension of the Flix programming language.

Flix is a functional, imperative, and logic programming language that supports algebraic data types, pattern matching, higher-order functions, parametric polymorphism, type classes, higher-kinded types, first-class Datalog constraints, channel and process-based concurrency, and has a polymorphic type and effect system [23, 21, 22, 24]. The Flix compiler project, including the standard library and tests, is approximately 230,000 lines of code.

Adding restrictable variants required approximately 2,000 lines of code. Most of the code was straightforward; the most complex components were the implementation of the type inference rules and Boolean unification on set formulas.

Flix, with our extension, is open source, ready for use, and freely available at:

<https://flix.dev/> and <https://github.com/flix/flix/>

5 Expressiveness and Comparison to Other Systems

In this section, we compare the expressiveness of restrictable variants to other nominal and/or structural type systems. We focus on type systems that support complete type inference. We remind the reader that in Section 2 we used restrictable variants to express:

```
def simplify(e: Expr[s]): Expr[(s - Xor) + {Not, And, Or}]
def subst(m: Map[Int32, Bool], e: Expr[s]): Expr[(s - Var) + Cst]
def fasteval(e: Expr[s & {Cst, Not, And, Or}]): Bool
```

which allowed us to use function composition to define:

```
let fastrun = m -> simplify >> subst(m) >> fasteval
```

We now discuss our ability to express this in other systems with extensible variants.

5.1 Row Polymorphism à la Wand, Gaster and Jones, and Leijen

Row polymorphism is a classic solution to extensible records and variants [37]. A row polymorphic type system supports three primitive operations [11, 16] on variants which are *injection*, *embedding*, and *decomposition*:

$$\begin{aligned} \langle \ell = _ \rangle : \forall \alpha, r. \alpha \rightarrow \langle \ell : \alpha \mid r \rangle & \quad (\text{injection}) \\ \langle \ell \mid _ \rangle : \forall \alpha, r. \langle r \rangle \rightarrow \langle \ell : \alpha \mid r \rangle & \quad (\text{embedding}) \\ \langle \ell \in _ ? _ : _ \rangle : \forall \alpha, \beta, r. \langle \ell : \alpha \mid r \rangle \rightarrow (\alpha \rightarrow \beta) \rightarrow (\langle r \rangle \rightarrow \beta) \rightarrow \beta & \quad (\text{decomposition}) \end{aligned}$$

The last operation allows us to implement pattern matching. What is important is that each use of the ternary-like conditional ($\ell \in _ ? _ : _$) peels off a variant. Note that if we fail to match on ℓ then we refine the type to $\langle r \rangle$ which we continue with in the else branch.

Leijen gives the example [16]:

```
showEvent e =
  (key in e) ? (c -> showChar(c)) :
    (e' -> (mouse in e')) ? (p -> showPoint(p)) : error()
```

Here the idea is that `showEvent` pattern-matches on an extensible variant of the type:

$$\langle \text{key} : \text{KeyEvent} \mid \text{mouse} : \text{MouseEvent} \rangle$$

using the decomposition operator. Note that the program type-checks because both functions `showChar` and `showPoint` (and `error`) return a value of the same type, i.e. `Unit`.

In any case, the return type of the entire “pattern-match” is β , which means that the returned values must have the same type (modulo row-equivalence). Looking over our three functions, we see that⁶:

We can express the `eval` and `fasteval` functions which are given the types:

$$\begin{aligned} \text{eval} : \langle \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} : \cdot \mid \text{Xor} : \cdot \rangle \rightarrow \text{Bool} \\ \text{fasteval} : \langle \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} : \cdot \rangle \rightarrow \text{Bool} \end{aligned}$$

⁶ For simplicity, we ignore the fact that the data type is recursive. We just focus on the labels themselves.

Here the rows are closed and the two functions accept any Boolean formula as long as it only has one of the listed variants. In particular, we cannot accidentally call `eval` or `fasteval` with an open Boolean formula that has the `Var` label.

We can also express the `simplify` and `subst` functions which are given the types:

$$\begin{aligned} \text{simplify} &: \langle \text{Var} : \cdot \mid \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} : \cdot \mid \text{Xor} : \cdot \rangle \rightarrow \\ &\quad \langle \text{Var} : \cdot \mid \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} \rangle \\ \text{subst} &: \text{Map}[\text{Int32}, \text{Bool}] \rightarrow \langle \text{Var} : \cdot \mid \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} : \cdot \mid \text{Xor} : \cdot \rangle \rightarrow \\ &\quad \langle \text{Cst} : \cdot \mid \text{Not} : \cdot \mid \text{Or} : \cdot \mid \text{And} \mid \text{Xor} : \cdot \rangle \end{aligned}$$

Each function accepts a Boolean expression as input, with any labels, and returns a Boolean formula without the `Xor` and `Var` labels, respectively. However, their row types *cannot capture how the input is related to the output*. Hence, unlike with restrictable variants, when we compose the two functions we lose information about the output. In particular, the information that `simplify` has eliminated the `Xor` variant is lost. Hence we cannot call `fasteval`.

One might wonder if we could give the `simplify` function the type:

$$\text{simplify} : \langle \text{Xor} : \cdot \mid r \rangle \rightarrow \langle r \rangle$$

since that seems to capture what we want. However, this type judgment would be *unsound* since we could instantiate r to $\langle \text{Cst} : \text{Int32} \rangle$ and clearly the implementation of `simplify` is not exhaustive for that label. Moreover, if we fail to mention e.g. `Var` then we could also instantiate r to $\langle \text{Var} : \text{Banana} \rangle$ which is also not sound. Thus the only sound solution must mention *all* the variants that `simplify` is prepared to accept. Thus we lose the relationship between the input and output.

A challenge with extensible records and variants based on rows is the question of whether extensions adds a new field (or variant) or overrides an existing field (or variant). The literature has proposal several solutions to this problem:

Extensible Records and Variants with Qualified Types

Gaster and Jones present a type system for extensible records and variants extended with qualified types [11, 13]. The idea is that rows capture the structure of the record (or variant) while predicates are used to ensure that rows are not extended with labels that are already present. Thus the Gaster and Jones system ensures that a record (or variant) cannot be extended with a label it already has. For example, record extension is given the type:

$$(l := _ \mid _) : (r \setminus l) \Rightarrow \alpha \rightarrow \text{Rec } r \rightarrow \text{Rec } \{l : \alpha \mid r\}$$

where the predicate $(r \setminus l)$ in the qualified type captures that r must not contain the label l .

Extensible Records with Scoped Labels

Leijen proposes a different approach that embraces the idea of duplicate labels in records and variants [16]. In Leijen's type system, extensible records are allowed to have multiple fields with the same name (and of different type). This means that fields are scoped.

For example, we can have a record r with the type:

$$r : \{y : \text{Bool} \mid x : \text{Int32} \mid y : \text{Int32}\}$$

17:18 Restrictable Variants

This means that r has *two* fields named y ; one of type `Bool` and the other of type `Int32`. We can access the former, the outermost, with the expression $r.y$. To access the latter, the innermost, we must first remove the outermost y field. Thus we have to write $(r - y).y$. The advantage of Leijen’s over Gaster and Jones’s is that it has principal types without the need for qualified types. The disadvantage is its somewhat unnatural semantics.

What does this mean for a variant to be scoped? It roughly means that when we pattern-match (i.e. decompose) on an extensible variant we always see the outermost label. To find an inner label, we must decompose once, and then decompose again. In pseudo-code:

```
match v /* has type: { Label: Int32 | Label: String | ... } */ {
  case Label(n) => n + 123
  case rest => match rest /* has type: { Label: String | ... } */ {
    case Label(s) => String.toUpperCase(s)
  }
}
```

where we peel off one layer of v to expose the inner `Label` of type `String`. As Leijen writes, this is a “curious” feature and it is not so clear whether it is useful in practice.

Abstracting Extensible Data Types à la Morris et al.

Morris and McKinna presents a type system that unifies the previous type systems into one framework based on qualified types and row theories [30]. The framework can be instantiated to model the systems of Gaster and Jones and Leijen among others. Importantly, the framework also supports instantiations with row concatenation.

The framework can also support a form of extensible variants with the key constructs:

$$\begin{array}{ll}
 \lambda x . \ell \triangleright x & : \quad \tau \rightarrow \Sigma(\ell \triangleright \tau) & \text{(CONSTRUCTION)} \\
 \lambda x . x / \ell & : \quad \Sigma(\ell \triangleright \tau) \rightarrow \tau & \text{(EXTRACTION)} \\
 \lambda x . \text{inj } x & : \quad \forall z_1 z_2 . z_1 < z_2 \Rightarrow \Sigma z_1 \rightarrow \Sigma z_2 & \text{(INJECTION)} \\
 \lambda x y . x \nabla y & : \quad \forall z_1 z_2 z_3 \tau . z_1 \odot z_2 \sim z_3 \Rightarrow \\
 & \quad (\Sigma z_1 \rightarrow \tau) \rightarrow (\Sigma z_2 \rightarrow \tau) \rightarrow (\Sigma z_3 \rightarrow \tau) & \text{(MATCH)}
 \end{array}$$

The key idea is the use of qualified types with two predicates: the *containment* predicate $z_1 < z_2$ and the *combination* predicate $z_1 \odot z_2 \sim z_3$. Using these qualified type predicates, we can define the operations:

- (CONSTRUCTION) constructs a singleton variant with the label ℓ and type τ .
- (EXTRACTION) destructs a *singleton* variant and extracts the value of the variant.
- (INJECTION) extends a variant with additional labels. The operation uses the *containment* predicate $z_1 < z_2$. Its meaning is dependent on the specific row theory. For example, using a theory that disallows duplicates, it means that the labels of z_1 must be a subset of the labels of z_2 (with compatible types).
- (MATCH) is a combinator that composes two functions which operate on parts of a variant into a single function that works on the row concatenation of their input types. The operation uses the *combination* predicate $z_1 \odot z_2 \sim z_3$. Its meaning is again dependent on the specific row theory. For example, using a theory that disallows duplicates, it means that z_1 and z_2 must be disjoint sets of labels and z_3 must be their union. Note that the return type τ of the two functions must be same, hence the match construct does not relate its input type to its output type.

We illustrate this loss of precision with the following example:

$$\lambda x . \left(\left(\lambda y . \text{inj } (A \triangleright y/A) \right) \nabla \left(\lambda z . \text{inj } (B \triangleright z/B) \right) \right) \left(\text{inj } x \right) \quad :$$

$$\forall z_1, z_2, \tau_1, \tau_2 . z_1 \triangleleft (A \triangleright \tau_1, B \triangleright \tau_2), (A \triangleright \tau_1, B \triangleright \tau_2) \triangleleft z_2 \Rightarrow \Sigma z_1 \rightarrow \Sigma z_2$$

Informally, the function is simple the identity function on a variant with two labels A and B , i.e. it maps A to A and B to B . Assume – without loss of generality – that we work on a row theory based on Gaster and Jones which does not allow duplicate labels in variants.

The function receives a variant x , which is allowed to be a subset of the variant $\Sigma(A \triangleright \tau_1, B \triangleright \tau_2)$. It is first injected to be typable with the complete variant, then it is matched on in two different functions that either assume that the variant was A or B via their respective extraction (y/A or z/B). Lastly, the variant is constructed again in singleton variants and injected into the full variant type.

The intention of the function is clearly shown in the type; the input must be a subset of a variant with A and B and the output must be a superset of a variant with A and B . While this type is correct, it is unfortunately not as precise as we would have hoped. In particular, since the function is actually the identity we would have liked the type: $\forall z . z \triangleleft (A \triangleright \tau_1, B \triangleright \tau_2) \Rightarrow \Sigma z \rightarrow \Sigma z$.

The type systems of Gaster and Jones, Leijen, and Morris and McKinna do not solve the fundamental “co-domain problem” for extensible variants. Rather they expose difficulties with row-based variants which require additional machinery or unnatural semantics to fix. Restrictable variants do not suffer from such issues because they rely on *set formulas*.

5.2 Occurrence Typing à la Castagna

Castagna et al. present an expressive set-theoretic type system with a type-case expression [7]. The type system supports union, intersection, and negation types. In their system, the `Color` type can be represented as the *union* type of three singleton types:

$$\text{Red} \vee \text{Green} \vee \text{Blue}$$

and we can match on these using the type-case expression:

$$e_1 \in \tau ? e_2 : e_3$$

where control flow enters the e_2 branch if e_1 reduces to a value $v : \tau$, or e_3 if it does not; i.e. $v : \neg\tau$. The type-case expression is their powerful alternative to the *if-then-else/match/choose* expression, allowing an association between each possible type of the input and the respective type of the output. For example, in their system, the `isWarm` function can be expressed as:

$$\lambda x . x \in \text{Red} ? \text{True} : (x \in \text{Blue} ? \text{False} : \text{undefined})$$

which has the type:

$$(\text{Red} \rightarrow \text{True}) \wedge (\neg\text{Blue} \rightarrow \text{False})$$

Note that, in the last case, where $x \notin \text{Red}$ and $x \notin \text{Blue}$ the untypable expression `undefined` is used to indicate an unreachable case. The precision of the typing – essentially encoding the entire pattern-match at the type level – is very expressive and solves the “co-domain problem” we have outlined. However, the types can become very complex and unwieldy, and there is limited support recursive types and recursive functions [7]. For example, the `subst(m)` function would be given the large intersection type:

17:20 Restrictable Variants

$$(\text{Var}(\text{Int32}) \vee \text{Cst}(\text{Bool}) \rightarrow \text{Cst}(\text{Bool})) \wedge (\text{Not}(\text{Expr}) \rightarrow \text{Not}(\text{ClosedExpr})) \wedge (\text{Or}(\text{Expr}, \text{Expr}) \rightarrow \text{Or}(\text{ClosedExpr}, \text{ClosedExpr})) \wedge (\text{And}(\text{Expr}, \text{Expr}) \rightarrow \text{And}(\text{ClosedExpr}, \text{ClosedExpr})) \wedge (\text{Xor}(\text{Expr}, \text{Expr}) \rightarrow \text{Xor}(\text{ClosedExpr}, \text{ClosedExpr}))$$

where we also have to define the `Expr` and `ClosedExpr` data types as two large union types.

While the goal of $\lambda_{\text{var}}^{\text{res}}$ is to capture the introduction and elimination of variants, the occurrence typing system goes far beyond this, capturing a large amount of additional information as it maps variant to variant; the cost of the additional information is borne in the complexity of the types. Furthermore, it is not clear that the occurrence typing system is capable of inferring the type of recursive functions, meaning that in order to capture the same *elimination* and *introduction* properties, the programmer would have to provide the large type annotations themselves.

5.3 Relational Nullable Types à la Madsen et al.

Madsen and van de Pol present a relational nullable type system [25]. The type system captures the nullability (i.e. whether an expression may evaluate to null) of an expression in relation to the nullability of other related expressions. For example, using their type system, one can express a function:

```
let f = (host, port) -> match (host, port) {
  case (Absent, Absent)      => ...
  case (Present(h), Present(p)) => ...
}
```

which captures that *either* both `host` and `port` are `Absent` (i.e., “null”) *or* both `host` and `port` are `Present` (i.e., non-“null”). For example, the following two calls type-check:

```
f(Absent, Absent) // OK
f(Present("www.google.com"), Present(80)) // OK
```

whereas the next two calls are rejected by the type system:

```
f(Absent, Present(80)) // NOT OK
f(Present("www.google.com"), Absent) // NOT OK
```

The relational nullable type system associates every expression with a proper type π and a pair of Boolean formulas (φ, ψ) that over-approximate whether the expression *may* evaluate to `Absent` (i.e., null) and *may* evaluate to `Present` (i.e., non-null) [25]. The two Boolean formulas form a small lattice where: `String ? (F, F)` is an uninhabited type (i.e., a type that is neither null nor non-null), and e.g. `String ? (F, ψ)` is the type of non-null Strings.

Relational nullable types and restrictable variants share some similarities:

- The restrictable variants type system use *one* type-level *set formula* to over-approximate the set of variants of an expression, whereas the relational nullable type system uses *two* type-level *Boolean formulas* to over-approximate the nullability and non-nullability of an expression.
- Both systems extend Hindley-Milner with Boolean unification; their system on Boolean formulas and our system on set formulas.
- We find that the relational nullable types tend to be significantly more complex than restrictable variant types. For example, the function from above is given the type:

$$\forall t_1, t_2, t_3, b_1, b_2, b_3, b_4. (t_1, b_1 \wedge \neg b_3 \wedge \neg b_4, b_3) \rightarrow (t_2, b_2 \wedge \neg b_3 \wedge \neg b_4, b_4) \rightarrow t_3$$

5.4 Summary

We believe that restrictable variants offer a new simple and practical sweet-spot in the design space of “extensible” data types. In terms of expressive power, for the programming patterns we have shown, we identify restrictable variants as laying between row-based type systems and full-blown occurrence typing. Importantly, restrictable variants precisely capture the introduction and elimination of variants which leads to better compositionality than row-based variants.

6 Case Studies

We now report on three small case studies that use restrictable variants. The first is the running example of Boolean formulas. The second is a new data structure that combines the `Option`, `List`, and `NonEmptyList` data types. The third is a theoretical study of how restrictable variants can be combined with extensible records to model abstract syntax trees.

6.1 Case Study: Boolean Expressions

We have seen how we can use restrictable variants to represent Boolean formulas. The key idea is that we can use the same data type represent both simple formulas (made from the `Not`, `And`, `Or` connectives) and more complex formulas (e.g. using the `Xor` connective). We can also represent both open and closed formulas (i.e. formulas with or without `Vars`).

6.2 Case Study: Option, List, and NonEmptyList

The Flix standard library supports the three central functional data types: `Options`, `Lists`, and `Nels` (non-empty lists). The `Option` module offers 75 functions and spans 587 lines of code, the `List` module offers 136 functions and spans 1,398 lines of code, and finally the `Nel` module offers 104 functions and spans 703 lines of code. While this “batteries included” approach is great for programmers, the downside is that the implementations of `Option`, `List`, and `Nel` duplicate a lot of functionality. Given that `Option`, `List`, and `Nel` are really just sequences of different lengths ($0 - 1$ for `Option`, $0 - n$ for `List`, and $1 - n$ `Nel`), one might wonder if they could not be unified into one data type. As it turns out, they can!

We can define *one data type* for sequences of integers⁷:

```
enum Seq[s] {
  case Nil
  case One(Int32)
  case Cons(Int32, Seq[s])
}
```

We can then define `Option`, `List`, and `Nel` as type aliases:

```
type alias Option = Seq[{Nil, One}]
type alias List   = Seq[{Nil, Cons}]
type alias Nel    = Seq[{One, Cons}]
```

⁷ Flix naturally supports polymorphic data types, but for simplicity we focus on integer-valued sequences.

17:22 Restrictable Variants

A slightly more general type would be e.g., `type alias Option[s] = Seq[s & {Nil, One}]`. What's important is that we can define common operations on `Seq` *once* and reuse them for different types of sequences.

For example, we can write a `forall` function:

```
def forall(f: Int32 -> Bool, s: Seq[s]): Bool = choose s { ... }
```

And we can also write a `map` function:

```
def map(f: Int32 -> Int32, s: Seq[s]): Seq[s] = choose* s { ... }
```

Importantly, the `map` function preserves information about what variants can occur in the output based on the input. Thus, if we map over an `Option`, we know that the result is an `Option` and if we map over a `Nel`, we know the result is a `Nel`.

We can also write functions that only work for non-empty lists. For example:

```
def head(s: Seq[s - Nil]): Int32 = choose s { ... }
def last(s: Seq[s - Nil]): Int32 = choose s { ... }
```

More interestingly, we can express a function that appends an element to a sequence:

```
def append(elm: Int32, s: Seq[s]): Seq[One, Cons] = choose* s {
  case Nil          => One(w)
  case One(x)       => Cons(x, One(elm))
  case Cons(x, xs) => Cons(x, append(elm, xs))
}
```

The return type of `append`, which is equivalent to `Nel`, captures that the result lacks the `Nil` variant, hence is non-empty. We can use `append` to write a `reverse` function:

```
def reverse(s: Seq[s]): Seq[(s & {Nil}) + One, Cons] = choose* s {
  case Nil          => Nil
  case One(x)       => One(x)
  case Cons(x, xs) => append(x, reverse(xs))
}
```

The type of the `reverse` function is not as precise as we would like. In particular, if we reverse an `Option` type, we lose the information that the sequence has 0 – 1 elements. However, the type is sufficiently precise to capture that if we reverse a non-empty list then the result is also non-empty.

In summary, in our experience, most aggregation functions such as `head`, `forall`, and `count` can be implemented on the `Seq` data type. We can also implement structure preserving functions such as `map`. Where it gets more difficult is with transformations such as `append`, `reverse`, and `flatMap` which do not always have the types we would want. In such cases, we can sometimes implement 2 – 3 functions (corresponding to one for `Option`, `List`, and `Nel`) and thus still have the desired functionality.

6.3 Case Study: Restrictable Variants, Extensible Records

While we have presented *restrictable variants* as a better alternative to *extensible variants*, we have found that it is natural to combine restrictable variants with *extensible records*. For example, returning to the compiler use case, one can imagine an abstract syntax tree that is transformed and decorated with additional information through several compiler phases. We can use restrictable variants to capture the active labels and extensible records to capture the extra information. For example, we can define an abstract syntax tree:

```
enum Expr[s][r: RecordRow] {
  case Cst({value = Bool | r}),
  case Num({value = Int32 | r}),
  case Var({ident = String | r}),
  case Add({e1 = Expr[s, r], e2 = Expr[s, r] | r}),
  case Ite({e1 = Expr[s, r], e2 = Expr[s, r], e3 = Expr[s, r] | r})
  // ...
}
```

Here the the Expr data type has *two* type-level indices: The s index controls the variant part whereas the r index controls the record part. Assume that we also have a data type:

```
enum Type { case TBool, case TInt }
```

then we can use row extension to capture that type inference decorates the AST:

```
def infer(e: Expr[s][r]): Expr[s, (tpe = Type | r)] = ...
```

At the same time, we can also capture that code generation only works for closure-converted, lambda-lifted, and well-typed ASTs:

```
def codeGen(e: Expr[s - Lam][(tpe = Type | r)]): ByteCode = ...
```

This example illustrates that restrictable variants and extensible records complement each other well. We use the variant index to constrain what cases we are prepared to deal with and we use the record index to constrain what additional information we need.

6.4 Pretty Printing Types with Lower- and Upper Bounds

Programmers might find it difficult to read a type signature like:

```
def reverse(s: Seq[s]): Seq[(s & {Nil}) + {One, Cons}]
```

For this reason, we have experimented with showing lower- and upper-bounds of type-level set formulas. For example, the set formula: $\text{Seq}[(s \ \& \ \{\text{Nil}\}) \ + \ \{\text{One}, \ \text{Cons}\}]$ has the lower-bound: $\{\text{One}, \ \text{Cons}\}$ and the upper-bound: $\{\text{Nil}, \ \text{One}, \ \text{Cons}\}$. This means a **choose** or **choose*** must handle the One and Cons variants and may optionally handle the Nil variant.

7 Related Work

We have already discussed how the expressiveness of restrictable variants compares to several other existing systems. In this section, we aim to provide high-level overview of related work.

Row-based Extensible Records and Variants

Wand originally introduced the concept of row variables for an object-oriented setting [37]. A key challenge in the literature on row-based systems has been how to deal with duplicate labels. A challenge that remains to this day [30]. Gaster and Jones present a type system for extensible records and variants that use qualified types [13] to ensure that rows do not contain duplicate labels [11]. Leijen instead propose a type system that permits duplicate labels and gives a semantics to such “scoped” records and variants [16]. Another major challenge has been the question of *row concatenation* [30]. In this direction, Harper and Pierce presents a record calculus and type system that permits record concatenation [12], but lacks type inference. Morris and McKinnon presents a unified framework for row-polymorphic type systems based on *row theories* [30].

Row-based type systems have been used successfully in many applications other than extensible records and variants. For example, type systems based on rows have been used to track exceptions [31], to track effects in algebraic effect systems [17, 18], to model database queries [19], and to type first-class Datalog program values [22].

We refer to Gaster and Jones for a detailed introduction to row polymorphism [11].

Occurrence Typing, GADTs, Constructor Subtyping, and Relational Nullability

Castagna et al. present an occurrence-based type system [7] which uses set-theoretic types to infer precise function signatures. Applied to variants and pattern-matching, the system can track exactly how a function maps labels among each other. The system is purely structural and based on semantic subtyping, whereas our system includes nominal typing.

Generalized algebraic data types (GADTs) extend algebraic data types with additional expressive power by allowing the type scheme of a constructor to restrict its return type [15, 35]. The canonical example is the ability to write an algebraic data type for arithmetic and Boolean expressions $\text{Expr}[\alpha]$ and an evaluation function $\text{eval} : \text{Expr}[\alpha] \rightarrow \alpha$ where α is a type-level index that determines whether the expression evaluates to a `Bool` or `Int`. A significant body of work has focused on how to recover type inference in the presence of GADTs [14, 32]. We think it would be interesting future work to explore possible connections between restrictable variants and GADTs.

Constructor subtyping is an alternative to extensible and restrictable variants where one inductive type τ_1 is considered a subtype of another inductive type τ_2 if τ_2 has more constructors than τ_1 [3, 26]. In relation to restrictable variants, the idea would be to have multiple data types that share similar constructors and then use subtyping to allow functions to operate on multiple of these types.

Madsen and van de Pol propose a type system with support for *relational nullable types* [25]. While a nullable type system tracks whether an expression may evaluate to null based on its type, *relational nullable type systems* track whether an expression may evaluate to null based on its type and the type of *other* related expressions. As discussed, the Madsen and van de Pol system has some similarities to ours: both systems allow partial (non-exhaustive) pattern-matching and both systems are based on Hindley-Milner extended with Boolean unification. However, their system is purely structural and focuses on nullability, whereas our system combines nominal and structural typing.

Refinement Kinds

Luís and Toninho propose refinement typing at the kind level to enable metaprogramming with records [6]. We believe their system could be adapted to variants and pattern matching: The dependent types in their system precisely track the associations between the input and output types of functions. Refinement kinds, however, do not support type inference.

Boolean Unification

Boole studied Boolean unification in the single-variable case and presented a simplified version of the successive variable elimination algorithm [4]. Later, Löwenheim presented another Boolean unification algorithm [20]. Today, an accessible introduction to Boolean unification is provided by Martin and Nipkow [27]. Additional background information is provided by Baader [2], Boudet et al. [5], Robinson and Voronkov [34].

Boolean unification was first used in a type system by de Vries et al. who used it model uniqueness [9]. Later, Madsen and van de Pol presented a polymorphic type and effect system which used Boolean unification for inference [24].

8 Conclusion

We have presented *restrictable variants* as a simple and practical alternative to extensible variants. A restrictable variant is a sum type indexed by a type-level set formula of its active labels. We have also introduced the `choose` and `choose*` pattern-matching constructs which enable non-exhaustive patterns matches on restrictable variants. Notably, the `choose*` construct allow us to precisely track the *introduction* and *elimination* of variants through function composition.

We have presented a type system for a minimal calculus with restrictable variants. The type system, which based on Hindley-Milner extended with type-level set formulas, ensures that non-exhaustive pattern-matches cannot get stuck. The system supports complete inference via a suitable extension of Algorithm W with Boolean unification on set formulas.

We have implemented restrictable variants as an extension of the Flix programming language and used the implementation for a few case studies. The extension is ready for use, freely available, and open-source.

Programming with Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

Magnus Madsen ✉ 

Department of Computer Science, Aarhus University, Denmark

Jaco van de Pol ✉ 

Department of Computer Science, Aarhus University, Denmark

Abstract

We present purity reflection, a programming language feature that enables higher-order functions to inspect the purity of their function arguments and to vary their behavior based on this information. The upshot is that operations on data structures can selectively use lazy and/or parallel evaluation while ensuring that side effects are never lost or re-ordered. The technique builds on a recent Hindley-Milner style type and effect system based on Boolean unification which supports both effect polymorphism and complete type inference. We illustrate that avoiding the so-called ‘poisoning problem’ is crucial to support purity reflection.

We propose several new data structures that use purity reflection to switch between eager and lazy, sequential and parallel evaluation. We propose a `DelayList`, which is maximally lazy but switches to eager evaluation for impure operations. We also propose a `DelayMap` which is maximally lazy in its values, but also exploits eager and parallel evaluation.

We implement purity reflection as an extension of the Flix programming language. We present a new effect-aware form of monomorphization that eliminates purity reflection at compile-time. And finally, we evaluate the cost of this new monomorphization on compilation time and on code size, and determine that it is minimal.

1 Introduction

Programming languages are increasingly multi-paradigm. Kotlin and Scala embrace object-oriented, functional, and imperative programming. JavaScript has a functional core and its ecosystem is increasingly adopting a functional style. Rust, a decidedly imperative language, has a functional flavor with support for algebraic data types, pattern matching, and higher-order functions. C# and Java have adopted lambda expressions and added streams.

Nevertheless, the marriage of paradigms is not always a happy one: laziness and parallelism expose a deep rift between functional and imperative programming. The delayed or parallel evaluation of an impure function may cause its side effects to be lost, to occur out-of-order, or to interfere with each other, leading to potentially disastrous consequences. For these reasons, imperative programming languages tend to use eager and sequential semantics everywhere, thus foregoing the potential benefits of lazy and/or parallel evaluation.

Most mainstream languages, such as Java, Kotlin, and Scala, offer access to a limited form of laziness and parallelism with streams. Yet anarchy reigns: the use of side effects in streams can have unpredictable consequences and nothing prohibits stream operations from having side effects, except for stern warnings in the documentation. Stream pipelines are often described as declarative, but in the presence of side effects, they are anything but that.

We propose to overcome these challenges with a new programming language construct that enables higher-order functions to inspect the purity of their function arguments and to vary their behavior based on this information. For example, `List.map` can vary its behavior

18:2 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

as follows: when given a *pure* function it lazily maps the function over the list, whereas when given an *impure* function it eagerly maps the function over the list. Thus, `List.map` ensures that side effects are never lost or re-ordered while simultaneously allowing lazy evaluation for pure functions. We say that the `List.map` function is *purity reflective*. Similarly, `Set.count` can vary its behavior as follows: when given a *pure* function it performs the counting in parallel over the set, whereas when given an *impure* function it performs the counting sequentially following the order of the elements in the set. Thus, `Set.count` ensures that side effects do not lead to thread-safety hazards (like deadlocks, race conditions), while still admitting parallel evaluation when given a pure function. Purity reflection empowers programmers, and in particular library authors, to write new data structures that selectively use lazy and/or parallel evaluation under the hood, while semantically appearing to their clients *as-if* always under eager, sequential evaluation.

We argue that purity reflection, as a simple form of effect reflection [22], hits a “sweet spot” for practical programming. The distinction between pure and impure functions is straightforward and understandable by ordinary programmers, while at the same time providing sufficient information to be useful. We want to stress that purity reflection *increases the value of effect systems*. In particular, most use cases of type and effect systems focus on soundness, i.e. the ability to rule out certain erroneous programs. This is of course very desirable, but it does not really add any new expressive power to a programming language. With purity reflection (and effect reflection in general), we empower programmers to write new programs that they could not express before. Thus, “fighting the types and effects” now comes with an additional reward. Purity reflection is enabled by a recent technique to infer *fine-grained*, polymorphic effects automatically [27].

In this paper, we implement purity reflection, from end-to-end, in a production compiler. We use the implementation to retrofit existing and implement new data structures. A key implementation technique is the use of an effect-aware form of monomorphization. In theory, this technique could lead to an exponential blow-up in compilation time and code size, but we experimentally show that this is not the case.

In summary, the contributions of this paper are:

- **(Purity Reflection)** We introduce purity reflection, a new programming language feature that enables higher-order functions to inspect the purity of their function arguments and to vary their behavior based on this information. We argue that purity reflection is a “sweet spot” in the design space of effect reflection.
- **(Data Structures)** We propose several new data structures that use purity reflection to switch between lazy and eager, sequential and parallel evaluation, including the `DelayList` and `DelayMap` data structures.
- **(Compilation)** We discuss two compilation strategies supporting purity reflection: one based on extending the runtime to track purity information in closures and the other based on a new form of effect-aware monomorphization. We implement the latter.
- **(Implementation)** We extend the Flix programming language with purity reflection. We believe Flix is the first large-scale programming language development to support any form of effect reflection.
- **(Evaluation)** We experimentally evaluate the impact of effect-aware monomorphization on compilation time and code size. The results show that the overhead is minimal.

2 Motivation

We motivate our idea with an example. We will use the Flix programming language, but our technique is equally applicable to other ML-style programming languages.

2.1 A Word & Line Count Program

Imagine that we want to write a program that determines if a text contains a specific word. We might start with the program fragment:

```
use List.{flatMap, memberOf};
use String.splitOn;
let lines = haystack |> splitOn("\n");
let words = lines |> flatMap(1 -> splitOn(" ", 1));
memberOf(needle, words)
```

The program works as follows: Given two strings: `haystack` and `needle`, the program splits `haystack` into a list of lines, then it `flatMap`s over each line splitting it into a list of `words`, and finally it computes if `words` contains the string `needle`.

The program works as expected and is written in a natural style: We have two local variables: `lines` and `words` that hold understandable intermediate results. Unfortunately, the program is not very efficient. We construct several intermediate lists and these entire lists are not even needed if the search word `needle` occurs early in the text.

If evaluation of `splitOn` and `flatMap` were lazy, then the program would run fast and not require the construction of these large intermediate lists. Instead, `splitOn` and `flatMap` would build and operate on lazy lists, whose elements would be constructed on-demand when needed by `memberOf`. *But*, since Flix is strict, this is not the case at the moment.

Let us imagine that we later decide to extend the program to also count the number of lines and words in the text, reminiscent of the `wc` command from UNIX. Thus, we change the program to:

```
let lineCount = ref 0;
let wordCount = ref 0;
let lines = haystack |> splitOn("\n");
let words = lines |> flatMap(1 -> {
  lineCount := deref lineCount + 1;
  let ws = splitOn(" ", 1);
  wordCount := deref wordCount + length(ws);
  ws
});
println("Lines: ${deref lineCount}");
println("Words: ${deref wordCount}");
println("Found: ${memberOf(needle, words)}")
```

The extended program is more sophisticated. Running it might print: `Lines: 21, Words: 261, Found: true`. The new program uses a natural style of functional and imperative programming that is common in Java, Kotlin, and Scala. The core of the program remains functional, but the counting is performed in an imperative manner. The program could be written in a purely functional style, but this would require careful threading of state: We would have to operate on triples of the current words on a line and the two counters.

Importantly, this program must be evaluated eagerly. If we were to lazily evaluate `splitOn` and `flatMap` then the two counters would not be updated before they are printed, and the program would print the wrong result (e.g. `Lines: 0, Words: 0, true`).

18:4 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

The two programs expose a rift between functional and imperative programming. In the functional paradigm we would like certain operations to be lazy to improve performance, whereas in the imperative paradigm it is vital that effectful operations are evaluated eagerly.

We believe that the fundamental tension is between two different views on the essence of operations such as `filter`, `map`, and `flatMap`. In the *imperative view*, these operations *eagerly* transform one data structure into another data structure. If the transformation has any side effects, these occur immediately and in a deterministic order (e.g. the order of a list, the natural order of a tree, etc.). In the *declarative view*, these operations *describe* how a data structure should be transformed, but the transformation is not applied until *needed*. In this view, effectful transformations are evil; either banned outright (like in Haskell) or strongly discouraged with stern warnings (like in Java, Scala).

So what can be done? In this paper, we propose a technique, i.e. purity reflection, where we can have our cake and eat it too. Purity reflection allows both programs – *exactly as written* – to compute their expected results while the first is evaluated lazily and the second is evaluated eagerly. This allows us to *write programs the way we want* while ensuring that side effects are never lost and always occur in the expected order.

We can use purity reflection to switch between eager and lazy evaluation, but our technique is equally applicable to switching between sequential and parallel evaluation. For example, if we know that the predicate function passed to `Set.count` is pure, then it is safe to evaluate the function in parallel over disjoint subsets of the set.

2.2 Streams: An Unsound Solution

Before we proceed, we want to highlight the challenges posed by trying to combine side effects, laziness, and parallelism in a single programming language. Mainstream programming languages, such as Java and Scala, support a small collection of data structures that are lazy and/or parallel. Most prevalent is the support for *streams*, a lazy (and sometimes parallel) data structure that represents a sequence of elements.

2.2.1 Java

The `java.util.Stream` package offers a collection of utilities for working with “sequences of elements supporting sequential and parallel aggregate operations”. The documentation for the package states that¹:

“side effects in behavioral parameters to stream operations are, in general, discouraged, as they can often lead to unwitting violations of the statelessness requirement, as well as other thread-safety hazards.”

A bit later, the documentation goes on to state:

“[...] The ordering of side effects may be surprising. [...] The eliding of side effects may also be surprising. [...]”

In total, the documentation for `Stream` warns about side effects almost twenty times!

¹ <https://docs.oracle.com/en/java/javase/17/docs/api/java.base/java/util/stream/package-summary.html>

2.2.2 Scala

The `scala.collection.parallel` package offers a collection of parallel data structures. The documentation for the package states that²:

[...] These concurrent and “out-of-order” semantics of parallel collections lead to the [...] implications:

- *Side effecting operations can lead to non-determinism*
- *Non-associative operations lead to non-determinism*

Given the concurrent execution semantics of the parallel collections framework, operations performed on a collection which cause side effects should generally be avoided, in order to maintain determinism.”

The documentation for `ParIterable` goes on to state³:

[...] Since implementations of bulk operations may not be sequential, this means that side effects may not be predictable and may produce data-races, deadlocks or invalidation of state if care is not taken. [...]

As these examples illustrate, the combination of effectful operations with lazy and/or parallel evaluation is fraught with danger. A mindful programmer is left weary. Perhaps as a consequence, a study by Khatchadourian et al. finds that “stream parallelization is rarely used”, despite the fact that “streams tend not to have side effects” [17].

This paper provides a path out of the quagmire.

2.3 Proposed Solution

We propose a solution based on the following simple idea:

Data structure operations (such as `map`, `filter`, ...) may use lazy or parallel evaluation when they are given pure function arguments, but revert to eager, sequential evaluation when given impure function arguments to ensure that side effects are not lost and that the order of effects is preserved.

We illustrate this idea with two examples:

```
@LazyWhenPure
def map(f: a -> b & ef, l: List[a])
  = reifyEff(f) {
    case Pure(g) => mapL(g, l)
    case _       => mapE(f, l)
  }

@ParallelWhenPure
def cnt(f: a -> Bool & ef, s: Set[a])
  = reifyEff(f) {
    case Pure(g) => parCnt(g, s)
    case _       => fold(...)
  }
```

The program construct `reifyEff(exp)` allows us to reflect on the purity of the closure `exp`. In the program fragment on the left, which implements the `map` function on a list, we use `reifyEff` to inspect the purity of the function argument `f`. If it is pure, we use `mapL` to lazily apply the function `f` over the list (i.e. no evaluation happens yet). If, on the other hand, `f` is impure we use `mapE` to immediately apply `f` eagerly over the elements of the list.

² <https://docs.scala-lang.org/overviews/parallel-collections/overview.html>

³ <https://www.scala-lang.org/api/2.12.2/scala/collection/parallel/ParIterable.html>

18:6 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

Note that in the pure case, `reifyEff` rebinds `f` as `g` (i.e. it is the same function), but now `g` is typed as a pure function. This rebinding avoids the need for flow-sensitive typing.

In the program fragment on the right, we use `reifyEff` to determine whether to count the elements that satisfy a given predicate `f` sequentially or in parallel over a set. If `f` is pure then we perform the counting in parallel, otherwise, we perform it sequentially using an ordinary fold.

The annotations `@LazyWhenPure` and `@ParallelWhenPure` have no semantic meaning, but serve as documentation for the programmer.

The `reifyEff` construct is enabled by a recent Hindley-Milner style type and effect system that supports effect polymorphism, type inference, and computes purity information for every sub-expression in a program [27]. Building on this type and effect system, we can implement purity reflection as a compile-time programming construct that is eliminated by a new form of effect-aware monomorphization. For example, we will monomorph two versions of the `map` function: one for pure functions and one for impure functions.

We now discuss some properties of the proposed solution:

- (*Modular*) The technique supports abstraction: A library *author* can implement data structure operations that make selective use of lazy or parallel evaluation without leaking those details to the client. A library *user* can reason about his or her code *as-if* under eager and sequential semantics.
- (*Gradual*) It is easy to start using the technique: A data structure can be made gradually lazy or parallel without affecting the semantics of its clients[†].
- (*Programmable*) The technique is based on a new programming language construct. Thus, maximum power is placed in the hands of library authors (and programmers in general) who may have better knowledge of when to exploit laziness or parallelism.
- (*Zero Cost*[‡]) The new programming construct can be eliminated entirely at compile-time. Thus programs using the technique suffer no runtime overhead.
- (*Sound*^{††}) The technique is based on a sound type and effect system: It ensures that if an expression is pure then it cannot have a side effect. The typing of lazy expressions ensures that side effects cannot be hidden and later revealed.

[†] Of course, programmers and library authors should be aware that (i) switching from eager to lazy evaluation can potentially lead to space leaks, and (ii) switching from sequential to parallel evaluation may slow down the program. However, we believe both situations can be managed. For (i), lazy evaluation should only be used for stream-like data structures where space leaks are less likely to occur, and for (ii), parallel evaluation should use light-weight threads and only be enabled for sufficiently large data structures.

[‡] We use an effect-aware form of monomorphization that specializes (i.e. copies) higher-order functions based on the purity of their function argument(s). This ensures that there is no runtime overhead, but it could potentially lead to increased compilation time and increased code size. In Section 7 we experimentally evaluate this cost.

^{††} The technique does not magically guarantee correctness. For example, a programmer could mistakenly implement `List.map` to always return the empty list when given a pure function argument. This does not violate the soundness of the type and effect system itself, but it does violate the commonly understood specification of what `List.map` should do.

$c \in Cst = () \mid \text{true} \mid \text{false} \mid \dots$ $v \in Val = c \mid \lambda x. e$ $e \in Exp = x \mid v \mid e e$ $\mid \text{let } x = e \text{ in } e$ $\mid \text{if } e \text{ then } e \text{ else } e$ $\mid \text{lazy } e \mid \text{force } e$ $\mid \text{print } e$ $x, y \in Var = \text{a set of variables}$	$\tau \in Type = \alpha \mid \iota \mid \tau \xrightarrow{\varphi} \tau \mid \text{lazy } \tau$ $\varphi \in Formula = \mathbf{T} \mid \mathbf{F} \mid \beta \mid \neg\varphi \mid \varphi \wedge \varphi \mid \varphi \vee \varphi$ $\sigma \in Scheme = \tau \mid \forall\alpha. \sigma \mid \forall\beta. \sigma$ $\iota \in BaseType = \text{Unit} \mid \text{Bool} \mid \text{Int} \mid \dots$ $\alpha \in TypeVar = \text{a set of type variables}$ $\beta \in BoolVar = \text{a set of Boolean variables}$

(a) Expressions of $\lambda_{\mathcal{B}}$.(b) Types of $\lambda_{\mathcal{B}}$.

■ **Figure 1** Syntax and Types of $\lambda_{\mathcal{B}}$.

3 Purity Reflection

We begin with a brief introduction to the $\lambda_{\mathcal{B}}$ calculus and its Hindley-Milner-style type and effect system [12, 30, 7]. The system is from [27] but extended with the standard `lazy` and `force` constructs [31]. The $\lambda_{\mathcal{B}}$ calculus is the foundation for the Flix programming language implementation (which we build on top of). The $\lambda_{\mathcal{B}}$ calculus is proven sound in [27]. In Section 3.4, we propose a simple extension that requires just one new expression and one new type rule.

3.1 A Minimal Calculus

Syntax

The syntax of $\lambda_{\mathcal{B}}$ includes the standard lambda calculus constructs: variables, constants, lambda abstractions, and function application. As is standard in Hindley-Milner style type systems, the `let`-expression `let $x = e_1$ in e_2` supports polymorphic generalization of e_1 ⁴. The `if-then-else` expression is standard and included to illustrate how the type and effect system merges information from different control-flow paths. The `print` expression is included to have a side effect in the calculus. We add `lazy e` and `force e` to suspend and resume computations. We assume that `force e` uses memoization. Figure 1a shows the syntax of $\lambda_{\mathcal{B}}$.

Semantics

We assume a standard call-by-value semantics, i.e., function arguments are reduced to values before they are substituted into the body of a lambda abstraction. The same applies to `let`-bindings. The only exceptions are `if-then-else`, which uses short circuiting semantics, and `lazy` expressions, which are treated as closures that are computed only once when forced, and then memoized.

⁴ In Flix, which has mutable references, `let`-generalization is subject to the value restriction [8].

$$\begin{array}{c}
 \frac{\Gamma \vdash e : \tau_1 \& \varphi_1 \quad \tau_1 \equiv \tau_2 \quad \varphi_1 \equiv \varphi_2}{\Gamma \vdash e : \tau_2 \& \varphi_2} \text{ (T-EQ)} \\
 \frac{\text{typeOf}(c) = \sigma \quad \sigma \sqsubseteq \iota}{\Gamma \vdash c : \iota \& \mathbf{T}} \text{ (T-CST)} \\
 \frac{(x, \sigma) \in \Gamma \quad \sigma \sqsubseteq \tau}{\Gamma \vdash x : \tau \& \mathbf{T}} \text{ (T-VAR)} \\

 \frac{\Gamma \vdash e_1 : \mathbf{Bool} \& \varphi_1 \quad \Gamma \vdash e_2 : \tau \& \varphi_2 \quad \Gamma \vdash e_3 : \tau \& \varphi_3}{\Gamma \vdash \text{if } e_1 \text{ then } e_2 \text{ else } e_3 : \tau \& \varphi_1 \wedge \varphi_2 \wedge \varphi_3} \text{ (T-ITE)} \\
 \text{gen}(\Gamma, \tau) = \forall \alpha_1, \dots, \forall \alpha_n. \forall \beta_1, \dots, \forall \beta_n. \tau \quad \text{where } \{\alpha_1, \dots, \alpha_n, \beta_1, \dots, \beta_n\} = \text{ftv}(\tau) \setminus \text{ftv}(\Gamma)
 \end{array}$$

■ **Figure 2** Type Rules for $\lambda_{\mathcal{B}}$ with judgments of the form $\Gamma \vdash e : \tau \& \varphi$.

3.2 Type and Effect System

Types

The types of $\lambda_{\mathcal{B}}$ are separated into monotypes (τ) and type schemes (σ). The monotypes include type variables α , a set of base types ι , and function types $\tau_1 \xrightarrow{\varphi} \tau_2$ that represents functions from values of type τ_1 to values of type τ_2 with *latent* effect φ . We use the type $\text{lazy } \tau$ to denote suspended computations. The type schemes of $\lambda_{\mathcal{B}}$ include monotypes τ and quantified types $\forall \alpha. \sigma$ and $\forall \beta. \sigma$, where α is a type variable and β is a Boolean effect variable. Figure 1b shows the types and type schemes of $\lambda_{\mathcal{B}}$.

In $\lambda_{\mathcal{B}}$ the language of effects is a single Boolean formula φ , i.e. there is only a single “effect”: impurity. If the Boolean formula is equivalent to **true** (**T**) then the expression it describes must be pure. If the Boolean formula is equivalent to **false** (**F**) then the expression may have a side effect. A Boolean formula with variables in it captures the conditions under which the expression is pure. The system is over-approximating: An expression typed as pure *cannot* have a side effect whereas an expression typed as impure *may* have a side effect [27].

Type Judgements

Figure 2 shows the type rules of $\lambda_{\mathcal{B}}$. We define a context Γ as a *partial function* of bindings $x : \sigma$ from variables to type schemes. We also define $\text{ftv}(\sigma)$ to be the type variables that occur free in σ , and $\text{ftv}(\Gamma)$ as the union of all free type variables in its range. A type judgement is of the form $\Gamma \vdash e : \tau \& \varphi$, which states that under type environment Γ , the expression e has type τ and effect φ , where φ is a Boolean formula that captures when the expression is pure.

We now briefly discuss the most important type rules. Except for (T-EQ), the rules are syntax-directed. The (T-CST) rule states that a constant expression is pure. The (T-ITE) rule states in an *if* e_1 *then* e_2 *else* e_3 the overall effect is $\varphi_1 \wedge \varphi_2 \wedge \varphi_3$ where φ_i is the effect of expression e_i . The (T-ABS) and (T-APP) rules type lambda abstractions and applications. An abstraction takes the effect φ of an expression e and moves it onto the arrow type whereas an application releases the latent effect of the arrow type. The (T-VAR) and (T-LET) rules are the standard Hindley-Milner type rules. We add the (T-LAZY) and (T-FORCE) rules. Note that only pure expressions can be suspended. Thus effects cannot be delayed. The (T-EQ) rule states that we can use type equivalence. In $\lambda_{\mathcal{B}}$ two types are considered equivalent modulo Boolean equivalence.

For example, the following two functions types are equivalent:

$$\text{Int} \xrightarrow{x \vee \neg x} \text{Int} \quad \equiv_{\mathbb{B}} \quad \text{Int} \xrightarrow{\mathbf{T}} \text{Int}$$

By a suitable extension of Algorithm W with Boolean unification, the type and effect system supports complete type inference. We refer to [27] for the full details.

3.3 Effect Polymorphism

The $\lambda_{\mathcal{B}}$ calculus supports effect polymorphism, i.e. the effect of a higher-order function may depend on the effects of its function arguments. For example, the `List.map` function can be given the type:

$$\text{List.map} : \forall \alpha_1, \alpha_2, \beta. (\alpha_1 \xrightarrow{\beta} \alpha_2) \xrightarrow{\mathbf{T}} \text{List}[\alpha_1] \xrightarrow{\beta} \text{List}[\alpha_2]$$

which can be read as: the effect of `List.map` is the same as the effect of its function argument, i.e. `List.map` is pure if its function argument is.

Forward function composition `»` can be given the type:

$$\text{»} : \forall \alpha_1, \alpha_2, \alpha_3, \beta_1, \beta_2. (\alpha_1 \xrightarrow{\beta_1} \alpha_2) \xrightarrow{\mathbf{T}} (\alpha_2 \xrightarrow{\beta_2} \alpha_3) \xrightarrow{\mathbf{T}} (\alpha_1 \xrightarrow{\beta_1 \wedge \beta_2} \alpha_3)$$

which can be read as: the composition of f and g is pure if both are pure. Note that the purity of `»` is constructed from the purity of both f and g .

3.4 Purity Reflection with ReifyEff

We extend the $\lambda_{\mathcal{B}}$ calculus with a single new expression:

$$\text{reifyEff}(e_1)\{\text{case Pure}(f) \Rightarrow e_2, \text{case } _ \Rightarrow e_3\}$$

The idea is that if e_1 evaluates to a pure function v then it is bound to f and the whole `reifyEff` expression reduces to $e_2[f \mapsto v]$. Otherwise, the expression reduces to e_3 . Of course, one cannot in general determine whether a function is pure. Thus, we rely on the type and effect system to tell us whether a function value is pure. In other words, in the extended $\lambda_{\mathcal{B}}$ calculus (and Flix in general), only well-typed terms have an operational semantics [35]. In Section 5 we discuss two compilation strategies for how to implement the `reifyEff` construct.

The type rule for the `reifyEff` expression is straightforward and shown in Figure 3. The type rule requires that the expression e_1 has a function type $\tau_1 \xrightarrow{\varphi} \tau_2$ where φ is the latent effect of the function. We type check e_2 in an extended environment, where we introduce a new binder f for the function which is typed as pure (i.e., with effect \mathbf{T}). We *do not* introduce a new binder for the case where the function is impure. This asymmetry is for two reasons:

- The type and effect system is over-approximating: If an expression is pure then it cannot have a side effect, but the opposite is not true: an impure expression is not guaranteed to produce a side effect.

$$\frac{\Gamma \vdash e_1 : \tau_1 \xrightarrow{\varphi} \tau_2 \ \& \ \varphi_1 \quad \Gamma, f : \tau_1 \xrightarrow{\mathbf{T}} \tau_2 \vdash e_2 : \tau_3 \ \& \ \varphi_2 \quad \Gamma \vdash e_3 : \tau_3 \ \& \ \varphi_3}{\Gamma \vdash \text{reifyEff}(e_1)\{\text{case Pure}(f) \Rightarrow e_2, \text{case } _ \Rightarrow e_3\} : \tau_3 \ \& \ \varphi_1 \ \wedge \ \varphi_2 \ \wedge \ \varphi_3} \quad (\mathbf{T}\text{-REIFY-EFF})$$

■ **Figure 3** Type rule for the `reifyEff` construct.

18:10 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

- If we had introduced a new binder for f and given it the effect `impure` (i.e., effect `F`) then any use of f inside e_3 would cause the whole expression to be impure. But this would prevent purity reflection. We would not be able to use `reifyEff` inside `List.map` while keeping it effect-polymorphic.

3.4.1 Correctness

The correctness of the approach depends on the soundness of the type and effect system and completeness of type inference [27]. There, it is proved that the type system enjoys the progress- and preservation-property. Also, Algorithm W extended with Boolean unification will always compute the most general type and effect. Finally, it is proved that a pure expression can at no time perform an effectful step. So it is not possible to hide effects. Moreover, the `lazy` construct in Flix can only be applied to pure expressions, so it impossible to delay effects.

Of course, nothing in the type and effect system ensures that an implementation satisfies its specification. For example, a programmer could accidentally reverse a list before mapping an effectful function over it. In that case, the effects will happen in the wrong order. Ensuring *functional correctness*, i.e., that a function respects its specification of return values and emitted effects, is generally beyond the scope of Hindley-Milner style type systems.

3.5 Fine-Grained Purity and the Poisoning Problem

We stress that the type rules are *compositional* and *fine-grained*: the purity of an expression is constructed from the purity of its sub-expressions. This is in contrast to the situation in row-polymorphic type and effect systems [39, 20], where the effects of the sub-expressions are required to be the same. Such systems suffer from the so-called *poisoning problem* [40], where the effect of a sub-expression is over-approximated to fit its context.

We illustrate this issue with an example:

```
airplanes |>
  List.map(plane -> plane.pilot) |>
  List.map(pilot -> pilot.name) |>
  List.foreach(println)
```

Here a row polymorphic system infers that sub-expression `List.foreach(println)` has the `PRINT` effect. This in turn pollutes every sub-expression with the `PRINT` effect. Consequently, the row polymorphic system cannot be used to infer that the first two `List.map` operations are pure (and could be applied lazily with our technique). However, the Boolean effect system can infer that each of the `List.map` operations is given pure arguments, even through the polymorphic usage of the pipeline function `|>`. This example demonstrates that for purity reflection to work, one needs a *compositional* and *fine-grained* type and effect system.

3.6 Purity Reflection: A Sweet Spot

We believe that purity reflection hits a “sweet spot”. First, it is simple to explain to programmers: they only have to understand the distinction between pure and impure functions. Second, it requires us to maintain minimal information to implement, either at runtime or compile-time, as discussed in Section 5. Third, as we argue below, a richer effect system may be difficult to exploit in practice. In particular, it is difficult to determine when two effects may interfere. For example:

- **(Aliasing)** Given two effects $\text{READ}(p_1)$ and $\text{WRITE}(p_2)$ where p_1 and p_2 are pointers to mutable memory, can we safely evaluate them lazily or in parallel? The answer depends on whether p_1 and p_2 are aliased, i.e., can point to the same memory location. If they are, then any re-ordering or parallel execution may change the meaning of the program. Unfortunately, we cannot statically know if p_1 and p_2 are aliases without additional heavy machinery: either alias analysis or a sub-structural type system. To solve this, one needs more information, such as fine-grained regions [15, 37, 10].
- **(External Aliasing)** Given two effects $\text{READFILE}(f_1)$ and $\text{WRITEFILE}(f_2)$ where f_1 and f_2 are file paths, can we safely evaluate them lazily or in parallel? As before, the answer depends on whether f_1 and f_2 refer to the same file. We cannot statically determine if f_1 and f_2 may denote the same filename without some notion of control- and data flow analysis. Worse, even, if f_1 and f_2 are guaranteed to be distinct strings, the two file paths may still refer to the same file due to symbolic links in the underlying file system.
- **(Implicit Dependencies)** Given two effects WRITEFILE and CURRENTTIME , can we safely evaluate them lazily or in parallel? Maybe, but not if the programmer is trying to measure the time it takes for the WRITEFILE operation to complete.

These examples do not imply that the task is impossible. If we had a specification of each effect, i.e., if we had much more information from the programmer, we could probably apply lazy and/or parallel evaluation more aggressively. Instead, our system makes the simple and sound assumption that effects should never be omitted nor re-ordered.

4 Four New Data Structures

We now illustrate how `reifyEff` can be used to extend two existing and implement two new data structures that make selective use of lazy and/or parallel evaluation.

4.1 From List to LazyList to DelayList

4.1.1 From List to LazyList

In Flix, the familiar definition of `List` is:

```
enum List[a] {
  case Nil,
  case Cons(a, List[a])
}
```

A list is either the empty list `Nil` or a cons cell `Cons(x, xs)` with an element `x` and a tail `xs`. We can implement list operations such as `filter`, `map`, and `flatMap` in the standard way.

The definition of `List` does not permit lazy evaluation. We can fix that by redefining `List` to have a lazy tail:

```
enum List[a] {
  case Nil,
  case Cons(a, Lazy[List[a]])
}
```

Flix has two expressions to support lazy evaluation: `lazy e` and `force e`. The former suspends the evaluation of an expression `e` returning a thunk of type `Lazy[t]` where `t` is the type of the expression. The latter evaluates a thunk and memoizes the result. Recall that only pure expressions can be suspended. With the updated definition of `List`, we can express eager and lazy versions of every list operation.

18:12 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

For example, here is the lazy definition of `map`⁵:

```
def mapL(f: a -> b, l: List[a]): List[a] =
  match l {
    case Nil          => Nil
    case Cons(x, xs) =>
      // The tail is *not* yet evaluated.
      Cons(f(x), lazy mapL(f, force xs))
  }
```

The `mapL` function takes a pure function f from values of type a to type b and a list l of elements of type a . If the list is empty, it returns the empty list. Otherwise, there is a `Cons(x, xs)` cell where the tail xs is lazy. In this case, we evaluate f on the head x and construct a lazy computation that maps f over the rest of the list xs . Thus, no evaluation of the tail happens until it is needed. Note that the use of `lazy` and `force` requires the suspended computation to be pure. Consequently, f must be pure, as reflected in the function signature.

We can also implement an eager and *effect-polymorphic* version of `map`⁶:

```
def mapE(f: a -> b & ef, l: List[a]): List[a] & ef =
  match l {
    case Nil          => Nil
    case Cons(x, xs) =>
      let hd = f(x); // Eagerly evaluate f(x)
      let tl = mapE(f, force xs); // Force the rest of the list
      Cons(hd, lazy tl) // Tail is lazy, but fully evaluated
  }
```

The `mapE` function takes a function f from values of type a to type b with latent effect ef and a list l of elements of type a . It pattern-matches on l . If the list is empty it returns the empty list. Otherwise, there is a `Cons(x, xs)` cell where the tail xs is lazy. We evaluate f on the head x ; then we perform a recursive call on the tail xs (forcing the list). Note that moving the tail-computation to a `let`-binding makes it eager. Finally, we return a `cons`-cell with the new head and tail, where the tail is made lazy (but nevertheless has been fully evaluated). Unlike, `mapL`, the `mapE` function permits side effects, because it materializes those effects immediately.

We now have `mapL` and `mapE` which have lazy and eager semantics, respectively. We can use these two functions to define a *purity reflective* `map` function that varies its behavior depending on the purity of its function argument:

```
def map(f: a -> b & ef, l: List[a]): List[b] & ef =
  reifyEff(f) {
    case Pure(g) => mapL(g, l) // Use lazy evaluation.
    case _      => mapE(f, l) // Use eager evaluation.
  }
```

The implementation is straightforward: The `map` function matches on the purity of f . If f is pure, then we bind it to g (which is typed as pure) and call `mapL` passing g . Otherwise, f may be impure, and we call `mapE`.

⁵ The syntax $a \rightarrow b$ denotes a pure function from a to b .

⁶ The syntax $a \rightarrow b \ \& \ ef$ denotes an effect polymorphic function from values of type a to type b with latent effect ef .

Example I

The Flix program fragment⁷:

```
List.range(1, 1_000_000_000) |>           // Lazy
List.map(x -> {println("a"); x + 1}) |>    // Eager
List.map(x -> {println("b"); x * 2})      // Eager
```

Prints one billion a's followed by one billion b's. This takes a while, but ultimately the program terminates. The a's are printed before the b's preserving the order of effects.

Example II

The following Flix program fragment Prints `Some(4)` and terminates immediately. The two map operations are pure, consequently they are applied lazily and only evaluated for the first element of the list.

```
List.range(1, 1_000_000_000) |>           // Lazy
List.map(x -> x + 1) |>                   // Lazy
List.map(x -> x * 2) |>                   // Lazy
List.head |> println                       // Eager in head.
```

Example III

The Flix program fragment:

```
let count = ref 0;
List.range(1, 1_000_000_000) |>           // Lazy
List.map(x -> x + 1) |>                   // Lazy
List.take(1_000) |>                       // Lazy
List.map(x -> {                             // Eager
  count := deref count + 1; x * 2
});
println(deref count)
```

Prints 1000 and terminates rather quickly. The first map operation is applied lazily, and the subsequent take operation is also applied lazily. The final map operation is applied eagerly, but only to the first 1000 elements.

4.1.2 From LazyList to DelayList

While the previous lazy list data structure permits both eager and lazy evaluation, its representation is inefficient. In particular, the lazy list definition has two issues: (i) each use of `Lazy` introduces a layer of indirection. This indirection requires extra memory, slows down access, and puts additional pressure on the garbage collector, and (ii) each `force` operation is guarded by a lock to ensure that the thunk is evaluated at most once. This can cause lock contention and is antithetical to the idea that immutable data structures can be shared freely and efficiently in a concurrent program. To overcome these issues, we actually use the following definition:

⁷ The `List.range(b, e)` function returns a (suspended) list of integers from `b` until `e`.

18:14 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

```
enum DelayList[a] {  
  case ENil  
  case ECons(a, DelayList[a])  
  case LCons(a, Lazy[DelayList[a]])  
}
```

The idea is that a fully evaluated list is represented with the `ENil` and `ECons` constructors whereas a list with a lazy tail is represented with the `LCons` constructor. We implement all operations to be maximally lazy. Evaluation occurs for two reasons: (i) when required by a terminal operation (e.g., `count` and `foldLeft`), or (ii) when a non-terminal operation is given an impure function argument (e.g., `filter` and `map`).

We have implemented the `DelayList` data structure. The following pure operations are always lazy: `append`, `drop`, `flatten`, `from`, `intercalate`, `intersperse`, `range`, `repeat`, `replace`, `take`, and `zip`. The operations shown in Fig. 4a are lazy when given pure function arguments and otherwise eager.

We can use the `DelayList` data structure to realize the word count example from Section 2.

4.2 From Set to Parallel Set

We have refactored the Flix Standard Library implementation of the `Set` data structure to use parallel evaluation for all of its aggregation operations (shown in Fig. 4b). Each of these functions use `reifyEff` to inspect the purity of their function argument, and then they dispatch to either a sequential or a parallel function that operates on the underlying Red-Black tree. For example, here is the implementation of `Set.count`:

```
@ParallelWhenPure  
pub def count(f: a -> Bool & ef, s: Set[a]): Int32 & ef =  
  reifyEff(f) {  
    case Pure(g) if useParallelEvaluation(s) =>  
      RedBlackTree.parCount(g, s)  
    case _ =>  
      foldLeft((b, x) -> if (f(x)) b + 1 else b, 0, s)  
  }
```

Here we use purity reflection on f to determine whether it is safe to perform the count in parallel or if we must perform it sequentially (going from left to right). Moreover, we use the function `useParallelEvaluation` to estimate whether it is *worth* to perform the count in

<u>@LazyWhenPure</u>		<u>@ParallelWhenPure</u>

■ **Figure 4** Selective Lazy or Parallel datastructures, depending on purity of function arguments.

parallel. In particular, the `useParallelEvaluation` function relies on some heuristics, including the height of the Red-Black tree, to determine whether we *should* use parallel evaluation, given that we *could*.

The implementation of `RedBlackTree.parCount` is straightforward:

```
@Parallel
def parCount(f: (k, v) -> Bool, t: RedBlackTree[k, v]): Int32 =
  match t {
    case Leaf                => 0
    case DoubleBlackLeaf     => 0
    case Node(_, l, k, v, r) => // left, key, value, right
      par (cl <- parCount(f, l);
          cm <- if (f(k, v)) 1 else 0;
          cr <- parCount(f, r))
        yield cl + cm + cr
  }
```

Here we use the built-in Flix construct `par` to evaluate three expressions in parallel. Thus, the count is performed in parallel on the left subtree, on the key and value, and on the right subtree.

We might worry that spawning too many threads may impose an overhead much larger than the time saved by using parallel evaluation. With OS-level threads, which are expensive, this is likely to be the case. A standard solution to this problem is the use of thread pools and/or a fork-join framework. However, with the imminent arrival of light-weight threads in Java (Project Loom), we hope that such administration will no longer be necessary since `VirtualThreads` are very cheap.

4.3 From Map to Parallel Map

We have also refactored the Flix Standard Library implementation of the `Map` data structure (mapping keys to values), to use parallel evaluation for all the aggregation and transformation operations when given pure function arguments (shown in Fig. 4c). The `map` and `mapWithKey` functions are the most interesting since they allow parallel rebuilding of the map when applying a pure function to all of its values. As before, these functions use `reifyEff` to dispatch to the appropriate operation inside `RedBlackTree`.

For example, here is a simplified version `RedBlackTree.parMapWithKey`:

```
@Parallel
pub def parMapWithKey(f: (k, v1) -> v2, t: RedBlackTree[k, v1]):
  RedBlackTree[k, v2] =
  match t {
    case Leaf                => Leaf
    case DoubleBlackLeaf     => DoubleBlackLeaf
    case Node(c, l, k, v, r) =>
      par (l1 <- parMapWithKey(f, l);
          v1 <- f(k, v);
          r1 <- parMapWithKey(f, r))
        yield Node(c, l1, k, v1, r1)
  }
```

4.4 From Map and ParallelMap to DelayMap

We now turn to perhaps the most interesting new data structure: `DelayMap`, a data structure that uses *both* selective lazy and parallel evaluation. A `DelayMap[k, v]` is a map from strict keys (of type `k`) to lazy values (of type `v`). Pure transformations on the values of a `DelayMap`

18:16 Purity Reflection: Peaceful Coexistence of Effects, Laziness, and Parallelism

are lazy (e.g., `DelayMap.map`). Pure terminal operations use parallelism (e.g., `Delay.count`). The operations in Fig. 5a use lazy evaluation when given pure function arguments. The `unionWith` operation is especially interesting, as it enables the lazy merge of two maps (if the combine operation is pure). The operations in Fig. 5b use parallel evaluation when given pure function arguments. Consider the program fragment:

```
m1 |> DelayMap.map(x -> x + 1)           // Lazy.
      DelayMap.map(x -> x * 2)           // Lazy.
      DelayMap.count(x -> {println(x); x > 5}) // Parallel + sequential
```

Assume we start with a map `m1` from strings to integers. The first and second map operation transform the values and are applied lazily because they are pure. The last count operation is impure, hence must be applied eagerly. However, before doing so, we force the entire map in parallel (i.e., applying `x -> x + 1` and `x -> x * 2` to every value) and only then the counting is performed, sequentially from left to right. This example shows that we apply pure operations lazily, but once we have performed an impure operation, we force the entire data structure in parallel, and then switch back to sequential evaluation.

4.4.1 Example I

We can use a `DelayMap` to write code that is both natural and efficient. Assume that we have two maps m_1 and m_2 of type `DelayMap[String, Int32]`. Each map records the number of occurrences of a specific word drawn from some documents d_1 and d_2 . We can merge the two maps and then compute the total number of occurrences of the word “foo”:

```
let m1 = ...
let m2 = ...
let m3 = DelayMap.unionWith((x, y) -> x + y, m1, m2);
DelayMap.getWithDefault("foo", 0, m3) |> println
```

Here the `unionWith` function merges two maps using the supplied merge function to resolve conflicts when a key occurs in both maps. The merge operation is pure and hence `unionWith` is evaluated lazily. This means that we only have to merge and perform the addition for the key “foo” (and any other key we may look up).

@LazyWhenPure

```
def adjust(...)
def adjustWithKey(...)
def insertWith(...)
def insertWithKey(...)
def map(...)
def mapWithKey(...)
def unionWith(...)
def unionWithKey(...)
def update(...)
def updateWithKey(...)
```

(a) `DelayMap`: lazy when pure.

@ParallelWhenPure

```
def count(...)
def maximumKeyBy(...)
def maximumKeyBy(...)
def maximumValueBy(...)
def minimumKeyBy(...)
def minimumValueBy(...)
def sumWith(...)
def productWith(...)
```

(b) `DelayMap`: parallel when pure.

■ **Figure 5** Selective *Lazy* and *Parallel* datastructure, depending on purity of function arguments.

■ **Table 1** Overview of Data Structures. (*LWP* = Lazy When Pure, *PWP* = Parallel When Pure).

Data Structure	Lines	Tests	Functions	@LazyWhenPure	@ParallelWhenPure	LWP + PWP
Set	610	384	51	-	5	-
Map	924	591	80	-	9	-
DelayList	1,158	498	54	9	-	-
DelayMap	786	298	58	10	9	2

4.4.2 Example II

We can merge the two `DelayMaps`, while using a mutable list to compute all the words that occur in both maps:

```
let m1 = ...
let m2 = ...
let duplicates = MutList.empty();
let merge = (key, x, y) -> {
  MutList.add!(key, duplicates);
  x + y
};
let m3 = DelayMap.unionWithKey(merge, m1, m2)
```

The merge operation is impure and hence `unionWith` is evaluated eagerly. This ensures that the mutable list `duplicates` is updated correctly.

4.5 Summary

We have demonstrated the usefulness of `reifyEff` by using it in four data structures:

- We refactored the Flix Standard Library implementation of the `Set` and `Map` data structures to use selective parallel evaluation.
- We have introduced two new data structures: `DelayList` which uses selective lazy evaluation and `DelayMap` which uses selective lazy and parallel evaluation.

Table 1 shows an overview of the data structures that we have implemented. The `Data Structure` column gives the name of the data structure. The `Lines` column gives the number of Flix source code lines (excluding tests). The `Tests` column gives the number of manually written unit tests. The `Functions` column gives the number of functions implemented on the data structure. Most functions are first-order and “terminal”. For example, `Set.memberOf` is first-order and terminal, i.e., it does not transform the `Set` but rather returns a value. The `@LazyWhenPure` gives the number of functions that use purity reflection to enable lazy evaluation. The `@ParallelWhenPure` gives the number of functions that use purity reflection to enable parallel evaluation. The `LWP + PWP` gives the number of functions that use purity reflection to enable *both* lazy and parallel evaluation. For example, the line for `DelayMap` shows that the data structure is implemented in 786 lines of Flix code with 298 unit tests. The data structure offers 58 functions of which 10 use purity reflection to enable lazy evaluation, 7 use purity reflection to enable parallel evaluation, and 2 use purity reflection to enable both. Except for `DelayList`, these three data structures build on a Red-Black Tree, whose line counts are not included.

5 Compilation Strategies

We now discuss two ways to implement purity reflection: one based on runtime dispatch and the other on a novel form of effect-aware monomorphization. Both approaches rely on the type and effect system since we cannot readily determine if an expression will be pure at runtime. In other words, our extension of Flix only assigns meaning to well-typed programs.

5.1 Runtime Dispatch

Given a well-typed program, we can annotate each closure with a Boolean (or Boolean formula) to track if it is pure or impure. For a first-order function (i.e., a function without function arguments), its purity is readily determined by the typing judgment. For a higher-order function, its purity may depend on its function arguments. In this case, we label the closure with a Boolean formula that refers to the purity of the closure arguments. Given such an annotated closure, the `reifyEff` construct can be implemented by simply inspecting these annotations (and potentially evaluating a Boolean formula). For example, if we have the program fragment:

```
let f = x -> x + 1;
let g = x -> println(x);
let h = u -> v -> x -> u(v(x));
```

Then the closure of `f` stores a Boolean formula which is the constant true, the closure of `g` stores a Boolean formula which is the constant false, and the closure of `h` stores a Boolean formula which is the conjunction of the two bits of the higher-order arguments `u` and `v`. Thus, at runtime, the purity of `h` can be computed once `u` and `v` are known.

The cost of the runtime dispatch strategy is that we must store a Boolean formula with each closure. For first-order functions, this is just the constant true or false. For higher-order functions, it is a formula with several variables corresponding to its higher-order functions. Thus, in general, these formulas will be small since most functions are first-order and since higher-order functions tend to have only a few function arguments. Hence, the increase in code size should be modest. At runtime, the `reifyEff` construct has to evaluate small Boolean formulas which should be fast.

5.2 Effect-Aware Monomorphization

As an alternative to runtime dispatch, we propose an effect-aware form of monomorphization.

Monomorphization is a compile-time transformation that replaces polymorphic functions with copies that are specialized to the concrete types of their arguments. For example, if `List.map` is used with both integer and string lists, then monomorphization generates two copies of `List.map`: one specialized to integers and one specialized to strings. Monomorphization avoids boxing at the cost of larger executables. In practice, code size can be significantly reduced with the proper use of inlining and dead code elimination. A potential downside of monomorphization is that it may prevent separate compilation.

Before our work, the Flix compiler performed specialization of type variables and erased effect variables. In this work, we have extended the Flix compiler to specialize effect variables. In other words, the Flix compiler is now able to generate two versions of `List.map[Int]`: one specialized for pure functions and one specialized for impure functions. The upshot is that `reifyEff` can be eliminated – entirely at compile-time – because its argument is statically known to be pure or impure. Thus, the use of `reifyEff` incurs zero runtime overhead.

A technical detail is that during monomorphization a type or effect variable can potentially be left un-instantiated. For example, in the expression `Nil == Nil` each `Nil` can be given any type α . For effect variables, we can use two strategies to deal with such situations:

- **(Opportunistic)** We opportunistically treat all un-instantiated effect variables as pure. This is sound because the type system is closed under substitution (i.e., if a variable is free we may substitute it by \top).
- **(Conservative)** We reject programs that contain un-instantiated effect variables during monomorphization. The programmer can always resolve the situation with a type (or effect) annotation.

In our extension of Flix, we choose the conservative option because it is consistent with how ordinary un-instantiated type variables are treated. As an example, the following (contrived) program has an un-instantiated effect variable:

```
let f = g -> reifyEff(g) {
  case Pure(w) => g
  case -       => g
};
f(f)
```

Here the type of f is: $\forall \alpha_1, \alpha_2, \beta. (\alpha_1 \xrightarrow{\beta} \alpha_2) \xrightarrow{\top} (\alpha_1 \xrightarrow{\beta} \alpha_2)$. When f is applied to *itself* it returns a function of the same type which has an un-instantiated effect variable even after monomorphization. In Section 7, we investigate how common un-instantiated effect variables are in real programs. We have not observed un-instantiated effect variables in existing code.

5.3 Discussion

We believe that both the runtime dispatch and the effect-aware monomorphization approaches are viable. We decided to implement purity reflection via monomorphization since:

- Flix already uses monomorphization to eliminate parametric polymorphism.
- Monomorphization enables more aggressive optimizations performed by the Flix inliner.
- Monomorphization ensures that the technique imposes zero runtime overhead.

Finally, as our experiments in Section 7 demonstrate, the increase in compilation time and code size is small.

6 Implementation

We have implemented purity reflection as an extension of the Flix programming language.

6.1 The Flix Programming Language

Flix is a functional-first, imperative, and logic programming language that supports algebraic data types, pattern matching, higher-order functions, parametric polymorphism, type classes, higher-kinded types, polymorphic effects, extensible records, first-class Datalog constraints, channel and process-based concurrency, and tail call elimination [24, 25, 26, 27, 28].

The Flix compiler project, including the standard library and tests, consists of 230,000 lines of Flix and Scala code. Adding `reifyEff` and effect-aware monomorphization required less than 2,000 lines of code. The extended Flix Standard Library required approximately 4,000 lines of code with unit tests (see Section 4).

Flix, with our extension, is open source, ready for use, and freely available at:

<https://flix.dev/> and <https://github.com/flix/flix/>

6.2 Integration with Type Classes

Flix supports type classes and higher-kinded types. The Flix compiler implements type classes using monomorphization, i.e., there is no dynamic dispatch or dictionary passing. This also has the advantage that purity reflection works with type classes without any modifications. For example, if a polymorphic function requires a `Foldable` instance because of a call to `Foldable.count` then during monomorphization the call to `Foldable.count` will be replaced by a call to the appropriate instance function. Thus, the benefits of selective lazy and/or parallel evaluation are available even for polymorphic functions that use type classes.

7 Evaluation

We now turn to the question of the viability of an implementation strategy based on effect-aware monomorphization. In particular, we consider the following research questions:

- **RQ1:** What is the impact of effect-aware monomorphization on compilation time?
- **RQ2:** What is the impact of effect-aware monomorphization on code size?
- **RQ3:** How common are un-instantiated effect variables in practice?

7.1 RQ1 and RQ2: Impact on compilation time and code size

Monomorphization specializes (i.e., copies) functions for each of their concrete type arguments. For example, the `List.map` function has the polymorphic type:

$$\forall a, \forall b, \forall e. (a \xrightarrow{e} b) \rightarrow \text{List}[a] \xrightarrow{e} \text{List}[b]$$

Under standard monomorphization, the `List.map` function is copied for every instantiation of the type variables a and b . If, for example, `List.map` is called with the two functions that have types: `Int32 → Bool` and `String → Int32`, we would get two copies of `List.map`.

With effect-aware monomorphization, a function is copied for every instantiation of its type variables *and* its effect variables. In other words, `List.map` will be copied for every instantiation of a , b , and e . Every effect variable is either pure or impure which means that we can get two copies of a function per effect variable (in addition to its other type variables). In the worst case, this can lead to an exponential blow-up in the number of copies.

We can construct a worst-case example with three effect variables:

```
def hof(f: a -> b & ef1, g: a -> b & ef2, h: a -> b & ef3): Unit = ...

def p(): Unit & Pure = ... // a pure function
def i(): Unit & Impure = ... // an impure function

def main(): Unit & Impure =
  hof(p, p, p);
  hof(i, p, p);
  // ... omitted for brevity ...
  hof(i, i, i)
```

The higher order function `hof` takes three function arguments f , g , and h . Each function argument has an effect variable, which can be instantiated to pure or impure. Inside `main`, we call `hof` with all possible combinations of pure and impure function arguments. There are $2^3 = 8$ combinations of these. This means that during effect-aware monomorphization we will construct 8 copies of `hof`, which duplicates its entire function body. If `hof` is large this can lead to a blow-up in compilation time and code size.

■ **Table 2** Impact of Effect-Aware Monomorphization on Compilation Time and Code Size.

†: The “DeliveryDate” and “Stratifier” programs depend on the Flix Datalog engine, which is a part of the Flix Standard Library and implemented in Flix itself. Hence, these programs are not actually 35-116 lines of code, but more accurately thought of as 35-116 lines of code *plus* the 3,055 lines of code used to implement the Datalog engine in Flix.

Program	Std. Monomorphization				Effect-Aware Monomorphization		
	Lines	Time	Bytes	Classes	Time	Bytes	Classes

Analysis

Given a polymorphic function f with n type parameters (quantified type variables) and m effect parameters (quantified Boolean variables), effect-aware monomorphization will create at most $t^n \times 2^m$ copies of f where t is the number of types that occur in the program after type checking but before monomorphization. In practice, type-based monomorphization does not lead to an exponential blow-up, but what about effect-aware monomorphization?

Table 2 shows the impact of effect-aware monomorphization on compilation time and code size for several Flix programs. We briefly discuss each program: The Flix “Standard Library” is included for completeness. When the library is compiled alone, without any entry point, a mere 8 Java classes are generated. These 8 classes are hard-coded and are always emitted. One class represents the Unit value. Other classes represent various exceptions. “BoolTable” is a Flix program to generate a table of smallest formulas for all Boolean functions of 4 arguments. “DeliveryDate” is a Flix program that uses first-class Datalog constraints with lattice semantics to compute the earliest delivery date for a “component” that consists of subcomponents, each with its delivery date and assembly time. “fcwg” is a Flix program generator that generates wrapper code for Java classes. “flixball” is a basic multi-player, 2-dimensional shooter game, run in the console. Bots compete in a last-player standing arena, taking simultaneous turns to rotate, move, or fire their weapon. “IfNoSub” is an implementation of Algorithm W for Flix written in Flix. It captures the relational nullable type system from [28]. “JSON” is, as the name implies, a JSON library for Flix. “Regex” is, as the name implies, a Regex library for Flix (based on Java’s regex package). “Stratifier” is a Flix program that uses first-class Datalog constraints with lattice semantics to implement a version of Ullman’s algorithm to compute the stratification of a Datalog program. “TestX” is the collection of unit tests for the data structure X .

We now explain each column of the table: The `Program` column gives the name of the Flix program. The `Lines` column shows the number of lines of code in the program (excluding the Flix Standard Library), The `Time` column shows the total compilation time in seconds (without effect-aware monomorphization). The `Bytes` column shows the number of bytes generated by the compiler (without effect-aware monomorphization). The `Classes` column shows the number of classes generated by the Flix compiler (without effect-aware monomorphization). The last three columns then repeat but now with effect-aware monomorphization. The numbers in parentheses show the percentage increase (resp. decrease) in the specific measurement.

For example, the “`IfNoSub`” program consists of 1,870 lines of code (in addition to the 30,000 lines of code from the Flix Standard Library). Under type-based monomorphization, the Flix compiler generates 1,849 Java classes, totaling 1,967,390 bytes in 5.2s. With effect-aware monomorphization, the compiler generates 1,921 Java classes totaling 2,046,480 bytes in the same amount of time. This represents a 4% increase in code and classes.

As a second example, the “`TestDelayMap`” program consists of 2,039 lines of code, which contain all the unit tests for the `DelayMap` data structure. Every purity reflective function is tested with both a pure and impure function argument. Under type-based monomorphization, the Flix compiler generates 5,090 Java classes totaling 4,111,046 bytes in 5.1s. With effect-aware monomorphization, the compiler generates 5,631 Java classes totaling 4,750,187 bytes within the same time. This represents an 16% increase in code and an 11% increase in classes.

As Table 2 shows, the cost of effect-aware monomorphization is low. For real programs, there is no increase in compile time and the increase in code size is between 0% to 5%.

We offer a few explanations why real programs show only a modest increase:

- Most functions are first-order (i.e., they do not take function arguments). A first-order function cannot be copied by effect-aware monomorphization, hence it cannot lead to increased compilation time or code size. To give two examples: In the `Set` module 17/45 functions are higher-order whereas in the `String` module 24/94 functions are higher-order.
- The majority of function calls are to first-order functions. For example, `List.sum` is probably more widely used than e.g., `List.zipWith3`. In other words, there are fewer higher-order functions than first-order functions, and they are on the balance also less likely to be used.
- When a higher-order function is used, it is not necessarily used with both pure and impure function arguments. For example, in many of the programs, higher-order functions are always used with a pure or an impure function argument, but more rarely with both.

In sum, we conclude that effect-aware monomorphization is a viable implementation strategy.

7.2 RQ3: How common are un-instantiated effect variables in practice?

As discussed in Section 5.2, an effect variable is potentially left un-instantiated during monomorphization. We showed a carefully crafted example – which relied on self-application – that would lead to an un-instantiated effect variable. We discussed two sound solutions: (i) an optimistic strategy that treats every un-instantiated variable as `true` (i.e., as pure), and (ii) a conservative strategy that rejects programs with un-instantiated (effect) variables. Flix uses the conservative strategy.

An important empirical question is then how common such situations are. In more than 100,000 lines of Flix code, we have never encountered a single un-instantiated effect. In fact, we have only been able to trigger the rejection with our carefully crafted example. We conclude that un-instantiated effect variables are not of practical concern. Intuitively, most expressions are either pure or impure. A few expressions are effect-polymorphic, but they are almost always called with pure or impure function arguments. Consequently, during monomorphization, we always end up with expressions that are either pure or impure.

8 Related Work

We consider related work along three axes: type and effect systems, reflection, and streams.

8.1 Type and Effect Systems

The Flix type and effect system is based on Hindley-Milner [12, 30, 7] extended with Boolean unification [29, 27]. The Flix system is effect-polymorphic, a notion that goes back to Lucassen et al. [23].

Algebraic effects is a hot research topic [33, 14, 19, 1, 21, 3, 4]. An algebraic effect system allows the programmer to define a collection of effects that can be invoked and interpreted by *effect handlers* installed on the stack (similar to exceptions). A type and effect system for an algebraic effect system ensures that all effects are ultimately handled. Most prototype programming languages that support algebraic effects *and* complete type inference are based on row polymorphism. Purity reflection seems orthogonal to algebraic effects; we are not interested in a collection of effects nor in how to interpret them. We are interested in enabling higher-order functions to selectively use lazy or parallel evaluation when passed pure function arguments. As interesting future work, we can imagine a type and effect system that tries to combine algebraic effects with purity reflection while retaining complete type inference.

A line of research has used uniqueness and ownership type systems to prevent data races and deadlocks and to enable parallelism [2, 6, 9]. Boyapati et al. present a type system that prevents data races and deadlocks. In the system, programmers partition locks into equivalence classes and define a partial order on them. The type checker then verifies that the locks are acquired in descending order [2]. Craik and Kelly present a type, effect, and ownership system that uses read-and-write effect sets to reason about data dependence. This information is then exploited to enable data or task parallelism [6]. Gordon et al. present a type and effect system that restricts updates to mutable memory shared by multiple threads. The system relies on a combination of immutable and uniqueness types, which ensure the absence of data races [9].

8.2 Type Case and Effect Reflection

Tarditi et al. propose *type case*, a meta-programming construct that enables polymorphic functions to reflect on their concrete type arguments [11, 36]. In the TIL Standard ML compiler, type casing is used to implement several polymorphic functions more efficiently. For example, an array indexing (“subscript”) operation can be implemented more efficiently if the compiler knows the concrete type of the underlying array. One might think of our work as an *effect case* which is used to enable selective lazy or parallel evaluation.

Long et al. propose a calculus and type system with reflection for effects representing region accesses [22]. Their effects are first-class expressions that can be inspected by pattern matching. The features of their system are orthogonal to our system: they have a hybrid approach, based on static and dynamic types; their calculus provides over-approximating (may) and under-approximating (must) types, and is based on sub-typing/effecting and refinement types. Instead, we support type and effect polymorphism with inference based on Boolean unification. We also provide an implementation in a programming language.

8.3 Streams

Broadly speaking, the relation between our work and work on streams is that most stream implementations aim to provide lazy and/or parallel evaluation capabilities in programming languages that are eager and impure, at the risk of unsoundness. Purity reflection allows library authors to soundly determine *when* it is safe to use lazy and/or parallel evaluation.

Wadler et al. introduce the notion of “odd” and “even” lazy lists [38]. Wadler et al.’s observation is that in the standard definition of a lazy list, the first element of the list is eager whereas the rest of the list is lazy. In other words, the lazy list is not entirely lazy which can lead to unexpected behavior. We agree with this observation and in our real implementation of `DelayList` every element is lazy.

Jones et al. present an extension of Haskell, where the programmer can define a collection of rewrite rules that are applied to the program by the Haskell compiler [13]. Using rewrite rules, a programmer (typically a library author) can express program optimizations as a collection of transformations. The mechanism is extended and applied to stream fusion in [5]. The rewrite mechanism could provide an alternative implementation of purity reflection. Similar to our solution using monomorphization, rewrite rules are applied at compile time and induce no run-time overhead. However, we see two advantages in our solution based on purity reflection: First, rewrite rules only apply if there is a syntactic pattern match, while our technique also applies across various let-bindings or even function calls, since it is based on a type and effect system that propagates information. Second, a programmer could easily add unsound rewrite rules, while our type system provides some guarantees; in particular, impure functions cannot be postponed.

Prokopec et al. show that the overhead of functional combinators (e.g., `filter`, `map`) on the JVM can be overcome with a sufficiently aggressive JIT compiler [34]. Kiselyov et al. present a technique to overcome the overhead of stream operations through staging [18]. Møller and Veileborg propose to use static analysis to eliminate the overhead of stream pipelines in Java [32]. In summary, the bulk of this work has focused on *how* to make streams execute faster. In contrast, our work concerns *when* it is safe to do so. We use monomorphization to implement purity reflection. After monomorphization, we have a mono-typed program where each use of a non-terminal operation (e.g., `filter` and `map`) has been replaced by its eager or lazy version. We can pass the monomorphed AST to any technique that performs stream fusion without the risk of unsoundness.

Khatchadourian et al. present a study on the use and misuse of streams in Java [17]. Interestingly two of their findings are: “Finding 1: Stream parallelization is not widely used” and “Finding 3: Streams tend not to have side effects.” The former finding could suggest that even though parallel streams are readily available, developers are either unaware or reluctant to use them. With purity reflection, the choice of whether to use parallelism rests not just with the programmer but also with the library author. This suggests that purity reflection can help programmers by exploiting parallelism when they did not consider it themselves.

Khatchadourian et al. also present an automatic technique to refactor code to use streams more efficiently [16]. The technique is based on heavy-weight program analysis. Flix, with purity reflection, offers an alternative approach where reasoning about and reflecting on purity is built directly into the language.

9 Conclusion

We have proposed *purity reflection*, a new programming language feature that enables higher-order functions to vary their behavior depending on the purity of their function arguments. Purity reflection enables selective use of lazy and/or parallel evaluation, while ensuring that side effects are never lost or re-ordered. We have implemented purity reflection in the Flix programming language. We have retrofitted and extended the Flix Standard Library with new data structures that automatically use lazy or parallel evaluation when it is safe to do so. Effect-aware monomorphization provides a mechanism to implement purity reflection as

a construct that is entirely eliminated at compile-time. Therefore, the technique imposes no run-time overhead. Experimental results show that the cost of effect-aware monomorphization in compilation time and code size is minimal.

Exact Separation Logic

Towards Bridging the Gap Between Verification and Bug-Finding

Abstract

Over-approximating (OX) program logics, such as separation logic (SL), are used for *verifying* properties of heap-manipulating programs: all terminating behaviour is characterised, but established results and errors need not be reachable. OX function specifications are thus incompatible with true bug-finding supported by symbolic execution tools such as Pulse and Pulse-X. In contrast, under-approximating (UX) program logics, such as incorrectness separation logic, are used to *find* true results and bugs: established results and errors are reachable, but there is no mechanism for understanding if all terminating behaviour has been characterised.

We introduce exact separation logic (ESL), which provides fully-verified function specifications compatible with both OX verification and UX true bug-finding: all terminating behaviour is characterised and all established results and errors are reachable. We prove soundness for ESL with mutually recursive functions, demonstrating, for the first time, function compositionality for a UX logic. We show that UX program logics require subtle definitions of internal and external function specifications compared with the familiar definitions of OX logics. We investigate the expressivity of ESL and, for the first time, explore the role of abstraction in UX reasoning by verifying abstract ESL specifications of various data-structure algorithms. In doing so, we highlight the difference between *abstraction* (hiding information) and *over-approximation* (losing information). Our findings demonstrate that abstraction cannot be used as freely in UX logics as in OX logics, but also that it should be feasible to use ESL to provide tractable function specifications for self-contained, critical code, which would then be used for both verification and true bug-finding.

1 Introduction

Over-approximating (OX) program logics were introduced to reason about program correctness, starting with Hoare logic [18] and evolving to separation logic (SL) [27, 30]. SL is used for *verification* and features function specifications of the form $\{P\} f(\vec{x}) \{Q\}$, the meaning of which is that all terminating executions of the function f that start from a state in the pre-condition P end in a state covered by the post-condition Q . SL has the standard rule of *forward consequence*, which allows one to *lose information* (for example, if we had a post-condition with $x = 42$, we could soundly weaken this precise information to the less precise $x > 0$ or even to the non-informative `true`). In essence, the philosophy underlying the OX approach in general can be stated as:

no paths can be cut, but information can be lost.

A key property of SL is that function specifications are *compositional*, enabling *scalable* reasoning about the heap. This is due to their *locality*, which allows the pre-condition to describe only the partial state sufficient for the function to execute, and the *frame* property, which allows the function to be called in any larger state. SL function specifications have been used for verification of complex, real-world code in tools such as VeriFast [19], Iris [20], and Gillian [10, 23]. However, given that their post-conditions may describe states that are not reachable from their pre-conditions, such OX specifications are not compatible with true bug-finding, as found, for example, in Meta’s Pulse [28] and Pulse-X [21] tools.

Under-approximating (UX) program logics were recently introduced, originating from reverse Hoare logic (RHL) [8] for reasoning about correctness of probabilistic programs, and coming to prominence with incorrectness logic [26] and incorrectness separation logic (ISL) [28], which identified their bug-finding potential. ISL function specifications are of the form $[P] f(\vec{x}) [ok : Q_{ok}]$ and $[P] f(\vec{x}) [err : Q_{err}]$, the meaning of which is that any state in the success post-condition Q_{ok} or the error post-condition Q_{err} is reachable from some state in the pre-condition P by executing the function f ; this guarantees that all results and bugs reported in the post-conditions will be true. In contrast to SL, ISL uses the rule of *backward consequence*, which allows one to *cut paths* (for example, if we had a post-condition with $x > 0$, we could soundly strengthen this information to consider only the path in which $x = 42$). Therefore, the philosophy underlying UX logics in general can be summarised as:

paths can be cut, but no information can be lost.

When it comes to the use of ISL function specifications, whilst this has been implemented in Pulse-X, as far as we are aware, ISL does not feature function-call rules, and function compositionality for ISL and UX logics has not been proven. Moreover, as it is not possible to determine if UX specifications cover all terminating behaviour, they remain incompatible with verification and cannot therefore be used in tools such as VeriFast, Iris, and Gillian.

Our challenge is to develop a program logic in which we can state and prove function specifications that are compatible with *both* verification and true bug-finding. Our motivation comes from the unique flexibility and expressivity that such specifications would provide, as they could be used by verification and bug-finding tools alike, closing the gap between these two contrasting paradigms. From our experience in program logics and associated tool-building, we believe that the main use case for exact specification should be self-contained, critical code, such as widely-used data-structure libraries.

We introduce exact separation logic (ESL), with *exact* (EX) function specifications of the form $(P) f(\vec{x}) (ok : Q_{ok}) (err : Q_{err})$, whose meaning combines that of SL and ISL specifications: all terminating executions of the function that start from a state in the

pre-condition P end in a state covered by the post-conditions; *and* all states in two post-conditions are reachable from a state in the pre-condition by executing the function. The exactness of ESL can be captured by the slogan:

no paths can be cut and no information can be lost.

The slogan is supported by the rule of *equivalence*, which combines the forward consequence of SL and the backward consequence of ISL. In fact, ESL proof rules form a common core of SL and ISL, and ESL should therefore be a familiar setting to those acquainted with either.

We prove soundness for ESL with mutually recursive functions, which we believe is the first proof of function compositionality for a UX logic, and which transfers immediately to ISL. In doing so, drawing inspiration from InsecSL [25], we provide formal definitions of *external* and *internal* function specifications, which describe, respectively, the interface a function exposes towards its clients and towards its implementation, and highlight the difference in complexity between these two types of specifications in OX and UX reasoning.

Using numerous examples, we demonstrate here and in the extended version [24] how ESL can be used to reason about data-structure libraries, language errors, mutual recursion, and non-termination. In doing so, we introduce, for the first time, abstract predicates to UX reasoning and provide abstract function specifications for a number of data-structure algorithms, focussing on singly-linked lists and binary trees. In doing so, we highlight an important difference between the concepts of abstraction and over-approximation: in particular, abstraction corresponds to *hiding* information whereas over-approximation corresponds to *losing* it. Our findings demonstrate that, while abstraction cannot be used as freely in UX logics as in OX logics, sometimes resulting in less abstract specifications and more complex proofs, it should be feasible to use ESL to provide tractable function specifications for self-contained, critical code that can then be used for both verification and true bug-finding.

2 Exact Separation Logic by Example

We guide the reader through what it means to write ESL specifications and proofs by intuition and example, contrasting our findings with those known from SL and ISL.

Illustrative Example. Consider the command $C \triangleq \text{if } (x > 0) \{y := 42\} \text{ else } \{y := 21\}$, which can be specified, starting from the pre-condition $x \in \mathbb{Z}$, in ESL, SL, and ISL as follows:

<pre>(x ∈ ℤ) if (x > 0) { (x > 0) y := 42 (Q₁ : x > 0 ∧ y = 42) } else { (x ≤ 0) y := 21 (Q₂ : x ≤ 0 ∧ y = 21) } (Q₁ ∨ Q₂)</pre>	<pre>{ x ∈ ℤ } if (x > 0) { ... // Same as ESL ... } { Q₁ ∨ Q₂ } // Losing information { x ∈ ℤ ∧ y > 0 }</pre>	<pre>[x ∈ ℤ] if (x > 0) { [x > 0] y := 42 [Q₁ : x > 0 ∧ y = 42] } else { y := 21 } // Path cutting [x > 0 ∧ y = 42]</pre>
---	--	--

As ESL specifications must neither cut paths nor lose information (in this example, about the values of x and y), the ESL post-condition of C must be equivalent to $(x > 0 \wedge y = 42) \vee (x \leq 0 \wedge y = 21)$. In SL, it is possible to use forward consequence to weaken this

information and obtain, for example, $x \in \mathbb{Z} \wedge y > 0$, or just $x \in \mathbb{Z}$, or even just true . In ISL, it is possible to cut, for example, the **else** branch of the **if** statement, but the values of x and y must be maintained in the post-condition of the **then** branch, $x > 0 \wedge y = 42$.

One question that we have been often asked is whether it is simpler to prove an exact specification $(P) \text{ C } (ok : Q_{ok}) (err : Q_{err})$ in ESL, or to prove it separately in SL and ISL. The answer is that it is simpler to prove the specification in ESL. If a specification is exact, then it does not cut paths and it does not lose information. Therefore, the tools that make SL and ISL proofs simpler than ESL proofs, namely forward consequence and backward consequence, can only be used in very limited ways, if at all. From our experience, the ISL proof of an exact specification will turn out to be almost identical to the ESL one, and an SL proof on top of that would duplicate a large part of the work. In fact, if one were to try to prove the exact specification $(x \in \mathbb{Z}) \text{ C } ((x > 0 \wedge y = 42) \vee (x \leq 0 \wedge y = 21))$ from the above example in either SL or ISL, they would obtain exactly the same proof as in ESL.

We also emphasise that ESL is not meant to replace either SL or ISL. If one is interested in only verification or only bug-finding, then one should use a formalism tailored to that type of analysis to exploit the available shortcuts. However, if one wanted to use the same codebase for both verification and bug-finding, then ESL offers a way of providing specifications useful for both. One example of such a codebase would be a widely-used data-structure library, where some of the users use it for verification and others for bug-finding.

List-length in ESL: Intuition. We consider a list-length function, $\text{LLen}(x)$, which takes a list at x , does not modify it, and returns its length, and the following ESL specification:

$$(x = x \star \text{list}(x, n)) \text{ LLen}(x) (ok : \text{list}(x, n) \star \text{ret} = n)$$

This specification uses a standard list-length predicate, $\text{list}(x, n)$, which states that the length of the list at x equals n and is defined as follows:

$$\text{list}(x, n) \triangleq (x = \text{null} \star n = 0) \vee (\exists v, x'. x \mapsto v, x' \star \text{list}(x', n - 1)),$$

hiding the information about the values and internal node addresses of the list. Before proving this specification, we establish some intuition about why it holds. Let us assume that it does not hold and try to find a counter-example: by the meaning of ESL specifications, it is either not OX-valid or it is not UX-valid. The former, however, is not possible, as the analogous SL specification holds. The latter means that it is possible to find a state in the post-condition not reachable by the execution of f from any state in the pre-condition, and may be unfamiliar to the reader as UX program logics have been introduced only recently.

We start looking for such a state in the post-condition (post-model) by choosing some values for x and n : say, $x = 0$ and $n = 2$. This also fixes ret to 2. Then, we fully unfold $\text{list}(0, 2)$ to obtain $\exists v_1, x_1, v_2. 0 \mapsto v_1, x_1 \star x_1 \mapsto v_2, \text{null}$, and instantiate the existentials v_1 , x_1 , and v_2 : say, with 1, 4, and 9, respectively. In this way, we obtain the state described by the assertion $0 \mapsto 1, 4 \star 4 \mapsto 9, \text{null}$. When it comes to the pre-condition, x and n (and also x) are fixed by the post-model choices, and when we unfold the list, the pre-condition becomes $x = 0 \star \exists v_1, x_1, v_2. 0 \mapsto v_1, x_1 \star x_1 \mapsto v_2, \text{null}$. As the algorithm does not modify the list, it becomes clear that if we choose v_1 , x_1 , and v_2 as for the post-model (that is, 1, 4, and 9, respectively), the algorithm will reach our post-model. Given that the same reasoning would apply for any choice of x and n , we realise that the given specification is, in fact, also UX-valid and hence exact. This reveals an important observation, which is that

*abstraction does not always equate to over-approximation, that is,
hiding information does not always mean losing information.*

For those used to OX reasoning, it might appear that the post-condition $\text{list}(x, n) \star \text{ret} = n$ loses information about the structure of the list, but the insight here is that this information was never known in the pre-condition in the first place, as we also only had $\text{list}(x, n)$ there.

List-length in ESL: Proof Sketch. Reasoning about function specifications in the UX/EX setting has not been studied previously and requires subtle definitions of *external function specifications*, which provide the interface that the function exposes to the client, and *internal function specifications*, which provide the interface to the function's implementation. With OX logics, these are well-understood and the gap between them is small. For UX/EX logics, this gap is larger. We illustrate these concepts informally using the list-length example, and give the corresponding formal definitions in §4.

The proof sketch of the ESL external specification of the list-length algorithm is given in Figure 1. It is more complex than its SL counterpart (cf. [24]), but is manageable and comes with the benefit that this ESL specification can be used for both verification and bug-finding.

First, as the function is recursive, we have to provide a measure and prove the specification extended with this measure: in this case, the measure is $\alpha = n$, given by the length of the list. This measure is necessary to ensure the finite reachability property for mutually recursive functions in UX logics, and is a known technique from the work on total correctness specifications for OX logics [7, 9]. Recursive function calls are then allowed only if they use specifications of a strictly smaller measure, represented in the proof sketch by the function specification context $\Gamma(\alpha)$, which contains the specification of $\text{LLen}(x)$ for all $\beta < \alpha$.

The move from the external to the internal pre-condition initialises the local function variables to `null`. The ESL rule for the `if` statement, just like in SL, adds the condition to the then-branch, its negation to the else-branch, and collects the branch post-conditions using disjunction. The rules for the basic commands (here, the assignments $r := 0$ and $r := r + 1$ and the lookup $x := [x + 1]$) are also the same as in SL, as these are already exact. The unfolding of the list is also done in the same way, as unfolding always preserves equivalence; note how the condition of the `if` statement determines the appropriate disjunct for the list predicate. The recursive function call is allowed to go through as it is used with measure $n - 1$ (with the parts of the assertion representing the pre- and the post-condition highlighted).

The major difference between ISL/ESL and SL proofs is that we cannot lose information about the function parameters and local variables in the middle of the former. Therefore, we cannot simplify the assertions Q'_1 and Q'_2 further and cannot fold back the list predicate within the internal specification, as we would do in SL (cf. corresponding proof in [24]).

The most complex part of the proof sketch is the transition from the internal to the external post-condition, in which we have to somehow forget the local variables of the function, given that they must not spill out into the calling context. This is done by replacing them with fresh, existentially quantified logical variables, which in this case also allows us to use equivalence to fold back the list predicate and reach the target post-condition. The details of this transition, in which we denote $\text{ret} = n \star \alpha = n$ by R , are as follows:

$$\begin{aligned}
& \exists x_q, r_q. Q'[x_q/x][r_q/r] \star \text{ret} = r[x_q/x][r_q/r] \\
& \Leftrightarrow ((x = \text{null} \star n = 0) \vee (\exists x_q, r_q, v, x'. x_q = x' \star x \mapsto v, x' \star \text{list}(x', n - 1) \star r_q = n)) \star R \\
& \Leftrightarrow ((x = \text{null} \star n = 0) \vee (\exists v, x'. x \mapsto v, x' \star \text{list}(x', n - 1))) \star R \text{ // can fold now} \\
& \Leftrightarrow \text{list}(x, n) \star (n = 0 \vee n > 0) \star R \\
& \Leftrightarrow \text{list}(x, n) \star \text{ret} = n \star \alpha = n
\end{aligned}$$

Observe that, since we are proving an EX specification, we are not allowed to cut paths. This means that the ISL proof of the analogous ISL specification of $\text{LLen}(x)$ would be identical, noting that the use of equivalence would technically be replaced by backward consequence.

```

// Function is recursive and requires a measure:  $\alpha = n$ 
 $\Gamma(\alpha) \vdash (x = x \star \text{list}(x, n) \star \alpha = n)$ 
  LLen( $x$ ) {
    // Transition from external to internal pre-condition: initialise locals to null
    ( $x = x \star \text{list}(x, n) \star \alpha = n \star r = \text{null}$ )
    if ( $x = \text{null}$ ) {
      ( $x = x \star \text{list}(x, n) \star \alpha = n \star r = \text{null} \star x = \text{null}$ )
       $r := 0$ 
      ( $Q'_1 : x = x \star \text{list}(x, n) \star \alpha = n \star r = 0 \star x = \text{null}$ )
    } else {
      ( $x = x \star \text{list}(x, n) \star \alpha = n \star r = \text{null} \star x \neq \text{null}$ )
      // Unfold  $\text{list}(x, n)$  using the equivalence
      //  $\models \text{list}(x, n) \star x \neq \text{null} \Leftrightarrow \exists v, x'. x \mapsto v, x' \star \text{list}(x', n - 1)$ 
      ( $\exists v, x'. x = x \star x \mapsto v, x' \star \text{list}(x', n - 1) \star \alpha = n \star r = \text{null}$ )
       $x := [x + 1]$ ;
      ( $\exists v, x'. x = x' \star x \mapsto v, x' \star \text{list}(x', n - 1) \star \alpha = n \star r = \text{null}$ )
      // As  $\alpha - 1 < \alpha$ , we can use the specification of LLen( $x$ ) with measure  $\alpha - 1$ 
      ( $\exists v, x'. x = x' \star x \mapsto v, x' \star \text{list}(x', n - 1) \star \alpha - 1 = n - 1 \star r = \text{null}$ )
       $r := \text{LLen}(x)$ ;
      ( $\exists v, x'. x = x' \star x \mapsto v, x' \star \text{list}(x', n - 1) \star \alpha - 1 = n - 1 \star r = n - 1$ )
       $r := r + 1$ 
      ( $Q'_2 : \exists v, x'. x = x' \star x \mapsto v, x' \star \text{list}(x', n - 1) \star \alpha - 1 = n - 1 \star r = n$ )
    };
    ( $Q' : Q'_1 \vee Q'_2$ )
    return  $r$ 
    ( $Q' \star \text{ret} = r$ )
    // Transition from internal to external post-condition given in text
  }
  ( $\text{list}(x, n) \star \text{ret} = n \star \alpha = n$ )

```

■ **Figure 1** ESL proof sketch: $(x = x \star \text{list}(x, n)) \text{ LLen}(x) \text{ (ok : list}(x, n) \star \text{ret} = n)$.

List-insert in ESL: Intuition. The list-length function, $\text{LLen}(x)$, is an example of an algorithm where the EX specification is analogous to the traditional OX specification. At times, however, ESL specifications have to be more complex. Consider, for example, the list-insert algorithm $\text{LInsertFirst}(x, v)$, which inserts the element v at the beginning of the list x . Its traditional OX specification is:

$$\{x = x \star v = v \star \text{list}(x, vs)\} \text{ LInsertFirst}(x, v) \{ \text{list}(\text{ret}, v : vs) \}$$

where $\text{list}(x, vs)$ is the standard list predicate that exposes the values of the list:

$$\text{list}(x, vs) \triangleq (x = \text{null} \star vs = []) \vee (\exists v, x', vs'. x \mapsto v, x' \star \text{list}(x', vs') \star vs = v : vs')$$

Using the counter-example approach to check if this specification is EX-valid, we easily see that it loses information: in particular, no end-state where x is not the *second* pointer in the returned list ret is reachable from the given pre-condition. Consequently, for EX validity, we are required to use the following, less abstract, ESL specification for LInsertFirst :

$$(x = x \star v = v \star \text{list}(x, xs, vs)) \text{ LInsertFirst}(x, v) (\text{list}(\text{ret}, \text{ret} : xs, v : vs) \star \text{listHead}(x, xs))$$

where $\text{list}(x, xs, vs)$ is a predicate that exposes the internal pointers of a given list in addition to the values, and $\text{listHead}(x, xs)$ states that the list xs starts with x .

Further Examples. In §5 and [24], we give many additional examples of ESL specifications and proofs to illustrate reasoning about list algorithms and binary trees, as well as language errors, mutual recursion, non-termination, and client programs.

3 The Programming Language

We introduce ESL using a simple programming language, the syntax of which is given below.

Language Syntax

$$\begin{array}{l}
 v \in \text{Val} ::= n \in \text{Nat} \mid b \in \text{Bool} \mid s \in \text{Str} \mid \text{null} \mid \bar{v} \quad x \in \text{PVar} \\
 E \in \text{PExp} ::= v \mid x \mid E + E \mid E - E \mid \dots \mid E = E \mid E < E \mid \neg E \mid E \wedge E \mid \dots \mid E : E \mid E @ E \mid \dots \\
 C \in \text{Cmd} ::= \text{skip} \mid x := E \mid x := \text{nondet} \mid \text{error}(E) \mid \text{if } (E) C \text{ else } C \mid \text{while } (E) C \mid C ; C \mid \\
 \quad y := f(\bar{E}) \mid x := [E] \mid [E] := E \mid x := \text{new}(E) \mid \text{free}(E)
 \end{array}$$

Values, $v \in \text{Val}$, include: natural numbers, $n \in \text{Nat}$; Booleans, $b \in \text{Bool} \triangleq \{\text{true}, \text{false}\}$; strings, $s \in \text{Str}$; a dedicated value `null`; and lists of values, $\bar{v} \in \text{List}$. Expressions, $E \in \text{PExp}$, comprise values, program variables, $x \in \text{PVar}$, and various unary and binary operators (e.g., addition, equality, negation, conjunction, list prepending, and list concatenation). Commands comprise: the variable assignment; non-deterministic number generation; error raising; the `if` statement; the `while` loop; command sequencing; function call; and memory management commands, that is, lookup, mutation, allocation, and deallocation. The sets of program variables for expressions and commands, denoted by $\text{pv}(E)$ and $\text{pv}(C)$ respectively, and the sets of modified variables for commands, denoted by $\text{mod}(C)$, are defined in the standard way.

► **Definition 1 (Functions).** A function, denoted by $f(\bar{x}) \{ C; \text{return } E \}$, comprises: a function identifier, $f \in \text{Str}$; the function parameters, \bar{x} , given by a list of distinct program variables; a function body, $C \in \text{Cmd}$; and a return expression, $E \in \text{PExp}$, with $\text{pv}(E) \subseteq \{\bar{x}\} \cup \text{pv}(C)$.

Program variables in function bodies that are not the function parameters are treated as local variables initialised to `null`, with their scope not extending beyond the function.

► **Definition 2 (Function Implementation Contexts).** A function implementation context, $\gamma : \text{Str} \rightarrow_{\text{fin}} \text{PVar List} \times \text{Cmd} \times \text{PExp}$, is a finite partial function from function identifiers to their implementations. For $\gamma(f) = (\bar{x}, C, E)$, we also write $f(\bar{x}) \{ C; \text{return } E \} \in \gamma$.

We next define an operational semantics that gives a complete account of the behaviour of commands and does not get stuck on any input, as we explicitly account for language errors and missing resource errors.

► **Definition 3 (Stores, Heaps, States).** Variable stores, $s : \text{PVar} \rightarrow_{\text{fin}} \text{Val}$, are partial finite functions from program variables to values. Heaps, $h : \text{Nat} \rightarrow_{\text{fin}} (\text{Val} \uplus \emptyset)$, are partial finite functions from natural numbers to values extended with a dedicated symbol $\emptyset \notin \text{Val}$. Program states, $\sigma = (s, h)$, consist of a store and a heap.

Heaps are used to model the memory, and the dedicated symbol $\emptyset \notin \text{Val}$ is required for UX frame preservation¹ to hold (cf. Definition 10). In particular, $h(n) = v$ means that an allocated heap cell with address n contains the value v ; and $h(n) = \emptyset$ means that a heap

¹ UX frame preservation means that if a program runs with a non-missing outcome to a given final state, then it also runs with the same outcome to an extended final state, with the extension (the *frame*) unaffected by the execution. From ISL [28], it is known that losing deallocation information breaks UX frame preservation; the solution is to keep track of deallocated cells, which we achieve by using \emptyset .

cell with address n has been deallocated [11–14, 28]. This linear memory model is used in much of the SL literature, including ISL [28]. Onward, \emptyset denotes the empty heap, $h_1 \uplus h_2$ denotes heap disjoint union, and $h_1 \# h_2$ denotes that h_1 and h_2 are disjoint.

► **Definition 4** (Expression Evaluation). *The evaluation of an expression E with respect to a store s , denoted $\llbracket E \rrbracket_s$, results in either a value or a dedicated symbol denoting an evaluation error, $\dagger \notin \text{Val}$. Some illustrative cases are:*

$$\llbracket v \rrbracket_s = v \quad \llbracket x \rrbracket_s = \begin{cases} s(x), & x \in \text{dom}(s) \\ \dagger, & \text{otherwise} \end{cases} \quad \llbracket E_1 + E_2 \rrbracket_s = \begin{cases} \llbracket E_1 \rrbracket_s + \llbracket E_2 \rrbracket_s, & \llbracket E_1 \rrbracket_s, \llbracket E_2 \rrbracket_s \in \text{Nat} \\ \dagger, & \text{otherwise} \end{cases}$$

The big-step operational semantics uses judgements of the form $\sigma, C \Downarrow_\gamma o : \sigma'$, read: given implementation context γ and starting from state σ , the execution of command C results in outcome $o \in O = \{ok, err, miss\}$ and state σ' . The outcome can either equal: *ok* (elided where possible), denoting a successful execution; *err*, denoting an execution faulting with a language error, or *miss*, denoting an execution faulting with a missing resource error.

► **Definition 5** (Operational Semantics). *The representative cases of the big-step operational semantics are given in Figure 2. The complete semantics is given in [24].*

The successful transitions are straightforward: for example, the *nondet* command generates an arbitrary natural number; the function call executes the function body in a store where the function parameters are given the values of the function arguments and the function locals are initialised to `null`; and the control flow statements behave as expected. Allocation requires the specified amount of contiguous cells (always available as heaps are finite), and lookup, mutation, and deallocation require the targeted cell not to have been freed.

The semantics stores error information in a dedicated program variable `err`, not available to the programmer. For simplicity of error messages, we assume to have a function `str : PExp → Str`, which serialises program expressions into strings. The faulting semantic transitions are split into *language errors*, which can be captured by program-logic reasoning, and *missing resource errors*, which cannot, as such errors break the frame property. Language errors arise due to, for example, expressions being incorrectly typed (e.g. `null + 1`) or an attempt to access deallocated cells (that is, the use-after-free error). On the other hand, missing resource errors arise from accessing cells that are not present in memory.

4 Exact Separation Logic

We introduce an exact separation logic for our programming language, giving the assertion language in §4.1, specifications in §4.2, and the program logic rules in §4.3.

4.1 Assertion Language

To define assertions and their meaning, we introduce *logical variables*, $x, y, z, \in \text{LVar}$, distinct from program variables, and define the set of *logical expressions* as follows:

$$E \in \text{LExp} \triangleq v \mid x \mid \times \mid E + E \mid E - E \mid \dots \mid E = E \mid \neg E \mid E \wedge E \mid \dots \mid E \cdot E \mid E : E \mid \dots$$

Note that we can use program expressions in assertions (for example, $E \in \text{Val}$), as they form a proper subset of logical expressions.

$$\begin{array}{c}
\frac{\llbracket E \rrbracket_s = v \quad s' = s[x \rightarrow v]}{(s, h), x := E \Downarrow_\gamma (s', h)} \quad \frac{n \in \mathbb{N} \quad s' = s[x \rightarrow n]}{(s, h), x := \text{nondet} \Downarrow_\gamma (s', h)} \quad \frac{\llbracket E \rrbracket_s = \text{false}}{(s, h), \text{while } (E) \text{ C} \Downarrow_\gamma (s, h)} \\
\\
\frac{\llbracket E \rrbracket_s = \text{true} \quad (s, h), \text{C} \Downarrow_\gamma \sigma'' \quad \sigma'', \text{while } (E) \text{ C} \Downarrow_\gamma o : \sigma'}{(s, h), \text{while } (E) \text{ C} \Downarrow_\gamma o : \sigma'} \quad \frac{f(\vec{x}) \{ \text{C}; \text{return } E' \} \in \gamma \quad \llbracket \vec{E} \rrbracket_s = \vec{v} \quad \text{pv}(\text{C}) \setminus \{ \vec{x} \} = \{ \vec{z} \} \quad s_p = \emptyset [\vec{x} \rightarrow \vec{v}] [\vec{z} \rightarrow \text{null}] \quad (s_p, h), \text{C} \Downarrow_\gamma (s_q, h') \quad \llbracket E' \rrbracket_{s_q} = v'}{(s, h), y := f(\vec{E}) \Downarrow_\gamma (s[y \rightarrow v'], h')} \\
\\
\frac{\llbracket E \rrbracket_s = n \quad h(n) = v}{(s, h), x := [E] \Downarrow_\gamma (s[x \rightarrow v], h)} \quad \frac{\llbracket E_1 \rrbracket_s = n \quad h(n) \in \text{Val} \quad \llbracket E_2 \rrbracket_s = v \quad h' = h[n \mapsto v]}{(s, h), [E_1] := E_2 \Downarrow_\gamma (s, h')} \\
\\
\frac{(n' + i \notin \text{dom}(h)) \Big|_{i=1}^{\llbracket E \rrbracket_s - 1} \quad h' = h \uplus \{ (n' + i \mapsto \text{null}) \Big|_{i=1}^{\llbracket E \rrbracket_s - 1} \}}{(s, h), x := \text{new}(E) \Downarrow_\gamma (s[x \rightarrow n'], h')} \quad \frac{\llbracket E \rrbracket_s = n \quad h(n) \in \text{Val}}{(s, h), \text{free}(E) \Downarrow_\gamma (s, h[n \mapsto \emptyset])} \\
\\
\frac{\llbracket E \rrbracket_s = \downarrow \quad v_{\text{err}} = [\text{"ExprEval"}, \text{str}(E)]}{(s, h), x := [E] \Downarrow_\gamma \text{err} : (s_{\text{err}}, h)} \quad \frac{\llbracket E \rrbracket_s = n \notin \text{dom}(h) \quad v_{\text{err}} = [\text{"MissingCell"}, \text{str}(E), n]}{(s, h), x := [E] \Downarrow_\gamma \text{miss} : (s_{\text{err}}, h)} \\
\\
\frac{h(\llbracket E \rrbracket_s) = \emptyset \quad v_{\text{err}} = [\text{"UseAfterFree"}, \text{str}(E_1), \llbracket E \rrbracket_s]}{(s, h), x := [E] \Downarrow_\gamma \text{err} : (s_{\text{err}}, h)} \quad \frac{\llbracket E \rrbracket_s = v \quad v_{\text{err}} = [\text{"Error"}, v]}{(s, h), \text{error}(E) \Downarrow_\gamma \text{err} : (s_{\text{err}}, h)}
\end{array}$$

■ **Figure 2** Operational semantics (excerpt), with $s_{\text{err}} \triangleq s[\text{err} \rightarrow v_{\text{err}}]$ and $\text{str} : \text{PExp} \rightarrow \text{Str}$.

► **Definition 6** (Assertion Language). *The assertion language is defined as follows:*

$$\begin{aligned}
\pi \in \text{BASrt} &\triangleq E_1 = E_2 \mid E_1 < E_2 \mid E \in X \mid \dots \mid \neg\pi \mid \pi_1 \Rightarrow \pi_2 \\
P \in \text{Asrt} &\triangleq \pi \mid \text{False} \mid P_1 \Rightarrow P_2 \mid \exists x. P \mid \text{emp} \mid E_1 \mapsto E_2 \mid E \mapsto \emptyset \mid P_1 \star P_2 \mid \otimes_{E_1 \leq x < E_2} P
\end{aligned}$$

where $E, E_1, E_2 \in \text{LExp}$, $X \subseteq \text{Val}$, and $x \in \text{LVar}$.

Boolean assertions, $\pi \in \text{BASrt}$, lift Boolean logical expressions to assertions. Assertions, $P \in \text{Asrt}$, contain Boolean assertions, standard first-order connectives and quantifiers, and spatial assertions. Spatial assertions include: the empty memory assertion, emp ; the positive cell assertion, $E_1 \mapsto E_2$; the negative cell assertion, $E \mapsto \emptyset$ (as in [11–14] and denoted in ISL by $E \not\mapsto$ [28]), the separating conjunction (star); and its iteration (iterated star).

To define assertion satisfiability, we introduce *substitutions*, $\theta : \text{LVar} \rightarrow_{\text{fin}} \text{Val}$, which are partial finite mappings from logical variables to values, extending expression evaluation of Definition 4 to $\llbracket E \rrbracket_{\theta, s}$ straightforwardly, with a new base case for logical variables:

$$\llbracket x \rrbracket_{\theta, s} = \theta(x), \text{ if } x \in \text{dom}(\theta) \quad \llbracket x \rrbracket_{\theta, s} = \downarrow, \text{ if } x \notin \text{dom}(\theta)$$

► **Definition 7** (Satisfiability). *The assertion satisfiability relation, denoted by $\theta, \sigma \models P$, is defined as follows:*

$$\begin{aligned}
\theta, (s, h) \models \pi &\Leftrightarrow \llbracket \pi \rrbracket_{\theta, s} = \text{true} \wedge h = \emptyset \\
\theta, (s, h) \models \text{False} &\Leftrightarrow \text{never} \\
\theta, (s, h) \models P_1 \Rightarrow P_2 &\Leftrightarrow \theta, (s, h) \models P_1 \Rightarrow \theta, (s, h) \models P_2 \\
\theta, (s, h) \models \exists x. P &\Leftrightarrow \exists v \in \text{Val}. \theta[x \mapsto v], (s, h) \models P \\
\theta, (s, h) \models \text{emp} &\Leftrightarrow h = \emptyset \\
\theta, (s, h) \models E_1 \mapsto E_2 &\Leftrightarrow h = \{ \llbracket E_1 \rrbracket_{\theta, s} \mapsto \llbracket E_2 \rrbracket_{\theta, s} \} \\
\theta, (s, h) \models E_1 \mapsto \emptyset &\Leftrightarrow h = \{ \llbracket E_1 \rrbracket_{\theta, s} \mapsto \emptyset \} \\
\theta, (s, h) \models P_1 \star P_2 &\Leftrightarrow \exists h_1, h_2. h = h_1 \uplus h_2 \wedge \theta, (s, h_1) \models P_1 \wedge \theta, (s, h_2) \models P_2 \\
\theta, (s, h) \models \otimes_{E_1 \leq x < E_2} P &\Leftrightarrow \exists h_i, \dots, h_{k-1}. h = \uplus_{j=i}^{k-1} h_j \wedge \forall j. i \leq j < k \Rightarrow \theta, (s, h_j) \models P[j/x] \\
&\text{where } i = \llbracket E_1 \rrbracket_{\theta, s}, k = \llbracket E_2 \rrbracket_{\theta, s}, \text{ and } x \text{ is not free in } E_1 \text{ or } E_2.
\end{aligned}$$

19:10 Exact Separation Logic

Assertion satisfiability is defined in the standard way. For convenience, we choose Boolean assertions to be satisfiable only in the empty heap.

► **Definition 8** (Validity). *An assertion P is valid, denoted by $\models P$, iff $\forall \theta, \sigma. \theta, \sigma \models P$.*

4.2 Specifications

We define specifications for commands and functions, focussing in particular on external and internal function specifications and the relationship between them.

► **Definition 9.** Specifications, $t = (P) (ok : Q_{ok}) (err : Q_{err}) \in \mathcal{Spec}$, comprise a pre-condition, P , a success post-condition, Q_{ok} , and a faulting post-condition, Q_{err} .

We denote that command C has specification t by $C : t$, or by $(P) C (ok : Q_{ok}) (err : Q_{err})$ in quadruple form. Additionally, we use the following shorthand:

$$\begin{aligned} (P) C (Q) &\triangleq (P) C (ok : Q) (err : \text{False}) \\ (P) C (err : Q) &\triangleq (P) C (ok : \text{False}) (err : Q) \\ (P) C (Q) &\triangleq (P) C (ok : -) (err : -) \end{aligned}$$

noting the use of Q for cases in which the post-condition details are not relevant. We use quadruples rather than triples since, even though the post-condition could be expressed as a disjunction of *ok*- and *err*-labelled assertions, we find the quadruple distinction helpful as compound commands (e.g. sequence) treat the two differently (cf. Figure 3).

The EX-validity of a specification t for a command C in an implementation context γ requires both OX and UX frame-preserving validity.

► **Definition 10** (γ -Valid Specifications). *Given implementation context γ , command C , and specification $t = (P) (ok : Q_{ok}) (err : Q_{err})$, t is γ -valid for C , denoted by $\gamma \models C : t$ or $\gamma \models (P) C (ok : Q_{ok}) (err : Q_{err})$, if and only if:*

$$\begin{aligned} & // \text{Frame-preserving over-approximating validity} \\ & (\forall \theta, s, h, h_f, o, s', h''. \theta, (s, h) \models P \implies \\ & \quad (s, h \uplus h_f), C \Downarrow_{\gamma} o : (s', h'') \implies (o \neq \text{miss} \wedge \exists h'. h'' = h' \uplus h_f \wedge \theta, (s', h') \models Q_o)) \wedge \\ & // \text{Frame-preserving under-approximating validity} \\ & (\forall \theta, s', h', h_f, o. \theta, (s', h') \models Q_o \implies h_f \# h' \implies \\ & \quad (\exists s, h. \theta, (s, h) \models P \wedge (s, h \uplus h_f), C \Downarrow_{\gamma} o : (s', h' \uplus h_f))) \end{aligned}$$

Observe that the outcome o can either be success or a language error; it cannot be a missing resource error as this would break UX frame preservation. As our operational semantics is complete, we can also use ESL to characterise non-termination. In particular, if a command satisfies a specification with both post-conditions **False**, then the execution of the command is guaranteed to not terminate if executed from a state satisfying the pre-condition. Were the semantics incomplete (for example, if it did not reason about errors), then such a specification might also indicate the absence of a semantic transition.

Compared to traditional OX reasoning, UX reasoning brings additional complexity to proofs of function specifications. To handle this complexity, we introduce two types of function specifications: *external* specifications, which provide the interface the function exposes to the client, and the related *internal* specifications, which provide the interface to the function implementation. This terminology is also used informally in InsecSL [25]. We use these in subsequent sections to show that ESL exhibits function compositionality.

► **Definition 11** (External Specifications). *A specification $(P) (ok : Q_{ok}) (err : Q_{err})$ is an external function specification if and only if:*

- $P = (\vec{x} = \vec{x} \star P')$, for some distinct program variables \vec{x} , distinct logical variables \vec{x} , and assertion P' , with $\text{pv}(P') = \emptyset$; and
- either $\text{pv}(Q_{ok}) = \{\text{ret}\}$ or $Q_{ok} = \text{False}$, and either $\text{pv}(Q_{err}) = \{\text{err}\}$ or $Q_{err} = \text{False}$.

The set of external specifications is denoted by \mathcal{ESpec} .

► **Definition 12** (Function Specification Contexts). *A function specification context, $\Gamma : \text{Fid} \rightarrow_{\text{fin}} \mathcal{P}(\mathcal{ESpec})$, is a finite partial function from function identifiers to a set of external specifications, with the more familiar notation $(\vec{x} = \vec{x} \star P) f(\vec{x}) (ok : Q_{ok}) (err : Q_{err}) \in \Gamma$ at times used in place of $(\vec{x} = \vec{x} \star P) (ok : Q_{ok}) (err : Q_{err}) \in \Gamma(f)$.*

The constraints on external specifications are well-known from OX logics and follow the usual scoping of function parameters and local variables, which are limited to the function body: the pre-conditions only contain the function parameters, \vec{x} ; and the post-conditions may only have the (dedicated) program variables ret or err , which hold, respectively, the return value on successful termination or the error value on faulting termination.

Internal function specifications are more interesting for exact and UX than for OX reasoning. The internal pre-condition is straightforward, extending the external pre-condition by instantiating the local variables to null . The internal post-condition must therefore include information about the parameters and local variables, as the internal specification cannot lose information. This means that the connection between internal and external post-conditions is subtle, given the constraints on the latter. To address this, we define an internalisation function, relating an external function specification with a set of possible internal specifications. In particular, the external post-condition has to be equivalent to an internal one in which the parameters and local variables of the internal post-condition have been replaced by fresh existentially quantified logical variables.

► **Definition 13** (Internalisation). *Given implementation context γ and function $f \in \text{dom}(\gamma)$, a function specification internalisation, $\text{Int}_{\gamma, f} : \mathcal{ESpec} \rightarrow \mathcal{P}(\text{Spec})$, is defined as follows:*

$$\begin{aligned} \text{Int}_{\gamma, f}((P) (ok : Q_{ok}) (err : Q_{err})) = \\ \{(P \star \vec{z} = \text{null}) (ok : Q'_{ok}) (err : Q'_{err}) \mid & \models Q'_{ok} \Rightarrow E \in \text{Val} \star \text{True} \text{ and} \\ & \models Q_{ok} \Leftrightarrow \exists \vec{p}. Q'_{ok}[\vec{p}/\vec{p}] \star \text{ret} = E[\vec{p}/\vec{p}] \text{ and} \\ & \models Q_{err} \Leftrightarrow \exists \vec{p}. Q'_{err}[\vec{p}/\vec{p}]\}, \end{aligned}$$

where $f(\vec{x})\{C; \text{return } E\} \in \gamma$, $\vec{z} = \text{pv}(C) \setminus \text{pv}(P)$, $\vec{p} = \text{pv}(P) \uplus \{\vec{z}\}$, and the logical variables \vec{p} are fresh with respect to Q_{ok} and Q_{err} .

This approach also works for SL and ISL as well (with \Leftarrow instead of \Leftrightarrow for the post-conditions for SL, and \Rightarrow instead of \Leftrightarrow for ISL). It is not strictly necessary for SL, however, as information about program variables can be forgotten in the internal post-conditions before the transition to the external post-condition.

► **Definition 14** (Environments). *An environment, (γ, Γ) , is a pair consisting of an implementation context γ and a specification context Γ .*

An environment (γ, Γ) is *valid* if and only if every function specified in Γ has an implementation in γ and every specification in Γ has a γ -valid internal specification.

► **Definition 15** (Valid Environments). *Given an implementation context γ and a specification context Γ , the environment (γ, Γ) is valid, written $\models (\gamma, \Gamma)$, if and only if*

$$\text{dom}(\Gamma) \subseteq \text{dom}(\gamma) \wedge (\forall f, \vec{x}, C, E. f(\vec{x})\{C; \text{return } E\} \in \gamma \implies (\forall t. t \in \Gamma(f) \implies \exists t' \in \text{Int}_{\gamma, f}(t). \gamma \models C : t'))$$

Finally, a specification t is valid for a command C in a specification context Γ if and only if t is γ -valid for all implementation contexts γ that validate Γ .

► **Definition 16** (Γ -Valid Specifications). *Given a specification context Γ , a command C , and a specification $t = (P) (Q)$, the specification t is Γ -valid for command C , written $\Gamma \models C : t$ or $\Gamma \models (P) C (Q)$, if and only if $\forall \gamma. \models (\gamma, \Gamma) \implies \gamma \models (P) C (Q)$.*

4.3 Program Logic

We give the representative ESL proof rules in Figure 3 and all in [24]. We introduce and discuss in detail the function-related rules, given for the first time in a UX setting. We denote the repetition of the pre-condition in the post-condition by *pre*. When reading the rules, it is important to remember that we *must not drop paths and must not lose information*. The judgement $\Gamma \vdash (P) C (ok : Q_{ok}) (err : Q_{err})$ means that the specification t is *derivable* for a command C given the specifications recorded in Γ .

The basic command rules are fairly straightforward. The [NONDET] rule existentially quantifies the generated value via $x \in \mathbb{N}$ to capture all paths, in contrast with the RHL [8] and ISL [28] rules, which explicitly choose one value to describe one path. The $E' \in \text{Val}$ in the post-condition is necessary as we know that E' evaluates to a value from the pre-condition and cannot lose information; the same principle applies to many other rules. The [ASSIGN] rule requires that the evaluation of E does not fault in the pre-condition via $E \in \text{Val}$. Strictly speaking, we should have an additional case in which the assigned variable is not in the store. To avoid this clutter, we instead assume that program variables are always in the store as we are analysing function bodies and, in our programming language, all local variables are initialised on function entry. The error-related rules capture cases in which expression evaluation faults (e.g. [LOOKUP-ERR-VAL] rule, using $E \notin \text{Val}$), expressions are of the incorrect type, or memory is accessed after it has been freed (e.g. [LOOKUP-ERR-USE-AFTER-FREE] rule, using $E \mapsto \emptyset$). Note that missing resource errors cannot be captured without breaking frame preservation, as the added-on frame could contain the missing resource.

When it comes to composite commands, we opt for two *if*-rules, covering the branches separately. The sequencing rule shows how exact quadruples of successive commands can be joined together, highlighting, in particular, how errors are collected using disjunction. One interesting aspect of this rule is what happens when C_1 only throws an error or does not terminate, meaning that $R = \text{False}$. In both those cases, given the exactness of the rules, it has to be that $Q_{ok} = Q_{err}^2 = \text{False}$, and the post-condition of the sequence becomes $(ok : \text{False}) (err : Q_{err}^1 \vee \text{False})$, meaning that, if C_1 only throws an error (that is, $Q_{err}^1 \neq \text{False}$) then that is the only error that can come out of the sequence, and if C_1 does not terminate (that is, $Q_{err}^1 = \text{False}$) then the sequence does not terminate either.

The while rule is an adaptation of the RHL while rule [8], generalising the invariant of the SL while rule with two natural-number-indexed families of variants, P_i and Q_i , which explicitly maintain the iteration index. Note how the i in the premise is a meta-variable representing a natural number, which in the conclusion gets substituted for an existentially quantified logical variable; a similar principle will be applied later when dealing with environment extension. Interestingly, this rule does not require adjustment to reason about non-termination.

■ **Figure 3** ESL proof rules (excerpt), with $Q_{\text{err}}^* = (\text{pre} \star \text{err} = E_{\text{err}})$.

The structural rules are not surprising, with equivalence replacing the forward/backward consequence of OX/UX reasoning and with frame, existential introduction, and disjunction affecting both post-conditions. Disjunction allows us to derive the standard SL if rule, which captures both branches at the same time. Note that there, however, is no sound conjunction rule, as the conjunction rules of SL and ISL cannot be combined in ESL, since conjunction does not distribute over the star in both directions, breaking frame preservation.

Function Call. We discuss the ESL function-call rule in detail, creating it starting from the standard OX-sound SL rule, adapted for quadruples:

$$\frac{\{\vec{x} = \vec{x} \star P\} f(\vec{x}) \{ok : Q_{\text{ok}}\} \{err : Q_{\text{err}}\} \in \Gamma \quad y \notin \text{pv}(E_y)}{\Gamma \vdash \{y = E_y \star \vec{E} = \vec{x} \star P\} y := f(\vec{E}) \{ok : Q_{\text{ok}}[y/\text{ret}]\} \{err : y = E_y \star Q_{\text{err}}\}}$$

In order to make this rule UX-sound, we only have to ensure that no information from the pre-condition is lost in the post-conditions. In particular, we have to remember:

19:14 Exact Separation Logic

- that the evaluation of E_y does not fault, captured by $E_y \in \text{Val}$ and needed in the success post-condition only, as it is already implied by the error post-condition; and
- that $\vec{E} = \vec{x}$ holds (with the substitution $[E_y/y]$ needed in the success post-condition as the value of y may change if the function call succeeds);

bringing us to the ESL function call rule:

$$\frac{(\vec{x} = \vec{x} \star P) \quad f(\vec{x}) \quad (ok : Q_{ok}) \quad (err : Q_{err}) \in \Gamma \quad y \notin \text{pv}(E_y) \quad Q'_{ok} \triangleq E_y \in \text{Val} \star \vec{E}[E_y/y] = \vec{x} \star Q_{ok}[y/\text{ret}] \quad Q'_{err} \triangleq y = E_y \star \vec{E} = \vec{x} \star Q_{err}}{\Gamma \vdash (y = E_y \star \vec{E} = \vec{x} \star P) \quad y := f(\vec{E}) \quad (ok : Q'_{ok}) \quad (err : Q'_{err})}$$

Environment Formation. Whereas the ESL function-call rule does not deviate substantially from its OX counterpart, the environment formation rules illustrate the difference in complexity between OX and UX function compositionality. These rules use the judgement $\vdash (\gamma, \Gamma)$ to state that the environment (γ, Γ) is *well-formed*. The base case, $\vdash (\emptyset, \emptyset)$, is trivial and the same as for SL, stating that the environment consisting of an empty implementation context and an empty specification context is well-formed. For illustrative purposes, we give a simplified version of the extension rule, extending the environment with a single, possibly recursive, function. The full rule, which extends the environment with a group of mutually recursive functions, is given in [24]. We start from the corresponding OX-sound rule from SL:

$$\frac{\text{ENV-EXTEND-SL} \quad \vdash (\gamma, \Gamma) \quad f \notin \text{dom}(\gamma) \quad \gamma' = \gamma[f \mapsto (\vec{x}, C, E)] \quad \Gamma' = \Gamma[f \mapsto \{t\}] \quad \exists t' \in \text{Int}_{\gamma', f}(t). \Gamma' \vdash C : t'}{\vdash (\gamma', \Gamma')}$$

which states that a well-formed environment (γ, Γ) can be extended with a given function f and its external specification t to (γ', Γ') if some corresponding internal specification of f can be proven for the body of f under the extended specification context Γ' .² Note that using Γ' means that a specification can be used to prove itself, which is sound in SL but unsound in ISL: specifically, it would allow us to prove UX-invalid specifications of non-terminating functions. For example, we would be able to prove that the function $\mathbf{f}() \{ r := \mathbf{f}(); \text{return } r \}$ satisfies the EX-valid specification **(emp)** $\mathbf{f}()$ **(False)**, but also the EX-invalid specification **(emp)** $\mathbf{f}()$ **(ret = 42)**. The latter is vacuously OX-valid as there are no terminating executions, but when considered from the UX viewpoint, it implies the existence of an execution path from the pre- to the post-condition, contradicting the non-termination of \mathbf{f} .

Therefore, to be soundly usable in UX reasoning, specifications with satisfiable post-conditions (onward: terminating specifications) must come with a mechanism that disallows the above counter-example. We achieve this by following a standard approach for reasoning about termination [7, 9], based on decreasing measures on well-ordered sets. In particular, we require the terminating specification to be proven, $t \triangleq (P) \quad (ok : Q_{ok}) \quad (err : Q_{err})$ to be extended with a *measure* $\alpha \in \mathbb{N}$, denoting this extension by $t(\alpha)$:³

$$t(\alpha) \triangleq (P \star \alpha = E_\mu) \quad (ok : Q_{ok} \star \alpha = E_\mu) \quad (err : Q_{err} \star \alpha = E_\mu)$$

where E_μ is a logical expression describing how the measure is computed. Then, we prove that $t(\alpha)$ holds for every specific α , assuming that recursive calls to f can only use the terminating

² Internalisation is normally omitted in SL as forward consequence allows information about program variables to be lost, making internal and external post-conditions of SL specifications almost the same.

³ We can extend the measure beyond natural numbers to computable ordinals, $\mathcal{O} \triangleq \omega_1^{\text{CK}}$, allowing us to reason about a broader set of functions, such as those with non-deterministic nested recursion (cf. [24]).

specifications $t(\beta)$ of a measure β *strictly smaller* than α . This restriction is standard and, if the proof succeeds, ensures that f has at least one terminating execution. Also, it disallows the above-mentioned counter-example, as no measure given in the pre-condition would be able to decrease before the recursive call. Importantly, the measure is only a tool required for proving specification validity and once this proof has been completed, the specification without the measure is added to Γ and can be used in proofs of client code.

In addition, we incorporate reasoning about non-terminating specifications (NT-specifications). This is relevant in situations in which the operational semantics of the analysed language is complete, which allows non-termination to be captured using the post-condition **False**. As NT-specifications are vacuously UX-sound, our focus is on ensuring their OX-soundness, which we do by again imposing a measure α , but allowing recursive calls for a measure β *smaller or equal* than α , that is, for an NT-specification to be used to prove itself. This, for example, allows for a proof of the specification **(emp)** $f() \{ r := f(); \text{return } r \}$ **(False)** by choosing a constant measure α . The ESL environment extension rule, therefore, is as follows:

```

ENV-EXTEND
// Assume valid environment, extend implementation context with new function f
⊢ (γ, Γ)    f ∉ dom(γ)    γ' = γ[f ↦ (x̄, C, E)]

// Extend the specifications of f with a measure α
t ≜ (P) (ok : Qok) (err : Qerr)    t∞ ≜ (P∞) (False)    t∞(α) ≜ (P∞ * α = Eμ) (False)
t(α) ≜ (P * α = Eμ) (ok : Qok * α = Eμ) (err : Qerr * α = Eμ)

// Construct Γ(α): assume t for measure β < α and t∞ for measure β ≤ α
Γ(α) = Γ[f ↦ {t(β) | β < α} ∪ {t∞ | β ≤ α}]

// For every α, prove internal specifications of f corresponding to t and t∞
∀α. ∃t' ∈ Intγ',f(t(α)). Γ(α) ⊢ C : t'    ∀α. ∃t' ∈ Intγ',f(t∞(α)). Γ(α) ⊢ C : t'

// Extend Γ with t and t∞
Γ' := Γ[f ↦ {t, t∞}]

```

$$\vdash (\gamma', \Gamma')$$

4.4 Soundness

We state the soundness results for ESL and give intuition about the proofs; the full proofs can be found in [24].

► **Theorem 17.** *Any derivable specification is valid:* $\Gamma \vdash (P) \text{ C } (Q) \implies \Gamma \models (P) \text{ C } (Q)$.

Proof. By induction on $\Gamma \vdash (P) \text{ C } (Q)$. Most cases are straightforward; the [FUN-CALL] rule obtains a valid specification for the function body from the validity of the environment. ◀

► **Theorem 18.** *Any well-formed environment is valid:* $\vdash (\gamma, \Gamma) \implies \models (\gamma, \Gamma)$.

Proof. At the core of the proof is a lemma stating that $\models (\gamma, \Gamma) \implies (\forall \alpha. \models (\gamma', \Gamma(\alpha)))$, where γ' and $\Gamma(\alpha)$ have been obtained from γ and Γ as per [ENV-EXTEND]. Using this lemma, we derive the desired $\models (\gamma', \Gamma')$, where Γ' is obtained from Γ and $\Gamma(\alpha)$ as per [ENV-EXTEND]. The proof of this lemma is done by transfinite induction on α and has the standard zero, successor, and limit ordinal cases. We outline the proof for the case in which a single, possibly recursive, function f with body C_f is added; the generalisation to n mutually recursive functions is straightforward and can be seen in [24].

In all three cases, the soundness of all specifications except the NT-specification with the highest considered ordinal follows from the inductive hypothesis. This remaining NT-specification is vacuously UX-valid, meaning that we only need to prove its OX-validity. For this, we use a form of fixpoint induction called Scott induction (see, e.g., Winskel [31]), required when specifications can be used to prove themselves (e.g. any SL specification).

We set up the Scott induction by extending the set of commands with two pseudo-commands, `scope` and `choice`, with the former modelling the function call but allowing arbitrary commands to be executed in place of the function body, and the latter denoting non-deterministic choice. We then construct the greatest-fixpoint closure of these extended commands, denoted by \mathbb{C} , whose elements may contain infinite applications of the command constructors. We define a behavioural equivalence relation $\simeq_{\gamma'}$ on \mathbb{C} and denote by $\mathbb{C}_{\gamma'}$ the obtained quotient space. This relation induces a partial order $\sqsubseteq_{\gamma'}$, and a join operator that coincides with `choice`, and we show that $(\mathbb{C}_{\gamma'}, \sqsubseteq_{\gamma'})$ is a domain.

We next define S^α as the set of all equivalence classes that hold an element that, for every specification in $(\Gamma(\alpha))(f)$, OX-satisfies at least one of its internal specifications, and show that S^α is an admissible subset of $\mathbb{C}_{\gamma'}$, that is, that it contains the least element of $\mathbb{C}_{\gamma'}$ (represented, for example, by the infinite loop `while (true) { skip }`) and is chain-closed.

We then define the function $h(C) \triangleq C_f[C, \gamma', f]$, which replaces all function calls to f in C_f with C using the `scope` command, and the function g as the lifting of h to $\mathbb{C}_{\gamma'}$: $g([C]) := [h(C)]$. We next prove that g is continuous (that is, monotonic and supremum-preserving) and that $g(S^\alpha) \subseteq S^\alpha$, from which we can apply the Scott induction principle, together with a well-known identity of the least-fixpoint, which implies that $C_f \in \text{lfp}(g)$, to obtain that $[C_f] \in S^\alpha$. From there, we are finally able to prove that $\models (\gamma', \Gamma(\alpha))$. ◀

These two theorems, to the best of our knowledge, are the first to demonstrate sound function compositionality for UX logics. Previous work on UX logics [25, 28, 29] used function specifications in examples but did not include rules in the logic for calling functions and managing a function specification environment. Program logics that do not include function rules and function specification environments in effect delegate soundness responsibilities to the meta-logic within which they are embedded. This might be appropriate in some contexts, such as in interactive theorem provers, whose meta-logic is reliable. Charguéraud’s clean-slate tutorial SL implementation in Coq [6], for example, does not provide either function call rules or program-logic-level infrastructure for a function specification environment; instead, it relies on Coq’s induction mechanism and definitional mechanism to use and store function specifications. However, when implementing an SL/ISL/ESL-based tool in a mainstream non-ITP language, such as C++ or OCaml, no reliable meta-logic that can act as a safety net is available. This is particularly concerning for UX logics, which require complex rules for handling functions, including forgetting information about function-local mutable variables. In ESL, the handling of functions is fully internalised into the logic, no meta-logic facilities are required to handle function calls, and the program-logic-level facilities of ESL for handling functions are validated by the soundness proof.

The proof of Theorem 18 can be adjusted for ISL: the function call rule would remain the same, and [ENV-EXTEND] would not include NT-specifications, removing the need for Scott induction. On the other hand, the Scott induction itself could be easily adapted for SL.

5 Examples: ESL in Practice

We demonstrate how to use ESL to specify and verify correctness and incorrectness properties of data-structure algorithms, focussing on singly-linked lists and binary search trees.

We investigate, for the first time, the use of abstract predicates in a UX program logic, decoupling abstraction from over-approximation. Our findings show that UX/EX specifications can soundly incorporate abstraction, but also that it, ultimately, cannot be used as freely as in the OX setting. Firstly, since UX reasoning cannot lose information, not all algorithms can be UX-specified at all levels of abstraction, and hence sometimes specifications have to be less abstract than in OX reasoning. Secondly, because specifications are only composable when expressed at the same level of abstraction, specifications of a library client have to be written at the “least common level of abstraction” of the specifications of all of the library functions that the client calls.

Building on §2, we give further intuition on how to think informally about UX/EX specifications using a number of list algorithms and predicates describing lists with various degrees of abstraction (§5.1, §5.2), more detail on how to write formal ESL proofs (§5.3), and examples of ESL reasoning for binary-search-tree algorithms (§5.4).

5.1 List Predicates

We implement singly-linked lists in the standard way: every list consists of two contiguous cells in the heap (denoted $x \mapsto a, b$, meaning $x \mapsto a \star x + 1 \mapsto b$), with the first holding the value of the node, the second holding a pointer to the next node in the list, and the list terminating with a `null` pointer. To capture lists in ESL, we use a number of list predicates:

$$\begin{aligned}
 \text{list}(x) &\triangleq (x = \text{null}) \vee (\exists v, x'. x \mapsto v, x' \star \text{list}(x')) \\
 \text{list}(x, n) &\triangleq (x = \text{null} \star n = 0) \vee (\exists v, x'. x \mapsto v, x' \star \text{list}(x', n - 1)) \\
 \text{list}(x, vs) &\triangleq (x = \text{null} \star vs = []) \vee (\exists v, x', vs'. x \mapsto v, x' \star \text{list}(x', vs') \star vs = v : vs') \\
 \text{list}(x, xs) &\triangleq (x = \text{null} \star xs = []) \vee (\exists v, x', xs'. x \mapsto v, x' \star \text{list}(x', xs') \star xs = x : xs') \\
 \text{list}(x, xs, vs) &\triangleq (x = \text{null} \star xs = [] \star vs = []) \vee \\
 &\quad (\exists v, x', xs', vs'. x \mapsto v, x' \star \text{list}(x', xs', vs') \star xs = x : xs' \star vs = v : vs')
 \end{aligned}$$

These predicates expose different parts of the list structure in their parameters, *hiding* the rest via existential quantification: the $\text{list}(x)$ predicate hides all information about the represented mathematical list, just declaring that there is a singly-linked list at address x ; the $\text{list}(x, n)$ predicate hides the internal node addresses and values, exposing the list length via the parameter n ; the $\text{list}(x, xs)$ predicate hides information about the values of the mathematical list, exposing the internal addresses of the list via the parameter xs ; the $\text{list}(x, vs)$ predicate hides information about the internal addresses, exposing the list’s values via the parameter vs ; and the list predicate $\text{list}(x, xs, vs)$ hides nothing, exposing the entire node-value structure via the parameters xs and vs . These predicates are related to each other via logical equivalence; for example, it holds that:

$$\begin{aligned}
 \models \text{list}(x) &\Leftrightarrow \exists n. \text{list}(x, n) & \models \text{list}(x) &\Leftrightarrow \exists vs. \text{list}(x, vs) \\
 \models \text{list}(x) &\Leftrightarrow \exists xs, vs. \text{list}(x, xs, vs) & \models \text{list}(x, n) &\Leftrightarrow \exists vs. \text{list}(x, vs) \star |vs| = n
 \end{aligned}$$

5.2 Writing UX/EX Abstract Specifications

We consider a number of list algorithms, described in words, and guide the reader on how to write correct UX/EX specifications for these algorithms using the list abstractions given in the previous section (§5.1), comparing how the UX/EX approach and specifications differ from their OX counterparts. We provide detailed proofs and implementations for each type of algorithm (iterative/recursive, allocating/deallocating, pure/mutative, etc.) in [24].

An important point is to understand how to look for counter-examples to a given specification: from the definition of OX validity, it follows that breaking OX reasoning amounts to “finding a state in the pre-condition (pre-model) for which the execution of f terminates and does not end in a state in the post-condition”; from the definition of UX validity, breaking UX reasoning means “finding a model of the post-condition (post-model) not reachable by execution of f from any state in the pre-condition”; and from the definition of EX validity, it follows that breaking EX reasoning means breaking either OX or UX reasoning. In addition, it is useful to remember that, for breaking UX validity, it is sufficient to find information known in the pre-condition but lost in the post-condition.

Length. We first revisit the list-length function $\text{LLen}(x)$, which takes a list at address x , does not modify it, and returns its length. In §2, we have shown that it satisfies the exact specification $(x = x \star \text{list}(x, n)) \text{LLen}(x) (\text{list}(x, n) \star \text{ret} = n)$ and observed that

(O1) abstraction does not always equal over-approximation.

Using similar reasoning, we can come to the conclusion that the following, less abstract specifications for $\text{LLen}(x)$ are also EX-valid:

$$\begin{aligned} (x = x \star \text{list}(x, vs)) \text{LLen}(x) (\text{list}(x, vs) \star \text{ret} = |vs|) \\ (x = x \star \text{list}(x, xs, vs)) \text{LLen}(x) (\text{list}(x, xs, vs) \star \text{ret} = |xs|) \end{aligned}$$

On the other hand, if we consider the following OX-valid specification:

$$\{x = x \star \text{list}(x)\} \text{LLen}(x) \{\exists n \in \mathbb{N}. \text{list}(x) \star \text{ret} = n\}$$

we see that it is not UX-valid as the post-condition does not connect the return value to the list. In particular, if we choose a post-model for $\text{list}(x)$ that has length 2, but then choose, for example, $\text{ret} = 42$, we run into a problem: as the algorithm does not modify the list, we have to choose the same model of $\text{list}(x)$ for the pre-model to have a chance of reaching the post-model, but then the algorithm will return 2, not 42, meaning that this specification is indeed not UX/EX-valid. From this discussion, we observe that:

(O2) in valid UX/EX specifications, data-structure abstractions used in a post-condition must expose enough information to capture the behaviour of the function being specified with respect to the information given in the pre-condition.

Note that, given a specification less abstract than strictly needed, one can obtain more abstract ones by using validity-preserving transformations on specifications that correspond to the structural rules of the logic. We refer to these as *admissible* transformations, give the ones for existential introduction and equivalence below, and the rest in [24]:

$$\text{ADM-EXISTS} \frac{\Gamma \models (\vec{x} = \vec{x} \star P) f(\vec{x}) (ok : Q_{ok}) (err : Q_{err}) \quad y \notin \vec{x}}{\Gamma \models (\vec{x} = \vec{x} \star \exists y. P) f(\vec{x}) (ok : \exists y. Q_{ok}) (err : err : \exists y. Q_{err})}$$

$$\text{ADM-EQUIV} \frac{\Gamma \models (\vec{x} = \vec{x} \star P') f(\vec{x}) (ok : Q'_{ok}) (err : Q'_{err}) \quad \models P', Q'_{ok}, Q'_{err} \Leftrightarrow P, Q_{ok}, Q_{err}}{\Gamma \models (\vec{x} = \vec{x} \star P) f(\vec{x}) (ok : Q_{ok}) (err : Q_{err})}$$

For list-length, starting from the least abstract specification using $\text{list}(x, xs, vs)$, we can derive, for example, the specification using $\text{list}(x, n)$, as follows:

$$\begin{aligned} & (x = x \star \text{list}(x, xs, vs)) \text{LLen}(x) (\text{list}(x, xs, vs) \star \text{ret} = |xs|) \\ [\text{ADM-EXISTS}] & (\exists vs. x = x \star \text{list}(x, xs, vs)) \text{LLen}(x) (\exists vs. \text{list}(x, xs, vs) \star \text{ret} = |xs|) \\ [\text{ADM-EXISTS}] & (\exists xs, vs. x = x \star \text{list}(x, xs, vs)) \text{LLen}(x) (\exists xs, vs. \text{list}(x, xs, vs) \star \text{ret} = |xs|) \\ [\text{ADM-EQUIV}] & (x = x \star \text{list}(x, n)) \text{LLen}(x) (\text{list}(x, n) \star \text{ret} = n) \end{aligned}$$

Interestingly, from one more application of [ADM-EXISTS] and [ADM-EQUIV], we can derive

$$(x = x \star \text{list}(x)) \text{ LLen}(x) (\exists n. \text{list}(x, n) \star \text{ret} = n)$$

which further illustrates observation (O2), in that even though the pre-condition does not talk about the length of the list, the post-condition has to expose it because the function output depends on it, and hence the post-condition must connect up the return value to the length of the list, here by an existentially quantified variable.

This approach of deriving abstract specifications can be used in general for working with ESL: for a given algorithm, first prove the least abstract specification, which exposes all details, and then adjust the degree of abstraction to fit the needs of the client code. We discuss this further in the upcoming paragraph on reasoning about client programs.

Membership. Next, we consider the list-membership function $\text{LMem}(x, v)$, which takes a list at address x , does not modify it, and returns `true` if v is in the list, and `false` otherwise. Given (O2) and the fact that the function output depends on the values in the list, we understand that, for its UX/EX specification, we should be using a list abstraction that exposes at least the values, that is, $\text{list}(x, vs)$ or $\text{list}(x, xs, vs)$. The corresponding specifications are:

$$\begin{aligned} (x = x \star v = v \star \text{list}(x, vs)) \text{ LMem}(x, v) (\text{list}(x, vs) \star \text{ret} = (v \in vs)) \\ (x = x \star v = v \star \text{list}(x, xs, vs)) \text{ LMem}(x, v) (\text{list}(x, xs, vs) \star \text{ret} = (v \in vs)) \end{aligned}$$

and are proven similarly to list-length. We can check that a more abstract specification, say:

$$\{x = x \star v = v \star \text{list}(x)\} \text{ LMem}(x, v) \{\exists b \in \mathbb{B}. \text{list}(x) \star \text{ret} = b\}$$

is not UX-valid, by choosing, as the post-model, b to be `false` and the list at x to contain v . As for list-length, since list-membership does not modify the list, we have to choose the same model of $\text{list}(x)$ for the pre-model to have a chance of reaching the post-model, but then the algorithm will return `true`, not `false`, so this post-model is not reachable.

Swap-First-Two. Next, we consider the list-swap-first-two function $\text{LSwapFirstTwo}(x)$, which takes a list at address x , swaps its first two values if the list is of sufficient length, returning `null`, and throws an error otherwise without modifying the list. Given (O2), to specify this function we need an abstraction that captures list length and, apparently, also the list values; for example, $\text{list}(x, vs)$. As this function can throw errors, its full EX specification has to use the ESL quadruple, in which the two post-conditions are constrained with the corresponding, shaded, branching conditions:

$$\begin{aligned} (x = x \star \text{list}(x, vs)) \\ \text{LSwapFirstTwo}(x, v) \\ (ok : \exists v_1, v_2, vs'. \text{vs} = v_1 : v_2 : vs' \star \text{list}(x, v_2 : v_1 : vs') \star \text{ret} = \text{null}) \\ (err : \text{list}(x, vs) \star |vs| < 2 \star err = \text{“List too short!”}) \end{aligned}$$

observing that the success post-condition, given the used abstraction, has to not only state that the length of the list is not less than two, but also how the values are manipulated, and also that the error message is chosen for illustrative purposes.

However, note that the swapped values *are not featured in the function output*, but instead remain contained within the predicate. This indicates that a more abstract specification:

$$\begin{aligned} (x = x \star \text{list}(x, n)) \\ \text{LSwapFirstTwo}(x, v) \\ (ok : \text{list}(x, n) \star n \geq 2 \star \text{ret} = \text{null}) (err : \text{list}(x, n) \star n < 2 \star err = \text{“List too short!”}) \end{aligned}$$

which only reveals the list length, might be EX-valid, and indeed it is. Any list we choose in the error post-model will have length less than two, and can then be used in the pre-model to reach the post-model. On the other hand, whichever list we choose in the success post-model will have length at least two, that is, its values will be of the form $v_1 : v_2 : vs$ and it will have some addresses, and then we can choose a list with the same addresses and values $v_2 : v_1 : vs$ in the pre-model and we will reach the post-model by executing the function.

Pointer-Reverse. Let us now examine the list-pointer-reverse function, $\text{LPRev}(x)$, which takes a list at address x and reverses it by reversing the direction of the next-pointers, returning the head of the reversed list. Given (O2) and the fact that the algorithm manipulates pointers and returns an address, but the actual values in the list are not exposed, we will try to use the address-only $\text{list}(x, xs)$ predicate to specify this function as in the following OX triple, where xs^\dagger denotes the reverse of the mathematical list xs :

$$\{x = x \star \text{list}(x, xs)\} \text{LPRev}(x) \{\text{list}(\text{ret}, xs^\dagger)\}$$

which would seem to be UX-valid given our OX experience and previous examples, but is not. In particular, it has no information about the logical variable x , which exists only in the pre-condition. This is not an issue in OX reasoning, but in UX reasoning it would mean that there exists a logical environment that interprets the post-condition but not the pre-condition, and such a specification, by the definition, could never be UX-valid.

To understand which specific information about x is required, we first add the general $x \in \text{Val}$, making the post-condition $\text{list}(\text{ret}, xs^\dagger) \star x \in \text{Val}$, and then try to choose a post-model by picking values for ret , xs , and x . Note that, given the definition of $\text{list}(x, xs)$, we cannot just pick any non-correlated values for ret and xs : in particular, either xs is an empty list and ret is `null`, or xs is non-empty and ret is its last element. This observation, in fact, reveals the information needed about x : either x is `null` and xs is empty, or xs is non-empty and x is its first element. We capture this information using the $\text{listHead}(x, xs)$ predicate:

$$\text{listHead}(x, xs) \triangleq (xs = [] \star x = \text{null}) \vee (\exists xs'. xs = x : xs')$$

and arrive at the desired EX specification of the list-pointer-reverse algorithm:

$$(x = x \star \text{list}(x, xs)) \text{LPRev}(x) (\text{list}(\text{ret}, xs^\dagger) \star \text{listHead}(x, xs))$$

Let us make sure that this specification is UX-valid. If we pick a post-model with $xs = []$, then $x = \text{ret} = \text{null}$ and the pre-model with the same x and xs will work, as the list holds no values. For a post-model with non-empty xs , x must equal the head of xs , ret must equal the tail of xs , and we also have to pick some arbitrary values vs , with $|vs| = |xs|$. Then, given the described behaviour of the algorithm, we know that this post-model is reachable from a pre-model which has the list at x with addresses xs and values vs^\dagger .

Free. Next, we take a look at the $\text{LFree}(x)$ function, which frees a given list at address x . Its OX specification is $\{x = x \star \text{list}(x)\} \text{LFree}(x) \{\text{ret} = \text{null}\}$, but it does not transfer to UX contexts because no resource from the pre-condition can be forgotten in the post-condition as that would break the UX frame property [28]. Instead, we have to keep track of the addresses to be freed, which we can do using the $\text{list}(x, xs)$ predicate (or $\text{list}(x, xs, vs)$), and we also have to explicitly state in the post-condition that these addresses have been freed:

$$(x = x \star \text{list}(x, xs)) \text{LFree}(x) (\text{freed}(xs) \star \text{listHead}(x, xs) \star \text{ret} = \text{null})$$

using the $\text{freed}(xs)$ predicate, which is defined as follows:

$$\text{freed}(xs) \triangleq (xs = []) \vee (\exists x, xs'. xs = x : xs' \star x \mapsto \emptyset, \emptyset \star \text{freed}(xs'))$$

Client Programs and Specification Composition. We discuss the usability of ESL specifications in general and abstraction in particular in the context of client programs that call multiple library functions. Consider the following (slightly contrived) client program, which takes a list and: pointer-reverses it if its length is between 5 and 10; frees it and then throws an error if its length is smaller than 5; and does not terminate otherwise:

```

LClient(x) {
  l := LLen(x);
  if (l < 5)
    { r := LFree(x); error("List too short!") } else
    { if (l > 10) { while (true) { skip } } else { r := LPRev(l) } };
  return r
}

```

Our first goal is to understand which is the most abstract list predicate that could be used for reasoning about this client, since we want to minimise the amount of details we need to carry along in the proof, noting that the least abstract one, $\text{list}(x, xs, vs)$, will always work. Observe that, importantly, only specifications expressed at the same abstraction level are composable with each other, because they must be composed using equivalence. We explore this in more detail in the subsequent formal discussion (see, in particular, observation (O5)).

When it comes to $\text{LClient}(x)$, for list-length, we need information about the list length, meaning that we can use either $\text{list}(x, n)$, $\text{list}(x, xs)$, or $\text{list}(x, vs)$, but not $\text{list}(x)$. For list-free, we must have information about the addresses, meaning that $\text{list}(x, n)$ and $\text{list}(x, vs)$ will not work, leaving us with $\text{list}(x, xs)$, which is also usable for list-pointer-reverse. Therefore, we can write the specification of this client using the $\text{list}(x, xs)$ predicate, as follows:

$$\begin{aligned}
& (x = x \star \text{list}(x, xs)) \\
& \quad \text{LClient}(x) \\
& \quad (ok : 5 \leq |xs| \leq 10 \star \text{list}(\text{ret}, xs^\dagger) \star \text{listHead}(x, xs)) \\
& \quad (err : |xs| < 5 \star \text{freed}(xs) \star \text{listHead}(x, xs) \star err = \text{"List too short!"})
\end{aligned}$$

In general, however, it is sufficient for a client to call one function that works with addresses and another that works with values for the only applicable predicate to be $\text{list}(x, xs, vs)$, which is still abstract in the sense that it allows for unbounded reasoning about lists, but does not hide any of its internal information. This leads us to the following observation:

(O3) specifications that use predicates which hide data-structure information, albeit provable, may have limited use in UX client reasoning.

As a final remark on abstraction, note that we have only considered predicates that expose the data-structure sub-parts (for lists, these sub-parts are values vs and addresses xs) either entirely or not at all. It would be also possible to expose *some* of this structure for some of the algorithms, but because of (O3), specifications using such abstractions are only composable with specifications exposing the same partial structure, and hence likely to be of limited use.

Non-termination. We conclude our discussion on specifications with two remarks on EX reasoning about non-terminating behaviour. First, consider the non-terminating branch of the LClient function, which is triggered when $|xs| > 10$. Observe that this branch is implicit in the client specification, in that it is subsumed by the success post-condition (since $\models P \vee (|xs| > 10 \star \text{False}) \Leftrightarrow P$). However, to demonstrate that it exists, we can constrain the pre-condition appropriately to prove the specification $(x = x \star \text{list}(x, xs) \star |xs| > 10) \text{LClient}(x) (\text{False})$. This implicit loss of non-terminating branches can be characterised informally as follows:

(O4) if the post-conditions do not cover all paths allowed by the pre-condition, then the “gap” is non-terminating.

In this case, the pre-condition implies $|xs| \in \mathbb{N}$ and the post-conditions cover the cases where $|xs| \leq 10$, leaving the gap when $|xs| > 10$, for which we provably have client non-termination.

Second, we observe that, in contrast to terminating behaviour, for non-terminating behaviour EX is as expressive as OX; that is, the EX triple $(P) C (\text{False})$ is equivalent to the OX triple $\{P\} C \{\text{False}\}$ as the UX triple $[P] C [\text{False}]$ is vacuously true. This is not to say that all non-terminating behaviour can be captured by ESL specifications. For example, as in OX, if the code branches on a value that does not come from the pre-condition, and if one of the resulting branches does not terminate, and if the code can also terminate successfully, then the non-terminating branch will be implicit in the pre-condition, but no gap in the sense of (O4) will be present. This is illustrated by the code and specification below, where the pre- and the post-condition are the same, but a non-terminating path still exists:

```
(x = 0) x := nondet; if (x > 42) { while (true) { skip } } else { x := 0 } (x = 0)
```

5.3 More ESL Proofs: Iterative list-length

In §2, we have shown a proof sketch for a recursive implementation of the list-length algorithm, demonstrating how to handle the measure for recursive function calls; how the folding of predicates works in the presence of equivalence; and how to move between external and internal specifications. We highlight again the UX-specific issue that we raised and that is related to predicate folding, which can be formulated generally as follows:

(O5) if the code accesses data-structure information that the used predicate hides, then that predicate might not be foldable in a UX-proof in all of the places in which it would be foldable in the corresponding OX-proof.

Here, we show how to write ESL proofs for looping code, using as example an iterative implementation of the list-length algorithm. Proofs for the majority of the other algorithms mentioned in §5.2 can be found in [24]; the rest are similar.

Iterative list-length in ESL: Proof Sketch. In Figure 4, we give an iterative implementation of the list-length algorithm and show that it satisfies the same ESL specification as its recursive counterpart, $(x = x \star \text{list}(x, n)) \text{LLen}(x) (ok : \text{list}(x, n) \star \text{ret} = n)$. Since there is no recursion, we elide the (trivial) measure. To state the loop variant, we use the list-segment predicate, defined as follows:

$$\text{lseg}(x, y, n) \triangleq (x = y \star n = 0) \vee (\exists v, x'. x \mapsto v, x' \star \text{lseg}(x', y, n - 1))$$

and to apply the [WHILE] rule, we define:

$$P_i \triangleq \exists j. \text{lseg}(x, x, i) \star \text{list}(x, j) \star n = i + j \star r = i$$

Note that we could have chosen to elide i from the body of P_i in this simple example, but since this is not necessarily possible or evident in general as well as for instructive purposes, we chose to keep it in the proof. Note how, on exiting the loop, the negation of the loop condition collapses the existentials i and j . This allows us to obtain the given internal post-condition, from which we then easily move to the desired external post-condition. For this proof, we also use three equivalence lemmas, which state that a non-empty list segment can be separated into its last element and the rest, that the length of an empty list equals zero, and that a null-terminated list-segment is a list.

```

 $\Gamma \vdash (x = x \star \text{list}(x, n))$ 
  LLen(x) {
    (  $x = x \star \text{list}(x, n) \star r = \text{null}$  )
    r := 0
    (  $x = x \star \text{list}(x, n) \star r = 0$  )
    (  $P_0$  )
    while (x  $\neq$  null) {
      (  $P_i \star x \neq \text{null}$  )
      (  $\exists j, v, x'. \text{lseg}(x, x, i) \star x \mapsto v, x' \star \text{list}(x', j - 1) \star n = i + j \star r = i$  )
      x := [x + 1];
      (  $\exists j, v, x'. \text{lseg}(x, x', i) \star x' \mapsto v, x \star \text{list}(x, j) \star n = i + (j + 1) \star r = i$  )
      // equivalence:  $\models \text{lseg}(x, y, n + 1) \Leftrightarrow \exists x', v. \text{lseg}(x, x', n) \star x' \mapsto v, y]$ 
      (  $\exists j. \text{lseg}(x, x, i + 1) \star \text{list}(x, j) \star n = (i + 1) + j \star r = i$  )
      r := r + 1
      (  $P_{i+1}$  )
    }
    (  $x = \text{null} \star \exists i. P_i$  )
    (  $\exists i, j. \text{lseg}(x, x, i) \star \text{list}(x, j) \star n = i + j \star r = i \star x = \text{null}$  )
    (  $\text{lseg}(x, \text{null}, n) \star r = n \star x = \text{null}$  ) // equivalence:  $\models \text{list}(\text{null}, j) \Leftrightarrow j = 0$ 
    (  $\text{list}(x, n) \star r = n \star x = \text{null}$  ) // equivalence:  $\models \text{lseg}(x, \text{null}, n) \Leftrightarrow \text{list}(x, n)$ 
    return r
    (  $\text{list}(x, n) \star r = n \star x = \text{null} \star \text{ret} = r$  )
    (  $\exists x_q, r_q. \text{list}(x, n) \star r_q = n \star x_q = \text{null} \star \text{ret} = r_q$  )
    (  $\text{list}(x, n) \star \text{ret} = n$  )
  }
  (  $\text{list}(x, n) \star \text{ret} = n$  )

```

■ **Figure 4** ESL proof sketch: iterative list-length.

5.4 Beyond List Examples: Binary Search Trees

While list algorithms illustrate many aspects of exact reasoning, it is also important to understand how ESL specification and verification works with other data structures. For this reason, we discuss two algorithms operating over binary search trees (BSTs) that are intended to represent sets of natural numbers. We use two abstractions for BSTs, one in which only their values are considered as a mathematical set:

$$\text{BST}(x, K) \triangleq (x = \text{null} \star K = \emptyset) \vee (\exists k, l, r, K_l, K_r. x \mapsto k, l, r \star \text{BST}(r, K_r) \star \text{BST}(l, K_l) \star K = K_l \uplus \{k\} \uplus K_r \star K_l < k \star k < K_r)$$

and another that fully exposes the BST structure:

$$\text{BST}(x, \tau) \triangleq (x = \text{null} \star \tau = \tau_\emptyset) \vee (\exists k, l, r, \tau_l, \tau_r. E \mapsto k, l, r \star \text{BST}(r, \tau_r) \star \text{BST}(l, \tau_l) \star \tau = ((x, k), \tau_l, \tau_r) \star \tau_l < k \star k < \tau_r)$$

where τ is a mathematical tree, that is, an algebraic data type with two constructors representing, respectively, an empty tree and a root node with two child trees: $\tau \in \text{Tree} \triangleq \tau_\emptyset \mid ((x, n), \tau_l, \tau_r)$, where the notation (x, n) represents a BST node with address x and value n . Note the overloaded $<$ notation, where one of the operands can be a set or a tree, which carry the intuitive meaning.

BST algorithms. We first consider the BST-find-minimum algorithm, $\text{BSTFindMin}(x)$, which takes a tree with root at x , does not modify it, and returns its minimum element or throws an empty-tree error. Since that algorithm operates only on the values in the tree, we are able to state its ESL specification using the $\text{BST}(x, K)$ predicate as follows:

$$(\mathbf{x} = x \star \text{BST}(x, K)) \text{BSTFindMin}(x) \begin{array}{l} (\text{ok}: x \neq \text{null} \star \text{BST}(x, K) \star \text{ret} = \min(K)) \\ (\text{err}: x = \text{null} \star \text{BST}(x, K) \star \text{err} = \text{“Empty tree!”}) \end{array}$$

We have also considered the BST-insert algorithm, $\text{BSTInsert}(x, v)$, which takes a tree with root at x and inserts a new node with value v into it as a leaf if v is not already in the tree, or leaves the tree unmodified if it is. As this algorithm interacts both with values and addresses in the tree, the appropriate abstraction for it is $\text{BST}(x, \tau)$, and its ESL specification is:

$$\begin{array}{c} (\mathbf{x} = x \star v = v \star \text{BST}(x, \tau)) \\ \text{BSTInsert}(x, v) \\ (\exists x'. \text{BST}(\text{ret}, \text{BSTInsert}(\tau, (x', v))) \star \text{BSTRoot}(x, \tau)) \end{array}$$

where $\text{BSTInsert}(\tau, \nu)$ is the mathematical algorithm that inserts the node ν into the tree τ :

$$\text{BSTInsert}(\tau_\emptyset, (x', v)) \triangleq \text{BSTInsert}(((x, k), \tau_l, \tau_r), (x', v)) \triangleq \begin{array}{l} \text{if } v < k \text{ then } ((x, k), \text{BSTInsert}(\tau_l, (x', v)), \tau_r) \\ \text{else if } k < v \text{ then } ((x, k), \tau_l, \text{BSTInsert}(\tau_r, (x', v))) \\ \text{else } ((x, k), \tau_l, \tau_r) \end{array}$$

and the predicate $\text{BSTRoot}(x, \tau)$ is defined analogously to $\text{listHead}(x, xs)$:

$$\text{BSTRoot}(x, \tau) \triangleq (\tau = \tau_\emptyset \star x = \text{null}) \vee (\exists k, \tau_l, \tau_r. \tau = ((x, k), \tau_l, \tau_r))$$

This example shows how in EX verification, just as in OX verification, we end up relating an imperative heap-manipulating algorithm to its mathematical/functional counterpart (cf. Appel [3] for a recent reiteration of this idea). The additional work required is that EX mathematical models must be more detailed: we are, yet again, not allowed to lose information. In particular, in OX verification we could relate $\text{BSTInsert}(x, v)$ to mathematical sets, but in EX verification we must relate our imperative implementation to tree models, including both values and pointers. Moreover, our mathematical model of the algorithm, $\text{BSTInsert}(\tau, (x', v))$, must insert elements in the same way as the imperative implementation, that is, in this case at the leaves of the tree. The proofs for both algorithms are given in [24].

6 Related Work

In the previous sections, we have placed ESL in the context of related work on OX and UX logics and associated tools. Here, we discuss formalisms capable of reasoning both about program correctness and program incorrectness, as well as existing approaches to the use of function specifications (summaries) and abstraction in symbolic execution.

Program Logics for Both Correctness and Incorrectness. Developed in parallel but independently of ESL, Outcome Logic (OL) [33], much like ESL, brings together reasoning about correctness and incorrectness into one logic. Both OL and ESL rely on the traditional meaning of correctness, but OL introduces a new approach to incorrectness, based on reachability of sets of states. It has not yet been shown that this approach has the same bug-finding potential as that of ISL: in particular, bi-abduction has not yet been demonstrated to be compatible with OL. In addition, the OL work, in contrast to ESL, does not discuss function compositionality or the interaction between abstraction, reachability, and incorrectness.

LCL_A [4,5] is a non-function-compositional, first-order logic that combines UX and OX reasoning using abstract interpretation. It is parametric on an abstract domain A , and proves UX triples of the form $\vdash_A [P] C [Q]$ where, under certain conditions, the triple also guarantees verification. These conditions, however, normally mean that only a limited number of pre-conditions can be handled. The conditions also have to be checked per-command and if they fail to hold (due to, e.g., issues with Boolean guards, which are known to be a major source of incompleteness), then the abstract domain has to be incrementally adjusted; the complexity of this adjustment and the expressivity of the resulting formalism is unclear.

Compositional Symbolic Execution. There exists a substantial body of work on symbolic execution with function summaries (e.g. [1, 15–17, 22, 32]), which is primarily based on first-order logic. We highlight the work of Godefroid et al., which initially used exact summaries of bounded program behaviour to drive the compositional dynamic test generation of SMART [15], and later distinguished between may (OX) and must (UX) summaries, leveraging the interaction between them to design the SMASH tool for compositional property checking and test generation [16]. SMASH, however, is limited in its ability to reason about heap-manipulating programs because, for example, it lacks support for pointer arithmetic. Nevertheless, it shows that interactions between OX and UX summaries can be exploited for automation, which is an important consideration for any automation of ESL. For example, SMASH is able to use not-may summaries (which amount to non-reachability) when constructing must-summaries (which amount to reachability), using the former to restrict the latter. When it comes to abstraction, for example, Anand et al. [2] implement linked-list and array abstractions for true bug-finding in non-compositional symbolic execution, in the context of the Java PathFinder, and use it to find bugs in list and array partitioning algorithms. True bug-finding is maintained by checking for state subsumption, which requires code modification rather than annotation and a record of all previously visited states.

7 Conclusions

We have introduced ESL, a program logic for exact reasoning about heap-manipulating programs. ESL specifications provide a sweet spot between verification and true bug-finding: as SL specifications, they capture all terminating behaviour, and, as ISL specifications, they describe only results and errors that are reachable. ESL specifications are therefore compatible with tools that target OX verification, such as VeriFast [19] and Iris [20], tools that target UX true bug-finding, such as Pulse [26, 28], and tools capable of targeting both, such as Gillian [10, 23]. ESL supports reasoning about mutually recursive functions and comes with a soundness result that immediately transfers to SL and ISL, thus demonstrating, for the first time, scalable functional compositionality for UX logics.

We have verified exact specifications for a number of illustrative examples, showing that ESL can reason about data-structure libraries, language errors, mutual recursion, and non-termination. In doing so, we emphasise the distinction between the often-conflated concepts of abstraction and over-approximation. We have demonstrated that abstract predicates can be soundly used in EX and UX reasoning, albeit not as freely as in OX reasoning.

We believe that ESL reasoning, in its intended context of semi-automatic verification of functional correctness properties, is useful for the verification of self-contained, critical code that underpins a larger codebase. To demonstrate this, we will in the future incorporate UX and EX verification inside Gillian [10, 23], which already has support for function compositionality and semi-automatic predicate management as part of its OX verification.

Morpheus: Automated Safety Verification of Data-Dependent Parser Combinator Programs

Abstract

Parser combinators are a well-known mechanism used for the compositional construction of parsers, and have shown to be particularly useful in writing parsers for rich grammars with data-dependencies and global state. Verifying applications written using them, however, has proven to be challenging in large part because of the inherently effectful nature of the parsers being composed and the difficulty in reasoning about the arbitrarily rich data-dependent semantic actions that can be associated with parsing actions. In this paper, we address these challenges by defining a parser combinator framework called *Morpheus* equipped with abstractions for defining composable effects tailored for parsing and semantic actions, and a rich specification language used to define safety properties over the constituent parsers comprising a program. Even though its abstractions yield many of the same expressivity benefits as other parser combinator systems, *Morpheus* is carefully engineered to yield a substantially more tractable automated verification pathway. We demonstrate its utility in verifying a number of realistic, challenging parsing applications, including several cases that involve non-trivial data-dependent relations.

1 Introduction

Parsers are transformers that decode serialized, unstructured data into a structured form. Although many parsing problems can be described using simple context-free grammars (CFGs), numerous real-world data formats (e.g., pdf [34], dns [9], zip [35], etc.), as well as many programming language grammars (e.g., Haskell, C, Idris, etc.) require their parser implementations to maintain additional context information during parsing. A particularly important class of context-sensitive parsers are those built from *data-dependent grammars*, such as the ones used in the data formats listed above. Such *data-dependent* parsers allow parsing actions that explicitly depend on earlier parsed data or semantic actions. Often, such parsers additionally use global effectful state to maintain and manipulate context information. To illustrate, consider the implementation of a popular class of *tag-length-data* parsers; these parsers can be used to parse image formats like PNG or PPM images, networking packets formats like TCP, etc., and use a parsed length value to govern the size of the input payload that should be parsed subsequently. The following BNF grammar captures this relation for a simplified PNG image.

```

png ::= header . chunk*
chunk ::= length . typespec . content

```

The grammar defines a `header` field followed by zero or more `chunks`, where each `chunk` has a single byte `length` field parsed as an unsigned integer, followed by a single byte `chunk type specifier`. This is followed by zero or more bytes of actual `content`. A useful data-dependent safety property that any parser implementation for this grammar should satisfy is that “*the length of content plus typespec is equal to the value of length*”.

Parser combinator libraries [44, 25, 12, 33] provide an elegant framework in which to write parsers that have such data-dependent features. These libraries simplify the task of writing parsers because they define the grammar of the input language and implement the recognizer for it at the same time. Moreover, since combinator libraries are typically defined in terms of a shallowly-embedded DSL in an expressive host language like Haskell [1, 19] or OCaml [25], parser implementations can seamlessly use a myriad of features available in the host language to express various kinds of data-dependent relations. This makes them capable of parsing both CFGs as well as richer grammars that have non-trivial semantic actions. Consequently, this style of parser construction has been adopted in many domains [2, 1, 33], a fact exemplified by their support in many widely-used languages like Haskell, Scala, OCaml, Java, etc.

Although parser combinators provide a way to easily write data-dependent parsers, verifying the correctness (i.e., ensuring that all data dependencies are enforced) of parser implementations written using them remains a challenging problem. This is in large part due to the inherently effectful nature of the parsers being composed, the pervasive use of rich higher-order abstractions available in the combinators used to build them, and the difficulty of reasoning about complex data-dependent semantic actions triggered by these combinators that can be associated with a parsing action.

This paper directly addresses these challenges. We do so by imposing modest constraints on the host language capabilities available to parser combinator programs; these constraints *enable* mostly automated reasoning and verification, *without* comprising the ability to specify parsers with rich effectful, data-dependent safety properties. We manifest these principles in the design of a deeply-embedded DSL for OCaml called **Morpheus** that we use to express and verify parsers and the combinators that compose them. Our design provides a novel (and, to the best of our knowledge, first) automated verification pathway for this important application class. This paper makes the following contributions:

1. It details the design of an OCaml DSL **Morpheus** that allows compositional construction of *data-dependent* parsers using a rich set of primitive parsing combinators along with an expressive specification language for describing safety properties relevant to parsing applications.
2. It presents an automated refinement type-based verification framework that validates the correctness of **Morpheus** programs with respect to their specifications and which supports fine-grained effect reasoning and inference to help reduce specification annotation burden.
3. It justifies its approach through a detailed evaluation study over a range of complex real-world parser applications that demonstrate the feasibility and effectiveness of the proposed methodology.

The remainder of the paper is organized as follows. The next section presents a detailed motivating example to illustrate the challenges with verifying parser combinator applications and presents a detailed overview of **Morpheus** that builds upon this example. We formalize **Morpheus**’s specification language and type system in Secs. 3 and 4. Details about **Morpheus**’s implementation and benchmarks demonstrate the utility of our framework is given in Sec. 5. Related work and conclusions are given in Secs. 6 and 7, respectively.
