To motivate our ideas and give an overview of Morpheus, consider a parser for a simplified C language *declarations, expressions and typedefs* grammar. The grammar must handle context-sensitive disambiguation of *typename*s and *identifiers*¹. Traditionally, C-parsers achieve this disambiguation via cumbersome *lexer hacks*² which use feedback from the symbol table maintained in the parsing into the lexer to distinguish variables from types. Once the disambiguation is outsourced to the lexer-hack, the C-decl grammar can be defined using a context-free-grammar. For instance, the left hand side, Figure 1, presents a simplified context-free grammar production for a C declaration.

Unfortunately, ad-hoc lexer-hacks are both tedious and error prone. Further, this convoluted integration of the lexing and parsing phases makes it challenging to validate the correctness of the parser implementation. A cleaner way to implement such a parser is to disambiguate *typename*s and *identifiers* when parsing by writing an actual context-sensitive parser. One approach would be to define a shared *context* of two non-overlapping lists of *types* and *identifiers* and a stateful-parser using this context. The modified *context-sensitive* grammar is shown in right hand side, Figure 1.

The square brackets show context-sensitive checks e.g. $[\neg id \in (!identifier)]$ checks that the parsed *rawident* token *id* is not in the list of *identifiers*, while the braces show semantic actions associated with parser reductions, e.g. $\{typed.add id\}$, adds the token *id* to *types*, a list of *identifiers* seen thus far in the parse.

Given this grammar, we can use parser combinator libraries [25, 30] in our favorite language to implement a parser for C language declarations. Unfortunately, although cleaner than the using unwieldy lexer hacks, it is still not obvious how we might verify that implementations actually satisfy the desired *disambiguation* property, i.e. *typename*s and *identifiers* do not overlap. In the next section we provide an overview of Morpheus that informally presents our solution to this problem.

2.1 Morpheus Surface Language

An important design decision we make is to provide a surface syntax and API very similar to conventional monadic parser combinator libraries like Parsec [25] in Haskell or mParser [30] in OCaml; the core API that Morpheus provides has the signature shown in Figure 3. The library

```

■ **Figure 2** A simplified C-declaration parser written in Morpheus. Specifications in blue are provided by the programmer; specifications in gray are inferred by Morpheus. Line number 28 represents the complete multiline type specification.

defines a number of primitive combinators: `eps` defines a parser for the empty language, `bot` always fails, and `char c` defines a parser for character `c`. Beyond these, the library also provides a `bind (>>=)` combinator for monadically composing parsers, a `choice (<|>)` combinator to non-deterministically choose among two parsers, and a `fix` combinator to implement recursive parsers. The `return x` is a parser which always succeeds with a value `x`. As we demonstrate, these combinators are sufficient to derive a number of other useful parsing actions such as `many`, `count`, etc. found in these popular combinator libraries. From the parser writer's perspective, Morpheus programs can be expressed using these combinators along with a basic collection of other non-parser expression forms similar to those found in an ML core language, e.g., first-class functions, `let` expressions, references, etc.

```

type 'a t
val eps : unit t
val bot : 'a t
val char : char → char t
val (>>=) : 'a t → (a → 'b t) → 'b t
val <|> : 'a t → 'a t → 'a t
val fix : ('b t → 'b t) → 'b t
val return : 'a → 'a t

```

■ **Figure 3** Signatures of primitive parser combinators supported by Morpheus.

For instance a parser for option p , which either parses an empty string or anything that p parses can be written:

```
let option p = (eps >>= λ_. return None) <|> (p >>= λ x. return Some x)
```

We can also define more intricate parsers like *Kleene-star* and *Kleene-plus*:

```
let star p = fix (λ p_star. eps <|> p >>= λ x. p_star >>= λ xs . return (x :: xs) )
let plus p = fix (λ p_star. p <|> p >>= λ x. p_star >>= λ xs . return (x :: xs) )
```

Figure 2 shows a Morpheus implementation that parses a valid C language decl.³ The parser uses two mutable lists to keep track of types and identifiers. The structure is similar to the original data-dependent grammar, even though the program uses ML-style operators for assignment and dereferencing. For ease of presentation, we have written the program using *do-notation* as syntactic sugar for Morpheus’s monadic bind combinator.

The `typedcl` parser follows the grammar and parses the keyword *typedef* using the keyword parser (not shown).⁴ It uses a choice combinator (`<|>`) (line 32), which has a semantics of a non-deterministic choice between two sub-parsers. The interesting case occurs while parsing an identifier (lines 33 - 39), in order to enforce disambiguation between *typenames* and *identifiers*, the parser needs to maintain an invariant that the two lists, `types` for parsed *typenames* and `ids` for parsed *identifiers* are always *disjoint* or *non-overlapping*.

In order to maintain the non-overlapping list invariant, a parsed identifier token (line 33) can be a valid typename only if it is not parsed earlier as an identifier expression. i.e. it is not in the `ids` list. The parser performs this check at (line 35). If this check succeeds, the list of typenames (`types`) is updated and a `decl` is returned, else the parsing fails.

The disambiguation decision is required during the parsing of an *expression*. The expression parser defines multiple choices. The parser for the *casting* expression parses a typename followed by a recursive call to expression. The `typename` parser in turn (line 41) parses an identifier token and checks that the identifier is indeed a `typename` (line 44) and returns it, or fails.

The `ids` list is updated during parsing an identifier expression (line 20), here again to maintain disambiguation, before adding a string to the `ids` list, its non-membership in the current `types` list is checked (line 22).

Although the above parser program is easy to comprehend given how closely it hews to the grammar definition, it is still nonetheless non-trivial to verify that the parser actually satisfies the required disambiguation safety property. For example, an implementation in

³ For now, ignore the specifications given in `gray` and `blue`.

⁴ Morpheus, like other parser combinator libraries provides a library of parsers for parsing keywords, identifiers, natural numbers, strings, etc.

which line 34 is replaced with the commented expression above it would incorrectly check membership on the wrong list. We describe how Morpheus facilitates verification of this program in the following section.

2.2 Specifying Data-dependent Parser Properties

Intuitively, verifying the above-given parser for the absence of overlap between the *typenames* and *identifiers* requires establishing the following partial correctness property: if the *types* and *identifiers* lists do not overlap when the *typedecl* parser is invoked, and the parser terminates without an error, then they must not overlap in the output state generated by the parser. Additionally, it is required that the parser consumes some prefix of the input list. Morpheus provides an expressive specification language to specify properties such as these.

Morpheus allows standard ML-style inductive type definitions that can be refined with *qualifiers* similar to other refinement type systems [38, 43, 18]. For instance, we can refine the type of a list of strings to only denote *non-empty* lists as: `type nonempty = { ν : [string] | len (ν) > 0 }`. Here, ν is a special bound variable representing a list and (`len ν > 0`) is a *refinement* where `len` is a *qualifier*, a predicate available to the type system that captures the length property of a list.

2.2.1 Specifying effectful safety properties

Standard refinement type systems, however, are ill-suited to specify safety properties for effectful computation of the kind expressible by parser combinators. Our specification language, therefore, also provides a type for effectful computations. We use a specification monad (called a *Parsing Expression*) of the form `PE ε { ϕ } ν : τ { ϕ' }` that is parameterized by the *effect* of the computation ε (e.g., `state`, `exc`, `nondet`, and their combinations like `stexc` for (both `state` and `exc`), `stnon` (for both `state` and `nondet`), etc.); and Hoare-style pre- and post-conditions [31, 41, 40]. Here, ϕ and ϕ' are first-order logical propositions over qualifiers applied to program variables and variables in the type context. The precondition ϕ is defined over an abstract input heap h while the postcondition ϕ' is defined over input heap h , output heap h' , and the special result variable ν that denotes the result of the computation. Using this monad, we can specify a safety property for the *typedecl* subparser as shown at line 28 in Figure 2. The type should be understood as follows: The *effect* label `stexc` defines that the parser may have both `state` effect as it reads and updates the context; and `exc` effect as the parser may fail. The precondition defines a property over a list of identifiers `ids` and a list of typenames `types` in the input heap h via the use of the built-in qualifier `sel` that defines a select operation on the heap [27]; here, ν is bound to the result of the parse. Morpheus also allows user-defined qualifiers, like the qualifier `ldisjoint`. It establishes the *disjointness/non-overlapping* property between two lists. This qualifier is defined using the following definition:

```

qualifier ldisjoint [] l2 → true
  | l1 [] → true
  | (x :: xs) l2 → member (x, l2) = false ∧ ldisjoint (xs, l2)
  | l1 (y :: ys) → member (y, l1) = false ∧ ldisjoint (l1, ys)

```

This definition also uses another qualifier for list membership called `member`. Morpheus automatically translates these user-defined qualifiers to axioms, logical sentences whose validity is assumed by the underlying theorem prover during verification. For instance, given the above qualifier, Morpheus generates axioms like:

```

Axiom1:  $\forall l1, l2 : \alpha \text{ list. } (\text{empty}(l1) \vee \text{empty}(l2)) \Rightarrow \text{ldisjoint}(l1, l2) = \text{true}$ 
Axiom2:  $\forall xs, l2 : \alpha \text{ list, } x : \alpha. \text{ldisjoint}(xs, l2) = \text{true} \wedge \text{member}(x, l2) = \text{false} \Rightarrow \text{ldisjoint}((x::xs), l2) = \text{true}$ 
Axiom3:  $\forall l1, l2 : \alpha \text{ ldisjoint}(l1, l2) \Leftrightarrow \text{ldisjoint}(l2, l1)$ 

```

The specification (at line 28) also uses another qualifier, `included(inp,h,h')`, which captures the monotonic consumption property of the input list `inp`. The qualifier is true when the remainder `inp` after parsing in `h'` is a suffix of the original `inp` list in `h`.

The types for other parsers in the figure can be specified as shown at lines 11, 40, etc.; these types shown in gray are automatically inferred by `Morpheus`'s type inference algorithm. For example, the type for the `typename` parser (line 40) returns an optional string (`result` is a special option type) and records that when parsing is successful, the returned string is added to the `types` list, and when unsuccessful, the input is still monotonically consumed.

2.2.2 Verification using Morpheus

Note that the pre-condition in the specification (`ldisjoint(l1, l2) = true`) and the type ascribed to the membership checks in the implementation (line 35) are sufficient to conclude that the addition of a `typename` to the `types` list (line 36) maintains the `ldisjoint` invariant as required by the postcondition.

In contrast, an erroneous implementation that omits the membership check or replaces the check at line 34 with the commented line above it will cause type-checking to fail. The program will be flagged ill-typed by `Morpheus`. For this example, `Morpheus` generated 21 verification conditions (VCs) for the control-path representing a successful parse and generated 5 VCs for the failing branch. We were able to discharge these VCs to the SMT solver Z3 [7], which took 6.78 seconds to verify the former and 1.90 seconds to verify the latter.

3 Morpheus Syntax and Semantics

3.1 Morpheus Syntax

Figure 4 defines the syntax of λ_{sp} , a core calculus for `Morpheus` programs. The language is a call-by-value polymorphic lambda-calculus with effects, extended with primitive expressions for common parser combinators and a refinement type-based specification language. A λ_{sp} value is either a constant drawn from a set of base types (`int`, `bool`, etc.), as well as a special `Err` value of type `exception`, an abstraction, or a constructor application. Variables bound to updateable locations (ℓ) are distinguished from variables introduced via function binding (x). A λ_{sp} expression e is either a value, an application of a function or type abstraction, operations to dereference and assign to top-level locations (see below), polymorphic **let** expressions, reference binding expressions, a **match** expression to pattern-match over type constructors, a **return** expression that lifts a value to an effect, and various parser primitive expressions that define parsers for the empty language (`eps`), a character (`char`) parser, and \perp , a parser that always fails. Additionally, the language provides combinators to monadically compose parsers ($>>=$), to implement parsers defined in terms of a non-deterministic choice of its constituents ($<|>$), and to express parsers that have recursive ($\mu(x : \tau).p$) structure.

We restrict how effects manifest by requiring reference creation to occur only within **let** expressions and not in any other expression context. Moreover, the variables bound to locations so created (ℓ) can only be dereferenced or assigned to and cannot be supplied

■ **Figure 4** λ_{sp} Expressions and Types.

as arguments to abstractions or returned as results since they are not treated as ordinary expressions. This stratification, while arguably restrictive in a general application context, is consistent with how parser applications, such as our introductory example are typically written and, as we demonstrate below, do not hinder our ability to write real-world data-dependent parser implementations. Enforcing these restrictions, however, provides a straightforward mechanism to prevent aliasing of effectful components during evaluation, significantly easing the development of an automated verification pathway in the presence of parser combinator-induced computational effects.

3.2 Semantics

Figure 5 presents a big-step operational semantics for λ_{sp} parser expressions; the semantics of other terms in the language is standard. The semantics is defined via an evaluation relation (\Downarrow) that is of the form $(\mathcal{H}; e) \Downarrow (\mathcal{H}'; v)$. The relation defines how a **Morpheus** expression e evaluates with respect to a heap \mathcal{H} , a store of locations to base-type values, to yield a value v , which can be a normal value or an exceptional one, the latter represented by the exception constant Err , and a new heap \mathcal{H}' .

$$\boxed{(\mathcal{H}; e) \Downarrow (\mathcal{H}'; v)}$$

$$\begin{array}{c}
\text{P-EPS} \frac{}{(\mathcal{H}; \text{eps}) \Downarrow (\mathcal{H}; ())} \quad \text{P-}\perp \frac{}{(\mathcal{H}; \perp) \Downarrow (\mathcal{H}; \text{Err})} \quad \text{P-FIX} \frac{(\mathcal{H}; [\mu x : \sigma.p/x]p) \Downarrow (\mathcal{H}'; v)}{(\mathcal{H}; \mu x : \sigma.p) \Downarrow (\mathcal{H}'; v)} \\
\\
\text{P-CHAR-TRUE} \frac{(\mathcal{H}; e) \Downarrow (\mathcal{H}; 'c') \quad \mathcal{H}(\text{inp}) = ('c' :: s) \quad \mathcal{H}' = \mathcal{H}[\text{inp} \mapsto s]}{(\mathcal{H}; \text{char } e) \Downarrow (\mathcal{H}'; 'c')} \\
\\
\text{P-CHAR-FALSE} \frac{(\mathcal{H}; e) \Downarrow (\mathcal{H}; 'c') \quad \mathcal{H}(\text{inp}) \neq ('c' :: s) \quad \mathcal{H}' = \mathcal{H}[\text{inp} \mapsto \text{inp}]}{(\mathcal{H}; \text{char } e) \Downarrow (\mathcal{H}'; \text{Err})} \\
\\
\text{P-BIND-SUCCESS} \frac{(\mathcal{H}; p) \Downarrow (\mathcal{H}'; v_1) \quad (\mathcal{H}'; e) \Downarrow (\mathcal{H}'; (\lambda x : \tau. e')) \quad (\mathcal{H}'; [v_1/x]e') \Downarrow (\mathcal{H}''; v_2)}{(\mathcal{H}; p \gg e) \Downarrow (\mathcal{H}''; v_2)} \\
\\
\text{P-BIND-ERR} \frac{(\mathcal{H}; p) \Downarrow (\mathcal{H}'; \text{Err})}{(\mathcal{H}; p \gg e) \Downarrow (\mathcal{H}'; \text{Err})} \\
\\
\text{P-CHOICE-L} \frac{(\mathcal{H}; p_1) \Downarrow (\mathcal{H}'; v_1)}{(\mathcal{H}; (p_1 <|> p_2)) \Downarrow (\mathcal{H}'; v_1)} \quad \text{P-CHOICE-R} \frac{(\mathcal{H}; p_2) \Downarrow (\mathcal{H}''; v_2)}{(\mathcal{H}; (p_1 <|> p_2)) \Downarrow (\mathcal{H}''; v_2)}
\end{array}$$

■ **Figure 5** Evaluation rules for λ_{sp} parser expressions.

The empty string parser (rule P-EPS) always succeeds, returning a value of type **unit**, without changing the heap. A “bottom” (\perp) parser on the other hand always fails, producing an exception value, also without changing the heap. If the argument e to a character parser **char** yields value (a char ‘c’), and ‘c’ is the head of the input string (denoted by **inp**) being parsed, the parse succeeds (rule P-CHAR-TRUE), consuming the input and returning ‘c’, otherwise, the parse fails, with the input not consumed and the distinguished **Err** value being returned (rule P-CHAR-FALSE). The fixpoint parser $\mu x.p$ (P-FIX) allows the construction of recursive parser expressions. The monadic bind parser primitive (rule P-BIND-SUCCESS) binds the result of evaluating its parser expression to the argument of the abstraction denoted by its second argument, returning the result of the evaluating the abstraction’s body (P-BIND-SUCCESS); the P-BIND-ERR rule deals with the case when the first expression fails. Evaluation of “choice” expressions, defined by rules P-CHOICE-L and P-CHOICE-R, introduce an unbiased choice semantics over two parsers allowing non-deterministic choices in parsers.

4 Typing λ_{sp} Expressions

4.1 Specification Language

The syntax of Morpheus’s type system is shown in the bottom of Figure 4 and permits the expression of *base types* such as integers, booleans, strings, etc., as well as a special **heap** type to denote the type of abstract heap variables like **h**, **h’** found in the specifications described below. There are additionally user-defined datatypes **TN** (**list**, **tree**, etc.), a special sum type (**t result**) to define two options of a successful and exceptional result respectively, and a

special exception type. More interestingly, base types can be refined with *propositions* to yield monomorphic refinement types. Such types [41, 38, 43] are either *base refinement types*, refining a base typed term with a refinement; *dependent function types*, in which arguments and return values of functions can be associated with types that are refined by propositions; or a *computation type* specifying a type for an effectful computation.

Effectful computations are refined using an effect specification monad:

$$\text{PE}^\varepsilon \{ \forall h. \phi_1 \} \nu : \mathbf{t} \{ \forall h, \nu, h'. \phi_2 \}$$

that encapsulates a base type \mathbf{t} , parameterized by an effect label ε , with Hoare-style pre- ($\{ \forall h. \phi_1 \}$) and post- ($\{ \forall h, \nu, h'. \phi_2 \}$) conditions. This type captures the behavior of a computation that (a) when executed in a pre-state with input heap h satisfies proposition ϕ_1 ; (b) upon termination, returns a value denoted by ν of base type \mathbf{t} along with output heap h' ; (c) satisfies a post-condition ϕ_2 that relates h , ν , and h' ; and (d) whose effect is over-approximated by effect label ε [20, 45]. An effect label ε is either (i) a **pure** effect that records an effect-free computation; (ii) a **state** effect that signifies a stateful computation over the program heap; (iii) an **exception** effect exc that denotes a computation that might trigger an exception; (iv) a **nondet** effect that records a computation that may have non-deterministic behavior; or (v) a *join* over these effects that reflect composite effectful actions. The need for the last is due to the fact that effectful computations are often defined in terms of a composition of effects, e.g. a parser oftentimes will define a computation that has a state effect along with a possible exception effect. To capture these composite effects, base effects can be joined to build a finite lattice that reflects the behavior of computations which perform multiple effectful actions, as we describe below.

Propositions (ϕ) are first-order predicate logic formulae over base-typed variables. Propositions also include a set of qualifiers which are applications of user-defined uninterpreted function symbols such as `mem`, `size` etc. used to encode properties of program objects, `sel` used to model accesses to the heap, and `dom` used to model membership of a location in the heap, etc. Proposition validity is checked by embedding them into a decidable logic that supports equality of uninterpreted functions and linear arithmetic (EUFLIA).

A type scheme (σ) is either a monotype (τ) or a universally quantified polymorphic type over type variables expressed in prenex-normal form ($\forall \alpha. \sigma$). A **Morpheus** specification is given as a type scheme.

There are two environments maintained by the **Morpheus** type-checker: (1) an environment Γ records the type of variables, which can include variables introduced by function abstraction as well as bindings to references introduced by `let` expressions, along with a set of propositions relevant to a specific context, and (2) an environment Σ maps datatype constructors to their signatures. Our typing judgments are defined with respect to a typing environment

$$\Gamma ::= . \mid \Gamma, x : \sigma \mid \Gamma, \ell : \tau \text{ ref}$$

that is either empty, or contains a list of bindings of variables to either type schemes or references. The rules have two judgment forms: $(\Gamma \vdash e : \sigma)$ gives a type for a **Morpheus** expression e in Γ ; and $(\Gamma \vdash \sigma_1 <: \sigma_2)$ defines a dependent subtyping rule under Γ .

Since our type expressions contain refinements, we generalize the usual notion of type substitution to reflect substitution within refined types:

$$\begin{aligned} [x_a/x] \{ \nu : \mathbf{t} \mid \phi \} &= \{ \nu : \mathbf{t} \mid [x_a/x] \phi \} \\ [x_a/x] (y : \tau) \rightarrow \tau' &= (y : [x_a/x] \tau) \rightarrow [x_a/x] \tau', y \neq x \\ [x_a/x] \text{PE}^\varepsilon \{ \phi_1 \} \{ \nu : \mathbf{t} \} \{ \phi_2 \} &= \text{PE}^\varepsilon \{ [x_a/x] \phi_1 \} \{ \nu : \mathbf{t} \} \{ [x_a/x] \phi_2 \} \end{aligned}$$

4.2 Typing Base Expressions

Figure 6 presents type rules for non-parser expressions. The type rules for non-reference variables, functions, and type abstractions (T-TYP-FUN) are standard. The syntax for function application restricts its argument to be a variable, allowing us to record the argument's (intermediate) effects in the typing environment when typing the application as a whole.

Base Expression Typing $\boxed{\Gamma \vdash e : \sigma}$

$$\begin{array}{c}
\text{T-VAR} \frac{\Gamma(x) = \sigma}{\Gamma \vdash x : \sigma} \quad \text{T-FUN} \frac{\Gamma, x : \tau_1 \vdash e : \tau_2}{\Gamma \vdash \lambda(x : \tau_1).e : \tau_1 \rightarrow \tau_2} \quad \text{T-TYPAPP} \frac{\Gamma \vdash \Lambda\alpha.e : \forall\alpha.\sigma}{\Gamma \vdash \Lambda\alpha.e[t] : [t/\alpha]\sigma} \\
\\
\text{T-APP} \frac{\Gamma \vdash e_f : (x : \{\nu : t \mid \phi_x\}) \rightarrow \text{PE}^\varepsilon\{\phi\} \quad \nu : t \{\phi'\} \quad \Gamma \vdash x_a : \{\nu : t \mid \phi_x\}}{\Gamma \vdash e_f x_a : [x_a/x]\text{PE}^\varepsilon\{\phi\} \quad \nu : t \{\phi'\}} \\
\\
\text{T-TYPFUN} \frac{\Gamma \vdash e : \sigma \quad \alpha \notin FV(\Gamma)}{\Gamma \vdash \Lambda\alpha.e : \forall\alpha.\sigma} \quad \text{T-LET} \frac{\Gamma \vdash v : \forall\alpha.\sigma \quad \Gamma, x : \forall\alpha.\sigma \vdash e_2 : \sigma'}{\Gamma \vdash \text{let } x = v \text{ in } e_2 : \sigma'} \\
\\

\end{array}$$

■ **Figure 6** Typing Semantics for Morpheus Base Expressions.

The type rule for the return expression (T-RETURN) lifts its non-effectful expression argument e to have a computation effect with label **pure**, thereby allowing e 's value to be used in contexts where computational effects are required; a particularly important example of such contexts are bind expressions used to compose the effects of constituent parsers.

In the constructor application rule (T-CAPP), the expression’s type reflects the instantiation of the type and term variables in the constructor’s type with actual types and terms. A match expression is typed (rule T-MATCH) by typing each of the alternatives in a corresponding extended environment and returning a *unified type*. The pre-condition of the *unified* type is a conjunction of the pre-conditions for each alternative, while the post-condition over-approximates the behavior for each alternative by creating a disjunction of each of the possible alternative’s post-conditions. Location manipulating expressions (T-DEREF and T-ASSIGN) use qualifiers *sel* and *dom* to define constraints that reflect state changes on the underlying heap. The argument ℓ of a dereferencing expression (rule T-DEREF) is associated with a computation type over a *tref* base type. Its pre-condition requires ℓ to be in the domain of the input heap, and its post-condition establishes that ℓ ’s contents is the value returned by the expression and that the heap state does not change. The assignment rule (T-ASSIGN) assigns the contents of a top-level reference ℓ to the non-effectful value yielded by evaluating expression e . The pre-condition of its computation effect type requires that ℓ is in the domain of the input heap and that ℓ ’s contents in the output heap satisfies the refinement (ϕ) associated with its r-value. Finally, rule T-REF types a **let** expression that introduces a reference initialized to a value v . The body is typed in an environment in which ℓ is given a computational effect type. The pre-condition of this type requires that the input heap, i.e., the heap extant at the point when the binding of ℓ to *ref* v occurs, not include ℓ in its domain; its postcondition constrains ℓ ’s contents to be some value v' that satisfies the refinement ϕ associated with v , its initialization expression. The body of the **let** expression is then typed in this augmented type environment.

4.3 Typing Parser Expressions

Figure 7 presents the type rules for Morpheus parser expressions. The (T-SUB) rule defines the standard type subsumption rule. The empty string parser typing rule (T-P-EPS) assigns a type with *pure* effect and *unit* return type, while the postcondition establishes the equivalence of the input and the output heaps. The T-P-BOT rule captures the always failing semantics of \perp with an exception effect *exc* and corresponding return types and return values while maintaining the stability of the input heap. The type rules governing a character parser (T-P-CHAR) is more interesting because it captures the semantics of the success and the failure conditions of the parser. We use a sum type (α *result*) to define two options representing a successful and exceptional result, resp. (with the *Err* exception value in the latter case), using standard injection functions to differentiate among these alternatives. In the successful case, the returned value is equal to the consumed character, captured by an equality constraint over characters. In the successful case, the structure of the output heap with respect to the parse string *inp* must be the same as the input heap except for the absence of the 'c', the now consumed head-of-string character. In the failing case, the input remains unconsumed. Note that we also join the effect labels (*state* \sqcup *exc*), highlighting the state and exception effect. These effect labels form a standard join semi-lattice with an ordering relation (\leq)⁵.

Rule T-P-CHOICE defines the static semantics for a non-deterministic choice parser. It introduces a non-determinism effect to the parser’s composite type. The effect’s precondition requires that either of the choices can occur; we achieve this by restricting it to the conjunction of the two preconditions for the sub-parsers. The disjunctive post-condition requires that both the choices must imply the desired goal postcondition for a composite parser to be well-typed. The effect for the choice expression takes a join over the effects of the choices and the non-deterministic effect.

⁵ Details of the effect-labels and their join semi-lattice is provided in the accompanied technical report [28]

Parser Expression Typing $\boxed{\Gamma \vdash e : \sigma}$

$$\text{T-SUB} \frac{\Gamma \vdash e : \sigma_1 \quad \Gamma \vdash \sigma_1 <: \sigma_2}{\Gamma \vdash e : \sigma_2}$$

$$\text{T-P-EPS} \frac{}{\Gamma \vdash \text{eps} : \text{PE}^{\text{pure}} \{\forall h. \text{true}\} \nu : \text{unit} \{\forall h, \nu, h'. h' = h\}}$$

$$\text{T-P-CHOICE} \frac{\Gamma \vdash p_1 : \text{PE}^{\varepsilon} \{\phi_1\} \nu_1 : \tau \{\phi'_1\} \quad \Gamma \vdash p_2 : \text{PE}^{\varepsilon} \{\phi_2\} \nu_2 : \tau \{\phi'_2\}}{\Gamma \vdash (p_1 < | > p_2) : \text{PE}^{\varepsilon \sqcup \text{nondet}} \{(\phi_1 \wedge \phi_2)\} \nu : \tau \{(\phi'_1 \vee \phi'_2)\}}$$

$$\text{T-P-FIX} \frac{\Gamma, x : (\text{PE}^{\varepsilon} \{\phi\} \nu : \mathbf{t}\{\phi'\}) \vdash p : \text{PE}^{\varepsilon} \{\phi\} \nu : \mathbf{t}\{\phi'\} \quad x \notin FV(\phi, \phi')}{\Gamma \vdash \mu x : (\text{PE}^{\varepsilon} \{\phi\} \nu : \mathbf{t}\{\phi'\}). p : \text{PE}^{\varepsilon} \{\phi\} \nu : \mathbf{t}\{\phi'\}}$$

$$\text{T-P-BIND} \frac{\begin{array}{c} \Gamma \vdash p : \text{PE}^{\varepsilon} \{\phi_1\} \nu : \mathbf{t}\{\phi_{1'}\} \quad \Gamma \vdash e : (x : \tau) \rightarrow \text{PE}^{\varepsilon} \{\phi_2\} \nu' : \mathbf{t}'\{\phi_{2'}\} \\ \Gamma' = \Gamma, x : \tau, h_i : \text{heap} \quad h_i \text{ fresh} \\ \Gamma' \vdash p \gg e : \\ \text{PE}^{\varepsilon} \{\forall h. \phi_1 h \wedge \phi_{1'}(h, x, h_i) \Rightarrow \phi_2 h_i\} \\ \nu' : \mathbf{t}' \text{ result} \\ \{\forall h, \nu', h', y. (x \neq \text{Err} \Rightarrow \nu' = \text{Inl } y \wedge \phi_{1'}(h, x, h_i) \wedge \phi_{2'}(h_i, y, h')) \wedge \\ (x = \text{Err} \Rightarrow \nu' = \text{Inr } \text{Err} \wedge \phi_{1'}(h, x, h_i))\} \end{array}}{\Gamma \vdash p \gg e : \text{PE}^{\varepsilon} \{\forall h. \phi_1 h \wedge \phi_{1'}(h, x, h_i) \Rightarrow \phi_2 h_i\} \nu' : \mathbf{t}' \{\phi_{2'}\}}$$

Subtyping $\boxed{\Gamma \vdash \sigma_1 <: \sigma_2}$

$$\begin{array}{c} \text{T-SUB-BASE} \frac{\Gamma \vdash \{\nu : \mathbf{t} \mid \phi_1\} \quad \Gamma \vdash \{\nu : \mathbf{t} \mid \phi_2\}}{\Gamma \vDash \phi_1 \Rightarrow \phi_2} \quad \text{T-SUB-SCHEMA} \frac{\Gamma \vdash \sigma_1 <: \sigma_2}{\Gamma \vdash \forall \alpha. \sigma_1 <: \forall \alpha. \sigma_2} \\ \text{T-SUB-ARROW} \frac{\Gamma \vdash \tau_{21} <: \tau_{11} \quad \Gamma \vdash \tau_{12} <: \tau_{22}}{\Gamma \vdash (x : \tau_{11}) \rightarrow \tau_{12} <: (x : \tau_{21}) \rightarrow \tau_{22}} \quad \text{T-SUB-TVAR} \frac{}{\Gamma \vdash \alpha <: \alpha} \\ \text{T-SUB-COMP} \frac{\Gamma \vDash \phi_2 \Rightarrow \phi_1 \quad \Gamma \vdash \tau_1 <: \tau_2 \quad \Gamma \vdash \varepsilon_1 \leq \varepsilon_2 \quad \Gamma, \phi_2 \vDash (\phi_{1'} \Rightarrow \phi_{2'})}{\Gamma \vdash \text{PE}^{\varepsilon_1} \{\phi_1\} \tau_1 \{\phi_{1'}\} <: \text{PE}^{\varepsilon_2} \{\phi_2\} \tau_2 \{\phi_{2'}\}} \end{array}$$

■ **Figure 7** Typing semantics for primitive parser expressions and subtyping rules.

Rule (T-P-FIX) defines the semantics for the terminating recursive fix-point combinator. Given an annotated type τ for the parameter x , if the type of the body p in an extended environment which has x mapping to τ , is τ , then τ is also a valid type for a recursive

fixpoint parser expression. The T-P-BIND rule defines a typing judgement for the exceptional monadic composition of a parser expression p with an abstraction e . The composite parser is typed in an extended environment (Γ') containing a binding for the abstraction's parameter x and an intermediate heap h_i that acts as the output/post-state heap for the first parser and the input/pre-state for the second. The relation between these heaps is captured by the inferred pre-and post-conditions for the composite parser. There are two possible scenarios depending upon whether the first parser p results in a success (i.e. $x \neq \text{Err}$) or a failure ($x = \text{Err}$).

In the successful case, the inferred conditions capture the following properties: a) the output of the combined parser is a success; b) the post-condition for the first expression over the intermediate heap h_i and the output variable x should imply the precondition of the second expression (required for the evaluation of the second expression); and, c) the overall post-condition relates the post-condition of the first with the precondition of the second using the intermediate heap h_i . The case when p fails causes the combined parser to fail as well, with the post-condition after the failure of the first as the overall post-condition. Note that the core calculus is sub-optimal in size since λ_{sp} supports both `return` and `eps`, even though the latter could be modeled using `return`. However, this design choice enables decidable typechecking by limiting the combination of higher-order functions, combinators and states. This is achieved using a limited bind $p \gg e$, rather than the general $e \gg e$, allowing for the definition of semantic actions e that only perform limited state manipulation, i.e., reading and updating locations. Thus \gg and $\langle | \rangle$ only take parser arguments; thus, $\text{eps} \langle | \rangle p$ is not equivalent to $(\text{return } () \langle | \rangle p)$, in fact the latter is disallowed. Another such design restriction shows up in the typing rules, e.g., the typing rule for function application (T-APP) restricts the arguments to be of *basetype*, thus disallowing expressions returning abstractions or computations, like $\text{return } (\lambda x. e)$ or $\text{return } (x := e)$. A more general definition for \gg will allow valid HO arguments, like $\lambda x. e \gg e1$, but translating such general HO stateful programs to decidable logic fragments is not always feasible, as is discussed in other fully dependent type systems [41].

The subtyping rules enable the propagation of refinement type information and relate the subtyping judgments to logical entailment. The subtyping rule for a base refinement (T-SUB-BASE) relates subtyping to the logical implication between the refinement of the subtype and the supertype. The (T-SUB-ARROW) rule defines subtyping between two function refinement types. The (T-SUB-COMP) rule for subtyping between computation types follows the standard Floyd-Hoare rule for *consequence*, coupled with the subtyping relation between result types and an ordering relation between effects (\leq). The subtyping rule for type variables (T-Sub-TVar) relates each type variable to itself in a reflexive way, while the subtyping for a type-schema lifts the subtyping relation from a schema to another schema.

4.4 Properties of the Type System

► **Definition 1** (Environment Entailment $\Gamma \models \phi$). Given $\Gamma = \dots, \overline{\phi_i}$, the entailment of a formula ϕ under Γ is defined as $(\bigwedge_i \phi_i) \implies \phi$

In the following, $\Gamma \models \phi(\mathcal{H})$ extends the notion of semantic entailment of a formula over an abstract heap $\Gamma \models \phi(h)$ to a concrete heap using an interpretation of concrete heap \mathcal{H} to an abstract heap h and the standard notion of well-typed *stores* ($\Gamma \vdash \mathcal{H}$).⁶

To prove soundness of Morpheus typing, we first state a soundness lemma for pure expressions (i.e. expressions with non-computation type).

⁶ Details are provided in the accompanied technical report [28].

► **Lemma 2** (Soundness Pure-terms). *If $\Gamma \vdash e : \{ \nu : \mathbf{t} \mid \phi \}$ then:*

- Either e is a value with $\Gamma \models \phi (e)$
- OR Given there exists a v , such that $(\mathcal{H}; e) \Downarrow (\mathcal{H}; v)$ then $\Gamma \vdash v : \mathbf{t}$ and $\Gamma \models \phi (v)$

► **Theorem 3** (Soundness Morpheus). *Given a specification $\sigma = \forall \bar{\alpha}. \text{PE}^\varepsilon \{ \phi_1 \} \nu : \mathbf{t} \{ \phi_2 \}$ and a Morpheus expression e , such that under some Γ , $\Gamma \vdash e : \sigma$, then if there exists \mathcal{H} such that $\Gamma \models \phi_1(\mathcal{H})$ then:*

1. Either e is a value, and: $\Gamma, \phi_1 \models \phi_2 (\mathcal{H}, e, \mathcal{H})$
2. Or, if there exists an \mathcal{H}' and v such that $(\mathcal{H}; e) \Downarrow (\mathcal{H}'; v)$, then
 - ◻ $\exists \Gamma', \Gamma \subseteq \Gamma'$ and (consistent $\Gamma \Gamma'$), such that:
 - a. $\Gamma' \vdash v : \mathbf{t}$.
 - b. $\Gamma', \phi_1 (\mathcal{H}) \models \phi_2 (\mathcal{H}, v, \mathcal{H}')$

where (consistent $\Gamma \Gamma'$) is a Boolean-valued function that ensures that $\forall x \in (\text{dom}(\Gamma) \cap \text{dom}(\Gamma'))$. $\Gamma \vdash x : \sigma \implies \Gamma' \vdash x : \sigma$. Additionally, $\forall \phi. \Gamma \models \phi \implies \Gamma' \models \phi$.

Proof. The soundness proof is by induction on typing rules in Figures 6 and 7, proving the soundness statement against the evaluation rules in Figures 5.⁷ ◀

5 Evaluation

5.1 Implementation

Morpheus is implemented as a deeply-embedded DSL in OCaml⁸ equipped with a refinement-type based verification system. It encodes the typing rules given in Section 4 and a parser translating an OCaml-based surface language of the kind presented in our motivating example to the Morpheus core, described in Section 3. To allow Morpheus programs to be easily used in an OCaml development, its specifications can be safely erased once the program has been type-checked. Note that a Morpheus program, verified against a safety specification is guaranteed to be safe when erased since verification takes place against a stricter memory abstraction; in particular, since Morpheus programs are free of aliasing by construction and thus remain so when evaluated as an ML program. This obviates the need for a separate interpreter/compilation phase and gives Morpheus-verified parsers efficiency comparable to the parsers written using OCaml parser-combinator libraries [30, 3].

Morpheus specifications typically require meaningful qualifiers over inductive data-types, beyond those discussed in our core language; in addition to the qualifiers discussed previously, typical examples include qualifiers to capture properties such as the length of a list, membership in a list, etc. Morpheus provides a way for users to write simple inductive propositions over inductive data types, translating them to axioms useful for the solver, in a manner similar to the use of *measures* and *predicates* in other refinement type works [38, 42]. For example, a qualifier for capturing the length property of a list can be written as:

```
qualifier len [] → 0 | len (x :: xs) → len (xs) + 1.
```

Morpheus generates the following axiom from this qualifier:

```
∀ xs : α list, x : α. len (x :: xs) = len (xs) + 1 ∧ len [] = 0
```

⁷ The **decidability** theorem and proofs for all the theorems are provided in the technical report [28].

⁸ <https://github.com/aegis-iisc/morpheus.git>

Morpheus is implemented in approximately 9K lines of OCaml code. The input to the verifier is a Morpheus program definition, correctness specifications, and any required qualifier definitions. Given this, Morpheus infers types for other expressions and component parsers, generates first-order verification conditions using the typing semantics discussed earlier, and checks the validity of these conditions.

5.2 Results and Discussions

We have implemented and verified the examples given in the paper, along with a set of benchmarks capturing interesting, real-world safety properties relevant to data-dependent parsing tasks. The goal of our evaluation is to consider the effectiveness of Morpheus with respect to generality, expressiveness and practicality. Table 1 shows a summary of the benchmark programs considered. Each benchmark is a Morpheus parser program affixed with a meaningful safety property (last column). The first column gives the name of the benchmark. The second column of the table describes benchmark size in terms of the number of lines of Morpheus code, without the specifications. The third column gives a pair D/P, showing the number of unique derived (D) combinators (like `count`, `many`, etc.) used in the benchmark from the Morpheus library, and the number of primitive (P) parsers (like `string`, `number`, etc.) from the Morpheus library used in the benchmark; the former provides some insight on the usability of our design choices in realizing extensibility. The fourth column lists the size of the grammar along with the number of production rules in the grammar. The fifth column gives the number of verification conditions generated, followed by the time taken to verify them (sixth column). The overall verification time is the time taken for generating verification conditions plus the time Z3 takes to solve these VCs. All examples were executed on a 2.7GHz, 64 bit Ubuntu. The next column quantifies the annotation effort for verification. It gives a ratio ($\#A/\#Q$) of required user-provided specifications (in terms of the number of conjuncts in the specification) to the total specification size (annotated + inferred). User-provided specifications are required to specify a top-level safety property and to specify invariants for fix expressions akin to loop invariants that would be provided in a typical verification task. Finally, the last column gives a high-level description of the data-dependent safety property being verified.

Our benchmarks explore data-dependent parsers from several interesting categories.⁹ The first category, represented by `ldris do-block`, `Haskell case-exp` and `Python while-statement`, capture parsing activities concerned with layout and indentation introduced earlier. Languages in which layout is used in the definition of their syntax require context-sensitive parser implementations [1, 2]. We encode a Morpheus parser for a sub-grammar for these languages whose specifications capture the layout-sensitivity property.

The second category, represented by `png` and `ppm` consider data-dependent image formats like PNG or PPM. Verifying data-dependence is non-trivial as it requires verifying an invariant over a monadic composition of the output of one parser component with that of a downstream parser component, interleaved with internal parsing logic.

The next category, captured by `xauction`, `xprotein`, and `health`, represent data-dependent parsing in data-processing pipelines over XML and CSV databases. For `xauction` and `xprotein`, we extend XPath expressions over XML to *dependent* XPath expressions. Given that XPath expressions are analogous to regular-expressions over structured XML data, *dependent* XPath expressions are analogous to dependent regular-expressions over XML.

⁹ The grammar for each of our implementations is given in the technical report [28].

■ **Table 1** Summary of Benchmarks : #Loc Loc defines the size of the parser implementation in Morpheus; D/P gives the number of derived/primitive combinator uses in the parser implementation; grammar size $G(\# \text{ prod})$ defines size of the grammar along with the number of production rules in the grammar; #VCs defines number of VCs generated; T(s) is the time for discharging these VCs in seconds; $(\#A/\#Q)$ defines the ratio of number of conjuncts used in the specification provided by the user ($\#A$) to the total number of conjuncts ($\#Q$) across all files in the implementation; Property gives a high-level description of the data-dependent safety property.

Name	# Loc	D/P	G(#prod)	# VCs	T (s)	(#A/#Q)	data-dependence
haskell	110	5/4	20 (7)	17	8.11	9/39	layout-sensitivity
idris	115	5/5	22(8)	33	10.46	7/26	layout-sensitivity
python	47	3/3	25 (7)	23	7.44	6/20	layout-sensitivity
ppm	46	5/2	21 (7)	20	5.33	4/9	tag-length-data
png chunk	30	3/4	10 (2)	12	3.38	2/7	tag-length-data
xauction	54	4/4	31 (10)	19	6.70	2/8	data-dependent XPath expression
xprotein	45	3/3	24(6)	22	6.23	4/10	data-dependent XPath expression
health	40	4/3	15(5)	13	4.56	2/8	data-dependent CSV pattern-matching
c typedef	60	4/4	14 (5)	21	6.78	4/16	context-sensitive dis- ambiguation
streams	51	4/2	12 (4)	16	5.21	2/9	safe stream manipu- lation

We use these expressions to encode a property of the XPath query over XML data for an online auction and protein database, resp. Note that verifying such properties over XPath queries is traditionally performed manually or through testing. In the case of **health**, we extend regular custom pattern-matching over CSV files to stateful custom pattern-matching, writing a data-dependent custom pattern matcher. We verify that the parser correctly checks relational properties between different columns in the database.

The next two categories have one example each: we introduced the **c typedef** parser in Section 2 that uses data dependence and effectful data structures to disambiguate syntactic categories (e.g., *typenamees* and *identifiers*) in a language definition. Benchmark **streams** defines a parser over streams (i.e. input list indexed with natural numbers).

5.2.1 Annotation overhead vs inference

There are some interesting things to note in the second to last column($\#A/\#Q$); First, as the benchmarks (grammars) become more complex, i.e., have a greater number of functions (sub-parsers), the ratio decreases (small is better). In other words, the gains of type-inference become more visible (e.g., **haskell**, **idris**, **c typedef**). The worst (highest) ratio is for the PPM parser. This parser is interesting because, even though the grammar is small, it makes multiple calls to fixpoint combinators. Thus, the user must provide specifications for the top-level parser and each fix-point combinator, thus increasing ($\#A$). Additionally, given a small number of functions (sub-parsers) due to small grammar size, the gains due to inference are also low. In summary, these trends show that the efforts needed for verification are at par with other Refinement typed languages like, Liquid Types [38], FStar [41], etc, and as the parsers become bigger, the benefits of inference become more prominent.

<pre> DoBlock ::= 'do' OpenBlock Do* CloseBlock; Do ::= 'let' Name TypeSig '=' Expr 'let' Expr '=' Expr Name '←' Expr Expr '←' Expr Ext Expr Expr </pre>	<pre> expr = do t ← term symbol "+" e ← expr pure t + e symbol '*' </pre>

■ **Figure 8** An Idris grammar rule for a do block and an example input.

5.3 Case Study: Indentation Sensitive Parsers

As a case study to illustrate Morpheus’s capabilities, we consider a particular class of stateful parsers that are *indentation-sensitive*. These parsers are characterized by having indentation or layout as an essential part of their grammar. Because indentation sensitivity cannot be specified using a context-free grammar, their specification is often specified via an orthogonal set of rules, for example, the offside rule in Haskell.¹⁰ Haskell language specifications define these rules in a complex routine found in the lexing phase of the compiler [26]. Other indentation-sensitive languages like Idris [4] use parsers written using a parser combinator libraries like Parsec or its variants [25, 19] to enforce indentation constraints.

Consider the Idris grammar fragment shown in Figure 8a. The grammar defines the rule to parse a `do`-block. Such a block begins with the `do` keyword, and is followed by zero or more `do` statements that can be `let` expressions, a binding operation (`←`) over names and expressions, an external expression, etc. The Idris documentation specifies the indentation rule in English governing where these statements must appear, saying that the “*indentation of each do statement in a do-block Do* must be greater than the current indentation from which the rule is invoked* [13].” Thus, in the Idris code fragment shown in Figure 8b, indentation sensitivity constraints require that the last statement is not a part of the `do`-block, while the inner four statements are. A correct Idris parser must ensure that such indentation rules are preserved.

Figure 9 presents a fragment of the parser implementation in Haskell for the above grammar, taken from the Idris language implementation source, and simplified for ease of explanation. The implementation uses Haskell’s Parsec library, it implements indentation rules using a state abstraction (called `IState`) that stores the current indentation level as parsing proceeds. The parser then manually performs reads and updates to this state and performs indentation checks at appropriate points in the code (e.g. line 24, 53). The `IdrisParser` (line 8) is defined in terms of Parsec’s parser monad over an Idris state (here, `IState`), which along with other fields has an integer field (`ist`) storing the current indentation value. A typical indentation check (e.g. see lines 22 - 24) fetches the current value of `ist` using `getIst`, fetches the indentation of the next lexeme using the Parsec library function `indent`, and compares these values.

The structure of the implementation follows the grammar (Figure 8a): the `doBlock` parser parses a reserved keyword “`do`” followed by a block of `do_` statement lists. The indentation is enforced using the parser `indentedDoBlock` (defined at line 49) that gets the

■ **Figure 9** A fragment of a Parsec implementation for Idris `do`-blocks with indentation checks.

current indentation value (`allowed`) and the indentation for the next lexeme using `indent`, checks that the indentation is greater than the current indentation (line 53) and updates the current indentation so that each `do` statement is indented with respect to this new value. It then calls a parser combinator `many` (line 56), which is the Parsec combinator for the Kleene-star operation, over the result of `indentedDo`, i.e., `indentedDo*`. The `indentedDo` parser again performs a manual indentation check, comparing the indentation value for the next lexeme against the block-start indentation (set earlier by `indentedDoBlock` at line 55) and, if successful, runs the actual `do_` parser (line 26). Finally, `indentedDoBlock` resets the indentation value to the value before the block (line 57).

Unfortunately, it is non-trivial to reason that these manual checks suffice to enforce the indentation sensitivity property we desire. Since they are sprinkled throughout the implementation, it is easy to imagine missing or misplacing a check, causing the parser to misbehave. More significantly, the implementation make incorrect assumptions about the

```

2      t ← term
3      do
4          symbol "+"
5          e ← expr
6          pure t + e
7      "mplus" pure t

```

■ **Figure 10** An input expression that is incorrectly parsed by the implementation shown in Figure 9.

effective actions performed by the library that are reflected in API signatures. In fact, the logic in the above code has a subtle bug [1] that manifests in the input example shown in Figure 10.

Note that the indentation of the token “mplus” is such that it is not a part of either do block; the implementation, however, parses the last statement as a part of the inner do-block, thereby violating the indentation rule, leading to the program being incorrectly parsed.

The problem lies in a mismatch between the contract provided by the library’s `indent` function and the assumptions made about its behavior at the check at line 24 in the `indentedDo` parser (or similarly at line 53). Since checking indentation levels for each character is costly, `indent` is implemented (line 28) in a way that causes certain lexemes (user defined operators like “mplus”) to be ignored during the process of computing the next indentation level. It uses a `lookAheadMatches` parser to skip all lexemes that are defined as operators. In this example, `indent` does not check the indentation of lexeme “mplus”, returning the indentation of the token `pure` instead. Thus, the indentation of the last statement is considered to start at `pure`, which incorrectly satisfies the checks at line 24 or line 53, and thus causes this statement to be accepted as part of `indentedDoBlock`. Unearthing and preventing such bugs is challenging. We show how implementing the same parser in `Morpheus` allows us to catch the bug and verify a correct version of the parser. Figure 11 shows a `Morpheus` implementation for a portion of the Idris `doBlock` parser from Figure 9 showing the implementation of three parsers for brevity, `doBlock`, `indentedDo`, and `indent`, along with other helper functions. The structure is similar to the original Haskell implementation.

To specify an *indentation-sensitivity* safety property, we first define an inductive type for a parse-tree (`tree`) and refine this type using a dependent function type, (`offsideTree i`), that specifies an indentation value for each parsed result.

```

type tree = Tree {term : pterm; indentT : int; children : tree list}
type offsideTree i = Tree {term : pterm; indentT : { v : int | v > i }; children : (offsideTree i) list}

```

This type defines a tree with three fields:

- A term of type `pterm`.
- The indentation (`indentT`) of a returned parse tree, the refinement constraints on `indentT` requires its value to be greater than `i`.
- A list of sub-parse trees (`children`) for each of the terminals and non-terminals in the current grammar rule’s right-hand side, each of which must also satisfy this refinement.

`Morpheus` additionally automatically generates *qualifiers* like, `indentT`, `children`, etc, for each of the datatype’s constructors and fields with the same name that can be used in type refinements. However, this type is not sufficiently expressive to specify the required safety property for `doBlock` that requires “*the indentation of the parse tree returned by doBlock must be greater than the current value of ist*” because `ist` is an effectful heap variable.

<pre> 1 type α pdo = DoExp of α 2 DoExt of α ... 3 type pterm = 4 PDoBlock of ((pterm pdo) list) 5 let ist = ref 0 ... 6 </pre>	<pre> 21 </pre>
<pre> doBlock : PE^{stexc} {\forall h, I. sel(h, ist) = I} ν : (offsideTree I) result {\forall h, ν, h', I, I'. (ν = Inl(_) => (sel(h, ist) = I \wedge sel(h', ist) = I') => I' = I) \wedge ν = Inr(Err) => (sel(h', inp) \subseteq sel(h, inp)) } </pre>	<pre> indentedDo : PE^{stexc} {\forall h, I. sel(h, ist) = I } ν : tree result {\forall h, ν, h', I, I'. \forall i :int. (i <= I => sel(h', inp) \subseteq sel(h, inp)) \wedge (i > I => indentT(ν) = pos(sel(h, inp)) \wedge children(ν) = nil)} </pre>
<pre> 7 let doBlock = 8 do_m 9 dot \leftarrow reserved "do" 10 ds \leftarrow indentedDoBlock 11 return Tree {term = PDoBlock ds; 12 indentT = indentT(dot); 13 children = (dot :: ds) } 14 </pre>	<pre> 22 23 24 allowed \leftarrow !list 25 i \leftarrow indent 26 if (i <= allowed) then 27 fail("end of block") 28 else 29 do_ 30 </pre>
<pre> do_ : PE^{stexc} {\forall h, I. sel(h, inp) = I} ν : tree result {\forall h, ν, h', I, I'. (ν = Inl(_) => indentT(ν) = pos(sel(h, inp)) children(ν) = nil) \wedge ν = Inr(Err) => (sel(h', inp) \subseteq sel(h, inp)) } </pre>	<pre> 31 32 </pre>
<pre> 15 let do_ = ... 16 </pre>	<pre> 31 32 </pre>
<pre> lookAheadMatches : PE^{pure} {true} ν : bool { [h'=h] } </pre>	<pre> 31 32 </pre>
<pre> 17 lookAheadMatches p = 18 do_m 19 match \leftarrow lookAhead (optional p) 20 return (isJust match) </pre>	<pre> 33 34 35 if (lookAheadMatches (operator)) then 36 do_m 37 operator 38 return (sourceColumn !inp) 39 else 40 return (sourceColumn !inp) </pre>

■ **Figure 11** Morpheus implementation and specifications for a portion of an Idris Do-block with indentation checks, `dom` is a syntactic sugar for Morpheus’s monadic bind. Specifications given in Blue are provided by the parser writer; Gray specifications are inferred by Morpheus. Line number 21 represents the complete multiline type specification.

We can specify a safety property for a `doBlock` parser as shown on line 6 in Figure 11. Again, the type specification in blue are provided by the programmer. The type should be understood as follows: The effect label (`stexc`) defines that the possible effects produced by the parser include `state` and `exc`. The precondition binds the value of the mutable state variable `ist`, a reference to the current indentation level, to `l` via the use of the built-in qualifier `sel` that defines a select operation on the heap [27]. The return type (`offsideTree l result`) obligates the computation to return a parse tree (or a failure) whose indentation must be greater than `l`. The postcondition constraints that the final value of the indentation is to be reset to its value prior to the parse (a *reset* property) when the parser succeeds (case $\nu = \text{Inl}(_)$) or that the input stream `inp` is monotonically consumed when the parser fails (case $\nu = \text{Inr}(\text{Err})$). The types for other parsers in the figure can be specified as shown at lines 14, 21, 32, etc.; these types shown in gray are automatically inferred by Morpheus’s type inference algorithm.

5.3.1 Revisiting the Bug in the Example

The **bug** described in the previous paragraph is unearthed while typechecking the `indentedDo` implementation or the `indentedDoBlock` implementation. We discuss the case for `indentedDo` case here. To verify that `doBlock` satisfies its specification, Morpheus needs to prove that the type inferred for the body of `indentedDo` (lines 22- 29):

1. has a return type that is of the form, `offsideTree I`. Concretely, the indentation of the returned tree must be greater than the initial value of `ist` (i.e. `indentT (ν) > I`).
2. asserts that the final value of `ist` is equal to the initial value.

Goal (1) is required because `indentedDo` is used by `indentedDoBlock` (see Figure 9), which is then invoked by `doBlock`, where its result constructs the value for `children`, whose type is `offsideTree I list`. Goal (2) is required because `doBlock`'s specified post-condition demands it. Type-checking the body for `indentedDo` yields the type shown at line 21. The two conjuncts in the post-condition correspond to the *then* (failure case) and *else* (success case) branch in the parser's body.

The failure conjunct asserts that the input stream is consumed monotonically if the indentation level is greater than `ist`. The success conjunct is the post-condition of the `do_` parser. This inferred type is, however, too weak to prove goal (1) given above, which requires the combinator to return a parse tree that respects the offside rule. The problem is that `indent`'s type (line 32), inferred as:

```
indent : PEstate{true}  $\nu$  : int { $\forall h, \nu, h'. \text{sel}(h', \text{inp}) \subseteq \text{sel}(h, \text{inp})$ }
```

does not allow us to conclude that `indentedDo` satisfies the indentation condition demanded by `doBlock`, i.e., that it returns a well-typed (`offsideTree I`). This is because the type imposes no constraint between the integer `indent` returns and the function's input heap, and thus offers no guarantees that its result gives the position of the first lexeme of the input list.

We can revise `indent`'s implementation such that it does not skip any reserved operators and always returns the position of the first element of the input list, allowing us to track the indentation of every lexeme:

```
indent : PEstate{true}  $\nu$  : int{ $\forall h, \nu, h'. \nu = \text{pos}(\text{sel}(h, \text{inp})) \wedge \text{sel}(h', \text{inp}) \subseteq \text{sel}(h, \text{inp})$ }
let indent = dom s ← !inp
return (sourceColumn s)
```

This type defines a stronger constraint, sufficient to type-check the revised implementation and raise a type error for the original. For this example, Morpheus generated 33 Verification Conditions (VCs) for the revised successful case and 6 VCs for the failing case. We were able to discharge these VCs to the SMT Solver Z3 [7], yielding a total overall verification time of 10.46 seconds in the successful case, and 2.06 seconds in the case when type-checking failed.

This example highlights several key properties of Morpheus verification: The specification language and the type system allows verifying interesting properties over inductive data types (e.g., the `offsideTree` property over the parse trees). It also allows verifying properties dependent on state and other effects such as the *input consumption* property over input streams (`inp`). Secondly, the annotation burden on the programmer is proportional to the complexity of the top-level safety property that needs to be checked. Finally, the similarities between the Haskell implementation and the Morpheus implementation minimize the idiomatic burden placed on Morpheus users.

6 Related Work

Parser Verification. Traditional approaches to parser verification involve mechanization in theorem provers like Coq or Agda [29, 6, 10, 21, 39, 23, 15]. These approaches trade-off both automation and expressiveness of the grammar they verify to prove full correctness. Consequently, these approaches cannot verify safety properties of data-dependent parsers, the subject of study in this paper. For instance, RockSalt [29] focuses on regular grammars, while [21, 10] present interpreters for parsing expression grammars (without nondeterminism) and limited semantic actions without data dependence. Jourdan et al. [16] gives a certifying compiler for LR(1) grammars, which translates the grammar into a pushdown automaton and a certificate of language equivalence between the grammar and the automaton. More recently CoStar [23] presents a fully verified parser for the ALL(*) fragment mitigating some of the limitations of the above approaches. However, unlike *Morpheus*, CoStar does not handle data-dependent grammars or user-defined semantic actions.

Deductive synthesis techniques for parsers like Narcissus [8] and [37] focus mainly on tag-length-payload, binary data formats. Narcissus [8] provides a Coq framework (an `encode_decode` tactic) that can automatically generate correct-by-construction encoders and decoders from a given user format input, albeit for a restricted class of parsers. Notably, the system is not easily extensible to complex user-defined data-dependent formats such as the examples we discuss in *Morpheus*. This can be attributed to the fact that the underlying `encode_decode` Coq tactic is complex and brittle and may require manual proofs to verify a new format. In contrast, *Morpheus* enables useful verification capabilities for a larger class of parsers, albeit at the expense of automatic code generation and full correctness. Writing a safe parser implementation for a user-defined format in *Morpheus* is no more difficult than manually building the parser in any combinator framework with the user only having to provide an additional safety specification. EverParse [37] likewise focuses mainly on binary data formats, guaranteeing full-parser correctness, albeit with some expressivity limitations. For example, it does not support user-defined semantic actions or global data-dependences for general data formats. Compared to these efforts, the properties *Morpheus* can validate are more high-level and general. E.g., “non-overlapping of two lists of strings” in a C-decl parser; “layout-sensitivity properties”, etc.. Verifying these properties requires reasoning over a challenging combination of rich algebraic data types, mutable states, and higher-order functions.

[22] also explore types for parsing, defining a core type-system for context-free expressions. However, their goals are orthogonal to *Morpheus* and are targeted towards identifying expressions that can be parsed unambiguously.

Data-dependent and Stateful Parsers. *Morpheus* allows writing parsers for data-dependent and stateful parsers. There is a long line of work aimed at writing such parsers [14, 1, 2, 24]. None of these efforts, however, provide a mechanism to reason about the parsers they can express. Further, many of these systems are specialized for a particular class/domain of problems, such as [14] for data-dependent grammars with trivial semantic actions, or [1] for indentation sensitive grammars, etc. *Morpheus* is sufficiently expressive to both write parsers and grammars discussed in many of these approaches, as well as verifying interesting safety properties. Indeed, several of our benchmarks are selected from these works. In contrast, systems such as [14] argue about the correctness of the input parsed against the underlying CFG, a property challenging to define and verify as a *Morpheus* safety property, beyond simple string-patterns and regular expressions. We leave the expression of such grammar-related properties in *Morpheus* as a subject for future work.

Refinement Types. Our specification language and type system builds over a refinement type system developed for functional languages like Liquid Types [38] or Liquid Haskell [43]. Extending Liquid Types with *bounds* [42] provides some of the capabilities required to realize data-dependent parsing actions, but it is non-trivial to generalize such an abstraction to complex parser combinators found in Morpheus with multiple effects and local reasoning over states and effects.

Effectful Verification. Our work is also closely related to dependent-type-based verification approaches for effectful programs based on monads indexed with either pre- and post-conditions [31, 32] or more recently, predicate monads capturing the weakest pre-condition semantics for effectful computations [41]. As we have illustrated earlier, the use of expressive and general dependent types, while enabling the ability to write rich specifications (certainly richer than what can be expressed in Morpheus), complicates the ability to realize a fully automated verification pathway.

Verification using natural proofs [36] is based on a mechanism in which a fixed set of proof tactics are used to reason about a set of safety properties; automation is achieved via a search procedure over in this set. This idea is orthogonal to our approach where we rather utilize the restricted domain of parsers to remain in a decidable realm. Both our effort and these are obviously incomplete. Another line of work verifying effectful specifications use characteristic formulae [5]; although more expressive than Morpheus types, these techniques do not lend themselves to automation.

Local Reasoning over Heaps. Our approach to controlling aliasing is distinguished from substructural typing techniques such as the ownership type system found in Rust [17]. Such type systems provide a much richer and more expressive framework to reason about memory and effects, and can provide useful guarantees like memory safety and data-race freedom etc. Since our DSL is targeted at parser combinator programs which generally operate over a much simplified memory abstraction, we found it unnecessary to incorporate the additional complexity such systems introduce. The integration of these richer systems within a refinement type framework system of the kind provided in Morpheus is a subject we leave for future work.

Parser Combinators. There is a long line of work implementing Parser Combinator Libraries and DSLs in different languages [11]. These also include those which provide a principled way for writing stateful parsers using these libraries [1, 24]. As we have discussed, none of these libraries provide an automated verification machinery to reason about safety properties of the parsers. However, since they allow the full expressive power of the host language, they may, in some instances, be more expressive than Morpheus. For example, Morpheus does not allow arbitrary user-defined higher-order functions and builds only on the core API discussed earlier. This may require a more intricate definition for some parsers compared to traditional libraries. For example, traditional parser combinator libraries typically define a higher-order combinator like `many_fold_apply` with the following signature and use this combinator to concisely define a *Kleene-star* parser:

```
many_fold_apply : f : ('b → 'a → 'b) → (a : 'a) → (g : 'a → 'a) → p : ('a, 's) t → ('b, 's) t
let many p = many_fold_apply (fun xs x → x :: xs) [] List.rev p
```

Contrary to this, in Morpheus, we need to define Kleene-star using a more complex, lower-level fixpoint combinator.

7 Conclusions

This paper presents Morpheus, a deeply-embedded DSL in OCaml that offers a restricted language of composable effectful computations tailored for parsing and semantic actions and a rich specification language used to define safety properties over the constituent parsers comprising a program. Morpheus is equipped with a rich refinement type-based automated verification pathway. We demonstrate Morpheus’s utility by using it to implement a number of challenging parsing applications, validating its ability to verify non-trivial correctness properties in these benchmarks.

Abstract

The preceding decade has seen significant interest in use of active learning to build models of programs and protocols. But existing algorithms assume the existence of an idealized oracle – a so-called Minimally Adequate Teacher (MAT) – that cannot be fully realized in practice and so is usually approximated with testing. This work proposes a new framework for active learning based on an incomplete teacher. This new formulation, called iMAT, neatly handles scenarios in which the teacher has access to only a finite number of tests or otherwise has gaps in its knowledge. We adapt Angluin’s L^* algorithm for learning finite automata to incomplete teachers and we build a prototype implementation in OCaml that uses an SMT solver to help fill in information not supplied by the teacher. We demonstrate the behavior of our iMAT prototype on a variety of learning problems from a standard benchmark suite.

1 Introduction

Automata are among the most basic structures in computer science, yet they continue to offer profound insights for modeling and analyzing systems. Recent years have seen renewed interest in the problem of *closed-box inference* of automata, often motivated by applications in verification and security – see [33] for an overview.

Leibniz International Proceedings in Informatics
LIPIC Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Many of the algorithms developed for closed-box inference are based on the *minimally adequate teacher* (MAT) framework, in which a Learner interacts with a Teacher (also sometimes referred to as an oracle) in an attempt to learn a finite automaton known by the Teacher. The Learner can pose two types of queries to the Teacher: membership queries (“does the automaton accept a given input word?”) and equivalence queries (“is a given automaton correct?”). It turns out that these primitives are sufficient to show that the MAT framework terminates and produces the correct automaton. Numerous variants of the basic algorithm have been proposed (e.g., L^* [2], KV [19], TTT [18] or $L^\#$ [34]), using different data structures to collect and organize gathered information. The MAT framework has also been instantiated for other kinds of automata – e.g. Mealy machines, weighted automata [5], and nominal automata [28] to name a few.

Contrary to its name, however, in many practical settings, even finding a Minimally Adequate Teacher is challenging. For example, consider learning a model of a closed-box system. How would the Teacher determine whether a given automaton supplied by the Learner captures the behavior of the closed-box system? The best the Teacher can do is check whether they agree on a finite set of tests. Likewise, in settings where the Teacher only has access to a set of positive and negative examples (also known as passive learning) it is unclear how to answer membership queries for inputs that lie outside of the example set.

This paper presents an alternative to MAT: the *incomplete* Minimally Adequate Teacher (iMAT) framework. An iMAT is allowed to answer “don’t care” in response to membership queries and it does not answer equivalence queries at all. We show that Angluin’s classic L^* algorithm can be instantiated with an incomplete Teacher, by using an SMT solver to help fill in the missing information without needlessly expanding the size of the automaton. More precisely, we show – under modest assumptions – that our algorithm infers the minimal automaton compatible with the information provided by the Teacher. We present an OCaml prototype and demonstrate its behavior on well-known benchmarks [23, 29].

We see the framework developed in this paper as a first step towards building connections between several different areas. As we explain later, iMAT provides a bridge between active and passive learning. In active learning, additional information can always be gathered (i.e., from the Teacher), whereas in passive learning, the assumption is that all of the information that will be used for learning has been gathered in advance. With iMAT, one can use the passive information as an incomplete Teacher and proceed to learn the automaton using active techniques like L^* . A lack of perfect information about the language in question also arises in program synthesis, in particular in the “programming by example” paradigm [7, 22, 23, 25, 36]. Here, the goal is to infer a model that is correct for the examples, and hope that it generalizes to other scenarios – i.e., that the examples are somehow representative of a more general pattern. We explore this connection in our use of benchmarks from ALPHAREGEX [23].

The problem of using finite information to infer a DFA was first studied by Gold in the 1970s [14], and has since been studied by many others [32, 30, 21, 20]. Gold showed that finding a DFA with the minimum number of states is NP-complete [15]. As iMAT subsumes DFA inference from finite data, its scalability is necessarily limited.

Others have studied problems similar to iMAT in prior work, either in their use of incomplete information or SAT solvers [8, 29, 17, 16, 24]. Leucker and Neider’s paper [24] includes an “inexperienced teacher” and surveys several learners with similar capabilities as ours. Section 10 presents a detailed survey of their paper and other related work. No previous work has studied iMAT in full generality, including: formulating the problem, establishing correctness, building an open-source implementation, and exploring alternate formulations. Hence, compared to prior work, this paper makes the following contributions:

1. We review the MAT framework (Section 2) which sets the stage for our formulation of active learning based on an incomplete Teacher (Section 3). We also adapt the notion of a Learner, giving it access to a Solver.
 2. We instantiate the iMAT framework in the context of DFAs, using an SMT solver to fill in missing information (Section 4).
 3. We prove that the Learner terminates and returns a minimal automaton compatible with the known information (Section 5).
 4. We show how to modify our learning algorithm in the presence of the more limited Teacher that uses a simpler interface for compatibility checks (Section 6), and prove a (partial) correctness result (Section 7).
 5. We implement the Learner in OCaml and present optimizations to accelerate the search for a DFA. We evaluate our proposed optimizations with an ablation study, and present performance data on a standard benchmark suite [23, 29].
- Next, we review MAT and L^* , to set the stage for the iMAT framework in later sections.

2 The MAT framework

In the MAT framework, a Learner seeks to discover an unknown language by interacting with a Teacher who can answer two types of queries:

Membership: The Learner sends a word u to the Teacher, who answers “yes” if u belongs to the language or “no” if it does not.

Equivalence: The Learner sends a hypothesis automaton \mathcal{H} to the Teacher, who either confirms that \mathcal{H} is correct or provides a counterexample.

The MAT framework has been the basis for active model learning since its introduction in the late 1980s, providing the basis for a variety of algorithms, data structures, and proof techniques (e.g. L^* [2], KV [19], TTT [18], L^\sharp [34], etc.). The rest of this section presents Angluin’s L^* algorithm, which introduces the notation and concepts used in this paper.

2.1 Strings, Languages, and Automata

Fix an alphabet of symbols, Σ . We let $a \in \Sigma$ denote an arbitrary symbol and ε the empty string. For strings (also called words) $u, v \in \Sigma^*$, we write uv for the concatenation of u and v (we will occasionally write $u.v$ for emphasis). We use capital letters $U, V \subseteq \Sigma^*$ to denote languages – i.e. sets of strings. Concatenation of languages U, V is written $U \cdot V = \{uv \mid u \in U, v \in V\}$. The set of prefixes for a string s is written $\text{prefixes}(s) = \{u \mid s = uv, u, v \in \Sigma^*\}$. Likewise, $\text{suffixes}(s) = \{v \mid s = uv, u, v \in \Sigma^*\}$. We sometimes even take prefixes of a set $S \subseteq \Sigma^*$, written $\text{prefixes}(S) = \{u \mid u \in \text{prefixes}(s), s \in S\}$. A set $S \subseteq \Sigma^*$ is called *prefix-closed* (*suffix-closed*) if $S = \text{prefixes}(S)$ ($S = \text{suffixes}(S)$). Finally, we denote the symmetric difference of two sets by $S \oplus S' = S - S' \cup S' - S$.

An important class of languages is that of *regular languages*, which are the languages accepted by deterministic finite automata (DFAs). A DFA is a five-tuple $D = (Q, \Sigma, \delta, q_0, F)$ where Q is a finite set of states, Σ is the alphabet, $\delta: Q \times \Sigma \rightarrow Q$ is the transition function, $q_0 \in Q$ is the start state, and $F \subseteq Q$ are the accepting states. The transition function is extended to strings inductively by $\hat{\delta}: Q \times \Sigma^* \rightarrow Q$, where for any $q \in Q$, $\hat{\delta}(q, \varepsilon) = q$ and for any $a \in \Sigma, u \in \Sigma^*$, $\hat{\delta}(q, au) = \hat{\delta}(\delta(q, a), u)$. A string u is accepted by the automaton D iff $\hat{\delta}(q_0, u) \in F$. Moreover, the language accepted by D , written $L(D)$, is the set of all such strings: $L(D) = \{u \in \Sigma^* \mid \hat{\delta}(q_0, u) \in F\}$.

21:4 Automata Learning with an Incomplete Teacher

■ **Figure 1** The Minimally Adequate Teacher framework.

Regular languages have unique minimal representatives: for every regular language, there is a unique DFA with a minimal number of states. There are different ways to build such minimal DFA corresponding to a regular language, but the one that is used to prove correctness of L^* is based on so-called Myhill-Nerode equivalence classes. Given a language L and a word $s \in \Sigma^*$, the Myhill-Nerode equivalence class of s , denoted $[s]_L$ is the set of all words s' satisfying: $s \equiv_L s' \stackrel{\Delta}{\iff} \forall e \in \Sigma^* \cdot (se \in L \iff s'e \in L)$. Myhill-Nerode equivalence classes provide an alternative characterization of regular languages: a language is regular iff it has a finite number of Myhill-Nerode equivalence classes. Furthermore, there is a one-to-one correspondence between the states of the minimal automaton accepting a regular language L and its Myhill-Nerode equivalence classes.

2.2 L^* : Data Structures

L^* is an algorithm that implements a Learner according to the interfaces in the MAT framework (see Figure 1). The core data structure used in the algorithm is an observation table, which records the information gathered from membership queries and the counterexamples obtained from equivalence queries.

► **Definition 1** (Observation Table). *Given a language $L \subseteq \Sigma^*$, an observation table (wrt L) is a triple (S, E, T) , where:*

- $S \subseteq \Sigma^*$ is a prefix-closed set of “accessor strings”;
- $E \subseteq \Sigma^*$ is a suffix-closed set of “distinguishing strings”;
- $T: (S \cup S \cdot \Sigma) \cdot E \rightarrow \{+, -\}$ is a map on a finite set of words defined by

$$T(u) = \begin{cases} + & u \in L \\ - & u \notin L \end{cases}$$

Note that once L is fixed, T is fully determined by S and E , so sometimes we refer to the observation table as simply (S, E) . We can think of $L \subseteq \Sigma^*$ as a function $L: \Sigma^* \rightarrow \{+, -\}$ and then simply write $T(u) = L(u)$. Every u in the domain of T is obtained as a concatenation of a string $s \in S \cup S \cdot \Sigma$ and $e \in E$.

Intuitively, one can think of an observation table as a snapshot of a language L . When L is regular, we will show how the table is organized in a way that its rows can be used to recover the Myhill-Nerode equivalence classes of L , and therefore the minimal deterministic automaton. The use of accessor strings and distinguishing strings to name the elements of S and E will become clear when we explain how to build a DFA from a table.

Consider the regular language $L = \{w \in \{a, b\}^* \mid w \text{ has at least one } a\}$, and sets $S = \{\varepsilon, a\}$, and $E = \{\varepsilon, b\}$. The observation table (S, E) is given on the left in Figure 2. When depicting the table, we divide it into an upper part and a lower part. The rows in the upper part are labelled by strings in S , whereas the rows of the lower part are labelled by strings in $S \cdot \Sigma - S = \{sa \mid s \in S, a \in \Sigma, sa \notin S\}$. The strings in E label the columns of the table. The entries of the table correspond to the function T .

■ **Figure 2** An observation table and corresponding automaton.

It is important to note that depicting the finite map $T: (S \cup S \cdot \Sigma) \cdot E \rightarrow \{+, -\}$ as a table leads to some repetition. For example, the entry in row a , column b must match the entry in row ab , column ε – i.e., since $a.b = ab.\varepsilon$ we also have $T(a.b) = T(ab.\varepsilon)$. It will be convenient to access the rows of the table as follows:

$$\text{row}: S \cup S \cdot \Sigma \rightarrow E \rightarrow \{+, -\} \quad \text{row}(s)(e) = T(se).$$

We will sometimes abuse notation and apply row to a set of strings to obtain a set of rows. For example, in the table above $\text{row}(S)$ is the set of distinct rows in the upper part of the table – $\text{row}(S) = \{\{\varepsilon \mapsto +, b \mapsto +\}, \{\varepsilon \mapsto -, b \mapsto -\}\}$. Additionally, when E is clear from the context, we will sometimes omit the column indices, writing $\text{row}(S) = \{++, --\}$.

To build a DFA from an observation table, we will use as states the upper rows of the table, but the well-definedness of the construction requires two properties to be satisfied¹.

► **Definition 2** (Closedness and Distinctness). *A table (S, E, T) is closed if for each string $s \in S$ and letter $a \in \Sigma$, we have $\text{row}(sa) \in \text{row}(S)$. It is distinct if all the rows labelled by $s \in S$ are distinct: $s, s' \in S \Rightarrow \text{row}(s) \neq \text{row}(s')$.*

Note that the example table above is closed and distinct. We can now make the connection between observation tables and finite automata precise.

► **Definition 3** (DFA associated with a table). *Given a closed and distinct table (S, E, T) , with distinct rows in S , we associate a DFA, $\mathcal{D}(S, E, T) = (Q, \Sigma, \delta, q_0, F)$, where:*

$$Q = \text{row}(S) \quad \delta(\text{row}(s), a) = \text{row}(sa) \quad q_0 = \text{row}(\varepsilon) \quad F = \{\text{row}(s) \mid \text{row}(s)(\varepsilon) = +\}.$$

The above definition relies on the fact that S is prefix-closed and E is suffix-closed and so both contain ε . Moreover, the transition function δ is well-defined whenever the table is closed and distinct. The first property ensures that $\text{row}(sa) \in Q$, whereas the second ensures the well definedness of $\delta(\text{row}(s), a)$.

The DFA corresponding to the example observation table is depicted on the right in Figure 2. The start state is indicated with an incoming arrow, and final state with a double circle. Each state is labeled by its unique row vector.

2.3 L^* learner

We are now ready to present L^* , the algorithm in which a Learner incrementally builds an observation table based on interactions with a Teacher as depicted in Figure 1. The L^* Learner is shown in Figure 3. It starts with $S = E = \{\varepsilon\}$ and then explores potential new

¹ Readers familiar with L^* will notice we jettisoned consistency for a simpler property – keeping the upper rows of the table distinct. This optimization is due to Maler and Pnueli [27].

1. Initialize $S = \{\varepsilon\}$, and $E = \{\varepsilon\}$
2. While (S, E, T) is not closed, do:
 - $S \leftarrow S \cup \{sa\}$,
 - where $s \in S, a \in \Sigma$, but $\text{row}(sa) \notin \text{row}(S)$.
3. Conjecture $M = \mathcal{D}(S, E, T)$:
 - a. If M is correct, halt.
 - b. Otherwise, $E \leftarrow E \cup \text{suffixes}(c)$, where c is the provided counterexample. Goto 2.

■ **Figure 3** Angluin’s L^* (Maler-Pnueli version). Whenever S and E change, T is updated using membership queries. Note the extensions of S and E preserve distinctness as an invariant.

rows by examining the rows in the lower part of the table (labelled by strings in $S \cdot \Sigma - S$). If no new rows are found (i.e., as compared to the ones in $\text{row}(S)$), then we conclude that the table is closed. If, on the other hand, a row in the lower part of the table does not appear in the upper part, there is a closedness defect, which can be repaired by adding another string to S . In essence, this repair moves a row from the lower part of the table to the upper part. Accordingly, we generate new rows in the lower part until there is a row in the table for each $s \in S\Sigma$. Once the Learner finds a closed table (distinctness is maintained by construction), it poses an equivalence query to the Teacher. If the hypothesis is wrong the Teacher returns a counterexample which is used to extend the columns of the table.

L^* can also be understood as incrementally discovering the Myhill-Nerode equivalence classes for the Teacher’s language \mathcal{L} , which correspond to the states of the minimal DFA. Since the start state always corresponds to the equivalence class for the empty string ε , it starts with the observation table where $S = \{\varepsilon\}$ and $E = \{\varepsilon\}$. Each hypothesis is a refinement of the previous guess, getting closer and closer to the correct minimal automaton. Termination of the algorithm follows as every closedness defect repaired or counterexample processed, results in an automaton with more states than the previous hypothesis.

2.4 L^* Example

Suppose we choose $\Sigma = \{a\}$ and the Teacher knows the language L described by the regular expression $a(aaa)^*$. The Learner begins by building the observation table below, on the left:

	ε
ε	-
a	+

	ε
ε	-
a	+
aa	-

(1)

The table on the left is not closed, because the row for a is not represented in the upper part of the table, hence the Learner extends S and this yields the table above in the middle. This table is closed so the Learner conjectures the corresponding DFA on the right.

The Teacher returns counterexample aaa (which is accepted by the automaton in Equation (1) but should be rejected).² The Learner processes this counterexample by extending E with its suffixes $\{\varepsilon, a, aa, aaa\}$, yielding the table on the left below:

² In general, there is no requirement for the Teacher to return the shortest counterexample and, indeed, the original complexity analysis of L^* takes into account that longer counterexamples might be returned resulting in larger than needed tables. Note that, however, minimality is never compromised as equal rows will be mapped to the same state in the automaton.

Figure 4 The Incomplete Minimally Adequate Teacher framework (iMAT).

	ε	a	aa	aaa
ε	-	+	-	-
a	+	-	-	+
aa	-	-	+	-

	ε	a	aa	aaa
ε	-	+	-	-
a	+	-	-	+
aa	-	-	+	-
aaa	-	+	-	-

The table on the left above is not closed, as row(aa) is different from all other rows. To fix this, the Learner adds aa to S yielding the table above, on the right. This table is closed and distinct, so the Learner makes the following conjecture which the Teacher accepts:

Angluin [2] showed that the L^* learner finds the minimal DFA for the target language using a polynomial number of membership queries – results which also apply to the Maler-Pnueli version. However, this property relies on the assumption that the Teacher can answer membership and equivalence queries.

The rest of this paper is devoted to introducing an alternative to the MAT framework, in which the Teacher is incomplete – it might not have answers to all the membership questions – but there is a third agent in the process that can help the Learner guess the missing information. We will then devise, implement, and evaluate an algorithm based on L^* .

The challenges in devising and implementing such an algorithm are two-fold: on the one hand, since we do not have access to arbitrary membership queries, we will be building a table that has *holes*; on the other hand, the notion of minimality is now with respect to the existing information. Hence, progress towards this automaton is not as simple as in L^* , requiring the use of heuristics to guess the missing information while still minimizing the size of the final automaton.

3 The iMAT Framework

This section introduces iMAT, a new framework for automata learning in which the Teacher is *incomplete* (see Figure 4). In iMAT, the Learner still wants to infer a regular language L , but the teacher only has partial information about the language. In particular, instead of holding an explicit language L , the Teacher is assumed to hold disjoint, possibly infinite sets of positive L_+ and L_- negative examples. The Learner seeks to find any language L such that $L_+ \subseteq L$ and $L_- \cap L = \emptyset$. In the literature, such an L is said to *separate* L_+ and L_- [8]. We assume that at least one regular L exists, but there may be several.³

³ Note that we do *not* require that L_+ or L_- be regular. For example, neither $L_+ = a^n b^n, n > 0$ nor $L_- = b^n a^n, n > 0$ are regular, but they are separated by $L = a^* b^*$.

-
1. $\text{worklist} \leftarrow [(\{\varepsilon\}, \{\varepsilon\})]$
 2. Call to SMT solver to fill in \square s with $+$ or $-$ in $\text{hd}(\text{worklist})$.
 - a. if UNSAT then:
 - i. $\text{worklist} \leftarrow \text{tl}(\text{worklist}) @ [(S \cup \{s'\}, E) \mid s' \in S \cdot \Sigma - S]$
 - ii. Goto step (2).
 - b. if SMT solver returns table (S, E) , build the corresponding DFA and make a validity query.
 - i. If the validity query succeeds, return the DFA.
 - ii. Otherwise, get a counterexample c , set $E' = E \cup \text{suffixes}(c)$, build table with \square 's (S, E') and set $\text{worklist} \leftarrow (S, E') :: \text{worklist}$; goto step (2).
-

■ **Figure 5** L^* with blanks algorithm, L_{\square}^* . We use '@' and '::' to denote standard list operations (i.e., append and cons). As before, we omit membership queries; these occur whenever S and E are changed. Since observation tables are fully determined by S and E , we elide T .

The iMAT framework has three components: a Learner, an incomplete Teacher, and a Solver. The Teacher answers two types of queries, like MAT, but with weaker assumptions: **Membership:** The Learner sends a word u to the incomplete Teacher, who answers with “yes” (+), “no” (-), or “unknown” (\square).

Validity: Given a hypothesis automaton, \mathcal{H} , the teacher determines whether $L_+ \subseteq L(\mathcal{H})$ and $L_- \cap L(\mathcal{H}) = \emptyset$. If so, it returns *None*, otherwise, it returns a counterexample string either in $L_+ - L(\mathcal{H})$ or in $L_- \cap L(\mathcal{H})$.

The other component in the iMAT framework is the Solver which the Learner can ask for help in completing the hypothesis construction. The solver answers just one type of query:

Completion: The Learner sends an incomplete hypothesis to the solver and asks whether there is a way to complete it into a full automaton. The Solver either says “yes” and returns a complete hypothesis or “no”.

iMAT’s Validity query is obviously similar to MAT’s Equivalence query, but it is different in an important way: an incomplete Teacher cannot return any string not in L_+ or L_- as counterexamples as it lacks information about those strings. Hence, a Validity query returns “yes” whenever there is no evidence against the hypothesis, which is subtly different than confirming the hypothesis directly. So while Validity may seem just as complex as Equivalence, we include it here as a first step toward more practical queries.

► **Remark 4.** Note that if the incomplete Teacher happens to be a complete oracle, then the iMAT setup can be used for MAT. Consider an iMAT instance where (i) the membership queries always return “yes” or “no” and (ii) the validity query returns a counterexample iff one exists. It follows that the hypothesis \mathcal{H} can be built without ever calling the Solver (and with the same membership query complexity as MAT) and Validity queries correspond precisely to Equivalence queries.

4 L_{\square}^* : an iterative iMAT Learner

We now present an iMAT Learner, closely following the approach used in L^* . In essence, looking back at the schema in Figure 4 we want to devise a learner that exploits the loop of membership-validity queries to promote a steady construction of a minimum-size automaton with the minimum amount of information. For the Solver component of iMAT we use an SMT solver (i.e., Z3 [11]).

The Learner holds a (sorted, in increasing size) worklist of candidate observation tables with \square 's. The algorithm works by constructing a worklist of potential hypotheses of increasing size, starting from a table with just ε as row and column labels.

We iteratively take each of these candidate tables and use an SMT solver to attempt filling in the \square 's (Completion) so that the table is closed and distinct (see Figure 6). Based on the result of the SMT query, we will either pass the completed table to the Teacher (Validity) or try another candidate table. If the Validity query succeeds, we return it. Otherwise, if we get a counterexample c , we refine the current hypothesis table by adding all the suffixes of c to E , and add the table (with \square 's) back to the worklist. The resulting iterative algorithm, L^* with blanks (L^*_\square), is shown in Figure 5.

Given an observation table, (S, E, T) :

1. Declare a Boolean variable b_s for each string $s \in (S \cup S \cdot \Sigma) \cdot E$ for which $T(s) = \square$.
2. For strings in L_+ or L_- , we fix the Boolean constraints:

$$\bigwedge_{s \in L_+} b_s = \text{true} \quad (\text{Positive Evidence})$$

$$\bigwedge_{s \in L_-} b_s = \text{false} \quad (\text{Negative Evidence})$$

3. Define a predicate to assert rows equal:

$$\text{Eq}(s, s') \triangleq \bigwedge_{e \in E} b_{se} = b_{s'e} \quad (\text{Rows equal})$$

4. Assert the table is closed:

$$\bigwedge_{s' \in S \cdot \Sigma - S} \bigvee_{s \in S} \text{Eq}(s, s') \quad (\text{Closed})$$

5. Define a predicate to represent the property that a row is unique (more precisely, that it is the first time the row appears):

$$\text{Unique}(s) \triangleq \bigwedge_{s' \in S: s' <_{\text{lex}} s} \neg \text{Eq}(s, s') \quad (\text{Row unique})$$

6. Declare a Boolean u_s for each string $s \in S$. We set u_s to true if row(s) is the first time that row appears:

$$u_s = \text{Unique}(s)$$

7. Assert the uniqueness of the rows in S (to maintain distinctness invariant):

$$\bigwedge_{s \in S} \text{Unique}(s)$$

■ **Figure 6** SAT encoding for table constraints.

21:10 Automata Learning with an Incomplete Teacher

When the SMT solver finds that the instance is unsatisfiable, we know that the table cannot be made closed, but we do not know which s from $S \cdot \Sigma - S$ we need to promote to S to fix things as we would in classic L^* . So we make progress by extending separate “copies” of S with each string in $S \cdot \Sigma - S$, and adding these tables to the worklist.

► **Remark 5.** By adopting the Maler-Pnueli variation of L^* , the rows in S will always be distinct and correspond to nodes in a prefix tree. The worklist of tables with \square 's is providing an enumeration of the search space of prefix trees that correspond to DFAs of increasing size. The SMT solver will essentially be checking for every entry of the worklist whether, for a given prefix tree corresponding to a table, the other transitions not in the tree can be filled in to be consistent with the data. For example, consider the following snapshot of a table in the worklist and the corresponding prefix tree:

	ε	a	aa	baa
ε	\square	-	\square	+
a	-	\square	-	\square
b	-	+	+	+
ba	+	+	+	\square
aa	\square	-	\square	\square
ab	\square	-	\square	\square
baa	+	+	\square	\square
bab	-	+	\square	\square
bb	-	+	+	\square

It turns out this table can be made closed and distinct – which indeed means the remaining transitions can be filled in. Here is the filled-in table and the resulting DFA:

	ε	a	aa	baa
ε	\boxplus	-	\boxplus	+
a	-	\boxplus	-	\boxplus
b	-	+	+	+
ba	+	+	+	\boxplus
aa	\boxplus	-	\boxplus	\boxplus
ab	\boxplus	-	\boxplus	\boxplus
baa	+	+	\boxplus	\boxplus
bab	-	+	\boxplus	\boxplus
bb	-	+	+	\boxplus

4.1 L^*_{\square} Example

We illustrate the L^*_{\square} algorithm (from Figure 5) with a teacher that starts with the following data: $L_+ = \{\varepsilon, aa, ab\}$ and $L_- = \{a, bb, abb\}$. We begin with the following table on the left as the only item in the worklist.

	ε
ε	+
a	-
b	\square

	ε
ε	+
a	-
ab	+
aa	+
b	\square

	ε
ε	+
a	-
ab	+
aa	+
b	\boxplus

Next, we pop the table on the left off of the worklist and send it to the solver. We can see that even without filling in the blanks that the solver will return UNSAT (observe row(a) cannot possibly match row(ϵ)). So we add a to S and b to S and append the two new tables to the worklist (which was empty). We pop the middle table above off of the worklist and send it to the SMT solver. The solver finds that filling the single blank with a $+$ satisfies the constraints, resulting in the table on the right. We conjecture the corresponding machine on the right and get counterexample bb . We then add the suffixes of bb to E , and enqueue the horizontally extended (S, E, T) to the head the worklist. Thus we again pop the updated table and attempt to fill it in:

	ϵ	b	bb
ϵ	+	□	+
a	-	+	-
ab	+	-	□
aa	+	□	□
b	□	-	□

	ϵ	b	ab
ϵ	+	-	+
b	-	-	□
a	□	+	□
bb	-	□	□
ba	□	□	□
ab	+	-	□
aa	+	□	□

The table on the left is unsat. So we branch our search out by add ab , aa , and b to S on three new tables and append each of them to the worklist (which currently only holds the table with $S = \{\epsilon, b\}$). For brevity, we fast forward to the table from the last step where b was added, shown above on the right. We take the table off the worklist and the solver successfully fills in the blanks. We then conjecture the machine that corresponds to this table and this is correct on all data in L_+, L_- so the algorithm returns it.

The reader may have noticed that several times we naively added all row labels from the lower part of the table, when we could have localized the problem to a single row causing the unsat (we skipped ahead to these tables). This intuition leads to an optimization based on unsatisfiable cores, which we describe in Section 8.1.

5 Correctness of L_{\square}^*

In this section, we show that the Learner L_{\square}^* we introduced in the previous section is correct: the algorithm terminates with the minimum size automaton compatible with L_+, L_- (Theorems 10 and 11). We first show that the search proceeds monotonically in the size of S (and therefore in the size of automata).

► **Lemma 6** (Size of work lists). *The worklists generated in Figure 5 can contain tables of at most 2 sizes, n and $n + 1$. When both are present, all the tables of size n are at the front.*

Proof. The initial worklist is $[(\{\varepsilon\}, \{\varepsilon\})]$. So there is one size, $|S| = 1$, and claim is trivially satisfied. As we enter the cycle with a worklist of size n in step (2) note that we add to the worklist in two places. In step 2(a), we add a list of items of size $n + 1$ so the property is maintained in both cases (it may be that the item we popped was the last one of size n , in which case the list is now a single size). In step 2(b), we process the counterexample and add the table back to the front of the worklist – since we do not modify S this is an item of size n and the property is maintained. ◀

The following definition expresses the notion that an observation table is “on the path” to identifying some target DFA, which will be useful shortly:

► **Definition 7** (Compatible Observation Table). *An observation table (S, E, T) is compatible with a DFA $M = (Q, \Sigma, \delta, q_0, F)$ if:*

1. *The function $q: S \rightarrow Q$ defined by $q(s) = \hat{\delta}(q_0, s)$ is injective,*
2. *The blanks can be filled in by M to make the rows of S distinct, and*
3. *For each s such that $T(s) \neq \square$, then $T(s) = +$ if and only if $s \in L(M)$. (i.e. M agrees with the non-blank entries of (S, E, T)).*

In other words, a table which is compatible with a target DFA can be extended to find the target DFA by adding zero or more strings to S while maintaining the invariant that each row corresponds to a unique state. The next lemma ensures that the worklist will always have some compatible table with a minimum DFA.

► **Lemma 8.** *Let $M = (Q, \Sigma, \delta, q_0, F)$ be a minimum-size DFA consistent with L_+, L_- . All worklists generated in the algorithm in Figure 5 contain at least one table (S, E, T) that is compatible with M .*

Proof. First observe that M has no unreachable states since it is minimal. Initially, the table $(\{\varepsilon\}, \{\varepsilon\})$ is compatible with M since (a) any function from $S = \{\varepsilon\}$ is injective and (b) there is only one row, so it is distinct. We now check that the algorithm maintains the invariant of having a compatible table in the worklist. As we enter the cycle with a worklist of length n , the only interesting case is when the compatible table (S, E, T) is the head of the list, since in all other cases it will clearly still be on the worklist at the next iteration. We proceed to analyse what happens while processing (S, E, T) :

- In Step 2(a), we know that (S, E, T) could not be made closed by filling in blanks, but by induction hypothesis that the rows of S are distinguished by M . Hence, for at least one $s \in S \cdot \Sigma - S$ we have that s accesses a new state in M (if this were not the case, then SAT instance could be satisfied using M as an oracle, since then each row in the lower part would match the row in the upper part corresponding to the state accessed). By the same argument, after adding this s to S , we know it will still be distinguishable from the other rows, because if it were not, then using M as an oracle would have satisfied the core. Hence, the table obtained by adding s to S is compatible with M .
- Step 2(b)(i) does not return, so we need not maintain the invariant.
- In Step 2(b)(ii), we do not change S , so that condition (a) of Definition 7 is immediate. Any rows which can be distinguished by M using only the suffixes in E are still distinguished by additional suffixes in E' . So (S, E', T') is compatible with M . ◀

We now prove a lemma which illustrates that the crux of the search is finding the correct prefix set, S . At this point, we will make a validity query (possibly incorrectly – but the table will be satisfiable) until we are correct. If we have a particular oracle in mind (i.e., any correct automaton), then the lemma says that if S contains accessor prefixes for the states of

the oracle (and E is large enough to distinguish states), the table will be satisfiable. To be clear, in the algorithm we of course do not use an oracle to fill in the blanks – we use an SMT solver as we do not yet know the automaton. The point is simply that the satisfiability of the SMT instance when a solution exists will be used to establish correctness.

► **Lemma 9** (Existence of a solution). *Let L_+, L_- be example sets, and let $\mathcal{A} = (Q, \Sigma, \delta, q_0, F)$ be a minimum state DFA consistent with L_+, L_- . Let (S, E, T) be an observation table that is compatible with \mathcal{A} and such that $|S| = |Q|$. Then there is a closed, distinct, complete observation table (S, E, T') where $T'(s) = T(s)$ for all $T(s) \neq \square$.*

Proof. Use the DFA \mathcal{A} as an oracle to complete the table: let $T'(s) = +$ if $s \in L(\mathcal{A})$, otherwise $T'(s) = -$. Since \mathcal{A} is consistent with the datasets, so $T(s) = T'(s)$ whenever $T(s) \neq \square$.

(closed) Let $s \in S, a \in \Sigma$. If $sa \in S$, we are done, so assume $sa \notin S$. Let $q = \hat{\delta}(q_0, sa)$. By hypothesis, there is a string $s' \in S$ such that $\hat{\delta}(q_0, s') = q$. Then for each $e \in E$, $T'(sae) = \hat{\delta}(q_0, sae) = \hat{\delta}(\hat{\delta}(q_0, sa), e) = \hat{\delta}(q, e) = \hat{\delta}(\hat{\delta}(q_0, s'), e) = \hat{\delta}(q_0, s'e) = T'(s'e)$. Thus $\text{row}(sa) = \text{row}(s')$.

(distinct) By the fact that (S, E, T) is compatible with \mathcal{A} , we have that using \mathcal{A} to fill in the blanks of T distinguishes all of the rows labeled by S . ◀

► **Theorem 10** (Partial Correctness). *If the algorithm terminates, then it returns a DFA of minimal size consistent with L_+, L_- .*

Proof. Let M be any minimal DFA for L_+, L_- . Then by Lemma 8, at each point there is an observation table on the worklist that is compatible with M . Assume the algorithm eventually terminates. In the worst case, it is when we find the table (S, E, T) with $|S| = n$, for n the number of states of M , (and potentially with $E = \text{suffixes}(L_+ \cup L_-)$). By Lemma 6, we traverse the worklist in nondecreasing order. Hence, if we terminated earlier, it was by conjecturing a correct machine smaller than n , which is a contradiction. ◀

All that remains to be shown is that we make progress towards this solution and indeed the algorithm terminates.

► **Theorem 11** (Termination). *The L_{\square}^* algorithm terminates.*

Proof. Let M be a minimal DFA for L_+, L_- , and let (S, E, T) be a table in the worklist compatible with M guaranteed to exist by Lemma 8. Step 2(a) makes progress by increasing the size of S . Moreover, since there are finitely many automata M' whose size is less than or equal to M , there are only finitely many counterexamples we can get in Step 3(b) (because we never again misclassify an example we have seen). Each time we reach the compatible table, we enqueue a table with larger size by 1. When, at latest, we reach the compatible table whose size matches M , then we may need many, but only finitely many more validity queries before we are correct and terminate. ◀

6 Weakening the Teacher: iMAT with Distinguish

Next, we explore another kind of incomplete teacher that is not required to implement Validity queries, but only a weaker set of Distinguish queries. Two strings $s_1, s_2 \in \Sigma^*$ are said to be *distinguished* if there exists $e \in \Sigma^*$ such that,

- $s_1e \in L_+$ and $s_2e \notin L_+$ (or vice versa), or
- $s_1e \in L_-$ and $s_2e \notin L_-$ (or vice versa).

21:14 Automata Learning with an Incomplete Teacher

Membership: As before, the Learner sends a string u and the Teacher responds with “+” if $u \in L_+$, “-” if $u \in L_-$, and “ \square ” otherwise.

Distinguish: The learner sends two strings s_1 and s_2 , together with a finite “exclusion set” E , and the teacher responds “yes” with a suffix $e \notin E$ that distinguishes these two strings or “no” if it cannot distinguish the strings.

It should be clear that Distinguish queries are less powerful than Validity queries, as they only concern a pair of strings and not the full language. However, it turns out that when L_+ and L_- are finite, we can adapt the learner to still have a terminating procedure to learn a correct automaton. We prove these results in Section 7.

iMAT with Distinguish has close ties to foundational concepts in formal languages. In particular, the distinguish query is closely related to the Myhill-Nerode equivalence classes \equiv_L of the target language L .

► **Lemma 12.** *Given strings $s_1, s_2 \in \Sigma^*$ with distinguish \emptyset $s_1 s_2 = e$ for some $e \in \Sigma^*$, then there exists some language L that separates L_+ and L_- such that $s_1 \not\equiv_L s_2$. Moreover if, in addition, the result of membership queries to s_1e and s_2e are not \square , then for every L separating L_+ and L_- , we have that $s_1 \not\equiv_L s_2$.*

Proof. For the second claim, suppose $T(s_1e) \neq T(s_2e)$ and both are not \square . Without loss of generality, $T(s_1e) = +$ and $T(s_2e) = -$. Let L be any language separating L_+ and L_- . Clearly $s_1e \in L$ and $s_2e \notin L$. That $s_1 \not\equiv_L s_2$ follows from the definition of the Myhill-Nerode equivalence. Now for the first part, assume $T(s_1e) = -$ and $T(s_2e) = \square$ (the other cases are similar), and assume L is a regular language that separates L_+ and L_- . Then $L' = L \cup \{s_2e\}$ is also regular and separates L_+ and L_- . Moreover, for this L we have $s_1 \not\equiv_L s_2$. ◀

Although iMAT with Distinguish is guaranteed to terminate only when L_+ and L_- are finite, we can show that arbitrary problem instances can be modeled using finite instances. Hence, finite example sets are in a sense complete. More formally, suppose we are given possibly infinite sets of positive and negative examples L_+ and L_- . Then we can find finite subsets of L_+ and L_- that are sufficient for the Learner to recover the minimum-size DFA compatible with L_+ and L_- .

► **Theorem 13.** *Let $L_+, L_- \subseteq \Sigma^*$ be infinite, disjoint example sets (not necessarily regular), and let M be a minimum-size DFA that separates L_+ and L_- . Then there are finite subsets L_+, L_- such that M is also a minimum-size DFA separating L_+, L_- .*

Proof. Consider the set \mathcal{M} of all DFAs over Σ that have strictly fewer states than M . (Observe that \mathcal{M} is potentially very large, but finite). By the minimality of M on L_+, L_- , each $M' \in \mathcal{M}$ misclassifies a string from either L_+ or L_- . So we can define a function $c: \mathcal{M} \rightarrow \Sigma^*$ that maps each M' to one such counterexample string. Then the set $S = \{s \mid s = c(M'), M' \in \mathcal{M}\}$ is finite (in fact, $|S| \leq |\mathcal{M}|$). Moreover, we have by construction that for $S_+ = L_+ \cap S$ and $S_- = L_- \cap S$ that each $M' \in \mathcal{M}$ fails to separate S_+, S_- by misclassifying $c(M')$, so that M is a minimum-size separating automaton for S_+, S_- as needed. ◀

7 Correctness of L_{\square}^* with Distinguish

We now show how to adapt the L_{\square}^* to the situation that we only have an iMAT with Distinguish, not Validity. The idea is that we perform L_{\square}^* as before, but when we have a hypothesis machine, we do a series of distinguish queries instead of a validity query. Intuitively, we will ask a distinguish query for each pair of rows which are “made the same” by the hypothesis:

► **Definition 14** (Distinguish queries for a hypothesis). *Given a closed, distinct, complete table, (S, E, T) and associated DFA M , we say the distinguish queries for hypothesis M are:*

distinguish E s' s

for each $s' \in S \cdot \Sigma - S$ and for the unique s such that $\text{row}(s) = \text{row}(s')$.

Observe these distinguish queries are well-defined because each $s' \in S \cdot \Sigma - S$ is guaranteed to have a unique matching row in S .

The first theorem shows that if all of the distinguish queries for a hypothesis return None, then the hypothesis is correct.

► **Theorem 15** (Validity using Distinguish). *Suppose a learner has a hypothesis DFA $M = (Q, \Sigma, \delta, q_0, F)$ constructed from a closed, distinct, complete observation table (S, E, T) . Suppose also that the teacher returns None for all of the distinguish queries for M . Then $L_+ \subseteq L(M)$ and $L(M) \cap L_- = \emptyset$.*

Proof. We show the contrapositive. Suppose there is a counterexample string $c \in L_+$ such that $c \notin L(M)$ (without loss of generality; the other case is similar). It suffices to show that there is a distinguish query that is not None. First of all c cannot be in T since we inherit from L^* that hypotheses are correct on all evidence already considered. So we must have $c = s'_0 v_0$ for a prefix $s'_0 \in S \cdot \Sigma - S$, since $S \cdot \Sigma - S$ includes exactly one prefix of each word not in $S\Sigma$. By closedness of the table, there is an $s_0 \in S$ such that $\text{row}(s'_0) = \text{row}(s_0)$. Consider distinguish E s_0 s'_0 . If this query returns a suffix, we are done, so assume it is None. In particular, this means that $s_0 v_0 \in L_+$, since otherwise v_0 would be a response to the query. Moreover, since $\text{row}(s_0) = \text{row}(s'_0)$ we must have that $\hat{\delta}(\text{row}(s_0), v_0) = \hat{\delta}(\text{row}(s'_0), v_0)$, implying that $s_0 v_0 \notin L(M)$ and $s_0 v_0$ is also a counterexample. So, as before, there must be an $s'_1 \in S \cdot \Sigma - S$ and suffix v_1 such that $s_0 v_0 = s'_1 v_1$. Crucially, s_0 (as $s_0 \in S$) is a proper prefix of s'_1 , making v_1 a proper suffix of v_0 . Since, again, there must be an $s_1 \in S$ for which $\text{row}(s_1) = \text{row}(s'_1)$ We proceed by considering the query distinguish E s_1 s'_1 and applying the same reasoning, except that we have made progress because v_1 is a suffix of v_0 . Clearly we will see a distinguishing suffix after a finite number of these iterations: in particular by the time that $v_i = \varepsilon$, then $s'_i v_i = s'_i \in S \cdot \Sigma - S$. But that means s'_i is a string we have already seen and is also a counterexample (i.e., $s'_i \in L_+$ but rejected), which is impossible by the construction of the table (which means the distinguishing suffix must be at latest the previous round). ◀

We modify L_{\square}^* as follows:

1. Run L_{\square}^* until ready to make a validity query for hypothesis H .
2. In place of the validity query, make the distinguish queries for H .
 - a. If they are all None, stop and return H .
 - b. Otherwise, add the first suffix returned by the teacher to E , and return to Step 1.

► **Corollary 16.** *If the modified L_{\square}^* terminates, the learned machine is correct.*

Proof. This follows immediately from Theorem 15. ◀

Of course, this modified procedure is not guaranteed to terminate in general. For some sparse, infinite L_+ and L_- , it is possible for the teacher to have infinitely many suffixes that the learner must consider without making progress. For example, if we have $L_+ = (aa)^*$ and $L_- = (aaaa)^*a$, the learner will soon reach:

21:16 Automata Learning with an Incomplete Teacher

At this point, the Learner will ask the query distinguish $E \varepsilon aa$ and the trouble is that the teacher has an infinite set of suffixes to give in response to distinguish $E \varepsilon aa$, namely those strings in the set $(aa)^*a$. As a result, the procedure above will not terminate in this case. We are unaware of a query weaker than Validity that still guarantees termination – settling this is an interesting question for future work.

We do have, however, as a special case, guaranteed termination for finite example sets.

► **Corollary 17.** *Let L_+ and L_- be finite, disjoint sets of strings. A learner can still learn a correct automaton for L_+, L_- with only membership and distinguish queries.*

Proof. Run L_{\square}^* modified for distinguish. Because of Theorem 15, we need only show that it terminates. Each time through Step 2 that we do not terminate, the teacher returns a suffix e . But since we add e to E , the teacher can never return this suffix again, and since the examples are finite, they can only have finitely many suffixes. Termination follows. ◀

7.1 A Landscape of Teacher Queries

As we have already presented two variants of iMAT, it is natural to ask how it relates to other formulations of automata learning problems. In this section, we summarize some known results for a variety of queries provided by a Teacher including:

Query name	Type
membership	$\Sigma^* \rightarrow 2$
equivalence	$\text{DFA} \rightarrow \Sigma^* + 1$
membership $_{\square}$	$\Sigma^* \rightarrow \{+, -, \square\}$
distinguish	$\mathcal{P}_{\text{fin}}(\Sigma^*) \times \Sigma^* \times \Sigma^* \rightarrow \{+, -, \square\}$
validity	$\text{DFA} \rightarrow \Sigma^* + 1$

Recall that though equivalence and validity have the same type, they are provided by Teachers with different capabilities: an incomplete Teacher cannot return any string not in L_+ or L_- as counterexamples as it lacks information about those strings. Hence, a Validity query returns “yes” whenever there is no evidence against the hypothesis, which is subtly different than confirming the hypothesis directly, which is what a complete teacher proves through an Equivalence query.

We distinguish two classes of learning problems. For the first class, the Teacher knows a specific regular language and will not return “unknown” in response to Membership queries. Conversely, in the second class, the teacher is incomplete and may return “unknown” in response to Membership queries.

Teacher holds concrete regular language (i.e., no blanks)

Only Membership. Suppose we run L^* , but replace each equivalence query with a loop that queries all strings looking for a counterexample. It is a consequence of the Myhill-Nerode Theorem that this process will eventually discover the correct automaton. However, the Learner will never be able to determine that it has converged. If the Learner is told the number of states, a terminating procedure is possible [1].

Only Equivalence. We can obtain a trivial terminating procedure with only the equivalence query simply by conjecturing all automata in increasing order of states. Angluin [3] showed that we cannot improve the learner to a polynomial time procedure.

Membership and Equivalence. This is Angluin’s MAT: L^* is an efficient terminating procedure for determining the correct DFA [2]. See Section 2.

Teacher is incomplete (i.e., may return blanks)

Only Membership. Just as in the non-blanks case, a learner can identify a minimum-size correct machine eventually, but cannot determine that it has done so – so there is no terminating procedure. This is Gold’s notion of “identification in the limit” [13].

Membership and Validity. Because this problem subsumes all instances of DFA inference from finite data, it is NP-Hard [15] and cannot be approximated in polynomial time (unless $P = NP$) [32]. We give a terminating procedure, L_{\square}^* , in Section 4 and prove it correct in Section 5. The complexity comments from “Only Equivalence” also hold here.

Membership and Distinguish. We consider a modification of L_{\square}^* which produces a minimum-size automaton if it terminates. We explore this in Section 6.

8 Implementation

We have built an OCaml implementation of the learner (using Validity) presented in this paper. The goal of our implementation is to provide a reusable implementation of our framework in a functional language that can be used to explore the iMAT framework, run our algorithm, and implement other algorithms that use similar primitives. Our implementation consists of two packages: (i) `nerode`, a general library for regular languages, with data structures for regular expressions, DFAs, and NFAs, as well as conversions between them, and (ii) `nerode-learn`, which implements Angluin’s L^* algorithm, as well as the iMAT variants developed in this paper. The `nerode` package is approximately 2,400 lines of code, while the `nerode-learn` package is approximately 3,000 lines of code. We use Z3 as the backend solver for checking all SMT problems.

Data Structures

Our OCaml implementation uses the following types.

- Strings are encoded in a module called `Word`, where their representation is a list of Alphabet symbols. Alphabet symbols internally are `int`.⁴

```
type Word.t = Alphabet.symbol list
```

In particular, defining modules for `Word` and `Alphabet` allowed for a modular design and allows us to support different alphabets.

- The rows of the observation table (or more precisely, the labels of the rows) are encoded as a set of Words:

```
type RowLabels.t = WordSet.t
```

- The columns of the observation table are also encoded as a set of words:

```
type ColLabels.t = WordSet.t
```

⁴ We abuse OCaml syntax slightly: `type Word.t` is not a valid type definition, but we keep the module names to show our module boundaries, and concisely differentiate all of our types `t`.

21:18 Automata Learning with an Incomplete Teacher

- Individual entries in the observation table are encoded using the following data type:

```
type entry = True | False | Blank
```

Here, the constructors include `Plus`, `Minus`, and `Blank`.

- Thus we can encode the actual lookup function of the table as a map from words to entries:

```
type TblMap.t = entry WordMap.t
```

Putting these all together, an observation table is encoded as a record s, sa, e, t where s , sa , and e are sets of strings, and $tmap$ is a map from strings to entries:

```
type Table.t = {s : RowLabels.t; sa : RowLabels.t;
               e : ColLabels.t; tmap : TblMap.t}
```

When implementing algorithms on observation tables, there is an interesting data structure choice to be made. An obvious approach is to keep the entire table explicitly as a two-dimensional array. The advantage to this approach is that the row function corresponds precisely to rows in the array. The downside is that to update the entry for a string, one has to visit each location in the table corresponding to how the string can be decomposed into prefix and suffix. To avoid this, instead of keeping the whole table, we keep S , $S \cdot \Sigma - S$, and E as sets and T as a map from strings in $(S \cup S \cdot \Sigma) \cdot E$ to table entries. Thus entries for a string are updated everywhere they appear by a single update to T . The downside is that we must generate the row function “on the fly” by repeatedly accessing T .

Algorithms

We now present our OCaml implementation of L_{\square}^* . We encode the worklist as a list of tables, which is maintained as an argument in the main recursive loop. A collection of all entries in the observation tables is also maintained globally as an argument in the loop.

```
let wl : Table.t list = ...
let entry_map : entry WordMap.t = ...
```

The main algorithm is a recursive function that searches for the smallest table that is compatible with the given positive and negative examples:

```
let rec lstar_blanks wl (e: ColLabels.t) entry_map: Dfa.t =
  let t, entry_map = List.hd wl |> Table.extend_cols entry_map e in
  match fill_blanks_smt t with
  | None →
    let new_ts, entry_map' =
      List.fold
        ~f:(fun (ts_acc, em_acc) sa →
          let new_t, em_acc' = (Table.move_up em_acc sa t) in
          new_t::ts_acc, em_acc')
        ~init:([], entry_map) (Table.lower_rows t) in
    lstar_blanks (wl @ new_ts |> List.tl) e entry_map'
  | Some obs →
    let dfa = table_to_dfa obs in
    match conjecture dfa with
    | None → dfa
    | Some cex →
      lstar_blanks wl (ColLabels.union e (suffixes cex)) entry_map
```

For the most part, the OCaml implementation follows the pseudocode given in Figure 5, but there are a few differences. In particular, the columns of the tables (e) in the worklist are not updated until right before we attempt to fill them in. We keep a cumulative mapping from strings to table entries (`entry_map`) in the main loop, preventing redundant membership

queries, and we also accumulate the suffixes learned from counterexamples (e) in the main loop. Intuitively, this approach is sound because it is safe to share counterexamples across tables and thus have the same column labels (e) for each (see Lemma 19 below).

Operationally, the `lstar_blanks` function proceeds as follows. First, it removes an item t from the worklist. It adds additional suffixes in e to the table t , using membership queries to determine new column entries in e that cannot be found in `entry_map`, filling in t with `Plus`, `Minus`, or `Blank`; it also updates the entry collection `entry_map` with any new queries. Next, it attempts to fill the blanks in the observation table encoded by t , calling `fill_blanks_smt`, which uses an SMT solver as discussed below. If the SMT solver cannot find values for the blanks, the algorithm extends the worklist with each new table new_t obtained by adding one row from the bottom part of the table t , using `Table.add`, and recurses. It also updates the `entry_map` with any new query results while filling in new rows. Otherwise, the blanks can be filled, and it makes a conjecture to the teacher. If the conjecture is correct, we have the minimal DFA. Otherwise, the conjecture fails, so we add the suffixes for the new counterexample to e , keep t at the head of `wl`, and recurse.

Efficient SMT Encoding

The key to achieving good performance in any solver-aided algorithm, is having an efficient encoding of observation tables. We use the theory of bitvectors, which is widely supported by SMT solvers, to express the blank-filling constraints. Specifically, given a table with k columns, we encode the rows in the table as bitvector variables of length k . We add assertions to constrain the bitvectors so they correspond to the rows in the table⁵. For example, the bitvector variable for the j th row in the table would be declared as follows,

```
(declare-const s_j (_ BitVec k))
```

and if the entry in the i th column was positive, we would add an assertion:

```
(assert (= ((_ extract i i) s_j) #b1))
```

Alternatively, if the entry in the i th column were a blank, we would declare a bitvector variable of length 1 to encode the blank,

```
(declare-const b_ij (_ BitVec 1))
```

and add the corresponding constraint:

```
(assert (= ((_ extract i i) s_j) b_ij))
```

Hence, a model of the SMT formula corresponds to a way of filling in the blanks that is consistent with the positive and negative entries in the table.

Returning to our algorithm, recall that we need the rows in the upper part of the table to be distinct, and we need the table to be closed. For distinctness, we use the built-in `distinct` function from the bitvector theory. For closedness, we generate assertions stating that each row in the bottom part of the table must be equal to some row in the upper part.

For example, given the observation table on the left:

⁵ An earlier version used SAT, with individual entries as boolean variables, but we found that using the bitvector theory performed better

21:20 Automata Learning with an Incomplete Teacher

	ε	a
ε	+	□
a	□	-
b	□	+
aa	-	□
ab	□	□
ba	+	-
bb	□	□

 \Rightarrow

	ε	a
ε	+	⊠
a	⊠	-
b	⊠	+
aa	-	⊠
ab	⊠	⊠
ba	+	-
bb	⊠	⊠

Our SMT encoding would have 7 bitvectors of size 2, one for each row, and 7 bitvectors of size 1, one for each (unique) blank:

```
(declare-const s1 (_ BitVec 2)) (declare-const b1 (_ BitVec 1))
(declare-const s2 (_ BitVec 2)) (declare-const b2 (_ BitVec 1))
(declare-const s3 (_ BitVec 2)) (declare-const b3 (_ BitVec 1))
(declare-const s4 (_ BitVec 2)) (declare-const b4 (_ BitVec 1))
(declare-const s5 (_ BitVec 2)) (declare-const b5 (_ BitVec 1))
(declare-const s6 (_ BitVec 2)) (declare-const b6 (_ BitVec 1))
(declare-const s7 (_ BitVec 2)) (declare-const b7 (_ BitVec 1))
```

Note that in the table above, the blank in the first row, second column and the blank in the second row, first column must have the same value as they both encode the membership of the string a in the language. Our SMT encoding account for such constraints between blanks. Next, we add assertions to encode the entries in the table:

```
(assert(=((_ extract 1 1) s1) #b1)) (assert(=((_ extract 2 2) s1) b1))
(assert(=((_ extract 1 1) s2) b1)) (assert(=((_ extract 2 2) s2) #b0))
(assert(=((_ extract 1 1) s3) b2)) (assert(=((_ extract 2 2) s3) #b1))
(assert(=((_ extract 1 1) s4) #b0)) (assert(=((_ extract 2 2) s4) b3))
(assert(=((_ extract 1 1) s5) b4)) (assert(=((_ extract 2 2) s5) b5))
(assert(=((_ extract 1 1) s6) #b1)) (assert(=((_ extract 2 2) s6) #b0))
(assert(=((_ extract 1 1) s7) b6)) (assert(=((_ extract 2 2) s7) b7))
```

Note that the assertions reflect the fact the blanks in the first rows must be filled in with the same value, since they are both associated with the string “ a ”. We would also assert distinctness for the upper part,

```
(assert(distinct s1 s2 s3))
```

Finally, we would add assertions for closedness:

```
(assert(or (= s1 s4) (= s2 s4) (= s3 s4)))
(assert(or (= s1 s5) (= s2 s5) (= s3 s5)))
(assert(or (= s1 s6) (= s2 s6) (= s3 s6)))
(assert(or (= s1 s7) (= s2 s7) (= s3 s7)))
```

To fill in the rows in table, we can simply read off values assigned to the variables,

```
(define-fun b1 () (_ BitVec 1) #b0)
(define-fun b2 () (_ BitVec 1) #b1)
(define-fun b3 () (_ BitVec 1) #b0)
(define-fun b4 () (_ BitVec 1) #b1)
(define-fun b5 () (_ BitVec 1) #b0)
(define-fun b6 () (_ BitVec 1) #b1)
(define-fun b7 () (_ BitVec 1) #b0)
```

which corresponds to the table on the right above.

Teacher Module

Because our design relied on an abstract interface to the teacher, it was straightforward to implement the teacher in different ways. While the benchmarks we used for evaluation (Section 9) are lists of labeled examples, we also implemented a feature that allows the user to specify infinite L_+ and L_- using regular expressions. For example, we could specify $L_+ = (0101)^*$ and $L_- = 10^*$, and the system correctly identifies:

Note that the correct language has a smaller DFA than the one for L_+ !

8.1 Optimizations

We now look at several optimizations we implemented. The first one will reduce the number of tables generated in step 2(a) of Figure 5 by making use of unsat-cores; the second prevents the learner from making needlessly similar conjectures by reusing counterexamples that it gets from the teacher, and the third explores the use of a priority queue instead of a list.

Unsat-cores

When a table's blanks cannot be filled in by the SMT solver we explore the tables that result by adding each string from $S \cdot \Sigma - S$ to S . In many cases, however, we might be able to identify a row, say $s' \in S \cdot \Sigma - S$ that is already distinguished from every row in S by suffixes in E . In this case, any filling of the blanks would result in an unclosed table *because of this row*, so we can promote *only* this one, as in classic L^* .

To generalize this, we observe that the closedness assertion corresponding to the row s' above was unsatisfiable on its own. Modern SMT solvers can be configured to compute subsets of constraints that are unsatisfiable alone, called unsat cores, when returning “unsat” [26]. To justify that we are still guaranteed to find the minimal automaton boils down to extending the argument of Lemma 8:

► **Lemma 18.** *The invariant of Lemma 8 holds, even when L_{\square}^* is modified to add only tables resulting from promoting only strings in unsat core.*

Proof. The argument for Lemma 8 applies, but we need to justify that a string in the unsat core accesses a new state of M . This must be true, or else using M as an oracle would fill in the blanks to satisfy the unsat core. ◀

Suffix-set Sharing

The reader may have noticed that the L_{\square}^* Algorithm described above cleverly reuses counterexamples, accumulating the suffix set E . Hence, instead of maintaining a worklist with elements (S, E, T) , we only need a worklist that maintains prefix sets S for each individual table. For T , we maintain a cumulative mapping of strings to entries as a parameter in the main loop and simply update missing entries for columns of the popped table on each iteration. For E , we prove that sharing counterexamples is sound:

► **Lemma 19.** *Let M be a DFA, and let (S, E, T) be compatible with M and let (S, E', T') be a table such that $E \subseteq E'$. Then (S, E', T') is also compatible with M , where T' is the extension of T by membership queries for E' .*

Proof. Condition (a) of compatibility is immediate since S is unchanged. If M distinguishes the upper part rows with only the suffixes in E , they remain distinguished by E' , implying condition (b). Condition (c) holds by hypothesis. ◀

► **Corollary 20.** *The algorithm in Figure 5 is still guaranteed to produce minimal machines when modified to share a single E across the worklist.*

■ **Table 1** Performance results on established benchmarks. “Learn time” is the total time spent on an individual benchmark, while “Z3 time” is the time spent on a benchmark *within the SMT solver*. “Worklist items” are the number of tables processed from the worklist during learning.

Benchmark set	DFA Size	# Benchmarks	Mean Learn time (s)	Median Learn time (s)	Mean Z3 Time (s)	Mean worklist items
Lee, So, and Oh	2	1	0.0082	0.0082	0.0081	2.0000
	3	10	0.0234	0.0229	0.0226	5.0000
	4	9	0.0600	0.0417	0.0529	7.5556
	5	4	0.1676	0.1360	0.1401	19.0000
Oliveira and Silva	1	80	0.0056	0.0053	0.0055	1.0000
	2	15	0.0100	0.0093	0.0097	2.0667
	3	91	0.0226	0.0216	0.0213	4.0879
	4	84	0.0396	0.0338	0.0346	5.7619
	5	100	0.1237	0.0775	0.0935	8.6200
	6	105	0.3803	0.1684	0.2566	13.6381
	7	79	1.1251	0.6419	0.7583	20.0886
	8	93	10.6307	1.7830	6.1782	44.1613
	9	74	50.1672	7.7361	28.8381	96.8784
	10	25	98.0573	7.3782	65.2680	176.5200
	11	14	1498.4836	101.2503	988.9716	933.2857

Proof. Sharing E means instead of adding a counterexample to the current item’s E , traverse the worklist updating all E . By Lemma 19 adding additional strings to E does not affect compatibility, and so the invariant of Lemma 8 still holds and minimality follows. ◀

Heuristic prioritization

Our algorithm as described above uses a list that is sorted only by the size of the prefix set. By instead using a priority queue, we can apply heuristics to investigate tables which are more likely to be compatible with a minimal DFA (in the sense of Definition 7). Because we search monotonically by size, this trick can only save effort on the “last size searched,” since all smaller automata are checked first. Still, the number of prefix sets grows rapidly enough that the savings on even this last size justify the optimization.

9 Evaluation

To evaluate the performance of our implementation, we timed it on a portion of the benchmark sets created by Oliveira and Silva [29] (for their system BICA) and the benchmarks of Lee, So, and Oh⁶ [23]. We present summary data of these runs in Table 1 and Figure 7. Table 1 shows that median total learning times were consistently shorter than the mean total learning times, suggesting that, at each size, the more expensive examples are less common. The mean Z3 time column suggests the system spends around two-thirds of its running time in SMT solving at all sizes. The last column shows how the number of worklist items processed increases with DFA solution size. All benchmarks use the alphabet $\Sigma = \{0, 1\}$. We ran the experiments on a 2.10GHz Intel Xeon Silver 4216 machine with 512GB of memory.

⁶ We omit benchmark #9, which has a DFA solution of size 16.

■ **Figure 7** Performance on Oliveira and Silva benchmarks generated by automata of sizes 4 to 11.

Oliveira and Silva’s benchmark set is large: for each size from 4 states to 23 states, they produced 19 random DFAs. For each DFA, there are 5 sets of positive and negative example strings. Each example set is a set of 20 strings of length 30 produced by random walks on the generated DFA. Each problem also contains all the prefixes of those 20 strings. Using this process, they generated a total of 95 problems using each size of random DFA. Importantly, as a result of this generation process, it is very often the case that there is a smaller consistent machine than the one used in generation. In Table 1, summary data is presented for benchmarks generated from size 4 to size 11 machines, however, note that for Table 1 and Figure 8, the size shown is the size of the *learned* (i.e., minimum-size) automaton, not the one used to generate the examples.

From the results of our experiments, we conclude that the scalability of our system is limited. It is practical in cases where the DFA to be learned is of size 11 or smaller. However, in its current form, learning larger DFAs is prohibitively expensive (see Section 11 for a discussion of future work in this direction). In contrast, Heule and Verwer [17] report solving all of the Oliveira and Silva benchmarks for sizes 4 to 21 “within 200 seconds per instance,” although their method requires access to all of the finite examples at the start.

9.1 Evaluation of optimizations

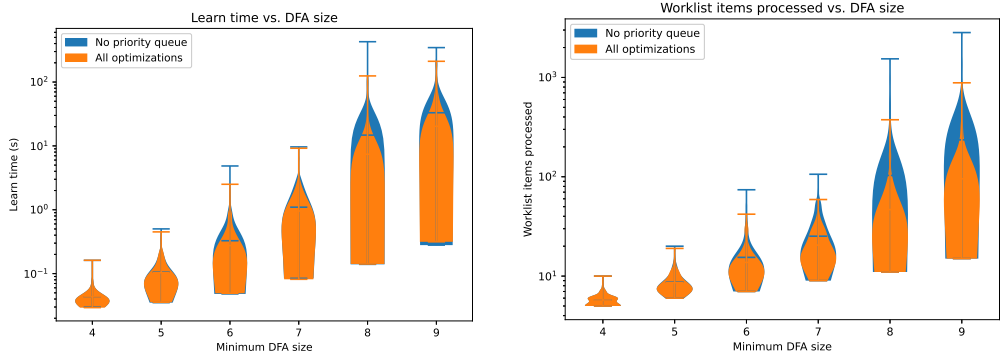

We evaluated the optimizations from Section 8.1 by conducting an ablation-style study, presented in Figure 8. The ablation study was performed in two stages. First, we ran the system on the Oliveira benchmarks (generated by sizes 4 to 9) with all optimizations turned on. Then, we ran the system on the same benchmarks a separate time for each of the three optimizations, with the optimization turned off. The results show significant time and search space savings for the unsat-cores optimization and heuristic prioritization. The “suffix-set sharing” optimization cannot affect the number of worklist items processed and turned out to result in an entirely negligible time improvement (these figures are omitted).

10 Related Work

DFA Inference from finite data. Inference of DFAs from finite data is a long standing problem and different solutions have appeared in the literature (see e.g [10] for an overview). Gold introduced the observation table and considered blank entries (“holes”) in the context of passive learning, but his algorithm does not guarantee minimality of the automaton produced [14]. Modern algorithms attack the problem from the perspective of “state

(a) Time reduction from unsat core optimization. (b) Search space reduction of unsat core optimization.

(c) Time reduction from heuristic prioritization. (d) Search space reduction of heuristic prioritization.

■ **Figure 8** Ablation study of optimizations proposed in Section 8.1. Data for “Suffix-set sharing” is omitted because it produced only negligible speedup.

merging” [30]. The main idea of these approaches is to build an automaton from the tree of all prefixes of positive examples, called the prefix tree acceptor (PTA), and then attempt to merge states, using the negative examples to validate merges. It is invariant that the positive examples are accepted, but a merge might cause a negative example to be accepted – in which case it is backtracked. Much research has gone into the selection of which merges to prioritize [21, 9]. State merging methods are much faster than the algorithm described in this paper but in general do not guarantee minimum size. A notable exception to this is the **exbar** Algorithm due to Lang [20], which gives a method for exhaustively exploring potential merges in a way that finding a minimum size DFA is guaranteed at exponential running time cost.

Inference of Separating Automata. Chen et al [8] use a similar notion of blanks in L^* (which they call “Don’t care”). The problem they solve is closely related, but it requires that the teacher start with two *regular* languages, for which they seek to find a minimal separating DFA. The algorithm they present, L^{sep} , computes the final DFA by first computing a 3-valued automaton (3DFA), which has “Don’t care” as output. They then convert this automaton to the minimum-size consistent DFA. Crucially, the interface they define with the teacher requires that the positive and negative example sets be regular languages. Thus in light of this restriction, the problem solved by L^{sep} may be seen as a special case of the iMAT setting.

DFA Inference using SAT solvers. Oliveira and Silva use constraint solvers to find a mapping from the states of a PTA to a particular size [29]. If the search fails, the size is increased until a DFA is found. Their work extends the method of Biermann and Feldman [6], who first explored such mappings from the PTA. Heule and Verwer [17] also use SAT solvers to infer DFAs from examples but their approach uses a SAT formulation closely tied to graph coloring. They first build a compatibility graph for states of the PTA, where states are compatible if their merge is not immediately ruled out by examples. The colors assigned in the coloring instance thus correspond to states in the smaller DFA, with the edges of the incompatibility graph ruling out incorrect merges.

Active learning of Network Invariants. Grinchtein, Leucker, and Piterman [16] present an algorithm that augments L^* to handle missing information with a SAT solver for inferring network invariants – i.e., in the sense of Wolper and Lovinfosse’s inductive technique verifying for large compositions of finite-state systems [35]. Their work, which improves the earlier method of Pena and Oliveira [31], extends the Angluin notions of table closedness and consistency to tables with blanks (called “weakly closed” and “weakly consistent”). The learner can proceed by performing L^* corresponding actions on tables while there are still blanks. Once the table is weakly closed and weakly consistent, they produce a series of SAT queries following Biermann and Feldman’s approach ([6], also mentioned below). The result of these SAT queries is a minimum-size automaton consistent with the examples in the table – in their scheme, they do not maintain the invariant that the minimum automaton is equal in size to the upper part of the table as in our approach, so they do not necessarily conjecture hypotheses monotonically.

In follow-on work Leucker and Neider [24] presented a framework which distills the essentials of the algorithm of [16] for learning DFAs. Their formal framework presents the teacher similar to our presentation in Section 3, but they do not highlight the solver as a first-class citizen in the framework and think of it as part of the Learner. They do give an overview of potential learners that work with inexperienced teachers. These encompass an approach without membership queries (a naive enumeration of all DFAs of increasing size) and the approach of [16] with a SAT solver, as well as the approach of [8], which we described above. They do not consider any modification similar to our iMAT with Distinguish, and they do not explore any implementation aspects or benchmarking.

11 Discussion

We have presented algorithms that solve the problem of automata inference from an incomplete teacher. The core ideas we applied to produce our algorithm are data structure agnostic and therefore a first direction for future work is whether we can adapt the work we did in this paper to recent optimizations of L^* , such as L^\sharp .

A particularly interesting optimization is the use of *discrimination trees*, an efficient replacement for observation tables [19, 18]. The first challenge will be to understand how the operations on discrimination trees can be generalized in the setting with \square ’s.

Another interesting direction would be to look at L^* variants developed for other automata models. We expect that the work in this paper applies directly to Mealy and Moore machines, with the caveat that the number of options for filling in blanks will be affected by the size of the output sets. But one could also explore how SMTs solvers could help in learning of weighted and symbolic automata, two models with interesting applications for which L^* -like algorithms were proposed [5, 4, 12].

Finally, there is another L^* adaptation, due to Bollig et al., that learns non-deterministic finite automata with access to an Angluin MAT. Another interesting direction for future work would be to investigate the adaptation of their approach to the incomplete setting.

A Another L_{\square}^* Example

Suppose we start with the following input.

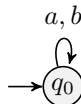

$$L_+ = \{ab, aab, bab, aaab, abab, baab, bbab\}$$

$$L_- = \{aa, ba, bb, aaa, baa, aba, bba, abb, bbb\}$$

We begin with the following table as the only item in the worklist.

	ε
ε	□
a	□
b	□

	ε
ε	⊠
a	⊠
b	⊠

We pop this table off of the worklist, and the SMT solver attempts to fill in its blanks. The solver finds that filling all the blanks with a - satisfies the constraints. We then conjecture the machine that corresponds to the filled-in table.

We get the counterexample *baab*, add its suffixes to *E*, and push the new (S, E, T) , below on the left, onto the top of worklist.

	ε	b	ab	aab	baab
ε	□	□	+	+	+
a	□	+	+	+	□
b	□	-	+	+	□

	ε	b	ab	aab	baab
ε	□	□	+	+	+
a	□	+	+	+	□
aa	-	+	+	□	□
ab	+	-	+	□	□
b	□	-	+	+	□

Now the table on the left is unsatisfiable. Hence, we add each element in $S\Sigma - S$ to *S* and add each resulting (S, E, T) to the tail of the worklist. Now the head of the worklist has $S = \{\varepsilon, a\}$ (table depicted on the right above), and the last item has $S = \{\varepsilon, b\}$. Once again, the solver fails because there is no way to fill in the blanks and maintain closedness. Once more, we add each element in $S\Sigma - S$ to *S* and add each new (S, E, T) to the tail of the worklist. Now the head of the worklist has $S = \{\varepsilon, b\}$, the next item has $S = \{\varepsilon, a, aa\}$, and the last item has $S = \{\varepsilon, a, ab\}$.

	ε	b	ab	aab	$baab$
ε	\square	\square	$+$	$+$	$+$
b	\square	$-$	$+$	$+$	\square
a	\square	$+$	$+$	$+$	\square
ba	$-$	$+$	$+$	\square	\square
bb	$-$	$-$	$+$	\square	\square

We pop the table above off of the worklist. Again the solver fails because there is no way to fill in the blanks and maintain closedness. We add each element in $S\Sigma - S$ to S and add each new (S, E, T) to the tail of the worklist. Now the head of the worklist has $S = \{\varepsilon, a, aa\}$, the next item has $S = \{\varepsilon, a, ab\}$, the next item has $S = \{\varepsilon, b, ba\}$, and the last item has $S = \{\varepsilon, a, bb\}$.

In the next step, we pop the table below on the left off of the worklist. Unsat again. We add each element in $S\Sigma - S$ to S and add each new (S, E, T) to the tail of the worklist. At the head of the list we now have the table on the right.

	ε	b	ab	aab	$baab$
ε	\square	\square	$+$	$+$	$+$
a	\square	$+$	$+$	$+$	\square
aa	$-$	$+$	$+$	\square	\square
aaa	$-$	$+$	\square	\square	\square
aab	$+$	\square	\square	\square	\square
ab	$+$	$-$	$+$	\square	\square
b	\square	$-$	$+$	$+$	\square

	ε	b	ab	aab	$baab$
ε	\square	\square	$+$	$+$	$+$
a	\square	$+$	$+$	$+$	\square
ab	$+$	$-$	$+$	\square	\square
aa	$-$	$+$	$+$	\square	\square
aba	$-$	$+$	\square	\square	\square
abb	$-$	\square	\square	\square	\square
b	\square	$-$	$+$	$+$	\square

This time SMT solver successfully fills in the blanks:

	ε	b	ab	aab	$baab$
ε	\boxplus	\boxplus	$+$	$+$	$+$
a	\boxplus	$+$	$+$	$+$	\boxplus
ab	$+$	$-$	$+$	\boxplus	\boxplus
aa	$-$	$+$	$+$	\boxplus	\boxplus
aba	$-$	$+$	\boxplus	\boxplus	\boxplus
abb	$-$	\boxplus	\boxplus	\boxplus	\boxplus
b	\boxplus	$-$	$+$	$+$	\boxplus

We get counterexample bbb , add its suffixes to E , and the head of the worklist becomes:

	ε	b	ab	aab	$baab$	bb	bbb
ε	\square	\square	$+$	$+$	$+$	$-$	$-$
a	\square	$+$	$+$	$+$	\square	$-$	\square
ab	$+$	$-$	$+$	\square	\square	\square	\square
aa	$-$	$+$	$+$	\square	\square	\square	\square
aba	$-$	$+$	\square	\square	\square	\square	\square
abb	$-$	\square	\square	\square	\square	\square	\square
b	\square	$-$	$+$	$+$	\square	$-$	\square

Finally the SMT solver successfully fills in the blanks:

21:30 Automata Learning with an Incomplete Teacher

	ε	b	ab	aab	$baab$	bb	bbb
ε	\square	\square	+	+	+	-	-
a	\square	+	+	+	\boxplus	-	\square
ab	+	-	+	\boxplus	\boxplus	\square	\square
aa	-	+	+	\boxplus	\boxplus	\square	\square
aba	-	+	\boxplus	\boxplus	\boxplus	\square	\square
abb	-	\square	\boxplus	\boxplus	\boxplus	\square	\square
b	\square	-	+	+	\boxplus	-	\square

The corresponding automaton is consistent with L_+ , L_- so we return it as the result.

Modular Verification of State-Based CRDTs in Separation Logic

Abstract

Conflict-free Replicated Datatypes (CRDTs) are a class of distributed data structures that are highly-available and weakly consistent. The CRDT taxonomy is further divided into two subclasses: state-based and operation-based (op-based). Recent prior work showed how to use separation logic to verify convergence and functional correctness of op-based CRDTs while (a) verifying implementations (as opposed to high-level protocols), (b) giving high level specifications that abstract from low-level implementation details, and (c) providing specifications that are modular (i.e. allow client code to use the CRDT like an abstract data type). We extend this separation logic approach to verification of CRDTs to handle state-based CRDTs, while respecting the desiderata (a)–(c). The key idea is to track the state of a CRDT as a function of the set of operations that produced that state. Using the observation that state-based CRDTs are automatically causally-consistent, we obtain CRDT specifications that are agnostic to whether a CRDT is state- or op-based. When taken together with prior work, our technique thus provides a unified approach to specification and verification of op- and state-based CRDTs. We have tested our approach by verifying StateLib, a library for building state-based CRDTs. Using StateLib, we have further verified convergence and functional correctness of multiple example CRDTs from the literature. Our proofs are written in the Aneris distributed separation logic and are mechanized in Coq.

1 Introduction

Conflict-free Replicated Data Types (CRDTs) are a class of distributed data structures that trade off strong consistency in favour of high availability. That is, local updates are not blocked by inter-replica synchronization; instead, they are immediately applied locally, and

then propagated to other replicas. Because of the lack of synchronization, CRDTs need a mechanism for resolving conflicting updates: a typical strategy is to make all updates commutative, so that they can be applied in any order.

There are two main implementation strategies for CRDTs, differing in how updates are propagated. *Operation-based* (op-based) CRDTs propagate local updates by reifying updates as operations, which are then transmitted to other nodes. Once these (now remote) operations are received by other replicas, they can be applied to their local states so they can “catch up”. By contrast, in *state-based* CRDTs, an update is first applied to the local state, and then the *state* is propagated to other replicas. This is achieved by letting the state be an element of a join-semilattice, constraining updates to be monotonic, and combining local and remote states via the lattice’s join operator. The choice of implementation style for a CRDT (op vs state-based) incurs several tradeoffs. Op-based based CRDTs are conceptually simpler, but make assumptions about the underlying delivery mechanism (e.g. at most once delivery). By contrast, the state-based approach can easily cope with duplicates and messages delivered out of order, because the merge operation (modelled with joins) is idempotent, associative, and commutative. On other hand, not only must the datatype semantics be encoded via joins, but also sending the entire state across the network might be inefficient.

Figure 1 shows a *grow-only counter* (g-counter) CRDT implemented in both styles. A g-counter is a datatype with two operations: it can be read and it can be incremented by a non-negative number. The op-based implementation defines the counter’s initial state (0), an `effect` function that adds the value we are incrementing by to the counter’s current state, and a `read` function that is just the identity. An *event* is a tuple containing an operation (the value to increment by) plus metadata, including the replica id where the operation originated. The state-based g-counter is more complex. The counter’s state is kept as a list of integers tracking each replica’s contribution to the counter’s value. The initial state is the list of all zeroes with size `numRep`, the number of replicas. A `mutator` function takes the current state and the increment value, and returns the updated list where the right entry, as determined by the operation’s origin, was incremented. The `merge` function takes two states and computes their join in the underlying lattice. For the g-counter, we take the pointwise maximum of the two lists. Finally, to read the value of the g-counter we just sum all entries in the state list. These purely functional implementations capture the g-counter’s core logic, but do not show how events are propagated between replicas.

The standard consistency model for CRDTs is *Strong Eventual Consistency* (SEC). SEC can, in turn, be divided into two sub-properties: *convergence* (two replicas that have processed the same set of updates must be in the same state) and *eventual delivery* (any update sent by a replica will eventually be delivered to all other replicas).

Additionally, the guarantees of SEC are sometimes strengthened to imply *causal consistency* [2], meaning that the causal order of updates is respected. In other words, given updates u and w , if u happened before w at a replica [12], then u must be processed before w at all other replicas. Causal consistency captures programmer’s intuitions on how the order of operations should be preserved; for example, it implies that reads are monotonic: a read always returns data that is “fresher” than what previous reads have returned.

1.1 Denotational Specifications

Specifying CRDTs is tricky because of their replicated nature and relaxed consistency model. Some works adopt SEC as the correctness criteria and do not provide functional correctness specifications of CRDTs [18, 7, 17]. Eventual consistency is a key correctness property, but this approach has at least two (related) shortcomings. First, given, e.g., a g-counter

```

(* op-based g-counter *)
let init = 0

let effect st e =
  let (op, _, _) = e in
  st + op

let read st = st

(* state-based g-counter *)
let init = List.init numRep (fun _ → 0)

let mutator st e =
  let (op, src) = e in
  List.mapi (fun i c →
    if i = src then c + op else c)

let merge st1 st2 =
  let max = fun p →
    Int.max (fst p) (snd p) in
  List.map max (List.combine st1 st2)

let read = List.fold_left (+) 0

```

■ **Figure 1** Op-based and state-based OCaml implementations of a grow-only counter. `numRep` is the number of replicas.

implementation, proving SEC shows that different replicas eventually converge, but does not tell us what they converge to. This means we cannot rule out bugs such as subtracting instead of adding in the definition of `effect` in Figure 1. Another problem is that by focusing on SEC we cannot abstract away from implementation details. For example, Figure 1 shows two g-counter implementations that use different techniques, but we should be able to reason about a g-counter as an *abstract data type* [15], without worrying about whether it is op-based or state-based.

Burckhardt et al. [3] were the first to give functional correctness specifications of CRDTs. Their key observation is that just like a sequential data type (e.g., a queue) can be specified as a partial function from a list of operations to a (final) state, a replicated data type can be specified as a partial function from a *set of events* to a state. As in Figure 1, an *event* contains an operation plus additional metadata, including the id of the replica that created the operation and a timestamp. The timestamps induce a partial or total order on the set of events and, furthermore, that order is consistent with causality.¹

We call this partial function from sets of events to the CRDT’s state after processing the events a *denotation*.² For example, the denotation for a g-counter is $\llbracket s \rrbracket = \sum_{e \in s} e.o$, where s is a set of events and $e.o$ extracts e ’s operation (the value to increment by). In this particular case we do not use the event metadata to specify the g-counter, but we do so for other, more complex, CRDTs where all operations do not naturally commute. Note that any CRDT specification that uses denotations trivially satisfies the convergence part of SEC, because $\llbracket \cdot \rrbracket$ is insensitive to the order in which events arrive at different replicas: if they have received the same set of events, then their states will be the same. Also notice that denotations are by nature closer to the informal op-based specification in Figure 1 than to the state-based one. This is because op-based CRDTs are framed in terms of individual operations.

1.2 Verifying with Denotations

The papers by Burckhardt et al. and Leijnse et al. [3, 13] are concerned with specifying CRDTs, but there is still a need for a mechanism that ties the high-level specifications, given in terms of denotations, to executable code written using features of a modern programming language: e.g., mutation, node-local concurrency, and higher-order functions. The recent

¹ In Burckhardt et al. [3] a *visibility* relation is used to order events, instead of a timestamp.

² The term is due to Leijnse et al. [13], who recast Burckhardt et al.’s formalism in a style more amenable to specifying CRDT combinators.

work of Nieto et al. [20] connects denotations to low-level CRDT implementations using the Aneris distributed separation logic [11]. Specifically, they show how to build separation logic propositions that track the local state of a CRDT, where, e.g., the return value of a read is then given by a denotation of the local state. Nieto et al. demonstrate their approach by verifying a library for building op-based CRDTs: the library user (the CRDT implementer) instantiates the library with a purely-functional implementation of the CRDT (similar to the op-based example in Figure 1), and obtain in return a replicated data type. The library handles network operations, concurrency control, and mutation of local state. Nieto et al. exclusively reason about operation-based CRDTs. As future work, the authors include a high-level sketch of how their techniques might be adapted to the state-based setting.

There is then, to the best of our knowledge, an unexplored gap in the literature for verifying functional correctness of *state*-based CRDTs using modular specifications.

Related to the last point, existing approaches to verifying CRDTs target either op-based [7, 16, 14, 17, 20] or state-based [23, 18, 24] CRDTs, but never both kinds. This is important because it means that it is not possible to give the *same* specification to two implementations of the same replicated data type, where each uses a different implementation strategy (as in Figure 1). Having specifications that hide away implementation details is something we take for granted for sequential data types (e.g. a set abstract data type can be implemented both via a linked list and a hash table, but both implementations can be given the same specification). It would be useful to have the same hold for CRDTs.

1.3 Contributions

We fill the gaps identified above through the following contributions:

1. We give the first modular specification of a general class of state-based CRDTs. Our specifications are given in the Aneris distributed separation logic and our proofs are mechanized in Coq.
2. Furthermore, when taken together with Nieto et al. [20], our work provides a *unified* framework for the specification and verification of *both* kinds of CRDTs. This is because our specifications of state-based CRDTs are compatible with Nieto et al.’s specifications of op-based CRDTs. We emphasize this point by re-verifying the example client program in Nieto et al. that uses a positive-negative counter CRDT, except we swap their op-based counter by a state-based equivalent. Crucially, the client’s safety proof remains virtually unchanged,³ showing that it is possible to specify CRDTs while hiding their implementation strategy.
3. We give the first formal proof that state-based CRDTs are causally-consistent.
4. We evaluate our approach by verifying a set of example CRDTs from the literature. The evaluation shows that our techniques can handle a variety of CRDTs, including counters, sets, and higher-order combinators.

2 Aneris Primer

Aneris [11] is a distributed separation logic built on top of the Iris program logic framework [9]. Aneris is designed to reason about safety properties of distributed systems written in Aneris-Lang, which can be thought of as a subset of OCaml deeply embedded in Coq. This subset

³ Modulo some manual editing of Nieto et al.’s proof development, which could be further eliminated with additional Coq engineering work that refactors some typeclasses

includes support for higher-order functions, mutable state, node-local concurrency (including the ability to fork new threads dynamically), as well as expressions for sending and receiving messages over UDP-style sockets. The operational semantics models an unreliable network: once sent, messages can be dropped, re-ordered, arbitrarily-delayed, and duplicated.

Figure 2 shows the fragment of Aneris most relevant to this paper. First, notice that the logic includes the usual connectives of a higher-order logic. The separation logic connectives include the separating conjunction $P * Q$, indicating ownership of a resource that can be split into two parts, one satisfying P and the other satisfying Q . The magic wand $P \multimap Q$ denotes resources that, when combined with a resource satisfying P then together satisfy Q . The points-to proposition $\ell \mapsto_{ip} v$ grants exclusive ownership of memory location ℓ on the node with IP address ip alongside the knowledge that value v is stored in ℓ . In other words, only the owner of this resource is allowed to read or modify ℓ 's contents. As usual, the Hoare triple $\{P\} \langle ip; e \rangle \{x. Q\}$ is a partial correctness assertion for expression e running on the node with IP address ip . Notice that in the postcondition we bind the return value of e to x , whose scope extends over Q .

Aneris inherits from Iris a notion of *invariant*. An invariant $\boxed{P}^{\mathcal{N}}$ (\mathcal{N} being the name – see below), once established at a point in a proof, asserts that the proposition P hold throughout the execution of the program from that point on and is respected by all threads and nodes. This is enforced by the program logic and is reflected in the invariant *opening* rule. The invariant opening rule allows invariants to be accessed around atomic expressions. That is, it allows us to assume that the invariant holds before the atomic step and enforces that after the atomic step executes, the invariant needs to be *closed* again, meaning that we have to show that it holds again after the execution of the atomic step. The notation $\boxed{P}^{\mathcal{N}}$ says that P is an invariant with *namespace* \mathcal{N} . One can think of \mathcal{N} as an identifier for the invariant that helps the logic keep track of which invariants are open at any given point in the proof: this is important because an invariant that is currently open cannot be re-opened.

The points-to proposition $\ell \mapsto_{ip} v$ is but one example of the kind of *resources* that one can assert ownership over. In fact, the user of the logic can define new kinds of resources by creating *partial-commutative monoids* (PCMs): monoids where the product is commutative and partial. Given a PCM \mathbb{M} and $a \in \mathbb{M}$ the proposition \boxed{a}^{γ} asserts ownership of *ghost state* a . Here, γ is the *ghost name* under which a is stored. Crucially, $\boxed{a}^{\gamma} * \boxed{b}^{\gamma}$ is equivalent to the monoid product $\boxed{a \cdot b}^{\gamma}$. The logic guarantees that the product of all resources stored under the same ghost name is well-defined: hence by choosing appropriate monoids we can tweak the properties of ghost state.

The proposition $\Box P$, read *persistently* P , tells us that P holds and it does not assert ownership of any exclusive resources. We say that P is a persistent proposition if $P \vdash \Box P$. Persistent propositions are duplicable in the sense that $\Box P \vdash \Box P * \Box P$. Finally, the *update* modality $\mathcal{E}_1 \boxRightarrow^{\mathcal{E}_2} P$ says that P holds after updating (allocating or modifying) resources; furthermore, we can assume that all invariants in the set \mathcal{E}_1 hold when establishing P but must also (re)establish all invariants in the set \mathcal{E}_2 . The notation $\boxRightarrow_{\mathcal{E}}$ is shorthand for $\mathcal{E} \boxRightarrow^{\mathcal{E}}$.

3 Main Ideas

The main idea of this paper is that, from a user's perspective, whether a CRDT is op-based or state-based is an implementation detail, and one that ought not affect the data structure's specification. To capture this idea formally we reach for two tools: separation logic propositions for tracking the global and local states of the CRDT as a function of sets of events (user operations), and high-level specifications for the CRDT based on denotations.

$P, Q \in iProp ::= \text{True} \mid \text{False} \mid P \wedge Q \mid P \Rightarrow Q \mid P \vee Q \mid \forall x. P \mid \exists x. P \mid \dots$	higher-order logic
$\mid P * Q \mid P \multimap Q \mid \ell \mapsto_{ip} v \mid \{P\} \langle ip; e \rangle \{x. Q\}$	separation logic
$\mid \boxed{P}^{\mathcal{N}} \mid \overline{a_i}^{\gamma}$	invariants and resources
$\mid \Box P \mid \varepsilon_1 \multimap \varepsilon_2$	modalities

■ **Figure 2** Aneris fragment adapted from Nieto et al. [20].

To track a CRDT’s state we construct propositions $\text{GlobSt}(s_g)$ and $\text{LocSt}(i, s_{own}, s_{for})$ for global and local states, respectively, as well as a global invariant GlobInv . Ownership of the global state tells us that s_g is *exactly* the set of all events issued by any replica. An event is a triple (**op**, **source**, **time**) where **op** is the user-provided operation (e.g. `inc(10)` for a g-counter), **source** is the id of the replica that issued the operation (ids are just natural numbers), and **time** is a logical timestamp that allows us to order events according to the usual *happens-before* relation. Ownership of the local state $\text{LocSt}(i, s_{own}, s_{for})$ tells us that replica i has issued *exactly* the events in s_{own} , and that it has received *at least* the events in s_{for} , which all originate outside of i (we only get an approximation of the events from outside of i because in between two user interactions with the CRDT at replica i , new merge operations might have taken place).

Once the above propositions have been defined, we prove a comprehensive suite of “resource lemmas” that allow a client to reason about the state of the CRDT. For example, we prove that if a user knows both $\text{GlobSt}(s_g)$ and $\text{LocSt}(i, s_{own}, s_{for})$, and they can find events e and e' where $e \in s_{own} \cup s_{for}$ (e is in the local state), $e' \in s_g$ (e' is in the global state) and e' happens before e , then e' must have been received at replica i as well: $e' \in s_{own} \cup s_{for}$. This is an encoding of causality in separation logic [8, 20]. We do not claim this formulation as a contribution; instead, our contribution is defining the above predicates in such a way that they can track state-based CRDTs, and then proving existing lemma statements for our definitions. In effect, we have re-implemented an existing interface. This is crucial because it means that from a client’s perspective it does not matter what kind of CRDT (state-based or op-based) they are working with: they all satisfy the same laws.

Technical Challenges

Resource lemmas like causality hold only in the presence of the global invariant GlobInv . This invariant guarantees that at all times the state of the system is *valid*. The system state is a tuple \vec{s}_i of the local state at every replica. Defining a notion of validity suitable for state-based CRDTs is one of the tricky technical parts of our proof. Two complications arise: how to represent local states, and how to represent time.

Defining local state as an element of the lattice over which the CRDT is implemented does not work, because we lose track of the individual events. For example, we might remember that the state of the counter is [4, 5], but not that it resulted from three events: two increments of 2 each at replica 0, and one increment of 5 at replica 1. Remembering events is needed to show the resource lemmas. We therefore represent local states as sets of events, but now we need a way to link these sets of events to the lattice element that is computed at runtime. We do this with denotations, which are functions from sets of events to lattice elements. In our proof, a local invariant ensures that, for every replica i , if s is the set of tracked events for i and the runtime CRDT state at i is st , we must have $\llbracket s \rrbracket = st$. The definition of denotation for a state-based CRDT must then satisfy a number of *coherence* properties with respect to the underlying lattice: for example, we require that, under certain

conditions, if $\llbracket s \rrbracket = st$ and $\llbracket s' \rrbracket = st'$, then $\llbracket s \cup s' \rrbracket = st \sqcup st'$. In other words, our proof tracks the logical state with a free lattice of events, while the implementation computes using the CRDT-specific lattice. The denotation is the homomorphism between the two.

For lemmas like causality we also need to be able to compare events according to time. Prior work on op-based CRDTs implements a causal broadcast library that tags each event with a (physical) *vector clock*⁴ that serves as a timestamp [20]. In our setting, since state-based CRDTs do not assume causal broadcast, we use a purely logical notion of time. Given an event e , its timestamp is taken to be the set of events that e causally depends on. This set is computed at the point e is created: if e was issued at replica i where the local state is an event set s , then e causally depends on every element of s . This works because we can show that local states are always *dependency-closed*: if $e' \in s$ and e_d is a dependency of e' , then $e_d \in s$ as well. Our definition of logical time allows us to give the first formal proof that state-based CRDTs are causally-consistent.

Verified Examples

With the above in place we turn to the verification of different state-based CRDTs. We implemented and verified five CRDTs from the literature [21]: a grow-only counter, a positive-negative counter, an add-only set, a combinator for products of CRDTs, and a combinator for maps from strings to an underlying CRDT type. We implemented these examples in two steps: first, we implemented a STATELIB library that factors out all the common elements in different examples: network calls, merging of remote states, and concurrency control. The library takes as input a purely-functional implementation of a state-based CRDT, in the form of a triple $(\text{init_st}, \text{mutator}, \text{merge})$, where init_st is the CRDT's initial (lattice based) state, mutator is a function that takes a state and an operation and produces the next state, and merge implements the lattice's least upper bound operation. STATELIB requires that the CRDT implementer proves the aforementioned coherence properties (e.g., that merging two states is the same as taking the denotation of the union of their corresponding event sets) about their purely-functional implementation. Given this core logic, the library returns a fully-fledged replicated data type and two functions, get_state and update , to query and update the state of the data-structure. In the second step, we wrote purely-functional implementations for each of the previously-mentioned examples and proved the relevant coherence properties so the library can be instantiated with them. The modular design of the library allows us to prove the library safe just once, and then re-use that proof to obtain safety proofs for each of the CRDTs.

Finally, we wanted to validate our claim that a client need not know whether the CRDT they are interacting with is state-based or not. We did this by using the example in Nieto et al. where they verify a client program together with an op-based positive-negative counter [20]. We were able to swap their op-based counter with our state-based positive-negative counter while leaving the proof virtually unmodified (small technical changes are required, but these could be eliminated with further Coq engineering). This shows that CRDTs can be true abstract data types, and can be specified while abstracting away implementation details.

The rest of the paper is structured as follows: Section 4 gives an overview of the CRDT resource lemmas in Nieto et al. [20], which we re-prove in the state-based context. Sections 5, 6, and 7 present STATELIB's design, specification, and safety proof, respectively. Section 8 describes the verified example CRDTs, as well as the proof of the client program that is agnostic to the CRDT class. Section 9 surveys related work and Section 10 concludes.

⁴ A vector of integers, with one entry per node in the system. The i th entry tells us how many updates have been done by replica i .

4 Background: CRDTs in Separation Logic

We give an overview of the separation logic approach to verification of op-based CRDTs in Nieto et al. [20]. Specifically, they introduce abstract separation logic resources (abstract predicates) for tracking the local and global states of a CRDT. The abstract resources are later used in the specifications of CRDT operations. Nieto et al. reason only about op-based CRDTs, but in this paper we show how to instantiate the abstract resources so that we can verify state-based CRDT implementations as well. As we will later see, this allows clients to reason about a CRDT while remaining agnostic of the CRDT’s implementation strategy.

4.1 Time, Events, and Denotations

We start by giving a few definitions that we will use throughout the paper.

Logical time allows us to order events in a distributed system using causal order. Time is axiomatized by a triple $(\text{Time}, \leq_t, <_t)$, where Time is a set of *timestamps*, \leq_t is a partial order on timestamps, and $<_t$ is the strict version of \leq_t . For example, for working with op-based CRDTs, Nieto et al. instantiate logical time by taking timestamps to be vector clocks and \leq_t to be the associated pointwise ordering.

Logical events represent operations that are executed by the CRDT, together with metadata. A logical event is a triple $(\text{op}, \text{source}, \text{time}) \in \text{Event} \triangleq \text{Op} \times \mathbb{N} \times \text{Time}$. Here Op is the type of *operations* on the CRDT (e.g. $\text{Op} \triangleq \{\text{inc}(n) \mid n \in \mathbb{N}\}$ for a g-counter), source is the id of the replica that generated the event, and time is a timestamp. For an event e we write $e.o$, $e.s$, and $e.t$ for the operation, source, and timestamp of e , respectively.

Given two event sets s and s' , we say that s is a *causally-closed subset* of s' , written $s \subseteq_{\text{cc}} s'$, if $s \subseteq s'$ and

$$\forall e e', e \in s' \Rightarrow e' \in s' \Rightarrow e.t \leq_t e'.t \Rightarrow e' \in s \Rightarrow e \in s$$

That is, if we start with two events from s' and the later one e' (according to timestamp ordering) is in s , then e (its causal dependency) must be in s as well.

Finally, we use *denotations* to specify CRDTs. A denotation is a tuple $(\text{Op}, \text{St}, s_{\text{init}} : \text{St}, \llbracket \cdot \rrbracket : \mathcal{P}(\text{Event}) \rightarrow \text{St})$. For example, as in Figure 1, for a g-counter we could have Op as previously defined, $\text{St} \triangleq \mathbb{N}$, $s_{\text{init}} \triangleq 0$, and $\llbracket s \rrbracket = \sum_{e \in s} \text{unwrap}(e.o)$ with $\text{unwrap}(\text{inc}(n)) = n$. We could have also chosen St to be the set of lists of naturals of length N , where N is the number of replicas. This latter denotation would be closer to the state-based implementation.

It is useful for denotations to be partial because we can avoid giving a meaning to ill-formed sets of events. For example, suppose we have $s = \{a, b\}$ with $a.t = b.t$ but $a \neq b$. We might know that in practice events with equal timestamps must be equal, so s can never arise during an execution. We might then choose $\llbracket s \rrbracket$ to be undefined.

4.2 Separation Logic Resources

So far we have not shown any Aneris definitions. We do so in Figure 3, which shows the types of different abstract separation logic resources (predicates) that, together with associated lemmas, can be used to reason about the state of CRDTs. Specifically, these resources appear in the pre and post-conditions of functions that operate on a CRDT. The abstract resources are designed to be generic so they can be used with multiple CRDTs. Indeed, Nieto et al. verified multiple op-based example CRDTs using these resources [20], and we have also verified multiple state-based examples. Notice that Figure 3 does not show the definition of the resources. The reader can think of Figure 3 as defining an *interface* in the

Resources (abstract predicates)

(Global invariant)	$\text{GlobInv} : iProp$
(Global state)	$\text{GlobSt} : \mathcal{P}(\text{Event}) \rightarrow iProp$
(Global snapshot)	$\text{GlobSnap} : \mathcal{P}(\text{Event}) \rightarrow iProp$
(Local state)	$\text{LocSt} : \mathbb{N} \rightarrow \mathcal{P}(\text{Event}) \Rightarrow \mathcal{P}(\text{Event}) \rightarrow iProp$
(Local snapshot)	$\text{LocSnap} : \mathbb{N} \rightarrow \mathcal{P}(\text{Event}) \Rightarrow \mathcal{P}(\text{Event}) \rightarrow iProp$

■ **Figure 3** CRDT resources and selected lemmas, from Nieto et al. [20].

software engineering sense. Nieto et al. implement this interface for op-based CRDTs, while we re-implement it for state-based CRDTs. For space reasons, we do not show the entire interface; the full interface can be found in the accompanying Coq code.

The defined resources are as follows: there is a *global invariant* GlobInv that holds throughout the CRDT’s existence. Then we define resources for tracking *global* (GlobSt) and *local* (LocSt) states. The intuition is that if $\text{GlobSt}(s_g)$ holds, then we know that s_g is *exactly* the set of events issued by any CRDT replica in the system. Similarly, ownership of $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$ tells us that replica i has processed *exactly* the events in s_{own} and *at least* the events in s_{for} . The events in s_{own} (the “own” events) must have all originated at i , while the ones in s_{for} (the “foreign” events) must all originate outside of i . This is because a client of the CRDT knows exactly which events it has issued, but is potentially not aware of all events that have been received “in the background” since the last interaction with the CRDT.

Global and local states are *exclusive* (not shown in Figure 3), meaning that only one copy of the resource (or one per replica in the case of local state) can exist: e.g., $\text{GlobSt}(s_g) \multimap \text{GlobSt}(s'_g) \multimap \perp$.

By contrast, the interface also declares *global and local snapshots* (GlobSnap and LocSnap), which are persistent (duplicable) and give us a *lower bound* on global and local states, respectively. Snapshots are useful as a “certificate” that an event was generated by a given replica: this is the case if one can prove, e.g., that $\text{GlobSnap}(s_g)$ and $e \in s_g$ for an event e . The use of global snapshots as certificates is validated by lemma GlobSnapIncl (Figure 3). The lemma says that under the global invariant, if we own $\text{GlobSnap}(s_g)$ and $\text{GlobSt}(s'_g)$, then we must have $s_g \subseteq s'_g$. This conclusion holds under the update modality \Rightarrow_E , which

$$\begin{array}{l}
\text{INCSPEC} \\
\{\text{LocSt}(i, s_{\text{own}}, s_{\text{for}}) * \text{GlobSt}(s_{\text{g}})\} \\
\langle ip_i; \text{inc}(n) \rangle \\
\left\{ \begin{array}{l} v. \exists e s'_{\text{for}}. s'_{\text{for}} \supseteq s_{\text{for}} * e \notin s_{\text{g}} * e.o = n * e.s = i \\ \llbracket s_{\text{own}} \cup \{e\} \cup s'_{\text{for}} \rrbracket = v * \text{LocSt}(i, s_{\text{own}} \cup \{e\}, s'_{\text{for}}) * \text{GlobSt}(s_{\text{g}} \cup \{e\}) \end{array} \right\}
\end{array}$$

■ **Figure 4** Simplified spec of an increment operation, which returns the counter’s current value.

means that it holds possibly after opening (and closing) all invariants in the mask E . The premise $\mathcal{N}^\uparrow \subseteq E$ tells us that the global invariant’s namespace \mathcal{N}^\uparrow is part of E . This means that GlobInv must not be open when the lemma is called (because the proof of the lemma opens GlobInv). LocSnapIncl provides similar inclusion guarantees for local snapshots, but note that we actually get the stronger causally-closed inclusion \subseteq_{cc} , as opposed to just \subseteq .

GlobStTakeSnap allows us to take snapshots of global states. LocSnapExt says that if two events in a local snapshot have equal timestamps, then the events must be equal.

Finally, we have three lemmas that tie together local and global states. LocSnapProv says that if e is tracked locally, then there must exist some global snapshot $\text{GlobSnap}(s_{\text{g}})$ such that $e \in s_{\text{g}}$. That is, all local events are also tracked globally. GlobSnapProv says that if an event $e \in s_{\text{g}}$ has origin i and we know $\text{GlobSnap}(s_{\text{g}})$ (e is tracked globally), then e must also be in the local state for i . Finally, Causality is our definition of causality in separation logic. This take on causality was originally developed for reasoning about a causally-consistent key value store by Gondelman et al. [8], and later generalized by Nieto et al. [20] so it can apply to events in an arbitrary CRDT. The lemma is as follows: suppose we have two events e and e' such that e' was recorded locally at node i (that is, $e' \in s_{\text{own}} \cup s_{\text{for}}$ and we know $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$). Next suppose that e happened before e' , and e is a logically tracked event (which we can show by presenting $\text{GlobSnap}(s_{\text{g}})$ with $e \in s_{\text{g}}$). Then causal delivery requires that e be observed locally at i as well: i.e., $e \in s_{\text{own}} \cup s_{\text{for}}$. Gondelman et al. [8] show how this definition of causality is strong enough to prove four *session guarantees* (monotonic reads, monotonic writes, read your writes, and writes follow reads) that programmers intuitively expect when interacting with a causally-consistent datatype.

Reasoning With Resources

To tie all the above together, Figure 4 shows how the previously-discussed resources can be used to specify the inc operation on a g-counter CRDT. We assume that inc both increments the counter and returns its current local value. The precondition for calling inc at replica i requires knowledge of both $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$ and $\text{GlobSt}(s_{\text{g}})$. This is because every single increment must be tracked both locally at the replica where it is performed and globally. In the postcondition we get back $\text{LocSt}(i, s_{\text{own}} \cup \{e\}, s'_{\text{for}})$, where e is the event generated by the increment and $s_{\text{for}} \subseteq s'_{\text{for}}$. Notice that the “own events” grow by exactly one event, e , but the “foreign events” grow to some superset s'_{for} of s_{for} . This is because since the last time inc was called any number of new events could have been propagated from other replicas to replica i . Notice how we connect the implementation to its functional correctness specification by saying that the return value v is the denotation of the locally-observed events $s_{\text{own}} \cup \{e\} \cup s'_{\text{for}}$. Finally, observe that by using denotations we automatically obtain convergence (the safety part of SEC), because the return value is a function of a *set* of events, so two replicas that have seen the same set of events must return the same result.

Resources for State-Based CRDTs

Two difficulties arise when instantiating the resource interface for state-based CRDTs.

1. *How should we track local state?* The replica state in an implementation of a state-based CRDT is a lattice element. By contrast, the resource interface logically tracks replica states as sets of events (operations). The solution is to link the two representations via a denotation: if the logical state is $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$, then the physical state must be $\llbracket s_{\text{own}} \cup s_{\text{for}} \rrbracket$, which in turn must be drawn from the appropriate lattice. The link is also needed when propagating a replica’s state to other replicas. In the implementation, a replica sends a message containing its entire state e , so others can merge it. Logically, we require that the sent state be paired with a local snapshot whose denotation is e .

2. *How do we track time to prove causal consistency?* For their treatment of op-based CRDTs, Nieto et al. [20] implemented a causal broadcast algorithm that ensures that every message sent by a CRDT replica is delivered in causal order. This is achieved via vector clocks in the standard way. But state-based CRDTs should not rely on causal broadcast; in fact, one of the main advantages of the state-based approach is that messages can be delivered out-of-order and re-delivered without causing issues (because of the properties of least upper bound). It is not immediately clear why the state-based design satisfies causal delivery. The first key observation is that if we start with a replica state st and look at the event set s that produced it, i.e., $\llbracket s \rrbracket = st$, then s “has no holes” with respect to causality. That is, if we take an event $e \in s$ and e' is another event that happened before e , then it must be the case that $e' \in s$ as well. This is formalized via the notion of *dependency-closure* (Section 7.1). The second observation is that when a new operation o is applied to a local state st with $\llbracket s \rrbracket = st$, it (logically) generates a new event e' with $e'.o = o$. e' ’s causal dependencies are *exactly* the events in s . This is important because it means that we can track an event’s dependencies *purely logically*, without the need for vector clocks. Using these ideas we are able to prove that the (Causality) lemma holds for state-based CRDTs (Lemma 5). To our knowledge, this is the first formal proof that state-based CRDTs are causally-consistent.

5 StateLib : a Library for Implementing State-Based CRDTs

We have structured our CRDT implementations so that common functionality is factored out into a separate library, which can then be instantiated as needed by different CRDT examples. The library, called STATELIB, is responsible for maintaining the CRDT’s internal state and inter-replica propagation. The library’s code is shown in Figure 5, together with an abridged example instantiating a *grow-only set* (g-set) CRDT, a set to which we can add elements, but from which we cannot remove them [21].

We start by describing the `init` function, which is the library’s entry point. A CRDT implementer calls `init` with the following arguments: serialization and de-serialization functions, a list of all replica addresses, the current replica id, and a `crdt` parameter that describes how the specific CRDT being instantiated should behave. The serialization functions have the expected types: `type 's serT = 's → string` and `type 's deserT = string → 's`. The `crdt` argument has type `('o, 's) crdtT`, parametrized on operations and states:

```
type 's mergeT = 's → 's → 's
type ('o, 's) mutT = int → 's → 'o → 's
type ('o, 's) crdtT = (('s * ('o, 's) mutT) * 's mergeT)
```

That is, a value of type `('o, 's) crdtT` is a triple `(init_st, mutator, merge)` containing an initial state, a mutator function, and a merge function. The mutator takes a replica id, the current state, and a new operation, and returns the state that results after applying the operation locally. The merge function takes two states and returns their least upper bound.

(* Instantiate via *)
let (get, upd) = init ... gset_crdt

```

■ **Figure 5** STATELIB implementation and a G-Set example. Linearization points are marked with an LP comment.

Back to the body of `init`, we see that it unpacks the `crdt` argument. It then allocates a local reference to hold the current state of the CRDT, a lock to control updates to the state, and a socket over which it can communicate with other replicas. The function then spawns two concurrent threads, `apply` and `broadcast`, in charge of receiving updates from other replicas and propagating local updates, respectively. Finally, `init` returns a pair of functions `get_state` and `update` allowing the library user to query and update the CRDT state.

Both `get_state` and `update` have simple implementations. The former just dereferences the local state, while the latter uses the user-provided mutator to compute the CRDT's next state. Both operations are guarded by a lock.⁵

The `apply` function, which is spawned off as a separate thread from `init`, is responsible for receiving updates from other replicas and then merging them with the local state, using the user-provided `merge` function. The call to `receiveFrom` blocks until a message is available at the given socket handle. The function `unSOME : 'a option → 'a` unwraps a value of an option type, crashing if the argument is `None`. Notice that the received message needs to be deserialized via the user-provided `deser` function. Also notice that `apply` does not terminate, but mutates the CRDT's state.

⁵ In the case of `get_state`, loads in `AnerisLang` are atomic, so the lock is not strictly needed; however, dereferences are not atomic in `OCaml` [6], which we use to run our code, so we use a lock.

The dual of `apply` is `broadcast`, which is tasked with propagating the local state to other replicas. This function also runs on a separate thread, and loops forever, working solely via side effects. The `broadcast` function retrieves a copy of the local state, serializes it, and then calls a helper function `sendToAll`. This helper takes a list of IP addresses `dst1`, the current replica id `i` and the message (state) to be sent. It then loops over the elements of `dst1` and sends the message to each of them (taking care to not send a message to itself).

Finally, Figure 5 sketches how one might implement a g-set via the library. We represent the state with a sequential set. The mutator is just set insertion, `merge` is implemented via set union, and the initial state is the empty set. We can then package these three components into a tuple `gset_crat`, and provide the latter as an argument to `init` (together with the serialization functions and replica IP addresses). From `init` we get back a pair functions for querying the current value of the set and updating it.

6 Specifying StateLib

The STATELIB library has two interfaces: an internal interface used by the CRDT *implementer*, consisting of the `init` function, and an external interface used by the CRDT *client*, consisting of `get_state` and `update`.

6.1 Internal Interface

Recall that STATELIB is initialized by the CRDT implementer through an `init` function, taking in (de-) serialization functions for the CRDT state, a list of replica IP addresses, and finally a `crat` argument describing the lattice being implemented (Figure 5). This last parameter is a triple `crat = (initSt, mut, merge)` consisting of the CRDT's initial state $\text{initSt} \in \text{LatSt}$, a *mutator* function $\text{mut} : \text{LatSt} \rightarrow \text{Event} \rightarrow \text{LatSt}$, and a *merge* function $\text{merge} : \text{LatSt} \rightarrow \text{LatSt} \rightarrow \text{LatSt}$.

The CRDT implementer first defines a poset (LatSt, \leq_L) and then proves that it is a lattice. Because our tracking of replica states is defined in terms of event sets (Figure 3) we need a way to connect said events to the physical CRDT state, which is a lattice element. Intuitively, we would like to guarantee that the CRDT's physical state is the denotation of the set of events received so far. For this to be true, we need certain coherence properties between event sets, their denotations, and lattice elements. These are shown in Figure 6 and consist of specifications for `initSt`, `mut` and `merge`.

INITSTSPEC says that the denotation of the empty set of events must be the initial state.

MUTATORSPEC says that if we start in a state $st = \llbracket s \rrbracket$ and through a mutation get to a state $st' = \text{mut}(st, op)$, then we can also arrive at st' by taking the denotation $\llbracket s \cup \{e\} \rrbracket$, where e is the event containing op . We also need to show that the mutator is monotonic: we must have $st \leq_L st'$ in the lattice order. In proving these goals we get to make additional assumptions about s and e . Specifically, we can assume that s is a set of events that is *valid with respect to coherence* (we explain validity in Section 7.1); additionally, we know that e is the maximum element with respect to timestamp ordering in the set $s \cup \{e\}$. Intuitively, this is because e is a new event being added, so it has every event in s as a causal dependency.

MERGESPEC shows coherence of merges. Here we start with two states st and st' that we want to merge to get a third state st'' . We know that $\llbracket s \rrbracket = st$ and $\llbracket s' \rrbracket = st'$, and we would like to conclude that $\llbracket s \sqcup s' \rrbracket = st''$ and also that `merge` is in fact computing the least upper bound, so $st \sqcup st' = st''$. Once again we get to assume validity of the relevant event sets, and now additionally we know an inclusion property of sections (a section is a subset of events that originates at a specific replica). The proposition `SectIncl(s, s')` tells us that if we

look at any particular section, say section i , then either $\text{sect}(s, i)$ is a subset of $\text{sect}(s', i)$, or the other way around. Intuitively, this is because sections are always “complete”: if a replica has received event $(6, 5)$, it must have also received all events in the range $(6, 1), \dots, (6, 4)$.

We package the three specifications in the assertion $\text{CRDTSPEC}(\text{crdt})$, which asserts that each of the components of the crdt tuple satisfies the corresponding spec above. Finally we have specification for the init function. In the precondition of INITSPEC , we assert that the crdt argument satisfies CRDTSPEC . In the postcondition, we learn that init returns a pair of functions get_state and update that satisfy the same-named specifications (described in the next section). We also gain ownership of the resource $\text{LocSt}(i, \emptyset, \emptyset)$, indicating that the local replica has yet to receive any events (because it has just been initialized).

6.2 External Interface

STATELIB’s external interface consists of two functions: get_state , which takes no arguments and returns the local state of the CRDT, and update , which takes an operation, updates the local state, and returns a Unit . Figure 7 shows specifications for both functions; these specifications are identical to the ones for the same-named functions in Nieto et al.’s library for op-based CRDTs [20]. This is by design: by proving that our library meets the same specification as the equivalent library for op-based CRDTs we then make it possible for client programs to use (and reason about) a replicated data type without knowledge of whether the data type is op-based or state-based. That is, we hide implementation details to turn CRDTs into true abstract data types.

Looking at Figure 7, the reader will notice that the specifications use angle brackets instead of braces: i.e. we write $\langle P \rangle e \langle Q \rangle^N$, instead of the usual Hoare triple $\{P\}e\{Q\}$. The former is a *logically-atomic* triple [10]. The motivation for these triples is that Aneris invariants can only be opened around *atomic* steps (otherwise concurrent threads might observe invariant violations); this means we cannot use a specification $\{P\}e\{Q\}$ if we need to open an invariant to prove P , provided e is not atomic, as is the case for both get_state and update . In particular, the precondition of update requires the global state $\text{GlobSt}(s_g)$, which a client is likely to keep in an invariant because it is shared by all (concurrent) replicas.

$$\begin{array}{l}

\langle ip_i; \text{get_state}() \rangle \\
\left\langle \begin{array}{l} v. \exists s'_{\text{for}} w. s'_{\text{for}} \supseteq s_{\text{for}} * \text{StCoh}(w, v) * \\ \text{LocSt}(i, s_{\text{own}}, s'_{\text{for}}) * \llbracket s_{\text{own}} \cup s'_{\text{for}} \rrbracket = w \end{array} \right\rangle \mathcal{N}
\end{array}
\quad
\begin{array}{l}
\text{UPDATESPEC} \\
\langle \text{LocSt}(i, s_{\text{own}}, s_{\text{for}}) * \text{GlobSt}(s_{\text{g}}) \rangle \\
\langle ip_i; \text{update}(v) \rangle \\
\left\langle \begin{array}{l} (). \exists e s'_{\text{for}}. s'_{\text{for}} \supseteq s_{\text{for}} * e \notin s_{\text{own}} * e \notin s_{\text{g}} * e.o = v * \\ e.s = i * e \in \text{maximals}(s_{\text{g}} \cup \{e\}) * \\ \text{maximum}(e, s_{\text{own}} \cup s'_{\text{for}} \cup \{e\}) * \\ \text{LocSt}(i, s_{\text{own}} \cup \{e\}, s'_{\text{for}}) * \text{GlobSt}(s_{\text{g}} \cup \{e\}) \end{array} \right\rangle \mathcal{N}
\end{array}$$

■ **Figure 7** External specifications. \mathcal{N} is any invariant namespace that includes `GlobInv`'s name. Adapted from Nieto et al. [20].

Logically-atomic triples solve this problem by allowing us to open invariants when proving the pre-condition. Their informal semantics are as follows: if we know $\langle P \rangle e \langle Q \rangle^{\mathcal{N}}$, then we know that e executes without crashing (although it might not terminate) provided that P holds. When proving P we are allowed to use any invariants that are not in namespace \mathcal{N} .⁶ We also need to show that if Q holds we can close any invariants that were open when proving P . Another point of view is that P and Q hold around a *linearization point* in e ; the linearization points for `get_state` and `update` are marked with an LP comment in Figure 5.

The specification of `get_state` can be read as follows. Before calling `get_state` we should know the local state at replica i : $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$; afterwards, the function returns a physical state v which is *coherent* with a logical state w ,⁷ the local state is now $\text{LocSt}(i, s_{\text{own}}, s'_{\text{for}})$ where $s'_{\text{for}} \supseteq s_{\text{for}}$ (reflecting the fact the set of local events is unchanged, but additional remote events might have been received), and the returned value w is the denotation of $s_{\text{own}} \cup s'_{\text{for}}$. Notice that the fact that the returned value is a function of the set of received events automatically gives us the safety part of eventual consistency (convergence): if two replicas have received the same set of events, then they are in the same state.

The specification of `update` says that we need to know both the local state $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$ at replica i and the global state $\text{GlobSt}(s_{\text{g}})$. This is because every event needs to be tracked both locally and globally. The function does not return any meaningful value, but we do get (logical) knowledge that the set of events has expanded: locally we now know $\text{LocSt}(i, s_{\text{own}} \cup \{e\}, s'_{\text{for}})$ with $s_{\text{for}} \subseteq s'_{\text{for}}$, and globally we have $\text{GlobSt}(s_{\text{g}} \cup \{e\})$. The new event e ($e \notin s_{\text{g}}$) has the value we are updating by as its payload ($e.o = v$) and it originates at replica i . Finally, we know that this new event is more recent than any other locally-received event ($\text{maximum}(e, s_{\text{own}} \cup s'_{\text{for}} \cup \{e\})$), and we also know that no other event (even globally) has the new event as its dependency: $e \in \text{maximals}(s_{\text{g}} \cup \{e\})$.

7 Verifying StateLib

To prove that STATELIB meets its external specification we follow a proof methodology inspired by previous Aneris developments [8, 20]:

1. We first model the CRDT as a state-transition system (STS), where the STS states are tuples detailing the state of the CRDT both globally and at each replica (Section 7.1). Transitions correspond to mutations and merges. Crucially, we show that transitions preserve *state validity*, a safety invariant from which we can derive properties of interest (e.g., causality). This is done in the meta-logic (i.e., Coq) and outside of separation logic.

⁶ This is to prevent a user of STATELIB from opening the global invariant, which is needed by STATELIB. Invariants cannot be reopened, to preserve soundness of the logic.

⁷ The *state coherence* predicate $\text{StCoh}(w, v)$ links the physical and logical states. This is useful when the physical state has a more involved representation due to limitations of AnerisLang: for example, v might be a pair of pairs while w is a 3-tuple, because AnerisLang only supports pairs.

2. We then embed the STS model inside Aneris via a combination of invariants and ghost state (defined via PCMs, see Section 7.3). We use state validity and the properties of the relevant PCMs to show that the resource interface from Section 4 holds.
3. Finally, using the separation logic resources defined in the previous step, we prove that STATELIB’s implementation meets its external specification (Section 7.4).

The rest of Section 7 is technical in nature, so the reader interested in an overview of our work can skip to Section 8. We highlight Lemmas 4 and 5, which, to our knowledge, are the first formal proofs that state-based CRDTs are causally-consistent.

7.1 State-Transition System Model

We model the execution of a CRDT via an STS that keeps track of the per-replica state, as well as the global state. We then show a number of safety invariants that hold for any execution of the STS. In later sections we show how the `AnerisLang` implementation simulates the STS, therefore inheriting its safety properties. We use the simulation to prove the resource laws in Figure 3.

The reader might wonder why we develop this STS model when state-based CRDTs already have a well-understood model that is lattice-based. We do this because our goal is to prove that STATELIB satisfies general functional correctness specifications that apply to both state-based CRDTs and op-based CRDTs. To this end we write our high-level specifications in terms of denotations, which talk about sets of events instead of lattice elements. This is why we need the STS model below. At an operational level, the STS model is needed to define the ghost state in Section 7.3 and as such is not directly exposed to the user.

We start by defining a purely logical notion of time that allows us to reason about causality in the absence of vector clocks. *Logical time* for state-based CRDTs is a triple $\text{LogTime}_{\text{st}} \triangleq (\mathcal{P}(\text{EvtId}), \subseteq, \prec)$, where $\text{EvtId} \triangleq \mathbb{N} \times \mathbb{N}$. Here EvtId is the set of *event ids*, which are pairs (r, n) of a *replica id* and a *sequence number*, respectively. We show that $\text{LogTime}_{\text{st}}$ satisfies the requirements on logical time from Section 4.1.

Given a set $d \in \mathcal{P}(\text{EvtId})$ of event ids we can extract the subset that originates at a given replica id via a *section*: $\text{sect}(d, i) \triangleq \{(i, n) \mid (i, n) \in d\}$. We can also compare event ids, but only if they are in the same section: $(s, n) \leq (s, n') \triangleq n \leq n'$.

We define logical events as triples $(\text{op}, \text{src}, \text{time}) \in \text{Op} \times \mathbb{N} \times \mathcal{P}(\text{EvtId})$. We tag each event e with the set of event ids of its *causal dependencies* $e.t$ and are then able to sort events according to causal order. For example, if $e.t = \{(1, 1)\}$ and $e'.t = \{(1, 1), (2, 1)\}$, then $e.t <_t e'.t$. Let $s \in \mathcal{P}(\text{Event})$. We lift causal dependencies to sets of events: $\text{deps}(s) \triangleq \bigcup_{e \in s} e.t$.

The *id* of an event e can be computed by counting the number of dependencies that originate at e ’s origin: $\text{id}(e) = (e.s, |\text{sect}(e.t, e.s)|)$. This way of computing event ids makes sense only if we assume that sequence numbers (a) start at 1 and (b) there are no “holes” in the ids stored in $e.t$. In our proof we maintain an invariant that implies these two properties.

To ensure causal consistency, we care about event sets that are closed with respect to causal dependencies. Let s be a set of events, then s is *dep-closed*, written $\text{depclosed}(s)$, if $\forall e \in s, \text{id} \in e.t, \exists e' \in s, \text{id}(e') = \text{id}$. For example, if $e \in s$ and $(1, 2) \in e.t$, then we must have $e' \in s$ with $\text{id}(e') = (1, 2)$. Dep-closure is preserved by set union, which is key because it will allow us to link logical and physical states when we take least upper bounds of the latter.

We now define *local states*, which track the state of the CRDT at a given replica. Unlike in the implementation the replica state will not be a lattice element, but a set of events: $\text{Lst} = \mathcal{P}(\text{Event})$. We lift sections to local states: if $s \in \text{Lst}$ then $\text{sect}(s, i) \triangleq \{e \mid e.s = i\}$.

Recall that $\text{numRep} \in \mathbb{N}$ denotes the number of replicas. We define *global states* $\text{Gst} \triangleq \mathcal{P}(\text{Event}) \times \text{Lst}^{\text{numRep}}$. The intuition for a global state $(s_g, \vec{s}_l) \in \text{Gst}$ is that the first component s_g gives us a *global view* of the system (we will ensure that s_g equals the union of all $s_{l,i}$). The second component \vec{s}_l is a vector of length numRep containing the local state at each replica.

► **Definition 1** (State-transition system model). *The state-transition system model is $\mathcal{S} = (\text{Gst}, \text{init}_{\mathcal{S}}, \rightarrow_{\mathcal{S}})$. STS states are elements of Gst and $\text{init}_{\mathcal{S}} \triangleq (\emptyset, \vec{\emptyset})$ is the initial state. The transition relation $\rightarrow_{\mathcal{S}} \subseteq \text{Gst} \times \text{Gst}$ is defined by the following two inference rules:⁸*

$$\frac{s_{l,i} = s \quad d = \text{deps}(s) \quad n = |\text{sect}(d, i)| + 1 \quad t = \{(i, n)\} \cup d \quad e = (\text{op}, i, t)}{(s_g, \vec{s}_l) \rightarrow_{\mathcal{S}} (s_g \cup \{e\}, \vec{s}_l[i \mapsto s \cup \{e\}])} \text{TUpdate}$$

$$\frac{s \subseteq s_{l,j} \quad \text{depclosed}(s)}{(s_g, \vec{l}) \rightarrow_{\mathcal{S}} (s_g, \vec{l}[i \mapsto s_{l,i} \cup s])} \text{TMerge}$$

The TUpdate rule models the execution of a new operation at a particular replica. The premises say that the local state at replica i is s and d is the set of dependencies of all events in s . Then we compute the sequence number for the new event: since it originates in i this needs to be exactly one larger than the number of dependencies in d that come from i , hence $n = |\text{sect}(d, i)| + 1$. Then we build a timestamp for the new event: every (old) event in s should be a causal dependency of the new event, plus the new event's id is also a dependency, so $t = \{(i, n)\} \cup d$. Finally we build the new event $e = (\text{op}, i, t)$. Given all the above, we can take a step in the STS from a state (s_g, \vec{s}_l) to a state that includes the new event e . Because e is new, it should be added both to the global state and the local state for i . The notation $\vec{s}_l[i \mapsto s']$ stands for the vector that is like \vec{s}_l except that the i 'th entry is now s' .

The TMerge rule models merge operations where a replica updates its state by receiving and merging a (potentially old) state that was sent by another replica. In the rule, we start with some subset s of the local state at replica j . It is crucial that said subset be dep-closed so that we can preserve causality. In the rule's conclusion, we merge s with the state at replica i . That is, we can think of this rule as saying that replica j transmitted its state to replica i , which subsequently merged it. Finally, notice that the fact that s is a subset of $s_{l,j}$ and not exactly $s_{l,j}$ allows us to model the delay imposed by the network on message transmission – the fact that s is a *dep-closed* subset of $s_{l,j}$ means that s is a version of the state of the j^{th} replica from the past.

7.2 Safety Invariants

The goal of the STS model is to allow us to show a number of safety invariants about the execution of the system. We do this through the notions of *local* and *global state validity*. Let $s \in \text{Lst}$. Then s is a *valid local state*, written $\text{LocStValid}(s)$, if all the following hold:

⁸ As usual $\rightarrow_{\mathcal{S}}^*$ denotes the reflexive transitive closure of $\rightarrow_{\mathcal{S}}$.

(DepClosed)	$\text{depclosed}(s)$
(SameOrigComp)	$\forall i, \forall e' \in \text{sect}(s, i), e.t <_t e'.t \vee e.t = e'.t \vee e'.t <_t e.t$
(ExtId)	$\forall e' \in s, \text{id}(e) = \text{id}(e') \Rightarrow e = e'$
(ExtTime)	$\forall e' \in s, e.t = e'.t \Rightarrow e = e'$
(OrigRange)	$\forall e \in s, e.s < \text{numRep}$
(SeqIdComplete)	$\forall e \in s, n \in \mathbb{N}, 0 < (e.s, n) \leq \text{id}(e) \Rightarrow (e.s, n) \in e.t$
(SeqIdNon0)	$\forall e \in s, r, n \in \mathbb{N}, \text{id}(e) = (r, n) \Rightarrow 0 < n$
(EvIdMon)	$\forall e' \in s, e.s = e'.s \Rightarrow e.t \leq_t e'.t \Rightarrow \text{id}(e) \leq \text{id}(e')$
(EvIdIncl)	$\forall e \in s, \text{id}(e) \in e.t$
(EvIdTime)	$\forall e' \in s, \text{id}(e) \in e'.t \Rightarrow e.t \leq_t e'.t$

The different requirements on valid local states are as follows. (DepClosed) requires that a valid state s be also dep-closed. (SameOrigComp) says that events with the same origin can be totally ordered by timestamp ordering. (ExtId) and (ExtTime) say that events with equal id, resp. timestamp, must be equal. (OrigRange) ensures that replica ids are in the expected range. (SeqIdComplete) says that if $e \in s$ and e 's id is e.g. $(4, 10)$, then all timestamps in the range $(4, 1) \dots (4, 9)$ must also be in e 's dependencies. (SeqIdNon0) says that all event ids have a sequence number that starts at 1. (EvIdMon) requires that timestamps ordering and event id ordering agree. (EvIdIncl) says that an event id must be included in the event's dependencies. Finally, (EvIdTime) requires that if e 's id is in the dependencies of e' then e must have in fact happened before e' according to timestamp ordering. The definition of local state validity has been simplified with respect to prior developments [8, 20]. This is because these works use vector clocks as their notion of logical and physical time, whereas we only track time logically via sets of dependencies.

From local state validity we obtain a number of derived lemmas. For example, we can relate dep-closed and causally-closed subsets:

► **Lemma 2.** *Let $s \subseteq s_g$ where $\text{depclosed}(s)$ and $\text{LocStValid}(s_g)$. Then $s \subseteq_{\text{cc}} s_g$.*

Now we define validity of global states. Let $q = (s_g, \vec{s}_l) \in \text{Gst}$. Then q is a *valid global state*, written $\text{GlobStValid}(q)$, if all the following hold:

(InclLocal)	$s_g = \bigcup_{1 \leq i \leq \text{numRep}} s_{l, i}$
(InclOrig)	$\forall e \in s_g, e \in s_{l, e.s}$
(GlobValid)	$\text{LocStValid}(s_g)$
(LocValid)	$\forall 1 \leq i \leq \text{numRep}, \text{LocStValid}(s_{l, i})$

Given a global state (s_g, \vec{s}_l) , global state validity amounts to requiring that s_g be the union of the $s_{l, i}$ (InclLocal), that events be present in the local state from which they putatively originate (InclOrig), that the global state s_g itself be valid if treated as a local state (GlobValid) and that each local state be valid (LocValid). The definition of global state validity is essentially unchanged from prior work [8, 20].

The definitions of local and global state validity are motivated by two desiderata: they must be *invariants*, i.e. hold for all reachable states (including the initial state); and they must imply the CRDT resource lemmas from Figure 3 “at the model level”.

► **Theorem 3 (Validity invariant).** *Let $q \in \text{Gst}$ such that $\text{init}_S \rightarrow_S^* q$. Then $\text{GlobStValid}(q)$.*

We use validity to show model-level counterparts of the lemmas in Figure 3. Intuitively, ownership of $\text{GlobSt}(s_g)$ tells us that the global state is (s_g, \vec{s}_l) , whereas if we know $\text{GlobSnap}(s'_g)$ all we can say is that $s'_g \subseteq s_g$. Similarly, ownership of $\text{LocSt}(i, s_{\text{own}}, s_{\text{for}})$

corresponds to knowing that the local state $s_{l,i}$ (which we can assume to be valid) equals $s_{\text{own}} \dot{\cup} s'_{\text{for}}$ (disjoint union), with $s_{\text{for}} \subseteq s'_{\text{for}}$. The local snapshot $\text{LocSnap}(i, s_{\text{own}}, s_{\text{for}})$ give us $s_{\text{own}} \dot{\cup} s_{\text{for}} \subseteq s_{l,i}$. With this analogy in mind, here is the model-level version of causality.

► **Lemma 4** (Model-level causality). *Let $q = (s_g, \vec{s}_i)$ and $\text{GlobStValid}(q)$. Also let $e \in s \subseteq_{\text{cc}} s_{l,i}$ and $e' \in s_g$, with $e'.t <_t e.t$. Then $e' \in s$.*

Proof. From $\text{GlobStValid}(q)$ we can conclude $\text{LocStValid}(s_{l,i})$, which in turn gives us $\text{depclosed}(s_{l,i})$. Since $s_{l,i} \subseteq s_g$, by Lemma 2 we get $s_{l,i} \subseteq_{\text{cc}} s_g$. Since we assumed $s \subseteq_{\text{cc}} s_{l,i}$, we can use transitivity of \subseteq_{cc} to conclude $s \subseteq_{\text{cc}} s_g$. This implies the conclusion. ◀

7.3 Separation Logic Encoding

The next step in the proof is to encode the validity invariant using separation logic. We do this using a combination of Iris invariants and resources [9]. Recall that Iris invariants are propositions that hold throughout the execution of the operational semantics and resources are elements of partial commutative monoids (PCMs).

Here we use resources whose ownership reveals what state the system is partially in (e.g. the set of events received by a specific replica). In particular, we use three main PCM constructions, which we review below:⁹

1. The *authoritative* PCM $\text{AUTH}(\mathbb{M})$, where \mathbb{M} is itself a PCM. Given a PCM \mathbb{X} , we can define the *extension order* on elements of the carrier as follows: $x \leq_{\mathbb{X}} y \triangleq \exists z, x \cdot z = y$. The authoritative construction gives us two kinds of resources: a *full part* $\bullet_{\mathbb{M}} g$ and one or more *fragmental parts* $\circ_{\mathbb{M}} s$, where $g, s \in \mathbb{M}$. Ownership of the full part is exclusive, while ownership of a fragment $\circ_{\mathbb{M}} s$ is exclusive or persistent depending on whether ownership of s is exclusive or persistent in \mathbb{M} . The fragmental parts are guaranteed to be smaller than the full part according to extension order, so that if we own $\{\bullet_{\mathbb{M}} g\}^\gamma * \{\circ_{\mathbb{M}} s\}^\gamma$ we can conclude $s \leq_{\mathbb{M}} g$. We also have that $\circ_{\mathbb{M}} g \cdot \circ_{\mathbb{M}} s = \circ_{\mathbb{M}} (g \cdot s)$.
2. The *fractional* PCM $\text{FRAC}(X)$, where X is a carrier set. Elements of this monoid are of the form s^p , where $s \in X$ and $p \in \mathbb{Q}_{(0,1]}$. This PCM allows us to split and re-combine fractions of a resource: $s^{p+q} = s^p \cdot s^q$. We also know that if we own multiple fractions then they must add to less than 1. This is useful to e.g. make a proposition exclusive (non-duplicable) by defining it as a fraction greater than $\frac{1}{2}$ as no two copies of such a resource can be owned separately. We also know that all fractions agree on the underlying element: $\{s^p\}^\gamma * \{r^q\}^\gamma$ implies $s = r$.
3. The *monotone* PCM $\text{MONO}(R)$, where $R \subseteq X \times X$ is a pre-order on a carrier set X [22]. This PCM allows us to lift R to the extension order of $\text{MONO}(R)$: any $x \in X$ can be injected into $\text{MONO}(R)$ via a principal_R function such that $xRy \iff \text{principal}_R(x) \leq_{\text{MONO}(R)} \text{principal}_R(y)$. Combining this with the authoritative PCM gives us a monoid $\text{AUTH}(\text{MONO}(R))$ where if we know $\{\bullet_{\mathbb{M}} \text{principal}_R(g)\}^\gamma * \{\circ_{\mathbb{M}} \text{principal}_R(s)\}^\gamma$ we can conclude sRg . We instantiate this construction with $R = \subseteq_{\text{cc}}$.

We use the defined invariants and resources to prove the interface described in Figure 3. In this section, we sketch out proofs for some of the interface lemmas.

⁹ We use a few additional PCMs in the Coq formalization but elide those additional structures here for the sake of brevity.

The global invariant uses the predicate **GI** below. The predicate states that there exists a (model-level) global state h which is valid. Furthermore, it asserts ownership of global and local resources defined by the predicates $\mathbf{GR}(s_g)$ and $\mathbf{LR}(i, s_{l,i})$, respectively.

$$\mathbf{GI} \triangleq \exists h \in \overline{\mathbf{Gst}}. h = (s_g, \vec{s}_i) * \mathbf{GlobStValid}(h) * \mathbf{GR}(s_g) * \bigstar_{i=1}^{\text{numRep}} \mathbf{LR}(i, s_{l,i})$$

Given the above definition and an invariant name ι , we can instantiate the $\mathbf{GlobInv}$ predicate from Figure 3 by allocating an Aneris invariant stating that **GI** holds after every execution step: $\mathbf{GlobInv} \triangleq \overline{\mathbf{GI}}^\iota$.

The *global resource* predicate $\mathbf{GR}(s_g)$ asserts ownership of two pieces of ghost state, both of which precisely track the value of s_g : $\mathbf{GR}(s_g) \triangleq \overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{gst}}} * \overline{\left[\bullet_{\mathbb{S}} s_g \right]}^{\gamma_{\text{gsnap}}}$.

The ghost state $\frac{1}{3}$ is drawn from the $\mathbf{FRAC}(\mathbf{Gst})$ PCM. Its purpose is to track the global set of events. The remaining $\frac{2}{3}$ fraction is kept *outside* of the invariant as the user-facing resource \mathbf{GlobSt} from Figure 3: $\mathbf{GlobSt}(s_g) \triangleq \overline{\left[\frac{2}{3} \right]}^{\gamma_{\text{gst}}}$. Because the fraction in \mathbf{GlobSt} is greater than a half, we can prove that $\mathbf{GlobSt}(s_g)$ is exclusive ($\mathbf{GlobStExcl}$, Figure 3).

The second part of $\mathbf{GR}(s_g)$ asserts ownership of $\bullet_{\mathbb{S}} s_g$. Here, \mathbb{S} is the PCM of finite sets of events, with set union as composition. This means that $p \leq_{\mathbb{S}} q$ iff $p \subseteq q$. Consequently, $\overline{\left[\bullet_{\mathbb{S}} s_g \right]}^{\gamma_{\text{gsnap}}} * \overline{\left[\bullet_{\mathbb{S}} s'_g \right]}^{\gamma_{\text{gsnap}}}$ implies $s'_g \subseteq s_g$. We keep the full part in the invariant and use the fragmental part to define global snapshots: $\mathbf{GlobSnap}(s) \triangleq \overline{\left[\bullet_{\mathbb{S}} s \right]}^{\gamma_{\text{gsnap}}}$. Note that these fragmental parts are persistent (duplicable) as the set union operation is idempotent.

The next step is to define the local resources predicate $\mathbf{LR}(i, s)$ which tracks in the invariant the local resources for replica i :

$$\begin{aligned} \mathbf{LR}(i, s) \triangleq & \exists s_{\text{own}} s_{\text{for}} s_{\text{sub}}, s = s_{\text{own}} \cup s_{\text{for}} * s_{\text{own}} \cup s_{\text{sub}} \subseteq_{\text{cc}} s_{\text{own}} \cup s_{\text{for}} \\ & * \mathbf{LocEv}(i, s_{\text{own}}) * \mathbf{ForEv}(i, s_{\text{for}}) * \mathbf{ForEv}(i, s_{\text{sub}}) * \overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{own}_i}} * \overline{\left[\frac{1}{2} \right]}^{\gamma_{\text{for}_i}} * \overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{sub}_i}} \\ & * \overline{\left[\bullet_{\mathbb{M}} \text{principal}_{\subseteq_{\text{cc}}} (s_{\text{own}} \cup s_{\text{for}}) \right]}^{\gamma_{\text{ccfor}_i}} * \overline{\left[\bullet_{\mathbb{M}} \text{principal}_{\subseteq_{\text{cc}}} (s_{\text{own}} \cup s_{\text{sub}}) \right]}^{\gamma_{\text{ccsub}_i}} \end{aligned}$$

The predicate $\mathbf{LR}(i, s)$ says that s can be broken up into two (disjoint) sets s_{own} and s_{for} . The sets are disjoint because every event in s_{own} originates at replica i , whereas all events in s_{for} originate outside of replica i . This is expressed by the predicates $\mathbf{LocEv}(i, p) = \forall e \in p. e.s = i$ and $\mathbf{ForEv}(i, p) = \forall e \in p. e.s \neq i$, respectively. Additionally, there is a third set s_{sub} which is a subset of s_{for} (this is implied by $s_{\text{own}} \cup s_{\text{sub}} \subseteq_{\text{cc}} s_{\text{own}} \cup s_{\text{for}}$). The intuition for s_{own} and s_{for} is that they precisely track the set of events that have been delivered at replica i and originate at i or outside of i , respectively. However, the user at replica i is not aware of all those events: specifically, while the user is aware of (the effects of) all its local events, it might not have observed all events that originate outside of i . The set s_{sub} precisely tracks the set of remote events, $\mathbf{ForEv}(i, s_{\text{sub}})$, that replica i has observed and is aware of. The tracking of all these event sets is precise because of the ownership of the fractions $\overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{own}_i}} * \overline{\left[\frac{1}{2} \right]}^{\gamma_{\text{for}_i}} * \overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{sub}_i}}$. Additionally, the invariant has “read-only” access to the three pieces of ghost state because it does not possess the full fractions. Before pressing on with the definition of $\mathbf{LR}(i, s)$, let us look at the definition of local state and snapshot from Figure 3:

$$\begin{aligned} \mathbf{LocSt}(i, s_{\text{own}}, s_{\text{sub}}) \triangleq & \overline{\left[\frac{1}{3} \right]}^{\gamma_{\text{own}_i}} * \overline{\left[\frac{2}{3} \right]}^{\gamma_{\text{sub}_i}} * \mathbf{LocSnap}(i, s_{\text{own}}, s_{\text{sub}}) \\ \mathbf{LocSnap}(i, s_{\text{own}}, s_{\text{sub}}) \triangleq & \mathbf{LocEv}(i, s_{\text{own}}) * \mathbf{ForEv}(i, s_{\text{sub}}) * \overline{\left[\bullet_{\mathbb{M}} \text{principal}_{\subseteq_{\text{cc}}} (s_{\text{own}} \cup s_{\text{sub}}) \right]}^{\gamma_{\text{ccsub}_i}} \end{aligned}$$

Notice that ownership of the local state resource gives us knowledge of some but not all of the missing fractions for s_{own} and s_{sub} : $\frac{1}{3}\gamma_{\text{own}_i} * \frac{2}{3}\gamma_{\text{sub}_i}$. This corresponds to our intuition that s_{sub} tracks the set of events the user is aware of. Notice that local state does not contain a fraction of s_{for} , because otherwise the library could not accept remote updates in a background thread.

We next explain the use of the PCM $\mathbb{M} \triangleq \text{MONO}(\subseteq_{\text{cc}})$, where $\subseteq_{\text{cc}}: \text{Event} \times \text{Event}$. We use two instances of this PCM, each under a different family of ghost names: γ_{ccsub_i} and γ_{ccfor_i} . The local state contains just γ_{ccsub_i} and the invariant contains both γ_{ccsub_i} and γ_{ccfor_i} . The intuition for holding the fragmental part $\circ_{\mathbb{M}} \text{principal}_{\subseteq_{\text{cc}}}(s_{\text{own}} \cup s_{\text{sub}})$ is to allow us to prove inclusion of local snapshots (`LocSnapIncl`, Figure 3).

We can now sketch the proof of the causality lemma. This proof is representative of our methodology: use the properties of the different PCMs to identify parts of a (valid) global state we are currently in, and then rely on a model-level lemma to get the result we want.

► **Lemma 5** (Causality, Figure 3). $\text{GlobInv} \multimap \text{LocSt}(i, o, s) \multimap \text{GlobSnap}(h) \multimap \text{LocSt}(i, o, s) * \forall e e', e \in h \Rightarrow e' \in o \cup s \Rightarrow e <_t e' \Rightarrow e \in o \cup s$.

Proof. We open the global invariant and learn that the current global state (s_g, \bar{s}_l) is valid. We also obtain global resources $\frac{1}{3}\gamma_{\text{gst}} * \bullet_{\text{S}} s_g^{\gamma_{\text{gsnap}}}$ and local resources $\frac{1}{3}\gamma_{\text{own}_i} * \frac{2}{3}\gamma_{\text{sub}_i}$, where $s_{\text{own}} \cup s_{\text{sub}} \subseteq_{\text{cc}} s_{\text{own}} \cup s_{\text{for}} = s_{l,i}$. From `LocSt` (i, o, s) we get $\frac{1}{3}\gamma_{\text{own}_i} * \frac{2}{3}\gamma_{\text{sub}_i}$, which tells us that $o = s_{\text{own}}$ and $s = s_{\text{sub}}$. From `GlobSnap` (h) we get $\frac{1}{3}\gamma_{\text{own}_i} * \frac{2}{3}\gamma_{\text{sub}_i}$, which tells us that $h \subseteq s_g$. This means we have $e \in s_g$ and e' is in a causally-closed subset of $s_{l,i}$, so we can finish by applying Lemma 4. ◀

There are additional two resources in the definition of $\mathbf{LR}(i, s)$: $\frac{1}{2}\gamma_{\text{for}_i}$ and $\bullet_{\mathbb{M}} \text{principal}_{\subseteq_{\text{cc}}}(s_{\text{own}} \cup s_{\text{for}})^{\gamma_{\text{ccfor}_i}}$. These are used in the definition of the lock invariant and socket protocol, respectively. We explain them in the next section.

In addition to proving the resource lemmas from Figure 3, we also need to show that the PCMs we have chosen can make frame-preserving updates that are compatible with the two transitions (`TUpdate` and `TMerge`) from Definition 1. We refer to reader to our Coq formalization for details.

7.4 Safety Proof

STATELIB's `init` function allocates a reference with the CRDT's initial state and spawns two concurrent threads: `apply` receives states from other replicas and merges them with the current state, and `broadcast` regularly sends the current state to all other replicas. Access to the (shared) local state is coordinated via a spinlock. The associated *lock invariant* [1], defined by the predicate $\mathbf{LI}(i, \ell)$ below, is the key ingredient of the library's safety proof (ℓ is the memory location holding the CRDT's state). When a thread acquires the lock, it gets to assume $\mathbf{LI}(i, \ell)$; unlike a regular invariant, which needs to be restored after a single atomic step, a lock invariant need not be restored until the thread releases the lock.

$$\begin{aligned} \mathbf{LI}(i, \ell) \triangleq \exists st s_{\text{own}} s_{\text{for}}. \text{LocEv}(i, s_{\text{own}}) * \text{ForEv}(i, s_{\text{for}}) * \ell \mapsto_{\text{ip}} st \\ * \llbracket s_{\text{own}} \cup s_{\text{for}} \rrbracket = st * \frac{1}{3}\gamma_{\text{own}_i} * \frac{1}{2}\gamma_{\text{for}_i} \end{aligned}$$

The lock invariant says that the CRDT's state is always the denotation of some set of events $s_{\text{own}} \cup s_{\text{for}}$ (ip is the IP address of replica i). Additionally, the invariant holds resources $\llbracket \frac{1}{3} \rrbracket_{s_{\text{own}}}^{\gamma_{\text{own}_i}} * \llbracket \frac{1}{2} \rrbracket_{s_{\text{for}}}^{\gamma_{\text{for}_i}}$ which guarantee that we are “in sync” with the logical state recorded for replica i in the global invariant **GlobInv**. Notice the lock invariant keeps γ_{for_i} and not γ_{sub_i} because the library knows exactly the set of foreign events that have been processed so far. The table below summarizes where the different fractions of γ_{own_i} , γ_{for_i} and γ_{sub_i} are kept:

	γ_{own_i}	γ_{for_i}	γ_{sub_i}
Global invariant	$\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$
Lock invariant	$\frac{1}{3}$	$\frac{1}{2}$	
Local state	$\frac{1}{3}$		$\frac{2}{3}$

As part of the proof we also need to define STATELIB's socket protocol $\mathbf{SP}(i, st)$; i.e. a predicate that holds for all states st received by a replica (which dually creates a proof obligation whenever a replica messages others). The abridged version below assumes that st is already deserialized and that i is the replica id of the message's sender:

$$\mathbf{SP}(i, st) \triangleq \exists s'_{\text{own}} s'_{\text{for}}. \text{LocEv}(i, s'_{\text{own}}) * \text{ForEv}(i, s'_{\text{for}}) * \llbracket s'_{\text{own}} \cup s'_{\text{for}} \rrbracket = st \\ * \text{LocStValid}(s'_{\text{own}} \cup s'_{\text{for}}) * \llbracket \text{OM principal}_{\subseteq_{\text{cc}}} (s'_{\text{own}} \cup s'_{\text{for}}) \rrbracket_i^{\gamma_{\text{ccfor}_i}}$$

The socket protocol assumes that the received state st is the denotation of the union $s'_{\text{own}} \cup s'_{\text{for}}$, where s'_{own} and s'_{for} are event sets that are local and foreign, respectively, relative to the message's sender (not relative to the receiver). Additionally, we know that $s'_{\text{own}} \cup s'_{\text{for}}$ is a causally closed subset of the events recorded at replica i (in particular, we know the sender is not accidentally including events that have not been previously recorded).

Since both `apply` and `broadcast` recurse forever, their specifications are not very interesting: in particular, we do not care about their post-conditions. We do care about preserving the lock and global invariants as they execute. We briefly sketch the proof of `apply`. Before `apply` updates the CRDT state via $st := \text{merge } !st \text{ st}'$, we know that all the following hold: the global invariant **GlobInv**, the lock invariant $\mathbf{LI}(i, st)$, and the socket protocol $\mathbf{SP}(j, st')$, where i and j are the ids of the local and sender replicas, respectively, and $i \neq j$. We open the lock invariant and get $!st = \llbracket s_{\text{own}} \cup s_{\text{for}} \rrbracket * \llbracket \frac{1}{3} \rrbracket_{s_{\text{own}}}^{\gamma_{\text{own}_i}} * \llbracket \frac{1}{2} \rrbracket_{s_{\text{for}}}^{\gamma_{\text{for}_i}}$. Similarly, from the socket protocol we know that $st' = \llbracket s'_{\text{own}} \cup s'_{\text{for}} \rrbracket * \text{LocStValid}(s'_{\text{own}} \cup s'_{\text{for}}) * \llbracket \text{OM principal}_{\subseteq_{\text{cc}}} (s'_{\text{own}} \cup s'_{\text{for}}) \rrbracket_i^{\gamma_{\text{ccfor}_i}}$. We would like to apply the coherence lemma (**MergeCoh**), which tells us that merging two states is the same as (1) merging the corresponding events that generated those states, and (2) then taking the denotation of the union of the event sets. The premises of (**MergeCoh**) all follow from local state validity after opening the global invariant, and from the fact that $\llbracket \text{OM principal}_{\subseteq_{\text{cc}}} (s'_{\text{own}} \cup s'_{\text{for}}) \rrbracket_i^{\gamma_{\text{ccfor}_i}}$ proves that the events we are merging have been previously recorded. The resulting logical state is $\llbracket \frac{1}{3} \rrbracket_{s_{\text{own}}}^{\gamma_{\text{own}_i}} * \llbracket (s_{\text{for}} \cup s'_{\text{own}} \cup \{e \in s'_{\text{for}} \mid e.s \neq i\}) \rrbracket_i^{\gamma_{\text{for}_i}}$.

The proof of `get_state` uses the lock invariant to conclude that the returned state is the denotation of the set of events received so far. It then uses the global invariant: specifically the relation $s_{\text{own}} \cup s_{\text{sub}} \subseteq_{\text{cc}} s_{\text{own}} \cup s_{\text{for}}$ in the definition of $\mathbf{LR}(i, s)$ to update the local state to $\text{LocSt}(i, o, f')$. The proof of `update` uses the preservation of global validity under a **TUpdate** transition (Theorem 3) to show that **GlobInv** is preserved. We refer the reader to our formalization for additional details.

8 Verified CRDTs

To test STATELIB we verified five example CRDTs from the literature: grow-only counter (g-counter), grow-only set, product combinator, map combinator, and positive-negative counter (pn-counter). We also verified a closed program consisting of client code that uses the pn-counter. This closed program appears in Nieto et al. [20], and we were able to swap out their op-based pn-counter for our state-based version without modifying their safety proof.¹⁰ We used the closed example as a case study in giving our state-based CRDT the same specification as its op-based counterpart, hiding implementation details in the process.

In this section we focus on describing the pn-counter and the closed program. A pn-counter is a data structure that supports two operations: `add(z)` adds the integer z , which may be negative, to the counter, and `get_value` returns the counter's current value. The initial value is 0. The denotation for pn-counter used in Nieto et al. [20] is $\llbracket s \rrbracket = \sum_{e \in s} e.o.$ We implemented the counter as a wrapper over the product `prod(g-counter, g-counter)`. We now explain how `g-counter` and `prod` work.

The `g-counter` is a simpler version of pn-counter where we can only add non-negative numbers. Operations are of the form `add(n)` with $n \in \mathbb{N}$. If N is the number of CRDT replicas, the lattice state is a vector \vec{c} with N entries. The i th entry tracks the contribution of replica i to the counter's state. The initial value is the 0-vector of length N . The mutator is defined as `mut(\vec{c}, e) = s[e.s \mapsto $\vec{c}_{e.s} + e.o$]`, and merges are done by taking the maximum of two vectors pointwise. The denotation $\llbracket s \rrbracket$ is the pointwise sum of all the vectors in s .

Given two CRDTs $C_A = (\text{Op}_A, \text{St}_A, \text{init}_A, \text{mut}_A, \text{merge}_A)$ and $C_B = (\text{Op}_B, \text{St}_B, \text{init}_B, \text{mut}_B, \text{merge}_B)$, their product is $C_{A \times B} = (\text{Op}_A \times \text{Op}_B, \text{St}_A \times \text{St}_B, \text{init}_A \times \text{init}_B, \text{mut}_{A \times B}, \text{merge}_{A \times B})$. Both the mutator and merge function operate in a component-wise fashion. The denotation $\llbracket s \rrbracket$ splits s into two sets s_A and s_B of A-events and B-events, respectively. It then computes the pair $(\llbracket s_A \rrbracket_A, \llbracket s_B \rrbracket_B)$.

We then implement the pn-counter as a wrapper over the product `prod(g-counter, g-counter)`. Specifically, we wrap the product's `get_state` and `update` as follows (`sum_entries` is the function that sums all the entries of a vector):

```
let pncounter_add z =
  if z >= 0 then prod_update((z, 0))
  else prod_update((0, -z))
let pncounter_get_value () =
  let (v1, v2) = prod_get_state () in
  (sum_entries v1) - (sum_entries v2)
```

Finally, we describe the closed program we verified. This example shows client code interacting with a pn-counter. The relevant snippet is shown below: we have two replicas, A and B , each of which increments the counter, reads it, and then asserts that the read returns one of two possible values. In A the possible values are 1 and 3, depending on whether the remote operation `add 2` has been propagated from B to A by the time the read happens. In either case, the `add 1` must be visible by the subsequent read because the latter happened later according to program order: this is the so-called *reads-follow-writes* session guarantee [8]. An analogous situation happens for replica B .

```
(* replica A *)
add 1;
let r = get_value () in
assert (r = 1 || r = 3)

(* replica B *)
add 2;
let r = get_value () in
assert (r = 2 || r = 3)
```

¹⁰We have added one additional property to the common CRDT resource interface (an excerpt of which was shown in Figure 3), and thus we extended the proof of Nieto et al. [20] such that this additional property is also proved for their op-based library.

The reader can consult Nieto et al. [20] for more details on the proof that the assertions in the example above do not fail, but the important part is that we were able to swap out the op-based counter implementation by our state-based counter, while (almost) keeping the proof intact. The two implementations are quite different: the op-based implementation relies on a causal broadcast algorithm, while ours does not and instead relies on lattice properties, as well as on applications of the product combinator. The fact that both implementations meet the same specification is good evidence that the denotation-based separation logic specifications are general, flexible, and can hide implementation details.

9 Related Work

As previously mentioned, the idea of specifying CRDTs as a partial function from event histories (including causality metadata) to the data type’s state comes from Burckhardt et al. [3]. We also learned from their paper that state-based CRDTs can be thought of as transitively delivering (the effects of) events when states are merged, which in turn makes it possible to prove, as we have done, that state-based CRDTs are causally-consistent.¹¹

Leijnse et al. [13] reformulate the above specification style so it can be better applied to higher-order combinators, coining the term CRDT denotation. They work solely with specifications, and do not implement these combinators nor verify an implementation.

The idea of tracking the state of a concurrent data structure via a logical set of operations that is divided into contributions by the current thread and those originating from other threads, as in our $\text{LocSt}(i, o, f)$ resource, has previously appeared in the context of the FCSL logic (where they are termed “self” and “other” contributions, respectively) [19, 5].

The Compass separation logic framework [4] (also Iris-based) can be used to specify and verify functional correctness of concurrent data structures in a relaxed memory model. There are a number of commonalities with our work: their specs are also given as logically-atomic triples that track the state of a data structure as a function of the set of writes that are visible by a given thread. They develop a notion of logical *views* that is similar to our local snapshots $\text{LocSnap}(i, o, f)$ (without the distinction between own and foreign events): ownership of a view provides a lower bound on the set of observed events, and the views contain logical metadata that tracks the happens-before relation between writes. The main difference with our work is that we operate at the intersection of weak consistency and message passing, whereas their work is in the context of shared memory.

Zeller et al. [24] implement and formally verify multiple state-based CRDTs in Isabelle/HOL. To our knowledge, they are the first to explicitly link denotation-style specifications to their lattice-based implementations. Like us, they prove both convergence and functional correctness. There are two main differences with our work: their system model is an STS where the states map each replica id to the replica state (this is very similar to our STS model from Section 7.1). By contrast, in our work the system model is the operational semantics of *AnerisLang*, with support for mutation, node-local concurrency, higher-order functions, etc. This means that while their technique can only be used to reason about a CRDT in isolation, ours can verify a system where the CRDT and a client (or a larger distributed system of which the CRDT is a small part) are executing together, and where both of these are implemented in a realistic programming language. The second difference is that in Zeller et al.’s work one needs to come up with a different invariant that implies

¹¹They do mention that state-based CRDTs are causally-consistent, but there is no formal proof, or even a precise lemma statement.

coherence between the denotation and the lattice for each implemented CRDT, as well as proving for each example that the invariant is preserved by the different transitions. In our work, we prove just one invariant, global state validity, and the CRDT implementer then needs to prove coherence given that global validity holds.

Nair et al. [18] verify several state-based CRDTs. These are not “pure” CRDTs in the sense that some of data structure’s operations are at times disabled. For example, they show how to verify a distributed lock implemented as a CRDT (the release-the-lock operation can only be enabled if the local replica owns the lock). Proof wise, this means that sometimes it is useful to enforce example-specific invariants on the CRDT being verified: it would be interesting to modify STATELIB so it can support these user-defined invariants and so can tackle the examples presented in their paper.

Gondelman et al. [8] verify functional correctness of a causally-consistent key-value store using *Aneris*. Their work introduces the encoding of causality in separation logic that we use. However, their key-value store is not a CRDT because it violates convergence. Additionally, their work is closer to op-based CRDTs because writes are propagated individually.

Timany et al. [23] develop an extension of *Aneris* called *Trillium* where one simultaneously proves both safety and also that the program being verified refines an STS model. Unlike in our work, where the STS is used just to prove safety, their refinement is *history-preserving*, which allows them to prove liveness properties as well. As one case study, they show that a state-based G-Counter CRDT is eventually consistent. They do not tackle any other (more complex) CRDTs, and their specification of the G-Counter relies on the fact that the G-Counter is monotonic. It would be interesting to recast our work using the *Trillium* methodology with the goal of showing that any CRDT implemented via STATELIB is eventually-consistency (that is, additionally showing eventual delivery).

The closest related work is Nieto et al. [20], from which we inherit the CRDT resource interface from Figure 3, the modular structure of the implementation (a core library that can be instantiated for different CRDT examples), as well as the general structure of the proof: a state-transition system model that is embedded in the logic, as well as a lock invariant that ties the denotation-style specification to the lattice-based state. The main difference is that their paper deals exclusively with op-based CRDTs: as mentioned in Section 4.2 adapting their technique to the state-based setting leads to a number of technical challenges we had to solve in our approach.

10 Conclusions

We have shown how to give modular specifications to realistic state-based CRDT implementations using the *Aneris* separation logic. Our specifications show both convergence and functional correctness relative to an abstract denotational model of the CRDT.

We have explored our approach by implementing and verifying a library, STATELIB, for building state-based CRDTs. Our library takes as input a purely-functional implementation of a state-based CRDT’s core logic, together with coherence proofs between the CRDT’s lattice-based and denotation-based models. The library then produces as output a fully-fledged CRDT that is replicated over multiple nodes. Using the library we implemented and verified multiple example CRDTs from the literature.

When taken together with Nieto et al. [20], our work presents a unified framework for the specification and verification of op- and state-based CRDTs. To show that we can abstract away from the fact that a CRDT is state-based, we re-prove Nieto et al.’s interface for resources tracking CRDT state using a new definition of resources that is compatible with

state-based CRDTs. We test this approach by showing that one can start with a client program that uses an op-based counter CRDT, swap out the counter’s implementation by our state-based implementation, and recover the safety proof for the entire closed program while making minimal changes to the original proof.

Abstract

A mandatory feature for blockchain software, such as smart contracts and decentralized applications, is determinism. In fact, non-deterministic behaviors do not allow blockchain nodes to reach one common consensual state or a deterministic response, which causes the blockchain to be forked, stopped, or to deny services. While domain-specific languages are deterministic by design, general-purpose languages widely used for the development of smart contracts such as Go, provide many sources of non-determinism. However, not all non-deterministic behaviours are critical. In fact, only those that affect the state or the response of the blockchain can cause problems, as other uses (for example, logging) are only observable by the node that executes the application and not by others. Therefore, some frameworks for blockchains, such as Hyperledger Fabric or Cosmos SDK, do not prohibit the use of non-deterministic constructs but leave the programmer the burden of ensuring that the blockchain application is deterministic. In this paper, we present a flow-based approach to detect non-deterministic vulnerabilities which could compromise the blockchain. The analysis is implemented in GoLiSA, a semantics-based static analyzer for Go applications. Our experimental results show that GoLiSA is able to detect all vulnerabilities related to non-determinism on a significant set of applications, with better results than other open-source analyzers for blockchain software written in Go.

1 Introduction

In the last decade, blockchain software has undergone a notable evolution. In 2008, Bitcoin [33] introduced a Turing-incomplete low-level language to specify locking conditions that must hold for a transaction to be accepted by the network [3]. In 2013, Ethereum [8, 4] provided a Turing-complete bytecode where smart contract rules are enforced by the blockchain consensus. The execution of the code takes place on the Ethereum Virtual Machine (EVM), resulting in software identified as *decentralized applications* (DApps). EVM bytecode is supported by high-level domain-specific languages (DSLs), such as Solidity and Vyper, that have been designed from scratch for the purpose of being executed in the restricted environment of blockchain. Subsequently, thanks to frameworks such as Hyperledger Fabric [2], Tendermint [6, 29], and Cosmos SDK [30], general-purpose programming languages (GPLs) such as Go, Java and JavaScript can also be used to develop smart contracts and DApps, with Go being the most popular in industrial blockchains.

The popularity of GPLs for writing smart contracts and DApps is steadily increasing. Their success is mostly due to the maturity of the languages themselves, directly resulting in wide communities, consolidated tools (such as IDEs and debuggers), and most importantly a pool of expert and knowledgeable developers that can write highly efficient smart contracts. Yet, GPLs were not conceived solely for blockchain ecosystems: code that is harmless and bug-free in other contexts may result in vulnerabilities and errors. Among these, one of the most insidious is non-determinism. When the result of an operation on a blockchain is non-deterministic, there is no guarantee that a common state can be reached by the network's nodes, possibly preventing it from reaching consensus. This can manifest, among other possibilities, as transaction failures or denial of service. Nevertheless, not all instances of non-determinism are intrinsically dangerous: logging the time of a transaction can result in different timestamps appearing in each node's logs, but it does not endanger consensus as it is not *observable* by other nodes. In fact, non-deterministic instructions are problematic only if they can affect the shared blockchain state.

As an example, consider the code in Figure 1, reporting an excerpt of the `ValidateBasic` method from module `x/authz` (part of the Cosmos SDK versions 0.43.x and 0.44.{0,1}) and affected by the vulnerability reported in CVE-2021-41135¹. The code is meant to fail the validation of expired grants. Note that the guard at line 2 involves the local clock of nodes (`time.Now()`) rather than leveraging the timestamp included in the Block header provided by the Byzantine Fault Tolerant clock, that is agreed upon by the consensus. As reported in the official Cosmos forum [12]:

Local clock times are subjective and thus non-deterministic. An attacker could craft many Grants, with different but close expiration times (e.g., separated by a few seconds), and try to exercise the granted functionality for all of them close to their expiration time. It is likely in such a scenario that some nodes would consider a grant to have expired while others would not, leading to a consensus halt.

The code was then fixed in version 0.44.2, but is still a clear example of a vulnerability arising from non-deterministic constructs.

The problem of non-determinism in blockchain software is clearly felt by the communities of the blockchain frameworks treated in this paper. As a representative example, the Tendermint Core documentation [27], while discussing non-determinism, reports:

¹ <https://nvd.nist.gov/vuln/detail/CVE-2021-41135>.

```
1 func (g Grant) ValidateBasic() error {
2     if g.Expiration.Unix() < time.Now().Unix() {
3         return sdkerrors.Wrap(ErrInvalidExpirationTime, "Time can't be in the past")
4     }
5     // [...]
6 }
```

■ **Figure 1** Cosmos SDK code affected by CVE-2021-41135.

While programmers can avoid non-determinism by being careful, it is also possible to create a special linter or static analyzer for each language to check for determinism. In the future we may work with partners to create such tools.

Paper contribution

This paper presents a software verification approach based on static analysis for the detection of non-deterministic vulnerabilities in blockchain ecosystems, covering the most popular frameworks for developing this kind of software, such as Hyperledger Fabric, Tendermint Core and Cosmos SDK. We shift the classical focus that has been applied in this context beyond the mere syntactic absence of non-deterministic constructs. In fact, we aim at distinguishing *harmful* usages of non-determinism, that is, constructs affecting the blockchain state and response, from *harmless* ones. As a consequence, the set of alarms issued to the user sensibly shrinks, as shifting from a syntactic approach towards a semantic one leads to a sensible reduction in false positives. We propose a semantic flow-based static analysis for detecting flows from non-deterministic constructs to blockchain state modifiers and response builders. The choice of a flow-based analysis seems natural when the problem is phrased as “*is there execution where a non-deterministic value affects the blockchain state or the contract’s response?*”. We thus exploit the well-consolidated literature in this area to adopt scalable solutions that soundly over-approximate all program executions.

We provide a static analyzer implementing our approach: GoLiSA², a sound static analyzer based on abstract interpretation [10] for Go applications. Intuitively, we use our analyzer’s fixpoint engine to mark *all* program variables (local variables, objects’ fields, ...) that can contain values affected, directly or indirectly, by a non-deterministic construct or computation. Specifically, we can perform a shallower analysis detecting only explicit flows using *Taint* analysis [43, 14], where non-deterministic constructs and blockchain state modifiers are modeled as sources and sinks, respectively. Alternatively, we can perform a deeper analysis able to also detect implicit flows by means of the *Non-interference* analysis [24, 25], where non-deterministic constructs and blockchain state modifiers are instead modeled as low and high variables, respectively. Both solutions are implemented in GoLiSA, whose analysis starts by syntactically visiting the input application to annotate all sources and sinks. The annotations are dynamically generated depending on the kind of application of interest (i.e., Hyperledger Fabric, Cosmos SDK, or Tendermint Core). Since there is no predefined set of sources in the target program, both *Taint* analysis and *Non-interference* are parametric: they consider as *harmful* (i.e., tainted or low integrity, depending on the analysis that is to be executed) only variables that are annotated as sources. The fixpoint engine then takes care of propagating values coming from sources on the entirety of the program, exploiting our analyses implementations. After the fixpoint converges, a mapping stating if each program variable is the result of a non-deterministic computation is available at each program

² <https://github.com/lisa-analyzer/go-lisa>

point. These are then used by our non-deterministic semantic checkers, that visit the whole application searching for statements annotated with the sink annotation. Whenever one is found, the mappings are used to determine if the values used as parameters of the call are critical or, in the case of *Non-interference*, if the call happens on a critical state.

Our approach, as highlighted by our evaluation, shows a significant decrease of false positives on real-world blockchain applications compared to other analyzers for blockchain non-determinism. The solution has been experimented on a benchmark of more than 600 real-world blockchain programs written in Go. These show that GoLiSA is able to perform the analysis on the totality of smart contracts in this significant benchmark, and to successfully report their non-determinism vulnerabilities.

The analyses are then evaluated in terms of precision of the results (true positive, false positive, and false negative alarms). Based on these criteria, GoLiSA outperforms existing open-source static analyzers for Go blockchain software. Moreover, the evaluation shows that the execution time of the analyses is not impractical for real use cases.

To the best of our knowledge, GoLiSA is the first sound semantic-based static analyzer for blockchain software able to precisely detect critical non-determinism behaviors while scaling to real-world programs.

Summarizing, our contribution is threefold, as we provide:

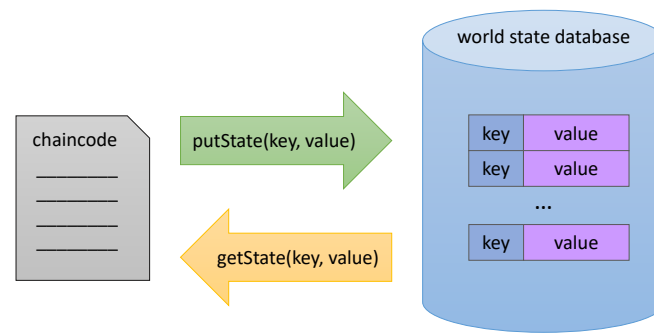

- a detailed investigation on the sources and the sinks that lead to non-determinism issues in the most popular blockchain frameworks;
- a flow-based static analysis for the detection of critical non-determinism behaviors, with two instantiations exploiting different formalizations;
- an open-source sound static analyzer for detecting critical non-deterministic behaviors in blockchain software written in Go.

Paper structure

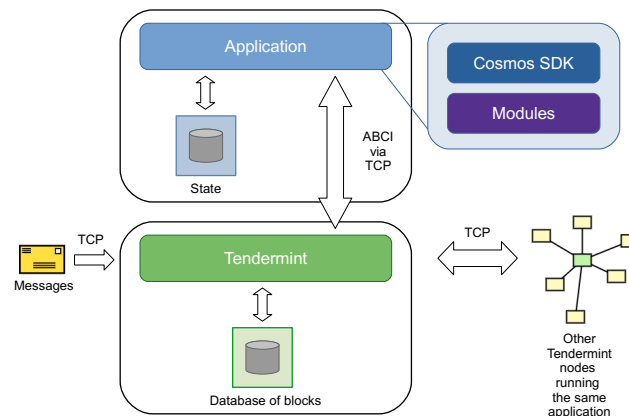

Sect. 2 reports an overview about blockchain software using Go and the most popular frameworks to develop it. Sect. 3 discusses the problem of non-deterministic behavior in blockchain context. After reporting an overview on information flow analyses, Sect. 4 presents our core contribution for detecting non-deterministic behavior in blockchain software, that relies on GoLiSA. Sect. 5 reports our experimental results. Sect. 6 discusses the related work. Finally, Sect. 7 concludes the paper.

2 Preliminaries: Go and Blockchain

Go (<https://golang.org>) is a statically typed, compiled, open-source, and general-purpose high-level programming language designed by Google to speed up software development, and that is appreciated for its cross-compilation feature. Its versatility and performance contributed to its diffusion in the blockchain environment: popular frameworks such as the Hyperledger Fabric³, Tendermint⁴ and the Cosmos SDK⁵ are written in Go. These rely on Go to develop efficient smart contracts and DApps, exploiting its high performances.

■ **Figure 2** The world state database of Hyperledger Fabric.

■ **Figure 3** Cosmos SDK architecture.

2.1 Blockchain Environments

Hyperledger Fabric (HF) is a permissioned blockchain framework designed to be adopted in enterprise contexts, supported by the Linux Foundation and other contributors such as IBM, Cisco, and Intel. In HF, smart contracts and DApps are written in *chaincode* that can be implemented in several GPLs such as Go, JavaScript, and Java. In most cases, the chaincode interacts only with the world state database component of the ledger, and not with the transaction log [26]. Go is currently the most popular language on GitHub related to *chaincode*⁶, as Go smart contracts are the best performing ones [23].

Tendermint Core, recently rebranded as *Ignite*, is a platform for building blockchain nodes, supporting both public and permissioned *proof-of-stake* (PoS) networks. It is a Byzantine Fault Tolerant (BFT) middleware that separates the application logic from the consensus and networking layers, allowing one to develop blockchain applications written in any programming language, including Go, and replicate them on many machines [7].

Cosmos SDK is an open-source Go framework that eases the development of blockchain applications while optimizing their execution by running them on Tendermint Core. As shown in Figure 3, Cosmos SDK abstracts all the boilerplate code needed to set up a Tendermint

³ <https://www.hyperledger.org/use/fabric>

⁵ <https://v1.cosmos.network/sdk>

⁶ Querying the keyword `chaincode` on GitHub (<https://github.com/search?q=chaincode>) results in more than 2100 repositories, about half of which are written in Go. Accessed: 01-12-2022.

Core node, allowing for customized protocol configurations. The programming style follows the object-capability model, where the security of subcomponents is imperative, especially those belonging to the core library. Cosmos SDK is a framework for DApps, supporting different functionalities through highly customizable modules (that can also manage smart contracts).

2.2 Blockchain Consensus

Consensus protocols ensure the validity and authenticity of transactions performed in the blockchain, as they check results of smart contracts or DApps computations through the state of the network's nodes. If a given number of nodes agree on the final state, consensus is reached and the transaction is validated. Otherwise, it is discarded and the nodes proposing spurious states are excluded from the network. When consensus cannot be reached, the blockchain either forks or halts. Deterministic execution is thus required for software that runs in a blockchain, as it guarantees that, when starting from a common state, the same result is reached in any distinct blockchain node, avoiding inconsistencies among peers and consensus failures. Nevertheless, GPLs provide several components that can explicitly lead to non-determinism, such as (pseudo-)random number generators or external computations. Furthermore, even methods that are explicitly sequential and deterministic pose a threat when executed on different nodes, such as the `time.Now()` call from Figure 1. Despite these threats, popular blockchain frameworks such as HF and Cosmos SDK do not enforce particular restrictions on the usage of non-deterministic methods and components.

3 Non-Deterministic Behaviors in Blockchain Software: Sources and Sinks

When trying to prevent non-deterministic vulnerabilities, a first solution is to limit the expressiveness of the GPL by either black- or white-listing APIs and constructs. Consider the Go snippets reported in Figure 4. Both fragments rely on the `time` API to retrieve a timestamp from the host system. In general, the results of calls to the `time` API are subjective to the node executing them, and they might lead to blockchain non-determinism due to different system settings (e.g., time, date, time zones, ...) or due to nodes executing the code at slightly different times. Specifically, Figure 4a shows a safe usage of the `time` API: the timestamp is only used for logging with no observable consequences on the blockchain state or the execution result. Instead, Figure 4b reports a problematic usage of the API, as the timestamp is stored in the blockchain using `PutState`, an HF-specific function that updates the shared network state. Since timestamps could differ on each node, this potentially leads to inconsistent executions (i.e., different blockchain states or execution results), causing transaction failure⁷.

It should thus be evident that identifying sources of non-determinism and preventing their usage is not enough when we aim at discerning between harmful and harmless non-deterministic constructs. In fact, one should also recognize how these are used, determining if they can influence the shared blockchain state. In the rest of this section we discuss, for each blockchain framework presented in Section 2, (i) the constructs that generate potentially harmful non-determinism (that is, *sources* of non-deterministic values), and (ii) the blockchain

⁷ In this case, the `GetTxTimestamp` method from the HF API should have been used instead of `time.Now`.

```

1 func transfer(from, to Address, value int64, stub *shim.ChaincodeStub) {
2     start := time.Now()
3     //... transfer operations that takes some milliseconds ...
4     elapsed := time.Now().Sub(start)
5     log.Println("Time elapsed for the transfer operations: ", elapsed)
6 }

```

(a) Example of safe use of the time API.

```

1 func transfer(from, to Address, value int64, stub *shim.ChaincodeStub) {
2     t := time.Now()
3     //... transfer operations ...
4     err := shim.PutState("transaction-time", t)
5     //... other operations ...
6 }

```

(b) Example of issue of non-determinism with the time API.

■ **Figure 4** Examples of harmless and harmful non-determinism in blockchain.

state modifiers and response builders (i.e., statements that make a transaction succeed or fail), namely *sinks* that are sensitive to non-determinism⁸. This will prepare the ground for the core contribution of this paper: a static approach to detect critical usages of non-determinism in blockchain software, reported in Section 4.

3.1 Sources of Non-Determinism

The sources of non-determinism can be logically split in two families, the first being related to the combination of framework and GPL adopted to develop the software. This family comprises a set of constructs and APIs allowed by the framework that may break the consensus during the execution of smart contracts or DApps. In Go, these are:

- *iteration over maps* that, being the iteration order unspecified⁹, is not guaranteed to be deterministic;
- *parallelization and concurrency*, that can lead to race conditions on shared resources, thus creating non-determinism on the computed values;
- *global variables*, that may change innately and cause inconsistencies to the results, since they depend on the application state of a peer and not on that of the blockchain [32, 5].
- *random value generators*, that can potentially be allowed in smart contracts [9] to employ custom logic while being non-deterministic by-definition.

The second family instead involves statements related to the underlying environment, such as file systems, operating systems, databases, and Internet connections. While these are not intrinsically non-deterministic, they become dangerous when their result is expected to be consistent on different environments. These comprise APIs handling:

- *file systems*, as the program might rely on files that are not present on all nodes, as they might have been deleted, edited, moved, or there might be insufficient disk space causing any operation to fail;
- *operating systems* (OS), since the blockchain might operate on various hosts and language APIs could return different results on each OS (e.g., time and date methods could return different values if nodes are not synchronized);

⁸ The complete list of sources and sinks of non-determinism is available at <https://github.com/lisa-analyzer/go-lisa/blob/master/go-lisa/sources-sinks.md>.

5     } else {
6         return shim.Success(nil)
7     }
8 }

```

■ **Figure 5** Example of issue of non-determinism related to the blockchain response.

- *databases*, where records might be deleted, edited, or contain different data;
- *Internet connections*, as networking setup or errors could cause some addresses to be unreachable on few nodes of the network.

Table 1 summarizes the instructions and libraries of Go¹⁰ that we considered as cases of non-determinism, where * represents the entirety of the package. For the sake of simplicity, the table reports instructions and packages omitting the full signatures of each method. Note that only few methods within those packages lead to non-deterministic behaviors: for instance, most methods from package `time` handling dates and times do not pose a threat in smart contracts and DApps, and are in fact quite common. However, operations such as retrieving the current time of the OS (i.e., methods `Since`, `Now`, `Until`) are potentially dangerous.

3.2 Sinks of Non-Determinism

Sinks of non-determinism comprise constructs and APIs with the ability of both modifying the common state of the blockchain or having an impact on the response of blockchain networks. While the former is inherently involved in consensus protocols, the execution of code within the blockchain does not necessarily change the shared state (e.g., functions that simply read a value). However, the execution may lead to non-deterministic responses, compromising the consensus of the network, as in the simple example reported in Figure 5. Table 2, where the **Critical point** column identifies what part of the API should not receive non-deterministic values, summarizes the main instructions and components that we consider as sinks for non-determinism.

3.2.1 Hyperledger Fabric APIs for Go

In HF, chaincode executes transaction proposals against world state data that may change its state. Programmatically, interface `ChaincodeStubInterface` from the HF Go APIs enables access and modification of the blockchain state. Table 2 reports the current components (as

¹⁰The full list of Go APIs sources considered in our analyses is available at https://github.com/lisa-analyzer/go-lisa/blob/master/go-lisa/src/main/resources/for-analysis/nondeterm_sources.txt. The list consider API until Go version 1.17.

■ **Table 2** Main sinks for blockchain software written in Go.

Framework	Package	Type/Interface	Statements/Methods	Critical point
<i>HyperLedger Fabric</i>	shim	ChaincodeStubInterface	PutState DelState PutPrivateData DelPrivateData Success Error	parameters parameters parameters parameters statement statement
<i>Tendermint Core</i>	abci/types	Application	ResponseBeginBlock ResponseDeliverTx ResponseEndBlock ResponseCommit ResponseCheckTx	instance returned instance returned instance returned instance returned

	types/errors		ABCIError Redact ResponseDeliverTx ResponseCheckTx WithType Wrap Wrapf	statement statement statement statement statement statement

of version 2.4) involved in the data-write proposal. The semantics of these components does not affect the blockchain state until the transaction is validated and successfully committed. Hence, if these components lead to different results (i.e., changes to the shared state) due to non-determinism, consensus will not validate the transaction and no new state will be committed. Regarding the response statements, HF provides the **Success** and **Error** methods to yield successful and failed transaction responses, respectively.

3.2.2 Tendermint Core APIs for Go

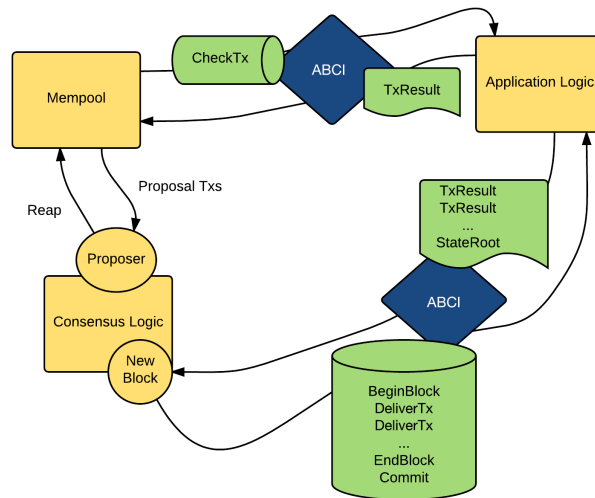

Tendermint Core is a middleware with no explicit access to application state by design, enabling communication through the *Application Blockchain Interface* (ABCI¹¹). Figure 6 depicts the consensus process used to validate and store a transaction using the ABCI methods. As reported in the official documentation [27] of Tendermint Core v. 0.35.1, only **BeginBlock**, **DeliverTx**, **EndBlock**, and **Commit** must be strictly deterministic to ensure consensus. Although the logic of these methods is different, they possess similar structure: they all accept a request and return a response (**ResponseBeginBlock**, **ResponseDeliverTx**, **ResponseEndBlock**, **ResponseCommit**), with the latter that must be deterministic.

3.2.3 Cosmos SDK APIs

Cosmos SDK handles both the application and the blockchain state through the *store*¹². At a high level, the store is a set of key-value pairs used to store and retrieve data, implemented by default as a *multistore* (i.e., a store of stores), as shown in Figure 7. The multistore encapsulation enables modularity of the Cosmos SDK, as each module declares and manages

¹¹ <https://github.com/tendermint/tendermint/blob/7983f9cc36c31e140e46ae5cb00ed39f637ef283/docs/introduction/what-is-tendermint.md#abci-overview>.

■ **Figure 6** ABCI methods and consensus flow.

■ **Figure 7** Main store of Cosmos SDK.

its own subset of the state using specific keys. Keys are typically held by *keepers*, a Cosmos SDK abstraction with the role of managing access to the multistore's subset defined by each module. The `Store` type is declared in several packages (e.g., `kv`, `tracekv`, `gaskv`, `ival`), with all definitions implementing the `KVStore` interface. The latter provides common APIs to access and modify the state of the blockchain using methods such as `Set` and `Del`. As for responses, Cosmos provides several methods (such as `ABCIError`, `Wrap`, `ResponseDeliverTx`) in package `types/errors` to return failed transaction responses.

4 Information Flow Analysis for Non-Determinism Detection

In this section we introduce and discuss our approach for detecting non-deterministic behaviors in blockchain software. In particular, we consider non-determinism as *critical* only if a non-deterministic value can affect the blockchain state, either directly (i.e., being stored inside the state) or indirectly (e.g., guarding the execution of state updates). Any other usage of non-determinism is considered safe, as it does not affect the blockchain state or response. As such, when mentioning non-determinism in the remainder of the chapter, we implicitly refer

<pre> 1 var l, h 2 h := 1 </pre>	<pre> 1 var l, h 2 if l = true then 3 h := 3 4 else 5 h := 42 </pre>	<pre> 1 var l, h 2 if h = 1 then 3 (* time-consuming work *) 4 l := 0 </pre>
(a)	(b)	(c)

■ **Figure 8** Example of (a) explicit, (b) implicit, and (c) side channel flows, where `h` and `l` represent secret and public variables respectively.

to its critical version. We rely on information flow analysis for detecting values originating from sources of non-determinism that can affect the state of the blockchain. We only focus on static analyses, since they soundly over-approximate all possible behaviors of target programs and can thus give guarantees about the absence of such behaviors. We instantiate two types of analyses: a *Taint* analysis, able to capture the so-called *explicit flows*, and a *Non-interference* analysis, that can also detect *implicit flows*.

4.1 An Overview on Information Flow

Information flow analyses [11, 38] address the problem of understanding how information *flows* from one variable to another during a program’s execution. These analyses usually partition the space of program variables into *private* (or *secret*) and *public*, with the latter being accessible to – and in some cases also modifiable by – an external attacker. The goal of these analyses is then to find program executions where information *flows* from one partition to the other, that is, where values of variables from one partition can affect the values of variables from the other one. Figure 8 reports examples¹³ of the three main types of flows, namely:

- *explicit flow*: when a secret variable is assigned to a value obtained starting from public variables;
- *implicit flow*: when an assignment to a secret variable is conditionally executed depending on values of public variables;
- *side channel*: where some observable properties of the execution, e.g., the amount of computational resources used, depends on the values of some secret variables.

In general, the term *source* is traditionally used for variables holding values that one wants to track along program executions, while *sink* is used to describe locations where values coming from sources should not flow. Using this terminology, when the property of interest ensures the *integrity* of secret variables, information flow analyses can be instantiated using public variables as sources and private ones as sinks, exactly as in Fig. 8 and in the list above. These are able to detect situations where (i) a possibly corrupted value provided by a malicious attacker could be stored into variables whose content is supposed to be reliable, or (ii) such a value governs the update to private variables. If, however, one wants to ensure the *confidentiality* of secret variables, the same analyses can be recasted with private variables acting as sources and public ones as sinks, thus searching for flows in the opposite direction. The target of the analysis is then to find disclosures of private data to external entities.

In the context of non-deterministic behaviors in blockchain environments, information flow analyses can be used to detect when non-deterministic values end up or affect the blockchain’s state, thus checking the *integrity* of that state w.r.t. non-deterministic values.

¹³[https://en.wikipedia.org/wiki/Information_flow_\(information_theory\)](https://en.wikipedia.org/wiki/Information_flow_(information_theory)).

As such, we are interested in information flowing from public to private variables, and we will use *sources* to identify ones that are initialized to non-deterministic values and *sinks* to identify all variables that have an effect on the blockchain’s state. Moreover, we will focus on explicit and implicit flows. In fact, side channels are typically studied to detect secret information leaking through, for instance, execution time, thus violating the confidentiality of that information instead of its integrity. On the other hand, explicit and implicit flows identify non-deterministic values that are either used to update the blockchain’s state or a transaction’s result, or that govern their execution. As a concrete example, recall the code from Figure 1: the vulnerability presented there is an implicit flow since the blockchain’s state is not directly updated with non-deterministic values, but the execution of the update (i.e., the `return` statement) is conditional to some non-deterministic value (i.e., `g.Expiration.Unix() < time.Now().Unix()`).

In the following, we introduce two well-established information flow analyses that we will use for non-determinism detection.

4.1.1 Non-Interference

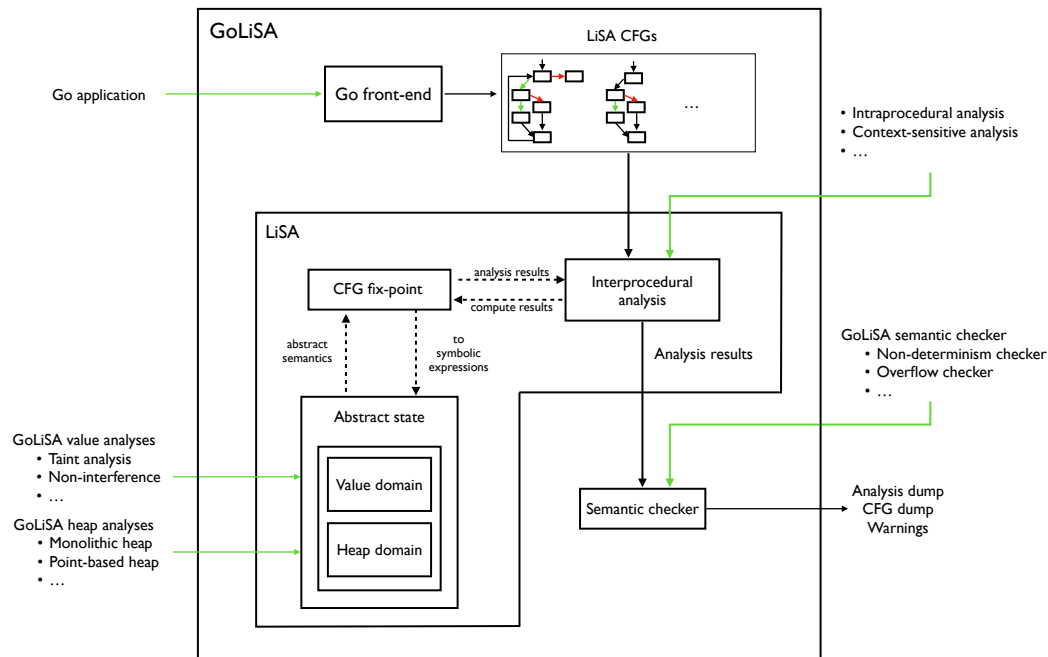

Non-interference [24, 25] is a notion of security capturing the idea that if computations over private information are independent from public information, then no leakage of the former can happen. In simple terms, after partitioning the space of inputs of a program P into *low* (private or secret, denoted by \mathbb{L}), and *high* (public or available to anyone, denoted by \mathbb{H}), *Non-interference* is satisfied if changes in the high input do not affect the observable (i.e., low) output of the program:

$$\forall i_{\mathbb{L}} \in \mathbb{L}, \forall i_{\mathbb{H}}, i'_{\mathbb{H}} \in \mathbb{H} . P(i_{\mathbb{L}}, i_{\mathbb{H}})_{\mathbb{L}} = P(i_{\mathbb{L}}, i'_{\mathbb{H}})_{\mathbb{L}}$$

This notion is often instantiated in language-based security by partitioning the space of program variables between \mathbb{L} and \mathbb{H} , and finding instances of explicit or implicit flows between these partitions. Such analysis computes, for each program point, a mapping from variables to the information level they hold (low or high), while also keeping track of an execution state depending on the information level of the Boolean conditions that guard the program point. Violations of *Non-interference* for integrity can then be detected whenever an assignment to a variable in \mathbb{H} either (i) assigns a low value (that is, an expression involving variables in \mathbb{L}), or (ii) happens with a low execution state (that is, guarded by at least a Boolean condition that involves variables in \mathbb{L}), thus identifying both explicit and implicit flows. This can be formalized as a type system for security [38].

4.1.2 Taint Analysis

Taint analysis [43, 14] is an instance of information flow analysis that can be seen as simplification of *Non-interference* considering only explicit flows. In this context, variables are partitioned into *tainted* and *untainted* (or *clean*), with the former representing variables that can be tampered with by an attacker and the latter representing variables that should not contain tainted values across all possible program executions. Roughly, *Taint* analysis corresponds to the language-based *Non-interference* instantiation without the execution state, thus unable to detect implicit flows. *Taint* has been instantiated to detect many defects in real-world software, such as web-application vulnerabilities [16], privacy issues [22] (also related to GDPR compliance [20]), and vulnerabilities of IoT software [17].

■ **Figure 9** GoLiSA overall execution.

4.2 The GoLiSA Static Analyzer

GoLiSA¹⁴ is an abstract interpretation [10] based static analyzer for Go applications, on which we will rely for the rest of the paper for reasoning about blockchain software written in Go. In this section, we present its architecture and its main feature. GoLiSA relies on LiSA [19, 34] (Library for Static Analysis¹⁵), a Java library that provides a complete infrastructure for the development of static analyzers based on abstract interpretation. In particular, LiSA implements several standard components of abstract interpretation-based analyzers, such as an extensible control-flow graph representation (CFG), a common analysis framework for the development of new static analyses, and fixpoint algorithms on LiSA CFGs.

The high-level analysis process of GoLiSA is reported in Fig. 9. The analysis starts with the *Go front-end* (a sub-component of GoLiSA) that compiles Go source code into LiSA CFGs and defines the semantics, types and language-specific algorithms that implement the Go execution model, capturing the peculiarities of Go in order to make them understandable to LiSA (e.g., scoping and shadowing of variables¹⁶). These CFGs are then passed to LiSA, that analyzes them in a generic language-independent fashion. Roughly, CFGs are passed to an *interprocedural analysis*, a component that cooperates with a *call graph* to resolve calls and compute their results. The interprocedural analysis computes fixpoints over CFGs according to some implementation-specific logic (e.g., modularly, relying on call chains, ...). Each individual fixpoint relies on language-specific analysis-independent semantics for CFG nodes, that is directly provided by GoLiSA: each node is rewritten into a sequence of *symbolic expressions*, modelling the effects that executing a high-level instruction has on the program state through low-level atomic semantic operations. Each of these symbolic expressions is fed

¹⁴ Available at <https://github.com/lisa-analyzer/go-lisa>

¹⁵ LiSA project and documentation available at <https://github.com/lisa-analyzer/lisa>

¹⁶ https://go.dev/ref/spec#Declarations_and_scope

to an *abstract state* [15], a combination of an abstract domain modelling the dynamic memory of the program (*heap domain*, e.g., point-based heap analysis [1]) and one for tracking values of program variables and memory locations (*value domain*, e.g., intervals [10]). The abstract state and its underlying domains compute a sound over-approximation of the expression's effects according to their specific logic, and this can later be exploited by *semantic checks* to issue warnings that are of interest for the user. All analysis components (interprocedural analysis, call graph, abstract state, heap domain, value domain and semantic checks) are part of LiSA's configuration, enabling modular composition and implementation of each component.

4.3 GoLiSA for Non-Deterministic Behaviors Detection

At this point, we are in position to instantiate GoLiSA for the static detection of non-deterministic behaviors in blockchain software. The core idea of our solution is to track the values generated by the hotspots identified in Section 3.1 during the execution of a program using either *Taint* analysis or *Non-interference*. Similarly, after the analysis completes, we can use a semantic checker to exploit the abstract information provided by the domain of choice, checking if any of the sinks specified in Section 3.2 receives one such non-deterministic value as parameter or, in the case of *Non-interference*, if the sink is found in a *low* execution state.

GoLiSA's analysis is instantiated as follows:

- *Taint* analysis and *Non-interference* are implemented as value domains, both of them being non-relational domains (i.e., mapping from variables to abstract values – taintedness and integrity level respectively – with no relations between different variables), with *Non-interference* keeping track of the abstractions for each guard;
- field-insensitive program point-based heap domain (Section 8.3.4 of [37]), where any concrete heap location allocated at a specific program point is abstracted to a single abstract heap identifier;
- context-sensitive [39, 28] interprocedural analysis, abstracting full call-chain results until a recursion is found;
- runtime types-based call graph, using the runtime types of call receivers to determine their targets;
- two semantic checkers, for *Taint* analysis and *Non-interference*, that scan the code in search for sinks, checking the taintedness or integrity level of each sink.

The analysis begins by visiting the input program to detect the statements annotated as sources and propagating the information from them. The analyses produce, for each program point, a mapping stating if each variable is the result of a non-deterministic computation. These mappings are then used by our semantic checkers, that visit the program in search for statements annotated as sinks. When one is found, the mappings are used to determine if values used as parameters of the call are critical or, in the case of *Non-interference*, if the call happens on a critical state. The choice of the analysis to run (and thus of the checker to execute) is left to the user.

For instance, let us consider the fragment reported in Figure 4a. At line 5, despite variable `elapsed` being marked as tainted, no warning is raised by GoLiSA regardless of the chosen analysis, as it does not reach any sensitive sink. Instead, analyzing the fragment from Figure 4b results in the following alarm:

```
The value passed for the 2nd parameter of this call is tainted,
and it reaches the sink at parameter 'value'
```

The warning is issued with both analyses, since variable `t` is marked as tainted and reaches a blockchain state modifier through an explicit flow.

Consider now the example reported in Figure 1. Here, no explicit flow happens at line 3, that contains the blockchain state modifier `Wrap`, but its execution depends on the non-deterministic value used in the condition at line 2, that is, `time.Now().Unix()`. As this is an implicit flow, the *Taint* analysis is not able to detect it. GoLiSA will however discover it with *Non-interference*, raising the following alarm:

```
The execution of this call is guarded by a tainted condition,
resulting in an implicit flow
```

4.4 Detection of Sources and Sinks in GoLiSA

To exploit information flow analyses, the analyzer must know which are the sources and sinks of the program. In this regard, GoLiSA provides a solution based on annotations, marking the corresponding statements as sources and sinks. In the following, we describe how GoLiSA annotates sources (Table 1) and sinks (Table 2) depending on their types.

Methods and functions

As shown in Tables 1 and 2, all sinks and several sources correspond to functions and methods of APIs from either the Go runtime or the blockchain frameworks. GoLiSA contains a list of the signature of these functions and methods and it automatically annotates the corresponding calls in the program by syntactically matching them. While we rely on manual annotations, they can also be generated using automated tools (e.g., SARL [18]). For instance, when GoLiSA iterates over the following snippet, it is able to discover the call to `time.Now`, that gets annotated as source, and the one to `PutState`, whose parameters get annotated as sinks:

```
1 key := "key"
2 tm := time.Now()
3 stub.PutState(key, []byte(tm))
```

Then, the information flow analysis propagates taintedness from the return value of `time.Now` to the second parameter of `PutState`, thus issuing an alarm at line 3.

Map iterations

To detect iterations over maps, one needs to reason about typing. GoLiSA exploits runtime types inferred by the analysis to identify `range` statements happening over maps. If a map iteration occurs, that is, if the object in a `range` statement is inferred to be a map, then GoLiSA marks as sources the variables used to store keys and values of the map. Consider as an example the following code snippet:

```
1 s := ""
2 kvs := map[string]string{"a": "hello", "b": "world!"}
3 for k, v := range kvs {
4     s += v
5 }
6 stub.PutState("key", []byte(s))
```

While analyzing the code, `range` statements are checked for the types of their parameter. GoLiSA annotates as sources both `k` and `v`, as `kvs` is inferred to be a map, while the sink at line 6 is detected through already discussed annotations. Information flow analyses can then propagate the taintedness from `v` to `s`, that in turn flows to the second parameter of `PutState`, issuing an alarm at line 6.

23:16 Information Flow Analysis for Detecting Non-Determinism in Blockchain

Global variables

GoLiSA syntactically annotates every global variable appearing in the program as a source of non-determinism, as their value could be modified independently on each peer. For instance, in the following code, the value of global variable `glob` could differ from peer to peer depending on the number of times function `inc` has been executed. This can happen as not all peers simulate the same transaction, for instance due to differences in the endorsement policy of each peer [32].

```
1 var glob string
2 func inc() {
3     glob += "a"
4 }
5 func (s *SmartContract) transaction(stub shim.ChaincodeStubInterface) sc.Response {
6     stub.PutState("key", []byte(glob))
7 }
```

Before the analysis, GoLiSA iterates over all program components, annotating `glob` as a source. The sink at line 6 is annotated as sink as previously discussed. Then, the information flow analysis propagates taintedness from `glob` to the second parameter of the call to `PutState`, raising an alarm at line 6.

Go routines

GoLiSA inspects the code of Go routines, checking the scope of variables they use. If these are defined outside the routine using them, they are effectively shared among threads, potentially leading to race conditions or non-deterministic behaviors. Hence, GoLiSA annotates the such variables as sources. As an example, the following snippet defines and invokes a simple Go routine that modifies a variable defined in an enclosing scope:

```
1 s := ""
2 go func(){
3     for i := 1; i <= 10000; i++ {
4         s += "0"
5     }
6 }
7 stub.PutState("key", []byte(s))
```

When GoLiSA finds the Go routine, it checks the scopes of each variable, inferring that `s` is declared outside the routine itself. Hence, GoLiSA annotates `s` at line 1 as source, while the sink at line 7 is annotated as previously discussed. Then, the information flow analysis propagates taintedness from `s` to the second parameter of `PutState`, issuing an alarm at line 7 since the value of `s` depends how many times the Go routine has executed the loop body.

Go channels

Channels are pipes that connect concurrent Go routines. Operator `<-` allows interaction with channels to retrieve a value from them, blocking until one is available. GoLiSA annotates as sources the instructions reading values from channels, as the order in which these are written is intrinsically non-deterministic. Consider the following example:

```
1 c := make(chan int)
2 go myroutine1(c)
3 go myroutine2(c)
4 x, y := <- c, <- c
5 stub.PutState("key", []byte(x))
```

GoLiSA iterates over the program searching for occurrences of the operator `<-`. It then annotates variables `x` and `y` as sources, as they receive a value from channel `c`. The sink at line 5 is detected as previously discussed. The information flow analysis can then propagate taintedness from `x` to the second parameter of `PutState`, resulting in an alarm at line 5.

5 Experimental Evaluation

In this section, we discuss the experimental evaluation of the information flow analyses implemented in GoLiSA to detect non-determinism issues in real-world blockchain software. First, we study them from a quantitative point of view, on a set of 651 real-world HF smart contracts retrieved from public GitHub repositories. The evaluation focuses on the HF framework since, to the best of our knowledge, it is the only framework supported by several static analyzers detecting non-determinism issues. This will allow us to compare GoLiSA against state-of-the-art static analyzers in this domain. Furthermore, HF is currently the most popular and widespread blockchain framework among public GitHub repositories, with most smart contracts written in Go. Nevertheless, GoLiSA provides support also for detecting non-determinism behaviors for Cosmos SDK and Tendermint Core smart contracts and DApps.¹⁷

We compare GoLiSA with two open-source static analyzers for chaincodes, namely `Reve^CC` and `ChainCode Analyzer`. The experiments show that GoLiSA produces more precise results in detecting non-deterministic behaviors, outperforming existing static analyzers.

Then, we evaluate the quality of our results on two specific real-world applications, to show how the static analyses discussed in Section 4 work and how the information is propagated in smart contracts. In particular, we selected the first application from the HF benchmark, while the second one is a Cosmos SDK application.¹⁸

All the experiments was performed on a HP EliteBook 850 G4 equipped with an Intel Core i7-7500U at 2,70/2,90 GHz and 16 GB of RAM running Windows 10 Pro 64bit, Oracle JDK version 13, and Go version 1.17.

5.1 Quantitative Evaluation

The experimental artifact set has been retrieved from 954 GitHub repositories, by querying for the `chaincode` keyword, as smart contracts are called in HF, and selecting chaincodes from unforked Go repositories only¹⁹, that include the `Invoke` and `Init` methods: these are the transaction requests' entry points for chaincodes.²⁰ Then, we filtered out files unrelated to smart contracts and removed chaincodes not analyzable due of failures either GoLiSA or the tools discussed in Sect. 5.1.1. In particular, GoLiSA failures on such chaincodes are due to current missing support of high-order functions, recursion, and C code invocation via the built-in Go `cmd/go` package.²¹ This resulted in a benchmark consists of 651 chaincodes only (~ 167391 LoCs), that, from here on, we refer to as `HF`. Then, each chaincode has been manually inspected before applying GoLiSA to search for critical non-deterministic behavior. In particular, for each chaincode, we manually searched for sources of non-determinism (if present) and checked if the result of the corresponding instructions could have an impact (i.e., an update) on the blockchain global state or on the response. If so, we classified this behaviour as critical/harmful. On the selected benchmark, we have found a total of 124 critical/harmful non-deterministic behaviours. In our evaluation, a warning raised by an

¹⁷ An industrial application of GoLiSA for detecting non-determinism in Cosmos SDK can be found here [36].

¹⁸ The example reported in Figure 1 contains a snippet of code of this application

¹⁹ <https://api.github.com/search/repositories?q=chaincode+fork:false+language:Go+archived:false&sort=stars&order=desc>. Accessed: 17-10-2022.

²⁰ See <https://pkg.go.dev/github.com/hyperledger/fabric-chaincode-go/shim>.

²¹ We decided not to implement those standard features since this would have required a relevant effort to support only a few more chaincodes.

■ **Table 3** Analysis evaluation.

Analysis	#A	#U	ET	AT	#W	#TP	#FP	#FN
<i>Taint</i>	68	583	2h:15m:03s	12.45s	173	118	55	7
<i>Non-interference</i>	69	582	2h:25m:18s	13.39s	195	124	71	0

analyzer has been classified as true positive (TP) if it was part of the 124 critical behaviours mentioned above, and as false positive (FP) if not. All the critical behaviours, part of the 124 manually detected, for which there was no warning, have been marked as false negative (FN).

Table 3 reports the results of the experimental evaluation of GoLiSA over the benchmark $\mathbb{H}\mathbb{F}$, where **#A** is the number of affected chaincodes (i.e., chaincodes where at least a warning was issued), **#U** is the number of unaffected chaincodes (i.e., chaincodes where no warning was raised), **ET** is the total execution time, **AT** is the average execution time, **#W** is the total number of warnings issued, **#TP** is the number of true positives among the raised warnings, **#FP** is the number of false positives among the raised warnings, and **#FN** is the number of false negatives. In terms of execution time, the analyses performed averagely in around 15 seconds per chaincode. The experiments shows that *Non-interference* performs better than *Taint* in terms of precision, being able to detect all the true positives contained in $\mathbb{H}\mathbb{F}$, with a ratio of false positives less than 40%. This was expected since, as we have already discussed in Section 4 and unlike *Non-interference*, *Taint* is only able to track explicit information flows. In fact, the 7 false negatives (column **#FN** of Table 3) produced by *Taint* correspond to implicit non-deterministic behaviors.

5.1.1 Comparison

We compared GoLiSA with the open-source static analyzers for Go chaincode described in Section 6, namely ChainCode Analyzer and Revive^{CC}. Table 4 reports the comparison between GoLiSA and these tools over the same benchmark $\mathbb{H}\mathbb{F}$ discussed in Section 5.1.

The comparison shows that GoLiSA - *Non-interference* finds all the true issues contained in the benchmark, achieving the best and most accurate result in terms of precision with a 36.41% false positives ratio. Instead, although it has some false negatives, GoLiSA - *Taint* is the analysis with the lowest percentage of false positives with the 31.79% .

Revive^{CC} triggers 351 warnings out of which 77.49% are false positives. The only non-deterministic behaviour not detected by Revive^{CC} (last column) is due to the fact that it considers the `ioutil.ReadFile` API as safe, although reading a file should be considered non-deterministic in the blockchain context. Finally, ChainCode Analyzer is more precise w.r.t. Revive^{CC}, with 66.50% of false positives, but it has also the greatest number of false negatives, failing to detect a huge number of critical non-deterministic behaviors. This can be attributed to the fact that ChainCode Analyzer does not consider several APIs leading to non-determinism as critical and it fails to soundly detect iteration over maps.

Note that the amount of true positives discovered by GoLiSA analyses differs from the ones of other tools. In fact, GoLiSA is the only tool involved in our comparison that issues warnings on sinks rather than sources. This translates to fewer alarms being issued whenever values of multiple sources flow to the same sink (here, GoLiSA issues a single warning, while other tools issue one for each source), and to more alarms being raised whenever the value of a single source flows to multiple sinks (here instead, other tools issue a single warning, while GoLiSA issues one for each sink).

■ **Table 4** Warnings triggered by the analyzers on $\mathbb{H}\mathbb{F}$.

Tools	# W	# TP	# FP	# FN
GoLiSA - <i>Taint</i>	173	118	55	7
GoLiSA - <i>Non-interference</i>	195	124	71	0
ChainCode Analyzer	203	68	135	53
Revive [^] CC	351	79	272	1

9 // [...]
10 }

```

■ **Figure 10** Method `registrarBoleto` of `boleto` contract.

5.2 Qualitative Evaluation

5.2.1 Explicit Flow: the Boleto Contract

The `boleto` contract²², taken from $\mathbb{H}\mathbb{F}$, comes with a real non-determinism issue that can be found with explicit flows, and that was also detected by other tools during the comparison of Section 5.1.1. The `boleto` contract (Figure 10) seems to be a proof of concept application handling tickets in an e-commerce store, with the method `registrarBoleto` used to register a ticket.

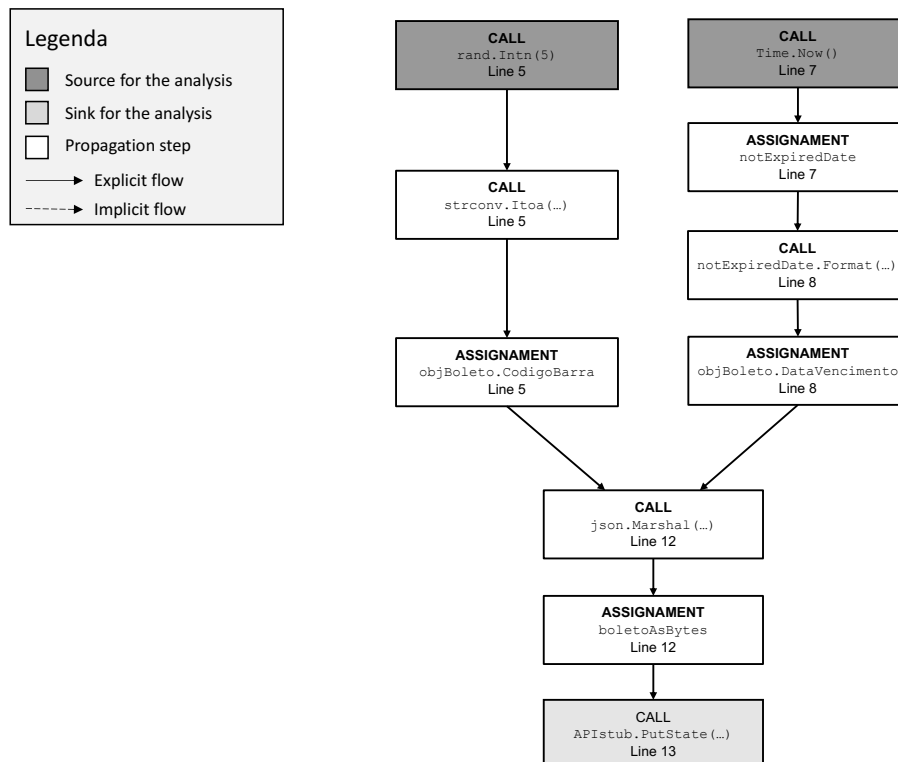

Analyzing `boleto`, GoLiSA detects the explicit flow leading to a non-deterministic behavior with both *Taint* and *Non-interference*. Method `registrarBoleto` contains two different sources of non-determinism that directly flow into the same sink. The first source detected by GoLiSA is the usage of the *Random API* to generate a barcode at line 3. Instead, the second source is the usage of the *OS API* that retrieves the local machine's time to set a date at line 4. As values from both sources are used to update fields of `objBoleto`, the latter is marked as tainted by the analysis, resulting in `boletoAsBytes` being tainted as well. As reported in Table 2, `PutState`'s parameters are considered as sinks by GoLiSA's analyses. According to the official documentation of $\mathbb{H}\mathbb{F}$ ²³, the `PutState` method does not affect the ledger until the transaction is validated and successfully committed. However, a transaction needs to produce the same results among different peers to be validated. Hence, as passing non-deterministic values to `PutState` will cause the transaction to fail, GoLiSA raises a warning on line 8.

5.2.2 Implicit Flow: Cosmos SDK v.43

Analyzing the code in Figure 1, GoLiSA is able to detect an implicit flow that leads to a non-deterministic behavior, that can only be detected using *Non-interference*. The `ValidateBasic` method of Cosmos SDK v. 0.43.x and v. 0.44. $\{0,1\}$ was designed to validate

²² <https://github.com/arthurmsouza/boleto/blob/master/boleto-chaincode/boleto.go>

²³ <https://github.com/hyperledger/fabric-chaincode-go/blob/1476cf1d3206f620db7eea12312c98669d39fa22/shim/interfaces.go>.

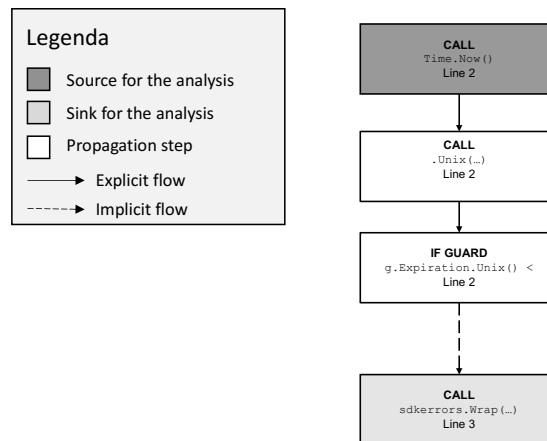

■ **Figure 11** Simplified view of explicit flow computed by GoLiSA during the analysis of registrarBoleto.

a grant to ensure it has not yet expired. In this case, the source detected by GoLiSA is the *OS API* used to retrieve the local machine time involved in the expiration check of the grant time at line 2 of Figure 1. By propagating the information, GoLiSA detects that the expiration check governs the execution of return statement. Since the *Wrap* method is annotated as a sink, GoLiSA triggers an alarm at line 3 of Figure 1 as the sink is contained in a block whose guard depends on non-deterministic values.

5.3 Limits

Unlike some frameworks and GPLs used in other blockchains, frameworks targeted by this paper are used to develop *permissioned*, and often *private*, blockchains, meaning that the related software is not publicly available or released with open-source licenses. This is also the reason why the benchmark $\mathbb{H}\mathbb{F}$ crawled from GitHub consists of 651 chaincodes, a number that is not comparable with smart contract benchmarks obtained investigating other (public and permissioned) blockchains. For instance, [44] collects 3075 distinct smart contracts from the Ethereum blockchain, resulting in a wider benchmark.

The proposed solution for detecting non-deterministic behaviors is fully static. It is well known that static analysis is intrinsically conservative and may produce false positives. Even if few have been raised by GoLiSA on the selected benchmark, one should expect more false positives when applying our approach to arbitrary DApps.

■ **Figure 12** Simplified view of implicit flow computed by GoLiSA during the analysis of Figure 1.

6 Related Work

The non-determinism of smart contracts written in GPLs is a well-known issue [32, 45]. Frameworks such as Takamaka [41, 42] enforce determinism adopting a conservative approach that limits the set of instructions and APIs of the target language, avoiding unsafe statements that might lead to non-deterministic behaviors through white-listing fully deterministic APIs. This approach ensures safe development while preventing that API extensions coming with new language versions can bypass the check. However, it also severely limits the exploitable features of the GPL. On the other hand, black-listing undesired APIs is a much harder approach to maintain, but it seems the most widespread technique in Go analyzers. For instance, ChainCode Analyzer [31] and Revive^{CC} [40] detect mainly black-listed imports related non-deterministic APIs using a syntactical approach. Besides, they can detect non-deterministic map iterations by AST traversal with minimal syntactic reasoning. Signature of invoked functions can also be black-listed instead of imports [32]. These tools and frameworks inherently limit API usage, sensibly reducing the benefits of adopting a GPL even when the code poses no harm to the blockchain. The problem of detecting non-determinism has also been covered for parallel applications, suggesting that non-determinism is “*most often the result of a mistake on the part of the programmer*” [13].

7 Conclusion

In this paper, we proposed a flow-based approach for detecting critical non-deterministic behaviors, namely the ones affecting the blockchain state. Our proposal has been implemented in GoLiSA, a static analyzer for Go applications. To the best of our knowledge, GoLiSA is the first semantic-based static analyzer for blockchain software able to detect non-deterministic behaviors, with an extremely low false alarm prevision. In the context of smart contracts, the proposed approach is placed in an off-chain architecture, i.e., the analysis is done before smart contracts are deployed in the blockchain, and it is not mandatory. As future work, besides supporting the missing Go features discussed in Section 5 to enhance the analysis coverage, we plan to test GoLiSA in an on-chain architecture [35], making the non-determinism checker part of the consensus protocol, with the goal of keeping the code stored within the blockchain deterministic. The analysis could be enriched with a context-sensitive flow reconstructor,

such as BackFlow [21], that starting from the results of a information flow engine, reconstructs how the information flows inside the program and builds paths connecting sources to sinks. Moreover, we have focused on the non-determinism problem, but our future research will address the problem of detecting other and equally critical vulnerabilities that can affect blockchain software written using general-purpose languages, such as numerical overflow.

Our proposal follows a fully static approach, justified by the fact that we aim at proving the determinism of blockchain software, regardless of the possible executions. However, even if the evaluation on the selected benchmark shows optimal results, the risk of getting false alarms analyzing other applications is still present, being our approach based on over-approximating possible executions via abstract interpretation. In future works, hybrid approaches between static and dynamic analyses will be investigated to get the benefits of both techniques.

Finally, in order to assess the effectiveness of our proposal, we have conducted our evaluation on Hyperledger Fabric blockchain software, mostly because it is the most popular framework among those cited in the paper. To give a larger coverage to GoLiSA of the blockchain software that can analyze, the next step will be to design significant benchmarks also for the other frameworks, such as Tendermint core and Cosmos SDK, on which we can experiment our static analyzer.

Abstract

We introduce a new symbolic reflection API for implementing tool-independent summaries for the symbolic execution of C programs. We formalise the proposed API as a symbolic semantics and extend two state-of-the-art symbolic execution tools with support for it. Using the proposed API, we implement 67 tool-independent symbolic summaries for a total of 26 LIBC functions. Furthermore, we present SUMBOUNDVERIFY, a fully automatic summary validation tool for checking the bounded correctness of the symbolic summaries written using our symbolic reflection API. We use SUMBOUNDVERIFY to validate 37 symbolic summaries taken from 3 state-of-the-art symbolic execution tools, *angr*, *Binsec* and *Manticore*, detecting a total of 24 buggy summaries.

1 Introduction

Symbolic execution [14, 34] is a program analysis technique that allows for the exploration of all the execution paths of the given program up to a bound, by executing the program with symbolic values instead of concrete ones. For each execution path, the symbolic execution engine builds a first order formula, called path condition, which accumulates the constraints on the symbolic inputs that cause the execution to follow that path. Symbolic execution engines rely on an underlying SMT solver [20, 9] to check the feasibility of execution paths

and the validity of any assertions supplied by the developer. Despite being extensively used in practice [15, 26, 7, 54], symbolic execution suffers from two main limitations when applied to real-world code: interactions with the runtime environment (e.g. file system, network, operating system) and path explosion. An effective approach to deal with these two issues is to use symbolic summaries to model the behaviour of both external runtime functions as well as internal functions with a high level of branching [6].

Symbolic summaries constrain the symbolic state of the given program so as to simulate the behaviour of the modelled functions without having to symbolically execute them. The idea is that instead of symbolically executing the code of a given concrete function on some symbolic inputs, one implements a symbolic summary that models the behaviour of that function, and then executes the summary instead of the concrete function. Importantly, symbolic summaries allow developers to merge different symbolic execution paths into a single path by explicitly interacting with the current symbolic state [6, 52]. Hence, they provide an effective mechanism for containing the number of paths to be explored during symbolic execution, allowing developers to mitigate the effect of the path explosion problem.

When writing a symbolic summary, tool developers must carefully construct the symbolic state that properly captures the outcome of all the execution paths that the summary is supposed to model. They do this by directly interacting with the various elements of the given symbolic state using symbolic reflection mechanisms [6, 52]. This is often a challenging task that is both error prone and difficult to validate. For this reason, most symbolic execution tools for C have very limited support for external functions and commonly used library functions, such as those of the Standard C Library (libc).

State-of-the-art symbolic execution tools [50, 15, 38] come with their own symbolic summaries implemented in the programming languages used to build each tool. For instance, *angr*'s [50] summaries are implemented in Python, *KLEE*'s [15] summaries in C, and *BINSEC*'s [19] summaries in OCaml, even though all these tools target C code. These summaries often rely on specific aspects of the tools for which they were implemented, making it extremely difficult to share summaries between different symbolic execution tools. Surprisingly, and although there is a clear lack of appropriate tool support for developing and sharing symbolic summaries across different symbolic execution tools, the research community has not yet given much attention to this topic. The current state of affairs is, however, dire: even though the Standard C Library (libc) includes more than one thousand functions, the symbolic execution tool with the broadest support for libc is *angr* [50], with only 128 unverified symbolic summaries. This situation is made considerably worse by the fact that even the few existing summaries are written manually and not verified, potentially compromising the correctness and coverage guarantees of their corresponding symbolic execution tools.

In this paper, we introduce a new symbolic reflection API for the implementation of tool-independent symbolic summaries for the C programming language. The proposed API consists of a set of symbolic reflection primitives [52] for the explicit manipulation of C symbolic states in a tool-independent way. Our symbolic primitives include a variety of instructions for: creating symbolic variables and first-order constraints, checking the satisfiability of constraints, and extending the path condition of the current symbolic state with a given constraint. Symbolic summaries implemented using our API are written directly in C and can therefore be shared across different symbolic execution tools, provided that these tools implement the proposed API. Importantly, the goal of our API is not to make symbolic summaries simpler or easier to write, but rather to establish a symbolic reflection interface shared by all symbolic execution tools, allowing for the decoupling of symbolic summaries from

the internal details of each tool. To illustrate the applicability of our API, we have extended the symbolic execution tools *anqr* [50] and *AVD* [45] with support for it and developed 67 tool-independent symbolic summaries for a total of 27 LIBC functions, including string-manipulating, number-parsing, input/output, and heap-manipulating functions. Furthermore, we formalised our symbolic reflection API as a symbolic semantics [52, 21] and used this semantics to formally characterise the correctness properties that symbolic summaries are expected to observe, specifically, over- and/or under-approximation.

Leveraging our symbolic reflection API, we developed *SUMBOUNDVERIFY*, a new fully-automated tool for the bounded verification of symbolic summaries. *SUMBOUNDVERIFY* works by comparing the execution paths modelled by the given summary against those generated by symbolically executing its corresponding concrete function up to the chosen bound. In order to assess the effectiveness of *SUMBOUNDVERIFY*, we used it to verify summaries belonging to three state-of-the-art symbolic execution tools: *anqr* [50], *Binsec* [19, 39, 18], and *Manticore* [38]. Out of the 37 analysed summaries, 24 were flagged as buggy, clearly demonstrating the need for tool support when it comes to designing and implementing symbolic summaries. This need is further confirmed by our own experience in the development of symbolic summaries, which we typically found to be highly complex and error-prone. This paper bridges this gap by providing the first verification tool specifically aimed at the development of correct symbolic summaries.

In summary, the contributions of this paper are the following: (1) a formally defined API for developing symbolic summaries for C; (2) a library of 67 symbolic summaries modelling 26 LIBC functions; and (3) *SUMBOUNDVERIFY*, an automatic bounded verification tool for validating symbolic summaries against their corresponding concrete implementations.

2 Overview

In this section, we first contrast the existing methodology for implementing symbolic summaries with our proposed approach (§2.1) and then give a high-level overview of *SUMBOUNDVERIFY* (§2.2), illustrating how it can be used to verify symbolic summaries.

2.1 Tool-Specific vs. Tool-Independent Symbolic Summaries

A symbolic summary is an operational model of a function that simulates its behaviour by interacting directly with the underlying symbolic state. So far, each symbolic execution tool for C comes with its own summaries directly implemented in the programming language used to build the tool. Existing symbolic summaries are therefore tightly connected to the architecture of their corresponding tools, preventing summaries from being shared between different tools. In order to cater for the reuse of symbolic summaries, we propose an alternative approach: *Symbolic summaries are to be directly implemented in C using a shared symbolic reflection API for direct manipulation of symbolic states at the programming language level.*

To illustrate the difference between tool-specific and tool-independent summaries, we compare Manticore’s [38] symbolic summary for `strlen` (Figure 1) with the equivalent summary written directly in C using our API (Figure 2).

Manticore’s Tool-Specific Summary

Figure 1 shows Manticore’s summary for the function `strlen`. This summary first checks if the given string pointer is itself symbolic, in which case it throws an error (lines 3-4). Then, the summary uses the Manticore’s internal function `find_zero` to determine the index of the

24:4 Toward Tool-Independent Summaries for Symbolic Execution

```
1 def strlen_approx(state: State, s: Union[int, BitVec]) -> Union[int, BitVec]:
2
3     if issymbolic(s):
4         raise ConcretizeArgument(state.cpu, 1)
5
6     #Find max string length
7     cpu = state.cpu
8     zero_idx = _find_zero(cpu, state, s)
9     ret = zero_idx
10
11     #Build nested ITE formula
12     for offset in range(zero_idx - 1, -1, -1):
13         byt = cpu.read_int(s + offset, 8)
14         if issymbolic(byt):
15             ret = ITEBV(cpu.address_bit_size, byt == 0, offset, ret)
16
17     return ret
```

■ **Figure 1** Implementation of Manticore’s `strlen` summary.

first concrete null character in the input string, `zero_idx`. Note that if the string does not contain any symbolic character, `zero_idx` coincides with the length of the string. In the final for-loop, the summary iterates over the characters of the given string to construct a symbolic expression denoting its length. For instance, given the symbolic string `[c0, c1, c2, \0]`, the loop will generate the expression:

$$\text{ret} = \text{ITE}(c0 == \backslash 0, 0, \overline{\text{ITE}(c1 == \backslash 0, 1, \overline{\text{ITE}(c2 == \backslash 0, 2, 3))})})$$

signifying that: if the first character (`c0`) is null, then the return value is 0; if the second character (`c1`) is null, then the return value is 1; if the third character (`c2`) is null, then the return value is 2; otherwise, the return value is 3. Note that the overlines have no semantic meaning, being only there to facilitate the reading.

Tool-Independent Summary

Figure 2 shows our equivalent C implementation of Manticore’s summary for `strlen`. Although both summaries implement approximately the same logic,¹ our summary is written directly in C using our symbolic reflection API. It uses the following primitives: (1) `is_symbolic(x)` to check if variable `x` denotes a symbolic value; (2) `new_sym_var(size)` to create a new symbolic variable to represent a value of size `size`; (3) `_solver_EQ(a, b)` to build a constraint stating that the two given values are equal; (4) `assume(c)` to add the constraint `c` to the path condition of the current symbolic state; and (5) the primitive `_solver_IF(c, a, b)` to build an if-then-else symbolic expression of the form `ITE(c, a, b)`.

Why use symbolic summaries?

To better understand the benefits of symbolic summaries, let us consider the symbolic execution of the concrete implementation of `strlen` on the symbolic string `[c0, c1, c2, \0]`. That execution would generate four execution paths, each corresponding to one of the possible outputs. In contrast, the execution of either of the symbolic summaries described above generates a single execution path representing all four outputs. Both symbolic summaries

¹ The C summary assumes that it is never given a symbolic pointer as input.

```

1 size_t strlen(char* s){
2     int i = 0;
3     char char_zero = '\0';
4
5     //Calculate max string length
6     while(is_symbolic(&s[i]) || s[i] != '\0'){
7         i++;
8     }
9     int len = i;
10    symbolic ret = new_sym_var(INT_SIZE);
11    cnstr_t ret_cnstr = _solver_EQ(&ret, &len, INT_SIZE);
12
13    //Build nested ITE constraint
14    for(i = len-1; i >= 0; i--){
15
16        if(is_symbolic(&s[i])){
17
18            cnstr_t c_eq_zero = _solver_EQ(&s[i], &char_zero, CHAR_SIZE);
19            cnstr_t ret_eq_i = _solver_EQ(&ret, &i, INT_SIZE);
20
21            ret_cnstr = _solver_IF(c_eq_zero, ret_eq_i, ret_cnstr);
22        }
23    }
24    assume(ret_cnstr);
25    return ret;
26 }

```

■ **Figure 2** Implementation of *Manticore's* `strlen` in C.

achieve this by directly extending the path condition of the calling state with a formula that constrains the return value appropriately, depending on the symbolic characters appearing in the given string.

2.2 Bounded Verification of Symbolic Summaries

In this section we show how `SUMBOUNDVERIFY` can be used to verify the symbolic summary of `strlen` given above. We support two flavours of correctness properties: *under-approximating* [40] and *over-approximating* [5]. A summary is *under-approximating* if all the execution paths modelled by the summary are contained in the set of concrete paths of its corresponding function. In other words, an *under-approximating* summary guarantees that all its generated paths have corresponding concrete paths. Conversely, a symbolic summary is *over-approximating* if it models all the concrete paths of its corresponding function; that is, an over-approximating summary must take into account all possible concrete paths. If a summary is both under- and over-approximating, we say that it is *exact*, following recent terminology in the context of separation-logic-based verification [37]. Naturally, the type of correctness property to be aimed at depends on how the summary is going to be used. For instance, over-approximating summaries are essential for security applications that must guarantee the absence of security vulnerabilities; in contrast, under-approximating summaries may be a better fit for debugging tools that aim at reporting only real bugs.

Bounded Verification

Let us now take a closer look at the inner workings of `SUMBOUNDVERIFY`. In a nutshell, `SUMBOUNDVERIFY` requires the developer to provide the summary to be verified, its corresponding concrete implementation, and an integer bound on the size of its parameters; for instance, for inputs of array type, this bound corresponds to the maximum length of

```

1 int main(){
2
3 char s[4];
4 for (int i = 0; i < 2; i++){
5   s[i] = new_sym_var_array("c", i, CHAR_SIZE);
6 }
7 s[3] = '\0';
8
9 state_t fresh_state = save_current_state();
10
11 int ret1 = concrete_strlen(s);
12 cnstr_t c1 = get_cnstr(&ret1, INT_SIZE);
13 store_cnstr("cnstr", c1);
14
15 switch_state(fresh_state);
16
17 int ret2 = summ_strlen(s);
18 cnstr_t c2 = get_cnstr(&ret2, INT_SIZE);
19 store_cnstr("summ", c2);
20
21 result_t res = check_implications("summ", "cnstr");
22 print_counterexamples(res);
23 return 0;
24 }

```

(a) Test code.

Reference Implementation Formula:

$$\begin{aligned}
&(c_0 = \backslash 0) \wedge (ret = 0) \vee \\
&(c_0 \neq \backslash 0) \wedge (c_1 = \backslash 0) \wedge (ret = 1) \vee \\
&(c_0 \neq \backslash 0) \wedge (c_1 \neq \backslash 0) \wedge (c_2 = \backslash 0) \wedge (ret = 2) \vee \\
&(c_0 \neq \backslash 0) \wedge (c_1 \neq \backslash 0) \wedge (c_2 \neq \backslash 0) \wedge (c_3 = \backslash 0) \\
&\wedge (ret = 3)
\end{aligned}$$

Symbolic Summary Formula:

$$\begin{aligned}
&ITE(c_0 = \backslash 0, r = 0, \\
&\quad ITE(c_1 = \backslash 0, r = 1, \\
&\quad\quad ITE(c_2 = \backslash 0, r = 2, 3)) \wedge ret = r
\end{aligned}$$

(b) Generated formulas.

■ **Figure 3** Bounded Verification of the `strlen` summary given in Figure 2.

the array. Given the signature of the summarised function, `SUMBOUNDVERIFY` synthesises a set of symbolic tests to check the correctness of the given summary. These tests can be executed by any symbolic execution tool that implements our reflection API. If the summary passes all the generated tests, then it is correct up to the pre-established bound. If it does not, then `SUMBOUNDVERIFY` generates a concrete input that is not correctly modelled by the summary.

Figure 3 illustrates one of the tests generated for the `strlen` summary discussed in §2.1, assuming that the developer specified bound 3. The test first creates an array of size 4, initialises the first 3 characters to new symbolic characters, and sets the fourth element of the array to be the null character (lines 3-7). Then, the test uses the API function `save_current_state` to save the current symbolic state (line 9). Next, the test calls the concrete `strlen` function on the created symbolic string and stores the generated return values and final path conditions for future reference (lines 12-14). Then, the test re-establishes the symbolic state saved in line 10 by calling the API function `switch_state` (line 15), which simply replaces the current symbolic state with the given symbolic state. Having re-established the original symbolic state, the test calls the summary on the input string and stores the generated return values and final path conditions (lines 17-19). Finally, the test compares the return values and path conditions generated by the summary against those generated by the concrete function.

A summary can be classified as being: under-approximating correct, over-approximating correct, or incorrect. In a nutshell, the two correct cases are checked as follows:

- *Under-approximating*: the formula describing the final state resulting from the symbolic execution of the summary implies the formula describing the final state resulting from the symbolic execution of its reference implementation;
- *Over-approximating*: the formula describing the final state resulting from the symbolic execution of the reference implementation implies the formula describing the final state resulting from the symbolic execution of the summary.

The `strlen` summary given in Figure 2 is exact (i.e., both under- and over-approximating). Figure 3b shows the formulas generated by the execution of both the reference implementation and the summary. As the summary is exact, the solver can check both implications.

3 Symbolic Reflection API

We formally define the semantics of our API for developing symbolic summaries (§3.1) and use this semantics to characterise the correctness properties that symbolic summaries are expected to observe (§3.2). Then, we illustrate how our reflection API can be used to develop symbolic summaries for string-manipulating and number-parsing LIBC functions (§3.3).

3.1 Formal Semantics

We define the formal semantics of our Symbolic Reflection API on top of a core C-like language in the style of the core language used in [41], which we extend with our symbolic reflection primitives. Importantly, and in order not to clutter the formalism with unnecessary technical details, the formal model is a simplified version of our proposed API. The syntax of the language is given in the table below.

Syntax

e	$:=$	$n \mid x \mid \ominus(e) \mid \oplus(e_1, e_2) \mid \otimes(e_1, e_2, e_3)$
\hat{s}	$:=$	$x := e \mid \mathbf{skip} \mid \hat{s}_1; \hat{s}_2 \mid \mathbf{if}(e) \{ \hat{s}_1 \} \mathbf{else} \{ \hat{s}_2 \} \mid \mathbf{while}(e) \{ \hat{s} \} \mid \mathbf{return} e$ $\mid x := e_1[e_2] \mid e_1[e_2] := e_3 \mid x := \mathbf{new}(e) \mid rs$
rs	$:=$	$\mathbf{assert}(e) \mid \mathbf{assume}(e) \mid x := \mathbf{is_symbolic}(e) \mid x := \mathbf{symb}() \mid x := \mathbf{is_sat}(e)$ $\mid x := \mathbf{maximize}(e) \mid x := \mathbf{minimize}(e) \mid x := \mathbf{cur_pc}() \mid x := \mathbf{eval}(e)$ $\mid x := \mathbf{block_size}(e) \mid x := \mathbf{constr}_{uop}(e) \mid x := \mathbf{constr}_{bop}(e_1, e_2)$
bop	$:=$	$\mathbf{or} \mid \mathbf{and} \mid \mathbf{eq} \mid \mathbf{neq} \mid \mathbf{lt} \mid \mathbf{le}$
uop	$:=$	\mathbf{not}

Expressions $e \in Expr$ include integers n , program variables x , unary, binary, and ternary operators. Statements $\hat{s} \in Stmt$ include: (i) the typical imperative statements, i.e. variable assignment, skip, sequence, if, while, and return statements; (ii) statements for interaction with a linear memory, and (iii) symbolic reflection primitives $rs \in \mathcal{RS}$. In the following we use \hat{s} for statements that may include reflection primitives and s for statements that do not. Accordingly, we use \hat{s} for symbolic summaries and s for reference implementations.

The statements for memory interaction are the following: (1) the statement $x := e_1[e_2]$ assigns to x the value stored in the memory block denoted by e_1 at the offset denoted by e_2 ; (2) the statement $e_1[e_2] := e_3$ stores the value denoted by e_3 in the memory block denoted by e_1 at the offset denoted by e_2 ; and (3) the statement $x := \mathbf{new}(e)$ creates a memory block with the size denoted by e and assigns the obtained pointer to x .

The symbolic reflection primitives $rs \in \mathcal{RS}$ are the following: (1) $\mathbf{assert}(e)$ to check if the current path condition implies the constraint denoted by e ; (2) $\mathbf{assume}(e)$ to extend the current path condition with the constraint denoted by e ; (3) $x := \mathbf{is_symbolic}(e)$ to assign to variable x a boolean value indicating if e denotes a symbolic expression; (4) $x := \mathbf{symb}()$ to assign a fresh symbolic value to x ; (5) $x := \mathbf{is_sat}(e)$ to check if the constraint denoted by e is satisfiable when conjoined with the current path condition; (6) $x := \mathbf{maximize}(e)$ to assign the largest possible value that may be denoted by e to x ; (7) $x := \mathbf{minimize}(e)$ to assign the smallest possible value that may be denoted by e to x ; (8) $x := \mathbf{cur_pc}()$ to assign the formula denoting the current path condition to x ; (9) $x := \mathbf{eval}(e)$ to assign one of the concrete values denoted by e to x ; (10) $x := \mathbf{block_size}(e)$ to assign the size of the memory block pointed to by e to x ; (11) $x := \mathbf{constr}_{uop}(e)$ to assign the constraint resulting from the application of the logical unary operator uop to the symbolic value denoted by e to x ; and (12) $x := \mathbf{constr}_{bop}(e_1, e_2)$ to assign the constraint resulting from the application of the logical binary operator bop to the symbolic values denoted by e_1 and e_2 .

■ **Figure 4** Core Semantics: Imperative Fragment.

Symbolic Execution – Trace Semantics

The symbolic semantics of our core language operates on symbolic states, which store symbolic values given by the grammar: $\hat{v} \in \hat{\mathcal{V}} ::= n \mid \hat{x} \mid \ominus(\hat{v}) \mid \oplus(\hat{v}, \hat{v}) \mid \otimes(\hat{v}, \hat{v}, \hat{v})$. Symbolic values include: integers n , symbolic variables $\hat{x} \in \hat{\mathcal{X}}$, and unary, binary, and ternary operators, respectively ranged by \ominus , \oplus , and \otimes . Furthermore, we use $\pi \in \Pi$ to range over symbolic values of type Boolean. Symbolic states $\hat{\sigma} \in \text{SymSt}$ are composed of:

- a *symbolic heap*, $\hat{\mu} : \mathbb{N} \rightarrow \hat{\mathcal{V}} \times \mathbb{N} \times \mathbb{N}$, mapping integer pointers $l \in \mathbb{N}$ to triples of the form (\hat{v}, k_l, k_r) , where \hat{v} denotes the symbolic value stored at location l and k_l and k_r respectively denote the number of cells that can be accessed to the left and to the right of l using l as the accessing pointer;
- a *symbolic store*, $\hat{\rho} : \mathcal{X} \rightarrow \hat{\mathcal{V}}$, mapping program variables to symbolic values; and
- a *path condition*, $\pi \in \Pi$, keeping track of the constraints on which the current symbolic execution branched so far.

Note that our symbolic execution model requires heap locations to always be concrete; hence, we take the domain of symbolic heaps to be the set of naturals, \mathbb{N} , rather than that of symbolic values, $\hat{\mathcal{V}}$. Symbolic heaps, as concrete heaps, are organised in *blocks*, with each block being a sequence of memory locations; blocks can be univocally identified by their first location, which is referred to as the *head of the block* (i.e., l is the head of a block in $\hat{\mu}$, if $\hat{\mu}(l) = (-, 0, -)$, meaning that one cannot access any location before l within its block). Furthermore, we assume heaps to be *well-formed*, meaning that ranges of adjacent locations are consistent with each other; put formally, a heap $\hat{\mu}$ is said to be *well-formed* if and only if:

$$\begin{aligned}
\forall l \in \text{dom}(\hat{\mu}). \hat{\mu}(l) = (-, 0, k_r) &\implies \forall 0 \leq i < k_r. \hat{\mu}(l+i) = (-, i, k_r-i) \\
\forall l \in \text{dom}(\hat{\mu}). \hat{\mu}(l) = (-, k_l, k_r) &\implies \hat{\mu}(l-k_l) = (-, 0, k_l+k_r)
\end{aligned}$$

$$\begin{array}{c}
\text{ALLOC} \\
\frac{l = |\text{dom}(\hat{\mu})| \quad \hat{\mu}' = \hat{\mu}[l+i \mapsto (0, n-i, i) \mid 0 \leq i < n]}{\mathbf{alloc}(\hat{\mu}, n) \triangleq \langle \hat{\mu}', l \rangle} \\
\\
\text{BLOCK-SIZE} \\
\frac{\hat{\mu}(l) = (-, -, k_r)}{\mathbf{b_size}(\hat{\mu}, l) \triangleq k_r} \\
\\
\text{LOAD - IN BOUNDS} \\
\frac{\hat{\mu}(l) = (-, k_l, k_r) \quad -k_l \leq i < k_r \quad \pi' = \hat{\sigma} = i \quad \hat{\mu}(l+i) = (\hat{v}, -, -)}{\mathbf{load}(\hat{\mu}, l, \hat{\sigma}) \rightsquigarrow_s \mathbb{S}\langle \hat{v}, \pi' \rangle} \\
\\
\text{STORE - IN BOUNDS} \\
\frac{\hat{\mu}(l) = (-, k_l, k_r) \quad -k_l \leq i < k_r \quad \hat{\mu}(l+i) = (-, k'_l, k'_r) \quad \hat{\mu}' = \hat{\mu}[l+i \mapsto (\hat{v}, k'_l, k'_r)]}{\mathbf{store}(\hat{\mu}, l, \hat{\sigma}, \hat{v}) \rightsquigarrow_s \mathbb{S}\langle \hat{\mu}', \pi' \rangle}
\end{array}$$

■ **Figure 5** Core Semantics: Memory Actions.

In order to define the symbolic semantics of our core language, we make use of computation *outcomes* [21, 36], which capture the flow of execution and are generated by the following grammar: $\hat{\sigma} \in \hat{\mathcal{O}} ::= \mathbb{C}\langle \hat{s} \rangle \mid \mathbb{C}\langle \cdot \rangle \mid \mathbb{R}\langle \hat{v} \rangle \mid \mathbb{E}\langle \pi \rangle$. We make use of four types of outcomes: **(1)** the non-empty continuation outcome $\mathbb{C}\langle \hat{s} \rangle$, signifying that the execution of the current statement generated a new statement to be executed next; **(2)** the empty continuation outcome $\mathbb{C}\langle \cdot \rangle$, signifying that the execution may proceed to the next instruction; **(3)** the return continuation outcome $\mathbb{R}\langle \hat{v} \rangle$, signifying that the current execution terminated with return value \hat{v} ; and **(4)** the error outcome $\mathbb{E}\langle \pi \rangle$, signifying that the current execution generates an error.

We define the symbolic semantics of our core language using a semantic judgement of the form: $\hat{\sigma}, s \rightsquigarrow \hat{\sigma}', \hat{\sigma}$, meaning that the symbolic evaluation of statement s in the state $\hat{\sigma}$ generates the state $\hat{\sigma}'$ and outcome $\hat{\sigma}$. We splice the components of the state into the semantic transition, simply writing $\langle \hat{\mu}, \hat{\rho}, \pi, s \rangle \rightsquigarrow \langle \hat{\mu}', \hat{\rho}', \pi', \hat{\sigma} \rangle$ when $\hat{\sigma} = (\hat{\mu}, \hat{\rho}, \pi)$ and $\hat{\sigma}' = (\hat{\mu}', \hat{\rho}', \pi')$. The semantic rules are given in Figures 4 and 6, where the former focus on the core language and the latter on symbolic reflection API. Due to space constraints, we omit all error-generating transitions with the exception of those describing errors generated by API primitives. We further omit the elements of the configuration that are neither updated nor inspected by the current rule, writing, for instance, $\hat{\rho}, s \rightsquigarrow \hat{\rho}', \hat{\sigma}$ to mean $\langle \hat{\mu}, \hat{\rho}, \pi, s \rangle \rightsquigarrow \langle \hat{\mu}, \hat{\rho}', \pi, \hat{\sigma} \rangle$. Note that the semantics is non-deterministic, meaning the symbolic execution of a statement on a given state may generate multiple states and continuations.

The symbolic semantics of the imperative fragment is straightforward. It makes use of the auxiliary function **alloc** and relations **load** and **store** for interacting with the linear memory; their meanings are as follows:

- **alloc**($\hat{\mu}, n$) allocates a new memory block of size n ;
- **load**($\hat{\mu}, l, \hat{\sigma}$) $\rightsquigarrow_s \mathbb{S}\langle \hat{v}, \pi' \rangle$ successfully loads the value \hat{v} stored at the offset $\hat{\sigma}$ of location l in memory $\hat{\mu}$; as the loading operation may cause the execution to branch, it additionally generates a new formula π' with the conditions that must hold for the symbolic value \hat{v} to be returned;
- **store**($\hat{\mu}, l, \hat{\sigma}, \hat{v}$) $\rightsquigarrow \mathbb{S}\langle \hat{\mu}', \pi' \rangle$ successfully stores the symbolic value \hat{v} at the offset $\hat{\sigma}$ of location l in memory $\hat{\mu}$ under the path condition π , returning a new memory $\hat{\mu}'$; as for the loading operation, the storing operation may cause the execution to branch, hence the returned constraint π' .

In the above, we use the symbol \mathbb{S} to distinguish the successful transitions of **load** and **store** from their error-leading transitions, which are labelled with \mathbb{E} .

The definitions of **alloc**, **load**, and **store** are given in Figure 5. In contrast to **load** and **store** which may cause the current execution to branch, **alloc** is assumed to be deterministic. Hence, it is modelled as a function. Load and store operations *fail* if they attempt to read/update the contents of a memory cell beyond the bounds of the inspected

\end{array}$$

■ **Figure 6** Core Semantics: Symbolic Reflection API.

location (the failing rules are omitted due to space constraints). In the success case, both load and store operations branch on the value of all legal offsets. This means that these operations may generate unsatisfiable path conditions (for instance, when the given offset is concrete), in such cases the symbolic execution path is unfeasible and will be filtered out by symbolic execution.

Finally, Figure 6 gives the rules that describe the semantics of our proposed API. The rules are straightforward. Note that constraints are simply symbolic values of boolean type; hence, various rules either assign constraints to variables (e.g. CUR-PC) or obtain a constraint as the result of symbolically evaluating an expression (e.g. ASSERT, ASSUME, ISSAT).

Symbolic Execution – Collecting Semantics

So far, we have defined the semantics of a single symbolic execution trace. In the following, we extend this definition to account for multiple traces. We use $\hat{\phi}$ and $\hat{\omega}$ to range over input and output symbolic configurations, respectively.² We further use $\hat{\Omega}$ to range over sets of

² Input configurations differ from output configurations in that former are composed of a symbolic state and a statement whereas the latter are composed of a symbolic state and an outcome.

output configurations. We capture the semantics of multiple-trace symbolic execution using a big-step relation of the form $\hat{\phi} \Downarrow \hat{\Omega}$, meaning that if we “run” the symbolic semantics on the input configuration $\hat{\phi}$, we obtain the set of output configurations $\hat{\Omega}$. As symbolic execution often diverges, we additionally introduce a bounded version of the collecting semantics, writing $\hat{\phi} \Downarrow_k \hat{\Omega}$ to mean that if we “run” the symbolic semantics on the input configuration $\hat{\phi}$ and ignore symbolic traces with more than k steps, we end up with the set of output configurations $\hat{\Omega}$. In order to formalise these relations, we make use of collecting one-step transitions, writing $\hat{\phi} \searrow \hat{\Omega}$ to mean $\hat{\Omega}$ contains all the configurations resulting from the application of a single symbolic step on the input configuration $\hat{\phi}$ and no other; put formally:

$$\hat{\Omega} = \frac{\{\langle \hat{\mu}', \hat{\rho}', \pi', \hat{\delta} \rangle \mid \langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \rightsquigarrow \langle \hat{\mu}', \hat{\rho}', \pi', \hat{\delta} \rangle\}}{\langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \searrow \hat{\Omega}}$$

Definition 1 formalises the collecting semantics for bounded symbolic execution (the unbounded version can be easily obtained from the bounded one by dropping the constraints on k). The definition makes use of the following auxiliary predicates and functions:

- The predicates **Final**($\hat{\omega}$) and **NonFinal**($\hat{\omega}$) respectively hold if the output configuration $\hat{\omega}$ is, respectively, final and non-final, with a configuration being final if it contains either a return or an error outcome.
- The function **Next** can only be applied to non-final output configurations, turning the given output configuration into an input configuration by unwrapping the statement contained in its non-empty continuation output.

We say that **Final/NonFinal** holds for a set of configurations if it holds for all of them.

► **Definition 1** (Symbolic Execution – Collecting Semantics).

$$\frac{\text{BOUNDED - BASE} \quad \langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \searrow \hat{\Omega}_1 \cup \hat{\Omega}_2 \quad \pi \text{ SAT} \quad \text{Final}(\hat{\Omega}_1) \quad \text{NonFinal}(\hat{\Omega}_2)}{\langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \Downarrow_1 \hat{\Omega}_1} \quad \frac{\text{BOUNDED - FALSE} \quad \pi \text{ UNSAT}}{\langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \Downarrow_k \emptyset}$$

$$\frac{\text{BOUNDED - REC} \quad \langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \searrow \hat{\Omega} \cup \{\hat{\omega}_i \mid_{i=1}^n\} \quad \text{Final}(\hat{\Omega}) \quad k > 1 \quad \pi \text{ SAT} \quad \text{Next}(\hat{\omega}_i) \Downarrow_{k-1} \hat{\Omega}_i \mid_{i=1}^n}{\langle \hat{\mu}, \hat{\rho}, \pi, \hat{s} \rangle \Downarrow_k \cup_{i=1}^n \hat{\Omega}_i \cup \hat{\Omega}}$$

3.2 Summary Correctness Properties

In contrast to most works on verification in which a concrete program is proven correct with respect to a specification [5], here we take the concrete function associated with the given summary to be the ground truth. Given a summary \hat{s} and its associated concrete implementation s , we say that:

- \hat{s} is an *over-approximation* of s if all the concrete executions of s are contained in the set of the executions modelled by \hat{s} ;
- \hat{s} is an *under-approximation* of s if all the executions modelled by \hat{s} are contained in the set of concrete executions of s .

When a summary satisfies both properties, we say that it is *exact*. In the following, we make use of the concrete and symbolic semantics of our core language to establish the rigorous definitions underpinning these concepts.

Symbolic State Interpretation

We write $\sigma \in \llbracket \hat{\sigma} \rrbracket$ to mean that the concrete state σ is in the interpretation of the symbolic state $\hat{\sigma}$. The interpretation of a symbolic state $\hat{\sigma}$ is the set of concrete states that can be obtained from $\hat{\sigma}$ by mapping the symbolic values of $\hat{\sigma}$ to concrete values in a way that is

consistent with its path condition. For instance, if $\hat{\sigma} = \langle \hat{\mu}, \hat{\rho}, \hat{x} \neq 0 \rangle$, then the symbolic variable \hat{x} cannot be replaced by 0 in $\hat{\mu}$ and $\hat{\rho}$. Accordingly, the interpretation function $\llbracket \cdot \rrbracket :: \text{SymSt} \rightarrow \wp(\text{ConcSt})$ takes as input a symbolic state and returns a set of concrete states. We define the interpretation function for symbolic states with the help of two auxiliary interpretation functions, one for symbolic memories and one for symbolic stores. These interpretation functions require a *valuation function*, $\varepsilon : \hat{\mathcal{X}} \rightarrow \mathcal{V}$, that maps symbolic variables to concrete variables. We write $\llbracket \hat{\mu} \rrbracket_\varepsilon = \mu$ to mean that the interpretation of $\hat{\mu}$ under ε yields the concrete memory μ (analogously for stores). We interpret symbolic memories and stores point-wise, applying the valuation function to each memory/store cell. Put formally:

$$\begin{array}{ccc} \text{HEAP-INTERP.} & \text{STORE-INTERP.} & \text{STATE-INTERP.} \\ \frac{\hat{\mu}(l) = (\hat{v}, k_l, k_r)}{\llbracket \hat{\mu} \rrbracket_\varepsilon(l) \triangleq (\llbracket \hat{v} \rrbracket_\varepsilon, k_l, k_r)} & \frac{\hat{\rho}(x) = \hat{v}}{\llbracket \hat{\rho} \rrbracket_\varepsilon(x) \triangleq \llbracket \hat{v} \rrbracket_\varepsilon} & \frac{\hat{\sigma} = \langle \hat{\mu}, \hat{\rho}, \pi \rangle}{\llbracket \hat{\sigma} \rrbracket \triangleq \{ (\llbracket \hat{\mu} \rrbracket_\varepsilon, \llbracket \hat{\rho} \rrbracket_\varepsilon) \mid \llbracket \pi \rrbracket_\varepsilon = \text{true} \}} \end{array}$$

In the definitions that follow, we characterise the correctness of a given summary with respect to its corresponding reference implementation. In this context, the contents of the store are not relevant as they are discarded after the execution of the function. To account for this, we make use of *truncated state interpretations*, which ignore the store component. We use $\llbracket \hat{\sigma} \rrbracket$ to refer to the truncated interpretation of the symbolic state $\hat{\sigma}$, which is defined as follows: $\llbracket \langle \hat{\mu}, \hat{\rho}, \pi \rangle \rrbracket \triangleq \{ (\llbracket \hat{\mu} \rrbracket_\varepsilon \mid \llbracket \pi \rrbracket_\varepsilon = \text{true}) \}$. For convenience, we lift truncated symbolic state interpretation to pairs of symbolic states and symbolic outcomes as follows: $\llbracket (\langle \hat{\mu}, \hat{\rho}, \pi \rangle, \hat{o}) \rrbracket \triangleq \{ (\llbracket \hat{\mu} \rrbracket_\varepsilon, \llbracket \hat{o} \rrbracket_\varepsilon) \mid \llbracket \pi \rrbracket_\varepsilon = \text{true} \}$.

Correctness Properties

We are now at a position to formally define the correctness properties of symbolic summaries. Definitions 2 and 3 respectively define over- and under-approximating summaries. We omit the definition of *exactness*, which is simply the conjunction of the first two. Both definitions rely on the concrete semantics of our core language, using $\langle \mu, \rho, s \rangle \rightarrow_k \langle \mu', \rho', o \rangle$ to state that the concrete execution of s in the concrete memory μ and store ρ , finishes in k steps and generates the concrete memory μ' , store ρ' , and outcome o .

► **Definition 2 (Bounded Over-Approximating Summary).** *A symbolic summary \hat{s} is said to be a k -bound over-approximation of a concrete implementation s with respect to a symbolic memory $\hat{\mu}$ and symbolic store $\hat{\rho}$, if and only if it holds that:*

$$\begin{aligned} \langle \hat{\mu}, \hat{\rho}, \text{true}, \hat{s} \rangle &\rightsquigarrow^* \langle \hat{\mu}', \hat{\rho}', \pi, \hat{o} \rangle \wedge \text{Final}(\hat{o}) \\ \implies \forall \mu, \mu', \rho, \rho', o, k'. (\mu, \rho) \in \llbracket \langle \hat{\mu}, \hat{\rho}, \pi \rangle \rrbracket &\wedge \langle \mu, \rho, s \rangle \rightarrow_{k'} \langle \mu', \rho', o \rangle \wedge k' \leq k \wedge \text{Final}(o) \\ \implies (\mu', o) \in \llbracket \langle \hat{\mu}', \hat{\rho}', \pi, \hat{o} \rangle \rrbracket & \end{aligned}$$

► **Definition 3 (Under-Approximating Summary).** *A symbolic summary \hat{s} is said to be an under-approximation of a concrete implementation s with respect to a symbolic memory $\hat{\mu}$ and symbolic store $\hat{\rho}$, if and only if it holds that:*

$$\begin{aligned} \langle \hat{\mu}, \hat{\rho}, \text{true}, \hat{s} \rangle &\rightsquigarrow^* \langle \hat{\mu}', \hat{\rho}', \pi, \hat{o} \rangle \wedge \text{Final}(\hat{o}) \\ \implies \forall \mu', o. (\mu', o) \in \llbracket \langle \hat{\mu}', \hat{\rho}', \pi, \hat{o} \rangle \rrbracket & \\ \implies \exists \mu, \rho, \rho'. (\mu, \rho) \in \llbracket \langle \hat{\mu}, \hat{\rho}, \pi \rangle \rrbracket &\wedge \langle \mu, \rho, s \rangle \rightarrow^* \langle \mu', \rho', o \rangle \end{aligned}$$

The proposed definitions are unusual in that they relate the symbolic execution of the summary \hat{s} with the concrete executions of its reference implementation s . Typical definitions of this type [21, 36, 48, 47] relate symbolic execution of a given program with its concrete execution. In our setting, we have two different programs being related: a symbolic summary and its reference implementation.

■ **Table 1** C-Implemented summaries.

Class	N	Lines of code	API calls	Memory	Effects	Symbolic	Return
				×	✓	×	✓
<i>Strings</i>	34	1639	194	24	10	18	16
<i>Number Parsing</i>	6	563	56	6	0	0	6
<i>I/O</i>	6	79	16	4	2	5	1
<i>Memory</i>	14	508	71	8	6	9	5
<i>Heap</i>	7	174	29	5	2	7	0
Total	67	2814	344	47	20	39	28

Finally, we note that the proposed definitions require that over/under-approximating summaries allocate memory in the exact same order of their corresponding reference implementations. This requirement could be relaxed by modifying our definition of symbolic heap interpretation for it to relate each symbolic heap with all its valid concrete reshufflings instead of simply those that follow its allocation order. We opted, however, for the more restrictive definitions in order to simplify the presentation.

3.3 Modelling LIBC Functions

We illustrate how the symbolic reflection API can be used to implement symbolic summaries for two families of LIBC functions: string manipulation functions and number-parsing functions. In total, we have implemented 67 summaries targeting 24 LIBC functions. Table 1 gives an overview of the 67 implemented summaries, showcasing for each category of summaries: (1) the total number of lines of code; (2) the total number of calls to the symbolic reflection API; (3) the number of summaries that update the heap memory; and (4) the number of summaries that return symbolic values. In the following, we give an example of a summary from each category.

Example – String Summaries

Figure 7 shows the implementation of an under-approximating symbolic summary for the `strlen` function (recall that the summary given in Figure 2 is exact). This summary iterates over an input string until it finds a concrete null character. During this process, if it finds a symbolic character, it tries to prove that the corresponding byte can only be a null character. If it succeeds, then the summary returns the current length, otherwise it assumes that the current character is not the null character and continues iterating. More concretely, if a character `s[i]` is symbolic, the summary builds the constraint `cnstr ≡ (s[i] ≠ \0)` and uses the primitive `is_sat` to check if `s[i]` can only be the null character (i.e., `!is_sat(cnstr)`), in which case the summary simply returns the value of `i`. Otherwise, `cnstr` is added to the current path condition using the primitive `assume`, making the summary under-approximating. For example, given the symbolic string `[c0, 'a', c2, \0]`, where `c0` and `c2` denote unconstrained symbolic characters, the summary outputs the value 3 and adds the constraints `c0 ≠ \0` and `c2 ≠ \0` to the path condition.

```

1 int strlen2(char* s){
2   char charZero = '\0'; int i = 0;
3   while(1){
4     if(is_symbolic(&s[i])){ //s[i] is symbolic
5       cnstr_t cnstr = _solver_NEQ(&s[i], &charZero, CHAR_SIZE); // s[i] ≠ '\0'
6       if(!is_sat(cnstr)) break;
7       else assume(cnstr); //Add cnstr to symbolic state
8     }
9     else if(s[i] == charZero) break;
10    i++;
11  }
12  return i;
13 }

```

■ **Figure 7** Under-approximating Summary of `strlen`.

```

1 int atoi2(char *str){
2   ...
33  else {
34    symbolic retval = new_sym_var(INT_SIZE);
35    int size = strlen(str); //Max possible length
36
37    //Determine bounds
38    int lower_bound = pow(10,size-1) * -1;
39    int upper_bound = pow(10,size);
40
41    //Build interval with constraints
42    cnstr_t val_GT_lower = _solver_SGT(&retval, &lower_bound, INT_SIZE);
43    cnstr_t val_LT_upper = _solver_SLT(&retval, &upper_bound, INT_SIZE);
44    cnstr_t bounds_cnstr = _solver_And(val_GT_lower,val_LT_upper);
45
46    //Add constraints to symbolic state
47    assume(bounds_cnstr);
48    return retval;
49  }
50 }
51 return res * sign;
52 }

```

■ **Figure 8** Fragment of Over-approximating Summary of `atoi`.

Example – Number summaries

Figure 8 shows a fragment of an over-approximating summary for `atoi`. The `atoi` function is used to parse strings denoting integer values. The key for guaranteeing that the summary is over-approximating is to return a fresh symbolic value and constrain this value to be: (i) greater than or equal to the smallest possible value that may be denoted by the given string; and (ii) smaller than or equal to the largest possible value that may be denoted by the given string. To this end, the summary determines the maximum possible length of the given string and uses it to compute the interval of possible return values. For example, considering a symbolic string `[c0, c1, c2, \0]`, the summary constrains the returned symbolic value, `retval` to lie within the interval `retval ∈ [−99, 999]`.

3.4 Reflection API Implementation

The proposed API can be implemented on top of any symbolic execution tool whose representation of symbolic states includes a symbolic memory and a path condition. We have found this to be the case for all the symbolic execution tools that we have analysed so

far [50, 19, 8, 15, 38, 43, 17, 16, 31]. In the formalism we have chosen to include a symbolic store component, to simplify the presentation, but this component is not essential for implementing the API.

In order to illustrate the effort involved in implementing the API, we have extended *AVD* [45] and *angr* [50], two current symbolic execution tools, with support for it. *AVD* is a novel symbolic execution tool developed by the authors, whereas *angr* is a widely used binary analysis toolkit. In both cases, the API implementation was straightforward, with the API code totalling 330 LoC for *angr* and 529 LoC for *AVD*. Table 2 shows the number of LoC of both implementations per type of API primitive. API primitives were implemented differently in *AVD* and *angr*. In *AVD*, we have implemented each reflection primitive as if it were a native symbolic summary, interacting directly with our own internal representation of symbolic states. In *angr*, we have used an internal API provided by the tool for developers to implement their own *angr* summaries directly in Python, associating each API primitive to an *angr simprocedure*.

■ **Table 2** Lines of code per type of API primitive implemented in *AVD* and *angr*.

	Reflection Primitives				Total
	Core	Memory	Symbolic Values	Constraints	
AVD	206	54	56	213	529
angr	100	23	53	154	330

We believe that extending other symbolic execution tools with support for the proposed API should be as straightforward as extending *angr* and *AVD* since most tools already possess internally, albeit with variations, the reflection mechanisms captured by our API. The main difficulty in the implementation of the API is that it requires a thorough understanding of the inner-workings of the targeted tool and therefore should be done by the tools' own engineering teams rather than by external users. This effort should, however, pay off as implementing our API requires considerably less code than implementing a comprehensive library of symbolic summaries for LIBC from scratch, while also being conceptually simpler.

4 SumBoundVerify: Bounded Verification of Symbolic Summaries

In this section, we introduce our proposed methodology for the bounded verification of symbolic summaries. We first introduce our main summary verification algorithm (§4.1) and then explain how we leverage this algorithm to build `SUMBOUNDVERIFY` by automatically generating symbolic tests for the summaries to be verified (§4.2).

4.1 Bounded Summary Verification Algorithm

Symbolic State Lifting

In order to verify the correctness properties of a summary, we introduce a lifting operator $[\cdot] :: \mathcal{P}(\text{SymSt} \times \hat{\mathcal{O}}) \rightarrow \Pi$ that transforms a set of output configurations (i.e. symbolic states paired up with symbolic outcomes) into a boolean formula. We write $[\hat{\Omega}] = \pi$ to denote that the lifting of the output configurations in $\hat{\Omega}$ generates the formula π . The lifting operator is formally defined as follows:

$$[\hat{\Omega}] \triangleq \bigvee \left\{ [\hat{\mu}]_m \wedge \pi \wedge (\text{ret} = \hat{v}) \mid (\langle \hat{\mu}, \hat{\rho}, \pi \rangle, \mathbb{R}\langle \hat{v} \rangle) \in \hat{\Omega} \right\}$$

24:16 Toward Tool-Independent Summaries for Symbolic Execution

Essentially, a set of output configurations is transformed into a disjunction of boolean formulas, each describing its corresponding configuration. The formula created for each configuration has three components: (i) a memory component $[\hat{\mu}]_m$ describing the content of the symbolic memory (defined below); (ii) a path condition component π ; and (iii) a return component $\mathbf{ret} = \hat{v}$, describing the return value of the function in the execution path that led to the given configuration. We use two dedicated variable \mathbf{ret} and \mathbf{count} to refer to the return value of a function and the number of cells in the current heap, respectively. Importantly, the lifting of a set of output configurations is only defined if all configurations are associated with a return outcome. The lifting operator for symbolic memories $[\cdot]_m :: \mathit{SymMem} \rightarrow \Pi$, which takes a symbolic memory $\hat{\mu}$ and returns a boolean formula $[\hat{\mu}]_m$ describing its contents, is defined as follows:

$$\frac{\text{MEMORY LIFTING} \quad \pi_{\mathit{blocks}} = \bigwedge_{l \in \mathit{blocks}(\hat{\mu})} [\hat{\mu}]_b^l \quad \pi_{\mathit{count}} = \mathbf{count} = |\mathbf{dom}(\hat{\mu})|}{[\hat{\mu}]_m \triangleq \pi_{\mathit{blocks}} \wedge \pi_{\mathit{count}}} \quad \frac{\text{BLOCK LIFTING} \quad \hat{\mu}(l) = (-, 0, k_r)}{[\hat{\mu}]_b^l \triangleq \bigwedge_{0 \leq i < k_r} \{\mathbf{cell}(l+i, \hat{\mu}(l+i))\}}$$

A symbolic memory $\hat{\mu}$ is encoded into the conjunction of its blocks, which are, in turn, encoded using an auxiliary encoding function $[\cdot]_b : \mathit{SymMem} \times \mathbb{N} \rightarrow \Pi$ for lifting memory blocks to formulas. The memory encoding function makes use of an auxiliary function $\mathbf{blocks} : \mathit{SymMem} \rightarrow \wp(\mathbb{N})$ to obtain the locations in the given memory corresponding to the beginning of blocks. The block-lifting function transforms each memory block into a formula describing the contents of each cell in the given block. To this end, we make use of an uninterpreted predicate \mathbf{cell} to denote that the cell at a given address has the given content.

Bounded Verification Algorithm

Algorithm 1 describes our procedure for verifying if a summary \hat{s} is under/over-approximating with respect to a concrete implementation s , symbolic memory $\hat{\mu}$, and symbolic store $\hat{\rho}$. In a nutshell, this algorithm compares the symbolic state(s) resulting from the execution of the summary, $\hat{\Omega}_{\mathit{sum}}$, against those generated by its reference implementation, $\hat{\Omega}_{\mathit{ref}}$. We do not bound the symbolic execution of the summary given that summaries should be designed to be convergent. In contrast, we bound the execution of their reference implementations as they often diverge. In a nutshell, we conclude that:

- a summary is *over-approximating* if $[\hat{\Omega}_{\mathit{ref}}] \implies [\hat{\Omega}_{\mathit{sum}}]$, i.e. the set of symbolic states generated by the reference implementation are contained in those generated by the summary;
- a summary is *under-approximating* if $[\hat{\Omega}_{\mathit{sum}}] \implies [\hat{\Omega}_{\mathit{ref}}]$, i.e. the set of symbolic states generated by the summary are contained in those generated by the corresponding reference implementation.

These implications are, however, too strong as they do not account for the creation of new symbolic values within the execution of the summary. To account for these, we have to existentially quantify the symbolic variables created during the execution of the summary. Algorithm 1 makes use of an auxiliary function $\mathbf{existentials}$ for computing the variables to be existentially quantified according to the following equation:

$$\mathbf{existentials}(\pi, \hat{\mu}, \hat{\rho}) \triangleq \mathbf{lvars}(\pi) \setminus (\mathbf{lvars}(\hat{\mu}) \cup \mathbf{lvars}(\hat{\rho}))$$

Essentially, all the symbolic variables created during the execution of the summary must be existentially quantified; these correspond to the symbolic variables that exist in the final symbolic states obtained from the summary execution but do not in the initial state.

Algorithm 1 Bounded Summary Verification.

```

1 function VERIFYSUMMARY( $prop, \hat{s}, s, \hat{\mu}, \hat{\rho}, k$ )
2    $\langle \hat{\mu}, \hat{\rho}, true, \hat{s} \rangle \Downarrow \hat{\Omega}_{sum}$ 
3    $\langle \hat{\mu}, \hat{\rho}, true, s \rangle \Downarrow_k \hat{\Omega}_{ref}$ 
4    $\pi_{sum} \leftarrow \lceil \hat{\Omega}_{sum} \rceil$ 
5    $\pi_{ref} \leftarrow \lceil \hat{\Omega}_{ref} \rceil$ 
6    $xs_{sum} \leftarrow \text{existentials}(\pi_{sum}, \hat{\mu}, \hat{\rho})$ 
7   if  $prop = over$  then
8      $out \leftarrow \text{isValid}(\pi_{ref} \implies \exists xs_{sum}. \pi_{sum})$ 
9   else
10     $out \leftarrow \text{isValid}(\exists xs_{sum}. \pi_{sum} \implies \pi_{ref})$ 
11  return  $out$ 

```

Correctness Result

Theorem 4 is our main correctness result. Essentially, it states that if we apply VERIFYSUMMARY in over-approximation mode and it returns *true*, then the given summary is a bounded over-approximation of the given concrete implementation and analogously for under-approximation mode.

► **Theorem 4** (Summary Correctness). *Let \hat{s} be a symbolic summary, s its reference implementation, $\hat{\mu}$ a symbolic memory, $\hat{\rho}$ a symbolic store, and k and a positive integer; then, it holds that:*

- *If $\text{VERIFYSUMMARY}(over, \hat{s}, s, \hat{\mu}, \hat{\rho}, k) = true$, then \hat{s} is a k -bound over-approximation of s with respect to $\hat{\mu}$ and $\hat{\rho}$;*
- *If $\text{VERIFYSUMMARY}(under, \hat{s}, s, \hat{\mu}, \hat{\rho}, k) = true$, then \hat{s} is an under-approximation of s with respect to $\hat{\mu}$ and $\hat{\rho}$.*

4.2 Automatic Symbolic Test Generation

In §4.1, we introduced a method for checking whether or not a given summary \hat{s} is correct with respect to a reference implementation s , a symbolic memory $\hat{\mu}$, and a symbolic store $\hat{\rho}$. Naturally, one would like to prove that a summary is correct with respect to all symbolic memories and stores consistent with the signature of the summarised function instead of only a particular symbolic memory and store. SUMBOUNDVERIFY solves this problem partially by bounding the size of memories and stores to be explored and using the type information in the signature of the summarised function to generate the initial symbolic states for which to check the summary up to the pre-established bound. In this section, we explain the procedure by example, leaving its formalisation for future work.

Instead of directly creating the symbolic states on which to run the summaries to be evaluated, we generate the initialisation code that creates such states from the signature of the function to be summarised. In general, the generated initialisation code depends on the type of the arguments given to the summary:

- For *non-character arrays*, we generate one fully symbolic array for each array size under the specified bound;
- For *character arrays*, we generate a single fully symbolic array terminated with a concrete null character with size given by the specified bound (note that this single character array models all strings of size lower than the specified bound since the intermediate symbolic characters of the array may denote the null character);

24:18 Toward Tool-Independent Summaries for Symbolic Execution

- For *non-recursive structures*, we generate a single fully symbolic test with the elements of the structure being mapped to fresh symbolic values;
- For *recursive structures*, we generate one fully symbolic test for each unfolding of the recursive structure up to the specified bound.

The test generation algorithm has two important limitations. First, it does not cover cases in which there are mutual dependencies between the parameters of the function to be summarised (e.g. a function with two array parameters with shared elements). Second, when it comes to recursive structures, the algorithm does not consider structures with loops, such as doubly-linked lists. If the arguments of the summarised function may exhibit one of these features, then the corresponding tests should be created manually.

Examples - Non-Character vs. Character Arrays

We now illustrate the test generation algorithm with two simple examples, covering non-character and character arrays. Suppose we want to validate a summary for a function with signature `int f(int* arr)`; in this case, `SUMBOUNDVERIFY` would generate a set of tests, each with an initial section in charge of creating the symbolic integer array associated with the parameter `arr`. An example of one such initialisation code is given below.

```
1 int arr[4];
2 for (int i = 0; i < 4; i++) { arr[i] = new_sym_var_array("i", i, INT_SIZE); }
```

Essentially, the initialisation code allocates an integer array of size 4 in the stack and fills the four elements of the array with fresh symbolic integers. Suppose now, we want to validate a summary for a function with signature `int g(char* s)`; in this case, `SUMBOUNDVERIFY` would generate a single test with the initialisation code given below.

```
1 char s[BOUND];
2 for (int i = 0; i < BOUND-1; i++) { s[i] = new_sym_var_array("c", i, CHAR_SIZE); }
3 s[BOUND-1] = '\0';
```

The initialisation code for character arrays has two main differences with respect to the code generated for non-character arrays: **(1)** the size of the character array allocated in the stack is always set to the specified bound and **(2)** the last element of the allocated character array is always set to the concrete null character.

5 Evaluation

This section answers the following evaluation questions:

- EQ1** - Is the proposed symbolic reflection API sufficiently expressive to allow for the implementation of under/over-approximating summaries?
- EQ2** - Can tool independent symbolic summaries be used to contain path explosion in symbolic execution?
- EQ3** - Can `SUMBOUNDVERIFY` be used to analyse real-world symbolic summaries developed in the context of state-of-the-art symbolic execution tools?

5.1 EQ1: API Expressivity

In order to illustrate the expressivity of our symbolic reflection API, we implement a library of symbolic summaries consisting of 67 summaries covering 26 LIBC functions from three different header files: `string.h`, `stdlib.h` and `stdio.h`. For most of these functions, we have implemented

at least two summaries, each illustrating a different correctness property. We then used `SUMBOUNDVERIFY` to check the correctness properties of the implemented summaries by comparing them against their corresponding reference implementations. The fact that we were able to implement both under/over-approximating summaries for a large number of LIBC functions gives us a strong confidence that our library is expressive enough to model a wide range of behaviours.

Table 3 shows, for each function category, the number of implemented summaries and their corresponding correctness properties. In the table, N represents the total number of implemented summaries; N/A represents the number of implemented summaries that do not satisfy any correctness property; and the remaining columns represent the number of implemented summaries that satisfy the corresponding property (Under, Over, or Exact).

■ **Table 3** Correctness properties for the C-implemented summaries.

Category	N	N/A	<i>Under-approx.</i>	<i>Over-approx.</i>	<i>Exact</i>
<i>Strings</i>	34	14	7	6	7
<i>Memory</i>	14	6	4	2	2
<i>Number Parsing</i>	6	2	–	4	–
<i>System Calls</i>	13	13	–	–	–
Total	67	35	11	12	9

Note that the summaries modelling functions that use system calls (e.g., `malloc` and `fgets`) cannot be verified against their respective reference implementations. The reason is that the symbolic execution of the reference implementations would necessarily step outside the perimeter of the language and, therefore, of the symbolic execution engine. For instance, the function `fgets` uses the `read` system call to obtain the string with the contents of the given file. In order to symbolically execute `fgets`, we always need to have a summary of `read` to start with, and this bootstrapping summary cannot be symbolically checked. Additionally, some summaries are neither over- nor under-approximating for performance reasons. These summaries assume that the function inputs satisfy certain preconditions, which we explicitly specify as comments in the summary code. The formal characterisation and verification of the properties satisfied by these summaries is, however, left for future work.

5.2 EQ2: Performance of Tool Independent Summaries

We measure the performance gains that can be obtained through the use of symbolic summaries implemented with our API and compare the performance of tool-independent summaries against that of native summaries. In order to carry out this experiment we set up a symbolic test suite focusing on LIBC function usage. To the best of our knowledge, no such test suite exists in the literature. In particular, we have analysed both the TestComp [11, 12] and SVComp [10, 13] test suites, counting for each test suite the number of calls to LIBC functions. We concluded that both these test suites make scarce use of LIBC functions, each calling fewer than 3 functions per test on average. Furthermore, the LIBC functions used in these test suites are mostly called with concrete arguments, rendering the use of symbolic summaries pointless.

■ **Table 4** Summarized results in *angr* and *AVD* for both datasets.

			Memory Out	Timeout	Success	Avg.	Avg.	Avg.	Avg.
			×	×	✓	N_{Paths}	N_{Libc}	N_{API}	$Time (s)$
Hash Map	<i>angr</i>	Concrete	7	0	3	2.2k	6.3k	3.6k	–
		C-Summaries	0	0	10	80	419	7.7k	199.66
		Native Summ	0	0	10	72	390	222	97.99

Experimental Set-up and Symbolic Test Suites

As the test bed for this experiment, we used *angr* [50] and *AVD* [45] extended with our symbolic reflection API (see §3.4). All tests were run on a Ubuntu server (18.04.5 LTS) with an Intel Xeon E5–2620 CPU and 32GB of RAM. Additionally, each test was given 16GB of RAM with a maximum timeout of 30 minutes (1800 seconds).

We searched GitHub for open source C libraries that make intensive use of LIBC string-processing functions. We found two such libraries: (1) the *HashMap* library [55], which provides an implementation of a standard array-based hash table, and (2) the *Dynamic Strings* library [46], which provides an implementation of heap-allocated strings that extend the functionality offered by LIBC strings. Neither of these libraries came with concrete test suites. We created a symbolic test suite for each library: 10 symbolic tests for *HashMap* and 12 symbolic tests for *Dynamic Strings*. The symbolic test suites cover all the functions exposed by two libraries that interact with LIBC functions.

Results

We ran both symbolic test suites on *angr* and *AVD* using: (1) our tool-independent symbolic summaries implemented in C (C Summaries); (2) the native symbolic summaries originally included in each tool (Native Summaries); and (3) the corresponding C reference implementations. Part of these implementations were obtained from *Verifiable C* [4], a toolset for proving the functional correctness of C programs which comes with verified LIBC implementations [3]. The remaining functions were obtained from *glibc* [23] and *libiberty* [22] LIBC implementations.

Results are summarised in Table 4, which shows for each test suite run: (1) the number of tests that failed due to lack of memory (Memory Out); (2) the number of tests that failed for exceeding the time limit (Time Out); (3) the number of tests that finished executing within the given time limit (Success); (4) the average number of explored paths per test (Avg. N_{Paths}); (5) the average number of calls to LIBC functions per test (Avg. N_{Libc}); (6) the average number of calls to API primitives per test (Avg. N_{API}); and (7) the average execution time per test (Avg. $Time$). Note that we do not include the average execution time for the concrete summaries as the majority of the corresponding executions do not finish within the time limit. In contrast, we do include the average execution time for both C summaries and native summaries given that they execute successfully the exact same set of tests.

Unsurprisingly, results clearly show that symbolic summaries substantially improve the performance of symbolic execution tools. For the *HashMap* test suite, we observe that, for both tools, 7 out of the 10 symbolic tests fail to execute without summaries. Using reference implementations, all but the three smallest tests, either exhausted all the available memory or hit the timeout of 30 minutes. The results for the *Dynamic Strings* test suite are analogous. When using reference implementations: 8 out of 12 tests fail to execute with *anqr* and 7 out of 12 tests fail to execute with *AVD*. When it comes to the path explosion problem, we observe that, for both libraries, the number of execution paths generated by symbolic execution with reference implementations is always at least one order of magnitude greater than that generated by symbolic execution with summaries. Table 4 also shows the average number of calls to LIBC functions and API functions. The number of calls to LIBC functions is lower for symbolic execution with summaries than with reference implementations; this is expected as symbolic execution with reference implementations generates a much larger number of paths. Note that, there are calls to the symbolic reflection API even when using reference implementations; this is due to the fact that we always model system calls with summaries.

Finally, we observe that tool-independent summaries are generally less performant than native summaries implemented directly within the code base of the corresponding tools. This slowdown is expected since tool-independent summaries are interpreted, whereas tool-specific summaries are executed natively. Furthermore, our test suites were specifically created to make heavy use of LIBC, making the slowdown more significant than for typical codebases, which interact less frequently with LIBC functions. Importantly, the proposed reflection API was not designed to obtain either performance or expressivity gains with respect to tool-specific summaries, but rather to allow for the implementation of verified, tool-independent summaries that can be shared across multiple SE tools. If the performance of a given tool-independent summary becomes an execution bottleneck for a specific application, then that summary should be implemented natively for the job at hand. However, we believe that will not be the case for the majority of summaries.

5.3 EQ3: Bugs in Symbolic Execution tools

In order to test the applicability of `SUMBOUNDVERIFY`, we used it to find bugs in summaries used in three high-profile symbolic execution tools: *anqr* [50], *Binsec* [19] and *Manticore* [38]. Additionally, we also used `SUMBOUNDVERIFY` to verify the summaries that came with the *AVD* tool. In the following, we classify a summary as *buggy* if it is neither *under-* nor *over-approximating* and if there is no additional information about the expected behaviour of the summary regarding missing/incorrect paths (for instance, in the form of a code comment clarifying how the inputs should be constrained). As we implemented our API in both *AVD* and *anqr*, we were able to use their summaries directly. In contrast, we had to manually re-write *Binsec*'s and *Manticore*'s summaries using our reflection API, following the original algorithms line-by-line. Using this methodology, we were able to validate a total of 52 LIBC symbolic summaries against their corresponding reference implementations.³

The results for all the validated summaries are shown in Table 5. Out of the analysed summaries, we found 14 buggy summaries in *anqr*, 9 in *Binsec*, 1 in *Manticore*, and 13 in *AVD*. These summaries include spurious paths and exclude correct paths, meaning that they are neither under- nor over-approximating. Importantly, only a few summaries included

³ As in §5.2, we use as reference the LIBC implementations from the *Verifiable C* tool chain, and the *glibc* and *libiberty* libraries

24:22 Toward Tool-Independent Summaries for Symbolic Execution

comments restricting the conditions under which they could be soundly applied. However, even these summaries contained bugs that were not ruled out by their authors’ comments, which clearly demonstrates that the development of sound symbolic summaries is a difficult and error prone task that requires automated assistance.

■ **Table 5** Summary bugs found in state-of-the-art symbolic execution tools.

	$N_{Evaluated}$	N_{Bugs}	Bugs Found					
<i>angr</i>	24	14	atoi strncat strtol	atol strncmp strtoul	strcasecmp strncpy wcscasecmp	strchr strstr wcscmp	strcmp strtok_r	
<i>Binsec</i>	9	9	memcmp strcpy	memcpy strncmp	memset strncpy	strchr strchr	strcmp	
<i>Manticore</i>	4	1	strcmp					
Total	37	24						
<i>AVD</i>	15	13	atoi strcat strtol	memcmp strchr tolower	memcpy strcmp toupper	memmove strncmp	memset strncpy	
Total (incl. <i>AVD</i>)	52	37						

To illustrate the type of bug uncovered by SUMBOUNDVERIFY, we present three bugs, each corresponding to a different tool and all three to the function `strcmp`. This function is used to compare two strings lexicographically, returning: (i) a positive integer if the first string is greater than the second one, (ii) a negative integer if it is lower, and (iii) 0 if the two strings coincide. Even though the reference implementation of this function is very compact with less than 10 LoC, its corresponding summaries can be extremely complex (for instance, *angr*’s summary has 160 LoC).

Bug in *angr*

The possible execution paths for the `strcmp` function can be divided into two main sets according to the returned value: the execution paths where the return value is equal to zero and those where it is different. *angr* correctly models all the execution paths that return the value zero, i.e., the cases where the two symbolic input strings are equal. Regarding the execution paths with a return value different from zero, i.e, the cases where the input strings are different, *angr* always constrains the return value to 1. Hence, by returning a fixed positive integer for all paths where the two strings differ, the summary does not satisfy any of the correctness properties. Assuming, for example, two symbolic input strings of size 3, *str1* and *str2*, SUMBOUNDVERIFY produces the following counterexample for *angr*’s summary:

Missing Path: $[str1 = [A, A, A, \backslash 0] \wedge str2 = [B, B, B, \backslash 0] \wedge ret = -1]$

Wrong Path: $[str1 = [A, A, A, \backslash 0] \wedge str2 = [B, B, B, \backslash 0] \wedge ret = 1]$

Essentially, the missing path describes a concrete execution that is not covered by the summary, whereas the wrong path describes a behaviour covered by the summary that is not generated by the execution of the concrete function.

Bug in *Manticore*

Manticore's `strcmp` summary iterates over the two strings to build a nested if-then-else formula over pairs of symbolic bytes. This formula means that if two symbolic bytes are different, then the summary must return the difference of those bytes; if they are equal, the summary must return the value 0 when they are the last two bytes of the strings or continue iterating otherwise. For instance, considering two symbolic input strings: $str1 = [c1, c2, \backslash 0]$ and $str2 = [c3, c4, \backslash 0]$, this summary will create the following if-then-else formula:

$$ret = \text{ITE}(c1 \neq c3, c1 - c3, \text{ITE}(c2 \neq c4, c2 - c4, 0))$$

Even though it appears to be correct, *Manticore*'s summary does not take into account the fact that intermediate symbolic bytes may also be the null character ($\backslash 0$). When validating this summary on the input strings $str1$ and $str2$, `SUMBOUNDVERIFY` produces the following counterexample:

$$\text{Missing Path: } [str1 = [\backslash 0, A, \backslash 0] \wedge str2 = [\backslash 0, B, \backslash 0] \wedge ret = 0]$$

$$\text{Wrong Path: } [str1 = [\backslash 0, B, \backslash 0] \wedge str2 = [\backslash 0, A, \backslash 0] \wedge ret = 1]$$

Bug in *Binsec*

Unlike the previous summary, *Binsec*'s `strcmp` summary takes into account the case where the intermediate symbolic bytes are null characters, but still gets it wrong. For instance, given the same two symbolic input strings: $str1 = [c1, c2, \backslash 0]$ and $str2 = [c3, c4, \backslash 0]$, this summary generates the following formula:

$$\begin{aligned} ret = & \text{ITE}(c1 = \backslash 0, \\ & \text{ITE}(c3 = \backslash 0, 0, 1), \\ & \text{ITE}(c1 = c3, \\ & \quad \text{ITE}(c2 = \backslash 0, \\ & \quad \quad \text{ITE}(c4 = \backslash 0, 0, 1), \\ & \quad \quad \text{ITE}(c2 = c4, 0, \text{ITE}(c2 > c4, 1, -1))), \\ & \text{ITE}(c1 > c3, 1, -1))) \end{aligned}$$

Note that, when comparing each pair of symbolic bytes, this formula first checks if the current byte of $str1$ (e.g., $c1$) is equal to the null character, in which case it then checks if the corresponding byte of $str2$ (e.g., $c3$) is also equal to null; if it is, it evaluates to 0; otherwise, it evaluates to 1 and here lies the problem. When validating this summary on the input strings $str1$ and $str2$, `SUMBOUNDVERIFY` produces the following counterexample:

$$\text{Missing Path: } [str1 = [A, \backslash 0, \backslash 0] \wedge str2 = [A, B, \backslash 0] \wedge ret = -1]$$

$$\text{Wrong Path: } [str1 = [A, \backslash 0, \backslash 0] \wedge str2 = [A, B, \backslash 0] \wedge ret = 1]$$

When the first string is shorter than the second one, *Manticore*'s summary assumes that `strcmp` returns 1 when it should instead return -1 .

Bug in Verifiable C

During our validation experiments we saw unexpected results when using the `strcmp` implementation of *Verifiable C* to validate the corresponding symbolic summaries. In particular, we observed different results for the same `strcmp` summaries when using as reference implementation that of *Verifiable C* and those of the *glibc* and *libiberty* libraries. We found

a bug in the `strcmp` implementation of *Verifiable C* [53]: it compares characters as signed values instead of unsigned ones as mandated by the POSIX specification of `libc`. The code had been proven correct, but for a specification too weak to bring the bug to light. This illustrates yet another application of `SUMBOUNDVERIFY`: it can be used to validate reference implementations against each other.

6 Related Work

There is a vast body of work on summaries for different types of program analysis, such as program logics [30, 44], abstract interpretation [56], and symbolic execution [25, 29]. However, in contrast to program logics, which are typically designed to be compositional and therefore place a heavy emphasis on summaries, in the form of function specifications and their usage, the study of summaries in symbolic execution literature is much more uneven. In particular, while there is a large number of symbolic execution tools that make use of operational summaries in the style of those described in this paper [50, 19, 8, 15, 38, 43, 17, 16, 31], we believe we are the first to address the issue of their formalisation and verification. The existing work on the use of summaries in symbolic execution can broadly be divided into two main groups: (1) *first-order summaries* that either do not reason about the heap memory or do so in a very limited way; and (2) *structural summaries* that rely on various types of representations to model the effects of heap-manipulating functions. In the following, we give a brief outline of research in both categories of summaries, focusing on the work that is closest to ours.

Godefroid et al. were the first to explore the use of first-order summaries in symbolic execution [24, 2, 28]. The first compositional tool in this line of work was `SMART` [24], a dynamic symbolic execution tool with support for summaries. `SMART` analyses functions in isolation in a bottom-up manner, encoding the testing results of each function as a first-order summary to be re-used in the analysis of other functions. Then, the authors proposed a variation of their original algorithm to allow for the lazy exploration of the search space in a top-down manner [2]. Later, the authors presented `SMASH` [28], a framework for testing and verifying C programs. Analogously to `SMART`, `SMASH` is incremental, analysing one function at a time and generating summaries that can be used in the analysis of other functions. The novelty of `SMASH` is that it allows for the combined use of both under- and over-approximating summaries in a demand-driven way. Importantly, the summaries of all three tools consist only of first-order formulas that cannot describe heap effects.

First-order summaries have also been used in the context of loop-summarisation [27, 51, 35]. These works typically combine symbolic execution with a custom-made static analysis component for detecting the induction variables of the loops to be summarised and constructing partial invariants describing their behaviour. Along this line of research, Kapus et al. [32] have recently proposed a new algorithm for inferring loop invariants for string-manipulating C programs using counter-example guided synthesis [1, 49]. These works are, however, complementary to ours since our goal is not to automatically generate summaries but rather to validate manually-written ones.

When it comes to structural summaries, Qiu et al. [42] proposed a new approach for compositional symbolic execution where function summaries are expressed as *memoization trees*. A *memoization tree* is a tree-like data structure that describes the various paths taken by the summarised function, *including* their effects on the heap. To this end, memoization tree nodes describe both the variable store as well as the contents of the heap of the summarised function. The proposed tool is compositional, analysing one function at a time and expanding the contents of symbolic objects by need, following the lazy initialisation approach [33].

Recently, Frago Santos et al. [48] proposed JaVerT 2.0, a new compositional symbolic execution tool for JavaScript. JaVerT 2.0 combines separation-logic-based summaries with static symbolic execution. More concretely, it allows for the incremental analysis of the given program, generating separation-logic-based specifications that can later be used during symbolic execution. The use of separation-logic summaries during symbolic execution has also been explored in the design of the Gillian framework [21, 36], which resulted from the generalisation of JaVerT 2.0 to a multi-language setting.

7 Conclusions

Symbolic summaries are a key element of modern symbolic execution engines. They are an essential tool for both containing the path explosion problem and modelling interactions with the runtime environment. The implementation of symbolic summaries is time-consuming and error-prone, but until now there was a lack of mechanisms and methodologies for sharing symbolic summaries across different tools and for their validation.

This paper proposes a new API for developing and verifying tool-independent summaries. Using the proposed API, symbolic summaries can be directly implemented in C and shared across different symbolic execution tools, provided that these tools implement the API. To demonstrate the expressiveness of our API, we extended the symbolic execution tools *anqr* and *AVD* with support for it and developed tool-independent symbolic summaries for 26 different LIBC functions, comprising string-manipulating functions, number-parsing functions, input/output functions, and heap functions. Furthermore, we presented *SUMBOUNDVERIFY*, a new tool for the bounded verification of the summaries written with our symbolic reflection API. We applied *SUMBOUNDVERIFY* to 37 symbolic summaries taken from 3 state-of-the-art symbolic execution tools, *anqr*, *Binsec* and *Manticore*, detecting a total of 24 buggy summaries.

As future work, we intend to design a tool for automating the creation of symbolic summaries by synthesising them from declarative specifications, such as separation logic triples. To this end, we plan to leverage recent results on code synthesis from separation logic specifications [41], with the key difference being that our goal is to synthesise symbolic summaries instead of reference implementations.

Abstract

Modeling sequential and parallel composition of effectful computations has been investigated in a variety of languages for a long time. In particular, the popular `do`-notation provides a lightweight effect embedding for any instance of a monad. Idiom bracket notation, on the other hand, provides an embedding for applicatives. First, while monads force effects to be executed sequentially, ignoring potential for parallelism, applicatives do not support sequential effects. Composing sequential with parallel effects remains an open problem. This is even more of an issue as real programs consist of a combination of both sequential and parallel segments. Second, common notations do not support invoking effects in direct-style, instead forcing a rigid structure upon the code.

In this paper, we propose a mixed applicative/monadic notation that retains parallelism where possible, but allows sequentiality where necessary. We leverage a direct-style notation where sequentiality or parallelism is derived from the structure of the code. We provide a mechanisation of our effectful language in Coq and prove that our compilation approach retains the parallelism of the source program.

1 Introduction

Programming language designers often select a few common effects (state, IO, network) and bake them into the language. It is, however, impossible to predict what effects developers will need in the future (as was the case with integrated queries [32, 30, 4], reactive programming [31], asynchronous programming [51, 5], multitier programming [36, 43], differentiable programming [23], etc). Thus, we argue that language designs should be equipped with support for developer-implementable effects.

Modeling effectful computations has long been the subject of investigation in the context of various languages. As a result, there exist different abstractions and notations with different properties. A prominent abstraction for modeling effectful computations are monads (e.g., known from Haskell) and the do-notation that emerged from monadic comprehensions [55] providing a lightweight way to embed monads into programs. But monads force effects to be executed sequentially, ignoring potential for parallelism. Notations for parallelism, such as idiom bracket notation for applicatives [29], on the other hand, do not support sequential effects. Yet, programs are rarely only parallel or only sequential; thus it is desirable to support both sequential and parallel composition of effectful operations.

To the best of our knowledge, there are no approaches that provide such support. The `ApplicativeDo` approach by Marlow et al. [27, 28] attempts to retrofit parallelism into the do-notation, i.e., with `ApplicativeDo`, developers write code using the do-notation and an optimising compiler tries to infer which computations are parallelizable. Yet, in the general case, it is not possible to decide statically whether two monadic operations are actually parallelizable or whether the result of one operation depends on the execution of the other. Hence, there is a danger that the compiler either incorrectly decides that two operations can be executed in parallel, which can lead to race conditions, or conservatively decides to not parallelize operations that could actually be parallelized, reducing the potential for improved performance. To counteract race conditions, the `ApplicativeDo` approach requires developers to adhere to specific coding conventions such as only using expressions which are either all read-only or write-only [27].

Another weak point of Haskell's do-notation (and thus also of the approach by Marlow et al.) is that it enforces a specific structure upon the code with strict adherence to one effect per line, which does not allow effects in arbitrary places. The do-notations in Idris [21] and Lean [25, 52] are less restrictive and support direct-style effect usage. Scala supports both structuring effectful code in do-notation via for-comprehensions and for in some cases in direct-style via `async-await` [44]; but, both are based on monads, thus force sequential execution. Although `async-await` was explicitly designed for concurrency, developers must be careful to start parallel execution before accessing their result to preserve parallelism.

In this paper, we propose a direct-style notation that enables sequential and parallel composition of effectful operations (using monads and applicatives, respectively) without forcing a specific structure of the code. We present a one-pass translation from direct-style to monadic effect combinators. Instead of trying to infer the potential for parallelism on top of sequential programs, our approach preserves parallelism that is inherent in the structure of the code thanks to direct style. This makes it easier to reason about the correctness of the proposed translation process and we present a correctness proof and its mechanization in Coq [9]. We conceptualize the preservation of parallelism as the span of a term (the length of the longest path of effectful operations) and the work of a term (the sum of all effectful operations therein). Our translation is span-preserving leveraging applicatives and monads. In contrast, notations based on monads alone are not span-preserving, as they have to chain all effectful operations into a single sequence.

Our compilation has an elegant description as a set of equations forming a structurally recursive function over the syntax, whose equations are the well-known monadic and applicative laws and free theorems. Implementations for do-notation are essentially compilers for an effectful language. They can produce efficient code by avoiding administrative redexes and generating proper tail calls. Including this optimisation in standard effectful languages modeled by monads can be seen as performing partial evaluation of the code via the semantics, extended by the monad laws. In our case, we target mixed monadic and applicative code. Therefore, our optimised translation also combines the use of the monadic laws with the use of applicative laws.

Contributions. In summary, this paper makes the following contributions:

- We present the first mixed applicative/monadic direct-style effect notation.
- We formalize an optimised one-pass translation from direct-style to effect combinators.
- We prove that our translation preserves typability, semantics, and parallelism.
- We mechanize the proof using parametric higher order abstract syntax.
- We implement the proposed translation in the Scala programming language using Scala macros, which enables us to stay close to the formal development.

Structure. The remainder of the paper is structured as follows. Section 2 provides code examples and an intuitive overview of our approach. Section 3 formally defines the proposed translation and provides a proof that it preserves typability, semantics, and parallelism, which is mechanized using parametric higher order abstract syntax. Section 4 presents the implementation in Scala. Section 5 surveys related work. Section 6 concludes the paper and presents ideas for future work.

2 Overview

In this section, we (a) briefly discuss the difference between monadic, applicative, and mixed notations by examples in Scala, and (b) informally present our mixed direct notation and its implementation by translation to effect combinators.

2.1 Monadic, Applicative, Mixed and Direct Style Notations

Functors, Applicatives and Monads. A functor (in functional programming) for $F: \text{Type} \rightarrow \text{Type}$ is a method `map` that turns a function on values into a function on values wrapped in the functor. Intuitively, a value of type $F\ A$ represents an effectful computation of type A . An applicative for F is a functor and a method `pure` to wrap a value into the functor, and a method `ap` (which we occasionally also write $f \diamond \times$ instead of `ap f x`) to apply an effectful computation returning a function, to an effectful computation returning an argument. A monad for F is an applicative for F and a method `bind`, which runs an effectful computation and feeds the resulting value to another effectful computation. Below we show the mathematical description and an encoding in Scala via traits:

<pre>map: (A → B) → (F A → F B) pure: A → F A ap: F (A → B) → (F A → F B) bind: (A → F B) → (F A → F B)</pre>	<hr/> <pre>trait Functor[F[_]]: def map(f: A ⇒ B, a: F[A]): F[B] trait Applicative[F[_]] extends Functor[F]: def pure(a: A): F[A] def ap(f: F[A ⇒ B], a: F[A]): F[B] trait Monad[F[_]] extends Applicative[F]: def bind(f: A ⇒ F[B], a: F[A]): F[B]</pre> <hr/> <p style="text-align: right; font-size: small;">Scala</p>
---	---

25:4 A Direct-Style Effect Notation for Sequential and Parallel Programs

For convenience, we will write `pure(x)`, `x.bind(f)` and `f.ap(x)`, so we define them in Scala as a `extension` methods for every object which has a corresponding instance, and `pure(x)` as a top-level function. Note that we swapped arguments for `bind` as a method `x.bind(f)` with regard to its type as a function `bind(f)(x)`.

Monadic Notation. To illustrate monadic notations, consider the two lines of code below (left side) that use a for-comprehension `for ... yield ...`¹. The programs execute two effectful statements `fetchX` and `fetchY` and bind the result in variables `x` and `y`, respectively, to be combined by a function call to `f`. The for-comprehension (monadic notation) is desugared into explicit use of monadic `bind` (right side).

<pre style="margin: 0;">for x ← fetchX; y ← fetchY yield f(x)(y) for y ← fetchY; x ← fetchX yield f(x)(y)</pre>	<pre style="margin: 0;">fetchX.bind(x ⇒ fetchY.bind(y ⇒ pure(f(x)(y)))) fetchY.bind(y ⇒ fetchX.bind(x ⇒ pure(f(x)(y))))</pre>
Scala	Scala

Applicative Notation. In the programs above, `x` does not depend on `y` and vice versa. If all statements in the program of an applicative are independent from each other – e.g., none of the variables that are introduced in the for-comprehension are used in the `for` part, but only after the `yield`, which has access to all variables introduced above – we can interpret the for-comprehension as an applicative notation instead of monadic notation. Then, the program below on the left side would be translated into the program below on the right side, using applicative `ap` to encode actual parallelism, where `ap` is parallel execution followed by function application. In the example program, `pure(f)`, `x` and `y` are executed in parallel, followed by the function application of the result of `pure(f)` to the result of `x` and the result of `y`:

<pre style="margin: 0;">for x ← fetchX; y ← fetchY yield f(x)(y)</pre>	<pre style="margin: 0;">pure(f).ap(fetchX).ap(fetchY)</pre>
Scala	Scala

Mixed Notation. To illustrate where these notations for effectful computations fall short, consider the following larger program that fetches four resources from the Internet. The program first fetches a resource `urlXX`, which contains another url `urlX`, and then fetches a resource from `urlX` and stores it in `x`. The program further fetches a resource `urlYY`, which contains another url `urlY`, and then fetches the resource from `urlY` and stores it in `y`. Finally, the program concatenates `x` and `y`:

```
val urlXX = "https:// example.org/configx "
val urlYY = "https:// example.org/configy "
for urlX ← fetch(urlXX)
  x ← fetch(urlX)
  urlY ← fetch(urlYY)
  y ← fetch(urlY)
yield x ++ y
```

Scala

Observe that `urlXX` needs to be fetched before `urlX` can be fetched and `urlYY` needs to be fetched before `urlY` can be fetched. But fetching `urlXX` and `urlYY` is independent from each other; and so is `urlX` and `urlY` (as illustrated in the diagram above). Thus, the example contains

¹ For-comprehensions `for ... yield ...` are Scala's equivalent of Haskell's do-notation `do ...; return ...`. The main difference besides Scala's and Haskell's monadic notation is that every for-comprehension must end with a `yield`. Yet, this does not reduce expressive power, as any do-block without a final return can be expressed with an additional binding, e.g., `do ...; e` can be represented by `for ...; tmp ← e yield tmp`.

both parallel and sequential elements. However, if implemented via monadic notation, the program will run sequentially, fetching `urlXX`, then `urlX`, then `urlYY`, then `urlY`. The applicative notation, on the other hand, is not even possible because it would require all effects to be independent from each other.

Direct-Style Mixed Notation. In our direct-style notation, we combine the syntactic form `for ... yield ...` into a single instruction `purify`. Now, the program can be written to look like the following snippet, which reads *Concatenate (1) the result of fetching the value pointed to by a URL by fetching `urlXX` with (2) the result of fetching the value pointed to by a URL by fetching `urlYY`*:

```
purify:
  fetch(fetch(urlXX).↓).↓ ++ fetch(fetch(urlYY).↓).↓
```

Scala

The `purify` operation introduces an operation of type $\downarrow: F[X] \Rightarrow X$ used like `... .↓` into the local scope, which represents direct-style effect execution. If the enclosed code does not make use of the `↓`, the operation `purify` works exactly like `pure`. Otherwise, effect execution `↓` is translated into proper use of `bind` and `ap`.

In direct style, potential for parallelism is implicitly defined by the structure of the code. In particular, the function arguments of `concat ++` naturally have no dependency on each other, and can therefore be executed in parallel. The corresponding program with explicit mixed monadic/applicative combinators is:

```
pure(x => y => x ++ y).ap( fetch(urlXX).bind(fetch) ).ap( fetch(urlYY).bind(fetch) )
```

Scala

The approach we propose in this paper exploits the information encoded in our direct-style notation to define a compositional (e.g., structurally recursive) and provably correct compiler that transforms such direct-style programs into semantically equivalent mixed applicative/monadic programs.

2.2 Discussion

We discuss the similarities and differences between different notations. For illustration, consider that monadic code in the `for/yield` notation can be easily refactored into direct style, roughly by replacing `←` with `= ↓`. In turn, monadic code is compiled into explicit use of monadic operators by calling `bind` on each value and calling `map` on the last:

<pre>for x ← a y ← b z ← c yield e</pre> <p style="text-align: right;">Scala</p>	<pre>purify : val x = a.↓ val y = b.↓ val z = c.↓ e</pre> <p style="text-align: right;">Scala</p>	<pre>a.bind { x => b.bind { y => c.map { z => e }}}}</pre> <p style="text-align: right;">Scala</p>
--	---	---

Scaling. A benefit of direct-style code is that it “scales” better for larger programs in the sense that it integrates well with common language constructs. In particular, direct style composes better with branching. Consider the following versions of the same program. On the left, the program is written in monadic notation, implemented in pure Scala, which requires us to leave and enter monadic notation a second time. The program fetches the time of the last change and the last caching of a certain request. If the resource has been updated since the last caching, we count the cache miss for statistics, request the resource freshly,

25:6 A Direct-Style Effect Notation for Sequential and Parallel Programs

pass it to the cache and return it. Otherwise, we count the cache hit for statistics, and return the answer from the cache. Now, compare the program on the left with a clearer direct-style representation on the right, which is implemented using our approach (code on the right).

<pre> for freshtime ← fetch (freshtimeUrl) cachetime ← fetch (cachetimeUrl) result ← if freshtime > cachetime then for _ ← countFresh tmp1 ← fetchFresh tmp2 ← writeCache (tmp1) yield tmp2 else for _ ← countCache tmp ← readCache yield tmp yield result </pre>	<pre> purify : if fetch (freshtimeUrl).↓ > fetch (cachetimeUrl).↓ then countFresh .↓ parseAndCache(fetchFresh .↓).↓ else countCache.↓ readCache.↓ </pre>
Scala	Scala

Sub-notations. Direct-style notation subsumes three different explicit effect notations (Table 1). First, if a `purify` expression contains exactly one down arrow \downarrow as a mark for effect execution (Row 1), then the notation translates to solely using the Functor interface. This case corresponds to a standard map operation.

Second, if a `purify` expression contains multiple such marks, which are “parallel” with regard to each other (Row 2) – i.e., when they are side-by-side inside different arguments to a function – then the expression translates to solely using the Applicative interface. Crucially, in this case, different effect executions cannot depend on each other. We call these effect executions “parallel” as contrasted with “sequential” code, where a statement can depend on the previous one. Such parallel composition enables parallel execution of effects at run time.

Third, if the expression makes use of nested marks (Row 3) – or equivalently of marks which make use of previously bound variables which contained marks (Row 4) – then the expression translates to using the full Monad interface, which models sequential code.

Direct-style enables to define parallelism naturally by structuring code such that the execution of effects are independent, which gives rise to parallel execution of code where this is possible and using sequential execution where necessary.

2.3 From Laws to a Rewrite System

We refresh the laws of functors, applicatives, and monads and give an intuition how they can be used to optimise effectful programs. Then we state a completion of the laws into a rewrite system. We use the symbol \circ for function composition as in $f \circ g$, and use the symbol (\circ) as the name of function composition, when not used as an infix operator, i.e., $(\circ) f g v := f (g v)$.

■ **Table 1** Subnotations.

Scheme	Description	Typeclass
<code>purify{ ... ↓ ... }</code>	one mark	Functor <code>map</code>
<code>purify{ ... ↓ ... ↓ ... }</code>	multiple marks	Applicative <code>ap</code>
<code>purify{ ... (... ...↓ ...)↓ ... }</code>	nested marks	Monad <code>bind</code>
<code>purify{ ...; val x = ...↓; ... ↓ ... }</code>	consecutive marks	Monad <code>bind</code>

Laws. Typically, the coherence laws are formulated as follows [29, 26].

For Functors, `map` preserves identity and composition, i.e., applying the identity function to an effectful computation is the same as not doing anything; and applying two function in sequence to an effectful value is the same as applying the composite once.

```
identity      : map id v      = id v
composition   : map (f ∘ g) v = map f (map g v)
```

For Applicatives, `pure` creates a effect-free, i.e., *pure* value from a value. The *homomorphism law* states that, applying a pure function to a pure argument is pure. The *identity law* states that, if the function is just pure, then there is nothing to do. The *interchange law* states that, if the argument is pure, then we can swap the pure argument with the effectful function.

```
homomorphism  : pure f ∘ pure v = pure (f v)
identity      : pure id ∘ v      = v
interchange   : f ∘ pure v      = pure (λ f', f' v) ∘ f
composition   : u ∘ (v ∘ w)     = pure (∘) ∘ u ∘ v ∘ w
```

For Monads, the first and second laws state that executing a pure computation amounts to not having to execute any effect at all, allowing us to eliminate the `bind`. The third law states that `bind` is associative, i.e., applying two effectful functions in sequence is the same as applying the effectful composite of the two functions once.

```
leftunit     : bind f (pure v) = f v
rightunit    : bind pure v     = v
associativity : bind g (bind f v) = bind (bind g ∘ f) v
```

Free theorems. The laws are phrased as an equational theory – to create a compiler from the laws, we need to rephrase them as a terminating rewrite system. To do so, we first complete our set of equations with the following free theorems. Free theorems hold in programming languages with parametric polymorphism by parametricity for free [54, 53], therefore they are often not stated specifically in the laws, because there is no additional effort required to make them hold. On the other hand, as we are interested in making use of laws for optimisation purposes, we are allowed to make use of the free theorems as well.

Consider the function `pure`: $\forall A, A \rightarrow F A$. Because it must work over all A it cannot change or create new elements of type A , but only duplicate or forget values of type A . Therefore, it does not matter whether we apply a function `g` to change the A s into B s before or after applying `pure`. On the left we apply `f` on the argument of `pure`, on the right we apply `f` on the result:

```
free_pure : map f (pure v) = pure (f v)
```

Similarly, consider the function `ap`: $\forall A B, F (A \rightarrow B) \rightarrow F A \rightarrow F B$ and `bind`: $\forall A B, (A \rightarrow F B) \rightarrow (F A \rightarrow F B)$. On the left we apply `f` on the argument of `ap` and `bind`, on the right we apply `f` on the result, where $(f \circ)$ stands for $\lambda g, f \circ g$:

```
free_ap   : ap (map (f ∘) g) v = map f (ap g v)
free_bind : bind (map f ∘ g) v = map f (bind g v)
```

25:8 A Direct-Style Effect Notation for Sequential and Parallel Programs

We instantiate `g` with `pure id` in the applicative case and with `pure` in the monadic case, then we can extend the equation chain to the left by the free theorem of `pure` (`map f ∘ pure = pure ∘ f`), and to the right by the identity applicative law (`ap (pure id) v = v`) respectively the left-unit monad law (`bind pure v = v`):

```
*free_ap  : ap (pure f) v      = ap (map (f ∘) (pure id)) v = map f (ap (pure id) v) = map f v
*free_bind : bind (pure ∘ f) v = bind (map f ∘ pure) v    = map f (bind pure v)    = map f v
```

In fact, these two equations share a common right-hand side, and thus we can combine them to get a connection between applicative `ap` and monadic `bind`:

```
ap_bind:  ap (pure f) v = bind (pure ∘ f) v
```

Completion. We can use the free theorems to complete the functor, applicative and monad laws into a more suitable form. In particular, we replace the identity law of the applicative with their generalization derived above. Similarly, the right hand side of the interchange law contained the left hand side of the identity law, therefore we simplify it by composition with the identity law. Further, observe that the homomorphism law becomes superfluous, as it can be constructed by applying the identity law (or equivalently by the interchange law) followed by the free theorem of `pure`; however we will still make use of it in swapped direction, such that reading the laws from left to right, it does not overlap with the other applicative laws. The complete set of equations is now:

```
identity      : map id v      = v
composition   : map f (map g v) = map (f ∘ g) v

homomorphism  : pure (f v)    = pure f ∘ pure v          -- swapped
identity      : pure f ∘ v    = bind (λ v', pure (f v')) v -- generalised by ap_bind
interchange   : f ∘ pure v    = bind (λ f', pure (f' v)) f  -- combined with identity
composition   : u ∘ (v ∘ w)   = map (∘) u ∘ v ∘ w          -- combined with identity

leftunit      : bind f (pure v) = f v
rightunit     : bind pure v     = v
associativity  : bind g (bind f v) = bind (bind g ∘ f) v
```

Looking at the equations above, we see that the identity and interchange law show that a non-pure argument to `ap` on the left and on the right can each be represented by a `bind`, so one might think both laws can be unified by a single law, using two binds like `fs ∘ xs = bind (λ f, bind (λ x, pure (f x)) xs) fs`. However, it is not valid to assume this equation. Actually, there are *at least two* possible trivial instances of an applicative for any monad, the left-to-right applicative above, but also the right-to-left applicative: `fs ∘ xs = bind (λ x, bind (λ f, pure (f x)) fs) xs`. There is no reason to prefer one over the other, and, in general, the assumption of either of these equations is too strong; committing to one such equation would allow elimination of all `aps` into `binds`, and thus implies full sequentiality. To support parallelism, we have to make neither assumption and only rely on the equations derived from the applicative laws.

2.4 Translation

We present a rewrite system based on the laws, and prove its terminating by phrasing it as a structurally recursive function.

We distinguish between a source language and a target language below. The source language consists of term formers for variables, function application, and the direct-style effect execution \downarrow represented as `Each`. The target language consists of term formers for variables, function application, and effect combinators `Pure`, `Bind` and `Ap`; and parallelism is explicitly structured by those combinators.

$$\begin{aligned} (\text{Src}) \quad e, f &::= \text{Var } x \mid \text{App } f \ e \mid \text{Each } e \\ (\text{Tgt}) \quad g, h &::= \text{Var } x \mid \text{App } g \ h \mid \text{Pure } g \mid \text{Ap } g \ h \mid \text{Bind } g \ h \end{aligned}$$

The source language uses direct style. In programs written in the source language, parallelism is implicitly defined by the structure of the code. In particular, function arguments naturally have no dependency on each other, and can therefore be executed in parallel. Our compiler translates direct style into monadic and applicative combinators. The essence of our compilation strategy is to use the monadic and applicative laws directly as the actual transformation rules.

Basic Translation. The translation starts with the `PURE` expression, which is implemented as a structurally recursive function over syntax, expanding the direct-style use of effects \leftarrow into the effect operation `Bind`, while variables are wrapped in a `PURE`, and function application is translated to applicative `Ap`, realising that function arguments can be executed in parallel.

$$\begin{aligned} \text{PURE: Src} &\rightarrow \text{Tgt} \\ \text{PURE (Var } x) &= \text{Pure (Var } x) \\ \text{PURE (Each } e) &= \text{Bind (PURE } e) \text{ id} \\ \text{PURE (App } f \ e) &= \text{Ap (PURE } f) \text{ (PURE } e) \end{aligned}$$

Optimising Translation. If we only cared about a correct translation from the direct-style notation to the pure calculus with explicit combinators, then the translation we discussed so far is sufficient. Yet, we consider an optimising translation (Figure 1), where instead of term using the constructors `Bind` and `Ap` (capitalized) directly, we use the smart constructors `AP` and `BIND` (all capitals) instead. Both the constructor and the smart constructor of a term do construct terms that are semantically indistinguishable, i.e., $\text{AP } f \ x \approx \text{Ap } f \ x$. Smart constructors, however, internalize the optimisation by reducing to a simpler term if possible. The translation `PURE` we have described earlier can be seen as such a smart constructor for the `Pure` term constructor. It also preserves the semantics, i.e., $\text{PURE } x \approx \text{Pure } x$.

The only difference between the basic and the optimised translation, is that the optimised smart constructor `PURE` calls to the smart constructor `AP` instead of using the term constructor `Ap` directly, which can lead to further optimisations. In this way, we can leverage smart constructors to integrate the translation with an optimisation into a one-pass optimised translation. For the optimisation, the smart constructors apply the monadic and applicative laws, only in the other direction than the translation, i.e., bubbling up `Pure` in a structurally recursive way through the term, and thereby removing superfluous effect combinators in the generated code.

In particular, `AP` (Figure 1) will reduce the applicative application of a pure function to a pure argument back into the pure function application with only the result wrapped into `Pure` (which is simply the reverse rule of the homomorphism law we used above). Similarly, if either side of `AP` is pure, there are no two effects to be executed in parallel but just a single effect. Hence, we can reduce the term to a single monadic bind. Finally, if neither argument to `AP` is marked as pure, then we simply return the actual term former `Ap` and retain the

■ **Figure 1** Optimised Translation.

parallelism. The optimisation rules that apply to BIND (Figure 1) are similar. If either of its arguments is marked as pure, we can avoid performing effects at all. If we have nested binds, we can apply the associativity rule to generate a chain of binds.

Overall, seven of the ten equations above come from our generalized laws; two hold by semantic *indistinguishability*, and one is the basis for our *effect translation*, namely the translation of the imperative \leftarrow to an explicit bind.

In the following section, we extend the language, formalize the language and the translation using a Coq mechanisation, and prove correctness.

3 Mechanisation

We define the source language that features our effect notation and a translation to a target language which is the subset of the source language that does not include the effect notation. We prove that our translation preserves typability, semantics, and parallel execution, which we measure through the program's span and work. We have mechanized our language and proofs in Coq.

3.1 Definitions

We use (parametric) higher-order abstract syntax (PHOAS) [40, 8], which enables us to reuse the binders of the host language as binders of the guest language. PHOAS avoids the need to define first-order syntax, an operational semantics and capture-avoiding substitution, thereby removing intricate lemmas regarding substitution and hundreds of lines of code from the mechanisation, bringing the proof more in line with a more legible pen-and-paper formalisation.

Further, we use intrinsically typed terms [11, 3, 1, 2], and a type-theoretic semantics [17]. Using intrinsically typed terms together with dependent pattern matching allows us to define total evaluation (in contrast to using untyped terms or simple pattern matching where we could just define partial evaluation). The reason is that such an approach only needs to consider well-formed terms that *don't go wrong* [33].

■ **Listing 1** Lawful Monad.

```

Class Monad F := {
  map {A B}: (A → B) → F A → F B;
  pure {A} : A → F A;
  ap {A B}: F (A → B) → F A → F B;
  bind {A B}: (A → F B) → F A → F B;
}.

Class LawfulMonad F := {
  monad :> Monad F;

  idl {A B} (f: A → F B) {x}: bind f (pure x) = f x;
  idr {A B} (f: A → B) {x}: bind (pure ∘ f) x = map f x;
  asc {A B C} (f: A → F B) (g: B → F C) {x}: bind g (bind f x) = bind (bind g ∘ f) x;

  apl {A B} (f: A → B) {x}: ap (pure f) x = map (λ x', f x') x;
  apr {A B} (f: F (A → B)) {x}: ap f (pure x) = map (λ f', f' x) f;
  aplr {A B} (f: A → B) {x}: map f (pure x) = pure (f x);

  map_map {A B C} (g: A → B) (f: B → C) {x}: map f (map g x) = map (λ x, f (g x)) x;
}.

```

Coq

The common strategy behind all these approaches is to carve out a subset of the host language, that is the language we want to define (the guest language), and then reusing all the power of the host language to define the guest language, avoiding having to reimplement tedious implementation details: The guest types simply mirror the host types, the guest terms mirror the host terms, and the evaluation function maps guest terms to host terms.

Lawful monads. For brevity, we do not define Functor, Applicative and Monad separately. We define a class `Monad` and a class `LawfulMonad` (Listing 1). `Monad` contains the functions `map`, `pure`, `ap`, and `bind`. `LawfulMonad` extends `Monad` and further contains `idl`, `idr`, `asc`, `apl`, `apr`, `aplr`, and `map_map`, corresponding to the left and right unit law, and the associativity law of the monad, and the identity and interchange law of the applicative, the free theorem of pure, and the composition law of the functor.

Static semantics. From Coq, we use units ($\text{tt}: \text{Unit}$), products $((a,b): A \times B)$, functions $((\lambda a, b): A \rightarrow B)$. Mirroring the data types of the host language, we define the types for unit (\mathbb{T}), sums $(s \vee t)$, products $(s \wedge t)$, functions $(s \rightsquigarrow t)$ and effects (\mathbb{M}) in the guest language (Listing 2a). We define a data type `ef` to label terms with, as belonging to the source language `src`, the target language `tgt`, or the either language `com` (common) (Listing 2c). Label denotation $\text{EF } m: \text{ef} \rightarrow (\text{Type} \rightarrow \text{Type})$ assigns each functor in the host language. Concretely, the target and common label is assigned the identity effect functor (e.g. no effect), and the source language is assigned the effect `m` given as an argument.

We define a data type `tm` $\Gamma \text{ B } t$ for the syntax of our guest language (Listing 2d). The terms are parametrized by a type denotation Γ , a language label `B` and a type `t`. The common term formers are abstraction `Lam e`, application `App e f` and variables `Var v` to represent functions; unit `Unt e`, tuple `Prd (e, f)` and projections `Fst e` and `Snd e` to represent products. The source language has an additional term former `Each e`, which represents the direct-style effect application \downarrow from above. The target language has additional term formers `Pure e`, `Ap e`, `Map f e`, and `Join e` representing the effect combinators.

25:12 A Direct-Style Effect Notation for Sequential and Parallel Programs

The term former `Lam` binds variables. In PHOAS, guest-level bindings are represented using the host language's bindings. This is why this construct takes as an argument a function which binds a variable, represented as a value of type Γt .

Example. In our encoding, the terms of the guest language can be written similarly to the terms of the host language where each term former of the host language is wrapped by a term former of the guest language.

For example, the identity function $(\lambda x, x)$ can be encoded in the guest language as `Lam` $(\lambda x, \text{Var } x)$. A term $(\lambda x y, \text{add } x y) a b$ – an eta-expanded addition function applied to some arguments – can be expressed as `Lam` $(\lambda x, (\text{Lam } (\lambda y, \text{add } \text{`App` } (\text{Var } y) \text{`App` } (\text{Var } x)))) \text{`App` } (\text{Var } a) \text{`App` } (\text{Var } b)$, writing application $x \text{`App` } y$ infix for convenience. Constructing a term of unit type `tt` is written in the guest language as `Unt tt`. Similarly, projection on a pair (a,b) is written in the guest language as `Fst (Prd (a,b))`.

Dynamic semantics. Next, we define the dynamic semantics corresponding to the static semantics. The static semantics has three parts: the types, the language labels and the terms. Therefore, the dynamic semantics also defines three parts.

The denotation of a type `EVAL m: ty \rightarrow Type` (Listing 2b) maps each guest type to its corresponding host type, and is parametrized by a type constructor `m`, corresponding to the monad we evaluate in.

The denotation of a term with regard to the previously defined type denotation `eval ... : tm (EVAL m) B t \rightarrow EF m B (EVAL m t)` (Listing 2d) interprets the terms in a specific monad depending on which language the terms are labeled from. More concretely it takes a term of type `t` and of label `B` to be evaluated in monad `m`, and returns a value of the denotation of the type `EVAL m t` wrapped in the denotation of the label `EF m B`. The evaluation for terms from the source language implicitly have effects and can therefore only be interpreted in a monadic interpreter. For the common and the target language, we define an evaluation as simply the mapping of guest term formers to their corresponding host expressions, while mapping variables to variables.

The decision of which monad to use is governed by the label denotation `EF m: ef \rightarrow ty \rightarrow ty` (Listing 2c) mapping the target and the common language (whose terms do not have implicitly any effects) to the identity effect, e.g., no effect, while the `src` language is mapped to the effect `M`.

Note the way we defined the common, source and target terms, we can relate common terms into source or target terms, e.g., into any other language label `relabel: T Γ com t \rightarrow T Γ e t`.

Example. Consider the evaluation of the following term, which constructs and then destructs a pair of units, which is equal to unit: `eval com (Fst (Prd (Unt tt, Unt tt))) = tt`.

Translation. The compilation from the target into the source language is performed by the smart constructor `PURE`, i.e., we compile from an effectful language into a pure language that uses monadic effect combinators. We formally define `PURE` (Listing 3) that performs both the action of a normal `pure`, e.g., wraps the argument into an additional effect `tm Γ src t \rightarrow tm Γ tgt (M t)`, and additionally performs a translation from terms from the source language with effect application `Each` to terms of the target language using combinators `Pure`, `Map`, `Ap` and `Bind`. This translation makes use of the smart constructors `AP` and `JOIN`, that perform optimisations.

Coq

The Var, App and Each cases were discussed in Section 2.4: The direct-style use of effects Each is expanded into effect operation Bind, while variables are wrapped in PURE, and function application is translated to applicative Ap. The lambda and empty terms describe values and are simply wrapped into a pure as well.

In the case of projections and the case of tuples, we follow the general pattern of the homomorphism law, e.g., we map both the function (projection, tuple) into a Pure and we wrap all arguments in a PURE, and we apply them applicatively.

Example. Assume our language contains an effectful operation fetch. Then, translating the term e := Prd (Each (fetch "foo"), Each (fetch "bar")) yields PURE e = Pure (Lam (λ e', (Lam (λ f', Prd (Var e', Var f')))) `AP` (fetch "foo") `AP` (fetch "bar")).

Span and Work. We define span and work (Listing 4), which we use to express the degree of parallelism. Span is the length of the longest chain of unhandled effectful operations, i.e., the longer the path, the more operations need to run sequentially. Hence, a shorter span for the same number of operations means a higher amount of parallelism. Work is the sum of all unhandled effectful operations. Just like evaluation interprets the value of a term, span and work are interpretations to a numeric value of a term.

As our syntax is defined from types, label and terms, we define these new interpretations as a type denotation, an effect denotation and a term denotation as well. The effect denotation for span and work is the identity function, and the type denotation is the constant function mapping all guest types to the type of natural numbers (SPAN, WORK).

More formally, we define the span of an expression to be zero for variables and values, such as empty and lambda, and for pure expressions. The span of Join and direct-style effect application Each is one more (successor S) than the span of their argument. For assertion and projection (access to first and second component), the span is simply the span of its

■ **Listing 4** Span and Work.

(a) Span.

(b) Work.

Equations WORK: $ty \rightarrow Type := | _ \Rightarrow nat.$

Equations

```
work {B x} (e: tm WORK B x): nat :=
| Var i   => 0 | Lam e   => 0
| Unt tt  => 0 | Pure e  => 0
| Fst e   => work e
| Snd e   => work e
| Prd (e, f) => work e + work f
| App e f  => work e + work f
| Ap e f   => work e + work f
| Map e f  => work e + work f
| Join e   => S (work e)
| Each e   => S (work e).
```

Coq

argument, while the span of a tuple is the maximum of its left or right branch. The span for function application, applicative application and mapping is the maximum of the span of its arguments as well, plus the span of the execution of the specified function on the argument. However, we defined our static semantics such that direct-style effect application cannot be performed under a lambda, therefore the span of the execution of any function is zero.

Analogously, we define the work of an expression to be zero for variables, values, and pure expressions. Similar to the span, the work of Join and direct-style effect application Each is one more (successor S) than the work of their argument. The work of assertion and projection is the work of its argument. Other than span (which takes the maximum), the work of a tuple is the sum of both arguments. The work for function application, applicative application and mapping is the sum of the work of its arguments, plus the work of the execution of the specified function on the argument, which is zero, because lambdas cannot contain Join or Each.

Example. Assume our language contains an effectful operation `fetch`. We calculate the span and work of a term in the source language $e := \text{Prd}(\text{Each}(\text{fetch } \text{"foo"}), \text{Each}(\text{fetch } \text{"bar"}))$ as follows: $\text{span } e = 1$ and $\text{work } e = 2$. This expresses the fact that the two effects can be performed in parallel. The corresponding target language term is $e' := \text{Pure}(\text{Lam}(\lambda e', (\text{Lam}(\lambda f', \text{Prd}(\text{Var } e', \text{Var } f'))))) \text{ `AP` } (\text{fetch } \text{"foo"}) \text{ `AP` } (\text{fetch } \text{"bar"})$. We get the same results for this term: $\text{span } e' = 1$ and $\text{work } e' = 2$.

3.2 Proof

Our translation should only change the encoding from direct-style to effect combinators, while the semantics, typability and parallelism of the term should be preserved. We prove that our translation preserves typability, semantics, span and work. Intuitively, the theorems hold, because our translation performed by PURE, AP, and JOIN are the functor, monad and applicative laws.

► **Theorem 3.1** (PURE preserves types). The translation function takes a well-typed term and produces a well-typed term, i.e., $\text{PURE}: \forall t, \text{tm } \Gamma \text{ src } t \rightarrow \text{tm } \Gamma \text{ tgt } (\mathbb{M} t)$

Proof. Using intrinsically-typed representation of terms, the well-typedness of the translated term is guaranteed by the fact that the definition of the translation function PURE is itself well-typed in Coq. ◀

25:16 A Direct-Style Effect Notation for Sequential and Parallel Programs

We now consider the preservation of semantics. First, we show that the semantics of the smart constructors is equal to that of the normal constructors, so that they merely represent optimizations of those.

► **Lemma 3.2** (AP respects semantics). $\forall f\ e, \text{ eval_tgt } (\text{AP } f\ e) = \text{eval_tgt } (\text{Ap } f\ e)$

► **Lemma 3.3** (JOIN respects semantics). $\forall f\ e, \text{ eval_tgt } (\text{JOIN } e) = \text{eval_tgt } (\text{Join } e)$

Proof. By case distinction on the term structure of the arguments, using the functor, monad and applicative laws. ◀

Next, we see that embedding the pure com sublanguage in the target language preserves the semantics:

► **Lemma 3.4** (relabel preserves semantics). $\forall e, \text{ eval_tgt } (\text{relabel } e) = \text{eval_com } e$

Proof. By induction on the structure of e . ◀

From this, we can deduce that the PURE transformation preserves the semantics of the source program.

► **Theorem 3.5** (PURE preserves semantics). *For all lawful monads M to be evaluated in,*
 $\forall e, \text{ eval_tgt } (\text{PURE } e) = \text{eval_src } e$

Proof. By induction on the structure of e , using Lemmas 3.2–3.4. ◀

We now want to show that PURE preserves the work and span of the program. This is similar to semantics preservation, except that the functions we consider map to a monoid (the natural numbers with addition and maximum, respectively) rather than a monad.

We show that AP and JOIN do not increase the span and work of a term, compared to the normal constructors.

► **Lemma 3.6** (AP respects span and work).

$\forall f\ e, \text{ span_tgt } (\text{AP } f\ e) \leq \text{span_tgt } (\text{Ap } f\ e) \quad \text{and} \quad \text{work_tgt } (\text{AP } f\ e) \leq \text{work_tgt } (\text{Ap } f\ e)$

► **Lemma 3.7** (JOIN respects span and work).

$\forall e, \text{ span_tgt } (\text{JOIN } e) \leq \text{span_tgt } (\text{Join } e) \quad \text{and} \quad \text{work_tgt } (\text{JOIN } e) \leq \text{work_tgt } (\text{Join } e)$

Proof. By case distinction on the term structure of the arguments, using the monoid laws. ◀

The pure terms in the com sublanguage are effect-free; therefore, their span and work is equal to 0.

► **Lemma 3.8** (com is effect-free). $\forall e, \text{ span_com } e = 0 \quad \text{and} \quad \text{work_com } e = 0$

Proof. By induction on the term structure of e . ◀

Embedding pure terms into the target language produces a term that does not perform any effects, either.

► **Lemma 3.9** (relabel terms remain effect-free).

$\forall e, \text{ span_tgt } (\text{relabel } e) = 0 \quad \text{and} \quad \text{work_tgt } (\text{relabel } e) = 0$

Proof. By induction on the term structure of e . ◀

We can then show that the translation PURE does not increase the span or work of the source program, thereby demonstrating that it is parallelism-preserving.

► **Theorem 3.10** (PURE preserves span and work).

∀ e, $\text{span } \text{tgt}(\text{PURE } e) \leq \text{span } \text{src } e$ and $\text{work } \text{tgt}(\text{PURE } e) \leq \text{work } \text{src } e$

Proof. By induction on the term structure of e , using the monoid laws of addition and maximum as well as Lemmas 3.6–3.9. ◀

4 Implementation

In this section, we describe the differences and similarities between the mechanisation in Coq and the implementation in Scala built on a macro-based AST transformation.

Structural Recursion. We keep our implementation in a general-purpose language as close to the formal model of our core calculus as possible. To this end, our implementation follows the formal translation as a structurally recursive function over the terms where possible. We use Scala macros to get access to code as AST data type, similar to the `tm` data type in the formalization.

Type-preserving Compilation. In Scala, we process the untyped AST for fine-grained detailed manipulations. Knowing that the translation is typability-preserving by our Coq proof, increases confidence in the implementation.

Exhaustiveness Checks. A difference between the Coq and the Scala implementation is that `Bind`, `Ap` and `Pure` are not syntax forms in Scala but represented by variable and function application in the embedding. Still, we can treat them as syntax forms to construct and destruct by defining custom patterns for pattern matching. Further, Scala macros do not define the Scala syntax as an algebraic data type (to hide compiler internals), and therefore do not offer exhaustiveness checks. Yet, by the fact that the Coq implementation is total, the Scala implementation can be expected to be as well.

Custom Effects. In the formalization, we have only a single effect, while, in the implementation, we allow every use of the notation to be instantiated with a different effect, based on the type of the expression. Our macro inspects the expression’s type and, based on this type, picks the corresponding generated combinators `bind/ap/pure` of the respective effect.

Arity. In Scala, functions may take multiple arguments. Generally, we can model functions taking multiple arguments as functions taking a single argument of a tuple with multiple fields with appropriate currying and uncurrying. Functions with multiple arguments make the compiler no longer structurally recursive over terms because, besides terms, the compiler additionally needs to mutually recurse over the list of arguments, which would complicate the proof, but is necessary for our implementation.

5 Related work

Do-Notation. Do-notations have been popular for studying a variety of styles for writing effectful code: Wadler extends list-comprehension syntax [55] to monadic comprehensions, from which modern do-notation sprung, and McBride introduced applicatives and idiom brackets as a notation for applicatives [29]. To the best of our knowledge, the only support for mixed sequential and parallel programming was introduced as a Haskell extension [27, 28] to optimise do-notation into mixed monadic/applicative operations (`ApplicativeDo`). In contrast, our notation preserves the parallelism inherent in the structure of the program, thereby allowing sequentiality where necessary and giving parallelism where possible.

Implementations. Besides theory, implementations for effectful guest language notations are a popular endeavor, for example: In Scala, we can find projects to supports effectful programs through compiler plugins such as coroutines [47], Scala async [44], Monadless [7], Effectfull [10], Scala Workflow [49], Scala ContextWorkflow [22], Scala Computation Expressions [46], Dsl.scala [57], Dotty CPS [50]. In other languages we have: F# computation expressions [39], In particular proof-assistants and dependently typed languages have an interest for good support of notations for guest languages, which we can see in Idris’ [6, 21] Lean’s [52, 25], and Kind’s [24] notation. None of them support parallelism.

Further, the following approaches are similar to `ApplicativeDo`: OCaml’s monadic and applicative `let` [37], Scala `avocADO` [45], and Scala `parallel-for` [48]. But these do not support direct-style effect usage, and do not preserve parallelism.

CPS Translations. In general, effects are implemented by translating to other already known effects. In particular, all effects can be represented by the continuation effect [14], and thus, by translating to continuation passing style (CPS) [42, 15]. However, naive CPS translations introduce so called administrative redexes, e.g., expressions containing subexpressions which do not need to be evaluated at run-time, but can already be optimised by a partial evaluation pass at compile-time. Eventually, Danvy and Nielsen [12] optimised the CPS-translation into a first-order, one-pass, compositional translation.

Their trick for achieving an optimal result in one pass is to build optimisations into the definitions of their translation functions. We use a similar approach in our translation through the definition of smart constructors which simplify terms using monad and applicative laws when called.

Host supporting effects. Because effects can be implemented by translation to equally or more powerful effects, besides giving a denotational semantics modelling a compiler, there is another approach – that we did not follow – by forwarding effects to the host language as well. Then, compile-time translations like ours can be avoided and effects can be implemented in languages as a library, given the host languages has sufficient powerful effects. Filinski [14] studied the implementation of effects in languages with delimited continuations (e.g. `shift` and `reset`). In such an impure language it is possible to implement so called monadic reflection – a function taking an effectful function and returning a “pure” function. This is of course only possible by exploiting the impurity of the host language to implement the effect using delimited continuation. Later, Forster [16] studied the translations between monadic reflection, effect handlers and delimited control. The approach to extend the underlying virtual machine by support for delimited continuations, which are sufficiently efficient for then implementing effects as normal libraries is followed by: the JVM proposal for delimited continuations [41], the Haskell proposal for continuation marks [18] and `multicore-ocaml` [35].

We are looking for a more general solution for compiling a language, that works independent of whether the runtime already supports delimited continuations or not.

Formalisation Techniques. To focus on the interesting parts of our formalisation, we used modern techniques to define features of the guest language in terms of features of the host language: In particular, we use parametric higher order abstract syntax (PHOAS) [40, 19, 8] to inherit binders and capture-avoiding substitution from the host language, and intrinsically-typed syntax [11, 3, 1, 2] to inherit type checking. The choice of PHOAS implies a limitation of our work, namely that we can formally only prove theorems about closed terms. Yet, this is a common restriction and lifting it is subject to future work.

6 Conclusion

Existing notations for composing effectful computations fall short on providing both sequential and parallel composition of effects at the same time. In this paper, we proposed a notation for mixed sequential/parallel code. Our notation allows direct-style effects, a feature that enables the sequentiality or parallelism of the effects to be determined by the structure of the code. We proved that our compilation preserves the parallelism of the source program and mechanized the proof in Coq.

An interesting next step for this line of research on direct-style notations for effects is to investigate how to cover more programming language features such as loops and branches, to integrate effects more seamlessly into the language. Besides monad and applicative functors, other effect functors, such as selectives [34, 56], comonads [38], and the theory behind effectful recursion [13] and generalizations such as arrows [20, 26] are promising possibilities.

Abstract

Browsers are the main way in which most users experience the internet, which makes them a prime target for malicious entities. The best defense for the common user is to keep their browser always up-to-date, installing updates as soon as they are available. Unfortunately, updating a browser is disruptive as it results in loss of user state. Even though modern browsers reopen all pages (tabs) after an update to minimize inconvenience, this approach still loses all local user state in each page (e.g., contents of unsubmitted forms, including associated JavaScript validation state) and assumes that pages can be refreshed and result in the same contents. We believe this is an important barrier that keeps users from updating their browsers as frequently as possible.

In this paper, we present the design, implementation, and evaluation of SINATRA, which supports instantaneous browser updates that do not result in any data loss through a novel Multi-Version eXecution (MVX) approach for JavaScript programs, combined with a sophisticated proxy. SINATRA works in pure JavaScript, does not require any browser support, thus works on closed-source browsers, and requires trivial changes to each target page, that can be automated. First, SINATRA captures all the non-determinism available to a JavaScript program (e.g., event handlers executed, expired timers, invocations of `Math.random`). Our evaluation shows that SINATRA requires 6MB to store such events, and the memory grows at a modest rate of 253KB/s as the user keeps interacting with each page. When an update becomes available, SINATRA transfer the state by re-executing the same set of non-deterministic events on the new browser. During this time, which can be as long as 1.5 seconds, SINATRA uses MVX to allow the user to keep interacting with the old browser. Finally, SINATRA changes the roles in less than 10ms, and the user starts interacting with the new browser, effectively performing a browser update with zero downtime and no loss of state.

1 Introduction

Browsers are the main way in which most users experience the internet. Browsers are responsible for the safety of user sensitive data, in the form of cookies, saved passwords, and credit card information, and other personal information used to auto-complete forms.

Browsers are also responsible for ensuring the integrity of the websites that the user visits, checking certificates and negotiating encrypted HTTPS channels. Given all this, browsers are prime targets for malicious entities. For the common user, the best way to protect their browsers (and the personal data they keep) is to keep the browsers as up-to-date as possible.

Unfortunately, users are slow to update their browser to a new version. In terms of percentage of users, data for Google Chrome [53] and Mozilla Firefox [41] show that a new browser version takes about 2 weeks to overtake the previous version, and about 4 weeks to reach its peak. Given the fast pace of browser releases (6 weeks for Google Chrome and 4 weeks for Mozilla Firefox), the amount of users running outdated versions is significant at any given time.

Browser developers are aware of the problems caused by running outdated versions, and provide features to entice users to update, from reminding the user that a new update is available to minimizing the inconvenience by reopening all pages (tabs) after the update. Even though popular, the latter feature has three main flaws. **First**, it disrupts the user interaction by closing the browser, downloading the new version, and then opening it. **Second**, it assumes that pages can simply be refreshed after the update. Such an assumption fails if a login session expires, which causes the page to refresh to the login portal; or if the contents of the page change with each refresh, as is the case with modern social media. **Third**, refreshing a page loses all user state accumulated on that page since it was loaded. Such state includes, among others, data in HTML forms and JavaScript state.

The result is simple: **Browser updates are disruptive for the average user**. Dynamic Software Updating (DSU) techniques can be used for eliminating such disruption, updating a program in-process. Unfortunately, state-of-the-art DSU tools cannot handle programs as complex as modern commercial internet browsers (Section 2.1). Also, simply dumping the old browser memory state to disk and reloading it in the new browser does not work, as the new browser may change the internal state representation.

In this paper, we present the design and implementation of **Sinatra— Stateful Instantaneous browser updates** – a novel MVX technique implemented in pure JavaScript. SINATRA requires little changes to the target JavaScript application (Section 3), which can be performed automatically for all the pages accessed through an HTTP proxy (Section 3.1).

To perform an update (Section 3.2), SINATRA captures all sources of non-determinism accessed by the browser. Then, when an update becomes available, SINATRA launches the updated browser as a separate process, and feeds it the same non-determinism, thus synchronizing the JavaScript state between both browsers. During this time, SINATRA allows the user to keep interacting with the old browser by performing MVX until the updated browser's state is up-to-date. Once the update was successful, SINATRA terminates the old browser and the user can start interacting with the new browser.

Note that simply transferring the JavaScript between browsers is not sufficient for two reasons. First, the user cannot interact with either browser while transferring the state. Second, failed updates may still result in loss of user data. Multi-Version eXecution (MVX) solves both problems by allowing the user to interact with the old browser while the new browser is receiving the state, and by allowing SINATRA to cancel a failed update simply by closing the new browser. Unfortunately, state-of-the-art MVX tools cannot handle modern commercial internet browsers (Section 2.2), and performing MVX at the JavaScript is not as straightforward due to the event-driven programming paradigm (Section 2.3).

SINATRA captures all sources of non-determinism available to a JavaScript program, including execution of event handlers (Sections 3.3), and non-deterministic functions such as `Math.random` (Section 3.4). We implemented SINATRA in pure JavaScript using an extra

coordinator process to enable communication between browsers (Section 4.1) that serializes JavaScript non-determinism as JSON (Section 4.2). Our implementation also handles all other sources of state in a JavaScript application (Sections 4.2 and 4.3).

This paper also presents an extensive evaluation of SINATRA using 4 JavaScript applications and realistic workloads (Section 6.1) and 2 real-world modern websites (Section 6.8). Our results show that SINATRA runs with very little performance overhead, adding at most 1.896ms to the execution of event handlers (Section 6.2), which is not noticeable by the user. For realistic user interactions, SINATRA requires less than 6MB of memory to store the events until a future update happens (Section 6.3). Furthermore, the amount of memory grows constantly with the length of active user interactions, with a maximum rate of 253KB/s (Section 6.4), which shows that SINATRA scales well with typical user interactions with modern websites. For websites that make use of frequent XML HTTP Requests (XHR) in the background, SINATRA requires a modest 36MB of storage for a 14h run (Section 6.6). Furthermore, SINATRA supports realistic workloads on modern websites as complex as Twitter, with complex JavaScript that requires over 4500 events to load (Section 6.8).

When performing an update, SINATRA requires at most 1.5 seconds to transfer the state between browsers (Section 6.5.1). We note that the user can continue to interact with the browser during this time. To switch to the updated browser, SINATRA imposes a pause in user interaction of less than 10ms (Section 6.5.2), which is perceived as instantaneous. At its core, SINATRA is an MVX system that delivers events from one browser to another in 19ms or less (Section 6.7).

In short, this paper has the following contributions:

1. The design, and implementation of SINATRA, a system for performing MVX on JavaScript applications.
2. A technique to use SINATRA to perform instantaneous updates to modern commercial closed-source internet browsers, without any loss of state.
3. An extensive evaluation of SINATRA using 4 realistic JavaScript stateful applications and 2 popular websites (Google and Twitter); including widely used JavaScript frameworks Angular [21], JsAction [23], and React [38].

SINATRA's source [1] and research artifact [50] are freely available.

2 Background

Performing *Dynamic Software Updating (DSU)* on a running browser presents many unique challenges. First, state-of-the-art DSU tools require source code changes and do not support programs as complicated as modern internet browsers (Section 2.1). SINATRA circumvents that problem by using *Multi-Version eXecution (MVX)* to perform DSU [44]. Unfortunately, state-of-the-art MVX tools also do not support programs as complicated as modern internet browsers (Section 2.2). SINATRA moves the level of MVX from low-level system calls to high-level JavaScript events. However, performing MVX in the traditional sense is not possible in JavaScript, due to its event-driven paradigm (Section 2.3).

2.1 Dynamic Software Updating (DSU)

Dynamic Software Updating (DSU) allows to install an update on a running program without terminating it, and without losing any program state (e.g., data in memory, open connections, open files). DSU has three fundamental problems to solve: (1) when to stop the running program, (2) how to transform the program state to a representation that is *compatible* with

the new version but *equivalent* to the old state, and (3) how to restart the program in the new version. Solving these problems requires modifying the source code of the updatable program [47, 24, 44] adding *safe-update points* to solve problem 1, *state transformation functions* to solve problem 2, and *control-flow migration* to solve problem 3. This is not possible for popular modern internet browsers (e.g., Google Chrome, Microsoft Edge, Apple Safari), as they are closed-source.

Modern DSU approaches focus on *in-process updates* – the new version of the program replaces the old version in the same process – which trivially keep outside resources available between updates (e.g., open network connections and files), but limits existing DSU tools to programs that execute in a single process. This is not the case of modern internet browsers (e.g., Google Chrome uses one process per open tab to improve performance and provide strong isolation between open pages). Finally, modern internet browsers are examples *self-modifying code* given their Just-In-Time (JIT) JavaScript compiler, which is a well known limitation of state-of-the-art DSU tools [24, 44]. Therefore, existing DSU tools cannot update modern browsers.

2.2 Multi-Version eXecution (MVX)

The main goal of MVX is to ensure that many program *versions* execute over the same inputs and generate the same outputs. MVX can be used to perform DSU by launching the updated program as a separate process, transferring the state between processes (e.g., by forking the original process), and resuming execution on the updated process after terminating the outdated process [44].

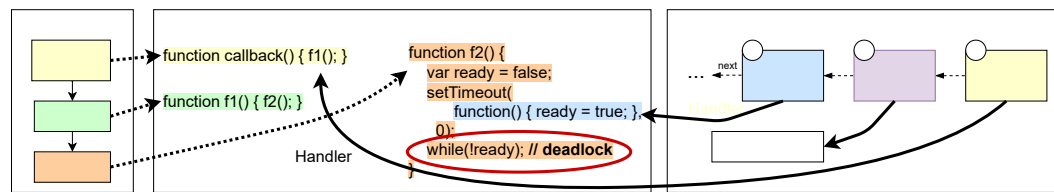

Unlike DSU, state-of-the-art MVX techniques do not require access to the source code of the target program. Instead, MVX interposes *system-calls* through ptrace [35] or binary-code instrumentation [27, 43]. This way, MVX tools can ensure that all processes read the same data, by capturing relevant system-calls (e.g., read) and ensuring that they return the same sequence of bytes.

Unfortunately, existing MVX tools cannot be applied to modern internet browsers. Doing so results in immediate termination due to *benign divergences* – equivalent behavior expressed by different sequences of system calls. For instance, consider how a JIT compiler decides which code to compile/optimize using performance counters based on CPU time. Interacting with such counters does not result in system-calls, and causes JIT compilers to optimize different code, which then results in different system calls. It is possible to tolerate such benign divergences [46], but doing so requires developer support and significant engineering effort, which is not practical.

MVX also suffers from some of the same issues as DSU: no support for multi-process applications, and no support for self-modifying code.

2.3 JavaScript Messages, Event-Loop, and Non-Determinism

JavaScript [16] is an event-driven programming language animated by an *event loop*, as depicted in Figure 1, which processes *messages* from an *event queue*. The event loop takes one message from the event queue and executes its *handler* to completion. If the queue is empty, the event-loop simply waits for the next event. A handler is a JavaScript closure associated with each message. Given that the event loop is *single-threaded*, there is a single *call stack* and one *program counter* (not depicted) to keep the state of processing the current event.

■ **Figure 1** JavaScript's event loop processing 3 messages. Processing Message 1 causes Message 3 to be added to the queue. Message 2 was added when a button was clicked while processing Message 1. Due to JavaScript's event-driven model, this example will never process Message 3, causing a deadlock.

On a browser, events can come from two sources: (1) user interaction with DOM elements (e.g., `onclick` on a `button` element), and (2) browser-generated events, such as expiring timers (e.g., `setTimeout` or `setInterval`) or receiving replies to pending XML HTTP requests. Each event generates a message that keeps track of the event details: the event handler (a closure to be executed for that event), the event target (e.g., the DOM element that generated the message), and other properties. Events handlers in JavaScript are not executed immediately when the event is triggered. Instead, each event is added to the end of the event queue as it is triggered. For instance, in Figure 1, a button was clicked while running function `callback`, which results in adding Message 2 to the event queue.

Events are processed by a single-threaded *event-loop* that runs each event handler to completion before processing any other event, which has two important consequences. **First**, the order and types of events processed are a major part of the non-determinism used to execute a JavaScript program. Apart from asynchronous non-determinism, described below, rerunning the same events in the same order results in the same execution of the same JavaScript program [39, 10, 5, 25, 57]. **Second**, it is not possible for an event handler to issue an event and wait for its completion. This causes the code in Figure 1 to *deadlock* when waiting for the flag `ready` to become `true` [6] because the handler that sets the flag never executes. The handler is associated with a timeout (of zero), which adds a message to the end of the queue. The event loop never finishes executing the current handler, so it never processes any more messages on the queue.

Besides the *synchronous non-determinism* created by events, described above, a JavaScript program can also call functions that are non-deterministic, which we call *asynchronous non-determinism*. The main non-deterministic functions are `Math.random`, which generates random numbers between 0 and 1; and methods of the `Date` object (e.g., `Date.getTime`), which access the current time and date. Notably, it is not possible to seed the pseudo random number generator behind `Math.random`.

Given JavaScript's limitations, **it is not possible to perform traditional MVX on the asynchronous non-determinism**. For instance, when generating a random number, typical MVX approaches ensure each version waits for a message with the same random number (perhaps from a central coordinator process). In JavaScript's case, this would create the same deadlock as shown above. Section 3.4 describes how SINATRA overcomes this limitation.

3 Sinatra Design

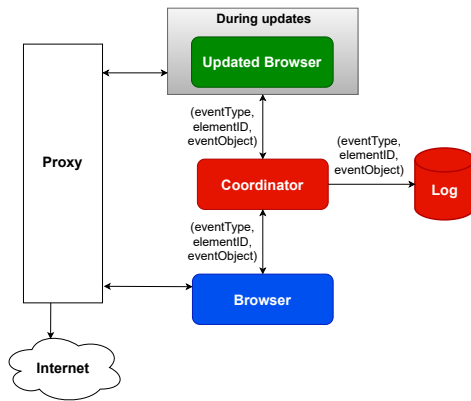

SINATRA supports updating internet browsers through a combination of MVX and DSU [44], both at the JavaScript level. SINATRA requires trivial modifications to web pages, which are shown in Figure 2 – Lines 3–4 need to be added. The required changes ensure that

```

01: <html>
02:   <head>
03: +   <script src="mvx/sinatra.js" type="text/javascript"></script>
04: +   <script src="mvx/sinatra_init.js" type="text/javascript" defer></script>
05:   </head>
06:   <body>
07:     <button id="button" onclick="console.log('DOM0 inline')"></button>
08:     <input id="input_textbox" type="text" />
09:
10:     <script>
11:       let button = document.getElementById("button");
12:       button.onmouseover = function(event) { console.log("DOM0"); };
13:
14:       let textbox = document.getElementById('input_textbox');
15:       let closure = function(ev) { console.log('DOM2'); };
16:       textbox.addEventListener('change', closure);
17:     </script>
18:   </body>
19: </html>

```

■ **Figure 2** Sample HTML code. SINATRA requires adding Lines 3–6.

■ **Figure 3** SINATRA architecture.

■ **Figure 4** SINATRA update phases. Most of the time is spent in Phase 1. Phase 2 transfers state to an updated browser. Phase 2* is optional, and allows to validate if the update was successful. Phase 3 exposes the updated browser to the user.

SINATRA intercepts event handlers immediately (Line 3) and executes its initialization after the page is loaded but before any other JavaScript code executes (due to the `defer` attribute in Line 4). We note that these are simple modifications that can be performed automatically by a sophisticated proxy [12], as we describe in Section 3.1.

After applying the required changes, SINATRA leverages the first-class nature of functions in JavaScript, and replaces a number of important functions to intercept all sources of non-determinism: `[HTMLElement, HTMLDocument].prototype.addEventListener`, `Math.random`, `setTimeout`, `setInterval`, and others; which we describe in Sections 3.3 through 3.5.

3.1 Sinatra Architecture

SINATRA uses three components at all times, shown in Figure 3: (1) the browser, (2) the coordinator, and (3) a proxy. When a browser update is available, SINATRA requires the new version of the browser to be installed at the same time as the old (current) version. The updated browser becomes, temporarily, SINATRA’s fourth component. We note that modern browsers can have multiple versions installed side-by-side by performing manual installation into different folders.

Users interact with the browser, which captures JavaScript events and sends them to the coordinator. The coordinator either saves those events in a log, when there is no update taking place, or sends them to the updated browser, thus performing MVX. Users only start interacting with the updated browser after the update is complete, as we describe in Section 3.2.

The proxy serves three main purposes. **First**, the proxy ensures that the updated browser accesses exactly the same resources as the original browser did. Accessing different resources means that each browser processes different JavaScript events and leads to benign divergences, as described in Section 2.2. **Second**, the proxy ensures that outgoing connections remain open while SINATRA changes the roles of the browsers. This is important to ensure that responses to XML HTTP requests are not lost, which can result in errors in the JavaScript application. **Third**, as SINATRA requires minimal changes to the target page, the proxy performs those changes automatically for all the pages accessed by the browser. The proxy must also be able to intercept HTTPS traffic.

There is an off-the-shelf proxy that meets all the requirements: `mitmproxy`[12] can intercept HTTPS traffic (through an extra root certificate), is highly configurable with custom Python code, and can redirect traffic from one connection to another. We validated the feasibility of using `mitmproxy` for SINATRA’s purposes through a series of small throw-away prototypes, and we report that `mitmproxy` can indeed be used with SINATRA. However, for the sake of implementation and experimentation simplicity, our current implementation does not use a proxy, as we perform all the changes manually on static HTML pages that do not issue XML HTTP requests.

3.2 DSU with Sinatra

SINATRA performs updates over 3 different phases, as shown in Figure 4.

Phase 1 executes for the vast majority of the time, when no update is taking place. This is the *single-version phase*, which runs a single browser version in isolation. In this phase, SINATRA intercepts all JavaScript events and sends them to a *Coordinator* process, which simply keeps them in memory until the events are needed by later phases. Of course, the coordinator needs to have enough memory to store all the events generated on the browser due to user interaction. Sections 6.3 and 6.4 show that SINATRA’s memory requirements are modest, well within the capabilities of modern computers. In instances where a webpage executes network requests in the background, the observed memory requirements remain modest even with a long-running session. A webpage left open will also record any network activity that takes place, such as updates to a live Twitter feed. We describe such an experiment on Section 6.6, which requires 36MB of event storage for a 14h run.

Phase 2 is when updates start, during which the user launches the new browser version. For each page, SINATRA sends all the events from the coordinator and to the new version. Note that SINATRA transfers the state in the background, which allows users to continue to interact with the old browser. Events generated by user interaction during Phase 2 are simply added to the end of the list of events that the new browser needs to process. Section 6.5.1 shows that SINATRA takes, at most, 1.5 seconds in Phase 2.

Phase 2* is optional, and starts when the new browser has processed all the events in the coordinator’s log. During Phase 2*, SINATRA performs MVX between the old browser and the new browser. Phase 2* allows to validate whether an update was successful, by comparing each page on the leader with its version on the follower (e.g., matching their DOM tree). If the pages do not match, Phase 2* allows to stop an update that results in loss of data without any disruption, simply by terminating the follower and reverting to Phase 1.

```

1: let originalHandler = element.onclick;
2: if (originalHandler) {
3:   closure = function (ev) { id = element.sinatra_id;
4:     sendToCoordinator("onclick", id, ev);
5:     originalHandler.call(element, ev); }
6:   registerHandler(element, "onclick", originalHandler);
7:   element.onclick = closure; }

```

■ **Figure 5** Interception of a DOM0 event in the leader. Functions `sendToCoordinator` and `registerHandler` shown in Figure 8 and discussed in Section 3.5.

Validating the pages can be done manually (asking the user if all pages look the same to the user) or automatically (fuzzy matching the DOM contents, or using computer vision algorithms to find differences in screenshots of the rendered pages [25, 67]). Our prototype supports Phase 2* for benchmarking convenience, allowing us to measure the time to transfer logs and to swap roles with great accuracy.

Phase 3 effectively finishes the update by switching the browser exposed to the user. SINATRA *demotes* the old browser version, which becomes the follower, and *promotes* the new browser version, which becomes the leader. At this point, SINATRA can terminate the old browser and start a new *Phase 1*, as the browser was successfully updated with zero downtime and without losing any state. Phase 3 causes the only user-noticeable pause, which we measured in Section 6.5.2 as less than 10ms. For evaluation convenience, our prototype keeps executing the old browser as the follower until the user terminates the old browser.

3.3 Intercepting Events

SINATRA establishes the foundation for MVX and browser updates by intercepting events and sending them from the leader to the follower (through the coordinator). This section explains how SINATRA captures browser events in pure JavaScript by intercepting handlers along with their parameters on the leader.

SINATRA intercepts events by replacing the original event handler with a special handler. This way, when a message causes the event loop to execute a handler, SINATRA's code executes instead, which allows SINATRA to intercept the event that triggered the handler together with the actual handler that is executing. Messages are generated by either DOM0 or DOM2 event listeners:

DOM0 events. DOM0 events can be registered in-line on the HTML page (e.g., Line 7 on Figure 2), and through JavaScript properties on the DOM elements (e.g., Line 12 on Figure 2).

Intercepting DOM0 events is straightforward, as these handlers can be listed/modified directly from DOM elements, simply by reading/writing the respective property, respectively (e.g., Lines 1 and 7 on Figure 5). However, there are two challenges with intercepting DOM0 events. **First**, DOM0 handlers are only present *after* the HTML page loads and executes all in-line scripts. SINATRA's initialization code runs precisely at the right time, just after the HTML page loads but before any handler can be triggered, as shown in Line 3 of Figure 2. At this time, a simple DOM traversal can intercept all inline DOM0 event handlers. **Second**, the page can change DOM0 events without SINATRA noticing. SINATRA uses a mutation listener [60] to register a closure that runs when properties of elements change.

Figure 5 shows how SINATRA uses to intercepts DOM0 events. For each DOM0 handler (Lines 1), SINATRA captures the original handler (Line 2) and replaces it with its own closure (Line 8) that captures the current DOM element – `element` – and the event – `ev`, sends them to the coordinator (Line 5), and runs the handler originally registered by the JavaScript application (Line 6). Note that SINATRA only installs DOM0 events when needed (Line 3).

```

1: const originalAddEventListener = HTMLElement.prototype.addEventListener;
2: HTMLElement.prototype.addEventListener = function(evType, evListener, u) {
3:   ownerId = this.sinatra_id;
4:   registerHandler(this, evType, evListener);
5:   let closure = function (ev) { id = ev.target.sinatra_id;
6:                               sendToCoordinator(evType, ownerId, id, ev);
7:                               evListener.call(this, ev, u); }
8:   originalAddEventListener.call(this, evType, closure, u); }

```

■ **Figure 6** Interception of DOM2 events on the leader. Functions `sendToCoordinator` and `registerHandler` shown in Figure 8 and discussed in Section 3.5.

DOM2 events. DOM2 events register handlers by calling method `addEventListener` on the target element (e.g., Lines 14–16 on Figure 2). Registering a DOM2 handler requires two arguments: (1) type of event (e.g., `change` for when the target text input box changes), and (2) the event handler itself, specified as a JavaScript closure. Unfortunately, it is not possible to list handlers installed via DOM2. Furthermore, DOM2 describes a complicated logic about how events “bubble” and call all registered event handlers by following the DOM tree and combining DOM0 and DOM2 events. We discuss how bubbling affects SINATRA in Section 4.2. SINATRA intercepts DOM2 events by replacing `[HTMLElement, HTMLDocument].prototype.addEventListener` with its own closure, shown in Figure 6. Note that it is not possible for the underlying JavaScript program to install a DOM2 handler before SINATRA installs its own because SINATRA installs the handler before any other code runs, shown in Line 3 of Figure 2 (scripts without `defer` are downloaded and executed immediately). From this point onwards, when the JavaScript application calls `addEventListener`, SINATRA’s code executes instead (Lines 3–8). To intercept DOM2 events, SINATRA installs its own closure using the original `addEventListener` function (Line 8). Then, events that trigger the handler execute SINATRA’s closure which starts by sending the event to the coordinator (Line 4) before calling the original handler that the JavaScript application registered (Line 5).

Dynamically created elements. Dynamically created elements can also have event listeners, even before being added to the DOM tree. DOM2 listeners are automatically instrumented, as they use the prototype `HTMLElement` which SINATRA already instruments. SINATRA intercepts DOM0 events through a *Mutation Observer* [60] for new nodes added to the DOM tree, which SINATRA instruments as described above in this section.

Timers. Timers register a closure to execute after a specified time interval through functions `setTimeout` – a one-off event – and `setInterval` – a repeating event, as shown in Lines 3–5 of Figure 7. Of course, such timers are yet another source of synchronous non-determinism that SINATRA must handle. SINATRA uses an approach similar explained above in Section 3.3 and replaces functions `setTimeout` and `setInterval` with SINATRA’s own (Line 9). Then, when the underlying application registers a timer, SINATRA transparently intercepts those calls to register its own timer (Lines 13). When the timer expires, SINATRA intercepts the timer event and sends it to the coordinator before executing it (Line 12).

XML HTTP Requests (XHR). XML HTTP Requests (XHR) require an `XMLHttpRequest` object, which defines a number of properties with different roles: (1) hold the data obtained from the remote server (e.g., `status`, `responseText`), or (2) hold closures to be invoked with the XHR changes state (e.g., `onload`, `onreadystatechange`). SINATRA intercepts the function that creates such objects (i.e., `new XMLHttpRequest`) to return a proxy XHR object

26:10 Sinatra: Instantaneous Updates for Browsers Through Multi-Version eXecution

```
01: // Sample program
02: buttons = [] // A list of buttons
03: setInterval(30, function() { // Expensive computation
04:     r = Math.random(); button[r].enabled = true; });
05: setInterval(300, function() { buttons[...].enabled = false; });
06:
07: // Interception
08: let uniqueID = 0;
09: let realSetInterval = setInterval;
10: setInterval = function(origHandler, delay) {
11:     let myID = uniqueID++;
12:     registerInterval(delay, myID, origHandler);
13:     let closure = function() { intervalToCoordinator(myID); origHandler(); };
14:     return realSetInterval(closure, delay); }
```

■ **Figure 7** Sample JavaScript program that uses timeouts (Lines 1–5) and `Math.random` (Line 4); and how SINATRA intercepts timer events (Lines 8–14). Function `registerInterval` and `intervalToCoordinator` are explained Figure 8 and on Section 3.5.

that contains a real XHR object internally. Then, SINATRA defines the same properties as the real XHR object, through `Object.defineProperty`, and uses them to intercept how the JavaScript manipulates the proxy XHR object [14].

As with the DOM events described above, the leader issues XHR requests and sends the returned values to the follower. The follower does not issue any XHR request, it simply gets the data from the leader. When the leader executes a closure associated with XHR state change, it sends information to the follower to trigger the execution of the same closure with the same data. Note that leader and follower issue the same XHR requests by the same order, so SINATRA identifies each XHR request uniquely by the order in which they are issued.

3.4 Intercepting Asynchronous Non-Determinism

As described in Section 2.3, JavaScript programs can call functions that are non-deterministic. The most important such function is `Math.random`, which is used extensively by many JavaScript applications. Unfortunately, using the same approach described in Section 3.3 does not work due to the asynchronous nature of the call to such non-deterministic functions.

For instance, consider the example shown in Figure 7. In this example, there is a list of buttons (Line 2), all disabled. Every 30 seconds, the program performs an expensive computation (Line 3) and enables one button at random (Line 4). Every 5 minutes (300 seconds), the program disables all buttons again (Line 5).

Now consider the following implementation: SINATRA captures the 30 second event, sends it to the coordinator, then captures the execution of `Math.random`, and also sends it to the coordinator. This approach works if all the events are known in-advance (i.e., Phase 2 of Figure 4 and existing record-replay approaches). However, **this approach does not work for MVX** (i.e., Phases 2* and 3 of Figure 4). In this case, it is possible that the follower receives the timer event and reaches the call to `Math.random` before the leader, as the time required to perform the expensive computation may not match in both versions, and the follower may complete it before the leader. At this point, the follower does not know which number to return to match the leader. Making matters even worse, the follower cannot simply wait for the leader, because doing so in JavaScript’s event-loop model results in a deadlock, as explained in Section 2.3.

Functions that result in asynchronous non-determinism thus need special consideration. One way to deal with `Math.random` is to use the same seed for the underlying Pseudo-Random Number Generator (PRNG). Unfortunately, it is not possible to seed JavaScript’s PRNG.

An alternative is to replace calls to `Math.random` with a custom PRNG that can be seeded, on all variants, which may result in a lower quality source of randomness. Instead, SINATRA starts by generating a sequence of N random numbers when the page loads (i.e., in the `script` tag on Line 3 of Figure 2). Then, each call to `Math.random` consumes one number from the sequence. The leader replenishes the sequence by sending a fresh random number to the coordinator for each number consumed. This approach allows a fast follower to consume up to N random numbers asynchronously at its own pace, ensures all random numbers match between leader and follower, and provides a fresh supply of browser-grade randomness. This approach also simplifies detecting divergences between leader and follower, as we can check in the sequence of random numbers how far/behind one variant is. We found that a cautious value of $N = 100$ works well in practice.

Methods in the `Date` object also require special treatment. The leader starts by consulting the current date/time, saves it in a variable, and sends it to the follower. Then, when the JavaScript program attempts to consult the date, both leader and follower return the saved date, and increment it (e.g., by 100). As such, both versions agree on all dates generated. To ensure fresh and realistic dates/times, every so often, just before sending another message to the follower, the leader refreshes its saved date with the system's and adds date information to the message being sent.

3.5 Multi-Version Execution in JavaScript

So far, this document describes how to capture all the sources of non-determinism used by a JavaScript program on the leader browser. But this is only one half of the problem. To transfer the state between browsers, and to keep them synchronized after that, SINATRA needs to ensure that the follower browser sees exactly the same non-determinism (i.e., the same events in the same order on the same DOM elements).

Matching elements. SINATRA assigns IDs (monotonically increasing numbers) to each DOM element by adding a new property `sinatra_id`, traversing the initial DOM tree after the page is loaded, and then for each dynamically added element (described in Section 3.3). Given that SINATRA traverses the same DOM tree in a deterministic way, and executes `createElement` in the same order in both browsers, the same element always receives the same ID in both browsers.

SINATRA keeps a global structure with all the handlers registered, as shown in Figure 8 (Line 2). When registering events, SINATRA keeps a map for each element ID (Lines 6–9). The map associates event types (e.g., `onclick`) to the respective handler and the target element in which the event was registered (Line 9). We note that each browser keeps references to its own handler and element.

The leader sends events to the coordinator via function `sendToCoordinator`, which serializes the event as discussed in Section 4.2. The follower receives deserialized events from the coordinator via function `receiveFromCoordinator`, which consults the global structure to get the target element (Line 19) and the handler (Line 20) registered for the current event being triggered. Then, the follower calls the handler directly, setting the receiver as the target element (Line 21).

Ensuring the same causal ordering. Given JavaScript's event-driven model, is possible to violate causal ordering in the follower where events are delivered targeting elements that do not exist (yet). For instance, consider a page with one button (1) that, when pressed, creates another button dynamically (2). Consider also an execution in which the user presses buttons

26:12 Sinatra: Instantaneous Updates for Browsers Through Multi-Version eXecution

```
01: // Globals in both leader and follower
02: let globalHandlerTable = {};
03: let intervalHandlerTable = {};
04:
05: // Executed by both leader and follower
06: function registerHandler(el, eventType, handler) {
07:     let id = el.getAttribute("sinatra_id");
08:     if (!globalHandlerTable[id]) globalHandlerTable[id] = {};
09:     globalHandlerTable[id][eventType] = {"handler": handler, "target": el}; }
10: function registerInterval(delay, id, handler) {
11:     intervalHandlerTable[id] = { "delay": delay, "handler": handler }; }
12:
13: // Leader calls:
14: function sendToCoordinator(eventType, elementID, eventObject) { ... }
15: function intervalToCoordinator(id) { ... }
16:
17: // Follower calls:
18: function receiveFromCoordinator(eventType, elementID, eventObject) {
19:     let targetElement = globalHandlerTable[elementID][eventType]["target"];
20:     let handler        = globalHandlerTable[elementID][eventType]["handler"];
21:     handler.call(targetElement, eventObject); }
22: function intervalFromCoordinator(id) { intervalHandlerTable[id]["handler"](); }
```

■ **Figure 8** Matching events and timers to handlers and elements in both leader and follower browsers.

(1) and (2). On the follower, it is possible that both button presses are added to the message queue (depicted in Figure 1). Creating the hypothetical button (2) generates another event, which is then added to the message queue *after* the event for pressing that same button (2). This execution violates causal ordering and results in pressing a non-existing button.

To keep causal order consistent between variants, SINATRA uses the latest `sinatra_id` as a logical clock sent with each event from the leader to the follower. Adding new DOM elements results in generating a new `sinatra_id`. When receiving an event, the follower checks the event's `sinatra_id` against the follower's latest `sinatra_id`. If the values do not match, the follower simply postpones processing the event by adding it to the end of the queue with `timeout(0)`, as explained in Figure 1. SINATRA does the same for all events, including XHR requests.

Matching timers. The follower never registers timers and XML HTTP Requests with the browser. Instead, the follower executes the closures registered with each handler in the order that the leader issues them through the coordinator. However, this creates a problem: How can the follower distinguish between many different closures? For instance, consider the example shown in Figure 7. This example installs two closures associated with different timeouts, one in Line 3 and another in Line 5. When one of these expires and the leader executes it, how can the follower know which to execute?

SINATRA uses a unique ID to differentiate each closure registered with a timer (Lines 8 and 11 in Figure 7). Given that SINATRA ensures that the follower executes the same event handlers by the same order as the leader, the IDs always match between variants. Both variants then keep a table from IDs to closures and delays (Line 3 and Lines 10–11 in Figure 8). When sending an event about an expired timer, the leader sends the ID of the closure associated with the timer (Line 12 in Figure 7). The follower then uses the ID to address its table, get the correct closure, and execute it (Line 22 in Figure 8).

Promotion/demotion. When the roles of the browsers switch (Phase 3 in Figure 4), SINATRA uses the information kept on the global structure (Line 2 on Figure 8) to install all event handlers on the respective DOM elements on the promoted browser, and removes them on the demoted browser. SINATRA also cancels all the timers on the demoted browser, and installs them on the promoted browser (with the original timeout value). Because SINATRA does not track how much time passed since each timer was installed, this approach may cause timers to expire after longer than needed ($2\times$ in the worst case). However, this is correct as timers in JavaScript guarantee only a minimum amount of time to wait before triggering the associated closure. Pending XHR at the time of promotion cause the leader to postpone the swap until the pending requests are completed. During this time, all new requests are deferred until the follower is fully promoted and eligible to initiate the requests. This leads to user observable pauses until the pending XHR requests are resolved, which Section 6.6 measures as 86ms on a realistic workload.

Read-only Follower. In the context of MVX we now have two browsers, as shown in Figure 4. The user interacts with a *leader* browser, which sends all the non-determinism to the coordinator process. Then, a *follower* browser receives the same non-determinism from the coordinator. This way, SINATRA ensures both leader and follower are always synchronized.

Users can inspect the state of the follower browser, but they cannot modify it because the follower intercepts all the handlers as described in Section 3.3, but does not install any event handlers with the browser. Instead, the follower registers events just with SINATRA (i.e., Line 7 in Figure 5 sets `onclick` to `null`, Line 7 in Figure 6 and Line 13 in Figure 7 are omitted). Also, this approach ensures that the follower executes timer handlers in sync with the leader, running them only when the leader sends the respective events.

4 Implementation

In this section, we describe the implementation details of SINATRA. SINATRA is implemented in pure JavaScript, totaling 2013 lines of code. The web APIs leveraged by SINATRA to intercept user and system generated events are compatible with the most recent versions popular browsers, such as Google Chrome, Mozilla Firefox, Apple Safari, and others. SINATRA works out of the box for most browsers, without requiring external packages, tools, or plugins.

4.1 Coordinator and Protocol

The coordinator process enables communication between both browsers, which is at the core of SINATRA's approach to MVX, and keeps a log of JavaScript events during Phase 1, as shown in Figure 4. We implemented the coordinator process using *node.js* [3], so it executes in its own separate (headless) process without a browser. We use the *SocketIO* [4] JavaScript library to enable bi-directional communication between the coordinator and each browser.

The initialization protocol for SINATRA is quite simple. First, the coordinator should be executing before any browser is launched. On browser launch, SINATRA starts by connecting to the coordinator using a pre-configured address and port, and sends a message. The coordinator replies with the role of this browser, which is *leader* for the first browser and *follower* for the second.

Upon learning its role, a leader browser generates the list of random numbers mentioned in Section 3.4, sends it to the coordinator, and starts sending all events from that point on. A follower browser, conversely, waits for the coordinator to send the list of random

numbers, followed by the events that were kept during the leader's execution. At this point, the coordinator informs the follower that it is synchronized, and MVX starts. During MVX, the coordinator sends each event, received from the leader, to the follower as it is received.

Given that communication is bidirectional, the coordinator does not have to establish new channels when promoting the follower/demoting the leader. Instead, each browser simply changes roles and execution continues in MVX, but in the opposite direction. The promotion/demotion event starts from the leader (outdated browser), when the user presses a button that SINATRA injects at the top of the page. Together with a special promotion/demotion message, SINATRA also sends the list of pending timers that were cancelled and their timeouts, as described in Section 3.5.

4.2 Serializing/Deserializing Events and Bubbling

When the underlying JavaScript program executes an event handler on the leader, SINATRA's code is first called with the event. First, SINATRA gets the **name** of the event, (e.g., defined as argument `evType` in Line 2 of Figure 6). Second, SINATRA gets the **ID of the target element** – the element that triggered the change (e.g., defined as argument `element.sinatra_id` in Line 3 of Figure 6). As explained in Section 3.5, SINATRA ensures that all elements have a unique ID. Finally, SINATRA creates a JavaScript object to hold a copy of the event object, and populates it with **all the fields in the event object**, which include the coordinates of mouse events, which key was pressed that triggered the event, and other relevant data.

At this point, SINATRA can send the JavaScript object to the coordinator. The SocketIO implementation automatically turns the JavaScript object into its JSON representation [15] through function `JSON.stringify` on send, and back into a JavaScript object using function `JSON.parse`. The coordinator simply keeps a list of tuples (name, element ID, event) received from the leader. Sending this list to the follower, when it becomes available, requires another round of serializing to JSON by the coordinator, and deserializing back into JavaScript objects by the follower.

An important note is that SINATRA feeds the deserialized event directly into each handler in the follower, as shown in Line 21 of Figure 8. SINATRA does not create/trigger a new synthetic browser event, as some record-replay systems for JavaScript do through `DOMnode.fireEvent` [39]. This design decision simplifies handling *event bubbling*, when many handlers trigger for a single event (e.g., when a child DOM element has a different handler for the same event as its parent). Instead, SINATRA simply captures the order in which the leader executes the event handlers, and their respective targets; and then calls the same handlers by the same order in the follower. The alternative of creating synthetic events has well-known corner-cases that require special consideration. Furthermore, SINATRA can handle browser updates that change the bubbling behavior.

4.3 Stateful DOM Elements and Text Selection

DOM elements, such as radio buttons, check boxes, and text boxes, keep internal state. For instance, when the user selects a check box, the state of that check box changes (it is now selected). Updating the state does not execute any JavaScript handler, which means that SINATRA cannot intercept it directly. Fortunately, there are only a limited number of such elements, and SINATRA handles them as a special case by installing its own event handler associated with the **change** event, even when there is no application handler. The event handler simply captures the updated state of the DOM element, which allows the follower to remain synchronized with the execution on the leader.

Another source of state, and non-determinism, is the text selected by the user. JavaScript can access and manipulate the current text selection, based on a range of characters on a text element (start and end). To detect when the text selection changes, the leader listens for left mouse button releases, and **SHIFT** key releases. At that point, SINATRA can obtain the current text selection (if any), create a JavaScript object that captures the start and span of the selection, and send it to the coordinator. On the follower side, SINATRA uses the information received to select the same text.

5 Practical Considerations and Limitations

The main design goal of SINATRA is to remove all barriers to instantaneous and stateful browser updates, so that users can enjoy automatic browser updates without even noticing them. Another important design goal is to be applicable to all browsers by targeting JavaScript's execution model. This design choice leaves out of scope state maintained inside the browser itself, such as Websockets. For instance, the recent WebRTC standard allows for real-time audio-visual communication, started from JavaScript but implemented inside the browser [63]. Of course, by its design goals, SINATRA does not support such features implemented internally by browsers.

We argue that SINATRA is a practical approach in its current form. SINATRA deals with the browser state that is the most complex and hard to migrate: the JavaScript engine. State-of-the-art DSU approaches excel at dealing with the remaining state inside the browser [24, 36], which would require browser modifications. Perhaps browser vendors can provide an API to migrate open connections and other browser state. Finding such state, and how to migrate it, is exciting future work that is out-of-scope for SINATRA.

Still, SINATRA can deal with pages that hold internal browser state in three possible ways. First, simply reload them. In the WebRTC example, this means that the video-conference connection would drop and reconnect, which is a relatively common event that users tolerate. Second, wait until all such pages are closed and then update the browser. Third, list the unsupported pages and ask users if they accept reloading them.

The current prototype of SINATRA requires two external components: the proxy and the coordinator. We believe that these components can be implemented as plugins to popular browsers [40, 22], and present them here as separate components to highlight the fact that SINATRA works on unmodified browsers.

Other limitations. The main design goal of SINATRA is to allow instantaneous and stateful browser updates. As such, we designed SINATRA under the assumption that only one user interacts with each JavaScript program, and that each JavaScript program does not execute for a long time. All these assumptions break for server-side JavaScript applications written in node.js [3]: many users interact with each JavaScript program, and each program executes for a long time. Even though SINATRA can be applied to such programs, to update the node.js virtual machine, this is not feasible, as such applications handler numerous events within a short time span and result in very large log files. This is outside of the scope of SINATRA.

The current version of SINATRA does not handle persistent state created through `Window.localStorage` [62]. Our evaluation ensures that the persistent state is empty before each run. Supporting persistent state is straightforward: `function Object.keys(localStorage)` can iterate over all the persistent state at the start of execution, and SINATRA can send that to the follower to ensure the same initial persistent state.

SINATRA does not support the Web Workers (WW) API [61], which introduces multi-threading. However, each WW thread executes its own event loop (Figure 1 shows one event loop, each WW has its own event loop), and WWs can only communicate through sending/receiving messages or through a shared `ArrayBuffer` object. Supporting WW requires capturing the total-order of messages sent between different threads, which can be accomplished through Lamport clocks [33, 27, 43, 58]. We plan to add support for WW in future versions of SINATRA.

6 Experimental Evaluation

In this section, we evaluate the feasibility of using SINATRA to deploy browser updates in practice, by measuring the overhead it introduces in terms of perceived latency by the user, and extra memory needed by the user’s computer. We also evaluate SINATRA’s performance as an MVX tool to enable future research. In that regard, we pose the following *research questions (RQs)*:

- **RQ1:** Is the latency added by SINATRA noticeable by the user?
- **RQ2:** What is the average size of the log that SINATRA keeps?
- **RQ3:** How does the size of the log that SINATRA keeps grow with user interaction?
- **RQ4:** How long does SINATRA take to perform a browser update?
- **RQ5:** How much resources does SINATRA require to support XHR on realistic pages?
- **RQ6:** What is the latency when SINATRA is used as a JavaScript MVX system?
- **RQ7:** Can SINATRA be realistically used with modern pages that use complex JavaScript?

We used two versions of two popular internet browsers, Mozilla Firefox versions 82.0 and 83.0, and Google Chrome versions 88.0.4323.150 and 89.0.4389.72. Unless when using updates, both leader and follower used the lowest version of each browser. The experimental evaluation took place in a modern desktop computer running Ubuntu Linux 20.04 LTS 64bit, with an Intel(R) Core(TM) i7-9700K CPU 3.60GHz and 32GB of RAM.

6.1 Applications and Workloads

We evaluated SINATRA with the 4 JavaScript applications (describe below). Each application requires user interaction, using the keyboard and/or mouse. We automated such interaction using the tool `Atbswp` [2] to record mouse and keyboard interactions – *workloads* – for each application, and then replay them. `Atbswp` records mouse and keyboard interactions and writes an executable Python script that replays those events using the library `pyautogui` [56]. We now describe each program, and the workload we used:

nicEdit [31] uses JavaScript to add a rich-text editing toolbar to an HTML `div` element. The toolbar applies styles (e.g., bold, italic, underline, font, color, size) to the text selected via the `document.execCommand` JavaScript API [29]. `nicEdit` creates the toolbar dynamically, using `document.createElement` to generate buttons and custom screens (e.g., to input the URL and text of an hyperlink), and attaches DOM0 event listeners to each generated element (i.e., buttons on the toolbar). `nicEdit` also creates a `textarea` element dynamically, where the user can input text.

The workload for `nicEdit` is representative of a user editing text. It starts with a pre-generated text, selects sections of text, and edits each in a different way: making the text bold, italic; changing the font size, font family (Arial, Helvetica, etc), and font format (heading and paragraph). The workload also changes the indentation of a paragraph, increasing it twice and then returning the paragraph back to its original indentation.

DOMTRIS [52] is a dynamic-HTML based Tetris game that uses JavaScript to implement the game mechanics: generate random pieces of different sizes, shapes, and colors; intercept user input; and schedule the movement of each piece inside the Tetris board. DOMTRIS uses `setTimeout` to schedule the downwards movement of the current piece, and `Math.random` to pick the next piece from the available set of pieces. The player interacts with DOMTRIS solely via the directional arrows on the keyboard, intercepted via DOM2 event listeners. Each piece is created dynamically with `document.createElement`.

We automated a Tetris game that drops each piece (without rotating it) on the center, extreme left, and extreme right of the board. As time goes on, the board fills along the center and edges until there is no space left, at which point the game ends. We understand that this is not how people play Tetris, but we cannot use `Atbswp` to automate a valid Tetris game because DOMTRIS uses a different random seed for every game. Even though SINATRA could generate a fixed sequence of random values to ensure deterministic replays, doing so would not show that SINATRA keeps the random values synchronized between browsers.

Painter [49] allows users to draw pictures using the mouse, with various colors and tools (free-hand brushes, lines, rectangles and circles). The user interacts with Painter using only the mouse over 3 HTML5 `canvas` elements [64]: (1) the tool set, (2) the drawing area, and (3) the color and line-width picker. Painter tracks the mouse position and button click/drag using DOM2 events, and reacts to different tool and color selections using DOM0 events. Painter generates a large number of events as it tracks the mouse movements at all times.

Our workload draws a tic-tac-toe board with the brush and line tools, then draws different shapes of different colors inside the board. This requires selecting different tools, colors, and brush strokes; effectively interacting with all parts of Painter. Note that `Atbswp` records the mouse with coarse precision between mouse clicks, which results in a low fidelity replay. For instance, when dragging the mouse along a line, `Atbswp` only captures the mouse position on the start of the line when the mouse button is pressed, one or two positions along the line, and the final position when the mouse button is released. We edited the generated Python script to ensure that the recording replays mouse movements on a pixel-by-pixel basis, to ensure high fidelity and accurate event counts. Unfortunately, due to `pyautogui`'s low performance when replaying a large number of mouse movements, the Painter workload takes minutes to execute what took us seconds to draw.

Color Game [28] is a game that tests reaction time via the Stroop Effect [54] (delay in reaction time between congruent and incongruent stimuli). The game shows players one color name, and requires players to press the button with the same name (out of 4 buttons), but with a different background color (e.g., press the red button with text “Blue” when the game specifies the color “Blue”). The game keeps track of the score (+5 for each correct click, -3 otherwise) during a 30 second round. Color Game is a complex application due to its use of the **Angular JS framework [21]**. Internally, Angular uses `document.createElement`, a combination of DOM0 and DOM2 event handlers, `setTimeout`, `setInterval`, and `Math.random`.

The workload consists of one run of the game (30 seconds), clicking each of the four color buttons in arbitrary order after every one second until the game ends.

Google and Twitter are popular pages representative of realistic workloads. The Google search page uses the **JsAction framework [23]** and Twitter uses the **React framework [38]**. The workload simply allows each page to load and then we interact with each manually.

■ **Table 1** Time required to run event handlers, average of 5 runs with standard deviation.

Program	Browser	Vanilla	Sinatra	Overhead	
				Relative	Absolute
nicEdit	Firefox	$2.600ms \pm 0.144$	$4.496ms \pm 0.371$	1.729×	+1.896ms
	Chrome	$3.779ms \pm 0.265$	$4.547ms \pm 0.208$	1.203×	+0.768ms
Painter	Firefox	$0.102ms \pm 0.018$	$1.570ms \pm 0.055$	15.361×	+1.468ms
	Chrome	$0.114ms \pm 0.004$	$0.982ms \pm 0.080$	8.639×	+0.869ms
DOMTRIS	Firefox	$0.495ms \pm 0.101$	$1.497ms \pm 0.094$	3.025×	+1.002ms
	Chrome	$0.250ms \pm 0.021$	$0.757ms \pm 0.027$	3.025×	+0.507ms
Color Game	Firefox	$1.457ms \pm 0.084$	$1.797ms \pm 0.041$	1.233×	+0.340ms
	Chrome	$0.663ms \pm 0.035$	$0.761ms \pm 0.026$	1.148×	+0.098ms

6.2 Sinatra Latency

To measure the extra latency added by SINATRA to each event on the leader, we compared the execution of each program without SINATRA (*vanilla*) and with SINATRA. The vanilla version measures the time taken to execute each original event handler during the workload. The SINATRA version measures the time taken to also execute SINATRA’s logic together with the original event handler. We measure the runtime of each event handler triggered during the workload, and report the average time among all the event handler executions observed. Table 1 shows the results.

This experiment highlights the extra latency that SINATRA adds to each event. Table 1 shows that SINATRA increases the latency by a maximum of +1.896 (nicEdit on Firefox), from 2.6ms to 4.496ms. The maximum increase in relative terms is for Painter on Firefox, at 15.361×, which translates to a low absolute increase of +1.468ms, from 0.102ms to 1.570ms. The results answer **RQ1: Users cannot notice the extra latency introduced by Sinatra.**

6.3 Log sizes

SINATRA spends the vast majority of the time executing in single-leader mode, as described in Section 3.2. In this mode, SINATRA stores a log in the coordinator with all the events and handlers that the (single) leader executed. In this experiment, we executed the workload for each application in single-leader mode to measure the size of the log on the coordinator, in number of events and size of the log. Table 2 shows the results.

We can see that the number of events varies widely between different experiments. nicEdit has the smallest number of events, as styling text results in a low number of button clicks and text selections. Color Game has twice as many events as DOMTRIS, which involve user input, timers expiring, and random number generation. Finally, as expected, Painter generates the largest number of events due to its fine-grained tracking of mouse events. In terms of absolute log size, we can see that all logs are below 5.4MB. The results of this experiment allow to answer **RQ2: Sinatra requires a modest amount of memory to store the log, below 5.4MB per page.** This result shows the practical applicability of SINATRA, given that average modern computers measure memory in tens of GB.

■ **Table 2** Log sizes in single-leader mode, average of 5 runs with standard deviation.

Program	Browser	# of events	Log size (bytes)
nicEdit	Firefox	278 ± 0.0	142,717 ± 0
	Chrome	286 ± 0.0	122,197 ± 4
Painter	Firefox	2,077 ± 2.0	5,305,731 ± 5,056
	Chrome	2,049 ± 1.3	4,201,712 ± 2,708
DOMTRIS	Firefox	683 ± 0.4	980,094 ± 46
	Chrome	682 ± 0.0	851,230 ± 9
Color Game	Firefox	1,030 ± 8.7	1,533,970 ± 25,632
	Chrome	744 ± 4.9	949,111 ± 12,141

6.4 Sinatra scalability

User interactions with websites may differ in length of time and number of events triggered. To measure how SINATRA behaves with different lengths of interaction, we designed an experiment that uses 3 workloads for each application – small, medium, and large – modified as follows.

nicEdit. Repeat the experiment N times, each time performing the same various text changes that have been described previously. **Small:** $N = 2$. **Medium:** $N = 4$. **Large:** $N = 6$.

DOMTRIS. Move Tetris pieces to one, two, or three sides of the board. **Small:** Left side only. **Medium:** Left and right sides. **Large:** Left, right, and center.

Painter. Repeat the drawing N times, pressing the “Clear” button (which clears the canvas) in between. **Small:** $N = 2$. **Medium:** $N = 4$. **Large:** $N = 6$.

Color Game. Play a game N times, restarting it at the end of each 30 second run by pressing the “Restart” button. **Small:** $N = 1$. **Medium:** $N = 3$. **Large:** $N = 5$.

We repeated the experiment for each size, in single-leader mode, and we measured the duration (seconds), the total number of events in the log (thousands), the size of the log (MB), and the bandwidth needed to send all the events (KB/s). The bandwidth is computed from the duration and the size of the log, and intended to show how much the log grows as the user keeps interacting with a page over time. Table 3 shows the results.

For most experiments, the bandwidth remains roughly constant even as the length of interaction increases, which is to be expected. Color Game is the notable exception, in which the bandwidth increases with the length (and intensity) of user interaction. We believe this is due to internal AngularJS behavior that: (1) never cancels timers with the browser, simply executes a test to return from cancelled timers, which results in more timers expiring as the game is played again and again; and (2) installs `hover` handlers for all elements, which call `Math.random` and result in more handlers executing as the experiment moves the mouse to the “Replay” button and back to the playing area. Over time, this results in Color Game generating the largest log files, which is understandable as Color Game is a game that requires intense user interaction. Painter generates large log files because it targets all the mouse movements with a fine level of detail (pixel by pixel, as discussed above). Overall, the bandwidth stays under $253KB/s$, which is acceptable.

We note that the original Painter interaction took about 20sec, the runtimes shown in Table 3 are artificially inflated by the slow speed of `pyautogui`. The original bandwidth would be $1MB/s$, which is acceptable for applications that track the mouse with fine detail.

■ **Table 3** Duration, number of events, log size, and bandwidth needed for growing workloads. **S** means *small*, **M** means *medium*, and **L** means *large*. **FF** means *Firefox*, and **Chr** means *Chrome*. Average of 5 runs.

		nicEdit			DOMTRIS			Painter			Color Game		
		S	M	L	S	M	L	S	M	L	S	M	L
Duration (sec)	FF	51	85	119	53	73	91	466	914	1,364	42	122	202
	Chr	51	85	119	53	73	90	464	921	1,366	43	122	202
# of evts ×1000	FF	0.46	0.82	1.18	0.47	0.64	0.63	4.12	8.36	12.14	1.81	9.24	22.53
	Chr	0.48	0.86	1.24	0.47	0.47	0.66	4.09	8.17	12.24	1.76	8.73	21.01
Size (MB)	FF	0.26	0.48	0.71	0.67	0.94	1.16	10.56	21.46	31.15	3.05	19.51	50.97
	Chr	0.22	0.42	0.61	0.58	0.83	1.00	8.40	16.78	25.16	2.59	16.15	41.25
Bandwidth (KB/s)	FF	5.0	5.7	6.0	12.7	12.8	12.8	22.7	23.5	22.8	71.7	159.6	252.3
	Chr	4.3	4.9	5.1	11.0	11.4	11.0	18.1	18.2	18.4	60.9	132.0	204.1

The results of this experiment provide an answer to **RQ3: Sinatra logs grow at a rate of 253KB/s as the user interacts with a page.** This result is acceptable, as mouse-based user interactions are short and the bandwidth is not a bottle-neck for inter-process communication. We note that the result is much smaller for all the other cases.

6.5 Browser updates with Sinatra

SINATRA can be used to deploy a browser update without incurring any loss of (JavaScript) state on the pages opened by the running browser. Such updates involve: (1) transferring the JavaScript state to the updated browser, running as follower, by processing the log it receives from the coordinator; and (2) promoting the follower to be the new leader. This section describes two experiments, one for each of the steps.

6.5.1 Log processing time

This experiment measures the time that the updated browser, running as follower, takes to process all the events in the log sent by the coordinator. We executed the workload for each program (to completion), and then launched the new browser as a follower. On the follower, we took two measurements: (1) the time taken since the page is loaded until the follower is up-to-date with the leader, and (2) the time taken just processing the event log sent by the coordinator. Note that (1) includes all the SINATRA initialization logic plus (2). Columns “Process log” and “Start executing” of Table 4 show the results for (2) and (1), respectively.

We can see that processing the log of events is an important portion of the overall time required to start a follower. Most cases take under $338ms$, except Color Game. Color Game takes much longer to process the events in both browsers. We believe this is due to the underlying Angular.JS initializing a large number of libraries it uses as dependencies. Color Game takes longer on Firefox than on Chrome, which we believe is due to Chrome’s higher performance when executing Angular.JS code.

6.5.2 Time taken to promote follower

This experiment measures how long it takes to promote the follower to be the new leader (and demote the leader to become a follower) once the follower is up-to-date (i.e., after the follower processes all events sent by the coordinator). The experiment uses two browsers: B_1 as the initial leader, and B_2 as the initial follower. We execute half the workload by

■ **Table 4** Time from launching a follower until its state is up-to-date, time to promote, and round-trip time (RTT) between the leader triggering an event and receiving an acknowledgement from the follower for that event. Average of 5 runs with standard deviation.

Program	Browser	Process log (ms)	Start executing (ms)	Promote (ms)	Round-trip-time (ms)
nicEdit	Firefox	75 ± 6	168 ± 7	8.4 ± 2.3	13.56 ± 0.51
	Chrome	138 ± 7	277 ± 43	8.0 ± 2.0	19.77 ± 2.50
Painter	Firefox	338 ± 56	658 ± 111	6.7 ± 2.4	4.08 ± 0.05
	Chrome	491 ± 23	691 ± 13	4.6 ± 1.6	6.47 ± 1.51
DOMTRIS	Firefox	147 ± 19	420 ± 50	6.6 ± 2.2	32.61 ± 9.10
	Chrome	248 ± 87	438 ± 43	3.8 ± 0.8	26.71 ± 0.09
Color Game	Firefox	1,067 ± 103	1,435 ± 129	7.2 ± 2.9	19.03 ± 1.29
	Chrome	704 ± 52	1,180 ± 59	4.0 ± 2.0	17.15 ± 0.49

■ **Table 5** Latency observed by SINATRA when contacting a server via XHR with a fixed latency, and time require to change roles between variants. Average of 5 runs with standard deviation.

XHR Latency (ms)	Browser	Observed Latency (ms)	Promote (ms)
0	Firefox	7.12 ± 0.34	12.75 ± 1.30
	Chrome	6.60 ± 0.34	11.00 ± 3.08
50	Firefox	56.42 ± 0.42	52.50 ± 2.69
	Chrome	57.27 ± 0.32	56.75 ± 5.07
100	Firefox	107.42 ± 1.13	102.50 ± 1.66
	Chrome	108.84 ± 1.14	111.00 ± 6.78
1000	Firefox	1,008.25 ± 0.92	1,006.00 ± 6.20
	Chrome	1,009.74 ± 2.18	1,012.25 ± 9.44

interacting with B_1 , then switch their roles, then finish the workload by interacting with B_2 . We checked visually that the experiment behaves as expected, and measure the time taken since switching the roles of each browser. Column “Promote” on Table 4 shows the results. We can see that all promotions happen under $10ms$.

6.5.3 Time to perform an update

Putting together Sections 6.5.1 and 6.5.2 allows us to estimate the minimum time required to perform an update. Even though it may take a follower browser as long as 1.435 seconds to synchronize its state with the leader, this process takes place in the background and does not cause the user to stop interacting with the (leader) browser. Then, once the follower’s state is up-to-date, the promote/demote process takes less than $10ms$, which humans perceive as instantaneous. These two experiments also allow us to answer **RQ4: Sinatra requires an imperceptible pause (10ms) to update a running browser, and requires less than 1.5 seconds to prepare that update in the background since launching the updated browser.**

6.6 XML HTTP Request support

We evaluate SINATRA’s support for XML HTTP Request (XHR) with two experiments. First, we designed an experiment in which a leader and a follower perform 100 XHR requests in sequence to a local server that waits a certain amount of time (0ms, 50ms, 100ms, and 1s)

before sending back 100 bytes. On the 50th request, we swap the roles immediately after performing an XHR request, to force SINATRA to postpone the role swap as described in Section 3.3. We measure two things: (1) the latency observed by the leader, and (2) the time required to swap the roles. The results, presented on Table 5, show that SINATRA introduces little extra latency on top of the maximum XHR latency observed. Note that a latency of 100ms is not noticeable by the user.

In our second experiment, we captured all the XHR traffic during a period of 14h on a page that receive very frequent updates – the twitter feeds the local traffic and weather channel¹ – on both Chrome and Firefox. Then, we replay those requests using SINATRA and check the total log size needed. In this experiment, we measured an average number of requests of 5,676 for (1), 27,022 for (2); and an average log size under 6MB for (1), and under 36MB for (2). The overall average latency we observed was 86ms. These experiments allow us to answer **RQ5: Sinatra supports realistic XHR with modest storage requirements (under 36MB/14h), and introduces an imperceptible pause due to pending XHR (under 100ms).**

6.7 Using Sinatra as an MVX system

At its core, SINATRA is an MVX system targeting JavaScript. In this role, we are interested in measuring the latency between an event being triggered on the leader, and that same event being visible on the follower. We designed an experiment that measures the *Round-Trip Time (RTT)* of each event by sending an acknowledgement from the follower, for each event received, back to the leader, through the coordinator. The RTT provides a reasonable estimate of the leader-follower latency. This experiment runs the workloads for all the applications while measuring the RTT. Table 4 shows the results.

In all cases, the RTT is under $33ms$, which indicates a leader-follower latency of half the RTT, around $17ms$. The results from this experiment answer **RQ6: Used as an MVX system, Sinatra delivers events to the follower in 10ms after the leader.**

6.8 Using Sinatra on realistic webpages

To test whether SINATRA can be applied to pages that represent a realistic modern workload, we applied it to the Google search page and the Twitter home page (after login, showing a feed of tweets). We downloaded all the resources used by each page in advance, including XHR requests, to be able to observe the same execution reliably. We then modified the downloaded pages to add the required SINATRA headers, as explained in Section 3 and on Figure 2. We used Google Chrome for this experiment, and repeated each experiment 10 times. We measure the time to load each page by adding a closure with `timeout(0)` that readds itself, and measuring the time between each execution. Initially, the time between executions is high as the event-loop is busy loading the page. We measured an idle event-loop imposing a time between executions below $6ms$. When we observe 5 executions below $6ms$, we consider the page loaded.

Loading Google and Twitter, takes $267 \pm 61ms$ and $2891 \pm 321ms$, respectively. SINATRA processes a total of a total of 163 ± 2 events in $431 \pm 85ms$ and 4583 ± 37 events in $4234 \pm 451ms$, respectively. The overhead is 1.61 for Google, adding about $100ms$; and 1.46 for Twitter, adding about $1sec$.

¹ <https://twitter.com/TotalTrafficCHI>

Once loaded, the pages are fully functional and allow for user interaction. In MVX mode, the interaction on the leader is replicated on the follower without any noticeable delay, confirming that the results in previous experiments generalize to larger pages. Furthermore, we modified our local HTTP server to allow Google XHR traffic to go through, which enabled the search autocomplete feature as the user types to work correctly on the leader, being then replicated on the follower by SINATRA. The results from this experiment answer **RQ7: Sinatra can indeed be used on modern pages with sophisticated JavaScript that generate thousands of events with no loss of functionality and modest overhead.**

Threats to validity. Despite our best efforts, the evaluation in this document still has some threats to validity: (1) the websites we tested may not be representative of common websites, (2) the browsers/versions used may not be representative of popular browsers, (3) our results may be affected by bugs in SINATRA, and (4) using SINATRA on other websites may be affected by bugs in SINATRA.

7 Related Work

The problem of Dynamic Software Updating (DSU) has been a focus of past research, resulting in DSU systems for programs written in popular languages such as C [11, 24, 17, 18, 19] and Java [47, 55, 65, 66, 30, 45]. SINATRA differs from these systems in two important ways. First, SINATRA updates the *execution environment* and not the program running on that environment. For instance, DSU systems for Java do not support updating the underlying Java Virtual Machine while running the same program, which would be the closest to the goal of SINATRA. In fact, to the best of our knowledge, SINATRA is the first such DSU system outside of the Smalltalk community [20, 9] to target the execution environment specifically. Second, DSU systems typically require modifications to the programs being updated to support stopping the program in one version and resuming it in the next, and to express how to transform the state in the old program to an equivalent representation that is compatible with the updated code. In contrast, SINATRA works on unmodified closed-source commercial internet browsers. Instead of migrating the state directly, SINATRA launches the new browser as a separate process and migrates the state for each page individually. The only state kept outside of SINATRA is persistent HTTP connections, which SINATRA’s proxy keeps open during updates.

SINATRA uses Multi-Version eXecution (MVX) to synchronize the old and new versions of the updated browser. MVX has been used mostly in programs written in C/C++ by intercepting and synchronizing system-calls between processes. The main goal of MVX are: (1) to increase security [32, 13, 59], detecting divergences in potentially suspect processes; (2) to increase reliability [27, 8, 34, 37, 51], tolerating faults in one process by using the other processes; and (3) availability [26, 44, 48], by performing updates on a forked process and terminating it when updates fail, without any disruption. In fact, Mvedsua [44] is the most similar MVX system to SINATRA, given that it also combines MVX with DSU and allows users to build confidence on the validity of the update by executing both old and new versions for a period of time. However, Mvedsua targets C programs updated via Kitsune [24], intercepts system calls, requires modifications to the programs being updated and machine-parseable descriptions of the update-induced divergences. SINATRA requires much less developer effort, which can be fully automated using an HTTP proxy.

Record-Replay (RR) can be described as “offline Multi-Version eXecution”. It operates in two phases, typically using two different (automatically generated) programs. First, it records all non-determinism observed during an execution in a log file. Then, it uses that

log file to replay the same execution over the same program. By contrast, MVX records each non-deterministic datum in one process and replays it immediately on another process, thus keeping the state on both processes perfectly synchronized. MVX also needs to account for differences in execution speed that may result in a replayer overtaking the recorder and reaching a program point that requires non-determinism before that data is available. For this reason, RR approaches require the log to be complete before being able to replay it. Furthermore, RR approaches do not allow a replayer to become a recorder as they target a different problem: Accurate replication of bugs observed in production during development.

Techniques for RR target programs written in multiple popular programming languages: C [42], Java [7], and even web browsers [39, 10, 5, 25, 57]. Most techniques require a modified web browser. Dolos [10] and Jardis [5] use modified implementations of browser components (Webkit and ChakraCore) to record bugs in production and replay them in development and provide developers with time-travel debugging capabilities, respectively. Jardis focuses on node.js applications [3]. ReJS [57] also provides support for time-travelling debugging, but for any JavaScript code in general, through a modified version of Microsoft's ChakraCore JavaScript engine that performs heap checkpoints via a modified garbage-collector.

Working in pure JavaScript, Mugshot [39] is an RR system that demonstrates the feasibility of capturing all the needed non-determinism to ensure an accurate replay without the need for a modified web browser. Mugshot influenced the design of SINATRA by listing all the sources of non-determinism that need to be handled to capture all interactions between the environment and a JavaScript program executing in a browser. However, Mugshot relies on event listeners on the topmost DOM element (i.e., `window`) to intercept all events, and replays them through synthetic browser events (i.e., `DOMElement.fireEvent`). As a result, Mugshot has to deal with browser-specific behavior that impacts event bubbling and event ordering. SINATRA's approach of intercepting each handler individually avoids such complexity and naturally supports any browser without special handling. Similarly to SINATRA, X-Check [25] also works in pure JavaScript and works on different browsers (all other techniques require the same browser and version to replay the recorded logs). X-Check records logs on one browser and replays them on different browsers, with the goal of detecting cross-browser differences that developers can then replicate and address.

The closest system to SINATRA is Cocktail [67], an MVX system for web browsers with the goal of improving the security of internet browsers by feeding input to many different browsers and voting on the output. Cocktail can thus detect and defeat attacks that target a particular browser, or a particular browser version. Despite the very different goal, there are more important differences between SINATRA and Cocktail. First, Cocktail is implemented as a browser plugin and SINATRA is implemented in pure JavaScript. As such, SINATRA can be directly applied to any web browser, but Cocktail requires developer effort to write a new plugin for that browser. Also, Cocktail's plugin can intercept asynchronous non-determinism, such as calls to `Math.random`, and block until all browsers reach the same point. This is not possible in JavaScript's execution model, as described in Section 2.3. Second, Cocktail relies on an UI component to intercept mouse and keyboard events before they reach the browser. SINATRA captures the events at a finer level of detail, ensuring that all browsers execute the same JavaScript handlers by the same order, regardless of implementation-specific browser quirks that may show the same element on different positions in different websites. In fact, SINATRA can replicate the execution even if the leader and follower have different window dimensions, which is a limitation of Cocktail.

8 Conclusions and Future Work

This paper presented the design of SINATRA, a system that allows to update internet browsers without losing any state in the process. SINATRA works fully at the JavaScript level, using first-class function interception to keep track of all events, and then using MVX to perform updates on the new version of the browser while the old version keeps providing service. As a result, SINATRA works on popular, closed-source, commercial internet browsers such as Google Chrome. SINATRA requires a small amount of JavaScript source changes, performed to each page opened in the target browser. The changes required are easy to automate with a sophisticated internet proxy.

This paper also presented an extensive experimental evaluation, where SINATRA is applied to JavaScript applications with different combinations of features. When not performing an update, SINATRA imposes low overhead on the execution of event handlers (a max increase of 2.107ms). Also, the state that SINATRA keeps to support future updates grows at a modest rate of 10.8KB/s (at most) during intense user interaction. If a page remains open performing XML HTTP Request requests, SINATRA requires a modest 36MB of storage for a 14h run.

SINATRA can perform updates in short order, requiring just 1.5s (at most) to transfer the state from the old browser to the new browser. While SINATRA transfer the state, the user keeps interacting with the old browser. Then, to finish the update and allow the user to interact with the new browser version, SINATRA requires a very short pause in user interaction of less than 10ms, which is barely noticeable for most users.

Besides its role in browser updates, SINATRA doubles as an MVX tool for JavaScript applications. The experimental evaluation showed that SINATRA can keep two browsers synchronized, with an action on one browser taking effect on the other almost instantaneously, within 19ms.

In the modern internet age, an up-to-date internet browser is the first line of user defense. SINATRA dramatically lowers the barrier to deploy automatic and fully transparent browser updates by eliminating any data loss or service interruption associated with such updates. We strongly believe that SINATRA has the potential to improve the average user's safety by making disruptive browser updates a thing of the past.

Future Work. It is possible to use SINATRA to move a page from one browser to another (e.g., from Mozilla Firefox to Google Chrome). This feature can be valuable to security conscious users, who can switch browsers as a vulnerability is disclosed. We tested this feature of SINATRA informally to ensure it works, but did not evaluate it or develop it further.

SINATRA is OS and platform agnostic, and we plan to implement SINATRA on popular platforms (e.g., Microsoft Windows and Apple OSX) and apply SINATRA to the official browser in each platform (e.g., Microsoft Edge and Apple Safari).

An Efficient Vectorized Hash Table for Batch Computations

Hesam Shahrokhi  
University of Edinburgh, UK

Amir Shaikhha  
University of Edinburgh, UK

Abstract

In recent years, the increasing demand for high-performance analytics on big data has led the research on batch hash tables. It is shown that this type of hash table can benefit from the cache locality and multi-threading more than ordinary hash tables. Moreover, the batch design for hash tables is amenable to using advanced features of modern processors such as prefetching and SIMD vectorization. While state-of-the-art research and open-source projects on batch hash tables made efforts to propose improved designs by better usage of mentioned hardware features, their approaches still do not fully exploit the existing opportunities for performance improvements. Furthermore, there is a gap for a high-level batch API of such hash tables for wider adoption of these high-performance data structures. In this paper, we present Vec-HT, a parallel, SIMD-vectorized, and prefetching-enabled hash table for fast batch processing. To allow developers to fully take advantage of its performance, we recommend a high-level batch API design. Our experimental results show the superiority and competitiveness of this approach in comparison with the alternative implementations and state-of-the-art for the data-intensive workloads of relational join processing, set operations, and sparse vector processing.

1 Introduction

Hash tables are one of the most important data structures in programming. They are widely used in high-performance analytics workloads including database query processing, sparse linear algebra, graph processing, and computer networks. Besides the great efforts in algorithmic improvement of hash tables [10, 18, 20], the recent advances in modern processors, further motivated the research on high-performance hash tables that leverage the hardware characteristics including parallelization, prefetching, and vectorization.

Previous research [19] has shown that batch operations (e.g., batch lookups) on a hash table result in higher performance in comparison with ordinary scalar-parameter operations. This is because of the improved cache locality and the freedom given to the hash table designer for hand-tuning the code, which is not available when dealing with ordinary scalar-parameter operations over hash tables. Thus, hash tables with batch operations have gained more attention; both research [12, 14, 19, 23, 22, 32] and open-source projects [1, 3, 6] have proposed hash table designs with the support for batch lookups, insertions, and deletions.

■ **Table 1** A summary of state-of-the-art batch lookups in hash tables. H: Horizontal Vectorization.

Approach	Parallelization	Prefetching	SIMD Vectorization
Hirota [3], R hashmap [6]	○	○	○
DPDK [1]	●	●	● (H)
Cuckoo++ [23]	○	●	● (H)
Polychroniou et al. [19]	●	○	●
<i>Vec-HT (this paper)</i>	●	●	●

The current literature on batch hash tables considers the following hardware features:

- Parallelization: The batch of inputs is divided into separate partitions that are processed in parallel [1, 19].
- Prefetching: The memory prefetching feature of processors is used to hide the latency of frequent memory accesses for a group of elements [1, 2, 9, 23].
- Vectorization: The Single Instruction, Multiple Data (SIMD) instructions of the processing unit are used for faster processing of a vector of inputs [1, 2, 9, 19, 23].

Although the existing approaches made noticeable efforts on improving the performance of batch hash tables, none of them fully exploits all of the three optimization dimensions mentioned above (cf. Section 2). The existing approaches for vectorization can be categorized into two classes (cf. Figure 1): (1) *Horizontal Vectorization*, where the SIMD instructions are used for the operations on a single input over multiple hash table entries [1, 9, 23], and (2) *Vertical Vectorization*, where the SIMD instructions are used for the operations on an input batch over single hash table entries [19]. The first approach is not inherently batch based; it can be applied to ordinary hash tables. By conducting intensive benchmarks, Polychroniou et al. [19] and Shankar et al. [30] have shown that vertical vectorization is faster than the horizontal approach. However, prefetching has only been considered for horizontal vectorization [1, 23], and the only existing implementation of the vertically vectorized approach [19] does not support prefetching.

This paper makes the following contributions:

- We present Vec-HT, the first batch hash table that is fully optimized in all three dimensions; Vec-HT is a multi-threaded, vertically-vectorized, and prefetching-enabled hash table that can be used for high-performance data analytics. We explain the architecture and the high-level batch API of Vec-HT in Section 3.
- Previous research has shown that in most high-performance use cases, optimizing the lookup performance is more important than the other operations (Section 2). Thus, the focus of this research is on batch lookups. We show the design decisions, the applicable optimizations, and the way we combine them for efficient batch lookups in Section 4.
- We consider several data analytics tasks that can benefit from batch hash tables, such as hash-join in query processing, set processing, and sparse vector operations (Section 5).
- We present the implementation challenges we faced (e.g., memory management and parallel iteration) and how we addressed them in Section 6.
- We experimentally evaluate (Section 7) the performance of our hash table on a set of micro benchmarks across different use case domains. Our results show that Vec-HT outperforms the state-of-the-art batch and non-batch hash tables.

2 Background and Related Work

In this section, we introduce the main concepts and techniques for building high-performance hash tables while summarizing the previous efforts in this area of research. Table 1 presents a summary of the state-of-the-art in batch hash tables.¹ To position the contributions of this paper, our approach is also appended to the table.

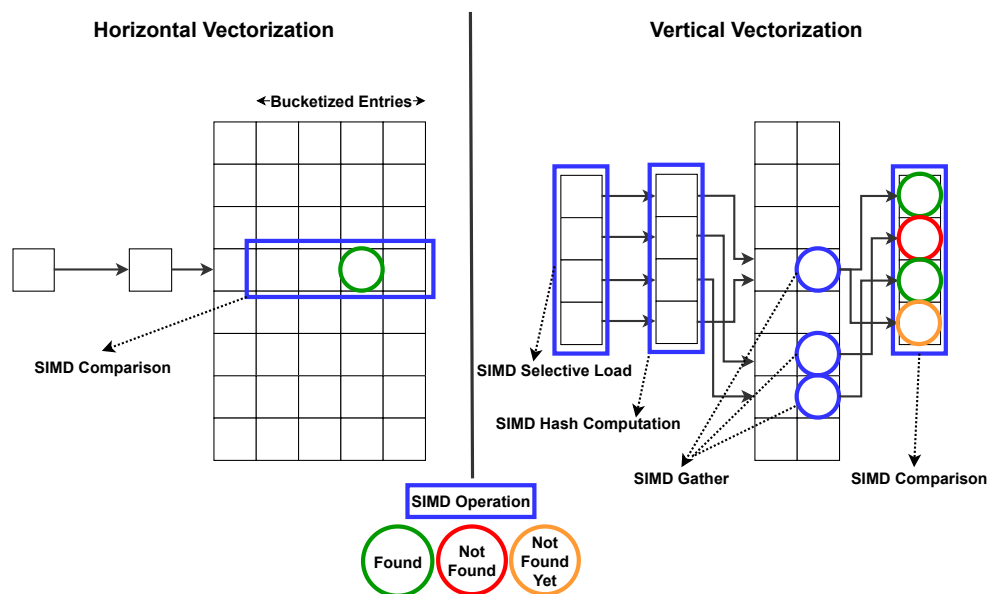

Batch Hash Tables. Batch Hash Tables accept a vector of keys or key/value pairs as their API arguments and do the operation on the inputs in batch. By taking batch inputs, the batch hash tables benefit from the cache locality and are also amenable to the use of Single Instruction, Multiple Data (SIMD), parallelism, and prefetching. The SIMD is a hardware feature that allows the simultaneous execution of an operation on a vector of values. On the other hand, prefetching is a hardware feature that allows the program to request future memory accesses in advance and asynchronous to the other computations. We will cover the more-detailed definitions of these two concepts later in this section.

Among the open-source projects [1, 3, 6], Hirola [3] presents a fast batch hash table written in C which is an alternative for `dict/set` in Python. Similarly, by considering the fact that most values in the R language are vectors and matrices, R-hashmap[6] presents a batch hash table for R, which is built over some existing ordinary hash tables in C. These two libraries are only using the cache-locality of the batch input as a way of performance improvement. As a more advanced open-source project, DPDK [1] offers a specific-purpose batch hash table for networking use cases. It is both SIMD-aware and prefetch-enabled.

There is also state-of-the-art research [9, 12, 14, 19, 22, 23, 32] on batch hash tables. Some of the approaches [12, 14, 32] are only using batch processing to benefit from the cache locality and prefetching while others [9, 19, 22, 23] use SIMD techniques on a vector of inputs. Similar to DPDK [1], Horton [9] and Cuckoo++[23] have focused on improving the performance of batch hash tables by applying SIMD and prefetching techniques to a specific type of SIMD-aware batch hash table designs called Bucketized Cuckoo Hash Tables (BCHTs). On the other hand, Polychroniou et al. [19] present a generic design for SIMD-aware batch hash tables and compare the performance of different design decisions by doing intensive benchmarks. To answer some of the open questions in vectorized hash tables, [30] conducted a survey on state-of-the-art and conducted micro-benchmarks to position each work with respect to the others.

SIMD-Aware Batch Hash Tables. To use SIMD features of a CPU in an operation (logical, arithmetic, memory, etc.), we first need to construct a vector of operands that fit the CPU register size. Then, the prepared register could concurrently process the data by using SIMD instructions. Modern CPUs offer even more advanced SIMD instructions such as selective load/store and scatter/gathers. Selective load/store makes the parallel optional load/store from/to a contiguous memory location possible by accepting a mask register. The gather/scatter operations provide the ability to load/write from/into different parts of the memory in parallel. At the time of writing this paper, the SIMD scatter is not widely adopted, and is only provided by specific hardware (e.g., Intel Xeon Phi).

¹ Although in the literature the terms batch and vectorized are used interchangeably, for the sake of consistency, in this paper, we use the term batch to refer to a collection of elements, and vectorized to refer to SIMD vectors.

■ **Figure 1** The comparison between horizontal and vertical vectorization.

As mentioned earlier, SIMD techniques can be used to improve the performance of batch hash tables. In high-level, the usage of SIMD in hash tables could be categorized in two: (1) Horizontal Vectorization and (2) Vertical Vectorization. A simplified visualization of these two approaches is depicted in Figure 1.

In horizontal vectorization, each cell of the hash-table entries array is bucketed into N inner cells. Then, while doing a lookup on the hash table and after computing the hash value, using the SIMD logical operations, the lookup algorithm can concurrently check the value of N bucket keys. This is much faster than having only one key per cell. By using this approach the hash table load factor can be improved without increasing the average lookup time. Regardless of the mentioned benefits of horizontal vectorization, it is wasteful if we expect to look up fewer than N buckets on average per probing key [19]. One of the famous open-addressing collision resolution algorithms in hash tables is Cuckoo Hashing [18]. A BCHT, as defined earlier, is actually the horizontally-vectorized version of cuckoo hashing. Many of the existing approaches on SIMD-aware batch hash tables [9, 22, 23] are in fact the improved version of BCHTs. Besides presenting a BCHT approach, Polychroniou et al. [19] also proposed and compared other horizontally-vectorized hash tables based on double hashing and linear probing hashing schemes.

Vertical vectorization [19] is a more generalizable but more complex approach to benefit from SIMD in batch hash tables. It is more generalizable because it does not change the inner structure of a hash table. However, it is more complex as it needs the collision-resolution algorithm to be translated into SIMD operations. Contrary to horizontal vectorization, in this approach, the input of a lookup operation must be a vector of probing keys. In each vectorized lookup, the vertical approach will pass a vector (of register size) of inputs through the lookup process and by using mask registers and advanced SIMD features (like SIMD permutations) probe those keys at the same time. When the status of a key lookup is determined (found/not-found), its related CPU-register lane will be assigned to the next key

in the batch of keys that are waiting to be processed. By conducting different experiments, Polychroniou et al. [19] and Shankar et al. [30] have shown that vertical vectorization yields higher performance than the horizontal approach. In vertical vectorization, since the hashing scheme must be translated into SIMD code, we need to use gathers and scatters to read/write from/to different entries of a hash table. As mentioned earlier, the scatter instruction is only available in limited types of processors hence the vertically-vectorized insertions can only be implemented on specific hardware.

The third category for SIMD-aware batch hash table design is a hybrid approach. However, the experiments in [30] show that the results of mixing the vectorized and horizontal vectorization approaches will not further improve the performance.

Besides the SIMD-aware vectorization methods discussed above, SIMD operations can also be used in the development of hash functions in any hash table [2]. Although this approach can improve the performance of hashing, it is orthogonal to the scope of this paper.

Prefetching-Enabled Hash Tables. Modern CPUs support hardware and software prefetching. Prefetching improves the performance of a program by amortizing the costs of memory access over time (in parallel to running computations).

Hardware prefetching is automatically enabled by the compiler and executed by the CPU when long and contiguous access to memory (e.g. iteration on a large vector) is requested by the program. The developer does not have much control over the hardware prefetching. On the other hand, in software prefetching, the developers can issue on-demand asynchronous prefetching commands to prefetch their future memory accesses.

In hash tables, regardless of the hashing scheme, accessing entries is based on the value of the computed hash for each provided key. This is an example of random access to a non-contiguous memory that can be improved by using the software prefetching. To have an effective prefetching in hash tables we need (1) a batch of operations and (2) a large hash table. The batch of operations provides enough computational tasks for the CPU while the prefetching instructions for future memory accesses are being processed. Also, if the hash table is not large enough, its content can entirely fit into the CPU cache. This cancels the benefits of prefetching and only puts its overheads on the CPU.

The effects of using software prefetching in hash tables have been studied in [11, 23, 32]. In the networking community, Scouarnec et al. [23] and Zhou et al. [32] have shown the effects of using prefetching on network-specific batch hash tables. They proposed different approaches and improvements in applying prefetching on BCHTs. In the database community, by proposing two generic techniques of using prefetching, Chen et al. [11] have shown their impact on the performance of relational hash joins. Among the off-the-shelf open-source hash tables, we found phmap [5] as the one that provides a `prefetch_hash` API in its interface. However, it delegates the responsibility of using this API (and designing a good prefetching strategy) to the developer who is not necessarily a system-level developer. There exist challenges in combining software prefetching with vectorization in the context of hash tables. We cover these challenges and their related design decisions in Section 4.3.

Parallel (Concurrent) Hash Tables. There is a long tail of research and open-source projects on parallel (i.e., multi-threaded) hash tables. The state-of-the-art systems [5, 7, 13, 15] have tried to enable concurrent insertion, lookup, and deletion on hash tables. These approaches can generally be divided into two categories: (1) the approaches that resolve the contentions using lock-based mechanisms, and (2) the lock-free hash tables that use atomic instructions, such as Compare-and-Swap (CAS) as their synchronization mechanism. Although these

parallel hash tables offer better performance in comparison with the sequential hash tables, they are not fully exploiting the advanced features of modern hardware such as SIMD awareness and prefetching. This is due to the lack of a batch API.

Although most of the batch hash tables offer batch insertions or deletions, previous research has shown that in most of the high-performance use cases (e.g. join processing in relational algebra, vector/tensor processing in linear algebra, and packet processing in computer networks), the amortized cost of insertions is negligible in comparison with the overall cost of highly frequent (or even endless and continuous) lookups [9]. Thus, in this paper, we only consider optimizing the lookup performance.

3 Architecture

In this section, we discuss the structure of Vec-HT and its high-level API.

3.1 Hash-Table Structure

The hash table consists of an array of `bucket` objects each of which contains a key (32 bits) and its related value (32 bits). As the hashing scheme, we use open addressing with linear probing (similar to [19]). We also use multiplicative hashing as our hash function.

Generally and without considering any optimization, to look up a key in the hash table, we first compute the hash of the key and then find its corresponding bucket in the array. If the key of that bucket is empty (the value of the empty key is defined during hash table initialization) we return the empty key which means “not found”. Otherwise, we check if the key in the bucket equals the probing key or not. If it is, we return the value, otherwise, we continue checking the next buckets to find an equal key or an empty bucket.²

3.2 High-Level API

To make a batch hash table more accessible to developers, we expose an easy-to-understand API. The Vec-HT namespace consists of three classes. A batch hash table class (`lp_map`) that is currently designed by having the open-addressing linear-probing hashing scheme (Figure 2), a batch-iterator class (`iter_batch`) that defines the data type containing the result of batch lookup, which also supports parallel iterations (Figure 3), and the `bucket` class (cf. Section 3.1) that is related to each entry of the hash table.

Batch Hash Table Class. The constructor of `lp_map` takes three arguments. The first one (`size`) is for setting the maximum number of elements that will be inserted into the hash table. The second parameter sets the group size for the internal prefetching. And the third parameter (`threads`), determines the number of threads (cores when the Hyper-Threading is disabled) to enable concurrent batch processing.

The methods exposed by the API of `lp_map` are categorized into two sets: non-batch and batch methods. The non-batch methods include `insert`, `find` that are similar to the standard hash table interfaces such as `std::unordered_map`. These methods give the developers the freedom of using Vec-HT without batch processing.

There are five batch-based methods. The method `insert_batch` inserts an array of keys and their related values into the hash table. The remaining methods are related to vectorized lookup which is the main focus of this work (cf. Section 2). The method `find_batch` accepts

² Currently, due to the restrictions imposed by SIMD-vectorization, Vec-HT only supports 32-bit integer keys (similar to [1, 19, 23]).

```

namespace vec_ht
{
    using K = uint32_t;
    using V = uint32_t;
    using P = uint32_t;
    // ---- Linear-Probing Batch Hash Table Class ----
    class lp_map
    {
        // ...
    public:
        lp_map (size_t size, size_t group_size=64, size_t threads=1);
        // ---- Non-Batch APIs ----
        inline bool insert (const K& key, const V& value);
        inline bucket* find (const K& key);
        // ---- Batch APIs ----
        inline size_t insert_batch (uint32_t* keys, uint32_t* values,
            size_t size);

        inline size_t find_batch (uint32_t* keys, size_t size,
            bool complement, iter_batch* res_it);

        inline size_t find_batch_apply (uint32_t* keys, size_t size,
            bool complement,
            std::function<void(K& key, V& value)>const& f);

        inline size_t zip (uint32_t* keys, uint32_t* payloads,
            size_t size, bool complement, iter_batch* res_it);

        inline size_t zip_apply (uint32_t* keys, uint32_t* payloads,
            size_t size, bool complement,
            std::function<void(K& key, V& value, P& payload)>const& f);
    };
}

```

■ **Figure 2** High-level API of Vec-HT in C++.

three arguments: (1) an array of keys to look up, (2) the size of that array, (3) a boolean flag called `complement` that is used to request for the not-found elements instead of the successfully-found ones, and (4) an object of a Vec-HT-specific class called `iter_batch`. The `iter_batch` class is responsible for keeping the results of a vectorized lookup and making the (parallel) iterations over them possible. The other method in `lp_map` is `zip`. Although it is not a usual API for ordinary hash tables, we found it very useful in the case of batch hash tables. This method, similar to the `find_batch`, does a lookup for the provided array of keys. However, it takes one additional argument; `payloads` assigns one value to each key in the keys array. When the method `zip` is called, the result also contains the related payloads of the found keys. The `iter_batch` class can also keep the results of a `zip` API. We show how `zip` can be used in practice in Section 5.

The remaining useful APIs are `find_batch_apply` and `zip_apply`. These APIs do the same job as their related discussed APIs. However, a user can pass their customized lambda function to be applied on the tuples of key-values (or key-value-payloads) whenever a match is found. As a result, there is no need to pass a `iter_batch` object to these APIs since it is

```

namespace vec_ht
{
    // Container and Iterator Class for find_batch/zip Results
    class iter_batch
    {
    // ...
    public:
        iter_batch (size_t max_size, size_t threads,
            bool for_zip=false)

        K** get_keys();
        V** get_values();
        P** get_payloads();

        inline void foreach
            (std::function<void(K& key, V& value)> f);

        inline void foreach
            (std::function<void(K& key, V& value, P& payload)> f);

        inline void foreach_parallel
            (std::function<void(K& key, V& value)> f);

        inline void foreach_parallel
            (std::function<void(K& key, V& value, P& payload)> f);
    };
}

```

■ **Figure 3** High-level API of batched iterator in C++.

the user's responsibility to handle the output. These two APIs can improve the performance of pipelined analytical tasks because they eliminate the need for the materialization of intermediate results (`iter_batch`). In other words, using these APIs, the user can fuse the batch lookups with the following operations in the pipeline. This is especially useful in the context of pipelined analytical query processing [25, 29, 17].

Batch Iterator Class. The `iter_batch` class can be constructed by passing (1) an upper bound on the size of the results, (2) the number of threads (it must be the same as the one in `lp_map`), and (3) a boolean that shows if we want to pass this object to a `zip` or a `find_batch` API. By receiving these parameters, the memory needed for the storage of parallel-processed results will be allocated. Then, the class is ready to be sent to the methods `find_batch` or `zip` in a *destination-passing style* [26, 31]. The destination-passing style improves the performance of computational workloads by bringing the memory-allocation overheads out of the performance-critical part of the workload. The `iter_batch` class has also two overloads of `foreach`. After the execution of `find_batch` or `zip`, their relevant `foreach` method can be used for a sequential iteration over the results. The `foreach` method takes a lambda function that will be applied to each of the stored results in the `iter_batch`. Similar to the `foreach` methods, `iter_batch` also offers `foreach_parallel` methods that use multiple threads to apply the provided lambda function on the stored results. In the `foreach_parallel`

■ **Figure 4** The architecture of batch lookup in Vec-HT.

```
template<typename FUNC_TYPE>
inline size_t parallel_dispatcher(uint32_t* keys,
                                uint32_t* payloads,
                                size_t size,
                                bool complement,
                                FUNC_TYPE func,
                                iter_batch* res_iter)
```

■ **Figure 5** The signature of `parallel_dispatcher`, a function used internally for parallelization.

methods, since they are internally implemented based on `tbb::parallel_for_each` [7], the developer can also use parallel containers such as `tbb::enumerable_thread_specific` or any other off-the-shelf parallel container to handle storing/aggregation of lambda outputs.

4 Design

In this section, we discuss the design decisions behind the optimizations in our approach and show how they relate to each other. Figure 4 shows the architecture of a batch lookup in Vec-HT. As it is shown in this Figure, the batch input is partitioned into smaller chunks on different levels and for different optimization purposes. In this section, these levels of input partitioning and the rationale behind them will be covered.

4.1 Parallel Processing

To make the most out of the multi-core processor, in case of a batch lookup, we partition the input batch of keys and assign each partition to a thread for parallel batch processing. When the `find_batch` or `zip` methods are called, they call the `parallel_dispatcher` method internally. This lower-level method is responsible for managing the threads needed for the computation and passing them the contextual information. The interface of `parallel_dispatcher` is shown in Figure 5.

The `parallel_dispatcher` method takes six arguments:

1. the keys that we want to look up in the hash table,
2. the associated payloads (set to `NULL` if the caller method is `find_batch`),
3. the size of the `keys`,
4. the `complement` flag (cf. Section 3.2),
5. the lambda function that is passed when the user calls `find_bath_apply` or `zip_apply`,
6. the `iter_batch` which is passed in case of calling `find_batch` or `zip`.

4.2 SIMD-Awareness

In this section, we explain the vertical-vectorization approach for batch lookups at a high level and refer the interested reader to Polychroniou et al. [19] for more details.

Suppose that a number of W keys can be stored in a CPU register. When the batch lookup starts, W keys of the input vector will be fetched into the `keys` register. To load the input keys, we use the selective load SIMD operation. This operation uses a mask to select which lanes of the target register must be filled with the new values and which of them must be set to zero. In the beginning, we define a register (`invalid`) with all lanes activated and pass it to the selective load as the mask. This means that we plan to read W new keys from the input. Then using the SIMD operators, the hash value of all the keys in `keys` is computed simultaneously and stored in the `hash` register. In Vec-HT, as we use a simple multiplicative hash function, the computation of hash values consists of logical and arithmetic SIMD operations such as vectorized multiplication and shift.

By having the hash values, we use the SIMD `gather` operation to retrieve the needed hash table entries. The `gather` operation reads multiple memory addresses (stored in a register) at the same time. Since the value of each computed hash shows the possible offset of each key in the hash table entries, we apply `gather` on the address of the hash-table entries array and the `hash` register. As a result of executing two `gather` operations, two registers for the retrieved keys (`tab_keys`) and values (`tab_vals`) will be created.

Next, based on the linear probing algorithm, we check the equality of key in `keys` and `tab_keys`. We do this check using SIMD logical operators. This check can have three different results for each lane: (1) the key is empty which means that the key is not found in the table (2) the keys are equal which means the key is found (3) the key is not empty or is not equal to the given input key and thus it needs further probing in the next rounds. For the not-found keys, we activate their relevant lanes in `invalid` register. For the found keys, we define and activate the relevant lanes in a new register called `output`. Finally, for the ones that need further probing, we create a new register called `offset`, initialize it with 0, and increment its relevant lanes by 1.

In this phase of the algorithm, we first add `out` to `invalid` and store the result in `invalid`. We do this since we are finished with both found and not-found keys and we want to fetch the new keys instead of them in the next round of lookups. Then, by using a static permutation table, we extract the permutation masks needed to align the active lanes of `invalid` and `output` to one side of the register. These permutation masks will be used in the SIMD `permute` operation, which changes the order of lanes in the register using a provided mask. First, we use the permutation mask of `out` on `out` itself and on `keys`. Now, we are ready to save the found keys to the target memory (reserved memory in `iter_batch`) using a selective store SIMD operation that its mask is the permuted `out`. The total number of output keys will also be updated at this stage. It is notable that the original vertical vectorization [19] uses a buffer to store the results temporarily and spills them to the output whenever the buffer is full.

After the work on the found keys is finished, we count the active lanes in `invalid` to know how many new keys are needed to be fetched. Then, we apply the `invalid` permutation mask on `keys`, `hash`, and `offset` to make them ready for the next run. By starting the next round of lookups, again the new keys will be fetched based on the updated `invalid` register. It is important to mention that this time all of the hashes are re-computed and the ones with inactive lanes in `invalid` will also be incremented by `offset` to point to the next entry in the hash table.

To return the value of found keys in the table and also their related payloads we need further considerations. For the hash table values, which are stored in `tab_val`, we can permute them using the `out` permutation mask and store them in their related memory in `batch_iter`. Similarly, the payloads can be selectively loaded exactly similar to the new key. Then they will be passed through the algorithm by similar permutations, and finally will be stored in the relevant output memory.

If the size of input keys is less than W or in the case of processing the last W keys, the algorithm switches to a normal scalar (non-SIMD) lookup in the hash table and stores the result into the `batch_iter`. This is because there are not enough keys to do a safe and efficient SIMD lookup.

4.3 Prefetching and Its Adaption Challenges

Vec-HT is a prefetching-enabled vectorized approach; we apply the prefetching on top of the parallel vertical vectorization. There is a large design space for combining prefetching and SIMD vectorization. We examined this design space through micro-benchmarking (cf. Section 7). The important design parameters for this combination are as follows:

- **Standard vs Group Prefetching:** putting the prefetching commands at the beginning of the main loop of the vertical vectorization is the standard solution for adding prefetching. We compare it with another approach (Group Prefetching) proposed by Chen et al. [11] in the context of databases.
- **Group Size for Group Prefetching:** Considering the group prefetching approach, the selection of the different group sizes might affect the performance of the system.
- **Optimistic vs Pessimistic Linear Probing:** Given that we use linear probing, there are two choices for prefetching for each key. Optimistic: we consider that the probe hits the correct location on the first try (or finds the location to be empty) and does not need to probe further; thus we only prefetch the hashed location. Pessimistic: we consider the case of not having a hit and thus prefetching the next location(s) as well.
- **Memoization of Computed Hashes:** We need the hash values in two places: (1) prefetching stage, and (2) vertical vectorization stage. We have the option of memoizing the hash value in the first stage and reusing/recomputing it in the second stage.
- **Buffering:** In vertical vectorization, we can write the output into an output buffer and if it is not carefully adapted to the prefetching design, it might result in performance overheads.

Figure 6 depicts a generic and high-level algorithm for combining prefetching with vertical vectorization (based on the assumption that we take the group-prefetching approach instead of standard prefetching, which is a take-away message of micro-benchmarks in Section 7). In this algorithm, by setting the `GROUP_SIZE` parameter, we can enable the grouping loop that partitions the input keys into parts of size `GROUP_SIZE` and then run the algorithm on these smaller batches. By having a group of keys as input, before starting the vertical vectorization, we define a loop over the group keys (prefetching loop). In each iteration of the prefetching loop, we first compute the hash of W elements using the SIMD approach mentioned before. By setting the `HASH_MEMOIZE` parameter to `true`, we can store the hash values and reuse them inside the vertical vectorization algorithm. After making a decision on memoization, we raise W software prefetch commands for the address of target entries in the hash table. Here we can do the prefetching also for the next bucket by setting the `OPTIMISTIC` parameter to `false`. After finishing the prefetching loop, all the related entries are prefetched. At this stage, the vertical vectorization algorithm will be executed for the current group and if the `OUT_BUFFER` parameter is enabled, the output buffering happens.

```

foreach group in array by GROUP_SIZE {
  // prefetching stage
  foreach vector in group {
    vector_h <- simd_hash(vector)
    if(HASH_MEMOIZE)
      mem_h += vector_h
    foreach h in vector_h {
      prefetch(buckets[h])
      if(!OPTIMISTIC)
        prefetch(buckets[h+1])
    }
  }
  // vertical vectorization stage using linear probing
  while(vec_elems not probed in group) {
    if(HASH_MEMOIZE)
      vector_h <- mem_h[vec_elems]
    else
      vector_h <- simd_hash(vec_elems)
    res <- vertical_vectorization(vec_elems, vector_h)
    if(OUT_BUFFER) {
      buffer += res
      if(buffer is full)
        flush(buffer)
    }
  }
  if(OUT_BUFFER) {
    flush(buffer)
  }
}

```

■ **Figure 6** A generic algorithm showing the design space of combining prefetching with vertical vectorization.

5 Use Cases

In this section, we show the usability of our proposed batch table, by showing several high-performance data analytics use cases.

5.1 Relational Hash Join

First, the code for a join on two relations (S and R) is shown in Figure 7. We assume that the relations are stored in columnar format (i.e., struct of arrays) which is a popular design decision in high-performance query engines [17]. The code is executed using a prefetching group size of 64 on 4 threads. We keep these settings for all of the use cases covered in Section 5.

Build Phase. In the beginning, the batch hash table is initialized with the table size, group size, and the number of threads. The size is set to twice the number of the elements in the relation on the build side of the hash join (S). We do so to keep the fill ratio of the hash table less than or equal to 50%. Then, using the `insert_batch` method, all the key/value pairs from S are inserted into the hash table in a batch style.

```

// build phase
auto ht = vec_ht::lp_map(2*S_size, 64, 4);
ht.insert_batch(S_A, S_B, S_size);
// probe phase
auto res_it = vec_ht::iter_batch(R_Size/3, 4, true);
ht.zip(R_A, R_F, R_size, false, res_it);
// printing the output
res_it.foreach_parallel(
[] (auto& key, auto& value, auto& payload){
    std::cout << "S_A/R_A: " << key << " | ";
    std::cout << "S_B: " << value << " | ";
    std::cout << "R_F: " << payload << std::endl;
});

```

■ **Figure 7** Implementation of a hash join operator (on S and R relations) using Vec-HT.

```

auto ht = vec_ht::lp_map(2*S2_size, 64, 4);
for (int i=0; i<S2_size; i++) ht.insert(S2[i], 1);
auto res_it = vec_ht::iter_batch(S1_Size/5, 4, false);
ht.find_batch(S1, S1_size, true, res_it);
res_it.foreach_parallel([] (auto& key, auto& value){
    std::cout << "Item: " << key << std::endl;
});

```

■ **Figure 8** Implementation of a Set-Difference operation ($S1 \setminus S2$) using Vec-HT.

Probe Phase. Before running the batch lookups on the hash table, we first prepare the `iter_batch` for the results. This object is initialized by setting three parameters. The first one is an upper bound for the join result size. The more precise this estimation is, the less memory allocation time is spent during the batch lookups. The second parameter is the number of threads that must be equal to the one already passed to the hash table. The last parameter is a flag that shows if the `iter_batch` object will be used in a `zip` or `find_batch` API. Next, by having the `res_it` object, we can run our `zip` method to join the relations based on the `R_A` and `S_A` columns and by considering the `R_F` column as the payload.

After the `zip` execution is finished, we use the `foreach_parallel` method of `res_it` to iterate over the join results and print them. The desired functionality (printing) is passed to the `foreach_parallel` using a user-defined lambda function.

5.2 Set Operations

As our second use case, we show the implementation of a set difference operation ($S1 \setminus S2$) using our approach in Figure 8. The sets `S1` and `S2` are stored in two arrays. The code is almost the same as the one in the relational-join example. Its main difference is in using `find_batch` instead of `zip`. It is because there is no payload to be passed into the `zip` API. Furthermore, in this example, we see the usage of `complement` parameter as we need the elements of `S1` that are not found in `S2`. To implement the set intersection we need to use the `zip` method, which is similar to the vector inner product, that is presented next.

```

auto ht = vec_ht::lp_map(2*V1_size, 64, 4);
ht.insert_batch(V1_idx, V1_val, V1_size);
auto res_it = vec_ht::iter_batch(V1_size, 4, true);
ht.zip(V2_idx, V2_val, V2_size, false, res_it);
uint32_t sum = 0;
res_it.foreach([](auto& key, auto& value, auto& payload){
    sum += value * payload;
});

```

■ **Figure 9** Implementation of an Inner-Product operation ($V1 \cdot V2$) using Vec-HT.

5.3 Sparse Vector Operations

The last use case that we cover in this section is the inner product of two vectors ($V1 \cdot V2$). The related code is shown in Figure 9. In this implementation, we again use the `zip` method, since there are payloads on the `V2` side (values of `V2` for each index). After the `zip` execution is finished, this time we do a non-parallel iteration (`foreach` API) over `res_it` to prevent contentions on the `sum` shared memory. As mentioned in Section 3.2, a developer can easily use the concurrent containers (e.g. `tbb::enumerable_thread_specific<uint32_t>`) instead of `sum` here. However, in this case, we are interested in exhibiting the usage of non-parallel `foreach`.

6 Implementation

In this section, we give a more detailed explanation of the implementation behind Vec-HT.

Attributes of `lp_map`. The attributes of `lp_map` class are shown in Figure 10. All these attributes are initialized in the class constructor. The `size`, `threads_`, and `group_size_` attributes are set to the values that are passed by the constructor. The `hash_factor_` is set to a randomly generated number. The `empty_key_` attribute is set to the maximum possible value for `uint32_t` type. Lastly, we use an array of `bucket` structs (`entries_`) as the entries of our hash table. It has been shown that using an array of structs instead of a struct of arrays does not affect the performance of hash tables [21]. The memory of this array is allocated after the calculation of `size_` attribute.

Attributes of `iter_batch`. The attributes of the `iter_batch` class are shown in Figure 11. Here `max_size_` is passed by the constructor and shows an upper bound on the number of results for a `find_batch` or `zip` method call. The `threads_` and `for_zip` attributes are given by the constructor. The next three attributes are the storage for results of a `find_batch` or `zip` method call. In the constructor, we allocate arrays of arrays to these pointers; this will allocate memory of size `max_size_` for each thread. In the case of a `find_batch` method call, we do not allocate and use the `payloads_` pointer. As the last attribute, we have `threads_res_size_` that will be extended to the size of `threads_`. Each element of this vector is used by a thread to store the size of the results for that thread. By using this attribute, the iterations over the results will be more efficient (cf. Figure 12).

Implementation of `foreach_parallel`. In Figure 12, the implementation details of `foreach_parallel` are presented. In this method, we create a range of integers from 0 to `thread_-1` and assign each number in the range to a thread. Then, by execution of a

```

namespace vec_ht
{
    class lp_map
    {
    private:
        size_t size_;
        size_t threads_;
        uint32_t group_size_;
        uint32_t hash_factor_;
        uint32_t empty_key_;
        bucket* entries_;

        template<typename FUNC_TYPE>
        inline size_t parallel_dispatcher(uint32_t* keys,
            uint32_t* payloads, size_t size, bool complement,
            FUNC_TYPE func, iter_batch* res_iter)

        template<typename FUNC_TYPE>
        inline size_t find_batch_inner(uint32_t* keys,
            uint32_t* payloads, size_t size, bool complement,
            FUNC_TYPE func, iter_batch* res_iter, size_t thread_id)
    public:
        // ...
    };
}

```

■ **Figure 10** The internal of the `lp_map` class.

`tbb::parallel_for_each` and passing the prepared range to it, we run a lambda function on each thread with `thread_id` as its single argument. In the lambda function, using the `thread_id` argument, the `max_size_` attribute of `batch_iter` class, and the vector of result sizes for each thread (`threads_res_size_`), we compute the boundaries of the result vectors that are assigned to the current thread. By having those boundaries, we can finally apply the developer-provided lambda (`func`) on each triple of `key`, `value`, and `payload` in the results assigned to this thread.

Implementation of `zip`. The implementation of the `zip` method is presented in Figure 13. To bypass the overheads of dispatching in the parallel scenario, this method (and other performance-critical methods such as `find_batch`), checks the `threads_` attribute of the current `vec_ht`. If it detects a sequential setting, then calls the internal method that is responsible for the vertical vectorization and prefetching (`find_batch_inner`). Otherwise, the method calls the `parallel_dispatcher` (cf. Section 4) to partition and dispatch the work among the pre-determined number of threads. To call either of these two internal methods, the `zip` method provides them with the appropriate arguments or `null` types where required.

Implementation of `find_batch_inner`. Figure 14 shows a simplified implementation for `find_batch_inner`. This method is the most complex method in `Vec-HT`. It operates over a subset of batch input (the partition that is assigned to each thread) and is responsible to do the following tasks:

27:16 An Efficient Vectorized Hash Table for Batch Computations

```
namespace vec_ht
{
    class iter_batch
    {
    private:
        size_t max_size_;
        size_t threads_;
        bool for_zip_;

        uint32_t** keys_;
        uint32_t** values_;
        uint32_t** payloads_;

        std::vector<size_t> threads_res_size_;
    public:
        // ...
    };
}
```

■ **Figure 11** The internal of the `iter_batch` class.

```
inline void foreach_parallel
(std::function<void(K& key, V& value, P& payload)> f)
{
    auto range = std::vector<size_t>(threads_);
    for (size_t i=0; i<threads_; i++) range[i] = i;
    tbb::parallel_for_each(range, [&](size_t thread_id)
    {
        for (size_t j=0; j<threads_res_size_[thread_id]; j++)
            func(keys_[thread_id][j],
                values_[thread_id][j],
                payloads_[thread_id][j]);
    });
}
```

■ **Figure 12** The implementation of `foreach_parallel` in `iter_batch`.

- To partition the input into group-sized batches.
- To compute and memoize the hashes for each group.
- To do the group prefetching for each group.
- To run the entire vertical vectorization algorithm for each group.
- To buffer the found keys and their related values and payloads.
- To store the results into the `iter_batch` or apply `func` over them.

We present a brief overview of the above-mentioned steps in Figure 14. The sections with high similarity to the code provided by Polychroniou [19] et al. are removed for the sake of brevity. We refer the interested reader to see those parts in the referenced work. Note that in Figure 14, the `vector_size` is a global constant (8) which is a function of the selected data-type size (32 bits) and the SIMD vector size (256 bits), computed as vector size divided by data-type size.

```

inline size_t zip (uint32_t* keys, uint32_t* payloads, size_t size,
bool complement, iter_batch* res_it)
{
    if (threads_ == 1)
        return find_batch_inner<no_func_type>(keys, payloads, size,
        complement, nullptr, res_it);
    else
        return parallel_dispatcher<no_func_type>(keys, payloads,
        size, complement, nullptr, res_it);
}

```

■ **Figure 13** Implementation of zip in lp_map.

As the last topic in this section, to implement the complement behaviour in Vec-HT, we have slightly changed the original vertical-vectorization algorithm. In the case of a complement, we replace the keys with an *invalid* status with the keys with an *output* status. In other words, the found keys are considered *invalid* and the not-found keys are the *valid* ones that must be stored in the output.

7 Evaluation

In this section, we first present our experimental setup for the evaluation. Then, we show the performance of our approach in different use case scenarios and compare its performance with various competitors.

7.1 Experimental Setup

All experiments are done on a single machine equipped with 16GB of DDR4 RAM, and an Intel Core i5-10210U 1.6GHz with 4 cores and 256KB, 1MB, and 6MB of L1, L2, and L3 cache respectively. Hyper-threading is disabled for the experiments. We have used Ubuntu 20.04.3 as OS. Our C++ code is compiled with G++ 9.4.0 using the `-O3` flag. To enable SIMD operations, we use the `-march=core-avx2` flag. All of the experiments were executed with 5 warmup rounds followed by 5 timed iterations. Then, we took the average of the timed iterations.

Workloads. To run the experiments, we use three different workloads. For the micro-benchmarks and the join experiments, we use the random data generator from [19]. By focusing on the notion of inner joins in databases, it generates two random data sets as inner and outer relations. The elements of the inner data set are inserted into the hash table creating the build side of the join. The elements of the outer data set shape the probe side of the join. The data generator accepts arguments for `inner_size`, `outer_size`, and `selectivity` of the join.

The second workload is used for the set and sparse vector experiments. The set/vector generator receives `size`, `density`, and `maximum_value` as input parameters. For each set of size N , it generates $N \times \text{density}$ unique random numbers from the range of $[0, N)$ as the value of items in the set. Similar to the sets, for the vectors, it generates unique random numbers but uses them as vector indexes. Then, using the `maximum_value` parameter, it generates random integer numbers in the range of $(0, \text{maximum_value}]$ as vector values.

27:18 An Efficient Vectorized Hash Table for Batch Computations

```
inline size_t find_batch_inner (uint32_t* keys, uint32_t* payloads,
                               size_t size, bool complement,
                               FUNC_TYPE func, iter_batch* res_iter,
                               size_t tid)
{
    // Partitioning the input keys into group-sized batches
    size_t inner_batch_size = group_size_;
    for(size_t i=0; i<size; i+=group_size_)
    {
        if (size-i<group_size_)
            inner_batch_size = size%group_size_;
        // Hash memoization and Group prefetching
        uint32_t hashes[inner_batch_size];
        for (size_t j=0; j<inner_batch_size; j+=vector_size)
        {
            // Hash computation for keys using SIMD operations
            // ...
            // Hash memoization and Group prefetching
            for (size_t k=0; k<vector_size; k++)
            {
                // Storing the hash in hashes[j+k]
                // ...
                // Prefetching the computed and stored hash
                _mm_prefetch(&entries_[hashes[j+k]], _MM_HINT_T0);
            }
        }
        // Execution of vert. vect. using memoized hash values
        // considering the "complement" flag (if enabled) ...

        // Buffering the matched keys, values (and payloads) ...

        // Flushing the buffer into the iter_batch container or
        // Applying the lambda function on the buffered tuples ...
    }
}
```

■ **Figure 14** A simplified representation of the `find_batch_task` implementation in `lp_map`.

As the last workload, we use the well-known TPC-H [8] benchmark with a scaling factor (SF) of 1 (1 GB of data) for the evaluation of our approach in analytical queries. It is important to note that in all of the benchmarks, we keep the fill ratio of all alternative hash tables less than or equal to 50%.

Alternatives and Competitors. In the micro-benchmarks, to evaluate our proposed approach, we compare it with (1) a scalar implementation of Vec-HT without any optimization (2) a scalar + prefetching version (3) and the vertical-vectorization approach by Polychroniou et al. [19]. For all alternatives, we consider sequential and parallel versions. As mentioned in Section 6, we reuse the code from [19] as the base for our implementations. We do not add the comparison with the approaches such as DPDK [1], as it is previously shown [19] that the BCHT approach is slower than vertical vectorization which is the basis for Vec-HT.

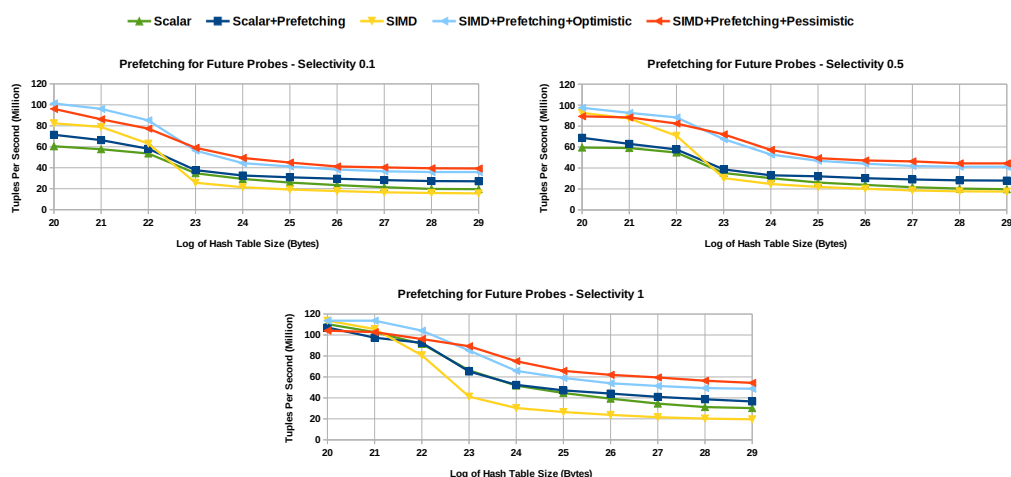

■ **Figure 15** Comparing the performance of standard vs group prefetching for combining prefetching with vertical vectorization. The charts show the number of tuples processed per second (higher is better) for a simplified relational inner-join operation with a probe size of 1,500,000 over an increasing build-side size.

We also compare our implementations with state-of-the-art hash tables. TBB [7] is a well-known parallel computation framework. We use its `tbb::concurrent_unordered_map` as one of our competitors. Libcuckoo [13] is a research project on fast parallel hash tables and we use its open-source implementation `libcuckoo::cuckoohash_map`. As the last competitors, from the open-source high-performance hash-table project phmap [5], we use its sequential and parallel data structures `phmap::flat_hash_map` and `phmap::parallel_flat_hash_map`. The implementation of Vec-HT that we use in the benchmarks has a group size of 64, taking an optimistic approach, with enabled memoization and simple buffering inside each group.

7.2 Benchmarks

In this section, we first consider the design space of combining prefetching with vectorization and show the best implementation. In addition, we evaluate the effectiveness of our implementation in comparison with scalar, scalar + prefetching, and pure vertical vectorization in a holistic micro-benchmark for hash join processing. Then, we show its superiority over the existing hash table packages in different use cases. We consider benchmarks on set and vector kernels that are largely used in big data analytics frameworks such as query processors (e.g., BigTable, SparkSQL) and linear algebra frameworks (e.g., MLlib, SystemDS, distributed TensorFlow). We finally cover benchmarks on database query processing over a selected subset of TPC-H queries, the main benchmark for analytical queries.

Standard vs Group Prefetching Micro-Benchmark. The first micro-benchmark related to the design space (cf. Section 4.3) is shown in Figure 15. In these experiments, our focus is to show the performance difference between the standard prefetching and group prefetching approaches. The results show that even though the standard way of prefetching offers performance improvements compared to non-prefetched approaches, it cannot beat the performance and scalability of the group prefetching.

■ **Figure 16** Comparing the performance of different alternatives by focusing on the optimistic and pessimistic approaches for prefetching. The workload is similar to Figure 15.

Optimistic vs Pessimistic Prefetching Micro-Benchmark. As mentioned in Section 4.3, by having a linear probing scheme in the hash table, for a given key, we can prefetch more than one bucket to improve the chance of a cache hit after an unsuccessful lookup. Although it seems to be an interesting strategy to take, the limited prefetching capability of CPUs, the variety in workload characteristics, and the parameters such as the fill ratio of the hash table can affect the benefits of this strategy. Figure 16 shows the performance results for prefetching with optimistic and pessimistic approaches. Both optimistic and pessimistic approaches perform better than the alternatives. However, for the smaller hash tables, the performance of the pessimistic approach is worse than the optimistic one and sometimes even worse than pure vertical vectorization. Thus, we decided to take the optimistic approach for our final implementation of Vec-HT.

Group-Size Micro-Benchmark. Figure 17 depicts the performance of group prefetching with different group sizes by also altering between the optimistic and pessimistic strategy. Overall, we see a performance improvement by increasing the group size, however, this improvement no longer holds after the group size of 64. The results show that selecting a group size of 64 with the optimistic strategy is a reasonable choice.

Hash Memoization Micro-Benchmark. Our last micro-benchmark investigates the effects of memoizing the hash values during the prefetching stage. Figure 18 presents the results of these experiments. In selectivities of 0.1 and 0.5, it is clear that the memorized version performs better than the non-memoized one. With a selectivity of 1, the non-memoized version does better (with a narrow improvement compared to memorized version) for larger hash tables, however, the memoized version is faster for smaller hash tables. Thus, we select the memoized version for Vec-HT.

Relational Inner Join for State-of-the-Art Hash Tables. In these experiments, using the first workload described in Section 7.1, we run a simplified relational inner-join operation using different hash table implementations to measure the performance of each approach.

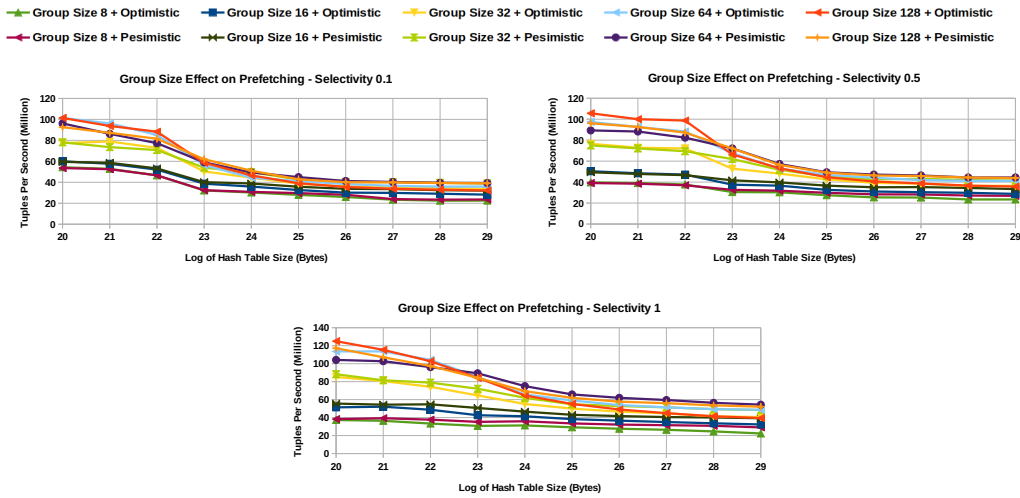

Figure 17 Comparing the performance of different combinations for group size and optimistic/pessimistic approaches for group prefetching. The workload is similar to Figure 15.

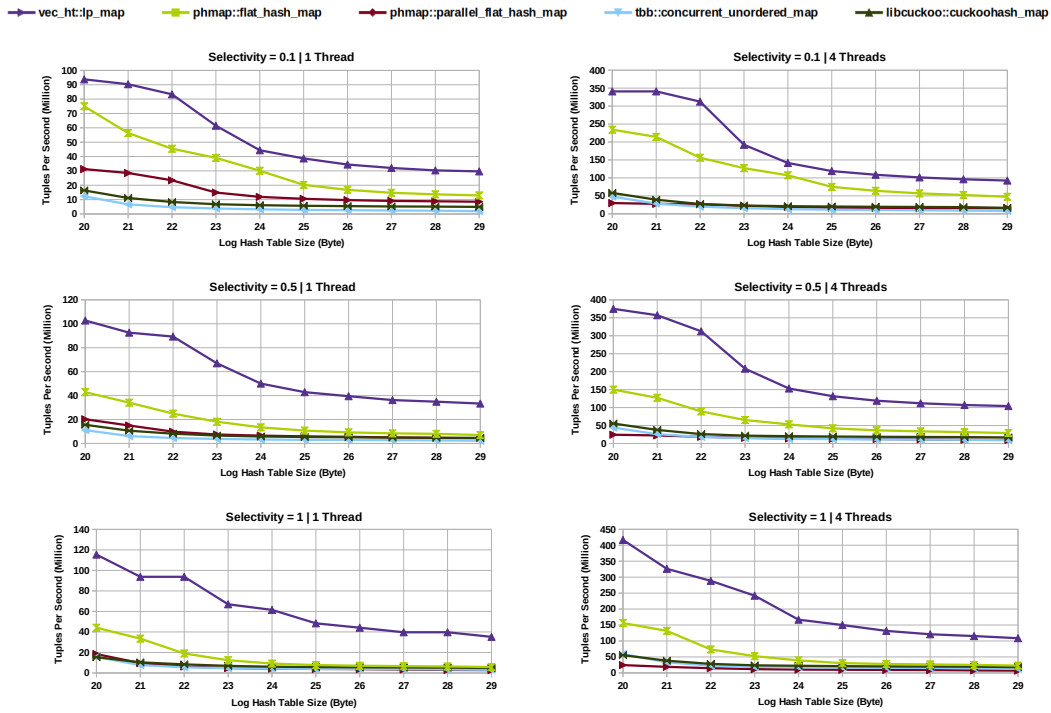

Figure 18 Comparing the performance of different alternatives by focusing on enable/disabled memoization for group prefetching. The workload is similar to Figure 15.

As it is shown in Figure 19, our approach `vec_ht::lp_map` outperforms other approaches irrespective of the build size, join selectivity or concurrency level. It is on average 5× faster on both 1- and 4-cores.

Set Operations Use Case. To show the performance of our approach in set operations, we run experiments on the set intersection and set difference. To run the operations, we iterate over the first set (S1) and look up the values in the other one (S2). Since the hash tables in our experiments (except `tbb::concurrent_unordered_map`) do not support parallel iterations, to have a more comprehensive benchmark, we keep S1 in the vector format and only make a hash table for S2. For the set-difference operation, we use an implementation similar to Section 5.2. Figure 20 depicts the results of our set experiments. In these experiments, using a fixed size for S1 and S2 and a fixed density for S1, we observe the changes in the run time of each competitor while increasing the density of S2.

27:22 An Efficient Vectorized Hash Table for Batch Computations

■ **Figure 19** The number of tuples processed per second (higher is better) for a simplified relational inner-join operation with a probe size of 1,500,000 over an increasing build-side size. Charts on each side, represent the results for the join selectivities of 0.1, 0.5, and 1 on 1 or 4 threads.

In the set-difference experiments, our approach outperforms the others with an average of $11\times$ speedup on 1 and 4 cores. Similarly, in set intersections, our approach performs better than the others excluding `phmap::flat_hash_map`. By excluding `phmap`, the proposed approach is on average $6\times$ and $5\times$ faster than the others on 1 and 4 cores, respectively. For the small S_2 sizes, when the log of S_2 density is less than or equal to -4 , the hash table can still be fitted into the L3 cache, thus the benefit of using our prefetched approach is not promising and the overall performance is near to what `phmap::flat_hash_map` offers. However, after passing that size limit, `phmap::flat_hash_map` run time goes higher while our approach keeps its good performance thanks to software prefetching.

Vector Operations Use Case. In Figure 21, the results of running experiments on vector inner-product (cf. Section 5.3) and pair-wise multiplication are shown. Similar to the set operations, here we keep V_1 in the vector format and embed V_2 into a hash table. The experiment parameters are also set to the values that we had in the set experiments. In both vector operations, our approach is still faster than the alternatives. However, since the scenario of these two vector operations is very similar to the set intersection, we see similar behaviour in the performance of our approach versus `phmap::flat_hash_map`. We explained the reason behind this behaviour in the set experiments. The experiments on set and vector operations show that our approach is a great choice when we deal with large amounts of data; while the performance of other approaches degrades with increasing the hash table size, our approach maintains good performance even for heavier workloads.

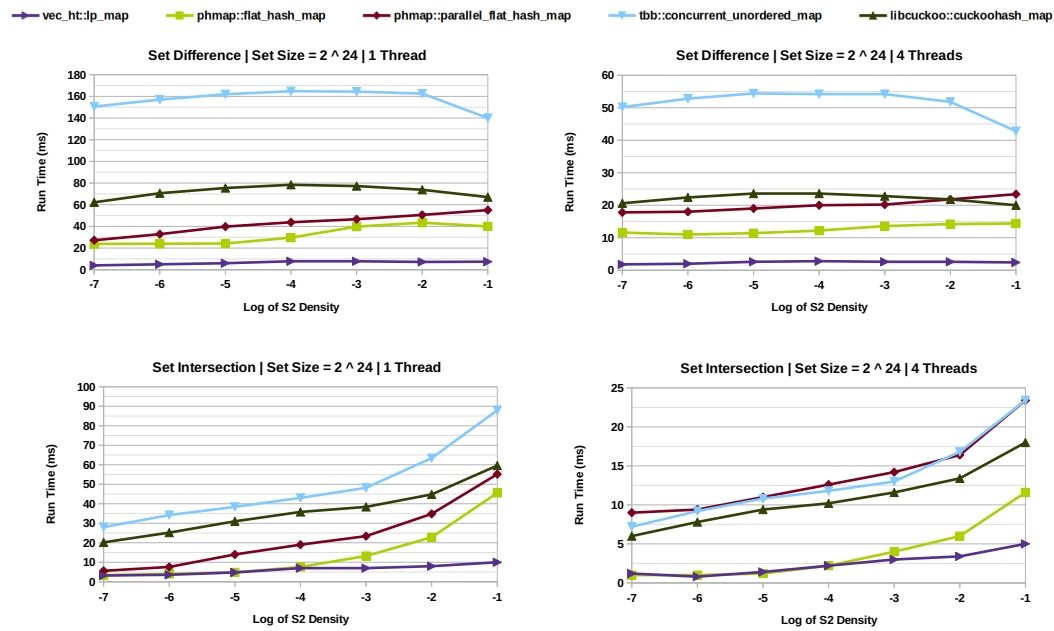

Figure 20 The run time (lower is better) for the set difference and intersection operations by varying the density of the second set on 1 and 4 threads. For both operands (S1 and S2), the size is 2^{24} . For S1, the density is set to 2^{-6} .

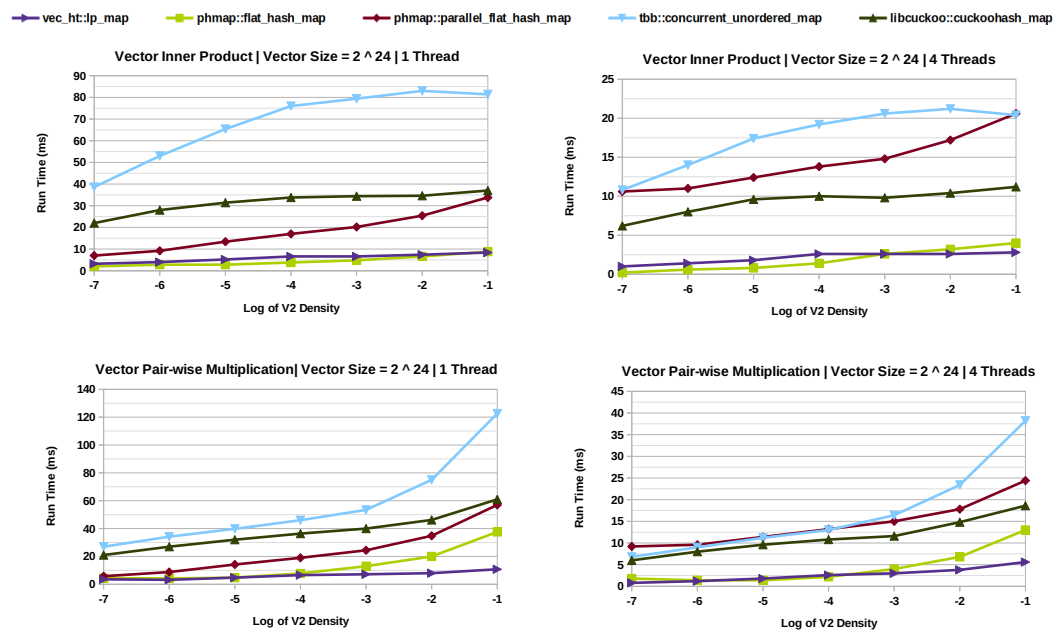

Figure 21 The run time (lower is better) for the vector inner-product and pair-wise multiplication operations by increasing the density of the second vector on 1 and 4 threads. For both operands (V1 and V2), the size is 2^{24} . For V1, the density is set to 2^{-6} .

■ **Table 2** Modified TPC-H queries we used in the experiments.

Query	SQL Code
Q4	<pre>select o_orderpriority, count(*) from orders where exists (select * from lineitem where l_orderkey=o_orderkey and l_commitdate<l_receiptdate) group by o_orderpriority</pre>
Q8	<pre>select o_year, sum(case when nation = 'BRAZIL' then volume else 0 end) / sum(volume) from (select extract(year from o_orderdate) as o_year, l_extendedprice * (1 - l_discount) as volume, n2.n_name as nation from part, supplier, lineitem, orders, customer, nation n1, nation n2, region where p_partkey = l_partkey and s_suppkey = l_suppkey and l_orderkey = o_orderkey and o_custkey = c_custkey and c_nationkey = n1.n_nationkey and n1.n_regionkey = r_regionkey and r_name = 'AMERICA' and s_nationkey = n2.n_nationkey and o_orderdate between date '1995-01-01' and date '1996-12-31') as all_nations group by o_year</pre>
Q12	<pre>select l_shipmode, sum(case when o_orderpriority = '1-URGENT' or o_orderpriority = '2-HIGH' then 1 else 0 end) , sum(case when o_orderpriority <> '1-URGENT' and o_orderpriority <> '2-HIGH' then 1 else 0 end) from orders, lineitem where o_orderkey = l_orderkey group by l_shipmode</pre>

Analytical Queries Use Case. As the last set of experiments, we use the TPC-H benchmark and dataset. The queries we consider satisfy three criteria. (1) The join-build side of the query must result in a large hash table. (2) The join-probe part of the query must be a time-consuming part of it. (3) The build-side hash table can only have integers as keys and values. Based on these criteria we selected a modified version of Q4, Q8, and Q12 (cf. Table 2). Then, we implemented a manually fine-tuned version of them in C++ by taking the query plans of HyPer [4] and using the code generator of SDQL.py [24]. We used `phmap::flat_hash_map` as the competitor for `vec_ht::lp_map`, because it is the hash table of choice behind existing query processing systems that use open source hash tables [24, 28]. We alternate between these two hash tables only in the most time-consuming join operation in the query.

Table 3 shows the results of this benchmark. Our approach performs better than its alternative almost in all these queries. However, in the 4-core setup of Q4, it results in an 11% total performance degradation. In this case, the speedup of probing is still very high (1.33×) but the lack of parallel insertions in Vec-HT resulted in a faster hash table building by the competitor, which is a promising direction for the future.

Finally, it is worth mentioning that the speedups of using Vec-HT for the original Q8 (without modification on the build side to make the hash table larger) are 0.9× and 0.85× for 1- and 4-core respectively. This means that Vec-HT is a perfect choice whenever we are facing a large volume of data resulting in the creation of a large hash table.

■ **Table 3** Performance improvements of using `vec_ht::lp_map` instead of `phmap::flat_hash_map` in the probes of the most time-consuming hash-join of TPC-H queries 4, 8, and 14.

	TPC-H Query					
	Q4		Q8		Q12	
	Total	Probe	Total	Probe	Total	Probe
1-Core Run Time <code>vec_ht</code> (ms)	246	102	354	321	260	236
1-Core Run Time <code>phmap</code> (ms)	487	261	512	465	718	533
1-Core Total Run Time Speedup	1.98×	2.56×	1.44×	1.45×	2.76×	2.25×
4-Core Run Time <code>vec_ht</code> (ms)	151	29	105	83	102	82
4-Core Run Time <code>phmap</code> (ms)	134	38	140	107	395	149
4-Core Total Run Time Speedup	0.89×	1.33×	1.34×	1.29×	3.86×	1.82×

8 Conclusion and Future Work

In this paper, we presented Vec-HT, a vectorized hash table that offers fast batch lookups backed by multi-threading, prefetching, and usage of SIMD-vectorization methods. We presented the design decisions for the structure, API, and the optimizations for high-performance batch hash table implementations. We showed the usefulness of our approach by implementing a handful of use cases using Vec-HT. Finally, by running a set of micro-benchmarks on various use case scenarios, we showed that our proposed design performs faster than the state-of-the-art approaches.

In the future, we aim to improve this approach by providing the support for complex keys and values and parallel iterations over such batch hash tables. It is also interesting to apply the current optimizations (especially vertical vectorization) to the other hashing schemes such as Cuckoo [18] and Robinhood [10] hashing. Another promising direction is to use the batch API as a wrapper for traditional hash tables and ordered dictionaries [27] to allow programmers to benefit from the batch processing offered by this API. Finally, one can integrate other SIMD query operators (e.g., selection [19, 16]) and use Vec-HT for a wider range of database analytical queries as well as sparse tensor processing.

Abstract

This paper introduces hinted dictionaries for expressing efficient ordered sets and maps functionally. As opposed to the traditional ordered dictionaries with logarithmic operations, hinted dictionaries can achieve better performance by using cursor-like objects referred to as hints. Hinted dictionaries unify the interfaces of imperative ordered dictionaries (e.g., C++ maps) and functional ones (e.g., Adams' sets). We show that such dictionaries can use sorted arrays, unbalanced trees, and balanced trees as their underlying representations. Throughout the paper, we use Scala to present the different components of hinted dictionaries. We also provide a C++ implementation to evaluate the effectiveness of hinted dictionaries. Hinted dictionaries provide superior performance for set-set operations in comparison with the standard library of C++. Also, they show a competitive performance in comparison with the SciPy library for sparse vector operations.

1 Introduction

Sets and maps are two essential collection types for programming used widely in data analytics [12]. The underlying implementation for both are normally based on 1) hash tables or 2) ordered data structures. The former provides (average-case) constant-time lookup, insertion, and deletion operations, while the latter performs these operations in a logarithmic time. The trade-off between these two approaches has been heavily investigated in systems communities [7].

An important class of operations are those dealing with two collection types, such as set-set-union or the merge of two maps. One of the main advantages of hash-based implementations is a straightforward implementation for such operations with a linear computational complexity. However, naïvely using ordered dictionaries results in an implementation with a computational complexity of $O(n \log(n))$.

Motivating Example. The following C++ code computes the intersection of two sets, implemented by `std::unordered_set`, a hash-table-based set:

```
std::unordered_set<K> result;
for(auto& e : set1) {
    if(set2.count(e))
        result.emplace(e);
}
```

28:2 Hinted Dictionaries: Efficient Functional Ordered Sets and Maps

However, the same fact is not true for ordered data structures; changing the dictionary type to `std::set`, an ordered implementation, results in a program with $O(n \log(n))$ computational complexity. This is because both the `count` (lookup) and `emplace` (insertion) methods have logarithmic computational complexity.

As a partial remedy, the standard library of C++ provides an alternative insertion method that can take linear time, if used appropriately. The `emplace_hint` method takes a hint for the position that the element will be inserted. If the hint correctly specifies the insertion point, the computational complexity will be amortized to constant time.¹

```
std::set<K> result;
auto hint = result.begin();
for(auto& e : set1) {
    if(set2.count(e))
        hint = result.emplace_hint(hint, e);
}
```

However, the above implementation still suffers from an $O(n \log(n))$ computational complexity, due to the logarithmic computational complexity of the lookup operation (`count`) of the second set. Thanks to the orderedness of the second set, one can observe that once an element is looked up, there is no longer any need to search its preceding elements at the next iterations. By leveraging this feature, we can provide a *hinted* lookup method with an amortized constant run-time.

Hinted Data Structures. The following code, shows an alternative implementation for set intersection that uses such hinted lookup operations:

```
hinted_set<K> result;
hinted_set<K>::hint_t hint = result.begin();
for(auto& e : set1) {
    hinted_set<K>::hint_t hint2 = set2.seek(e);
    if(hint2.found)
        hint = result.insert_hint(hint, e);
    set2.after(hint2);
}
```

The above *hinted set* data-structure enables faster insertion and lookup by providing a cursor through a *hint object* (of type `hint_t`). The `seek` method returns the hint object `hint2` pointing to element `e`. Thanks to the invocation of `set2.after(hint2)`, the irrelevant elements of `set2` (which are smaller than `e`) are no longer considered in the next iterations. The expression `hint2.found` specifies if the element exists in `set2` or not. Finally, if an element exists in the second set (specified by `hint2.found`), it is inserted into its correct position using `insert_hint`.

This paper introduces *hinted dictionaries*, a class of functional ordered data structures. The essential building block of hinted dictionaries are *hint objects*, that enable faster operations (than the traditional $O(\log n)$ complexity) by maintaining a pointer into the data structure.

Related Work. The existing work on efficient ordered dictionaries can be divided into two categories. First, in the imperative world, there are C++ ordered dictionaries (e.g., `std::map`) with *limited* hinting capabilities only for insertion through `emplace_hint`, but not for deletion and lookup, as observed previously.

¹ https://www.cplusplus.com/reference/set/set/emplace_hint/

Second, from the functional world, Adams' sets [1] provide efficient implementations for set-set operators. Functional languages such as Haskell have implemented ordered sets and maps based on them for more than twenty years [15]. Furthermore, it has been shown [4] that Adams' maps can be used to provide a parallel implementation for balanced trees such as AVL [2], Red-Black [3], Weight-Balanced [9], and Treaps [11]. However, Adams' maps do not expose any hint-based operations to the programmer. At first glance, these two approaches seem completely irrelevant to each other.

Contributions. *The key contribution of this paper is hinted dictionaries, an ordered data structure that unifies the techniques from both imperative and functional worlds.* The underlying representation for hinted dictionaries can be sorted arrays, unbalanced trees, and balanced trees by sharing the same interface. In our running example, alternative data-structure implementations can be easily provided by simply changing the type signature of the hinted set from `hinted_set` to another implementation, without modifying anything else.

This paper is organized as follows:

- We present monoid dictionaries, the most general form of dictionaries without any orderedness constraint on keys (Section 2). Such dictionaries subsume sets and maps and provide a restricted form of iterations in the form of map-reduce for computing associative and commutative aggregations over them (Section 2.4).
- Afterwards, we show ordered dictionaries, a more restricted class of dictionaries where the keys need to be ordered (Section 3). The iterations over these dictionaries are more general than monoid dictionaries, by relaxing the commutative requirement and providing associative aggregations. We show two particular interfaces for implementing associative aggregations in Section 3.3.
- We introduce hinted dictionaries, an implementation technique for ordered dictionaries (Section 4). A key ingredient of hinted dictionaries are the hint objects. In Section 4.2 we show operations over hint objects.
- Hinted dictionaries provide both sequential and parallel implementations for associative aggregations (Section 5).
- In order to support binary operations over dictionaries, hinted dictionaries provide a bulk operation interface (Section 6). The design choice for these bulk operations results in a completely different instantiation of hinted dictionaries. We present two implementations in this paper: insert-based (Section 6.1) and join-based (Section 6.2) hinted dictionaries.
- We present the implementation for hint objects in Section 7. More specifically, we present *focus-based hints*, hint objects focusing on a particular position in the dictionary (Section 7.1), and the corresponding focus-based hinted dictionaries (Section 7.2).
- We present the concrete implementations for hinted dictionaries in Section 8. More specifically, we show the implementation of ordered dictionaries using sorted arrays (Section 8.1), unbalanced trees (Section 8.2), and balanced trees (Section 8.3). Then, we connect all the components together in Section 8.4.
- Finally, we provide a C++ prototype for hinted dictionaries and discuss the challenges for tuning its performance in Section 9.1. We compare its performance with the standard library of C++ for set-set and sparse vector operations and show its asymptotic improvements in Section 9.2. For the latter workload we show its competitive performance with SciPy.

Throughout the paper, we use Scala to present the different components. The main ideas behind hinted dictionaries, however, can be implemented in other object-oriented and functional languages with support for generic types and lambda expressions (e.g., Haskell,

```

trait Monoid[V] {
  def op(e1: V, e2: V): V
  def zero: V
}

trait Equalable[K] {
  def equiv(e1: K, e2: K): Boolean
}

```

■ **Figure 1** The interface for monoid and equalable type classes.

OCaml, Java, Julia, Rust, and C++), as demonstrated in Section 9.1. The former is required for implementing the structural interfaces (e.g., `Monoid[T]`) and generic dictionaries (e.g., `Dict[K, V]`), while the latter is essential for implementing higher-order functions (e.g., `mapReduce`) in hinted dictionaries.

2 Monoid Dictionary

In this section, we present the most general form of dictionaries that we support; the ones where the values form a monoid structure, referred to as monoid dictionaries. We start by defining monoid and equalable values. Afterwards, we introduce the interface for monoid dictionaries. Finally, we show the class of iterations that can be expressed over them.

2.1 Monoid

A monoid is defined as a set of values V , with a binary operator `op` and a `zero` element, such that the following properties hold:

- **Associativity:** For all elements a, b, c in V : $\text{op}(\text{op}(a, b), c) = \text{op}(a, \text{op}(b, c))$
- **Identity Element:** For all elements a in V : $\text{op}(a, \text{zero}) = \text{op}(\text{zero}, a) = a$

An important class of monoids, supports the following additional axiom:

- **Commutativity:** For all elements a, b in V : $\text{op}(a, b) = \text{op}(b, a)$

Such monoids are referred to as *commutative monoids*. Important examples of commutative monoids are boolean values under conjunction and disjunction, integer numbers under multiplication and addition. Matrices of real numbers are commutative monoids under addition, but are non-commutative monoids under multiplication.

The Scala interface for monoid structures is shown in Figure 1. This interface can be thought of as a type class, where providing concrete implementations for this interface results in type class instances.

2.2 Equalable

In order to perform lookups over dictionaries, one requires to check for the equality of keys. This is achieved by the `Equalable` type class (Figure 1). Each type class instance provides the implementation strategy for checking the equivalence between two keys by overriding the `equiv` method.

2.3 Dictionary Interface

Given the key type K with an `Equalable[K]` constraint, and the value type V with a `Monoid[V]` constraint, one can define the interface `Dict[K, V, D]` for a dictionary type D (Figure 2).

```

trait Dict[K, V, D] {
  implicit val equ: Equalable[K]
  implicit val mon: Monoid[V]
  def find(dict: D, key: K): V
  def insert(dict: D, key: K, value: V): D
  def delete(dict: D, key: K): D
  def size(dict: D): Int
  def count(dict: D): Int
  def empty(): D
  def isEmpty(dict: D): Boolean
  final def single(key: K, value: V): D = insert(empty(), key, value)
}

```

■ **Figure 2** The interface for (monoid) dictionaries.

The specification of the methods of monoid dictionaries is as follows:

- **find**: performs a look up for the associated value with **key** in the dictionary **dict**. If the key does not exist in the dictionary, the identity element of the monoid structure over **V** is returned (**mon.zero**).
- **insert**: first performs a look up for the associated value with **key**. If the key does not exist, the pair of **key** and **value** is inserted in the dictionary. If the key already exists, the associated value, **old_value**, is updated by applying the binary operator of monoid to **old_value** and **value** (**mon.op(old_value, value)**). As the result, the updated dictionary is returned.
- **delete**: returns a new dictionary where **key** and its associated value is removed.
- **size**: returns the number of key-value pairs in the dictionary.
- **count**: returns the number of key-value pairs with non-zero values in the dictionary.
- **empty**: returns an empty dictionary of type **D** with keys and values of type **K** and **V**.
- **isEmpty**: check if the given dictionary is empty or not.
- **single**: returns a singleton dictionary containing the pair of **key** and **value**. This can be implemented by inserting into an empty dictionary.

By providing appropriate monoid structures for values, one can instantiate different collections from monoid dictionaries. As an example, using boolean values results in sets, using natural numbers results in bags, and using **Option** types results in maps.²

2.4 Iterations over Dictionaries

Next, we introduce the constructs required for performing iterations over dictionaries. As monoid dictionaries do not enforce any order over the keys, the iterative computation over them must be order-agnostic. Otherwise, the iterative computation results in different outcomes depending on the underlying organization of dictionary keys.

We provide the **mapReduce** method for expressing sound iterations over monoid dictionaries. This method performs map-reduce operations by starting from the initial element **z**, computing a transformation between key-value pairs to element of result type by **map**, and reducing the result elements by **red**. To ensure the soundness of aggregate computations, the **red** binary operator must be both commutative and associative.

² Using **Option** types incurs boxing and unboxing costs that is avoided by libraries such as **scala-unboxed-option** [5] for Scala and **unpacked sums** in GHC for Haskell [8]

```

trait DictIteration[K, V, D] { this: Dict[K, V, D] =>
  // precondition: 'red' must be commutative and associative
  def mapReduce[R](dict: D, z: R, map: (K, V) => R, red: (R, R) => R): R
  // precondition: 'R' must form a commutative monoid
  def aggregate[R: Monoid](dict: D, map: (K, V) => R): R = {
    val monR = implicitly[Monoid[R]]
    mapReduce[R](dict, monR.zero, map, monR.op)
  }
  def size(dict: D): Int =
    aggregate[Int](dict, (k, v) => 1)
  def count(dict: D): Int =
    aggregate[Int](dict, (k, v) => if(v == monR.zero) 0 else 1)
}

```

■ **Figure 3** The interface for iterations on dictionaries.

As an alternative interface, we provide `aggregate` with a monoid constraint over the result type. This method can be implemented in terms of `mapReduce` (cf. Figure 3). To do so, we need to use the zero element and the binary operator of an instance of the type class `Monoid[R]`. The Scala type system can provide an instance for type class `T` by using `implicitly[T]` [10]. In this case, `implicitly[Monoid[R]]` returns an instance of type `Monoid[R]`, where its zero element (`monR.zero`) and binary operator (`monR.op`) are passed as the initial value and reduction functions of `mapReduce`, respectively. Note that for sound aggregations, the result type should form a commutative monoid.

One can easily provide an implementation for `size` using the `aggregate` method. As we are only interested in counting the number of key-value pairs, it is sufficient to transform them to 1. Note that `size` returns the number of all pairs in the dictionary, while `count` only returns the number of pairs containing non-zero values.

For a cleaner presentation, we use the `DictIteration` interface to define the iteration-based methods (cf. Figure 3). This way, we avoid a large interface for `Dict`. To do so, we need to make sure that all classes and interfaces that extend `DictIteration`, also extend the `Dict` interface. This is achieved by ascribing the type of `this` object of the `DictIteration` interfaces with `Dict[K, V, D]`. Such dependency injection technique is known as *cake pattern* in the Scala programming language. It is important to note that using this technique is not essential; we can implement this code in a language without this feature by removing the interface for `DictIteration` altogether. Instead, all the method definitions of `DictIteration` are added to `Dict`.

3 Ordered Dictionary

In this section we present ordered dictionaries, the keys of which should follow a total order. First, we define the required interface for orderable keys in Section 3.1. Then, we introduce the interface for ordered dictionaries including bulk operations of them in Section 3.2. Finally, similar to monoid dictionaries, we show the class of iterations expressible over ordered dictionaries in Section 3.3.

3.1 Orderable

In this section, we introduce the interface required for the keys of ordered dictionaries (cf. Figure 4). In ordered dictionaries, apart from the need to check for the equality of two keys (using `equiv` derived from `Equalable`), a total order must also be provided.

```

trait Orderable[K] extends Equalable[K] {
  def compare(e1: K, e2: K): Int
  def max: K
  def min: K
  final def lt(e1: K, e2: K): Boolean = compare(e1, e2) < 0
  final def gt(e1: K, e2: K): Boolean = compare(e1, e2) > 0
  final def lteq(e1: K, e2: K): Boolean = compare(e1, e2) <= 0
  final def gteq(e1: K, e2: K): Boolean = compare(e1, e2) >= 0
  final def equiv(e1: K, e2: K): Boolean = compare(e1, e2) == 0
}

```

■ **Figure 4** The interface for orderable.

The `compare` method is sufficient to provide the total order information. If its return value is a positive number, the first element is greater than the second value, and for a negative number, vice versa. Otherwise, if the return value is zero, this means that both elements are equal. All comparison operators can be implemented using the `compare` method, as can be seen in Figure 4.

As we are only interested in finite dictionaries, one can provide an upper bound and lower bound for keys. These values are specified using `max` and `min` in the `Orderable` interface. We will see in Section 7.1 how upper bounds can be used for implementing hint objects.

3.2 Ordered Dictionary Interface

The interface of ordered dictionaries is very similar to monoid dictionaries. The `Equalable` type class instance is the same as the one used for `Orderable`. This is because the `Orderable` interface subsumes the interface of `Equalable` by using inheritance.

The additional methods provided for ordered dictionaries are as follows:

- `toList`: this method converts ordered dictionaries into a list of type `List[(K, V)]`.³
- `append`: for two ordered dictionaries `left` and `right`, where all the keys of `left` are less than the keys of `right`, this method returns an ordered dictionary containing the elements of both dictionaries.
- `join`: given two ordered dictionaries `left` and `right` and a key-value pair `key` and `value`, this method creates an ordered dictionary containing the elements of `left` and `right` as well as the pair of `key` and `value`. In this method, all the keys of `left` must be less than `key`, and all the keys of `right` must be more than `key`.

Note that the mentioned preconditions for the last two methods are necessary to preserve the dictionary's order, and violating any of them makes hinted dictionaries not work. Furthermore, these two methods are bulk operations and thus are defined in a separate `OrderedDictBulkOps` interface (Figure 5) following the cake pattern. These methods are critical for providing different concrete ordered dictionary implementations, as will be observed in Section 6.

3.3 Iterations over Ordered Dictionaries

As opposed to monoid dictionaries, ordered dictionaries do not need the reduction function to be commutative. This is because even with non-commutative reductions, ordered dictionaries will result in a deterministic order for key-value pairs.

³ Unordered dictionaries cannot implement `toList` as there is no deterministic order for the key-value pairs.

```

trait OrderedDict[K, V, D] extends Dict[K, V, D] {
  implicit val ord: Orderable[K]
  implicit val equ: Equalable[K] = ord
  def toList(dict: D): List[(K, V)]
}

trait OrderedDictBulkOps[K, V, D] { this: OrderedDict[K, V, D] =>
  // precondition: keys(left) < keys(right)
  def append(left: D, right: D): D
  // precondition: keys(left) < k < keys(right)
  def join(left: D, key: K, value: V, right: D): D
}

```

■ **Figure 5** The interface for ordered dictionaries and bulk operations over them.

The `toList` method can be implemented by `mapReduce` and `aggregate` methods. Figure 6 shows its implementation using `aggregate`; it is sufficient to map each of the key-value pairs into a singleton list. This requires the following instance of `Monoid[List[T]]`:

```

implicit def MonoidList[T] = new Monoid[List[T]] {
  def op(e1: List[T], e2: List[T]): List[T] = e1 ++ e2
  def zero: List[T] = Nil
}

```

Here, the binary operator is list append (`++`) and the zero element is the empty list (`Nil`). The `toList` method returns the result of appending all these singleton lists.

3.3.1 Sequential Iterations

Similar to functional lists in functional languages, ordered dictionaries also provide a `foldLeft` method for performing accumulating computations over their elements from left to right. This method is provided in the `OrderedDictFoldLeft` interface (cf. Figure 6).

The `mapReduce` method can be implemented using `foldLeft` by passing the initial value and defining the accumulating function as applying the `red` function to the previous state `s` and the result of `map(k, v)`.

3.3.2 Parallel Iterations

Thanks to the associative nature of reduction functions, there is no need to perform aggregations only sequentially from left to right. Instead, one can perform aggregations in a tree-structured manner, which is more parallel-friendly.

The `foldTree` method provided in the `OrderedDictFoldTree` interface (cf. Figure 6) is responsible for computing parallel iterations. This is provided by performing a top down traversal over the logical tree representation. Similar to `foldLeft`, this method accepts an initial state (`z`). At each stage, it computes the stage to be passed to each of the subtrees. The `op` method produces a triple of elements when applied to the current key-value pair and the previous state. The first two elements of this triple are the states to be passed to each of subtrees. The last element corresponds to a hidden state of type `M`. This hidden state is used after the aggregation for subtrees are computed. The `comb` method applies this hidden state alongside with the current key-value and the states return by the subtrees and computes the next state.

```

trait OrderedDictIteration[K, V, D] extends DictIteration[K, V, D] {
  this: OrderedDict[K, V, D] =>
  // precondition: 'red' should only be associative
  def mapReduce[R](dict: D, z: R, map: (K, V) => R, red: (R, R) => R): R
  def toList(dict: D): List[(K, V)] =
    aggregate[List[(K, V)]](dict, (k, v) => List((k, v)))
}

trait OrderedDictFoldLeft[K, V, D] extends OrderedDictIteration[K, V, D] {
  this: OrderedDict[K, V, D] =>
  def foldLeft[R](dict: D, z: R, op: (R, K, V) => R): R
  override def mapReduce[R](dict: D, z: R, map: (K, V) => R, red: (R, R) => R): R =
    foldLeft[R](dict, z, (s, k, v) => red(s, map(k, v)))
}

trait OrderedDictFoldTree[K, V, D] extends OrderedDictIteration[K, V, D] {
  this: OrderedDict[K, V, D] =>
  def foldTree[R, M](dict: D, z: R, op: (K, V, R) => (R, R, M),
    comb: (K, V, M, R, R) => R): R
  override def mapReduce[R](dict: D, z: R, map: (K, V) => R, red: (R, R) => R): R =
    foldTree[R, Unit](dict, z, (k, v, s) => (s, s, ()),
      (k, v, _, s1, s2) => red(red(s1, map(k, v)), s2))
}

```

■ **Figure 6** The interface for iterations over ordered dictionaries. The `foldLeft` method corresponds to computing aggregations sequentially and `foldTree` method is a parallel-friendly aggregate computation strategy.

The `mapReduce` method can be implemented using `foldTree` as well. As the `op` method, we return the previous state `s` to both subtrees. As the `comb` method, we apply the reduction method twice. The first application involves the return state of left subtree (`s1`) and the mapping of key-value pair `map(k, v)`. The second application is over the result of the previous reduction and the state of the right subtree (`s2`).

Note that for implementing `mapReduce` there was no hidden state required, and thus the unit value `()` with unit type `Unit` was provided. We will see cases where this hidden state will be required in Section 5.2.1.

By carefully keeping the value of aggregation in the ordered dictionary, one can provide a more efficient implementation for `mapReduce`. This is similar to the idea of augmented trees, and has already been investigated in Augmented Maps [17].

4 Hinted Dictionary

In this section, we introduce hinted dictionaries, an implementation strategy for ordered dictionaries. First, we present the interface of hinted dictionaries in Section 4.1. Then, we show the interface for hint objects in Section 4.2.

4.1 Hinted Dictionary Interface

Hinted dictionaries inherit all the methods of both monoid dictionaries and ordered dictionaries. Additionally, they provide the following methods:

- **begin**: returns the hint object corresponding to the beginning of dictionary. This method is useful for accessing the head of an ordered dictionary.

28:10 Hinted Dictionaries: Efficient Functional Ordered Sets and Maps

```
trait HintedDict[K, V, D, H] extends OrderedDict[K, V, D] {
  def begin(dict: D): H
  def middle(dict: D): H
  def end(dict: D): H
  def isEnd(dict: D, hint: H): Boolean
  def next(dict: D, hint: H): H
  def seek(dict: D, key: K): H
  // precondition: current(hint)._1 == key
  def findHint(dict: D, hint: H, key: K): V
  // precondition: current(hint)._1 == key
  def insertHint(dict: D, hint: H, key: K, value: V): D
  // precondition: current(hint)._1 == key
  def deleteHint(dict: D, hint: H, key: K): D
  def insert(dict: D, key: K, value: V): D =
    insertHint(dict, seek(dict, key), key, value)
  def delete(dict: D, key: K): D =
    deleteHint(dict, seek(dict, key), key)
  def find(dict: D, key: K): V =
    findHint(dict, seek(dict, key), key)
}
```

■ **Figure 7** The interface for hinted dictionaries.

- **middle**: returns the hint object of the middle of the dictionary. This method is useful for cases that require viewing the dictionary as a tree. For example, it can be used for a binary search where one needs to access the middle of a collection.
- **end**: returns the hint object specifying the end of dictionaries.
- **isEnd**: checks whether the given hint object corresponds to the end of the dictionary. This is useful for terminating an iteration over the hinted dictionary.
- **next**: returns the hint object succeeding the given hint object over the input dictionary.
- **seek**: returns the hint object for the position in the array where **key** would be placed. This means that the preceding elements have smaller keys and succeeding elements have larger keys. In the case that the dictionary contains the **key**, the corresponding hint object is returned.
- **findHint**: returns the associated value with the given key using the provided hint object. As the precondition, the hint should point to the correct position.
- **insertHint**: inserts the given key-value pair to the position provided by the hint object. Similar to the previous method, the hint object assumed to point to the correct position.
- **deleteHint**: deletes the key-value pair corresponding to the input key using the provided hint object. A similar precondition to the previous two methods hold.

By using the **seek** method to compute the correct hint object, one can have an implementation for **find**, **insert**, and **delete** using the corresponding hinted methods. Once hinted dictionaries are supplied with (amortized) constant-time operations for these hinted methods, one can better benefit from their efficiency.

4.2 Hint Operations

The hint objects can be thought as pointers to different locations of an ordered dictionary (cf. Figure 8). Rather than providing a concrete implementation for hint object, we provide an interface for them in Figure 9. We leave the actual implementation for these operators to Section 7.

■ **Figure 8** An example hinted dictionary representation showing the hint objects returned by `begin`, `middle`, and `end` methods and the outcome of `before`, `current`, and `after` over the hint object returned by `middle`.

```

trait HintOps[K, V, D, H] { this: HintedDict[K, V, D, H] =>
  def before(hint: H): D
  def after(hint: H): D
  def current(hint: H): (K, V)
}

```

■ **Figure 9** The interface for operations on hint objects.

The methods for hint objects are as follows:

- **before**: returns the dictionary of elements located before the hint object.
- **after**: returns the dictionary of elements that are after the hint object.
- **current**: returns the key-value pair of the entry of the dictionary that hint object is pointing into. If for a given key, there is no associated value, the identity element of monoid is returned, similar to what was observed for `find`.

As it was shown in Figure 7 we can use these methods to provide preconditions for the hinted dictionary methods. In addition, all the implementations of the `seek` method need to enforce the following post-condition. Assuming the result hint object is `res`, the key of this element should be the same as the input key (`current(res)._1 == key`).⁴ Furthermore, the keys of the dictionary before the result hint object (`before(res)`) should be less than `key`. Similarly, the keys of the dictionary after the result hint object (`after(res)`) should be greater than `key`.

5 Iterations

In this section, we use the methods provided by hinted dictionaries to implement sequential and parallel iterations over them.

5.1 Sequential Implementation

The interface of `HintedDictFoldLeft` containing the implementation for `foldLeft` is presented in Figure 10. Recall that this method is useful for stateful iterations over dictionaries. The initial state is specified by `z`, and the state is updated by applying the function `op` to the current state and key-value pairs.

In order to implement `foldLeft`, we define a recursive function `foldLeftTR` inside it. This function has two input parameters `hint` and `res`, which specify the current hint object and the computed state by iterating up to that hint object. We start by passing the initial

⁴ Note that tuple indexing in Scala starts from 1, and `tup._i` where `i` is an integer shows the `i`th element of the tuple.

28:12 Hinted Dictionaries: Efficient Functional Ordered Sets and Maps

```
trait HintedDictFoldLeft[K, V, D, H] extends OrderedDictFoldLeft[K, V, D]
  with HintedDict[K, V, D, H] with HintOps[K, V, D, H] {
  def foldLeft[R](dict: D, z: R, op: (R, K, V) => R): R = {
    @tailrec def foldLeftTR(hint: H, res: R): R =
      if(!isEnd(dict, hint)){
        val (key, value) = current(hint)
        val next_res = op(res, key, value)
        val next_hint = next(dict, hint)
        foldLeftTR(next_hint, next_res)
      }
      else
        res
    foldLeftTR(begin(dict), z)
  }
}
```

■ **Figure 10** The implementation of sequential (fold-left-based) iterations over hinted dictionaries.

state `z` as the value of `res`, and the beginning of the dictionary as the value of `hint`. The function `foldLeftTR` is recursively called until the hint object does not point to the end of dictionary (`!isEnd(dict, hint)`). At each recursive call, we compute the next state value (`next_res`) by applying `op` to the current state (`res`) and key-value pair and the next hint object (`next_hint`) by `next(dict, hint)`.

Note that the definition of `foldLeftTR` is annotated with `@tailrec`. This means that this function is tail recursive – all recursive calls are appearing as the last statement. This annotation ensures that the Scala compiler can turn this method into imperative `while` loops, which results in better performance by removing the need to increase the stack frame size.

5.1.1 Example: Sparse Vector Inner Product

Figure 11 shows the interface for sparse vectors. A sparse vector `Vec` can be represented as a dictionary from indices to a scalar value `Sca`. In order to support operation such as inner product that involve multiplication over scalar values, we need to define a type class instance for monoid over scalar values under multiplication (specified by `prod`).

An efficient sequential implementation of the inner product is provided in Figure 11. The `foldLeft` method accepts a pair of states containing the result of inner product as well as the rest of the second vector to process. The state is initially set to the monoid identity element (`dict.mon.zero`) and the second vector (`v2`). At each iteration, the `seek` method for the given key is invoked over the remaining part of the second vector. Then, the result of inner product is updated by adding the previous result (`res`) to the outcome of multiplying (`prod.op`) the current value (`v`) with the value specified by the hint object (`current(hint)._2`). Note that in the case that the second vector does not have any elements at index `k`, the specified value by its hint object would be zero (`dict.mon.zero`). Finally, the rest of the second vector is computed by taking only the elements of dictionary happening after the hint object (`after(hint)`).

5.2 Parallel Implementation

The `foldTree` method can also be used for performing stateful iterations over hinted dictionaries. As opposed to `foldLeft`, this method can perform the computation in a divide-and-conquer manner. Figure 12 demonstrates the process of applying `foldTree` over a

```

trait SparseVectorOps[Sca, Vec] {
  implicit val prod: Monoid[Sca]
  def inner(v1: Vec, v2: Vec): Sca
}

trait SparseVectorFoldLeftOps[Sca, Vec, H] extends SparseVectorOps[Sca, Vec] {
  val dict: HintedDict[Int, Sca, Vec, H]
  val dictFolding: OrderedDictFoldLeft[Int, Sca, Vec]
  val hintOps: HintOps[Int, Sca, Vec, H]
  import dict._
  import dictFolding._
  import hintOps._
  def inner(v1: Vec, v2: Vec): Sca =
    foldLeft[(Sca, Vec)](v1, (dict.mon.zero, v2), (s, k, v) => {
      val (res, v2p) = s
      val hint = seek(v2p, k)
      dict.mon.op(res, prod.op(v, current(hint)._2)) -> after(hint)
    })._1
}

```

■ **Figure 11** The implementation of the inner product of two sparse vectors using sequential iteration.

■ **Figure 12** The process of executing `foldTree` on a logical tree view of an ordered dictionary. The recursive invocations of `foldTree` on the two sub-trees can be evaluated in parallel.

hinted dictionary viewed as a tree. The divide phase involves recursively applying `foldTree` to the left and right subtrees, where the initial state for each recursive call is computed using the function `op`. The conquer phase uses the function `comb` to combine the results of recursive calls to compute the output state of the entire tree.

The interface of `HintedDictFoldTree` provides the implementation for `foldTree` using hinted dictionaries (cf. Figure 13). If the input dictionary is empty the initial value is returned. Otherwise, the following steps are performed. First, the hint object returned by `middle` is used to retrieve the key-value pairs in the middle of the dictionary. The `op` function is applied to this key-value pair and the previous state `z`. This results in the initial state of the left and right sub-trees (`zLeft` and `zRight`) as well as the hidden state (`hidden`). The

28:14 Hinted Dictionaries: Efficient Functional Ordered Sets and Maps

```
trait HintedDictFoldTree[K, V, D, H] extends OrderedDictFoldTree[K, V, D]
  with HintedDict[K, V, D, H] with HintOps[K, V, D, H] {
  def foldTree[R, M](dict: D, z: R, op: (K, V, R) => (R, R, M),
    comb: (K, V, M, R, R) => R): R =
    if(isEmpty(dict)) z
    else {
      val hint = middle(dict)
      val (key, value) = current(hint)
      val (zLeft, zRight, hidden) = op(key, value, z)
      val resLeft = foldTree(before(hint), zLeft, op, comb)
      val resRight = foldTree(after(hint), zRight, op, comb)
      comb(key, value, hidden, resLeft, resRight)
    }
}
```

■ **Figure 13** The implementation of parallel (fold-tree-based) iterations over hinted dictionaries.

`foldTree` method is recursively invoked for both left and right sub-trees (`before(hint)` and `after(hint)`) using their corresponding initial states. These two invocations are independent of each other and can be run in parallel. Finally, the key-value pair, the hidden state, and the results of recursive calls (`resLeft` and `resRight`) are combined by applying the `comb` function.

Next, we show example usages of these iteration constructs.

5.2.1 Example: Set-Set Union

A set of type `S`, consisting elements of type `K` can be expressed as a dictionary with keys of type `K` and values of type `Boolean`. Hence, they can also be expressed using hinted dictionaries.

Figure 14 provides the interface for set-set operations such as `union`, `intersect`, and `difference`. For the sake of brevity here we only show the implementation for `union` using `foldTree`. The `foldLeft`-based implementation and the one for `intersect` and `difference` can be similarly obtained.

The result type of `foldTree` (cf. Figure 14) is the set type `S`, and the type of its hidden state is the hint type `H`. The iteration is over `set1` with the initial state of `set2`. At each stage, the `seek` method looks for the key `k` in the set specified by its current state `s`. As the state for the left and right sub-trees, the dictionaries with preceding and succeeding elements (`before(hint)` and `after(hint)`) are provided, and as the hidden state the hint object `hint` is returned. For the combine operation, the state returned by the left sub-tree (`s1`), the current key-value pair with update value (`k` and `mon.op(v, current(hidden)._2)`), and the state returned by the right sub-tree (`s2`) are joined.

6 Bulk Operations

In this section, we provide two design decisions for implementing bulk operations. The first design is insert-based hinted dictionaries, where the bulk operations are derived from the implementation for the hinted insertion method (Section 6.1). The second design revolves around using the `join` method as the central operator (Section 6.2).

```

trait SetSetOps[S] {
  def union(set1: S, set2: S): S
  def intersect(set1: S, set2: S): S
  def difference(set1: S, set2: S): S
}

trait SetSetFoldTreeOps[K, S, H] extends SetSetOps[S] {
  val dict: HintedDict[K, Boolean, S, H]
  val dictFolding: OrderedDictFoldTree[K, Boolean, S]
  val hintOps: HintOps[K, Boolean, S, H]
  val dictDictOps: OrderedDictBulkOps[K, Boolean, S]
  import dict._
  import dictFolding._
  import hintOps._
  import dictDictOps._

  def union(set1: S, set2: S): S =
    foldTree[S, H](set1, set2, (k, v, s) => {
      val hint = seek(s, k)
      (before(hint), after(hint), hint)
    }, (k, v, hidden, s1, s2) => join(s1, k, mon.op(v, current(hidden)._2), s2))
    // ...
}

```

■ **Figure 14** The implementation of set-set union using fold-tree-based iteration.

6.1 Insert-Based Hinted Dictionaries

The hinted insertion method (`insertHint`) is an expressive operation. By providing a concrete implementation for this method, one can guide how an ordered dictionary can be inductively constructed starting from an empty dictionary.

Figure 15 shows the implementation of insert-based hinted dictionaries. The `insertHint` method is left as abstract. Providing different implementations result in a completely different strategy for maintaining ordered dictionaries.

The `append` method is implemented by iterating over the second dictionary and adding its elements one-by-one to the first dictionary. This is achieved by `foldLeft` over `right`, with an initial state of `left`, and adding the key-value pairs of `right` to the end of the previously computed result. This implementation is correct because we know that the keys appearing in the second dictionary are greater than the keys of the first dictionary. By assuming that we provide an implementation for `insertHint` with an amortized constant-time complexity, the `append` operation will have an amortized linear run-time complexity.

The `join` method can be implemented in terms of `append` and `insertHint`. First, we need to insert the given key-value pair to the end of the first dictionary. Afterwards, this intermediate dictionary is appended by the second dictionary. By making the same assumptions as `append`, this operation has also an amortized linear run-time complexity.

6.2 Join-Based Hinted Dictionaries

An alternative way for defining hinted dictionaries is based on the join operator. This is inspired by Adams' sets [1] and the follow up parallel implementations [4].

```

trait InsertBasedDict[K, V, D, H] extends HintedDict[K, V, D, H]
  with HintOps[K, V, D, H] with OrderedDictBulkOps[K, V, D]
  with HintedDictFoldLeft[K, V, D, H] {
  // precondition: keys(left) < keys(right)
  def append(left: D, right: D): D =
    foldLeft[D](right, left, (s, k, v) =>
      insertHint(s, end(s), k, v)
    )
  // precondition: keys(left) < key < keys(right)
  def join(left: D, key: K, value: V, right: D): D =
    append(insertHint(left, end(left), key, value), right)
  // precondition: current(hint)._1 == key
  def insertHint(dict: D, hint: H, key: K, value: V): D
}

```

■ **Figure 15** The implementation of insert-based hinted dictionaries.

The implementation of join-based hinted dictionaries is shown in Figure 16. The `join` method does not have a concrete implementation. It has been shown [4] that different balanced tree representations such as AVL [2], Red-Black [3], Weight-Balanced [9], and Treaps [11] can be expressed by providing an appropriate implementation for the `join` method.

The `append` method is expressed as follows. If the second dictionary is empty, the first dictionary is returned. Otherwise, the hint object for the beginning of the second dictionary is used to retrieve its first key-value pair. Then, the `join` method is applied to the first dictionary, the first key-value pair, and the rest of the second dictionary. If the `join` method is an amortized linear operation, the `append` method also follows the same run-time complexity.

The `insertHint` method is expressed by joining the dictionary preceding the hint object (`before(hint)`), the key-value pair with updated value (`mon.op(current(hint)._2, value)`), and the dictionary succeeding the hint object (`after(hint)`). Note that this way of implementing `insertHint` is suboptimal given that the `join` is a linear time operator. Thus, one has to try avoid using `insertHint` for join-based hinted dictionaries for performance reasons.

The efficiency of hinted dictionaries is not solely dependent on efficient `join` and `insertHint` operations. Having an efficient hint object implementation is also essential, which will be presented next.

7 Hint Implementation

This section starts with a concrete representation for hint objects. Using this representation we provide the implementation for hint operations in Section 7.1. Afterwards, we provide the implementation of the rest of the methods of hinted dictionaries in Section 7.2.

7.1 Focus-Based Hints

As it was stated in Section 4.2, hint objects can be viewed as pointers to different locations of an ordered dictionary. In this section, we consider them as objects focusing on a particular position in the dictionary. The key-value pair that the hint object focuses on, specifies the `key` and `value` fields of the `FocusHint` class. The lack of a key-value pair is specified by putting the identity element of the underlying monoid for type `V`. The sub-dictionary containing the elements preceding/succeeding the focused key-value pair are stored in `left/right`.

```

trait JoinBasedDict[K, V, D, H] extends HintedDict[K, V, D, H]
  with HintOps[K, V, D, H] with OrderedDictBulkOps[K, V, D] {
  // precondition: keys(left) < keys(right)
  def append(left: D, right: D): D = {
    if (isEmpty(right))
      left
    else {
      val hint = begin(right)
      val (key, value) = current(hint)
      val rightNew = after(hint)
      join(left, key, value, rightNew)
    }
  }
  // precondition: keys(left) < key < keys(right)
  def join(left: D, key: K, value: V, right: D): D
  // precondition: current(hint)._1 == key
  def insertHint(dict: D, hint: H, key: K, value: V): D =
    join(before(hint), key, mon.op(current(hint)._2, value), after(hint))
}

```

■ **Figure 16** The implementation of join-based hinted dictionaries.

```

case class FocusHint[K, V, D](left: D, key: K, value: V, right: D)

trait FocusHintOps[K, V, D] extends HintOps[K, V, D, FocusHint[K, V, D]] {
  this: HintedDict[K, V, D, FocusHint[K, V, D]] =>
  type H = FocusHint[K, V, D]
  def before(hint: H): D = hint.left
  def after(hint: H): D = hint.right
  def current(hint: H): (K, V) = (hint.key, hint.value)
}

```

■ **Figure 17** The implementation for focus hint and its operations.

The implementation of the hint operations using focus-based hints is very natural: `before` and `after` return `left` and `right` fields of the `FocusHint` object, and `current` returns the pair `(hint.key, hint.value)`.

7.2 Focus-Based Hinted Dictionaries

Figure 18 shows the implementation of focus-based hinted dictionaries, where the hint objects are `FocusHints`. The following methods are left as abstract: `empty`, `isEmpty`, `begin`, and `middle`. Depending on the underlying data structure, the implementation for these methods can be different.

The methods implemented by focus-based dictionaries are as follows:

- **seek**: If the given dictionary is empty, an empty `FocusHint` object is returned the key of which is the same as the input key. Otherwise, it performs a binary search to return an appropriate hint object. For binary search, the key of the middle of the dictionary is compared with the input key. If the middle key is the same as the input key, the middle hint object is returned. If the input key is less than the middle key, the process is recursively invoked for the preceding dictionary (`seek(1, key)`), and the result hint object is computed by substituting its right dictionary by joining it with the rest of the input dictionary. A similar process is performed when the input key is greater than the middle key.

28:18 Hinted Dictionaries: Efficient Functional Ordered Sets and Maps

```
trait FocusHintedDict[K, V, D] extends HintedDict[K, V, D, FocusHint[K, V, D]]
  with FocusHintOps[K, V, D] with OrderedDictBulkOps[K, V, D] {
  // postcond: res.key == key
  def seek(dict: D, key: K): H = {
    if(isEmpty(dict))
      FocusHint(empty(), key, mon.zero, empty())
    else {
      val hint@FocusHint(l, m, v, r) = middle(dict)
      if(ord.equiv(key, m)) {
        hint
      } else if(ord.lt(key, m)) {
        val hint2 = seek(l, key)
        hint2.copy(right = join(hint2.right, m, v, r))
      } else {
        val hint2 = seek(r, key)
        hint2.copy(left = join(l, m, v, hint2.left))
      } } }
  def end(dict: D): H = FocusHint(dict, ord.max, mon.zero, empty())
  def isEnd(dict: D, hint: H): Boolean = hint == end(dict)
  def next(dict: D, hint: H): H = {
    val rightDict = after(hint)
    val nextHint = begin(rightDict)
    if(isEnd(rightDict, nextHint))
      end(dict)
    else {
      val (k, v) = current(nextHint)
      FocusHint(before(hint), k, v, after(nextHint))
    } }
  def deleteHint(dict: D, hint: H, k: K): D = append(hint.left, hint.right)
  def findHint(dict: D, hint: H, k: K): V = hint.value
}
```

■ **Figure 18** The implementation of focus-based hinted dictionary.

- **end**: Returns an empty `FocusHint` object with the key set to the upper bound of keys (`ord.max`).
- **isEnd**: Check if the given hint is the same as the end hint object.
- **next**: The hint object for the succeeding dictionary is constructed. If this hint object corresponds to the end of that dictionary, then the end of the input dictionary is returned. Otherwise, the return hint object is constructed by using this hint object and the preceding dictionary of the input dictionary.
- **deleteHint**: It is computed by appending the preceding and succeeding dictionaries together.
- **findHint**: The associated value with the hint object is returned. In the case where the key does not exist, the hint object stores the identity of the underlying monoid.

8 Concrete Implementations

In this section, provide three categories of concrete implementations for hinted dictionaries. We start by using sorted arrays as the underlying implementation in Section 8.1. Then, we show how unbalanced trees can be used for implementing hinted dictionaries in Section 8.2. Finally, we use balanced trees as the representation for hinted dictionaries in Section 8.3.

```

import scala.collection.mutable.ArrayBuffer

case class ArrayView[T](buffer: ArrayBuffer[T], lower: Int, upper: Int)

trait ArrayDict[K, V] extends FocusHintedDict[K, V, ArrayView[(K, V)]] {
  type D = ArrayView[(K, V)]
  def empty(): D = ArrayView(ArrayBuffer(), 0, 0)
  def isEmpty(dict: D): Boolean = dict.upper == dict.lower
  def begin(dict: D): H =
    if(isEmpty(dict)) end(dict)
    else {
      val (k, v) = dict.buffer(dict.lower)
      FocusHint(empty(), k, v, ArrayView(dict.buffer, dict.lower + 1, dict.upper))
    }
  def middle(dict: D): H = {
    if(isEmpty(dict)) end(dict)
    else {
      val mid = (dict.lower + dict.upper) / 2
      val (k, v) = dict.buffer(mid)
      val l = ArrayView(dict.buffer, dict.lower, mid)
      val r = ArrayView(dict.buffer, mid + 1, dict.upper)
      FocusHint(l, k, v, r)
    }
  }
}

class CopyingArrayDict[K, V](
  implicit override val ord: Orderable[K], val mon: Monoid[V]) extends
  ArrayDict[K, V]
  with InsertBasedDict[K, V, ArrayView[(K, V)], FocusHint[K, V, ArrayView[(K,
  V)]]] {
  def insertHint(dict: D, hint: H, key: K, value: V): D = {
    val array = dict.buffer.clone() // can be removed if dict is no longer used
    val idx = before(hint).upper
    val (prevKey, prevValue) = current(hint)
    val newUpper =
      if(prevValue == mon.zero) {
        array.insert(idx, (key, value))
        dict.upper + 1
      } else {
        array(idx) = (key, mon.op(prevValue, value))
        dict.upper
      }
    ArrayView(array, dict.lower, newUpper)
  }
}

```

■ **Figure 19** The implementation of hinted dictionaries using an underlying sorted array.

8.1 Sorted Array

Using sorted arrays is one of the main techniques for a sequential implementation of ordered dictionaries. In the C++ world, the `flat_map` container provided by the Boost library [14] uses sorted arrays for representing dictionaries. This data structure is particularly useful for the workloads where the insertions are applied to the end of the ordered dictionary.

Inspired by these C++ implementations, Figure 19 provides the implementation of hinted dictionaries using sorted arrays. In order to preserve an underlying array we use `ArrayBuffers`, mutable containers similar to `std::vectors` of C++. The `ArrayView` data type represents a subset of an `ArrayBuffer` bounded by the indices specified by `lower` and `upper`.

The implementations for `empty`, `isEmpty`, and `begin` are straightforward. For the `middle` method, we need to first retrieve the index of the middle element (`mid`). Then, we compute the preceding dictionary by using the same lower bound, but with the upper bound specified by `mid`. Similarly, the succeeding dictionary uses the lower bound specified by `mid+1`, but with the same upper bound. Finally, we return the focused hint object based on the key-value pair of the middle element and the preceding and succeeding dictionaries.

To create the left and right `ArrayViews` of the hint object, we can share the underlying buffer of the current `ArrayDict` without copying it. Since `ArrayView` is using `ArrayBuffer` as the underlying array and the start and end of the `ArrayView` are determined by `lower` and `upper`, changing these parameters can result in a new dictionary. This sharing opportunity frees the code from copying elements every time we are using `middle`. A similar opportunity is available for `before` and `after`.

Because of using arrays as the underlying representation, it would be more efficient to follow an `InsertBasedDict` interface. To implement the `insertHint` method, we need to check if the hint object points to an actual element. This is achieved by checking if the associated value is different than the identity element of the underlying monoid. In the case of the existence of an element with the same key, the size of the underlying `ArrayBuffer` does not need to change; it is sufficient to update the value of the existing element by applying the binary operator of the monoid to the previous value and the new value to be inserted (`mon.op(prevValue, value)`). If the hint object does not point to an actual element, we need to insert the given key-value pair in the specified position. Finally, we adjust the upper bound and return the updated array.

Note that in the case that there is no more references to the input dictionary in the user program, one can perform in-place update and there would be no need to copy the original array. We leave the implementation of the in-place update version for the sake of brevity.

8.2 Unbalanced trees

An alternative implementation for hinted dictionaries is based on a tree-based representation. We first give a generic implementation for tree-based hinted dictionaries that can be used for both unbalanced and balanced tree representations. Afterwards, we show a simple representation where no smart effort is invested for maintaining the tree in balance.

Figure 20 provides the generalized implementation for ordered dictionaries using trees. The `Tree` data type is defined as an ADT (Algebraic Data Type), where `Leaf` corresponds to a leaf and `Bin` specifies an intermediate node. As the tree nodes can maintain additional information (e.g., height for balanced trees), the type member `Entity` is used for keeping the type of the information kept by each tree node. The `key` and `value` methods are used to extract keys and values from the elements, respectively.

As opposed to sorted arrays, the tree-based hinted dictionaries have a straightforward implementation for `middle`; for leaves the hint object for `end` is returned, whereas for intermediate nodes the focused-hint object with 1) the left sub-tree as the preceding dictionary, 2) the right sub-tree as the succeeding dictionary, and 3) the key/value of its element as the key-value pair is returned. To implement `begin`, the helper method `seekFirst` is defined, which looks for the smallest key-value pair and returns them alongside the succeeding dictionary. These values are used to return the hint object with an empty preceding dictionary.

```
sealed trait Tree[T]
case class Bin[T](l: Tree[T], v: T, r: Tree[T]) extends Tree[T]
case class Leaf[T]() extends Tree[T]

trait TreeDict[K, V, E] extends FocusHintedDict[K, V, Tree[E]] {
  type Entity = E
  type D = Tree[E]
  def key(e: Entity): K
  def value(e: Entity): V
  def empty(): D = Leaf()
  def isEmpty(dict: D): Boolean = dict == Leaf()
  def seekFirst(dict: D): (D, K, V) = {
    val FocusHint(l, k, v, r) = middle(dict)
    if(isEmpty(l)) (r, k, v)
    else {
      val (tp, kp, vp) = seekFirst(l)
      (join(tp, k, v, r), kp, vp)
    }
  }
  def begin(dict: D): H =
    if(isEmpty(dict)) end(dict)
    else {
      val (r, k, v) = seekFirst(dict)
      FocusHint(empty(), k, v, r)
    }
  def middle(dict: D): H = dict match {
    case Leaf() => end(dict)
    case Bin(l, e, r) => FocusHint(l, key(e), value(e), r)
  }
}
```

■ **Figure 20** The generalized implementation for tree-based representations of hinted dictionaries.

```
class UnbalancedDict[K, V](implicit override val ord: Orderable[K], val mon:
  Monoid[V])
  extends TreeDict[K, V, (K, V)]
  with JoinBasedDict[K, V, Tree[(K, V)], FocusHint[K, V, Tree[(K, V)]]]
  with HintedDictFoldTree[K, V, Tree[(K, V)], FocusHint[K, V, Tree[(K, V)]]] {
  def key(e: Entity): K = e._1
  def value(e: Entity): V = e._2
  def join(left: D, key: K, value: V, right: D): D = Bin(left, (key, value), right)
}
```

■ **Figure 21** The implementation of hinted dictionaries using unbalanced binary trees.

Figure 21 shows the implementation for hinted dictionaries that use unbalanced trees. Because of the tree-based representation, a natural interface for `UnbalancedDict` is the join-based hinted dictionary, although one could use the insert-based one with worse performance. The tree nodes do not need to maintain any additional information. Thus, the entity type of the tree nodes is the key-value pair $((K, V))$. The implementation for the `join` is to simply create an intermediate node with the given key-value pair as the content, and first and second dictionaries as the left and right sub-trees.

```

trait BalancedDict[K, V, N] extends TreeDict[K, V, (K, V, N)]
  with JoinBasedDict[K, V, Tree[(K, V, N)], FocusHint[K, V, Tree[(K, V, N)]]] {
  def key(e: Entity): K = e._1
  def value(e: Entity): V = e._2
  def info(e: Entity): N = e._3
  def zeroInfo: N
  def info(e: D): N = e match {
    case Leaf() => zeroInfo
    case Bin(_, entity, _) => info(entity)
  }
  def newInfo(left: N, right: N): N
  def rotateLeft(tree: D): D = tree match {
    case Bin(l, e1, Bin(l2, e2, r2)) =>
      bin(bin(l, key(e1), value(e1), l2), key(e2), value(e2), r2)
    case _ => throw new Exception("Not left rotatable")
  }
  def rotateRight(tree: D): D = // elided for brevity
  def isHeavier(left: D, right: D): Boolean
  def isVeryHeavier(left: D, right: D): Boolean
  def joinRight(left: D, key: K, value: V, right: D): D =
    if(!isHeavier(left, right)) bin(left, key, value, right)
    else {
      val hint = middle(left)
      val (leftLeft, leftRight) = (before(hint), after(hint))
      val (k, v) = current(hint)
      val newRight = joinRight(leftRight, key, value, right)
      if(isHeavier(newRight, leftLeft)) {
        val newHint = middle(newRight)
        if(isVeryHeavier(before(newHint), after(newHint)))
          rotateLeft(bin(leftLeft, k, v, rotateRight(newRight)))
        else rotateLeft(bin(leftLeft, k, v, newRight))
      } else bin(leftLeft, k, v, newRight)
    }
  }
  def joinLeft(left: D, key: K, value: V, right: D): D = // elided for brevity
  def bin(left: D, key: K, value: V, right: D): D =
    Bin(left, (key, value, newInfo(info(left), info(right))), right)
  def join(left: D, key: K, value: V, right: D): D =
    if(isHeavier(left, right)) joinRight(left, key, value, right)
    else if (isHeavier(right, left)) joinLeft(left, key, value, right)
    else bin(left, key, value, right)
}

```

■ **Figure 22** The generalized interface for hinted dictionaries using balanced binary trees.

8.3 Balanced trees

Figure 22 shows the generalized implementation for balanced-tree-based hinted dictionaries. This interface subsumes AVL trees and WBB trees. It is possible to implement Red-Black tree and Treaps as hinted dictionaries by appropriately overriding the `join` method, however, as it was shown that AVLs and WBBs have superior performance in comparison with them [4], we only present their implementation in this paper.

The interface of `BalancedDict` accepts the extra parameter `N` for the extra information kept by the tree nodes. For example, AVL trees store the height of the tree in each node and WBB trees store the size of the tree as the weight information.

```

class AVLDict[K, V](implicit override val ord: Orderable[K], val mon: Monoid[V])
  extends BalancedDict[K, V, Int] {
  type N = Int
  def zeroInfo: Int = 0
  def newInfo(left: N, right: N): N = math.max(left, right) + 1
  def isHeavier(left: D, right: D): Boolean = info(left) > info(right) + 1
  def isVeryHeavier(left: D, right: D): Boolean = info(left) > info(right)
}
class WBBDict[K, V](implicit override val ord: Orderable[K], val mon: Monoid[V])
  extends BalancedDict[K, V, Int] {
  type N = Int
  val ALPHA = 0.29
  val RATIO = ALPHA / (1 - ALPHA)
  val BETA = (1 - 2 * ALPHA) / (1 - ALPHA)
  def zeroInfo: Int = 1
  def newInfo(left: N, right: N): N = left + right - 1
  def isHeavier(left: D, right: D): Boolean = RATIO * info(left) > info(right)
  def isVeryHeavier(left: D, right: D): Boolean =
    info(left) > BETA * newInfo(info(left), info(right))
}

```

■ **Figure 23** The implementation for hinted dictionaries based on AVL and WBB trees.

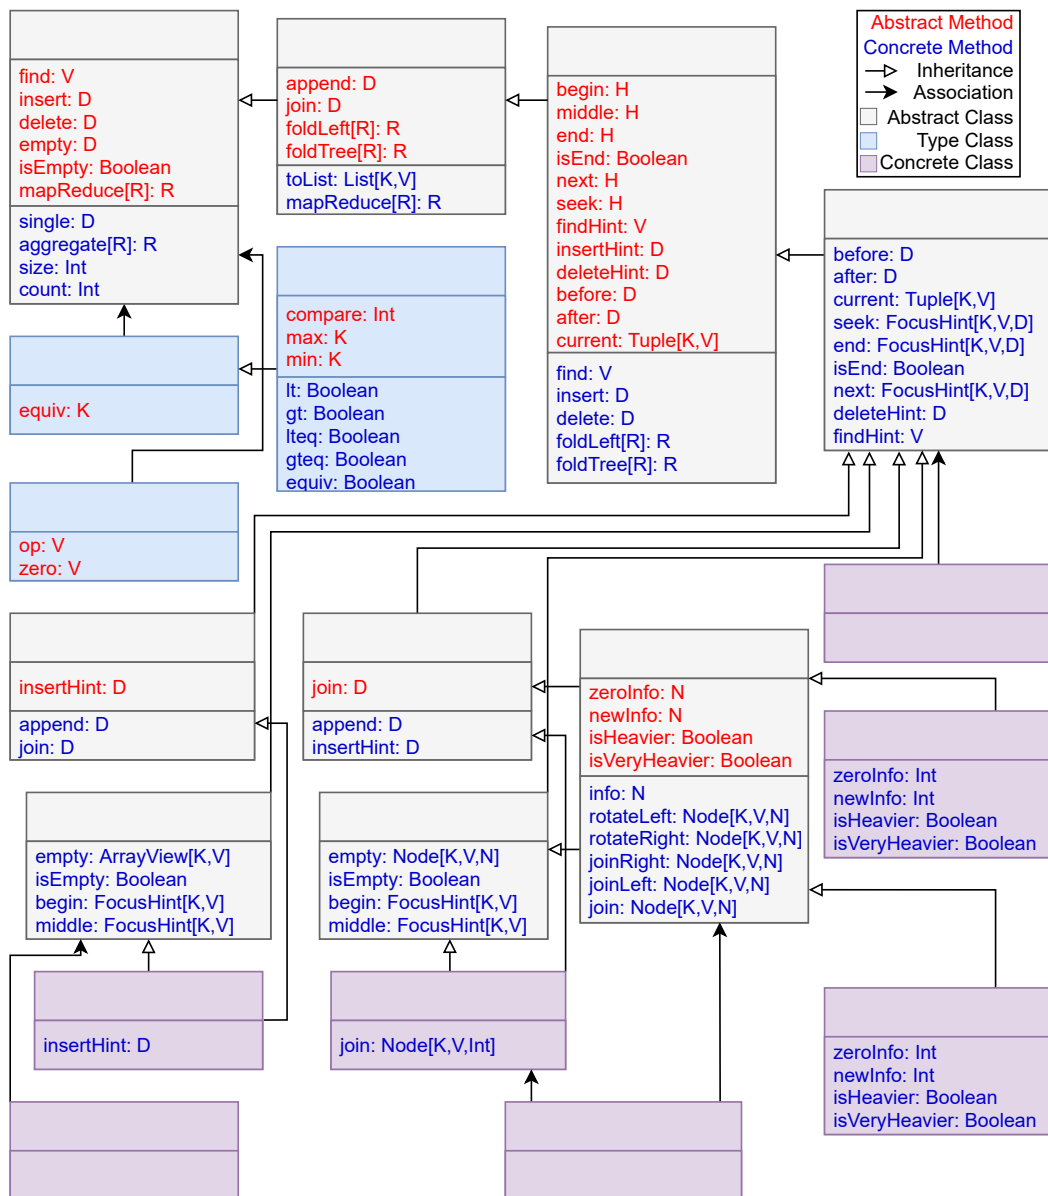

In order to preserve correct bookkeeping information, the smart constructor `bin` is added. This method invokes the abstract method `newInfo` in order to compute the updated information based on the information of the sub-trees. This method needs to be overridden by concrete balanced tree implementation choices.

The `join` method starts with checking if the tree is unbalanced towards either of its sub-trees. If this is not the case, the smart construct `bin` is invoked to simply construct the new root node. However, if either of the sides is heavier, an appropriate recursive method is invoked in order to take care of possible rotations.

In Figure 22 we show the implementation of `joinRight`, which is invoked when the left sub-tree is heavier than the right sub-tree. The implementation of `isHeavier` is again postponed to the concrete implementation of a balanced tree. The rest of the implementation of `joinRight` mirrors a generalized version of what has been reported before in [4]. An interesting case is when there needs to be a double rotation involved. This is checked by `isVeryHeavier`, which needs to be implemented by a concrete balanced tree implementation.

Figure 23 shows the implementation of AVL and WBB trees using the generalized interface mentioned above. The AVL tree maintains the height of the tree as the extra information. The height of a new tree is computed by incrementing the maximum height of its sub-trees by one. A sub-tree is heavier than another sub-tree when its height is more than an increment of the height of the other sub-tree. And finally, a node needs double rotation only if the height of its left sub-tree is more than the height of its right sub-tree.

The WBB tree considers the size of the tree (added by one) as the extra information, referred to as weight [1]. The updated weight is computed by adding the weight of sub-trees (decremented by one). The `RATIO` and `BETA` parameters control whether rotation or double rotation need to be performed. The values for these parameters specify the trade-off between the tree being in a perfect balance and the number of re-balancing invocations. There were follow up research on fixing the balancing issues related to the parameter values originally suggested by Adams [6, 16]. We use the parameters reported by [4].

■ **Figure 24** The bird's eye view of all the interfaces.

8.4 Putting It All Together

Finally, we give an overall picture of hinted dictionaries by connecting all the pieces together. Figure 24 shows the different interfaces defined throughout this paper. To reduce the number of classes, we merged the definition of several interfaces with each other (e.g., `DictIterations` is merged with `Dict`). Crucially, there is no cake-pattern-based interface in Figure 24, as this technique is not essential for implementing hinted dictionaries.

```

template<class K, class V, class Compare, class Mon>
class array_dict {
private:
    typedef std::vector<std::pair<K, V>> vector_t;
    typedef std::pair<int, bool> hint_t;
    int lower; int upper;
    vector_t buffer;
public:
    void insert(K& key, V& value);
    hint_t insert_hint(hint_t& hint_obj, K& key, V& value);
    bool is_end(hint_t& hint_obj);
    template<SearchMethod search_method>
    hint_t seek(K& key);
    void after(hint_t& hint_obj);
    template<class R, class Func>
    void inplace_fold_left(R& z, Func op);
    /* Elided for brevity */
}

```

■ **Figure 25** The interface of sorted-array-based dictionaries in C++.

9 Evaluation

In this section, we evaluate the performance of hinted dictionaries. First, we present an efficient C++ prototype for them. Then, we show the experimental results by comparing our C++ implementation with competitors for set-set and sparse vector operations.

9.1 Tuned Implementation in C++

The hinted dictionaries can have an efficient low-level implementation in C++. We provide the following hinted dictionary implementations: 1) `array_dict`, an array-based implementation that uses `std::vector<std::pair<K, V>>` as the underlying representation, and 2) `wbb_dict`, a tree-based implementation based on WBBs [9, 1].

We do not use the hierarchy presented in Figure 24 for performance reasons; we merge the definitions of all the parent interfaces of hinted dictionaries into `array_dict` and `wbb_dict`. The implementation for `wbb_dict` stays very similar to the one presented in Section 8.3. However, we have applied the following performance tuning tricks for `array_dict`, the interface of which is shown in Figure 25.

Pointer-Based Hints. In Section 7.1 we presented `FocusHint` objects that materialize the entire dictionaries before and after a hint object. However, this design results in unnecessarily copying of arrays (cf. Section 8.1). The `array_dict` implementation only maintains a pointer to the appropriate place by using pointer-based hint objects of type `std::pair<int, bool>`. If the hint object points to an actual element of the hinted dictionary, the first element of the pair specifies its index and the second element is set to `true`. For keys that do not exist in the dictionary (i.e., the associate value is the zero element of the underlying monoid), the first element is the index of an element with the *least upper bound* key and the second element is set to `false`.

Binary Search vs. Linear Search. In Section 7.2 we used binary search (by calling `middle`) in order to implement `seek`. However, as we observe in the next section, in many cases it could be beneficial to use linear search. We provide a template parameter for the `seek` method in order to specify the underlying search method.

In-Place Updates. Finally, we use in-place updates to improve the performance in the following cases. First, the methods that return a subset of the hinted dictionary (`before` and `after`) can perform an in-place modification of the boundary of the dictionary (`lower` and `upper`). Second, the aggregation-based methods that produce dictionaries can use a single mutable dictionary and modify it in-place, instead of passing around new dictionaries (cf. `inplace_fold_left` in Figure 25).

Constant-time Size. The `array_dict` implementation can compute the size of the dictionary by evaluating `upper - lower`. Similarly, `wbb_dict` can compute the size using the meta data (`info`). However, both dictionaries still require iterations for `count` (i.e., the number of elements with a non-zero value). Thanks to the fast size computation, we can make sure that we always iterate over smaller dictionaries for all binary operations over dictionaries (e.g., set-set operations).

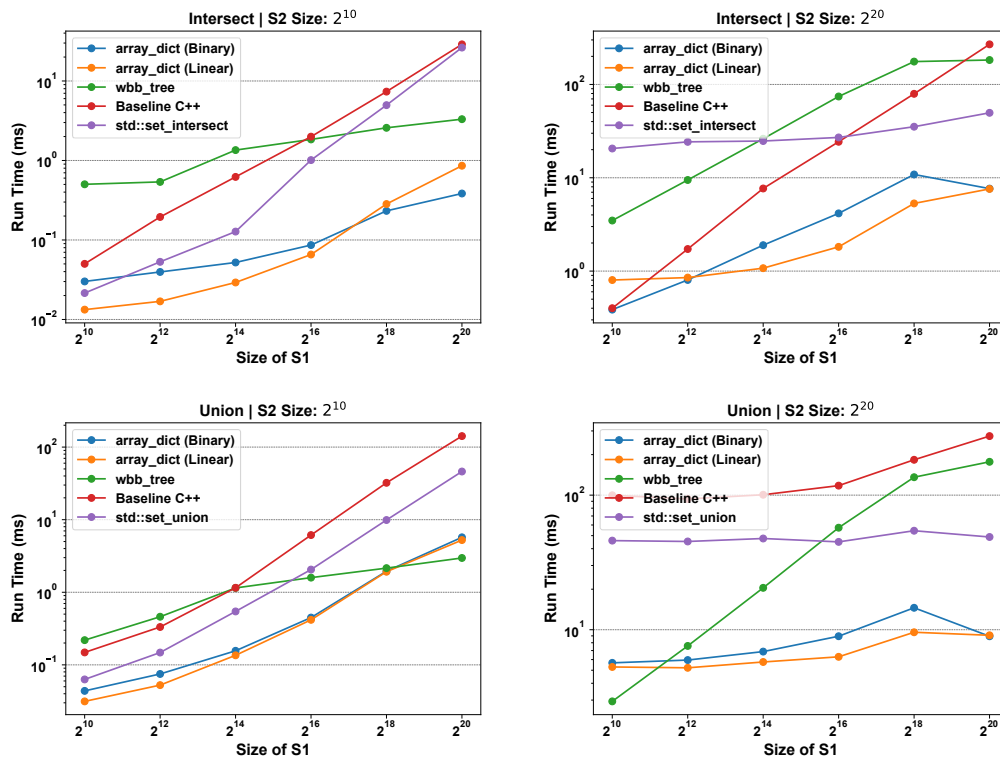

9.2 Experimental Results

Experimental Setup. We run our experiments on a machine running Ubuntu 20.04.3 equipped with an Intel Core i5 CPU running at 1.6GHz, 16GB of DDR4 RAM. We use G++ 9.4.0 for compiling the generated C++ code using the `O3` flag. We also use SciPy 1.8.0 (on Python 3.8.10) as the competitor.

Workloads. We consider the following set-set and sparse vector operations: 1) set-set union, 2) set-set intersection, 3) sparse vector addition, 4) sparse vector element-wise multiplication, and 5) sparse vector inner product. For all the experiments, we generate randomly synthetic data by varying the size of sets and the density of vectors. We run all the experiments for ten times and measure their average run time.

Competitors. We consider the following alternatives of our C++ prototype and other frameworks:

- **array_dict (Linear):** array-based dictionary with linear-search-based seek.
- **array_dict (Binary):** array-based dictionary with binary-search-based seek.
- **wbb_dict:** tree-based dictionary that uses a WBB-based representation.
- **Baseline C++:** a baseline implementation using the operations provided by `std::set` (for the set experiments) or `std::map` (for the sparse vector experiments).
- **std::set_intersect, std::set_union:** set-set operations provided by the standard library of C++. As input arguments we use `std::set` collections.
- **SciPy:** sparse linear algebra operators provided by the SciPy library. A sparse vector is represented as a row matrix with a CSR (Compressed Sparse Row) or a column matrix with a CSC (Compressed Sparse Column) format.

■ **Figure 26** Experimental results for set-set operations.

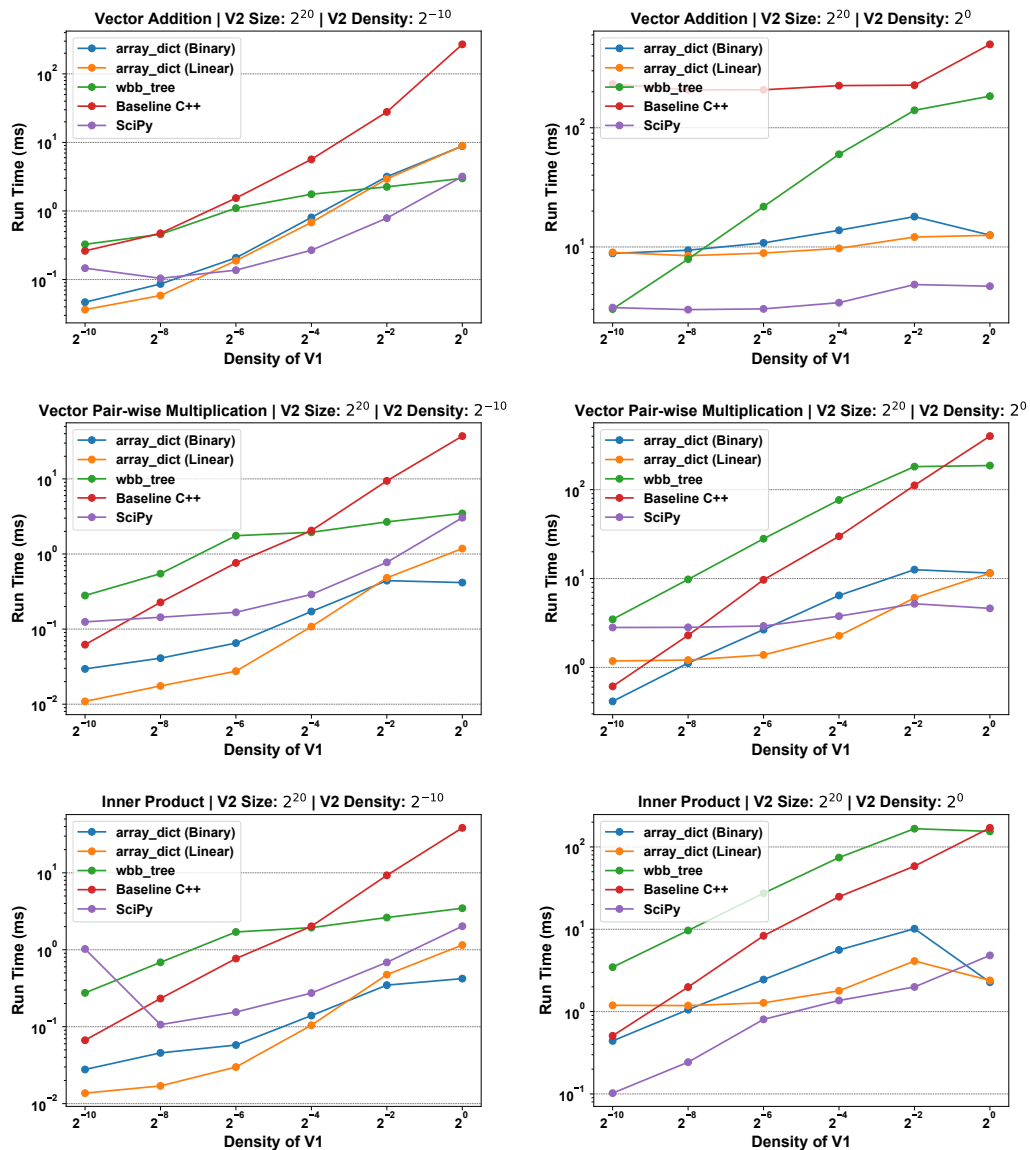

Set-Set Experiments. Figure 26 shows the results for the union and intersection operations over sets. We make the following observations. First, in most cases, we observe a superior performance for the `array_dict` implementations. In most cases, the linear-search-based approach has better performance. However, as the difference between the size of sets widens, the binary-search starts showing better performance. This is because of the additional run-time improvements caused by skipping irrelevant elements.

Furthermore, we observe that the `wbb_dict` implementation does not show superior performance in most cases. As shown before [4], one of the advantages of such join-based implementations is their amenability to parallelism that we leave for the future.

Finally, we observe an asymptotically improved performance over the baseline C++ implementation. This is thanks to turning $O(\log n)$ lookup and insertion operations into amortized constant-time ones. The implementations provided by the standard library of C++ suffer from a similar issue. In addition, due to a concurrent linear iteration over both sets, they show worse performance for the sets with a large difference in their sizes.

Sparse Vector Experiments. The implementations for sparse vector addition and element-wise multiplication are identical to the ones for set union and intersection, respectively. The sparse vector addition uses real number addition instead of boolean disjunction, and the element-wise multiplication uses real number multiplication instead of boolean conjunction. The results for vector inner product are also very similar to the ones for the element-wise multiplication (cf. Figure 27).

The SciPy framework uses a CSR format for representing all vectors, except for the second operand of the vector inner product. This is because the second vector needs to be transposed which makes the CSC format a better representation. Overall, this framework

■ **Figure 27** Experimental results for sparse vector operations.

shows superior performance for vectors with a large density. This can be related to their better storage layout (struct of array instead of array of struct) that leads to improved cache locality. The `array_dict` variants show better performance for vectors with a higher degree of sparsity.

10 Conclusion and Outlook

In this paper, we introduced hinted dictionaries, a unified technique for implementing ordered dictionaries. We have shown how hinted dictionaries unify the existing techniques from both imperative and functional languages. These dictionaries can be used as the collection type for data-intensive workloads. It would be interesting to see the usage of such data structures for real-world use-cases such as query processing (relying on relations in the form of sets and bags) as well as sparse linear algebra (relying on sparse vectors and matrices).

The performance improvement offered by hinted dictionaries does not come for free. The programmers must be careful on how to use hinted dictionaries. As presented in Section 4, certain preconditions need to be preserved for hint objects. Violating these preconditions by the programmers destroys the invariants of hinted dictionaries leading to runtime errors or, even worse, undefined behaviour, which can hinder the productivity of programmers. One interesting future direction is to statically detect the violation of the hinted dictionaries' invariants.

Furthermore, we envision the following future directions for hinted dictionaries. First, we plan to consider real-world applications that require batch processing of sets and maps, including relational query engines and sparse tensor processing frameworks. Furthermore, it would be interesting to use code generation and multi-stage programming techniques to generate low-level code. This way, one can automatically improve the performance by removing allocation of unnecessary intermediate objects (e.g., `FocusHint` objects) or to use in-place updates (cf. Section 9.1) from a purely functional implementation. Finally, for applications such as query processing the trade-offs between hashing and sorting have been debated for a long time. We believe hinted dictionaries provide a nice abstraction layer for DSLs based on dictionaries (e.g., the physical query plan of query engines) to automatically tune the choice of the underlying dictionary implementation [13].

Abstract

Noninterference is the strong information-security property that a program does not leak secrets through publicly-visible behavior. In the presence of effects such as nontermination, state, and exceptions, reasoning about noninterference quickly becomes subtle. We advocate using *interaction trees* (*ITrees*) to provide compositional mechanized proofs of noninterference for multi-language, effectful, nonterminating programs, while retaining executability of the semantics. We develop important foundations for security analysis with *ITrees*: two *indistinguishability* relations, leading to two standard notions of noninterference with adversaries of different strength, along with metatheory libraries for reasoning about each. We demonstrate the utility of our results using a simple imperative language with embedded assembly, along with a compiler into that assembly language.

1 Introduction

Information-flow guarantees state that programs respect the information-security specifications of their inputs and outputs. The most basic is *noninterference*, which states that secret data cannot influence publicly observable behavior. There are many languages designed to enforce information-flow properties, guaranteeing that programs treat their sensitive inputs correctly [28, 39, 40]. The importance of information-security properties has increasingly led to verification efforts for such languages and systems [7, 20]. These efforts, however, are mostly limited to source-level guarantees for a single language. For security guarantees to be meaningful, the entire language toolchain must support them.

One of the key decisions when formalizing any effectful, possibly-nonterminating language is the choice of representation. Much prior work focuses on operational semantics defined as a relation on syntax, or on trace models defined as a predicate over lists or streams of observations [21, 25, 36]. However, such definitions often require auxiliary constructs, like program counters or evaluation contexts, making proofs brittle and hard to compose. These concerns are particularly pronounced for information-security properties, which often rely on subtle definitions with delicate correctness proofs. The complexity of multi-language settings further complicates the already-fraught choice of language representation.

Interaction Trees (ITrees) [57, 59] provide an alternative: a runnable denotational semantics for effectful, potentially-nonterminating programs, with a library implemented in Coq [29]. Intuitively, ITrees represent programs as interactions with the environment. At a technical level, ITrees are a coinductive data type based on free monads [50]. Programs are either done and provide a return value, emit an *event* to the environment and continue once the environment provides a response, or produce a “silent event,” allowing ITrees to represent (silently) diverging programs in strongly normalizing metalanguages. By interpreting the events into a suitable monad [31], ITrees can express the semantics of diverse programming-language features, and thus many different languages. This versatility makes ITrees well-suited to cross-language reasoning [57] and reasoning about real-world toolchains [59, 24].

ITrees come equipped with a notion of program equivalence based on *weak bisimilarity*, which considers programs equivalent if they differ only by a finite number of silent steps. Properties like noninterference, however, require more nuanced reasoning because some program behaviors are visible to an attacker while others are not.

This work introduces two *indistinguishability* relations for ITrees to capture these intuitions: one *progress-sensitive* and one *progress-insensitive*. These definitions – motivated by corresponding notions found in the information-flow security literature [56, 55, 45] – adapt the notion of bisimilarity to account for what information is available to an adversary. They require delicate treatment of the interplay between nontermination and the interactions of a program with its environment. Progress-sensitive noninterference is a very strong guarantee, but is overly restrictive for many real-world programming tasks. For instance, it generally disallows loops that depend on secret data. Progress-insensitive noninterference is less demanding, but provides considerably less security [6].

While the definitions of ITrees and our indistinguishability relations are coinductive, we provide metatheoretic results allowing a proof engineer to reason with these relations without manual coinduction. These results further connect these indistinguishability relations to the standard ITrees notion of bisimilarity, providing compatibility with existing results.

We validate this design with a simple toolchain for cross-language noninterference. The toolchain consists of a simple imperative language, IMP, and a simple assembly language, ASM. There are two type systems for IMP and a compiler from IMP to ASM. One type system enforces progress-sensitive noninterference and the other enforces progress-insensitive noninterference. In addition to standard information flow typing rules, the type systems allow for *semantic typing*: any semantically secure program can be considered well typed. This flexibility allows IMP to support embedded ASM blocks without giving a type system to ASM, and it demonstrates the powerful semantic composition of our security reasoning. We further verify that our IMP-to-ASM compiler preserves both kinds of noninterference. This preservation relies only on semantic security, not the type system, which is required to allow for security preservation with semantic typing.

To further demonstrate the utility of our approach, we include exceptions in IMP. Exceptions show how our indistinguishability semantics interact with effects that may alter control flow, which are a particular challenge for information-flow reasoning. This inclusion also requires an extension to the ITrees library that is orthogonal to the security extensions.

Section 2 reviews background on information-flow control and ITrees, the IMP language, and its semantics defined with ITrees. The contributions of this paper are as follows.

- Section 3 extends the ITrees library with exceptions and exception handlers.
- Section 4 adapts ITrees metatheory to reason about security guarantees, defining progress-sensitive and progress-insensitive notions of indistinguishability and noninterference.
- Section 5 uses ITrees and the new relations to prove the security of two standard information-flow type systems for IMP.
- Section 6 extends Xia et al.’s [57] simple compiler from IMP to ASM with exceptions and print effects. We then show that Xia et al.’s notion of compiler correctness immediately implies security preservation using only the metatheory of indistinguishability.

Finally, Section 7 discusses related work and Section 8 concludes. All definitions and theorems described in this paper have been formalized in Coq.

2 Background

We now review background on information-flow control, interaction trees, and IMP.

2.1 Information-Flow Control

We represent information-security policies using a set of *information-flow labels* \mathcal{L} that must form a preorder. That is, there is a reflexive, transitive relation \sqsubseteq (pronounced “flows to”) on labels where $\ell \sqsubseteq \ell'$ means that any *adversary* who can see information with label ℓ' can also see information with label ℓ . We also identify adversaries with labels. An adversary at label ℓ can only see information with labels that flow to ℓ . Information-flow systems use a variety of orderings, including simply “public” and “secret,” subsets of permissions [62], lattices over principals making up a system [33, 5, 49], and orderings based on logical implication [39].

The classic information-flow security policy is *noninterference*: if an adversary cannot distinguish a program’s inputs, they should not be able to distinguish its outputs or its interactions with the environment. Because information-flow labels determine which data an adversary can observe, a semantic version of noninterference requires a semantic model of information-flow labels. Sabelfeld and Sands [46] suggest modeling labels as partial equivalence relations (PERs) on terms. PERs are relations that are symmetric and transitive, but not necessarily reflexive. PERs act like equivalence relations on a subset of their domain. For information-flow security, such PERs are called “indistinguishability relations.”

This model further asserts that indistinguishable programs take indistinguishable inputs to indistinguishable outputs. That is, related programs, applied to related inputs, produce related computations. This closure property allows a semantic version of noninterference to be defined as self-relation of a program. A program is related to itself – and noninterfering – if and only if, for every adversary, given any two inputs an adversary cannot distinguish, it produces two computations that adversary cannot distinguish.

As we will see in Section 4, indistinguishability gives a natural way to reason about noninterference using ITrees. Requiring every indistinguishability relation to be a PER, however, corresponds to strong assumptions about the adversary. In particular, it requires that the adversary be able to distinguish a program that silently diverges from a program that takes arbitrarily long to produce an observable interaction with its environment. Noninterference against this strong adversary is known as *progress-sensitive* noninterference. While this strength provides more security, enforcing progress-sensitive noninterference results in a prohibitively expensive programming model [45, 55, Section 5.1]. To allow for enforcement of *progress-insensitive* noninterference, the indistinguishability model is often relaxed to not require transitivity [54, 42, 16].

2.2 Basic Definitions for Interaction Trees

Interaction Trees (ITrees) [57] are a coinductive data structure designed to give denotational semantics to effectful, possibly divergent programs. ITrees model such computations as branching trees where internal nodes represent *events*, or interactions with the environment, with a branch for each different possible response from the environment. The use of coinduction means that these trees can be infinite, modeling diverging programs. Because ITrees give a denotational semantics to programs, they are a language-agnostic view of programs. Thus, we can use ITrees as a common domain for multiple languages, allowing us to reason about how those languages interact.

The type of an ITree includes an event signature E and a result type R . The result type simply specifies the output type if the program halts normally. The event signature E defines the interface by which the environment interacts with the program. $E : Type \rightarrow Type$ is a type transformer that takes an answer type A and returns $E A$, the type of an event that produces a value of type A . For example, the event signature, **stateE**, modeling a state effect might have two constructors: **get** and **set**. A **get** event represents a state access that returns a number, so it has type **stateE**(\mathbb{N}). A **set** event represents an assignment that need not return any useful information, so it has type **stateE**(**unit**).

ITrees have the following constructors.

$$\frac{r : R}{\mathbf{ret} \ r : \mathbf{itree} \ E \ R} \quad \frac{t : \mathbf{itree} \ E \ R}{\tau \cdot t : \mathbf{itree} \ E \ R} \quad \frac{e : E \ A \quad k : A \rightarrow \mathbf{itree} \ E \ R}{\mathbf{Vis} \ e \ k : \mathbf{itree} \ E \ R}$$

In this paper, a double line in an inference rule means that it should be interpreted coinductively, while a single line is interpreted inductively, as usual. This definition, then, is a fully coinductive definition, since the only single-line definition is a base case.

The ITree **ret** r represents a program terminating with a value r . The ITree $\tau \cdot t$ represents a silent internal step of computation, followed by the ITree t . Because ITrees are a *coinductive* data structure, we can chain an infinite number of τ 's together in the ITree $t_{\text{spin}} = \tau \cdot t_{\text{spin}}$. Here, t_{spin} models a divergent program that causes no side effects. Finally, the ITree **Vis** $e \ k$ represents a visible event e of type $E \ A$ for some answer type A , followed by a continuation k that takes an answer of type A and produces an **itree** $E \ R$. Intuitively, k defines how the computation proceeds after the environment handles event e . Since k 's behavior may differ depending on the value returned by e , there is one possible computational “branch” for each value of type A . In this view, ITrees are potentially infinitely long trees.

For any event signature E , **itree** E forms a monad [31]. The unit operation is provided by the **ret** constructor, and the bind operation, written $m \gg= k$, is defined as a corecursive function which replaces every **ret** r in m with $k \ r$. We will also use the common monad notation $x \leftarrow t_1 ; t_2$ in place of $t_1 \gg= \lambda x.t_2$. ITrees satisfy the monad laws up to strong bisimulation, which we use as an equivalence on ITrees since they are potentially infinite objects. Two ITrees are strongly bisimilar when they have exactly the same shape (including the values returned at corresponding leaves).

In combination with the monad operations, another useful operation is **trigger**, which lifts an event into an ITree that immediately returns the environment's response:

$$\mathbf{trigger} \ e = \mathbf{Vis} \ e \ \mathbf{ret}$$

ITrees also support an *iteration* operation:

$$\mathbf{iter} : \forall A, B. (A \rightarrow \mathbf{itree} \ E \ (A \oplus B)) \rightarrow A \rightarrow \mathbf{itree} \ E \ B$$

Intuitively, **iter** *body* a acts as a do-while loop, running *body* on input a and either continuing with a new value of type A , or stopping with a final value of type B .

Expressions	$e ::= x \mid n \mid e + e \mid e - e \mid e * e$
Commands	$c ::= \text{skip} \mid x := e \mid c_1 ; c_2 \mid \text{while } (e) \text{ do } \{c\}$ $\quad \mid \text{if } (e) \text{ then } \{c_1\} \text{ else } \{c_2\} \mid \text{print}(\ell, e) \mid \text{inline } \{a\}$
Inlined Assembly	$a ::=$ (see Section 6)

■ **Figure 1** IMP syntax, where x is a variable, n is a number, and ℓ is an information-flow label.

2.3 Semantics for Imp with Security Labels

To explore how ITrees can help us verify noninterference properties, we will use a simple imperative language, IMP, as a running example and case study. Conveniently, previous work on both ITrees [57] and noninterference [45] use IMP as case studies, ensuring that the connection we make corresponds with existing tools and techniques in both domains. Our version of IMP, presented in Figure 1, includes features not present in the works cited above: the ability to print expressions to one of several output streams, and the ability to inline code from a simple assembly language. Section 3 will further extend IMP to allow throwing and catching exceptions. The output streams are indexed by information-flow labels, and we think of stream ℓ as being visible to any adversary at or above ℓ , but no others. Thus, printing secret information to a public stream leaks data.

The assembly language, ASM, is a simplification of standard assembly language. We allow an infinite number of registers, and we assume that the heap is addressed by variables, as in IMP. We also do not allow dynamic jumps, only jumps to fixed addresses. Beyond those simplifications, we include features similar to those in IMP: we allow printing to streams indexed by information-flow labels and, as we show later, the ASM semantics can model *uncaught* exceptions, both features necessary for correct compilation of IMP code. We discuss the syntax and semantics of ASM in more detail in Section 6.

As in languages like C, embedding ASM in IMP allows developers more control over the performance of their code. For instance, the simple compiler in Section 6 would compile the IMP program $y := x + 1 ; z := x + 2$ to an ASM program that loads data from x into a register twice, once for each assignment. Since Loads are relatively expensive, when the IMP code above appears in a critical loop a developer might replace it with the following ASM code:

```

START : LOAD   $0 ← x
        ADD    $0 ← $0, 1
        STORE  y ← $0
        ADD    $0 ← $0, 1
        STORE  z ← $0
        JMP    EXIT

```

This program starts from the START label, and terminates the program by jumping to the EXIT label. Unlike our compiler’s output, this custom ASM only has one load instruction.

Giving semantics to IMP using ITrees requires defining events representing possible interactions between an IMP program and its environment. IMP has three types of events: **stateE** for the heap state, **regE** for the register state, and **printE** for output. There are two constructors for **stateE** events, one for reading and one for writing.

$$\text{get} : \text{var} \rightarrow \text{stateE}(\mathbb{N}) \qquad \text{set} : \text{var} \rightarrow \mathbb{N} \rightarrow \text{stateE}(\text{unit})$$

The **regE** events require another two constructors, again one for reading and one for writing.

$$\text{getreg} : \text{reg} \rightarrow \text{regE}(\mathbb{N}) \qquad \text{setreg} : \text{reg} \rightarrow \mathbb{N} \rightarrow \text{regE}(\text{unit})$$

$$\begin{array}{l}
\boxed{\llbracket e \rrbracket_e : \text{itree progE } \mathbb{N}} \qquad \boxed{\llbracket c \rrbracket_c : \text{itree progE unit}} \\
\\
\llbracket x \rrbracket_e = \text{trigger get}(x) \qquad \llbracket \text{skip} \rrbracket_c = \text{ret } () \\
\llbracket n \rrbracket_e = \text{ret } n \qquad \llbracket x := e \rrbracket_c = n \leftarrow \llbracket e \rrbracket_e ; \text{trigger set}(x, n) \\
\llbracket e_1 + e_2 \rrbracket_e = x \leftarrow \llbracket e_1 \rrbracket_e ; \\
\qquad y \leftarrow \llbracket e_2 \rrbracket_e ; \\
\qquad \text{ret } (x + y) \qquad \llbracket \text{print}(\ell, e) \rrbracket_c = n \leftarrow \llbracket e \rrbracket_e ; \text{trigger print}(\ell, n) \\
\llbracket c_1 ; c_2 \rrbracket_c = \llbracket c_1 \rrbracket_c ; \llbracket c_2 \rrbracket_c \\
\llbracket \text{if } e \\
\text{then } \{c_1\} \\
\text{else } \{c_2\} \rrbracket_c = \begin{array}{l} \text{if } n \neq 0 \\ n \leftarrow \llbracket e \rrbracket_e ; \text{then } \llbracket c_1 \rrbracket_c \\ \text{else } \llbracket c_2 \rrbracket_c \end{array} \\
\llbracket \text{while } (e) \text{ do } \{c\} \rrbracket_c = \text{iter} \left(\begin{array}{l} \lambda_. n \leftarrow \llbracket e \rrbracket_e ; \\ \text{if } n \neq 0 \\ \text{then } (\llbracket c \rrbracket_c ; \text{ret inl}()) \\ \text{else ret inr}() \end{array} \right) () \\
\llbracket \text{inline } \{a\} \rrbracket_c = \llbracket a \rrbracket_{\text{asm}}
\end{array}$$

■ **Figure 2** Imp denotational semantics.

There is only one constructor for `printE` events: `print` : $\mathcal{L} \rightarrow \mathbb{N} \rightarrow \text{printE}(\text{unit})$.

As IMP programs can produce all three types of events, we combine them with disjoint union. The resulting event type for IMP programs is `progE` = `regE` \oplus `stateE` \oplus `printE`. For notational simplicity, we elide the injection operator when using these compound events.

Figure 2 presents the denotation of IMP using these events. Note that there are two denotation functions: $\llbracket \cdot \rrbracket_e$ for expression and $\llbracket \cdot \rrbracket_c$ for commands. As expressions produce numbers and commands have no output, $\llbracket \cdot \rrbracket_e$ produces computations of type `itree progE` \mathbb{N} , while $\llbracket \cdot \rrbracket_c$ produces computations of type `itree progE` `unit`. The function $\llbracket \cdot \rrbracket_{\text{asm}}$ gives ITree-based semantics to ASM. Its full definition can be found in the work of Xia et al. [57]; we discuss the modifications necessary to accommodate our changes in Section 6.

The denotation for expressions is fairly straightforward, and, importantly for proofs, completely compositional – an expression’s meaning is constructed from that of its subexpressions. The denotation of a variable is a `get` event, a literal n becomes `ret` n , and arithmetic expressions simply denote each argument and return the resulting value using `bind`.

Most commands are equally simple and compositional. `skip` is an immediate `ret`. Both assignment and `print` first denote the argument and then bind the result into the appropriate event. Sequencing is implemented with `bind` on a unit value that we elide. Conditionals first denote the condition, and then return the denotation of either the left or right command depending on the result.

Loops are more complex and make use of the `iter` combinator. The combinator expects a function that returns `itree progE` (`unit` \oplus `unit`), where a left value indicates “continue” and a right value indicates that the loop should terminate. The function given to `iter` first computes the value of the loop’s guard expression. If the value is not zero, it sequences a single denotation of the loop body with `ret inl`(), indicating the loop should continue. Otherwise, if the value is zero, it signals to halt the iteration with `ret inr`() .

2.4 Handlers and Interpretations

The events in an ITree can be thought of as a kind of syntax. Even though we give them names that suggest certain behaviors, like `get` and `set`, nothing about their structure enforces this behavior. Consider the ITree `trigger set(x, 0) ; trigger get(x)`: while the names suggest

that the result of this `get` should be 0, it actually produces a tree with one branch for every natural number. Likewise, the $\text{ITree } \llbracket c \rrbracket_c$ representing an IMP program c does not fully express the behavior we would expect from c because it has uninterpreted state events.

The behavior of events is determined by a function called an *event handler* from events to effectful computations. As is standard, we represent effectful computations as elements of a monad M , giving an event handler the type $\forall A. E A \rightarrow M A$. For example, consider h_{prog} which uses the standard monadic interpretation of state to interpret `progE` events:

$$\begin{aligned} h_{prog}(\text{get}(x)) &= \lambda(r, h). \text{ret } (r, h, h(x)) \\ h_{prog}(\text{set}(x, n)) &= \lambda(r, h). \text{ret } (r, h[x \mapsto n], ()) \\ h_{prog}(\text{getreg}(x)) &= \lambda(r, h). \text{ret } (r, h, r(x)) \\ h_{prog}(\text{setreg}(x, n)) &= \lambda(r, h). \text{ret } (r[x \mapsto n], h, ()) \\ h_{prog}(\text{print}(\ell, n)) &= \lambda(r, h). \text{trigger print}(\ell, n) ; \text{ret } (r, h, ()) \end{aligned}$$

Any event handler can be lifted to a function from ITrees to effectful computations using the `interp` function, which traverses an ITree , replacing each event with the effectful computation assigned by the handler. The full semantics of an IMP program is the *interpreted* ITree , `interp` $h_{prog} \llbracket c \rrbracket_c$.

2.5 Inlined Asm and Undefined Behavior

Adding support for inlined ASM code introduces a new complication to the semantics of IMP: undefined behavior. To analyze the correctness and security of a language toolchain, we need to define the behavior of source-level programs. The semantics defined in Section 2.3 and Section 2.4 do that for IMP as long as any inlined ASM has well-defined behavior. However, consider the following IMP program, which contains inlined ASM.

```
p = c ; inline { START : BRZ   $0 A1 A2
                  A1 : LOAD  X ← 0
                      JMP   EXIT
                  A2 : LOAD  X ← 1
                      JMP   EXIT }
```

The inlined ASM program looks at the value in register 0 and, if it is zero, jumps to address A1; otherwise it jumps to address A2. Thus, the value of X after executing program p depends on the value of register $\$0$ after c is executed. However, it is not clear what the register's value will be when this program is compiled and run, since reasonable compilers could use the register $\$0$ in different ways – or not at all – to compile the IMP command c , resulting in different register states. We thus consider inlining any ASM program that relies on the initial values of registers to be undefined behavior. We formalize this property in Section 5.3. We further take the same approach as `CompCert`,¹ and only verify the correctness and security of programs that are well-defined.

2.6 Weak Bisimulation

Much of the power of ITrees comes from their equational theory. While it is natural to reason about coinductive structures like ITrees using *bisimulation*, the “obvious” bisimulation relation is too strong for our needs. For example, the more complex operations we have

¹ Personal Communication with Xavier Leroy.

$$\begin{array}{c}
\frac{\mathcal{R}(r_1, r_2)}{E \vdash \text{ret } r_1 \approx_{\mathcal{R}} \text{ret } r_2} \\
\\
\frac{E \vdash t_1 \approx_{\mathcal{R}} t_2}{E \vdash \tau \cdot t_1 \approx_{\mathcal{R}} \tau \cdot t_2} \\
\\
\frac{e : E \ A \quad \forall(a : A), E \vdash k_1(a) \approx_{\mathcal{R}} k_2(a)}{E \vdash \text{Vis } e \ k_1 \approx_{\mathcal{R}} \text{Vis } e \ k_2} \\
\\
\frac{E \vdash t_1 \approx_{\mathcal{R}} t_2}{E \vdash \tau \cdot t_1 \approx_{\mathcal{R}} t_2} \\
\\
\frac{E \vdash t_1 \approx_{\mathcal{R}} t_2}{E \vdash t_1 \approx_{\mathcal{R}} \tau \cdot t_2}
\end{array}$$

■ **Figure 3** Inference rules for weak bisimulation.

introduced, like `iter` and `interp`, insert some (finite number of) silent internal τ steps, which would be convenient to ignore. For this reason, we often prefer to work with a coarser equivalence called *weak bisimulation*, or *equivalence-up-to-tau* (`eutt`), which ignores finite numbers of τ s when comparing two ITrees.

Weak bisimulation is defined by the inference rules in Figure 3, where the relation is parameterized by a relation \mathcal{R} used to compare return values. Furthermore, the event signature of the two ITrees is made explicit by the E parameter. The first three inference rules correspond to the three constructors of an ITree and are exactly the definition of strong bisimulation. The last two rules allow us to ignore any finite number of τ s. The fact that these rules are inductive rather than coinductive is crucial. If these rules were coinductive, we could use them to show that a diverging ITree with only τ constructors is equivalent to any other ITree. Using this technique of mixed induction and coinduction, coinductive rules may be used infinitely often, while inductive rules can only be used a finite number of times before either terminating with a base case or applying a coinductive rule.

Xia et al. [57] formalize the ITrees data structure and its metatheory in a Coq library,² providing a rich equational theory up to this definition of weak bisimulation. This theory allows users to prove termination-sensitive properties about ITrees without explicitly performing coinductive proofs, greatly reducing the proof burden.

3 Exceptions with Interaction Trees

As mentioned in Section 1, we include exceptions in IMP since they are an important example of an effect which can change the control flow. In this section, we show how to model exceptions with ITrees by adding `throw` and `catch` constructs to IMP as follows:

Commands $c ::= \dots \mid \text{throw}(\ell) \mid \text{try } \{c_1\} \text{ catch } \{c_2\}$

Note that the `throw` command includes an information flow label, specifying who may see the exception.

3.1 Exceptions as Halting Events

We model exceptions in ITrees as *halting events*. Recall from Section 2.2 that events create one branch for every possible response from the system. If an event has an uninhabited response type, then that continuation can never be run since the answer type has no values. We call such events *halting* because they force the computation to stop. We formalize this with the following lemma:

² This Coq development, as well as our extension of it, defines coinductive relations using the `paco` library [18, 60] for coinductive reasoning.

► **Lemma 1.** *Suppose A is an uninhabited type and e is an event of type E A , then given any continuations k_1 and k_2 and any return relation \mathcal{R} , $E \vdash \text{Vis } e \ k_1 \approx_{\mathcal{R}} \text{Vis } e \ k_2$.*

The continuation of a halting event cannot be run and has no effect on the computational content of the ITree. This allows a programmer to assign such an ITree any desired return type without changing its computational content. This property makes halting events useful for modeling (uncaught) exceptions: an exception can have any type and causes computation to stop. To represent exceptions using this strategy, we use an event type excE with only a single constructor $\text{exc} : \text{Err} \rightarrow \text{excE}(\emptyset)$ which takes the exception’s data payload and produces an event with an empty answer type. This allows us to define $\llbracket \text{throw}(\ell) \rrbracket_c = \text{trigger } \text{exc}(\ell)$.

3.2 Catching Exceptions

Real-world languages do not just throw exceptions, they also *handle* them. To implement exception handling in ITrees, we use a common monadic interpretation of exceptions: we allow programs to return either a standard return value or an exception. Specifically, we move from an ITree of type $\text{itree } (\text{excE } \text{Err} \oplus E) R$ to one of type $\text{itree } (\text{excE } \text{Err} \oplus E) (\text{Err} \oplus R)$ using interp to lift the following h_{exc} event handler to the entire ITree, as described in Section 2.4.

$$\begin{aligned} h_{\text{exc}} &: \forall A, (\text{excE } \text{Err} \oplus E) A \rightarrow \text{itree } (\text{excE } \text{Err} \oplus E) (\text{Err} \oplus A) \\ h_{\text{exc}}(\text{inl}(\text{exc}(e))) &:= \text{ret } \text{inl}(e) \\ h_{\text{exc}}(\text{inr}(e)) &:= x \leftarrow \text{trigger } \text{inr}(e); \text{ret } \text{inr}(x) \end{aligned}$$

Even though the resulting ITree cannot have exception events, we still assign it a type that allows them so it can cleanly compose with ITrees that do contain exception events. This choice allows monadic bind to apply exception handlers – which may themselves contain exception events – to any left values (exceptions) while leaving right values (normal returns) unmodified. The result is the following exception-handling combinator, where $\text{case } k_1 \ k_2$ chooses the continuation k_1 or k_2 if the return value is inl or inr , respectively.

$$\text{trycatch}(t, k_c) := \text{interp } h_{\text{exc}} \ t \gg= \text{case } k_c \ \text{ret}$$

This trycatch combinator has a straightforward metatheory. In particular, we show how it interacts with the constructors of ITrees, allowing proof engineers to reason about trycatch without using manual coinduction.

► **Theorem 2.** *The trycatch operator satisfies the following equivalences:*

$$\begin{aligned} E \vdash \text{trycatch}(\text{ret } r, k_c) &\approx= \text{ret } r \\ E \vdash \text{trycatch}(\tau \cdot t, k_c) &\approx= \text{trycatch}(t, k_c) \\ E \vdash \text{trycatch}(\text{Vis } \text{inr}(a) \ k, k_c) &\approx= \text{Vis } \text{inr}(a) \ \lambda x. \text{trycatch}(k(x), k_c) \\ E \vdash \text{trycatch}(\text{Vis } \text{inl}(\text{exc}(\varepsilon)) \ k, k_c) &\approx= k_c(\varepsilon) \end{aligned}$$

Finally, the trycatch operator provides a simple denotation of IMP’s try-catch blocks:

$$\llbracket \text{try } \{c_1\} \ \text{catch } \{c_2\} \rrbracket_c = \text{trycatch}(\llbracket c_1 \rrbracket_c, \lambda _ . \llbracket c_2 \rrbracket_c)$$

4 Indistinguishability of Interaction Trees

To leverage the common semantic domain of ITrees to guarantee the security of a toolchain, we define our indistinguishability relation purely semantically. Intuitively, for programs to be indistinguishable, they must return indistinguishable results and have indistinguishable interactions with their environments.

Since return values can be arbitrary types, we follow `eutt` by parameterizing indistinguishability over a *return relation* \mathcal{R} . For indistinguishability, \mathcal{R} describes when two values *appear* to be the same to the adversary. For example, consider a program that outputs a pair (a, b) where a is visible to Alice and b is visible to Bob, but not vice versa. The values $(1, 1)$ and $(1, 2)$ are not equal, but they are indistinguishable from Alice’s perspective, as she can only see the first element. We can represent Alice’s view of the output with a relation $\mathcal{R}_{\text{Alice}}$ defined by $\mathcal{R}_{\text{Alice}}((a, b), (a', b')) \iff a = a'$.

We could simply use `eutt` with a return relation \mathcal{R} modeling indistinguishability. The resulting relation would model an adversary who can only see some part of the program’s output, but it would require the two programs to interact with the environment in precisely the same way. Most settings, however, allow adversaries to see some interactions, but not others. For example, memory may be partitioned into a protected heap the adversary can never see, and an unprotected heap that it can see at all times. Reasoning about security when some events are visible and others are not requires changing `eutt` to account for what the adversary can observe.

4.1 Secure Equivalence Up-To Taus

Our indistinguishability relation is called *secure equivalence up-to tau* or `seutt`. In addition to a return relation, `seutt` is also parameterized by a label ℓ , representing what the adversary can see, and a *sensitivity function* ρ that maps events to labels, representing who may observe which events. Intuitively, two ITrees are related by `seutt` if the environment interactions appear the same to an adversary who can see events only at or below label ℓ , and the return values are related by \mathcal{R} . We write the relation as $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}}^{\ell} t_2$.

Notably, we base the relation on `eutt`, which makes it progress sensitive. Recall from Section 2.1 that progress-sensitive noninterference allows any adversary to determine if a program silently diverges, and is often prohibitively expensive to enforce. We will also define `pi-seutt`, a progress-insensitive version of `seutt`, in Section 4.3. The judgments take the same form, so we annotate the turnstile with a subscript ps or pi to distinguish them visually.

For presentation, we separate the rules for `seutt` into three groups: rules covering returns, τ s, and public events (Figure 4), rules covering secret events that do not halt the program (Figure 5), and rules covering secret halting events (Figure 6).

Public Events and Returns. When an adversary is able to see an event, indistinguishability acts just like weak bisimulation. The rules, found in Figure 4, are almost identical to the rules of `eutt`, but with the added requirement that any visible event be visible to the adversary. That is, we require $\rho(e) \sqsubseteq \ell$ in `PUBVIS`.

It might seem mysterious that we *require* the event to be visible in `PUBVIS`. But allowing this rule to apply no matter the visibility would allow the adversary too much power, since they would know that the same result is returned on both sides of the equivalence. As we will see, the rule for invisible events is stricter. We will also see how this strictness, when proving a program p indistinguishable from itself, corresponds to proving that the behavior

$$\begin{array}{c}

\end{array}$$

■ **Figure 5** Inference rules for indistinguishability, where events are not visible but answer types are inhabited.

of p does not differ in runs in *low-equivalent* environments. If we were to allow high events in PUBVIS, this would allow our proof to only consider the behavior of p in one environment, breaking our correspondence with information-flow security.

Private Events With Responses. When the adversary is *unable* to view an event, \mathbf{seutt} cannot act like \mathbf{eutt} . In this case, the rules are designed to formalize two intuitions. If the computation continues after a secret event, we should treat the event like a τ , since the adversary cannot observe either. If the event halts the computation, the event should be equivalent to a silently nonterminating computation.

The rules in Figure 5, along with symmetric analogues of PRIVVISTAU and PRIVVISINDL, handle the case where the event allows computation to continue – that is, the event’s answer type is inhabited. The first rule, PRIVVISTAU, relates a private event $\mathbf{vis} e k$ with a $\tau \cdot t$. In addition to requiring the event to be secret ($\rho(e) \not\sqsubseteq \ell$) and have a non-empty answer type ($\neg \mathbf{empty}(A)$), it also requires the continuation k produce an ITree indistinguishable from t for *every* possible response. This requirement ensures that the adversary’s future observations cannot depend on the response to the private event. Note that the requirement that A be non-empty does more than just specify when the rule applies. Without it, a private halting event would trivially satisfy this condition, allowing it to relate to any ITree with a τ in front. Since the adversary can determine when a program has halted, they should be able to distinguish, for example, a program that throws a private exception from a program which, after a τ , prints to a public channel. This rule ensures that this intuition holds.

$$\begin{array}{c}
E; \rho \vdash_{ps} \mathbf{Vis} \ e \ k \approx_{\mathcal{R}}^{\ell} t \\
e : E \ A \quad \mathit{empty}(A) \\
\rho(e) \not\sqsubseteq \ell \\
\hline
[\text{EMPVISTAU}] \frac{}{E; \rho \vdash_{ps} \mathbf{Vis} \ e \ k \approx_{\mathcal{R}}^{\ell} \tau \cdot t}
\end{array}
\qquad
\begin{array}{c}
\forall b, E; \rho \vdash_{ps} \mathbf{Vis} \ e_1 \ k_1 \approx_{\mathcal{R}}^{\ell} k_2(b) \\
e_1 : E \ A \quad e_2 : E \ B \\
\mathit{empty}(A) \quad \rho(e_1) \not\sqsubseteq \ell \quad \rho(e_2) \not\sqsubseteq \ell \\
\hline
[\text{EMPVISVISL}] \frac{}{E; \rho \vdash_{ps} \mathbf{Vis} \ e_1 \ k_1 \approx_{\mathcal{R}}^{\ell} \mathbf{Vis} \ e_2 \ k_2}
\end{array}$$

■ **Figure 6** Inference rules for indistinguishability, where events are halting and not visible.

PRIVVISINDL is analogous to TAUL, but for secret events instead of τ nodes. This rule has the same premises as PRIVVISTAU for the same reasons. Moreover, it only removes a node from the head of one ITree, not both. As with the definition of **seutt**, TAUL, and TAUR, we therefore make PRIVVISINDL inductive, not coinductive, to avoid relating an infinite stream of secret events to all other ITrees.

Finally, PRIVVISVIS removes a private event from the head of both sides of the relation. As with the previous rules, we require both events to be private and have non-empty answer types. This time, we require the continuations of the two events to be indistinguishable for every possible response *of both events separately*. This requirement formalizes the idea that the adversary should not be able to distinguish the program's behavior on any pair of secret responses.

To see the power of this rule, consider whether an adversary who can see l but not h would find the following ITrees indistinguishable from themselves:

$$\begin{array}{ll}
t_{\text{sec}} \triangleq x \leftarrow \mathbf{trigger} \ \mathbf{get}(l); & t_{\text{insec}} \triangleq x \leftarrow \mathbf{trigger} \ \mathbf{get}(l); \\
y \leftarrow \mathbf{trigger} \ \mathbf{get}(h); & y \leftarrow \mathbf{trigger} \ \mathbf{get}(h); \\
\mathbf{trigger} \ \mathbf{set}(h, x + y) & \mathbf{trigger} \ \mathbf{set}(l, x + y)
\end{array}$$

One would hope that t_{sec} would be indistinguishable from itself, while t_{insec} would not be, and indeed that is the case. To (attempt to) prove that either tree is equivalent to itself, we walk through each ITree. Since l is visible, so is **get**(l), so PUBVIS applies and requires only that each possible value of x produce an ITree that is indistinguishable from itself. Because h is secret, the adversary should not be able to observe or infer its value, so we must use PRIVVISVIS to remove **get**(h). PRIVVISVIS requires that, for all possible *pairs* of values y_1, y_2 , the continuations be indistinguishable. Thus in t_{sec} , **trigger set**($h, x + y_1$) must be indistinguishable from **trigger set**($h, x + y_2$). Since h is secret, so are the **set** events, so PRIVVISVIS can remove them even when they differ. After removing **set**, the remaining continuation always produces **ret** (), so RET finishes the proof.

However, in t_{insec} , PRIVVISVIS does not apply to the **set** events since l is visible. PUBVIS only relates ITrees starting with the same event, but **set**($l, x + y_1$) \neq **set**($l, x + y_2$) when $y_1 \neq y_2$. As a result, no rule applies after removing **get**(h), so the adversary can distinguish t_{insec} from itself. In other words, t_{insec} is, indeed, insecure.

Private Halting Events. Finally, we turn to the case where an event the adversary cannot see halts the computation. In this case, the adversary should be unable to tell that the event took place, and therefore should not be able to distinguish a program with a secret halt from a program that never terminates. However, the adversary should still be able to distinguish it from any ITree that contains an event the adversary can see.

This intuition means that a private halting event should not be treated like a τ , as a private non-halting event is, but rather should be indistinguishable from *an infinite stream of τ s*. We formalize this approach with the rules presented in Figure 6 along with their symmetric analogues. EMPVISTAU peels a single τ off the right ITree, leaving the private halting event on the left unmodified. EMPVISVISL does the same for a private event.

There are two interesting properties about these rules. First, unlike the rules for private events and τ s that leave one side of the equivalence unmodified, these rules are coinductive, not inductive. This choice allows us to relate a private halting event to an entire nonterminating program, as long as that program has no public events. Indeed, no rule allows us to remove a private halting event, as there would be nothing left to compare. Second, EMPVISVISL has no requirement that B , the answer type of the not-necessarily-halting event, be non-empty. This choice avoids the need to explicitly handle the case where both ITrees contain private halts. If B is non-empty, then EMPVISVISL treats the event as a τ . If B is empty, then the first premise of the rule is trivially satisfied, which is desirable, as in that case both ITrees begin with a private halt event and should be equivalent.

4.2 The Metatheory of Indistinguishability

The seutt relation captures intuitions about when two ITrees are indistinguishable to some adversary, but using it requires a delicate mix of induction and coinduction. To both demonstrate the power of our definition and better support verification, we also develop a library of metatheory for indistinguishability. This library supports reasoning about cross-language toolchains without the need for explicit coinduction, as we will see when we verify the correctness of a security type system and compiler for IMP (Sections 5 and 6, respectively).

Indistinguishability as a PER Model. Recall from Section 2.1 that Sabelfeld and Sands [46] argue for indistinguishability forming a partial equivalence relation (PER). It would be nice if seutt always formed a PER, but because it is parameterized on an arbitrary relation for return values, that is not always the case. Instead, we prove generalized versions of transitivity and reflexivity. In particular, if we let $\overleftarrow{\mathcal{R}}$ denote the reverse relation of \mathcal{R} – that is, $\overleftarrow{\mathcal{R}}(x, y) \triangleq \mathcal{R}(y, x)$ – then the following theorems hold.

► **Theorem 3.** *For all \mathcal{R} , E , ρ , and ℓ , if $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}}^{\ell} t_2$, then $E; \rho \vdash_{ps} t_2 \approx_{\overleftarrow{\mathcal{R}}}^{\ell} t_1$.*

► **Theorem 4.** *If $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}_1}^{\ell} t_2$ and $E; \rho \vdash_{ps} t_2 \approx_{\mathcal{R}_2}^{\ell} t_3$ then $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}_1 \circ \mathcal{R}_2}^{\ell} t_3$.*

Note that if \mathcal{R} is symmetric, then $\mathcal{R} = \overleftarrow{\mathcal{R}}$, and if \mathcal{R} is transitive, then $\mathcal{R} \circ \mathcal{R} \subseteq \mathcal{R}$. These properties allow us to prove the following corollary.

► **Corollary 5.** *If \mathcal{R} is a PER, then so is $E; \rho \vdash_{ps} - \approx_{\mathcal{R}}^{\ell} -$ for any E , ρ , and ℓ .*

ITree Combinators. ITrees are often defined using the combinators from Section 2.2, making it important to understand how indistinguishability interacts with those combinators. The definition of seutt directly describes how to relate simple programs defined using only ret and trigger , but they say nothing about larger ITrees built using bind and iteration .

bind allows for the sequential composition of programs. We would like indistinguishable programs t_1 and t_2 followed by indistinguishable continuations k_1 and k_2 to compose into larger indistinguishable programs $t_1 \gg k_1$ and $t_2 \gg k_2$. The following theorem says that this result holds whenever the relation \mathcal{R}_1 , securely relating t_1 and t_2 , puts enough constraints on their possible outputs to ensure that k_1 and k_2 are always securely related at some relation \mathcal{R}_2 .

► **Theorem 6.** *If $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}_1}^{\ell} t_2$ and for all values a, b , $\mathcal{R}_1(a, b)$ implies $E; \rho \vdash_{ps} k_1(a) \approx_{\mathcal{R}_2}^{\ell} k_2(b)$, then $E; \rho \vdash_{ps} t_1 \gg k_1 \approx_{\mathcal{R}_2}^{\ell} t_2 \gg k_2$.*

Iteration represents loops, which have two parts: an initial value, and a body that produces a value from the previous value. Indistinguishable initial values paired with indistinguishable bodies produce indistinguishable loops, as we can see in the following theorem.

► **Theorem 7.** *If $\mathcal{R}_1(a_1, b_1)$ and, for any $a, b, E; \rho \vdash_{ps} k_1(a) \approx_{\text{caseR}(\mathcal{R}_1, \mathcal{R}_2)}^\ell k_2(b)$ whenever $\mathcal{R}_1(a, b)$, then $E; \rho \vdash_{ps} \text{iter } k_1 \ a_1 \approx_{\mathcal{R}_2}^\ell \text{iter } k_2 \ b_1$.*

This rule is conceptually similar to a loop invariant from a Hoare-style logic. \mathcal{R}_1 is a property that is initially true and is preserved on each iteration except the final one, while the final iteration guarantees that \mathcal{R}_2 holds. The $\text{caseR}(\mathcal{R}_1, \mathcal{R}_2)$ function lifts two relations to a single relation over sum types such that \mathcal{R}_1 is applied to two left values, \mathcal{R}_2 is applied to two right values, and no other combination is related.

Relationship with Equivalence Up-To Taus. Recall that weak bisimulation of ITrees (eutt) requires two ITrees to contain the same pattern of interaction with their environment. Our notion of indistinguishability assumes that adversaries distinguish programs purely based on their interactions with the environment. One would thus expect that combining eutt with indistinguishability should result in indistinguishability. The following theorem shows this to be the case.

► **Theorem 8 (Mixed Transitivity).** *If both $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}_1}^\ell t_2$ and $E \vdash t_2 \approx_{\mathcal{R}_2} t_3$ then we can conclude that $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}_1 \circ \mathcal{R}_2}^\ell t_3$.*

This is a very powerful theorem. In particular, many program transformations preserve equality. That is, they take source programs with equivalent-up-to-taus ITree representations to target programs with the same property. Mixed transitivity tells us that compilers built from such transformations also preserve indistinguishability. For instance, since noninterference – the security property we are ultimately considering – is defined as a program being indistinguishable from itself, mixed transitivity supports a very simple proof that the compiler in Section 6 preserves noninterference. While this result might be surprising, it reflects the utility of ITrees and indistinguishability. By looking at which labels can distinguish an ITree from itself, we can discover where leaks are possible.

4.3 Progress-Insensitive Indistinguishability

The type systems that enforce progress-sensitive noninterference are extremely restrictive. Thus, information-flow control literature mostly studies progress-*insensitive* type systems. These type systems enforce noninterference against adversaries who cannot see when a program has begun to silently loop forever. Intuitively, such adversaries believe that silently looping programs could break out of their loops at any moment, and so do not distinguish them from programs which have produced visible events.

In order to support such reasoning, we introduce pi-seutt , a progress-insensitive version of indistinguishability for ITrees. This leads to the following definition:

► **Definition 9 (pi-seutt).** *The relation pi-seutt , the progress-insensitive version of indistinguishability, is defined by modifying the definition of seutt by completely removing the rules for halting events (all rules in Figure 6) and making every other rule coinductive (this modifies TAUL and TAUR in Figure 4 as well as PRIVVISINDL in Figure 5 and its not-presented symmetric counterpart).*

This relation is strictly more permissive than seutt , since it relates every ITree to silently diverging ITrees and private halts. These facts can be formalized in the following theorems:

► **Theorem 10.** *If $E; \rho \vdash_{ps} t_1 \approx_{\mathcal{R}}^{\ell} t_2$ then $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}}^{\ell} t_2$.*

► **Theorem 11.** *Given any ITree t , $E; \rho \vdash_{pi} t_{spin} \approx_{\mathcal{R}}^{\ell} t$.*

► **Theorem 12.** *Given any ITree t , if e is a halting event, then $E; \rho \vdash_{pi} \text{Vis } e \ k \approx_{\mathcal{R}}^{\ell} t$.*

Just as with the progress-sensitive version of indistinguishability, we can show that indistinguishability plays well with the usual ITree combinators. This allows us to prove ITrees indistinguishable in many cases without resorting to hand-rolled coinduction.

► **Theorem 13.** *If $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}_1}^{\ell} t_2$ and $E; \rho \vdash_{pi} k_1(a) \approx_{\mathcal{R}_2}^{\ell} k_2(b)$ whenever $\mathcal{R}_1(a, b)$, then $E; \rho \vdash_{pi} t_1 \gg_{\mathcal{R}_1}^{\ell} k_1 \approx_{\mathcal{R}_2}^{\ell} t_2 \gg_{\mathcal{R}_2}^{\ell} k_2$.*

► **Theorem 14.** *If $\mathcal{R}_1(a_1, a_2)$ and for any a, a' , $E; \rho \vdash_{pi} k_1(a) \approx_{\text{caseR}(\mathcal{R}_1, \mathcal{R}_2)}^{\ell} k_2(a')$ whenever $\mathcal{R}_1(a, a')$, then $E; \rho \vdash_{pi} \text{iter } k_1 \ a_1 \approx_{\mathcal{R}_2}^{\ell} \text{iter } k_2 \ a_2$.*

Moreover, mixed transitivity again holds, allowing for simple proofs of compiler safety:

► **Theorem 15 (Mixed Transitivity).** *If both $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}_1}^{\ell} t_2$ and $E \vdash t_2 \approx_{\mathcal{R}_2} t_3$ then we get $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}_1 \circ \mathcal{R}_2}^{\ell} t_3$.*

Progress-insensitive indistinguishability behaves differently from the progress-sensitive sibling version in one important way: it does not form a PER. Because it relates a diverging ITree to every other ITree, `pi-seutt` is not transitive. This is not surprising, since progress-insensitive indistinguishability is not a PER [54, 42, 16]. It does, however, retain generalized symmetry, and a weakened but still-useful version of generalized transitivity:

► **Theorem 16.** *If $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}}^{\ell} t_2$ then $E; \rho \vdash_{pi} t_2 \approx_{\mathcal{R}}^{\ell} t_1$.*

► **Theorem 17.** *If $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}_1}^{\ell} t_2$, $E; \rho \vdash_{pi} t_2 \approx_{\mathcal{R}_2}^{\ell} t_3$, and t_2 converges along all paths, then $E; \rho \vdash_{pi} t_1 \approx_{\mathcal{R}_1 \circ \mathcal{R}_2}^{\ell} t_3$.*

Where an ITree is considered convergent if it is either a `ret`, a τ followed by a convergent ITree, or a non-halting event followed by a continuation that converges for any input.

Unlike progress-sensitive indistinguishability, we can easily show that loops produce no events that are observable to some adversary at ℓ via `pi-seutt`. Suppose that we want to show that `iter` body a_0 emits no events that are observable to some adversary at ℓ . We can do so by showing that `iter` body a_0 and `ret` b are indistinguishable with some return relation \mathcal{R} . This shows that the body of the loop both emits no observable events and, if the loop terminates, it returns a value c where $\mathcal{R}(c, b)$. Importantly, we have not made any statement about whether the loop terminates; we have merely said that it will not produce events, regardless of its termination behavior. We formalize this in the following theorem:

► **Theorem 18.** *For any relation \mathcal{R}_{inv} , if*

$$\mathcal{R}_{inv}(a_0, b) \quad \text{and} \quad \forall a, \mathcal{R}_{inv}(a, b) \implies E; \rho \vdash_{pi} \text{body } a \approx_{\text{leftcase}(\mathcal{R}_{inv}, \mathcal{R})}^{\ell} \text{ret } b,$$

then $E; \rho \vdash_{pi} \text{iter } \text{body } a_0 \approx_{\mathcal{R}}^{\ell} \text{ret } b$, where the relation `leftcase` is defined as follows:

$$\text{leftcase}(\mathcal{R}_1, \mathcal{R}_2)(\text{inl}(a), b) = \mathcal{R}_1(a, b) \quad \text{leftcase}(\mathcal{R}_1, \mathcal{R}_2)(\text{inr}(a), b) = \mathcal{R}_2(a, b)$$

4.4 Noninterference and Interpretation

Recall from Section 2.1 that we can define noninterference using an indistinguishability relation on programs by saying that a program is noninterfering if it is related to itself – given indistinguishable inputs, it will produce indistinguishable computations. We could define noninterference on ITrees using `seutt` (or `pi-seutt`), as they provide such indistinguishability relations by design. This approach produces a sensible definition, but one that assumes an extremely strong adversary.

Consider the following IMP program, where the h_i s have label ℓ_h and the l_i s have label ℓ_l :

```
if ( $h_1 = 0$ ) then  $\{h_2 := l_1\}$  else  $\{h_2 := l_2\}$ 
```

Since the program writes only to secret variables, intuitively this program seems secure. However, according to `seutt`, it is not related to itself at ℓ_l since reading from l_1 and l_2 produce different `get` events with label ℓ_l . All adversaries have the power to observe *reads* of public state, not just writes.

The visibility of public read events is not the only problem. Using just `seutt` also means a computation cannot publicly depend on the result of reading a secret variable, even if a public value were written to that variable. For instance, the following program would also be considered insecure:

```
 $h := l$ ; print( $\ell_l, h$ )
```

If h cannot change between assignments, this program is intuitively secure, but `seutt` at ℓ_l requires `print`(ℓ_l, h) to produce the same output regardless of the value of h , which it clearly does not.

On uninterpreted ITrees, `seutt` models a system where both reads and writes are visible to anyone who can see the variable, and the value of a secret variable may silently change between a read and a write. This model makes perfect sense in some contexts – like distributed computation [27] – but we usually consider weaker adversaries.

We can remove these assumptions and model a weaker adversary by interpreting state, as we discussed in Section 2.4. Interpreting these programs would result in two meta-level functions (i.e., Coq functions) which take a state as input and produce an ITree returning an output state. For example in Section 2.4, we define the semantics of an IMP program c as an interpreted ITree – that is, as a function from states to ITrees – not as a single ITree with state events. We thus adjust our notions of indistinguishability and noninterference to account for this semantic construct.

Intuitively, we start with a family of relations $\mathcal{R}_{S,\ell}$ that describes when states are indistinguishable to an adversary at level ℓ and use it to define the following observational equivalence. For technical reasons, we require $\mathcal{R}_{S,\ell}$ to be an equivalence relation at all labels. For IMP, we use a relation \cong_1^ℓ which only requires states to agree on a variable x if the label of x flows to ℓ .

► **Definition 19** (Stateful Indistinguishability). *Two stateful computations p_1 and p_2 are px-statefully indistinguishable under $\mathcal{R}_{S,\ell}$ and \mathcal{R} at label ℓ if, for every pair of states σ_1 and σ_2 such that $\mathcal{R}_{S,\ell}(\sigma_1, \sigma_2)$,*

$$E; \rho \vdash_{px} p_1 \sigma_1 \approx_{\mathcal{R}_{S,\ell} \times \mathcal{R}}^{\ell} p_2 \sigma_2$$

$$\text{where } \mathcal{R}_{S,\ell} \times \mathcal{R}((\sigma'_1, a_1), (\sigma'_2, a_2)) \stackrel{\Delta}{\iff} \mathcal{R}_{S,\ell}(\sigma'_1, \sigma'_2) \text{ and } \mathcal{R}(a_1, a_2)$$

$$\frac{\Gamma(x) \sqsubseteq \ell}{\Gamma \vdash x : \ell} \qquad \frac{}{\Gamma \vdash n : \ell} \qquad \frac{\Gamma \vdash e_1 : \ell_1 \quad \Gamma \vdash e_2 : \ell_2}{\Gamma \vdash e_1 \odot e_2 : \ell_1 \sqcup \ell_2}$$

■ **Figure 7** Typing rules for expressions in security-typed IMP.

As described above, stateful indistinguishability with \cong_{Γ}^{ℓ} defines security against an adversary who can observe public writes, but not secret writes or secret reads. This indistinguishability relation leads to a much more common definition of noninterference, and it is the one we will use in our case studies in Sections 5 and 6.

► **Definition 20** (Noninterference). *A stateful computation is px-noninterfering with state relations $\mathcal{R}_{S,\ell}$ and return relation \mathcal{R} if, given any label ℓ , it is px-statefully indistinguishable from itself under state relation family $\mathcal{R}_{S,\ell}$ and return relation \mathcal{R} .*

5 Security Sensitive Type Systems For Imp

To see how to use this theory of indistinguishability and ITrees, we now provide an information-security guarantee for an example toolchain for IMP. We begin by verifying two information-flow type systems, and proceed with a simple compiler in Section 6. The two notions of noninterference – progress sensitive and progress insensitive – require slightly different type systems, so we use our ITrees-based semantics to formally verify that both enforce their respective notions of noninterference. As is common in such type systems, we assume \mathcal{L} forms a join semilattice with a unique least element \perp representing “completely public.”

5.1 Two Type Systems

Both type systems have two typing judgments: one for expressions and one for commands. The typing judgments for expressions take the form $\Gamma \vdash e : \ell$, where Γ is a map from variables to information flow labels, and ℓ is a label. The judgment says that e is well-typed and depends only on information at or below label ℓ . The typing rules for expressions, which are the same for both type systems, are presented in Figure 7.

The typing rules for commands are presented in Figure 8. As these rules differ between the progress-sensitive and progress-insensitive type systems, we annotate the turnstyles with ps for progress-sensitive rules, pi for progress-insensitive rules, and px for rules that are identical in both type systems.

The typing judgments for commands take the form $\Gamma; pc \vdash_{px} c \diamond \ell_{ex}$, where pc and ℓ_{ex} are information-flow labels. The pc label is a *program-counter label* that tracks the sensitivity of the control flow, while the second label ℓ_{ex} is an upper bound on the label of any exceptions c might raise. Note that the rules listed in Figure 8 do not include any way to type check an inlined ASM program. We address this concern in Section 5.3.

Program-counter labels are a standard technique to control *implicit information flows* – that is, information leaked by the control flow [45]. For example, consider the following program where h has label ℓ_h and l has label ℓ_l with $\ell_h \not\sqsubseteq \ell_l$:

if ($h = 0$) then $\{l := 0\}$ else $\{l := 1\}$

While l is only ever explicitly set to constant values, its final value clearly depends on the secret h . The pc label allows us to detect and eliminate these flows by tracking the sensitivity of the control flow. Specifically, the IF rule requires the condition’s label to flow to the pc in

Shared Typing Rules

■ **Figure 8** Typing rules for commands in security-typed IMP.

each branch, and the ASSIGN rule requires the pc to flow to the label of the variable being assigned. In the above example, the label of the condition $h = 0$ is ℓ_h , so IF requires c_1 and c_2 to type check with a pc where $\ell_h \sqsubseteq pc$. Since $\Gamma(l) = \ell_l$, ASSIGN requires $pc \sqsubseteq \ell_l$. Transitivity of \sqsubseteq thus requires $\ell_h \sqsubseteq \ell_l$, which it does not, so the program correctly fails to type check.

Exceptions can affect the control flow of a program, and therefore can also cause implicit flows of information. Consider the following program.

if ($h = 0$) then {throw(ℓ_h)} else {skip}; $l := 1$

Much like the previous example, this program only assigns l to a constant, yet it still leaks the value of h . We use a standard technique [32, 40] that relies on exception labels in the typing judgment. As previously mentioned, the exception label of a program c is an upper bound on the labels of any exception c might raise. To eliminate exception-based leaks, the SEQ rule increases the pc label of the second command by the exception label of the first. The TRY rule makes similar use of the exception label, increasing the pc in the catch block, as that command only executes if an exception is thrown.

The SKIP rule is simple, as skip can never have an effect. PRINT produces a flow of information to an output channel labeled ℓ' , so it checks that ℓ' may safely see both the expression being written and the fact that this command executed.

The rules for while loops and throw statements are different for the progress-sensitive and progress-insensitive type systems, so we handle them separately.

Progress-Sensitive While and Throw Rules. In a progress-sensitive setting, the adversary can observe nontermination. As a result, a program's termination behavior can only safely depend on completely public information. WHILE-PS enforces this requirement in a standard,

but highly restrictive way [55]: the loop condition and the pc of the context must both be the fully public label \perp . Moreover, any exceptions thrown in the body of the loop could also influence termination behavior, so those must be fully public as well.

Recall from Section 4 that a low observer cannot distinguish between an uncaught secret exception and an infinite loop. Thus non-public exceptions create the same implicit flows as while loops, so THROW-PS restricts exceptions in much the same way as WHILE-PS restricts loops: everything must be fully public.

Progress-Insensitive While and Throw Rules. In a progress-insensitive setting, the adversary cannot see nontermination, so secrets can safely influence the termination behavior of a program. The WHILE-PI rule therefore allows loops with any pc . Since both the loop condition and any exceptions the loop body throws influence whether the body is run, WHILE-PI increases the pc in the loop body by both the loop guard label and the body's exception label.

For the same reason, THROW-PI is more permissive than its progress-sensitive counterpart. In particular, the label on the exception just needs to be at least as secret as the pc label.

5.2 Proving Security

Both type systems enforce their respective notions of noninterference (Definition 20). Unlike many existing proofs of noninterference, our proofs using ITrees proceed by simple induction over the syntax of IMP. This simplicity is made possible by the combination of two facts: our IMP semantics is given by simple induction using ITrees combinators, and those combinators interact with indistinguishability in predictable ways, as described by the metatheory of Section 4.

Type systems are inherently compositional: we are able to conclude that a program is secure knowing nothing about subprograms other than that they also type check. However, our semantic definition of noninterference is *not* fully compositional. To see this, consider the IMP program $p = l := h ; \text{throw}(\ell)$. This program updates the state in an insecure way, assigning a high-security value to a low-security variable, and then throws a low-security exception. In fully interpreted programs, the updated state is part of the return value, but adversaries cannot observe that return value if an exception is thrown (see Section 3), making p semantically secure. However, if we catch the exception, the adversary once again can see the effect of the assignment $l := h$. Thus, p does not compose securely.

In order for our type system to enforce security compositionally, it enforces two properties beyond noninterference. Each rules out programs which, like p above, are secure but do not compose securely. The first describes how state and exceptions interact in a secure setting, which will rule out the example program above. The second, called *confinement*, defines how effects are bound by the type system.

Interaction of Exceptions and State. Our first goal is to semantically rule out programs like p above, allowing us to reason compositionally about exception handlers. In order to do so, we need to reason about what state updates are performed before an exception is thrown. However, since in our semantics of IMP we interpret state events while leaving exceptions as ITree events, the result state of an IMP program is forgotten when an exception is thrown.

This correctly models our adversary, who cannot distinguish between private exceptions and silently diverging programs. But in order to achieve compositionality, we need to keep information about the final state before an exception is raised. We accomplish this with a condition on an alternative semantics for IMP programs. In this semantics, exceptions are

interpreted into the standard sum type representation before state events are interpreted. This interpretation, $\text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket c \rrbracket_c)$, is a stateful function that returns a final state along with either a result of type `unit` or the label of an exception. We can inspect this final state to ensure that the program always takes indistinguishable states to indistinguishable states.

We formalize this property as follows, where the relation \cong_{\top}^{ℓ} requires that states agree on a variable x only when $\Gamma(x) \sqsubseteq \ell$, as in Section 4.4.

► **Definition 21** (Exceptions-and-State Property). *A command c satisfies the px-exceptions-and-state property if $\text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket c \rrbracket_c)$ is statefully indistinguishable from itself under \cong_{\top}^{ℓ} and \top at every label ℓ .*

Note the use of \top as the output relation means we ignore whether or not c threw an exception, while we still ensure that the final states are indistinguishable. Ignoring this information in this property is acceptable because it is captured by our standard noninterference condition.

Confinement. Even with the exceptions-and-state property, implicit flows, like the motivating our use of pc labels, can still break compositionality. Confinement fixes this.

In the typing judgment for commands, the pc and ℓ_{ex} labels are both designed to constrain effects. If a command type checks with pc and ℓ_{ex} , it should have no effects visible *below* pc and no (uncaught) exceptions *above* ℓ_{ex} . Semantically, a program has no visible effects below pc if, for any label ℓ where $pc \not\sqsubseteq \ell$, it is indistinguishable from `skip`. For any uncaught exception terminating a ITree, we simply check that the exception's label flows to ℓ_{ex} . We formalize this idea into the following property called *confinement*.

► **Definition 22** (Confinement). *A command c is px-confined to pc with ℓ_{ex} exceptions, if, for all labels ℓ such that $pc \not\sqsubseteq \ell$, the following conditions hold.*

1. c is indistinguishable from `skip` at ℓ : $\text{interp } h_{\text{prog}} \llbracket c \rrbracket_c$ and $\text{interp } h_{\text{prog}} \llbracket \text{skip} \rrbracket_c$ are px -statefully indistinguishable under \cong_{\top}^{ℓ} and $=$ at ℓ .
2. c makes no modifications to the state visible at ℓ : $\text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket c \rrbracket_c)$ and $\text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket \text{skip} \rrbracket_c)$ are px -statefully indistinguishable under \top and $=$ at ℓ .
3. For all initial state heap states h and register states r where c throws an exception, the label of that exception flows to ℓ_{ex} :

$$E \vdash (\text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket c \rrbracket_c))(r, h) \approx_{=} \text{ret } (r', h', \text{inr}(\ell'_{\text{ex}})) \implies \ell'_{\text{ex}} \sqsubseteq \ell_{\text{ex}}$$

Together, these definitions restrict programs to those that compose securely, as required by the type system. With this compositionality property, we can prove that our type system enforces the conjunction of all three properties.

► **Theorem 23.** *If $\Gamma; pc \vdash_{px} c \diamond \ell_{\text{ex}}$, then c is px -noninterfering (Definition 20), satisfies the px -exceptions-and-state property, and is px -confined to pc with ℓ_{ex} exceptions.*

5.3 Semantic Typing and Inline Asm

Both type systems above enforce security, but are highly conservative. Many secure programs fail to type check, notably including any secure program with inlined ASM. To support our goal of cross-language security reasoning and address this concern without the need to introduce a type system for ASM, we provide a *semantic typing* [21] rule.

One would hope that the three conditions discussed above would be sufficient. However, the possibility of undefined ASM behavior (see Section 2.5) necessitates an additional condition. We thus introduce the notion of *inline validity*, which requires inlined ASM to depend only on the initial heap state, not the initial register state, thereby ruling out undefined behavior.

► **Definition 24** (Inline Validity). *An ASM program a is inline-valid if, given any two register states r_1 and r_2 , and any heap states h , then a run with (r_1, h) and (r_2, h) produces the same changes to the heap. That is, if $p = \text{interp } h_{\text{prog}} (\text{interp } h_{\text{exc}} \llbracket a \rrbracket_{\text{asm}})$, then*

$$\text{printE} \vdash p(r_1, h) \approx_{\top \times =} p(r_2, h).$$

Note that any ASM program that only ever reads from a register after it has written to that register will satisfy this property. We also lift this definition to whole IMP programs by applying it separately to each inlined ASM block.

► **Definition 25** (Validity). *c is a valid IMP program if any inlined ASM program it contains is an inline-valid ASM program.*

Including validity with our other semantic conditions is sufficient to guarantee security, so we can safely define the following semantic typing rule.

$$\begin{array}{c} c \text{ is px-noninterfering} \\ c \text{ satisfies the px-exceptions-and-state property} \\ c \text{ is px-confined to } pc \text{ and } \ell_{ex} \\ c \text{ is valid (Definition 25)} \\ \hline \text{[SEMANTIC]} \frac{}{\Gamma; pc \vdash_{px} c \diamond \ell_{ex}} \end{array}$$

Adding this new rule to both type systems allows them to reason about multi-language programs including inline ASM and larger systems, even when the syntactic type system cannot reason about every component. Importantly, SEMANTIC (??) is sound from a security perspective. That is, Theorem 23 continues to hold for both extended type systems.

6 Preserving Noninterference Across Compilation

For a compiled language like IMP, noninterference is only part of the story. After all, rather than run IMP code directly, programmers instead compile IMP to ASM and run the ASM. Compilation can change programs significantly, and can introduce insecurity in the process. Thus, we need to ensure that the compiler translates noninterfering IMP programs into noninterfering ASM programs. We now turn our attention to the proof-engineering effort involved in providing such an assurance. In particular, we show that (a) adding exceptions and information-flow labels to IMP does not complicate the proof of compiler correctness, and (b) turning a proof of correctness into a proof of noninterference preservation is simple using mixed transitivity (Theorem 8).

Note that, to build our compiler, we had to fix the number of information-flow labels. We thus specialize our discussion of IMP from Section 5 to the two-point lattice $\mathcal{L} = \{\top, \perp\}$. Using any other finite lattice would require only minimal changes.

6.1 Asm, Its Semantics, and the Compiler

Figure 9 presents the syntax of ASM, the simple assembly language that our compiler targets. An ASM program is a sequence of *blocks*, where each block starts at some address A and consists of a sequence of straight-line instructions followed by a single jump. The first block must be at the special address `START`.

Registers	r	$::=$	$\$0 \mid \$1 \mid \dots$
Operands	o	$::=$	$r \mid n$
Instructions	i	$::=$	$\text{ADD } r_1 \leftarrow r_2, o \mid \text{SUB } r_1 \leftarrow r_2, o \mid \text{MUL } r_1 \leftarrow r_2, o$ $\mid \text{EQ } r_1 \leftarrow r_2, o \mid \text{LEQ } r_1 \leftarrow r_2, o \mid \text{NOT } r \leftarrow o$ $\mid \text{MOV } r_1 \leftarrow r_2 \mid \text{LOAD } r \leftarrow x \mid \text{STORE } x \leftarrow r \mid \text{print}(\ell, r)$
Branches	b	$::=$	$\text{JMP } A \mid \text{BRZ } r \ A1 \ A2 \mid \text{RAISE } \ell$
Blocks	B	$::=$	$A : i_1 ; \dots ; i_n ; b$
Programs	p	$::=$	$\text{START} : i_1 ; \dots ; i_n ; b$ $B_1 ; \dots ; B_m$

■ **Figure 9** Secure ASM syntax where x is a variable, A is an address, n is a natural number, and ℓ is an information-flow label.

Most ASM instructions write to exactly one register, computing the written value from a combination of other registers and integer constants. For instance, $\text{ADD } \$0 \leftarrow \$1, 1$ takes the value of register $\$1$, adds one, and stores the result in register $\$0$. The MOV instruction copies the value of one register into another, while LOAD and STORE move information between registers and the heap. Finally, the PRINT instruction prints information to a stream, depending on the label ℓ .

Jumps are either direct jumps, conditional jumps, or exceptions. A direct jump $\text{JMP } A$ immediately moves execution to the beginning of the block with address A . A conditional jump $\text{BRZ } r \ A1 \ A2$ move execution to $A1$ if register r contains zero and $A2$ otherwise. The $\text{RAISE } \ell$ branch raises an exception. Note that there is no equivalent of catching an exception. We assume that ASM programs always jump to either the address of one of the program's blocks or a special EXIT address.

Rather than representing ASM syntax directly in our Coq code, we take a more compositional approach and represent *sub-Control-Flow Graphs (sub-CFGs)*. These represent the structure of part of an ASM program. While a complete ASM program contains a unique START address, sub-CFGs may contain multiple addresses accessible to the outside. We refer to addresses which are accessible to the outside as *input* addresses. Likewise, sub-CFGs may jump to undefined addresses, whereas complete ASM programs always jump either to a defined address or EXIT . We refer to the undefined addresses a sub-CFG may jump to as its *output* addresses. Thus, a complete ASM program is a sub-CFG with exactly one input address (START) and exactly one output address (EXIT).

Intuitively, sub-CFGs execute starting at some input address, potentially jumping internally several times before they jump to some output address. To represent this pattern, we give sub-CFGs semantics as functions from an address to an ITree that return an address. That is, the semantics of a sub-CFG takes as input the input address at which to start executing, and produces an ITree that returns the output address the program jumps to. This structure is due to Xia et al. [57], and their semantic needed only minor changes to accommodate printing and exception-throwing.

In Xia et al.'s original compiler, IMP code always mapped to complete ASM programs. However, to accommodate exception throwing, our compiler has an extra step of indirection. We map IMP programs to sub-CFGs with exactly one input address but *three* output addresses. The first represents EXIT , as in a complete ASM program, while the second two represent the location of exception handler code. Thus, we compile $\text{throw}(\ell)$ to a jump to the second address if $\ell = \perp$ and the third address if $\ell = \top$. To compile a try-catch command, we place one copy of the handler at the second address and a second copy at the third address. That

means any exception will jump to the handler code, regardless of the label of the exception, matching the semantics we gave IMP in Section 3. Note that we still need separate addresses for each label to properly compile *uncaught* exceptions.

For inlined ASM code, we would hope to include it in the compiled code directly with no changes. Unfortunately, if inlined ASM throws an exception with a RAISE instruction, the surrounding IMP code can catch it, but embedding the RAISE unmodified in the compiled output would render the exception uncatchable. To support catching these exceptions, we process inlined ASM to replace RAISE instructions with jumps to the appropriate address. This change causes the inlined exception to properly jump to the handler code.

While the infrastructure described above translates IMP code into sub-CFGs, the end goal of our compiler is to translate complete IMP programs into complete ASM programs. The final step uses the two output addresses for exceptions by linking the sub-CFG of the complete IMP program with *two different* handlers. The low-security exception handler raises a low-security exception, while the high-security exception handler raises a high-security exception. Thus, any IMP code that raises an exception compiles to a complete ASM program that raises that same exception, while IMP code that catches an exception compiles to a complete ASM program with equivalent control flow.

6.2 Compiler Correctness

We adapt Xia et al.’s [57] proof of compiler correctness to account for the modifications we have made to IMP and ASM. We formalize correctness by comparing the source and the target programs – after interpretation – using weak bisimilarity. Intuitively, two stateful programs are weakly bisimilar if, whenever they are given *related* start states, the resulting ITrees are weakly bisimilar. We use a return relation \mathcal{R}_{env} . \mathcal{R}_{env} ignores the register files and compares heaps using a relation \cong , which ensures that they map equal variables to equal values. We can now state the correctness theorem for the `compile` function.

► **Theorem 26.** *For any initial heap states h_1, h_2 such that $h_1 \cong h_2$, any register states r_1, r_2 , and a valid IMP command c , the following equation holds*

$$\text{excE} \oplus \text{printE} \vdash \text{interp } h_{imp} \llbracket c \rrbracket_c (r_1, h_1) \approx_{\mathcal{R}_{env}} \text{interp } h_{asm} \llbracket \text{compile}(c) \rrbracket_{asm} (r_2, h_2)$$

where $\mathcal{R}_{env}((_, h_1, _), (_, h_2, _)) \iff h_1 \cong h_2$.

Notably, the changes necessary to adapt Xia et al.’s [57] proof of correctness to our modified compiler are small and isolated. Most cases of the inductive proof, corresponding to existing language features, needed only cosmetic changes. The new language features required new, but conceptually uninteresting, cases.

6.3 Compiler Security

We finally turn to our ultimate goal: proving that our compiler preserves security. There are two important notions of security for our compiler, both of which require cross-language reasoning. The first is that secure source programs are indistinguishable – by all adversaries – from target programs. This property directly relates an IMP program to an ASM program. The second is that the compiler preserves noninterference. While noninterference itself is a property of a single program, *preserving* noninterference is a property of a translation between two languages, which requires cross-language reasoning.

In order to formalize the idea of a secure IMP program being indistinguishable from its compilation, we need to compare these programs, even though they come from different languages. Because we defined `seutt` purely semantically, we can use it as easily as if we

were comparing programs in the same language. We use the return relation \mathcal{R}_Γ^ℓ , which again ignores the register file and ensures that they map equal *visible* variables to equal values. The theorem then takes the following form.

► **Theorem 27.** *For any valid IMP program c , if $\text{interp } h_{\text{prog}} \llbracket c \rrbracket_c$ is noninterfering with state relation \mathcal{R}_Γ^ℓ and return relation $=$, and c is a valid IMP program, then the following **seutt** equation holds for any label ℓ , arbitrary register states r_1, r_2 and heap states h_1, h_2 such that $h_1 \cong_\Gamma^\ell h_2$.*

$$\text{excE} \oplus \text{printE} \vdash_{\text{px}} \text{interp } h_{\text{prog}} \llbracket c \rrbracket_c (r_1, h_1) \approx_{\mathcal{R}_\Gamma^\ell} \text{interp } h_{\text{prog}} \llbracket \text{compile}(c) \rrbracket_{\text{asm}} (r_2, h_2)$$

Our second theorem is simply that our compiler takes noninterfering IMP programs to noninterfering ASM programs.

► **Theorem 28 (Noninterference Preservation).** *For a valid IMP program c , if $\text{interp } h_{\text{prog}} \llbracket c \rrbracket_c$ is noninterfering with state relations \mathcal{R}_Γ^ℓ and return relation $=$, then the same holds for its compilation. That is, $\text{interp } h_{\text{prog}} \llbracket \text{compile}(c) \rrbracket_{\text{asm}}$ is noninterfering with \mathcal{R}_Γ^ℓ and $=$. This result holds for both progress-sensitive and progress-insensitive noninterference.*

Notably, the proofs of both theorems follows directly from Theorem 26 and mixed transitivity, showing the utility of mixed transitivity for cross-language security reasoning.

7 Related Work

Goguen and Meseguer [15] introduced noninterference to formalize confidentiality; that is, the intuitive notion that secret data does not leak to an adversary. Volpano et al. [56] enforce progress-insensitive noninterference with a type system, and Volpano and Smith [55] modify the type system to be progress-sensitive. These results led to a long line of work introducing noninterference to an increasing complicated settings [40, 32, 45, 64, 33, 61, 41, 30, 53, 4, 44, 51, 1]. Proving the security of these varied type systems led to complicated arguments for noninterference, but also gave rise to an informal library of proof techniques. This work fits into a tradition of proof techniques for noninterference via models.

Most models view noninterference either as a trace (hyper)property or as the result of an indistinguishability relation. These perspectives are not mutually exclusive; we can view two programs as indistinguishable if they produce equivalent traces. Their focus, however, can be quite different. Trace-based models view noninterference as a 2-safety hyperproperty [12]. That is, noninterference can be falsified using finite prefixes of two traces. Specifically, for any interfering program there are two inputs that differ only on secrets but produce distinguishable events after a finite number of steps.

Indistinguishability models focus more on building compositional relations. Pioneered by Abadi et al. [1] and Sabelfeld and Sands [46], these models use PERs and define secure programs as those that are self-related. Two such approaches have yielded recent notable results. First, logical-relations techniques [43] inductively assign each type a binary relation. By constructing the relation to reflect the security requirements of the type, logical relations can reason about information flow control and noninterference [54, 42, 16]. Second, bisimulation approaches directly match up program executions to define indistinguishability [48, 13].

This work straddles these methods. ITrees intuitively collect all possible traces of a program into one infinite data structure. Our binary indistinguishability relation on ITrees is thus combining the hyperproperty model of noninterference with the indistinguishability model. Moreover, our indistinguishability relation is built on top of weak bisimulation. To give meaning to a type system, we also build a small logical relation connecting types to our bisimulation arguments.

To remain practical, many languages provide only progress-insensitive guarantees [28, 27, 56, 40], despite the fact that termination channels alone can leak arbitrary amounts of data [6]. Techniques for enforcing progress-sensitive guarantees [55, 45] exist, but have seen little use. Recent work attempts to unify the two by explicitly considering termination leaks as declassifications [11]. Like other models of noninterference [16], `seutt` is naturally progress-sensitive, giving a strong guarantee. We include the progress-insensitive `pi-seutt` to give ITree-based semantics to more-practical systems as well.

A few other works provide mechanized proofs of noninterference using different techniques [16, 3, 52]. However, each verifies existing paper proofs [52] or mechanizes an existing proof technique designed for a single-language setting [16, 3] (e.g., parametricity [3] or logical relations [16]). This work is unique among mechanizations of noninterference in its use denotational semantics designed to support multi-language settings.

Originally defined by Xia et al. [57], ITrees are based on free monads and their derivatives [22, 23, 50]. This gives rise to a natural interpretation of effects via monad transformers [19, 26] that behave like algebraic-effect handlers [47, 10, 38, 37, 35, 34]. The information-flow community also studies effects deeply since they can leak information. Traditionally, information-flow languages use a program-counter label to reason about effects, as we saw in Section 5. Recent work by Hirsch and Cecchetti [17] connects program-counter labels with monads, giving the former semantics using the latter.

Secure compilation is a very active research area. For instance, Barthe et al. [8] show how to securely compile to a low-level ASM-like target language. However, they use a type system for the target language to enforce security. Other efforts focus on particular language features, such as cryptographic constant time [9]. Moreover, until recently, most work on secure compilation focused on fully-abstract compilation [25]. Unfortunately, Abate et al. [2] recently showed that full abstraction is not sufficient to guarantee preservation of hyperproperties like noninterference. Our Mixed Transitivity theorems (Theorems 8 and 15) show that *equivalence-preserving* compilation does preserve noninterference.

Beyond work on secure compilation, most work on noninterference does not address multiple interacting languages. In one notable exception, Focardi et al. [14] examine the relationship between a process-calculus-based notion of security and simple imperative language with information-flow control, similar to IMP. They translate their version of IMP into CCS and show that they preserve IMP’s security guarantees. However, their work contains only pencil-and-paper proofs, rather than formally verifying their translation or its security.

Finally, this work focuses on an approach for verifying language toolchains, but running any program requires hardware. Most language-based security and verification work assumes the hardware is predictable and reliable, but cannot enforce security. Hardware enforcement of information-security properties [63, 58] provides dynamic enforcement of properties like noninterference at the cost of space and power usage. Combining these mechanisms with our approach could reduce the overhead of hardware enforcement for verified-secure programs and provide a means to guarantee that interactions with unverified programs remain safe.

8 Conclusion

This paper uses ITrees to reason semantically about noninterference. Our main technical contributions are two new indistinguishability relations on ITrees that we use to define noninterference – one progress sensitive and one progress insensitive – and their metatheory. While both noninterference definitions are coinductive, our metatheory library supports verifying properties of a language toolchain with no direct use of coinduction.

The two indistinguishability relations describe security in many settings, and we plan to include them in the ITrees library. Importantly, because they do not place any restrictions on the events in an ITree, they can be used for reasoning about a variety of language features. However, we recognize that many variations of noninterference appear in the literature, depending on the adversarial model and desired language features. For instance, *declassification* allows private information to be made public in controlled circumstances, creating a need for more complicated security conditions. We hope that the relations studied here both become the basis of verification efforts larger than our case study *and* that they serve as a starting point for further exploration of indistinguishability relations for ITrees.

Abstract

This paper presents a specification framework for monadic, recursive, interactive programs that supports auto-active verification, an approach that combines user-provided guidance with automatic verification techniques. This verification tool is designed to have the flexibility of a manual approach to verification along with the usability benefits of automatic approaches. We accomplish this by augmenting Interaction Trees, a Coq datastructure for representing effectful computations, with logical quantifier events. We show that this yields a language of specifications that are easy to understand, automatable, and are powerful enough to handle properties that involve non-termination. Our framework is implemented as a library in Coq. We demonstrate the effectiveness of this framework by verifying real, low-level code.

1 Introduction

Formal verification is starting to see adoption in industry as a tool for ensuring the security and correctness of software. For instance, the formally verified seL4 microkernel [13] has established a foundation that is seeing investment from a wide variety of industrial partners. Block-chain companies are using formal verification to ensure the security of cryptocurrency [15]. Amazon has even incorporated formal verification into the CI/CD process of their s2n cryptographic library [7].

Unfortunately, formal verification still remains expensive, not just in terms of time and effort but also in terms of the expertise required to formally verify a system. A number of powerful frameworks have been developed for manual formal verification, including Iris [12], VST [2], and FCSL [24]. These frameworks can specify a wide array of behaviors on a wide array of languages, but they require an expert to be used effectively. Other powerful frameworks have been developed for automatic verification, including approaches such as

bounded model-checking [4] and property-directed reachability [5]. While these approaches can be operated by non-experts, they are limited in their expressiveness, leaving important properties unverified.

It is particularly difficult to reason about low-level code that contains complicated manipulations of pointer structures on the heap, as is common in languages like C, C++, and LLVM. Recently, researchers have tackled this problem using the observation that programs that are well-typed in a memory-safe, Rust-like type system are basically functional programs [9, 17, 18, 3, 10]. That is, there exists a program in a functional language whose behavior is equivalent to the original, heap-manipulating program. We call this functional program a *functional specification*. While many projects rely only implicitly on the functional specification, some, like the Heapster project [9], reify functional specifications into concrete code. Engineers can then verify properties about the derived functional code, and ensure those properties hold on the original program.

The Heapster tool consists of two components: a memory-safe type system for LLVM code, and a translation tool that produces an equivalent functional program from any well-typed LLVM program. Heapster uses these components to break verification of heap manipulating programs into two phases: a memory-safe type-checking phase that generates a monadic, recursive, interactive program that is equivalent to the original program; and a behavior-verification phase that ensures that the generated program has the correct behavior. Previous work has left open major questions about the behavior verification phase, namely, what should the language of specifications be and how do we actually prove that the programs satisfy the specifications.

This work answers these questions by developing a logic well-suited to reasoning about the programs output by Heapster, as well as tools to work with these logical formulae. Taken together, the Heapster tool and this work form a two-step pipeline for verifying low-level, heap manipulating programs. Heapster transforms low-level, heap manipulating programs into equivalent functional programs. The techniques in this paper enable proof engineers to write and prove specifications over the resulting functional programs.

In this work, we present *interaction tree specifications*, or ITree specifications. ITree specifications are an *auto-active verification framework* for *monadic, recursive, interactive programs* based on *interaction trees* [29], or ITrees. Auto-active verification is a verification technique that merges user input and automated reasoning to leverage the benefits of each. Monadic, recursive, interactive programs have the ability to diverge, can interact with their environment, but otherwise act as pure functional programs. Interactions with the environment can include making a system call, sending a message from a server, and throwing an error. ITrees are a model for monadic, recursive, interactive programs formalized in Coq. ITree specifications are designed to be able to write and verify specifications about the output programs of the Heapster translation tool, which are written in terms of ITrees.

The main body of work that takes on the task of verifying monadic programs is the Dijkstra monad literature [16, 28, 1, 27]. However, most of the Dijkstra monad literature cannot handle the kinds of termination sensitive specifications that we need. These papers either assume a strongly normalizing language, or handle only partial specifications. The exception to this is the work of Silver and Zdancewic [25]. However, while that work does have a rich enough specification language for our goals, it has two significant shortcomings. First, the work provides no reasoning principles for arbitrary recursive specifications. Second, the work does not attempt to automate the verification of these specifications. Our work accomplishes both of these goals.

This work is based on the idea of augmenting ITrees with operations for logical quantifiers. We show that this idea leads to a language of specifications that is:

- easy to read, because the specifications are simply programs annotated with logical quantifiers,
- capable of encoding recursive specifications, because the underlying computational language has a powerful recursion operator, and
- amenable to auto-active verification, because specifications are syntactic constructs enabling syntax-directed inference rules.

ITrees represent computations as potentially infinite trees whose nodes are labelled with *events*. Events are syntactic representations of computational effects, like raising an error, or sending data from a server. ITrees can be used to represent the semantics of recursive, monadic, interactive programs. ITree specifications are ITrees enriched with events for logical quantifiers. This language of specifications has the capability to express purely executable computations, fully abstract specifications, and combinations of both. For example, consider the following executable specification `server_impl` for a simple server program that sorts lists which are sent to it:

```
Definition server_impl : unit → itree_spec E void :=
  rec_fix_spec (fun rec _ =>
    l ← trigger rcvE;;
    ls ← sort l;;
    trigger (sendE ls);;
    rec tt
  ).
```

This specification is defined with `rec_fix_spec`, a recursion operator (defined in Section 4) where applications of the `rec` argument correspond to recursive calls. The body of the recursive function first calls `trigger rcvE`, which triggers the use of the receive event `rcvE`, causing the program to wait to receive data. The list `l` that is received is then passed to the `sort` function, defined in Section 6, which is a recursive implementation of the merge sort algorithm. Finally, the sorted list returned by `sort` is sent as a response with `trigger (sendE ls)`, and the server program loops back to the beginning by calling `rec`.

Now, consider the following specification of the behavior of our server using a combination of executable and abstract features:

```
Definition server_spec : unit → itree_spec E void :=
  rec_fix_spec (fun rec _ =>
    l ← trigger rcvE;;
    ls ← exists_spec (list nat);;
    assert_spec (Permutation l ls);;
    assert_spec (sorted ls);;
    trigger (sendE ls);;
    rec tt).
```

This function acts mostly like `server_impl` but, instead of computing a sorted list, it uses the existential quantification operation `exists_spec` to introduce the list value `ls`, which it then asserts is a sorted permutation of the initial list. By leaving this part of the specification abstract, it allows the user to express that it is unimportant how the list is sorted, as long as the response is a sorted permutation of the input list. The send and receive events, however, are left concrete, allowing the user to specify what monadic events should be triggered in what order. This specification implicitly defines a liveness property of the server, it will reject any program that fails to eventually perform the next send or receive. By using a single language for programs and specifications, our approach provides a natural way for users to control how concrete or abstract the various portions of their specifications are. Our approach then provides auto-active tools for proving that programs refine these specifications.

30:4 Interaction Tree Specifications

```
Class EncodingType (E:Type) : Type :=  
  response_type : E → Type.
```

■ **Figure 1** EncodingType typeclass definition.

Necessary background explaining ITrees and Heapster is given in Section 2 and Section 3. The contributions of this paper are as follows:

- ITree specifications, a data structure for representing specifications over monadic, recursive, interactive programs, presented in Section 4
- a specification refinement relation over ITree specifications, along with collection of verified, syntax-directed proof rules for refinement also presented in Section 4,
- tools for encoding and proving refinements involving total correctness specifications in ITree specifications presented in Section 5,
- an auto-active verification technique briefly discussed in Section 6
- an evaluation of the presented techniques in the form of verifying a collection of realistic C functions using ITree specifications and Heapster presented in Section 6.

2 Background

ITrees are a formalization for denotational semantics implemented as a coinductive variant of the free monad in Coq. ITrees represent programs as potentially infinite trees. The nodes of these trees are labelled with *events*. Events can, depending on the context, either represent algebraic effects or recursive function calls. The ITree type is parameterized by a return type R and a type family E , where E has an instance of the `EncodingType` type class defined in Figure 1. The `EncodingType` type class consists of function, named `response_type`, from E to `Type`. A value of type `itree E R` is a potentially infinite tree whose internal nodes are each labelled with an *event* e of type E , with one branch for each element of the `response_type e` whose leaves are labelled with an element of type R . Such a tree represents an effectful computation, where the leaves represent termination of the computation with a return value in R while the nodes represent uses of monadic effects. The event e of type E that labels a node represents a monadic effect that returns a value of type `response_type e`, and the children of that node represent the possible continuations of that computation depending on the return value of the effect. This is formalized in the following Coq code¹.

```
CoInductive itree (E : Type) {EncodingType E} (R : Type) :=  
  | Ret (r : R)  
  | Tau (t : itree E R)  
  | Vis (e : E) (k : response_type e → itree E R).
```

The ITree datatype has three constructors. The `Ret` constructor represents a pure computation that simply returns a value. The `Ret` constructor forms the leaves of an ITree. The `Tau` constructor represents one step of silent internal computation followed by another ITree. Finally, the `Vis` constructor contains an event e along with a continuation function k which defines all the branches of this `Vis` node.

Because ITrees are defined coinductively, we can construct ITrees with infinitely long branches. Such ITrees represent divergent computations. For example, the following code describes an ITree that consists of an infinite stream of `Tau` constructors with no events.

¹ In the actual formalization, we use a negative coinductive types presentation of this data structure.

```

Class ReSum (E1 : Type) (E2 : Type) `{EncodingType E1} `{EncodingType E2} :=
{
  resum : E1 → E2;
  resum_ret : forall {e : E1}, response_type (resum e) → response_type e;
}.

```

```

Notation "E1 -< E2" := (ReSum E1 E2) (at level 10).

```

```

Definition trigger {E1 E2} `{EncodingType E1} `{EncodingType E2} `{E1 -< E2} :forall (e1
  : E1), (itree E2 (response_type e1)) :=
  fun e => Vis (resum e) (fun x => Ret (resum_ret x)).

```

■ **Figure 2** ReSum Definition.

```

CoFixpoint spin : itree E R := Tau spin.

```

In practice, ITrees often end up using an event type family E that is a composition of several smaller type families combined in a large sum. This can easily clutter and complicate the notation. To avoid this burden, the ITrees library introduces the `ReSum` typeclass defined in Figure 2. An instance of `ReSum E1 E2`, written `E1 -< E2`, contains two functions: the `resum` function that injects an element of $E1$ into $E2$, and the `resum_ret` function that maps elements from the response type of `resum e` to the response type of e . It can be thought of as a kind of subevent typeclass. The `ReSum` typeclass allows for the definition of the `trigger` function in Figure 2. The `trigger` function takes an event $e : E1$ and injects it into `itree E (response_type e)` by injecting e into $E2$, placing that in a `Vis` node, and applying the `resum_ret` function to the response.

2.1 Equivalence up to Tau

One of the major advantages of the ITrees library is its rich equational theory. The primary notion of equivalence used for ITrees is called `eutt` or *equivalence up to tau*. Xia et al. [29] defines `eutt` as a bisimulation relation that quotients out finite differences in the number of `Tau` constructors. We use this relation because `Tau` constructors are supposed to indicate *silent* steps of computation. Ignoring finite numbers of `Tau` constructors lets us equate two ITrees that vary only in the number of silent computation steps.

The `eutt` relation is parameterized by a relation RR over return values. If the relation RR is *heterogeneous*, relating values over distinct types $R1$ and $R2$, then `eutt RR` is also a heterogeneous relation over `itree E R1` and `itree E R2`. Intuitively, if `eutt RR t1 t2`, then the `Vis` nodes of $t1$ precisely match those of $t2$, and if equivalent paths in $t1$ and $t2$ lead to the leaves `Ret r1` and `Ret r2` then the values $r1$ and $r2$ are related by RR . Often, we are interested in `eutt eq` and denote this relation with the symbol \approx .

The `eutt` relation is implemented in Coq using both *inductive* and *coinductive* techniques. Observe the following definition of `eutt`:

```

Inductive euttF (RR : R1 → R2 → Prop) (sim : itree E R1 → itree E R2 → Prop) :
  itree E R1 → itree E R2 → Prop :=
| eutt_Ret (r1 : R1) (r2 : R2) : euttF RR sim (Ret r1) (Ret r2)
| eutt_Tau (t1 : itree E R1) (t2 : itree E R2) :
  sim t1 t2 → euttF RR sim (Tau t1) (Tau t2)
| eutt_Vis (e : E) (k1 : response_type e → itree E R1)
  (k2 : response_type e → itree E R2) :
  (forall a, sim (k1 a) (k2 a)) → euttF RR sim (Vis e k1) (Vis e k2)
| eutt_TauL (t1 : itree E R1) (t2 : itree E R2) :

```

30:6 Interaction Tree Specifications

Example `spin ≈ spin`.

Example `Tau (Ret 0) ≈ Ret 0`.

Example `~(spin ≈ Ret 0)`.

■ **Figure 3** `eutt` Examples.

```
euttF RR sim t1 t2 → euttF RR sim (Tau t1) t2
| eutt_TauR (t1 : itree E R1) (t2 : itree E R2) :
  euttF RR sim t1 t2 → euttF RR sim t1 (Tau t2).
```

Definition `eutt (RR : R1 → R2 → Prop) := gfp (euttF RR)`.

The `euttF` relation is an inductively defined relation, defined in terms of the `sim` argument. The `eutt` relation is then defined as the greatest fixpoint of `euttF`. In this paper, all greatest fixpoints are defined using the `paco` library[11] for coinductive proofs. Calls to the `sim` argument in the definition of `euttF` correspond to coinductive calls of `eutt`. Recursive calls to `euttF` correspond to inductive calls of `eutt`. This method of defining `eutt` allows the coinductive constructors to be called infinitely often in sequence, while only a finite number of calls to inductive constructors can be called without an intervening call to a coinductive constructor. Specifically, only finitely many `eutt_TauL` and `eutt_TauR` steps, that remove a `Tau` from only one side, are allowed before one of the remaining rules must be used to relate the same constructor on both sides.

This definition allows us to achieve our goal of ignoring any finite difference in numbers of `Tau` constructors. In particular the equations and inequalities presented in Figure 3 hold.

ITrees form a monad. Monads are type families with a `ret` combinator that denotes a pure value, and a `bind` combinator that sequentially composes two monadic computations into one. The `ret` combinator is implemented with the `Ret` constructor, while the `bind t k` combinator is implemented as a coinductive function that traverses the ITree `t` and replaces each leaf `Ret r` with the new subtree `k r`. This is implemented in the following Coq code:

```
CoFixpoint bind (t : itree E R) (k : R → itree E S) :=
  match t with
  | Ret r ⇒ k r
  | Tau t ⇒ Tau (bind t k)
  | Vis e kvis ⇒ Vis e (fun x ⇒ bind (kvis x) k)
  end.
```

2.2 Mutually Recursive Computations

This section explains the recursion operator introduced by Xia et al. [29]. That work demonstrated how to use events as a piece of syntax for writing collections of mutually recursive functions over ITrees. Specifically, it introduced the `mrec` combinator, which lifts a collection of function bodies that syntactically reference one another to a collection of actually recursive functions. A similar recursion combinator is used extensively in Section 4 and Section 6.

When using the `mrec` combinator, you must first choose an event type `D`, with an `EncodingType` instance, to serve as the type of recursive calls. An element `d : D` packages together the choice of the function being called along with the arguments being supplied to that function. The return type of the function call `d` is `response_type d`. In this context, an ITree with the type `itree (D + E) R` represents the body of a mutually recursive function viewing the recursive calls as inert `D` events. This ITree defines a recursive function in terms of

```

Variant evenoddE : Type:=
  | even (n : nat) : evenoddE
  | odd (n : nat) : evenoddE.
Instance EncodingType_evenoddE : EncodingType evenoddE := fun _ => bool.

Definition evenodd_body : forall eo : evenoddE, (itree (evenoddE + voidE)) (
  response_type eo) :=
  fun eo =>
    match eo with
    | even n => if Nat.eqb n 0
                then Ret true
                else trigger (odd (n -1))
    | odd n => if Nat.eqb n 0
                then Ret false
                else trigger (even (n -1))
    end.
Definition evenodd : evenoddE → itree voidE bool :=
  mrec evenodd_body.

```

■ **Figure 4** evenodd Definition.

syntactic recursive calls. In order to resolve these syntactic recursive calls, we need a mapping from recursive calls to a single layer of unfolding of the recursive function. This is represented as a function of type `bodies : forall (d:D), itree (D + E) (response_type d)`. The variable name `bodies` refers to the fact that this term represents the body of each function in this collection of mutually recursive functions. We can then take this ITree, corecursively replace each `d : D` event with the unfolded function body `bodies d`, and then repeat the process with the resulting ITree. This is formalized in the following `interp_mrec` function.

```

CoFixpoint interp_mrec {R : Type}
  (bodies : forall (d:D), itree (D + E) (response_type d))
  (t : itree (D + E) R) : itree E R :=
  match t with
  | Ret r => Ret r
  | Tau t => Tau (interp_mrec bodies t)
  | Vis (inr e) k => Vis e (fun x => interp_mrec bodies (k x))
  | Vis (inl d) k => Tau (interp_mrec bodies (bind (bodies d) k))
  end.

```

Given this function that can resolve the recursive calls in an ITree, we can define the `mrec` function that takes an initial recursive call `init : D` and computes its result.

```

Definition mrec (bodies : forall (d:D), itree (D + E) (response_type d)) (init : D)
  :=
  interp_mrec bodies (bodies init).

```

Figure 4 provides an example of a mutually recursive function defined with `mrec`. The `evenoddE` type represents calls to compute the parity of a natural number. The `evenodd` function computes either the `even` or the `odd` function depending on the initial recursive call event that it is given. The `evenodd` function defines these computations mutually recursively using the `mrec` function.

This section briefly introduces the classes of relations that we will need in order to reason about specification refinement in the presence of mutually recursive computations. The definition of `eutt` is parameterized by a return relation, making it easy to define a relation for ITrees that have identical tree structures up to Taus, with identical event nodes, but allows freedom to choose what conditions to enforce on return values. It is natural to consider generalizing `eutt` to allow variation not only in the return values but also in the event nodes.

```

Definition Rel (A B : Type) : Type := A → B → Prop.
Definition PostRel (D1 D2 : Type) {EncodingType D1} {EncodingType D2} : Type :=
  forall (d1 : D1) (d2 : D2), response_type d1 → response_type d2 → Prop.

Inductive RComposePostRel
  (R1 : Rel D1 D2) (R2 : Rel D2 D3) (PR1 : PostRel D1 D2) (PR2 : PostRel D2 D3) :
  PostRel D1 D3 :=
  | RComposePostRel_intros (d1 : D1) (d3 : D3) (a : response_type d1) (c :
    response_type d3) :
    (forall (d2 : D2), R1 d1 d2 → R2 d2 d3 →
      exists b, PR1 d1 d2 a b ∧ PR2 d2 d3 b c) →
    RComposePostRel R1 R2 PR1 PR2 d1 d3 a c.

```

■ **Figure 5** Heterogeneous Event Relation Types.

This kind of generalization is explored in Silver and Zdancewic [25]². The generalized relation analyzes uninterpreted events, typically those representing recursive function calls, with respect to pre-conditions and post-conditions. We want to relate `Vis` nodes whose events satisfy the pre-condition and whose continuations are related given any inputs that satisfy the post-condition. This corresponds to assuming that two function calls return related outputs as long as they are given related inputs.

Definitions of pre-condition and post-condition types are presented in Figure 5. Pre-conditions, `Rel`, are encoded as two-argument, heterogeneous relations, i.e. functions of type $D \rightarrow E \rightarrow \text{Prop}$, and utilize standard relational combinators like relational sums, `sum_rel`, and relational composition, `rcompose`. Post-conditions, `PostRel`, are encoded as four-argument, dependent relations. In particular, `forall (d:D) (e:E), encoded_by d → encoded_by e → Prop`, where both `D` and `E` have an `EncodingType` instance. Intuitively, post-conditions are a function from events to relations over their response types. These post-conditions admit a standard definition of relational sums. For relational composition, in addition to requiring two `PostRel` relations, it also requires two standard relations, called *coordinating relations*. The full definition is presented in Figure 5.

To relate four values `d1:D1`, `d3:D3`, `a:encoded_by d1`, `c:encoded_by d3`, we require that given any `d2:D2` that is related by the coordinating relations to `d1` and `d3`, there exists a `b:encoded_by d2` such that both `PR3 d1 d2 a b` and `PR4 d2 d3 b c`.

Later in the paper, we recover an `eutt`-like definition of specification refinement by specializing the event relations to be an appropriate form of equality. For `Rel`, this is precisely the equality relation. For `PostRel`, we define an inductive datatype that enforces equality on response values.

```

Variant PostRelEq : PostRel E E :=
  PostRelEq_intro e a : PostRelEq e e a a.

```

3 Specification Extraction with Heapster

This section introduces the Heapster tool for specification extraction. We present Heapster in order to provide context for the evaluation of this work in Section 6. In the evaluation, we demonstrate how effective ITree specifications can be when paired with a tool like Heapster. We start with a collection of low-level, heap manipulating C programs, use Heapster to produce equivalent functional programs, and finally use ITree specifications to specify and verify the output programs.

² In Silver and Zdancewic [25] this relation is referred to as `euttEv`. It has since been renamed to `ruTT` in release branches of the Interaction Trees library.

Value Types	T	$::=$	$\text{bv } n \mid \text{llvmptr } n \mid \dots$
Expressions	e	$::=$	$n \mid \text{llvmword } e \mid \dots$
RW Modality	rw	$::=$	$W \mid R$
Permissions	τ	$::=$	$\text{ptr}((rw, e) \mapsto \tau) \mid \tau_1 * \tau_2 \mid \tau_1 \vee \tau_2 \mid \exists x:T.\tau \mid \text{eq}(e) \mid \mu X.\tau \mid X \mid \dots$

■ **Figure 6** An Abbreviated Grammar of the Heapster Type System.

There is a growing body of work [9, 17, 18, 3] based on the idea that programs that satisfy memory-safe type systems like Rust can be represented with equivalent functional programs. Rust’s pointer discipline, which ensures that all pointers in a program are either shared read or exclusive write, allows us to reason about the effects of pointer updates purely locally. This locality property can be used to define a pure functional model, referred to as a *functional specification*, of the behaviors of a program, which can in turn be used to verify properties of that program.

Whereas some work uses this notion of a functional model implicitly, *specification extraction* is the idea that the functional model can be extracted automatically as an artifact that can be used for verification. Specification extraction separates verification into two phases: a type-checking phase, where the functions in a program are type-checked against user-specified memory-safe types; and a behavior verification phase, where the user verifies the specifications that are extracted from this type-checking process. The Heapster tool [9] is an implementation of the idea of specification extraction. Heapster provides a memory-safe, Rust-like type system for LLVM, along with a typechecker. Heapster also provides a translation from well-typed LLVM programs to monadic, recursive, interactive programs, modeled with ITrees, that describe a behavioral model of the original program. This translation is inspired by the Curry-Howard isomorphism. Heapster types are essentially a form of logical propositions regarding the heap, so, by the Curry-Howard isomorphism, it is natural to view typing derivations, a form of proof, as a program. We give a brief overview of the Heapster type system and its specification extraction process in this section and illustrate it with an example.

The Heapster type system is a permission type system. Typing assertions of the form $x : \tau$ mean that the current function holds permissions to perform actions allowed by τ on the value contained in variable x . The central permission construct of Heapster is the permission to read or write a pointer value. Like Rust, Heapster is an affine type system, meaning that the permissions held by a function can change at different points in the function. In particular, a command can consume a permission, preventing further commands from using that permission again. Also like Rust, Heapster allows read-only permissions to be duplicated, allowing multiple read-only pointers to the same address, but does not allow write permissions to be duplicated. This enforces the invariant that all pointers are either shared read or exclusive write, a powerful property for proving memory-safety.

Figure 6 gives an abbreviated grammar for the Heapster type system. The value types T are inhabited by pieces of first order data. In particular, they contain the type $\text{bv } n$ of n -bit bitvectors (i.e., n -bit binary values) and the type $\text{llvmptr } n$ of n -bit LLVM values, among other value types not discussed here. Heapster uses the CompCert memory model [14], where LLVM values are either a word value or a pointer value represented as a pair of a memory region plus an offset in that region. The expressions e include numeric literals n and applications of the llvmword constructor of the LLVM value type to build an LLVM value from a word value.

30:10 Interaction Tree Specifications

The first permission type in Figure 6, $\text{ptr}(\langle rw, e \rangle \mapsto \tau)$, represents a permission to read or write (depending on rw) a pointer at offset e . Write permission always includes read permission. This permission also gives permission τ to whatever value is currently pointed to by the pointer with this permission. Permission type $\tau_1 * \tau_2$ is the separating conjunction of τ_1 and τ_2 , giving all of the permissions granted by τ_1 or τ_2 , where τ_1 and τ_2 contain no overlapping permissions. Permission type $\tau_1 \vee \tau_2$ is the disjunction of τ_1 and τ_2 , which either grants permissions τ_1 or τ_2 . The existential permission $\exists x:T.\tau$ gives permission τ for some value x of value type T . The equality permission $\text{eq}(e)$ states that a value is known to be equal to an expression e . This can be viewed as a permission to assume the given value equals e . Finally, $\mu X.\tau$ is the least fixed-point permission, where permission variable X is bound in τ . This satisfies the fixed-point property, that $\mu X.\tau$ is equivalent to $[\mu X.\tau/X]\tau$.

As a simple example, the user can define the Heapster type

```
int64 =  $\exists x:\text{bv } 64.\text{eq}(\text{llvmword } x)$ 
```

This Heapster type describes an LLVM word value, i.e., an LLVM value that equals `llvmword x` for some bitvector x .

As a slightly more involved example, consider the following definition of a linked list structure in C:

```
typedef struct list64_t { int64_t data;
                        struct list64_t *next; } list64_t;
```

A C value of type `list64_t*` represents a list, where a NULL pointer represents the empty list and a non-NULL pointer to a `list64_t` struct represents a list whose head is the 64-integer contained in the `data` field and whose tail is given by the `next` field.

The following Heapster type describes this linked list structure:

```
list64 $\langle rw \rangle$  =  $\mu X.\text{eq}(\text{llvmword } 0) \vee (\text{ptr}(\langle rw, 0 \rangle \mapsto \text{int64}) * \text{ptr}(\langle rw, 8 \rangle \mapsto X))$ 
```

The `list64 $\langle rw \rangle$` type is parameterized by a read-write modality rw , which says whether it describes a read-only or read-write pointer to a linked list. The permission states that the value it applies to either equals the NULL pointer, represented as `llvmword 0`, or points at offset 0 to a 64-bit integer and at offset 8^3 to an LLVM value that itself recursively satisfies the `list64 $\langle rw \rangle$` permission. Note that the fact that it is a least fixed-point implicitly requires the list to be loop-free.

Figure 7 illustrates the process of Heapster type-checking on a simple function `is_elem` that checks if 64-bit integer `x` is in the linked list `l`. Note that Heapster in fact operates on the LLVM code that results from compiling this C code, but the type-checking is easier to visualize on the C code rather than looking at its corresponding LLVM. Ignoring the Heapster types for the moment, which are displayed with a grey background in the figure, `is_elem` first checks if `l` is NULL, and if so returns 0 to indicate that the check has failed. If not, it checks if the head of the list in `l->data` equals `x`, and if so, returns 1. Otherwise, it recurses on the tail `l->next`.

The Heapster permissions for this function are

```
 $x:\text{int64}, l:\text{list64}\langle R \rangle \multimap r:\text{int64}$ 
```

³ We assume a 64-bit architecture, so offset 8 references the second value of a C struct.

```

int64_t is_elem (int64_t x, list64_t *l) {
  x:int64,l:list64(R)
  x:int64,l:eq(llvword 0) OR x:int64,l:ptr((R,0) ↦ int64) * ptr((R,8) ↦ list64(R))
  if (l == NULL) {
    x:int64,l:eq(llvword 0)
    return 0;
  } else {
    x:int64,l:ptr((R,0) ↦ int64) * ptr((R,8) ↦ list64(R))
    if (l->data == x) { return 1; }
    else {
      list64_t *l2 = l->next;
      x:int64,l:ptr((R,0) ↦ int64) * ptr((R,8) ↦ eq(12)),l2:list64(R)
      return is_elem (x, l2);
    }
  }
}

```

■ **Figure 7** Type-checking the `is_elem` Function Against Type $x:\text{int64}, l:\text{list64}(R) \multimap r:\text{int64}$.

The lollipop symbol, \multimap , is used to write Heapster function types. This type means that input x is a 64-bit integer and l is a read-only linked list pointer and the return value r is a 64-bit integer value.

To type-check `is_elem`, Heapster starts by assuming the input types for the arguments. This is displayed in the first grey box of Figure 7. In order to type-check the `NULL` comparison on `l`, Heapster must first unfold the recursive permission on `l` and then eliminate the resulting disjunctive permission. This latter step results in Heapster type-checking the remaining code twice, once for each branch of the disjunct. More specifically, the remaining code is type-checked once under the assumption that `l` equals `NULL` and once under the assumption that it points to a valid `list64_t` struct. In the first case, the `NULL` check is guaranteed to succeed, and so the `if` branch is taken with those permissions, while in the second, the `NULL` check is guaranteed to fail, so the `else` branch is taken.

In the `if` branch, the value `0` is returned. Heapster determines that this value satisfies the required output permission `int64`. In the `else` branch, `l->data` is read, by dereferencing `l` at offset `0`. This is allowed by the permissions on `l` at this point in the code. If the resulting value equals `x`, then `1` is returned, which also satisfies the output permission `int64`. Otherwise, `l->next` is read, by dereferencing `l` at offset `0`, and the result is assigned to local variable `l2`. This assigns `list64(R)` permission to `l2`. The permission on offset `8` of `l` is updated to indicate that the value currently stored there equals `12`. The `list64(R)` permission on `l2` is then used to type-check the subsequent recursive call to `is_elem`.

Once a function is type-checked, Heapster performs specification extraction to extract a pure functional specification of the function’s behavior. Specification extraction translates permission types to Coq types and typing derivations to Coq programs. The type translation is defined as follows:

$$\begin{array}{ll}
\llbracket \text{ptr}((rw, e) \mapsto \tau) \rrbracket &= \llbracket \tau \rrbracket & \llbracket \tau_1 * \tau_2 \rrbracket &= \llbracket \tau_1 \rrbracket * \llbracket \tau_2 \rrbracket \\
\llbracket \tau_1 \vee \tau_2 \rrbracket &= \llbracket \tau_1 \rrbracket + \llbracket \tau_2 \rrbracket & \llbracket \exists x:T. \tau \rrbracket &= \{x : \llbracket T \rrbracket \} \& \llbracket \tau \rrbracket \\
\llbracket \text{eq}(e) \rrbracket &= \text{unit} & \llbracket \mu X. \tau \rrbracket &= \text{user-specified type } A \\
&&&& \text{isomorphic to } \llbracket [\mu X. \tau / X] \tau \rrbracket
\end{array}$$

Pointer permissions $\text{ptr}((rw, e) \mapsto \tau)$ are translated to the result of translating the permission τ of the value that is pointed to. This means that specification extraction erases pointer types, which are no longer needed in the resulting functional code. Conjunctive permissions are

30:12 Interaction Tree Specifications

```

Definition is_elem_spec : bitvector 64 * list (bitvector 64) →
  itree_spec E (bitvector 64) :=
  rec_fix_spec (fun rec '(x,l) ⇒
    either
      unit (bitvector 64 * list (bitvector 64)) (* input types *)
      (itree_spec _ (bitvector 64))           (* output type *)
      (fun _ ⇒ Ret (intToBv 64 0))           (* nil case *)
      (fun '(hd,tl) ⇒
        if bvEq 64 hd x then Ret (intToBv 64 1) (* return 1 *)
        else rec (x,tl))                       (* recursive call *)
      (unfoldList 1)).                          (* unfolded argument *)

```

■ **Figure 8** Extracted Specification for `is_elem`.

translated to pairs, disjunctive permissions are translated to sums, and existential permissions are translated to dependent pairs (using a straightforward translation $\llbracket T \rrbracket$ of value types that we omit here). The equality type `eq(e)` is translated to the Coq unit type `unit`, meaning that they contain no data in the extracted specifications. We already proved the equality in the typechecking phase, and we have no use for the particular equality proof the typechecker provided. To translate a least fixed-point type $\mu X.\tau$, the user specifies a type that satisfies the fixed-point equation, meaning a pair of functions

$$\text{fold} : \llbracket [\mu X.\tau/X]\tau \rrbracket \rightarrow \llbracket \mu X.\tau \rrbracket \quad \text{unfold} : \llbracket \mu X.\tau \rrbracket \rightarrow \llbracket [\mu X.\tau/X]\tau \rrbracket$$

that form an isomorphism.

As an example, the translation of `int64` is the Coq sigma type `{x:bitvector 64 & unit}`. Note that Heapster will in fact optimize away the unnecessary `unit` type, yielding the type `bitvector 64`. As a slightly more complex example, in order to translate the `list64⟨rw⟩` described above, the user must provide a type `T` that is isomorphic to the type

```
unit + (bitvector 64 * T)
```

The simplest choice for `T` is the type `list (bitvector 64)`. In this way, the imperative linked list data structure defined above in `C` is translated to the pure functional list type.

Rather than defining the translation of Heapster typing derivations into Coq programs here, we illustrate the high-level concepts with our example and refer the interested reader to He et al. [9] for more detail. The translation of `is_elem` is given as a Coq specification `is_elem_spec` in Figure 8. At the top level, this specification uses `rec_fix_spec` to define a recursive function to match the recursive definition of `is_elem`. This binds a local variable `rec` to be used for recursive calls to the specification.

To understand the rest of the specification, we step through the Heapster type-checking depicted in Figure 7. The first step of that type assignment unfolds the permission type `list64⟨W⟩` on `l`. The corresponding portion of the specification is the call to `unfoldList`, which unfolds the input list `l` to a sum of a unit or the head and tail of the list. The next step of the Heapster type-checking is to eliminate the resulting disjunctive permission on `l`. The corresponding portion of the specification is a call to the `either` sum elimination function. In the left-hand case of the disjunctive elimination, the `NULL` test of the `C` program succeeds, and `0` is returned. Similarly, in the Coq specification, the `nil` case returns the `0` bitvector value.

In the right-hand case of the disjunctive elimination of the Heapster type-checking, the `NULL` test fails, and so `l` is a valid pointer to a `C` struct with `data` and `next` fields. This is represented by the pattern-match on the `cons` case in the Coq specification, yielding variables `hd` and `tl` for the head and tail of the list. The body of this case then tests whether the head

equals the input variable x , corresponding to the $x==1 \rightarrow \text{data}$ expression in the C program. If so, then the bitvector value 1 is returned. Otherwise, the specification performs a recursive call, passing the same value for x and the tail of the input list for 1.

4 ITree Specifications and Refinement

In this paper, we introduce a specialization of the `ITree` data type that encodes specifications over `ITrees`. To do this, we take some base event type family E , and extend it with constructors for universal and existential quantification. This is formalized in the following definition for `SpecEvent`.

```
Inductive SpecEvent (E : Type) {EncodingType E} : Type :=
| Spec_vis (e : E) : SpecEvent E
| Spec_forall (A : type) : SpecEvent E
| Spec_exists (A : type) : SpecEvent E
```

The `Spec_vis` constructor allows you to embed a base event $e : E$ into the type `SpecEvent E`. The `Spec_forall` constructor signifies universal quantification, and the `Spec_exists` constructor signifies existential quantification. For the purposes of specifying Heapster programs, we only need to quantify over a fixed grammar of first order types⁴. This includes natural numbers, bit vectors, functions, products, logical propositions, and sums. We have omitted the definition of the particular fixed grammar of types used in this work for space.

We define *ITree specifications* as the type of `ITrees` with a `SpecEvent` as the event type.

```
Definition itree_spec (E : Type) {EncodingType E} (R : Type) :=
  itree (SpecEvent E) R.
```

Because `ITree` specifications are actually a special kind of `ITree`, they inherit all the useful metatheory and code defined for `ITrees`. In particular, we can reason about them equationally with `eut`, and apply the monad functions to them.

4.1 ITree Specification Refinement

The notion that a program adheres to a specification is defined with the notion of refinement. Refinement is the main judgment involved in using `ITree` specifications, and is for instance the primary form of proof goal proved by the provided automation tool. Intuitively, the logical quantifier events mean that an `ITree` specification represents a set of computations. A fully concrete `ITree` specification, with no logical quantifier events, represents a singleton set, while a more abstract specification might represent a larger set. The refinement relation is then defined such that, if one `ITree` specification refines another, then the former represents a subset of the latter. So, for instance, if we prove that a concrete specification refines a more abstract specification, then we have shown that the singleton program in the set represented by the concrete specification satisfies the specification. Note that refinement is actually a coarser relation than subset; this is discussed later in Section 4.4.

The `ITree` specification refinement relation is based on the idea of refinement of logical formulae with the `eut` relation. As in a sequent calculus, we can eliminate quantifiers in our specification logic using quantifiers in the base logic, in this case `Coq`. Quantifiers on the right of a refinement get eliminated to the corresponding `Coq` quantifiers, while quantifiers on

⁴ While we could quantify over `Type` in these definitions, this introduces universe level constraints that we prefer to avoid

30:14 Interaction Tree Specifications

the left get eliminated to the dual of the corresponding Coq quantifier. This means that both a `Spec_forall` on the right and a `Spec_exists` on the left get eliminated to a Coq `forall`. And both a `Spec_exists` on the right and a `Spec_forall` on the left get eliminated to a Coq `exists`. ITree specifications form a lattice with refinement serving as the preorder, `Spec_forall` acting as the complete meet, and `Spec_exists` acting as the complete join. The portions of ITree specifications with computational content, including the `Ret` leaves, `Spec_vis` nodes, and silent `Tau` nodes, get compared as they do in the `eutt` relation.

The ITree specification refinement relation shares many mechanical details with the `eutt` relation. Both are defined by taking the greatest fixed point of an inductively defined relation to get a mixture of inductive and coinductive properties. Both behave identically on `Tau` and `Ret` nodes. The refinement relation differs in its inductive rules for eliminating logical quantifiers, and in its usage of heterogeneous event relations to enforce pre- and post-conditions on `Spec_vis` events. These pre- and post-conditions are necessary in order to give the refinement relation the flexibility needed to state the reasoning principle for `mrec`. The initial inductively defined relation, `refinesF`, contains the following header code.

```

Inductive refinesF
  (RPre : Rel E1 E2) (RPost : PostRel E1 E2) (RR : Rel R1 R2)
  (sim : itree_spec E1 R1 → itree_spec E2 R2 → Prop)
  : itree_spec E1 R1 → itree_spec E2 R2 → Prop :=

```

Much like in the definition of `euttF`, the `sim` argument represents corecursive calls of the `refines` relation, and the `RR` argument is the relation used for return. Unlike in `euttF`, `refinesF` takes in arguments for a `PreRel` and a `PostRel`. These arguments are included in order to represent pre- and post-conditions on mutually recursive function bodies.

The `refinesF` relation has several constructors that work precisely the same as the corresponding `euttF` constructors. These constructors define the relation's behavior on `Ret` and `Tau` nodes.

```

| refines_Ret (r1 : R1) (r2 : R2) : RR r1 r2 → refinesF RPre RPost RR sim (Ret r1)
  (Ret r2)
| refines_Tau (phi1 : itree_spec E1 R1) (phi2 : itree_spec E2 R2) : sim phi1 phi2
  →
  refinesF RPre RPost RR sim (Tau phi1) (Tau phi2)
| refines_TauL (t1 : itree_spec E1 R1) (t2 : itree_spec E2 R2) :
  refinesF RPre RPost RR sim t1 t2 → refinesF RPre RPost RR sim (Tau t1) t2
| refines_TauR (t1 : itree_spec E1 R1) (t2 : itree_spec E2 R2) :
  refinesF RPre RPost RR sim t1 t2 → refinesF RPre RPost RR sim t1 (Tau t2)

```

The constructor dealing with `Spec_vis` nodes generalizes the constructor dealing with `Vis` nodes in `euttF`. This constructor relates `Spec_vis` nodes as long as two conditions hold on the events, `e1` and `e2`, and the continuations, `k1` and `k2`. The ITree specifications must satisfy the precondition, by having `e1` and `e2` satisfy `RPre`. And the ITree specifications must satisfy the post condition by having `k1` a refine `k2` b, whenever `a` and `b` are related by `RPost e1 e2`.

```

| refines_Spec_vis (e1 : E1) (e2 : E2)
  (k1 : response_type e1 → itree_spec E1 R1) (k2 : response_type e2
  → itree_spec E2 R2) :
  RPre e1 e2 → (forall a b, RPost e1 e2 a b → sim (k1 a) (k2 b)) →
  refinesF RPre RPost RR sim (Vis (Spec_vis e1) k1) (Vis (Spec_vis e2) k2)

```

The added complications of this rule allow us to reason about mutually recursive functions. It ensures that related function outputs assume that function calls with arguments related by the precondition return values related by the post condition when analyzing mutually recursive functions.

Finally, we need constructors dealing with quantifier events. This definition uses only inductive constructors to eliminate quantifier events. We made this choice to avoid certain peculiar issues related to ITree specifications that consist of infinite trees of only quantifiers. Given coinductive constructors for quantifier events, we would be able to prove that such

```

Class CoveredType (A : Type) := {
  encoding : type;   surjection : response_type encoding → A;
  surjection_correct : forall a : A, exists x, surjection x = a; }.

Definition forall_spec {E}
  `{EncodingType E}
  (A:Type) `{CoveredType A} :
  itree_spec E A :=
  Vis (Spec_forall encoding)
  (fun x ⇒ Ret (surjection x)).

Definition exists_spec {E}
  `{EncodingType E}
  (A:Type) `{CoveredType A} :
  itree_spec E A :=
  Vis (Spec_exists encoding)
  (fun x ⇒ Ret (surjection x)).

Definition assume_spec {E}
  `{EncodingType E} (P : Prop) :
  itree_spec E unit :=
  forall_spec P;; Ret tt.

Definition assert_spec {E}
  `{EncodingType E} (P : Prop) :
  itree_spec E unit :=
  exists_spec P;; Ret tt.

```

■ **Figure 9** Basic Specifications.

ITree specifications both refine and are refined by any other arbitrary ITree specification. That choice would cause certain ITree specifications to serve as both the top and bottom elements of the refinement order. This would serve as a counterexample to the transitivity of refinement, a desired property. So we chose to only use inductive constructors for quantifier events. This means that ITree specifications that consist of infinite trees of only quantifiers cannot be related by refinement to any other ITree specifications.

Quantifiers on the right get directly translated into Coq level quantifiers.

```

| refines_forallR (t : itree_spec E1 R1) (A:type) (k : response_type A →
  itree_spec E2 R2) :
  (forall a, refinesF RPre RPost RR sim t (k a)) →
  refinesF RPre RPost RR sim t (Vis (Spec_forall A) k)
| refines_existsR (t : itree_spec E1 R1) (A : type) (k : response_type A →
  itree_spec E2 R2) :
  (exists a, refinesF RPre RPost RR sim t (k a)) →
  refinesF RPre RPost RR sim t (Vis (Spec_exists A) k)

```

Quantifiers on the left get translated into their dual quantifier at the Coq level. Eliminating a `Spec_forall` on the left gives you an `exists`. Eliminating a `Spec_exists` on the left gives you an `forall`.

```

| refines_forallL (A : type) (k : response_type (Spec_forall A) → itree_spec E1 R1)
  (t : itree_spec E2 R2) :
  (exists a, refinesF RPre RPost RR sim (k a) t) →
  refinesF RPre RPost RR sim (Vis (Spec_forall A) k) t
| refines_existsL (A : type) (k : response_type (Spec_exists A) → itree_spec E1 R1)
  (t : itree_spec E2 R2) :
  (forall a, refinesF RPre RPost RR sim (k a) t) →
  refinesF RPre RPost RR sim (Vis (Spec_exists A) k) t

```

This `refinesF` relation is used to define the `refines` relation as follows.

```

Definition refines RPre RPost RR := gfp (refinesF RPre RPost RR).

```

4.2 Padded ITrees

Useful refinement relations should respect the `eutt` relation. When using ITrees as a denotational semantics, `eutt` is the basis of any program equivalence relation. Equivalent programs and specifications should not be observationally different according to the refinement relation. However, the `refines` relation does not respect `eutt`

We can easily demonstrate this with the following three ITree specifications.

30:16 Interaction Tree Specifications

```
CoFixpoint spin : itree_spec E R := Tau spin.
CoFixpoint phi1 : itree_spec E R := Vis (Spec_forall t) (fun _ => Tau (phi1)).
CoFixpoint phi2 : itree_spec E R := Vis (Spec_forall t) (fun _ => phi2).
```

The `spin` specification represents a silently diverging computation. The `phi1` specification is an infinite stream that alternates between `Spec_forall` nodes and `Tau` constructors. The `phi2` specification is a similar `ITree` to `phi1` that just lacks the `Tau` nodes. As these `ITree` specifications all diverge along all paths and lack any `Spec_vis` nodes, the `RPre`, `RPost`, and `RR` relations that we choose do not matter. Given any choice for those relations, `spin` refines `phi1` as we can use the inductive `refines_forallL` rule to get rid of the `Spec_forall` nodes, allowing us to match `Tau` nodes on both trees and apply the coinductive `refines_Tau` rule. This process can be extended coinductively allowing us to construct the refinement proof. The `phi1` `ITree` specification is `eutt` to `phi2`, as the only difference between the specifications is a single `Tau` node after every `Vis_forall` node. However, `spin` does not refine `phi2`, as there is no coinductive constructor that we can apply in order to write a proof for these divergent `ITree` specifications. Problems like this arise with any `ITree` specifications that consist of infinitely many quantifier nodes with nothing between them.

To fix this problem, we restrict our focus to a subset of `ITrees` that does not include ones like `phi2`. This is the set of *padded* `ITrees`, in which every `Vis` node must be immediately followed by a `Tau`. We formalize this with the coinductive `padded` predicate, whose definition has been omitted to save space. The refinement relation does not distinguish between different `ITree` specifications that are `eutt` to one another as long as they are padded. This means that can rewrite one `ITree` specification into another under a refinement according to `eutt` as long as both are padded.

Furthermore, it is easy to take an arbitrary `ITree`, and turn it into a padded `ITree`. That is implemented by the `pad` function, which corecursively adds a `Tau` after every `Vis` node. From here, we can focus primarily on the following definition of `padded_refines` which pads out all `ITree` specifications before passing them to the `refines` relation.

```
Definition padded_refines RPre RPost RR phi1 phi2 :=
  refines RPre RPost RR (pad phi1) (pad phi2).
```

In Figure 9, we introduce several simple `ITree` specifications that implement quantification over some types, and assumption and assertion of propositions. The `forall_spec` and `exists_spec` specifications rely on the `CoveredType` type class. A `CoveredType` instance for a type `A` contains an element of the restricted type grammar, `encoding`, whose interpretation corresponds to `A`. It also contains a valid surjection from the interpreted type `response_type encoding` to the original type `A`. In practice, we always instantiate this surjection with the identity function, but this type class formalization gives us the tools that we need without needing to do too much dependently typed programming. We can use `forall_spec` and `exists_spec` to define assumption and assertion, respectively, as `Prop` is part of the restricted grammar of types that `SpecEvent` can quantify over.

4.3 Padded Refinement Meta Theory

This subsection introduces some of the useful, verified metatheory we provide for `ITree` specifications in terms of `padded_refines` relation.

We prove that we can compose refinement results with the monadic `bind` operator.

```
Theorem padded_refines_bind (phi1 : itree_spec E1 R1) (phi2 : itree_spec E2 R2)
  (kphi1 : R1 → itree_spec E1 S1)
  (kphi2 : R2 → itree_spec E2 S2) :
  padded_refines RPre RPost RR phi1 phi2 →
  (forall r1 r2, RR r1 r2 → padded_refines RPre RPost RS (kphi1 r1) (kphi2 r2)) →
  padded_refines RPre RPost RS (bind phi1 kphi1) (bind phi2 kphi2).
```

```

CoFixpoint interp_mrec_spec {R : Type}
  (bodies : forall (d:D), (itree_spec (D + E)) (response_type d)) (t : itree_spec (D + E)
    ) R) : itree_spec E R :=
  match t with
  | Ret r => Ret r
  | Tau t => Tau (interp_mrec_spec bodies t)
  | Vis (Spec_forall A) k => Vis (@Spec_forall E _ A) (fun x : response_type (Spec_forall
    A) => interp_mrec_spec bodies (k x))
  | Vis (Spec_exists A) k => Vis (@Spec_exists E _ A) (fun x => interp_mrec_spec bodies (
    k x))
  | Vis (Spec_vis (inr e)) k => Vis (Spec_vis e) (fun x => interp_mrec_spec bodies (k x))
  | Vis (Spec_vis (inl d)) k => Tau (interp_mrec_spec bodies (bind (bodies d) k))
  end.

```

```

Definition mrec_spec (bodies : forall (d:D), (itree_spec (D + E)) (response_type d)) (
  init : D) :=
  interp_mrec_spec bodies (bodies init).

```

■ **Figure 10** `mrec_spec` Definition.

We prove that the `padded_refines` relation is transitive. To state the transitivity result in full generality, we need to use the composition relation introduced in Figure 5.

```

Theorem padded_refines_trans : forall (phi1 : itree_spec E1 R1) (phi2 : itree_spec E2
  R2) (phi3 : itree_spec E3 R3),
  padded_refines RPre1 RPost1 RR1 phi1 phi2 →
  padded_refines RPre2 RPost2 RR2 phi2 phi3 →
  padded_refines (RCompose RPre1 RPre2)
    (RComposePostRel RPre1 RPre2 RPost1 RPost2) (RCompose RR1 RR2) phi1 phi3.

```

We prove a reasoning principle for mutually recursive specifications as well. To do this, we first provide a slightly different definition of mutual recursion that handles the quantifier events correctly, defined in Figure 10. The key to proving refinements between `mrec_spec` specifications is to use the `PreRel` and `PostRel` relations to establish pre- and post-conditions on recursive calls. This involves choosing a `PreRel` over recursive call events, `RPreInv`, and a `PostRel` over recursive call events, `RPostInv`. Just like any form of invariants in formal verification, correctly choosing `RPreInv` and `RPostInv` requires striking a careful balance between choosing preconditions that are weak enough to hold, but strong enough to imply post conditions. The rule is expressed in the following code.

```

Theorem padded_refines_mrec : forall (init1 : D1) (init2 : D2),
  RPreInv init1 init2 →
  (forall d1 d2, RPreInv d1 d2 →
    padded_refines (SumRel RPreInv RPre)
      (SumPostRel RPostInv RPost)
      (RPostInv d1 d2)
      (bodies1 d1) (bodies2 d2)) →
  padded_refines RPre RPost (RPostInv init1 init2)
    (mrec_spec bodies1 init1)
    (mrec_spec bodies2 init2).

```

The hypotheses in this theorem state that the initial recursive calls, `init1` and `init2`, are in the precondition `RPreInv`, and that given any two recursive calls related by the precondition, `d1` and `d2`, the recursive function `bodies` refine one another, where recursive calls are related by `RPreInv` and `RPostInv` and any other events are related by `RPre` and `RPost`. These reasoning principles allow us to prove complicated propositions involving the coinductively defined refinement relation without needing to perform direct coinduction.

While we include several parameter relations with the definition of `padded_refines`, at the top level, we are typically interested in the case where all relations are set to equality. We call this relation *strict refinement*, and refer to it with the \leq symbol.

30:18 Interaction Tree Specifications

```
Notation "phi1 '≤' phi2" :=
  (padded_refines eq PostRelEq eq phi1 phi2).
```

Strict refinement is a transitive relation, and is strong enough to allow rewrites under the context of any other application of `padded_refines`.

4.4 ITree specification Incompleteness

One way to interpret ITree specifications is as sets of ITrees. The following code defines *concrete* ITree specifications, which correspond to executable ITrees.

```
Variant concreteF {E R} `{EncodingType E} (F : itree_spec E R → Prop) : itree_spec E
  R → Prop :=
  | concreteRet (r : R) : concreteF F (Ret r)
  | concreteTau (t : itree_spec E R) : F t → concreteF F (Tau t)
  | concreteVis (e : E) (k : response_type e → itree_spec E R) :
    (forall a, F (k a)) → concreteF F (Vis (Spec_vis e) k).
Definition concrete {E R} `{EncodingType E} : itree_spec E R → Prop := gfp concreteF.
```

A concrete ITree specification contains no quantifiers along any of its branches. We can map each ITree specification to the set of *concrete* ITree specifications that refine it.

However, ITree specifications are not complete with respect to this interpretation. In particular, there are pairs of ITree specifications that represent equivalent sets of concrete ITree specifications, but do not refine one another. To see why, consider the following two ITree specification over an empty event signature `voidE`.

```
Definition top1 : itree_spec voidE unit :=
  forall_spec void;; Ret tt.
```

```
Definition top2 : itree_spec voidE unit :=
  or_spec spin (Ret tt).
```

Both `top1` and `top2` are refined by all concrete ITree specifications of type `itree_spec voidE unit`. We can prove the refinement for `top1` by applying the right `forall` rule, and reducing to a trivially satisfied proposition. For `top2`, we know that every concrete ITree specification of this type is `eutt` to either `spin` or `Ret tt`⁵. In each case, apply the right `exists` rule and choose the corresponding branch. However, given any relations `RE`, `REAns`, `RR`, we cannot prove `padded_refines RE REAns RR top1 top2`. This is because the only way to eliminate the `Spec_forall` on the left is to provide an element of the `void` type, which does not exist. This, along with the transitivity theorem, demonstrates that `padded_refines` is strictly weaker than the subset relation on sets of refining concrete ITree specification.

5 Total Correctness Specifications

This section discusses how to encode and prove simple pre- and post- condition specifications using ITree specifications. We also discuss how these definitions relate to our syntax-directed proof automation.

Suppose we have a program that takes in values of type `A` and returns values of type `B`. Suppose we want to prove that if given an input that satisfies a precondition `Pre : A → Prop`, it will return a value that satisfies a postcondition `Post : A → B → Prop` without triggering any other events. The postcondition is a relation over `A` and `B` to allow the postcondition to depend on the initial provided value. We can encode these conditions in the following ITree specification.

⁵ Proving this fact requires a nonconstructive axiom like the Law of The Excluded Middle.

```
Definition call_spec (a : A) : itree_spec (callE A B + E) B := trigger (inl (Call a)).
```

```
Definition calling' {F} {EncodingType F} : (A → itree F B) →
  (forall (c : callE A B) , itree F (response_type c)) :=
  fun f c => f (unCall c).
```

```
Definition rec_spec (body : A → itree_spec (callE A B + E) B) (a : A) :
  itree_spec E B :=
  mrec_spec (calling' body) (Call a).
```

```
Definition rec_fix_spec
  (body : (A → itree_spec (callE A B + E) B) → A →
   itree_spec (callE A B + E) B) :
  A → itree_spec E B :=
  rec_spec (body call_spec).
```

■ **Figure 11** `rec_fix_spec` Definition.

```
Definition total_spec : A → itree_spec E B :=
  fun a => assume_spec (Pre a);;
  b ← exists_spec B;;
  assert_spec (Post a b);;
  Ret b.
```

The specification assumes that the input satisfies the precondition, existentially introduces an output value, asserts the post condition holds, and finally returns the output.

The `total_spec` specification can be effectively used compositionally. Consider a merge sort implementation, named `sort`, built on top of two recursively defined helper functions, one for splitting a list in half, named `halve`, and one for merging sorted lists, named `merge`. If we have already proven specializations of `total_spec` for these sub functions, it becomes easier to prove a specification for `sort`. Immediately we can replace these sub functions with their total correctness specification. Now consider how this total correctness specification will behave on the left side of a refinement. First, we can eliminate `assume_spec (Pre a)` as long as we can prove `Pre a`. Once we have done that, we get to universally introduce the output `b`, along with a proof that it satisfies the post condition. We are finally left with only `Ret b` with the assumption `Post a b`. This is a much simpler specification than our initial executable specification, which relied on several control flow operators including a recursive one.

However, this easy to use specification is not easy to directly prove. The `padded_refines_mrec` rule gives us a sound reasoning principle for proving that a recursively defined function refines another recursively defined function, but it does not give any direct insight into how to prove any refinement that does not match that syntactic structure. To address this, we introduce a recursively defined version of `total_spec_fix` that we can apply our recursive reasoning principle on.

First, we introduce a specialization of the `mrec_spec` combinator called `rec_fix_spec`, defined in Figure 11. The `rec_fix_spec` function has a type similar to that of a standard fixpoint operator. The first argument, `body`, is a function that takes in a type of recursive calls `A → itree_spec (callE A B + E) B` and an initial argument of type `A` and produces a result in terms of an ITree specification. It relies on the `calling'` function to transform this value into a value of type `forall (c : callE A B) , itree_spec (callE A B + E) B` which the `mrec_spec` function requires. From there it relies on the `call_spec` and `rec_spec` functions to wrap values of type `A` into `Call` events and `trigger` them.

Given this recursion operator, we introduce an equivalent version of the total correctness specification, `total_spec_fix`.

30:20 Interaction Tree Specifications

```
Definition total_spec_fix : A → itree_spec E B :=
  rec_fix_spec (fun rec a ⇒
    assume_spec (Pre a);;
    n ← exists_spec nat;;
    trepeat n (
      a' ← exists_spec A;;
      assert_spec (Pre a' ∧ Rdec a' a);;
      rec a'
    );;
    b ← exists_spec B;;
    assert_spec (Post a b);;
    Ret b).
```

This specification is reliant on the `trepeat n t` function, which simply binds an ITree, `t`, onto the end of itself `n` times. Note that `total_spec_fix` is defined recursively, and contains the elements of `total_spec` inside the recursive body. This makes it easier to relate to recursively defined functions. It begins by assuming the precondition and ends by introducing an output, asserting it satisfies the post condition, and returning the output. What comes between these familiar parts requires more explanation. Recall the discussion of the `padded_refines_mrec` rule. This reasoning principle lets you prove refinement between two recursively defined ITree specifications when a single layer of unfolding of each specification match up one to one with recursive calls.

This means that to have a useful, general, and recursively defined version of total correctness specification we need to allow our recursive definition for total correctness specification to choose the number of recursive calls the function requires. For this reason, `total_spec_fix` existentially introduces a number `n` that specifies how many recursive calls are needed for one level of unfolding of the recursive function starting at `a`. The specification then includes `n` copies of a specification that existentially chooses a new argument `a'`, asserts a predicate holds on it, and then recursively calls the specification on this new argument. This asserted predicate contains two parts. First, we assert the precondition. A correct recursively defined function should not call itself on an invalid input if given a valid input. Second, we assert that `a'` is *less than* `a` according to the relation `Rdec`. In order for `total_spec_fix` to actually be equivalent to `total_spec`, we need to assume that `Rdec` is well-founded⁶. The fact that `Rdec` is well-founded ensures that this specification contains no infinite chains of recursive calls. This allows us to prove that `total_spec_fix` refines `total_spec` as long as `Rdec` is well-founded.

```
Theorem total_spec_fix_correct :
  well_founded Rdec → forall (a : A), total_spec_fix a ≤ total_spec a.
```

This theorem allows us to initially prove refinement specifications for recursive functions using the `padded_refines_mrec` rule with `total_spec_fix` and then replace it with the easier to work with `total_spec`.

Both `total_spec` and `total_spec_fix` do not accept any ITree specifications that trigger any events. As a result, these total correctness specifications do not allow any exceptions to be raised, as you would expect with total correctness specifications.

5.1 Demonstration

To demonstrate how to work with `total_spec`, we describe how to verify the `merge` function, a key component of the merge sort algorithm. The `merge` function takes two sorted lists and combines them into one larger sorted list which contains all the original elements. In

⁶ We use the Coq standard library's definition of well-foundedness for this.

```

Definition merge : (list nat * list nat)
  →
  itree_spec E (list nat) :=
  rec_fix_spec (fun rec '(l1,l2) ⇒
    b1 ← is_nil l1;;
    b2 ← is_nil l2;;
    if b1 : bool then
      Ret l2
    else if b2 : bool then
      Ret l1
    else
      x ← head l1;;
      tx ← tail l1;;
      y ← head l2;;
      ty ← tail l2;;
      if Nat.leb x y then
        l ← rec (tx, y::ty);;
        Ret (x :: l)
      else
        l ← rec (x::tx, ty);;
        Ret (y::l)).

Definition merge_pre p :=
  let '(l1,l2) := p in
  sorted l1 ∧ sorted l2.
Definition merge_post '(l1,l2) l :=
  sorted l ∧ Permutation l (l1 ++ l2).

Definition rdec_merge '(l1,l2) '(l3,l4) :=
  length l1 < length l3 ∧
  length l2 = length l4 ∨
  length l1 = length l3 ∧
  length l2 < length l4.

Theorem merge_correct : forall l1 l2,
  merge (l1,l2) ≤ total_spec merge_pre
  merge_post (l1,l2).

```

■ **Figure 12** Merge implementation.

Figure 12, we present a recursively defined implementation of `merge` along with relevant relations and the correctness theorem. The `merge` function is based on the standard list manipulating functions `is_nil`, `head`, and `tail`. We assume that the event type `E` contains some kind of error event which is emitted if `head` or `tail` is called on an empty list.⁷

The `merge` function relies on its arguments being sorted and guarantees that its output is a single, sorted list that is a permutation of the concatenation of the original lists. We formalize these conditions in `merge_pre` and `merge_post`. To prove that `merge` is correct, we want to show that it refines the total specification built from its pre- and post- conditions. To accomplish this, it suffices to choose a well founded relation and prove that `merge` satisfies the resulting `total_spec_fix` specification. For this function, we use `rdec_merge` which ensures that the pairs of lists that we recursively call `merge` on either both decrease in length, or one decreases in length and the other has the same length.

This leaves us with a refinement goal between two recursively defined specifications. We can then apply the `padded_refines_mrec_spec` theorem. For the relational precondition, we require that each pair of `Call` events is equal, and that `Pre` holds on the value contained within the call. For the relational postcondition, we require that equal `Call` events return equal values and that `Post` holds on them. Finally, we can prove that the body `merge` refines the body of `total_spec_fix` given these relation pre- and postconditions. We accomplish this by setting the existential variables on the right to make a single recursive call and give it the same argument as the recursive call that the body of `merge` makes.

With this technique, we can verify the simple server introduced in Section 1. Recall that the `server_impl` program executes an infinite loop of receiving a list of numbers, sorting it, and sending it back as a message. To verify `server_impl`, we first verify `halve`, the remaining sub function of `sort`, using the same technique we used to prove the correctness of `merge`. We can then use these facts to prove the correctness of `sort`, and use the correctness of `sort` to prove the correctness of `server_impl`.

```

Theorem server_correct :
  (server_impl tt) ≤ (server_spec tt).

```

⁷ We manage this assumption with a Coq type class called `ReSum`. For more information please read the original ITrees paper [29] or inspect the associated artifact.

30:22 Interaction Tree Specifications

Function Name	Description	C LoC	Proof LoC
<code>mbox_free_chain</code>	Deallocate an <code>mbox</code> chain	11	18
<code>mbox_len</code>	Compute the length in bytes of an <code>mbox</code> chain	9	40
<code>mbox_concat</code>	Concatenates an <code>mbox</code> chain after a single <code>mbox</code>	5	18
<code>mbox_concat_chains</code>	Concatenates two <code>mbox</code> chains	14	24
<code>mbox_split_at</code>	Split an <code>mbox</code> chain into two chains	25	147
<code>mbox_copy</code>	Copy a single <code>mbox</code>	13	74
<code>mbox_copy_chain</code>	Copy an <code>mbox</code> chain	18	173
<code>mbox_detach</code>	Detach the first <code>mbox</code> from a chain	18	18
<code>mbox_detach_from_end</code>	Detach the first N bytes from an <code>mbox</code> chain	3	50
<code>mbox_randomize</code>	Randomize the contents of an <code>mbox</code>	9	121
<code>mbox_drop</code>	Remove bytes from the start of an <code>mbox</code>	12	23

6 Automation and Evaluation

6.1 Auto-active Verification

A key goal of this work is to provide auto-active automation for ITree specifications refinement. To this effect, the current section presents an automated Coq tactic for proving refinement goals called `prove_refinement`. The `prove_refinement` tactic is designed to reduce proof goals about refinement of programs to proof goals about the data and assertions used in those programs. In the spirit of auto-active verification, this is done mostly automatically, but with the user guiding the automation in places where human insight is needed.

The `prove_refinement` tactic defers to the user in two specific places. The first is in defining invariants for uses of the `mrec` recursive function combinator. The tool defers to the user to provide these invariants because inferring such invariants is undecidable. The second place where `prove_refinement` defers to the user is in proving non-refinement goals regarding first order data. The user can then apply other automated and/or manual proof techniques for the theories of the resulting proof goals.

The `prove_refinement` tactic is defined using a collection of syntax-directed inference rules for proving refinement goals. The tactic proves refinement goals by iteratively choosing and applying a rule that matches the current goal and then proceeding to prove the antecedents. The `prove_refinement` tactic implements this strategy using the Coq hint database mechanism, which is already a user-extensible mechanism for proof automation using syntax-directed rules.

We omit further implementation details both for space and because we do not claim the implementation of the `prove_refinement` tactic is novel or interesting. What is novel and interesting is that ITree specifications are designed in such a way that the straightforward implementation is able to achieve impressive results.

6.2 Evaluation

He et al. [9] discussed using Heapster to verify the interface of `mbox`, a key datastructure in the implementation of the Encapsulating Security Payload (ESP) protocol of IPSec. The `mbox` datastructure represents a data packet as a linked list of fixed length arrays. He et al. [9] type checked and extracted functional specifications for several functions that manipulate `mbox`. Using ITree specifications, we specified and verified the behavior of these functional

specifications using our auto-active verification tool. These functions are nontrivial, combining loops, recursion, and pointer manipulations. We present the list of verified functions in Figure 13.

For each function, we include the function’s name, a description of its behavior, the number of lines of C code in its definition, and the number of lines of Coq code required to verify it. Lines of code are, of course, a very coarse metric for judging the complexity of code and proofs. However, these metrics do demonstrate the viability of this verification approach, showing that the remaining proof burden after the automation is of a reasonable size. The primary advantage this approach has over others is that the system reduces the verification down to facts about first order data. In this case, the data is a variant of the `mbox` datastructure written in Coq.

7 Related Work

The most closely related work is the work on Dijkstra monads [16, 28, 1, 27]. Dijkstra monads are a framework for writing specifications over arbitrary monads. This framework is the basis for verifying programs with effects in F^* [26], a programming language specifically designed for verification. Dijkstra monads arise from the interaction of three structures, a *monad* M , a *specification monad* W , and an *effect observation* function `obs`. The monad M represents computations to be verified, while the specification monad W is a monad for writing specifications about those computations. The effect observation function `obs` is a monad homomorphism that embeds computations in M to the most precise specification in W that they satisfy. The specification monad is also equipped with a refinement relation that expresses when one specification implies or is contained in another. As an example, Dijkstra monads arose out of generalizing the notion of weakest precondition computations, by viewing the weakest precondition transformer of a computation as itself being a stateful computation from postconditions to preconditions. The mapping from a computation to its weakest precondition transformer is then a monad homomorphism from the computation monad to the weakest precondition monad.

ITree specifications in fact form a Dijkstra monad, where the type `itree_spec E R` acts as the specification monad and the corresponding ITree monad `itree E R` without logical quantifier events forms the computation monad. The effect observation homomorphism is then the natural embedding from the ITree type without quantifiers to the type with quantifiers. Most Dijkstra monads are specialized to act as either partial specification logics, which always accept any nonterminating computations, or total specification logics, which always reject any nonterminating computations. This means that most existing Dijkstra monads cannot reason about termination-sensitive properties like liveness. ITree specifications have the advantage of admitting specifications that accept particular divergent computations and not others. For example, an ITree specification could accept any computation that produces an infinite pattern of messages and responses from a server, and reject any computation that silently diverges.

A notable exception is the work of Silver and Zdancewic [25], who also provided a Dijkstra monad for ITrees. Much like ITree specifications it was capable of expressing specifications that allow for specifying infinite behavior. However, it did not provide reasoning principles for general recursion. The fact that ITree specifications represent specifications as syntax rather than semantics, as an ITree rather than some function relating ITrees to `Prop`, enabled us to write reasoning principles for general recursion and to build automation around the refinement rules.

A lot of work on verifying monadic computations has been based on notions of equational reasoning. This was in fact a key part of Moggi’s original work [19]. Pitts [21] and Moggi [20] extend this approach by building general theories of an evaluation predicate for reasoning about return values of computations. This approach provides no explicit means to reason about the effects, however, and also has no direct way of handling non-termination in specifications such as the specifications needed for a server process. Plotkin and Pretnar [22] further extend this approach with a general-purpose logic for algebraic effects, allowing it to reason about the effects themselves and not just return values. This approach cannot handle general Hoare logic assertions, however, and although there is a high-level discussion about handling recursion, it is not clear how well it works for those sorts of specifications. Rauch et al. [23] extends monads with native exceptions and non-termination and provides a logic for these monads. Much like in our work, monads in Rauch et al. [23] can be annotated with assertions. However, it restricts the language of assertions, and does not provide assumptions, or general universal or existential quantification. It also handles only tail recursive programs, and not general, mutual recursion.

One particularly effective approach in the space of equational reasoning was that of Gibbons and Hinze [8]. This work showed how to use the specialized monad laws of each sort of effect in a computation to define rewrite rules for simplifying and reasoning about effectful computations, and then demonstrated that this approach is both straightforward to use and powerful enough to verify a number of small but interesting programs.

The ultimate goal of this work is to provide techniques for auto-active verification of imperative code. Therefore, it is natural to compare this work to semi-automated separation logic tools like VST-Floyd[2] and CFML[6]. We argue this approach has two major advantages over these related techniques. First, while VST-Floyd is specialized to C and CFML is specialized to Caml, ITree specifications can be used to specify any programs with an ITrees based semantics. When paired with Heapster techniques, ITree specifications can be used to specify a wide array of imperative, heap-manipulating languages with a memory-safe type system. In particular, the Heapster type system is closely related to the Rust type system, meaning these techniques should be adaptable to specify and verify Rust code. Second, the Heapster types are able to perform all the separation logic specific reasoning, freeing the verifier to focus on the underlying mathematical structures.

8 Conclusion

This paper introduces ITree specifications along with verified metatheory and proof automation for reasoning about them. ITree specifications are a specialization of ITrees with a general notion of specification refinement. Unlike previous work developing specifications for ITrees, this paper provides techniques for working with the general recursion operator provided by the ITrees library. Finally, this paper demonstrates the effectiveness of its techniques by applying them on a collection of realistic C functions.

Abstract

The λ_{DAT} calculus brings together the power of functional and declarative logic programming in one language. In λ_{DAT} , Datalog constraints are first-class values that can be constructed, passed around as arguments, returned, composed with other constraints, and solved.

A significant part of the expressive power of Datalog comes from the use of negation. Stratified negation is a particularly simple and practical form of negation accessible to ordinary programmers. Stratification requires that Datalog programs must not use recursion through negation.

For a Datalog program, this requirement is straightforward to check, but for a λ_{DAT} program, it is not so simple: A λ_{DAT} program constructs, composes, and solves Datalog programs at runtime. Hence stratification cannot readily be determined at compile-time.

In this paper, we explore the design space of stratification for λ_{DAT} . We investigate strategies to ensure, at compile-time, that programs constructed at runtime are guaranteed to be stratified, and we argue that previous design choices in the Flix programming language have been suboptimal.

1 Introduction

Datalog is an expressive and powerful declarative logic programming language. A Datalog program consists of facts and rules. Facts represent knowledge (e.g. “an owl is a bird”) whereas rules allow one to infer new facts from existing facts (e.g. “if x is a bird and x is not a penguin then x can fly.”). The facts and rules imply a minimal model, a unique solution to every Datalog program [18] (e.g. “an owl is a bird” and “an owl can fly”).

Datalog has been used in a diverse set of applications including big-data analytics [20, 39, 41], social network analysis [39, 40], machine learning [32, 34], bio-informatics [25, 38], disassembly [15], micro-controller programming [46], networking and distributed systems [1, 10, 29], program analysis [7, 42, 43], and smart contract security [44].

Over the years, a plethora of Datalog extensions have been developed, adding support for object types [4], logic formulas [6], decidable arithmetic functions [23], disjunctive rule heads [13], distributed evaluation [24], and more. Many Datalog solvers have also been developed, including DLV [2], Soufflé [22], LogicBlox [3], QL [4], Formulog [6], and Flix [31].

A significant part of both the theoretical and practical expressive power of Datalog comes from the use of negation. However, negation also brings challenges: ensuring a meaningful semantics for logic programming with negation is a historically well-studied problem [14, 16, 17, 27, 36, 37]. Stratified negation has emerged as a simple and practical

semantics that is accessible to ordinary programmers [48]. Informally, a Datalog program is stratified when there is no recursion through negation, i.e. no predicate symbol can negatively depend on itself. Stratification splits a Datalog program D into a sequence of Datalog programs D_1, \dots, D_n where the “output facts” of D_i become the “input facts” of D_{i+1} . Computing *whether* a Datalog program is stratified, and if so, computing its strata, is straightforward, e.g. using Ullman’s algorithm [45].

The λ_{DAT} calculus extends the lambda calculus with first-class Datalog constraints [30]. In λ_{DAT} , Datalog constraints, or programs, are values that can be constructed, passed as arguments to functions, returned from functions, composed with other Datalog program values, and have their minimal model computed. The minimal model is itself a set of facts, hence a Datalog value. This makes it possible to construct pipelines of Datalog computations. The type system of λ_{DAT} is based on Hindley-Milner [12, 47] extended with row polymorphism [28]. The type system permits Datalog constraints to be polymorphic, while ensuring type safety [30]. The λ_{DAT} calculus and its type system has been implemented in the Flix programming language.

For a λ_{DAT} program, we cannot readily determine whether the Datalog values constructed at runtime are stratified. We *can* defer stratification until runtime, but this has two significant downsides: (1) we must perform the stratification repeatedly, and worse, (2) we have to abort execution if a non-stratified Datalog program is ever constructed.

In this paper, we explore the design space of compile-time techniques, which ensure that λ_{DAT} programs never construct non-stratified Datalog values at runtime. We also show that these techniques enable stratification of Datalog programs with lattice semantics.

In summary, the paper makes the following contributions:

- **(Design Space)** We explore the design space of compile-time stratification in the presence of first-class Datalog constraints.
- **(Framework)** We formulate the design space in a mathematical framework that allows us to express each design point as a specific instantiation of the framework. We introduce the notion of a *labelled dependency graph* and discuss how it can be used to soundly over-approximate the dependency edges of a Datalog expression.
- **(Comparison)** We identify the current state-of-the-art, i.e. the technique currently used in the Flix programming language, in the design space and illustrate that some of its design choices have been sub-optimal.
- **(Implementation)** We extend the Flix programming language with different design choices that admit more programs (i.e. allow more safe programs to pass the type checker). In particular, our extension uses rule-level granularity (**choice 1c**), and uses predicate arity and predicate term types in the labelled dependency graph (**choice 2b** and **2c**).
- **(Case Study)** We conduct a case study of a graph library that we implement in Flix. The study shows that use of stratified negation and lattice semantics is prevalent.

This paper is structured as follows: We motivate our work in Section 2. In Section 3 we present background material on Datalog, on stratified negation, and on the λ_{DAT} calculus. We explore the design space of stratification for λ_{DAT} in Section 4, Section 5, and Section 6. In Section 7 we discuss the design choices that we have made and our implementation in the Flix programming language. We use this implementation for a graph library case study in Section 8. Section 9 presents related work and Section 10 concludes. To ensure that the paper is self-contained, the background section has to cover a lot of material. Readers who are already familiar with Datalog, stratified negation, or the λ_{DAT} calculus are encouraged to skip the background material.

■ **Figure 1** An undirected graph. We want to compute the connected components of the graph and introduce edges that connect them. The components are indicated by thick gray lines. The edges we want to compute are indicated by dashed lines. The double circled nodes are the representatives of each connected component.

2 Motivation

We motivate our work with an example. Consider the following problem:

Given an undirected graph, compute its connected components and introduce an edge between each component.

Figure 1 illustrates the problem with an example. The graph has nodes numbered one to eight. The connected components are $\{1, 2, 7\}$, $\{3, 5\}$, and $\{4, 6, 8\}$. We want to compute the three (undirected) edges: $\{1, 2, 7\} \leftrightarrow \{3, 5\}$, $\{1, 2, 7\} \leftrightarrow \{4, 6, 8\}$, and $\{3, 5\} \leftrightarrow \{4, 6, 8\}$, as shown in Figure 1.

We can use the Flix programming language, with its support for first-class Datalog constraints, to elegantly solve this problem. Figure 2 shows a Flix program that does so. The program consists of two functions: `connectedComponents` and `connectGraph`.

The `connectedComponents` function computes the connected components (CCs) of the given (undirected) graph. The graph is represented as a set of `nodes` (of type `Set[Int32]`) and a set of `edges` (of type `Set[(Int32, Int32)]`). First, the function converts the `nodes` and `edges` into `Node` and `Edge` facts. Next, the function defines a local variable `r` which is a Datalog program value. The Datalog program defines `Reachable` as the (undirected) transitive closure of the `Edge` relation. Using `Reachable`, it computes the representative of each node in a CC as follows: Every node in a CC is associated with the lexicographically largest node in the same CC (`ReachUp`). The representative of a CC is then the node which is the largest in each CC, i.e. has no larger parent. Finally, the `connectedComponents` function composes the node (`ns`) and edge (`es`) facts with the Datalog program (`r`), computes its minimal model, and extracts all the `ComponentRep` facts. The polymorphic row extension in the return type `#{... | r}` allows the caller to type the returned Datalog program with additional predicates.

The `connectGraph` function computes a set of edges that connect CCs in a graph. That is, the function returns a set of edges that connect *sets of nodes*. The `connectGraph` function takes a graph as input (using the same representation as before), and calls the `connectedComponents` function to compute the CCs, specifically the `ComponentRep` relation which holds the representative of each node in the graph. The function defines the local variable `d` which is a Datalog program value. The Datalog program uses the `ComponentRep` to build a map `Component` which maps each representative to the set of nodes it represents. The rule:

```
1 Component(rep; Set#{n}) :- ComponentRep(n, rep).
```

states that if there is a `ComponentRep(n, rep)` fact, for some `n` and `rep`, then we infer a `Component(rep; Set#{n})` *lattice* fact where `rep` is mapped to the singleton set $\{n\}$. The `Component` lattice implicitly combines facts using the ordering on `Set[Int32]`, which is subset

31:4 Breaking the Negative Cycle

```
1  /// Given an undirected graph represented by nodes and edges,
2  /// computes its connected components and returns a relation
3  /// that maps each node to its representative.
4  def connectedComponents(nodes: Set[Int32], edges: Set[(Int32, Int32)]):
5      #{ ComponentRep(Int32, Int32) | r } =
6      let ns = inject nodes into Node;
7      let es = inject edges into Edge;
8      let r = #{

28  /// Given an undirected graph represented by nodes and edges,
29  /// connects all connected components. The returned edges are
30  /// between components, i.e. they are edges between *sets* of nodes.
31  def connectGraph(nodes: Set[Int32], edges: Set[(Int32, Int32)]):
32      #{ Edge(Set[Int32], Set[Int32]) | r } =
33      let d = #{
34          // Component(rep; c) captures that the node rep is the
35          // representative of the component c which is a set of nodes. The
36          // semicolon makes c use lattice semantics which aggregates all
37          // the nodes represented by rep into one set.
38          Component(rep; Set#{n}) :- ComponentRep(n, rep).
39          // Introduce an edge between every pair of components sets.
40          // The fix keyword ensures that the Component relation is fully
41          // materialized before this rule is evaluated, i.e. that a
42          // component contains all its nodes.
43          Edge(c1, c2) :- fix Component(_; c1), fix Component(_; c2).
44      };
45      solve connectedComponents(nodes, edges), d project Edge
46
47  def main(): Unit \ IO =
48      let connectedGraph = connectGraph(Set.range(1, 9),
49          Set#{ (1, 2), (2, 7), (5, 3), (8, 6), (6, 4), (4, 8)});
50      let result = query connectedGraph select (c1, c2) from Edge(c1, c2);
51      println(result)
```

■ **Figure 2** Flix program that connects an undirected graph using Datalog.

inclusion. In other words, if there are multiple `ComponentRep` facts with the same `rep` then every set is union'ed together. The last rule introduces edges between the components:

```
1  Edge(c1, c2) :- fix Component(_; c1), fix Component(_; c2).
```

The `fix` keyword ensures that the `Component` lattice *is fully computed* before the rule is evaluated. We will explain the full details in Section 6.

2.1 Stratified Negation

The Flix program in Figure 2 uses negation in the following rule:

```
ComponentRep(n, rep) :- Reachable(n, rep), not ReachUp(rep).
```

where the `ReachUp` predicate symbol occurs negated.

Datalog has the theoretically interesting and practically useful property that every Datalog program has a unique solution; the minimal model. However, in the presence of negation, an additional side condition is necessary to ensure the existence of the minimal model.

To understand why, consider a Datalog program with the two rules:

```
WinBlack(x)  $\Leftarrow$  not WinWhite(x). WinWhite(x)  $\Leftarrow$  not WinBlack(x).
```

The rules try to capture the idea that “if x is not a winning move for white then x is a winning move for black” and “if x is not a winning move for black then x is a winning move for white”. The problem is that this Datalog program has *two* models, neither of which is minimal: $\{\text{WinBlack}(p)\}$ and $\{\text{WinWhite}(p)\}$ for some p . We want to avoid such situations.

Stratified negation overcomes this problem by imposing a simple restriction: A predicate symbol cannot negatively depend on itself. This requirement is sometimes expressed as “no recursion through negation”. It is straightforward to determine if a Datalog program is stratified: We simply compute the dependency graph of the program and determine if it contains a cycle with a negative edge.

Returning to Figure 2, if we look at all the rules, we can see the following negative cycle:

```
Edge  $\Leftarrow$  Component  $\Leftarrow$  ComponentRep  $\Leftarrow$  ReachUp  $\Leftarrow$  Reachable  $\Leftarrow$  Edge
```

But does the Flix program in Figure 2 actually construct a Datalog value with a negative cycle at runtime? Fortunately this is not the case. The reason is as follows: the `Edge`, `Reachable`, and `ReachUp` predicates are used to compute the `ComponentRep` relation. This Datalog program is fully solved before `ComponentRep` is used to compute a new set of `Edges`.

We can now describe the problem this paper aims to solve:

In Flix, in the presence of first-class Datalog values, how can it be statically guaranteed that every Datalog value that may be constructed at runtime will be stratified?

In the example above, we used very ad-hoc reasoning to justify that a negative cycle cannot occur. While a very powerful and precise control- and data-flow analysis may be able to provide similar justification, in this paper we are interested in simpler and more light-weight techniques. We want to build on the type system of the λ_{DAT} calculus and of Flix. In the dependency `Edge \Leftarrow ComponentRep`, the type of `Edge` is $(\text{Set}[\text{Int32}], \text{Set}[\text{Int32}])$, whereas in the dependency `Reachable \Leftarrow Edge`, the type of `Edge` is $(\text{Int32}, \text{Int32})$. The type system ensures that predicate symbols with different types cannot occur in the same Datalog program value. This means that we can exclude the existence of edges based solely on the type information. Interestingly, we could also use the type system in a different way to exclude the negative cycle. The rule using negation mentions three predicate symbols: `ComponentRep`, `Reachable`, and `ReachUp`. The rule which closes the supposed cycle mentions two predicate symbols: `Component` and `Edge`. Since the program has no expression with a type that contains *all* these predicate symbols, we know that the cycle cannot occur.

We can now summarize the overall goal of this paper:

We want to explore the design space of type-based techniques that can statically ensure that Flix programs, in the presence of first-class Datalog constraints, are stratified.

3 Background

We begin with an introduction to Datalog and stratified negation before we move on to describe the λ_{DAT} calculus [30]. This paper contains a lot of background material. Readers who are already familiar with Datalog are encouraged to jump to Section 3.3.

3.1 Datalog

We give a brief introduction to Datalog. A comprehensive introduction is available in [9, 18].

3.1.1 Syntax

A Datalog *program* D is a set of constraints C_1, \dots, C_n . A *constraint* is of the form $A_0 \Leftarrow B_1, \dots, B_n$ where A_0 is the *head atom* and each B_i is a *body atom*. A head atom $p(t_1, \dots, t_n)$ consists of a predicate symbol p and a sequence of terms t_1, \dots, t_n . A *body atom* is similar to a head atom, except that it can be negated, which is written with “not” in front of the predicate symbol. A constraint without a body is called a *fact*. A constraint with a body is called a *rule*. A *term* is either a variable x or a literal constant c . An atom without variables is said to be *ground*. A fact or rule with only ground atoms is said to be ground. Figure 3 shows the grammar of Datalog.

$D \in \text{Programs}$	$= C_1, \dots, C_n$	$t \in \text{Terms}$	$= x \mid c$
$C \in \text{Constraints}$	$= A_0 \Leftarrow B_1, \dots, B_n.$	$c \in \text{Literals}$	$=$ a set of literal constants.
$A \in \text{Head Atoms}$	$= p(t_1, \dots, t_n)$	$x, y \in \text{VarSym}$	$=$ a set of variable symbols.
$B \in \text{Body Atoms}$	$= p(t_1, \dots, t_n)$	$p, q \in \text{PredSym}$	$=$ a set of predicate symbols.
	$ \text{ not } p(t_1, \dots, t_n)$		

■ **Figure 3** Syntax of Datalog.

A Datalog program must satisfy three syntactic properties that are not naturally captured by the grammar in Figure 3: (i) every fact must be ground, (ii) every variable that occurs in the head of a rule must also occur in its body, and (iii) every variable that occurs in a negated body atom must also occur in at least one positive body atom of the rule. If a program satisfies these properties it is said to be *well-formed*. In addition, every Datalog program which uses negation must be stratified, as we will explain in Section 3.2.

3.1.2 Semantics

The meaning of a Datalog program is usually defined in terms of the *minimal model*: the smallest interpretation (i.e. set of facts) that satisfy all the constraints (i.e. rule instantiations) of the program [18]. While the semantics of Datalog – and logic programs in general – is an interesting subject worthy of study, in this paper our focus is on stratification.

3.2 Stratified Negation

A significant part of the expressive power of Datalog comes from the use of negation, but unrestricted use of negation poses problems. Recall the Datalog program from Section 2:

$$\text{WinBlack}(x) \Leftarrow \text{not WinWhite}(x). \quad \text{WinWhite}(x) \Leftarrow \text{not WinBlack}(x).$$

If the program contains the constant 42, then the program has *two* solutions (models):

$$M_1 = \{\text{WinBlack}(42)\} \quad \text{and} \quad M_2 = \{\text{WinWhite}(42)\}$$

Neither model is a subset of the other. Hence neither model is minimal. This breaks one of the fundamental properties of Datalog: that every program has a unique solution. Defining a consistent semantics for logic programming languages with negation has long been studied and many proposals have been made [14, 16, 17, 27, 36, 37]. Stratified negation has emerged as a particularly simple semantics that can be mastered by ordinary programmers [48].

Informally, a Datalog program is said to be *stratified* if its predicate symbols can be partitioned into a sequence of *strata* such that a predicate symbol in a stratum only depends on predicate symbols in the same or lower strata. Intuitively, stratification splits a Datalog program D into a sequence of sub-programs D_1, \dots, D_n such that the output of D_i becomes the input of D_{i+1} .

We can determine if a Datalog program is stratified by computing its dependency graph:

► **Definition 1** (Dependency Graph). *The dependency graph (also called the precedence graph) of a Datalog program D is a directed graph of predicate symbols that contains:*

- a positive edge $a \leftarrow b$ if D contains a rule where a is the predicate symbol of the head atom and b is a predicate symbol of a positive body atom, and
- a negative edge $a \leftarrow\!-\! b$ if D contains a rule where a is the predicate symbol of the head and b is a predicate symbol of a negative body atom.

We write dependency edges as $a \leftarrow b$ and $a \leftarrow\!-\! b$ since this matches the “direction” of Datalog rules. We say that a depends on b . If $a \leftarrow\!-\! b$ we say that b must be computed before a . We write $\mathcal{DG}(D)$ for the dependency graph of the Datalog program D . Note that the dependency graph of a Datalog program D is unique.

We can now formally state when a Datalog program is stratified:

► **Definition 2** (Stratified). *A Datalog program D is stratified if its dependency graph contains no cycles with a negative edge.*

► **Example 3.** We will use the following running example. Consider the following Datalog program and its dependency graph:

$$\begin{aligned} \text{Cold}(x) &\leftarrow \text{Kettle}(x), \text{Off}(x). \\ \text{Warm}(x) &\leftarrow \text{Kettle}(x), \text{not Cold}(x). \end{aligned}$$

which does not contain a cycle with a negative edge. The strata of this program are:

$$s_1 = \{\text{Cold}, \text{Kettle}, \text{Off}\} \quad s_2 = \{\text{Warm}\}$$

which means that the Cold, Kettle, and Off relations must be computed before we compute the Warm relation.

► **Example 4.** Consider a modification of the previous Datalog program with its new dependency graph:

$$\begin{aligned} \text{Cold}(x) &\leftarrow \text{Kettle}(x), \text{not Warm}(x). \\ \text{Warm}(x) &\leftarrow \text{Kettle}(x), \text{not Cold}(x). \end{aligned}$$

31:8 Breaking the Negative Cycle

$ \begin{aligned} v \in \text{Val} &= c \mid \lambda x. e \mid \#\{C_1, \dots, C_n\} \\ e \in \text{Exp} &= x \mid v \mid e e \mid \text{let } x = e \text{ in } e \\ &\quad \mid e \langle + \rangle e \mid \text{solve } e \mid \text{project } p e \\ c \in \text{Literals} &= \text{a set of literal constants.} \\ x, y \in \text{VarSym} &= \text{a set of variable symbols.} \\ p, q \in \text{PredSym} &= \text{a set of predicate symbols.} \end{aligned} $	$ \begin{aligned} C \in \text{Constraints} &= A_0 \Leftarrow B_1, \dots, B_n. \\ A \in \text{Head Atoms} &= p(t_1, \dots, t_n) \\ B \in \text{Body Atoms} &= p(t_1, \dots, t_n) \\ &\quad \mid \text{not } p(t_1, \dots, t_n) \\ &\quad \mid \text{fix } p(t_1, \dots, t_n) \\ t \in \text{Terms} &= x \mid c \end{aligned} $
---	--

■ **Figure 4** Syntax of λ_{DAT} .

$ \begin{aligned} \tau \in \text{Type} &= \alpha \mid \iota \mid \tau_1 \rightarrow \tau_2 \mid r \\ r, s \in \text{Row} &= \rho \mid \{ \} \mid \{ p = (\tau_1, \dots, \tau_n) \mid r \} \\ \iota &= \text{a set of base types.} \end{aligned} $	$ \begin{aligned} \sigma \in \text{Scheme} &= \forall \bar{\alpha} \forall \bar{\rho}. \tau \\ \alpha \in \text{TypeVar} &= \text{a set of type variables.} \\ \rho \in \text{RowVar} &= \text{a set of row variables.} \end{aligned} $
---	---

■ **Figure 5** Type System of λ_{DAT} .

The graph contains a negative cycle between the **Cold** and **Warm** predicate symbols hence the program is not stratified and should be rejected. In this case, the negative cycle involves two predicate symbols and two negative dependencies, but in general a negative cycle consist of any number of dependency edges with at least one negative dependency edge.

3.3 First-Class Datalog Constraints

We now describe the λ_{DAT} calculus, a minimal lambda calculus with first-class Datalog constraints, originally introduced by [30]. We use a slightly simplified version of the calculus that illustrates the challenges posed by stratified negation.

3.3.1 Syntax

The grammar of λ_{DAT} is shown in Figure 4. The language includes the usual constructs from the lambda calculus: constants, variables, lambda abstractions, function applications, and let-bindings. Let-bindings support Hindley-Milner-style parametric polymorphism [11, 21, 33]. The values of λ_{DAT} include constants c , lambda abstractions $\lambda x. e$, and *Datalog values* $\#\{C_1, \dots, C_n\}$. A Datalog value is a collection of Datalog facts and rules. The grammar of Datalog values mirrors that of Figure 3. The fix body atom will be explained in Section 6. The expressions of λ_{DAT} include variables x , values v , function applications $e e$, and let-bindings $\text{let } x = e \text{ in } e$. The calculus has three expressions for working with Datalog values:

- (i) a *composition expression* $e_1 \langle + \rangle e_2$ to compute the union of two Datalog values,
- (ii) a *project expression* $\text{project } p e$ to extract all p facts from a Datalog value, and
- (iii) a *solve expression* $\text{solve } e$ to compute the minimal model of a Datalog value.

The Flix programming language, which implements the λ_{DAT} calculus, supports a richer set of operations for working with Datalog values. However, for our purposes, the above calculus is sufficient to illustrate the challenges. For the full details on the λ_{DAT} calculus, we refer the reader to [30].

3.3.2 Type System

The λ_{DAT} type system is based on Hindley-Milner [12, 47] extended with row polymorphism [28]. Each row type tracks the predicate symbols (and the types of the term parameters of each predicate) of a Datalog expression. The type system is sound; satisfying the usual progress and preservation theorems [30].

The type system splits types into mono- and poly types as shown in Figure 5. The mono types consist of type variables α , a set of base types denoted by ι (e.g. `Bool`), function types $\tau_1 \rightarrow \tau_2$, and row types r . A row type is either a row type variable ρ , an empty row $\{\}$, or a row extension $\{p = (\tau_1, \dots, \tau_n) \mid r\}$. A row type describes the type of a Datalog expression.

► **Example 5.** The following Datalog expression is typeable with the shown row type:

$$\#\{\text{Bird}(\text{“Eagle”}), \text{Flying}(x) \Leftarrow \text{Bird}(x), \text{not Penguin}(x).\} : \\ \{\text{Bird} = \text{String} \mid \{\text{Flying} = \text{String} \mid \{\text{Penguin} = \text{String} \mid \rho\}\}\}$$

The order of predicate symbols within a row is immaterial. Hence the same row is equivalent to (written as \cong):

$$\{\text{Penguin} = \text{String} \mid \{\text{Flying} = \text{String} \mid \{\text{Bird} = \text{String} \mid \rho\}\}\}$$

Figure 5 shows the poly types (or type schemes) of λ_{DAT} . A poly type is of the form $\forall \alpha_1, \dots, \alpha_n \forall \rho_1, \dots, \rho_m. \tau$. Thus, the λ_{DAT} calculus separates regular type variables α from row type variables ρ .

► **Example 6.** The following Datalog expression is typeable with the shown poly type:

$$\#\{\text{Path}(x, z) \Leftarrow \text{Path}(x, y), \text{Edge}(y, z).\} : \forall \alpha_1, \alpha_2 \forall \rho. \{\text{Path} = (\alpha_1, \alpha_2), \text{Edge} = (\alpha_2, \alpha_2) \mid \rho\}$$

This expression is polymorphic in the types of the terms of the `Edge` and `Path` atoms (α_1 and α_2) and row polymorphic in the type of the rest of the row (ρ). As can be seen from the rule, the variables y and z must share the same type (α_2) because of their occurrences in the `Path` atoms. The two types of polymorphism serve two different purposes: the regular polymorphism allows the expression to be used with terms of different types (e.g. `Edge` and `Path` facts over integers, strings, etc) whereas the row polymorphism allows the expression to be composed with other Datalog expressions that may have additional predicate symbols.

The type system of λ_{DAT} has three mutually inductive typing judgments: one for expressions ($\Gamma \vdash e : \tau$), one for constraints ($\Gamma \vdash_c C : r$), and one for atoms ($\Gamma \vdash_p p(t_1, \dots, t_n) : r$).

3.3.2.1 Type Rules

We briefly describe the (T-HEAD-ATOM) and (T-CONSTRAINT) type rules of λ_{DAT} .

The typing judgement $\Gamma \vdash_p p(t_1, \dots, t_n) : r$ captures that the head or body atom $p(t_1, \dots, t_n)$ can be typed with row type r under the type environment Γ . In particular, the

$$\frac{\forall i. \Gamma \vdash t_i^h : \tau_i}{\Gamma \vdash_p p(t_1^h, \dots, t_n^h) : \{p = (\tau_1, \dots, \tau_n) \mid r\}} \quad (\text{T-HEAD-ATOM})$$

rule states that a head atom can be typed as a row type in which the predicate symbol p is mapped to a tuple type whose elements are the types of the head terms t_1^h, \dots, t_n^h . The type rules for body atoms are similar. What is important, for our purposes, is that to type a head or body atom, its predicate symbol and term types must be part of the row type.

The typing judgement $\Gamma \vdash_c C : r$ captures that the constraint C can be typed as r under the type environment Γ . In particular, the

$$\frac{\Gamma, x_1 : \tau_1, \dots, x_m : \tau_m \vdash_p A_0 : r \quad \forall i. \Gamma, x_1 : \tau_1, \dots, x_m : \tau_m \vdash_p B_i : r_i \quad \forall i. r \cong r_i}{\Gamma \vdash_c \forall (x_1 : \tau_1, \dots, x_m : \tau_m). A_0 \Leftarrow B_1, \dots, B_n. : r} \quad (\text{T-CONSTRAINT})$$

31:10 Breaking the Negative Cycle

type rule states that to type an entire constraint, the row type of the head atom and all the body atoms must be equivalent, i.e. contain the same predicate symbols mapped to the same term types, modulo the order of predicate symbols. In λ_{DAT} , the unbound Datalog variables are explicitly quantified.

We refer the reader to [30] for a complete description of the type system. We will use the type system when we define soundness of labelled dependency graphs in Section 5.

3.4 The Problem: Stratification and First-Class Constraints

We are now ready to define what it means for a λ_{DAT} program to be stratified:

► **Definition 7** (Stratification for λ_{DAT}). *A λ_{DAT} calculus program P is stratified if every Datalog value constructed during evaluation of P is stratified.*

The challenge is to statically determine when that is the case. Consider the λ_{DAT} program:

$$f = \lambda c_1. \lambda c_2. \text{let } r = \#\{P(x) \Leftarrow A(x), \text{not } Q(x).\} \text{ in } c_1 \langle + \rangle c_2 \langle + \rangle r$$

To determine whether f returns a stratified program we must know at least:

- whether the argument c_1 is itself stratified,
- whether the argument c_2 is itself stratified,
- whether the composition of c_1 and c_2 is stratified, and finally,
- whether the composition of c_1 , c_2 with the rule r is stratified.

At run time, the values of c_1 , c_2 , and r are known and we can use Ullman’s algorithm [45] to compute their stratification. But again, moving the stratification check to run time would force the program to crash if it ever encounters a Datalog value that cannot be stratified!

Before we explore the design space of techniques to ensure compile-time stratification of λ_{DAT} calculus programs, let us pause and reflect on what makes a design “good”. As discussed, we are interested in techniques that are fully automatic, hence imposes no additional burden on the programmer. In addition, we want a system that: (i) has high precision (i.e. few programs are unfairly rejected), (ii) is fast (i.e. can be run continuously during program development), (iii) offers understandable error messages (i.e. does not require too much knowledge from the programmer “when things go wrong”), and (iv) is robust under refactoring (i.e. harmless refactorings should not break stratification). As is often the case, some of these goals are conflicting.

4 Dependency Graph Types: A Purely Type-based Approach

We now present a type system that captures the entire dependency graph in the type system itself. This type system is expressive, precise, and its types can be fully inferred. As we shall discuss, it is also impractical, since each type may be quadratic in the number of predicates.

We extend the λ_{DAT} type system to track the *entire* dependence graph of every Datalog expression in the type system. The key idea is straightforward: We represent a dependency edge $p \leftarrow q$ or $p \leftarrow\!-\! q$ as a single “label” and then use row polymorphism to track a row of all these labels. The type system does not concern itself with the types of terms and should be understood as being in addition to the existing type system.

The new row types are given by the grammar:

$$r = \rho \mid \{ \} \mid \{ p \leftarrow q \mid r \} \mid \{ p \leftarrow\!-\! q \mid r \}$$

The type rule for a Datalog constraint is straightforward:

$$\frac{A_0 = p_h(t, \dots, t) \quad E = \{p_h \leftarrow p_b^i \mid B_i = p_b^i(t, \dots, t)\} \cup \{p_h \leftarrow\! \times p_b^i \mid B_i = \text{not } p_b^i(t, \dots, t)\}}{\Gamma \vdash_e \forall(x_1 : \tau_1, \dots, x_m : \tau_m). A_0 \Leftarrow B_1, \dots, B_n. : \{E \parallel r\}}$$

where $\{E \parallel r\}$ is the row type with all be labels in the set E , e.g. $\{\{x, y\} \parallel r\} = \{x \mid \{y \mid r\}\}$. Intuitively, the type rule states that if we have a constraint $A_0 \Leftarrow B_1, \dots, B_n$ where the head predicate symbol is p_h and there is a positive body atom $B_i = p_b^i(t, \dots, t)$, then the row contains the positive edge $p_h \leftarrow p_b^i$. Similarly, if there is a negative body atom $B_i = \text{not } p_b^i(t, \dots, t)$, then the row contains the negative edge $p_h \leftarrow\! \times p_b^i$.

For this type system, we conjecture the important property:

► **Theorem 8 (Soundness).** *Let $\Gamma \vdash e : r$ and define e' to be e where all the free variables have been substituted for values of the types given in Γ . If $e' \rightarrow^* v$ then the dependency graph of v is a subset of g , i.e. $\mathcal{DG}(v) \subseteq g$, where g is the graph defined by the edges present in the row type of v .*

We now give two examples of how the type system works. We will use the abbreviations Warm (W), Kettle (K), Cold (C), and Off (O) moving forward:

► **Example 9.** The left expression is typeable with the abbreviated type on the right:

<pre>let p = #{ Cold(x) :- Kettle(x), Off(x). Warm(x) :- Kettle(x), not Cold(x). }</pre>	$\forall \rho. \{C \leftarrow K, C \leftarrow O,$ $W \leftarrow K, W \leftarrow\! \times C, \rho\}$
--	--

► **Example 10.** Consider the expressions on the left and their abbreviated types on the right:

<pre>let p1 = #{ Cold(x) :- Kettle(x), not Warm(x). }; let p2 = #{ Warm(x) :- Kettle(x), not Cold(x). };</pre>	$p_1 : \forall \rho_1. \{C \leftarrow K, C \leftarrow\! \times W \mid \rho_1\}$ $p_2 : \forall \rho_2. \{W \leftarrow K, W \leftarrow\! \times C, \rho_2\}$
--	--

The composition of p_1 and p_2 has the following row type which contains a negative cycle between W and C and is rejected.

$$\forall \rho_3. \{C \leftarrow K, C \leftarrow\! \times W, W \leftarrow K, W \leftarrow\! \times C, | \rho_3\}$$

4.1 Discussion

The type system has several advantages:

- it captures the dependency graph of each Datalog expression in its type,
- it supports row polymorphism, and
- it has complete type inference.

The type system is a simple and straightforward application of row types. But the strength of the type system is also its weakness: The type of each expression needs to store the whole dependency graph between all pairs of predicate symbols in the expression. The amount of information to be stored in each type is quadratic in the number of predicate symbols.

To understand why a type needs to store, for each pair of predicate symbols A and B , whether or not A is reachable from B in the dependency graph, consider the Datalog value $\#\{A(x) \Leftarrow \text{not } B(x)\}$. If this value is composed with another Datalog value v , the resulting Datalog program is stratified if and only if B does not depend on A in v . Since A and B could be arbitrary predicate symbols, the type of v needs to store, for every possible pair

31:12 Breaking the Negative Cycle

of predicate symbols (A, B) , whether or not there is a dependence in v . While we have not implemented the system, this complexity leads to concerns about efficiency of type inference. In particular, the rows used to track all dependency edges are now very long. Instead, we want to explore the design space of a hybrid approach: We keep the original type system of [30] and we combine it with global information about the constraints in the entire program.

5 Labelled Dependency Graph: A Hybrid Approach

We now describe a hybrid approach that combines local information from the type system with global information about the λ_{DAT} program. As it turns out, the choice of what information to collect about the entire program opens up a large design space.

General Framework

We want to statically ensure that a λ_{DAT} program is stratified in the sense of Definition 7. To do so, we take the following overall approach:

For each Datalog expression e in a well-typed λ_{DAT} program P (i.e. we have $\Gamma \vdash e : r$), we want to construct a dependency graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ that soundly over-approximates the dependency graph(s) of every Datalog value v that e could evaluate to at runtime. In other words, define e' to be e where all the free variables have been substituted for values of the types given in Γ . These values must be chosen from compositions of the Datalog literals in the program. If $e' \rightarrow^* v$ then $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ over-approximates $\mathcal{DG}(v)$. The role of the parameter $\mathcal{LG}(P)$ will be discussed shortly.

If the dependency graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ for the expression e is stratified, then every Datalog value v that the expression e could evaluate to must also be stratified: if the over-approximate dependency graph does not contain a negative cycle then any sub-graph cannot contain a negative cycle. If this is true for every expression e in a program P , then the entire program must be stratified in the sense of Definition 7.

We construct the over-approximate graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ using two types of information:

- Local information about the expression e (the $e : r$ part).
- Global information about the entire program P (the $\mathcal{LG}(P)$ part).

We call the data structure that records the global information the *labelled dependency graph* $\mathcal{LG}(P)$. The graph records all (positive and negative) dependencies between predicate symbols in all Datalog rules appearing anywhere in λ_{DAT} the program. The dependency edges are annotated with labels that record various constraints about each dependency. When constructing a specific dependency graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ for a specific expression e of type r , local information about the expression recorded in the type r will be combined with the constraints recorded in the edge labels to determine that certain edges represent global dependencies that are incompatible with some characteristics of the local expression e . These edges from the global dependency graph are removed to construct a more precise local dependency graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ specific to the local expression e .

Formally, we define the labelled dependency graph as:

► **Definition 11** (Labelled Dependency Graph). *The labelled dependency graph $\mathcal{LG}(P)$ of a λ_{DAT} program P is a directed graph between predicate symbols where each edge is labelled with information that is used to determine if that edge is possible w.r.t. to a specific row type.*

and we require that the \mathcal{LG} and $\widehat{\mathcal{DG}}$ functions satisfy the following important property:

► **Definition 12** (Soundness Criterion). *Given a well-typed λ_{DAT} program P , assume that e is a sub-expression of P and that $\Gamma \vdash e : r$. Define e' to be e where all the free variables have been substituted for values of the types given in Γ . These values must be chosen from compositions of the Datalog literals in P . If $e' \rightarrow^* v$ then the dependency graph $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ is a sound over-approximation of the dependency graph of v , i.e. $\mathcal{DG}(v) \subseteq \widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$.*

The choice of what information to record in the labelled dependency graph opens a large design space. For example, it could include information about the constraints that occur in the program, their predicate symbols, and the types of their terms. The design space contains various choices of possible constraints that can be recorded in the labels of the global dependency graph.

5.1 Design Choice 1: Granularity of the Labelled Dependence Graph

We now turn to the choice of which labels to use on the labelled dependency graph $\mathcal{LG}(P)$.

5.1.1 Degenerate

The simplest choice is to leave the labelled dependency graph unlabelled. This is a degenerate choice which corresponds to the most pessimistic assumption: that all Datalog values could be composed into one big Datalog value. We include it for completeness.

► **Example 13.** Consider the Datalog expression on the left:

```
let p = #{
  Cold(x) :- Kettle(x), Off(x).
  Warm(x) :- Kettle(x), not Cold(x).
}
```

which gives rise to the labelled dependency graph on the right. The dependency edges carry no additional information and hence any local information about the type of a specific Datalog expression cannot help narrow down the set of possible edges. We have to consider all edges as possible.

5.1.2 Source and Destination Granularity

A straightforward improvement is to label each dependency edge with its source and destination predicate. This is information that is already represented by the graph itself.

► **Example 14.** Consider again the Datalog expression:

```
let p = #{
  Cold(x) :- Kettle(x), Off(x).
  Warm(x) :- Kettle(x), not Cold(x).
}
```

which now has the labelled dependency graph on the right. Each edge is now labelled with its source and destination predicate symbols. We can use this information as follows.

Suppose we are given an expression e with type r :

$$r = \{ \dots \mid \text{Cold} = \dots \mid \text{Off} = \dots \mid \text{Warm} = \dots \mid \dots \}$$

where r does not contain the **Kettle** predicate symbol. If so, we know that e cannot evaluate to a Datalog value v which would give rise to the dependency edges d_1 and d_3 (because these

31:14 Breaking the Negative Cycle

edges are labelled with the Kettle predicate symbols and the type system guarantees that e cannot evaluate to a Datalog value with a Kettle predicate). On the other hand, we cannot exclude the d_2 and d_4 edges because their labels occur in the type.

5.1.3 Rule-level Granularity

A more interesting design choice is to label each dependency edge with *all* predicate symbols that occur in the rule from which the edge originates.

► **Example 15.** Consider again the Datalog expression:

```
let p = #{
  Cold(x) :- Kettle(x), Off(x).
  Warm(x) :- Kettle(x), not Cold(x).
}
```

which now has the labelled dependency graph on the right. Each dependency edge is now labelled with *all the predicate symbols that occur in the rule* from where the edge originates.

For example, the edge $C \xleftarrow{\{C, K, O\}} K$ represents that Cold depends on Kettle but it can only occur if Cold, Kettle, *and* Off can occur in the Datalog value.

Suppose, as before, that we are given an expression e with type r :

$$r = \{\dots \mid \text{Cold} = \dots \mid \text{Off} = \dots \mid \text{Warm} = \dots \mid \dots\}$$

where r does not contain the Kettle predicate. We are now able to exclude *all* dependency edges because they are all labelled with Kettle. Intuitively, the Datalog expression on the left uses the Kettle predicate in both rules. Thus, if a Datalog expression does not contain the Kettle predicate then neither rule can contribute to its dependency graph.

Suppose, on the other hand, that we are given an expression e_2 with type r_2 :

$$r_2 = \{\dots \mid \text{Cold} = \dots \mid \text{Kettle} = \dots \mid \text{Warm} \mid \dots\}$$

where r_2 does not contain the Off predicate. If e_2 evaluates to a Datalog value v_2 , we can exclude the dependency edges d_1 and d_2 from its dependency graph, but we cannot exclude d_3 nor d_4 . This is because we are able to exclude the dependency edges from the first rule, but not from the second.

5.1.4 Datalog Value-level Granularity

The last and most powerful option is to label each dependency edge with *all* predicate symbols that occur within the same Datalog literal.

► **Example 16.** Consider one last time the Datalog expression:

```
let p = #{
  Cold(x) :- Kettle(x), Off(x).
  Warm(x) :- Kettle(x), not Cold(x).
}
```

which now has the labelled dependency graph on the right. Each dependency edge is labelled with *all the predicate symbols that occur in the same Datalog literal*. For example, the edge $C \xleftarrow{\{C, K, O, W\}} K$ represents that Cold depends on Kettle but only if *all* the predicates Warm, Cold, Kettle, *and* Off can occur in the Datalog value.

Suppose we are given an expression e with type r :

$$r = \{\dots \mid \text{Cold} = \dots \mid \text{Kettle} = \dots \mid \text{Warm} = \dots \mid \dots\}$$

which does not contain the `Off` predicate symbol. If so, we know that e cannot evaluate to a Datalog value v with *any* of the four dependency edges. Note, in particular, that we are able to exclude the dependency edge $W \leftarrow C$ even though the predicate symbol `Off` has nothing to do with `Warm` or `Cold` or even the rule from which the edge arises.

While this design choice is very powerful, it suffers from the problem that a simple refactoring can break stratification. For example, if we take the same program and refactor it to:

```
let p1 = #{
  Cold(x) :- Kettle(x), Off(x).
};
let p2 = #{
  Warm(x) :- Kettle(x), not Cold(x).
};
let pr = p1 <+> p2
```

then it is no longer the case that the rule in p_1 must occur together with p_2 . Consequently, if we have an expression e with the type r (as above), we can no longer exclude the dependency edges d_3 and d_4 . Thus, while this design choice is powerful, it is also brittle under refactoring.

5.1.5 Summary

In summary, the four design choices are:

- **Choice 1a:** The degenerate case where $\mathcal{LG}(P)$ is unlabelled.
- **Choice 1b:** Label the $\mathcal{LG}(P)$ with the source and destination predicate symbols from which the dependency edge arises.
- **Choice 1c:** Label the $\mathcal{LG}(P)$ with *all the predicate symbols that occur in the same rule* from where the dependency edge originates.
- **Choice 1d:** Label the $\mathcal{LG}(P)$ with *all the predicate symbols that occur in the same Datalog literal* from where the dependency edge originates.

For the purpose of exposition, we assume **choice 1c** for the next subsections.

5.2 Design Choice 2: Enriched Labelling and Type Filtering

We can increase precision by including information about the types of the predicate symbols in the labelled dependency graph.

5.2.1 Predicate Symbol Arity

We can include the arity of the predicate symbols in the labelled dependency graph to add precision. We define the labels to be a set of pairs (p, n) of predicate symbols and their arity. We then define $\widehat{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ to include an edge $a \xrightarrow{\ell} b$ when the arities in ℓ agree with the arities in the row type r .

► **Example 17.** Consider a λ_{DAT} program P that contain the two Datalog expressions:

```
#{Path(x, y) :- Road(x, l, y).
  Path(x, z) :- Path(x, y), Road(y, l, z).}
#{Unconnected(x, y) :-
  ..., not Road(x, y).}
```

In the Datalog expression on the left, the `Road` predicate symbol has three terms whereas in the Datalog expression on the right, the `Road` predicate has two terms. The labelled dependency graph, $\mathcal{LG}(P)$, is:

31:16 Breaking the Negative Cycle

which includes the arity of each predicate in the labels on the edges. Suppose the program contains an expression e with the row type r :

$$r = \{\text{Road} = (\text{Int32}, \text{Int32}) \mid \text{Unconnected} = (\text{Int32}, \text{Int32}) \mid \dots\}$$

If the e evaluates to a Datalog value v , then the type system guarantees that every atom in v with the predicate symbol `Road` must have two terms, both of which are of type `Int32`. Thus we can exclude the two dependency edges d_1 and d_2 because the arities on the labels do not match.

5.2.2 Predicate Term Types

We can increase precision even further by including the term types of predicate symbols in the labelled dependency graph. We define labels to be pairs $(p, \bar{\tau})$ of a predicate symbol and the types of its terms, also written $p(\bar{\tau})$ on the labelled graphs. We then define $\overline{\mathcal{DG}}(e : r, \mathcal{LG}(P))$ to include an edge $a \xrightarrow{\ell} b$ when the term types in ℓ unify with term types in the row r .

► **Example 18.** Consider a λ_{DAT} program P that contain the two Datalog expressions:

<pre>#{Road("Lyon", 120, "Paris"). Path(x, z) :- Path(x, y), Road(y, l, z).}</pre>	<pre>#{Road("Lyon", "Icy", "Paris"). Path(x, z) :- Path(x, y), Road(y, l, z).}</pre>
--	--

In each Datalog expression, the `Road` predicate has arity two. In the expression on the left, the label on a `Road` fact represents the current weather (type `String`), whereas in the expression on the right, the label represents the current speed limit (type `Int32`).

The labelled dependency graph, omitting the `Path` predicate in labels, is:

5.2.3 Relational and Lattice Predicate Symbols

In Flix, as we shall discuss further in Section 6, every predicate symbol is given either a relational or a lattice interpretation. The type system ensures that relational and lattice predicate symbols cannot be mixed. That is, within a Datalog value every predicate symbol has exactly one interpretation. Similarly to how we extended the labelled dependency graph with arity and term types, we can also extend it to account for this information.

In summary, the four options are:

- **Option 2a:** Enrich $\mathcal{LG}(P)$ to track the arity of the predicates.
- **Option 2b:** Enrich $\mathcal{LG}(P)$ to track term types of the predicates.
- **Option 2c:** Enrich $\mathcal{LG}(P)$ to distinguish between relations and lattices.
- **Option 2d:** Do not enrich $\mathcal{LG}(P)$.

These options are not mutually exclusive and can be combined.

5.3 Choice 3: Stratify With or Without Monomorphization

We have shown how local information, i.e. information about the row type of an expression, enables us to filter the labelled dependency graph. An orthogonal design choice, which affects precision, is whether to perform stratification with or without monomorphization.

Monomorphization is a compile-time transformation that replaces polymorphic functions by copies that are specialized to their concrete type arguments. For example, if `List.map` is used with both integer and string lists, then monomorphization generates two copies of `List.map`: one specialized to integers and one specialized to strings. While the primary purpose of monomorphization is to avoid boxing, monomorphization can also be used to improve the precision of stratification.

Monomorphization improves precision in two ways:

- (i) by specializing polymorphic Datalog expressions to concrete types, boosting the precision of type-based filtering, and
- (ii) by eliminating unreachable Datalog expressions.

► **Example 19.** Consider the Flix program fragment:

```
def f(): #{A(t), B(t)} =
  #{ A(x) :- B(x). }

def g(): #{A(t), B(t)} =
  # { B(x) :- B(x), not A(x). }

def main(): Unit =
  let c1 = f() <+> A(123).;
  let c2 = g() <+> A("hello").;
  solve c1
```

The functions f and g return Datalog values with row types that contain the predicate symbols A and B , which are polymorphic in the type parameter t . The two Datalog constraints form a negative cycle between A and B . Because the types of the two expressions are

$$\forall\alpha_1, \forall\rho_1. \{A = \alpha_1 \mid \{B = \alpha_1 \mid \rho_1\}\} \quad \text{and} \quad \forall\alpha_2, \forall\rho_2. \{A = \alpha_2 \mid \{B = \alpha_2 \mid \rho_2\}\}$$

we cannot exclude that these two types could occur in the same Datalog value and consequently we cannot exclude that the overall program might construct a non-stratified Datalog program at runtime. However, if we monomorphize the program first, i.e. specialize f and g to their concrete type arguments whenever they are used in the program, then we obtain the program:

```
def f1(): #{A(Int32), B(Int32)} =
  #{ A(x) :- B(x). }

def g1(): #{A(String), B(String)} =
  # { A(x) :- A(x), not B(x). }

def main(): #{A(Int32), B(Int32)} =
  let c1 = f1() <+> A(123).;
  let c2 = g1() <+> A("hello").;
  solve c1
```

where $f1$ and $g1$ are no longer polymorphic and the types of their Datalog expressions are:

$$\{A = \text{Int32} \mid B = \text{Int32}\} \quad \text{and} \quad \{A = \text{String} \mid B = \text{String}\}$$

We can now use the types to determine that the two rules cannot occur in the same Datalog value and consequently the program is stratified.

Monomorphization increases precision, but has two practical downsides: the labelled dependency graphs are larger and consequently more costly to stratify, and intertwining monomorphization and stratification may make it difficult for programmers to understand why or when a program fails to be stratified.

In summary, the two design choices are:

- **Choice 3a:** Stratify *without* monomorphization.
- **Choice 3b:** Stratify *with* monomorphization.

6 The Fix Modifier, Lattice Semantics, and Stratification

We now explain the role of the fix modifier and its semantics. Intuitively, the fix modifier enables us to safely use lattice values in relations. Given the rule:

$$A(x) \Leftarrow \text{fix } B(x), C(x).$$

The use of “fix” in front of the atom $B(x)$ forces the relation B to be fully computed before the rule is applied. Therefore, A must belong to a stratum strictly greater than B . Thus, the fix modifier has the same effect on stratification as negation. For a normal Datalog program, fix does not change the minimal model, only the evaluation order. However, for Datalog programs with lattice semantics [31], the fix construct solves a long-standing problem.

In Flix, every predicate symbol is associated with a *relational* or *lattice* interpretation. We will write p for a predicate symbol that has a relational interpretation and p_ℓ for a predicate symbol that has a lattice interpretation. We syntactically distinguish between relational and lattice predicates by writing a relational predicate as $A(t_1, \dots, t_n)$, whereas we write a lattice predicate as $A(t_1, \dots, t_n; t)$, with a semi-colon before the last term.

► **Definition 20** (Key and Lattice Positions). *Given an atom $p(t_1, \dots, t_n)$ where p has relational interpretation, we say that the terms t_1, \dots, t_n are in key position. Given atom $p_\ell(t_1, \dots, t_n; t)$ where p_ℓ has a lattice interpretation, we say that the terms t_1, \dots, t_n are in key position and t is in lattice position.*

► **Definition 21** (Key and Lattice Variables). *We split variables into key and lattice variables. A variable is a key variable if all its occurrences are in key positions. Otherwise it is a lattice variable.*

As the definition states, a variable that occurs in *both* a key and lattice position is considered a lattice variable. The original version of Flix disallows such “dual-use” of variables; enforcing that lattice variables cannot be used in key position.

► **Example 22.** To better understand key and lattice variables, consider the Datalog rules:

```
A(k1, k2; l) :- B(k1, k2; l), C(k1, k2; l). // legal
A(k1, k2, l) :- B(k1, k2; l), C(k1, k2; l). // illegal
A(k1, k2; l) :- B(k1, k2; l), C(k1, k2, l). // illegal
A(k1, l; k2) :- B(k1, k2; l), C(k1, k2; l). // illegal
```

In each rule, the variable l is a lattice variable because it occurs in at least one lattice position. The first rule is legal since the lattice variable l only occurs lattice positions. The second rule is illegal since the lattice variable l occurs in a key position in the head of the rule (where A has a relational interpretation). The third rule is illegal since the lattice variable l occurs in a key position in the body of the rule (where C has a relational interpretation). The fourth rule is illegal since the lattice variable l occurs in a key position in the head of the rule.

Formally, the original version of Flix enforces the *lattice range restriction*:

► **Definition 23** (Lattice Range Restriction). *Every lattice variable must occur in a lattice position.*

To understand the lattice range restriction, let us revisit the example from Section 2.

► **Example 24.** Figure 2 contains the Datalog rule:

```
Edge(c1, c2) :- fix Component(_, c1), fix Component(_, c2).
```

Assume that the rule did not use `fix` and that we ignore the lattice range restriction. Suppose we have the following lattice facts:

```
Component(7; {1}).      Component(7; {2}).      Component(7, {7}).
Component(5, {3}).     Component(5, {5}).
```

The minimal model has two facts: `Component(7; {1, 2, 7})` and `Component(5; {3, 5})`. We would thus assume that the above rule would compute the undirected edge fact: `{1, 2, 7} ↔ {3, 5}`. But this is not what the program computes! It derives nonsensical facts such as `{1} ↔ {3}`, `{1} ↔ {3, 5}`, and all other edges between intermediate lattice values. The lattice range restriction avoids this problem by banning the program. We propose to allow the program as long as the lattice is `fix`'ed, i.e. fully computed, before it is used in a relation.

As the example shows, the lattice range restriction is overly strict. We can allow lattice variables to be used in key positions in head atoms provided that we ensure that the head predicate symbol occurs in a strictly higher stratum than every body atom in which the lattice variable occurs. This ensures that the lattice predicates are fully computed before they are used as keys. We introduce the extended dependency graph to capture this notion:

► **Definition 25** (Extended Dependency Graph). *The extended dependency graph of a Datalog program D with lattice semantics is a directed graph of predicate symbols that contains:*

- a weak edge $a \leftarrow b$ if D contains a rule where a is the predicate symbol of the head atom and b is a predicate symbol of a positive body atom, and
- a strong edge $a \leftarrow\!-\! b$ if D contains a rule where a is the predicate symbol of the head and b is a predicate symbol of a fixed or negative body atom.

We use the word *strong* to represent either a *fixed* or a *negative* dependency.

We also update the range restriction:

► **Definition 26** (Extended Lattice Range Restriction). *If every occurrence of a lattice variable is under a `fix` in the body of a rule, then the variable may be treated as a key in the head of the rule.*

Finally, we update our definition of stratification for the λ_{DAT} calculus and for Flix:

► **Definition 27** (Extended Stratification). *A Datalog program D_L , enriched with lattice semantics, is stratified if the extended dependency graph does not contain a cycle with a strong edge. A λ_{DAT} calculus program P_L , enriched with lattice semantics, is stratified if every Datalog value constructed during evaluation of P_L is stratified.*

► **Example 28.** We conclude with a small example of how the `fix` construct can be used¹:

```
Degree("Kevin Bacon"; Down(0)).
Degree(x; n + Down(1)) :- Degree(y; n), StarsWith(y, x).
Layer(n; Set#{x}) :- fix Degree(x; n).
Count(n, Set.size(s)) :- fix Layer(n; s).
```

This program computes the number of people who are separated by n -degrees from Kevin Bacon. For example, the 2nd-degree is *the number of people* who have starred in a movie where someone in that movie has also starred in another movie with Kevin Bacon.

¹ Here, the `Down` constructor defines a lattice with the reverse ordering of the underlying type.

7 Implementation

We now describe where the original version of Flix, and our proposed future version of Flix, reside in the design space.

7.1 The Original Flix Implementation

The original Flix implementation and its associated paper [30] do not use the terminology of this paper. Nevertheless, we can recast their design choices in our framework.

Flix uses a labelled dependency graph constructed from the entire program and filtered based on the type of each Datalog expression, the hybrid approach. The labels are predicate symbols where each dependency edge is annotated with its source and destination (**choice 1b**). No enriched labelling or types are used (**choice 2d**). Stratification is performed *without* monomorphization (**choice 3a**).

7.2 Our Flix Extension

While all design choices are valid, in our view, **choice 1b** and **choice 2d** are sub-optimal.

- For **choice 1b**, by only using the predicate symbols that are the source and destination of each dependency edge, we lose the important information that most dependency edges arise from rules where multiple predicate symbols are involved and thus where *all* of these predicate symbols must be present for the edge to be relevant. Instead, **choice 1c** or **choice 1d** offer increased precision with little downside.
- For **choice 2d**, ignoring the arity and term types of each predicate symbol loses important contextual information. In other logic programming languages, such as Prolog, predicate symbols are often overloaded and use the arity as part of their name, e.g. `spawn/2` and `spawn/3`. Given that λ_{DAT} and Flix are statically typed, it seems like a missed opportunity not to use types to distinguish predicate symbols, e.g. `Path(Int32, Int32)` vs. `Path(String, String)`.

For these reasons, in our proposed extension, we settled on **choice 1c** and **choice 2b** combined with **choice 2c**. We chose **choice 1c** because of its increased precision while still remaining explainable to the programmer. For **choice 2b** and **choice 2c**, we think that incorporating types and the distinction between relational and lattice predicates into the dependence graph increases precision significantly while also remaining understandable to the programmer.

We keep the rest of the design choices the same. We explored the idea of moving the stratifier after monomorphization **choice 3b**, which would boost precision. However, monomorphization is a relatively expensive compiler phase that is traditionally not part of the Flix compiler frontend. Thus, if stratification depends on monomorphization, then it becomes part of the frontend and must be run whenever the program is “type checked” by an IDE. We were worried that this would have unacceptable performance implications².

In summary, our Flix extension makes the following design choices:

- We use the hybrid approach based on the *labelled dependency graph*.
- **Choice 1c**: We use *rule-level* granularity.
- **Choice 2b**: We enrich the graph with *term types*.
- **Choice 2c**: We enrich the graph with *relation and lattice* information.
- **Choice 3a**: We stratify *without* monomorphization.

² This frontend versus backend problem is not unique to stratification. For example, many C or C++ compilers will report additional compilation warnings or errors when expensive backend optimizations are enabled. This might seem counter-intuitive, but the reason is that expensive program analysis enables the compiler to know more about the program and thus to report more warnings or errors.

7.3 Implementation Details

We have implemented the above design choices in an extension of the Flix compiler.

Flix is a functional-first, imperative, and logic programming language that supports algebraic data types, pattern matching, higher-order functions, parametric polymorphism, type classes, higher-kinded types, polymorphic effects, extensible records, first-class Datalog constraints, channel and process-based concurrency, and tail call elimination [30, 31].

The Flix compiler project, including the standard library and tests, consists of 161,000 lines of Flix and Scala code. We re-wrote the Stratifier compiler phase which required ~1,000 lines of code and added support for the “fix” construct which required ~700 lines of code.

Flix, with our extensions, is ready for use, open source, and freely available at:

<https://flix.dev> and <https://github.com/flix/flix>

7.4 When a Program Does Not Stratify

When Flix programmers encounter a stratification error, there are essentially two possibilities:

- The program contains an actual stratification error.
- The type system is too imprecise to rule out the possibility of a stratification error.

We want to support the programmer in both scenarios. First, this means giving the programmer useful error messages such that they can accurately identify which of the two cases is applicable. Second, we want to give the programmer the ability to refactor their program such that it passes the stratification.

If a programmer should encounter a stratification error due to imprecision, they can:

1. Rename a predicate symbol to avoid a clash with a conceptually different predicate symbol. For example, instead of `Node`, a more suitable name could be `City`.
2. Introduce an extra predicate symbol in a rule to exclude the clash.
3. Change the arity of a predicate symbol, for example by recording more or less information.
4. Enrich the types of the terms in a predicate; for example, the programmer could introduce a new type `Celsius` instead of `Int32` or a new type `City` instead of `String`.

We think these are flexible and reasonable strategies that a Flix programmer will be able to use. Of course these strategies cannot necessarily resolve *all* stratification issues, but the space of accepted programs is much larger than in the original version of Flix where only strategy (1) is available.

7.5 The Motivating Example, Revisited

We now revisit the motivating example from Section 2. Figure 6 shows the labelled dependency graph for the program in Figure 2. The graph reflects our design choices:

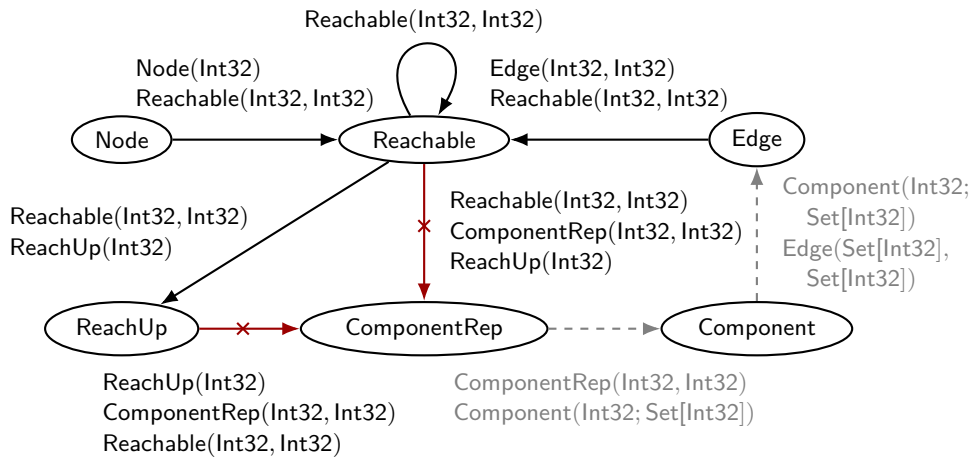

- (i) the dependency edges are labelled with all predicate symbols from the rule that gives rise to the dependency, and
- (ii) the labels carry the term types of each predicate symbol.

The braces and commas of the label sets are omitted. Inspecting the graph, we see two potential negative cycles. However, no expression in the program in Figure 2 has a type where the cycles cannot be excluded.

As an example, on line 26, the composition of the expressions `ns`, `es`, and `r` has the type:

```
{ComponentRep = (Int32, Int32), Reachable = (Int32, Int32),
  Node = (Int32), Edge = (Int32, Int32), ReachUp = (Int32)}
```

31:22 Breaking the Negative Cycle

■ **Figure 6** The labelled dependency graph of the program in Figure 2 based on the design decisions of Section 7.2. The gray dashed lines are the edges that are filtered out when looking at the union of `ns`, `es`, `r` on line 26.

This excludes the dashed dependency edges shown in gray in Figure 6. For example, the edge between `Component` and `Edge` is ruled out since the term types of `Edge` do not match and since `Component` is not present. The resulting graph, shown with solid arrows, does not contain any negative cycles. Hence the expression is stratified. This is true for all expressions in the program, hence Flix is able to statically determine that the program is stratified.

8 Case Study: A Small Graph Library in Flix

We have implemented a small open-source graph library for Flix³. The graph library provides a range of queries on graphs, as shown in Table 1. Each query is implemented as a Flix function that internally uses Datalog. The purpose of the case study is to explore how a graph library can be implemented using first-class Datalog constraints in Flix and to check that the proposed stratification strategy is practical.

Table 1 shows an overview of the functions that we have implemented in the graph library. In total, we have implemented 24 functions in 450 lines of code. The columns of the table are as follows: The `Function` and `Lines` columns give the name and number of source code lines for a specific function. The `Lattices` column indicates whether the Datalog program uses lattice semantics. The `Stratified Negation` column indicates whether the Datalog program uses stratified negation. The `Fix Construct` column indicates whether the Datalog program uses the fix construct.

To look at a specific example, the table shows that the `stronglyConnectedComponents` function consists of 26 lines of code, it uses lattice semantics and the fix construct, but it does not use stratified negation. To give an idea of how the library is implemented, the complete source code for the `stronglyConnectedComponents` function is shown in Figure 7. As the code shows, each query is implemented using first-class Datalog constraints and there is some code-reuse in the form of the `nodes` and `reachability` functions which return Datalog program values.

³ <https://github.com/flix/flix/blob/master/main/src/library/Graph.flix>

■ **Table 1** Overview of the Flix Graph Library. The line count includes the number of lines of helper functions. The features used in a function also include features used in helper functions.

Function	Lines	Features Used		
		Lattices	Stratified Negation	Fix Construct
boundedDistances	20	Y	N	Y
closure	17	N	N	N
cutPoints	30	Y	Y	Y

In total, the library contains 31 distinct predicate symbols and 64 rules. The library was developed using our extended Flix compiler. During development, we never encountered a spurious stratification error. However, if we compile the library with the original Flix compiler, it is unfairly rejected due to a spurious negative cycle.

In summary, Table 1 shows that: (i) we have 24 functions that co-exist, using overlapping predicate names from the same domain, without spurious stratification errors, (ii) the majority of functions (15/24) require stratification via `not`, `fix`, or both, (iii) many functions use lattice semantics (13/24), (iv) the `fix` construct is used more often than the `not` construct, and (v) the library is accepted by our extended Flix compiler, but is rejected by the original Flix compiler due to a spurious negative cycle in the dependency graph.

Flix is a whole-program optimizing compiler. When the graph library is compiled together with the standard library, the stratification is computed in 0.16 seconds whereas the total compilation time is 7.3 seconds. In particular, compilation time is dominated by the cost of type inference. In conclusion, we find the stratification does not unfairly reject our library and that the cost of computing the stratification is low.

31:24 Breaking the Negative Cycle

```
1 /// Returns the strongly connected components of the directed
2 /// graph 'g'. Two nodes are in the same component if and only
3 /// if they can both reach each other.
4 pub def stronglyConnectedComponents(g: m[(t, t)]): Set[Set[t]]
5   with Foldable[m], Boxable[t] = {
6   let edges = inject g into Edge;
7   let connected = #{
8     // If 'n1' can reach 'n2' and 'n2' can reach 'n1' then they are
9     // part of the same strongly connected component.
10    Connected(n1; Set#{n2}) :- Reachable(n1, n2), Reachable(n2, n1).
11  };
12  let components = #{
13    // After the full computation of 'Connected', duplicates are
14    // removed by checking that 'n' is the minimum in the strongly
15    // connected component.
16    Components(s) :- fix Connected(n; s), if Some(n) == Set.minimum(s).
17  };
18  let res = query edges, nodes(), reachability(), connected, components
19    select x
20    from Components(x);
21  List.toSet(res)
22 }
```

9 Related Work

9.1 First-class Datalog

Magnus and Lhoták present the λ_{DAT} calculus which is the foundation for the current work [30]. The authors briefly discuss stratified negation and propose a simple solution based on type filtering similar to **choice 1b** without any information on the labels (**choice 2d**). As we have seen, some of these choices are sub-optimal.

9.2 Negation and Aggregation Semantics

There are many proposed semantics for Datalog with negation but stratified negation is the most prevalent one. Kolaitis and Papadimitriou present inflationary semantics that produce facts in such a way that a fixpoint exists for all programs using negation. The fixpoint is not guaranteed to be minimal [26]. There are also variations in the realm of stratification. Negation can be restricted to guarded negation, which in broad terms means that all first-order variables in negated atoms exist in a single atom. This makes additional questions like query containment decidable [5]. Local stratification stratifies the program on instances of rules instead of the quantified rules. This is a property that is hard to verify, but in its most expressive form, it allows deducing $\text{even}(i + 1)$ from $\neg\text{even}(i)$, since this is not circular reasoning for any instantiations of i [36].

Aggregation is non-monotone like negation, which is why it has been studied using many of the same ideas. Aggregation can naturally be stratified like negation but another option is group-stratification based on the standard group-by operation. This means that a group of the predicate should not depend on itself [35]. Zaniolo et al. studies both negation and aggregation with a syntactically restricted form of local stratification that essentially tracks the dynamic strata on the facts [48].

9.3 Datalog Extensions

There have been many efforts to increase the expressive power and usability of Datalog while maintaining practical feasibility. One extension is the existential quantification of variables in the rule head. This was motivated by the ontological reasoning that is needed in web-standards for databases [19]. Datalog[∃] is undecidable, so a family of languages called Datalog[±] [8] makes restrictions that reduce the complexity to classes ranging from AC₀ to EXPTIME. One of these is Warded Datalog[±] [19], which has a syntactic restriction on the usage of variables that may be bound to non-constant variables in evaluation and flow into the rule head. They must be within a single predicate, the “ward”. It uses stratified negation and negative constraints that restrict the inclusion of certain facts.

10 Conclusion

Flix is a functional, imperative, and logic language with support for first-class Datalog constraints. In Flix, Datalog constraints are values that can be constructed, passed as arguments to functions, returned from functions, composed with other Datalog values, and solved. Flix is based on the λ_{DAT} calculus which itself builds on the Hindley-Milner type system extended with row polymorphism. A significant part of the expressive power of Datalog comes from the use of negation. Stratified negation is a particular simple form of negation that prohibits recursion through negation and is easily accessible to ordinary programmers. While it is straightforward to determine if a Datalog program is stratified, it is much more difficult to statically determine if a λ_{DAT} program is stratified. In this paper, we have explored the design space of stratification for λ_{DAT} . We have proposed several improvements to stratification in Flix and we have implemented these. With our extension, Flix accepts a much broader range of programs that use stratified negation. Finally, we have also extended Flix with a new “fix” construct that enables lattice values to be used as relational values.

Asynchronous Multiparty Session Type Implementability is Decidable – Lessons Learned from Message Sequence Charts

Felix Stutz  

MPI-SWS, Kaiserslautern, Germany

Abstract

Multiparty session types (MSTs) provide efficient means to specify and verify asynchronous message-passing systems. For a global type, which specifies all interactions between roles in a system, the implementability problem asks whether there are local specifications for all roles such that their composition is deadlock-free and generates precisely the specified executions. Decidability of the implementability problem is an open question. We answer it positively for global types with sender-driven choice, which allow a sender to send to different receivers upon branching and a receiver to receive from different senders. To achieve this, we generalise results from the domain of high-level message sequence charts (HMSCs). This connection also allows us to comprehensively investigate how HMSC techniques can be adapted to the MST setting. This comprises techniques to make the problem algorithmically more tractable as well as a variant of implementability that may open new design space for MSTs. Inspired by potential performance benefits, we introduce a generalisation of the implementability problem that we, unfortunately, prove to be undecidable.

1 Introduction

Distributed message-passing systems are omnipresent and, therefore, designing and implementing them correctly is very important. However, this is a very difficult task at the same time. In fact, it is well-known that verifying such systems is algorithmically undecidable in general due to the combination of asynchrony (messages are buffered) and concurrency [13].

Multiparty Session Type (MST) frameworks [37, 38] provide efficient means to specify and verify such distributed message-passing systems (e.g., see the survey [5]). They have also been applied to various other domains like cyber-physical systems [46], timed systems [9], web services [65], and smart contracts [27]. In MST frameworks, global types are global specifications, which comprise all interactions between roles in a protocol. From a design perspective, it makes sense to start with such a global protocol specification – instead of a system with arbitrary communication between roles and a specification to satisfy.

Let us consider a variant of the well-known two buyer protocol from the MST literature, e.g., [54, Fig. 4(2)]. Two buyers *a* and *b* purchase a sequence of items from seller *s*. We informally describe the protocol and *emphasise* the interactions. At the start and after every purchase (attempt), buyer *a* can decide whether to buy the next item or whether they are *done*. For each item, buyer *a* *queries* its price and the seller *s* replies with the *price*.

■ **Figure 1** Two Buyer Protocol: the finite state machine for the semantics of G_{2BP} on the left, the first step of projection in the middle, and as HMSC on the right; a transition label $a \rightarrow s : q$ jointly specifies a send event $a \triangleright s ! q$ for buyer a and a receive event $s \triangleleft a ? q$ for seller s ; styles of states indicate their kind, e.g., recursion states (dashed lines) while final states have double lines.

Subsequently, buyer a decides whether to *cancel* the purchase process for the current item or proposes to *split* to buyer b that can *accept* or *reject*. In both cases, buyer a notifies the seller s if they want to *buy* the item or *not*. This protocol is specified with the following global type:

$$G_{2BP} := \mu t. + \left\{ \begin{array}{l} a \rightarrow s : query. s \rightarrow a : price. + \left\{ \begin{array}{l} a \rightarrow b : split. (b \rightarrow a : yes. a \rightarrow s : buy. t + b \rightarrow a : no. a \rightarrow s : no. t) \\ a \rightarrow b : cancel. a \rightarrow s : no. t \end{array} \right. \\ a \rightarrow s : done. a \rightarrow b : done. 0 \end{array} \right.$$

The first term μt binds the recursion variable t which is used at the end of the first two lines and allows the protocol to recurse back to this point. Subsequently, $+$ and the curly bracket indicate a choice by buyer a as it is the sender for the next interaction, e.g., $a \rightarrow s : query$. For our asynchronous setting, this term jointly specifies the send event $a \triangleright s ! query$ for buyer a and its corresponding receive event $s \triangleleft a ? query$ for seller s , which may happen with arbitrary delay. The state machine in Figure 1a illustrates its semantics with abbreviated message labels.

The Implementability Problem for Global Types and the MST Approach

A global type provides a global view of the intended protocol. However, when implementing a protocol in a distributed setting, one needs a local specification for each role. The *implementability problem* for a global type asks whether there are local specifications for all roles such that, when complying with their local specifications, their composition never gets stuck and exposes the same executions as specified by the global type. This is a challenging problem because roles can only partially observe the execution of a system: each role only knows the messages it sent and received and, in an asynchronous setting, a role does not know when one of its messages will be received by another role. In contrast, in a synchronous setting, there are no channels, yielding finite state systems. Still, we could not find a reference that precisely settles the decidability of synchronous implementability. We sketch a proof in Section 7. In this work, we solely deal with the asynchronous setting.

In general, one distinguishes between a role in a protocol and the process which implements the local specification of a role in a system. We use the local specifications directly as implementations so the difference is not essential and we use the term role instead of process.

Classical MST frameworks employ a partial *projection operator* with an in-built *merge operator* to solve the implementability problem. For each role, the projection operator takes the global type and removes all interactions the role is not involved in. Figure 1a illustrates the semantics of \mathbf{G}_{2BP} while Figure 1b gives the projection onto seller s before the merge operator is applied – in both, messages are abbreviated with their first letter. It is easy to see that this procedure introduces non-determinism, e.g., in q_3 and q_4 , which shall be resolved by the merge operator. Most merge operators can resolve the non-determinism in Figure 1b. A merge operator checks whether it is safe to merge the states and it might fail so it is a partial operation. For instance, every kind of state, indicated by a state’s style in Figure 1b, can only be merged with states of the same kind or states of circular shape. For a role, the result of the projection, if defined, is a local type. They act as local specifications and their syntax is similar to the one of global types.

Classical projection operators are a best-effort technique. This yields good (mostly linear) worst-case complexity but comes at the price of rejecting implementable global types. Intuitively, classical projection operators consider a limited search space for local types. They bail out early when encountering difficulties and do not unfold recursion. In addition, most MST frameworks do effectively not allow a role to send to different receivers or receive from different senders upon branching. This restriction is called *directed choice* – in contrast to *sender-driven choice* which is more permissive and allows these patterns. Among the classical projection operators, the one by Majumdar et al. [45] is the only to handle global types with sender-driven choice but it suffers from the shortcomings of a classical projection approach. We define different merge operators from the literature and visually explain their supported features by example. We show that the presented projection/merge operators fail to project implementable variations of the two buyer protocol, showcasing the sources of incompleteness for the classical approach. For non-classical approaches, we refer to Section 7.

As a best-effort technique, it is natural to focus on efficiency rather than completeness. The work by Castagna et al. [16] is a notable exception. Their notion of completeness [16, Def. 4.1] is not as strict as the one considered in this work and only a restricted version of their characterisation is algorithmically checkable. In general, it is not known whether the implementability problem for global types, with directed or sender-driven choice, is decidable. We answer this open question positively for global types with sender-driven choice. To this end, we relate the implementability problem for global types with the safe realisability problem for high-level message sequence charts and generalise results for the latter.

Lessons Learned from Message Sequence Charts

The two buyer protocol \mathbf{G}_{2BP} can also be specified as high-level message sequence chart (HMSC) [47], as illustrated in Figure 1c. Each block is a basic message sequence chart (BMSC) which intuitively corresponds to straight-line code. In each of those, time flows from top to bottom and each role is represented by a vertical line. We only give the names in the initial block, which is marked by an incoming arrow at the top. An arrow between two role lines specifies sending and receiving a message with its label. The graph structure adds branching, which corresponds to choice in global types, and control flow. Top branches from the global type are on the left in the HMSC while bottom branches are on the right.

While research on MSTs and HMSCs has been pursued quite independently, the MST literature frequently uses HMSC-like visualisations for global types, e.g., [15, Fig. 1] and [38, Figs. 1 and 2]. The first formal connection was recently established by Stutz and Zufferey [57].

The HMSC approach to the implementability problem, studied as safe realisability, differs from the MST approach of checking conditions during the projection. For an HMSC, it is known that there is a candidate implementation [2], which implements the HMSC if it is implementable. Intuitively, one takes the HMSC and removes all interactions a role is not involved in and determinises the result. We generalise this result to infinite executions.¹

Hence, algorithms and conditions center around checking implementability of HMSCs. In general, this problem is undecidable [44]. For *globally-cooperative* HMSCs [31], Lohrey [44] proved it to be EXPSPACE-complete. We show that any implementable global type belongs to this class of HMSCs.¹ These results give rise to the following algorithm to check implementability of a global type. One can check whether a global type is globally-cooperative (which is equivalent to checking its HMSC encoding). If it is not globally-cooperative, it cannot be implementable. If it is globally-cooperative, we apply the algorithm by Lohrey [44] to check whether its HMSC encoding is implementable. If it is, we use its candidate implementation and know that it generalises to infinite executions.

While this algorithm shows decidability, the complexity might not be tractable. Based on our results, we show how more tractable but still permissive approaches to check implementability of HMSCs can be adapted to the MST setting. In addition, we consider *payload implementability*, which allows to add payload to messages of existing interactions and checks agreement when the additional payload is ignored. We present a sufficient condition for global types that implies payload implementability. These techniques can be used if the previous algorithms are not tractable or reject a global type.

Furthermore, we introduce a generalisation of the implementability problem. A network may reorder messages from different senders for the same receiver but the implementability problem still requires the receiver to receive them in the specified order. Our generalisation allows to consider such reorderings of arrival and can yield performance gains. In addition, it also renders global types implementable that are not implementable in the standard setting. Unfortunately, we prove this generalisation to be undecidable in general.

Contributions and Outline

We introduce our MST framework in Section 2 while Section 7 covers related work. In the other sections, we introduce the necessary concepts to establish our main *contributions*:

- We give a visual explanation of the classical projection operator with different merge operators and exemplify its shortcomings (Section 3).
- We prove decidability of the implementability problem for global types with sender-driven choice (Section 4) – provided that protocols can (but do not need to) terminate.
- We comprehensively investigate how MSC techniques can be applied to the MST setting, including algorithmics with better complexity for subclasses as well as an interesting variant of the implementability problem (Section 5).
- Lastly, we introduce a new variant of the implementability problem with a more relaxed role message ordering, which is closer to the network ordering, and prove it to be undecidable in general (Section 6).

¹ For this, we impose a mild assumption: all protocols can (but do not need to) terminate.

2 Multiparty Session Types

In this section, we formally introduce our Multiparty Session Type (MST) framework. We define the syntax of global and local types and their semantics. Subsequently, we recall the implementability problem for global types which asks if there is a deadlock-free communicating state machine that admits the same language (without additional synchronisation).

Finite and Infinite Words. Let Σ be an alphabet. We denote the set of finite words over Σ by Σ^* and the set of infinite words by Σ^ω . Their union is denoted by Σ^∞ . For two strings $u \in \Sigma^*$ and $v \in \Sigma^\infty$, we say that u is a *prefix* of v if there is some $w \in \Sigma^\infty$ such that $u \cdot w = v$ and denote this with $u \leq v$ while $\text{pref}(v)$ denotes all prefixes of v and is lifted to languages as expected. For a language $L \subseteq \Sigma^\infty$, we distinguish between the language of finite words $L_{\text{fin}} := L \cap \Sigma^*$ and the language of infinite words $L_{\text{inf}} := L \cap \Sigma^\omega$.

Message Alphabet. We fix a finite set of messages \mathcal{V} and a finite set of roles \mathcal{P} , ranged over with p, q, r , and s . With $\Sigma_{\text{sync}} = \{p \rightarrow q : m \mid p, q \in \mathcal{P} \text{ and } m \in \mathcal{V}\}$, we denote the set of interactions where sending and receiving a message is specified at the same time. For our asynchronous setting, we also define individual send and receive events: $\Sigma_p = \{p \triangleright q!m, p \triangleleft q?m \mid q \in \mathcal{P}, m \in \mathcal{V}\}$ for a role p . For both send events $p \triangleright q!m$ and receive events $p \triangleleft q?m$, the first role is *active*, i.e., the sender in the first event and the receiver in the second one. The union for all roles yields all (asynchronous) events: $\Sigma = \bigcup_{p \in \mathcal{P}} \Sigma_p$. For the rest of this work, we fix the set of roles \mathcal{P} , the messages \mathcal{V} , and both sets Σ_{sync} and Σ . We may also use the term Σ_{async} for Σ . We define an operator that splits events from Σ_{sync} , $\text{split}(p \rightarrow q : m) := p \triangleright q!m. q \triangleleft p?m$, which is lifted to sequences and languages as expected. Given a word, we might also project it to all letters of a certain shape. For instance, $w \downarrow_{p \triangleright q!}$ is the subsequence of w with all of its send events where p sends any message to q . If we want to select all messages of w , we write $\mathcal{V}(w)$.

Global and Local Types – Syntax

We give the syntax of global and local types following work by Majumdar et al. [45]. In this work, we consider global types as specifications for message-passing concurrency and omit features like delegation.

► **Definition 2.1** (Syntax of global types). Global types for MSTs are defined by the grammar:

$$G ::= 0 \mid \sum_{i \in I} p \rightarrow q_i : m_i . G_i \mid \mu t . G \mid t$$

The term 0 explicitly represents termination. A term $p \rightarrow q_i : m_i$ indicates an interaction where p sends message m_i to q_i . In our asynchronous semantics, it is split into a send event $p \triangleright q_i!m_i$ and a receive event $q_i \triangleleft p?m_i$. In a choice $\sum_{i \in I} p \rightarrow q_i : m_i . G_i$, the sender p chooses the branch. We require choices to be unique, i.e., $\forall i, j \in I. i \neq j \Rightarrow q_i \neq q_j \vee m_i \neq m_j$. If $|I| = 1$, which means there is no actual choice, we omit the sum operator. The operators μt and t allow to encode loops. We require them to be guarded, i.e., there must be at least one interaction between the binding μt and the use of the recursion variable t . Without loss of generality, all occurrences of recursion variables t are bound and distinct.

Our global types admit *sender-driven choice* as p can send to different receivers upon branching: $\sum_{i \in I} p \rightarrow q_i : m_i . G_i$. This is also called generalised choice by Majumdar et al. [45]. In contrast, *directed choice* requires a sender to send to a single receiver, i.e., $\forall i, j \in I. q_i = q_j$.

► **Example 2.2** (Global types). The two buyer protocol \mathbf{G}_{2BP} from the introduction is a global type. Instead of \sum , we use $+$ with curly brackets.

► **Definition 2.3** (Syntax of local types). For a role p , the local types are defined as follows:

$$L ::= 0 \mid \bigoplus_{i \in I} q_i!m_i.L_i \mid \&_{i \in I} q_i?m_i.L_i \mid \mu t.L \mid t$$

We call $\bigoplus_{i \in I} q_i!m_i$ an internal choice while $\&_{i \in I} q_i?m_i$ is an external choice. For both, we require the choice to be unique, i.e., $\forall i, j \in I. i \neq j \Rightarrow q_i \neq q_j \vee m_i \neq m_j$. Similarly to global types, we may omit \bigoplus or $\&$ if there is no actual choice and we require recursion to be guarded as well as recursion variables to be bound and distinct.

► **Example 2.4** (Local type). For the global type \mathbf{G}_{2BP} , a local type for seller s is

$$\mu t. \& \left\{ \begin{array}{l} a?query. a!price. (a?buy. t \& a?no. t) \\ a?done. 0 \end{array} \right.$$

Implementing in a Distributed Setting

Global types can be thought of as global protocol specifications. Thus, a natural question and a main concern in MST theory is whether a global type can be implemented in a distributed setting. We present communicating state machines, which are built from finite state machines, as the standard implementation model.

► **Definition 2.5** (State machines). A state machine $A = (Q, \Delta, \delta, q_0, F)$ is a 5-tuple with a finite set of states Q , an alphabet Δ , a transition relation $\delta \subseteq Q \times (\Delta \cup \{\varepsilon\}) \times Q$, an initial state $q_0 \in Q$ from the set of states, and a set of final states F with $F \subseteq Q$. If $(q, a, q') \in \delta$, we also write $q \xrightarrow{a} q'$. A sequence $q_0 \xrightarrow{w_0} q_1 \xrightarrow{w_1} \dots$, with $q_i \in Q$ and $w_i \in \Delta \cup \{\varepsilon\}$ for $i \geq 0$, such that q_0 is the initial state, and for each $i \geq 0$, it holds that $(q_i, w_i, q_{i+1}) \in \delta$, is called a run in A with its trace $w_0 w_1 \dots \in \Delta^\infty$. A run is maximal if it ends in a final state or is infinite. The language $\mathcal{L}(A)$ of A is the set of traces of all maximal runs. If Q is finite, we say A is a finite state machine (FSM).

► **Definition 2.6** (Communicating state machines). We call $\{\{A_p\}\}_{p \in \mathcal{P}}$ a communicating state machine (CSM) over \mathcal{P} and \mathcal{V} if A_p is a finite state machine with alphabet Σ_p for every $p \in \mathcal{P}$. The state machine for p is denoted by $(Q_p, \Sigma_p, \delta_p, q_{0,p}, F_p)$. Intuitively, a CSM allows a set of state machines, one for each role in \mathcal{P} , to communicate by sending and receiving messages. For this, each pair of roles $p, q \in \mathcal{P}$, $p \neq q$, is connected by two directed message channels. A transition $q_p \xrightarrow{p \triangleright q!m} q'_p$ in the state machine of p denotes that p sends message m to q if p is in the state q_p and changes its local state to q'_p . The channel $\langle p, q \rangle$ is appended by message m . For receptions, a transition $q_q \xrightarrow{q \triangleleft p?m} q'_q$ in the state machine of q corresponds to q retrieving the message m from the head of the channel when its local state is q_q which is updated to q'_q . The run of a CSM always starts with empty channels and each finite state machine is in its respective initial state. A deadlock of $\{\{A_p\}\}_{p \in \mathcal{P}}$ is a reachable configuration without outgoing transitions such that there is a non-empty channel or some participant is in a non-final local state. The formalisation of this intuition is standard and can be found in the technical report [56].

A global type always specifies send and receive events together. In a CSM execution, there may be independent events that can occur between a send and its respective receive event.

► **Example 2.7** (Motivation for indistinguishability relation \sim). Let us consider the following global type which is a part of the two buyer protocol: $a \triangleright b : cancel. a \triangleright s : no. 0$. This is one of its traces: $a \triangleright b!cancel. b \triangleleft a?cancel. a \triangleright s!no. s \triangleleft a?no$. Because the active roles in

$b \triangleleft a?cancel$ and $a \triangleright s!no$ are different and we do not reorder a receive event in front of its respective send event, any CSM that accepts the previous trace also accepts the following trace: $a \triangleright b!cancel. a \triangleright s!no. b \triangleleft a?cancel. s \triangleleft a?no$.

Majumdar et al. [45] introduced the following relation to capture this phenomenon.

► **Definition 2.8** (Indistinguishability relation \sim [45]). *We define a family of indistinguishability relations $\sim_i \subseteq \Sigma^* \times \Sigma^*$, for $i \geq 0$. For $w \in \Sigma^*$, we have $w \sim_0 w$. For $i = 1$, we define:*

1. *If $p \neq r$, then $w.p \triangleright q!m.r \triangleright s!m'.u \sim_1 w.r \triangleright s!m'.p \triangleright q!m.u$.*
2. *If $q \neq s$, then $w.q \triangleleft p?m.s \triangleleft r?m'.u \sim_1 w.s \triangleleft r?m'.q \triangleleft p?m.u$.*
3. *If $p \neq s \wedge (p \neq r \vee q \neq s)$, then $w.p \triangleright q!m.s \triangleleft r?m'.u \sim_1 w.s \triangleleft r?m'.p \triangleright q!m.u$.*
4. *If $|w \downarrow_{p \triangleright q!}| > |w \downarrow_{q \triangleleft p?}|$, then $w.p \triangleright q!m.q \triangleleft p?m'.u \sim_1 w.q \triangleleft p?m'.p \triangleright q!m.u$.*

Let w, w' , and w'' be words s.t. $w \sim_1 w'$ and $w' \sim_i w''$ for some i . Then, $w \sim_{i+1} w''$. We define $w \sim u$ if $w \sim_n u$ for some n . It is straightforward that \sim is an equivalence relation. Define $u \preceq v$ if there is $w \in \Sigma^$ such that $u.w \sim v$. Observe that $u \sim v$ iff $u \preceq v$ and $v \preceq u$. For infinite words $u, v \in \Sigma^\omega$, we define $u \preceq^\omega v$ if for each finite prefix u' of u , there is a finite prefix v' of v such that $u' \preceq v'$. Define $u \sim v$ iff $u \preceq^\omega v$ and $v \preceq^\omega u$.*

We lift the equivalence relation \sim on words to languages:

For a language L , we define $\mathcal{C}^\sim(L) = \left\{ w' \mid \bigvee \begin{array}{l} w' \in \Sigma^ \wedge \exists w \in \Sigma^*. w \in L \text{ and } w' \sim w \\ w' \in \Sigma^\omega \wedge \exists w \in \Sigma^\omega. w \in L \text{ and } w' \preceq^\omega w \end{array} \right\}$.*

This relation characterises what can be achieved in a distributed setting using CSMs.

► **Lemma 2.9** (L. 21 [45]). *Let $\{\{A_p\}_{p \in \mathcal{P}}\}$ be a CSM. Then, $\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}) = \mathcal{C}^\sim(\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}))$.*

Global and Local Types – Semantics

Hence, we define the semantics of global types using the indistinguishability relation \sim .

► **Definition 2.10** (Semantics of global types). *We construct a state machine $\text{GAut}(\mathbf{G})$ to obtain the semantics of a global type \mathbf{G} . We index every syntactic subterm of \mathbf{G} with a unique index to distinguish common syntactic subterms, denoted with $[G, k]$ for syntactic subterm G and index k . Without loss of generality, the index for \mathbf{G} is 1: $[\mathbf{G}, 1]$. For clarity, we do not quantify indices. We define $\text{GAut}(\mathbf{G}) = (Q_{\text{GAut}(\mathbf{G})}, \Sigma_{\text{sync}}, \delta_{\text{GAut}(\mathbf{G})}, q_{0, \text{GAut}(\mathbf{G})}, F_{\text{GAut}(\mathbf{G})})$ where*

- $Q_{\text{GAut}(\mathbf{G})}$ is the set of all indexed syntactic subterms $[G, k]$ of \mathbf{G}
- $\delta_{\text{GAut}(\mathbf{G})}$ is the smallest set containing $([\sum_{i \in I} p \rightarrow q_i : m_i.[G_i, k_i], k], p \rightarrow q_i : m_i.[G_i, k_i])$ for each $i \in I$, and $([\mu t.[G', k'_2], k'_1], \varepsilon, [G', k'_2])$ and $([t, k'_3], \varepsilon, [\mu t.[G', k'_2], k'_1])$,
- $q_{0, \text{GAut}(\mathbf{G})} = [\mathbf{G}, 1]$, and $F_{\text{GAut}(\mathbf{G})} = \{[0, k] \mid k \text{ is an index for subterm } 0\}$.

We consider asynchronous communication so each interaction is split into its send and receive event. In addition, we consider CSMs as implementation model for global types and, from Lemma 2.9, we know that CSM languages are always closed under the indistinguishability relation \sim . Thus, we also apply its closure to obtain the semantics of \mathbf{G} : $\mathcal{L}(\mathbf{G}) := \mathcal{C}^\sim(\text{split}(\mathcal{L}(\text{GAut}(\mathbf{G}))))$.

The closure $\mathcal{C}^\sim(-)$ corresponds to similar reordering rules in standard MST developments, e.g., [38, Def. 3.2 and 5.3].

► **Example 2.11.** Figure 1a (p.2) illustrates the FSM $\text{GAut}(\mathbf{G}_{2\text{BP}})$. In the following global type, p sends a list of book titles to q : $\mu t.(p \rightarrow q: \text{title}.t + p \rightarrow q: \text{done}.0)$. Its semantics is the union of two cases: if the list of book titles is infinite, i.e., $\mathcal{C}^\sim((p \triangleright q! \text{title}.q \triangleleft p? \text{title})^\omega)$; and the one if the list is finite, i.e., $\mathcal{C}^\sim((p \triangleright q! \text{title}.q \triangleleft p? \text{title})^*. p \triangleright q! \text{done}.q \triangleleft p? \text{done})$. Here, there are only two roles so $\mathcal{C}^\sim(-)$ can solely delay receive events (Rule 4 of \sim).

We distinguish states depending on which subterm they correspond to: *binder states* with their dashed line correspond to a recursion variable binder, while *recursion states* with their dash-dotted lines indicate the use of a recursion variable. We omit ε for transitions from recursion to binder states.

Local Types. For the semantics of local types, we analogously construct a state machine $\text{LAut}(-)$. In contrast, we omit the closure $\mathcal{C}^\sim(-)$ because languages of roles are closed under \sim (cf. [45, Lm. 22]). For the full definition, we refer to the technical report [56]. Compared to global types, we distinguish two more kinds of states for local types: a *send state* (internal choice) has a diamond shape while a *receive state* (external choice) has a rectangular shape. For states with ε as next action, we keep the circular shape and call them *neutral states*. Because of the ε -transitions, Figure 1b (p.2) does not represent the state machine for any local type but illustrates the use of different styles for different kinds of states.

The Implementability Problem for Global Types

The implementability problem for global types asks whether a global type can be implemented in a distributed setting. The projection operator takes the intermediate representation of local types as local specifications for roles. We define implementability directly on the implementation model of CSMs. Intuitively, every collection of local types constitutes a CSM through their semantics.

► **Definition 2.12** (Implementability [45]). *A global type \mathbf{G} is said to be implementable if there exists a deadlock-free CSM $\{\{A_p\}_{p \in \mathcal{P}}\}$ such that their languages are the same (protocol fidelity), i.e., $\mathcal{L}(\mathbf{G}) = \mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\})$. We say that $\{\{A_p\}_{p \in \mathcal{P}}\}$ implements \mathbf{G} .*

3 Projection – From Global to Local Types

In this section, we define and visually explain a typical approach to the implementability problem: the *classical projection operator*. It tries to translate global types to local types and, while doing so, checks if this is safe. Behind the scenes, these checks are conducted by a partial merge operator. We consider different variants of the merge operator from the literature and exemplify the features they support. We provide visual explanations of the classical projection operator with these merge operators on the state machines of global types by example. In the technical report [56], we give general descriptions but they are not essential for our observations. Lastly, we summarise the shortcomings of the full merge operator and exemplify them with variants of the two buyer protocol from the introduction.

Classical Projection Operator with Parametric Merge

► **Definition 3.1** (Projection operator). *For a merge operator \sqcap , the projection of a global type \mathbf{G} onto a role $\mathbf{r} \in \mathcal{P}$ is a local type that is defined as follows:² $0 \uparrow_{\mathbf{r}}^\sqcap := 0$ $t \uparrow_{\mathbf{r}}^\sqcap := t$*

$$\left(\sum_{i \in I} \mathbf{p} \rightarrow \mathbf{q}_i : m_i . G_i\right) \uparrow_{\mathbf{r}}^\sqcap := \begin{cases} \oplus_{i \in I} \mathbf{q}_i ! m_i . (G_i \uparrow_{\mathbf{r}}^\sqcap) & \text{if } \mathbf{r} = \mathbf{p} \\ \&_{i \in I} \mathbf{p} ? m_i . (G_i \uparrow_{\mathbf{r}}^\sqcap) & \text{if } \mathbf{r} = \mathbf{q} \\ \sqcap_{i \in I} G_i \uparrow_{\mathbf{r}}^\sqcap & \text{otherwise} \end{cases} \quad (\mu t . G) \uparrow_{\mathbf{r}}^\sqcap := \begin{cases} \mu t . (G \uparrow_{\mathbf{r}}^\sqcap) & \text{if } G \uparrow_{\mathbf{r}}^\sqcap \neq t \\ 0 & \text{otherwise} \end{cases}$$

² The case split for the recursion binder changes slightly across different definitions. We chose a simple but also the least restrictive condition. We simply check whether the recursion is vacuous, i.e. $\mu t . t$, and omit it in this case. We also require to omit μt if t is never used in the result.

Intuitively, a projection operator takes the state machine $\text{GAut}(\mathbf{G})$ for a global type \mathbf{G} and projects each transition label to the respective alphabet of the role, e.g., $p \rightarrow q : m$ becomes $q \triangleleft p ? m$ for role q . This can introduce non-determinism that ought to be resolved by a partial merge operator. Several merge operators have been proposed in the literature.

► **Definition 3.2** (Merge operators). *Let L_1 and L_2 be local types for a role r , and \sqcap be a merge operator. We define different cases for the result of $L_1 \sqcap L_2$:*

$$(1) L_1 \text{ if } L_1 = L_2 \quad (2) \left(\begin{array}{cc} \&_{i \in I \setminus J} q ? m_i . L'_{1,i} & \& \\ \&_{i \in I \cap J} q ? m_i . (L'_{1,i} \sqcap L'_{2,i}) & \& \\ \&_{i \in J \setminus I} q ? m_i . L'_{2,i} & \end{array} \right) \text{ if } \begin{cases} L_1 = \&_{i \in I} q ? m_i . L'_{1,i}, \\ L_2 = \&_{i \in J} q ? m_i . L'_{2,i} \end{cases}$$

$$(3) \mu t_1 . (L'_1 \sqcap L'_2 [t_2/t_1]) \text{ if } L_1 = \mu t_1 . L'_1 \text{ and } L_2 = \mu t_2 . L'_2$$

Each merge operator is defined by a collection of cases it can apply. If none of the respective cases applies, the result of the merge is undefined. The plain merge \sqcap [23] can only apply Case (1). The semi-full merge \sqcap [64] can apply Cases (1) and (2). The full merge \sqcap [54] can apply all Cases (1), (2), and (3).

We will also consider the availability merge operator \sqcap by Majumdar et al. [45] which builds on the full merge operator but generalises Case (2) to allow sender-driven choice. We will explain the main differences in Remark 3.12.

► **Remark 3.3** (Correctness of projection). This would be the correctness criterion for projection: Let \mathbf{G} be some global type and let plain merge \sqcap , semi full merge \sqcap , full merge \sqcap , or availability merge \sqcap be the merge operator \sqcap . If $\mathbf{G} \uparrow_p^\sqcap$ is defined for each role p , then the CSM $\{\{\text{LAut}(\mathbf{G} \uparrow_p^\sqcap)\}\}_{p \in \mathcal{P}}$ implements \mathbf{G} .

We do not actually prove this so we do not state it as lemma. *But why does this hold?*

The implementability condition is the combination of deadlock freedom and protocol fidelity. Coppo et al. [23] show that *subject reduction* entails protocol fidelity and progress while progress, in turn, entails deadlock freedom. Subject reduction has been proven for the plain merge operator [23, Thm. 1] and the semi-full operator [64, Thm. 1]. Scalas and Yoshida pointed out that several versions of classical projection with the full merge are flawed [54, Sec. 8.1]. Hence, we have chosen a full merge operator whose correctness follows from the correctness of the more general availability merge operator. For the latter, correctness was proven by Majumdar et al. [45, Thm. 16].

► **Example 3.4** (Projection without merge / Collapsing erasure). In the introduction, we considered $\mathbf{G}_{2\text{BP}}$ and the FSM for its semantics in Figure 1a. We projected (without merge) onto seller s to obtain the FSM in Figure 1b. In general, we also collapse neutral states with a single ε -transition and their only successor. We call this *collapsing erasure*. We only need to actually collapse states for the protocol in Figure 4a. In all other illustrations, we indicate the interactions the role is not involved with the following notation: $[p \rightarrow q : l] \rightsquigarrow \varepsilon$.

On the Structure of $\text{GAut}(\mathbf{G})$

We now show that the state machine for every local and global type has a certain shape. This simplifies the visual explanations of the different merge operators. Intuitively, every such state machine has a tree-like structure where backward transitions only happen at leaves of the tree, are always labelled with ε , and only lead to ancestors. The FSM in Figure 1a (p.2) illustrates this shape where the root of the tree is at the top.

► **Definition 3.5** (Ancestor-recursive, non-merging, intermediate recursion, etc.). *Let $A = (Q, \Delta, \delta, q_0, F)$ be a finite state machine. We say that A is ancestor-recursive if there is a function $\text{lvl}: Q \rightarrow \mathbb{N}$ such that, for every transition $q \xrightarrow{x} q' \in \delta$, one of the two holds:*

- (a) $\text{lvl}(q) > \text{lvl}(q')$, or
 (b) $x = \varepsilon$ and there is a run from the initial state q_0 (without going through q) to q' which can be completed to reach q : $q_0 \xrightarrow{\bar{}} \dots \xrightarrow{\bar{}} q_n$ is a run with $q_n = q'$ and $q \neq q_i$ for every $0 \leq i \leq n$, and the run can be extended to $q_0 \xrightarrow{\bar{}} \dots \xrightarrow{\bar{}} q_n \xrightarrow{\bar{}} \dots \xrightarrow{\bar{}} q_{n+m}$ with $q_{n+m} = q$. Then, the state q' is called ancestor of q .

We call the first (a) kind of transition forward transition while the second (b) kind is a backward transition. The state machine A is said to be free from intermediate recursion if every state q with more than one outgoing transition, i.e., $|\{q' \mid q \xrightarrow{\bar{}} q' \in \delta\}| > 1$, has only forward transitions. We say that A is non-merging if every state only has one incoming edge with greater level, i.e., for every state q' , $\{q \mid q \xrightarrow{\bar{}} q' \in \delta \wedge \text{lvl}(q) > \text{lvl}(q')\} \leq 1$. The state machine A is dense if, for every $q \xrightarrow{x} q' \in \delta$, the transition label x is ε implies that q has only one outgoing transition. Last, the cone of q are all states q' which are reachable from q and have a smaller level than q , i.e., $\text{lvl}(q) > \text{lvl}(q')$.

► **Proposition 3.6** (Shape of $\text{GAut}(\mathbf{G})$ and $\text{LAut}(L)$). *Let \mathbf{G} be some global type and L be some local type. Then, both $\text{GAut}(\mathbf{G})$ and $\text{LAut}(L)$ are ancestor-recursive, free from intermediate recursion, non-merging, and dense.*

For both, the only forward ε -transitions occur precisely from binder states while backward transitions happen from variable states to binder states. The illustrations for our examples always have the initial state, which is the state with the greatest level, at the top. This is why we use greater and higher as well as smaller and lower interchangeably for levels.

Features of Different Merge Operators by Example

In this section, we exemplify which features each of the merge operators supports. We present a sequence of implementable global types. Despite, some cannot be handled by some (or all) merge operators. If a global type is not projectable using some merge operator, we say it is *rejected* and it constitutes a *negative* example for this merge operator. We focus on role r when projecting. Thus, rejected mostly means that there is (at least) no projection onto r . If a global type is projectable by some merge operator, we call it a *positive* example. All examples strive for minimality and follow the idea that roles decide whether to take a left (l) or right (r) branch of a choice.

► **Example 3.7** (Positive example for plain merge). The following global type is implementable:

$$\mu t. + \left\{ \begin{array}{l} p \rightarrow q : l. (q \rightarrow r : l. 0 + q \rightarrow r : r. t) \\ p \rightarrow q : r. (q \rightarrow r : l. 0 + q \rightarrow r : r. t) \end{array} \right.$$

The state machine for its semantics is given in Figure 2a. After collapsing erasure, there is a non-deterministic choice from q'_0 leading to q_1 and q_4 since r is not involved in the initial choice. The plain merge operator can resolve this non-determinism since both cones of q_1 and q_4 represent the same subterm. Technically, there is an isomorphism between the states in both cones which preserves the kind of states as well as the transition labels and the backward transitions from isomorphic recursion states lead to the same binder state. The result is illustrated in Figure 2b. It is also the FSM of a local type for r which is the result of the (syntactic) plain merge: $\mu t. (q?l.0 \ \& \ q?r.t)$.

Our explanation on FSMs allows to check congruence of cones to merge while the definition requires syntactic equality. If we swap the order of branches $q \rightarrow r : l$ and $q \rightarrow r : r$ in Figure 2a on the right, the syntactic merge rejects. Still, because both are semantically the same protocol specification, we expect tools to check for such easy fixes.

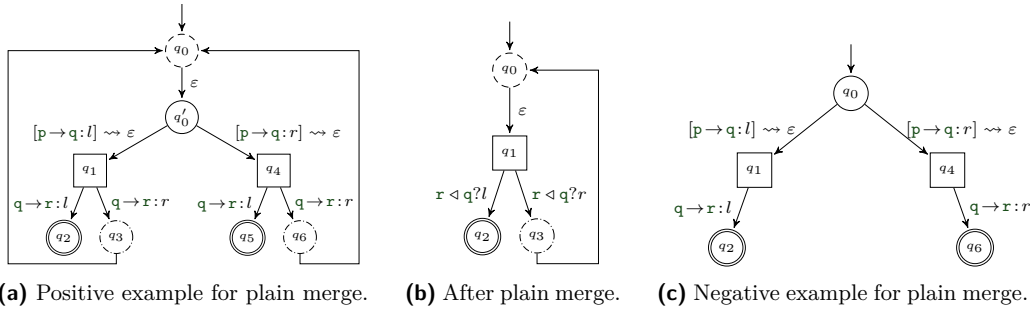

Figure 2 The FSM on the left represents an implementable global type that is accepted by plain merge. It implicitly shows the FSM after collapsing erasure: every interaction r is not involved in is given as $[p \rightarrow q:l] \rightsquigarrow \epsilon$. The FSM in the middle is the result of the plain merge. The FSM on the right represents an implementable global type that is rejected by plain merge. It is obtained from the left one by removing one choice option in each branch of the initial choice.

► **Example 3.8** (Negative example for plain merge). We consider the following simple implementable global type where the choice by p is propagated by q to r : $\mu t. + \left\{ \begin{array}{l} p \rightarrow q:l. q \rightarrow r:l. 0 \\ p \rightarrow q:r. q \rightarrow r:r. 0 \end{array} \right.$. The corresponding state machine is illustrated in Figure 2c. Here, q_0 exhibits non-determinism but the plain merge fails because q_1 and q_4 have different outgoing transition labels.

Intuitively, the plain merge operator forbids that any, but the two roles involved in a choice, can have different behaviour after the choice. It basically forbids propagating a choice. The semi-full merge overcomes this shortcoming and can handle the previous example. We present a slightly more complex one to showcase the features it supports.

► **Example 3.9** (Positive example for semi-full merge). Let us consider this implementable global type: $\mu t. + \left\{ \begin{array}{l} p \rightarrow q:l. (q \rightarrow r:l. 0 + q \rightarrow r:m. 0) \\ p \rightarrow q:r. (q \rightarrow r:m. 0 + q \rightarrow r:r. t) \end{array} \right.$, illustrated in Figure 3a. After applying collapsing erasure, there is a non-deterministic choice from q_0 leading to q_1 and q_4 since r is not involved in the initial choice, We apply the semi-full merge for both states. Both are receive states so Case (2) applies. First, we observe that $r \triangleleft q?l$ and $r \triangleleft q?r$ are unique to one of the two states so both transitions, with the cones of the states they lead to, can be kept. Second, there is $r \triangleleft q?m$ which is common to both states. We recursively apply the semi-full merge and, with Case (1), observe that the result $q_{3|5}$ is simply a final state. Overall, we obtain the state machine in Figure 3b, which is equivalent to the result of the syntactic projection with semi-full merge: $\mu t. (q?l. 0 \ \& \ q?m. 0 \ \& \ q?r. t)$.

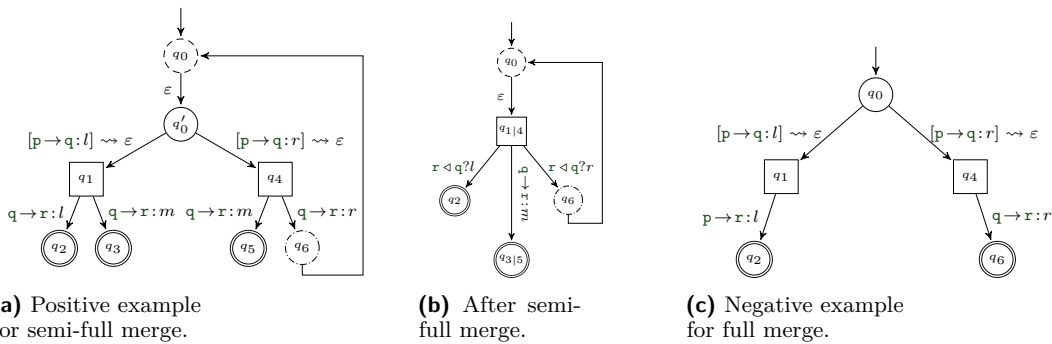

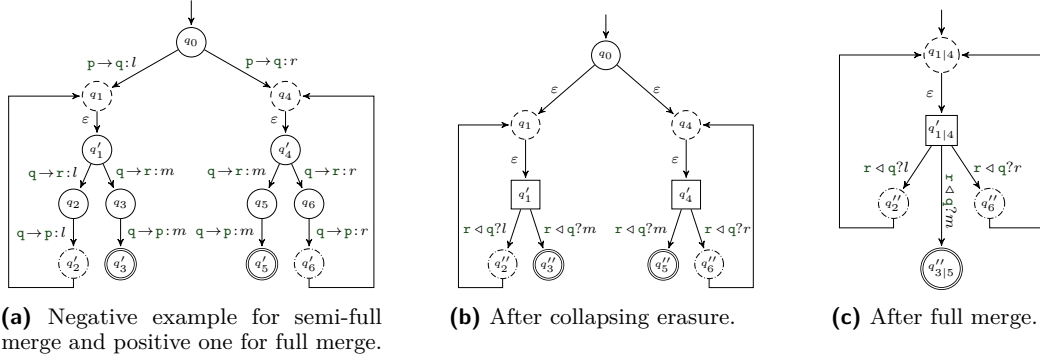

Figure 3 The FSM on the left represents an implementable global type (and implicitly the collapsing erasure onto r) that is accepted by semi-full merge. The FSM in the middle is the result of the semi-full merge. The FSM on the right is a negative example for the full merge operator.

■ **Figure 4** The FSM on the left represents an implementable global type that is rejected by the semi-full merge. It is accepted by the full merge: collapsing erasure yields the FSM in the middle and applying the full merge the FSM on the right.

► **Example 3.10** (Negative example for semi-full merge and positive example for full merge). The semi-full merge operator rejects the following implementable global type:

$$+ \left\{ \begin{array}{l} p \rightarrow q:l. \mu t_1. (q \rightarrow r:l. q \rightarrow p:l. t_1 + q \rightarrow r:m. q \rightarrow p:m. 0) \\ p \rightarrow q:r. \mu t_2. (q \rightarrow r:m. q \rightarrow p:m. 0 + q \rightarrow r:r. q \rightarrow p:r. t_2) \end{array} \right.$$

Its FSM and the FSM after collapsing erasure is given in Figures 4a and 4b. Intuitively, it would need to recursively merge the parts after both recursion binders in order to merge the branches with receive event $r \triangleleft q?m$ but it cannot do so. The full merge can handle this global type. It can descend beyond q_1 and q_4 and is able to merge q'_1 and q'_4 . To obtain $q''_{3|5}$, it applies Case (1) while $q'_{1|4}$ is only feasible with Case (2). The result is embedded into the recursive structure to obtain the FSM in Figure 4c. It is equivalent to the (syntactic) result, which renames the recursion variable for one branch: $\mu t_1. (q?l. t_1 \& q?m. 0 \& q?r. t_1)$.

► **Example 3.11** (Negative example for full merge). We consider a simple implementable global type where p propagates its decision to r in the top branch while q propagates it in the bottom branch: $+ \left\{ \begin{array}{l} p \rightarrow q:l. p \rightarrow r:l. 0 \\ p \rightarrow q:r. q \rightarrow r:r. 0 \end{array} \right.$. It is illustrated in Figure 3c. This cannot be projected onto r by the full merge operator for which all receive events need to have the same sender.

► **Remark 3.12** (On sender-driven choice). Majumdar et al. [45] proposed a classical projection operator that overcomes this shortcoming. It can project the previous example. In general, allowing to receive from different senders has subtle consequences. Intuitively, messages from different senders could overtake each other in a distributed setting and one cannot rely on the FIFO order provided by the channel of a single sender. Majumdar et al. employ a message availability analysis to ensure that there cannot be any confusion about which branch shall be taken. Except for the possibility to merge cases where a receiver receives from multiple senders, their merge operator suffers from the same shortcomings as all classical projection operators. For details, we refer to their work [45].

Shortcomings of Classical Projection/Merge Operators

We present slight variations of the two buyer protocol that are implementable but rejected by all of the presented projection/merge operators.

► **Example 3.13.** We obtain an implementable variant by omitting both message interactions $a \rightarrow s: no$ with which buyer a notifies seller s that they will not buy the item:

$$\mu t. + \left\{ \begin{array}{l} a \rightarrow s: query. s \rightarrow a: price. (a \rightarrow b: split. (b \rightarrow a: yes. a \rightarrow s: buy. t + b \rightarrow a: no. t) + a \rightarrow b: cancel. t) \\ a \rightarrow s: done. a \rightarrow b: done. 0 \end{array} \right.$$

This global type cannot be projected onto seller s . The merge operator would need to merge a recursion variable with an external choice. Visually, the merge operator does not allow to unfold the variable t and try to merge again. However, there is a local type for seller s :

$$\mu t_1. \& \begin{cases} a?query. \mu t_2. a!price. (a?buy. t_1 \& a?query. t_2 \& a?done. 0) \\ a?done. 0 \end{cases}$$

The local type has two recursion variable binders while the global type only has one. Classical projection operators can never yield such a structural change: the merge operator can only merge states but not introduce new ones or introduce new backward transitions.

► **Example 3.14** (Two Buyer Protocol with Subscription). In this variant, buyer a first decides whether to subscribe to a yearly discount offer or not – before purchasing the sequence of items – and notifies buyer b if it does so: $\mathbf{G}_{2BPWS} := + \begin{cases} a \rightarrow s: login. \mathbf{G}_{2BP} \\ a \rightarrow s: subscribe. a \rightarrow b: subscribed. \mathbf{G}_{2BP} \end{cases}$. The merge operator needs to merge a recursion variable binder μt with the external choice $b \triangleleft a?subscribed$. Still, there is a local type L_b for b such that $\mathcal{L}(L_b) = \mathcal{L}(\mathbf{G}_{2BPWS}) \downarrow_{\Sigma_b}$:

$$L_b := \& \begin{cases} a?split. (a!yes. L(t_1) \oplus a!no. L(t_2)) \\ a?cancel. L(t_3) \\ a?done. 0 \\ a?subscribed. L(t_4) \end{cases} \quad \text{where } L(t) := \mu t. \& \begin{cases} a?split. (a!yes. t \oplus a!no. t) \\ a?cancel. t \\ a?done. 0 \end{cases}$$

In fact, one can also rely on the fact that buyer a will comply with the intended protocol. Then, it suffices to introduce one recursion variable t in the beginning and substitute every $L(-)$ with t , yielding a local type L'_b with $\mathcal{L}(L_b) \subseteq \mathcal{L}(L'_b)$.

Similarly, classical projection operator cannot handle global types where choices can be disambiguated with semantic properties, e.g., counting modulo a constant. Scalas and Yoshida [54] also identified another shortcoming: most classical projection operators require all branches of a loop to contain the same set of active roles. Thus, they cannot project the following global type. It is implementable and if it was projectable, the result would be equivalent to the local types given in their example [54, Fig. 4 (2)].

► **Example 3.15** (Two Buyer Protocol with Inner Recursion). This variant allows to recursively negotiate how to split the price (and omits the outer recursion):

$$\mathbf{G}_{2BPIR} := a \rightarrow s: query. s \rightarrow a: price. \mu t. + \begin{cases} a \rightarrow b: split. (b \rightarrow a: yes. a \rightarrow s: buy. 0 + b \rightarrow a: no. t) \\ a \rightarrow b: cancel. a \rightarrow s: no. 0 \end{cases}$$

These shortcomings have been addressed by some non-classical approaches. For example, Scalas and Yoshida [54] employ model checking while Castagna et al. [16] characterise implementable global types with an undecidable well-formedness condition and give a sound algorithmically checkable approximation. It is not known whether the implementability problem for global types, neither with directed or sender-driven choice, is decidable. We answer this question positively for the more general case of sender-driven choice.

4 Implementability for Global Types from MSTs is Decidable

In this section, we show decidability of the implementability problem for global types with sender-driven choice, using results from the domain of message sequence charts. We introduce high-level message sequence charts (HMSCs) and recall an HMSC encoding for global types. In general, implementability for HMSCs is undecidable but we show that global types, when encoded as HMSCs, belong to a class of HMSCs for which implementability is decidable.

■ **Figure 5** Highlighting the elements of an MSC $(N, p, f, l, (\leq_p)_{p \in \mathcal{P}})$ [57, Fig. 3].

4.1 High-level Message Sequence Charts

Our definitions of (high-level) message sequence charts follow work by Genest et al. [30] and Stutz and Zufferey [57]. If reasonable, we adapt terminology to the MST setting.

► **Definition 4.1** (Message Sequence Charts). A message sequence chart (MSC) is a 5-tuple $M = (N, p, f, l, (\leq_p)_{p \in \mathcal{P}})$ where

- N is a set of send (S) and receive (R) event nodes such that $N = S \uplus R$ (where \uplus denotes disjoint union),
- $p: N \rightarrow \mathcal{P}$ maps each event node to the role acting on it,
- $f: S \rightarrow R$ is an injective function linking corresponding send and receive event nodes,
- $l: N \rightarrow \Sigma$ labels every event node with an event, and
- $(\leq_p)_{p \in \mathcal{P}}$ is a family of total orders for the event nodes of each role: $\leq_p \subseteq p^{-1}(p) \times p^{-1}(p)$.

We visually highlight the elements of an MSC in Figure 5.

An MSC M induces a partial order \leq_M on N that is defined co-inductively:

$$\frac{e \leq_p e'}{e \leq_M e'} \text{ PROC} \quad \frac{s \in S}{s \leq_M f(s)} \text{ SND-RCV} \quad \frac{}{e \leq_M e} \text{ REFL} \quad \frac{e \leq_M e' \quad e' \leq_M e''}{e \leq_M e''} \text{ TRANS}$$

The labelling function l respects the function f : for every send event node e , we have that $l(e) = p(e) \triangleright p(f(e))!m$ and $l(f(e)) = p(f(e)) \triangleleft p(e)?m$ for some $m \in \mathcal{V}$.

All MSCs in our work respect FIFO, i.e., there are no p and q such that there are $e_1, e_2 \in p^{-1}(p)$ with $e_1 \neq e_2$, $l(e_1) = l(e_2)$, $e_1 \leq_p e_2$ and $f(e_2) \leq_q f(e_1)$ (also called degenerate) and for every pair of roles p, q , and for every two event nodes $e_1 \leq_M e_2$ with $l(e_i) = p \triangleright q! _$ for $i \in \{1, 2\}$, it holds that $\mathcal{V}(w_p) = \mathcal{V}(f(w_p))$ where w_p is the (unique) linearisation of $p^{-1}(p)$. A *basic MSC* (BMSC) has a finite number of nodes N and \mathcal{M} denotes the set of all BMSCs. When unambiguous, we omit the index M for \leq_M and write \leq . We define \leq as expected. The language $\mathcal{L}(M)$ of an MSC M collects all words $l(w)$ for which w is a linearisation of N that is compliant with \leq_M .

If one thinks of a BMSC as straight-line code, a high-level message sequence chart adds control flow. It embeds BMSCs into a graph structure which allows for choice and recursion.

► **Definition 4.2** (High-level Message Sequence Charts). A high-level message sequence chart (HMSC) is a 5-tuple (V, E, v^I, V^T, μ) where V is a finite set of vertices, $E \subseteq V \times V$ is a set of directed edges, $v^I \in V$ is an initial vertex, $V^T \subseteq V$ is a set of terminal vertices, and $\mu: V \rightarrow \mathcal{M}$ is a function mapping every vertex to a BMSC. A path in an HMSC is a sequence of vertices v_1, \dots from V that is connected by edges, i.e., $(v_i, v_{i+1}) \in E$ for every i . A path is maximal if it is infinite or ends in a vertex from V^T .

Intuitively, the language of an HMSC is the union of all languages of the finite and infinite MSCs generated from maximal paths in the HMSC and is formally defined in the technical report [56]. Like global types, an HMSC specifies a protocol. The implementability question was also posed for HMSCs and studied as *safe realisability*. If the CSM is not required to be deadlock-free, it is called weak realisability.

► **Definition 4.3** (Safe realisability of HMSCs [3]). *An HMSC H is said to be safely realisable if there exists a deadlock-free CSM $\{\{A_p\}_{p \in \mathcal{P}}\}$ such that $\mathcal{L}(H) = \mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\})$.*

Encoding Global Types from MSTs as HMSCs

Stutz and Zufferey [57, Sec. 5.2] provide a formal encoding $H(-)$ from global types to HMSCs. We refer to the technical report [56] for the definition. We adapt their correctness result to our setting. In particular, our semantics of \mathbf{G} use the closure operator $\mathcal{C}^\sim(-)$ while they distinguish between a type and execution language. We also omit the closure operator on the right-hand side because HMSCs are closed with regard to this operator [57, Lm. 5].

► **Theorem 4.4.** *Let \mathbf{G} be a global type. Then, the following holds: $\mathcal{L}(\mathbf{G}) = \mathcal{L}(H(\mathbf{G}))$.*

4.2 Implementability is Decidable

We introduce a mild assumption for global types. Intuitively, we require that every run of the protocol can always terminate but does not need to. Basically, this solely rules out global types that have loops without exit (cf. Example 4.20). In practice, it is reasonable to assume a mechanism to terminate a protocol for maintenance for instance. Note that this assumption constitutes a structural property of a protocol and no fairness condition on runs of the protocol.

► **Assumption** (0-Reachable). *We say a global type \mathbf{G} is 0-reachable if every prefix of a word in its language can be completed to a finite word in its language. Equivalently, we require that the vertex for the syntactic subterm 0 is reachable from any vertex in $H(\mathbf{G})$.*

The MSC approach to safe realisability for HMSCs is different from the classical projection approach to implementability. Given an HMSC, there is a canonical candidate implementation which always implements the HMSC if an implementation exists [2, Thm. 13]. Therefore, approaches center around checking safe realisability of HMSC languages and establishing conditions on HMSCs that entail safe realisability.

► **Definition 4.5** (Canonical candidate implementation [2]). *Given an HMSC H and a role p , let $A'_p = (Q', \Sigma_p, \delta', q'_0, F')$ be a state machine with $Q' := \{q_w \mid w \in \text{pref}(\mathcal{L}(H) \downarrow_{\Sigma_p})\}$, $F' := \{q_w \mid w \in \mathcal{L}_{\text{fin}}(H) \downarrow_{\Sigma_p}\}$, and $\delta'(q_w, x, q_{wx})$ for $x \in \Sigma_{\text{async}}$. The resulting state machine A'_p is not necessarily finite so A'_p is determinised and minimised which yields the FSM A_p . We call $\{\{A_p\}_{p \in \mathcal{P}}\}$ the canonical candidate implementation of H .*

Intuitively, the intermediate state machine A'_p constitutes a tree whose maximal finite paths give $\mathcal{L}(H) \downarrow_{\Sigma_p} \cap \Sigma_p^*$. This set can be infinite and, thus, the construction might not be effective. We give an effective construction of a deterministic FSM for the same language which was very briefly hinted at by Alur et al. [3, Proof of Thm. 3].

► **Definition 4.6** (Projection by Erasure). *Let p be a role and $M = (N, p, f, l, (\leq_p)_{p \in \mathcal{P}})$ be an MSC. We denote the set of nodes of p with $N_p := \{n \mid p(n) = p\}$ and define a two-ary next-relation on N_p : $\text{next}(n_1, n_2)$ iff $n_1 \leq_p n_2$ and there is no n' with $n_1 \leq_p n' \leq_p n_2$. We define the projection by erasure of M on to p : $M \downarrow_p = (Q_M, \Sigma_p, \delta_M, q_{M,0}, \{q_{M,f}\})$ with*

$$Q_M := \{q_n \mid n \in N_p\} \uplus \{q_{M,0}\} \uplus \{q_{M,f}\} \text{ and}$$

$$\delta_M := \{q_{M,0} \xrightarrow{\varepsilon} q_{n_1} \mid \forall n_2. n_1 \leq n_2\} \uplus \{q_{n_1} \xrightarrow{l(n_1)} q_{n_2} \mid \text{next}(n_1, n_2)\} \uplus \{q_{n_2} \xrightarrow{l(n_2)} q_{M,f} \mid \forall n_1. n_1 \leq n_2\}$$

where \uplus denotes disjoint union. Let $H = (V, E, v^I, V^T, \mu)$ be an HMSC. We construct the projection by erasure for every vertex and identify them with the vertex, e.g., Q_v instead of $Q_{\mu(v)}$. We construct an auxiliary FSM $(Q'_H, \Sigma_p, \delta'_H, q'_{H,0}, F'_H)$ with $Q'_H = \biguplus_{v \in V} Q_v$, $\delta'_H = \biguplus_{v \in V} \delta_v \uplus \{q_{v_1, f} \xrightarrow{\varepsilon} q_{v_2, 0} \mid (v_1, v_2) \in E\}$, $q'_{H,0} = q_{v^I, 0}$, and $F'_H = \biguplus_{v \in V^F} q_{v, f}$. We determinise and minimise $(Q'_H, \Sigma_p, \delta'_H, q'_{H,0}, F'_H)$ to obtain $H \downarrow_p := (Q_H, \Sigma_p, \delta_H, q_{H,0}, F_H)$, which we define to be the projection by erasure of H onto p . The CSM formed from the projections by erasure $\{\{H \downarrow_p\}\}_{p \in \mathcal{P}}$ is called erasure candidate implementation.

► **Lemma 4.7** (Correctness of Projection by Erasure). *Let H be an HMSC, p be a role, and $H \downarrow_p$ be its projection by erasure. Then, the following language equality holds: $\mathcal{L}(H \downarrow_p) = \mathcal{L}(H) \downarrow_{\Sigma_p}$.*

The proof is straightforward and can be found in the technical report [56]. From this result and the construction of the canonical candidate implementation, it follows that the projection by erasure admits the same finite language.

► **Corollary 4.8.** *Let H be an HMSC, p be a role, $H \downarrow_p$ be its projection by erasure, and A_p be the canonical candidate implementation. Then, it holds that $\mathcal{L}_{\text{fin}}(H \downarrow_p) = \mathcal{L}_{\text{fin}}(A_p)$.*

The projection by erasure can be computed effectively and is deterministic. Thus, we use it in place of the canonical candidate implementation. Given a global type, the erasure candidate implementation for its HMSC encoding implements it if it is implementable.

► **Theorem 4.9.** *Let \mathbf{G} be a global type and $\{\{H(\mathbf{G}) \downarrow_p\}\}_{p \in \mathcal{P}}$ be its erasure candidate implementation. If $\mathcal{L}_{\text{fin}}(\mathbf{G})$ is implementable³, then $\{\{H(\mathbf{G}) \downarrow_p\}\}_{p \in \mathcal{P}}$ is deadlock-free and $\mathcal{L}_{\text{fin}}(\{\{H(\mathbf{G}) \downarrow_p\}\}_{p \in \mathcal{P}}) = \mathcal{L}_{\text{fin}}(\mathbf{G})$.*

This result does only account for finite languages so we extend it for infinite sequences. For both, the proof can be found in the technical report [56].

► **Lemma 4.10** ("Finite implementation" generalises to infinite language for 0-reachable global types). *Let \mathbf{G} be a 0-reachable global type and $\{\{A_p\}\}_{p \in \mathcal{P}}$ be an implementation for $\mathcal{L}_{\text{fin}}(\mathbf{G})$. Then, it holds that $\mathcal{L}_{\text{inf}}(\{\{A_p\}\}_{p \in \mathcal{P}}) = \mathcal{L}_{\text{inf}}(\mathbf{G})$, and, thus, $\mathcal{L}(\{\{A_p\}\}_{p \in \mathcal{P}}) = \mathcal{L}(\mathbf{G})$.*

► **Corollary 4.11.** *Let \mathbf{G} be a 0-reachable implementable global type. Then, the erasure candidate implementation $\{\{H(\mathbf{G}) \downarrow_p\}\}_{p \in \mathcal{P}}$ implements \mathbf{G} .*

So far, we have shown that, if \mathbf{G} is implementable, the erasure candidate implementation for its HMSC encoding $H(\mathbf{G})$ implements \mathbf{G} . For HMSCs, this is undecidable in general [44]. We show that, because of their syntactic restrictions on choice, global types fall into the class of globally-cooperative HMSCs for which implementability is decidable.

► **Definition 4.12** (Communication graph [31]). *Let $M = (N, p, f, l, (\leq_p)_{p \in \mathcal{P}})$ be an MSC. The communication graph of M is a directed graph with node p for every role p that sends or receives a message in M and edges $p \rightarrow q$ if M contains a message from p to q , i.e., there is $e \in N$ such that $p(e) = p$ and $p(f(e)) = q$.*

It is important that the communication graph of M does not have a node for every role but only the active ones, i.e., the ones that send or receive in M .

³ Implementability is lifted to languages as expected.

■ **Figure 6** An implementable HMSC which is not globally-cooperative with its implementation.

► **Definition 4.13** (Globally-cooperative HMSCs [31]). *An HMSC $H = (V, E, v^I, V^T, \mu)$ is called globally-cooperative if for every loop, i.e., v_1, \dots, v_n with $(v_i, v_{i+1}) \in E$ for every $1 \leq i < n$ and $(v_n, v_1) \in E$, the communication graph of $\mu(v_1) \dots \mu(v_n)$ is weakly connected, i.e., all nodes are connected if every edge is considered undirected.*

We can check this directly for a global type \mathbf{G} . It is straightforward to define a communication graph for words from Σ_{sync}^* . We check it on $\text{GAut}(\mathbf{G})$: for each binder state, we check the communication graph for the shortest trace to every corresponding recursion state.

► **Theorem 4.14** (Thm. 3.7 [44]). *Let H be a globally-cooperative HMSC. Restricted to its finite language $\mathcal{L}_{\text{fin}}(H)$, safe realisability is EXPSPACE-complete.*

► **Lemma 4.15.** *Let \mathbf{G} be an implementable 0-reachable global type. Then, its HMSC encoding $H(\mathbf{G})$ is globally-cooperative.*

The proof can be found in the technical report [56] and is far from trivial. We explain the main intuition for the proof with the following example where we exemplify why the same result does not hold for HMSCs in general.

► **Example 4.16** (Implementable HMSC but not globally cooperative). HMSC H_{ing} in Figure 6a is implementable but neither globally-cooperative nor representable with a global type. In the first loop, p sends a message m to q while r sends a message m to s so the communication graph is not weakly connected. In the second loop, only the interaction between p and q is specified, while, in the third one, it is only the one between r and s . For a variant of the protocol without the second loop, any candidate implementation can always expose an execution with more interactions between p and q than the ones between r and s , due to the lack of synchronisation. Here, the second loop can make up for such executions so any execution has a path in H_{ing} . The CSM in Figure 6b implements H_{ing} . In the technical report [56], we explain in detail why there is a path in H_{ing} for any trace of the CSM and how to modify the example not to have final states with outgoing transitions.

► **Theorem 4.17.** *Checking implementability of 0-reachable global types with sender-driven choice is in EXPSPACE.*

Proof. Let \mathbf{G} be a 0-reachable global type with sender-driven choice. We construct $H(\mathbf{G})$ from \mathbf{G} and check if it is globally-cooperative. For this, we apply the coNP-algorithm by Genest et al. [31] which is based on guessing a subgraph and checking its communication graph. If $H(\mathbf{G})$ is not globally cooperative, we know from Lemma 4.15 that \mathbf{G} is not implementable. If $H(\mathbf{G})$ is globally cooperative, we check safe realisability for $H(\mathbf{G})$. By Theorem 4.14, this is in EXPSPACE. If $H(\mathbf{G})$ is not safely realisable, it trivially follows that \mathbf{G} is not implementable. If $H(\mathbf{G})$ is safely realisable, \mathbf{G} is implemented by the erasure candidate implementation with Theorem 4.9 and Lemma 4.10. ◀

Thus, the implementability problem for global types with sender-driven choice is decidable.

► **Corollary 4.18.** *Let \mathbf{G} be a 0-reachable global type with sender-driven choice. It is decidable whether \mathbf{G} is implementable and there is an algorithm to obtain its implementation.*

► **Remark 4.19 (Progress).** The property deadlock freedom is sometimes also studied as *progress* – in the sense that a system should never get stuck. For infinite executions, however, a role could starve in a non-final state by waiting for a message that is never sent [16, Sec. 3.2]. Thus, Castagna et al. [16] consider a stronger notion of progress (Def. 3.3: live session) which requires that every role could eventually reach a final state. Our results also apply to this stronger notion of progress, which entails that any sent message can eventually be received. The notion only requires it to be possible but we can ensure that no role starves in a non-final state in two ways. First, we can impose a (strong) fairness assumption – as Castagna et al. [16]. Second, we can require that every loop branch contains at least all roles that occur in interactions of any path with which the protocol can finish.

The Odd Case of Infinite Loops Without Exits. In theory, one can think of protocols for which the 0-Reachability-Assumption (p.15) does not hold. They would simply recurse indefinitely and can never terminate. This allows interesting behaviour like two sets of roles that do not interact with each other as the following example shows.

► **Example 4.20.** Consider the following global type: $\mathbf{G} = \mu t. p \rightarrow q : m. r \rightarrow s : m. t$. This is basically the protocol that consists only of the first loop of H_{ing} (Example 4.16). It describes an infinite execution with two pairs of roles that independently send and receive messages. This can be implemented in an infinite setting but the loop can never be exited due to the lack of synchronisation, breaking protocol fidelity upon termination.

Expressiveness of Local Types. Local types also have a distinct expression for termination: 0. Thus, if one considers the FSM of a local type, every final state has no outgoing transition. Our proposed algorithm might yield FSMs for which this is not the case. However, the language of such an FSM cannot be represented as local type since both our construction and FSMs for local types are deterministic. The latter are also ancestor-recursive, free of intermediate recursion, non-merging and dense (Proposition 3.6). For FSMs from our procedure, this is not the case but the ones without final states with outgoing transitions could possibly be transformed to local types, making subtyping techniques applicable. One could also study subtyping for FSMs as local specifications. We leave both for future work.

On Lower Bounds for Implementability. For general globally-cooperative HMSCs, i.e., that are not necessary the encoding of a global type, safe realisability is EXPSPACE-hard [44]. This hardness result does not carry over for the HMSC encoding $H(\mathbf{G})$ of a global type \mathbf{G} . The construction exploits that HMSCs do not impose any restrictions on choice. Global types, however, require every branch to be chosen by a single sender.

5 MSC Techniques for MST Verification

In the previous section, we generalised results from the MSC literature to show decidability of the implementability problem for global types from MSTs, yielding an EXPSPACE-algorithm. In this section, we consider further restrictions on HMSCs to obtain algorithms with better complexity for global types. First, we transfer the algorithms for \mathcal{I} -closed HMSCs, which requires an HMSC not to exhibit certain anti-patterns of communication, to global types.

Second, we explain approaches for HMSCs that introduced the idea of choice to HMSCs and a characterisation of implementable MSC languages. Third, we present a variant of the implementability problem. It can make unimplementable global types implementable without changing a protocol's structure. From now on, we may use the term implementability for HMSCs instead of safe realisability.

\mathcal{I} -closed Global Types

For globally-cooperative HMSCs, the implementability problem is EXPSPACE-complete. The membership in EXPSPACE was shown by reducing the problem to implementability of \mathcal{I} -closed HMSCs [44, Thm. 3.7]. These require the language of an HMSC to be closed with regard to an independence relation \mathcal{I} , where, intuitively, two interactions are independent if there is no role which is involved in both. Implementability for \mathcal{I} -closed HMSCs is PSPACE-complete [44, Thm. 3.6]. As for the EXPSPACE-hardness for globally-cooperative HMSCs, the PSPACE-hardness exploits features that cannot be modelled with global types and there might be algorithms with better worst-case complexity.

We adapt the definitions [44] to the MST setting. These consider atomic BMSCs, which are BMSCs that cannot be split further. With the HMSC encoding for global types, it is straightforward that atomic BMSCs correspond to individual interactions for global types. Thus, we define the independence relation \mathcal{I} on the alphabet Σ_{sync} .

► **Definition 5.1** (Independence relation \mathcal{I}). *We define the independence relation \mathcal{I} on Σ_{sync} :*

$$\mathcal{I} := \{(p \rightarrow q : m, r \rightarrow s : m') \mid \{p, q\} \cap \{r, s\} = \emptyset\}.$$

We lift this to an equivalence relation $\equiv_{\mathcal{I}}$ on words as its transitive and reflexive closure:

$$\equiv_{\mathcal{I}} := \{(u.x_1.x_2.w, u.x_2.x_1.w) \mid u, w \in \Sigma_{sync}^* \text{ and } (x_1, x_2) \in \mathcal{I}\}.$$

We define its closure for language $L \subseteq \Sigma_{sync}^$: $\mathcal{C}^{\equiv_{\mathcal{I}}}(L) := \{u \in \Sigma_{sync}^* \mid \exists w \in L \text{ with } u \equiv_{\mathcal{I}} w\}$.*

► **Definition 5.2** (\mathcal{I} -closed global types). *Let \mathbf{G} be a global type \mathbf{G} . We say \mathbf{G} is \mathcal{I} -closed if $\mathcal{L}_{\text{fin}}(\text{GAut}(\mathbf{G})) = \mathcal{C}^{\equiv_{\mathcal{I}}}(\mathcal{L}_{\text{fin}}(\text{GAut}(\mathbf{G})))$.*

Note that \mathcal{I} -closedness is defined on the state machine $\text{GAut}(\mathbf{G})$ of \mathbf{G} with alphabet Σ_{sync} and not on its semantics $\mathcal{L}(\mathbf{G})$ with alphabet Σ_{async} .

► **Example 5.3.** The global type \mathbf{G}_{2BP} is \mathcal{I} -closed. Buyer a is involved in every interaction. Thus, for every two consecutive interactions, there is a role that is involved in both.

► **Algorithm 1** (Checking if \mathbf{G} is \mathcal{I} -closed). *Let \mathbf{G} be a global type. We construct the state machine $\text{GAut}(\mathbf{G})$. We need to check every consecutive occurrence of elements from Σ_{sync} for words from $\mathcal{L}(\text{GAut}(\mathbf{G}))$. For binder states, incoming and outgoing transition labels are always ε . This is why we slightly modify the state machine but preserve its language. We remove all variable states and rebend their only incoming transition to the state their only outgoing transition leads to. In addition, we merge binder states with their only successor. For every state q of this modified state machine, we consider the labels $x, y \in \Sigma_{sync}$ of every combination of incoming and outgoing transition of q . We check if $x \equiv_{\mathcal{I}} y$. If this is true for all x and y , we return true. If not, we return false.*

► **Lemma 5.4.** *A global type \mathbf{G} is \mathcal{I} -closed iff Algorithm 1 returns true.*

The proof can be found in the technical report [56]. This shows that the presented algorithm can be used to check \mathcal{I} -closedness. The algorithm considers every state and all combinations of transitions leading to and from it.

► **Proposition 5.5.** *For global type \mathbf{G} , checking if \mathbf{G} is \mathcal{I} -closed is in $O(|\mathbf{G}|^2)$.*

The tree-like shape of $\mathbf{GAut}(\mathbf{G})$ might suggest that this check can be done in linear time. However, this example shows that recursion can lead to a quadratic number of checks.

► **Example 5.6.** Let us consider the following global type for some $n \in \mathbb{N}$.

$$\mu t. + \begin{cases} p \rightarrow q_0 : m_0. q_0 \rightarrow r_0 : m_0. r_0 \rightarrow s_0 : m_0. 0 \\ p \rightarrow q_1 : m_1. q_1 \rightarrow r_1 : m_1. r_1 \rightarrow s_1 : m_1. t \\ \vdots \\ p \rightarrow q_n : m_n. q_n \rightarrow r_n : m_n. r_n \rightarrow s_n : m_n. t \end{cases}$$

It is obvious that $(p \rightarrow q_i : m_i, q_i \rightarrow r_i : m_i) \notin \mathcal{I}$ and $(q_i \rightarrow r_i : m_i, r_i \rightarrow s_i : m_i) \notin \mathcal{I}$ for every i . Because of the recursion, we need to check if $(r_i \rightarrow s_i : m_i, p \rightarrow q_j : m_j)$ is in \mathcal{I} for every $0 \neq i \neq j$. This might lead to a quadratic number of checks.

If a global type \mathbf{G} is \mathcal{I} -closed, we can apply the results for its \mathcal{I} -closed HMSC encoding $H(\mathbf{G})$, for which checking implementability is in PSPACE. With Corollary 4.11, the projection by erasure implements \mathbf{G} .

► **Corollary 5.7.** *Checking implementability of 0-reachable, \mathcal{I} -closed global types with sender-driven choice is in PSPACE.*

► **Example 5.8.** This implementable global type is not \mathcal{I} -closed: $p \rightarrow q : m. r \rightarrow s : m. 0$.

Detecting Non-local Choice in HMSCs

For HMSCs, there are no restrictions on branching. Similar to choice for global types, the idea of imposing restrictions on choice was studied for HMSCs [8, 50, 48, 34, 31]. We refer to [45] for an overview. Here, we focus on results that seem most promising for developing algorithms to check implementability of global types with better worst-case complexity. The work by Dan et al. [26] centers around the idea of non-local choice. Intuitively, non-local choice yields scenarios that make it impossible to implement the language. In fact, if a language is not implementable, there is some non-local choice. Thus, checking implementability amounts to checking non-local choice freedom. For this definition, they showed insufficiency of Baker's condition [6] and reformulated the closure conditions for safe realisability by Alur et al. [2]. In particular, they provide a definition that is based on projected words of a language in contrast to explicit choice. While it is straightforward to check their definition for finite collections of k BMSCs with n events in $O(k^2 \cdot |\mathcal{P}| + n \cdot |\mathcal{P}|)$, it is unclear how to check their condition for languages with infinitely many elements. The design of such a check is far from trivial as their definition does not give any insight about local behaviour and their algorithm heavily relies on the finite nature of finite collections of BMSCs.

Payload Implementability

A deadlock-free CSM implements a global type if their languages are precisely the same. In the HMSC domain, a variant of the implementability problem has been studied. Intuitively, it allows to add fresh data to the payload of an existing message and protocol fidelity allows to omit the additional payload data. This allows to add synchronisation messages to existing

interactions and can make unimplementable global types implementable while preserving the structure of the protocol. It can also be used if a global type is rejected by a projection operator or the run time of the previous algorithms is not acceptable.

► **Definition 5.9** (Payload implementability). *Let L be a language with message alphabet \mathcal{V}_1 . We say that L is payload implementable if there is a message alphabet \mathcal{V}_2 for a deadlock-free CSM $\{\{A_p\}_{p \in \mathcal{P}}\}$ with A_p over $\{p \triangleright q!m, p \triangleleft q?m \mid q \in \mathcal{P}, m \in \mathcal{V}_1 \times \mathcal{V}_2\}$ such that its language is the same when projecting onto the message alphabet \mathcal{V}_1 , i.e., $\mathcal{C}^\sim(L) = \mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}) \downarrow_{\mathcal{V}_1}$, where $(p \triangleright q!(m_1, m_2)) \downarrow_{\mathcal{V}_1} := p \triangleright q!m_1$ and $(q \triangleleft p?(m_1, m_2)) \downarrow_{\mathcal{V}_1} := q \triangleleft p?m_1$ and is lifted to words and languages as expected.*

The finite language $\mathcal{L}_{\text{fin}}(H)$ of a local HMSC H is always payload implementable with a deadlock-free CSM of linear size.

► **Definition 5.10** (Local HMSCs [31]). *Let $H = (V, E, v^I, V^T, \mu)$ be an HMSC. We call H local if $\mu(v^I)$ has a unique minimal event and there is a function $\text{root}: V \rightarrow \mathcal{P}$ such that for every $(v, u) \in E$, it holds that $\mu(u)$ has a unique minimal event e and e belongs to $\text{root}(v)$, i.e., for $\mu(u) = (N, p, f, l, (\leq_p)_{p \in \mathcal{P}})$, we have that $p(e) = \text{root}(v)$ and $e \leq e'$ for every $e' \in N$.*

► **Proposition 5.11** (Prop. 21 [31]). *For any local HMSC H , $\mathcal{L}_{\text{fin}}(H)$ is payload implementable.*

With Lemma 4.10, we can use the implementation of a local $H(\mathbf{G})$ for a 0-reachable global type \mathbf{G} .

► **Corollary 5.12.** *Let \mathbf{G} be a 0-reachable for which $H(\mathbf{G})$ is local. Then, \mathbf{G} can be implemented with a CSM of linear size.*

The algorithm to construct a deadlock-free CSM [31, Sec. 5.2] suggests that the BMSCs for such HMSCs need to be maximal – in the sense that any vertex with a single successor is collapsed with its successor. If this was not the case, the result would claim that the language of the following global type is payload implementable: $\mu t. + \begin{cases} p \rightarrow q: m_1. r \rightarrow s: m_2. t \\ p \rightarrow q: m_3. 0 \end{cases}$. However, it is easy to see that it is not payload implementable since there is no interaction between p , which decides whether to stay in the loop or not, and r . Thus, we cannot simply check whether $H(\mathbf{G})$ is local. In fact, it would always be. Instead, we first need to minimise it and then check whether it is local. If we collapse the two consecutive vertices with independent pairs of roles in this example, the HMSC is not local. The representation of the HMSC matters which shows that local as property is rather a syntactic than a semantic notion.

► **Algorithm 2** (Checking if $H(\mathbf{G})$ is local – directly on $\text{GAut}(\mathbf{G})$). *Let \mathbf{G} be a global type \mathbf{G} . We consider the finite trace w' of every longest branch-free, loop-free and non-initial run in the state machine $\text{GAut}(\mathbf{G})$. We split the (synchronous) interactions into asynchronous events: $w = \text{split}(w') = w_1 \dots w_n$. We need to check if there is $u \sim w$ with $u = u_1 \dots u_n$ such that $u_1 \neq w_1$. For this, we can construct an MSC for w [30, Sec. 3.1] and check if there is a single minimal event. This works because MSCs are closed under \sim [57, Lm. 5]. If the MSC of every trace w' has a single minimal event, we return true. If not, we return false.*

It is straightforward that this mimics the corresponding check for the HMSC $H(\mathbf{G})$ and, with similar modifications as for Algorithm 1, the check can be done in $O(|\mathbf{G}|)$.

► **Proposition 5.13.** *For a global type \mathbf{G} , Algorithm 2 returns true iff $H(\mathbf{G})$ is local.*

Ben-Abdallah and Leue [8] introduced local-choice HMSCs, which are as expressive as local HMSCs. Their condition also uses a root-function and minimal events but quantifies over paths. Every local HMSC is a local-choice HMSC and every local-choice HMSC can be translated to a local HMSC that accepts the same language with a quadratic blow-up [31]. It is straightforward to adapt the Algorithm 2 to check if a global type is local-choice. If this is the case, we translate the protocol and use the implementation for the translated protocol.

6 Implementability with Intra-role Reordering

In this section, we introduce a generalisation of the implementability problem that relaxes the total event order for each role. We prove that this generalisation is undecidable in general.

A Case for More Reordering

From the perspective of a single role, each word in its language consists of a sequence of send and receive events. Choice in global types happens by sending (and not by receiving). Because of this, one can argue that a role should be able to receive messages from different senders in any order between sending two messages. In practice, receiving a message can induce a task with non-trivial computation that our model does not account for. Therefore, such a reordering for a sequence of receive events can have outsized performance benefits. In addition, there are global types that can be implemented with regard to this generalised relation even if no (standard) implementation exists.

► **Example 6.1** (Example for intra-role reordering). Let us consider a global type where a central coordinator p distributes independent tasks to different roles in rounds:

$$\mathbf{G}_{\text{TC}} := \mu t. \begin{cases} p \rightarrow q_1 : \text{task} \dots p \rightarrow q_n : \text{task} \cdot q_1 \rightarrow p : \text{result} \dots q_n \rightarrow p : \text{result} \cdot t \\ p \rightarrow q_1 : \text{done} \dots p \rightarrow q_n : \text{done} \cdot 0 \end{cases}$$

Since all tasks in each round are independent, p can benefit from receiving the results in the order they arrive instead of busy-waiting.

We generalise the indistinguishability relation \sim accordingly.

► **Definition 6.2** (Intra-role indistinguishability relation \approx). We define a family of intra-role indistinguishability relations $\approx_i \subseteq \Sigma^* \times \Sigma^*$, for $i \geq 0$ as follows. For all $w, u \in \Sigma^*$, $w \sim_i u$ entails $w \approx_i u$. For $i = 1$, we define: if $q \neq r$, then $w.p \triangleleft q ? m.p \triangleleft r ? m'.u \sim_1 w.p \triangleleft r ? m'.p \triangleleft q ? m.u$. Based on this, we define \approx analogously to \sim . Let w, w', w'' be words s.t. $w \approx_1 w'$ and $w' \approx_i w''$ for some i . Then $w \approx_{i+1} w''$. We define $w \approx u$ if $w \approx_n u$ for some n . It is straightforward that \approx is an equivalence relation. Define $u \preceq_{\approx} v$ if there is $w \in \Sigma^*$ such that $u.w \approx v$. Observe that $u \sim v$ iff $u \preceq_{\approx} v$ and $v \preceq_{\approx} u$. We extend \approx to infinite words and languages as for \sim .

► **Definition 6.3** (Implementability w.r.t. \approx). A global type \mathbf{G} is implementable with regard to \approx if there exists a deadlock-free CSM $\{\{A_p\}_{p \in \mathcal{P}}\}$ such that (i) $\mathcal{L}(\mathbf{G}) \subseteq \mathcal{C}^{\approx}(\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}))$ and (ii) $\mathcal{C}^{\approx}(\mathcal{L}(\mathbf{G})) = \mathcal{C}^{\approx}(\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}))$. We say that $\{\{A_p\}_{p \in \mathcal{P}}\} \approx$ -implements \mathbf{G} .

In this section, we emphasise the indistinguishability relation, e.g., \approx -implementable. We could have also followed the definition of \sim -implementability and required $\mathcal{C}^{\approx}(\mathcal{L}(\mathbf{G})) = \mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\})$. This, however, requires the CSM to be closed under \approx . In general, this might not be possible with finitely many states. In particular, if there is a loop without any send events for a role, the labels in the loop would introduce an infinite closure if we require that $\mathcal{C}^{\approx}(\mathcal{L}(\mathbf{G})) \downarrow_{\Sigma_p} = \mathcal{L}(A_p)$.

► **Example 6.4**. We consider a variant of \mathbf{G}_{TC} from Example 6.1 with $n = 2$ where q_1 and q_2 send a log message to r after receiving the task and before sending the result back:

$$\mathbf{G}_{\text{TCLog}} := \mu t. \begin{cases} p \rightarrow q_1 : \text{task} \cdot p \rightarrow q_2 : \text{task} \cdot q_1 \rightarrow r : \text{log} \cdot q_2 \rightarrow r : \text{log} \cdot q_1 \rightarrow p : \text{result} \cdot q_2 \rightarrow p : \text{result} \cdot t \\ p \rightarrow q_1 : \text{done} \cdot p \rightarrow q_2 : \text{done} \cdot 0 \end{cases}$$

There is no FSM for r that precisely accepts $\mathcal{C}^{\approx}(\mathcal{L}(\mathbf{G}_{\text{TCLog}})) \downarrow_{\Sigma_r}$. If we rely on the fact that q_1 and q_2 send the same number of log-messages to r , we can use an FSM A_r with a single state (both initial and final) with two transitions: one for the log-message from q_1 and q_2

each, that lead back to the only state. For this, it holds that $\mathcal{C}^{\approx}(\mathcal{L}(\mathbf{G}_{\text{TCLog}})) \downarrow_{\Sigma_r} \subseteq \mathcal{L}(A_r)$. If we cannot rely on this, the FSM would need to keep track of the difference, which can be unbounded and thus not recognisable by an FSM.

This is why we chose a more permissive definition which is required to cover at least as much as specified in the global type (i) and the \approx -closure of both are the same (ii).

It is trivial that any \sim -implementation for a global type does also \approx -implement it.

► **Proposition 6.5.** *Let \mathbf{G} be a global type that is \sim -implemented by the CSM $\{\{A_p\}\}_{p \in \mathcal{P}}$. Then, $\{\{A_p\}\}_{p \in \mathcal{P}}$ also \approx -implements \mathbf{G} .*

For instance, the erasure candidate implementation is a \sim -implementation as well as a \approx -implementation for the task coordination protocol \mathbf{G}_{TC} from Example 6.1. Still, \approx -implementability gives more freedom and allows to consider all possible combinations of arrivals of results. In addition, \approx -implementability renders some global types implementable which would not be otherwise. For instance, those with a role that would need to receive different sequences, related by \approx though, in different branches it cannot distinguish (yet).

► **Example 6.6** (\approx -implementable but not \sim -implementable). Let us consider the following global type: $(p \rightarrow q : l. p \rightarrow r : m. q \rightarrow r : m. 0) + (p \rightarrow q : r. q \rightarrow r : m. p \rightarrow r : m. 0)$. This cannot be \sim -implemented because r would need to know about the choice to receive the messages from p and q in the correct order. However, it is \approx -implementable. The FSMs for p and q can be obtained with projection by erasure. For r , we can have an FSM that only accepts $r \triangleleft p ? m. r \triangleleft q ? m$ but also an FSM which accepts $r \triangleleft q ? m. r \triangleleft p ? m$ in addition. Note that r does not learn the choice in the second FSM even if it branches. Hence, it would not be implementable if it sent different messages in both branches later on. However, it could still learn by receiving and, afterwards, send different messages.

Implementability with Intra-role Reordering is Undecidable

Unfortunately, checking implementability with regard to \approx for global types (with directed choice) is undecidable. Intuitively, the reordering allows roles to drift arbitrarily far apart as the execution progresses which makes it hard to learn which choices were made.

We reduce the *Post Correspondence Problem* (PCP) [53] to the problem of checking implementability with regard to \approx . An instance of PCP over an alphabet Δ , $|\Delta| > 1$, is given by two finite lists (u_1, u_2, \dots, u_n) and (v_1, v_2, \dots, v_n) of finite words over Δ , also called tile sets. A solution to the instance is a sequence of indices $(i_j)_{1 \leq j \leq k}$ with $k \geq 1$ and $1 \leq i_j \leq n$ for all $1 \leq j \leq k$, such that $u_{i_1} \dots u_{i_k} = v_{i_1} \dots v_{i_k}$. To be precise, we present a reduction from the modified PCP (MPCP) [55, Sec. 5.2], which is also undecidable. It simply requires that a match starts with a specific pair – in our case we choose the pair with index 1. It is possible to directly reduce from PCP but the reduction from MPCP is more concise. Intuitively, we require that the solution starts with the first pair so there exists no trivial solution and choosing a single pair is more concise than all possible ones. Our encoding is the following global type where $x \in \{u, v\}$, $[x_i]$ denotes a sequence of message interactions with message $x_i[1], \dots, x_i[k]$ each for x_i of length k , message $c-x$ indicates choosing tile set x , and message $ack-x$ indicates acknowledging the tile set x :

$$\mathbf{G}_{\text{MPCP}} := + \begin{cases} G(u, r \rightarrow p : ack-u. 0) \\ G(v, r \rightarrow p : ack-v. 0) \end{cases} \quad \text{with}$$

$$G(x, X) := p \rightarrow q : c-x. p \rightarrow q : 1. p \rightarrow r : 1. q \rightarrow r : [x_1]. \mu t. + \begin{cases} p \rightarrow q : 1. p \rightarrow r : 1. q \rightarrow r : [x_1]. t \\ \vdots \\ p \rightarrow q : n. p \rightarrow r : n. q \rightarrow r : [x_n]. t \\ p \rightarrow q : d. p \rightarrow r : d. q \rightarrow r : d. X \end{cases}$$

■ **Figure 7** HMSC encoding $H(\mathbf{G}_{\text{MPCP}})$ of the MPCP encoding.

The HMSC encoding $H(\mathbf{G}_{\text{MPCP}})$ is illustrated in Figure 7. Intuitively, r eventually needs to know which branch was taken in order to match $ack-x$ with $c-x$ from the beginning. However, it can only know if there is no solution to the MPCP instance. In the full proof in technical report [56], we show that \mathbf{G}_{MPCP} is \approx -implementable iff the MPCP instance has no solution.

► **Theorem 6.7.** *Checking implementability with regard to \approx for 0-reachable global types with directed choice is undecidable.*

This result carries over to HMSCs if we consider safe realisability with regard to \approx .

► **Definition 6.8** (Safe realisability with regard to \approx). *An HMSC H is said to be safely realisable with regard to \approx if there exists a deadlock-free CSM $\{\{A_p\}_{p \in \mathcal{P}}\}$ such that the following holds: (i) $\mathcal{L}(H) \subseteq \mathcal{C}^\approx(\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}))$ and (ii) $\mathcal{C}^\approx(\mathcal{L}(H)) = \mathcal{C}^\approx(\mathcal{L}(\{\{A_p\}_{p \in \mathcal{P}}\}))$.*

► **Corollary 6.9.** *Checking safe realisability with regard to \approx for HMSCs is undecidable.*

It is obvious that a terminal vertex is reachable from every vertex in $H(\mathbf{G}_{\text{MPCP}})$. In fact, the HMSC encoding for \mathbf{G}_{MPCP} also satisfies a number of channel restrictions. The HMSC $H(\mathbf{G}_{\text{MPCP}})$ is existentially 1-bounded, 1-synchronisable and half-duplex [57]. For details on these channel restrictions, we refer to work by Stutz and Zufferey [57, Sec. 3.1].

The MPCP encoding only works since receive events can be reordered unboundedly in an execution. If we amended the definition of \approx to give each receive event a budget that depletes with every reordering, this encoding would not be possible. We leave a detailed analysis for future work.

7 Related Work

In this section, we solely cover related work which was not discussed before.

Multiparty Session Types. Session types originate in process algebra and were first introduced by Honda et al. [35] for binary sessions. For systems with more than two roles, they have been extended to multiparty session types [37]. We explained MST frameworks with classical projection operators. Other approaches do not focus on projection but only apply ideas from MST without the need for global types [54, 43].

Completeness and Sender-driven Choice. Our decidability result applies to global types with sender-driven choice. To the best of our knowledge, the work by Castagna et al. [16] is the only one to attempt completeness for global types with sender-driven choice. However, their definition of completeness is “less demanding than other ones” [16, Abs.]. For one

global type, they accept different implementations that generate different sets of traces [16, Def. 4.1 and Sec. 5.3]. Their conditions, given as inference rules, are not effective and their algorithmically checkable conditions can only exploit local information to disambiguate choices. In contrast, Majumdar et al. [45] employ a global availability analysis but, as classical projection operator, it suffers from the shortcomings presented in this work. For a detailed overview of MST frameworks with sender-driven choice, we refer to their work [45]. The global types by Castellani et al. [17] specify send and receive events independently and allow to receive from different senders. Dagnino et al. [25] consider similar global types but each term requires to send to a single receiver and to receive from a single sender upon branching though.

On the Synchronous Implementability Problem. We could not find a reference that shows decidability of the implementability problem in a synchronous setting, i.e., without channels. Before giving a proof sketch, let us remark that there are global types that can be implemented synchronously but not asynchronously, e.g., $p \rightarrow q:l.r \rightarrow q:l.0 + p \rightarrow q:r.r \rightarrow q:r.0$ because q can force the right choice by r . We sketch how to prove decidability of the synchronous implementability problem for global types (with sender-driven choice). One defines the synchronous semantics of CSMs and HMSCs as expected. For global types, one uses the independence relation \mathcal{I} (Def. 5.1), which defines reasonable reorderings for synchronous events in a distributed setting, similar to the indistinguishability relation \sim . It is straightforward that the HMSC encoding $H(-)$ for global types [57] also works for the synchronous setting (cf. Thm. 4.4). Thus, every implementation for $H(\mathbf{G})$ is also an implementation for \mathbf{G} . For the asynchronous setting, we used [2, Thm. 13], which shows that the canonical candidate implementation implements an HMSC if it is implementable. Alur et al. [2, Sec. 8] also considered the synchronous setting. They observe that both Theorem 5 and 8, basis for Theorem 13, stay valid under these modified conditions. Together with our results, the erasure candidate implementation implements a global type if it is implementable. Because of the synchronous semantics, its state space is finite and can be model-checked against the global type, yielding a PSPACE-procedure for the synchronous implementability problem, and thus decidability. Closest are works by Jongmans and Yoshida [40] and Glabbeek et al. [62]. Jongmans and Yoshida consider quite restrictive synchronous semantics for global types [40, Ex. 3] that does not allow the natural reorderings in a distributed setting, as enabled by \mathcal{I} , e.g., $p \rightarrow q:m.r \rightarrow s:m.0$ (Ex. 5.8) is considered unimplementable. Glabbeek et al. [62] present a projection operator that is complete for various notions of lock-freedom, a typical liveness property, and investigate how much fairness is required for those.

Subtyping and MST Extensions. In this work, we do not distinguish between local types and implementations but use local types directly as implementations. Intuitively, subtyping studies how to give freedom in the implementation while preserving the correctness properties. The intra-role indistinguishability relation \approx , which allows to reorder receive events for a role, resembles subtyping to some extent, e.g., the work by Cutner et al. [24]. A detailed investigation of this relation is beyond the scope of this work. For details on subtyping, we refer to work by Chen et al. [22, 21], Lange and Yoshida [42], and Bravetti et al. [14]. Various extensions to make MST verification applicable to more scenarios were studied: for instance delegation [36, 37, 18], dependent session types [59, 29, 60], parametrised session types [20, 29], gradual session types [39], or dynamic self-adaption [33]. Context-free session types [58, 41] provide a more expressive way to specify protocols. Research on fault-tolerant MSTs [63, 7] investigates ways to weaken the strict assumptions about reliable channels.

Communicating State Machines. The connection of MSTs and CSMs was studied soon after MSTs had been proposed [28]. CSMs are known to be Turing-powerful [13]. Decidable classes have been obtained for different semantics, e.g., half-duplex communication for two roles [19], input-bounded [10], and unreliable/lossy channels [1], as well for restricted communication topology [52, 61]. Similar restrictions for CSMs are existential boundedness [30] and synchronisability [12, 32]. It was shown that global types can only express existentially 1-bounded, 1-synchronisable and half-duplex communication [57] while Bollig et al. [11] established a connection between synchronisability and MSO logic.

High-level Message Sequence Charts. Globally-cooperative HMSCs were independently introduced by Morin [49] as c-HMSCs. Their communication graph is weakly connected. The class of bounded HMSCs [4] requires it to be strongly connected. Historically, it was introduced before the class of globally-cooperative HMSCs and, after the latter has been introduced, safe realisability for bounded HMSCs was also shown to be EXPSPACE-complete [44]. This class was independently introduced as regular HMSCs by Muscholl and Peled [51]. Both terms are justified: the language generated by a *regular* HMSC is regular and every *bounded* HMSC can be implemented with universally bounded channels. In fact, a HMSC is bounded if and only if it is a globally-cooperative and it has universally bounded channels [31, Prop. 4].

8 Conclusion

We have proven decidability of the implementability problem for global types with generalised choice from MSTs – under the mild assumption that protocols can (but do not need to) terminate. To point at the origin for incompleteness of classical projection operators, we gave a visual explanation of the projection with various merge operators on finite state machines, which define the semantics of global and local types. To prove decidability, we formally related the implementability problem for global types with the safe realisability problem for HMSCs. While safe realisability is undecidable in general, we showed that implementable global types do always belong to the class of globally-cooperative HMSCs. There are global types that are outside of this class but the syntax of global types allowed us to prove that those cannot be implemented. Another key was the extension of the HMSC results to infinite executions. We also gave a comprehensive overview of MSC techniques and adapted some to the MST setting. Furthermore, we introduced a performance-oriented generalisation of the implementability problem which, however, we proved to be undecidable in general.

Abstract

SAT/SMT-solvers and model checkers automate formal verification of sequential programs. Formal reasoning about scalable concurrent programs is still manual and requires expert knowledge. But scalability is a fundamental requirement of current and future programs.

Sequential imperative programs compose statements, function/method calls and control flow constructs. Concurrent programming models provide constructs for concurrent composition. Concurrency abstractions such as threads and synchronization primitives such as locks compose the individual parts of a concurrent program that are meant to execute in parallel. We propose to rather compose the individual parts again using sequential composition and compile this sequential composition into a concurrent one. The developer can use existing tools to formally verify the sequential program while the translated concurrent program provides the dearly requested scalability.

Following this insight, we present *ConDRust*, a new programming model and compiler for Rust programs. The *ConDRust* compiler translates sequential composition into a concurrent composition based on threads and message-passing channels. During compilation, the compiler preserves the semantics of the sequential program along with much desired properties such as determinism.

Our evaluation shows that our *ConDRust* compiler generates concurrent deterministic code that can outperform even non-deterministic programs by up to a factor of three for irregular algorithms that are particularly hard to parallelize.

1 Introduction

Formal verification of sequential programs can be automated to a large extent which makes it ready for widespread adoption. Verification of concurrent multi-core shared-memory programs, instead, can only be automated to some extent and requires expert knowledge. This is a major hurdle for safe systems which must rely on scalable parallelism to overcome the physical boundary in current and future processors.

A formally verified program carries mathematical proof that certain properties of the program hold. Determinism is such an interesting property. Deterministic programs are straightforward to debug [12]. A deterministic execution increases the time predictability of IoT systems [50] and establishes latency boundaries of service-level agreements in the cloud [20, 4]. In recent database management systems with transaction support, determinism removes costly synchronization and challenging distributed failure scenarios [52, 40].

Formal verification of program properties, such as determinism, proceeds along two directions. Proof assistants such as Coq allow expressing properties in higher-order logic but require a manual proof from the developer. SAT/SMT-based verifiers such as Prusti and model checkers such as Kani for Rust programs are restricted to properties formulated in first-order logic but calculate the proof automatically [3, 54]. That is, the hard part of formal verification is automated which makes them particularly interesting for widespread adoption. But concurrent programs require separation logic to state and prove their properties [51, 43]. Encoding separation logic into first-order logic is still ongoing research [15, 14, 44, 43] and needs to sacrifice important (higher-order) parts. Expert knowledge in Coq is required to take full advantage of separation logic [30]. At the time of this writing, none of the formal verification tools for Rust programmers supports reasoning about concurrent programs.

Our insight is that two main steps are needed to translate a sequential program into a concurrent one. We call these steps *Decompose* and *Recompose*. The Decompose step breaks the sequential composition of a program to create independent parts that can execute in parallel. The Recompose step composes these parts again using concurrency abstractions such as threads and synchronization primitives such as locks or message-passing. We refer to this as *concurrent composition*. In programming models such as threads with locks, message-passing or software transactional memory (STM), the developer has to perform both steps manually. Automatic approaches to tackle both steps require a precise points-to analysis to create a concurrent program without concurrency hazards such as data races or deadlocks. This analysis is known to be undecidable in general [48]. Hence, researchers resort to speculative approaches [17] or language constraints for a precise dependence analysis [6].

The *ConDRust* approach

In this paper, we propose *ConDRust*, a new *sequential* programming model for the *concurrent composition* in the Recompose phase. Our *ConDRust* compiler translates a sequential composition into a concurrent one automatically. This allows for testing and formal verification to be performed on the sequential program, with guarantees that are carried into the concurrent

one. More specifically, our current prototype compiler supports a well-defined subset of *safe* Rust for sequential composition and generates concurrent dataflow composition in a well-defined subset of *safe* Rust with threads and message-passing. The dataflow execution model is the runtime representation for scalable parallelism in many domains such as embedded systems, database systems and machine learning frameworks [38, 23, 27, 58]. Our compiler design is based on rewriting steps that preserve the semantics of the sequential input program. This includes the semantics of control flow constructs such as loops but also properties such as determinism. Formally verifying the compiler is a larger effort [39] that is beyond the scope of this paper. This paper, instead, investigates to what extent the programming model is applicable to real-world programs and whether the compiler can generate scalable concurrent composition that is at least on par with existing concurrent programming models. Throughout the paper, we point to novel and interesting research directions that our approach introduces.

Concretely, we make the following contributions:

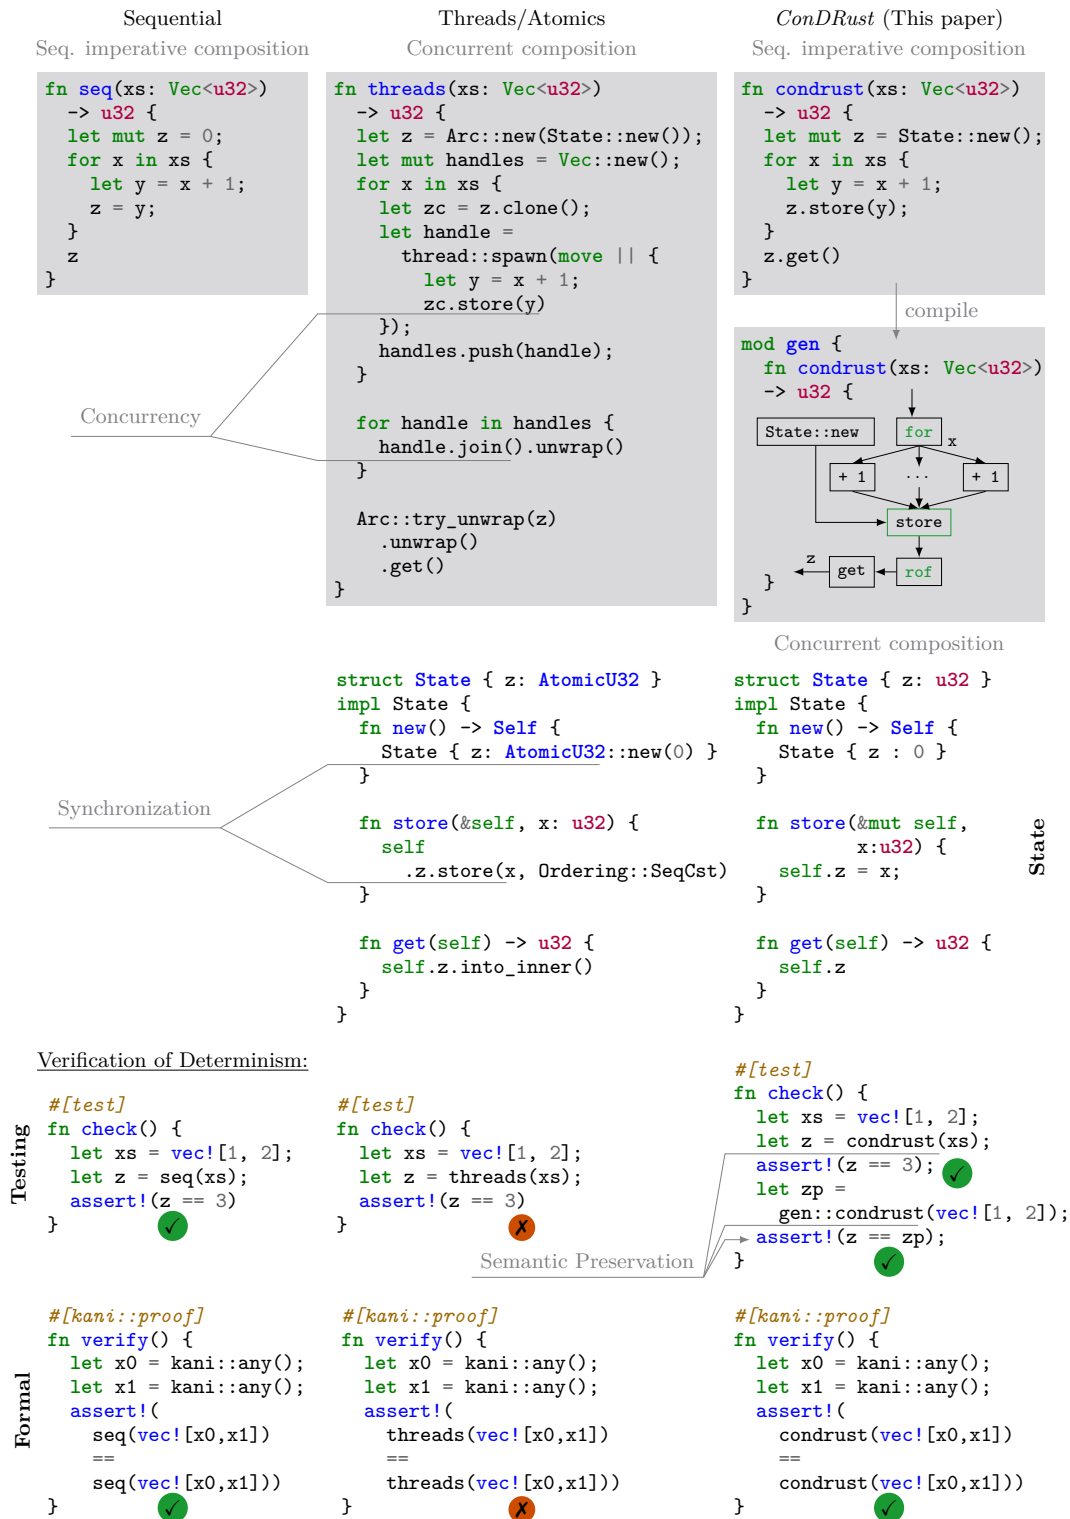

- The main contribution of this paper is a new programming model and compiler for the compositional fragment, i.e., subset, of safe Rust (Sections 2 and 3).
- We define \mathbb{R}_s , a subset of Rust for sequential imperative composition with abstractions, calls, variables but without references, and formally specify its type system and operational semantics (in Section 4 and the Appendix).
- We formally specify \mathbb{R}_p , the subset of Rust for concurrent composition that the *ConDRust* compiler targets in Section 6. The appendix contains the operational semantics, type system and a proof sketch for the deterministic execution.
- The key part of our compiler, visualized in Figure 1, is a transformation of sequential imperative \mathbb{R}_s composition into a functional representation based on the well-defined concept of state threads [35]. Our compiler lowers this functional representation into dataflow, a well-established abstraction for parallel execution [5, 2, 37, 29] (Section 5.1).
- Key to scalable concurrent composition are two transformations to exploit data parallelism even in stateful applications with (tail) recursion (Sections 5.2 and 5.3).
- Our current *ConDRust* prototype compiler consists of ca. 20K lines of Haskell code that can be lifted to Coq in future work to formally-verify semantic preservation (Section 7).
- To provide a fair baseline with the same guarantees, we re-implemented a deterministic STM (DSTM) algorithm [49] for an existing STM implementation in Rust. We ported 7 benchmarks from 3 different benchmark suites and provide implementations for sequential, threads/DSTM, threads/STM and *ConDRust* (ca. 12K lines of Rust code). Our evaluation in Section 8 shows that *ConDRust* produces programs that outperform all threads/DSTM and even some of the non-deterministic threads/STM programs by up to a factor of 3. We highlight directions for future work whenever *ConDRust* programs do not scale.

We review related work in Section 9 and conclude in Section 10.

2 Programming for Scalability: Decompose and Recompose

Before we introduce our programming model in more detail, we reflect on concurrent programming. We argue that concurrent programming and our *ConDRust* programming model contain the same *Decompose–Recompose* steps. That is, the reasoning for the developer to prepare a scalable concurrent program is the same as for writing a *ConDRust* program. But the implications are different. Figure 2 uses an inarguably contrived but easy to follow example for a side-by-side comparison. The left column shows the sequential program. The middle column lists the program with threads and atomics, i.e., transactions on a single variable. And the right column shows the sequential *ConDRust* program.

33:4 ConDRust: Scalable Deterministic Concurrency from Verifiable Rust Programs

■ **Figure 2** Comparison between sequential, concurrent and *ConDRust* programs and their properties. The sequential program executes deterministically and is amenable to verification. The concurrent program offers parallel speedup but compromises determinism and verifiability. The *ConDRust* approach preserves determinism and verifiability and compiles the program into a concurrent dataflow for scalable parallel execution.

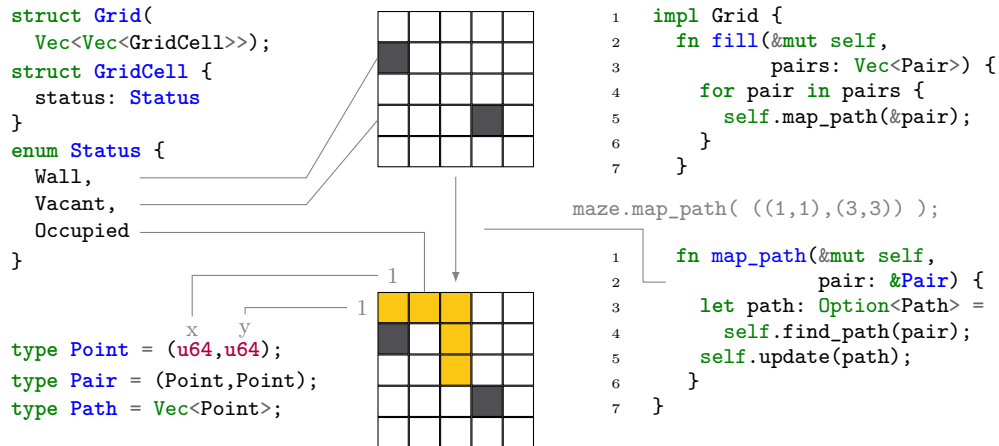

The sequential program on the left iterates over a vector of numbers `xs`. For each number, the program computes its increment and assigns it to a shared state `z`. The resulting value of `z` is always the increment of the last number in `xs`. This is by definition of the sequential execution order of statements and loop iterations in Rust. As such, we can check deterministic execution with a simple test case for a vector with 2 elements and let Kani formally verify this property in a simple proof harness (see bottom of left column in Figure 2). Apart from detecting potential overflow, which is inconsequential for this example, Kani succeeds.

To arrive at a scalable concurrent version of the program, the developer needs two steps. In the *Decompose* step, the developer identifies the parts of the program that can/should be executed in parallel and the state that needs to be shared. In our example, the developer selected the body of the loop for parallel execution. Any approach, that seeks to automate this step, needs to solve the thread granularity problem [47, 1]. Tools now assist in identifying the state [21]. The focus of this paper is on the second step. In the *Recompose* step, the developer replaces the sequential composition with a *concurrent composition*, e.g., for the loop iterations. Prevalent concurrent programming models for imperative programs consist of two parts for composition: *concurrency abstractions* and *synchronization primitives* to access (shared) state. The concurrent version of the program spawns a thread for each computation on the elements of the input vector `xs`. Thereby, it removes the sequential execution order of the `for` loop. Accesses to the state variable `z` now need to be protected with atomic operations (or transactions) to prevent data races. But this protection cannot recover the deterministic update order on `z`, even when opting for the strongest and least performing memory ordering: sequential consistency (`SeqCst`). The test's post-condition now may see `z == 2`. That is, the determinism property of the program is lost. Even worse, Kani cannot even help to detect this flaw because verification of concurrent programs needs a higher-order (separation) logic which is (currently) out of reach for model checkers like Kani².

To construct a *ConDRust* version of the program, the developer has to follow the same two steps. The *Decompose* step is the same as in the construction of the concurrent version. The developer identifies independent parts and shared state. In the *Recompose* step, the developer uses the sequential composition constructs of the host language such as for example statements, `for` loops, function calls and (imperative) method calls. The *ConDRust* program defines the update to the state `z` with a method rather than an assignment. Assignments are not supported in this paper because we tried to keep Θ_s minimal but can be added easily. The program is free of concurrency abstractions and synchronization primitives. The deterministic property on the result of the program can be tested and formally verified in the same way as for the sequential version. Note that formal verification is performed on the sequential `condrust` program. The *ConDRust* compiler is aware of the semantics of the composition constructs and preserves them during compilation. The generated dataflow graph (in `gen::condrust`) exhibits data parallelism for the computation of the increments and pipeline-parallelizes this with the update of the state `z`. The state update order is preserved. We can then dynamically verify that the generated concurrent program `gen::condrust` preserves the semantics, including the determinism property.

Concurrency vs. Parallelism. Throughout the paper, we use the words *concurrent* and *parallel* in the following well-established sense [53]. Concurrency means interleaved execution of computations. Parallelism exploits additional (multi-core) hardware to execute computations simultaneously. That is, concurrency does not necessarily imply parallelism. But in this

² <https://model-checking.github.io/kani/rust-feature-support.html#concurrency>

■ **Figure 3** Illustration of the labyrinth benchmark on a 2D grid in imperative sequential Rust.

paper, we focus on scalable concurrency. Scalable concurrency assumes multi-core hardware to turn explicit concurrency in the program into implicit parallelism. Hence, whenever we refer to parallelism, we mean independent concurrent computations in the program. ◀

3 The *ConDRust* programming model

In this section, we present the *ConDRust* programming model that we formally specify and embed into the Rust programming language (see Section 4). We compare programming in *ConDRust* to concurrent programming with threads and software transactional memory (STM). As a running example, we use Labyrinth, an irregular application from the STAMP benchmark suite [41]. Irregular programs contain algorithms where concurrent programming models particularly shine because such algorithms are notoriously hard to parallelize at compile-time. We start from the sequential version of the labyrinth algorithm and then develop a version based on threads and STM to compare it against programming in *ConDRust*.

3.1 The Labyrinth benchmark

The labyrinth benchmark implements Lee’s algorithm to find wire-paths between points on a multi-layer printed circuit board [36]. The challenge consists in finding paths that do not overlap across layers. The original STAMP implementation and our re-implementation in Rust execute on a 3D board (or 3D grid). In this section, we restrict ourselves to a 2D grid because it is easier to visualize while retaining the core principles required by our exposition.

Figure 3 illustrates the problem and shows a sequential imperative Rust implementation. The left-hand side defines a grid as a vector of vectors where a grid cell holds one of the three states: wall (in dark grey), vacant (in white) or occupied (in yellow). A point in the grid is a tuple of an x- and a y-coordinate. A pair is a tuple of two points and a path is a sequence of points represented as a vector. The algorithm to `fill` a given grid is given on the right-hand side of the figure. For each pair, the function `map_path` finds a path and declares the corresponding grid cells as occupied. Note that both steps `find_path` and `update` require access to the grid. That is what makes introducing concurrency particularly challenging for the developer.

3.2 Concurrent Labyrinth

Concurrently mapping paths onto the grid requires changes to the algorithm. Two candidate paths computed concurrently may overlap and thus one of them has to be re-computed. We visualize this effect in the middle column of Figure 4 and compare the threads/STM version in the left column with the *ConDRust* version in the right column. These alternative implementations are discussed in the following.

3.2.1 Threads/STM

We use threads for concurrency and synchronize grid access via STM. We chose STM over locks for two reasons. First, STM guarantees data-race freedom without creating deadlocks. Second, deterministic STM algorithms exist that provide the same deterministic execution properties as *ConDRust*. For this paper, we used `rust-stm`³, an STM implementation in Rust, that follows the design of the STM in Haskell [28].

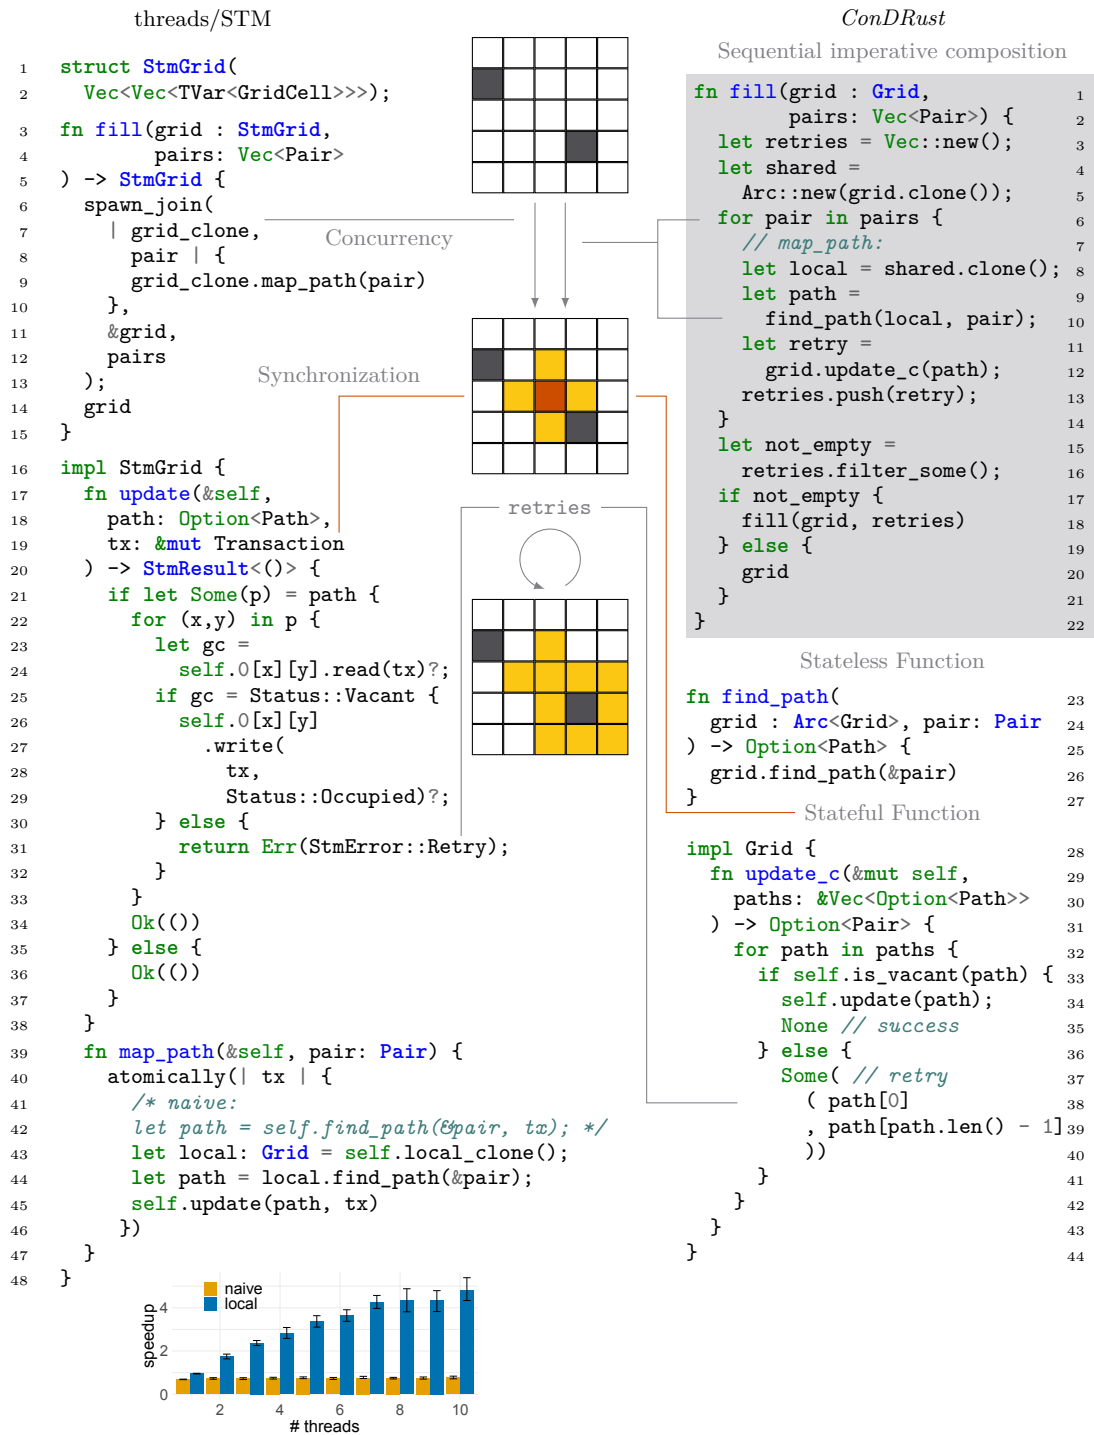

The threads/STM implementation in the left-hand column of Figure 4 starts with a re-definition of the grid data structure. Cells hold the state of the grid that the algorithm mutates and hence must be protected to prevent data races. Wrapping the cells into transactional variables (TVars) means that all grid methods need to be redefined for two reasons: First, accesses are now through the TVar. Second, each access needs a transaction which is an additional parameter to every grid method. That is the reason why all benchmarks in STAMP are implemented twice: with and without STM.

Concurrency is introduced in Line 7 of the Threads/STM implementation. We deliberately assume a higher-order function `spawn_join` to abstract from the verbose spawn-join pattern given in Figure 2. For every pair, the closure from Line 7–10 tries to map a path on the grid. The combination of the loop over the pairs and the closure’s `move` semantics for threads demand a clone of the grid for every loop iteration. The `update` method of the new `StmGrid` then tries to occupy the corresponding cells on the grid for a computed path. When a path cell is already occupied, a retry error (Line 30) aborts the transaction and triggers a retry.

For this particular example, the `map_path` method is particularly important for scalability reasons. The general structure of `map_path` is straightforward. It consists of a closure with the two steps of the algorithm (Lines 39–46): finding a path (Line 44) and updating the grid (Line 45). Line 39 places the closure onto a transaction. The key to scalability lies in the updates to the shared state. A naive implementation for `find_path`, as shown in the comment on Line 42, would operate directly on the grid (`StmGrid`) through the TVar (see Line 24). As a result, the transaction’s read set increases dramatically which leads to a much higher probability for collisions in `update`. A common pattern is thus to have the path-finding operate on a non-transactional clone of the grid (`local`). To illustrate the effect, the bar plot below the `map_path` function compares the scalability of the naive version to that of the optimized one.

The function `map_path` is representative of a common pattern found in irregular applications. The optimization described above requires the developer to find the maximal set of accesses that still preserves data-race freedom. This, in turn, requires carefully distinguishing the parts of the program that have side-effects on the state from the ones that are pure. Making this distinction explicit is a core idea behind the *ConDRust* programming model.

³ <https://github.com/Marthog/rust-stm>

■ **Figure 4** Introducing concurrency into the labyrinth benchmark adds collisions. The left column shows the implementation with threads and STM. The right column shows the imperative sequential *ConDRust* program.

3.2.2 *ConDRust*

The right-hand column in Figure 4 presents the *ConDRust* version of the labyrinth benchmark. We start with an informal introduction to the *ConDRust* programming model. We then explain how concurrency and synchronization arise naturally from a *ConDRust* program while preserving determinism and verifiability.

3.2.2.1 Programming model

A *ConDRust* program consists of three abstractions: *functions*, *stateless function calls* and *stateful function calls*.

► **Definition 1** (*ConDRust Functions*). A *ConDRust function* is a top-level function or an anonymous (lambda) function definition in the host language that the *ConDRust compiler* translates into a concurrent dataflow graph.

We highlight the *ConDRust* function for `fill` and `map_path` with a gray background. In the actual code base, the two functions would be located in a dedicated Rust module that is input to the *ConDRust* compiler. A *ConDRust* function may use control flow constructs of the host language, call other *ConDRust* functions or call stateless/stateful functions. We focus on loops because conditionals are rather unimportant when it comes to concurrency.

► **Definition 2** (*Stateless Function Call*). A *stateless function call* is a (host language) term of the form $f(t_1, \dots, t_n)$ where t_1, \dots, t_n are terms and f is a function symbol.

► **Definition 3** (*Stateful Function Call*). A *stateful function* is a (host language) term of the form $t_s.f(t_1, \dots, t_n)$ where t_s, t_1, \dots, t_n are terms and f is a function symbol.

Stateless functions such as `find_path` (Lines 23–27) represent pure computations to the *ConDRust* compiler. Stateful functions such as `update_c` (Lines 29–43) represent computations with side-effects to a particular state. The implementation of the stateless and stateful functions are outside the realm of the *ConDRust* compiler. That is, the developer may use the full set of the host language’s, i.e., Rust’s, features inside these functions without violating the stateless/stateful semantics.

The *ConDRust* programming model is general enough for embedding it into other languages such as Java or Python. But Rust is particularly well-suited because it allows to enforce state encapsulation via its type system. That is, the *ConDRust* compiler can reject programs with stateful function calls that return references to their state. Our Rust embedding does not support references as of now. Moving forward, we are interested in *ConDRust* in the context of share-nothing software architectures (e.g., serverless computing), where references do not exist. In the shared-memory context of this paper, the developer can either pass data by value or by reference using Rust’s `Arc`’s. In Section 4, we present the details of the type system for *ConDRust*.

3.2.2.2 Concurrency and synchronization

The *ConDRust* compiler translates the input program into a concurrent dataflow graph. In this graph, pipeline and task-level parallelism arise naturally from the data and control flow dependencies in the program. Our transformation, defined in Section 5, introduces data parallelism for stateless function calls inside loops. In the labyrinth benchmark, the `find_path` computation is a good candidate. It is located inside the loop of `fill` function and actually does not have side effects on the grid. But in the sequential version of Figure 3,

`find_path` is a method on the grid. To tell the *ConDRust* compiler that this computation is stateless, the developer turns the method into a stateless function (Lines 23–27). At Line 26, the stateless `find_path` function just wraps the `find_path` method on the `Grid` data type.

Note that the *ConDRust* version of `map_path` (right column, Lines 7–12) is almost identical to the STM/threads version (left column, Lines 38–46). At Line 8, the *ConDRust* compiler requires the developer to create a clone of the grid. State, in this case the `grid`, may only be used once inside a loop, i.e., the loop in `fill` at Lines 6–11. The *ConDRust* compiler forces the developer into the optimization that the STM/threads version needed to scale. As a consequence, the new `update_c` method on the `Grid` now needs to take collisions and retries into account. This is almost identical to the `StmGrid::update` method but is not based on a transaction for retrying. Instead, it returns the colliding pair at Lines 37–40.

After the loop, the remaining code in `fill` first filters the successfully mapped paths (Line 16) and then uses a (tail) recursion to retry the collisions. That is, the `fill` function explicitly defines the recursion that is implicit in the concept of a transaction. But the execution semantics is different.

3.2.2.3 Determinism

Transaction execution order in STM is non-deterministic but the generated dataflow program executes deterministically. The *ConDRust* program presented in the right-hand column of Figure 4 is a valid, i.e., well-typed, sequential Rust program. The Rust compiler translates this into a deterministically executing binary. The *ConDRust* compiler preserves the semantics of the program including the deterministic execution property. For the labyrinth benchmark, this boils down to the sequential order in which the stateful function `update_c` is called within the loop in `fill`. The *ConDRust* compiler preserves this order even though the paths are computed concurrently (in a data-parallel fashion).

In Section 5, we define a transformation to take advantage of amorphous data parallelism in irregular algorithms. This transformation produces code that limits the number of collisions, and thereby re-computations, for a single recursion round. To activate this transformation, the developer has to change the type of the input `pairs` from an ordered vector `Vec<Pair>` into a `HashSet` with deterministic iteration order. All of the transformations that we introduce in this paper preserve determinism and the semantics of the input program.

3.2.2.4 Verification

Semantic preservation allows the developer to apply and even formally verify further optimizations to the algorithm. The *ConDRust* version of the labyrinth benchmark is free of concurrency constructs. Kani fully supports `Arc`'s⁴. As such, the developer can formally verify properties of the *ConDRust* labyrinth implementation.

Zero-clone concurrent labyrinth. Note that both the threads/STM and the previously discussed *ConDRust* versions required cloning the state for scalability reasons. By cleverly using *ConDRust* and the underlying Rust semantics it is possible to avoid having to clone in the first place, while retaining determinism and verifiability. This is again a pattern that extends to other irregular applications.

The zero-clone implementation for concurrent path-finding is shown in Figure 5. For the reader's reference, the comments in the code contain the previous implementation from Figure 4. On the left-hand side, we restate the *ConDRust* version of the `fill` function from

⁴ <https://model-checking.github.io/kani/rust-feature-support.html>

```

1  fn fill(grid : Grid, pairs: Vec<Pair>) {
2      let /* retries */ paths = Vec::new();
3      let shared =
4          Arc::new(grid/* .clone() */);
5      for pair in pairs {
6          let local = shared.clone();
7          let path = find_path(local, pair);
8          /* let retry =
9              grid.update_c(path);
10             retries.push(retry); */
11         paths.push(path);
12     }
13     /* let not_empty =
14         retries.filter_some(); */
15     let (paths, grid) = unarc(paths, shared);
16     let (not_empty, retries) =
17         grid.updates(paths);
18     if not_empty {
19         fill(grid, retries)
20     } else {
21         grid
22     }
23 }

impl Grid {
1  fn updates(
2      &mut self,
3      paths: Vec<Option<Path>>
4  ) -> (bool, Vec<Pair>) {
5      let mut retries = Vec::new();
6      for path in paths {
7          let r = self.update_c(path);
8          retries.push(r)
9      }
10     let not_empty =
11         retries.filter_some();
12     (not_empty, retries)
13 }
14 }
15 }

fn unarc<S,T>(
16     s:S, t: Arc<T>
17 ) -> (S,T) {
18     match Arc::<T>::try_unwrap(t) {
19         Ok(t) => (s,t),
20         _ => panic!("Failed to unarc.")
21     }
22 }
23 }

```

■ **Figure 5** The `unarc` optimization provides a *ConDRust* version of the labyrinth benchmark that does not have to clone the grid.

Figure 4. We extracted the updates to the grid from Lines 8–9 to Lines 16–17 after the loop. This requires defining a new method (/stateful function) `updates` on the `Grid` that performs the loop over the computed paths. The corresponding code in the upper right part of Figure 5 also directly filters the retries. At this point, the key observation is that we can safely reuse the grid after the loop. At Line 4, `Arc::new` takes ownership of the grid. We had to clone the `grid` to use it inside the loop for updates and after the loop for the recursion. In the new version, the updates happen after the loop and the `find_path` actually takes ownership of the cloned `Arc` from Line 6. That is, when all path computations are done, we can safely take the `grid` out of the `Arc` again. This is what we specify at Line 15 and in the *ConDRust* version of Figure 4 at Line 24.

Figure 5 defines the stateless function `unarc` in the lower right part. The `unarc` function unpacks the `Arc`, its first argument, but leaves the second unchanged. We have to add a `panic` for the case where the `Arc` is still held elsewhere. But this is impossible by definition of Line 15. We verified this property and among the 422 reachable checks Kani reports:

```

Check 321: <std::vec::Vec<std::option::Option<benchs::Path>>
          as benchs::Unarc>::unarc.assertion.1
- Status: SUCCESS
- Description: "Failed to unarc."
- Location: src/benchs.rs:269:18
  in function <std::vec::Vec<std::option::Option<benchs::Path>>
          as benchs::Unarc>::unarc

```

Due to the semantic preserving transformations in *ConDRust*, this property also holds for the generated concurrent dataflow code.

Terms $t ::= x \mid v \mid |x : T| \rightarrow T \{ t \} \mid t(t) \mid \mathbf{let} \ x : T = t; t \mid \mathbf{let \ mut} \ x : T = t; t \mid$
 $\mathbf{f}_{\text{SL}}(t_1) \mid t_s.\mathbf{f}_{\text{SF}}(t_1) \mid \mathbf{for} \ x \ \mathbf{in} \ t \{ t \} \mid \mathbf{trfix} \ t \ t$
 Values $v ::= l \mid v_{\text{Ⓢ}} \mid |x : T| \rightarrow T \{ t \}$

■ **Figure 6** Syntactical constructs of Ⓢ_s .

Note that this `unarc` optimization is only necessary because the compiler presented in this paper does not support references. Support for references is future work but will remove such optimizations from the code and move them into the compiler. In the meantime, the developer can formally verify such optimizations with existing tools such as Kani.

4 Ⓢ_s – A subset of Rust for sequential composition

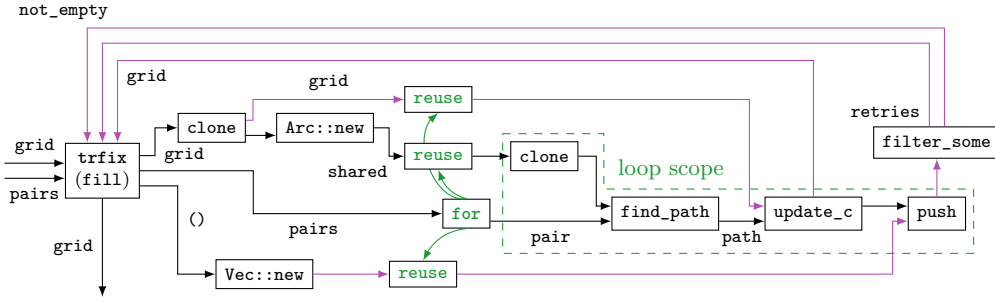

In this section, we formally specify Ⓢ_s , the subset of the Rust language that embeds the *ConDRust* programming model. Since Ⓢ_s is a subset of Rust, the operational semantics are the same as for Rust. Therefore, we restrict the presentation to the syntactical constructs. The appendix defines the type system and the operational semantics for the interested reader.

ConDRust supports the subset of Rust’s syntax that is necessary to compose calls to stateless and stateful functions (also called methods). We define this subset in Figure 6 as Ⓢ_s – a subset of Rust for sequential composition. For this paper, we restrict the terms of the language to variables x , abstractions (closures in Rust) $|x : T| \rightarrow T \{ t \}$, algorithm application $t(t)$, immutable and mutable bindings, `for`-loops and tail-recursion (`trfix`). We restrict the definition of Ⓢ_s in the following (common) ways:

1. Abstractions and calls may only have a single parameter. The extension to support multiple parameters is straightforward.
2. We desugar top-level algorithm definitions into `let`-bound closures such that a top-level defined function can be used in multiple locations of succeeding function definitions.

The key ingredient in *ConDRust*’s programming model are *stateless function calls* $\mathbf{f}_{\text{SL}}(t_1)$ and *stateful function calls* $t_s.\mathbf{f}_{\text{SF}}(t_1)$.⁵ The definition of stateless and stateful functions is not part of Ⓢ_s , as discussed before. Inside these functions, developers re-gain the full features of Rust. We further restrict control flow to loops and tail recursion leaving out other forms such as conditionals that play only a minor role in the parallel execution of a program. In Section 5 and in our implementation, loops may in fact iterate over all data types that implement Rust’s `Iterator` trait which for instance includes `HashSet`. This allows the developer to specify that the loop does not depend on a particular order and enables our second transformation that extracts amorphous data parallelism. To model this in Ⓢ_s , we assume a stateless function that uses the iterator to collect the items into a list before looping over them. In fact, `collect` is a standard function of Rust’s `Iterator`. We allow loops with an unknown iteration count via tail recursion. Tail recursion is a derived form. Precise definitions with their restrictions on variable usage are in the appendix. In the context of this paper, we are particularly interested in the case where the arguments to the recursion are a state to be updated and a worklist that triggers these updates.

⁵ We allow *ConDRust* algorithms to be called from anywhere in a Rust program. Such a call may have arguments.

■ **Figure 7** *ConDRust* dataflow graph for the (unoptimized) labyrinth code listed in Figure 4. The graph contains *state arcs* that transfer state into and out of the *loop scope*. The *for* and *reuse* nodes make sure that processing inside the loop is well-balanced, i.e., does not get stuck.

$$\begin{array}{ll}

■ **Figure 8** Transformation of an imperative program into a functional one based on state threads.

Limitations. Currently, $\textcircled{\text{S}}$ does not include include references and in particular borrowing. The support for references and their translation into dataflow is interesting future work.

5 Compiling *ConDRust* algorithms to dataflow

In this section, we describe the main steps in *ConDRust* compilation from an imperative algorithm to a dataflow graph. The dataflow representation of the program is not the usual program dependence graph that is used in classic compilers such as LLVM for dataflow analyses. The dataflow graph that *ConDRust* targets is a runtime representation and parallel execution model of a program. Dataflow runtimes are the foundation for scalable database engines, data streaming for embedded systems and data analytics [38, 23, 27, 58]. This dataflow model is a perfect fit for such systems because it makes parallelism explicit in the graph. In this section, we focus primarily on the 3 forms: task-level, pipeline and data parallelism. We start with the translation of algorithms into dataflow and present the dataflow representation informally to define our transformations for data parallelism. In Section 6, we formally specify the semantics of the dataflow graph construction and execution as part of *ConDRust*'s code generation process.

5.1 From sequential-imperative to parallel-functional dataflow

ConDRust's programming model with its restrictions on variable usage enable the compiler to translate a $\textcircled{\text{S}}$ program into a dataflow graph that exposes pipeline and task-level parallelism while preserving the program's semantics. This translation encompasses two steps that we

define in Figure 8. In the first step, *ConDRust* translates an algorithm in \mathbb{E}_s into applicative normal (ANF) form. In \downarrow_{ST} , every call to a stateful function becomes a *state thread (ST)*: **let** $(x'_s, x) = x_s.f(x_1)$. The state x'_s is the updated state after the call. To make sure that succeeding stateful function calls on x_s operate on the new state x'_s , we substitute x_s with x'_s in t . In the second step, the compiler removes the global notion of imperative state and effectively transforms the program into a functional one. This transformation relies on the notion of state threads [35, 56, 25]. \uparrow^{STL} turns every loop into a state thread, i.e., a *state-threading loop (STL)*. The resulting states of a loop are all states of the state threads inside the loop. We restrict the definition to a single state x'_s for brevity. \downarrow_{ST} rewrites the term before recursing into the subterms. To handle nested loops, \uparrow^{STL} recurses into the subterms first and rewrites the current term with the already rewritten subterms.

From this functional program representation, the *ConDRust* compiler translates stateless and stateful calls into nodes. Data dependencies become arcs that transfer data values in FIFO order. We denote the different types of nodes in a *ConDRust* dataflow graph as follows:

$$n ::= \boxed{f_{\text{SL}}} \mid \boxed{f_{\text{SF}}} \mid \boxed{\text{for}} \mid \boxed{\text{reuse}} \mid \boxed{\text{trfix}}$$

The first two node types execute calls to stateless and stateful functions respectively. In order to perform a call, a node needs to retrieve a data value from each of its incoming arcs and emits the result of the call to its outgoing arc before the next call is constructed. Stateful nodes additionally emit their updated state via a dedicated outgoing arc.

ConDRust translates loops and tail recursions directly into dedicated dataflow nodes. The **for** node streams the elements of the vector into its outgoing arc. The **trfix** node ties the knot of the recursion. Both language constructs, loops and tail recursion, open a new contextual scope, i.e., a subgraph. For tail recursion, this subgraph is closed such that the only way for data to enter and leave the graph is the **trfix** node. For loops, data enters the subgraph via **for** and **reuse** nodes and leaves it via a stateful function call node.

The dataflow construction is best explained on the dataflow graph for the labyrinth benchmark, shown in Figure 7. *ConDRust* generated this graph from the \mathbb{E}_s specification on the right of Figure 4. Data that enters the loop subgraph via the **for** node *drives* the computation. State variables entering the loop body are **retries** and **grid**. The corresponding arcs are gated by **reuse** nodes that receive the data entering the loop. The **reuse** node attaches a reuse count n where n is the number of loop iterations, i.e., elements in the vector of pairs. Function call nodes with such a reuse count as input reuse the data values for n calls.

Task-level and pipeline parallelism

Task-parallelism automatically arises whenever nodes are (data) independent of each other, such as for example the **clone** node and the **Vec::new** node. The **for** node introduces pipeline parallelism between all data dependent nodes in the loop scope subgraph. As such the computation of the path for the third pair can already start while at the same time, the grid is updated with the found path for the second pair and the result of the first computed path is pushed onto **retries**, the result vector.

Task-level and pipeline parallelism fall out naturally from a dataflow representation of a program, but they are insufficient to compete with a threads/STM-based program. This is because exploiting data parallelism is key for scalability. Almost all programs in shared memory benchmark suites such as STAMP and PARSEC contain some data-parallel part [41, 8]. Apart from data parallelism, scalability in threads/STM implementations also depends on the retry overhead introduced by the STM in case of collisions.

■ **Figure 9** Data parallelism inside a dataflow graph.

5.2 Dynamic data parallelism in a static dataflow

Data parallelism arises from an implicit (in-)dependence between the same stateless function call across loop iterations. As such, every stateless function call inside a loop is an opportunity for data parallelism. The `find_path` call in the labyrinth algorithm is an example of this. But introducing data parallelism into a static dataflow graph as shown in Figure 9a may lead to suboptimal performance. This is especially the case when the n nodes $f_{SL}^1 \dots f_{SL}^n$ feature different computation times for different input values. For example, `find_path` executes the same code but some pairs are more difficult to connect than others. As such the deterministic merge in the `collect` node stalls, waiting for straggling work [26]. This stalling does not occur in the threads/STM execution because STM does not enforce a deterministic order.

The performance problems of static work assignments are well known. This motivated Cilk’s dynamic dataflow model (fork/join) and its work-stealing runtime scheduler [11]. To mitigate these problems without sacrificing determinism, we integrate dynamic dataflow into our static dataflow graph. In a dynamic dataflow graph, nodes are created at runtime. A node executes a task, i.e., a stateless function call, that gets *spawned* (*forked*) on demand and executes once. Spawning a task creates a handle to its *future value*, i.e., the result of the stateless function call. This handle provides a `get` method to *join* the forked task with the spawning task by blocking until the call completed and the result is available. In Rust, the API for futures is equivalent to `thread spawn` and `join` as presented in the thread/STM version in Section 3. Tasks are processed by a pool of threads, as in Cilk. Whenever a thread is idling, it may steal tasks from other threads to reduce idle time. In the case of the labyrinth benchmark, a thread that already finished its path computation may steal queued path computations from a thread with a long-running path computation.

Determinism. The transformation in Figure 9b integrates dynamic dataflow to data-parallelize nodes with stateless function calls and uses the static dataflow to preserve the data value order, i.e, determinism and the semantics of the algorithm. Instead of replicating the stateless function call f_{SL} node, we lift it into a `spawn<fSL>` node. For every received input, when normally a stateless function call would be executed, the `spawn<fSL>` node submits this computation as a task to a work-stealing runtime system and emits the corresponding *future*. The downstream `get` node retrieves the value from the future. No reordering takes place because both `spawn<fSL>` and `get` are stateless function call nodes in the static dataflow graph connected via a FIFO channel.

5.3 Amorphous data parallelism

The (data) parallelism in threads/STM-based programs is implicitly affected by two aspects: the available compute cores of the system and the operating system scheduler. Both impact the number of collisions. Our amorphous data parallelism transformation makes these implicit

effects explicit in the dataflow graph and exposes a knob to fine-tune runtime performance at compile-time. We first explain how the implicit effects influence the performance of threads/STM vs. *ConDRust* programs. Then we describe our transformation.

The implicit cap in threads/STM

In the *ConDRust*-based version of the labyrinth algorithm, the number of collisions per round is capped by n , the number of input **pairs**. In the worst case, $n - 1$ paths need to be recomputed. This is independent of whether the algorithm executes sequentially or is compiled into a dataflow graph for concurrent and parallel execution. Although the STM-based version spawns the same n threads/computations, it is unlikely for this implementation to hit this upper bound. For example, when we input 256 pairs then 256 threads race for updating the grid. In a system with 24 cores, the operating system scheduler will delay the execution of most of the threads. Putting concurrency aside for easier analysis, the first “round” would consist of 24 threads, of which at most 23 would collide. We refer to this bound as *collision limit*. The limit defines how many computations will see an outdated **grid**, i.e., shared data structure, and could thus lead to collisions. In the case of the *ConDRust* version, the algorithm defines the limit to be 256, i.e., all pairs, (for the first round) which translates into the worst case collision count of 255.

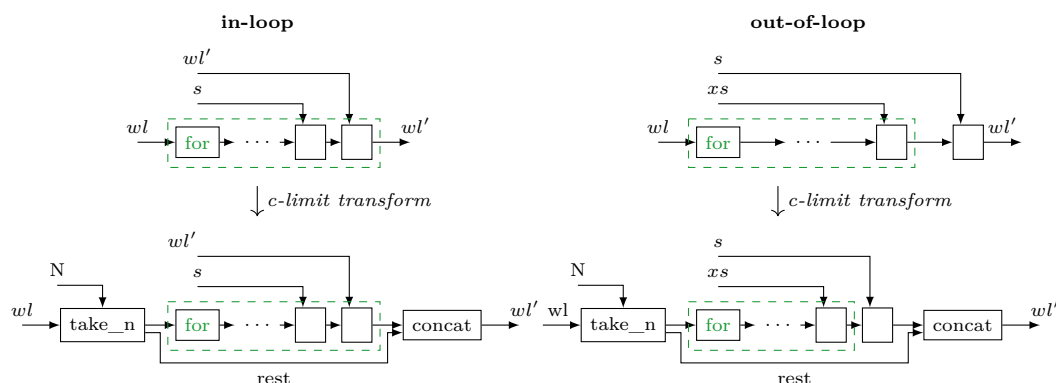

Setting a cap into irregular *ConDRust* algorithms

To compete with STM implementations, the *ConDRust* programming model makes the cap on the collision limit explicit in the algorithm. We do so by automatically transforming the algorithmic skeleton used across irregular applications to update state. As exemplified by the labyrinth benchmark, irregular applications (tail-)recurse over a worklist wl to evolve a complex data structure, i.e., a state s . In the benchmark, the worklist updates the grid.

The transformation is shown in Figure 10. To make sure it preserves the semantics, the worklist wl must be of type **Set**, i.e., the developer has to explicitly specify that there is no particular order for the elements of the worklist. The transformation distinguishes two different structures. In the *in-loop* version, the state s is updated inside the loop. The unoptimized *ConDRust* version of the labyrinth benchmark from Figure 4 is an example of this. In the *out-of-loop* version, the state update occurs at some point after the loop. This structure occurs in the **unarc** version of the *ConDRust* labyrinth implementation presented in Figure 5. In both cases, the **take_n**-node extracts the first N data items from the worklist wl and concatenates the *rest* with the recomputations *after* s was updated. Now, the compiler can optimize the parameter N , something that is not possible for threads/STM programs. N is an interesting target for further research in compiler optimization.

Determinism. Even though this transformation relies on the developer specifying that the worklist is a set, it preserves a deterministic execution. This holds as long as the set implements a deterministic iteration order when the same elements are inserted. For example, in Rust, several libraries exist that provide this property to hash set and hash map implementations.⁶ Intuitively speaking, when the worklist is a set then the algorithm is independent of a particular iteration order. Our transformation essentially picks one of these orders at compile time. But when the generated program is executed then it will always be the same deterministic order that the worklist is being processed.

6 Ⓜ_p — A subset of Rust for parallel composition

With the transformations in place, we now formally specify the backend of the *ConDRust* compiler. We present the syntactic constructs for Ⓜ_p — a subset of Rust for parallel composition, that the *ConDRust* compiler targets in Figure 11. Ⓜ_p terms basically consist of two parts:

Graph construction An arc is a channel (c) in Rust’s message-passing terminology and we define n , i.e., a term for each type of node in the dataflow graph.

Graph execution We abstract over an explicit implementation of a scheduler for a dataflow graph with a single `run` construct.

For the construction, we abstract over a concrete channel implementation. All we rely upon is the FIFO ordering property. Composition of nodes via arcs works solely via variable bindings. For example, the term in Figure 12 constructs a graph with a single (stateless) identity function (`idSL`) call node. For execution, we pass the receiving endpoint `result` and the list of nodes to `run` which executes the graph and reduces to the final result.

```
let src : Recv<i32>      = chan(5);
let (result : Recv<i32>,
    out : Send<i32>)    = chan();
run(result, (NSL(idSL, src, out) ~: [ ]))
```

■ **Figure 12** A Ⓜ_p program with a single identity node and the corresponding dataflow graph.

```
let (out, result) = std::sync::mpsc::channel();
let mut nodes = Vec::new();
nodes.push(Box::new(move || -> _ {
  let x = id(5);
  out.send(x)?;
  Ok(())
}));
run(nodes);
result.recv()?;
```

■ **Figure 13** The generated code for the graph of Figure 12.

We assume a type `Node` for nodes and align our specification for channels closely with `std::mpsc::channel` from Rust’s standard library where `Receiver<T>` and `Sender<T>` represent the receiving and the sending endpoint of a channel, respectively. In our encoding, the types `Recv<T>` and `Send<T>` are reference types (in T_{ref}) for locations l in the store μ , i.e., channels are values in the store. The types T , the context Γ (without usage tracking), the store μ , the store typing Σ and the environment Δ follow the specification in TS_s . The appendix has the complete definition of the syntax, the operational semantics of TS_p and a sketch of the proof for determinism. Informally, dataflow graphs in TS_p are essentially Kahn Process Networks (KPN) [31]. KPNs execute deterministically because incoming arcs have blocking semantics⁷ and the executed code of the node is scott-continuous. Our evaluation relation adheres to both of these properties.

7 Implementation

The current prototype of *ConDRust* comes with batteries included. No need for the developer to provide any specific implementations for channels, nodes or even a scheduler. *ConDRust* is currently implemented in 20K lines of Haskell code and takes advantage of existing language parsers with defined abstract syntax tree data structures for Rust⁸. Our implementation slightly diverges from the formal description of TS_p in terms of the `reuse` nodes. The *ConDRust* compiler implementation contains additional transformations in the backend to fuse `reuse` nodes with their downstream neighbours into a single node. That way we do not have to define reuse and non-reuse versions of all the nodes. Otherwise, our backend generates code that closely aligns with the formalization in Section 6. Figure 13 presents the generated code for the single-id-node graph of Figure 12. The *ConDRust* compiler does not create source channels but inlines values directly into the corresponding nodes. The generated Rust code uses Rust’s channels from the standard library and creates a closure for each of the nodes in the dataflow graph. The code generator moves the channels into the closure of the node such as for example `out`, the sending endpoint of the channel for the final result. The `run` function just spawns a thread for each of the nodes and rejoins them, just as in the threads/STM code of Figure 2. For the dynamic dataflow part, the compiler generates code that uses the `tokio` runtime which provides a work-stealing scheduler.⁹ *Our compiler generates safe Rust code and as such the Rust compiler verifies the absence of data races.*

Limitations. Our current implementation does not yet fully implement the type system that we formally specified in Section 4. In particular, we did not yet rigorously implement the guard for amorphous data parallelism transformation that checks whether the worklist is indeed a (hash) set. This is not due to a fundamental restriction. We believe that implementing this is straightforward and thus focused on more challenging aspects, such as implementing the transformations and code generation.

8 Evaluation

We evaluate *ConDRust* on benchmarks from 3 different benchmark suites. Our selected benchmarks cover a broad spectrum ranging from stateless to irregular algorithms. In our evaluation, we seek to answer the following questions:

⁷ Blocking semantics prevent the construction of a non-deterministic merge node, the explicit notion of non-determinism in dataflow [2].

■ **Figure 14** Benchmark description.

1. Is the *ConDRust* programming model expressive enough for a broad range of applications?
2. What is the effort to translate the sequential benchmark code to *ConDRust* code? (Appendix Section A.2 has a first comparison of the effort to convert sequential programs into threads/STM programs and *ConDRust* programs.)
3. Can the *deterministic* code, that the *ConDRust* compiler generates, deliver performance that is on par with the *non-deterministic* threads/STM-based code?
4. What is the effect of the amorphous data parallelism transformation from Section 5.3?

Benchmarks. Figure 14 summarizes the benchmarks used in our evaluation. We selected 7 benchmarks from 3 different benchmark suites: STAMP [41], PARSEC [8], and YCSB [19]. STAMP is a benchmark suite intended to investigate the performance of software and hardware transactional memory implementations. Benchmarks in STAMP basically fall into two categories: (1) Algorithms where most of the execution time is spent inside transactions and (2) algorithms with very small transactions. Transaction size directly correlates to the amount of computation that depends on the global state structure. We selected several benchmarks from both categories. Labyrinth, Intruder and Genome fall into the first category, K-Means is located in the second. K-Means clustering spends only 7% of the execution time inside transactions. No other STAMP benchmark spends fewer cycles inside transactions. Labyrinth is one of the 3 benchmarks in STAMP that spend nearly 100% of their execution time inside lengthy transactions. It is also one of 2 STAMP benchmarks with an irregular algorithmic structure. The other benchmarks in STAMP have similar characteristics to the ones that we selected [41]. SSCA2 has characteristics similar to K-Means while Yada (Delaunay Mesh Refinement) and Bayes are similar to Labyrinth. Vacation is similar to Genome. Vacation simulates database transactions with STM which is not possible in real-world database systems where transactions involve network I/O between the client and the database server. For a more realistic setting with I/O, we chose YCSB, the state-of-the-art benchmark for key-value stores. We selected 2 more benchmarks, Canneal and BlackScholes, from PARSEC that both fall into the second category with small transactions. Canneal performs simulated annealing and is also irregular. Transactions in Canneal are short but the overall time spent inside transactions is about 70%. BlackScholes is the baseline for linear scalability. Overall our benchmark set consists of ca. 12k lines of Rust code.

Setup. Our experiments ran on an Intel Core i9-10900K CPU with 3.70 GHz, 32 GB RAM and 20 hardware threads, i.e., 10 cores and 10 hyperthreads. The operating system was Ubuntu version 20.04. We used the latest `rust-stm` version 0.4.0 and extended it to support deterministic transactions [49]. We executed each experiment 30 times and report the mean.

■ **Figure 15** Speedup comparison of threads/DSTM, threads/STM and *ConDRust* across different benchmarks. Baseline is the sequential version.

Whenever possible, we used the data sets of the original benchmarks. Otherwise, we ported the data generation too. Appendix Section A has the input configurations.

Metrics. For our experiments, we ported the C/C++ reference implementations from STAMP and PARSEC to safe Rust. For each benchmark, we created 4 versions:

sequential a sequential baseline implementation,

threads/DSTM a concurrent version based on threads and DSTM, and

threads/STM a concurrent version based on threads and STM,

ConDRust a *ConDRust* version.

Benchmarks in STAMP, PARSEC and other benchmark suites (such as Lonestar for Galois programs [32]) for concurrent programming do not address the problem of finding the best granularity of work to place onto a thread. The benchmark code explicitly splits work into chunks and the size of these chunks is determined by the number of parallel threads. We follow this principle because *ConDRust* does not address the thread granularity problem either. For the STAMP and PARSEC benchmarks, we report the speedup over the sequential baseline. For the YCSB benchmark, we measure throughput.

Since we are particularly interested in the exploitation of data parallelism, we vary the *number of data parallel cores*. This is the natural metric for these applications and their respective threads/STM implementations. For the *ConDRust* versions, there are more threads because every dataflow node is assigned its own thread and we vary the number available threads for the dynamic part of the dataflow graph. Although *ConDRust* executes deterministically, we expect *ConDRust* programs to have performance that is on par with the threads/STM version if the collision-limit is tuned properly. For this reason, we explore different values of the limit and compare with the threads/STM performance. Auto-tuning approaches or heuristics can be used in the future to automatically tune the collision-limit.

8.1 Benchmark study

Figure 15 shows the overview of our benchmark study. For BlackScholes, K-means clustering, Labyrinth, and Canneal, the deterministic *ConDRust* programs outperform even the non-deterministic threads/STM counterparts. Benchmarks for genome sequencing and intrusion detection exploit data parallelism that *ConDRust* cannot yet exploit. In all of these benchmarks, DSTM synchronization delivers poor performance. In the following, we analyze the benchmark results from left to right and present further details. We add features one at a time. We start with dynamic data parallelism, then investigate irregular algorithms and then turn to *ConDRust*'s limitations. Afterwards, we case study a key-value store.

Dynamic data parallelism

The first benchmark is BlackScholes, a bulk data parallel workload. We present two versions. The first version is most intuitive. It creates vectors for the results on-demand and joins these vectors into a single result vector. That is, memory allocation is interspersed with the computation of stock options that does not require a shared data structure. This final result vector is shared state that requires synchronization. The second version pre-allocates all memory. This is the version that is most commonly used in the literature [16].

In the experiment of Figure 15, we used the intuitive benchmark version and naively opted for DSTM and STM to do the synchronization. The single-threaded *ConDRust* version completed the calculation of 40M stock options in 650 ms. The DSTM/STM versions timed out after 10 minutes. This shows that protecting a data structure blindly with STM is not really a practical solution. Efficient transactions have to be fine-grained and as such require a re-implementation of the data structure. That is why STAMP includes several dedicated STM-based data structure implementations.

To be fair, we also compared the *ConDRust* version against 3 more versions. The first version (T+lock) uses a lock instead of a transaction to protect the data structure. Figure 16 shows that this version does finish but features poor performance. Protecting large data structures with locks is no option either, and thus fine-grained locking is required. To explore this, we use an available implementation of a concurrent queue. But even this T+ConcQueue version does not scale well either. Finally, in Rust, threads are implemented as futures, i.e., when joined, they return a result of the computation on the thread. Figure 16 shows that only futures deliver performance comparable with the dataflows that *ConDRust* generates.

We also evaluated the second version of the benchmark that pre-allocates the memory. The *ConDRust* and futures versions both pre-allocate the individual result vectors for the parallel computations. To avoid the memory-allocations and copies to produce a single flat result vector, these version return a vector with the nested individual result vectors, i.e., a vector of vectors. We also created a futures (unsafe) version that mimics exactly the C version of PARSEC. That is, it pre-allocates the result vector and passes ranges to the individual computations where the results can be written to. In safe Rust, we did not find a way to tell the borrow checker that these ranges do not overlap and data races cannot occur. Hence, we had to introduce unsafe code. The results in Figure 17 show that the *ConDRust* version benefits from pre-allocating memory but is not yet on par with the futures versions. This is due to the fact that the computations are rather small such that additional runtime overhead of the concurrent *ConDRust* code becomes visible. We are certain that optimizations are possible that reduce this runtime overhead further.

K-means clustering is the first recursive algorithm with state. The K-means plot in Figure 15 shows that scalability of deterministic *ConDRust* programs is on par with the non-deterministic threads/STM counterparts.

Amorphous data parallelism

Labyrinth and Canneal are irregular applications. The plots in Figure 15 show that *ConDRust* generates programs that even outperform the threads/STM versions. This is because costly synchronization overhead is not present in the generated dataflow programs. In both benchmarks, we used the `unarc` optimization from Section 3 to avoid state cloning. *ConDRust* performed both transformations from Section 5, for dynamic data parallelism and amorphous data parallelism. To gain insights into the algorithm structure and the effects of these transformations, we perform further analyses.

■ **Figure 16** BlackScholes with memory allocation.

■ **Figure 17** BlackScholes without memory allocation.

■ **Figure 18** In-loop vs. out-of-loop state updates.

State update placement. We study the effect of placing the update to the state inside or outside the loop that iterates the worklist (Section 5.3), with results shown in Figure 18. The in-loop version has the update to the state inside the loop. Respectively, the generated dataflow combines data parallel computations with pipeline parallel state update. The outside-loop version performs the state update only after the loop when all computations have been computed. Pipeline parallelism does not arise but the algorithm can leverage the `unarc` optimization from Section 3 for a zero-clone version. The results show that pipeline parallelism does not really lead to speedups on either of the two benchmarks. In the case of labyrinth, both versions have the same performance and for canneal, the in-loop version does not scale at all. Pipeline parallelism only pays off when pipeline stages are balanced. This is not the case for both benchmarks where the first stage computes while the second stage only updates. The results also show that the performance of the Labyrinth benchmark is not sensitive to the update placement. This is mainly because of the low overhead incurred in cloning the state of the labyrinth. Canneal has a much larger state which explains the bad scalability of the in-loop update.

Collision-limit. To study the effect of the amorphous data parallelism transformation in *ConDRust*, we compiled both benchmarks once with and once without this transformation. Figure 19 shows that the amorphous data parallelism has no effect on the performance of Canneal but has a big impact on the performance of Labyrinth. The plots in Figure 20 vary the collision-limit (*c-limit*) as a multiple of the thread count such that work distributes evenly across the data parallel workers (i.e., threads). The right-most bars in the plots show the performance without amorphous data parallelism. In Canneal (re-)computation is cheap and the state large. Setting a low collision limit just prevents data parallelism to take full effect. In Labyrinth, finding a path is expensive and so are re-computations. As such, the collision-limit for optimal performance is only a small multiple of the thread count. With our optimization, the compiler can tune performance along these complexity coordinates: state size and (re-)computation complexity.

Threads/STM. For the Canneal benchmark, the *ConDRust* version in Figure 15 even greatly outperforms the threads/STM version. In fact, the threads/STM version for Canneal does not scale at all. This is due to the characteristics of the algorithm. The workload issues tens to hundreds of thousands of rather *short* transactions which makes the STM overheads a dominating factor. This is not the case in the Labyrinth benchmark where long-running transactions outweigh their overhead.

Figure 19 Amorphous.

Figure 20 Collision-limit effects.

Figure 21 Throughput comparison for the key-value store implementations.

8.2 Beyond data parallelism

For Intruder and Genome, *ConDRust* fails to extract the data parallelism. Both benchmarks operate on a partitionable state structure. Intruder uses a hash map to reassemble network packets. Similarly, Genome uses a hash map to assemble and deduplicate genome sequences. The computation is stateful but operates only on a local part of the structure, for example, a bucket in the hash map. Deriving parallelism from extended knowledge about the state type and its structure is an interesting future research direction.

Conclusions. Overall, from the results in Figure 15 and our detailed analysis in Figures 16–20, we conclude that *ConDRust* generates dataflow programs that scale for certain application classes. The generated code executes deterministically while the sequential input programs remain verifiable. We managed to implement several benchmarks which establishes confidence that the programming model is expressive for a broad range of applications. Stateful functions with local effects on the state, as well as platforms with heterogeneous hardware [45] are an interesting future research direction.

8.3 Case study: Key-value store

For the YCSB benchmark, we populated the key-value store with 10,000 entries and configured a load of 30,000 operations, executed by 8 threads in parallel. We ran 3 configurations: (1) a write-heavy configuration with 50% reads and 50% writes, (2) a cloud-typical configuration

with mostly reads (95%) and (3) a read-only configuration. Figure 21 presents the throughput results for the key-value store implementations. In addition to the threads/(D)STM versions, we add another version called threads/(D)STM++. The threads/(D)STM++ version uses additional atomic-read instructions for read operations. We provide this implementation for fairness reasons because the threads/(D)STM version does not scale at all. This is due to the fact that the benchmark essentially just queries the data structure or updates it, with no substantial computation. Hence, the load creates a lot of accesses to the data structure, similar to Canneal. Even worse, STM clones the read value to provide an isolated private view on the read data. In the case of the key-value store, that data is essentially the entire underlying hash map. The atomic-read operations prevent this effect.

Even compared against the threads/(D)STM++ optimized version, the *ConDRust* generated code scales better in the write-heavy configuration and is almost on par with threads/STM++ in the cloud-typical configuration. Naturally, threads/(D)STM++ performs better when there are only reads. The *ConDRust* key-value store implementation cannot extract the parallelism from partitioning the hash map of the key-value store, similar to the Intruder and Genome benchmarks. The takeaway of this experiment is that the developer can write simple sequential code and the *ConDRust* compiler provides speedups that are on par with fine-tuned threads/STM implementations, while preserving determinism.

9 Related work

Various approaches exist to make concurrent programming deterministic but they either are not expressive enough or target functional rather than imperative programs. Language extensions such as the effect (type) system proposed by the Deterministic Parallel Java (DPJ) project primarily focus on proving the deterministic guarantees and providing these to the developer in the most non invasive way [13]. The DPJ authors conclude: “[...] *studying a wide range of realistic parallel algorithms has shown us that some significantly more powerful capabilities are needed for such algorithms.*” NESL is a functional language with the well-known higher-order functions `map` and `reduce` to parallelize stateless applications [9]. MapReduce is the programming model that has seen popularity for the very same reasons but has fallen from grace due to its limited expressivity, i.e., no states, no variables, no loops etc. None of the approaches derives scalable concurrency straight from imperative sequential programs that can be formally verified. The closest in spirit is MOLD, a tool that translates sequential imperative Java programs into MapReduce programs [46]. But MOLD does neither define a precise subset that it can translate nor reasons about verifiability or determinism of the compiled program.

Deterministic parallelism is a well-studied area but so far no approach could provide on-par performance with non-deterministic executions. To provide deterministic parallelism in MapReduce, the developer has to make sure that the function passed as an argument to `reduce` is associative and commutative. Commutativity also plays a key role in revisions, an extension to NESL’s programming model to support shared state [10]. In this case, the developer has to provide a commutative function that is used at runtime to acquire a lock on a data value. Programming-wise, this shares similarities to programming lattice-based data structures [33]. Semantic-wise, the execution of revisions is the same as for software transactions which underpin most of the runtime approaches for deterministic parallelism in one form or the other. Notable examples include deterministic Galois [42], DeSTM [49] and LiTM [57]. Even CoreDet, the only fully compiler-based approach, uses the notion of a transaction and a barrier to synchronize threads and enforce a deterministic commit

order [7]. DMP, CoreDet’s predecessor, fully relied on software transactions which did not scale because the transactions became too large [22]. CoreDet relied on hardware transactions, but implementations of these turned out to support only very small transactions and were even disabled again from Intel processors because their inherent complexity allowed various side-channel attacks [24, 18, 34]. *ConDRust* requires no additional commutativity properties nor specialized hardware. Nevertheless, we do acknowledge that performance could certainly benefit from properties such as associativity and commutativity.

We are not the first to recognize the benefits of dynamic task scheduling and the collision limit for irregular applications. However, we are the first to build atop a dataflow runtime and are not aware of a compiler with explicit transformations for these key performance concepts. Higher-level abstractions for data parallelism often build upon dynamic dataflow constructs such as Cilk’s fork/join primitives [11]. Examples include Galois collections and the parallel loops in the style of NESL in the revisions programming framework. All other approaches, use threads to let the operating system schedule operations. Similar to our collision limit, the authors of revisions perform rounds of computations in batches to bound the number of computations per round [10]. LiTM implements revisions as simple transactions and the internal algorithm that executes these transactions is almost identical to the result of the in-loop state update transformation to limit the collisions per round in Figure 10 [57]. But LiTM again inherits all the overhead that is connected with an STM implementation such as maintaining read/write sets and lock tables. *ConDRust* does not incur such overheads because there are no data races in the generated dataflow programs and as such no synchronization is required.

10 Conclusion and Future Work

We presented *ConDRust*, a new programming model and compiler to translate verifiable sequential imperative Rust programs into scalable concurrent ones. The developer can use existing tools such as Kani to formally verify the sequential program. For scalable concurrency, the *ConDRust* compiler translates the sequential composition into a concurrent one based on threads and message-passing channels. Our compiler design fosters semantic-preserving transformations that preserve interesting properties such as determinism. In our evaluation, the *ConDRust* compiler generated code that even outperformed non-deterministic concurrent programs. Our compiler is aware of stateful calls and serializes them without costly synchronization. This benefit is big enough to outweigh the cost of enforcing a particular deterministic order even for stateful irregular applications that are notoriously hard to parallelize. Our results motivate the following interesting directions for future work:

Semantic preservation In this paper, we argued only informally that our compiler transformations preserve the semantics of the input program. Nevertheless, the described transformations can serve as the foundation for a formally-verified version of our compiler.

References \oplus_s , the subset for sequential imperative composition, presented in this paper, does not include references. The developer has to use runtime-checked reference implementations (**Arcs**) and according optimizations such as the **unarc** optimization from Section 3. Adding references to \oplus_s is certainly an interesting future research direction.

Partitioned state A limitation of our programming model so far is the missing notion of functions that operate on disjoint parts of a state structure. Performance for such algorithms is not on par with their concurrent counterparts. What is a sufficient encoding of partitioned state in \oplus_s ?

A Evaluation

This section provides the details for our evaluation. We list configuration parameters and afterwards show code metrics to compare the threads/STM programs with the *ConDRust* programs.

A.1 Configurations

Benchmark	Arguments
BlackScholes	in_40M.txt
K-Means	-n 40 -t 0.00001 random-n65536-d32-c16.txt
Labyrinth	random-x512-y512-z7-n512.txt
Canneal	-swaps 15000 -t 2000 -m 128 400000.nets
Intruder	-a 10 -l 16 -n 4096 -s 1
Genome	-g 16384 -s 64 -n 16777216
YCSB	kv-store size = 10,000 records, operation count: 30,000

■ **Figure 22** Benchmark parameters and inputs.

Figure 22 lists the configurations that we used in our experiments. Whenever possible, we used the data sets from the original benchmarks. When this was not possible, we ported the data generation too.

A.2 Programmability Comparison

Table 1 compares *ConDRust* and threads/STM in terms of the programming effort required to derive the respective implementation from a sequential one. Of course effort in itself is hard to measure, as different abstractions and frameworks require different thought processes

■ **Table 1** Comparison of the programming effort required to adapt a sequential program to *ConDRust* (ConD_{rs}) and threads/STM.

Benchmark	State		Function		Synchronization		Concurrency	
	Modifications		Recompositions		Primitives		Code	
	ConD _{rs}	STM	ConD _{rs}	STM	ConD _{rs}	STM	ConD _{rs}	STM
K-Means	0	2	7	7	0	11	0	2
Labyrinth	1	1	10	6	0	4	0	2
Canneal	12	3	12	8	0	31	0	2
Intruder	0	1	4	4	0	12	0	2
Genome	3	8	11	5	0	15	0	4

when used. Therefore, the table compares how a number of key properties of the applications in question changed. State modifications denote changes to fields of the program state and are a direct result of adapting an application to another framework. In order to derive a *concurrent composition* and accomodate state modifications, functions must be changed. These changes are denoted as function recompositions. Furthermore, the derivation of a concurrent application requires in case of the threads/STM approach the introduction of concurrency and synchronization code. Of course, some modifications prompt further changes affecting categories. A state change may require adjusting multiple function signatures and bodies, while added concurrency requires synchronization. Hence, fewer modifications are always better, as they require less effort. Note that this comparison is potentially biased, as the original STAMP suite did not include sequential versions. We derived these manually from the parallel code, which may result in the sequential versions being easier to port to the threads/STM framework.

The first difference is that *ConDRust* programs are free of concurrency abstractions and synchronization primitives. This does not only enable verification but prevents the introduction of concurrency hazards such as data races or deadlocks. We observe that increased use of synchronization primitives results in more transaction conflicts and degraded performance. As synchronization in threads/STM works on the type level, the framework requires generally more state modifications, but fewer individual function recompositions. This means that while a smaller percentage of the code base is changed, the changes are more substantial. A single recomposition here may include incorporating synchronization or concurrency, such that functions or parts thereof can be run in a transaction. Since transactions may fail, failure models have to be considered while altering the code. Also, since transactions can not be nested, special care must be taken to avoid that. Finally, transaction size plays an important role in the overall performance and must therefore be carefully chosen.

ConDRust on the other hand for the most part only needs few state changes. These are mostly done to remove types that are not thread-safe and could hence not be used in a concurrent environment. In the case of Canneal, a large struct had to be used to replace a non type safe state sharing approach. The main work required to derive a *ConDRust* implementation indeed lies in the decomposition and recomposition of functions. In contrast to threads/STM this often only entails breaking up bigger functions into several smaller ones (which are counted individually) and removing references from function definitions. As a result, the code bases became more fine-grained and compartmented, with each function only handling a single task.

Terms	$t ::= x \mid v \mid x : T \rightarrow T \{ t \} \mid t(t) \mid \text{let } x : T = t; t \mid \text{let mut } x : T = t; t \mid$ $f_{\text{SL}}(t_1) \mid t_s.f_{\text{SF}}(t_1) \mid \text{for } x \text{ in } t \{ t \} \mid \text{trfix } t t$
Evaluation context	$E ::= \square \mid E(t) \mid v(E) \mid \text{let } x : T = E; t \mid \text{let mut } x : T = E; t \mid$ $f_{\text{SL}}(E) \mid E.f_{\text{SF}}(t) \mid v_s.f_{\text{SF}}(E) \mid$ $\mid \text{for } x \text{ in } E \{ t \} \mid \text{for } x \text{ in } v \{ E \} \mid \text{trfix } E t \mid \text{trfix } v E$

■ **Figure 23** Syntactical constructs and evaluation context of Ⓢ_s .

Overall, we observe that *ConDRust* requires less severe changes to the code base. The changes that are required are merely the breaking up of functions to expose parallelism and the removal of state sharing.

B Ⓢ_s – A subset of Rust for sequential composition

In this section, we formally specify Ⓢ_s , the subset of the Rust language that encompasses the *ConDRust* programming model. We start with the syntax and the operational semantics with focus on the integration of stateless and stateful function calls. Afterwards, we specify the type system that guards the usage of state. A clear specification of state is important for the compiler to reason about the various forms of parallelism in the derived dataflow representation of the program.

B.1 Syntax

ConDRust supports the subset of Rust’s syntax that is necessary to compose calls to stateless and stateful functions (also called methods). We define this subset in Figure 23 as Ⓢ_s – a subset of Rust for sequential composition. The semantics of Ⓢ_s are the same as for Rust. For this paper, we restrict the terms of the language to variables x , abstractions (closures in Rust) $|x : T| \rightarrow T \{ t \}$, algorithm application $t(t)$, immutable and mutable bindings, **for**-loops and tail-recursion (**trfix**). We restrict the presentation of Ⓢ_s in the following (common) ways:

1. Abstractions and calls may only have a single parameter. The extension to support multiple parameter is straightforward.
2. We desugar top-level algorithm definitions into **let**-bound closures such that a top-level defined function can be used in multiple locations of succeeding function definitions.

The evaluation context E specifies that terms evaluate from left to right in a call-by-value fashion. Ⓢ_s and Rust are imperative languages such that require a store μ to model the state of the program. Store locations l are part of the syntactical constructs. The small-step operational semantics $t \mid \mu \rightarrow t' \mid \mu'$ relates a term t and a store μ to a term t' and a store μ' . The store μ maps labels to values where $\mu, l \mapsto v$ denotes the usual conjunction of store mappings μ and the mapping from label l to value v . Values are store locations, (tail recursion) abstractions and the values defined in the Rust language itself. In the specification of Ⓢ_s ’s operational semantics, we assume general types and values for booleans, tuples and lists with constructors $[]$ for the empty list and $v \sim: vs$ (**cons**) where v is the head with the tail vs . In Rust, the corresponding data structure to a list is a vector (**Vec**).

B.2 Operational Semantics

The usual way for values to enter the evaluation is via the key ingredient in *ConDRust*'s programming model: *stateless function calls* $f_{\text{SL}}(t_1)$ and *stateful function calls* $t_s.f_{\text{SF}}(t_1)$.¹⁰ The definition of stateless and stateful functions themselves are not part of \mathfrak{S}_s . We define Δ as an environment in the typing relation that holds the typing information for the stateless and stateful functions used in the term to be evaluated. As such, the operational semantics for calls to stateless and stateful functions rely upon the evaluation relation of Rust ($\Downarrow_{\mathfrak{S}}$):

$$\boxed{t \mid \mu \longrightarrow t' \mid \mu'}$$

$$\frac{f_{\text{SL}}(v) \mid \emptyset \Downarrow_{\mathfrak{S}} v_r \mid \emptyset}{f_{\text{SL}}(v) \mid \mu \longrightarrow v_r \mid \mu} \text{E-FSL} \qquad \frac{l_s.f_{\text{SF}}(v_1) \mid l_s \mapsto v_s \Downarrow_{\mathfrak{S}} v_r \mid l_s \mapsto v'_s}{l_s.f_{\text{SF}}(v_1) \mid \mu, l_s \mapsto v_s \longrightarrow v_r \mid \mu, l_s \mapsto v'_s} \text{E-FSF}$$

Inside these functions, developers re-gain the full feature set of Rust. Stateless calls do not have side-effects. Side-effects for stateful calls are restricted to a particular state location l_s in the store μ . These are the only rules that leverage Rust's evaluation relation ($\Downarrow_{\mathfrak{S}}$). In fact, calls are the only places where computation takes place while the rest of the language is for composition. Our operational semantics are based on the standard beta-reduction such that $[x \mapsto t_1]t_2$ with $x \in FV(t_2)$ replaces all occurrences of the free variable x in t_2 with t_1 . The usual rule then covers application of simple abstractions:

$$[x : T \mapsto T \{ t_2 \}(v_1) \mid \mu \longrightarrow [x \mapsto v_1]t_2 \mid \mu \text{ (E-ABSAPP)}$$

Stateless bindings solely rely on beta-reduction. Mutable bindings register values in the store.

$$\begin{aligned} \mathbf{let} \ x : T = v_1; \ t_2 \mid \mu &\longrightarrow [x \mapsto v_1]t_2 \mid \mu && \text{(E-LET)} \\ \mathbf{let mut} \ x : T = v_1; \ t_2 \mid \mu &\longrightarrow [x \mapsto l_1]t_2 \mid \mu, l_1 = v_1 \quad \text{where } l_1 \notin \text{dom}(\mu) && \text{(E-LETMUT)} \end{aligned}$$

As such, the only values in the store refer to mutable state references. We further restrict control flow to loops and tail recursion leaving out other forms such as conditionals that play only a minor role in the parallel execution of a program. Loops iterate over a list of values.

$$\begin{aligned} \mathbf{for} \ x \ \mathbf{in} \ [] \ \{ t_2 \} \mid \mu &\longrightarrow () \mid \mu && \text{(E-LOOPDONE)} \\ \mathbf{for} \ x \ \mathbf{in} \ v \sim: vs \ \{ t_2 \} \mid \mu &\longrightarrow \mathbf{let} \ x_1 = [x \mapsto v_1]t_2; \ \mathbf{for} \ x \ \mathbf{in} \ vs \ \{ t_2 \} \mid \mu && \text{(E-LOOPSTEP)} \\ &\text{where } x_1 \notin FV(t_2) \end{aligned}$$

In Section 5 and in our implementation, loops may in fact iterate over all data types that implement Rust's `Iterator` trait which for instance includes `HashSet`. This allows the developer to specify that the loop does not depend on a particular order and enables our second transformation that extracts amorphous data parallelism. To model this in \mathfrak{S}_s , we assume a stateless function that uses the iterator to collect the items into a list before looping over them. In fact, `collect` is a standard function of Rust's `Iterator`. We allow loops with an unknown iteration count via tail recursion. Tail recursion is a derived form:

¹⁰We allow *ConDRust* algorithms to be called from anywhere in a Rust program. Such a call may have arguments. The assumptions would be stated in Γ and require another context to access them during evaluation. We omit this detail at this point in favor of a concise presentation.

$$\boxed{\Delta, \Gamma \mid \Sigma \vdash t : T}$$

$$\frac{\Sigma(l) = T}{\Gamma \mid \Sigma \vdash l : \mathbf{Ref}\langle T \rangle} \text{T-LOC} \qquad \frac{}{\Delta, x : (1, T) \mid \Sigma \vdash x : T} \text{T-VAR}$$

$$\frac{\Delta, \Gamma_1 \mid \Sigma \vdash t_1 : T_1 \quad \Delta, \Gamma_2 \mid \Sigma \vdash t_2 : T_1 \rightarrow T_2}{\Delta, \Gamma_1 \oplus \Gamma_2 \mid \Sigma \vdash t_2(t_1) : T_2} \text{T-APPABS} \qquad \frac{x \notin \Gamma \quad \Gamma, x : (n, T_1) \mid \Sigma \vdash t : T_2}{\Delta, \Gamma \mid \Sigma \vdash | x : T_1 | \rightarrow T_2 \{ t \} : T_1 \rightarrow T_2} \text{T-ABS}$$

$$\frac{\Delta, \Gamma_1 \mid \Sigma_1 \vdash t_1 : T_1 \quad \Delta, \Gamma_2, x : (1, T_1) \mid \Sigma_2 \vdash t_2 : T_2}{\Delta, \Gamma_1 \oplus \Gamma_2 \mid \Sigma_1, \Sigma_2 \vdash \mathbf{let} x : T_1 = t_1; t_2 : T_2} \text{T-LET}$$

$$\frac{\Delta, \Gamma_1 \mid \Sigma_1 \vdash t_1 : T_1 \quad \Delta, \Gamma_2, x : (n, \mathbf{Ref}\langle \mathbf{mut} T_1 \rangle) \mid \Sigma_2 \vdash t_2 : T_2}{\Delta, \Gamma_1 \oplus \Gamma_2 \mid \Sigma_1, \Sigma_2 \vdash \mathbf{let mut} x : T_1 = t_1; t_2 : T_2} \text{T-LETMUT}$$

$$\frac{\Delta, \Gamma \mid \Sigma \vdash t_1 : T_1 \quad \Delta(\mathbf{f}_{SL}) = T_1 \rightarrow T_2}{\Delta, \Gamma \mid \Sigma \vdash \mathbf{f}_{SL}(t_1) : T_2} \text{T-FSL} \qquad \frac{\Delta, \Gamma_1 \mid \Sigma_1 \vdash t_1 : \mathbf{Ref}\langle \mathbf{mut} T_1 \rangle \quad \Delta, \Gamma_2 \mid \Sigma_2 \vdash t_2 : T_2 \quad \Delta(\mathbf{f}_{SF}) = \mathbf{mut} T_1 \rightarrow T_2 \rightarrow \circ T_3}{\Delta, \Gamma_1 \oplus \Gamma_2 \mid \Sigma_1, \Sigma_2 \vdash t_1.\mathbf{f}_{SF}(t_2) : T_3} \text{T-FSF}$$

$$\frac{\Delta, \Gamma_2 \mid \Sigma \vdash t_2 : \mathbf{Vec}\langle T_1 \rangle \quad \Delta, \Gamma_3, s : (1, \mathbf{Ref}\langle \mathbf{mut} T_s \rangle), x_1 : (n, T_1) \mid \Sigma \vdash t_3 : ()}{\Delta, \Gamma_2 \oplus \Gamma_3, s : (1, \mathbf{Ref}\langle \mathbf{mut} T_s \rangle) \mid \Sigma \vdash \mathbf{for} x_1 \mathbf{in} t_2 \{ t_3 \} : ()} \text{T-LOOP}$$

where $\forall s \in FV(t) \wedge s \neq x_1$

$$\frac{\Delta, \emptyset \mid \Sigma \vdash t_1 : (\mathbf{bool}, T_2, T_1) \quad \Delta, \emptyset \mid \Sigma \vdash t_2 : T_1 \rightarrow (\mathbf{bool}, T_2, T_1)}{\Delta, \emptyset \mid \Sigma \vdash \mathbf{trfix} t_1 t_2 : T_2} \text{T-FIX}$$

■ **Figure 24** *ConDRust*'s type system tracks and restricts variable usage.

$$\mathbf{let} f = | x : T_1 | \rightarrow T_2 \{
\begin{array}{l}
\mathbf{let} (x_1, x_2, x_3) = t_b; \\
\mathbf{if} x_1 \{ x_2 \} \\
\mathbf{else} \{ f(x_3) \}
\end{array}
\};$$

$$\stackrel{\text{def}}{=}$$

$$\mathbf{let} f = | x_0 : T_1 | \rightarrow T_2 \{
\begin{array}{l}
\mathbf{let} f' = | x : T_1 | \rightarrow (\mathbf{bool}, T_2, T_1) \{ t_b \}; \\
\mathbf{trfix} f'(x_0) f'
\end{array}
\};$$

Desugaring captures t_b , the computation of the recursion, as f' . Our tail-recursive combinator **trfix** takes two arguments. Argument 1 is an application f' to x_0 , the initial parameter of a recursive call. This application reduces to a triple (x_1, x_2, x_3) with the boolean discriminator x_1 , the final term x_2 and x_3 , the argument to the tail-recursive call. Argument 2 is f' for recursion. We encode the conditional that guards this tail recursive call into **trfix**'s semantics:

$$\mathbf{trfix} (\mathbf{true}, v_2, v_3) v_4 \mid \mu \longrightarrow v_2 \mid \mu \quad (\text{E-FIXDONE})$$

$$\mathbf{trfix} (\mathbf{false}, v_2, v_3) v_4 \mid \mu \longrightarrow \mathbf{trfix} v_4(v_3) v_4 \mid \mu \quad (\text{E-FIXRECUR})$$

In case the discriminator is **true**, we return the final result v_2 . Otherwise, we apply the recursive argument v_3 to the abstraction that is always the second argument of **trfix**. Again, we restrict the presentation to a single recursive argument and argue that the extension to multiple arguments is straightforward. In the context of this paper, we are particularly interested in the case where the arguments to the recursion are a state to be updated and a worklist that triggers these updates.

B.3 Type system

The *ConDRust* programming model carefully distinguishes between stateless and stateful computations. This enables the compiler to perform the translation of an algorithm into a dataflow representation and extract data parallelism while preserving the algorithm semantics.

The type system enforces the following programming discipline:

1. A variable may either be used as state or as input to a function call.
2. A variable that is input to a function call may only be used once.
3. A state variable may be used more than once except for a loop term where it may only be used once.

These somewhat restrictive rules are key enablers of our approach.

Data often needs to be shared across the concurrent parts of the program. A good example of this is the grid in the STM implementation that required a deep clone to make the concurrent execution scale. Often, introducing parallelism into a program represents a trade-off between speedup and memory efficiency. To make sophisticated decisions that strike a good balance for this trade-off, data structure knowledge is required by the compiler. We leave this to future work and enable the developer to explicitly make that decision by `cloneing` or sharing cloned `Arcs`. These techniques are already common practice for sharing data in Rust.

In *ConDRust*'s type system, presented in Figure 24, we use concepts from linear types to track and restrict variable usage [55]. The typing context Γ (defined in Figure 23) captures not only the types of variables but also their usage count (see rule T-VAR). The types T_{\oplus} are the types of the Rust programming language. With the rules T-LET and T-LETMUT, we distinguish between variables that are input to functions and state. In T-LET, *input variables* have a non-referential type and require a usage count of 1, i.e., they can only be used exactly once.¹¹ In T-LETMUT, *state variables* reference locations in the store μ and are marked with Rust's annotation for mutable types. Rules T-FSL and T-FSF specify the use of input and state variables in the type of the stateless and stateful function. Values in input position t_1 are of type T_1 while the state position t_s is required to be of type mutable reference $\text{Ref}\langle T_s \rangle$. We define the state encapsulation property of a stateful function on the output type as $\bigcirc T_3$. A type T has this property if it does not contain borrowed references.

The type information of the values behind the references is captured in the store typing Σ . As such, a typing judgement $\Delta, \Gamma \mid \Sigma \vdash t : T$ reads as follows:

► **Definition 4** (Well-typed). *Given an environment Δ and a (local variable) context Γ with type assumptions on store locations Σ ; a term t is well-typed if there exists a type T such that $\Delta, \Gamma \mid \Sigma \vdash t : T$.*

The rule T-LOOP restricts state variables to a single usage in the loop term t_3 . Only due to this restriction, the *ConDRust* compiler can derive pipeline parallelism. Rule T-FIX prevents tail recursive functions from accessing contextual variables at all by requiring $\Gamma = \emptyset$. Accessing captured variables in a recursive closure is also uncommon in Rust because the closure needs to explicitly communicate the lifetime of such variables. That is particularly challenging, for a closure that performs an unknown number of iterations.¹² In the spirit of

¹¹We treat unused variables as an undesirable property of a program that would benefit from a similar error message. Rust actually has similar warnings/errors for unused variables.

¹²Recursive closures need to be captured in structs to explicitly communicate lifetime information for the captured variables to the borrow checker. For more details see: <https://stevedonovan.github.io/rustifications/2018/08/18/rust-closures-are-hard.html>

$$\begin{aligned}
\Gamma \oplus \quad \quad \quad \emptyset &= \emptyset \\
\emptyset \oplus \quad \quad \quad \Gamma &= \Gamma \\
\Gamma_1, x : (n : T) \oplus \Gamma_2, x : (m : T) &= \Gamma_1 \oplus \Gamma_2, x : (n + m, T)
\end{aligned}$$

■ **Figure 26** Syntactical constructs of \oplus_p .

linear types, we merge store typings via logical conjunction and define the conjunction for contexts in Figure 25. Based on this Rust subset, the *ConDRust* compiler can translate a sequential algorithm into a dataflow graph that makes all inherent parallelism explicit.

C \oplus_p – A subset of Rust for parallel composition

With the transformations in place, we now formally specify the backend of the *ConDRust* compiler to show that the generated code executes deterministically. We present the syntactic constructs for \oplus_p – a subset of Rust for parallel composition, that the *ConDRust* compiler targets in Figure 26. Terms in this subset basically consist of two parts:

Graph construction An arc is a channel (c) in Rust’s message-passing terminology and we define n , i.e., a term for each type of node in the dataflow graph.

Graph execution We abstract over an explicit implementation of a scheduler for a dataflow graph with a single `run` construct.

We abstract over a concrete channel implementation. All we rely upon is the FIFO ordering property which we specify via the usual list constructors: $[\]$ empty list, $v \sim: v'$ (cons) where v is the head with the tail v' and the dual $v' \sim: v$ (snoc) where v is the last element in the list and v' the list of the preceding elements. Additionally, we assume the presence of tuples in the Rust values v_{\oplus} and types T_{\oplus} . Composition of nodes via arcs works solely via variable bindings. For example, the following term constructs a graph with a single (stateless) identity function (`idSL`) call node:

```

let src : Recv<i32> = chan(5);
let (result : Recv<i32>, out : Send<i32>) = chan();
run(result, (nSL(idSL, src, out) ~: [ ]))

```

For execution, we pass the receiving endpoint `result` and the list of nodes to `run` which executes the graph and reduces to the final result. We assume a type `Node` for nodes and align our specification for channels closely with `std::mpsc::channel` from Rust’s standard library where `Receiver<T>` and `Sender<T>` represent the receiving and the sending endpoint

$$\boxed{\Delta, \Gamma \mid \Sigma \vdash t : T}$$

■ **Figure 27** The linear type system of \mathbb{S}_p for the construction and execution of the dataflow graph.

of a channel, respectively. In our encoding, the types $\mathbf{Recv}\langle T \rangle$ and $\mathbf{Send}\langle T \rangle$ are reference types (in $T_{\mathbb{S}}$) for locations l in the store μ , i.e., channels are values in the store. In fact, channels and their respective elements are the only values in the store. This simplification is possible because in *ConDRust* every state arrives along an arc, i.e., channel, where we preserve it across loop iterations. The context Γ (without usage tracking), the store μ , the store typing Σ and the environment Δ follow the specification in \mathbb{S}_s .

In the following, we first define the specifics of graph construction via the typing rules and afterwards present the operational semantics for graph execution to finally present our proof (sketch) for determinism.

C.1 Linear dataflow construction

Figure 27 defines the type system of \mathbb{S}_p . A dataflow graph consists of channels and nodes. In a dataflow graph each arc has exactly one sending node and one receiving node. To encode this invariant, we again resort to a linear type system approach and highlight linear aspects accordingly. The rules T-LOC and T-VAR type locations and variables. Channel construction is typed in rules T-LETSRC and T-LETCHAN. Source channels ($\mathbf{chan}(t)$) bind only a sending endpoint to pipe parameters from the surrounding Rust program into the dataflow graph. All other channels ($\mathbf{chan}()$) bind a receiving and a sending endpoint. In both cases, the usual conjunction of typing contexts (Γ_1, Γ_2) assures that each endpoint is

used exactly once. The rest of the rules (T-NSL, T-NSF, T-NLP, T-NRU, T-NFIX) concern the construction of nodes and the execution of the graph (T-RUN). We increase readability of the inference rules in the typing and evaluation relation in two ways. First, to make the flow of the different types of data more obvious, we highlight **receiving** and **sending** endpoints, **value reuse** and **state**. Second, to better align the type assumptions, we deliberately present the terms for nodes and **run** with variables instead of subterms, i.e., $n_{SL}(x_1, x_2)$ instead of $n_{SL}(t_1, t_2)$. This is not a restriction because we defined that channel endpoints have to be bound such that (node and **run**) terms requiring endpoint types can only be variables.

To keep the formal specification concise, only the T-NSF rules enables the reuse of data – in this case state. In the full formal specification and in our implementation, there are at least two versions for all nodes: one where the received input is of type T and another where it has an attached reuse count (\mathbb{N}, T) . Without loss of generality, we show this only for the state input of the stateful function call node n_{SF} .

C.2 Operational semantics

In the small-step operational semantics, we use the store μ to define the relation of nodes that can be executed. Evaluation is again from left to right as in \mathbb{S}_s following the E-CTXT rule from Figure 23. The construction of channels allocates dedicated locations in the store and the types **Send** and **Recv** are effectively references to a store location l .

$$\boxed{t \mid \mu \longrightarrow t' \mid \mu'}$$

$$\text{let } x_1 : \text{Recv}_{<_>} = \text{chan } v; t \mid \mu \longrightarrow [x_1 \mapsto l]t \mid \mu, l \mapsto (v \sim: []) \quad (\text{E-LETSRC})$$

where $l \notin \text{dom}(\mu)$

$$\text{let } (x_1 : \text{Recv}_{<_>}, x_2 : \text{Send}_{<_>}) = \text{chan}; t \mid \mu \longrightarrow [x_1 \mapsto l, x_2 \mapsto l]t \mid \mu, l \mapsto [] \quad (\text{E-LETCHAN})$$

where $l \notin \text{dom}(\mu)$

For a source channel, the corresponding value is stored directly into the list and only the receiving end is emitted. Hence, the channel emits exactly one data value and remains empty for the rest of the computation. The receiving end x_1 and the sending end x_2 for all other channels, point to the **same location** l in the store. A channel is initially an empty list. For both types of channels, the evaluation makes a step using beta reduction.

The interesting part is the execution of the dataflow graph. Computation is complete when there is a value in the channel of the final endpoint.

$$\frac{}{\text{run}(v, l) \mid \mu, l \mapsto (v \sim: []) \longrightarrow v \mid \mu} \text{E-DONE} \quad \frac{\exists v_n \in v_g. v_n \mid \mu \longrightarrow v_n \mid \mu'}{\text{run}(v_g, l) \mid \mu, l \mapsto [] \longrightarrow \text{run}(v_g, l) \mid \mu'} \text{E-RUN}$$

Otherwise, there must a node v_n in the list of nodes v_g that can take a step that updates the store μ . This property holds because our linear typed construction does not allow for dangling channels and the following rules for the nodes in the graph always send data in every step. A stateless call node can make a step if its incoming channel referenced by label l_1 has data available:

$$\frac{\mathbf{f}_{SL}(v_1) \mid \emptyset \Downarrow_{\mathbb{S}} v'_1 \mid \emptyset}{n_{SL}(\mathbf{f}_{SL}, l_1, l_2 \mid \mu, \begin{matrix} l_1 \mapsto (v_1 \sim: v_{12}), \\ l_2 \mapsto v_2 \end{matrix}) \longrightarrow n_{SL}(\mathbf{f}_{SL}, l_1, l_2 \mid \mu, \begin{matrix} l_1 \mapsto v_{12}, \\ l_2 \mapsto (v_2 \sim: v'_1) \end{matrix})} \text{E-NSL}$$

The node retrieves the head v_i of the channel's list, performs the call and appends the resulting data value v'_1 to the list of the outgoing channel (l_2). The execution of the stateless function itself is the same as defined in the operational semantics for stateless calls (E-FSL) in \mathbb{S}_s defined in Section 4. Loop nodes follow the same execution pattern:

$$\frac{v_1.\text{size}() \mid \emptyset \Downarrow_{\mathbb{S}} n \mid \emptyset}{\text{for}(l_1, l_2, l_3) \mid \mu, \begin{array}{l} l_1 \mapsto (v_1 \sim: v_{12}), \\ l_2 \mapsto v_2, \\ l_3 \mapsto v_3 \end{array} \longrightarrow \text{for}(l_1, l_2, l_3) \mid \mu, \begin{array}{l} l_1 \mapsto v_{12}, \\ l_2 \mapsto (v_2 \sim: v_1), \\ l_3 \mapsto (v_3 \sim: n) \end{array}} \text{E-NLOOP}$$

A loop node streams the incoming list v_1 by concatenating ($\sim:$) it with the outgoing channel's list v_2 . We define list concatenation as usual:

$$xs \sim: (y_1 \sim: (y_2 \sim: \dots (y_n \sim:))) = (\dots ((xs \sim: y_1) \sim: y_2) \dots \sim: y_n)$$

The loop node additionally emits the number of streamed elements n to a reuse node that pairs it with the gated value:

$$\text{reuse}(l_1, l_2, l_3) \mid \mu, \begin{array}{l} l_1 \mapsto (v_1 \sim: v_{12}), \\ l_2 \mapsto (v_2 \sim: v_{22}), \\ l_3 \mapsto v_3 \end{array} \longrightarrow \text{reuse}(l_1, l_2, l_3) \mid \mu, \begin{array}{l} l_1 \mapsto v_{12}, \\ l_2 \mapsto v_{22}, \\ l_3 \mapsto (v_3 \sim: (n, v_1)) \end{array} \quad (\text{E-NREUSE})$$

In our presentation, only state is reused. To do so, the stateful function node receives the state value v_2 with the attached reuse count n on its state channel l_3 .

$$\frac{l_s.\text{f}_{SF}(v_1) \mid l_s \mapsto v_3 \Downarrow_{\mathbb{S}} v_{22} \mid l_s \mapsto v'_3}{\text{n}_{SF}(\text{f}_{SF}, \begin{array}{l} l_1, \\ l_2, \\ l_3, \\ l_4 \end{array}) \mid \mu, \begin{array}{l} l_1 \mapsto (v_1 \sim: v_{12}), \\ l_2 \mapsto v_2, \\ l_3 \mapsto ((n, v_3) \sim: v_{31}), \\ l_4 \mapsto v_4 \end{array} \longrightarrow \text{n}_{SF}(\text{f}_{SF}, \begin{array}{l} l_1, \\ l_2, \\ l_3, \\ l_4 \end{array}) \mid \mu, \begin{array}{l} l_1 \mapsto v_{12}, \\ l_2 \mapsto (v_2 \sim: v_{22}), \\ l_3 \mapsto ((n-1, v'_3) \sim: v_{31}), \\ l_4 \mapsto v_4 \end{array}} \text{E-NSFREUSE}$$

$$\frac{l_s.\text{f}_{SF}(v_1) \mid l_s \mapsto v_3 \Downarrow_{\mathbb{S}} v_{22} \mid l_s \mapsto v'_3}{\text{n}_{SF}(\text{f}_{SF}, \begin{array}{l} l_1, \\ l_2, \\ l_3, \\ l_4 \end{array}) \mid \mu, \begin{array}{l} l_1 \mapsto (v_1 \sim: v_{12}), \\ l_2 \mapsto v_2, \\ l_3 \mapsto ((1, v_3) \sim: v_{31}), \\ l_4 \mapsto v_4 \end{array} \longrightarrow \text{n}_{SF}(\text{f}_{SF}, \begin{array}{l} l_1, \\ l_2, \\ l_3, \\ l_4 \end{array}) \mid \mu, \begin{array}{l} l_1 \mapsto v_{12}, \\ l_2 \mapsto (v_2 \sim: v_{22}), \\ l_3 \mapsto v_{31}, \\ l_4 \mapsto v_4 \sim: v'_3 \end{array}} \text{E-NSFEMIT}$$

Rule E-NSFREUSE preserves the computed state v'_3 with a decremented reuse count in the *incoming* state channel l_3 . When the reuse count is 1 then Rule E-NSFEMIT emits v'_3 to the outgoing state channel. Both rules rely on $\Downarrow_{\mathbb{S}}$ which requires the state value v_3 to be behind a reference l_s . But l_s exists solely to satisfy this requirements. It is not contained anymore in our store μ . That is the result of the translation from an imperative into a functional program in the *ConDRust* compiler. The `trfix` node (which we omit at this point for brevity) follows the same principle to wait for a single recursive call to complete: It enqueues a \perp data value into its incoming arc x_1 that is dequeued only when a recursion is finished and the resulting value was sent along the respective channel x_6 (see T-NFIX).

C.3 Determinism

With the operational semantics and typing relation defined, we can prove that evaluation in \mathbb{S}_p and as such execution in *ConDRust* is deterministic. The evaluation relation keeps the selection of the next node abstract. It just states the particular data availability requirements

for the nodes to be evaluated. Stateful call nodes have more than one outgoing channel effectively creating subgraphs, i.e., task-level parallelism, and potentially adding more than a single successor into the evaluation relation. Additionally, a for-node emits a whole stream of data values allowing the downstream nodes to be executed repeatedly, i.e., in a pipeline parallel fashion. As such, there may be more than one node ready to be evaluated. The evaluation relation does not specify a concrete evaluation order and applies to any scheduler that follows the defined evaluation rules. As such, we show that evaluation in $t \mid \mu \longrightarrow t' \mid \mu'$ is deterministic.

► **Lemma 5 (Single-step Determinism).** *If $t : T$ is a well-typed term in \mathbb{S}_p then*

$$\begin{aligned} t \mid \mu, l \mapsto vs &\longrightarrow t' \mid \mu', l \mapsto (v \sim: vs) \quad \wedge \\ t \mid \mu, l \mapsto vs &\longrightarrow t'' \mid \mu'', l \mapsto (v \sim: vs) \Rightarrow t' = t'' \wedge \mu' = \mu''. \end{aligned}$$

Proof Sketch. The proof is by induction on a derivation of t and the store μ . Assume a term t' whose activation into the evaluation relation requires data value v available at store location l . For a term t whose evaluation places v into store location l , we distinguish the following two cases:

1. t is the construction of a source channel or
2. t is the evaluation of an upstream node.

The first case is immediate. In the second case, we also know that by the induction hypothesis the activations of this (upstream) node is deterministic. Now assume that t evaluates to t'' by storing a value at location l . By the linear construction of the channels in the dataflow graph, store location l only has a single receiver that is owned by exactly one node. Hence, $t' = t''$ and consequently $\mu' = \mu''$. ◀

Dataflow graphs in \mathbb{S}_p are essentially Kahn Process Networks (KPN) [31]. KPNs execute deterministically because incoming arcs have blocking semantics¹³ and the executed code of the node is scott-continuous. Our evaluation relation essentially adheres to both of these properties.

However, lemma 5 is insufficient to prove determinism for the whole computation, i.e., for the multi-step evaluation $t \mid \mu \longrightarrow^* v \mid \mu'$:

► **Theorem 6 (Determinism).** *If $t : T$ is a well-typed term with $t_s \xrightarrow{\text{ConDRust}} t$ then*
 $t \mid \mu \xrightarrow{c}^* v \wedge t \mid \mu \xrightarrow{c}^* v' \Rightarrow v = v'$.

The proof of this theorem needs a proof of termination which in turn requires two things: well-founded recursion and cycle freedom. Cycle freedom is based on a formal specification of the transformations in *ConDRust* to prove that the dataflow graph does not have cycles other than the ones guarded by `trfix` nodes. This formalization is outside the scope of this paper and left for future work.

¹³Blocking semantics prevent the construction of a non-deterministic merge node, the explicit notion of non-determinism in dataflow [2].

Dependent Merges and First-Class Environments

Abstract

In most programming languages a (runtime) *environment* stores all the definitions that are available to programmers. Typically, environments are a meta-level notion, used only conceptually or internally in the implementation of programming languages. Only a few programming languages allow environments to be *first-class values*, which can be manipulated directly in programs. Although there is some research on calculi with first-class environments for statically typed programming languages, these calculi typically have significant restrictions.

In this paper we propose a statically typed calculus, called E_i , with first-class environments. The main novelty of the E_i calculus is its support for first-class environments, together with an expressive set of operators that manipulate them. Such operators include: *reification* of the current environment, environment *concatenation*, environment *restriction*, and *reflection* mechanisms for running computations under a given environment. In E_i any type can act as a context (i.e. an environment type) and contexts are simply types. Furthermore, because E_i supports subtyping, there is a natural notion of context subtyping. There are two important ideas in E_i that generalize and are inspired by existing notions in the literature. The E_i calculus borrows *disjoint intersection types* and a *merge operator*, used in E_i to model contexts and environments, from the λ_i calculus. However, unlike the merges in λ_i , the merges in E_i can depend on previous components of a merge. From implicit calculi, the E_i calculus borrows the notion of a *query*, which allows *type-based* lookups on environments. In particular, queries are key to the ability of E_i to reify the current environment, or some parts of it. We prove the determinism and type soundness of E_i , and show that E_i can encode all well-typed λ_i programs.

1 Introduction

In most programming languages, (runtime) *environments* are used to store all the available definitions at a given point in a program. Typically, an environment is a dictionary that maps variable names to values. However, environments are normally a meta-level concept, which does not have any syntactic representation in source programs. Environments may be used internally in the implementation of programming languages. For example, in implementing functional languages, closures are often used to keep the lexical environment of a function around. However, it is impossible for programmers to write directly a closure or manipulate environments explicitly.

First-class environments [18, 23, 24, 29, 36], are environments that can be created, composed, and manipulated at runtime. In programming languages with first-class environments, programs have an explicit syntactic representation for environments that enables them to be first-class values. As argued by Gelernter et al. [18], with first-class environments, the distinction between declarations and expressions can be eliminated. Furthermore many programming language constructs – including *closures*, *modules*, *records* and *object-oriented constructs* – can be modelled with first-class environments. However, only a few programming languages allow environments to be first-class values. These languages are mainly dynamically typed languages such as dialects of Lisp [18] and the R language [17]. Typically, operations on environments include: reification (transforming environments into data objects), reflection (treating data objects as environments), environment restriction (returning part of an environment), and environment composition/concatenation. While dynamically typed languages with first-class environments give users high flexibility in manipulating environments, several runtime type errors are unavoidable due to the absence of static typing.

Compared with work on dynamically typed languages, there is much less research on statically typed languages with first-class environments [44, 45, 47]. In these works, environments as first-class values have a special kind of type which is called an *environment type*. Although static typing prevents some of the runtime errors, subtyping is not included in existing type systems with environment types. At the term level, there are two constructs for environments: one is an evaluation operation $e[[a]]$ that evaluates the expression a under an environment e , and the other is an operator returning the current environment. While these two constructs model importing and exporting of environments respectively, there are no facilities for concatenation or restriction of environments in these calculi.

In this paper we propose a statically typed calculus, called E_i , with first-class environments. The main novelty of the E_i calculus is its support for first-class environments with an expressive set of operators that manipulate first-class environments. In E_i , both reflection mechanisms for running computations under a given environment and reification of the current environment are supported. Moreover, compared with previous work on typed calculi with first-class environments, environment *concatenation* and environment *restriction* are allowed. In E_i , types and contexts (i.e. environment types) are completely unified. That is, any type can act as a context and contexts are simply types. Unlike previous calculi, E_i also supports subtyping and has a natural notion of subtyping of environments. In E_i , users can benefit from static typing for handling type errors at compile-time, while still having various flexible mechanisms to manipulate environments.

In order to model environments, the E_i calculus borrows *disjoint intersection types* and the *merge operator* from the λ_i calculus [32]. The novelty in E_i is to additionally use intersection types to model environment types (or contexts), and disjointness to model disjointness/uniqueness of variables in an environment. Correspondingly, in E_i , the merge operator enables constructing and concatenating environments. Moreover, unlike λ_i , the merges in E_i can depend on previous components of a merge. In other words, merges in E_i are *dependent* (note that the dependency in a merge is term-level dependency, and it should not be confused with dependent types). Unifying contexts and types enables type information flowing from the left branch to the right branch in a merge, such that the type of the left branch becomes part of the context of the right branch. Consequently, with reification, the right branch of a merge can construct an expression based on the left branch of a merge. For example, the following program (with syntactic sugar)

$$\{x = 1\}, \{y = x\}$$

is well-typed in E_i . Here y in the right branch can access x and build a value under the environment $\{x = 1\}$. The merge will be evaluated to $\{x = 1\} \circ \{y = 1\}$. Dependent merges are useful for modelling dependent declarations, which are not expressible in λ_i since a field in a single record cannot access the field in a previous record in a merge.

Instead of looking up values by names as in traditional lambda calculi, the E_i calculus borrows the notion of a *query*, which enables *type-based* lookups on environments, from *implicit calculi* [12,31,46]. In implicit calculi, queries are used to query *implicit* environments by type. However, in E_i , queries are applied directly to runtime environments instead, and they are key to the ability of E_i to reify the current environment, or some parts of it. Effectively, a query can synthesize the current context (in typing) and the current environment (during reduction). With type annotations, queries can choose part of the environment based on those annotations, modelling environment restriction.

In our work, we prove the determinism and type soundness of E_i , and show that E_i can encode all λ_i programs. The E_i calculus and all the proofs presented in this paper have been formalized in the Coq theorem prover [9]. In summary, the contributions of this paper are:

- **Dependent merges as first-class environments:** We propose the novel notion of dependent merges, which allow dependencies appearing in merges. With dependent merges, dependent declarations and first-class environments can be modelled easily in a natural way.
- **The E_i calculus:** We present a statically typed calculus called E_i with support for creation, reification, reflection, concatenation and restriction of first-class environments. In addition, we study an extension with fixpoints (shown in the appendix). Both calculi are deterministic and type sound.
- **Encoding of the λ_i calculus:** We show that E_i can encode the type system of the λ_i [32] via a type-directed translation. In other words, standard variables, lambda abstractions, and non-dependent merges can be fully encoded in E_i .
- **Coq formalization:** All the results presented in this paper have been formalized in the Coq theorem prover and they are available in the artifact associated to this paper: <https://github.com/tjhao/ecoop2023>

2 Overview

This section gives an overview of our work. We start with some background on the merge operator, first-class environments and program fragments. Then we discuss challenges of modelling first-class environments as merges and finally we discuss the key ideas in our work.

2.1 Background

The merge operator and disjoint intersection types. The original non-dependent merge operator (denoted here by \circ) was firstly introduced by Reynolds [38] and later refined by Dunfield [15]. Merges add expressiveness to terms, enabling constructing values that inhabit intersection types. Essentially, with the merge operator, values are allowed to have multiple types. For example, the following program is valid:

```
let x : Bool & Int = true , 1 in (not x, succ x)
```

In the program above, the variable x has types `Bool` and `Int`, encoded by the intersection type `Bool & Int`. At the term level, x is created with the merge operator and can be regarded as either a boolean or an integer when used. For instance, in the program above there are two uses of x , one as a boolean (as the argument to `not`) and one as an integer (as the argument to `succ`). A language with the merge operator is able to extract the value of the right type

34:4 Dependent Merges and First-Class Environments

■ **Table 1** Summary of common operators on environments. E denotes an environment, I denotes a set of identifiers, and $T1$ and $T2$ denote terms in the language.

Operator	Description
<code>export</code>	Exports/reifies the full <i>current</i> environment.
$E \setminus I$	Returns a new <i>restricted</i> environment that only contains the identifiers in I from the environment E .
<code>import(T1, T2)</code>	Evaluates $T1$ to be an environment $E1$, and uses $E1$ to evaluate $T2$.
<code>import(I, T1, T2)</code>	Evaluates $T1$ to be an environment $E1$, checks that a set of identifiers I are defined in $E1$, then uses $E1$ to evaluate $T2$.
$E1, E2$	Composes/concatenates two environments.

from merges. In many classical systems with intersection types, but without the presence of the merge operator, the type `Bool & Int` cannot be inhabited and the program above is not expressible [34].

An important issue that the merge operator introduces is ambiguity. What happens if merges contain multiple values of the same type? For example, we could have $(1, 2) : \text{Int}$, but if this is allowed, then it could result in either 1 or 2. To address the ambiguity problem, Oliveira et al. [32] presented the λ_i calculus, which imposed a restriction where only merges of values that have *disjoint types* are accepted (we use $A * B$ to represent that A is disjoint with B). In this way, ambiguous programs such as $1, 2$ are rejected since `Int` is not disjoint with itself. However, `Bool` and `Int` are disjoint, and thus `true, 1` is a well-typed expression.

As Dunfield [15] argued, with the merge operator, many language features such as *dynamic typing*, *multi-field records*, and *operator overloading* can be easily encoded. After that, several non-trivial programming language features, including *dynamic mixins* [2], *first-class traits* [5], *nested composition* [6, 22] have been enabled with the help of the merge operator and disjoint intersection types. These features provide the foundations for *compositional programming* [51], which is a programming paradigm that enables a simple and natural solution to the Expression Problem [49] and other modularity problems. Compositional programming is realized in the CP language [51], which has been used to demonstrate the expressive power of the paradigm.

First-class environments. Normally, environments are not a syntactic entity of a programming language. Instead, environments exist implicitly at the meta-level for defining formal semantics and implementing languages. However, some dynamically typed languages, including dialects of Lisp [18] or the R language [17], include support for first-class environments. There is a line of research work on first-class environments for dynamically typed languages [18, 23, 24, 29, 36]. First-class environments provide a lot of expressive power, and they are used to model many other language constructs. With first-class environments, it is possible to model *closures*, *modules*, *records* or *object-oriented constructs* [18]. Moreover, it is also possible to model declarations directly, eliminating the need to distinguish between declarations and expressions.

To allow environments manipulated by not only compilers or interpreters but also programmers, a form of *reification* and *reflection* of environments is needed. Reification transforms environments into data objects and reflection enables data objects to be treated as environments [23, 24]. While formalizations differ, generally speaking, environments are formalized as a mapping from variables to data objects, which can be manipulated at runtime. We summarize typical supported operators to manipulate environments [36] in Table 1 (with notations slightly changed).

Work on first-class environments for typed languages [44, 45, 47] comes with significant restrictions compared to what is supported in dynamically typed languages. In these calculi, types and environment types are defined such that environment types are a special kind of type. The definition of types is $A, B ::= A \rightarrow B \mid \dots \mid E$, and each environment type E has the form of $\{x_1 : A_1, \dots, x_m : A_m\}$ where A_i ($1 \leq i \leq m$) is a type and each variable x_i must be distinct (or disjoint) with each other. Environment types encode exactly the normal typing context, which is a set that consists of typing assumptions $x_i : A_i$. Correspondingly, an environment has the form of $\{a_1/x_1, \dots, a_m/x_m\}$ that binds variables x_i with terms a_i [44, 47]. There are two constructs related to environments:

- The first construct returns the current environment which acts similarly to `export`.
- The second construct is an evaluation operation $e[[a]]$ that evaluates the expression a under an environment e . Note that, this operation is similar to `import(T1, T2)` in Table 1 (where `T1` corresponds to e and `T2` corresponds to a).

With these two constructs, one can create an environment at run-time and use it for evaluation. However, types are not totally unified with environment types in this setting, which results in special treatment of environments. For example, the expression e in $e[[a]]$ can only be an environment. To avoid runtime errors, the typing rule for $e[[a]]$ restricts the type that e has to be an environment type. Existing type systems with environment types do not consider subtyping. At the term level, though environments can be computed by evaluation under other environments and function applications, concatenation or restriction of environments are not supported. Therefore, an environment with a larger/smaller width cannot be constructed on the fly either. In short, there is no subtyping and the operations that are supported in dynamically typed languages in Table 1 are not fully supported in typed calculi with first-class environments.

Program fragments and separate compilation. To motivate our work we will show how first-class environments can be helpful to model a simple form of modules. Our form of modules is inspired by Cardelli’s [7] *program fragments*. Here we first introduce the notion of program fragments, and in Section 2.3 we will see how we can model program fragments in E_i .

A *program fragment*, or *module*, is a syntactically well-formed expression where free variables may occur [7]. *Separate compilation* decomposes a program into program fragments that can be typechecked and compiled separately. A program fragment may contain free variables. However, if the required interface that contains adequate type information is specified, then the types of the free variables can be found (without any concrete implementation). Thus, the typechecking of a program fragment can still be carried out *separately*.

In a conventional calculus, such as the simply typed lambda calculus (STLC), we express abstractions over a variable annotated with a type. However, there are no facilities for abstracting over an interface that may consist of multiple (nested) type assumptions. In other words, the STLC is not powerful enough to model separate compilation.

Cardelli [7] proposed a calculus of program fragments for the STLC, and specified high-level abstractions for modules and interfaces. In Cardelli’s framework, interfaces are interpreted as typing contexts that are *external* to the language. A module that may require an interface/context is represented as a binding judgment $E \vdash d \cdot S$, where E is a context, d a list of definitions, S a list of type declarations. Take the following modules from Cardelli as an example:

34:6 Dependent Merges and First-Class Environments

```
module
import nothing
export x: Int
begin
  x : Int = 3
end.

module
import x: Int
export f: Int → Int, z: Int
begin
  f : Int → Int = λ(y: Int). y+x
  z : Int = f(x)
end.
```

These two modules can be modelled as two binding judgments:

$$\emptyset \vdash (x : \text{Int} = 3) \therefore (x : \text{Int})$$
$$x : \text{Int} \vdash (f : \text{Int} \rightarrow \text{Int} = \lambda(y : \text{Int}). y + x, z : \text{Int} = f(x)) \therefore (f : \text{Int} \rightarrow \text{Int}, z : \text{Int})$$

A module is encoded as a list of definitions d , with an import list modelled as a context E and an export list as type declarations S . In the second module, z relies on f . To model such dependency, the binding judgment $E \vdash d \therefore S$ is designed to be *dependent*: each component depends on its previous components in d , in the sense that every free variable in this component can refer to its corresponding type. To check whether $z : \text{Int} = f(x)$ is matched by $z : \text{Int}$, the type declaration $f : \text{Int} \rightarrow \text{Int}$ is appended to the original context $x : \text{Int}$ to be a type assumption. In this way, the second binding judgment can be checked separately since each variable can access sufficient type information.

Though each binding judgment can be separately compiled to a self-contained entity called a linkset, user-defined abstractions cannot be expressed in Cardelli's work, since a binding judgment itself is a meta-level notion that cannot be created by programmers. In our work, we also regard interfaces as typing contexts. However, we unify typing contexts and types, and there are *first-class* constructs that abstract over a type/interface. We will discuss our ideas in detail in Section 2.3.

2.2 Limitations of Non-Dependent Merges

As Section 2.1 argued, both the (non-dependent) merge operator and first-class environments are useful to model a variety of other language constructs. Some of these language constructs can even be modelled by both merges or first-class environments. Given the overlap between merges and first-class environments it is reasonable to try to unify them, to obtain a more powerful model of statically typed languages with first-class environments. Our goal is to use merges to model first-class environments. However, non-dependent merges in existing calculi such as λ_i are inadequate for this purpose. This section discusses the limitations of non-dependent merges that are addressed by us.

No support for reification and reflection of environments. Intersection types and the merge operator are powerful tools that enable many language features, one of which is multi-field records [40]. In fact, multi-field record types can be turned into an intersection of single-field record types:

$$\{l_1 : A_1, \dots, l_n : A_n\} \equiv \{l_1 : A_1\} \& \dots \& \{l_n : A_n\}$$

Recall the syntax of conventional typing contexts: $\Gamma ::= \cdot \mid \Gamma, x : A$. A typing context is a list of pairs that bind variables with types. If we view variables as labels, typing contexts can be encoded as multi-field records, which are further desugared to intersections of single-field record types. Similarly, at the term level, a multi-field record is expressed as a merge of single-field ones:

$$\{l_1 = e_1, \dots, l_n = e_n\} \equiv \{l_1 = e_1\}, \dots, \{l_n = e_n\}$$

For example, $\{x = 2, y = 4\}$ is encoded as $\{x = 2\}, \{y = 4\}$. In calculi with a merge operator, merges are always *first-class* expressions and thus they can be passed to functions.

However, in previous calculi with the merge operator [15, 32, 38], merges are not used to model environments. Therefore, there are no reification and reflection facilities for environments in those calculi. Furthermore, intersection types are not used to model contexts, and there is no construct that enables running some computation under a local environment. In short, previous calculi with the merge operator support concatenation, but they do not support other operations in Table 1.

No dependent merges. An important limitation of merges in previous work with respect to environments is that they cannot be dependent. Many programming languages, as well as Cardelli’s program fragments, support declarations such as:

```
let x = 2
let y = 4
```

which allows several declarations to be associated with expressions. For the declarations above, we can easily model them as a (non-dependent) merge of two single field records:

```
{x = 2}, {y = 4}
```

where variables x and y are encoded as field names (or labels), and the values assigned to variables are modelled as record fields.

The previous declarations are *non-dependent*, in the sense that the expression assigned to y does not refer to x . However, in practice many declarations are *dependent*, where the current declaration relies on previous ones. For instance, fairly often we may have a program:

```
let x = 2
let y = x + x
let main = x + y
```

where y depends on x and main depends on both y and x . The traditional non-dependent merge operator cannot capture such cases. To be concrete, consider the typing rule for merges from λ_i [32]:

$$\frac{\Gamma \vdash e_1 \Rightarrow A \quad \Gamma \vdash e_2 \Rightarrow B \quad A * B}{\Gamma \vdash e_1, e_2 \Rightarrow A \& B} \text{TYP-MERGE}$$

Here $A * B$ expresses that A and B are disjoint types. For typing a merge e_1, e_2 , the typing context for the right branch e_2 is Γ and does not contain any type information about the left branch e_1 . When typing e_2 , the type of e_1 is never used during the typing procedure. As a result, e_2 cannot be built by referring to e_1 . Moreover, to cooperate with the static semantics, the two branches of e_1, e_2 are evaluated separately without dependency involved in the dynamic semantics of λ_i . That is, the environment for evaluating e_2 does not contain the evaluation result of e_1 .

The incapacity of encoding dependent declarations as first-class expressions exposes that λ_i is not able to fully model *module*-related language features. Since dependent definitions/declarations often occur in a module, as shown in our discussion on program fragments in Section 2.1.

2.3 Key Ideas

In this work, we utilize the merge operator together with new constructs to enable dependent merges and first-class environments. We concretize these ideas in a new calculus called E_i . The key ideas of our work are discussed next.

Typing contexts as types. In E_i the typing context in the typing judgment is a *type* instead of an association list. Our grammar for *both* types and contexts is:

$$A, B, \Gamma ::= \text{Int} \mid \text{Top} \mid A \rightarrow B \mid A \& B \mid \{l : A\}$$

A typing assumption $x : A$ in conventional calculi is modelled as a record type, and the intersection of two types plays a similar role to the concatenation of two association lists. However, the contexts in our work are not restricted to intersections of record types. In fact, any type (e.g., Int) defined in the syntax of E_i can be a typing context. If a context consists only of Top (the top type), then there is no type information in this context, which corresponds to an empty association list. As we will see, viewing typing contexts as types opens up the possibility of creating interesting language features.

Unifying environments and expressions. Just as typing contexts are types in E_i , environments in the reduction semantics are just *values* instead of association lists which bind variable names to values. Hence, environments are *first-class* in our setting. The top value \top is used to model the empty environment. A merge of two values can be viewed as concatenation of two environments. For example, the merge $\{x = 1\} \circ \{y = 2\}$ is a valid environment that binds 1 and 2 to x and y respectively. In E_i , we denote the merge operator by a single comma (\circ) to follow the notation conventionally used in programming languages to denote the concatenation of two environments. With record projection, the value bound to a label can be accessed. Note that unifying environments and values and viewing variables as labels means that extra syntax (or data structures) for environments is not needed. This is different from previous work on typed calculi with first-class environments where an explicit notion of environments is introduced [44, 45, 47].

In E_i , we have two constructs to support reification (or exporting) and reflection (or importing) of environments. For reification, we employ the *query* construct $?$. The query construct is inspired by the implicit calculus [12], where queries are used to query *implicit* environments by type. In E_i we apply queries directly to runtime environments instead, whereas in the implicit calculus, access to the regular environments is done conventionally using named variables. The typing rule for $?$ is simply:

$$\Gamma \vdash ? \Rightarrow \Gamma$$

i.e. the query $?$ synthesizes the current context. For example, $\{x : \text{Int}\} \vdash ?.x \Rightarrow \text{Int}$ is valid. Here $?$ obtains the current environment and accesses the field x .

Regarding the reflection of environments, there is a construct $e_1 \triangleright e_2$ that is called *box* in E_i . In a box, e_2 is assigned an expression e_1 , which is evaluated to be a value that acts as an environment for evaluating e_2 . Take $\{x = 1 + 1\} \triangleright ?.x + 1$ as an example. The expression $\{x = 1 + 1\}$ is given as the environment to $?.x + 1$. Then $\{x = 1 + 1\}$ is evaluated to $\{x = 2\}$, under which $?.x + 1$ is evaluated to 3. The box construct can be seen as the inverse operator of the query, since $? \triangleright e$ is equivalent to e in the sense that $?$ exports the full environment by default. Allowing e_1 in the box $e_1 \triangleright e_2$ to be any well-typed expression instead of a value adds expressiveness to reflection. For example, environment injection can be encoded as $(? \circ v) \triangleright e$ where v is added to the original environment for e *locally*.

In E_i , type annotations play a role in information hiding. For example, for a merge with an annotation $(\{x = 1\}, \{y = 2\}) : \{x : \text{Int}\}$, only $\{x = 1\}$ is visible. Type annotations provide a mechanism to enable restriction, since they are able to prevent visibility of certain values. Since environments are values in our setting, type annotations can seal the environment, such that only components named in the type are accessible. Therefore, reification and reflection are *type-directed* in E_i . With type annotations, users can choose part of the environment that they desire. In summary, E_i can essentially model all the operations on environments in Table 1 with the following expressions:

- $?$ reifies the entire environment;
- $? : A$ obtains part of the environment that has type A ;
- $e_1 \triangleright e_2$ evaluates e_1 to an environment and uses that to evaluate e_2 under that environment;
- $(e_1 : A) \triangleright e_2$ evaluates e_1 , but restricts the resulting environment to A and uses that to evaluate e_2 ;
- e_1 , e_2 concatenates two environments e_1 and e_2 .

Dependent merges. To model dependent declarations, the merges in our work are dependent. The right branch can refer to the type of the left branch. The typing rule for dependent merges is:

$$\frac{\Gamma \vdash e_1 \Rightarrow A \quad \Gamma \& A \vdash e_2 \Rightarrow B \quad A * \Gamma \quad A * B}{\Gamma \vdash e_1 , e_2 \Rightarrow A \& B} \text{ TYP-DMERGE}$$

Modelling *typing contexts as types* enables type information flowing from the left branch to the right branch in a merge. Specifically, for e_1 , e_2 , the type of e_1 is added into the current context such that e_2 synthesizes a type under the intersection type $\Gamma \& A$.

Suppose that the current context Γ is a subtype of some type B , with type annotation, $? : B$ exports B from Γ . With the query construct, a dependent declaration can be encoded as a dependent merge:

$$\{x = 2\} , \{y = (? : \{x : \text{Int}\}) . x + (? : \{x : \text{Int}\}) . x\}$$

which has type $\{x : \text{Int}\} \& \{y : \text{Int}\}$. The annotated query $? : \{x : \text{Int}\}$ exports $\{x : \text{Int}\}$ from the context, and projection $(? : \{x : \text{Int}\}) . x$ infers the type Int . Note that E_i is meant as a minimal core calculus and it is not built with convenience in mind. So the expression above is more cumbersome than what a programmer would expect to write in a source language. With some basic support for type inference and syntactic sugar in a source language, we could write instead:

$$\{x = 2\} , \{y = ? . x + ? . x\}$$

or even:

$$\{x = 2\} , \{y = x + x\}$$

In Section 5 we show how some of this syntactic sugar and inference can be achieved. For readability purposes, in the following examples, we will take the liberty to use a more lightweight syntax for the examples written in E_i as well.

In general, dependent declarations can be modelled as a merge of expressions e_1 , \dots , e_n , where the type information accumulates from e_1 to e_n . Modelling declarations as merges means that while we can benefit from the expressiveness of the merge operator, we do not need to introduce an additional syntax for declarations. Besides the condition $A * B$ that avoids conflicts between two branches in a merge, in the typing rule for dependent merges there is an extra disjointness condition $A * \Gamma$ to ensure that the new environment has no conflicts. This extra disjointness condition is needed to ensure that reduction is deterministic in E_i .

34:10 Dependent Merges and First-Class Environments

TDOS environment-based semantics. In E_i , an environment-based semantics, expressed by a reduction relation of the form $v \vdash e_1 \hookrightarrow e_2$, is employed to capture the dynamic behavior of expressions. In contrast to more conventional small-step reduction relations, which are typically based on substitution and beta reduction, here v plays the role of the runtime environment and no substitution is needed during reduction. Basically, an environment is stored during evaluation and the expression being evaluated can access it. During the reduction procedure, the environment can be changed *locally*. For example, suppose that the current environment is v , to evaluate a dependent merge e_1, e_2 . The left branch e_1 is evaluated to a value v_1 first. After that, v_1 is merged with v such that e_2 is evaluated under v, v_1 . As a result, e_2 is able to access and fetch v_1 . For instance, the dependent merge

$$\{x = 2\}, \{y = ?.x + ?.x\}$$

is evaluated to $\{x = 2\}, \{y = 4\}$ under \top , since

$$\{y = ?.x + ?.x\}$$

is evaluated to $\{y = 4\}$ under the environment $\top, \{x = 2\}$.

The reduction semantics is based on a *type-directed operational semantics* (TDOS), following the semantics of calculi with the merge operator [21]. As we have seen, type annotations can be used to remove information from values. Thus, unlike many other calculi, the semantics of E_i is type-dependent. That is, types affect the runtime behavior. To deal with such type-dependent semantics based on giving an operational behavior to type annotations we use a TDOS. In the TDOS there is a *casting* relation $v \hookrightarrow_A v'$, where types are used to guide reduction. Since an environment can be selected by a type annotation, casting also acts as a tool for *synthesizing* values in E_i . During the reduction of an annotated query $? : A$ under environment v , casting is triggered, and v' is synthesized as the result. Take the program above as an example, to evaluate $? : \{x : \text{Int}\}$, which is needed in the projection $?.x$, the following cast is triggered:

$$\top, \{x = 2\} \hookrightarrow_{\{x:\text{Int}\}} \{x = 2\}$$

In essence, the cast extracts the value $\{x = 2\}$ matching the type being cast. With this value, we can further build an expression for the right part of the merge.

Abstractions in E_i . In E_i , an abstraction has the form $\{e\}^m$ where m denotes a mode. There are two modes for abstractions: \bullet and \circ . Here we focus on $\{e\}^\bullet$. Compared with a normal lambda abstraction $\lambda x.e$, there is no variable binding in $\{e\}^\bullet$, since values in the environment are *looked up by types* via the query construct instead of by variable names. For example, after $\{?\}^\bullet : \text{Int} \rightarrow \text{Int}$ is applied with integer 1, the input 1 is put in the environment for evaluating $? : \text{Int}$, and then the query construct looks up a value of type Int , which is 1. We require that a well-typed abstraction $\{e\}^\bullet$ has a type annotation. The (slightly simplified) typing rule for abstractions is:

$$\frac{\Gamma * A \quad \Gamma \& A \vdash e \Leftarrow B}{\Gamma \vdash \{e\}^\bullet : A \rightarrow B \Rightarrow A \rightarrow B} \text{TYP-ABS}$$

Similarly to typing normal lambda abstractions, where a typing assumption $x : A$ is added to the typing context, for typing $\{e\}^\bullet$ in E_i , the input type of $\{e\}^\bullet$ is added into the context to type check the body e . For example, $\text{Top} \vdash \{?\}^\bullet : \text{Int} \rightarrow \text{Int} \Rightarrow \text{Int} \rightarrow \text{Int}$ is valid, since under $\text{Top} \& \text{Int}$, $?$ can check against Int . Besides, there is also a disjointness condition in this rule, which ensures that there are no conflicts between the context and the input type.

Ambiguity would happen without such a condition since, if the body e contains a $?$, there would be different answers to the query $?$, as shown in the following example ($\Gamma \vdash e$ is used to denote the situation that the current context for e is Γ):

$$\text{Int} \vdash (\{?\}^\bullet : \text{Int} \rightarrow \text{Int}) 2$$

Suppose that the current environment contains only the value 1, which is of type Int . After the function is applied to 2, both 1 and 2 appear in the environment, and they have the same type Int . If $?$ desires a value of type Int , then there are two candidates, which results in ambiguity. Thus the condition $\Gamma * A$ prevents such programs. On the other hand, the following program is safe in the context Int , since there is only one value, which is 1, having type Int in the environment.

$$\text{Int} \vdash (\{?\}^\bullet : \text{Bool} \rightarrow \text{Int}) \text{true}$$

In general, conventional calculi where variables are involved normally ensure that a typing context is unique, i.e., all variables in it are distinct. In our calculus, disjointness plays a similar role as uniqueness. A function cannot accept expressions that have overlapping types with the current context. For record types, $\{x : \text{Int}\}$ is not disjoint with itself, so the following is not allowed:

$$\{x : \text{Int}\} \vdash (\{?.x\}^\bullet : \{x : \text{Int}\} \rightarrow \text{Int}) \{x = 1\}$$

In contrast, the following expression is well-typed in the context $\{x : \text{Int}\}$, since two record types are disjoint if they have distinct labels:

$$\{x : \text{Int}\} \vdash (\{?.x\}^\bullet : \{y : \text{Int}\} \rightarrow \text{Int}) \{y = 1\}$$

Note that the use of records and distinct label names is how we can model conventional functions that take several arguments of the same type. That is, we can use labels to unambiguously distinguish between arguments of the same type, similarly to the use of distinct variable names in conventional lambda abstractions.

The abstractions in E_i essentially abstract over an interface if we view interfaces as types. The example from Cardelli in Section 2.1 can be encoded in our calculus:

$$\begin{aligned} \{M = \{x = 3\}\} \\ \{N = \{f = \{?.y + ?.x\}^\circ : \{y : \text{Int}\} \rightarrow \text{Int}\}, \{z = (?f) (?x)\}^\bullet : \{x : \text{Int}\} \rightarrow \{f : \text{Int} \rightarrow \text{Int}\} \& \{z : \text{Int}\}\} \end{aligned}$$

Each module is modelled as a record (if the module does not import anything) or a function that returns a record (if the module imports something). A group of related definitions is expressed as a dependent merge of some other records. An interface, such as the interface of N , that contains typing assumption(s) is encoded as input type(s) of an abstraction, and the export list is the output type. Since merges are dependent in E_i , in the second module z is able to call f . With the \circ mode abstraction, standard lambda abstractions can also be encoded (we will discuss this in Section 5). Both modules are typeable separately (in the empty context). Moreover, we can apply N with M , since $(?.N) (?M)$ is typeable in the context containing N and M . Note that such an application is not expressible in Cardelli's work, since modules are not first-class in his setting.

Closures as a special case of boxes. As in usual environment-based semantics, closures are used in E_i to keep lexical environments around. However, given that we have the box construct in E_i , we do not need to invent a separate construct for closures. In fact, closures

34:12 Dependent Merges and First-Class Environments

have the form $v \triangleright \{e\}^\bullet : A \rightarrow B$, which is just a special case of a box. In a box closure, the environment is a value and the expression under the environment is an annotated abstraction. Note that closures are values and the abstraction inside is not evaluated. Instead, when a closure is applied with a value, the value is put in the environment of the closure, and the body of the abstraction is going to be evaluated under the extended environment. Take the following evaluation as an example:

$$\begin{aligned} & (\{\{?\}^\bullet : \text{Int} \rightarrow \text{Bool}\}^\bullet : \text{Bool} \rightarrow \text{Int} \rightarrow \text{Bool}) \text{ true } 1 \\ \hookrightarrow & (\top \triangleright \{\{?\}^\bullet : \text{Int} \rightarrow \text{Bool}\}^\bullet : \text{Bool} \rightarrow \text{Int} \rightarrow \text{Bool}) \text{ true } 1 \\ \hookrightarrow^* & (\top, \text{true} \triangleright \{?\}^\bullet : \text{Int} \rightarrow \text{Bool}) 1 \\ \hookrightarrow & \top, \text{true}, 1 \triangleright ? : \text{Bool} \\ \hookrightarrow^* & \text{true} \end{aligned}$$

The abstraction takes a boolean and an integer as input and returns the boolean. At first, it is packed up with the empty environment to form a closure. Then the two values `true` and `1` are merged with the environment to evaluate the body `? : Bool`. With casting, the annotated query is evaluated to `true`.

Encoding λ_i . To demonstrate the expressiveness of E_i we show that it can encode all well-typed programs in the λ_i calculus [32]: an existing calculus with non-dependent merges and without first-class environments. There are two non-obvious obstacles in the encoding. Firstly, unlike E_i , the λ_i calculus is a conventional lambda calculus with conventional lambda abstractions and variables. Our encoding of λ_i shows that queries and abstractions in E_i can encode conventional variables and lambda abstractions. The second obstacle in the encoding is that dependent merges have more disjointness constraints than non-dependent merges. Therefore, it is not clear how some non-dependent merges may be encoded. However, a combination of dependent merges and other constructs in the E_i calculus enables an encoding of all non-dependent merges. Section 5 details the encoding and proves that all typeable programs in λ_i are encodable and typeable in E_i .

3 The E_i Calculus

In this section we present the E_i calculus, which is a calculus with dependent merges and first-class environments. In E_i , type contexts are types, and run-time environments can be assembled, composed, manipulated explicitly, and used to run computations under such environments.

3.1 Syntax

The syntax of E_i is as follows:

Labels	l, x, y, z, \dots
Types and Contexts	$A, B, \Gamma ::= \text{Int} \mid \text{Top} \mid A \rightarrow B \mid A \& B \mid \{l : A\}$
Function modes	$m ::= \bullet \mid \circ$
Expressions	$e ::= ? \mid i \mid \top \mid \{e\}^m \mid e_1 \triangleright e_2 \mid e_1 e_2 \mid e_1, e_2 \mid e : A \mid \{l = e\} \mid e.l$
Values	$v ::= i \mid \top \mid v \triangleright (\{e\}^\bullet : A \rightarrow B) \mid v \triangleright (\{e\}^\circ : \{l : A\} \rightarrow B) \mid \{l = v\} \mid v_1, v_2$

Types and contexts. In E_i there is no syntactic distinction between types and contexts: contexts are types and any type can be a context. In standard calculi typing contexts are lists of typing assumptions of the form $x : A$ that associates variable x with type A . This

particular case is encoded in E_i with a single-field record type $\{x : A\}$. For clarity, we use different meta-variables to denote different uses of types (A, B, C , etc.) and contexts (Γ). Two basic types are included: the integer type Int and the top type Top . Function types and intersection types are created with $A \rightarrow B$ and $A \& B$ respectively. $\{l : A\}$ denotes a record type in which A is the type of the field. Multi-field record types can be desugared to an intersection of single-field record types [32, 40].

Expressions. Meta-variable e ranges over expressions. Expressions include some constructs in standard calculi with a merge operator: integers (i); a canonical top value \top , which can be seen as a merge of zero elements; annotated expressions ($e : A$); application of a term e_1 to term e_2 (denoted by $e_1 \ e_2$); and merge of expressions e_1 and e_2 ($e_1 \ ; \ e_2$). The expression $\{l = e\}$ denotes a single-field record where l is the label and e is its field. Similarly to record types, a multi-field record can be viewed as a merge of single-field records. Projection $e.l$ selects the field from e via the label l .

Besides these standard constructs, there are some novel constructs in our system. Unlike standard calculi, where variables are used to lookup values, we borrow the query construct $?$ from implicit calculi [12] to *synthesize values by types*. However, unlike implicit calculi, in E_i we can completely eliminate the need for variables, since a combination of queries and other constructs can encode traditional uses of variables. Such encoding will be discussed in detail in Section 5. The absence of variables simplifies binding in comparison to other calculi. $\{e\}^m$ stands for *abstractions* in which m is the mode of an abstraction and can be either \bullet or \circ . Abstractions play the same role as lambda abstractions, but they abstract over the input type of the function, instead of abstracting over a variable. The \circ mode denotes a special form of abstraction that is useful to encode lambda abstractions. The term $e_1 \triangleright e_2$ is called a *box*. A box assigns a local environment e_1 for e_2 , and e_2 is not affected by the global context or environment. In other words, boxes allow the computation of e_2 to be performed under the runtime environment resulting from e_1 .

Values. The meta-variable v ranges over values. Values include integers, the canonical \top value, *closures*, merges of values and records in which the field is a value. Closures are a special kind of box, in which the local environment e_1 is a value and e_2 is an annotated abstraction. For closures, the type annotation for $\{e\}^\bullet$ can be any arrow type, whereas the input type of the type annotation for $\{e\}^\circ$ can only be a record type.

3.2 Subtyping and Disjointness

Subtyping. The subtyping rules, shown in Figure 1, are standard for a calculus with intersection types [13], but they include an additional rule S-RCD for subtyping record types. Note that the combination of the subtyping rules for intersection types and record types enables us to express both depth and width subtyping for multi-field record types (which are just encoded as intersections of single-field record types). This extended subtyping relation is reflexive and transitive [22].

Disjointness. Compared to λ_i , disjointness is defined in a slightly different way, inspired by an approach suggested by Rehman et al. [37]. To make two functions or two records mergeable, we define disjointness based on ordinary types whose definition is shown in Figure 1. There are two variants of ordinary types in E_i . The one for defining disjointness contains premises marked in gray. In this variant, ordinary types are inductively defined to be types where the top type and intersection types can never appear (except as input types of functions). With the help of ordinary types, we define disjointness as:

34:14 Dependent Merges and First-Class Environments

$A <: B$			<i>(Subtyping)</i>
$\frac{\text{S-Z}}{\text{Int} <: \text{Int}}$	$\frac{\text{S-TOP}}{A <: \text{Top}}$	$\frac{\text{S-ARR} \quad B_1 <: A_1 \quad A_2 <: B_2}{A_1 \rightarrow A_2 <: B_1 \rightarrow B_2}$	$\frac{\text{S-ANDL} \quad A_1 <: A_3}{A_1 \& A_2 <: A_3}$
$\frac{\text{S-ANDR} \quad A_2 <: A_3}{A_1 \& A_2 <: A_3}$	$\frac{\text{S-AND} \quad A_1 <: A_2 \quad A_1 <: A_3}{A_1 <: A_2 \& A_3}$	$\frac{\text{S-RCD} \quad A <: B}{\{l : A\} <: \{l : B\}}$	
Ordinary A			<i>(Ordinary Types)</i>
$\frac{\text{O-INT}}{\text{Ordinary Int}}$	$\frac{\text{O-ARROW} \quad \text{Ordinary } B}{\text{Ordinary } A \rightarrow B}$	$\frac{\text{O-RCD} \quad \text{Ordinary } B}{\text{Ordinary } \{l : B\}}$	

■ **Figure 1** Subtyping and ordinary types.

► **Definition 1** (Disjointness). $A * B \equiv \neg(\exists C, \text{Ordinary } C \wedge A <: C \wedge B <: C)$

Two types are disjoint if and only if the two types do not share any common ordinary supertype. We have proved that our definition of disjointness is equivalent to the one employed by Huang et. al [22] in their formulation of λ_i . This definition states that atomic values, which can inhabit the two types, cannot have overlapping types. Importantly, our definition allows two arrow types or two record types to be disjoint. For example, $\text{Int} \rightarrow \text{Bool}$ is disjoint with $\text{Int} \rightarrow \text{Char}$ as the two types do not share a common ordinary supertype. Note that there is also an equivalent algorithmic definition of disjointness, which is shown in the appendix. Some of the fundamental properties of disjointness are shown next:

► **Lemma 2** (Disjointness Properties). *Disjointness satisfies:*

1. If $A * B$, then $B * A$.
2. $A * (B \& C)$ if and only if $A * B$ and $A * C$.
3. If $A * (B_1 \rightarrow C)$, then $A * (B_2 \rightarrow C)$.
4. $A * B$ if and only if $\{l : A\} * \{l : B\}$.
5. $C * D$ if and only if $(A \rightarrow C) * (B \rightarrow D)$.
6. If $A <: B$ and $A * C$, then $B * C$.

3.3 Bidirectional Typing

The type system of E_i shown in Figure 2 is bidirectional. There are two modes of typing, where \Rightarrow and \Leftarrow denote the synthesis and checking modes respectively. The notation \Leftrightarrow is a metavariable for typing modes. The meaning of typing judgment $\Gamma \vdash e \Leftrightarrow A$ is standard: under the context Γ (which is a type), expression e can synthesize (with \Rightarrow) or check against (with \Leftarrow) A .

Typing the query construct. Rule TYP-CTX states that $?$ can synthesize the context. With rule TYP-SUB, $?$ checks against any type that is a supertype of the context. In addition, with rule TYP-ANNO, under a context Γ , for any supertype A of Γ , $? : A$ can synthesize A . Since

$$\boxed{\Gamma \vdash e \Leftarrow A} \quad (\text{Bidirectional Typing})$$

$$\begin{array}{c}
\text{TYP-LIT} \quad \text{TYP-CTX} \quad \text{TYP-TOP} \quad \text{TYP-ANNO} \\
\frac{}{\Gamma \vdash i \Rightarrow \text{Int}} \quad \frac{}{\Gamma \vdash ? \Rightarrow \Gamma} \quad \frac{}{\Gamma \vdash \top \Rightarrow \text{Top}} \quad \frac{}{\Gamma \vdash e \Leftarrow A} \\
\frac{}{\Gamma \vdash e : A \Rightarrow A}
\end{array}$$

$$\begin{array}{c}
\text{TYP-ABS} \quad \text{TYP-APP} \\
\frac{\Gamma * A \quad C <: A_m \quad \Gamma \& A \vdash e \Leftarrow B}{\Gamma \vdash \{e\}^m : A \rightarrow B \Rightarrow C \rightarrow B} \quad \frac{\Gamma \vdash e_1 \Rightarrow A \rightarrow B \quad \Gamma \vdash e_2 \Leftarrow A}{\Gamma \vdash e_1 e_2 \Rightarrow B}
\end{array}$$

$$\begin{array}{c}
\text{TYP-BOX} \quad \text{TYP-RCD} \quad \text{TYP-PROJ} \\
\frac{\Gamma \vdash e_1 \Rightarrow \Gamma_1 \quad \Gamma_1 \vdash e_2 \Rightarrow A}{\Gamma \vdash e_1 \triangleright e_2 \Rightarrow A} \quad \frac{\Gamma \vdash e \Rightarrow A}{\Gamma \vdash \{l = e\} \Rightarrow \{l : A\}} \quad \frac{\Gamma \vdash e \Rightarrow \{l : A\}}{\Gamma \vdash e.l \Rightarrow A}
\end{array}$$

$$\begin{array}{c}
\text{TYP-SUB} \quad \text{TYP-MERGEV} \\
\frac{\Gamma \vdash e \Rightarrow A \quad A <: B}{\Gamma \vdash e \Leftarrow B} \quad \frac{\Gamma \vdash v_1 \Rightarrow A \quad \Gamma \vdash v_2 \Rightarrow B \quad v_1 \approx v_2}{\Gamma \vdash v_1, v_2 \Rightarrow A \& B}
\end{array}$$

$$\begin{array}{c}
\text{TYP-DMERGE} \quad \text{Type Extraction } A_m \\
\frac{\Gamma \vdash e_1 \Rightarrow A \quad \Gamma \& A \vdash e_2 \Rightarrow B \quad A * \Gamma \quad A * B}{\Gamma \vdash e_1, e_2 \Rightarrow A \& B} \quad \boxed{\begin{array}{l} A_{\bullet} = A \\ \{l : A\}_{\circ} = A \end{array}}
\end{array}$$

■ **Figure 2** Bidirectional type system of E_i . The syntax for the bidirectional modes is defined as $\Leftarrow ::= \Rightarrow \mid \Leftarrow$.

contexts are types in our system, a supertype of a type means a portion of a typing context. By annotating $?$ with a supertype of the context, we can proactively pick the desired type information (or equivalently, hide part of type information) from the context. For example, $\text{Int} \& \text{Bool} \vdash ? : \text{Int} \Rightarrow \text{Int}$ is valid, and allows us to pick Int from a typing context with $\text{Int} \& \text{Bool}$.

$$\begin{array}{c}
\text{TYP-SUB} \quad \frac{\text{Int} \& \text{Bool} \vdash ? \Rightarrow \text{Int} \& \text{Bool} \quad \text{Int} \& \text{Bool} <: \text{Int}}{\text{Int} \& \text{Bool} \vdash ? \Leftarrow \text{Int}} \\
\text{TYP-ANNO} \quad \frac{}{\text{Int} \& \text{Bool} \vdash ? : \text{Int} \Rightarrow \text{Int}}
\end{array}$$

Typing abstractions. Rule TYP-ABS is the typing rule for abstractions. An abstraction can synthesize an arrow type, in which the shape of the input type is determined by the mode. For $\{e\}^{\bullet} : A \rightarrow B$ we simply synthesize the type $A \rightarrow B$. For $\{e\}^{\circ}$ with an annotation, $\{e\}^{\circ}$ is well-typed only if the input type is a record type. Furthermore $\{e\}^{\circ} : \{l : A\} \rightarrow B$ synthesizes $A \rightarrow B$ where A is extracted from $\{l : A\}$. This peculiar treatment of $\{e\}^{\circ} : \{l : A\} \rightarrow B$ is because we wish to be able to model conventional lambda abstractions of the form $\lambda l. e : A \rightarrow B$ faithfully. In conventional lambda abstractions, the labels or variable names are only used *internally*, but they are not reflected on the type. The $\{e\}^{\circ}$ abstractions model this behavior and also hide the label information on the type. While an abstraction with the \bullet mode accepts an expression of a type which is the exact input type of its annotation, a well-typed abstraction with the \circ mode can only have an annotation of form $\{l : A\} \rightarrow B$. The label information for the input type is forgotten for the overall type of the abstraction.

Note also that, for obtaining type preservation, there is a subtyping condition in rule TYP-ABS, similarly to the approach employed by Huang and Oliveira [21]. In an implementation of E_i , this subtyping condition can be omitted and we can let $\{e\}^m : A \rightarrow B$ infer $A_m \rightarrow B$ directly, since the condition is only used in E_i to ensure that closures, which are used during

34:16 Dependent Merges and First-Class Environments

reduction at runtime, are type-preserving. In addition to avoiding ambiguity of the type-based lookups, when we introduce assumptions into the context, we need to ensure that the new assumptions are disjoint to the existing assumptions in the environment. Thus rule TYP-ABS also has a disjointness premise to ensure this.

Typing dependent merges. Rule TYP-DMERGE is the typing rule for merges. Unlike previous work for intersection types and the merge operator [22], the merges are *dependent* in our work. For a specific merge $e_1 \text{ , } e_2$, the right branch e_2 may depend on the left branch e_1 . The typing context for e_2 in the premises is the intersection type $\Gamma \& A$, which means that e_2 is affected by not only the global context Γ but also the synthesized type of e_1 . In this way, e_2 can be constructed with the information of e_1 , as illustrated by the following example:

$$\{z : \text{Int}\} \vdash \{x = 1\} \text{ , } \{y = (? : \{x : \text{Int}\}).x + 1\} \Rightarrow \{x : \text{Int}\} \& \{y : \text{Int}\}$$

The right branch $\{y = (? : \{x : \text{Int}\}).x + 1\}$ makes use of the type information of the left branch, by using $?$ to pick $\{x : \text{Int}\}$ from $\{z : \text{Int}\} \& \{x : \text{Int}\}$. Then it will be able to utilize the value information from $\{x = 1\}$ to evaluate the expression in the right branch of the merge.

There are two disjointness conditions in rule TYP-DMERGE. One is $A * B$, which makes two branches e_1 and e_2 be merged safely without ambiguities as in previous work [22]. However, this condition is not sufficient to prevent all the conflicts between values when the merges are dependent. An additional disjointness condition $A * \Gamma$ is needed to ensure that the synthesized type of the left branch e_1 is disjoint with the context. Without this extra condition, there can be conflicts between e_1 and the current environment. Take the following as an example:

$$(\text{Int} \rightarrow \text{String}) \& \text{Int} \vdash 2 \text{ , } ((? : \text{Int} \rightarrow \text{String}) (? : \text{Int}))$$

The context contains type $\text{Int} \rightarrow \text{String}$ and Int , and the left branch, 2 , has type Int which clashes with the Int that is already in the context. The right branch is an application, which picks a closure and another integer value, say 1 , from the current environment. Suppose that the closure returns the string representation of the input integer. Then $? : \text{Int}$ in the right branch can choose either 1 from the environment or 2 from the left branch, and the merge above can be non-deterministically evaluated to either $2 \text{ , } "1"$ or $2 \text{ , } "2"$. Since we wish to have deterministic evaluation, we prevent such cases with the additional disjointness condition $A * \Gamma$.

Consistency, boxes and closures. Rule TYP-MERGEV is the typing rule for consistent merges. This rule is identical to the rule in previous work using non-dependent merges [21]. Like in previous work, rule TYP-MERGEV is a special run-time typing rule for merges of values and can be omitted in a programming language implementation. If two consistent values are well-typed then it is safe to merge them together. One may wonder why in this rule the context is not extended with A to type-check v_2 . The reason is that values are *closed*, so they cannot depend on the information that is present in the context. During the reduction process, such information has been already filled in into the values. Consistency is defined in terms of casting (whose definition is shown in Figure 3):

► **Definition 3 (Consistency).** *Two values v_1 and v_2 are said to be consistent (written as $v_1 \approx v_2$) if for any type A , the result of casting for the two values is identical.*

$$v_1 \approx v_2 \equiv \forall A, \text{ if } v_1 \hookrightarrow_A v'_1 \text{ and } v_2 \hookrightarrow_A v'_2 \text{ then } v'_1 = v'_2$$

$$\boxed{v \hookrightarrow_A v'} \quad (\text{Casting})$$

$$\begin{array}{c}
\text{CASTING-INT} \quad \text{CASTING-TOP} \quad \text{CASTING-ARROW} \\
\frac{}{i \hookrightarrow_{\text{Int}} i} \quad \frac{}{v \hookrightarrow_{\text{Top}} \top} \quad \frac{\neg \upharpoonright D \upharpoonright \quad C <: A_m \quad B <: D}{v \triangleright (\{e\}^m : A \rightarrow B) \hookrightarrow_{C \rightarrow D} v \triangleright (\{e\}^m : A \rightarrow D)}
\end{array}$$

$$\begin{array}{c}
\text{CASTING-ARROWTL} \quad \text{CASTING-MERGEVL} \\
\frac{\upharpoonright D \upharpoonright \quad C <: A_m \quad B <: D}{v \triangleright (\{e\}^m : A \rightarrow B) \hookrightarrow_{C \rightarrow D} (C \rightarrow D)^\uparrow} \quad \frac{v_1 \hookrightarrow_A v'_1 \quad \text{Ordinary } A}{v_1 \wp v_2 \hookrightarrow_A v'_1}
\end{array}$$

$$\begin{array}{c}
\text{CASTING-MERGEVR} \quad \text{CASTING-AND} \quad \text{CASTING-RCD} \\
\frac{v_2 \hookrightarrow_A v'_2 \quad \text{Ordinary } A}{v_1 \wp v_2 \hookrightarrow_A v'_2} \quad \frac{v \hookrightarrow_A v_1 \quad v \hookrightarrow_B v_2}{v \hookrightarrow_{A \& B} v_1 \wp v_2} \quad \frac{v \hookrightarrow_A v'}{\{l = v\} \hookrightarrow_{\{l:A\}} \{l = v'\}}
\end{array}$$

■ **Figure 3** Casting of E_i .

Given two values, if they have disjoint types, then they are consistent:

► **Lemma 4** (Disjointness implies consistency). *If $A * B$, $\Gamma_1 \vdash v_1 \Rightarrow A$, and $\Gamma_2 \vdash v_2 \Rightarrow B$, then $v_1 \approx v_2$.*

Rule TYP-BOX is the rule for boxes. To make a box $e_1 \triangleright e_2$ well-typed, the global context Γ is replaced for e_2 with type Γ_1 , which is the synthesized type of the local environment e_1 . In other words, the expression e_2 in the box is only affected by the local context. As a special kind of box, closures are closed since the local environment for them is a value and this information is stored for the abstraction. Thus, it is always safe to change the context for closures to any other context. However, we cannot do that for abstractions. For example, if the context for $\{?\}^\bullet : \text{Int} \rightarrow \text{Int}$ is changed from **Top** to **Int**, then the disjointness condition in rule TYP-ABS is broken.

Generally speaking, changing the typing context may introduce more type information such that disjointness does not hold anymore. For example, suppose that the current context is **Int**, which is disjoint with **Char & Bool**. If we replace **Int** with **Int & Bool**, then the new type information **Bool** is introduced in the context and it conflicts with **Char & Bool**. For disjoint values, Lemma 4 ensures that the values are also consistent, so they can be merged together. Therefore, typing two disjoint values does not rely on rule TYP-DMERGE, which restricts the type of the left branch to be disjoint with the context. In fact, another way to describe the closedness of values is to show that the typing context for values can be replaced arbitrarily:

► **Lemma 5** (Value closedness). *If $\Gamma_1 \vdash v \Leftrightarrow A$, then $\Gamma_2 \vdash v \Leftrightarrow A$.*

3.4 Semantics

We now introduce the call-by-value semantics of E_i using an environment-based operational semantics. The semantics employs a type-directed operational semantics (TDOS) [21]. In TDOS, in addition to a reduction relation, there is also a *casting* relation, which is introduced to reduce values based on the type of a given value.

34:18 Dependent Merges and First-Class Environments

$$\begin{array}{c}
 \text{Frames } F ::= [] : A \mid [], e \mid \{l = []\} \mid [], l \mid [], e \mid v [] \mid [], \triangleright e \\
 \\
 \boxed{v \vdash e \hookrightarrow e'} \qquad \text{(Reduction)} \\
 \\
 \begin{array}{ccc}
 \text{STEP-CTX} & \text{STEP-ANNOV} & \text{STEP-MERGER} \\
 \frac{}{v \vdash ? \hookrightarrow v} & \frac{v_1 \hookrightarrow_A v'_1}{v \vdash v_1 : A \hookrightarrow v'_1} & \frac{v, v_1 \vdash e \hookrightarrow e'}{v \vdash v_1, e \hookrightarrow v_1, e'} \\
 \\
 \text{STEP-CLOSURE} & & \text{STEP-BOX} \\

 \\
 \text{STEP-BOXV} & \text{STEP-PROJV} & \text{STEP-EVAL} \\
 \frac{}{v \vdash v_1 \triangleright v_2 \hookrightarrow v_2} & \frac{}{v \vdash \{l = v_1\}.l \hookrightarrow v_1} & \frac{v \vdash e \hookrightarrow e'}{v \vdash F[e] \hookrightarrow F[e']} \\
 \\
 \text{STEP-BETA} & & \text{Value Construction } A_m^v \\
 \frac{v_1 \hookrightarrow_{A_m} v'_1}{v \vdash (v_2 \triangleright (\{e\}^m : A \rightarrow B)) v_1 \hookrightarrow (v_2, A_m^v) \triangleright (e : B)} & & \boxed{\begin{array}{l} A_\bullet^v = v \\ \{l : A\}_o^v = \{l = v\} \end{array}}
 \end{array}
 \end{array}$$

$$\boxed{v \vdash e \hookrightarrow^* e'} \qquad \text{(Multistep Reduction)}$$

$$\begin{array}{ccc}
 \text{MULTI-REFL} & & \text{MULTI-STEP} \\
 \frac{}{v \vdash e \hookrightarrow^* e} & & \frac{v \vdash e \hookrightarrow e' \quad v \vdash e' \hookrightarrow^* e''}{v \vdash e \hookrightarrow^* e''}
 \end{array}$$

■ **Figure 4** Call-by-value reduction and multistep reduction of E_i .

Casting. The casting relation, shown in Figure 3, is defined on values. The casting relation is essentially the same as the relation in Huang et al.’s work [22]. The only difference is that, instead of having lambda abstractions as values, we now have closures as values. So the rules `CASTING-ARROW` and `CASTING-ARROWTL` change correspondingly to adapt to the new form of values. Rule `CASTING-INT` casts any integer value to itself under type `Int`. Rule `CASTING-TOP` casts any value to a \top under the top type. For merges, rule `CASTING-MERGEVL` and rule `CASTING-MERGEVR` cast one of the two branches under an ordinary type. These two rules can be viewed as value selectors for merges. The definition of ordinary types is the variant without the conditions marked in gray shown in Figure 1. In other words, ordinary types used in casting are those types that are not the top type or intersection types. With rule `CASTING-AND`, a value is cast under two parts of an intersection type respectively, and a merge is returned by combining the two results via the merge operator. Rule `CASTING-RCD` casts a record value under a record type with the same label, and the result is a new record that is constructed from the result of casting the inner value under the inner type of the record type.

A closure $v \triangleright \{e\}^m : A \rightarrow B$ can be cast under an arrow type $C \rightarrow D$ to be a new value. If D is not top-like, then rule `CASTING-ARROW` casts the closure such that the return type is changed to D . Rule `CASTING-ARROWTL` ensures the determinism of casting by casting a closure to be a value generated by the value generator function (A^\dagger) for top-like types. Without this rule, casting a merge of two closures via a top-like type can lead to different results. The definition of top-like types and the value generator are shown in the appendix.

Reduction. Reduction is shown in Figure 4. In the reduction relation $v \vdash e_1 \hookrightarrow e_2$, the environment v is a value. Since environments are involved in reduction, the definition of multi-step reduction is changed accordingly as shown in Figure 4. Briefly speaking, $v \vdash e_1 \hookrightarrow^* e_2$ means that e_1 can be reduced to e_2 by multiple steps under the same environment v , though the environment is possibly changed locally, during single-step reductions.

Synthesizing values by types. Rule STEP-CTX reduces a query $?$ to the current environment. Rule STEP-ANNOV is the rule for annotated values, which triggers casting. In TDOS, casting uses type information from type annotations to guide the reduction to ensure determinism. Moreover, in E_i , casting also allows values to be fetched by types from the environment.

$$\text{MULTI-STEP} \frac{\text{STEP-EVAL} \frac{\text{STEP-CTX} \frac{}{v \vdash ? \hookrightarrow v}}{v \vdash ? : A \hookrightarrow v : A} \quad \text{STEP-ANNOV} \frac{v \hookrightarrow_A v'}{v \vdash v : A \hookrightarrow v'}}{v \vdash ? : A \hookrightarrow^* v'}$$

As shown in the derivation tree above, with $v \hookrightarrow_A v'$, we can conclude that $? : A$ will be evaluated to v' eventually. That is, the answer to a query that is equipped with a specific type, is the result of casting the current environment under that type. For example, suppose that the environment is $1, \text{true}$. Then the answer to the query $? : \text{Int}$ is 1 while the answer to the query $? : \text{Bool}$ is true .

Evaluating dependent merges. Similarly to the reduction strategy in calculi with intersection types and a merge operator, merges are evaluated from left to right in E_i . That is, for a merge e_1, e_2 , the right branch e_2 is evaluated only if the left branch e_1 is a value. However, since merges are dependent in E_i , the evaluation of e_2 relies on e_1 . Specifically, for a merge v_1, e in which v_1 is already a value, rule STEP-MERGER evaluates the right branch e under a new environment v, v_1 such that e can access not only the original environment v but also v_1 . The following is an example of evaluating dependent merges, assuming an initial environment \top :

$$\begin{aligned} & \{x = 1\}, \{y = (? : \{x : \text{Int}\}).x + 1\} \\ \hookrightarrow & \{x = 1\}, \{y = ((\top, \{x = 1\}) : \{x : \text{Int}\}).x + 1\} \\ \hookrightarrow & \{x = 1\}, \{y = (\{x = 1\}).x + 1\} \\ \hookrightarrow & \{x = 1\}, \{y = 1 + 1\} \\ \hookrightarrow & \{x = 1\}, \{y = 2\} \end{aligned}$$

The initial merge is evaluated to $\{x = 1\}, \{y = 2\}$. In every single step of the evaluation above, rule STEP-MERGER is triggered and the right branch $\{y = \dots\}$ is evaluated under $\top, \{x = 1\}$.

Closures and the beta rule. In our call-by-value semantics, when a function, which is not a value, is applied with a value, rule STEP-CLOSURE transforms the function to a closure by assigning the current environment to it. Then rule STEP-BETA reduces the application, where the argument is cast first with the input type of the annotation of the closure. After that, the casting result is merged with the environment in the closure, and this merge becomes the local environment of a box. The body of the box is the body of the abstraction inside the applied closure. Thus, the body of the abstraction will be evaluated further under the new environment, which is a merge carrying the information from both the argument and the environment of the closure.

In rule STEP-BETA, the value $A_m^{v'_1}$ that is added to the environment is different according to the mode of the abstraction. For $v_2 \triangleright (\{e\}^\bullet : A \rightarrow B)$, $A_\bullet = A$ and $A_\bullet^{v'_1} = v'_1$, which is the result of casting v_1 with type A . If the mode is \circ , then the input type for the abstraction can only be a record type, say $\{l : A\}$. Thus for $v_2 \triangleright (\{e\}^\circ : \{l : A\} \rightarrow B)$, $\{l : A\}_\circ = A$ and $\{l : A\}_\circ^{v'_1} = \{l = v'_1\}$. That is, $v_2 \triangleright (\{e\}^\circ : \{l : A\} \rightarrow B)$ can accept a value of type A as input, and the value is given the name l such that it becomes a record during *runtime*. In this way, the body of the abstraction e can use the label to access the information in the record. When the evaluation context is the body of a box, rule STEP-EVAL evaluates the local environment under the global environment until it is a value. After that, rule STEP-BOX evaluates the body of the box under the local environment. A condition is set in rule STEP-BOX to prevent closures from being reduced further. When the body is evaluated to a value, rule STEP-BOXV returns that value.

4 Determinism and Type Soundness

In this section, we show that the operational semantics of E_i is deterministic and type-sound. Unlike previous work on calculi with the merge operator, the typing contexts and the environments appearing in the theorems are generalized to arbitrary ones, since environments are first-class and can be manipulated explicitly in our system.

4.1 Determinism

To obtain the determinism of reduction, the determinism of casting is needed. With the help of consistency, any well-typed value that is cast under the same type results in a unique value.

► **Lemma 6** (Determinism of casting). *If $\Gamma \vdash v \Rightarrow B$, $v \hookrightarrow_A v_1$, and $v \hookrightarrow_A v_2$, then $v_1 = v_2$.*

With determinism of casting, we can prove the following generalized version of determinism, which states that if an expression e is well-typed under the type of the environment v , then the reduction result is the same.

► **Theorem 7** (Generalized determinism). *If $\Gamma \vdash e \Leftrightarrow A$, $\text{Top} \vdash v \Rightarrow \Gamma$, $v \vdash e \hookrightarrow e_1$, and $v \vdash e \hookrightarrow e_2$, then $e_1 = e_2$.*

We cannot prove the standard theorem (where the typing context for e is Top and the environment v is \top) directly. The reason is that the environment is changed in rule STEP-MERGER (from v to $v \circ v_1$) and rule STEP-BOX (from v to v_1). If we prove the standard theorem directly, then the premises in the inductive hypothesis restrict the environment to be \top , which is not strong enough. Therefore, we generalize the theorem. Also note that the typing context for v can be any type in the theorem, since from Lemma 5 we know that the context for a well-typed value can be arbitrary. This fact is important for the proofs of metatheory. When a value is well-typed, we want it also to be well-typed under the context (say Top) appearing in the formalization of the theorem. Consider rule STEP-BOX for example. The environment v_1 in the box is well-typed under the type of v , and it is also well-typed under Top , which meets the condition in the inductive hypothesis.

The standard determinism theorem can then be obtained as a corollary:

► **Corollary 8** (Determinism). *If $\text{Top} \vdash e \Leftrightarrow A$, $\top \vdash e \hookrightarrow e_1$, and $\top \vdash e \hookrightarrow e_2$, then $e_1 = e_2$.*

4.2 Progress and Preservation

For progress and preservation, we need the following properties of casting:

- ▶ **Lemma 9** (Progress of casting). *If $\Gamma \vdash v \Leftrightarrow A$ then there exists v' such that $v \hookrightarrow_A v'$.*
- ▶ **Lemma 10** (Transitivity of casting). *If $v \hookrightarrow_A v_1$ and $v_1 \hookrightarrow_B v_2$ then $v \hookrightarrow_B v_2$.*
- ▶ **Lemma 11** (Consistency after casting). *If $\Gamma \vdash v \Rightarrow C$, $v \hookrightarrow_A v_1$ and $v \hookrightarrow_B v_2$, then $v_1 \approx v_2$.*
- ▶ **Lemma 12** (Preservation of casting). *If $v \hookrightarrow_A v'$ and $\Gamma \vdash v \Rightarrow B$ then $\Gamma \vdash v' \Rightarrow A$.*

These lemmas follow the logic of proving type soundness by Huang and Oliveira [21]. Lemma 9 states that a well-typed value can always be cast with its type. Lemma 10 ensures that casting results in the same value whether a value is cast directly or not. With this property and the determinism of casting, we can prove that the casting results of a value are consistent (Lemma 11), which ensures that casting preserves types (Lemma 12).

Progress and preservation. Similarly to generalized determinism, we have generalized progress and preservation lemmas. Both theorems are proved by induction on the typing judgment.

- ▶ **Theorem 13** (Generalized progress). *If $\Gamma \vdash e \Leftrightarrow A$, then*
 - *e is a value, or*
 - *for any value v , if $\text{Top} \vdash v \Rightarrow \Gamma$, then there exists e' s.t. $v \vdash e \hookrightarrow e'$.*
- ▶ **Theorem 14** (Generalized preservation). *If $\Gamma \vdash e \Leftrightarrow A$, $\text{Top} \vdash v \Rightarrow \Gamma$, and $v \vdash e \hookrightarrow e'$, then $\Gamma \vdash e' \Leftrightarrow A$.*

With the generalized theorems above, the standard progress and preservation theorem can then be obtained as corollaries:

- ▶ **Corollary 15** (Progress). *If $\text{Top} \vdash e \Leftrightarrow A$, then e is a value, or there exists e' s.t. $\top \vdash e \hookrightarrow e'$.*
- ▶ **Corollary 16** (Preservation). *If $\text{Top} \vdash e \Leftrightarrow A$ and $\top \vdash e \hookrightarrow e'$, then $\text{Top} \vdash e' \Leftrightarrow A$.*

Type-safety. Combining generalized progress and preservation, we have generalized type safety where the multistep relation is involved. Basically, this generalized result indicates that under a well-typed environment, a well-typed expression will never get stuck.

- ▶ **Corollary 17** (Generalized type safety). *If $\Gamma \vdash e \Leftrightarrow A$, $\text{Top} \vdash v \Rightarrow \Gamma$, v is a value, and $v \vdash e \hookrightarrow^* e'$, then either e' is a value or there exists e'' s.t. $v \vdash e' \hookrightarrow e''$.*

Thus, the standard type safety is an immediate corollary where the environment is instantiated to be the top value.

- ▶ **Corollary 18** (Type safety). *If $\text{Top} \vdash e \Leftrightarrow A$ and $\top \vdash e \hookrightarrow^* e'$, then either e' is a value or there exists e'' s.t. $\top \vdash e' \hookrightarrow e''$.*

5 Encoding of λ_i

In this section, we show that E_i can encode the type system of the λ_i [32] via a type-directed translation. In other words, every well-typed expression in λ_i can be translated into a well-typed expression in E_i . We do not prove the operational correspondence because of the significant differences between the formulations of the semantics of λ_i and the environment-based semantics of E_i . However, as we discussed in Section 2, the E_i calculus enables first-class environments and dependent merges, which cannot be modelled by λ_i . The translation of λ_i to E_i demonstrates a few different things:

1. **Variables and lambda abstractions are encodable.** The first purpose of this translation is to show that standard variables and lambda abstractions can be fully encoded in E_i . Since λ_i has conventional lambda abstractions, the translation from λ_i to E_i demonstrates that lambdas are encoded in a general way.
2. **Non-dependent merges are encodable.** The second purpose of the translation is to show that non-dependent merges are also encodable. This encoding is not obvious since dependent merges introduce new disjointness restrictions that are not present in calculi such as λ_i . We show that a combination of E_i constructs can express all non-dependent merges without loss of generality.
3. **The E_i calculus subsumes λ_i .** Finally, with the two previous points, we can generally conclude that all typeable programs in λ_i can be encoded in E_i . So E_i is more powerful than λ_i . This is a desirable property since E_i is designed as a potential replacement for λ_i . Therefore, we should be able to express all the programs that are expressible in λ_i .

5.1 Syntax

The definitions of types, expressions, and typing contexts of λ_i are shown as follows:

Types	$A, B ::= \text{Int} \mid \text{Top} \mid A \rightarrow B \mid A \& B$
Expressions	$E ::= x \mid i \mid \top \mid \lambda x. E \mid E_1 E_2 \mid E_1 , , E_2$
Contexts	$\Gamma ::= \cdot \mid \Gamma, x : A$

Note that λ_i is a conventional lambda calculus with standard lambda abstractions and a standard context definition. Moreover, in λ_i contexts are *not* types, and environments are not first class.

5.2 Type-Directed Translation of λ_i to E_i

To utilize the information from λ_i contexts to construct expressions of E_i , we need to transform λ_i contexts to E_i contexts which are types. The translation function for contexts is defined as follows.

► **Definition 19** (Context translation). $|\Gamma|$ transforms contexts of λ_i to types of E_i .

$$\begin{aligned} |\cdot| &= \text{Top} \\ |\Gamma, x : A| &= |\Gamma| \& \{x : A\} \end{aligned}$$

Figure 5 shows the typing rules of λ_i with an elaboration into E_i . Four of the rules are straightforward. Rule STYP-LIT simply translates an integer to itself. Similarly, Rule STYP-TOP translates the top value to itself. Rule STYP-SUB produces an expression by adding a type annotation, which is a super type of the type of the expression in the premise. Rule STYP-APP simply combines the two elaborated expressions into an application in E_i .

$$\boxed{\Gamma \vdash E : A \rightsquigarrow e} \quad (\text{Typing with elaboration})$$

$$\begin{array}{c}
\text{STYP-LIT} \qquad \qquad \text{STYP-TOP} \qquad \qquad \text{STYP-VAR} \\
\frac{}{\Gamma \vdash i : \text{Int} \rightsquigarrow i} \qquad \frac{}{\Gamma \vdash \top : \text{Top} \rightsquigarrow \top} \qquad \frac{x : A \in \Gamma}{\Gamma \vdash x : A \rightsquigarrow (? : \{x : A\}).x} \\
\text{STYP-SUB} \qquad \qquad \text{STYP-ABS} \\
\frac{\Gamma \vdash E : A \rightsquigarrow e \quad A <: B}{\Gamma \vdash E : B \rightsquigarrow e : B} \qquad \frac{\Gamma, x : A \vdash E : B \rightsquigarrow e}{\Gamma \vdash \lambda x. E : A \rightarrow B \rightsquigarrow \{e\}^\circ : \{x : A\} \rightarrow B} \\
\text{STYP-APP} \\
\frac{\Gamma \vdash E_1 : A \rightarrow B \rightsquigarrow e_1 \quad \Gamma \vdash E_2 : A \rightsquigarrow e_2}{\Gamma \vdash E_1 E_2 : B \rightsquigarrow e_1 e_2} \\
\text{STYP-MERGE} \\
\frac{\Gamma \vdash E_1 : A \rightsquigarrow e_1 \quad \Gamma \vdash E_2 : B \rightsquigarrow e_2 \quad A * B \quad \text{fresh } x}{\Gamma \vdash E_1, E_2 : A \& B \rightsquigarrow \{x = ?\} \triangleright (? . x \triangleright e_1), ((? : \{x : |\Gamma|\}).x \triangleright e_2)}
\end{array}$$

■ **Figure 5** Type system of λ_i and its type-directed translation into E_i .

Encoding variables. Rule STYP-VAR uses labels to model variables. If a variable x has type A , then $x : A$ must appear in the context. This information from contexts is encoded as a record type $\{x : A\}$ in E_i . Thus, it becomes safe to annotate the query $?$ with $\{x : A\}$. To get the type of x , a record projection is performed to extract the value of type A from $\{x : A\}$.

Encoding lambda abstractions. Similarly, the type information of the bound variable x in a λ_i lambda abstraction is also translated to $\{x : A\}$. For any $\lambda x. E$ of type $A \rightarrow B$, rule STYP-ABS encodes it as $\{e\}^\circ : \{x : A\} \rightarrow B$, which has type $A \rightarrow B$ instead of $\{x : A\} \rightarrow B$. In this way, it can accept values of type A instead of $\{x : A\}$. For example, $\lambda x. x$ with type $\text{Int} \rightarrow \text{Int}$ is translated to $\{(\{x : \text{Int}\}).x\}^\circ : \{x : \text{Int}\} \rightarrow \text{Int}$, which can accept the integer 1 as input in an application.

Encoding non-dependent merges. Merges in λ_i are non-dependent and are encoded in an interesting way in E_i . For dependent merges, the global context should be disjoint with the type of the left branch. To prevent overlapping between $|\Gamma|$ and A , a fresh label x that does not appear in the existing types is picked to create a record $\{x : |\Gamma|\}$ that holds the current environment. This record becomes the context for the merge and is disjoint with A , since x is fresh and consequently A cannot contain a record with a field x . With the box construct, the merge is assigned the local environment $\{x = ?\}$. For the left branch of the merge, projection $? . x$ unwraps the context to take back the original context $|\Gamma|$. Similarly, unwrapping is needed for the right branch. However, since A appears in the typing scope for the right branch in a dependent merge, the annotation $\{x : |\Gamma|\}$ is needed for hiding A . In this way, only $|\Gamma|$ appears in the typing context of e_2 .

Example. In λ_i , the merge $x, \lambda y. y$ can have type $\text{Int} \& (\text{Int} \rightarrow \text{Int})$ in the context $x : \text{Int}$. This expression is translated to the following expression in E_i :

$$\{z = ?\} \triangleright (? . z \triangleright (? : \{x : \text{Int}\}). x), ((? : \{z : \{x : \text{Int}\}\}). z \triangleright \{(? : \{y : \text{Int}\}). y\}^\circ : \{y : \text{Int}\} \rightarrow \text{Int})$$

where z is the fresh label that wraps the environment. This E_i expression infers $\text{Int} \& (\text{Int} \rightarrow \text{Int})$ in the context $\{x : \text{Int}\}$.

Type safety of the translation. The following result shows the type-safety of the translation, and that the type system of λ_i can be translated into E_i without loss of expressivity. Importantly, normal lambda abstractions and non-dependent merges are expressible in E_i .

► **Theorem 20** (Well-typed encoding of λ_i). *If $\Gamma \vdash E : A \rightsquigarrow e$, then $|\Gamma| \vdash e \Rightarrow A$.*

6 Related Work

First-class environments. First-class environments enable environments to be manipulated by programmers. Gelernter et al. [18] invented a programming language called Symmetric Lisp that enriches Lisp with a kind of first-class environment, which can be used to evaluate expressions. They argued using several examples that the first-class environments they defined generalize a variety of constructs including modules, records, closures, and classes. However, the formal semantics of the language is not included in their work. Miller and Rozas [29] also proposed an extension to the Scheme programming language. In their work, environments are created with `make-environment`, and a binary `eval` function is used to perform computations under a first-class environment. Jagannathan [23, 24] defined a dialect of Scheme called Rascal, in which two key operators related to first-class environments are introduced: `reify` that returns the current environment as a data object, and `reflect` which transforms data objects to an environment.

Queinnec and de Roure [36] present a form of first-class environments as an approach to share data objects for the Scheme programming language. Operators on environments, such as composition, importing, and exporting, are supported in their setting. Moreover, the first-class environments they proposed obey the quasi-static discipline [26] such that variables are either static or quasi-static during importing and exporting. Note that our treatment of variable names is similar to the quasi-static scoping approach [26] in some sense. To solve the issue of name capturing, in quasi-static scoping, a free variable has an *internal* name and an *external* name. The external name is for sharing variable bindings and is not α -convertible. The programmer has to resolve it before dereferencing. In our setting, the label x in the abstraction $\{?.x\}^\bullet : \{x : \text{Int}\} \rightarrow \text{Int}$ acts as an external name. In order to avoid ambiguities, the external names in quasi-static scoping must be different in their setting, which is similar to our approach where names are ensured to be different via disjointness.

All the work above is done in a dynamically typed setting. Regarding typed languages, there is little work on first-class environments, which are basically based on explicit substitutions [1]. Sato et al. [44, 45] introduced a simply typed calculus called $\lambda\varepsilon$ with environments as first-class values. In their work, full reduction is supported, and lambda abstractions allow local renaming of bounded variables to fresh names. Sato et al. proved some desirable properties, such as subject reduction, confluence and strong normalizability, for this calculus. First-class environments are called explicit environments in $\lambda\varepsilon$, which are sets of variable-value pairs. Moreover, there is an evaluation operation $e[[a]]$ that evaluates the expression a under an environment e . This construct is similar to the box construct in E_i . However, reification and environment concatenation are not supported in his work. Nishizaki [47]

proposed a similar calculus with first-class environments, in which a construct called *id* is introduced to return the current environment. This construct acts as reification and is similar to our queries, but Nishizaki’s calculus does not support restriction. In E_i queries together with type annotations can retrieve parts of an environment, and model environment restriction. While there is an operator called extension, which can be viewed as a special case of concatenation in Nishizaki’s work, the types do not accumulate. In contrast, environment concatenation in E_i is modelled via dependent merges with type information flowing from left to right. Subtyping is not included in existing type systems with environment types. In contrast, E_i supports subtyping and has a natural notion of subtyping of environments. As a result, it enables more applications. For instance, objects and inheritance can be modelled in E_i [5].

Module systems. Module systems [27] are a key structuring mechanism to build reusable components in modular programming. In ML-style languages, module systems serve as a powerful tool for data abstraction. Generally speaking, a module is a named collection of (dependent) declarations that aim to define an environment. Since dependent merges are supported in E_i , a simple form of modules is allowed by using records and merges in our work. For example, the record $\{M = \{x = 1\}, \{y = ?.x\}\}$ in E_i defines a module named M that contains dependent declarations. Conventionally, ML-style languages are stratified into two parts: a core language, which is associated with ordinary values and types; and a module language consisting of modules and module types (or signatures). In this way, modules are second-class since a module cannot be passed as an argument to a function. In E_i , a simple form of *first-class* modules is enabled via first-class environments. Therefore in our setting, modules can be created and manipulated on the fly. For instance, the above module M encoded as a record can be passed to a function, such that the values bound with x and y could be updated.

There is much work on getting around this stratification to enable first-class modules. One approach is to utilize dependent types. Harper and Mitchell proposed XML calculus [20] which is a dependent type system to formalize modules as Σ and Π types. After that, translucent sums [19] and singleton types [48] were present as extensions and refinement of the XML calculus. On the other hand, Rossberg et al. proposed the F-ing method [42] to encode the ML module system using System F_ω [3] rather than dependent types. Following the F-ing method, 1ML was proposed by Rossberg [41] in which core ML and modules are collapsed into one language. Compared with E_i , the calculi in this kind of work are more expressive due to the use of powerful type systems, where type declarations and abstract types are typically supported. However, expressions, declarations, and modules are separate in the syntax. In contrast, we demonstrate a new approach to enable a simple form of first-class modules via a unified syntax in our work. A variety of entities, including environments, records, declarations, and modules, are simply expressions in E_i .

Implicit calculi. Implicits are a mechanism for implicitly passing arguments based on their types, which are supported in Scala as a generic programming mechanism to reduce boilerplate code. Oliveira et al. [11] investigated the connection between Haskell type classes and Scala implicits. They showed that many extensions of the Haskell type class system can be encoded using implicits. After that, Oliveira et al. [12] synthesized the key ideas of implicits formally in a general core calculus that is called the implicit calculus. The implicit calculus supports a number of source language features that are not supported by type classes. In implicit calculi there are two kinds of contexts and/or environments: there are regular contexts (and environments) tracking variable bindings; and there is also an implicit environment, which tracks values that can be used to provide implicit arguments

automatically. In E_i , we borrow the notion of a query, which enables type-based lookups on implicit environments, from the implicit calculus. While queries are used to query *implicit* environments by type in the implicit calculus, queries in E_i are applied directly to *runtime* environments and there is no distinction between implicit and regular environments.

Rouvoet [43] extended the work of Oliveira et al. and showed that the ambiguous resolution from the implicit calculus is undecidable. Following up on the earlier work on the implicit calculus [12], Schrijvers et al. [46] reformalized the ideas of implicits and presented a coherent and type-safe formal model, which supports first-class overlapping implicits and higher-order rules. Moreover, a more expressive unification-based algorithmic resolution, which is closely related to the idea of propositions as types [50], is described. While a highly complex mechanism is imposed to ensure coherence and the semantics is given by elaboration in their work, in E_i we adopt a TDOS to utilize the type information for guiding reduction and to enable determinism in a natural way. Odersky et al. [31] proposed the SI calculus. The SI calculus generalizes implicit parameters in Scala to implicit function types that have the form of $T? \rightarrow T$, which provides a way to abstract over the contexts consisting of running code. The idea of this generalization was inspired by an early draft of Schrijvers et al.'s work. Unlike the work of Schrijvers et al. and our work, SI lacks unambiguity. Thus a disambiguation scheme is needed in the implementation. While forms of implicit contextual abstraction are offered in the implicit calculi above, a form of contextual abstraction is also supported in E_i . Indeed, since environments are first-class values in E_i , one can easily abstract over the contexts by using abstractions. More recently, Marntirosian et al. [28] added modus ponens to subtyping to make resolution a special case of subtyping and to enable *implicit* first-class environments. Unlike E_i , the runtime environments in their work are still second class.

The merge operator. The merge operator was firstly proposed by Reynolds in the Forsythe language [38] to add the expressiveness for calculi with intersection types. Reynolds' merge operator is quite restrictive and does not allow, for instance, overloaded functions. Since then, several other researchers [8, 15, 32, 33] have removed restrictions and shown more applications of the merge operator. Dunfield [15] presents a powerful calculus with an unrestricted merge operator and an elaboration semantics that can encode various language features. While the elaboration semantics is type-safe, determinism or coherence [39] cannot be ensured. To enable determinism, a disjointness restriction on merges has been proposed in the work of Oliveira et al. [32]. In this work we borrow the idea of merges, intersection types and disjointness from previous work on the merge operator. Unlike previous work, our merges are dependent and E_i has operators to manipulate first-class environments that are not available in earlier calculi with the merge operator. In previous calculi, environments are not first class and the only operators supported on merges are concatenation and restriction.

Staged calculi and modal logic. Staging is a technique to separate the computations of a program, such that abstraction can be realized without loss of efficiency. Davies and Pfenning [14] proposed a type system that captures staged computation based on the intuitionistic variant of the modal logic S4 [35]. The modal necessity operator \Box is introduced, and $\Box A$ represents the type of code that will be evaluated in an upcoming stage. At the term level, expressions of type $\Box A$ have the form $\text{box}(e)$. Corresponding to the modal rule of necessitation, $\text{box}(e)$ has type $\Box A$ if e has type A in the *empty* context. Later, after this work, the box construct is generalized by Nanevski et al. in the work of contextual modal type theory [30]. In this work, the box construct has the form $\text{box}(\Psi.e)$ where Ψ is a context and e can utilize the information in Ψ . The construct $\text{box}(\Psi.e)$ is similar to $e_1 \triangleright e_2$ in

E_i in the sense that the context Ψ shadows the current context. Both constructs capture the dependence of expressions on contexts, in effect modelling data injection. However, since Ψ is a context, e in $\text{box}(\Psi.e)$ can only utilize type information, whereas in $e_1 \triangleright e_2$, e_2 relies on the concrete environment information from the expression e_1 directly. Furthermore, in modal type theory contexts Ψ are defined in the usual way and are not types, nor are first class in the language. In contrast, contexts are types in E_i , and environments are first class values.

Abstract machines. Abstract machines, such as the SECD machine [25], Krivine’s machine, the categorical abstract machine [10], and the CEK machine [16], are state transition systems that serve as a basis for the implementation of functional languages. Typically, a state in abstract machines is a tuple that contains an expression, an environment, and some other entities (such as stack and continuation) for reduction. Similarly, in E_i the semantics is an environment-based semantics, and closures are used to keep environments around during the reduction. However, abstract machines are models for lambda calculus, and thus they are not aimed at providing languages with first-class environments. In contrast, the E_i calculus supports first-class environments and operators that manipulate environments.

7 Conclusion

In this paper, we have presented a statically typed calculus called E_i , that supports the creation, reification, reflection, concatenation and restriction of first-class environments. The E_i calculus borrows disjoint intersection types and a merge operator from the λ_i [32] calculus, but employs them to model environments. In E_i , intersection types are used to model contexts, and disjointness is imposed to model (and generalize) the uniqueness of variables in an environment. However, unlike previous work, merges in E_i are dependent, which enables modelling dependent declarations. From *implicit calculi* [12, 31, 46], E_i borrows queries to synthesize the full current context (at the type level) and the entire current environment (at the term level), and to enable type-based lookups. We prove the determinism and type-soundness of E_i . Furthermore, we show that the type system of λ_i can be encoded by E_i via a type-directed translation. In other words, standard variables, lambda abstractions, and non-dependent merges are all encodable in E_i , enabling the E_i calculus to subsume λ_i . We also study an extension of the calculus with fixpoints. The E_i calculus, as well as the extension, and all the proofs presented in this paper have been formalized using Coq theorem prover.

As for future work, we are interested in extensions with more features. For example, we plan to investigate how to incorporate BCD subtyping [4]. With the merge operator and BCD subtyping, a powerful form of composition called nested composition [6] can be enabled. We would also like to extend the current calculus with polymorphism and show that abstract types can be encoded with the extended calculus. In this setting, since type variables could occur in contexts, we plan to use labels to model type variables, just like what we have done for term variables.

A Some Relations

A.1 Algorithmic Disjointness

$A \sqcap B$	<i>(COSTs)</i>			
$\frac{\text{COST-INT}}{\text{Int} \sqcap \text{Int}}$	$\frac{\text{COST-ANDL}}{A \sqcap C}$ $\frac{}{A \& B \sqcap C}$	$\frac{\text{COST-ANDR}}{B \sqcap C}$ $\frac{}{A \& B \sqcap C}$	$\frac{\text{COST-RANDL}}{A \sqcap B}$ $\frac{}{A \sqcap B \& C}$	$\frac{\text{COST-RANDR}}{A \sqcap C}$ $\frac{}{A \sqcap B \& C}$
	$\frac{\text{COST-ARR}}{B \sqcap D}$ $\frac{}{A \rightarrow B \sqcap C \rightarrow D}$		$\frac{\text{COST-RCD}}{A \sqcap B}$ $\frac{}{\{l : A\} \sqcap \{l : B\}}$	

Here we define a relation called COSTs (Common Ordinary Super Types), which is used to define algorithmic disjointness as following:

► **Definition 21** (Algorithmic Disjointness). $A *_a B \equiv \neg(A \sqcap B)$

The algorithmic disjointness is equivalent to the specification of disjointness (Definition 1).

► **Theorem 22** (Disjointness Equivalence). $A *_a B$ if and only if $A * B$.

A.2 Top-like Types

$$\boxed{\lceil A \rceil} \quad (\text{Top-like Types})$$

$$\frac{}{\lceil \text{Top} \rceil} \text{TL-TOP} \quad \frac{\lceil A \rceil \quad \lceil B \rceil}{\lceil A \& B \rceil} \text{TL-AND} \quad \frac{\lceil B \rceil}{\lceil A \rightarrow B \rceil} \text{TL-ARR} \quad \frac{\lceil B \rceil}{\lceil \{l : B\} \rceil} \text{TL-RCD}$$

A.3 Value Generator

► **Definition 23** (Value Generator). A^\uparrow generates a value for top-like type A .

$$\begin{aligned} \text{Top}^\uparrow &= \top \\ (A \rightarrow B)^\uparrow &= \top \triangleright (\{B^\uparrow\}^\bullet : A \rightarrow B) \\ (A \& B)^\uparrow &= A^\uparrow, B^\uparrow \\ \{l : A\}^\uparrow &= \{l = A^\uparrow\} \end{aligned}$$

B Fixpoints

In this section, we discuss an extension of E_i with fixpoints.

$$\begin{array}{ll} \text{Expressions} & e ::= \dots \mid \text{fix } A.e \\ \text{Values} & v ::= \dots \mid v \triangleright (\text{fix } A.e : B) \end{array}$$

Syntax and typing. Expressions are extended with fixpoint $\text{fix } A.e$ in which A is the type annotation. For values, closures are extended with boxes containing a fixpoint. Note that for $\text{fix } A.e$ in a closure, an additional type annotation B is required. Rule **TYP-FIX** is the typing rule for fixpoints, which is shown at the top of Figure 6. To make $\text{fix } A.e$ well-typed, the body e needs to be checked under the context extended with A . Similarly to the typing rule for abstractions, there is also a disjointness condition $\Gamma * A$ to prevent ambiguities.

Casting and reduction. The extended casting and reduction rules for fixpoints are shown in Figure 6. Basically, $v \triangleright (\text{fix } A.e : B)$ is cast with a supertype C and the result depends on whether C is top-like or not. If C is not a top-like type, then the casting result is $v \triangleright (\text{fix } A.e : C)$. Otherwise, $v \triangleright (\text{fix } A.e : B)$ is cast to a value generated by the value generator for C . This is similar to the treatment of casting abstractions for ensuring determinism. Note that C is required to be ordinary in rule **CASTING-FIX** and rule **CASTING-FIXTL**. This is to avoid overlapping with rule **CASTING-AND** when C is an intersection type.

For reduction, there are three rules for fixpoints. Rule **STEP-FIX** transforms $\text{fix } A.e$ to a closure by assigning the current environment and giving an additional annotation to it. When $v_2 \triangleright \text{fix } C.e : A \rightarrow B$ is applied to value v_1 , rule **STEP-FIXBETA** “unwinds” the closure in the sense that the closure is put into the environment. In this way, when the application $(e : A \rightarrow B) v_1$ is evaluated, it can access and utilize the closure containing the fixpoint again. Note that the closure put in the environment is $v_2 \triangleright \text{fix } C.e : C$ instead of $v_2 \triangleright \text{fix } C.e : A \rightarrow B$. This is to ensure that the body e of the fixpoint is well-typed under the same context $\Gamma \& C$ for type preservation. Similarly, when a record projection is required, rule **STEP-FIXPROJ** “unwinds” the closure, and evaluates $(e : \{l : B\}).l$ under the environment that contains the fixpoint information.

34:32 Dependent Merges and First-Class Environments

$$\boxed{\Gamma \vdash e \Leftrightarrow A}$$

(Extended Bidirectional Typing)

$$\frac{\text{TYP-FIX} \quad \Gamma * A \quad \Gamma \& A \vdash e \Leftarrow A}{\Gamma \vdash \text{fix } A.e \Rightarrow A}$$

$$\boxed{v \hookrightarrow_A v'}$$

(Extended Casting)

$$\frac{\text{CASTING-FIX} \quad B <: C \quad \neg \lceil C \rceil \quad \text{Ordinary } C}{v \triangleright (\text{fix } A.e : B) \hookrightarrow_C v \triangleright (\text{fix } A.e : C)} \quad \frac{\text{CASTING-FIXTL} \quad B <: C \quad \lceil C \rceil \quad \text{Ordinary } C}{v \triangleright (\text{fix } A.e : B) \hookrightarrow_C C^\uparrow}$$

$$\boxed{v \vdash e \hookrightarrow e'}$$

(Extended Reduction)

$$\frac{\text{STEP-FIX}}{v \vdash \text{fix } A.e \hookrightarrow v \triangleright (\text{fix } A.e : A)}$$

$$\frac{\text{STEP-FIXBETA}}{v \vdash (v_2 \triangleright \text{fix } C.e : A \rightarrow B) v_1 \hookrightarrow (v_2 \text{ , } (v_2 \triangleright \text{fix } C.e : C)) \triangleright (e : A \rightarrow B) v_1}$$

$$\frac{\text{STEP-FIXPROJ}}{v \vdash (v_2 \triangleright \text{fix } A.e : \{l : B\}).l \hookrightarrow (v_2 \text{ , } (v_2 \triangleright \text{fix } A.e : A)) \triangleright (e : \{l : B\}).l}$$

■ **Figure 6** Extended typing, casting, and reduction rules for E_i with fixpoints.

Determinism and type-soundness. The extension with fixpoints retains the properties of determinism and type-soundness. All the metatheory does not require significant changes for this extension and is formalized in the Coq theorem prover.

Synthesis-Aided Crash Consistency for Storage Systems

Abstract

Reliable storage systems must be *crash consistent* – guaranteed to recover to a consistent state after a crash. Crash consistency is non-trivial as it requires maintaining complex invariants about persistent data structures in the presence of caching, reordering, and system failures. Current programming models offer little support for implementing crash consistency, forcing storage system developers to roll their own consistency mechanisms. Bugs in these mechanisms can lead to severe data loss for applications that rely on persistent storage.

This paper presents a new *synthesis-aided* programming model for building crash-consistent storage systems. In this approach, storage systems can assume an *angelic crash-consistency* model, where the underlying storage stack promises to resolve crashes in favor of consistency whenever possible. To realize this model, we introduce a new *labeled writes* interface for developers to identify their writes to disk, and develop a program synthesis tool, DepSynth, that generates *dependency rules* to enforce crash consistency over these labeled writes. We evaluate our model in a case study on a production storage system at Amazon Web Services. We find that DepSynth can automate crash consistency for this complex storage system, with similar results to existing expert-written code, and can automatically identify and correct consistency and performance issues.

1 Introduction

Many applications build on storage systems such as file systems and key-value stores to reliably persist user data even in the face of full-system crashes (e.g., power failures). Guaranteeing this reliability requires the storage system to be *crash consistent*: after a crash, the system should recover to a consistent state without losing previously persisted data. The state of a storage system is consistent if it satisfies the representation invariants of the underlying persistent data structures (e.g., a free data block must not be linked by any file’s inode). Crash consistency is notoriously difficult to get right [34, 22, 35], due to performance optimizations

in modern software and hardware that can reorder writes to disk or hold pending disk writes in a volatile cache. In normal operation, these optimizations are invisible to the user, but a crash can expose their partial effects, leading to inconsistent states.

A number of general-purpose approaches exist to implement crash consistency, including journaling [23], copy-on-write data structures [24], and soft updates [11]. However, implementing a storage system using these approaches is still challenging for two reasons. First, practical storage systems combine crash consistency techniques with optimizations such as log-bypass writes and transaction batching to improve performance [30]. These optimizations and their interactions are subtle, and have led to severe crash-consistency bugs in well-tested storage systems [17, 7]. Second, developers must implement their system using low-level APIs provided by storage hardware and kernel I/O stacks, which offer no direct support for enforcing consistency properties. Instead they provide only durability primitives such as flushes, and require the developer to roll their own consistency mechanisms on top of them. While prior work offers testing [18, 34] and verification [8, 27] tools for validating crash consistency, these tools do not alleviate the burden of implementing crash-consistent systems.

This paper presents a new synthesis-aided programming model for building crash-consistent storage systems. The programming model consists of three parts: a high-level storage interface based on *labeled writes*; a synthesis engine for turning labeled writes and a desired crash consistency property into a set of *dependency rules* that writes to disk must respect; and a *dependency-aware buffer cache* that enforces the synthesized rules at run time. Together, these three components let developers keep their implementation free of hardcoded optimizations and mechanisms for enforcing consistency. Instead, developers can focus on the key aspects of their storage system – functional correctness, crash consistency, and performance – one at a time. Their development workflow consists of three steps.

First, developers implement their system against a higher-level storage interface by providing *labels* for each write their system makes to disk. Labels provide information about the data structure the write targets and the context for the write (e.g., the transaction it is part of). For example, a simple journaling file system might require two writes to append to the journal: one to append the data block to the tail of the journal (labeled *data*) and one to update a superblock that records a pointer to that tail (labeled *superblock*). This higher-level interface allows the developer to assume a stronger *angelic nondeterminism* model for crashes – the system promises that crash states will *always* satisfy the developer’s crash consistency property if possible – simplifying the implementation effort.

Second, to make their implementation crash consistent even on relaxed storage stacks, the developer uses a new program synthesizer, DepSynth, to automatically generate *dependency rules* that writes to disk must respect. A dependency rule uses labels to define an ordering requirement between two writes: writes with one label must be persisted on disk before corresponding writes with the second label. The DepSynth synthesizer takes three inputs: the storage system implementation, a desired *crash consistency predicate* for disk states of the storage system (i.e., a representation invariant for on-disk data structures), and a collection of small *litmus test* programs [2, 5] that exercise the storage system. Given these inputs, DepSynth searches a space of happens-before graphs to automatically generate a set of dependency rules that guarantee the crash-consistency predicate for every litmus test. Although this approach is example-guided and so only guarantees crash consistency on the supplied tests, the dependency rule language is constrained to make it difficult to overfit to the tests, and so in practice the rules generalize to arbitrary executions of the storage system.

Third, developers run their storage system on top of a *dependency-aware buffer cache* that enforces the synthesized dependency rules. For example, in a journaling file system, the superblock pointer to the tail of the journal must never refer to uninitialized data. DepSynth will synthesize a dependency rule enforcing this consistency predicate by saying that data writes must happen before superblock writes. At run time, the dependency-aware buffer cache enforces this rule by delaying sending writes labeled `superblock` to disk until the corresponding `data` write has persisted. The dependency-aware buffer cache is free to reorder writes in any way to achieve good performance on the underlying hardware (e.g., by scheduling around disk head movement or SSD garbage collection) as long as it respects the dependency rules.

We evaluate the effectiveness and utility of DepSynth in a case study that applies it to ShardStore [4], a production key-value store used by the Amazon S3 object storage service. We show that DepSynth can rapidly synthesize dependency rules for this storage system. By comparing those rules to the key-value store’s existing crash-consistency behavior, we find that DepSynth achieves similar results to rules hand-written by experts, and even corrects an existing crash-consistency issue in the system automatically. We also show that dependency rules synthesized by DepSynth generalize beyond the example litmus tests used for synthesis, and that DepSynth can be used for storage systems beyond key-value stores.

In summary, this paper makes three contributions:

- A new programming model for building storage systems that automates the implementation of crash consistency guarantees;
- DepSynth, a synthesis tool that can infer the dependency rules sufficient for a storage system to be crash consistent; and
- An evaluation showing that DepSynth supports different storage system designs and scales to production-quality systems.

The remainder of this paper is organized as follows. Section 2 gives a walk-through of building a simple storage system with DepSynth. Section 3 defines the DepSynth programming model, including labeled writes and dependency rules. Section 4 describes the DepSynth synthesis algorithm for inferring dependency rules, and Section 5 details DepSynth’s implementation in Rosette. Section 6 evaluates the effectiveness of DepSynth. Section 7 discusses related work, and Section 8 concludes.

2 Overview

This section illustrates the DepSynth development workflow by walking through the implementation of a simple storage system. We show how a developer can build a storage system with labeled writes while assuming a strong crash consistency model, and use DepSynth to automatically make that system crash consistent on real storage stacks.

2.1 Log-structured storage systems

A log-structured storage system persists user data in a sequential log on disk [25]. This design forsakes complex on-disk data structures in favor of one with simple invariants and, as a result, simpler crash consistency requirements. However, although log-structured storage systems are well studied, their precise consistency requirements can be subtle in the face of the caching and reordering optimizations used by the modern storage stack.

Consider implementing a simple key-value store as a log-structured storage system. The on-disk data structure comprises two parts as shown in Figure 2a: a log that stores key-value pairs (with one pair per block), and a superblock that holds pointers to the head and tail of the log. We will assume that single-block writes (`disk.write`) are atomic, that each

```

class KeyValueStore(DepSynth):
    def __init__(self):
        self.superblock = disk.read(0)
        if self.superblock.empty(): # initialize an empty disk
            self.superblock_head, self.superblock_tail = 1, 1
        else:
            self.superblock_head, self.superblock_tail = from_block(superblock)
        self.epoch = 0

    def put(self, key: int, value: int):
        address = self.superblock_tail
        self.superblock_tail += 1

        new_block = to_block(key, value)
        disk.write(address, new_block, ("log", self.epoch))

        new_superblock = to_block(self.superblock_head, self.superblock_tail)
        disk.write(0, new_superblock, ("superblock", self.epoch))

        self.epoch += 1

    def get(self, key: int) -> Optional[int]:
        address = self.superblock_tail - 1
        while address >= self.superblock_head:
            block = disk.read(address)
            current_key, current_value = from_block(block)
            if current_key == key:
                return current_value
            address -= 1
        return None

```

■ **Figure 1** Implementation of a simple log-structured key-value store.

key-value pair fits in one block, and that the log does not run out of space. To implement this system, the developer writes `put` and `get` methods that interact with the disk as shown in Figure 1.

Calls to `disk.read` and `disk.write` illustrate our new higher-level storage interface: `disk.read` is unchanged from the usual system call, taking as input an address on the disk to read from; and `disk.write` takes as input an address on the disk to write to, the block data to write to that address, and a third *label* argument. A label is a pair of a string *name* and an integer *epoch*. Labels serve as identities for writes: the name describes the data structure the write targets, while the epoch relates writes across different data structures. This implementation uses the name part of the label to distinguish writes of new log blocks and writes to the superblock,¹ and uses the epoch part as a logical clock that relates the two writes generated by a single `put` call. Labels exist only in memory while a write is in-flight, and are never persisted to disk.

¹ For this system we could distinguish the two data structures without labels – superblock writes are to address 0 while log writes are to non-zero addresses – but in general, storage systems reuse addresses over time and so this mapping is not static.

(a) On-disk layout of a simple log-structured key-value store. Each block holds a (key, value) pair. The first block is a superblock that holds pointers to the head and tail of the log. (b) Possible on-disk state after a crash, leaving the superblock pointing to a range that includes an invalid block.

■ **Figure 2** The on-disk layout of a simple key-value store. Arrows denote pointers and boxes are blocks.

While this implementation is functionally correct, it would not be crash consistent if implemented on a classical storage stack. The issue is with the ordering of log and superblock writes: even though the code suggests that the superblock write comes after the log write, optimizations in the storage stack could reorder the two writes and lead to a crash state where the superblock is updated but its corresponding new log block is not, as Figure 2b shows. This would leave the `superblock_tail` pointer referring to an uninitialized disk block. What we need for consistency is a way to preclude this reordering. One solution in the DepSynth programming model would be for the developer to manually implement a *dependency rule* that prevents this reordering:

```
def __init__(self):
    self.rule("superblock", "log", eq)
```

A dependency rule `rule("a", "b", eq)` specifies an ordering constraint: a write labeled with name "a" must not be sent to disk until after a write labeled with name "b". We say that such a rule means write "a" *depends on* write "b", or equivalently that write "b" must *happen before* write "a". The third argument to `rule` is an *epoch predicate* that scopes the rule using the epoch in each label. Here, the `eq` predicate restricts the rule to only apply to pairs of writes whose labels have equal epochs. This rule means that superblock updates cannot be persisted on disk until a log block write with the same epoch is persisted first, ruling out the reordering behavior that could make the log inconsistent.

2.2 Dependency rule synthesis

While the developer could specify the above dependency rule manually, our programming model does not require them to, and distilling the correct set of rules for a complex storage system is difficult to do by hand. The challenge is a semantic gap: the developer's desired high-level consistency property is about the on-disk data structure as a whole, but the implementation of consistency can only refer to individual block-sized writes. We bridge this gap with DepSynth, a program synthesis tool that can *automatically infer* the dependency rules sufficient to make a storage system crash consistent.

DepSynth takes three inputs. First, it takes as input the implementation of the storage system. Second, it takes as input a crash consistency predicate, written as an executable checker over a disk state. The crash consistency predicate defines the property that should be true of *every* state of the disk, including after crashes. For our log-structured key-value store, our desired consistency property is that the `superblock_tail` pointer never gets ahead of the blocks that have been written to the log. We can implement this property by checking that all blocks in the log are valid log blocks (we omit an implementation of `valid` for brevity, but it could validate a checksum of the block):

35:6 Synthesis-Aided Crash Consistency for Storage Systems

```
def consistent(self) -> bool:
    ret = True
    for address in range(self.superblock_head, self.superblock_tail):
        block = disk.read(address)
        ret = ret and valid(block)
    return ret
```

Finally, DepSynth takes as input a collection of *litmus tests*, small programs that exercise the storage system. Litmus tests are widely used to communicate the semantics of memory consistency models [2, 32], and have also been used to communicate crash consistency models [5]. A DepSynth litmus test comprises two executable programs *initial* and *main*. Both programs take as input a reference to the storage system. The *initial* program sets up some initial state in the system, and cannot crash. The *main* program manipulates the system state, and can crash at any point. For example, this is a simple litmus test that starts from a single log entry and appends two more:

```
class SingleEntry_TwoAppend(LitmusTest):
    def initial(self, store: KeyValueStore):
        store.put(0, 42)

    def main(self, store: KeyValueStore):
        store.put(1, 81)
        store.put(2, 37)
```

As with previous work on memory consistency models [2, 6], the developer can draw litmus tests from a number of sources: they may be hand-written by the developer, drawn from a common set of tests for important properties, generated automatically by a fuzzer or program enumerator, or intelligently generated by analyzing the on-disk data structures used by the storage system [1].

Given these three inputs, DepSynth automatically synthesizes a set of dependency rules that suffice to guarantee the crash-consistency predicate holds on all crash states generated by all litmus tests. For our example log-structured key-value store, DepSynth synthesizes two dependency rules:

```
def __init__(self):
    self.rule("superblock", "log", eq)
    self.rule("superblock", "superblock", gt)
```

The first rule is the same rule we hand-wrote earlier. The second rule fixes a subtle crash-consistency bug in our hand-written implementation: while the first rule ensures consistency for a *single* put operation, it still allows `superblock_tail` to get ahead of the log if writes from *multiple* puts are reordered with each other (for example, reordering writes from the first and second puts in the litmus test above). The second rule prevents this reordering using the `gt` epoch predicate, which specifies that a superblock write with epoch i cannot be persisted to disk until all superblock writes with lower epochs $j < i$ are persisted first. The combination of these rules precludes the problematic reordering and guarantees that the superblock always refers to a valid *range* of log blocks, rather than only requiring the block at `superblock_tail` to be valid.

3 Reasoning About Crash Consistency

The DepSynth workflow includes a new high-level interface for building storage systems and a synthesis tool for automatically making those systems crash consistent. This section describes the high-level interface, including labeled writes and dependency rules, and presents a logical encoding for reasoning about crashes of systems that use this interface. Section 4 then presents the DepSynth synthesis algorithm for inferring sufficient dependency rules to make a storage system crash consistent.

3.1 Disk Model and Dependency Rules

In the DepSynth programming model, storage systems run on top of a disk model d that provides two operations:

- $d.\text{write}(a, v, l)$: write a data block v to disk address a with label l
- $d.\text{read}(a)$: read a data block at disk address a

We assume that single-block write operations are atomic, as in previous work [27, 8]. These interfaces are similar to the standard POSIX `pwrite` and `pread` APIs, except that the `write` operation additionally takes as input a *label* for the write. A label $l = \langle n, t \rangle$ is a pair of a *name* string n and an *epoch* integer t . Labels allow the developer to provide identities for each write their system performs, which dependency rules (described below) can inspect to enforce ordering requirements. Although the two components of a label together identify a write, developers use them for separate purposes: the name indicates which on-disk data structure the write targets, while the epoch associates related writes with different names. Names are strings but are not interpreted by our workflow other than to check equality between them. Epochs are integers that dependency rules use as logical clocks to impose orderings on related writes.

3.1.1 Dependency rules

DepSynth synthesizes declarative *dependency rules* to enforce consistency requirements for a storage system that uses labeled writes.

► **Definition 1** (Dependency rule). *A dependency rule $n_1 \rightsquigarrow_p n_2$ comprises two names n_1 and n_2 and an epoch predicate $p(t_1, t_2)$ over pairs of epochs. Given two labels $l_a = \langle n_a, t_a \rangle$ and $l_b = \langle n_b, t_b \rangle$, we say that a dependency rule $n_1 \rightsquigarrow_p n_2$ matches l_a and l_b if $n_a = n_1$, $n_b = n_2$, and $p(t_a, t_b)$ is true.*

Dependency rules define ordering requirements over all writes with labels that match them, and the dependency-aware buffer cache enforces these rules at run time. More precisely, the dependency-aware buffer cache enforces *dependency safety* for all writes it sends to disk:

► **Definition 2** (Dependency safety). *A dependency-aware buffer cache maintains dependency safety for a set of dependency rules R if, whenever a storage system issues two writes $d.\text{write}(a_1, s_1, l_1)$ and $d.\text{write}(a_2, s_2, l_2)$, and a rule $n_a \rightsquigarrow_p n_b \in R$ matches l_1 and l_2 , then the cache ensures the write to a_1 does not persist until the write to a_2 is persisted on disk.*

In other words, all crash states of the disk that include the effect of the first write must also include the effect of the second write. Section 3.3 will specify dependency safety more formally by defining the crash behavior of a disk in first-order logic.

The epoch predicate of a dependency rule reduces the scope of the rule to only apply to some writes labeled with the relevant names. Given two labels $l_1 = \langle n_1, t_1 \rangle$ and $l_2 = \langle n_2, t_2 \rangle$, a dependency rule $n_1 \rightsquigarrow_p n_2$ can use one of three epoch predicates: $=$, $>$, and $<$, which restrict

the rule to apply only when $t_1 = t_2$, $t_1 > t_2$, and $t_1 < t_2$, respectively. These variations allow dependency rules to specify ordering requirements over unbounded executions of the storage system without adding unnecessary dependencies between *all* operations with certain names.

Together, the name and epoch components of labels allow dependency rules to define a variety of important consistency requirements, depending on how the developer chooses to label their writes. For example, if all writes generated by a related operation (e.g., a top-level API operation like `put` in a key-value store) share the same epoch t , then rules using the $=$ epoch predicate can impose consistency requirements on individual operations, such as providing transactional semantics. As another example, rules using the $>$ epoch predicate can be used as barriers for all previous writes, and so can help to implement operations like garbage collection that manipulate an entire data structure.

3.1.2 Dependency-aware buffer cache

At run time, storage systems implemented with the DepSynth programming model execute on top of a *dependency-aware buffer cache*. This buffer cache is configured with a set of dependency rules at initialization time, and enforces those rules on all writes executed by the storage system.

The dependency-aware buffer cache is inspired by previous higher-level storage APIs such as those used by Featherstitch [10] and ShardStore [4], which also provide interfaces for specifying ordering requirements for writes. Both of these interfaces are imperative: they require the developer to manually construct a dependency graph for each write they execute, and so closely intertwine the ordering requirements with the implementation, as constructing these graphs requires sharing graph nodes (*patchgroups* in Featherstitch and *dependencies* in ShardStore) across threads and operations. In contrast, the dependency-aware buffer cache interface is declarative: the dependency rules are configured once, and then automatically applied to all relevant writes without requiring the developer to manually construct graphs or invoke consistency primitives like `fsync`.

The implementation details of the dependency-aware buffer cache are outside the scope of this paper and follow the examples of Featherstitch and ShardStore. An implementation could use a variety of consistency and durability primitives provided by disks, including force-unit-access writes, cache flush commands, or ordering barriers. We trust the correctness of the dependency-aware buffer cache, and specifically we assume it enforces dependency safety (Definition 2).

3.2 Storage Systems and Litmus Tests

To apply DepSynth, developers provide three inputs: a storage system implementation, a collection of litmus tests that exercise the storage system, and a crash consistency predicate for the system.

3.2.1 Storage system implementations

Developers implement a storage system for DepSynth by defining a collection of API operations \mathcal{O} and an implementation function for each operation:

► **Definition 3** (Storage system implementation). *A storage system implementation $\mathcal{O} = \{O_a, O_b, \dots\}$ is a set of API operations O_i and, for each O_i , an implementation function $I_{O_i}(d, \mathbf{x})$ that takes as input a disk state d and a vector of other inputs \mathbf{x} and issues write operations to mutate disk d .*

DepSynth requires implementation functions to support being symbolically evaluated with respect to a symbolic disk state d . In this paper, we use Rosette [28] as our symbolic evaluator; this requires implementation functions to be written in Racket and allows them to be automatically lifted to support the necessary symbolic evaluation, so long as their executions are deterministic and bounded.

We say that a *program* P is a sequence of calls $[O_1(x_1), \dots, O_n(x_n)]$ to API operations $O_i \in \mathcal{O}$. Given a program P , we write $Evaluate_{\mathcal{O}}(P)$ for the function that symbolically evaluates each $I_{O_i}(d, x_i)$ in turn, starting from a symbolic disk d , and returns a *trace* of labeled write operations $[w_1, \dots, w_n]$ that the program performed. The trace does not need to include read operations as they cannot participate in ordering requirements.

3.2.2 Litmus tests

DepSynth synthesizes dependency rules from a set of example *litmus tests*, which are small programs that exercise the storage system and demonstrate its desired consistency behavior. A litmus test $T = \langle P_{initial}, P_{main} \rangle$ is a pair of programs that each invoke operations of the storage system. The initial program $P_{initial}$ sets up an initial state of the storage system by, for example, prepopulating the disk with files or objects. It will be executed starting from an empty disk, and cannot crash. The main program P_{main} then tests the behavior of the storage system starting from that initial state. DepSynth will exercise all possible crash states of the main program.

Litmus tests are widely used to communicate the semantics of memory consistency models to developers [2, 32], and have also been used to communicate crash consistency [5] and to search for crash consistency bugs in storage systems [18]. DepSynth is agnostic to the source of the litmus tests it uses so long as they fit the definition of a program (i.e., are straight-line and deterministic).

3.2.3 Crash consistency predicates

To define crash consistency for their system, developers also provide a *crash-consistency predicate* $Consistent(d)$ that takes a disk state d and returns whether the disk state should be considered consistent. The crash-consistency predicate should include representation invariants for the storage system’s on-disk data structures. For example, a file system like ext2 might require that all block pointers in inodes refer to blocks that are allocated (i.e., no dangling pointers). These properties correspond to those that can be checked by an `fsck`-like checker [12]. The crash-consistency predicate can also include stronger properties such as checking the atomic-replace-via-rename property for POSIX file systems [5, 22].

3.3 Reasoning About Crashes

To reason about the crash behaviors of a storage system, we encode the semantics of dependency rules and litmus tests in first-order logic based on existing work on storage verification [27]. We first encode the behavior of a single write operation, and then extend that encoding to executions of entire programs.

3.3.1 Write operations

We model the behavior of a disk write operation as a transition function $f_{\text{write}}(d, a, v, s)$, that takes four inputs: the current disk state d , the disk address a to write to, the new block value v to write, and a *crash flag* s , a boolean that is used to encode the effect of a crash on the resulting disk state. Given these inputs, f_{write} returns the resulting disk state after applying the operation. The effect of a write operation is visible on the disk only if s is true:

$$f_{\text{write}}(d, a, v, s) = d[a \mapsto \text{if } s \text{ then } v \text{ else } d(a)].$$

3.3.2 Program executions

Given the trace of write operations $[w_1, \dots, w_n] = \text{Evaluate}_{\mathcal{O}}(P)$ executed by a program P against storage system \mathcal{O} , and for each write its corresponding crash flag s_i , we can define the final disk state of the program by just applying the transition function in sequence:

$$\begin{aligned} & \text{Run}([\text{write}(a_1, v_1, l_1), w_2, \dots, w_n], [s_1, \dots, s_n], d) \\ &= \text{Run}([w_2, \dots, w_n], [s_2, \dots, s_n], f_{\text{write}}(d, a_1, v_1, s_1)) \\ & \quad \text{Run}([], [], d) = d \end{aligned}$$

We call the vector $\mathbf{s} = [s_1, \dots, s_n]$ of crash flags for each operation in the trace a *crash schedule*.

Not all crash schedules are possible. At run time, the dependency-aware buffer cache constrains the set of *valid crash schedules* by applying the dependency rules it is configured with:

► **Definition 4** (Valid crash schedule). *Let $[w_1, \dots, w_n] = \text{Evaluate}_{\mathcal{O}}(P)$ be the trace of operations executed by a program P on storage system \mathcal{O} , R be a set of dependency rules, and $\mathbf{s} = [s_1, \dots, s_n]$ the crash schedule for the trace. The crash schedule \mathbf{s} is valid for the program P and set of rules R , written $\text{Valid}_R(\mathbf{s}, P)$, if for all operations $w_i = \text{write}(a_i, v_i, l_i)$ and $w_j = \text{write}(a_j, v_j, l_j)$, whenever there exists a rule $n_a \rightsquigarrow_p n_b \in R$ that matches l_i and l_j , then $s_i \rightarrow s_j$.*

This definition is a logical encoding of dependency safety (Definition 2): if $s_i \rightarrow s_j$, then write w_j is guaranteed to be persisted on disk whenever write w_i is.

Finally, we can define crash consistency for a litmus test $T = \langle P_{\text{initial}}, P_{\text{main}} \rangle$ as a function of a set of dependency rules R :

► **Definition 5** (Single-test crash consistency). *Let $T = \langle P_{\text{initial}}, P_{\text{main}} \rangle$ be a litmus test. Let $d_{\text{initial}} = \text{Run}(\text{Evaluate}_{\mathcal{O}}(P_{\text{initial}}), \top, d_0)$ be the disk state reached by running the program P_{initial} against storage system \mathcal{O} on the all-true (i.e., crash-free) crash schedule \top starting from the empty disk d_0 . A set of dependency rules R makes T crash consistent if, for all crash schedules \mathbf{s} such that $\text{Valid}_R(\mathbf{s}, P_{\text{main}})$ is true, $\text{Consistent}(\text{Run}(\text{Evaluate}_{\mathcal{O}}(P_{\text{main}}), \mathbf{s}, d_{\text{initial}}))$ holds.*

► **Example 6.** Consider the `SingleEntry_TwoAppend` litmus test from Section 2. Interpreting the initial and main programs gives two traces:

$$\begin{aligned} \text{Interpret}(P_{\text{initial}}) &= [\text{write}(1, \text{to_block}((0, 42)), \langle \text{log}, 0 \rangle), \\ &\quad \text{write}(0, \text{to_block}((1, 2)), \langle \text{superblock}, 0 \rangle)] \\ \text{Interpret}(P_{\text{main}}) &= [\text{write}(2, \text{to_block}((1, 81)), \langle \text{log}, 1 \rangle), \\ &\quad \text{write}(0, \text{to_block}((1, 3)), \langle \text{superblock}, 1 \rangle), \\ &\quad \text{write}(3, \text{to_block}((2, 37)), \langle \text{log}, 2 \rangle), \\ &\quad \text{write}(0, \text{to_block}((1, 4)), \langle \text{superblock}, 2 \rangle)] \end{aligned}$$

Let $\mathbf{s} = [s_1, s_2, s_3, s_4]$ be a crash schedule for P_{main} . Applying the two synthesized rules from Section 2 restricts the valid crash schedules (Definition 4):

- $\text{superblock} \rightsquigarrow_{=} \text{log}$ requires $s_2 \rightarrow s_1$ and $s_4 \rightarrow s_3$.
- $\text{superblock} \rightsquigarrow_{>} \text{superblock}$ requires $s_4 \rightarrow s_2$.

Combined, these constraints yield seven valid crash schedules. Besides the two trivial crash schedules $\mathbf{s} = \top$ and $\mathbf{s} = \perp$, the other five crash schedules yield five distinct disk states:

- (1) $[s_1 = \top, s_2 = \perp, s_3 = \perp, s_4 = \perp]$
(only the first log block is on disk)

- (2) $[s_1 = \perp, s_2 = \perp, s_3 = \top, s_4 = \perp]$
(only the second log block is on disk)

- (3) $[s_1 = \top, s_2 = \perp, s_3 = \top, s_4 = \perp]$
(both log blocks are on disk)

- (4) $[s_1 = \top, s_2 = \top, s_3 = \perp, s_4 = \perp]$
(the first log block and first superblock write are on disk)

- (5) $[s_1 = \top, s_2 = \top, s_3 = \top, s_4 = \perp]$
(the first log block, first superblock write, and second log block are on disk)

Each of these states satisfies the key-value store’s crash-consistency predicate $\text{Consistent}(d)$ defined in Section 2, as in each case the superblock’s `head` and `tail` pointers refer only to log blocks that are also on disk. Some states result in data loss after the crash – for example, neither key can be retrieved from crash state 1 above, as the superblock is empty – but these states are still consistent (i.e., they satisfy the log’s representation invariant). This set of two rules therefore makes the `SingleEntry_TwoAppend` litmus test crash consistent according to Definition 5.

If the second rule $\text{superblock} \rightsquigarrow_{>} \text{superblock}$ was excluded, the rule set with one remaining rule allows 2 additional crash states:

- (6) $[s_1 = \top, s_2 = \perp, s_3 = \top, s_4 = \top]$
(the first log block, second log block, and second superblock write are on disk)

$[s_1 = \perp, s_2 = \perp, s_3 = \top, s_4 = \top]$
 (7) (the second log block and second superblock write are on disk)

State 6 satisfies the crash-consistency predicate despite losing the first superblock write, as the second superblock write already contains the effects of the first one. However, state 7 violates the crash-consistency predicate: the first log block is invalid, but is included in the range between the superblock’s `head` and `tail` pointers. The set containing only the first rule therefore does not make `SingleEntry_TwoAppend` crash consistent.

4 Dependency Rule Synthesis

This section describes the `DepSynth` synthesis algorithm, which automatically generates a set of dependency rules that are sufficient to guarantee crash consistency for a set of litmus tests. It formalizes the dependency rule synthesis problem, gives an overview of `DepSynth`’s approach to synthesizing dependency rules, and then presents the core `DepSynth` algorithm (Figure 3).

4.1 Problem Statement

`DepSynth` solves the problem of finding a *single* set of dependency rules R that makes every litmus test T in a set of tests \mathcal{T} crash consistent (Definition 5). While Definition 5 suffices to find a set of rules R that guarantees crash consistency, it does not rule out *cyclic* solutions that cannot be executed on real hardware. For example, consider a program P where $Evaluate_{\mathcal{O}}(P) = [\text{write}(a_1, v_1, \langle n_1, t_1 \rangle), \text{write}(a_2, v_2, \langle n_2, t_2 \rangle)]$. The set of rules $R = \{n_1 \rightsquigarrow_{=} n_2, n_2 \rightsquigarrow_{=} n_1\}$ makes P crash consistent. These two rules do not admit any valid crash schedules other than the trivial $s = \top$ and $s = \perp$ schedules, as Definition 4 forces $s_1 = s_2$. In effect, crash consistency for P requires both writes to happen “at the same time”. But on real disks the level of write atomicity is only a single data block, so there is no way for both writes to happen at the same time. To rule out cyclic solutions, we follow the example of happens-before graphs [14] from distributed systems and memory consistency, and require the set of synthesized dependency rules R to be *acyclic*.

4.2 The `DepSynth` Algorithm

The `DEPSYNTH` algorithm (Figure 3) takes as input a storage system implementation \mathcal{O} , a set of litmus tests \mathcal{T} , and a crash-consistency predicate *Consistent*. Given these inputs, it synthesizes a set of dependency rules that is acyclic and sufficient to make all tests \mathcal{T} crash consistent.

`DEPSYNTH` does not try to generate a sufficient set of dependency rules for all tests in \mathcal{T} at once, since this would require a prohibitively expensive search over large happens-before graphs. Instead, it works incrementally: at each iteration of its top-level loop, `DEPSYNTH` chooses a single test T that is not made crash consistent by the current candidate set of dependency rules (line 4 in Figure 3), invokes the procedure `RULESFORTTEST` (Section 4.3) to synthesize dependency rules that make T crash consistent, and adds the new rules to the candidate set (line 11). Working incrementally reduces the number of litmus tests for which `DEPSYNTH` needs to synthesize rules; for example, in Section 6.1 we show that only 10 of 16,250 tests were passed to `RULESFORTTEST` to synthesize a sufficient set of dependency rules for a production key-value store. This reduction relieves developers from being selective about the set of litmus tests they supply to `DepSynth`, and makes it possible to, for example, use the output of a fuzzer or random test generator as input.

```

1 function DEPSYNTH( $\mathcal{O}$ ,  $\mathcal{T}$ , Consistent)
2    $R \leftarrow \{\}$ 
3   loop
4      $T \leftarrow \text{NEXTTEST}(\mathcal{T}, R, \mathcal{O}, \textit{Consistent})$ 
5     if  $T = \perp$  then  $\triangleright R$  makes all tests in  $\mathcal{T}$  crash consistent
6       return  $R$ 
7      $\mathcal{T} \leftarrow \mathcal{T} \setminus T$ 
8      $R' \leftarrow \text{RULESFORTEST}(T, \mathcal{O}, \textit{Consistent})$ 
9     if  $R' = \perp$  then  $\triangleright$  No rules can make  $T$  crash consistent
10      return UNSAT
11      $R \leftarrow R \cup R'$ 
12     if  $\neg \text{ACYCLIC}(R)$  then  $\triangleright$  Fail if new rules create a cycle in the rule set
13       return UNKNOWN
14 function NEXTTEST( $\mathcal{T}$ ,  $R$ ,  $\mathcal{O}$ , Consistent)
15   for  $T \in \mathcal{T}$  do
16     if  $\neg \text{CRASHCONSISTENT}(T, R, \mathcal{O}, \textit{Consistent})$  then
17       return  $T$ 
18   return  $\perp$ 
 $\triangleright$  Check Def. 5 with an SMT solver
19 function CRASHCONSISTENT( $T = \langle P_{\textit{initial}}, P_{\textit{main}} \rangle$ ,  $R$ ,  $\mathcal{O}$ , Consistent)
20    $d_{\textit{initial}} \leftarrow \text{Run}(\text{Evaluate}_{\mathcal{O}}(P_{\textit{initial}}), \top, d_0)$ 
21   return  $\forall s. \text{Valid}_R(s, P_{\textit{main}}) \Rightarrow \textit{Consistent}(\text{Run}(\text{Evaluate}_{\mathcal{O}}(P_{\textit{main}}), s, d_{\textit{initial}}))$ 

```

■ **Figure 3** The DepSynth algorithm takes as input a storage system implementation \mathcal{O} , a set of litmus tests \mathcal{T} , and a crash-consistency predicate *Consistent*, and returns an acyclic set of dependency rules that make all tests in \mathcal{T} crash consistent (Definition 5). The search synthesizes dependency rules for one litmus test at a time. If the rules generated for two or more tests result in a cycle, this algorithm fails; Section 4.4 discusses an extension for continuing the search for an acyclic solution.

However, because the rules for each test are generated independently, it is possible for the union of the generated rules to contain a cycle – even if the rules for each individual test do not – and so be an invalid solution (Section 4.1). The algorithm in Figure 3 returns UNKNOWN if such a cycle is found. We have not seen this failure mode occur for the storage systems we evaluated (Section 6), but it is possible in principle. In Section 4.4, we explain how to extend DEPSYNTH to recover from cycles by generalizing RULESFORTEST to synthesize rules for multiple tests at once.

DEPSYNTH delegates checking for crash consistency to the procedure CRASHCONSISTENT (line 19), which takes as input a single litmus test and a set of dependency rules, and checks whether the rules make the test crash consistent according to Definition 5. This procedure uses symbolic evaluation of the storage system implementation \mathcal{O} to generate the logical encoding described in Section 3.3, and solves the resulting formulas using an off-the-shelf SMT solver [20].

4.3 Synthesizing Dependency Rules with Happens-Before Graphs

The core of the DEPSYNTH algorithm is the RULESFORTEST procedure in Figure 4, which takes as input a litmus test T , a storage system implementation \mathcal{O} , and a crash-consistency predicate *Consistent*, and synthesizes a set of dependency rules that makes T crash consistent. RULESFORTEST frames the rule synthesis problem as a search over *happens-before graphs* [14] on the writes performed by the test. An edge (w_1, w_2) between two writes in a happens-before graph says that write w_1 must persist to disk before write w_2 . Happens-before graphs and

```

22 function RULESFORTTEST( $T = \langle P_{initial}, P_{main} \rangle, \mathcal{O}, Consistent$ )
23    $W \leftarrow \{w \mid w \in Evaluate_{\mathcal{O}}(P_{main})\}$ 
24   return PHASE1( $\mathcal{T}, [], W, \mathcal{O}, Consistent$ )

25 function PHASE1( $T, order, W, \mathcal{O}, Consistent$ ) ▷ Search for total orders over writes
26   if  $W = \emptyset$  then
27      $G \leftarrow \{(order[i], order[j]) \mid 0 \leq i < j < |order|\}$ 
28     return PHASE2( $\mathcal{T}, G, \mathcal{O}, Consistent$ ) ▷  $G$  is a total order; minimize it in Phase 2
29   for  $w \in W$  do
30      $order' \leftarrow order + [w]$ 
31      $W' \leftarrow W \setminus \{w\}$ 
32      $G \leftarrow \{(order[i], order[j]) \mid 0 \leq i < j < |order|\} \cup$ 
33        $\{(w_1, w_2) \mid w_1 \in order \wedge w_2 \in W\} \cup$ 
34        $\{(w_1, w_2) \mid w_1, w_2 \in W\}$ 
35     if  $\neg CRASHCONSISTENT(T, RULESFORGRAPH(G), \mathcal{O}, Consistent)$  then
36       continue
37      $R \leftarrow PHASE1(T, order', W', \mathcal{O}, Consistent)$ 
38     if  $R \neq \perp$  then
39       return  $R$ 
40   return  $\perp$ 

39 function PHASE2( $T, G, \mathcal{O}, Consistent$ ) ▷ Minimize graph  $G$  by removing individual edges
40    $R \leftarrow RULESFORGRAPH(G)$ 
41   if  $\neg CRASHCONSISTENT(T, R, \mathcal{O}, Consistent)$  then
42     return  $\perp$ 
43   for  $(w_1, w_2) \in G$  do ▷ Try removing each edge from  $G$ 
44      $G' \leftarrow G \setminus \{(w_1, w_2)\}$ 
45      $R' \leftarrow PHASE2(T, G', \mathcal{O}, Consistent)$ 
46     if  $R' \neq \perp$  then
47       return  $R'$ 
48   if  $ACYCLIC(R)$  then
49     return  $R$  ▷  $G$  makes  $T$  crash consistent and no subgraph of  $G$  suffices
50   else
51     return  $\perp$ 

52 function RULESFORGRAPH( $G$ ) ▷ Generalize a happens-before graph into dependency rules
53    $R \leftarrow \{\}$ 
54   for  $(w_1, w_2) \in G$  do
55      $\langle n_1, t_1 \rangle \leftarrow LABEL(w_1)$  ▷ Get label  $l_1 = \langle n_1, t_1 \rangle$  for write  $w_1 = write(a_1, s_1, l_1)$ 
56      $\langle n_2, t_2 \rangle \leftarrow LABEL(w_2)$ 
57     if  $t_1 < t_2$  then
58        $R \leftarrow R \cup \{n_2 \rightsquigarrow_{>} n_1\}$  ▷ Invert order, as a rule  $n_a \rightsquigarrow_p n_b$  says  $n_a$  happens after  $n_b$ 
59     else if  $t_1 = t_2$  then
60        $R \leftarrow R \cup \{n_2 \rightsquigarrow_{=} n_1\}$ 
61     else
62        $R \leftarrow R \cup \{n_2 \rightsquigarrow_{<} n_1\}$ 
63   return  $R$ 

```

■ **Figure 4** The algorithm for generating sufficient dependency rules for a litmus test T searches the space of happens-before graphs over the writes performed by T . The first phase searches for total orders over the writes that are sufficient for crash consistency. Once such a total order is found, the second phase removes edges from it until the happens-before graph is minimal.

dependency rules have a natural correspondence: if a happens-before graph includes an edge (w_1, w_2) , a dependency rule $n_2 \rightsquigarrow_p n_1$ that matches the writes' labels is sufficient to enforce the required ordering. RULESFORTTEST searches for a minimal, acyclic happens-before graph that is sufficient to ensure crash consistency for T , and then syntactically generalizes that happens-before graph into a set of dependency rules.

RULESFORTTEST searches for a happens-before graph by first finding a *total order* on the writes that makes T crash consistent (PHASE1), and then searching for a minimal *partial order* within this total order that is both sufficient for crash consistency and yields an acyclic set of dependency rules (PHASE2). The algorithm is exhaustive: it tries all total orders and all minimal partial orders within a total order, until it finds a solution or fails because a solution does not exist.

RULESFORTTEST builds on the observation that crash consistency (Definition 5) is monotonic with respect to the subset relation on dependency rules – if a set of dependency rules R is not sufficient for crash consistency, then no subset of R is sufficient either:

► **Theorem 7** (Monotonicity of crash consistency). *Let T be a litmus test and R a set of dependency rules for a storage system \mathcal{O} . If R does not make T crash consistent (according to Definition 5), then no subset $R' \subset R$ can make T crash consistent.*

Proof sketch. If R does not make T crash consistent, there exists a valid crash schedule \mathbf{s} (Definition 4) that does not satisfy the crash consistency predicate *Consistent*. By Definition 4, each rule in R only adds additional constraints on the possible valid crash schedules. Removing a rule from R therefore only allows more valid crash schedules, and so if \mathbf{s} was a valid crash schedule for R , it is also a valid crash schedule for any subset of R . ◀

RULESFORTTEST applies this property by checking crash consistency for a happens-before graph G before exploring any subgraphs of G ; if G is not sufficient, then neither is any subgraph of G , and so that branch of the search can be skipped.

4.3.1 Total order search

PHASE1 (line 25) explores all possible total orders over the writes in T that are sufficient for crash consistency. At each recursive call, the list *order* represents a total order over some of T 's writes, and the set W contains all writes not yet added to that order. PHASE1 tries to add each write in W to the end of the total order. Each time, it checks whether the new total order leads to a crash consistency violation (line 33) and if so, prunes this branch of the search. For PHASE1 to be complete, this check must behave angelically for the writes in W that have not yet been added to the order – if there is *any possible* set of dependency rules for the remaining writes that would succeed, the check must succeed. We make the check angelic by including every possible dependency rule for the remaining writes (line 32). If the test cannot be made crash consistent even with every possible rule included, then by Theorem 7 no subset of those rules (i.e., formed by completing the rest of the total order) can succeed either, so the prefix is safe to prune. PHASE1 continues until every write has been added to the total order and then moves to PHASE2 to further reduce the happens-before graph.

4.3.2 Partial order search

Starting from a happens-before graph G that reflects a total order over all writes in T , PHASE2 (line 39) removes edges from the graph until it is minimal, i.e., removing any further edges would violate crash consistency. PHASE2 removes one edge at a time from the graph

G (line 44), checks if the graph remains sufficient for crash consistency (line 41), and if so, recurses to remove more edges. By greedily removing one edge at a time, PHASE2 is guaranteed to find a minimal result, and because PHASE2 considers removing every possible edge from G (except those that cannot lead by solutions by Theorem 7), it is complete – if an acyclic solution exists, PHASE2 will reach it.

4.3.3 Generating rules from happens-before graphs

The RULESFORTTEST search operates on happens-before graphs, but its goal is to synthesize dependency rules (Definition 1). The RULESFORGRAPH procedure (line 52) bridges this gap by taking as input a happens-before graph G and returning a set of dependency rules R that are sufficient to enforce the ordering requirements that G dictates. RULESFORGRAPH uses a simple syntactic approach to generate a rule for each edge in G : if $(w_1, w_2) \in G$, where w_1 and w_2 have labels $l_1 = \langle n_1, t_1 \rangle$ and $l_2 = \langle n_2, t_2 \rangle$, respectively, then it generates a rule of the form $n_2 \rightsquigarrow n_1$ (reversing the order because G is a happens-before graph but dependency rules are happens-after edges). To choose an epoch predicate for the generated rule, we compare the two epochs t_1 and t_2 and select the predicate that would make the rule match the labels l_1 and l_2 .

This approach can lead to rules that are too general, as some rules it generates may only need to apply to certain individual epochs but will instead apply to all epochs that match the predicate. Overly general rules risk sacrificing performance by preventing reordering or caching optimizations that would be safe. However, this same generality also allows RULESFORTTESTS to avoid overfitting to the input litmus tests. In Section 6.1 we show that generated rules generalize well in practice (i.e., are not overfit), and that they filter out few additional schedules compared to expert-written rules.

4.3.4 Properties of RulesForTest

The RULESFORTTEST algorithm is *sound*: all paths that return a solution are guarded by checks of crash consistency and of acyclicity, and so satisfy the requirements of Section 4.1. RULESFORTTEST is also *complete*: each of PHASE1 and PHASE2 are complete, as discussed above, and so together form a complete search over the space of total orders. Every possible acyclic solution must be a subgraph of some total order, since the transitive closure of edges in any happens-before graph is a (strict) partial order, and so exploring all total orders suffices to reach any possible acyclic solution. Finally, RULESFORTTEST is *minimal*, in the sense that removing any rule from a returned set R would violate crash consistency. PHASE2 continues removing edges from a candidate graph G until Theorem 7 says it cannot be made smaller, and is therefore guaranteed to find a minimal happens-before graph. Every rule in R is justified by (at least) one edge in that graph, and since dependency rules cannot overlap (in Definition 1, the possible epoch predicates are disjoint), removing any rule would incorrectly allow reordering of its corresponding edge(s).

► **Example 8.** Consider running RULESFORTTEST for the simple log-structured key-value store and `SingleEntry_TwoAppend` litmus test from Section 2. From Example 6 we know that this test produces a set W of four writes:

```

w1 = write(2, to_block((1, 81)), ⟨log, 1⟩),
w2 = write(0, to_block((1, 3)), ⟨superblock, 1⟩),
w3 = write(3, to_block((2, 37)), ⟨log, 2⟩),
w4 = write(0, to_block((1, 4)), ⟨superblock, 2⟩)

```

PHASE1 first chooses the first write to add to the total order. Suppose it chooses w_2 . This choice results in the following graph G at line 32 (shaded nodes are in *order*; white nodes are in W):

The check at line 33 finds that this graph is not crash consistent: it allows a crash schedule where w_2 is on disk but no other writes are, which violates the crash-consistency predicate as w_2 is a superblock write pointing to a log block that is not on disk. PHASE1 therefore continues (line 34), which prunes any total order that starts with $[w_2]$ from the search, and chooses a next write to consider, say w_3 . The total order starting with $[w_3]$ does pass the crash consistency check, so PHASE1 recurses with $order = [w_3]$ and $W = \{w_1, w_2, w_4\}$. In this recursive call, suppose we again first choose w_2 to add to the total order. This choice results in the following graph G :

Again, line 33 finds that this graph is not crash consistent, for the same reason as before (superblock write w_2 can be on disk when log write w_1 is not), and so the search continues, pruning any total order that starts with $[w_3, w_2]$. Suppose it next chooses w_1 to add to the total order. This choice succeeds, making the recursive call with $order = [w_3, w_1]$ and $W = \{w_2, w_4\}$. From here, any choice PHASE1 makes will succeed. Supposing it chooses w_2 first, PHASE1 eventually reaches line 28 and continues to PHASE2 with the following initial graph G :

PHASE2 proceeds by trying to remove one edge at a time from G . Suppose it first chooses to remove edge (w_3, w_1) , and so recurses at line 45 on the graph $G' = G \setminus \{(w_3, w_1)\}$. This graph still ensures crash consistency at line 41, as writing w_1 before w_3 does not affect consistency. The recursion can continue twice more by choosing and successfully removing edges (w_3, w_2) and then (w_1, w_4) as well, eventually reaching line 43 with the following graph G (now with write labels shown):

From here, the loop in PHASE2 now tries to remove each of the three remaining edges, but each attempted G' violates crash consistency and so returns \perp from the next recursive call. PHASE2 therefore exits the loop with the above graph G , which we now know is minimal as no further edges can be removed. Applying RULESFORGRAPH to G yields the two rules from Section 2:

$$\begin{array}{ll} \text{superblock} \rightsquigarrow_{=} \text{log} & \text{from edges } (w_3, w_4) \text{ and } (w_1, w_2) \\ \text{superblock} \rightsquigarrow_{>} \text{superblock} & \text{from edge } (w_2, w_4). \end{array}$$

4.4 Resolving Cycles in Dependency Rules

The top-level DEPSYNTH algorithm generates rules for each litmus test independently. Even though the rules generated for each test are guaranteed to be acyclic, it is possible for the *union* of those rules to contain a cycle, and so violate the requirements of Section 4.1. In practice, we have not seen this happen for the storage systems we evaluate in Section 6, and so the version of DEPSYNTH presented in Figure 3 fails if the synthesized rules contain a cycle.

To handle cyclic rules, RULESFORTEST can be extended to support synthesizing rules for multiple litmus tests at once. This extension adds the writes from *all* the tests into the set of writes W , searches for a total order over that entire set in PHASE1, and then searches for a minimal happens-before graph over the entire set in PHASE2. Edges between writes from different tests cannot influence the crash consistency of individual tests (in Definition 4 they will just lead to spurious additional implications), and they will eventually be removed by PHASE2, creating a forest of disjoint happens-before graphs. PHASE2 is therefore guaranteed to return an acyclic set of dependency rules for all the tests it was provided.

In the limit, DEPSYNTH could just invoke RULESFORTEST with its entire input set \mathcal{T} , but this would be prohibitively expensive for any non-trivial set of tests. Instead, our implementation resolves cycles in DEPSYNTH by identifying which individual litmus tests caused the cycle (i.e., which tests the rules in the cycle were generated from), and passes only that subset of tests to the extended RULESFORTEST.

5 Implementation

We implement both the DepSynth algorithm and the storage systems we study in Section 6 in Rosette [28], an extension of Racket [9] with support for verification and synthesis. Using Rosette as our host language gives us symbolic evaluation of the storage system implementation for free, and simplifies implementing the CRASHCONSISTENT query in Figure 3. The choice of Rosette and Racket is not fundamental; recent work has shown how to extend the symbolic evaluation approach to languages such as Python [27] or C [19] in which storage systems are more commonly implemented.

5.1 Ordering

The DEPSYNTH algorithm in Figure 3 is sensitive to the order in which NEXTTEST chooses tests to generate dependency rules for. Our implementation chooses tests in increasing order of size, minimizing the number of happens-before graphs for RULESFORTEST to explore. Similarly, RULESFORTEST is sensitive to the order it considers writes (PHASE1) and edges (PHASE2). In both cases, we exploit the following observation: while an execution that persists writes in program order is not *required* to be crash consistent (e.g., because storage

systems might selectively buffer or coalesce writes), it is often so in practice. `RULESFORTTEST` therefore prefers to choose writes in `PHASE1` in program order, and prefers to remove edges in `PHASE2` that contradict program order.

5.2 Reducing solver queries

Both `PHASE1` and `PHASE2` in Figure 4 have symmetry in their search space: for a fixed pair of writes w_1 and w_2 , there are many different branches of `PHASE1` that try to order w_2 after w_1 , and many different branches of `PHASE2` that try to remove the edge (w_1, w_2) from a happens-before graph. If we can determine ahead of time that such a choice for those writes is always doomed to fail, we can avoid considering these choices at all and so save the cost of an SMT solver query by `CRASHCONSISTENT`. Our implementation of `RULESFORTTEST` uses an SMT solver to pre-compute a set of *necessary* ordering edges – edges which *must* be in the happens-before graph – and uses that set to short-circuit `CRASHCONSISTENT`.

6 Evaluation

This section answers three questions to demonstrate the effectiveness of DepSynth:

1. Can storage system developers use DepSynth to synthesize dependency rules for a realistic storage system rather than implementing their own crash-consistency approach by hand? (§6.1)
2. Can DepSynth help storage system developers avoid crash-consistency bugs? (§6.2)
3. Does DepSynth’s approach support a variety of storage system designs? (§6.3)

6.1 ShardStore Case Study

To show that developers can use DepSynth to build realistic storage systems, we implemented a key-value store that follows the design of ShardStore [4], the exabyte-scale production storage node for the Amazon S3 object storage service.

6.1.1 Implementation

The first step in using DepSynth is to implement the storage system itself. ShardStore’s on-disk representation is a log-structured merge tree (LSM tree) [21], but with values stored outside the tree in a collection of extents. Our ShardStore-like storage system implementation consists of 1,200 lines of Racket code, including five operations: the usual `put`, `get`, and `delete` operations on single keys, as well as a garbage collection `clean` operation that evacuates all live objects in one extent to another extent, and a `flush` operation that persists the LSM tree memtable to disk. Our implementation does not handle boundary conditions such as running out of disk space or objects too large to fit in one extent, but is otherwise faithful to the published ShardStore design. As a crash consistency predicate, we wrote a checker that validates all expected objects are accessible by `get` after a crash, and that the on-disk LSM tree contains only valid pointers to objects in extents.

6.1.2 Synthesis

With a storage system implementation in hand, a developer can use DepSynth to synthesize dependency rules that make the system crash consistent. DepSynth takes as input a set of litmus tests – we randomly generated 16,250 litmus tests for the ShardStore-like system, ranging in length from 1 to 16 operations. Executing these tests against the system led to

■ **Table 1** Valid schedules allowed by the production ShardStore service versus the dependency rules we synthesized for our ShardStore-like reimplementation. A schedule allowed only by one implementation means either that implementation is not crash consistent (it allows a schedule it should forbid) or it admits more reordering opportunities (it allows a schedule it should allow). “Fixed” results are after fixing two issues in ShardStore (one consistency, one performance) that we identified by manually inspecting the “original” schedules.

Test	Test Length	Writes	Allowed by both		Allowed only by DepSynth		Allowed only by ShardStore	
			Original	Fixed	Original	Fixed	Original	Fixed
T_1	1	2	3	3	0	0	0	0
T_2	2	6	7	14	7	0	3	3
T_3	5	1	2	2	0	0	0	0
T_4	5	7	8	15	7	0	3	3
T_5	4	7	11	29	9	0	9	0
T_6	5	5	6	12	2	0	4	0
T_7	7	5	5	11	2	0	5	1
T_8	10	5	6	12	2	0	4	0
T_9	16	6	8	22	2	0	12	0
T_{10}	13	9	21	41	20	0	9	9

an average of 7.2 and a maximum of 20 disk writes per test. Given these inputs, DepSynth synthesized a set of 20 dependency rules for ShardStore in 49 minutes. To find a correct solution for all 16,250 litmus tests, the DepSynth algorithm invoked the RULESFORTTEST procedure (line 8 in Figure 3) only 10 times, showing that DepSynth’s incremental approach is effective at reducing the search space.

6.1.3 Comparison to an existing implementation

ShardStore is an existing production system and already supports crash consistency. Its implementation does not use a dependency-rule language like in DepSynth. Instead, it implements a soft-updates approach [11] by constructing dependency graphs (i.e, happens-before graphs) at run time and sequencing writes to disk based on those graphs, similar to patchgroups in Featherstitch [10]. We therefore compare our synthesized rules against ShardStore’s dependency graphs to see how well DepSynth may replace an expert-written crash consistency implementation.

For each of the 10 tests that DepSynth used while synthesizing dependency rules for ShardStore, we used an SMT solver to compute the set of valid crash schedules (Definition 4) according to those synthesized dependency rules. We then executed the same test using the production ShardStore implementation, collected the run-time dependency graph it generated, and used an SMT solver to compute the set of valid crash schedules according to that graph. Given these two sets of crash schedules, we computed the set intersection and difference to classify them into three groups: schedules allowed by both implementations (i.e., both implementations agree), and schedules allowed only by one or the other implementation (i.e., the two implementations disagree).

Table 1 shows the results of this classification across the 10 litmus tests. Overall, the two implementations agree on the validity of an average of 87% of crash schedules. The remaining crash schedules are in two categories:

1. Schedules allowed only by DepSynth mean either DepSynth’s rules allow some schedules that are not crash consistent (a correctness issue in the synthesized rules) or ShardStore precludes some schedules that are crash consistent (a performance issue in ShardStore).

We found that every schedule allowed by DepSynth is crash consistent, and that ShardStore inserts unnecessary edges in its dependency graphs, ruling out some reorderings that would be safe. These edges are not necessary to guarantee crash consistency of the overall storage system, and so DepSynth is correct to allow them. However, ShardStore engineers intentionally include these edges as they make the representation invariant for an on-disk data structure simpler, even though a more complex invariant that did not require these edges would still be sufficient for consistency. In other words, ShardStore engineers favored a stronger, simpler invariant in these cases, where DepSynth is able to identify opportunities for performance improvements.

2. Schedules allowed only by ShardStore mean either DepSynth’s rules preclude some schedules that are crash consistent (meaning DepSynth’s output is not optimal) or ShardStore allows some schedules that are not crash consistent (a correctness issue in ShardStore). 67% of these schedules are incorrectly allowed by ShardStore due to a rare crash-consistency issue that was independently discovered concurrently with this work. We have confirmed with ShardStore engineers that the issue was an unlikely edge case that could not lead to data loss, but could lead to “ghost” objects – resurrected pointers to deleted objects, where the object data has been (correctly) deleted, but the pointer still exists – which result in an inconsistent state. After fixing this issue in ShardStore, we manually inspected the remaining schedules it allowed and confirmed they are all cases where DepSynth’s rules generate extraneous edges (i.e., the synthesized rules are not optimal), and the crash-consistency predicate we wrote for our ShardStore reimplementation agrees that all the resulting states are consistent.

After fixing the two ShardStore issues discussed above, the synthesized dependency rules agree with ShardStore on the validity of an average of 99% of crash schedules. The few remaining schedules are ones that DepSynth’s synthesized dependency rules conservatively forbid due to the coarse granularity of the dependency rule language. Overall, this study shows that DepSynth achieves similar results to an expert-written crash consistency implementation, and can help identify correctness and performance issues in existing storage systems.

6.1.4 Generalization

One risk for example-guided synthesis techniques like DepSynth is that they can overfit to the examples (litmus tests) and not actually ensure crash consistency on unseen test cases. DepSynth’s design reduces this risk by using a simple dependency rule language (Definition 1) that cannot identify individual write operations. To test generalization, we randomly generated an additional 136,000 litmus tests for our ShardStore-like system. We also allowed these tests to be significantly longer than those used during synthesis – up to a maximum of 40 writes rather than the 20 in the input set of litmus tests. For each new test, we used the synthesized dependency rules to compute all valid crash schedules for the test, and found that every crash schedule resulted in a consistent disk state according to our crash consistency predicate. In other words, by limiting the expressivity of our dependency rule language, the rules we synthesize can generalize well beyond the tests they were generated from.

6.2 Crash-Consistency Bugs

To understand how effective DepSynth can be in preventing crash-consistency bugs, we surveyed all bugs reported by two recent papers [4, 18] in three production storage systems for which a known fix is available. We manually analyze each bug and determine whether DepSynth could discover and prevent them.

■ **Table 2** Sample crash-consistency bugs in three storage systems reported by two recent papers [4, 18]. Each bug includes its identifier (bug number for ShardStore, kernel Git commit for btrfs and f2fs). Most of these bugs could have been prevented by using DepSynth to automatically identify missing ordering requirements, but some crash-consistency issues are either not ordering related or are unlikely to be detected by DepSynth’s litmus-test-driven approach.

Storage system	Crash-consistency bug	Preventable by DepSynth?
ShardStore	Inconsistency in extent allocation (#6)	Yes
ShardStore	Mismatch between soft and hard write pointers (#7)	Yes
ShardStore	Index entries persisted before target data (#8)	Yes
ShardStore	Crash consistency predicate too strong (#9)	No – specification bug
ShardStore	Data loss after UUID collision (#10)	No – unlikely to detect
btrfs	Extents deallocated too early in recovery (bf50411)	Yes
btrfs	Inode rename commits out of order (d4682ba)	Yes
f2fs	<code>fsync</code> failed after directory rename (ade990f)	Yes
f2fs	Wrong file size when zeroing file beyond EOF (17cd07a)	No – not reordering

Table 2 shows the results of our survey. In six cases, DepSynth could have prevented the bug by synthesizing a dependency rule to preclude a problematic reordering optimization. Each of these bugs had small triggering test cases, suggesting they would be reachable by a litmus-test-based approach like ours. In the other three cases, our analysis shows that DepSynth would not prevent the bug. One bug in ShardStore was a specification bug in which the crash consistency predicate was too strong. DepSynth assumes that the crash consistency predicate is correct, and will miss specification bugs. Another bug in ShardStore involved a collision between two randomly generated UUIDs. While such a bug would be possible to find in principle using litmus tests, it would be very unlikely, and without a test that triggers the issue DepSynth cannot preclude it. One bug in f2fs involved an incorrect file size being computed when zero-filling a file beyond its existing endpoint. This bug was a logic issue rather than a reordering one (i.e., occurring even without a crash), and so no dependency rule would suffice to prevent it. Overall, our analysis indicates that DepSynth can prevent a range of ordering-related crash-consistency bugs, but other bugs would require a different approach.

6.3 Other Storage Systems

Beyond ShardStore, we expect DepSynth to effectively generate rules for any storage systems whose crash consistency properties can be ensured by correctly ordering writes. As Frost et al. describe in [10], write-before relationships underlie *every* crash consistency mechanism, including journaling, synchronous writes, copy-on write data structures, and soft updates. Though storage systems vary greatly in their mechanisms for storing and retrieving data, each must enable crash consistency by enforcing write-before relationships. Since DepSynth is a tool for automatically developing write-before relationships, this leads us to believe that DepSynth can be a useful tool for automating crash consistency in all such systems.

To demonstrate this point, we have also used DepSynth to implement a log-structured file system [25]. The file system supports five standard POSIX operations: `open`, `creat`, `write`, `close`, and `mkdir`. While our implementation is simple (300 lines of Racket code) compared to production file systems, it has metadata structures for files and directories, and so has its own subtle crash consistency requirements. For example, updates to data and inode blocks must reach the disk before the pointer to the tail of the log is updated. To synthesize dependency rules for this file system, we randomly generated 235 litmus tests with at most 6 operations. DepSynth synthesized a set of 18 dependency rules in 12 minutes

to make the file system crash consistent, and during the search, invokes `RULESFORTTEST` for only 13 tests. This result shows that DepSynth can automate crash consistency for storage systems other than key-value stores.

7 Related Work

7.1 Verified storage systems

Inspired by successes in other systems verification problems [16, 13], recent work has brought the power of automated and interactive verification to bear on storage systems as well. One of the main challenges in verifying storage systems is crash consistency, as it combines concurrency-like nondeterminism with persistent state. Yggdrasil [27] is a verified file system whose correctness theorem is a *crash refinement* – a simulation between a crash-free specification and the nondeterministic, crashing implementation. This formalization allows clients of Yggdrasil to program against a strong specification free from crashes, similar to our angelic crash consistency model. FSCQ [8] is a verified crash-safe file system with specifications stated in *crash Hoare logic*, which explicitly states the recovery behavior of the system after a crash. DFSCQ [7] extends FSCQ and its verification with support for crash-consistency optimizations such as log-bypass writes and the metadata-only `fdatasync` system call. The DepSynth programming model separates crash consistency of these optimizations from the storage system itself, and so can simplify their implementation.

Another approach to verified storage systems is at the language level. Cogent [3] is a language for building storage systems with a strong type system that precludes some common systems bugs. A language-level approach like Cogent is complementary to DepSynth: Cogent provides a high-level language for implementing storage systems, while DepSynth provides a synthesizer for making those implementations crash consistent.

7.2 Crash-consistency bug-finding tools

Ferrite [5] is a framework for specifying *crash-consistency models*, which formally define the behavior of a storage system across crashes, and for automatically finding violations of such models in a storage system implementation. One way to specify these models is with litmus tests that demonstrate unintuitive behaviors; DepSynth builds on this approach by automatically synthesizing rules from such litmus tests. DepSynth also takes inspiration from Ferrite’s synthesis tool for inserting `fsync` calls into litmus tests to make them crash consistent, but instead focuses on making the *storage system itself* crash consistent rather than the user code running on top of it. CrashMonkey [18] is a tool for finding crash-consistency bugs in Linux file systems. CrashMonkey exhaustively enumerates all litmus tests with a given set of system calls, runs them against the target file system, and then tests each possible crash state for consistency. Chipmunk [15] extends the CrashMonkey approach to persistent-memory file systems by exploring finer-grained crash states to account for the byte-addressable nature of non-volatile memory. Connecting CrashMonkey-like litmus test generation with DepSynth could provide developers with a comprehensive set of litmus tests for their system for free, lowering the burden of applying DepSynth. To give stronger coverage guarantees that do not depend on enumerating litmus tests, FiSC [33] and eXplode [34] use model checking to find bugs in storage systems.

One advantage of bug-finding tools is that they are significantly easier to apply to production systems than heavyweight verification tools. Bornholt et al. [4] describe the use of lightweight formal methods to validate the crash consistency (and other properties) of

ShardStore, the Amazon S3 storage node that we study in Section 6.1. Their approach applies property-based testing to automatically find and minimize litmus tests that demonstrate crash-consistency issues. DepSynth takes this idea one step further by automatically *fixing* such issues once they are found.

7.3 Program synthesis for systems code

Transit [31] is a tool for automatically inferring distributed protocols such as those used for cache coherence. It guides the search using *concolic* snippets [26] – effectively litmus tests that can be partially symbolic – and finds a protocol that satisfies those snippets for *any* ordering of messages. MemSynth [6] is a program synthesis tool for automatically constructing specifications of memory consistency models. MemSynth takes similar inputs to DepSynth – a set of litmus tests and a target language – and its synthesizer generates and checks happens-before graphs for those tests. Adopting MemSynth’s aggressive inference of partial interpretations [29] to shrink the search space of happens-before graphs would be promising future work.

8 Conclusion

DepSynth offers a new programming model for building crash-consistent storage systems. By offering a high-level angelic programming model for crash consistency, and automatically synthesizing low-level dependency rules to realize that model, DepSynth lowers the burden of building reliable storage systems. We believe that this work presents a promising direction for building systems software with the aid of automatic programming tools to resolve challenging nondeterminism and persistence problems.

Abstract

This paper presents SQUID, a new conjunctive query synthesis algorithm for searching code with target patterns. Given positive and negative examples along with a natural language description, SQUID analyzes the relations derived from the examples by a Datalog-based program analyzer and synthesizes a conjunctive query expressing the search intent. The synthesized query can be further used to search for desired grammatical constructs in the editor. To achieve high efficiency, we prune the huge search space by removing unnecessary relations and enumerating query candidates via refinement. We also introduce two quantitative metrics for query prioritization to select the queries from multiple candidates, yielding desired queries for code search. We have evaluated SQUID on over thirty code search tasks. It is shown that SQUID successfully synthesizes the conjunctive queries for all the tasks, taking only 2.56 seconds on average.

1 Introduction

Developers often need to search their code for target patterns in various scenarios, such as API understanding [29], code refactoring [56], and program repair [47]. According to recent studies [34, 30], existing efforts have to compromise between ease of use and capability. Most mainstream IDEs [23] only support string match or structural search of restrictive grammatical constructs although complex user interactions are not required. Besides, static program analyzers, such as Datalog-based program analyzers [44, 35, 3], provide deep program facts for users to explore advanced patterns, while users have to customize the analyzers to meet their needs [12]. For example, if users want to explore code patterns with the Datalog-based program analyzer CODEQL [3], they have to learn the query language to access the derived relational representation. However, there always exists a non-trivial gap

between a user's search intent and a customized query. A large number of complex relations make query writing involve strenuous efforts, especially in formalizing search intents and debugging queries, which hinders the usability of CODEQL for code search.

Our Goal. We aim to propose a query synthesizer to unleash the power of a Datalog-based program analyzer for code search. To show the search intent, a user can specify a synthesis specification consisting of positive examples, negative examples, and a natural language description. Specifically, positive and negative examples indicate desired and non-desired grammatical constructs, respectively, while the natural language description shows the search intent by a sentence. Our synthesizer is expected to generate a query separating positive examples from negative ones, which can support code search in the editor. In this work, we focus on conjunctive queries, which have been recognized as queries of an important form to support search tasks [17].

Consider a usage scenario: Find all the methods receiving a parameter with `Log4jUtils` type and giving a return with `CacheConfig` type. The user can provide the synthesis specification shown in Figure 1(a). With the relational representation in Figure 1(b) derived from the examples, our synthesizer would synthesize the conjunctive query in Figure 1(c) to express the search intent. In particular, our synthesis specification is easy to provide. The users can often copy desired grammatical constructs from an editor as positive examples [34] and then mutate them to form negative ones. Meanwhile, they can express their need to search code with a brief sentence as the description. Thus, an effective and efficient synthesizer enables the users to express the search intent from a high-level perspective, serving as a user-friendly interface for code search.

¹ We show five relations as examples, while a Datalog-based analyzer can derive over a hundred relations.

Challenges. Nevertheless, it is far from trivial to synthesize a conjunctive query for code search. First, a Datalog-based program analyzer can generate many relations with multiple attributes as the relational representation. For example, CODEQL exposes over a hundred relations to users for query writing [45]. The various choices of selecting relations and enforcing conditions on attributes induce a dramatically huge search space in the synthesis, which can involve both the comparisons between attributes and string constraints, posing a significant challenge to achieving high efficiency. Second, there often exist multiple query candidates that separate positive examples from negative ones, while several candidates can suffer from the over-fitting problem, failing to express the search intent with no bias [53]. An ineffective query candidate selection would mislead the synthesizer into returning wrong queries and further cause the failure of code search.

Existing Effort. There are three major lines of existing effort. The first line of the studies utilizes input-output examples to synthesize queries in various forms, such as analytic SQL queries [58, 13] and relational queries [42, 46]. Although the queries often have expressive syntax, the synthesizers only take a few relations as input, not facing hundreds of relations as ours. The second line of approaches is the component-based synthesis technique [14, 38], which leverages type signatures to enumerate well-typed programs. However, a significant number of comparable attribute pairs still induce an explosively huge search space even if we adopt the techniques by guiding the search with the schema. The third line of the studies derives program sketches from natural language descriptions via semantic parsing [28] and prioritizes feasible solutions with probability models [54, 4]. Unfortunately, the ambiguity of natural languages and the inadequacy of the training process can make a semantic parser ineffective and eventually miss optimal solutions [40]. It is also worth noting that existing techniques do not attempt to select a feasible solution that maximizes or minimizes a specific metric. Although several inductive logic learning-based techniques adopt heuristic priority functions to accelerate the synthesis [46], they do not guarantee the optimality of the synthesized queries, and thus can not resolve the query candidate selection in our problem.

Our Solution. Our key idea comes from three critical observations. First, only a few relations contribute to separating positive examples from negative ones. For example, the methods in Figure 1(a) have the same modifier, indicating that the relation `Modifier` is unnecessary. Second, adding an attribute comparison expression or a string constraint to the condition of a conjunctive query yields a stronger restriction on grammatical constructs. If a query misses a positive example, we cannot obtain a query candidate by strengthening the query. Third, a desired query tends to constrain grammatical constructs mentioned in the natural language description sufficiently. For the instance in Figure 1, the query extracting the methods with the return type `CacheConfig` is a query candidate but not a desired one, as it does not pose any restriction on parameters.

Based on the observations, we realize that it is possible to narrow down necessary relations and avoid their infeasible compositions to prune the search space, and meanwhile, select query candidates with the guidance of the natural language description. According to the insight, we present a multi-modal synthesis algorithm SQUID with three stages:

- To narrow down the relations, we introduce the notion of the *dummy relations* to depict the relations unnecessary for the synthesis and propose the *representation reduction* to exclude dummy relations, which prunes the search space effectively.
- To avoid infeasible compositions of relations, we perform the *bounded refinement* to enumerate the queries, skipping the unnecessary search for the queries that exclude a positive example. Particularly, the string constraints are synthesized by computing the longest common substrings, which is achieved efficiently in the refinement.

- To select desired queries, we establish the dual quantitative metrics, namely *named entity coverage* and *structural complexity*, and select query candidates by optimizing them as the objectives, which creates more opportunities for returning desired queries.

We implement SQUID and evaluate it on 31 code search tasks. It successfully synthesizes desired queries for each task in 2.56 seconds on average. Besides, the representation reduction and the bounded refinement are crucial to its efficiency. Skipping either of them would increase the average time cost to around 8 seconds, and several tasks cannot be finished within one minute. Meanwhile, dual quantitative metrics play critical roles in the selection. Applying only one metric would make 12 or 7 tasks fail due to the synthesized non-desired queries. We also state and prove the soundness, completeness, and optimality of SQUID. If there exist query candidates for a given synthesis specification, SQUID always returns query candidates optimizing two proposed metrics to express the search intent. To summarize, our work makes the following key contributions:

- We propose a multi-modal conjunctive query synthesis problem. An effective and efficient solution can serve as a user-friendly interface of a Datalog-based analyzer for code search.
- We design an efficient algorithm SQUID for an instance of our synthesis problem, which automates the code search tasks in real-world scenarios.
- We implement SQUID as a tool and evaluate it upon 31 code search tasks, showing that SQUID synthesizes the desired queries successfully and efficiently.

2 Overview

This section demonstrates a motivating example and briefs the key idea of our approach.

2.1 Motivating Example

Suppose a developer wants to avoid the security issue caused by `log4j` library [41]. He or she may examine the methods that receive a `Log4jUtils` object as a parameter and return a `CacheConfig` object. One choice is to leverage the built-in search tools of the IDEs to search the code lines containing `Log4jUtils` or `CacheConfig`, while the string matching-based search cannot filter grammatical constructs according to their kinds. Although several IDEs enable the structural search [23], their non-extensible templates only support searching for grammatical constructs of restrictive kinds. Another alternative is to write a query depicting the target pattern and evaluate it with a Datalog-based program analyzer, such as CODEQL [3]. However, it not only involves great laborious efforts in query language learning but also creates the burden of query writing and debugging.

To improve the usability and capability of code search, we aim to synthesize a query for a Datalog-based program analyzer. As shown in Figure 1(a), a user can specify the synthesis specification to indicate the search intent. Specifically, the positive and negative examples show the desired and undesired grammatical constructs, respectively, while the natural language description demonstrates the search intent in a sentence. Based on a Datalog-based program analyzer, we can convert the examples to a set of relations as the relational representation along with positive and negative tuples, which are shown in Figure 1(b). For example, the first tuple in the relation `Method` is the positive tuple indicating the method `foo` in Figure 1(a), which is a positive example. If we automatically synthesize the conjunctive query in Figure 1(c), the user does not need to delve into the relations and, instead specifies the synthesis specification from a high-level perspective.

■ **Figure 2** The overview of SQUID.

2.2 Synthesizing Conjunctive Queries

The query synthesizer should effectively generate the desired queries that express the search intent correctly. However, it is stunningly challenging to obtain an effective and efficient synthesizer. First, we have to tackle a great number of the relations and their attributes when we choose relevant relations and enforce correct constraints upon them, which can involve both comparisons over attributes and string constraints. Second, the non-uniqueness of query candidates creates the obstacle of selecting proper candidates. Any improper selection would return a non-desired query, leading to code search failure. To address the challenges, we propose a new multi-modal synthesis algorithm SQUID. As shown in Figure 2, SQUID consists of three phases, which come from the following three ideas.

Idea 1: Removing dummy relations. Although there are many relations potentially used in the synthesis, we can identify a class of relations, named *dummy relations*, as unnecessary ones and then discard them safely. Specifically, a relation is dummy if it cannot separate a positive tuple from a negative one. As an example, the methods in Figure 1(a) have the same modifier, which is shown by the same values of the foreign keys `mdf_id` of the relation `Method` in Figure 1(b). This indicates that the relation `Modifier` has no impact on excluding negative tuples and thus can be discarded to prune the search space. Based on this insight, we propose the **representation reduction** to remove the dummy relations, narrowing down the necessary relations for the synthesis.

Idea 2: Enumerating query candidates via refinement. According to the query syntax, the constraints, including attribute comparisons and string constraints, pose restrictions on grammatical constructs. This implies that we cannot obtain a query candidate by refining the query that excludes a positive tuple. In Figure 1, we may obtain a query that enforces both the parameter and the return value of a method have the same type. Obviously, the query excludes the method `foo`, which is a positive tuple, and thus, we should stop strengthening the restrictions on grammatical constructs. Based on this insight, we introduce the technique of the **bounded refinement**, which adds conditions for the query enumeration and discards the queries that exclude any positive tuples. Thus, we can avoid enumerating infeasible compositions of relations, which further prunes the search space effectively.

Idea 3: Dual quantitative metrics for selection. Desired queries not only separate positive tuples from negative ones but also tend to cover as many program-related named entities as possible. In Figure 1, we may obtain a query candidate that restricts the return type to be a `CacheConfig` object. However, it does not pose any restriction on the parameters and leaves the named entity “parameter” uncovered, showing that it does not express the intent sufficiently. Meanwhile, Occam’s razor [5] implies that desired queries should be as simple as possible. Hence, we introduce the *named entity coverage* and the *structural complexity*

as the dual quantitative metrics, and perform the **candidate selection** to identify desired queries by optimizing the metrics. Finally, we blend the selection with the refinement and terminate the enumeration when unexplored candidates cannot be better than the current ones, further avoiding the unnecessary enumerative search.

3 Problem Formulation

This section first presents the program relational representation (§ 3.1) and then introduces the conjunctive queries for code search (§ 3.2). Lastly, we state the multi-modal conjunctive query synthesis problem and brief the roadmap of technical sections (§ 3.3).

3.1 Program Relational Representation

First of all, we formally define the concept of the *relation* as the preliminary.

► **Definition 3.1** (Relation). A relation $R(a_1, \dots, a_n)$ is a set of tuples (t_1, \dots, t_n) , where n is the arity of R . For each $1 \leq i \leq n$, a_i is the attribute of the relation.

A relation is structured data that stores the details of different aspects of an entity. Concretely, a Datalog-based program analyzer encodes the program properties with a set of relations in a specific schema [3, 34, 37]. In what follows, we define the *relational representation* of a program.

► **Definition 3.2** (Relational Representation). Given a program, its relational representation \mathcal{R} is a set of relations over the following schema Γ . Specifically, Γ maps a relation symbol R to an n -tuple of pairs, where each element in the tuple $\Gamma(R)$ has one of the following form:

- (id, R) : The attribute id is the primary key of the relation R .
- (a, R') : The foreign key a in the relation R , referencing the primary key of $R' \in dom(\Gamma)$.
- (a, STR) : The attribute a has a string value indicating the textual information.

Particularly, we say Γ as the language schema. Without introducing the ambiguity, we use $(a, \cdot) \in \Gamma(R)$ to indicate that (a, \cdot) is an element of the tuple $\Gamma(R)$.

► **Example 3.1.** Figure 1(b) shows five relations as examples, where the values of the primary keys are italic and underlined, and the foreign keys are italic. Based on the first tuple in the relation `Method`, we can track the identifier, the return type, and the modifier of the method `foo` based on the foreign keys. Similarly, we can identify the identifier and the type of each parameter based on the relation `Parameter`.

Essentially, the relational representation of a program encodes the program properties with relations, which depicts the relationship of grammatical constructs in the program. In reality, various relations can be derived with Datalog-based program analyzers, such as `ReferenceType` and `VarPointsTo` provided by DOOP [44], depicting the type information and points-to facts, respectively. Due to the space limit, we only show five relations in Figure 1(b).

3.2 Conjunctive Queries

To simplify the presentation, we formulate the conjunctive queries as the relational algebra expressions [1] in the rest of the paper. In what follows, we first brief several relational algebra operations and then introduce the conjunctive queries for code search.

► **Definition 3.3** (Relational Algebra Operations). In a relational algebra, the selection, projection, Cartesian product, and rename operations are defined as follows:

- $\sigma_{\Theta}(R) := \{(t_1, \dots, t_n) \in R \mid [a_i \mapsto t_i \mid 1 \leq i \leq n] \models \Theta\}$ is the selection of a relation R with the selection condition Θ over its attributes.
- $\Pi_{\mathbf{a}'}(R) := \{(\mathbf{t}.a'_1, \dots, \mathbf{t}.a'_k) \mid \mathbf{t} \in R\}$ is the projection of a relation R upon a tuple of attributes \mathbf{a}' , denoted by $\Pi_{\mathbf{a}'}(R)$. Here $\mathbf{a}' = (a'_1, \dots, a'_k)$. $\mathbf{t}.a$ is the value of the attribute a in the tuple \mathbf{t} .
- $R_1 \times R_2 := \{(t_1^1, \dots, t_{n_1}^1, t_1^2, \dots, t_{n_2}^2) \mid (t_1^1, \dots, t_{n_1}^1) \in R_1, (t_1^2, \dots, t_{n_2}^2) \in R_2\}$ is the Cartesian product of two relations R_1 and R_2 .
- The rename of a relation R , denoted by $\rho_A(R)$, yields the same relation named A .

The relational algebra operations enable us to manipulate the relational representation to search desired grammatical constructs. Specifically, we often need to search specific grammatical constructs via string match and enforce them to satisfy several constraints simultaneously. Now we formalize the conjunctive queries to express the code search intent.

► **Definition 3.4** (Conjunctive Query). Given the relational representation \mathcal{R} , a conjunctive query R_Q is a relational algebra expression of the form $\Pi_{(A_i.*)}(\sigma_{\Theta}(\rho_{A_1}(R_1) \times \dots \times \rho_{A_m}(R_m)))$, where $R_i \in \mathcal{R}$, $\Theta := \phi_1 \wedge \dots \wedge \phi_n$, and each $\phi_i (1 \leq i \leq n)$ occurring in the selection condition Θ is an atomic condition in the following two forms:

- An atomic equality formula $A_j.\text{id} = A_k.a$, where a is the foreign key and $(a, R_j) \in \Gamma(R_k)$.
- A string constraint $p(A_k.a, \ell)$ over the string attribute $A_k.a$, where ℓ is a string literal, and $p \in \{\text{equal, suffix, prefix, contain}\}$.

In particular, $\Pi_{(A_i.*)}$ indicates the projection upon all the attributes of the relation A_i .

The form of the conjunctive queries in Definition 3.4 depicts the user intent from two aspects. First, the atomic equality formulas encode the relationship between the grammatical constructs. Second, the four string predicates support the common scenarios of string matching-based code search. We do not focus on synthesizing more expressive string constraints, which is the orthogonal direction of program synthesis [10, 27, 36]. Based on the conjunctive queries, we can simultaneously perform the string matching-based search and filter the constructs with various relations in the program relational representation.

► **Example 3.2.** We can formalize the query in Figure 1(c) as the relational algebra expression:

$$\Pi_{(A_1.*)}(\sigma_{\Theta}(\rho_{A_1}(\text{Method}) \times \rho_{A_2}(\text{Type}) \times \rho_{A_3}(\text{Parameter}) \times \rho_{A_4}(\text{Type})))$$

where the selection condition Θ in the selection operation is as follows:

$$\Theta := (A_1.\text{id} = A_3.\text{method_id}) \wedge (A_1.\text{ret_type_id} = A_2.\text{id}) \wedge (A_3.\text{type_id} = A_4.\text{id}) \wedge \\ \text{equal}(A_2.\text{name}, \text{“CacheConfig”}) \wedge \text{equal}(A_4.\text{name}, \text{“Log4jUtils”})$$

The conjunctive queries can be instantiated with various flavors [17, 1, 7]. The *select-from-where queries* are the instantiations of the conjunctive queries in SQL. Besides, a simple Datalog program can also express the conjunctive query with a single Datalog rule. In our paper, we formulate a conjunctive query as a relational algebra expression. Our implementation actually synthesizes the conjunctive queries as Datalog programs, which are evaluated by a Datalog solver over the program relational representation for code search.

3.3 Multi-modal Conjunctive Query Synthesis Problem

To generate the conjunctive query for code search, the users need to specify their intent as the specification. In our work, we follow the premise of the recent studies on the multi-modal program synthesis [10, 4] that multiple modalities of information can go arm in arm with each other, serving as the informative specification for the synthesis. Specifically, the users provide a natural language sentence to describe the target code pattern and provide several grammatical constructs as positive and negative examples. Notably, the multi-modal synthesis specification is easy to provide. When the users want to explore a specific code pattern, they can describe the pattern briefly in a natural language and provide several examples from their editors instead of delving into the details of the underlying relations and their attributes, enabling users to generate a query for code search in a declarative manner.

Based on the multi-modal synthesis specification, the positive and negative examples are converted to the tuples in a specific relation. For example, Figure 1 shows a set of relations as the relational representation of the examples. To formalize our problem better, we define the notion of the *relation partition* as follows.

► **Definition 3.5 (Relation Partition).** The relation partition of $R^* \in \mathcal{R}$ is a pair of two relations (R_p^*, R_n^*) satisfying $R^* = R_p^* \cup R_n^*$ and $R_p^* \cap R_n^* = \emptyset$. The relation partition is non-trivial if and only if $R_p^* \neq \emptyset$ and $R_n^* \neq \emptyset$. We say the tuples in R_p^* and R_n^* are positive and negative tuples, respectively.

► **Example 3.3.** As shown in Figure 1, we can construct the relation partition (R_p^*, R_n^*) , where $R_p^* = \{(M1, I1, T3, MDF1)\}$ and $R_n^* = \{(M2, I2, T3, MDF1), (M3, I3, T2, MDF1)\}$. Obviously, R_p^* and R_n^* are disjoint, and $R_p^* \cup R_n^*$ is exactly the relation Method.

The positive and negative tuples essentially depict the positive and negative examples, respectively. Based on the program’s relational representation, the examples specified by the users can determine the positive and negative tuples, which can be achieved in various manners. Specifically, users can select a grammatical construct in the IDEs or use a code sample in a specific coding standard [51] as a positive example and remove several sub-patterns from a positive example by mutation to construct negative ones. Such positive and negative examples further constitute a sample code snippet, from which a Datalog-based analyzer derives a set of relations as the relational representation. In this paper, we omit the details of positive/negative tuple generation and formulate a *multi-modal conjunctive query synthesis (MMCQS) problem* as follows.

Given a relational representation \mathcal{R} , a relation partition (R_p^*, R_n^*) of $R^* \in \mathcal{R}$, and a natural language description s , we aim to synthesize a conjunctive query R_Q containing the positive tuples in R_p^* and excluding the negative tuples in R_n^* .

► **Example 3.4.** Figure 1(a) shows the multi-modal synthesis specification, which consists of a positive example, two negative examples, and a natural language description s as “Find all the methods receiving a `Log4jUtils`-type parameter and giving a `CacheConfig`-type return”. Leveraging a Datalog-based analyzer, we obtain the relational representation and the relation partition of Method, which are shown in Figure 1(b). To automate the code search, we expect to synthesize the query in Fig 1(c) or Example 3.2 according to the relational representation, the relation partition, and the natural language sentence.

To promote the code search, we propose an efficient synthesis algorithm SQUID for the MMCQS problem, which is our main technical contribution. As explained in § 1, it is challenging to solve the MMCQS problem efficiently, which involves mitigating the huge

search space and selecting queries from multiple candidates. In the following two sections, we formalize the conjunctive query synthesis from a graph perspective (§ 4), and illustrate the technical details of our synthesis algorithm SQUID (§ 5), which prunes the search space and selects desired queries effectively.

4 Conjunctive Query Synthesis: A Graph Perspective

This section presents a graph perspective of our conjunctive query synthesis problem. Specifically, we introduce two graph representations of the language schema and the conjunctive queries, named the schema graph (§ 4.1) and the query graph (§ 4.2), respectively, which reduces the conjunctive query synthesis to the query graph enumeration. Lastly, we summarize the section and highlight the technical challenges from a graph perspective (§ 4.3).

4.1 Schema Graph

According to Definition 3.2, a relation in the language schema has three kinds of attributes, namely a unique primary key, foreign keys, and string attributes. Obviously, the selection condition Θ in R_Q should only compare the foreign key of a relation with its referenced primary key or constrain the string attributes with string predicates. To depict the possible ways of constraining the attributes, we define the concept of the *schema graph* as follows.

► **Definition 4.1** (Schema Graph). The schema graph G_Γ of a language schema Γ is (N_Γ, E_Γ) :

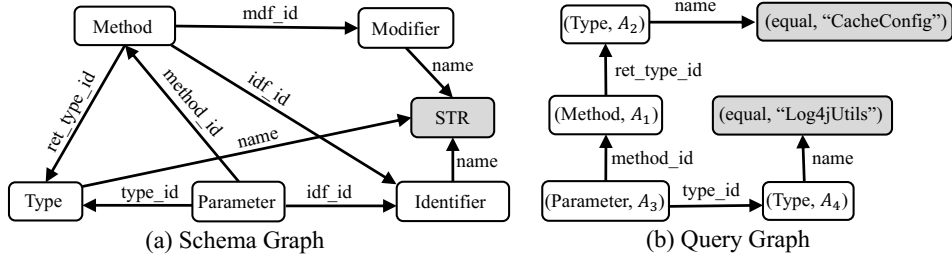

- The set N_Γ contains the relation symbols in the schema or the string type STR as the nodes of the schema graph, i.e., $N_\Gamma := \text{dom}(\Gamma) \cup \{\text{STR}\}$.
- The set E_Γ contains an edge (n_1, n_2, a) if and only if either of the conditions holds:
 - $n_1, n_2 \in \text{dom}(\Gamma)$ and $(a, n_2) \in \Gamma(n_1)$: The relation n_1 has a foreign key named a referencing the primary key of the relation n_2 .
 - $n_1 \in \text{dom}(\Gamma)$ and $(a, \text{STR}) \in \Gamma(n_1)$: a is the string attribute of the relation n_1 .

► **Example 4.1.** Consider the relations in the relational representation shown in Figure 1(b). We can construct the schema graph in Figure 3(a). The edge from Method to Modifier labeled with `mdf_id` shows that the attribute `mdf_id` of Method is a foreign key referencing the primary key of Modifier. Similarly, the edge from Type to STR labeled with `name` shows that the attribute `name` in Type is a string attribute.

Noting that there can exist multiple edges with different labels between two nodes in the schema graph, which indicate that a relation take multiple foreign keys referencing the same relation or string attributes as the attributes. Essentially, the schema graph encodes the available relations with its node set and depicts the valid forms of the atomic formulas appearing in the selection condition with its edge set. Although we can compare the attributes of any relations flexibly, a solution to our problem must take the valid form of the atomic formulas as its selection condition, comparing the foreign keys with the referenced primary keys or examining the string attributes of the relations appearing in a Cartesian product.

4.2 Query Graph

As formulated in Definition 3.4, there are two key components in the conjunctive query, namely the Cartesian product and the selection condition. Leveraging the schema graph, we can represent the components with nodes and edges on the graph, which uniquely determines a conjunctive query. Formally, we introduce the notion of the *query graph* as follows.

■ **Figure 3** The examples of the schema graph and the query graph.

► **Definition 4.2** (Query Graph). Given a conjunctive query Q , its query graph G_Q is (N_Q, E_Q, Φ_Q) :

- The set N_Q contains (R_i, A_i) or (p, ℓ) as a node in the query graph. $R_i \in \mathcal{R}$ is a relation and A_i is the unique relation identifier. p and ℓ are the string predicate and literal, respectively.
- The set E_Q contains (n_1, n_2, a) as an edge, corresponding to the equality atomic formula $A_j.a = A_k.id$ in the selection condition, where $n_1 = (R_j, A_j)$ and $n_2 = (R_k, A_k)$.
- The mapping Φ_Q maps a 3-tuple (R_j, A_j, a) to a node (p, ℓ) , indicating the edge from (R_j, A_j) to (p, ℓ) with the label a , which corresponds to the string constraint $p(A_j.a, \ell)$.

► **Example 4.2.** Figure 3(b) shows an query graph of R_Q in Example 3.2. The white nodes show the four relations appearing in the Cartesian product, while the gray nodes indicate the string predicates and literals in the selection condition. The edges depict two kinds of atomic conditions. For example, the edge from $(Parameter, A_3)$ to $(Method, A_1)$ labeled with `method_id` indicates the equality constraint $A_3.method_id = A_1.id$. Meanwhile, the edge induced by $\Phi_Q(\text{Type}, A_4, \text{name}) = (\text{equal}, \text{"Log4jUtils"})$ indicates the string constraint $\text{equal}(A_4.name, \text{"Log4jUtils"})$.

Essentially, a conjunctive query and a query graph are allotropes. That is, there exists a bijection κ mapping a conjunctive query R_Q to a query graph G_Q such that $G_Q = \kappa(R_Q)$ and $R_Q = \kappa^{-1}(G_Q)$. Thus, we can enumerate the conjunctive queries by enumerating the query graphs. Besides, the schema graph restricts the form of the selection condition over the attributes. If an edge with the label a connects (R_j, A_j) and (R_k, A_k) in a query graph, there should exist an edge labeled with a connecting the relations R_j and R_k in the schema graph. A similar argument also holds for the edge of the query graph indicated by the mapping Φ_Q . Therefore, we can reduce our conjunctive query synthesis to a search problem, of which the search space is characterized as the set of query graphs.

4.3 Summary

Leveraging the schema graph, we have reduced the conjunctive query synthesis process to query graph enumeration. To obtain the desired queries, we only need to select the nodes and edges from the schema graph and create the node (p, ℓ) with proper string predicates and literals for constructing a query graph G_Q , which should satisfy that the induced query $\kappa^{-1}(G_Q)$ separates positive tuples from negative ones.

Obtaining the desired queries with high efficiency is a non-trivial problem. The schema graph can be overwhelming, containing over a hundred nodes and edges, which leads to an enormous number of choices for relations occurring in the query graph. Even for a given set of

relations, the flexibility of instantiating equality constraints and string constraints over their attributes can induce a large number of selection choices of edges in a query graph, which exacerbates the search space explosion problem. Additionally, the existence of multiple query candidates necessitates the effective selection of candidates, which is crucial for conducting a code search task. In the next section, we will detail our synthesis algorithm that addresses these challenges, resulting in high efficiency and effectiveness for code search.

5 Synthesis Algorithm

This section presents our synthesis algorithm SQUID to solve the MMCQS problem. SQUID takes as input the relational representation \mathcal{R} of an example program, a relation partition (R_p^*, R_n^*) of $R^* \in \mathcal{R}$, and a natural language description s . It generates the query candidates separating positive tuples $\mathbf{t}_p \in R_p^*$ from negative ones $\mathbf{t}_n \in R_n^*$, which can be further selected and then used for code search. To address the challenges in § 4.3, SQUID works with the following three stages:

- To tackle a large number of relations, SQUID relies on the notion of dummy relations and conducts the representation reduction based on the positive and negative tuples, which effectively narrow down the relations that can appear in the query graph (§ 5.1).
- To avoid unnecessary enumeration of edges in query graphs, we propose the bounded refinement by enumerating the query graphs based on the schema graph, which essentially appends equality constraints and string constraints inductively (§ 5.2).
- To select query candidates, SQUID identifies the named entities in the natural language description s for the prioritization, and blends the selection with the refinement to collect the desired queries (§ 5.3).

We also formulate the soundness, completeness, and optimality of our algorithm (§ 5.4). For better illustration, we use the synthesis instance shown in Figure 1 throughout this section.

5.1 Representation Reduction

To tackle the large search space, we first propose the representation reduction to narrow down the relations possibly used in the query. Specifically, we introduce the notion of the dummy relations to determine the characteristics of unnecessary relations (§ 5.1.1) and propose the algorithm of removing dummy relations for the representation reduction (§ 5.1.2).

5.1.1 Dummy Relations

There exists a class of relations, named *dummy relations*, which cannot involve in distinguishing positive and negative tuples, such as the relation **Modifier** in Figure 1. Before defining them, we first introduce the *undirected relation path* and the *activated relation*.

► **Definition 5.1** (Undirected Relation Path). An undirected relation path from R_0 to R_{k+1} in the schema graph $G_\Gamma = (N_\Gamma, E_\Gamma)$ is $p : R_0 \xleftrightarrow{(a_0, d_0)} \cdots \xleftrightarrow{(a_k, d_k)} R_{k+1}$, where $R_i \in \text{dom}(\Gamma)$. Here, $d_i = 1$ if and only if $(R_i, R_{i+1}, a_i) \in E_\Gamma$, and $d_i = -1$ if and only if $(R_{i+1}, R_i, a_i) \in E_\Gamma$.

► **Definition 5.2** (Activated Relation). Given a tuple $\mathbf{t}_0 \in R_0$ and an undirected relation path $p : R_0 \xleftrightarrow{(a_0, d_0)} \cdots \xleftrightarrow{(a_k, d_k)} R_{k+1}$, the activated relation of \mathbf{t}_0 along p is

$$\mathcal{I}(\mathbf{t}_0, p) = \{\mathbf{t}_{k+1} \mid \mathbf{t}_{i+1} \in R_{i+1}, \text{ite}(d_i = 1, \mathbf{t}_i.a_i = \mathbf{t}_{i+1}.\text{id}, \mathbf{t}_i.\text{id} = \mathbf{t}_{i+1}.a_i), 0 \leq i \leq k\}$$

► **Example 5.1.** In Figure 1, the path $p_1 : \text{Method} \xleftrightarrow{(\text{method_id}, -1)} \text{Parameter} \xleftrightarrow{(\text{type_id}, 1)} \text{Type}$, and $\mathbf{t}_p = (\text{M1}, \text{l1}, \text{T3}, \text{MDF1}) \in R_p^*$. We have $\mathbf{t}_1 = (\text{P1}, \text{l4}, \text{T1}, \text{M1}) \in \text{Parameter}$, and $\mathbf{t}_2 = (\text{T1}, \text{Log4jUtils}) \in \text{Type}$. By inspecting other tuples, we have $\mathcal{I}(\mathbf{t}_p, p_1) = \{(\text{T1}, \text{Log4jUtils})\}$.

36:12 Synthesizing Conjunctive Queries for Code Search

Intuitively, an undirected relation path can depict the restriction upon the relations in the Cartesian product of the query. The activated relation actually contains the tuples enforcing the primary key of \mathbf{t}_0 to appear in a selected tuple. Therefore, it is possible to narrow down the relations for the synthesis by inspecting the activated relations of positive and negative tuples along each undirected relation path. According to the intuition, we formally introduce and define the notion of the *dummy relations* as follows.

► **Definition 5.3** (Dummy Relation). Given a relation partition (R_p^*, R_n^*) of $R^* \in \mathcal{R}$, a relation $R \in \mathcal{R}$ is dummy if for every undirected relation path p from R^* to R , either of the conditions is satisfied: (1) There exists $\mathbf{t}_p \in R_p^*$ such that $\mathcal{I}(\mathbf{t}_p, p) = \emptyset$; (2) $\mathcal{I}(\mathbf{t}_p, p) = \mathcal{I}(\mathbf{t}_n, p)$ for any $\mathbf{t}_p \in R_p^*$ and $\mathbf{t}_n \in R_n^*$.

Definition 5.3 formalizes two characteristics of relations unnecessary the synthesis. First, the empty activated relation of a positive tuple \mathbf{t}_p indicates the absence of the tuples in the relation R , making the tuple \mathbf{t}_p appear. Second, the relation R cannot contribute to separating positive tuples from negative ones if several tuples in R make all the positive and negative tuples appear simultaneously. Thus, such relations can be discarded safely.

► **Example 5.2.** Example 5.1 shows that $\mathcal{I}(\mathbf{t}_p, p_1) \neq \emptyset$. Similarly, $\mathcal{I}(\mathbf{t}_n, p_1) = \{(\text{T2}, \text{int})\} \neq \mathcal{I}(\mathbf{t}_p, p_1)$ when $\mathbf{t}_n = (\text{M2}, \text{l2}, \text{T4}, \text{MDF1}) \in R_n^*$. Hence, `Type` is not dummy. Besides, any undirected relation path p_2 from `Method` to `Modifier` has the form

$$\text{Method}[\xrightarrow{(\text{mdf_id}, +1)} \text{Modifier} \xrightarrow{(\text{mdf_id}, -1)} \text{Method}]^* \xrightarrow{(\text{mdf_id}, +1)} \text{Modifier}$$

where $[\cdot]^*$ indicates the repeated subpath. We find that $\mathcal{I}(\mathbf{t}_p, p_2) = \mathcal{I}(\mathbf{t}_n, p_2) = \{\text{MDF1}, \text{public}\}$ for any $\mathbf{t}_p \in R_p^*$ and $\mathbf{t}_n \in R_n^*$. Thus, the relation `Modifier` is a dummy relation.

5.1.2 Removing Dummy Relations

Based on Definition 5.3, identifying dummy relations involves two technical parts. First, we should collect all the undirected relation paths from R^* to each relation. Second, we need to compute $\mathcal{I}(\mathbf{t}_p, p)$ and $\mathcal{I}(\mathbf{t}_n, p)$ for each undirected relation path p and positive/negative tuple. However, the schema graph can contain a large and even infinite number of undirected relation paths from R^* . Any cycle induces the infinity of the path number, making it tricky to examine the conditions in Definition 5.3. Fortunately, we realize that the number of cycles in a path does not affect the activated relation, which is stated in the following property.

► **Property 5.1.** Given any $\mathbf{t}_0 \in R_0$, we have $\mathcal{I}(\mathbf{t}_0, p) = \mathcal{I}(\mathbf{t}_0, p')$ for p and p' as follows:

$$\begin{aligned} p &: R_0 \xrightarrow{(a_0, d_0)} \cdots R_l [\xrightarrow{(a'_l, d'_l)} \cdots R_{l+t} \xrightarrow{(a'_{l+t}, d'_{l+t})} R_l]^+ \xrightarrow{(a_l, d_l)} \cdots R_k \xrightarrow{(a_k, d_k)} R_{k+1} \\ p' &: R_0 \xrightarrow{(a_0, d_0)} \cdots R_l \xrightarrow{(a'_l, d'_l)} \cdots R_{l+t} \xrightarrow{(a'_{l+t}, d'_{l+t})} R_l \xrightarrow{(a_l, d_l)} \cdots R_k \xrightarrow{(a_k, d_k)} R_{k+1} \end{aligned}$$

Here, $[\cdot]^+$ indicates the cycle occurring at least one time.

Property 5.1 holds trivially according to Definition 5.2. For each undirected relation path p containing a cycle, the constraints over the tuples in $\mathcal{I}(\mathbf{t}_0, p)$ are the same as the ones over the tuples in $\mathcal{I}(\mathbf{t}_0, p')$. Thus, we can just examine the finite number of undirected relation paths in which a cycle appears at most one time.

■ **Algorithm 1** Removing dummy relations for representation reduction.

```

1 Procedure reduce( $\Gamma, \mathcal{R}, R_p^*, R_n^*$ ):
2    $\mathcal{R}' \leftarrow \emptyset$ ;
3    $G_\Gamma \leftarrow \text{SchemaGraph}(\Gamma)$ ;
4   foreach  $R \in \mathcal{R}$  :
5      $\mathcal{P} \leftarrow \text{augmentPathWithCycle}(\text{AcyclicPath}(R^*, R, G_\Gamma))$ ;
6     foreach  $p \in \mathcal{P}, \mathbf{t}_p \in R_p^*, \mathbf{t}_n \in R_n^*$  :
7       if  $\mathcal{I}(\mathbf{t}_p, p) \neq \mathcal{I}(\mathbf{t}_n, p)$  :
8          $\mathcal{R}' \leftarrow \mathcal{R}' \cup \{R\}$ ; break ;
9     foreach  $p \in \mathcal{P}, \mathbf{t}_p \in R_p^*$  :
10      if  $\mathcal{I}(\mathbf{t}_p, p) = \emptyset$  :
11         $\mathcal{R}' \leftarrow \mathcal{R}' \setminus \{R\}$ ; break ;
12  return  $\mathcal{R}'$ ;

```

Establish upon the above concepts and property, Algorithm 1 shows the details of the representation reduction by removing dummy relations. Initially, we construct the schema graph G_Γ according to Definition 4.1 (line 3). Then we compute the undirected relation paths from R^* to R in G_Γ , where any cycle repeats at most once (lines 4–5). Specifically, the function `AcyclicPath` collects all the acyclic undirected relation paths from R^* to R in the schema graph G_Γ , while the function `augmentPathWithCycle` augments each acyclic path by appending each cycle at most one time. For each undirected relation path p , we compute $\mathcal{I}(\mathbf{t}_p, p)$ and $\mathcal{I}(\mathbf{t}_n, p)$ according to Definition 5.2 for each $\mathbf{t}_p \in R_p^*$ and $\mathbf{t}_n \in R_n^*$, respectively. Therefore, we can identify R as a non-dummy relation if both the conditions in Definition 5.3 are violated (lines 6–11). Finally, we obtain the reduced relational representation \mathcal{R}' that excludes all the dummy relations (line 12).

► **Example 5.3.** Consider the undirected relation paths from Method to Modifier in Figure 3(a). Algorithm 1 collects the acyclic path $p_3 : \text{Method} \xrightarrow{(\text{mdf_id}, +1)} \text{Modifier}$ and augments it to form the path $p_4 : \text{Method} \xrightarrow{(\text{mdf_id}, +1)} \text{Modifier} \xrightarrow{(\text{mdf_id}, -1)} \text{Method} \xrightarrow{(\text{mdf_id}, +1)} \text{Modifier}$. Based on the activated relations $\mathcal{I}(\mathbf{t}, p_3)$ and $\mathcal{I}(\mathbf{t}, p_4)$ for each tuple \mathbf{t} in Method, we can find that $\mathcal{I}(\mathbf{t}_p, p) = \mathcal{I}(\mathbf{t}_n, p)$ for every $\mathbf{t}_p \in R_p^*$ and $\mathbf{t}_n \in R_n^*$. Thus, Modifier is a dummy relation.

Essentially, our representation reduction analyzes the example program upon its relational representation. The activated relations provide sufficient clues to identifying unnecessary relations, i.e., the dummy ones. As the first step of the synthesis, the representation reduction narrows down the relations used in the conjunctive query. Furthermore, in the enumeration of the edges of a query graph, i.e., the sets E_Q and Φ_Q , we only need to focus on the attributes in the non-dummy relations in the reduced relational representation, which prunes the search space significantly. Lastly, we formulate the soundness of the representation reduction as follows, which can further ensure the completeness of our synthesis algorithm in § 5.4. We provide a detailed proof in [49].

► **Theorem 5.1.** (Soundness of Representation Reduction) If an instance of the MMCQS problem has a solution, there must be a conjunctive query R_Q , of which the Cartesian product only consists of non-dummy relations, such that R_Q is also a solution.

5.2 Bounded Refinement

Based on the reduced relational representation \mathcal{R}' , we can enumerate query candidates by selecting proper nodes corresponding to non-dummy relations in \mathcal{R}' and edges connecting such nodes. However, the search space is potentially unbounded. The relations can occur in

a query multiple times, i.e., a node in the schema graph can be selected more than one time. Meanwhile, the literal in a string constraint can be instantiated flexibly, which increases the difficulty of enumerating a query graph with proper instantiation of Φ_Q . To achieve high efficiency, we propose the bounded refinement to expand query graphs on demand and strengthen the query with the strongest string constraints. Specifically, we first introduce the notions of the bounded query and the refinable query (§ 5.2.1), and then present the details of enumerating the query graphs (§ 5.2.2).

5.2.1 Bounded Query and Refinable Query

As shown in Example 3.2, a relation can appear multiple times in the Cartesian product of a conjunctive query, inducing an unbounded search space in the synthesis. The unboundedness of the search space poses the great challenge of enumerating the query candidates efficiently. However, we realize that the conjunctive query for a code search task often involves only a few relations, each of which appears quite a few times. Thus, it is feasible to bound the maximal multiplicity of the relation in the query and conduct the bounded enumeration. Formally, we introduce the notion of the (m, k) -bounded query as follows.

► **Definition 5.4** ((m, k) -Bounded Query). An (m, k) -bounded query is a conjunctive query with m relations such that (1) each relation appears at most k times; (2) there is a relation appearing exactly k times.

► **Example 5.4.** The conjunctive query $\Pi_{(A_1.*)}(\sigma_{\text{true}}(\rho_{A_1}(\text{Method})))$ is a $(1, 1)$ -bounded query. Similarly, the conjunctive query in Example 3.2 is a $(4, 2)$ -bounded query.

Intuitively, we can enumerate the (m, k) -bounded queries by selecting non-dummy relations at most k times, forming a query graph with m nodes. When constructing the sets E_Q and Φ_Q for the query graph enumeration, we only need to concentration on the attributes of the selected relations. However, not all the query graphs are worth enumerating. If R_Q excludes a positive tuple, there is no need to add more nodes and edges to its query graph, as it would induce a stronger selection condition, making the new query still exclude the positive tuple. Formally, we formulate the notion of the *refinable query* as follows.

► **Definition 5.5** (Refinable Query). A conjunctive query R_Q is a refinable query if and only if for any $\mathbf{t}_p \in R_p^*$ we have $\mathbf{t}_p \in R_Q$, i.e., $R_p^* \subseteq R_Q$.

► **Example 5.5.** Consider $R_Q := \Pi_{(A_1.*)}(\sigma_{\Theta}(\rho_{A_1}(\text{Method}) \times \rho_{A_2}(\text{Type}) \times \rho_{A_3}(\text{Parameter})))$, where the selection condition Θ in the selection operation is as follows:

$$\Theta := (A_1.\text{id} = A_3.\text{method_id}) \wedge (A_1.\text{ret_type_id} = A_2.\text{id}) \wedge \text{equal}(A_2.\text{name}, \text{"CacheConfig"})$$

It is a refinable query as $R_p^* \subseteq R_Q = \{(M1, I1, T3, MDF1), (M2, I2, T3, MDF1)\}$.

Essentially, a refinable query is the over-approximation of the positive tuples. When it excludes all the negative tuples, the query is exactly a query candidate. Thus, we can collect the query candidates by refining the refinable queries in the bounded enumeration.

5.2.2 Enumerating Query Candidates via Refinement

We denote the sets of (m, k) -bounded refinable queries and query candidates by $\mathcal{S}_R(m, k)$ and $\mathcal{S}_C(m, k)$, respectively, and set a multiplicity bound K to bound the multiplicity of a relation. To conduct a bounded enumeration, we have to compute the set $\mathcal{S}_C(m, k)$ for $k \leq K$,

■ **Algorithm 2** Enumerating query candidates via refinement.

```

1 Procedure refine( $\mathcal{S}_R, \mathcal{S}_C, R_p^*, R_n^*, m, k, \mathcal{R}'$ ):
2   if  $m = 1$  and  $k = 1$  :
3      $W \leftarrow \{(\emptyset, \emptyset, \perp)\}$ ;
4   if  $m > 1$  :
5      $W \leftarrow \{\kappa(R_Q) \mid R_Q \in \mathcal{S}_R(m-1, k)\}$ ;
6     if  $k > 1$  :
7        $W \leftarrow W \cup \{\kappa(R_Q) \mid R_Q \in \mathcal{S}_R(m-1, k-1)\}$ ;
8
9    $\mathcal{S}_R(m, k) \leftarrow \emptyset$ ;
10  while  $W$  is not empty do
11     $G_Q \leftarrow \text{pop}(W)$ ;  $V \leftarrow \emptyset$ ;
12    foreach  $R \in \mathcal{R}'$  :
13      if  $\text{multiplicity}(G_Q, R) < k$  and  $\kappa^{-1}(G_Q) \in \mathcal{S}_R(m-1, k)$  :
14         $V \leftarrow V \cup \text{expand}(G_Q, R)$ ;
15      if  $\text{multiplicity}(G_Q, R) = (k-1)$  and  $\kappa^{-1}(G_Q) \in \mathcal{S}_R(m-1, k-1)$  :
16         $V \leftarrow V \cup \text{expand}(G_Q, R)$ ;
17
18    foreach  $G_Q : (N_Q, E_Q, \Phi_Q) \in V$  and  $R_p^* \subseteq \kappa^{-1}(G_Q)$  :
19       $\mathcal{S}_R(m, k) \leftarrow \mathcal{S}_R(m, k) \cup \kappa^{-1}(G_Q)$  ;
20      foreach  $(R_i, A_i) \in N_Q$  and  $(a, STR) \in \Gamma(R_i)$  :
21         $(p, \ell) \leftarrow \text{synLCS}(G_Q, R_i, A_i, a, R_p^*)$ ;
22         $G'_Q \leftarrow (N_Q, E_Q, \Phi_Q[(R_i, A_i, a) \mapsto (p, \ell)])$  ;
23         $\mathcal{S}_R(m, k) \leftarrow \mathcal{S}_R(m, k) \cup \kappa^{-1}(G'_Q)$ ;
24
25   $\mathcal{S}_C(m, k) \leftarrow \{R_Q \mid R_Q \in \mathcal{S}_R(m, k), R_p^* = R_Q\}$ ;

```

which can be achieved by examining whether the queries in $\mathcal{S}_R(m, k)$ are query candidates. Obviously, exhaustive enumeration is impossible as the search space of (m, k) -bounded queries is exponential to m and k . To avoid unnecessary enumeration, we leverage the structure of $\mathcal{S}_C(m, k)$, which is formulated in the following property.

► **Property 5.2.** For every refinable query $R_Q \in \mathcal{S}_C(m, k)$ and $\kappa(R_Q) := (N_Q, E_Q, \Phi_Q)$, there exists a query graph G_Q^1 or G_Q^2 such that

- $N_Q = N_Q^1 \cup \{(R, A_i)\}$, $E_Q^1 \subseteq E_Q$, and $\Phi_Q^1 \subseteq \Phi_Q$, where R appears in G_Q^1 exactly $(k-1)$ times. Here, $G_Q^1 = (N_Q^1, E_Q^1, \Phi_Q^1)$ and $\kappa^{-1}(G_Q^1) \in \mathcal{S}_R(m-1, k-1)$.
- $N_Q = N_Q^2 \cup \{(R, A_i)\}$, $E_Q^2 \subseteq E_Q$, and $\Phi_Q^2 \subseteq \Phi_Q$, where R appears in G_Q^2 fewer than k times. Here, $G_Q^2 = (N_Q^2, E_Q^2, \Phi_Q^2)$ and $\kappa^{-1}(G_Q^2) \in \mathcal{S}_R(m-1, k)$.

Property 5.2 shows that the sets of the nodes and edges in a query graph of a refinable query are subsumed by the ones of a refinable query with fewer relations, which permit us to enumerate the query candidates by computing $\mathcal{S}_R(m, k)$ and $\mathcal{S}_C(m, k)$ inductively. Technically, we achieve the enumerative search via the bounded refinement. Assuming that we have $\mathcal{S}_R(m', k')$ and $\mathcal{S}_C(m', k')$ for all $m' < m$ and $k' \leq k$. Algorithm 2 computes the sets $\mathcal{S}_R(m, k)$ and $\mathcal{S}_C(m, k)$. The technical details of the refinement are as follows:

- For the base case, where $m = 1$ and $k = 1$, we construct an empty query graph (line 3). For a general case, we merge the sets of the query graphs induced by the refinable queries in $\mathcal{S}_R(m-1, k)$ and $\mathcal{S}_R(m-1, k-1)$ (lines 4-7). Hence, we obtain a set of query graphs W to maintain all the refinable queries with m relations.

■ **Figure 4** The example of the bounded refinement.

- For each query graph $G_Q \in W$, we leverage the function `expand` wraps a specific relation R as a new node and add new edges, producing a set of query graphs containing the relation R (lines 12–16). Such query graphs are maintained in the set V .
- For each query graph $G_Q \in V$ that induces a refinable query, we add the induced refinable query to the set $\mathcal{S}_R(m, k)$ (line 19) and attempt to synthesize a string constraint (lines 20–23). Specifically, the function `synLCS` examines the values of a string attribute a in the positive tuples to compute the longest common substring ℓ and the strongest string predicate p (line 21), where all the values of a in the positive tuples satisfy the string constraints induced by p and ℓ . By updating Φ_Q , we add a new edge to G_Q and produce a new query graph inducing a refinable query (lines 22–23).
- Finally, we check whether a (m, k) -bounded refinable query is a query candidate or not, which yields the set $\mathcal{S}_C(m, k)$ (line 25). The sets $\mathcal{S}_R(m, k)$ and $\mathcal{S}_C(m, k)$ are exactly the sets of (m, k) -bounded refinable queries and query candidates.

Notably, we construct the string constraints on demands to strengthen the selection condition of refinable queries, which is achieved by the function `synLCS` at line 21. The reduction from string constraint synthesis to the LCS computation enable us to leverage existing algorithms, such as general suffix automaton [33], to compute the string literal ℓ and select a string predicate p efficiently, which promote the efficiency of query refinement.

► **Example 5.6.** Figure 4 shows the part of the refinement for the instance in Example 3.4. G_Q^1 only contains the relation `Method`. After adding the nodes and edges, we construct the query graphs of refinable queries with more relations and atomic constraints, such as G_Q^2 , G_Q^3 , and G_Q^4 . Particularly, we identify the query candidate $\kappa^{-1}(G_Q^4)$, i.e., R_Q in Example 3.2.

5.3 Candidate Selection

Based on the bounded refinement, we collect the query candidates in which each relation appears no more than K times, where K is the multiplicity bound. However, not all the query candidates are the desired ones. In this section, we introduce dual quantitative metrics to prioritize queries (§ 5.3.1) and select query candidates during the refinement (§ 5.3.2).

5.3.1 Dual Quantitative Metrics

Desired queries are expected to express the search intent correctly, covering as many grammatical concepts in the natural language as possible. Also, they should be as simple as possible according to Occam’s razor. Based on the intuitions, we formalize the following two metrics and then define the total order to prioritize the query candidates.

► **Definition 5.6.** (Named-Entity Coverage) Given a function h mapping an attribute of a relation to a set of words in natural language, the named entity coverage of a conjunctive query R_Q with respect to a natural language description s is

$$\alpha_h(R_Q, s) = \frac{1}{|N(s)|} \cdot \left| \bigcup_{(R_i, a_j) \in \mathcal{A}(\Theta)} h(R_i, a_j) \cap N(s) \right|$$

Here, $\mathcal{A}(\Theta)$ contains the relations and their attributes appearing in the selection condition Θ while $N(s)$ is the set of the named entities in the description s .

► **Definition 5.7.** (Structural Complexity) Let $\delta(\Theta)$ be the number of the atomic formulas in the selection condition Θ . The structural complexity of a conjunctive query R_Q is

$$\beta(Q) = m + \delta(\Theta)$$

To compute the named entity coverage, we instantiate the function h manually and obtain the set $N(s)$ from the natural language description s based on the named entity recognition techniques [31]. The computation does not introduce much overhead, as the natural language description exhibits a fairly small length in our scenarios. Meanwhile, measuring the structural complexity is quite straightforward. The quantities m and $\delta(\Theta)$ can be totally determined by the sizes of the sets N_Q , E_Q and Φ_Q in a query graph. Thus, computing the two quantities does not introduce much overhead during the enumeration.

► **Example 5.7.** Assume that we instantiate the function h as follows:

$$\begin{aligned} h(\text{Parameter}, \text{id}) &= \{\text{parameter}\}, \quad h(\text{Method}, \text{id}) = \{\text{method}\}, \quad h(\text{Method}, \text{idf_id}) = \{\text{identifier}\} \\ h(\text{Method}, \text{ret_type_id}) &= \{\text{return}, \text{type}\}, \quad h(\text{Method}, \text{mdf_id}) = \{\text{modifier}\} \end{aligned}$$

Consider the natural language description s in Example 3.4 and the conjunctive query R_Q in Example 3.2, of which the query graph is shown in Figure 3(b). We can obtain a set of named entities $N(s) = \{\text{method}, \text{type}, \text{parameter}, \text{return}\}$. Therefore, we have $\alpha_h(R_Q, s) = 1$. According to $m = 4$ and $\delta(\Theta) = 5$, its structural complexity is $\beta(R_Q) = 4 + \delta(\Theta) = 9$.

Intuitively, the selection condition of a query is more likely to conform to the user intent if the query has a higher named entity coverage. Besides, the simpler form query can have better generalization power among the query candidates covering the same number of named entities. Based on Occam's razor, we should choose the simplest query from the candidates that maximizes the named entity coverage. Thus, we propose the *total order* of conjunctive queries as follows.

► **Definition 5.8** (Total Order). Given the function h in Definition 5.6, we have $R_Q^2 \preceq_s R_Q^1$ if and only if they satisfy one of the following conditions:

$$\begin{aligned} \alpha_h(R_Q^1, s) &\geq \alpha_h(R_Q^2, s) \quad \text{or} \\ \alpha_h(R_Q^1, s) &= \alpha_h(R_Q^2, s), \quad \beta(R_Q^1) \leq \beta(R_Q^2) \end{aligned}$$

► **Example 5.8.** Consider the following query candidates for the instance in Example 3.4.

$$R_Q^{c1} := \Pi_{(A_1.*)}(\sigma_{A_1.\text{name} = \text{"foo"}}(\rho_{A_1}(\text{Method})))$$

$$R_Q^{c2} := \Pi_{(A_1.*)}(\sigma_{\Theta_2}(\rho_{A_1}(\text{Method}) \times \rho_{A_2}(\text{Type}) \times \rho_{A_3}(\text{Parameter}) \times \rho_{A_4}(\text{Type})))$$

Here, $\Theta_2 := \Theta \wedge (A_1.\text{name} = \text{"foo"})$ and Θ is shown in Example 3.2. Given the function h shown in Example 5.7, we can obtain that $\alpha_h(R_Q^{c1}, s) = \frac{1}{4}$, $\alpha_h(R_Q^{c2}, s) = 1$, $\beta(R_Q^{c1}) = 2$, and $\beta(R_Q^{c2}) = 10$. According to Example 5.7, we have $R_Q^{c1} \preceq_s R_Q^{c2} \preceq_s R_Q$.

■ **Algorithm 3** Blending selection with refinement.

```

1 Procedure synthesize( $\Gamma, \mathcal{R}, R_p^*, R_n^*, s, K$ ):
2    $\mathcal{R}' \leftarrow \text{reduce}(\Gamma, \mathcal{R}, R_p^*, R_n^*)$ ;
3    $\tilde{\alpha} \leftarrow \frac{1}{|N(s)|} |\{w \in h(R, a) \cap N(s) \mid \exists R \in \mathcal{R}', T \in \mathcal{R}' \cup \{\text{STR}\} : (a, T) \in \Gamma(R)\}|$ ;
4    $\alpha_{max} \leftarrow \text{MIN\_INT}$ ;  $\beta_{min} \leftarrow \text{MAX\_INT}$ ;  $\mathcal{S}_Q \leftarrow \emptyset$ ;
5   foreach  $1 \leq m \leq K \cdot |\mathcal{R}'|$  :
6     if  $\mathcal{S}_R(m-1, k-1) = \emptyset$  and  $\mathcal{S}_R(m-1, k) = \emptyset$  :
7       continue ;
8     foreach  $1 \leq k \leq \min(K, m)$  :
9       refine( $\mathcal{S}_R, \mathcal{S}_C, R_p^*, R_n^*, m, k, \mathcal{R}'$ );
10      foreach  $R_Q \in \mathcal{S}_C(m, k)$  :
11         $(\alpha_{max}, \beta_{min}, \mathcal{S}_Q) \leftarrow \text{update}(R_Q, \alpha_{max}, \beta_{min}, \mathcal{S}_Q)$ ;
12         $\tilde{\beta} = \min(\{\beta(R_Q) \mid R_Q \in \mathcal{S}_R(m, k) \cup \mathcal{S}_R(m, k-1)\})$ ;
13        if  $\alpha_{max} = \tilde{\alpha}$  and  $\beta_{min} \leq \tilde{\beta}$  :
14          return  $\mathcal{S}_Q$ ;
15  return  $\mathcal{S}_Q$ ;
```

The total order is an adaption of Occam’s razor for our synthesis problem. Without the named entity coverage, we would select the query candidates with the lowest structural complexity, such as R_Q^{c1} in Example 5.8, even if they do not constrain the relationship of several grammatical constructs as expected. Based on the total order, we can select the query candidates by solving the dual-objective optimization problem, which finally yields the desired queries for code search.

5.3.2 Blending Selection with Refinement

Based on Definition 5.8, we propose Algorithm 3 that blends the candidate selection with the bounded refinement, which is more likely to obtain the desired queries for a code search task. First, we obtain the schema graph and remove the dummy relations via the representation reduction (line 2). We then compute the upper bound of the named entity coverage, which is denoted by $\tilde{\alpha}$ (line 3). After the initialization of α_{max} , β_{min} , and \mathcal{S}_Q (line 4), we conduct the bounded refinement and select the query candidates in each round (lines 5–14). Obviously, there are at most $K \cdot |\mathcal{R}'|$ relations in a query for a given multiplicity bound K (line 5), and a relation can only appear at most $\min(K, m)$ times in a query with m relations (line 8). In each round, we fuse the refinement and selection as follows:

- Enumerate (m, k) -bounded refinable queries and query candidates with Algorithm 2, strengthening the selection conditions of the refinable queries in previous rounds (line 9).
- Compute $\alpha_h(R_Q, s)$ and $\beta(R_Q)$ for each (m, k) -bounded query candidate R_Q and update the selected candidate set \mathcal{S}_Q , α_{max} , and β_{min} (lines 10–11). Particularly, α_{max} and β_{min} are updated to identify the largest candidates with respect to the total order.
- Terminate the iteration in advance and return the set \mathcal{S}_Q if α_{max} reaches the upper bound of the named entity coverage, i.e., $\tilde{\alpha}$, and the queries to be refined in the next round do not have lower structural complexities than β_{min} (lines 13–14).

The refinement strengthens the selection conditions to exclude all the negative tuples. Specifically, we explore the bounded search space containing the query graphs of refinable queries, avoiding the unnecessary enumerative search effectively. In real-world code search

tasks, the selection condition is often involved different kinds of grammatical constructs, making each relation appear often appear in the conjunction query one or two times. Therefore, we set the multiplicity bound K to 2 for real-world code search tasks in practice, of which the effectiveness will be evidenced by our evaluation.

The natural language description benefits our synthesis process from two aspects. First, the selected queries in \mathcal{S}_Q are the largest queries under the total order, and thus they are more likely to conform to the user’s search intent than other query candidates. Second, we terminate the enumerative search if the named entity coverage cannot increase with a smaller structural complexity, avoiding unnecessary enumerative search of bounded query candidates for the efficiency improvement.

► **Example 5.9.** Consider R_Q^{c1} , R_Q^{c2} and R_Q in Example 5.8. We obtain the query candidate R_Q^{c1} when $(m, k) = (1, 1)$, and discover the candidates R_Q and R_Q^{c2} when $(m, k) = (4, 2)$. Based on Definition 5.8, we select and maintain the query candidate R_Q in \mathcal{S}_Q . Also, we find $\alpha_{max} = \alpha_h(R_Q, s) = 1$ reaches $\tilde{\alpha}$, indicating that the candidates in the subsequent rounds cannot yield a larger named entity coverage with lower structural complexity. Algorithm 3 terminates and returns the set $\mathcal{S}_Q = \{R_Q\}$.

5.4 Summary

Our synthesis algorithm SQUID is an instantiation of a new synthesis paradigm of the multi-modal synthesis, which reduces the synthesis problem to a multi-target optimization problem. We now formulate and prove the soundness, completeness, and optimality of SQUID with three theorems as follows, which are proved in [49].

► **Theorem 5.2 (Soundness).** For any $R_Q \in \mathcal{S}_Q$, where \mathcal{S}_Q is returned by Algorithm 3, R_Q must contain all the positive tuples in R_p^* and exclude the negative tuples in R_n^* .

► **Theorem 5.3 (Completeness).** If an MMCQS problem instance has an (m, k) -bounded query as its solution and $k \leq K$, the set \mathcal{S}_Q returned by Algorithm 3 is not empty.

► **Theorem 5.4 (Optimality).** Denote $I = \{(m, k) \mid 1 \leq m \leq K \cdot |\mathcal{R}'|, 1 \leq k \leq \min(K, m)\}$ and $\tilde{\mathcal{S}} = \bigcup_{(m,k) \in I} \mathcal{S}_C(m, k)$. The returned query set \mathcal{S}_Q of Algorithm 3 satisfies:

- $R'_Q \preceq_s R_Q$ for every $R_Q \in \mathcal{S}_Q$ and $R'_Q \in \tilde{\mathcal{S}}$.
- There do not exist $R_Q \in \tilde{\mathcal{S}} \setminus \mathcal{S}_Q$ and $R'_Q \in \tilde{\mathcal{S}}$ such that $R'_Q \preceq_s R_Q$ and $R_Q \not\preceq_s R'_Q$.

6 Implementation

Established upon the industrial Datalog-based Java program analyzer in Ant Group, SQUID synthesizes conjunctive queries to support code search tasks in Java programs. Noting that our approach is general enough to support the conjunctive query synthesis for any Datalog-based analyzer as long as the generated relations can be formulated by Definition 3.2. In what follows, we provide more implementation details of SQUID.

Synthesis Input Configuration. We design a user interface to convenience the users to specify examples in a code snippet. Specifically, the users can copy a desired grammatical construct from their workspace as a positive example or write a positive example manually. By mutating a positive example, the users can create more positive and negative examples, eventually forming an example program. Then we convert the program to the relational representation, which consists of 173 relations with 1,093 attributes in total, and partitions a

relation into two parts to induce positive and negative tuples. To extract the named entities from the natural language description, we leverage the named entity recognition [31] and construct the dictionary of entities to filter unnecessary named entities in the post-processing. Specifically, the dictionary contains 205 words, which are the keywords describing grammatical constructs in Java programs, such as “method”, “parameter”, and “return”. Furthermore, we also instantiate the function h in Definition 5.6 to bridge the program relational representation with natural language words. We publish all the synthesis specifications and dictionary of entities online [48].

Synthesis Algorithm Design. Based on the language schema of Java, we construct the schema graph offline and persist it for synthesizing queries for a given synthesis specification. Instead of invoking the Datalog-based analyzer, we implement a query evaluator for conjunctive queries upon the relational representation to identify the refinable queries and query candidates, which can improve the efficiency of the query evaluation during the synthesis. In the bounded refinement, we set the multiplicity bound K to 2 by default to support code search tasks. To efficiently synthesize string constraints, we leverage the generalized suffix automaton [33] to identify the longest common substrings of a set of string values, which returns the string predicate p and the string literal ℓ with low time overhead. Currently, SQUID utilizes four predicates for string match, while we can further extend it to support regex match by adopting existing regex synthesis techniques [27, 10] to Algorithm 2.

7 Evaluation

To quantify the effectiveness and efficiency of SQUID, we conduct a comprehensive empirical evaluation and answer the following four research questions:

- **RQ1:** How effective is SQUID in the conjunctive query synthesis for code search tasks?
- **RQ2:** How big are the benefits of the representation reduction and the bounded refinement in terms of efficiency?
- **RQ3:** Is the query candidate selection effective and necessary for the synthesis?
- **RQ4:** How does SQUID compare to other approaches that could be used in our problem?

Benchmark. There are no existing studies targeting our multi-modal synthesis problem, so we construct a new benchmark for evaluation, which consists of 31 code search tasks. As shown in Table 1, the tasks cover five kinds of grammatical constructs, namely variables, expressions, statements, methods, and classes. Specifically, 14 tasks are the variants of C++ search tasks in [34] or the query synthesis tasks in [46]. We also consider more advanced tasks deriving from real demands. For example, Task 2 originates from the coding standard of a technical unit in Ant Group, while Task 21 is often conducted when the developers check the usage of the `log4j` library to improve reliability. For each task, we specify examples in a program and a sentence as the natural language description. The program is fed to the commercial Datalog-based analyzer in Ant Group to generate the relational representation and the relation partition, while the natural language description is processed via the named entity recognition technique [31]. The columns **L** and **(P, N)** in Table 1 indicate the line numbers of the programs and the numbers of positive/negative tuples, respectively.

Experimental Setup. We conduct all the experiments on a Macbook Pro with a 2.6 GHz Intel® Core™ i7-9750H CPU and 16 GB physical memory.

■ **Table 1** Experiment results of synthesizing conjunctive queries for code search tasks.

ID	Description	L	(P, N)	$ G_Q $	k	$ G'_T $	T_0 (s)
1	Local variables with double type	10	(2, 2)	(2, 1, 1)	1	(10, 19)	2.36
2	Float variables of which the identifier contains “cash”	10	(3, 1)	(3, 2, 2)	1	(9, 17)	2.37
3	Public field variables of a class	6	(2, 1)	(2, 1, 1)	1	(10, 21)	2.30
4	Public field variables whose names use “cash” as suffixes	8	(3, 2)	(2, 2, 2)	1	(10, 23)	2.49
5	Arithmetic expressions using double-type operands	9	(2, 2)	(3, 2, 2)	1	(9, 29)	2.62
6	Cast expressions from double-type to float-type [46]	11	(1, 2)	(3, 2, 2)	2	(9, 23)	2.31
7	Arithmetic expressions only using literals as operands	19	(2, 3)	(3, 2, 1)	2	(9, 29)	2.76
8	Expressions comparing a variable and a boolean literal [34]	16	(2, 1)	(2, 1, 1)	1	(8, 29)	2.36
9	New expressions of ArrayList	8	(2, 1)	(2, 1, 1)	1	(10, 25)	2.20
10	Logical conjunctions with a boolean literal [34]	11	(3, 1)	(2, 1, 2)	1	(9, 29)	2.31
11	Float increment expression [46]	11	(1, 2)	(3, 2, 2)	1	(9, 23)	2.55
12	Expressions comparing two strings with “==” [34]	14	(2, 1)	(3, 2, 3)	1	(11, 46)	3.01
13	Expressions performing downcasting [46]	25	(2, 1)	(3, 2, 0)	1	(11, 39)	2.63
14	The import of LocalTime	7	(1, 1)	(1, 0, 2)	1	(9, 23)	2.17
15	The import of the classes in log4j	9	(3, 1)	(1, 0, 1)	1	(9, 22)	2.22
16	Labeled statements using “err” as the label [34]	17	(1, 1)	(1, 0, 1)	1	(10, 21)	2.18
17	If-statements with a boolean literal as a condition [34]	16	(2, 1)	(2, 1, 0)	1	(9, 17)	2.24
18	For-statements with a boolean literal as the condition [34]	15	(2, 1)	(2, 1, 0)	1	(10, 25)	2.31
19	Invocation of unsafe time function “localtime” [34]	9	(2, 1)	(2, 1, 1)	1	(10, 23)	2.23
20	Public methods with void return type [34]	10	(2, 1)	(3, 2, 2)	1	(11, 26)	2.36
21	Methods receiving a parameter with Log4jUtils type	11	(2, 1)	(3, 2, 1)	1	(9, 20)	2.45
22	Methods using a boolean parameter as a if-condition [46]	29	(2, 2)	(4, 3, 0)	1	(11, 26)	3.23
23	Methods creating a File object	14	(2, 1)	(3, 2, 1)	1	(12, 30)	2.38
24	Mutually recursive methods [34, 46]	20	(2, 2)	(2, 2, 0)	2	(11, 27)	2.42
25	Overriding methods of classes [46]	25	(2, 4)	(5, 5, 0)	2	(8, 22)	5.89
26	User classes with “login” methods	15	(2, 1)	(2, 1, 2)	1	(11, 28)	2.53
27	Classes containing a field with Log4jUtils type	20	(2, 1)	(3, 2, 1)	1	(12, 35)	2.42
28	Classes having a subclass	25	(3, 3)	(2, 1, 0)	2	(13, 33)	2.21
29	Classes implementing Comparable interface	16	(2, 1)	(2, 1, 1)	1	(13, 35)	2.58
30	Classes containing a static method	17	(2, 1)	(3, 2, 1)	1	(11, 28)	2.46
31	Java classes with main functions	16	(2, 1)	(2, 1, 1)	1	(10, 28)	2.35

7.1 Overall Effectiveness

To evaluate the effectiveness of SQUID, we run it upon the synthesis specification for each code search task, examining whether the synthesized queries express the intent correctly, and meanwhile, measure the time cost of synthesizing queries in each task.

In Table 1, the column $|G_Q|$ indicates the numbers of the relations, equality constraints, and string constraints. The column k shows the maximal multiplicity of a relation in a synthesized query, while the column $|G'_T|$ indicates the numbers of nodes and edges in the subgraph of the schema graph induced by $\mathcal{R}' \cup \{\text{STR}\}$. The time cost of SQUID is shown in the column T_0 . According to the statistics, we can obtain two main findings. First, SQUID synthesizes the queries for all the tasks successfully. It manipulates more than three relations in Tasks 22 and 25, which are even non-trivial for a human to achieve. Second, SQUID synthesizes the queries with a quite low time cost. The average time cost is 2.56 seconds, while most of the tasks are finished in three seconds.

As mentioned in § 6, SQUID performs the bounded refinement with the multiplicity bound $K = 2$. In our benchmark, five code search tasks demand several relations appear two times. In practice, the searching condition can hardly relate to more than two grammatical constructs of the same kind, so our setting of the multiplicity bound K enables SQUID to synthesize

■ **Figure 5** The time cost comparison of SQUID, SQUIDNRR, and SQUIDNBR.

queries for code search tasks in real-world scenarios. Meanwhile, we quantify the time cost of the synthesis in the cases of $K = 3$ and $K = 4$. Averagely, SQUID takes 2.71 seconds and 3.98 seconds under the two settings, respectively. Thus, the overhead increases gracefully when K increases, demonstrating the great potential of SQUID in efficiently synthesizing more sophisticated queries with a larger multiplicity bound.

7.2 Ablation Study on Efficiency

We evaluate two ablations of SQUID, namely SQUIDNRR and SQUIDNBR, to quantify the impact of the representation reduction and the bounded refinement on the efficiency.

- SQUIDNRR: This ablation of SQUID does not perform the representation reduction but still leverages Algorithm 2 to conduct the bounded refinement.
- SQUIDNBR: The ablation performs the representation reduction as SQUID does, while it enumerates all the query graphs and permits each relation to appear at most K times.

We measure the time cost of two ablations to quantify their efficiency. Specifically, we set the time budget for synthesizing queries for a single task to 30 seconds, as a synthesizer would have little practical value for the real-world code search if it ran out of the time budget.

Figure 5 shows the comparison of the time cost of SQUID and the two ablations. First, the representation reduction can effectively reduce the time cost. Specifically, the average time cost of SQUIDNRR is 8.98 seconds, indicating that the representation reduction introduces a 71.49% reduction over the time cost. Second, the bounded refinement has a critical impact on the efficiency of SQUID. Without the refinement, SQUIDNBR has to explore the huge search space induced by the non-dummy relations, making 14 out of 31 tasks cannot be finished within the time budget, such as Task 4, Task 5, etc. For the failed tasks, we do not show the time cost of SQUIDNBR in Figure 5. SQUIDNBR also takes much more time than SQUID, consuming 7.89 seconds on average, even if it successfully synthesizes the queries.

To investigate how the efficiency is improved, we further measure the size of the subgraph of the schema graph induced by $\mathcal{R}' \cup \{\text{STR}\}$. Initially, the schema graph contains 174 nodes (including the node depicting STR) and 1,093 edges. As shown in the column $|\mathbf{G}'_{\mathbf{T}}|$ of Table 1, the induced subgraph only contains around ten nodes and no more than fifty edges. Although SQUIDNRR prunes unnecessary relations by enumerating several bounded queries at the beginning of the refinement, it has to spend more time on the query enumeration than SQUID, which demonstrates the critical role of the bounded refinement in our synthesis. Besides, the running time of SQUIDNBR is similar to SQUID on several benchmarks, such as Task 1, Task 2, Task 3, Task 9, etc., while it takes much longer time than SQUID in other benchmarks.

■ **Figure 6** The numbers of synthesized queries prioritized with different metrics.

Although SQUIDNBR does not discard infeasible queries, it still benefits from representation reduction. When a desired query is of small size and the reduced program representation induces a small schema graph G'_T , SQUIDNBR can terminate to find an optimal query by enumerating a few candidates. However, if G_Q and G'_T are large, SQUIDNBR enumerates a large number of infeasible queries, which introduces significant overhead.

7.3 Impact of Selection

To measure the impact of the query candidate selection, we adapt each metric separately for candidate prioritization. Specifically, we alter Algorithm 3 and select the queries minimizing the structural complexity and maximizing the named entity coverage, respectively. We then count the returned queries and inspect whether they are desired ones or not.

Figure 6(a) shows the numbers of the synthesized queries with the structural complexity as the metric. As we can see, SQUID produces non-desired queries in 12 tasks, while the returned set of synthesized queries in 10 tasks do not contain any desired query. For Task 3 and Task 30, it provides the desired queries along with non-desired ones, which makes the users confused about how to select a proper one. Similar to R_Q^{c1} in Example 5.8, the non-desired queries are caused by the over-fitting of positive and negative examples. Although they have the simplest form of the selection conditions, the relationship of grammatical constructs mentioned in the natural language description is not constrained, making synthesized queries not express the users' intent correctly.

Figure 6(b) shows the numbers of the queries maximizing the named entity coverage. SQUID returns at least one non-desired query for seven tasks. Similar to R_Q^{c2} in Example 5.8, non-desired queries come from over-complicated selection conditions. Although the selected queries have the same named entity coverage, several queries contain more atomic formulas than the desired ones, posing stronger restrictions upon the code. Besides, the synthesized queries in several tasks, e.g., Task 11 and Task 26, have complex selection conditions although they are equivalent under the context of code search. However, such queries exhibit higher structural complexity, posing more difficulty in understanding them.

7.4 Comparison with Existing Techniques

To the best of our knowledge, no existing technique or implemented tool targets the same problem as SQUID. To compare SQUID with existing effort, we adapt the state-of-the-art Datalog synthesizer EGS [46] as our baseline. Originally, it synthesizes a conjunctive query to separate a positive tuple from all the negative ones and then group all the conjunctive queries as the final synthesis result, which can be theoretically a disjunctive query. However,

■ **Figure 7** The time cost and the numbers of passed tasks of SQUID, EGS-STR, and EGS-STRDUAL.

EGS does not synthesize string constraints and only prioritizes feasible solutions based on their sizes, i.e., the structural complexity in our work. Thus, we construct two adaptations, namely EGS-STR and EGS-STRDUAL, to synthesize the queries under our problem setting.

- EGS-STR computes the longest substring of each string attribute in the positive tuple such that the string values of the attributes in negative ones do not contain it as the substring. We follow the priority function in EGS, which consists of the number of undesirable tuples eliminated per atomic constraint and the size of a query, to accelerate searching a query candidate with a small size. Finally, it obtains a query candidate for each positive tuple and groups the candidates as a result.
- EGS-STRDUAL further extends EGS-STR by considering the named entity coverage. Specifically, it prioritizes the refinable queries according to the three metrics, including the number of undesirable tuples eliminated per atomic constraint, the named entity coverage, and the size of a query. Other settings are the same as the ones of EGS-STR.

Figure 7 shows the results of the comparison. On average, EGS-STR and EGS-STRDUAL spend 2.85 and 3.18 seconds on a synthesis instance, respectively, while the average time cost of SQUID is 2.56 seconds. Although EGS-STR and EGS-STRDUAL accelerate the searching process with priority functions as the heuristic metrics, they have to process the positive tuples in each round, and thus, the number of positive tuples can increase the overhead.

Meanwhile, the two baselines only succeed synthesizing queries for 9 and 14 tasks, respectively. There are two root causes of their failures in synthesizing desired queries. First, they synthesize the query candidates for each positive query separately and, thus, are more prone to over-fitting problems than SQUID. Second, the core algorithms of EGS and the two adaptations, which are the instantiations of inductive logic programming, can not guarantee the obtained solutions are optimal under the given metrics. As reported in [46], the query may not be of the minimal size if EGS leverages the number of undesirable tuples eliminated per atomic constraint to accelerate the searching process of a query candidate. In our problem, our dual quantitative metrics increase the difficulty of achieving the optimal solutions with the two adaptations, which causes the failures of the code search tasks.

7.5 Discussion

In what follows, we demonstrate the discussions on the limitations of SQUID and several future works, which can further improve the practicality of our techniques.

Limitations. Although SQUID is demonstrated to be effective for code search, it has two major limitations. First, SQUID cannot synthesize the query where the multiplicity of a relation is larger than the multiplicity bound K . In other words, Theorem 5.3 actually ensures partial completeness. Although we may achieve completeness for all realizable instances by enumerating queries until obtaining a query candidate in Algorithm 3, SQUID would fail to terminate for unrealizable instances. Second, SQUID does not support synthesizing the queries with logical disjunctions. However, when a code search task involves the matching of multiple patterns, SQUID would not discover the correct queries, which are out of the scope of the conjunctive queries.

Future Works. In the future, we will attempt to propose an efficient decision procedure to identify unrealizable instances. Equipped with the decision procedure, we can only enumerate queries for realizable instances and generalize the query refinement by discarding the multiplicity bound. Besides, it would be promising to generalize SQUID for disjunctive query synthesis. One possible adaptation is to divide positive tuples into proper clusters and synthesize a conjunctive part for each cluster separately, following existing studies such as EGS [46] and RHOSYNTH [15]. In addition, we aim to expand SQUID to diverse program domains, such as serverless functions [50] and programs running on networking devices [57]. These use cases have gained significant attention in recent years, which can pose new challenges on code search where new approaches may be needed. Lastly, it would be meaningful to combine SQUID with the techniques in the community of human-computer interaction [8] to unleash its benefit for practice use.

8 Related Work

Multi-modal Program Synthesis. There has been a vast amount of literature on the multi-modal synthesis [11, 4, 9, 10, 40, 16, 34]. For example, the LTL formula synthesizer LTLTALK [16] maximizes the objective function that measures the similarity between the natural language description and the LTL formula, and searches for the optimal solution that distinguishes the positive and negative examples. SQUID bears similarities to LTLTALK in terms of the prioritization, while we use the named entities to avoid the failure of semantic parsing of a sentence. Another closely related work is a query synthesizer named SPORQ [34]. Based on code examples and user feedback, SPORQ iterates its PBE-based synthesis engine to refine the queries, which demands verbose user interactions and a long time period. In contrast, SQUID automates the code search by solving a new multi-modal synthesis problem, which only requires the users to specify code examples and a natural language description, effectively relieving the user's burden in the searching process.

Component-based Synthesis. Several recent studies aim to compose several components (e.g., the classes and methods in the libraries) into programs that achieve target functionalities [25, 18, 24, 38, 20, 21]. Typically, SyPET [14] and APIPHANY [19] both use the Petri net to encode the type signature of each function, and collect the reachable paths to enumerate the well-typed sketches of the programs, which prunes the search space at the start of the synthesis. In our work, SQUID leverages the schema graph to guide the enumerative search, which share the similarity with existing studies. However, our enumerative search space does not consist of the reachable paths in the schema graph, and instead, contains different choices of selecting its nodes and edges. Besides, unlike prior efforts [14, 24, 20, 19], SQUID computes the activated relations and then discards unnecessary components, i.e., dummy relations, which distinguishes SQUID significantly from other component-based synthesizers.

Datalog Program Synthesis. There have been many existing efforts of synthesizing Datalog programs [2, 42, 39, 43, 32]. For example, ZAATAR [2] encodes the input-output examples and Datalog programs with SMT formulas, and synthesizes the candidate solution via constraint solving. Unlike constraint-based approaches, ALPS [42] and GENSYNTH [32] synthesize target Datalog programs via the enumerative search, which is similar to our synthesis algorithm. However, existing studies do not tackle a large number of relations in the synthesis [2, 42, 32] or pursue an optimal solution with respect to a natural language description. Meanwhile, they do not support the synthesis of string constraints, making their approaches incapable of string matching-based code search. In contrast, SQUID ensures soundness, completeness, and optimality simultaneously and synthesizes string constraints for string matching, showing its potential in assisting real-world code search tasks.

Datalog-based Program Analysis. The past few decades have witnessed the increasing popularity of Datalog-based program analysis [22, 52, 55, 3, 44]. For example, CODEQL encodes a program with a relational representation and exposes a query language for query writing [3]. Several analyzers target more advanced semantic reasoning. For example, the points-to and alias facts are depicted by two kinds of relations in DOOP [6], and meanwhile, pointer analysis algorithms are instantiated as Datalog rules [44]. Other properties, such as def-use relation and type information, can also be analyzed by existing analyzers [26, 37]. Our effort has shown the opportunity of unleashing the power of Datalog-based program analyzers seamlessly to support the code search automatically.

9 Conclusion

We propose an efficient synthesis algorithm SQUID for a multi-modal conjunctive query synthesis problem, which enables automatic code search using a Datalog-based program analyzer. SQUID reduces the search space via the representation reduction and the bounded refinement, and meanwhile, conducts the query candidate selection with dual quantitative metrics. It efficiently synthesizes the queries for 31 code search tasks with the guarantees of soundness, completeness, and optimality. Its theoretical and empirical results offer strong evidence of its practical value in assisting code search in real-world scenarios.

Do Machine Learning Models Produce TypeScript Types That Type Check?

Abstract

Type migration is the process of adding types to untyped code to gain assurance at compile time. TypeScript and other gradual type systems facilitate type migration by allowing programmers to start with imprecise types and gradually strengthen them. However, adding types is a manual effort and several migrations on large, industry codebases have been reported to have taken several years. In the research community, there has been significant interest in using machine learning to automate TypeScript type migration. Existing machine learning models report a high degree of accuracy in predicting individual TypeScript type annotations. However, in this paper we argue that accuracy can be misleading, and we should address a different question: can an automatic type migration tool produce code that passes the TypeScript type checker?

We present TYPEWEAVER, a TypeScript type migration tool that can be used with an arbitrary type prediction model. We evaluate TYPEWEAVER with three models from the literature: DeepTyper, a recurrent neural network; LambdaNet, a graph neural network; and InCoder, a general-purpose, multi-language transformer that supports fill-in-the-middle tasks. Our tool automates several steps that are necessary for using a type prediction model, including (1) importing types for a project's dependencies; (2) migrating JavaScript modules to TypeScript notation; (3) inserting predicted type annotations into the program to produce TypeScript when needed; and (4) rejecting non-type predictions when needed.

We evaluate TYPEWEAVER on a dataset of 513 JavaScript packages, including packages that have never been typed before. With the best type prediction model, we find that only 21% of packages type check, but more encouragingly, 69% of files type check successfully.

1 Introduction

Gradual typing allows programmers to freely mix statically and dynamically typed code. This makes it possible to add static types to a large program incrementally, and slowly reap the benefits of static typing without requiring a complete rewrite of an existing codebase at once [22, 46, 48]. Over the past decade, gradual typing has proliferated, and there are now gradually typed versions of several mainstream languages [6, 7, 11, 14, 31, 33, 37, 48, 52].

TypeScript is a widely used gradually typed language, and a syntactic superset of JavaScript. Programmers can write their code in TypeScript, benefit from static typing, and then compile to JavaScript. However, the process of *migrating* an untyped JavaScript program to TypeScript has remained a labor-intensive manual effort in practice. For example, Airbnb engineers took more than two years to add TypeScript type annotations to 6 million lines of JavaScript [44], and there are several other accounts of multi-year TypeScript migration efforts [3, 8, 36, 39, 43].

To address this problem, there has been significant research interest in using machine learning to predict TypeScript types. Machine learning seems attractive because TypeScript has language features (e.g., `eval`) that are very difficult to accommodate with traditional, constraint-based approaches. Moreover, there is a significant quantity of open-source TypeScript that is available to serve as training data for a machine learning model. Over the last few years, advances in model architectures and high-quality training data have led to type annotation prediction with high accuracy on individual type annotations [23, 24, 25, 38, 50].

However, in this paper we argue that accuracy can be misleading, and that predicting individual type annotations is just the first step of migrating a codebase from JavaScript to TypeScript. We should address a different question: *can an automatic type migration tool produce code that type checks?* If so, we prefer type annotations that are non-trivial and useful (i.e., annotations that are not just `any`). On the other hand, if the code does not type check, it may have too many errors, which can overwhelm a user who may just turn off the tool. Moreover, it may not be feasible to fix the type errors automatically, since type errors refer to code locations whose typed terms are used, and not necessarily to faulty annotations.

To answer the type checking question, we present TYPEWEAVER, a TypeScript type migration tool that can be used with an arbitrary type prediction model. Our evaluation employs three models from the literature: DeepTyper [23], a recurrent neural network; LambdaNet [50], a graph neural network; and InCoder [18], a general-purpose, multi-language transformer that supports fill-in-the-middle tasks. Our tool automates several steps that are necessary for using a type prediction model, including:

Importing type dependencies Before migrating a JavaScript project, we must ensure that its dependencies are typed. This means transitively migrating dependencies, or ensuring that the dependencies have TypeScript interface declaration (`.d.ts`) files available.

Module conversion JavaScript code written for Node.js may use either the CommonJS or ECMAScript module system. However, when migrated to TypeScript, only ECMAScript modules preserve type information. Thus, to fully benefit from static type checking, code written with CommonJS modules should be refactored to use ECMAScript modules.

Type weaving Models that assign type labels to variables do not update the JavaScript source to include type annotations. Therefore, to ask if a program type checks, we must “weave” the predicted type annotations with the original JavaScript source to produce TypeScript.

Rejecting non-type predictions Models that predict type annotations as in-filled sequences of tokens can easily produce token sequences that are not syntactic types. These predictions need to be rejected or cleaned for type prediction to work.

```

1 function f(x) { return x+x; }
2 f(1) // returns 2
3 f("a") // returns "aa"
4 var point = {};
5 point.x = 42;
6 point.y = 54;

```

(a) JavaScript function that adds or concatenates its argument to itself.

(b) JavaScript that creates a “point” object.

■ **Figure 1** JavaScript code that cannot be easily typed in TypeScript.

After completing these tasks, it is then possible to type check the resulting TypeScript program and evaluate the effectiveness of TYPEWEAVER.

Our contributions are the following:

- We describe TYPEWEAVER, a TypeScript type migration tool for evaluating type prediction models, which automates several prerequisite steps (Section 3).
- We provide a dataset of 513 JavaScript packages, which are a subset of the top 1,000 most downloaded packages from the npm Registry. Our dataset includes packages without known type annotations, i.e., code that has never been used before to evaluate type prediction models (Section 4.1).
- We report the success rate of type checking. We answer the questions of how many packages type check, how many files type check, how many type annotations are trivial, and whether the predicted types match human-written types (Section 4.2).
- We discuss the common kinds of errors that result from a type migration (Section 4.3).
- We compare the results of a type migration before and after converting to the ECMAScript module system (Section 4.4).
- Finally, we examine four packages as case studies, to showcase other difficulties that arise during type migration (Section 4.5).

2 Background

In this section, we first provide background on the type migration problem and contrast it to type inference. We then discuss deep-learning-based type annotation prediction, focusing on the tools that we have used with TYPEWEAVER.

2.1 Type Migration vs. Type Inference

Type inference is related to, but distinct from, type migration. The goal of type inference is to *reconstruct* the types of variables, expressions, and functions, where some or all the type annotations are missing. In other words, the language is statically typed and the types exist implicitly within the program, so the type inference algorithm computes the missing annotations. Furthermore, inference can frequently compute the *principal type* of a variable, expression, or function, i.e., the most general type. As a result, there is a single answer for the type of a variable, expression, or function. Additionally, in languages that support type inference, the inferred type annotations are well defined and not added to the program text.

In this paper, we use *type migration* to describe the problem of migrating a program from an untyped language to a typed language, e.g., from JavaScript to TypeScript, a process that may require refactoring in addition to type inference. The type migration process starts from an untyped program without type annotations: there is no type information available, beyond the basic information available from literal values, operators, and control-flow statements, so type definitions may need to be inserted into the program. Furthermore, multiple type

annotations may be valid, rather than having a single principal type. For example, Figure 1a shows a JavaScript function where the parameter `x` on Line 1 could be annotated as `number` or `string`; without additional context, both annotations are valid. The example illustrates another challenge of type migration: `f` is called on Line 2 with a number and Line 3 with a string, so the only valid type annotation for `x` is `any`.¹ This satisfies the TypeScript compiler’s type checker, but may not be a helpful annotation in terms of documentation.

The type migration problem for TypeScript has several additional challenges and we highlight some of them here. TypeScript has a structural type system, which makes it even harder to determine the right annotation. Furthermore, structural types are often verbose, making it difficult for a programmer to understand the code, which defeats one of the benefits of a static type system. Another difficulty is that JavaScript code can be too dynamic to fit within TypeScript’s type system, e.g., there is no good way to handle `eval`, other than using the `any` annotation as an escape hatch. Finally, certain idioms and patterns in JavaScript code do not fit TypeScript and need to be refactored. For instance, consider Figure 1b, which initializes a “point” object in JavaScript. Line 4 initializes `point` to an empty object, and Lines 5 and 6 set the `x` and `y` properties. However, this cannot be easily typed in TypeScript,² and it is more appropriate to rewrite the code to use TypeScript classes.

In this landscape of challenges, recent work has focused on the narrower problem of assigning type annotations to TypeScript code, in particular, using deep learning approaches. We examine some of these approaches in the next subsection.

2.2 Deep-Learning-Based Type Annotation Prediction

We focus on JavaScript and TypeScript, since there have been a variety of proposed type prediction models for those languages. We evaluate three of them here: DeepTyper [23], LambdaNet [50], and InCoder [18].

DeepTyper was the first deep neural network for TypeScript type prediction, and uses a *bidirectional recurrent neural network* architecture. LambdaNet was another early approach, and it uses a *graph neural network* architecture. InCoder is a recent *large language model* that predicts arbitrary code completions, and while not trained specifically to predict type annotations, its “fill in the middle” capability makes it ideal for that task. All three models use training data from public code repositories.

We require a system that takes a JavaScript project as input and outputs a type-annotated TypeScript project. DeepTyper and LambdaNet output a probability distribution of types for each identifier, which we must then “weave” into the original JavaScript source to produce TypeScript; we describe this technique in Section 3.3. InCoder is a general-purpose, multi-language transformer, so we implemented a front end to use InCoder to predict type annotations and output TypeScript. Currently, our front end only supports type predictions for function parameters; we describe our implementation in Section 3.2.1.

Our approach can be adapted to work with any type prediction model. Older models may require some work to adapt their outputs, but our InCoder front end can easily be extended to support other fill-in-the-middle models, such as OpenAI’s model [4] and SantaCoder [5].

¹ The union type `number | string` produces a type error in the function.

² The correct, but awkward, type annotation is `{x?: number, y?: number}`, which declares `x` and `y` as optional properties. If `x` or `y` were required, the assignment on Line 4 would be a type error. Alternatively, `any` is valid, but unhelpful.

2.2.1 DeepTyper

DeepTyper [23] predicts types for variables, function parameters, and function results using a fixed vocabulary of types, i.e., it cannot predict types declared by the program under analysis unless those types were observed during training. DeepTyper treats type inference as a machine translation problem from one language (unannotated TypeScript) to another (annotated TypeScript). Specifically, it uses a model based on a *bidirectional recurrent neural network* architecture to translate a sequence of tokens into a sequence of types: for each identifier in the source program, DeepTyper returns a probability distribution of predicted types. Because the input token sequence is perfectly aligned with the output type sequence, this task can also be considered a sequence annotation task, where an output type is expected for every input token.³ However, this approach treats each input token as independent from the others, i.e., a source variable may be referenced multiple times and each occurrence may have a different type. To mitigate this, DeepTyper adds a consistency layer to the neural network, which encourages – but cannot enforce – the model to treat multiple occurrences of the same identifier as related.

DeepTyper’s dataset is based on the top 1,000 most starred TypeScript projects on GitHub, as of February 2018. After cleaning to remove large files (those with more than 5,000 tokens) and projects that contained only TypeScript declaration files, the dataset was left with 776 TypeScript projects (containing about 62,000 files and about 24 million tokens), which were randomly split into 80% (620 projects) training data, 10% (78 projects) validation data, and 10% (78 projects) test data. Further processing and cleaning of rare tokens resulted in a final vocabulary of 40,195 source tokens and 11,830 types.

The final training dataset contains both identifiers and types, where each identifier has an associated type annotation; this includes annotations inferred by the TypeScript compiler that were not manually annotated by a programmer. The testing dataset contains type annotations and no identifiers; specifically, the type annotations added by programmers are associated with their declaration sites, and all other sites are associated with “no-type.” As a result, DeepTyper’s predictions are evaluated against the handwritten type annotations, rather than all types in a project.

2.2.2 LambdaNet

Like DeepTyper, LambdaNet [50] predicts type annotations for variables, function parameters, and function returns: it takes an unannotated TypeScript program and outputs a probability distribution of predicted types for each declaration site. LambdaNet improves upon two limitations of DeepTyper. First, it predicts from an open vocabulary, beyond the types that were observed during training; i.e., it can predict user-defined types from within a project. Second, it only produces type predictions at declaration sites, rather than at every variable occurrence; in other words, multiple uses of the same variable will have a consistent type.

LambdaNet uses a *graph neural network* architecture and represents a source program as a so-called *type dependency graph*, which is computed from an intermediate representation of TypeScript that names each subexpression. The type dependency graph is a hypergraph that encodes program type variables as nodes, and relationships between those variables as labeled edges. By encoding type variables, LambdaNet makes a single prediction over all occurrences

³ The DeepTyper architecture must classify *every* input token, including ones where an output type does not make sense, such as `if`, `(`, `)`, and even whitespace. DeepTyper filters out these predictions, so a user will never observe these meaningless types.

37:6 Do Machine Learning Models Produce TypeScript Types That Type Check?

of a variable, rather than a prediction for each instance of a variable. Furthermore, the edges encode logical constraints and contextual hints. Logical constraints include subtyping and assignment relations, functions and calls, objects, and field accesses, while contextual hints include variable names and usages. Finally, LambdaNet uses a *pointer network* to predict type annotations.

LambdaNet’s dataset takes a similar approach to DeepTyper: they selected the 300 most popular TypeScript projects from GitHub that contained 500–10,000 lines of code, and had at least 10% of type annotations that referred to user-defined types. The dataset has about 1.2 million lines of code, and only 2.7% of the code is duplicated. The 300 projects were split into three sets: 200 (67%) for training data, 40 (13%) for validation data, and 60 (20%) for test data. The vocabulary was split into library types, which consist of the top 100 most common types in the training set, and user-defined types, which are all the classes and interfaces defined in source projects. Similar to DeepTyper, LambdaNet’s predictions are evaluated against the handwritten annotations that were added by programmers.

2.2.3 InCoder

InCoder [18] is a *large language model* (LLM) for generating arbitrary code that is trained with a *fill-in-the-middle* (FIM) objective on a corpus of several programming languages, including TypeScript.

InCoder’s corpus consists of permissively licensed, open-source code from GitHub and GitLab, as well as Q&A and comments from Stack Overflow. This raw data is filtered to exclude: (1) code that is duplicated; (2) code that is not written in one of 28 languages; (3) files that are extremely large or contain very few alphanumeric characters; (4) code that is likely to be compiler generated; and (5) certain code generation benchmarks. The result is about 159 GB of code, which is dominated by Python and JavaScript. TypeScript is approximately 4.5 GB of the training data.

We describe InCoder in more depth in Section 3.2.1, where we present what is necessary to use it as a type annotation prediction tool for TypeScript.

2.2.4 Evaluating on Accuracy

The main evaluation criteria for the type annotation prediction task is accuracy: what is the likelihood that a predicted type annotation is correct? Correct means the prediction *exactly* matches the ground truth, which is the handwritten type annotation at that location. Accuracy is typically measured as top- k accuracy, where a prediction is deemed correct if any of the top k most probable predictions is correct. For our evaluation, we would like a result that “just works,” i.e., a program that type checks. Therefore, we are only interested in top-1 accuracy, since we take the top guess as the only prediction.

DeepTyper’s test dataset makes up 10% (78 projects) of its original corpus and contains only the annotations that were manually added by programmers. Predictions are compared against this ground truth dataset, and DeepTyper reports a top-1 accuracy of 56.9%. Because DeepTyper may predict different types for multiple occurrences of the same variable, the authors also report an inconsistency metric: 15.4% of variables had multiple type predictions.

LambdaNet also compares its predictions against a ground truth of handwritten type annotations, but they use a different corpus and split 20% (60 projects) for the test dataset. LambdaNet can predict user-defined types, so the evaluation reports two sets of results: a top-1 accuracy of 75.6% when predicting only common library types, and a top-1 accuracy of 64.2% when predicting both library and user-defined types.

InCoder was not designed specifically to predict TypeScript type annotations, but the authors report an experiment to predict only the result types for Python functions. For this task, InCoder was evaluated on a test dataset of 469 functions, which was constructed from the CodeXGLUE dataset; InCoder achieved an accuracy of 58.1%.

However, we argue that accuracy is not the right metric for evaluating a type prediction model. As a first step, we would like to type check the TypeScript project. Additionally, when migrating a JavaScript project to TypeScript, there is frequently no ground truth of handwritten type annotations; instead, the ground truth is what the compiler accepts. This condition is much stronger than accuracy, as even a single, incorrect type annotation causes a package to fail to type check. On the other hand, less precise type annotations (e.g., `any`) and equivalent annotations (e.g., `number | string` vs. `string | number`) may be accepted, despite not matching the ground truth exactly.

In the next section, we describe our approach for type migration and evaluating type prediction models.

3 Approach

We take an end-to-end approach to type migration, starting from an untyped JavaScript project and finishing with a type-annotated TypeScript project that we try to type check. The first step, which is optional, is to convert from CommonJS modules to ECMAScript modules. Next, we invoke one of the type prediction models: DeepTyper and LambdaNet produce type predictions, while InCoder, with a front end we implemented, produces TypeScript. Because DeepTyper and LambdaNet do not produce TypeScript, we perform a step that we call *type weaving*, which combines type predictions with the original JavaScript source and outputs TypeScript. Finally, we run the TypeScript compiler to type check the now migrated TypeScript project.

3.1 CommonJS to ECMAScript Module Conversion

The first step is to convert projects from CommonJS module notation to ECMAScript module notation. This step is not necessary for type prediction, but is important for the type checking evaluation, as only ECMAScript modules preserve type information across module boundaries. Because we treat this step as optional, our dataset has two versions: the original projects, which may use CommonJS or ECMAScript modules, and a final version that only uses ECMAScript modules.

Most Node.js packages use the CommonJS module system, which was the original module system for Node.js and remains the default. Figures 2a and 2b show an example of the CommonJS module system, where files `a.js` and `b.js` implement separate modules. In this example, `a.js` sets the `foo` and `f` properties of the special `module.exports` object. Local variables like `x` are private and not exported. On Line 13, `b.js` uses the Node.js function `require` to load module `a.js` into the local variable `a`. As a result, `a` takes on the value of the `module.exports` object set by `a.js`, and both `foo` and `f` are available as properties of `a`.

ECMAScript 6 introduced a new module system, referred to as ECMAScript modules. Node.js supports ECMAScript modules when using the `.mjs` extension or setting a project-wide configuration in the `package.json` file. Figures 2c and 2d show the same program as before, but rewritten to use ECMAScript modules. In this example, `a.mjs` directly exports `foo` and `f`, rather than writing to a special `module.exports` object. Then, `b.mjs` directly imports the names with the `import` statement instead of loading an object.

37:8 Do Machine Learning Models Produce TypeScript Types That Type Check?

```
7 // a.js
8 var x = 2;    // private
9
10 module.exports.foo = 42;
11 module.exports.f = (i) => i+x;
```

(a) CommonJS: a.js exports foo and f.

```
12 // b.js
13 var a = require('./a.js');
14
15 console.log(a.foo); // 42
16 console.log(a.f(1)); // 3
```

(b) CommonJS: b.js imports the module a.js.

```
17 // a.mjs
18 var x = 2;    // private
19
20 export var foo = 42;
21 export var f = (i) => i+x;
```

(c) ECMAScript: a.mjs exports foo and f.

```
22 // b.mjs
23 import {foo,f} from './a.mjs';
24
25 console.log(foo); // 42
26 console.log(f(1)); // 3
```

(d) ECMAScript: b.mjs imports foo and f.

■ **Figure 2** An example comparing the CommonJS and ECMAScript module systems.

TypeScript supports both CommonJS and ECMAScript modules, depending on the project configuration. However, CommonJS modules in TypeScript are untyped; specifically, `require` is typed as a function that returns `any`. Therefore, even if a module has type annotations for the variables and functions it exports, those annotations are lost when the module is imported. On the other hand, with ECMAScript modules, the `import` statement preserves the type annotations of names it imports.

In order to make use of the most type information available, we would like to use ECMAScript modules in our evaluation. Therefore, we use the `cjs-to-es6` tool⁴ to transform our dataset to use ECMAScript modules. The conversion tool is not perfect, and in particular has difficulty when `require` is used to dynamically load a module. Some of these cases could be fixed manually, but many are genuine uses of dynamic loading in JavaScript.

3.2 Type Annotation Prediction

The next step is to invoke a deep learning model to predict type annotations for a JavaScript project. DeepTyper and LambdaNet require an additional step, which we call *type weaving*, to produce TypeScript, while InCoder, with our front end, outputs TypeScript directly.

We use the pretrained DeepTyper model available from its GitHub repository,⁵ which is not identical to the model used in the DeepTyper paper. DeepTyper reads in a JavaScript file, and for each identifier, predicts the top five most likely types, outputting the result in comma-separated values (CSV) format.

We use the pretrained LambdaNet model available from its GitHub repository,⁶ specifically the model that supports user-defined types. LambdaNet reads in a directory containing a JavaScript project, and predicts the top five most likely types for each variable and function declaration. We modify LambdaNet to output in CSV format.

DeepTyper predicts types for all identifiers in the program, including program locations that do not allow type annotations. Therefore, type weaving must also ensure that type annotations are applied correctly, i.e., only to variable declarations, function parameters, and function results. LambdaNet predicts types for variable and function declarations, and in

34   return x + 1;
35 }<|mask:1|><|mask:0|>
36 number, y: number<|endofmask|>

```

(c) InCoder often produces extra tokens after the type. Here it produces a new parameter that is not in the original program.

```

37 function f(x: number) {
38   return x + 1;
39 }

```

(d) We select a prefix of the generated program that is a syntactically valid TypeScript type.

■ **Figure 3** Generating types with InCoder.

the correct locations; however, type weaving is still required to produce TypeScript code. Our InCoder front end does not require type weaving, but only supports type predictions for function parameters. We use the pretrained InCoder model available from Hugging Face.⁷

3.2.1 InCoder

InCoder is trained to generate code in the middle of a program, conditioned on the surrounding code. To train on a single example (a file of code), the training procedure replaces a randomly selected contiguous span of tokens with a *mask sentinel* token. It appends the mask sentinel to the end of the example, followed by the tokens that were replaced and a special *end-of-mask* token. The model is then trained as a left-to-right language model. This approach generalizes to support several, non-overlapping masked spans, and its training examples have up to 256 randomly selected masked spans, though the majority have just a single masked span.

In principle one could give InCoder a program with up to 256 types to generate at once. However, we found that InCoder is more successful generating a single type at a time, and with a limited amount of context. To generate a type annotation with InCoder we (1) insert the mask sentinel token at the insertion point; (2) add the mask sentinel to the end of the file; (3) generate at the end of the file until the model produces the end-of-mask token; (4) move the generated text to the insertion point; and (5) remove all sentinels.

Figure 3 shows an example of generating a type annotation. However, a problem that we frequently encountered is that InCoder sometimes generates more than just a single type. For instance, Figure 3c shows an example where InCoder generates a new parameter that is not in the original program. The simplest approach is to reject this result and get InCoder to re-generate completions until it produces a type. However, we found that it is far more efficient to accept a prefix of the generated code if it is a syntactically valid type, which we check with a TypeScript parser in the generation loop.

⁷ <https://huggingface.co/facebook/incoder-6B>

3.3 Type Weaving

To produce type-annotated TypeScript code, we use a process we call *type weaving* to combine type predictions with the original JavaScript code. Type weaving takes two files as input: a JavaScript source file and an associated CSV file with type predictions. The type weaving program parses the JavaScript source into an abstract syntax tree (AST), and then traverses the AST and CSV files simultaneously, using the TypeScript compiler to insert type annotations into the program AST. Both DeepTyper and LambdaNet require type weaving, but their CSV files are in different formats. Our type weaving program can be extended to support custom CSV formats.

3.3.1 DeepTyper

Each row of a DeepTyper CSV file represents a lexical token from the source program. Rows with non-identifier tokens, such as keywords and symbols, contain two columns: the token text and the token type. Rows with identifiers contain columns for the token text, token type, as well as the top five most likely types and their probabilities.

The DeepTyper implementation has a few limitations that we handle during type weaving. First, the implementation uses regular expressions instead of a parser to tokenize JavaScript code. This results in some tokens that are missing or incorrectly classified as identifiers. Second, DeepTyper provides type predictions for every occurrence of an identifier, so we must use only the predictions for declarations. Finally, DeepTyper often predicts `complex` as a type; we do not believe it refers to a complex number type, so we replace it with `any`.

Our type weaving algorithm works as follows: as it traverses the program AST, if it encounters a declaration node, it queries the CSV file for a type prediction. However, the DeepTyper format does not record source location information, and the token classification is brittle, so it is not straightforward to identify which rows are actually declarations and which rows should be skipped. Our algorithm searches the CSV file for a short sequence of rows that corresponds to the declaration node in the AST. This algorithm works well in practice, but does not handle optional parameters or statements that declare multiple variables.

3.3.2 LambdaNet

For each declaration, LambdaNet prints the source location of the identifier (start line, start column, end line, and end column), followed by the top five most likely types and their probabilities. We modified LambdaNet to output in CSV format.

We observed that LambdaNet frequently predicts the following types: `Number`, `Boolean`, `String`, `Object`, and `Void`. The first four are valid TypeScript types, but are non-primitive boxed types distinct from `number`, `boolean`, `string`, and `object`. The TypeScript documentation strongly recommends using the lowercase type names,⁸ so we normalize those types during type weaving. Furthermore, `Void` is not a valid type, so we instead use `void`. Finally, LambdaNet does not support generic types, but will predict them without type arguments, which is not valid in TypeScript. While we cannot fix every generic type, we normalize `Array` to `any[]`, which is shorthand for `Array<any>`.

As our type weaving program traverses the program AST, if it encounters a declaration node, it computes the node's source location information, and uses that to query the CSV file for a type prediction. However, the type annotation cannot be applied directly to the

⁸ <https://www.typescriptlang.org/docs/handbook/declaration-files/do-s-and-don-ts.html#number-string-boolean-symbol-and-object>

■ **Table 1** Summary of dataset categories: number of packages, files, and lines of code.

Dataset category	Packages	Files	Lines of code
DefinitelyTyped, no deps	286	2,692	123,157
DefinitelyTyped, with deps	85	671	63,057
Never typed, no deps	102	255	20,729
Never typed, with deps	40	544	19,189
Overall	513	4,162	226,132

declaration node, as this modifies the AST and invalidates source location information. Therefore, type weaving for LambdaNet occurs in two phases. In the first phase, the traversal does not modify the AST, but saves the declaration node and type prediction in a map. Then, in the second phase, type weaving iterates over the map and updates the AST.

3.4 Type Checking

In the final step, we run the TypeScript compiler to type check the migrated projects. We run the compiler on each project, providing all the TypeScript input files as arguments, and setting the following compiler flags:

```
--noEmit Type check only, do not emit JavaScript
--esModuleInterop Improve handling of CommonJS and ECMAScript modules
--moduleResolution node Explicitly set the module resolution strategy to Node.js
--target es6 Enable ECMAScript 6 features, which are used by some packages
--lib es2021,dom Include ECMAScript 2021 library definitions and browser DOM definitions
```

We do not set the `--strict` flag, allowing the type checker to be more lenient in certain situations, which we expect to already be a significant challenge for automated type migration. Furthermore, we ensure that package dependencies are properly included in our dataset so that the compiler can resolve them.

4 Evaluation

4.1 Dataset

Our dataset for evaluation consists of 513 JavaScript packages. To build this dataset, we start from the top 1,000 most downloaded packages from the npm Registry (as of August 2021) and narrow and clean as follows:

1. We add any transitive dependencies that are not in the original set of packages, to ensure that the dataset is closed.
2. We try to fetch the original source code of every package, and eliminate any package where this is not possible (e.g., the package did not provide a repository URL or was deleted from GitHub). Fetching the source helps ensure we are working with original code, and not compiled or “minified” JavaScript.
3. We remove packages that were built from a “monorepo,” i.e., a single repository containing multiple packages that are published separately. For example, the Babel JavaScript compiler has over 100 separate packages, but all share the same monorepo; fetching each source package meant downloading the entire monorepo multiple times and including unnecessary packages.

37:12 Do Machine Learning Models Produce TypeScript Types That Type Check?

■ **Figure 4** Empirical cumulative distribution function of lines of code per package, over all datasets. The x -axis shows lines of code and the y -axis shows the proportion of packages with fewer than x lines of code.

4. We remove packages that were not implemented in JavaScript, do not contain code, or have more than 10,000 lines of code. The size limit helps us avoid timeouts, and mostly excludes large toolchains and standard libraries, such as the TypeScript compiler and `core-js` standard library.
5. We remove testing code from every package. Tests frequently require extra dependencies, and different frameworks set up the test environment in different ways, which makes large-scale evaluation harder. To remove testing code, we deleted directories named `test`, `tests`, `__tests__`, or `spec`, and files named `test.js`, `tests.js`, `test-*.js`, `*-test.js`, `*.test.js`, or `*.spec.js`.
6. Finally, we ensure that every package has *no dependencies*, or that *all its dependencies are typed*, meaning the dependencies have TypeScript type declaration (`.d.ts`) files available. (We do not require that *packages* are typed, but only that their *dependencies* are.) This requirement is necessary because a JavaScript package can only be imported into a TypeScript project if its interface has TypeScript type declarations. The DefinitelyTyped repository⁹ contains interface type declarations for many popular JavaScript packages, and a handful of packages include their own. We download type declarations of project dependencies and include them in our dataset for evaluation purposes – they are not used for type prediction.

After filtering and cleaning our dataset, we classify every package with two criteria: (1) whether the package has type declarations available; and (2) whether the package has dependencies.

If a package has type declarations available, we say it is “DefinitelyTyped” and we can use its type annotations as ground truth in our evaluation. (However, there is evidence that some of these type annotations are incorrect [16, 28, 29, 51].) Otherwise, we use the term “never typed”: these packages *have never been type annotated* and thus no ground truth exists, so machine learning models have never been evaluated on these packages before. If a package has dependencies, we classify it as “with deps” (and from our filtering, we know that every dependency is typed); otherwise, we classify the package as “no deps.” Thus, there are four dataset categories; we list them in Table 1 along with the number of packages, files, and lines of code for each category.

⁹ <https://github.com/DefinitelyTyped/DefinitelyTyped/>

■ **Table 2** Number and percentage of packages that type check.

Dataset category	DeepTyper			LambdaNet			InCoder		
	✓	Total	%	✓	Total	%	✓	Total	%
DefinitelyTyped, no deps	54	257	21.0	24	247	9.7	55	277	19.9
DefinitelyTyped, with deps	5	69	7.2	1	70	1.4	10	77	13.0
Never typed, no deps	31	95	32.6	11	87	12.6	25	100	25.0
Never typed, with deps	5	39	12.8	3	35	8.6	4	39	10.3
Overall	95	460	20.7	39	439	8.9	94	493	19.1

■ **Figure 5** Percentage of packages that type check.

Figure 4 is an empirical cumulative distribution function of the lines of code per package: the x -axis shows lines of code in a package and the y -axis shows the proportion of packages with fewer than x lines of codes. From the graph, we observe that approximately 90% of packages have fewer than 1,000 lines of code, and approximately 95% of packages have fewer than 2,000 lines of code.

4.2 Success Rate of Type Checking

Do Migrated Packages Type Check?

We first ask if entire packages type check after automated migration from JavaScript to TypeScript. However, not all packages successfully translate to TypeScript with every type migration tool; some packages cause the type migration tool to time out or error. Thus, we report the success rate of type checking as a fraction of the packages that successfully translate to TypeScript.

Table 2 and Figure 5 show the fraction of packages that type check with each tool. We observe that DeepTyper and InCoder perform similarly (20% success rate), and LambdaNet performs worse (9% success rate). Across all tools, packages without dependencies type check at a higher rate than packages with dependencies.

37:14 Do Machine Learning Models Produce TypeScript Types That Type Check?

These package-level type checking results are disappointing – but this is a very high standard to meet. Even a single incorrect type annotation causes the entire package to fail. Therefore, we next consider a finer-grained metric that is still useful.

How Many Files are Error Free?

As an alternate measure, we look at the percentage of *files with no compilation errors*. Instead of a binary pass/fail outcome, this gives us a more fine-grained result for a package. We motivate this metric by observing that TypeScript files are modules with explicit imports and exports. If a file type checks without errors, then it is using all of its internal and imported types consistently. Thus, when triaging type errors, a programmer may (temporarily) set these files aside and focus on the files with compilation errors. However, the programmer may later need to return to a file with no type errors and adjust its type annotations, for example, if a consumer of that file expects a different interface. We give examples of this in our case studies, specifically Section 4.5.2 and Section 4.5.3.

Table 3 and Figure 6 present the fraction of files with no compilation errors. The results are more encouraging: using InCoder, 69% of files are error free. With these results, it is not clear that packages without dependencies outperform packages with dependencies. Finally, in Figure 7 we calculate the percentage of error-free files for each package, and plot histograms of the distribution. Across all tools, most packages have type errors in most or all files.

What Percentage of Type Annotations Are Trivial?

Next, we examine what percentage of type annotations, *within the error-free files*, are trivial, i.e., what percentage are `any`, `any[]` (array of anys), or `Function` (function that accepts any arguments and returns anything). These annotations can hide type errors and allow more code to type check; however, they provide little value to the programmer.

Figure 8 shows the percentage of trivial type annotations within error-free files. DeepTyper produces the most (about 60%), LambdaNet produces the least (about 25%), while InCoder is in between (about 40%).

Comparing to the percentage of files with no compilation errors (Figure 6), DeepTyper produces more type-correct code than LambdaNet, but it also generates more trivial type annotations. InCoder produces the most type-correct code, while generating a moderate percentage of trivial type annotations.

Do Migrated Types Match Human-Written Types (When Available)?

Since our dataset is constructed from JavaScript packages instead of TypeScript packages, we do not have fully type-annotated files as our ground truth; instead, we use declaration files provided by the DefinitelyTyped repository or package author. We configure the TypeScript compiler to emit declarations during type checking, which it can do even if the whole package does not type check. Thus, we can compare handwritten, ground truth declarations against declarations generated from migrated packages.

We extract function signatures from declaration files and only compare a signature if it is in both the ground truth and generated declaration. We compare the function parameter types and return types one-to-one, ignoring modifiers (e.g., `readonly`), and we require an exact string match (i.e. `string | number` and `number | string` are considered different types). Following the literature, we skip a comparison if the ground truth is the `any` annotation.

Our results are presented in Table 4 and Figure 9. We observe that accuracy is better for packages without dependencies. Additionally, our results follow the same pattern in prior work, where LambdaNet has better accuracy than DeepTyper, despite performing worse in our other metrics.

■ **Table 3** Number and percentage of files with no compilation errors.

Dataset category	DeepTyper			LambdaNet			InCoder		
	✓	Total	%	✓	Total	%	✓	Total	%

Overall	117	364	32.1	157	378	41.5	51	187	27.3

How Many Errors Occur in Each Package?

Figure 10 shows an empirical cumulative distribution function of errors: the x -axis shows the number of errors and the y -axis shows the proportion of packages with fewer than x errors. For example, when migrating the “DefinitelyTyped, with deps” dataset with LambdaNet, approximately 80% of packages have fewer than 250 errors each. Additionally, all of DeepTyper’s packages and almost all of InCoder’s packages have fewer than 500 errors each.

4.3 Error Analysis

We now consider the kinds of errors that arise during migration. Every TypeScript compiler error has an associated code,¹⁰ making categorization straightforward. Figure 11 summarizes the top 10 most common errors and Table 5 provides the corresponding messages.

Most of the errors relate to types. These errors are the following: a property not existing on a type (TS2339 and TS2551); an assignment with mismatched types (TS2322); a function call with mismatched parameter and argument types (TS2345); calling a function that was assigned a non-function type annotation (TS2349); and a conditional that compares values from different types (TS2367). TS2314 refers to a generic type that was not provided type arguments; this is caused by DeepTyper and LambdaNet not fully supporting generic types.

¹⁰<https://github.com/Microsoft/TypeScript/blob/v4.9.3/src/compiler/diagnosticMessages.json>

■ **Figure 9** Accuracy of type annotations, compared to non-any ground truth.

The remaining errors are not directly related to types. TS2304 refers to an unknown name, which may not necessarily be a type. TS2554 is emitted because TypeScript requires the number of call arguments to match the number of function parameters, but JavaScript does not. TS2339 includes cases where an empty object is initialized by setting its properties, but TypeScript requires that the object’s properties are declared in its type. Finally, TS2307 indicates that the ECMAScript module conversion produced incorrect code.

4.4 ECMAScript Module Conversion

Recall that we described an optional step before running the evaluation: converting packages to use ECMAScript modules. In this section, we re-run our evaluation – generating types, weaving types, and type checking – to compare the results before and after the conversion step. Specifically, we examine the percentage of packages that type check (Table 6), the percentage of files with no errors (Table 7), and accuracy (Table 8). However, this is not a direct comparison between CommonJS and ECMAScript modules, as some of the original packages were already using ECMAScript modules. Furthermore, the conversion affected a small handful of packages: some packages successfully migrated to TypeScript after the conversion but failed before, and the inverse was true for other packages.

From Table 6, we observe that the ECMAScript module conversion makes fewer packages type check for DeepTyper and InCoder, but slightly improves the results for LambdaNet. In Figure 12, we examine packages that type checked before or after the ECMAScript module conversion; packages that never type checked were excluded. In general, if a package type checked before the conversion, it likely type checked after the conversion. However, if a package failed to type check before the conversion, it was unlikely to type check afterwards; in fact, this never happened for a package with dependencies.

Table 7 compares the percentage of files with no compilation errors. The conversion improves the results for LambdaNet and InCoder, but makes the results worse for DeepTyper. One dramatic result is the change for InCoder and the “never typed, with deps” dataset, where the ECMAScript module conversion results in 89% of files type checking, when it was only

37:18 Do Machine Learning Models Produce TypeScript Types That Type Check?

■ **Figure 10** Empirical cumulative distribution function of errors. The x -axis shows the number of errors and the y -axis shows the proportion of packages with fewer than x errors.

11% before. The difference is caused by a single package, `regenerate-unicode-properties`, which has over 400 files. With CommonJS modules, each file produces an error; however, with ECMAScript modules, those files type check successfully.

Finally, Table 8 compares the accuracy of type annotations, before and after the ECMAScript module conversion. Recall that for accuracy, we compare type annotations against the ground truth of handwritten TypeScript declaration files; these are the “DefinitelyTyped” datasets. Accuracy improves for DeepTyper and LambdaNet, but worsens slightly for InCoder.

4.5 Case Studies

In this section, we examine how the models performed on four packages, whether the packages type check, and what steps are left to migrate the packages to TypeScript.

4.5.1 Error Message Does Not Refer to Incorrect Type Annotation

`decamelize` is a package for converting strings in camel case to lowercase.¹¹ It is in the “DefinitelyTyped, no deps” dataset, as it ships with a `.d.ts` declaration file and has no dependencies. Figure 13 shows a simplified version of the function `handlePreserveConsecutiveUppercase`. This function is not exported, thus there are no programmer-written type annotations. Line 42 uses JavaScript’s arrow function notation to define a function that takes two arguments, and assigns it to the constant on Line 41. Elsewhere in the package (Line 51 in the listing), the helper function is called with `str` and `sep` string arguments.

A programmer inspecting the function can reason that Line 44 is a call to a string method that uses a regular expression on Line 45 to replace text in `decamelized` with the result on Line 46, where `separator` is concatenated with the regular expression match. Therefore, both the `decamelized` and `separator` parameters on Line 42 should be annotated as `string`.

¹¹<https://www.npmjs.com/package/decamelize>

■ **Figure 11** Distribution of the top 10 most common error codes, over all datasets.

The DeepTyper solution is listed on Line 54: it correctly annotates both function parameters as `string`, but incorrectly annotates `handlePreserveConsecutiveUppercase` as `string`. The compiler emits errors for Lines 51 and 55, because Line 51 is attempting to call a non-function, and Line 55 is attempting to assign a function to a non-function variable. However, the fix must be applied to the annotation on line Line 54.

4.5.2 Incorrect Type Annotation Can Type Check Successfully

The LambdaNet solution on Line 58 correctly annotates `handlePreserveConsecutiveUppercase` as `Function`, but it incorrectly annotates the `separator` parameter on Line 59 as `number`. We would expect the compiler to emit a type error, since Line 51 calls the function with string arguments. However, the code type checks successfully, because the generic `Function` type on Line 58 accepts any number of arguments of any type. The `Function` type annotation is similar to `any`, in that it enables more code to type check, but at the cost of fewer type guarantees.

Another example of this problem is the `ieee754` package, which reads and writes floating point numbers to and from buffers.¹² It is categorized as “DefinitelyTyped, no deps,” since it provides a `.d.ts` declaration file and has no dependencies. Figure 14 shows the original declaration for the `write` function on Line 61, and the handwritten, ground truth signature on Line 65.

Consider the DeepTyper solution: the compiler emits an error on Line 70, because a function is being assigned to a variable of type `void`. However, even if that error is fixed, there is another, more subtle error not detected by the compiler: the `isLE` parameter on Line 71 is incorrectly annotated as `number`, not `boolean`. Because this is compatible with the body of the function, there is no error. (The `Buffer` annotation is valid, despite not matching the ground truth `Uint8Array`, because `Buffer` is defined by the Node.js standard library as a subtype of `Uint8Array`.)

The InCoder solution on Line 75 type checks successfully. It also uses the `Buffer` type for `buffer`, and it uses `any` instead of `number` for the `value` parameter on Line 76. The `any` annotation may cause run-time errors if the function is called with arguments of the wrong type.

¹²<https://www.npmjs.com/package/ieee754>

■ **Table 5** The top 10 most common error codes.

Error code	Message	DeepTyper	LambdaNet	InCoder
TS2339	Property '{0}' does not exist on type '{1}'.	2,510	24,123	6,742
TS2322	Type '{0}' is not assignable to type '{1}'.	1,429	4,709	176
TS2345	Argument of type '{0}' is not assignable to parameter of type '{1}'.	304	3,930	828
TS2304	Cannot find name '{0}'.	217	598	2,094
TS2554	Expected {0} arguments, but got {1}.	330	1,234	1,200
TS2349	This expression is not callable.	977	529	26
TS2367	This condition will always return '{0}' since the types '{1}' and '{2}' have no overlap.	145	1,046	110
TS2307	Cannot find module '{0}' or its corresponding type declarations.	375	432	371
TS2551	Property '{0}' does not exist on type '{1}'. Did you mean '{2}'?	187	389	296
TS2314	Generic type '{0}' requires {1} type argument(s).	1	630	95
Other		1,089	3,528	2,557
Total		7,564	41,148	14,495

4.5.3 Run-Time Type Assertions

The `@gar/promisify` package,¹³ simplified and shown in Figure 15, is another example where a program type checks, but is incorrect. The example exports a function that takes an argument `thingToPromisify`, type annotated as `string` by LambdaNet. Line 80 performs a run-time type check with the `typeof` operator. This ensures that `thingToPromisify` is a function on Line 81, which is what the `promisify` function, defined by Node.js, expects. If `thingToPromisify` is not a function, the exception on Line 83 is thrown.

The example type checks successfully, because the TypeScript compiler treats the `typeof` check as a type guard, and reasons that on Line 81, the `thingToPromisify` variable has been narrowed¹⁴ to a more specific type. However, because `thingToPromisify` is annotated as `string`, the type guard always returns false. Therefore, Line 81 is actually unreachable, so the exception on Line 83 is always thrown.

4.5.4 Variable Used as Two Different Types

The example in Figure 16 is adapted from the `array-unique` package.¹⁵ The example contains two `for` loops: a traditional, counter-based `for` loop on Line 90, and a `for...in` loop on Line 92 that iterates over all enumerable string properties of an object. Both loops share the same loop variable, `i`, defined on Line 88 and annotated as `number` by LambdaNet.

The use of `i` on Line 92 causes a type error, as `for...in` loops require the loop variable to be `string`. However, changing the annotation on Line 88 to `string` causes a type error on Line 90, as counter-based `for` loops require the loop variable to be `number`. One solution is to

37:22 Do Machine Learning Models Produce TypeScript Types That Type Check?

```
40 // Original
41 const handlePreserveConsecutiveUppercase =
42   (decamelized, separator) => {
43     // code omitted and simplified...
44     return decamelized.replace(
45       /([A-Z]+)([A-Z][a-z]+)/gu,
46       (_, $1, $2) => $1 + separator + $2.toLowerCase(),
47     );
48   }
49
50 // Elsewhere in the package; str and sep are both strings
51 return handlePreserveConsecutiveUppercase(str, sep);
52
53 // DeepTyper solution
54 const handlePreserveConsecutiveUppercase: string =
55   (decamelized: string, separator: string) => { ... }
56
57 // LambdaNet solution
58 const handlePreserveConsecutiveUppercase: Function =
59   (decamelized: string, separator: number) => { ... }
```

■ **Figure 13** The `handlePreserveConsecutiveUppercase` function adapted from the `decamelize` package. The `DeepTyper` and `LambdaNet` solutions are also shown.

use the `any` annotation, and another is to use the union type `number | string`. Ultimately, the correct solution is to define separate loop variables; this example highlights that code written in JavaScript may need to be refactored for TypeScript.

5 Discussion

How should type prediction models be evaluated? Prior work has used accuracy to evaluate type prediction models, but in this paper, we argue that we should instead type check the generated code. However, we acknowledge that our proposed metric also has limitations: code may type check with trivial annotations (e.g., `any` or `Function`) that provide little benefit to the programmer. Furthermore, type correctness does not necessarily mean the type annotations are correct: `any` can hide type errors that are only encountered at run time.

We do not claim that our metric is the final word on evaluating type prediction models, but we believe it is an improvement over accuracy. We hope this paper can spark a discussion on how machine learning for type migration should be evaluated.

Can slightly wrong type annotations be useful? A type prediction model may suggest types that are slightly wrong and easily fixable by a programmer, but fail to type check. However, a tool that produces hundreds or thousands of slightly wrong type annotations would overwhelm the programmer, and we believe it is important to build tools that try to produce fewer errors. On the other hand, slightly wrong type annotations may still provide value, but we would need to define what “slightly wrong” means and how to measure it. Without a tool like `TYPEWEAVER`, which weaves type annotations into code and type checks the result, it would not be possible to ask these questions.

Should we evaluate on JavaScript or TypeScript programs? We choose to evaluate on JavaScript programs, so our dataset deviates from prior work, which only considered TypeScript. Our motivating problem is not to recover type annotations for TypeScript

```

```

78 // LambdaNet solution
79 export default function (thingToPromisify: string) {
80   if (typeof thingToPromisify === 'function') {
81     return promisify(thingToPromisify)
82   }
83   throw new TypeError('Can only promisify functions or objects')
84 };

```

■ **Figure 15** The LambdaNet solution for a function adapted from the `@gar/promisify` package.

programs that already type check, but to migrate untyped JavaScript programs to type-annotated TypeScript. For this problem, type prediction on its own is not enough, and other steps and further refactoring may be required.

Our methodology makes it possible to evaluate performance on code without known type annotations, i.e., code that has never been typed before. In contrast, prior work required the benchmarks to have ground truth type annotations. Our approach also reduces the likelihood of training data leaking into the test set.

However, there may be scenarios where a type prediction model is used to generate type annotations for a partially annotated TypeScript project. In these situations, type migration would likely not require additional refactoring steps.

Can we fully automate type migration? Our results show that automatically predicting type annotations is a challenging task and much work remains to be done. Furthermore, migrating JavaScript to TypeScript involves more than just adding type annotations: the two languages are different and some refactoring may be required. The models we evaluate in this paper do not refactor code, and we believe it is unlikely for automated type migration to be perfect. Thus, some manual refactoring will always be necessary for certain kinds of code, but we hope that tools can reduce the overall burden on programmers.

```

85 export default function(arr: any[]) {
86   var len: number = arr.length;
87   var o: object = {};
88   var i: number;
89
90   for (i = 0; i < len; i += 1) { ... }
91
92   for (i in o) { ... }
93 };

```

6 Related Work

There are many constraint-based approaches to type migration for the gradually typed lambda calculus (GTLC) and some modest extensions. The earliest approach was a variation of unification-based type inference [47], and more recent work uses a wide range of techniques [9, 12, 21, 34, 35, 40]. Since these approaches are based on programming language semantics, they produce sound results, which is their key advantage over learning-based approaches. However, these would require significant work to scale to complex programming languages such as JavaScript.

There are also several constraint-based approaches to type inference for larger languages. Anderson et al. [2] presents type inference for a small fragment of JavaScript, but is not designed for gradual typing. Rastogi et al. [42] infer gradual types for ActionScript to improve performance. More recently, Chandra et al. [13] infer types for JavaScript programs with the goal of compiling them to run efficiently on low-powered devices; their approach is not gradual by design and deliberately rejects certain programs. DRuby [20] infers types for Ruby and treats type annotations in a novel way: inference assumes that annotations are correct, and defers checking them to runtime.

Although this paper focuses on type migration for TypeScript, there are several other gradual type systems for JavaScript [15, 22, 30, 49]. These languages do not have support for type inference and do not provide tools for type migration. Instead, like Typed Racket [48], they require programmers to manually migrate their code to add types. However, there are tools that use dynamic profiles to infer types for these type systems [1, 19, 45].

Even when constraint-based type inference succeeds in a gradually typed language, it can fail to produce the kinds of types that programmers write, e.g., named types, instead of the most general structural type for every annotation. Soft Scheme [10] infers types for Scheme programs, but Flanagan [17, p. 41] reports that it produces unintuitive types. For Ruby, InferDL [27] uses hand-coded heuristics to infer more natural types, and SimTyper [26] uses machine learning to predict equalities between structural types and more natural types.

LambdaNet [50] and DeepTyper [23] are two different approaches for predicting types for TypeScript and JavaScript programs. This paper evaluates using both of them in its type migration pipeline. We discuss them at length in Sections 2.2.1 and 2.2.2. NL2Type [32] is another system for predicting JavaScript types that improves on DeepTyper.

There are also type prediction systems for Python. TypeWriter [41] is notable because it also asks if the resulting Python program type checks. If it does not, it searches its solution space for an alternative typing. A distinction between Python type systems and TypeScript is that Python code is predominantly nominally typed: the type of a variable is either a builtin type or a class, whereas TypeScript uses structural types.

DiverseTyper [24] is a recently published work that predicts both built-in and user-defined types for TypeScript and achieves state-of-the-art accuracy on type prediction. DiverseTyper builds on TypeBert [25], which trains a BERT-based model to predict types. Although this paper does not evaluate these models, they are most closely related to InCoder [18], which is a general-purpose code generation model that we do evaluate.

7 Conclusion

In this paper, we set out to answer the question: *do deep-learning-based type annotation prediction models produce TypeScript types that type check?* To answer this question, we build TYPEWEAVER, a type migration tool that automatically converts JavaScript projects into TypeScript. TYPEWEAVER uses a type annotation prediction model, but does the work of “weaving” predicted types into JavaScript code. It also automates other steps, such as converting JavaScript projects to ECMAScript module notation. Finally, TYPEWEAVER runs the TypeScript compiler to type check the generated code. TYPEWEAVER is designed so that any type prediction model can be plugged in, and we use three very different models: DeepTyper, LambdaNet, and InCoder.

In addition to building TYPEWEAVER, we also present a dataset of 513 widely used JavaScript packages that are suitable for type migration. Every package in our dataset has typed dependencies and many of them have never been typed before. With this dataset, we evaluate TYPEWEAVER with all three type prediction models.

The results are mixed. If we ask, “How many packages type check when migrated to TypeScript?” we find that most packages have some type errors. However, we also ask, “How many files are error free?” and the result is more promising. We find that most files have no type errors, which means that programmers performing type migration can focus their attention on a smaller number of files.

Our case studies highlight two insights: (1) certain patterns in JavaScript do not make sense in TypeScript, so a migration may require manual rewriting of the code; and (2) there are cases where programs successfully type check but still have run-time errors.

We believe that currently, while type prediction cannot always reliably migrate JavaScript to TypeScript, it can still be a powerful tool.

Future Work. There are several directions we would like to explore in future work. First, we would like to improve dataset quality. We observed projects that were trivially typable: there were few declarations to annotate, or the annotations were mostly primitive types, so those projects often type checked successfully. Second, we are interested in exploring different evaluation criteria for type prediction models. We believe that type checking the output of these models is only the first step, and that it may be necessary to evaluate the run-time behavior of migrated programs. Additionally, there may be utility in permitting “slightly wrong” type annotations. Finally, we would like to examine other deep learning models and type migration tasks beyond type annotation prediction.

Building Code Transpilers for Domain-Specific Languages Using Program Synthesis

Abstract

Domain-specific languages (DSLs) are prevalent across many application domains. Such languages let developers easily express computations using high-level abstractions that result in performant implementations. To leverage DSLs, however, application developers need to master the DSL's syntax and manually rewrite existing code. Compilers can aid in this effort, but part of building a compiler requires transpiling code from the source code to the target DSL. Such transpilation is typically done via pattern-matching rules on the source code. Sadly, developing such rules is often a painstaking and error-prone process.

In this paper, we describe our experience in using program synthesis to build code transpilers. To do so, we developed METALIFT, a new framework for building transpilers that transform general-purpose code into DSLs using program synthesis. To use METALIFT, transpiler developers first define the target DSL's semantics using METALIFT's specification language, and specify the search space for each input code fragment to be transpiled using METALIFT's API. METALIFT then leverages program synthesizers and theorem provers to automatically find transpilation expressed in the target DSL that is provably semantic equivalent to the input code. We have used METALIFT to build three DSL transpilers targeting different programming models and application domains. Our results show that the METALIFT-based compilers can translate many benchmarks used in prior work created by specialized implementations, but can be built using orders-of-magnitude fewer lines of code as compared to prior work.

1 Introduction

Domain-specific languages (DSLs) are now popular means to develop applications across many domains. Besides improving programmability, modern DSLs often expose *domain-specific optimizations* via their interfaces for applications to leverage specialized hardware accelerators [16, 32, 6, 21], or domain-specific code transformation [15, 43, 12].

Yet, to capitalize on the benefits provided by DSLs, developers must learn the interfaces provided by the target DSL. For existing applications, developers need to painfully reverse-engineer legacy code, potentially convoluted with optimizations, before rewriting it, only to realize that newly emerging frameworks can turn freshly rewritten code into legacy applications. Needless to say, each rewrite is another opportunity to introduce bugs into the application.

The classical mechanism to alleviate this problem is for DSL designers to build pattern-driven transpilers that translate programs, say written in general-purpose languages, into their DSLs [4]. While such transpilers are essentially part of all modern optimizing compilers, they often require developing a complex network of inter-connected translation rules [22, 31, 39], which is a highly tedious and error-prone task.

Instead of transpilation rules, researchers have leveraged advances in program synthesis [11, 17] for code transpilation, where the idea is to replace the rule-matching machinery with a code synthesizer that finds programs written in the target language that are semantically equivalent to the input code fragment [23, 14, 27, 20, 3]. However, using such techniques involves encoding the semantics of the input program as a synthesis problem. Furthermore, building such transpilers requires implementing specialized synthesis procedures, which relies on specialized knowledge of synthesis algorithms that most transpiler designers do not possess.

In this paper, we describe our experience in building code transpilers using program synthesis. To do so in a systematic manner, we designed a new framework called METALIFT. Our goal in building METALIFT is to free transpiler developers from designing a myriad of pattern matching rules for transpilation, while making synthesis technology easily accessible for code translation. Given input code written in the source language (METALIFT currently supports LLVM), developers can use METALIFT to implement a code transpiler that uses program synthesis to search for code in the target language that is *provably semantically equivalent* to the input. To use METALIFT, developers first define the semantics of their target DSL using MTL, i.e., METALIFT’s Specification Language. Then, using METALIFT’s search space API, developers specify the search space of DSL programs for each input. The search space can be constructed programmatically by analyzing each input code to transpile. Given the DSL definition and search space description, developers then write a transpiler driver that orchestrates the transpilation process.

METALIFT is designed with developer usability in mind in constructing transpilers. As we will discuss in detail, MTL is designed as a specification language embedded within Python for ease of use. As METALIFT focuses on ensuring semantic equivalency between the source and transpiled code, MTL consists of a small number of constructs, and is designed to be high-level so that developers can easily use it to express the semantics of each construct in their target DSL, and yet simple enough for METALIFT to compile down as the input to different synthesizers and verifiers. Likewise, the METALIFT’s API is also designed to abstract away the details of synthesis and verification from the developer.

To evaluate METALIFT, we have used the framework to reproduce three different transpilers described in prior work spanning multiple application domains and programming models. Our evaluation shows that they require order-of-magnitude fewer lines of code to build as compared to prior work, with the resulting transpiler generating the same (or very similar) code as the original implementations.

In summary, this paper makes the following contributions:

- We design MTL for developers to specify the semantics of different constructs in their DSLs. The design of MTL is general enough to support many real-world DSLs, yet simple enough to be translated as the input to various program synthesizers and verification engines.

■ **Figure 1** An overview of the METALIFT architecture.

- We describe METALIFT, a unified framework for developing transpilers for DSLs. Rather than designing pattern matching rules, METALIFT enables designers to use program synthesis to easily translate input code to their DSLs without requiring any program synthesis expertise. Furthermore, the translations generated by METALIFT are formally verified for semantic equivalence to the source code, so developers are assured of an accurate translation.
- We show how METALIFT generalizes previous work on building transpilers using program synthesis by creating two DSL transpilers that translate from general-purpose code to these DSLs. These three DSLs are aimed at different application domains. Our evaluations demonstrate how METALIFT dramatically reduces the effort required to build these compilers.

We organize the rest of the paper as follows. We provide an overview of METALIFT (Section 2). We describe METALIFT in more detail (Section 3) using a representative example. We evaluate METALIFT in Section 4 and review the prior approaches for building transpilers in Section 5. Finally, we conclude (Section 6) with directions for future work.

2 Overview

In this section, we provide an overview of the METALIFT framework. The high-level architecture of METALIFT is shown in Figure 1. For the majority of the paper, we use the example in Figure 2 as our running example and describe how to build a transpiler using METALIFT that translates sequential Java code to the Spark DSL. Spark [43] provides users with an interface to efficiently process large-scale distributed computations in a parallel and fault-tolerant manner.

Concretely, the example in Figure 2a takes as input a list of words and counts the frequency of each word in input list. Figure 2b shows the equivalent implementation using map reduce operators in the Spark DSL. The `map` operator returns `(word, 1)` for each word in the input list, and the `reduceByKey` operator then uses the reducer function `(v1 + v2)` to aggregate each unique key in the map operator’s output.

The Mold compiler [31] has implemented a syntax-driven compiler that automatically translates sequential Java code to Spark. To perform this translation, Mold uses rewrite rules that pattern match on the input source code. However, these rules can be hard to implement as

- 1) they must be expressive in order to capture all of the different coding patterns,
- 2) they must ensure semantic equivalence to the source code, and
- 3) they must be maintained as the DSLs change.

For instance, as described in their paper, Mold requires 22 different rules to generate the corresponding Spark program for the same word count program shown in Figure 2a.

38:4 Building Code Transpilers for Domain-Specific Languages Using Program Synthesis

```
1 map<string, int> countWords(vector<string> words) {
2     map<string, int> counts;
3     for (int j = 0; j < words.size(); j++) {
4         string word = words[j];
5         int prev = 0;
6         if (counts.find(word) != counts.end())
7             prev = counts[word];
8         counts[word] = prev + 1;
9     }
10    return counts;
11 }
```

(a) Input Source Code: Sequential C++ Code (Java benchmarks are converted to C++ since the METALIFT front-end currently supports C++).

```
1 Map<String, Integer> countWords(List<String> words) {
2     Map<String, Integer> counts = new HashMap<String, Integer>();
3     counts = words.mapToPair(v -> new Tuple2<String,Integer>(v, 1))
4         .reduceByKey((v1,v2) -> v2 + v1).collectAsMap();
5     return counts;
6 }
```

(b) Output: Apache Spark Code.

■ **Figure 2** Translation from sequential C++ code to Apache Spark DSL.

3 # code generation rules, see Figure 18
4
5 def transpiler(source): # driver program
6     liveVars, modVars, VC = analyze(source)
7     verifiedSummaries = synthesize(VC, targetLang(), grammar(liveVars, modVars))
8     transpiledCode = codeGen(verifiedSummaries)
9     return transpiledCode
```

■ **Figure 3** Example of the METALIFT driver code to transpile the running example shown in Figure 2.

Instead of designing syntax-driven rules, developers can use METALIFT to build this transpiler. METALIFT leverages program synthesis to search for transformations that are semantically equivalent to the source code. Figure 3 shows the driver code developers will write to implement a compiler using METALIFT, where they provide the following inputs to METALIFT:

1. **Target DSL Definition.** First, using MTL and the programming interface provided by METALIFT, developers define the semantics of the operators in their target DSL. Each operator represents a program construct in the target language. For instance, for our Spark compiler, we define the semantics of the map and reduce operators as shown in Figure 11. In Section 3.3, we discuss how MTL can be used to define the semantics for each construct in the target language.
2. **Search Space Definition.** Besides the target language, developers also define the search space description to guide METALIFT's synthesis engine (Figure 13). The search space provides the space of possible programs in which the synthesis engine can look for

equivalent program transformations. Using the variable information returned during the analysis phase performed by METALIFT, developers can use MTL to describe the search space. This will be discussed further in Section 3.6.

3. **Code Generation Rules.** The final input that developers provide is the syntax-driven rules to translate the summaries synthesized by METALIFT into executable target DSL code. Note that translating from summaries is much easier than translating directly from source code as the summaries are already encoded using the target DSL’s operators. Section 3.9 provides more details about how these rules can be implemented.

Developers then write a transpiler driver that invokes the inputs mentioned above (as shown in Figure 3), using METALIFT’s API as follows:

1. **Code Analysis.** METALIFT’s Analysis API takes as input the source code to be translated and compiles it into LLVM intermediate representation (IR), as shown in Line 6 in Figure 3. We use LLVM IR because it allows for the compilation of multiple general-purpose languages (e.g., C, C++, Fortran) using various front ends, giving METALIFT the flexibility to support multiple languages on the source side. The goal of the analysis phase is to compute verification conditions from the LLVM IR. Verification conditions (VCs) are logical statements that assert that the program is correct with respect to the given pre-condition and post-condition if they hold. The VCs serve as the specification for the synthesizer. The analysis phase also returns information about the output variables and the variables being modified in the source code. We describe METALIFT’s analysis phase in more detail in Section 3.1.
2. **Synthesis and Verification.** Once the analysis phase returns the VCs, developers then invoke METALIFT’s synthesis API, as shown in Line 7 in Figure 3. The VCs generated during the analysis phase form the synthesizer’s specification. METALIFT then synthesizes program summaries that meet these specifications. To make the search tractable, METALIFT’s synthesizer uses the search space description provided by the developers. These summaries are restricted to be expressed using only the operators in the target DSL defined by the developers. Logically, a program summary is the post-condition that captures the program’s final states after execution. Finally, METALIFT formally verifies that the generated program summary is semantically equivalent to the input source code using an automated theorem prover. Synthesis and verification phases of METALIFT are discussed in Section 3.7 and Section 3.8, respectively.
3. **Code Generator.** In the final step as shown in Line 8 in Figure 3, METALIFT invokes the user-defined code generation rules to convert the verified summaries into executable DSL code. The compiled code is then returned back to the user.

3 Framework

In this section, we discuss each component of METALIFT in detail by building a transpiler for our example in Figure 2.

3.1 Analysis

The front-end of METALIFT takes as input the source code written in a general-purpose languages which the developers want to transpile to their DSLs. As mentioned, our current prototype supports languages that can be compiled to LLVM IR. Once compiled to the LLVM IR, the next step in the analysis phase is to augment the generated LLVM IR to enable computation of verification conditions.

■ **Figure 4** Transformations performed on loop constructs during analysis phase.

Prior work [18, 24] has recently introduced frameworks for automated verification of software systems. These frameworks takes as input the description of the system to be verified, the specification that the system must satisfy, and internally reduces the problem to symbolic constraints that are then discharged to a theorem prover for verification. However, METALIFT cannot reuse any of these front-ends for generating VCs as they rely on the source code already having annotated with invariants and post-conditions. METALIFT instead models invariants and post-conditions as predicates that take in all live variables at the point when they are declared, and leave the body of the predicates to be *synthesized* later on, to be explained in Section 3.7.

Verification Conditions. In Floyd-Hoare logic (FHL) [19], the verification problem is abbreviated using the Hoare Triple $\{A\} S \{P\}$. To establish the validity of a Hoare triple, we need to prove that for all executions starting from states that satisfy A (pre-condition), after executing statement S , should satisfy P (post-condition). An example of a valid Hoare triple is $\{y \leq x\} z := x; z := z + 1 \{y < z\}$. This problem can be further simplified as finding a Boolean predicate which characterizes the set of pre-conditions from which every execution of S would lead a to state that satisfies P . These Boolean predicates are known as verification conditions. Formally, we can represent this as proving the following logical statement as $A \rightarrow VC(S, P)$.

An additional predicate called loop invariant is required for programs with loop constructs to prove that the post-condition is valid regardless of the number of iterations of the loop. Thanks to the efficient theorem provers [42, 7], such inference rules provided by FHL can be encoded in solvers such that any Hoare triple can be mechanically checked for its validity.

In METALIFT, S corresponds to the program statements in the input code to be transpiled, while A and P correspond to expressions written using MTL to be discussed in Section 3.3. Our goal is to synthesize a post-condition for each input code that are expressed using the target language constructs provided by the user, while ensuring that it forms a valid Hoare triple together with the input code S and pre-condition A .

Transformations for Loop Constructs. For programs that do not have any loop constructs, generating VCs is straightforward. However, programs with looping constructs requires more processing. In Figure 4a, we show a simplified control-flow graph of LLVM basic blocks for a program with loops. For such programs, we first identify the back edges, *i.e.*, the edge from the loop body to the loop head, and remove that edge to transform the bitcode into an acyclic graph. To preserve the semantics of the loop after removing the back edge, we annotate the start of the loop head block with *havoc* statement as shown in Figure 4b. The

havoc statement is introduced for all variables modified in the loop to update their contents to fresh symbolic variables. Doing so allow us to mimic the effect of executing an arbitrary iteration of the loop, which will be crucial in generating the correct verification condition.

The acyclic graph now represents any arbitrary iteration of the loop. To prove the validity of the Hoare triple $\{A\} \text{ while } G \text{ do } S \{P\}$, we must identify a *loop invariant* that holds at the beginning of the loop, at every iteration of the loop, and at the end of the loop terminates. As the input code is not annotated with loop variants, to generate VCs which can prove the validity of the described Hoare triple, we add the following annotations (shown in **bold** in Figure 6) to the LLVM code to be transpiled:

1. assert that invariant holds before the entry to the loop (Line 9)
2. havoc the variables being modified inside the loop (Line 13)
3. assume invariant holds before the execution the body (Line 15) and assume loop guard is true (Line 23)
4. assert invariant holds after the execution of the loop body (Line 35)
5. assert invariant holds after the loop exits (Line 38)
6. assume loop guard is false and assert that the post-condition holds before the program exits (Line 40)

3.2 Verification Condition Generation

There are several ways to prove functional equivalence of the source and target program. We adopt VCs as the specification for checking the functional equivalence. VCs enable us to prove complete functional equivalence between the source and generated target code, meaning that we can generate a proof of equivalence for all possible inputs. While there are other potential means to provide specifications, such as using the inputs and outputs from test cases or relying on the equivalence between a general-purpose program and its corresponding DSL program, these approaches have serious drawbacks:

1. Using testing as the specification only guarantees correctness for a finite set of inputs since it's not feasible to generate all possible test cases. Automating test case generation is also not always reliable, as it may not cover all paths of the program, and running these programs might not always be feasible. As a result, the synthesized program will only be semantically equivalent modulo the inputs and outputs from the test cases that were used as specification.
2. Checking equivalence between the source and target programs directly would require encoding the semantics of different constructs appearing in the source, and the most popular symbolic synthesizers [37, 41] or verifiers [42, 7] do not support semantic reasoning of loops. These symbolic synthesizers only reason about loops after they have been unrolled for a finite amount of iterations, effectively converting the loop into straight-line code. Because of this, it is challenging to check equivalence for programs with loops without generating VCs and loop invariants, as doing so only provides guarantees up to a certain bound.

Our VC generation algorithm is inspired from [8]. The LLVM compilation process generates LLVM bitcode which is represented using the LLVM IR. Figure 6 shows the abridged LLVM bitcode for the source code in Figure 2a. LLVM bitcode contains multiple basic blocks, i.e, contiguous sequence of LLVM IR instructions with just one entry and one exit point. A basic block after the transformation in the analysis phase has the general structure shown in Figure 5a.

```

1 blk: bbid
2   assume ea;
3   %i = ...;
4   %i1 = ...;
5   assert eb
6   br label %bbid'

```

(a) Basic Block structure after the analysis phase.

```

1 blk: bbid
2   assume ea;
3   assume %i = ...;
4   assume %i1 = ...;
5   assert eb
6   br label %bbid'

```

(b) Basic Block structure after converting instructions to assumes.

■ **Figure 5** Basic block structure of the LLVM bitcode.

```

1 blk: bb_start
2   %i = alloca %list* ;i = input variable words
3   %i1 = alloca %dict* ;i1 = output variable counts
4   %i2 = alloca i32 ;i2 = loop counter j
5   store %list* %arg, %list** %i
6   store call %dict* newMap(), %dict** %i1
7   store i32 0, i32* %i2
8   ;invariant is true before the execution of the loop
9   (assert call inv (load i1) (load i2) arg)
10  br label %bb_head
11
12 blk: bb_head
13  (havoc i1 i2)
14  ;invariant is true at the start of the loop body
15  (assume call inv ((load i1) (load i2) arg))
16  %i7 = load i32, i32* %i2
17  %i8 = load %list*, %list** %i
18  %i9 = call i32 @length(%list* %i8)
19  %i10 = icmp slt i32 %i7, %i9 ;j < words.size()
20  br i1 %i10, label %bb_body1, label %bb_exit
21
22 blk: bb_body1
23  (assume i10) ;loop guard is true
24  ;instructions to update the counts in the output map (not shown for brevity)
25  %i11 = ...
26  %i12 = ...
27  br label %bb_body2
28
29 ;instructions to update the counts in the output map
30 blk: bb_body2
31  %i28 = load i32, i32* %i2, align 4
32  %i29 = add nsw i32 %i28, 1
33  store i32 %i29, i32* %i2, align 4
34  ;invariant is true after executing the body of the loop
35  (assert call inv ((load i1) (load i2) arg))
36
37 blk: bb_exit
38  (assume not(i10)) ;loop guard is false
39  %i31 = load %dict*, %dict** %i1
40  (assert call ps (i31 arg)) ;post-condition is true

```

■ **Figure 6** LLVM bitcode for the source code in Figure 2a. Bitcode is annotated with assumes, asserts and calls to inv and ps for generating the verification conditions.

Our VC generation algorithm computes an assertion for each of the basic blocks. For each basic block BB in our bitcode we introduce a new Boolean variable BB_{ok} and the VC for that block is expressed as:

$$BB_{ok} = VC(S, \bigwedge_{B \in Succ(A)} B_{ok}) \quad (1)$$

where S represents all the instructions of the block and $Succ(A)$ represents the set of successor basic blocks of block BB .

In addition to the transformations during the analysis phase, we convert all the instructions in the block to assume statements, as illustrated in Figure 5b.

We then symbolically execute all the instructions in the block to generate the VCs. For symbolic execution, we maintain two dictionaries to model the *memory* (m) and *registers* (r). m maps memory cells to their values, while r keeps track of the results of the instructions' execution. The state of the symbolic executor is maintained as a quadruple $\langle m, r, a, b \rangle$ that represents the state of the memory, registers, assumptions encountered, and assertions encountered thus far during symbolic execution, respectively. a then represents the final VC for the input code fragment after symbolic execution terminates.

$$\begin{array}{c}
\text{STORE} \\
\frac{m' = m[r[i] \mapsto v]}{\llbracket \text{store } v \ i \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m', r, a, b \rangle} \\
\\
\text{MEMORY ALLOCATION} \\
\frac{\text{fresh } l \quad r' = r[i \mapsto l] \quad m' = m[l \mapsto \perp]}{\llbracket i = \text{alloca } t \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m', r', a, b \rangle} \\
\\
\text{LOAD} \\
\frac{r' = r[i \mapsto m[i_a]]}{\llbracket i = \text{load } i_a \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m, r', a \wedge (i = m[i_a]), b \rangle} \\
\\
\text{HAVOC} \\
\frac{\text{fresh } v' \quad m' = m[v \mapsto v']}{\llbracket \text{havoc } v \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m', r, a, b \rangle} \\
\\
\text{ARITHMETIC OPERATORS (AOP)} \\
\frac{v = \text{aop}(r[i_a], r[i_b]) \quad r' = r[i \mapsto v]}{\llbracket i = \text{aop } i_a \ i_b \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m, r', a, b \rangle} \\
\\
\text{BINARY COMPARISONS (BOP)} \\
\frac{v = \text{bop}(r[i_a], r[i_b]) \quad r' = r[i \mapsto v]}{\llbracket \text{icmp } \text{bop } i_a \ i_b \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m, r', a \wedge (i = v), b \rangle} \\
\\
\text{ASSUME} \\
\frac{}{\llbracket \text{assume } e \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m, r, a \wedge \llbracket e \rrbracket, b \rangle} \\
\\
\text{ASSERT} \\
\frac{}{\llbracket \text{assert } e \rrbracket (\langle m, r, a, b \rangle) \Rightarrow \langle m, r, a, a \rightarrow b \wedge \llbracket e \rrbracket \rangle}
\end{array}$$

■ **Figure 7** Computing the VC via symbolic execution on LLVM instructions. The symbol \wedge and \rightarrow denotes logical And and Implies operator respectively.

In Figure 7, we describe how we compute the VC for each type of LLVM opcode, while Table 1 shows our symbolic executor in action using these rules. To illustrate, the STORE rule in Figure 7 states that if the current state of the symbolic executor is $\langle m, r, a, b \rangle$, to symbolically execute a `store` instruction that stores value v to the cell location stored at register i , we create a new memory m' where the cell $r[i]$ is mapped to the value v , with all other cells and their mappings remain unchanged from m . Similarly, the MEMORY ALLOCATION rule states that given the current symbolic executor state $\langle m, r, a, b \rangle$, to symbolically execute an `alloca` instruction that allocates new memory pointing to a value of type t at cell l with l to be stored in register i , we create a fresh symbolic cell l representing the pointer to the newly allocated memory, update the register state r to map register i to l instead, and update the memory state m where cell l points to uninitialized value \perp . The new symbolic state $\langle m', r', a, b \rangle$ is then returned.

As a concrete example, we show the state of the memory, registers and assumes expression after the execution of each instruction in the block `bb_head` in Figure 6. For this block, `asserts = null` and `Succ(A) = {bb_body1, bb_exit}`. The computed VC according to the Equation (1) and rules in Figure 7 would then be:

$$\begin{aligned} BB_head_{ok} &= (assumes \rightarrow bb_body1 \wedge bb_exit) \\ &= inv(i1_0, i2_1, arg) \wedge (i7 = i2_1) \wedge (i8 = arg) \wedge (i9 = length(arg)) \\ &\quad \wedge (i10 = i2_1 < length(arg)) \end{aligned} \quad (2)$$

■ **Table 1** Symbolic Execution for the block `BB_head` in Figure 6 using the inference rules defined in Figure 7. Each row depicts an LLVM instruction as well as the resulting *memory* (m) and *registers* (r) state after the instruction is symbolically executed. Due to space constraints, we do not show `inv` (and `True`) in all the execution steps.

havoc i1 i2 $m = [i1 \mapsto i1_0, i \mapsto arg, i2 \mapsto i2_1]$ $r = []$ <code>assumes = True</code>
assume inv ((load i1) (load i2) arg) $m = [i1 \mapsto i1_0, i2 \mapsto i2_1, i \mapsto arg]$ $r = []$ <code>assumes = True \wedge inv(i1_0, i2_1, arg)</code>
assume %i7 = load i32, i32* %i2 $m = [i1 \mapsto i1_0, i2 \mapsto i2_1, i \mapsto arg]$ $r = [i7 \mapsto i2_1]$ <code>assumes = True \wedge (i7 = i2_1)</code>
assume %i8 = load %list*, %list** %i $m = [i1 \mapsto i1_0, i2 \mapsto i2_1, i \mapsto arg]$ $r = [i7 \mapsto i2_1, i8 \mapsto arg]$ <code>assumes = (i7 = i2_1) \wedge (i8 = arg)</code>
assume %i9 = call i32 @length(%list* %i8) $m = [i1 \mapsto i1_0, i2 \mapsto i2_1, i \mapsto arg]$ $r = [i7 \mapsto i2_1, i8 \mapsto arg, i9 \mapsto length(arg)]$ <code>assumes = (i7 = i2_1) \wedge (i8 = arg) \wedge (i9 = length(arg))</code>
assume %i10 = icmp slt i32 %i7, %i9 $m = [i1 \mapsto i1_0, i2 \mapsto i2_1, i \mapsto arg]$ $r = [i7 \mapsto i2_1, i8 \mapsto arg, i9 \mapsto length(arg), i10 \mapsto (i2_1 < length(arg))]$ <code>assumes = (i7 = i2_1) \wedge (i8 = arg) \wedge (i9 = length(arg)) \wedge (i10 = i2_1 < length(arg))</code>

Similarly, the VCs for other basic blocks can be constructed. Once the VCs have been generated for the all basic blocks, the VC for the entire program can be expressed as $R \rightarrow BB_start_{ok}$ where R is the conjunction of VCs for each block and BB_start_{ok} is the Boolean variable introduce for the first block in the LLVM bitcode.

Note that the calls to invariant and post-conditions are just placeholders and they are synthesized during the synthesis phase of METALIFT. At the end of the analysis phase METALIFT would generate the following verification conditions:

1. $\forall \sigma. Pre(\sigma) \rightarrow Inv(\sigma)$
2. $\forall \sigma, \sigma'. Inv(\sigma) \wedge Body(\sigma, \sigma') \rightarrow Inv(\sigma')$
3. $\forall \sigma. Inv(\sigma) \rightarrow Post(\sigma)$

For simplicity, we do not show the verification conditions using LLVM basic block structure. The verification conditions logically state that

- 1) invariant must hold before the loop
- 2) invariant must be inductive i.e. it should be true at every iteration of the loop and
- 3) invariant must assert the post-condition upon exiting the loop.

Internally, METALIFT represents the VCs using MTL which we describe in the next section.

3.3 MTL

We now describe MTL in detail. METALIFT provides developers with an API to use the constructs in the MTL to define the operators of their target DSL. This is in contrast to the prior standalone transpilers [3, 35, 20] where the semantics of the target DSL are embedded within the transpiler and are not reusable. In Section 3.5, we show how developers can use MTL to describe the semantics of the operators in their target DSL.

$$\begin{aligned}
 e \in \text{expr} &::= l \mid \text{var} \mid e_1 \text{ bop } e_2 \mid \text{if } e_1 \text{ then } e_2 \text{ else } e_3 \mid \neg e \mid \\
 &\quad f(e_1, e_2, \dots, e_n) \mid f_u(e_1, e_2, \dots, e_n) \mid e_{\text{list}} \mid e_{\text{map}} \mid e_{\text{tup}} \\
 e_{\text{list}} \in \text{listExpr} &::= \text{empty} \mid \text{length}(e) \mid \text{get}(e, i) \mid \text{append}(e, i) \mid \\
 &\quad \text{prepend}(i, e) \mid \text{concat}(e_1, e_2) \mid \text{tail}(e, i) \mid \text{take}(e, i) \\
 e_{\text{map}} \in \text{mapExpr} &::= \text{empty} \mid \text{get}(e_{\text{map}}, i) \mid \text{insert}(e_{\text{map}}, e_1, e_2) \\
 e_{\text{tup}} \in \text{tupExpr} &::= \text{make}(e_1, e_2, \dots, e_n) \mid \text{get}(e_{\text{tup}}, i) \\
 l \in \text{literal} &::= \text{True} \mid \text{False} \mid \text{Integer Constant} \\
 \text{bop} \in \text{binaryOp} &::= \text{and} \mid \text{or} \mid \text{implies} \mid = \mid + \mid - \mid * \mid / \mid > \mid <
 \end{aligned}$$

■ **Figure 8** Grammar definition of MTL.

MTL is a strongly-typed functional language that consists of three dialects: one for METALIFT to represent VCs internally, one for users to define their target language operators, and another for users to describe the search space. Figure 8 shows the core grammar of MTL that is shared between the three dialects. Even though MTL is a small language, it is expressive enough that can be used to specify the semantics of real-world DSLs, as we will discuss in Section 4.

As shown in Figure 8, the core expressions can be literals, variables passed in as arguments to the function, conditional expressions, expressions combined using Boolean operators (MTL supports all arithmetic, logical and relational operators). MTL also supports operations over list, tuples, and associative maps. It also supports uninterpreted functions (represented as f_u in Figure 8). Uninterpreted functions have no definition; their defining characteristic is simply

that they are deterministic, *i.e.*, for the same input, they always return the same output. They are useful in modeling certain operators (for example, complex math functions that are used in both the source and target languages) for which we only care about determinism.

MTL also provides support for three native data structures: lists, tuples and associative maps, along with some common operations over these data structures. For lists, in addition to standard list operations such as length, append, and value retrieval, MTL supports list comprehension functions, *tail*(*lst*, *index*), which returns all the elements after the first index elements of the list, and *take*(*lst*, *index*), which returns the first index elements of the list. For associative maps and tuples, MTL provides functions for inserting and retrieving values. Developers can also combine these data structures to construct nested data structures such as a list of tuples, a list of lists and a list of maps.

In summary, the different dialects of MTL are used for the following purposes during program transpilation:

1. To represent the VCs generated during the analysis phase.
2. To specify the semantics of the target DSL.
3. To describe the search space for valid program transformations.

3.4 Expressing Verification Conditions in MTL

$$v \in vcExpr := assert(e) \mid assume(e) \mid havoc(var)$$

■ **Figure 9** Additional constructs in MTL for verification condition generation.

Verification conditions generated during the analysis phase are encoded using the constructs in the MTL. As described in the Section 3.1, VC generation requires some additional constructs. We show these constructs in Figure 9 as *vcExpr*. These constructs include **assume**, **assert**, and **havoc**, which takes core expressions as arguments. Their semantics are defined earlier in Figure 7. *vcExpr* includes these constructs in addition to all the core constructs described in Figure 8. These constructs are useful for annotating the LLVM bytecode with invariant and post-condition placeholders. These are utilized by METALIFT internally and are not accessible to the developers via MTL API.

3.5 Expressing Target DSLs in MTL

As discussed in Section 2, METALIFT builds transpilers by leveraging program synthesis. METALIFT searches for program summaries that are semantically equivalent to the source code. Program summaries capture all the changes to the outputs of the source code and are expressed using the operators in the target DSLs. Once the program summaries are synthesized developers can write simple syntax-driven rules to translate them to the concrete syntax of the target DSL.

In order to synthesize the program summaries, the synthesizer requires the semantics of the DSL operators. Developers can implement their domain-specific operators using MTL as defined in Section 3.3. In Figure 11, we describe how map and reduce functions from the Spark DSL can be defined using MTL.

In METALIFT, each construct in the target language is defined using a dialect of MTL. In Figure 10, we show the two constructs, function declaration (*fnDecl*) and axioms (*axiom*), that are added to the core language described in Figure 8 to form this dialect for defining

$$\begin{aligned}
 f \in \text{fnDecl} & := \text{name}(arg_1 : t_1, arg_2 : t_2, \dots, arg_n : t_n) : t_r \rightarrow e \\
 a \in \text{axiom} & := \text{name}(arg_1 : t_1, arg_2 : t_2, \dots, arg_n : t_n) \rightarrow e
 \end{aligned}$$

■ **Figure 10** Additional constructs in MTL for defining the operators in the target language.

the operators in the target language. MTL supports recursive and higher-order functions. The target language definition is a collection of function declarations and axioms, where the body of both constructs are defined using *expr*'s in the core MTL.

In addition to the definitions of the operators in the target DSL, developers can provide properties specific to the operators in the DSL. Some of the properties that developers can define for the map and reduce operations are shown in Figure 11. These properties are helpful during the verification phase of METALIFT. We give more details about how these properties are used in Section 3.8.

Modern DSLs contain hundreds of functions and therefore searching for program summaries directly in the DSL APIs is not feasible. To make the synthesis algorithm tractable, METALIFT searches for summaries only using the operators defined by the developers. The high-level nature of MTL enables the developers to succinctly define the operators and abstract out the details of these operators in the DSL API. For example, the map definition in Figure 11 can represent the different variations of the map functions (*map*, *flatMap*, *mapToPair*) available in the Spark DSL.

3.6 Describing Search Space for Synthesis

Developers additionally provide the search space description for the synthesizer. Developers provide this description for program summaries as well as any invariant or functions to be synthesized (for example, in Spark, users can ask the synthesizer to generate the bodies of the λ_m and λ_r functions). In METALIFT, the search space is encoded using a context-free grammar (CFG), with the expression that needs to be synthesized at the top level, and the production rules specifying the possible values that the expression can take.

We use a different dialect of MTL for users to describe the search space. Built on top of the core language and as shown in Figure 12, MTL provides one non-deterministic construct, *Choose*, which the developers can use to describe the search space for the synthesis phase. The search space description is used to guide the synthesis process. Semantically, *Choose* lets the synthesizer return any of expressions in its argument list. It can be recursively nested or evaluate to one of the core expressions.

The search space description impacts the synthesizer's performance. If the grammar is too expressive, the synthesizer may take a long time to synthesize the correct expressions; conversely, if the grammar is too restrictive, the synthesizer may fail to find the correct expressions that satisfy the specification. Prior work [20, 2, 3, 14] specialized the grammar descriptions for the target domains and embedded them in the tools. Unfortunately, developers had no way of controlling the expressiveness of these grammars. METALIFT instead allows developers to programmatically control the grammars and even tune grammars for each benchmark separately.

The *Choose* function in Figure 12 is the basic construct that developers can use to describe the search space. *Choose*(e_c, e_c) allows the users to specify the set of candidate values for a particular expression. The candidate values (e in Figure 12) are described using the constructs in MTL (Figure 8). The synthesizer then selects from this set of possible

```

1 def targetLang():
2   fnDecl("map", lst, λm) =
3     if length(lst) == 0 then empty
4     else concat(λm(get(lst, 0)), map(tail(lst, 1)))
5
6   fnDecl("reduce", lst, λr) =
7     if length(lst) == 0 then 0
8     else λr(get(lst, 0), reduce(tail(lst, 1)))
9

37   implies(and((index ≥ 0), (index < length(lst))),
38     reduce(map(take(lst, index + 1), λm), λr) =
39     λr(reduce(map(take(lst, index), λm), λr), λm(get(lst, index))))

```

■ **Figure 11** Semantics of the operators in Spark DSL defined using constructs in MTL.

$$e_c \in \text{chooseExpr} \quad := \quad \text{Choose}(e_c, e_c) \mid e$$

■ **Figure 12** Additional constructs in MTL for description of the search space.

candidates, an expression that meets the specification. In terms of the CFG, *Choose* describes the production rules, i.e., the expansion rules for a non-terminal in the grammar. These grammars can potentially be recursive in nature. We provide a “bound” parameter in our API to control the depth of these grammar. This provides additional flexibility to the developers to programmatically define the depth of unrolling of their search space.

The VCs mentioned in Section 3.1 can be trivially satisfied by setting the invariant and post-condition to be True. The search space description helps prevent the synthesizer from generating such trivial solutions. At a high-level, METALIFT requires the post-condition search space to have the following structure:

$$\forall v_o \in \text{outputVars}. v_o = e_c \in \text{chooseExpr}$$

where *outputVars* is the set of all output variables in the source code. *e* in *chooseExpr* are expressions described using the core constructs in MTL using set of all the *input arguments* and the variables modified in the program. For the example in Figure 2, *outputVars* = {*count*} and *modVars* = {*j*, *word*}. Logically, it states that the output variables in the program should be expressed as an expression over the operators in the target DSL. METALIFT uses standard static analysis techniques to infer these variables during the analysis phase. In addition to restricting the synthesizer from generating trivial solutions, the search space description helps in scaling the synthesis problem.

Figure 13 shows one possible grammar description for the post-condition, invariant, mapper, and the reducer function for the translation problem described in Figure 2. The grammar for the program summary asserts that the output variable equals some MapReduce expression over the input data. The grammar for the invariant reasons about the bounds of the loop counter and how the count variable is modified in each iteration of the loop. The mapper function can return an empty list or a list of key-value pair and the reducer function can choose to reduce the input values using one of the arithmetic operators. In this grammar we have restricted the output to be a map, reduce or map followed by a reduce operation.

As mentioned earlier, developers can programmatically control the grammar structure. In the Spark transpiler, a few possible search strategies include incrementally increasing the number of map reduce operations that can be used to express the output variable or incrementally increasing the number of emit statements that the mapper function can use. Figure 14 shows how the driver code in Figure 3 can be modified (less than 20 LOC) to implement the incremental search for number of emit statements. In Figure 14, each iteration of loop increments the number of emits by 1 until the synthesizer finds the semantically equivalent program summaries. This programmatic definition of grammar allows developers to experiment with the synthesis engine without needing to be synthesis experts. Some of these strategies were encoded in the previous tools [3] to make the search tractable.

METALIFT automatically generates the program summaries once the developers have provided the semantics of their operators and the search space description.

3.7 Synthesis

We now discuss the synthesis phase of METALIFT. A typical program synthesis problem is characterized by three parameters: the specification, space of possible programs and the search techniques used by the synthesizer to search for candidate solutions. In METALIFT, the specification are the VCs generated from the source code during the analysis phase and the space of possible programs is represented by the operators and search space specified by the developer. During the synthesis phase, METALIFT uses this information to synthesize the program summaries and any necessary invariants. Essentially, program summaries are logical statements asserting what should be true if the program terminates and it should hold for all possible executions of the program starting from a state that satisfies the pre-condition.

Formally, the synthesis problem can be stated as

$$\exists ps, inv_1, inv_2, \dots, inv_n. \forall \sigma. VC(S, ps, inv_1, inv_2, \dots, inv_n, \sigma) \quad (3)$$

The goal of the synthesizer is to infer the definitions of *ps* and *inv* (in case of programs with loops) such that for all program states σ , the verification conditions (generated during the analysis phase) for a given input source code *S* is true.

21        isSynthesized = True
22      else:
23        numEmits += 1
24    transpiledCode = codeGen(verifiedSummaries)
25    return transpiledCode
```

■ **Figure 14** Modified driver code to implement incremental grammar search for controlling the number of emits in the λ_m function.

Many search techniques have been proposed to solve the problem stated in Equation (3). These include enumerative search [5], deductive search [30], constraint solving [38], statistical [34] and neural approaches [26]. Currently, METALIFT relies on Rosette, an off-the shelf synthesis solver [41] to perform this search; in principle, it could use any synthesis solver supporting the needed theories. To leverage Rosette as the synthesizer, we need to translate the MTL descriptions in the Rosette language. Due to the highly-syntactic nature of the Rosette language, this translation is straightforward. Synthesizer enumerates candidates for ps (and $invs$) from the search space described by the developer until it finds one that satisfies the specification.

Currently available synthesizers have limited support for handling recursive functions in the search space. Internally, synthesizers use theorem provers to determine whether a candidate is valid, i.e., whether it meets the specification. However, while MTL supports list and other data structures, the theory of lists in theorem provers is incomplete and thus insufficient to verify all possible summaries the synthesizer might generate. As a result, the synthesizers struggle to solve the synthesis problem described in Equation (3). To make synthesis tractable, we simplify the problem by first performing bounded synthesis, and subsequently sending candidate summaries that pass bounded synthesis to a general theorem prover to validate. In Equation (3), rather than searching for program summaries that satisfy the VCs for all program states (σ), we search only for a finite set of program states. For example, we limit all list data structures to lengths of up to size 2, and all integers to bit-widths of up to 7 bits. These parameters can be changed by the developers using METALIFT’s API. Note that we bound the program states only during the synthesis phase, and during verification we check if the synthesis phase output is true for all program states.

The summaries returned by the synthesizer using the target language and search space defined in Figure 11 and Figure 13, respectively, are shown in Figure 15. The output variable *count* is synthesized as a series of map and reduce operations. In the mapper phase, λ_m maps each word w in the input list to the key-value pair $(w, 1)$. In the reducer phase, *reduceByKey* groups all the unique keys in the map output, reduces each group using the add operator and returns a map containing the key-value pairs $(w, frequency)$.

After bounded synthesizer generates the summaries, they are parsed and represented using the constructs in MTL. Note that the generated summaries are not in the concrete syntax of Spark yet but it is expressed in the operators defined by the developers. Developers can easily convert these summaries using simple syntax-driven rules which we describe in Section 3.9. In the next section, we provide details about the verification of the synthesized summaries and invariants, as well as proving that the inferred invariant is indeed sound.

3.8 Verification

Given candidate summaries that are generated by the bounded synthesizer, METALIFT next automatically performs the full verification of the synthesized summaries and invariants. As previously stated, the synthesized summaries and invariants generated during the synthesis phase satisfy the verification conditions only for a finite set of program inputs. For instance, in our running example, the synthesis phase returns a solution that is only verified for lists with lengths up to 2 and, integers with bit-width up to 7. The goal of the verifier is to prove that the program summaries are valid for all the program states (all integers and lists sizes). METALIFT uses *satisfiability modulo theories* (SMT) solvers [10, 42, 7] to solve this verification problem. Formally, the theorem prover checks for the satisfiability of the following problem

$$\forall \sigma . \neg VC(S, ps, inv_1, inv_2, \dots, inv_n, \sigma) \quad (4)$$

```

def ps(counts, words):
    counts = reduceByKey(map(words,  $\lambda_m$ ),  $\lambda_r$ )
    return counts

def inv(j, count, words):
    return And((j  $\geq$  0), (j  $\leq$  length(words)),
              (count = reduceByKey(map(take(words, j)  $\lambda_m$ ),  $\lambda_r$ )))

def  $\lambda_m$ (v):
    return append(empty, Tuple(v,1))

def  $\lambda_r$ (v1, v2):
    return (v1 + v2)

```

■ **Figure 15** Program summaries and invariants generated by the synthesizer for the source code in Figure 2a.

where the definitions inferred during the synthesis phase are substituted for the placeholders for *ps* and *inv*'s in the VCs. Negating the assertion and checking if there exists some program state that satisfies the assertions is standard practice in program verification: if the theorem prover discovers a program state that satisfies the negated assertion then the generated program summaries or the invariants are incorrect. However, if there exists no such state then the inferred summaries and the invariants prove the validity of the verification conditions and thus the semantic equivalence of the summaries to the source code.

As mentioned in Section 3.3, MTL supports various data structures. METALIFT models list and tuples in MTL using the SMT solver's built-in functionality of algebraic data types. Algebraic data type definition requires the user to declare the data type and associate a sort (type) with the declaration. Following that, users declare the accessors and constructors for data retrieval and creation of new data structures, respectively. Associative maps in MTL are modeled using the the SMT solvers built-in theory of arrays. METALIFT generates the verification problem automatically by translating MTL to SMT-Lib format [9]. As the SMT-Lib format does not support higher order functions, we inline them while converting.

Figure 16 shows the simplified version of the verification condition generated during the analysis phase for the source code in Figure 2a. We now show that the invariant described in Figure 15 is necessary and sufficient to prove the verification conditions.

Initial Condition. The initial condition asserts that the loop invariant holds immediately before the loop. Before the loop executes, $j = 0$ and *counts* is an empty map. The invariant expresses *counts* as a series of map and reduce operation applied to the first j elements of the input words list. Since $j = 0$, the map reduce operation will be applied to an empty list, returning an empty map according to the definitions in Figure 11. Hence, the invariant holds in the initial state.

Preservation. The loop preservation VC asserts that if the loop invariant hold at any arbitrary iteration, j , of the loop then it should also hold in the next iteration, $j + 1$, of the loop. The notation $counts[w \mapsto e]$ denotes the assignments statement, i.e., the key w in *counts* gets assigned the value e . This is proved by induction. We first prove that the invariant holds at the initial condition, we assume that the invariant holds at iteration j , i.e., the map reduce operation has already computed the frequency of first j words in the list. We need to show that the invariant holds after one more execution of the loop. This is

true since in the $j + 1^{\text{th}}$ iteration of the loop, the map reduce operation would compute the frequency of the first $j + 1$ words from the input list, thereby incrementing the count of the $j + 1^{\text{th}}$ word in the output map *counts* by 1.

Termination. Finally, the termination condition states that if the loop terminates, the invariant should imply the post condition. This is true because at the end of the loop $j = \text{size}(\text{words})$ and the map reduce operation would have computed the frequencies for all the words in the list which is the same expression as the program summary.

Initial Condition	$\text{Inv}(j = 0, \text{counts} = \{\}, \text{words})$
Preservation	$\text{Inv}(j, \text{counts}, \text{words}) \wedge (j < \text{size}(\text{words})) \rightarrow \text{Inv}(j + 1, \text{counts}[\text{words}[j] \mapsto \text{words}[j] + 1], \text{words})$
Termination	$\text{Inv}(j, \text{counts}, \text{words}) \wedge \neg (j < \text{size}(\text{words})) \rightarrow \text{PS}(\text{count}, \text{words})$

■ **Figure 16** Verification conditions for the source code in Figure 2a.

3.8.1 Leveraging Additional Axioms

Verifying loop invariants in general is undecidable, as MTL supports recursion and higher-order functions. To aid in verification, developer can provide additional *axioms* to the theorem prover to prove the validity of loop invariants and program summaries for VCs such as in Figure 16. Figure 11 shows how developers can use MTL to provide operator specific axioms to METALIFT. These axioms are translated from MTL to SMT-Lib format and included in the verification problem by METALIFT. These axioms from our experience are simple properties like associativity, commutativity, and distributivity of the operators in the target language. If developers only need to ensure bounded correctness for the translation, they don't need to define these axioms.

Figure 17 shows the SMT-Lib translation of the map operator axioms described in Figure 11, where $\text{map_}\lambda_m$ is the inlined definition of the map operator. The first axiom states that the map operators is distributive over two input lists. While the second one asserts the inductive property of the map operator. Other properties described in Figure 11 can be similarly translated to SMT-Lib format.

```

1 ;distributive map lemma
2 (assert (forall ((lst1 (List T)) (lst2 (List T)) )
3 (= (map_λm (concat lst1 lst2)) (concat (map_λm lst1) (map_λm lst2))))))
4
5 ;inductive map lemma
6 (assert (forall ( (lst (List T)) (index U) )
7 (=> (and (>= index 0) (< index (length lst)))
8 (= (map_λm (tail lst index)) (concat (λm (get lst index))
9 (map_λm (tail lst (+ index 1))))))))))

```

■ **Figure 17** Translation of the axioms defined using MTL to SMT-Lib format.

3.9 Code Generation

The program summaries verified by METALIFT are expressed using the high-level operators defined by the developers. The final step is to implement syntax-driven rules to translate these summaries to the concrete syntax of the target DSL. This translation is much easier than the general translation from source language to target DSL API because the developers

- 1) only need to write rules for the operator they defined in the target language and
- 2) do not need to worry about semantic equivalence to the source code as METALIFT automatically verifies the program summaries.

In METALIFT, we conduct synthesis in the high-level MTL rather than searching through the concrete syntax of the DSL. This approach is used to make the search process more tractable during synthesis. A DSL may include multiple variations of the same operator, with each having minor differences while they are functionally equivalent. For instance, the Spark DSL contains multiple variations of the map operator (*map*, *flatMap*, *mapToPair*). Rather than searching through these different concrete implementations, we conduct the search using a single implementation that captures the different operators' high-level semantics. Once a solution is synthesized in the MTL, converting it to concrete syntax becomes straightforward. The developer can decide which variation to use on basis of the return value of the λ_m function. For example, if the λ_m function returns a key-value pair or list with single key-value pair, the developers can use *mapToPair* from the DSL. If the λ_m function returns a list containing multiple key-value pairs, the developers can then use *flatMapToPair*. Table 2 shows an excerpt of the translation rules for the Spark DSL. Applying the translation rules to the summary generated in Figure 15 would result in `words.mapToPair(v -> (v, 1)).reduceByKey((v1, v2) -> v1 + v2)`. Another advantage is that if the same operator can exist in multiple DSL (e.g. convolution in tensor processing libraries), we only need to perform the search once and then code generation rules can translate the summary into concrete syntax of any library. In Figure 18, we show the implementation for some of these rules for the Spark DSL.

■ **Table 2** Translation rules for converting program summaries in MTL to Spark DSL.

Pattern	Translation Rule
$\llbracket \text{map}(l, \lambda_m \rightarrow \text{list}(\text{Pairs})) \rrbracket$	<code>l.flatMapToPair($\llbracket \lambda_m \rrbracket$)</code>
$\llbracket \text{map}(l, \lambda_m \rightarrow (\text{Pair or list}(\text{Pair}))) \rrbracket$	<code>l.mapToPair($\llbracket \lambda_m \rrbracket$)</code>
$\llbracket \text{map}(l, \lambda_m \rightarrow T) \rrbracket$	<code>l.map($\llbracket \lambda_m \rrbracket$)</code>
$\llbracket \text{reduce}(l, \lambda_r) \rrbracket$	<code>l.reduce($\llbracket \lambda_r \rrbracket$)</code>
$\llbracket \text{reduceByKey}(l, \lambda_r) \rrbracket$	<code>l.reduceByKey($\llbracket \lambda_r \rrbracket$)</code>
$\llbracket \lambda_m(v) \rightarrow e \rrbracket$	<code>(v -> $\llbracket e \rrbracket$)</code>
$\llbracket \lambda_r(v1, v2) \rightarrow e \rrbracket$	<code>((v1, v2) -> $\llbracket e \rrbracket$)</code>
$\llbracket e_1 \text{ aop } e_2 \rrbracket$	<code>$\llbracket e_1 \rrbracket$ aop $\llbracket e_2 \rrbracket$</code>

4 Evaluation

We now describe our experience in building synthesis-driven transpilers using METALIFT. We have implemented the core of METALIFT in Python. We provide developers with a Python API for using the constructs in our MTL for defining the semantics of their DSL operators and search space description. METALIFT uses Rosette [41] as its synthesis back-end engine, and supports Z3 [42] and CVC5 [7] for verification.

In this section, we show that our MTL is general enough to be used to create compilers for different DSLs. We demonstrate this by creating compilers using our framework for two DSLs that target very different applications:

```

1 def codeGen(verifiedSummaries):
2   ps = verifiedSummaries['ps']
3   def eval(expr):
4     if expr[0] == "reducebykey":
5       return "%s.reducebykey(%s)"%(eval(expr[1]), eval(expr[2]))
6     elif expr[0] == "map":
7       if len(lm) == 1: map_func = "mapToPair"
8       else: map_func = "flatMaptoPair"
9       return "%s.%s(%s)"%(expr[1],map_func,eval(expr[2]))
10    ...
11   return eval(ps)

```

■ **Figure 18** Implementation of syntax-driven rules for translating summaries to executable code in target DSL.

1. **Distributed Computing DSL.** In this case study, we build a compiler that translates sequential Java code to Spark DSL [43]. Spark provides users with APIs to perform large-scale data processing efficiently by distributing the computations across multiple clusters.
2. **Hardware DSL.** In this case study, we build a compiler that translates Domino [35], which allows users to implement data-plane algorithms (such as congestion control and load balancing) for network switches to Banzai atoms, which represent atomic operations typically available in network switches. By combining these atoms, users can implement various programmable network switches with Banzai.
3. **Vector Operation DSL.** In this case study, we build a compiler that translates sequential C++ code to vector operations. For loops are generally slower compared to their vectorized operations on large datasets and libraries such as Scipy, Pytorch and Tensorflow provide efficient implementations of these vectorized operators.

These case studies differ in the program structure of the source code, in addition to targeting different domains. The Spark and vector case study contains programs with loops, whereas Domino contains only straight line programs with no looping constructs. Prior work [3, 35] implemented these case studies as two separate specialized compilers. We demonstrate that METALIFT can be used to create all these compilers, and that METALIFT simplifies the process of building DSL compilers that leverage program synthesis.

4.1 Case Study: Spark

MapReduce [15] is a popular programming paradigm which enables users to write compute intensive-applications capable of processing massive datasets by distributing the computations across multiple clusters. Mapreduce programming model decomposes the processing into two primitives *map* and *reduce*. MapReduce first breaks down the dataset into multiple independent chunks and then uses the following three stages to process the data:

1. **map phase:** each node in the cluster receives a small chunk of the data. Each node then locally processes the data by applying the mapper function and produces a set of key-value pairs.
2. **shuffle phase:** all the key-value pairs from different mapper functions are then sorted, grouped together by key and then redistributed to different nodes such that each node receives values belonging to the same key.
3. **reduce phase:** each node then aggregates the values using the reducer function.

Spark [43] is an open-source analytics framework. Spark provides users with highly-efficient implementations of map and reduce operations via its APIs in high-level languages such as Python and Java.

To leverage the optimizations provided by the MapReduce paradigm, Casper [3] and Mold [31] are two compilers that automatically translate legacy code written in Java to sequence of map and reduce operations. Casper used program synthesis to perform the transformations, whereas Mold used a syntax-driven rule based approach. We demonstrate that using METALIFT developers can build the core capabilities of the Casper toolchain by easily defining the semantics of the map and reduce using our MTL.

MetaLift’s implementation of Casper. We manually rewrote the Casper benchmarks from Java to C++, as METALIFT’s frontend currently do not support Java. We then define the semantics of the map and reduce operations using our MTL, as illustrated in Figure 11. We also provide additional axioms to assist the verifier in proving validity of the synthesized program summaries and loop invariants (Lines 23-39 in Figure 11). As shown in Figure 13, using MTL we provide the description of the search space for the program summaries, invariant, mapper and reducer functions. Casper implemented incremental grammar search to make the search tractable, and a cost-based evaluation model to select from different semantically equivalent program summaries. In our METALIFT implementation, we use incremental search and in Figure 14 we describe how developers can easily modify the driver code to implement such search strategies.

Results. We evaluate our implementation on the benchmarks [1] that were successfully translated by Casper. Our implementation translates **44** benchmarks of the **49** benchmarks that Casper translated. Synthesizer times out on the five benchmarks which our implementation failed to translate. We believe the reason for these failures is that METALIFT uses LLVM to generate verification conditions, whereas Casper implemented a specialized verification condition generator for Java source code directly, resulting in considerably more optimized VCs that synthesizers can easily solve. We use a timeout (synthesis + verification) of 60 minutes for all the benchmarks. The average running time for our implementation of the Casper benchmarks was \approx 3mins. We observed that METALIFT-generated code had the same structure to the ones which Casper synthesized (i.e., same number of map reduce stages and same implementation of the mapper and reducer functions), so we expect the output code to have similar performance as that generated by Casper. In contrast to Casper, which required **25578** lines of code, our implementation requires less than **1000** lines.

4.2 Case Study: Domino

Domino [35] is a domain-specific language for data-plane algorithms that run on programmable line-rate switches. The Domino DSL provides a C-like interface to define a “packet transaction” on a stream of network packets. While the syntax of Domino is a subset of C, there are a number of restrictions on memory allocation, loops, and control flow structure to prevent writing Domino programs which cannot be executed at “line-rate” (the speed with which packets arrive on a programmable switch). A particularly relevant restriction is that Domino is loopless, obviating the need to synthesize loop invariants as required in Spark. Figure 21 contains an example of a packet transaction written in Domino which implements a simple Rate-Control Protocol (RCP) [40] by accumulating the sum of packet round-trip-times (RTTs) for which the RTT is under the maximum allowable value.

```

1 StateResult atom_template(int state_1, int state_2, int pkt_1, int pkt_2) {
2   if (rel_op(Opt(state_1), Mux3(pkt_1, pkt_2, C()))) {
3     state_1 = Opt(state_1) + Mux3(pkt_1, pkt_2, C());
4   }
5   StateResult ret = new StateResult();
6   ret.result_state_1 = state_1;
7   ret.result_state_2 = state_2;
8   return ret;
9 }

```

■ **Figure 19** An example of a Banzai atom used in the Domino compiler [36].

Domino compiles to Banzai, a machine model for programmable line-rate switches. The Banzai target encodes hardware constraints fundamental to these switches, the most important of which is *atomicity*, thereby guaranteeing that packet operations occur transactionally. Banzai provides an abstraction over programmable switch architectures with the notion of an *atom*, a stateful processing unit that contains atomic operations which can be used to implement data-plane algorithms. An example of a Banzai atom is given in Figure 19.

Compilation to Banzai. The Domino compiler [35] has a three-stage pipeline to compile a feasible Domino program to Banzai. In the first stage, the compiler preprocesses the code by

- 1) recursively transforming branches into conditional assignments
- 2) rewriting operations on state variables to occur on temporary packet fields instead
- 3) converting to static single-assignment (SSA) form and
- 4) flattening to a three-address code representation.

In the second stage, the Domino compiler decomposes the input code into a sequence of “codelets”, a smaller block containing three-address code. To do so, the compiler executes dependency analysis on the input code to form a dependency graph. The compiler splits the input code into strongly-connected component blocks (“codelets”), and forms a meta-directed acyclic graph of these codelets, thereby capturing block-scale dependencies. The compiler then schedules the codelets in topological order to ensure that all dependencies are satisfied.

Finally, the Domino compiler performs code generation by

- 1) distributing work throughout codelets to ensure that no block takes too long (the “pipeline width” constraint) and
- 2) using the SKETCH [37] program synthesizer to map each codelet to one of a set of Banzai atoms which are feasible in hardware.

MetaLift implementation of Domino. We demonstrate how METALIFT can be used to significantly simplify the synthesis of Domino benchmarks to Banzai atoms. First, we encode the Banzai target language and grammar as a set of stateless operations, specified in Figure 20. By ensuring our target language and grammar contains only stateless operations, we guarantee atomicity. We then decompose the Domino benchmarks into codelets – which we represent as C++ functions – as in the second stage of Domino compiler. However, we make two key assumptions:

- 1) we assume that array reads and writes happen in between codelets to ensure our target language and grammar does not need stateful operations

```

1 def targetLang():
2   ## Variable and Constant Getters
3   def const(): return Choose(*CONSTANTS) # CONSTANTS is a list of allowed constants
4   def var(): return Choose(*VARS) # VARS contains the input to the codelet
5   def var_or_const(): return Choose(var(), const())
6   def opt(n): return Choose(n, 0)
7
8   ## Banzai Atoms
9   def arith_op(a, b): return Choose(a + b, a - b, a * b)
10  def rel_op(a, b): return Choose(a == b, a != b, a <= b, a < b, a > b, a >= b)
11  def raw(): return opt(var()) + var_or_const()
12  def rw(): return var_or_const()
13  def mul_acc(): return opt(var()) * var_or_const() + var() + var()
14
15  def pred_raw():
16    if rel_op(opt(var()), var_or_const()): return opt(var()) + var_or_const()
17    else: return var()
18
19  def if_else_raw():
20    if rel_op(opt(var()), var_or_const()): return opt(var()) + var_or_const()
21    else: return opt(var()) + var_or_const()
22
23  def sub(): ...
24
25  def nested_ifs(): ...

```

■ **Figure 20** The semantics of the target Banzai atoms defined using MTL.

```

1 #define MAX_ALLOWABLE_RTT 30
2 struct Packet { int size_bytes; int rtt; };
3
4 /* State variables */
5 int input_traffic_Bytes = 0;
6 int sum_rtt_Tr = 0;
7 int num_pkts_with_rtt = 0;
8
9 /* Transaction code */
10 void func(struct Packet pkt) {
11   input_traffic_Bytes += pkt.size_bytes;
12   if (pkt.rtt < MAX_ALLOWABLE_RTT) {
13     sum_rtt_Tr += pkt.rtt;
14     num_pkts_with_rtt += 1;
15   }
16 }

```

```

1 AddStateRet3(
2   # _input_traffic_Bytes
3   Add(_input_traffic_Bytes,
4     size_bytes),
5   # _sum_rtt_Tr
6   Add(rtt, _sum_rtt_Tr)
7   if Not(Ge(rtt, 30))
8   else _sum_rtt_Tr,
9   # _num_pkts_with_rtt
10  Add(_num_pkts_with_rtt, 1)
11  if Not(Ge(rtt, 30))
12  else Add(0, _num_pkts_with_rtt
13 )

```

■ **Figure 21** End-to-end synthesis of Domino DSL to Banzai via MetaLift.

- 2) and we assume that each codelet has up to three outputs, all stored in temporary packet fields, and that each later codelet in a “pipeline” receives the set of all relevant outputs from prior codelets.

Finally, we compile the decomposed Domino benchmark to LLVM IR using Clang, and then programmatically synthesize each codelet to the target language and grammar.

We show an end-to-end example of synthesizing a Domino benchmark in Figure 21. The METALIFT synthesized summary contains three atoms, two of which are `pred_raw` (see Figure 20 for atom definitions) and one is a stateless arithmetic operation. `AddStateRet3` is not an atom, but rather the language primitive to output three return values (the new state and packet variables) due to how it is represented the C++ Domino benchmark.

■ **Table 3** Comparison of *maximum* atoms per stage used in the synthesized output of the Domino compiler and METALIFT. The maximum atoms per stage for each benchmark are taken from the Domino paper [35].

Benchmark name	MetaLift atoms/stage	Domino atoms/stage
Bloom filter	3	3
Heavy Hitters	3	9
Flowlets	2	2
RCP	2	3
Sampled NetFlow	2	2
HULL	3	1
Adaptive Virtual Queue	3	3
Queueing priority computation	2	2
DNS TTL change tracking	2	3
CONGA	2	2

Results. We successfully synthesized all ten Domino benchmarks with our solution described above, which took a total of **1052** un-minified lines of code. For domino, the evaluation metric stated in the prior work [35] was not performance but rather feasibility, i.e., if we could transpile a program to a banzai atom then these are feasible to run on a programmable switch device. The average compilation time for these 10 benchmarks was ≈ 6 secs. The Domino compiler, measuring all C++ source files and headers, totals **4036** lines of code, so our solution leveraging METALIFT requires **74%** fewer lines of code. Table 3 shows that the synthesized output maximum atom count per stage from METALIFT is under the maximum number of atoms per stage that the Domino compiler used for all but one of the ten benchmarks. Differences can be partially attributed to different benchmark decompositions (and therefore, different numbers of stages): for example, in the “HULL” benchmark, the Domino compiler output had 7 stages with maximum 1 atom/stage while METALIFT had 5 stages with maximum 3 atoms/stage. The other primary source of variance is that the Domino compiler optimized for surface area and speed at the hardware level, while METALIFT only optimized for the number of atoms. As a result, certain benchmarks like “Heavy Hitters” were synthesized in far fewer atoms by METALIFT, but those atoms were slower at a hardware level. Nonetheless, the success of this case study further demonstrates the capability of METALIFT to decrease the complexity of verified lifting solutions while simultaneously raising the level of abstraction.

4.3 Case Study: Vector Operations

In machine learning workflows, one crucial step is to pre-process datasets, but writing processing pipelines using loops can be computationally expensive due to the large size of the datasets. To improve efficiency, libraries like Pytorch, Tensorflow, and Scipy offer highly optimized vector or matrix operations for performing these operations faster. To take advantage of the optimizations, we build a transpiler with METALIFT to translate loopy array processing programs to vectorized operations. For example, consider the program in Figure 23 that computes the sum of consecutive elements in an array. This sequential program can be implemented using a convolution operation with a kernel of $[1, 1]$ and a stride of 1. For this transpiler, we encode the semantics of the operators such as 1D convolution, element-wise vector (matrix) multiplication and dot-product using MTL. In Figure 23, we show the

definition of the 1D convolution operation in our MTL. Note that if we were to search for an equivalent convolution program using the concrete syntax of tensor libraries we will have to search and verify for each individual library. Instead, by lifting the semantics to our MTL, we need to perform this search only once and then using simple syntax-driven rules we can translate this to any of the tensor libraries such as Tensorflow or Pytorch.

Results. We evaluate our implementation on **5** array processing benchmarks which can be represented using the vector operations described above. These benchmarks are a combination of the stencil kernels introduced in prior work [20] and C++ kernels scraped from the web. We use the same 60 minutes timeout as the previous case studies. Since all these are loopy programs, METALIFT synthesizes any additional invariants also required to prove the functional equivalence. We can translate all the benchmarks with an average running time of ≈ 2 mins. Once we have the summaries synthesized in our MTL, we write code generation rules to translate them to PyTorch, Tensorflow and Scipy. Our implementation requires less than **500** lines of code.

```

1 vector<int> program(vector<int> data){
2     vector<int> result;
3     for (int i = 0; i < data.size() - 1; i++)
4         result.push_back(data[i] + data[i + 1]);
5     return result;
6 }
```

■ **Figure 22** Sequential C++ array processing program.

```

1 def conv(data, kernel, stride):
2     if length(1st) == 0 then empty
3     return prepend(dot_product(data, kernel), conv(tail(data, stride), kernel, stride))
```

5 Related Work

Program Synthesis-Based Compilers. Many tools have been developed previously which leverage program synthesis to translate code written in general-purpose programming languages to DSLs while preserving semantics. Examples of such compilers include STNG [20], which converts Fortran stencil computations to the Halide [32] DSL; QBS [14], which translates sequential Java database processing queries to SQL; Casper [3], which converts sequential Java code to map-reduce operations; and Domino [35], a compiler that translates network packet processing algorithms for programmable switches. All of these compilers are fully automated, but they are tailored to a specific DSL and cannot be reused to build a compiler for a new DSL. Implementing these tools required extensive knowledge of program synthesis and verification, making it difficult for developers to leverage the underlying approach of synthesis-based transformation for their own DSLs. METALIFT, on the other hand, uses MTL to provide a very high-level abstraction for developers to specify the semantics of their DSLs and automatically build compilers that can perform semantic preserving transformations. Other prior work [34] leverages program synthesis to perform superoptimization for the x86

instruction set and [23] employs a data-driven approach for verifying peephole optimization in LLVM. These tools perform transformations for low-level languages while METALIFT builds compilers for DSLs.

Syntax-Driven Transpilation. The traditional solution to the translation problem is to create a syntax-driven compiler. These rule-based systems rely on users to create rules that pattern match in order to perform the required translation. An example of one such compiler is [31], which translates sequential Java code to into MapReduce operations. As such, these rule-based systems tend to be difficult to design and are vulnerable to translation errors. Perhaps even more problematic is that such approach is brittle to changes in DSL semantics.

Neural Approaches for Transpiling. Recently, there has been lot of interest in using neural machine translation to perform source-to-source translations. A number of approaches, including supervised [25, 13] and unsupervised [33] learning based techniques have been proposed for translating between general-purpose programming languages. These models do not require any input from developers, but require massive amounts of data for training. For instance, [33] required over 100 million functions from C++, Python and Java to train their model. METALIFT targets DSLs for which such huge amounts of data may not be available always. Furthermore, the transformations performed by these neural models are not verified, which may provide an opportunity to introduce bugs in the code.

6 Conclusion and Future Work

In this paper we described METALIFT, a unified platform for building DSL compilers. METALIFT allows developers to build compilers for their own DSLs by utilizing the synthesis-based program transformation approach that has been the underlying technique for many previous DSL compilers [2, 20, 35]. METALIFT achieves this with its design of a specification language called MTL. Using MTL developers can express the semantics of their target DSL and search space description to guide the synthesis engine. This programmatic approach to describing DSLs allows METALIFT to build compilers for various DSLs. We described our experience in building synthesis-driven transpilers by using METALIFT to build three transpilers targeting very different application domains. We demonstrate that METALIFT significantly reduces the effort required to create specialized implementations of these three compilers. With a unified framework, METALIFT opens up new research directions for automated transpilation, such as leveraging dynamic execution traces to automatically infer loop invariants, and improving synthesis with neuro-symbolic methods, which can learn effectively search strategies from similar programs, as well as oracle-guided synthesis methods [28, 29], which integrate verification with synthesis and extend the expressive power of synthesis queries beyond SMT. METALIFT is modular to easily add any of these optimizations. As a framework, METALIFT has the potential of dramatically lowering the barrier for both research into synthesis driven transpilation and adoption of new specialized high performance hardware and DSLs.

Abstract

Memory safety issues are a serious concern in systems programming. Rust is a systems language that provides memory safety through a combination of a static checks embodied in the type system and ad hoc dynamic checks inserted where this analysis becomes impractical. The Morello prototype architecture from ARM uses capabilities, fat pointers augmented with object bounds information, to catch failures of memory safety. This paper presents a compiler from Rust to the Morello architecture, together with a comparison of the performance of Rust's runtime safety checks and the hardware-supported checks of Morello. The cost of Morello's always-on memory safety guarantees is 39% in our 19 benchmark suites from the Rust crates repository (comprising 870 total benchmarks). For this cost, Morello's capabilities ensure that even unsafe Rust code benefits from memory safety guarantees.

1 Introduction

Low-level programming entails delicate use of memory in a setting where common mistakes can lead to serious bugs and security vulnerabilities in critical code. *Memory safety* is the absence of these errors – where only correctly allocated regions of memory are accessed and freed. Unsafe uses of memory are the most critical software flaws today, they create security vulnerabilities, and they are widespread: out-of-bounds writes are the most dangerous security flaw in the Mitacs Common Weakness Enumeration [8]; Microsoft found that 70%

of the security bugs in Windows were as a result of unsafe use of memory [23]; and in the Chromium browser 36% of bugs are caused by use-after-free errors [33], with a further 33% stemming from other unsafe uses of memory [33].

It is possible to automatically enforce memory safety, avoiding all the attendant bugs and security flaws. This enforcement comes at a cost, however, and how exactly the cost is levied is a design choice. In this paper we compare the runtime performance of the mechanisms that enforce memory safety in *Rust* and in the *Morello* architecture, and ultimately combine them, improving the coverage of Rust's memory safety guarantee.

Rust provides a guarantee of memory safety to all well-typed code. Much of the cost of this guarantee is handled by a static analysis in the type system, but it also uses runtime checks when proving safety statically would be costly or impossible. One can forgo the safety guarantee and its checks by designating a block of code as **unsafe**: memory accesses within this block are not required to pass the full rigour of the type system. Unsafe code is used sparingly for interoperability with non-Rust components and for performance. **unsafe** annotations highlight code where memory errors can survive.

Rust alleviates memory errors in common code while remaining flexible enough to support systems programming through the provision of **unsafe** blocks. Rust imposes two costs: programmers must adhere to a more restrictive type system, and there are runtime costs to support the safety guarantee. The combination of safety, pragmatism, and performance is why Rust is now the official second language of the Linux kernel alongside C [24].

Morello is a prototype ARM processor that provides *capabilities*: fat pointers, augmented with permissions and bounds information. Morello processors use this metadata to enforce memory safety at run time, halting programs when safety is violated – for example if a program makes an out-of-bounds memory access. Programs that protect every memory access are described as *Purecap*, but one can forgo the safety checks by accessing memory in *Hybrid* mode. In contrast with Rust, full-scale systems programming is possible in Purecap mode: there are Purecap Morello ports of BSD, Linux and Android [34, 4, 3]. Programming in Purecap mode ensures memory safety from the first, albeit with the possibility of runtime errors where safety would otherwise be violated. Further development effort improves the stability of the system.

The safety guarantees provided by Rust and Morello are subtly different. Morello's capabilities track only approximate bounds information (see §2.3), recording the size of objects as a floating-point number; Rust applies compiler optimizations to the runtime checks that it emits, removing unnecessary checks and improving performance. Even so, Rust and Morello provide similar guarantees that may be used in a complementary way. Purecap-Morello will check pointers are used safely even in **unsafe** blocks, for example. This is where Rust and capability hardware mesh neatly, where Rust cannot validate the safety of memory use the underlying Morello hardware can.

In this paper we will explore the interplay between the Morello prototype hardware and the Rust programming language with a focus on runtime performance. We find the performance cost of always-on hardware memory safety checks to be quite high but not prohibitively so, and the design philosophies of Rust's static memory safety guarantees and Morello's dynamic memory safety to be well-matched. This comparison will also serve as a way to benchmark the real-world performance of improvements to the Morello architecture in the context of cutting edge memory-safe programming practices. We present the following contributions:

1. A Rust compiler that targets the Purecap- and Hybrid-mode Morello prototype capability hardware (§3).
 - This includes a reasoned choice for the semantics of `usize` on a machine where pointers are not just integers (§3.1).
2. A ported Rust standard library with fixes to incorporate capabilities (§3.6).
3. A performance analysis of Rust on Morello (§4, §5):
 - Our benchmark suite of 19 crates from the Rust crates repository (§4.6, Appendix A).
 - Analysis of the benefits of bounds checking elision on capability hardware (§5.1).
 - Comparison of Rust on Hybrid-Morello to Rust on Purecap-Morello (§5.2).
4. Our artefacts which will be made public upon publication.

2 Background

For a language to provide practical memory safety, it must present a usable interface to the programmer and have acceptable performance. *Memory safety* comes with a number of requirements:

- ① values must be initialized before reading, especially pointers,
- ② values must not be accessed after deallocation,
- ③ reads and writes must be within the bounds of an object’s memory allocation,
- ④ values must be deallocated exactly once.

There are a number of approaches to enforcing these requirements: from garbage collection as used by Java, Go, OCaml and many others; assorted static and dynamic validators – Rust is one such system, using linear types, lifetimes and dynamic bounds checking; and now hardware schemes like Morello.

2.1 Rust

Rust [21] is a relatively young programming language, version 0.1 was released in 2012 [27], and is notable for incorporating a number of features geared to providing memory safety, covering the desiderata above. Minimising runtime cost while providing powerful features to programmers is a central design aim for current Rust [35], so the majority of these features are applied statically during compilation. There are however still some cases where it is regarded as impractical to infer bounds statically.

The most relevant features to Rust’s memory safety are [18, 28]:

- uninitialised values are not normally¹ allowed ①;
- move semantics, the `Drop` trait, and references prevent access to deallocated values ②;
- array and slice indices are the only pointer arithmetic normally¹ available, and these are bounds checked at runtime ③;
- move semantics, the `Drop` trait, and careful API design protects against double free ④;
- move semantics and the `Drop` trait provide some protection against memory leaks by making the default behaviour that objects are freed when their lifetime ends ④, but can be defeated by functions like `std::mem::forget()` and `Box::leak()` and by other issues²;

The most important of these safety features is the combination of move semantics, the `Drop` trait, references, and lifetimes, which together provide much of Rust’s memory safety guarantees.

¹ In `unsafe` it is possible to break these conditions, but this is not the default.

² Reference counted pointers can leak if used improperly, and some edge cases in exception handling can cause `Drop` not to execute.

2.1.1 Move and Drop

The simplest way to allocate memory in Rust is to use the stack. This works much like C, with a value being allocated memory on entry to a block, and deallocated on exit when the stack frame is popped:

```
struct Data { a: i32, b: i32 }
fn automatic_memory() {
    // data automatically allocated on the stack here:
    let data = Data{a: 1, b: 2};
    // ...
    // data falls off stack here
}
```

Large values and data with a lifetime that doesn't match that of a scope require dynamic memory allocation, which in C would be provided via `malloc()` and `free()`. In Rust this is provided using a combination of move semantics and the `Drop` trait. `Drop` allows a type to provide a method that will be called automatically when an instance of it leaves scope, which means that memory allocations can be managed semi-automatically by so-called “smart pointers”. The simplest implementation of this in Rust is the standard library type `Box`, which allocates memory on the heap when instantiated and uses `Drop` to ensure that it will be deallocated when the `Box` leaves scope. The `Box` value itself acts as a handle, tracking the lifetime of the allocation and providing access to the allocated memory while remaining a technically separate value.

```
fn heap_memory() {
    // data allocated on the heap here:
    let data = Box::new(Data{a: 1, b: 2});
    // ...
    // Box falls out of scope here, heap allocation automatically freed
}
```

Move semantics expand the utility of this approach by allowing the `Box` to be moved to a different name or out of scope, while preventing it from being duplicated or deallocated, which might otherwise cause the allocation to be freed twice or left to leak [4](#).

```
fn inner_scope() -> Box<Data> {
    // data allocated on the heap here:
    let data = Box::new(Data{a: 1, b: 2});
    // ...
    data // data is moved out of the function here
}
fn moved_box() {
    // data moved to outer scope here:
    let data = inner_scope();
    // ...
    let new_name = data; // data moved to new_name here
    assert!(data.a == 1); // compiler error: use of moved value: `data`
    assert!(new_name.a == 1); // ok
    // data falls out of scope here, heap allocation automatically freed
}
```

`Box` covers a wide range of use cases, and the same general design can be used to build more complex, more powerful tools to cover more demanding problems. The standard library provides a number of options, including dynamically resizable arrays via `Vec`, and reference counted allocations via `Rc` using the same mechanism.

2.1.2 References and lifetimes

While move semantics and `Drop` cover many uses of dynamic memory allocation, values can only be in one place at a time, and the resulting passing around can quickly become inconvenient. The solution to this problem is Rust’s reference types. These behave similarly to ordinary pointers, but enforce extra rules that are checked by the compiler ¹:

- a reference must point to a value, i.e. there are no null references ①,
- values pointed to must be currently allocated and correctly aligned ①,
- a value can either be referenced once mutably, or multiple times immutably,
- values can only be mutated via a mutable reference ², and
- values cannot be moved or deallocated while referenced ②.

The compiler statically checks these rules using a system of inferred lifetimes, which allow references to be moved around and copied in non-trivial ways while maintaining safety. This concept has its roots in region-based memory management [14, 11], and it prevents access to values after deallocation while still providing power and flexibility ②.

In the example below, the two `&mut data` references are not permitted to have overlapping lifetimes. Rust infers that an object’s lifetime ends when the last reference to it goes out of scope – in this example, at the end of `referenced_box()`.

```
fn referenced_box() {
    // data allocated on the heap here:
    let mut data = Box::new(Data{a: 1, b: 2});
    // two immutable references exist during this call:
    use_data(&data, &data);
    // and two mutable references, which causes a compiler error:
    // cannot borrow `data` as mutable more than once at a time
    use_data(&mut data, &mut data);
    // reference only exists for duration of expression:
    *get_field(&mut data) = 3;
    // no references exist by here, so data freed without errors
}

fn get_field(data: &mut Data) -> &mut i32 {
    // compiler infers lifetime of return from argument
    &mut data.a
}

fn use_data(a: &Data, b: &Data) {
    assert!(a.a == b.a);
}
```

Dangling references, i.e. references to values which would be de-allocated at the end of a scope, are forbidden in Rust.

¹ Rust doesn’t currently have a formal specification, so the best sources for this information (besides the compiler source code) are the Rust Book [18] and the Rust Reference [28]

² Though this can be circumvented via a mechanism called “interior mutability”.

```
fn dangle() -> &u32 {
    let value = 0;
    &value
}
// this function's return type contains a borrowed value, but there is no
// value for it to be borrowed from
// help: consider using the `static` lifetime
```

Rust instead provides a mechanism for overriding the point at which a lifetime ends by explicit annotation:

```
fn dangle2<'a>() -> &'a u32 {
    let value = 0;
    &value
}
```

The *borrow checker* is the name of the machinery in Rust which statically detects invalid uses of references and keeps track of when objects' lifetimes end.

2.1.3 unsafe

Rust includes a mechanism that allows programmers to choose to break the rules described above. This is useful for performance-critical hand optimisation and working around the limitations of the compiler's static checking. Use of `unsafe` indicates that something odd is afoot, it should be used sparingly and serves as an explicit marker to signal to programmers and auditing tools alike that these pieces of code require additional scrutiny.

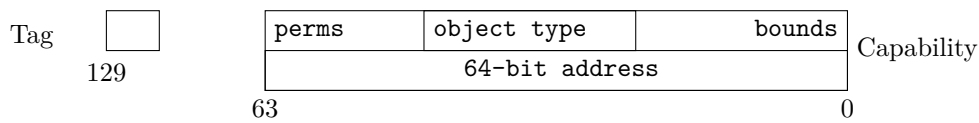

`unsafe` isn't a free pass to do anything – only a very specific set of extra privileges are available within these sections (see the Rust Book [18, §19.1]):

- ordinary C-like pointers called *raw pointers*, which don't have the limitations of references, can be dereferenced ~~1~~ ~~2~~ ~~3~~;
- functions and types marked `unsafe` can be used, allowing access to additional library APIs ~~1~~³ ~~2~~⁴ ~~3~~⁵ ~~4~~⁶;
- static variables can be accessed (which come with thread safety issues);
- traits marked `unsafe` can be implemented, automatically creating more `unsafe` code;
- unions can be accessed, which can be used to bypass type checking ~~1~~ ~~3~~;
- external C/C++ functions may be called, importing the memory safety concerns of those languages ~~1~~ ~~2~~ ~~3~~ ~~4~~.

In return, the programmer promises not to break any of the language's invariants.

The most important of these are the ability to use raw pointers and to call `unsafe` interfaces. Raw pointers are the most significant hole in the safety guarantees that Rust can provide, but *they are the primary point of compromise between full safety and a usable systems programming language*. Raw pointers are motivated by interoperability with non-Rust components, either through the operating system ABI or through linking C components into Rust programs, or Rust components into C programs. Raw pointers allow all the usual trickery, including creating them from integers, arbitrary arithmetic, null pointers, dangling

⁵ `slice::get_unchecked()`
⁶ `Box::from_raw()`

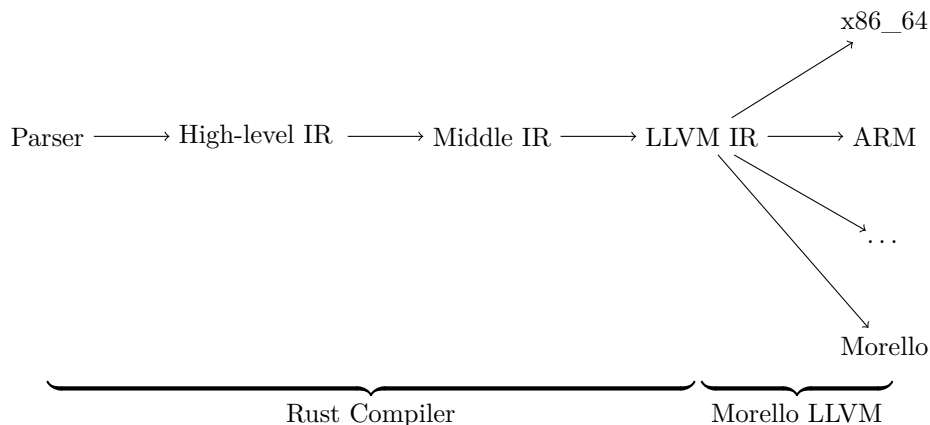

■ **Figure 1** The structure of a 128-bit capability.

pointers, freedom to cast between types, and so on. Access to `unsafe` interfaces enables use of a number of standard library features, notably `std::mem::transmute()`, which allows casting between any pair of types with the same size, and `std::mem::MaybeUninit`, which allows the creation of uninitialised values [\[1\]](#).

2.2 The Rust Compiler

The Rust compiler is mostly self-hosting, i.e. Rust is implemented in Rust. The front-end, type checking, middle intermediate representation (MIR), and an increasing number of optimisations are implemented in Rust. LLVM provides the backend and remaining optimisations, consuming LLVM IR and compiling to a range of targets including ARM and `x86_64`. This is all very convenient for porting Rust to Morello, as there is an existing LLVM implementation for Morello [20]. A sketch of the compiler’s structure is drawn below.

The majority of the compiler changes outlined in §3 are over the Middle IR portion of the compiler.

2.3 Capability hardware

CHERI is a generic instruction set extension to introduce *capabilities*, an extended pointer representation designed to add hardware security to memory accesses [36]. Capabilities add validity and permission information to pointers, expanding them to 128-bits on 64-bit platforms. Each capability is attached to a 1-bit *validity tag*, and this is required to be set to successfully perform memory accesses via the capability. Further, valid capabilities can only be constructed from other valid capabilities, and only in ways which don’t exceed the permissions of the parent capability. This property allows software to be separated into *compartments* which have limited, controlled access to one another.

Capabilities add four pieces of metadata to plain pointers: bounds, permissions, flags, and object type. An example of the structure of a 128-bit capability can be seen in Figure 1.

Bounds detail the range of memory which a capability is allowed to address; the hardware uses this information to perform automatic bounds checking. To be effective, the bounds of capabilities must be appropriately restricted to the object or buffer they point to. The

CHERI LLVM project extends the LLVM compiler infrastructure to do exactly this [20]. Most C and C++ programs, as well as a number of other languages with an LLVM backend, benefit because they automatically gain bounds checking with minimal to no modifications. It is worth noting, however, that CHERI's bounds checking has a limitation: to keep capability sizes reasonable, bounds information uses a floating point encoding. This means that bounds for larger regions become increasingly approximate, and marginally out of bounds accesses may succeed if regions are not padded to fill the extra space.

Permissions can be used to provide fine-grained read, write, execute, and capability manipulation protections for each capability.

Flags provide space for architecture-specific controls for each capability.

Object types are used as part of a mechanism to *seal* capabilities, such that they can only be dereferenced by specifically and deliberately chosen pieces of code. This opens up possibilities for compartmentalising programs and moving data and permissions through untrusted compartments without degrading security properties.

As a result of the requirement for capabilities to be derived from other valid capabilities, the provenance of each capability must be well-defined. This is a critical part of controlling the access rights of different parts of programs. For these limitations to hold, validity bits in uninitialised memory must be cleared before access is granted. This is expected to be provided by hardware or low level system software [37, §3.6.2]. This ensures that any uninitialised pointer will be invalid, and therefore impossible to dereference accidentally. The downside of the provenance property is that integer-to-pointer casts in existing code are likely to become invalid, though the changes needed to fix this are often minor. This is unsurprising given that integer-to-pointer casts are something of a headache for provenance analyses already [22].

Interpreted generously, bounds checking and provenance guarantees cover points ❶ (no use of uninitialised pointers) and ❸ (bounds checking) of §2. Research into ways that CHERI might be used to provide temporal safety guarantees is ongoing [39]. There is research investigating implementations of `free()` that can sweep the memory and invalidate any pointers into the free'd memory region [41] ❷. Even with temporal safety, memory leak bugs remain a problem to be solved by other tools ❹.

2.3.1 Morello prototype

Morello is a prototype platform for exploring capabilities, and is based on an application-class ARM SOC, the same sort that is found in modern smartphones and ARM-based personal computers. It is supported by a suite of open source software, including a C/C++ compiler based on LLVM [20], a FreeBSD port [34], and custom build automation tooling [9]. Software for Morello can be compiled in two different modes, both of which are supported by the CHERI BSD operating system we use [34].

Hybrid mode

In this mode of compilation, pointers are stored using a plain integer representation instead of capabilities, and normal ARM load and store operations are used to dereference them. Pointers are transparently restricted by the bounds of a single default capability provided by the operating system, with software running as if it were using normal ARM hardware. Rust code compiled with the non-CHERI compiler target triple `aarch64-unknown-freebsd` will run on CHERI BSD in this mode. While this mode is defined by the use of capability unaware load and store operations it is still possible to explicitly use capabilities, if the programmer desires and the facility is exposed by the language.

Purecap mode

In *pure capability* (Purecap) mode, all pointers are represented using capabilities, and capability instructions are used to access memory. Our modified compiler adds a new target triple to support this mode called `aarch64-unknown-freebsd-purecap`. This target configures the LLVM backend to emit capabilities instead of plain pointers, and the Rust compiler to use data layouts appropriate for capabilities. The details of the changes necessary to enable Rust for Purecap Morello are outlined in the next section.

Morello uses 128-bit capabilities, throws hardware exceptions if an invalid capability is dereferenced, and the maximum bounds size precisely representable is 4 KiB [1].

3 Adjustments to the Rust compiler and standard library

We describe the changes to accommodate capabilities in the Rust compiler. Recall that capabilities are 128-bit with one invisible tag bit which is maintained transparently by the hardware. To be able to use capabilities to represent pointers, a number of modifications to the compiler and standard library are necessary. Our port of Rust is based on release 1.56.0 (Edition 2021 Rust).

3.1 Rust semantics open question: `usize`

`usize` is an integer type, ambiguously defined by the documentation as the “[...] pointer-sized unsigned integer type.” [26] This is a straightforward definition on conventional architectures with integer pointer representations, but on Morello the meaning becomes unclear. There are two obvious interpretations for the semantics of `usize`:

- `usize` should be an integer and contain only an address, i.e. the lower word of a capability – a 64-bit number, or
- `usize` should behave like an integer and contain a whole capability, i.e. a Morello double-word sized 128-bit number.

We chose to explore the 64-bit approach for a number of reasons. First, the Rust community have sought to resolve this, and there are ongoing discussions that are leaning towards word-sized `usize` [31, 25]. Secondly, the previous work by Sim [32] explored 128-bit `usize` and was left with a handful of technical limitations which would be side-stepped by using machine-word-sized `usize`. Finally, there are several technical benefits to 64-bit `usize`, which we describe below.

Efficiency

`usize` is the only type of integer that can be used in array indexing, and is also used to represent lengths of arrays and sizes of types. These uses are very common, and only require that `usize` be able to represent the full range of addressable memory locations. In comparison, pointer-integer casts that would only function if `usize` stored a complete capability are rare. Making `usize` large enough to hold a capability would leave extra space that would be wasted in the vast majority of uses.

Robustness

While allowing `usize` to hold a valid capability would let simple pointer-integer-pointer round-trip casts work unmodified, it would also introduce inconsistent behaviour in many other cases. The tighter provenance model applied by CHERI invalidates capabilities derived only from integers, and also those produced by many arithmetic operations, including bitwise

39:10 Rust for Morello: Always-On Memory Safety, Even in Unsafe Code

logic. Given that bitwise logic is a common use case for integer-pointer casting, this would likely cause many unexpected capability faults. Ensuring instead that no `usize` can hold a valid capability guarantees that the compiler will always flag these cases, saving confusion and debugging time. This is traded against the cost of needing to make minor changes to simpler cases that might otherwise have worked unmodified, which we believe to be an acceptable sacrifice. Making this choice negates the major advantage of a 128-bit representation: being able to hold a valid capability.

Data compatibility

Under architectures currently supported by Rust, a cast from pointer to `usize` is expected to yield an integer containing the address being pointed to. Capabilities contain more information than this. Making `usize` a 64-bit integer containing only the address portion of the capability retains the expected behaviour.

3.2 Target specification

The Rust compiler has records of the size of various types for each platform it supports. This includes the size of pointers, which also decides the size of `usize`. To support Morello Purecap mode, the compiler needs more fine-grained information about the layout of pointers, and the size of `usize` needs to be decoupled from the in-memory size of pointers.

To do this, we have implemented *pointer width* and *pointer range*, where the compiler previously only had a single pointer size. Under mainstream architectures, these two values are all equal and redundant, but on Morello they are differentiated. *Pointer width* describes the in-memory size of pointers. Under Purecap, this will be the total size of a capability (128-bit), excluding the validity tag which is stored separately by the hardware. *Pointer range* describes the size of the address portion of pointers. Under Purecap, this will be the size of a plain pointer (64-bit), and the subset of a capability that contains the target address. Pointer range will also be the size of `usize`.

```
1 pub fn target() -> Target {
2     Target {
3         llvm_target: "aarch64-unknown-freebsd".to_string(),
4         pointer_range: 64,
5         pointer_width: 128,
6         data_layout: /* ... */,
7         arch: "aarch64".to_string(),
8         options: TargetOptions {
9             features: "+morello,+c64".to_string(),
10            llvm_abiname: "purecap".to_string(),
11            max_atomic_width: Some(128),
12            atomic_pointers_via_integers: false,
13            merge_functions: MergeFunctions::Disabled,
14            ..super::freebsd_base::opts()
15        },
16    }
17 }
compiler/rustc_target/src/spec/aarch64_unknown_freebsd_purecap.rs:3
```

■ **Figure 2** The Rust target options for the target triple `aarch64-unknown-freebsd-purecap`.

Information about a target is stored within the compiler using the structure shown in Figure 2. The target specification defines fundamental properties of the architecture and operating system. Morello inherits its base properties from the Aarch64 FreeBSD target, and then overrides some specifics. The new pointer entries can be seen on lines 4 and 5. Line 6 gives the standard data layout string describing the Morello architecture to LLVM, for brevity we do not expand on the details of this. For Purecap, this uses an extension specific to Morello LLVM [20] to specify that pointers be stored in address space 200, meaning that they should be represented using capabilities. Lines 9 and 10 specify the Purecap ABI, and are required to enable relevant features in Morello LLVM. Lines 12 and 13 disable some optimisations that are not yet compatible with Morello.

3.3 Constant evaluation

An unexpected source of problems for our changes to the compiler was Rust’s constant evaluation feature. Constant evaluation allows a subset of Rust expressions to be interpreted during compilation, as is demonstrated by the snippet below.

```

1  const MAGIC: u32 = long_multiply(3, 5)*7;
2  const fn long_multiply(a: u32, b: u32) -> u32 {
3      let mut a_shifted = a;
4      let mut b_shifted = b;
5      let mut result = 0;
6      while a_shifted != 0 {
7          if a_shifted & 1 == 1 {
8              result |= b_shifted;
9          }
10         a_shifted >>= 1;
11         b_shifted <<= 1;
12     }
13     result
14 }
```

This snippet contains only `consts`, and the compiler will fully evaluate the value of `MAGIC` at compile time. `long_multiply(3,5)` will be evaluated to 15, and then `MAGIC` will be evaluated to 105. The constant evaluator has an internal representation of memory so that it can run constant code even when it contains mutable values, as on lines 3, 4, and 5 of this example. Constant evaluation uses the same data layout as the rest of the compiler, and the subset of the language allowed includes support for pointers. Capabilities add extra non-address components to pointers, so constant evaluation must be modified to take these into account. While it might be possible to enforce the full set of capability rules during interpretation, we currently believe that Rust’s semantics already enforces them. For the time being we simply leave the unused space uninitialised, but the changes needed to the interpreter are still wide-reaching.

Values during interpretation can be represented either as large contiguous allocations, or single values represented directly⁷. Memory allocations are represented as arrays of data bytes, with auxiliary information about which bytes have been initialised. The compiler relies on type information to describe the structure of the data contained in the allocation.

⁷ Single values are handled separately as a performance optimisation.

39:12 Rust for Morello: Always-On Memory Safety, Even in Unsafe Code

Memory allocations themselves remain unchanged, the unused metadata bytes of capabilities are left uninitialised. References to subsets of memory allocations are passed around inside the compiler as the `AllocRange` type, so this must be extended to include width and range information. Without the extra information, the compiler does not know which bytes will be uninitialised metadata when operating on a referenced value. The extra information is also needed to allow conversion to types representing numeric values, which will need somewhere to inherit width and range information from. The modification to `AllocRange` is shown below.

```
pub struct AllocRange {
    pub start: Size,
    // Replacing: pub size: Size,
    pub range: Option<Size>,
    pub width: Size,
}
```

compiler/rustc_middle/src/mir/interpret/allocation.rs:75

Single numeric values are passed around as the types `Scalar` and `ScalarInt`. Because pointers are in some cases stored using these types, they must also carry width and range information. These changes are shown below.

```
pub enum Scalar<Tag = AllocId> {
    Int(ScalarInt),
    // Replacing: Ptr(Pointer<Tag>, u8),
    Ptr(Pointer<Tag>, u8, u8),
}
```

compiler/rustc_middle/src/mir/interpret/value.rs:124

```
pub struct ScalarInt {
    data: u128,
    // Replacing: size: u8,
    range: u8,
    width: u8,
}
```

compiler/rustc_middle/src/ty/consts/int.rs:122

The changes to the compiler to propagate and update the extra information on these three types are fairly simple, but very widespread, including changes to object layout, constant evaluation, and vtable construction.

3.4 Pointer code generation

Code generation for atomic pointers makes some unsound assumptions about pointers for the Morello platform. To work around the limitations of pointer operations on some targets, Rust generates code which casts the pointer to an integer – this is not permissible on Morello and yields capability faults at runtime. Thankfully, the fix here is simple: we have added an option to the target settings to disable this cast on the Morello target, which is shown in line 12 of Figure 2. The new option is then checked in the code generation pass, as shown below. On Morello, which supports 128-bit atomics, this avoids down-casting pointers to a pair of `isize` (64-bit) integers.

```
// Replacing: if ty.is_unsafe_ptr() {
if ty.is_unsafe_ptr() && bx.target_spec().atomic_pointers_via_integers {
    let ptr_llty = bx.type_ptr_to(bx.type_isize());
    ptr = bx.pointerCast(ptr, ptr_llty);
    val = bx.ptrtoint(val, bx.type_isize());
}
compiler/rustc_codegen_ssa/src/mir/intrinsic.rs:471
```

3.5 Tweaks to LLVM

The port of LLVM for Morello [20] is mature, and we have encountered few bugs.

Some LLVM optimisations currently cause incorrect code generation when compiling Rust for Morello, so we have disabled them until they can be debugged. The optimisations currently disabled are function merging, visible in line 13 of Figure 2; and the Scalar Replacement Of Aggregates optimisation, which requires minor changes inside LLVM.

We also encountered an edge case in LLVM code generation that caused 6 byte structures to be emitted as 96 bit integers, which then triggered a miscompilation. This ultimately lead to spurious capability faults during execution of affected parts of programs. While the underlying bug has now been fixed in upstream Morello LLVM [6], we found it could be worked around by padding affected structures to larger sizes.

The remaining adjustments that were needed were to the Rust standard library.

3.6 MPSC

Rust includes a large suite of tests for the compiler and libraries. Running the standard library tests on Morello has been our primary means of detecting code generation bugs and standard library compatibility issues. We had initially anticipated that the standard library would need many changes, given its size, low level nature, and need for performance. In actuality, we have so far only needed to make minor changes, and the modifications to the MPSC component are by far the most involved.

The Multi-Producer Single Consumer primitive in Rust (MPSC) is part of the standard library’s concurrency module, `std::sync`. It provides communication channel types that can pass objects between threads. The implementation of MPSC demonstrates exactly the sort of problem one might expect to see on Morello: pointers are passed between threads, but converted to integers and back as part of the trip. The same storage is also used to hold non-pointer signalling values. The problem stems from the code below which directly converts a `usize` into a pointer type (the type of `inner`).

This isn’t compatible with our changes to the compiler because the `usize` used by MPSC can no longer be used to carry a valid pointer, and the `usize` type is no longer the same size as a pointer. This causes casting to fail during compilation, but would still cause run time errors if it *did* compile. In CHERI C, one might use `uintptr_t`, but as no equivalent type is currently defined in Rust we have simply replaced the integer types with pointers. MPSC has no need to perform complex arithmetic or any other integer-specific operations, so this doesn’t create any problems. The signalling values can simply be cast into pointers before use, and because they should never be dereferenced it doesn’t matter that the resulting capabilities are invalid.

```
#[inline]
pub unsafe fn cast_to_ptr(self) -> *mut () {
```

39:14 Rust for Morello: Always-On Memory Safety, Even in Unsafe Code

```
// Replacing: pub unsafe fn cast_to_usize(self) -> usize {
    mem::transmute(self.inner)
}

#[inline]
pub unsafe fn cast_from_ptr(signal_ptr: *mut ()) -> SignalToken {
// Replacing: pub unsafe fn cast_from_usize(signal_ptr: usize) -> SignalToken {
    SignalToken { inner: mem::transmute(signal_ptr) }
}

library/std/src/sync/mpsc/blocking.rs:53
```

It is interesting to note that since our changes to MPSC for the port to Morello, very similar changes have happened upstream. The upstream changes are the product of work on pointer provenance in the MIR interpreter project (MIRI) [17].

3.7 FFI types

Rust's standard library makes use of the C standard library via a wrapper called `libc`. All use of C APIs from Rust requires a wrapper or *Foreign Function Interface*. In testing on Morello we found a number of incompatible type definitions, where the original API expected a pointer or pointer sized value, and the Rust wrapper declared the value to be `usize`. This is easy to fix by simply replacing the types appropriately. An example is drawn below, where we have replaced integer types with Rust pointer types.

```
pub type off_t = i64;
pub type useconds_t = u32;
pub type blkcnt_t = i64;
pub type socklen_t = u32;
pub type sa_family_t = u8;
// Replacing: pub type pthread_t = ::uintptr_t;
pub type pthread_t = *mut PThread;
pub type nfds_t = ::c_uint;
pub type regoff_t = off_t;

#[allow(missing_copy_implementations)]
pub struct PThread { _opaque: [u8; 0] }

library/libc-0.2.93/src/unix/bsd/mod.rs:1
```

There are likely to be interfaces not covered by tests that will require further work, we have taken a conservative approach to all the changes we have made in the compiler making the minimal alterations to get correct compilation of the tests we have. A different approach might be sensible here, where all `ptr_t` types should natively be Rust pointer types for Morello targets. It is not clear how significant the knock-on effects of this change would be on external libraries which expect integer semantics for C pointer types.

```
pub type size_t = usize;
pub type ptrdiff_t = isize;
pub type intptr_t = isize;
// TODO: Perhaps on Morello this should be `* ::c_void`
pub type uintptr_t = usize;
pub type ssize_t = isize;
```

```
pub type pid_t = i32;
pub type uid_t = u32;
pub type gid_t = u32;
pub type in_addr_t = u32;
pub type in_port_t = u16;
// Replacing: pub type sighandler_t = ::size_t;
pub type sighandler_t = *const ();
pub type cc_t = ::c_uchar;

library/libc-0.2.93/src/unix/mod.rs:19
```

4 Performance analysis methodology

We outline our method for measuring Rust programs running on the prototype Morello platform.

4.1 Test hardware

We are using the Morello Prototype hardware [2]. The Morello CPU is a 7nm quad-core “Neoverse N1” based Armv8-A processor clocked at 2.5 GHz, connected to 16 GiB of 2933 MT/s DDR4 memory. The firmware is updated to Release 1.3 [2]. The prototype is packaged as an ATX-style motherboard in a standard ATX computer case.

4.2 Operating system

As described earlier, we use the port of FreeBSD to Morello, called CHERI BSD [34]. CHERI BSD is very stripped back, with minimal system utilities running for network connectivity and multi-user support, making it ideal as a benchmarking platform. The operating system was compiled with the CTSRD port of LLVM for Morello [20] using the `cheribuild.py` utility [9].

4.3 Disabling bounds checking

Rust provides automatic checking of array accesses, ensuring that subscripting will be in-bounds. This covers a subset of the bounds checking provided by Morello, which checks the bounds of all pointer accesses. To compare Morello hardware bounds checking to the software bounds checking emitted by `rustc`, we added a code generation flag to the compiler which disables software bounds checking: `-C drop_bounds_checks`. This has the effect of making all array accesses the same as Rust’s `unsafe fn slice::get_unsafe()`. Enabling this option on normal hardware makes the compiler unsound, while on Purecap Morello soundness is mostly, though not entirely, restored by hardware bounds checking. Bounds checks on Morello are precise up to 4 KiB blocks of memory, becoming imprecise beyond that as a result of the floating point representation used to store bounds information. For the sake of the performance comparisons made in this paper, we think that this approach is reasonable to give some indication of the cost of bounds checks relative to the cost of CHERI extensions.

This method of disabling software bounds checking is similar to previous work on measuring the runtime cost of Rust’s safety checks by Zhang et al., although not identical [42].

39:16 Rust for Morello: Always-On Memory Safety, Even in Unsafe Code

```
fn bounds_check(
    &mut self,
    block: BasicBlock,
    slice: PlaceBuilder<'tcx>,
    index: Local,
    expr_span: Span,
    source_info: SourceInfo,
) -> BasicBlock {
    // We do return an un-modified access when the -C drop_bounds_check
    // flag is enabled
    let gcx = *self.tcx;
    if gcx.sess.opts.cg.drop_bounds_checks {
        return block
    }

    // Otherwise, generate MIR code to check the bounds of an access
    /* ... */
}
```

compiler/rustc_mir_build/src/build/expr/as_place.rs:666

Our modification adds an early return to the code generation of bounds checking assertions, which would normally be inserted when array subscripting. In Zhang's work they modify a later stage of code generation to disable the lowering of these assertions to LLVM IR, as well as assertions that check for integer-overflow. We ran benchmarks with both approaches and found similar results, but we present the results for tests with the modification listed above only, as we are not investigating the cost of integer-overflow checks on Morello.

4.4 cargo bench

We ported the standard Rust benchmarking infrastructure to Morello. Programs are cross-compiled on a normal Apple M1 or x86_64 system. Rust's infrastructure includes a remote test harness which sends binaries to a remote system under test using network sockets. We built a port of the receiving part of this software, called `remote-test-server` in C, which runs on the Morello prototype. We can then use the standard `cargo bench` command to orchestrate building and running tests, which runs benchmarks repeatedly and reports a time per iteration in nanoseconds, and the variance between runs in \pm nanoseconds. For each benchmark in the suite we produce four results to complete a comparison matrix by varying two parameters. The first parameter is the hardware mode which can be one of two values: Hybrid or Purecap, as described in §2.3.1, this is varied using the `--target` option and can be either `aarch64-unknown-freebsd` for Hybrid, or `aarch64-unknown-freebsd-purecap` for Purecap mode. The second parameter is the bounds checking mode, using our `-C drop_bounds_checks` compiler flag, which can be either: bounds checking disabled (Rust_{DBC}), or enabled (Rust).

For example the results below are produced by a test from the crate `hashbrown`. Time is in nanoseconds (ns).

<code>hashbrown-0.11.2/clone_from_large</code>				
	Rust		Rust _{DBC}	
	Time/iter	±	Time/iter	±
Purecap	15,779	8	15,818	59
Hybrid	15,557	53	15,601	16

Before each run in the test matrix, Rust and the Rust standard library is also recompiled with flags to enable/disable software bounds checking appropriately for Rust/Rust_{DBC}.

From this data, we calculate Relative Error (R_E) for each test using the formula below, and count the variance into several bins in Table 1.

$$R_E = \frac{\pm \text{time/iter (ns)}}{\text{Mean benchmark time/iter (ns)}}$$

For example, the R_E of Hybrid with bounds checking for `hashbrown-0.11.2/clone_from_large` is 0.34%. The benchmarks with high relative error are tests which are very fast running, and are limited by the measurement precision of `cargo bench` in nanoseconds.

4.5 Line counts

We include a count of the number of lines of code with the table of benchmarked projects in Appendix A. This is intended as a rough guide to the scale of the benchmarks. The table also includes a count of lines of `unsafe` code, as an indication of how much Morello’s safety guarantees might add to the soundness of the specimen code. Both counts are gathered using the `cargo count` tool [19]. In total across the 19 projects, there are 108k lines of Rust source of which 1041 are unsafe.

The lines of code count gives the number of non-blank, non-comment lines of Rust source code in the repository of each project, for every project we use a benchmark suite from. The lines of `unsafe` count gives the number of non-blank, non-comment lines inside `unsafe` blocks and `unsafe` functions.

It should be noted that both of these measures are approximate and meant as a guide only. The number of lines of code is given for the whole of each project repository, and will include the library code under test, the benchmark suite, and any additional tests and Rust build scripts present, but will exclude any code in dependencies (of which each project generally has several). The number of lines of `unsafe` is particularly approximate, for two reasons. Firstly, the effects of `unsafe` are not well quantified by counting lines of code; the impact of a single line in a frequently and widely called function may be much higher than a large `unsafe` block that executes only once during the lifetime of the program. Further, a single line of `unsafe` can call an arbitrary amount of external unsafe code through the foreign function interface. Secondly, there are some known edge cases in the counting tool that may cause slightly inaccurate counts [19].

4.6 Test suites

A full list of test suites is available in Appendix A. These were picked for having low-level implementations of fast data structures, and having a small set of external dependencies. The suites cover arithmetic, array computations, cryptography, data-structures, Fourier analysis, hashing, and graph algorithms. Each test was taken directly from the standard Rust package repository (<https://crates.io>) and checked out to a version which is compatible with our Rust compiler. Cargo will satisfy dependencies with the latest available package which meets the requirements, but frustratingly that doesn’t include the Rust edition, so

39:18 Rust for Morello: Always-On Memory Safety, Even in Unsafe Code

for several packages we had to pin dependencies at older compatible versions too. Our test script automatically collects repositories from Git, and applies the minor patches to the `Config.toml` to pin dependencies where necessary. In total there is a little over 108k lines of Rust source code in these suites, and plenty more in the dependencies. There are 870 individual benchmarks which are run for each of the four modes described above.

5 Results

■ **Figure 3** Performance analysis of Rust programs in each of the modes described in §4, normalised to Hybrid-mode.

We present the aggregate execution times of each mode of Rust on Morello in the table below. They are normalised to Hybrid mode with software bounds checking enabled. Lower numbers indicate higher average performance.

■ **Table 1** Count of benchmark relative error into categories.

Relative error	Count
0 – 1%	3300
1 – 5%	142
≥ 5%	38

	Rust	Rust _{DBC}
Purecap	1.39	1.38
Hybrid	1.00	0.99

Individual benchmark suite results are shown in Figure 3. Again, for each of our benchmark results, we normalise against Hybrid-mode Rust with the Rust compiler’s software bounds checks enabled. We then take the geometric mean of each mode to aggregate the normalised performance change of the benchmarks within a benchmark suite, *i.e.* **hashbrown**, which internally contains 41 benchmarks. Bars above 1.0 are slower than Hybrid Rust with software bounds checks enabled, bars below are faster. These numbers represent the change in performance versus Rust on a modern Aarch64 machine today. Rust on Purecap Morello is approximately 39% slower than Rust on the equivalent Aarch64 machine.

In this section we will contrast the cost of bounds checking on the software and hardware, and consider the types of workload whose performance is affected the most by hardware bounds checking.

5.1 The cost of software bounds checking

Toggling software bounds checks (Rust_{DBC} vs. Rust) makes minimal difference in the performance we observe in our benchmark suites. The performance is similar because compiler optimisations remove most unnecessary bounds checks from code before runtime, and the performance cost of what remains is extremely low. Note that we are dropping bounds checks as aggressively as possible, even dropping them where Morello would provide imprecise bounds (as discussed in §4.3) – so we have here an upper-bound on the performance gain achievable in a sound implementation of Rust. We therefore conclude that re-engineering the Rust compiler to drop bounds checks on Morello is without merit.

5.2 The cost of hardware bounds checking

By-and-large the cost of hardware bounds checking is very significant, with only **lebe** showing a negligible difference. The performance hit, though large, is still relatively small compared to other techniques for always-on bounds checking for arbitrary binaries – such as running a program under **valgrind** or **purify** [13, 10]. For many applications this 39% cost for running on Morello is acceptable, and will likely only improve with any future hardware designs. This does open an interesting point for future work: off-loading as much bounds-checking to software, ideally statically enforced, and maintaining hardware bounds-checks where these guarantees cannot be enforced by software alone, could provide performance *and* strong safety guarantees.

5.3 Benchmarks

We present the results aggregated by benchmark suite in Figure 3. This shows consistent slowdowns in Purecap modes, but reveals some variation depending on the workload. The worst slowdowns are in `arrayvec` and `smawk` which perform a substantial number of array accesses, maximally exercising the capability protections afforded by Purecap Morello. `lebe`, which does endianness conversions for integers, is unaffected by differences under Purecap Morello, or whether bounds checks are enabled or not. The story is similar for other arithmetic heavy crates, like `fixedbitset`; code that leans less heavily on memory access suffers the lowest performance hit when running on Purecap Morello.

5.4 Validity of results

We address potential concerns for the validity of our results, and how we believe we have mitigated these.

5.4.1 Prototype hardware

The Morello prototype is just that, a prototype. There are known issues with real-world performance characteristics of the first prototype when operating in Purecap mode, which are reflected in our performance analysis. When the details of these limitations are released, or when a future revision of the hardware is released (to which ARM have *not* committed themselves), re-running our performance analysis to see if the overhead of capabilities can be brought in-line with normal performance of Aarch64 would be of significant interest. The comparison to Hybrid-bounds in this section gives the clearest picture of the behaviour of a comparable Aarch64 machine with no hardware bounds checking: in Hybrid mode the Morello prototype allows regular loads and stores using 64-bit pointers. That being said, the implementation is still customised compared to normal Aarch64 and micro-architectural quirks might be present which mean this comparison is invalid compared to “wild” Aarch64 implementations. Table 1 shows that our measurements are precise and run-to-run variance is very small in the vast majority of benchmarks.

5.4.2 Choice of benchmark suite

We have used benchmark suites included with large popular projects from the Rust package repository `crates.io`, spanning a range of different applications: hashing and cryptography (arithmetic heavy); tree and graph like data structures (indirection heavy); and big integer and matrix operations (array heavy). This is different to previous approaches to measuring Rust runtime performance, notably in recent work by Zhang et al., where synthetic micro-benchmarks were used [42]. We have chosen to use benchmarks that test real world Rust code as this is more likely to give a representative picture of how the cost of bounds checking will be felt in regular Rust programs. We found some benchmarks (for example, `RustFFT` and `itertools`) would compile for Morello, but not run correctly on Purecap modes because of assumptions about pointers which are invalid in Purecap mode.

6 Related Work

In this section we discuss the context for Morello and the necessary related work that enabled us to build the Rust for Morello compiler.

6.1 Rust and type-safe systems programming

Rust itself has been a subject of significant academic research. On the topic of formally specifying Rust, notable work includes Rust Belt [16] and Oxide [38]. We are interested in the formal treatment of Rust, especially in the context of the formal specification of Morello, but for this paper we consider this to be future work.

Additionally, there has been a history of other attempts at designing safe systems programming languages which, like Rust, use some notion of lifetimes to manage memory allocation and prevent memory errors. Cyclone [14] is one such language, which uses type-level *regions* among other type-system machinery to ensure safety while still admitting low-level systems code. The specifics of preventing memory errors in safe systems programming languages is discussed more in §6.3.

6.2 Prior work porting Rust to CHERI

There is existing work that explores extending the Rust compiler to target CHERI MIPS hardware. Nicholas Sim’s MSc thesis [32] describes the initial steps of targeting CHERI in the Rust compiler. Crucially, Sim chose the 128-bit representation of `usize`, whereas we opted for 64-bit `usize` (discussed in §3.1). This has cascading effects on the rest of the compiler and leads to various issues.

A major concern of Sim was divergence from upstream, which we agree is a real consideration. The wording of the documentation does not make it totally clear how large `usize` should be on Morello, it states [29]:

`usize`

The pointer-sized unsigned integer type.

The size of this primitive is how many bytes it takes to reference any location in memory. For example, on a 32 bit target, this is 4 bytes and on a 64 bit target, this is 8 bytes.

There is clearly room for argument one way or the other. We are of the opinion that 64-bit `usize` on Morello is compatible with the spirit of this definition, Morello is a 64-bit platform with 64-bit addresses, so in order to range over all memory addresses it suffices for `usize` to be 64-bit. Conversely, supporting Sim’s initial choice, to reference a location in memory on Morello it is necessary to use a capability which is 128-bit.

Sim also reported a number of technical issues resulting from 128-bit `usize`, including performance problems, and the need for inserting integer-truncate and integer-extend operations when calling LLVM intrinsics like `memcpy` and `inttoptr`. We have not had to contend with these issues in our implementation, and agree with Sim’s assessment that 64-bit `usize` is preferable for this reason.

6.3 Bounds checking

There has been significant prior research on enforcing memory safety by preventing out-of-bounds accesses, either by statically proving accesses will be in-bounds, or by augmenting programs with dynamic bounds checking (or a combination of both).

A key result on statically eliminating bounds violations comes from Xi and Pfenning, who demonstrate that, with a *dependent type system*, array accesses may be accompanied by *proofs* that the computed index is within the array bounds [40]. This gives a compile-time guarantee that no bounds violations will occur on any array access, and thus safety can be maintained without the need for any dynamic checks. This was done in the context of a high-level, ML-like language, so there was no need to deal with gnarly C-like pointer arithmetic.

Prior work also explores static elimination of *some* bounds checking as a compiler optimisation. An optimising compiler or just-in-time compiler may seek to reduce the number of required bounds checks in a program by proving that some subset of accesses will always succeed. Early work demonstrated how this may be done with dataflow analysis [12]. This has been of particular interest to implementors working with the Java programming language, as the specification states that out-of-bounds array accesses must be caught at runtime, but bounds checks are not expressible in standard Java bytecode. To address this problem, lightweight techniques for eliminating some bounds checks at runtime within a Just-in-Time compiler have been developed [7].

In addition to minimising or eliminating bounds checks when compiling high-level languages like Java, there has been interest in enforcing memory safety in existing C and C++ programs. Doing automatic bounds checking in C or C++ is difficult because of the need to track, at run-time, what object each pointer value is intended to point to [15]. Unlike languages like Java, C and C++ allow programmers to do *pointer arithmetic* in order to compute (for example) an index into the middle of an array. These pointers into the interiors of objects may be written to a data structure or passed to a function within the application; in order to check the latter dereferencing of such pointers, it is necessary to keep track of the *intended referent* of the pointer as the pointer value flows through the program. There have been several approaches to solving this problem and preventing or catching out-of-bounds errors in existing systems code.

One heavyweight approach is *binary instrumentation*. Binary instrumentation tools like `purify` and `valgrind` are able to arbitrarily add metadata to pointers and detect a wide range of memory referencing errors [13]. Of course, as these tools are designed for debugging, they impose a significant runtime overhead that makes them impractical for use in production software. Additionally, `purify` can end up missing some memory safety violations if pointer arithmetic happens to yield a pointer to a different but still valid object.

Another approach involves changing pointer representations. Systems like SafeC [5] and Cyclone [14] use an extended pointer representation (“fat pointers”) to record information about the intended referent. These fat pointers work similarly to Morello’s capabilities, but their enforcement mechanisms are implemented in software rather than in hardware. SafeC and Cyclone allow for dynamic checking, but also produce code that is incompatible with external, unchecked code. A different approach, which maintains backwards compatibility with legacy C code, was proposed by Jones and Kelly: store the address ranges of live objects and ensure that pointer arithmetic never crosses out of the one object and into another valid object [15]. In this approach, address ranges are stored in a global table, and the table is referenced before every pointer arithmetic operation. Unsurprisingly, this introduces a large amount of overhead at run-time – over 5x overhead on many programs and, in subsequent work that extended this approach to cover a larger class of C programs, over 11x overhead [30]. Later work by Dhurjati and Adve demonstrated that the overhead of backwards-compatible array bounds checks in C could be drastically reduced by exploiting a fine-grain partitioning of memory called Automatic Pool Allocation [10].

7 Future work

The relationship between Rust and Morello seems clear, both aim to provide a programmer with guarantees that memory safety violations cannot happen in their programs. Rust achieves this through linear types, and runtime bounds checks, and Morello achieves this

through hardware pointer provenance and hardware bounds checking. It would be interesting to show a formal relationship between the semantics of Rust and the guarantees provided by Morello.

With the Morello prototype running in Hybrid mode it is possible to mix the use of capability instructions, where the hardware enforces bounds checking at run time, with normal load/store instructions. Through static analysis it might be possible to find the pointers in Rust which require runtime bounds checks and to promote those to capabilities on a per-pointer basis: thereby pushing bounds checks into hardware, rather than by emitting additional code. This could also be used to martial code in/out of unsafe components or through the FFI. Using capabilities to compartmentalise each `unsafe` block and each FFI call could bring new safety guarantees to Rust code which interacts with components that could introduce memory safety violations.

If ARM later commits to incorporating CHERI extensions into the ARM ISA at large, then incorporating the changes from our prototype Rust compiler into upstream Rust would be a natural extension of this work.

8 Conclusions

Morello provides a costly, but not impractical, means for achieving always-on memory safety. Like Rust, Morello has been built with the benefit of hindsight: memory safety is the most significant problem for building bug-free code. We have found that the overhead for Morello in this first prototype is around 39%, and elimination of Rust's bounds checks might yield a 1% speed up.

There is a two-way benefit for a programmer using Rust on Morello. When using safe Rust, a programmer knows that for all their safe code they cannot get a CHERI protection error which would cause their code to fault at runtime – unlike if they were to program in C. When using `unsafe` Rust, the programmer knows that if things do go terribly wrong, the Morello platform will protect them from memory errors which could cause security vulnerabilities.

The Rust for Morello compiler presented in this paper is fully featured. We have demonstrated the compiler works for a significant chunk of wild Rust code, without modification. In-all, the code we've compiled and run for Morello is around 108k lines of Rust, all from the Rust Crates repository, and all without modification to the Rust code.

This compiler forms the groundwork for future research into safe systems programming on hardware designed from the ground up to provide memory safety.

Abstract

Typestates are a notion of behavioral types that describe protocols for stateful objects, specifying the available methods for each state. Ensuring methods are called in the correct order (protocol compliance), and that, if and when the program terminates, all objects are in the final state (protocol completion) is crucial to write better and safer programs. Objects of this kind are commonly shared among different clients or stored in collections, which may also be shared. However, statically checking protocol compliance and completion when objects are shared is challenging. To evaluate the support given by state of the art verification tools in checking the correct use of shared objects with protocol, we present a survey on four tools for Java: VeriFast, VerCors, Plural, and KeY. We describe the implementation of a file reader, linked-list, and iterator, check for each tool its ability to statically guarantee protocol compliance and completion, even when objects are shared in collections, and evaluate the programmer's effort in making the code acceptable to these tools. With this study, we motivate the need for lightweight methods to verify the presented kinds of programs.

1 Introduction

In object-oriented programming, one naturally defines objects where their methods' availability depends on their internal state [49]. For example, the `next` method of an iterator can only be called if there are items to be retrieved, otherwise it throws an exception. One might represent their intended usage protocol with an automaton or a state machine [60, 61, 25]. **Behavioral types** [34, 3], when used for object-oriented languages, allow us to statically check if all code of a program respects the protocol of each object, helping us to write safer programs with fewer errors. The crucial properties verified are **protocol compliance**, ensuring methods are called in the correct order, and **protocol completion**, guaranteeing that if and when the program terminates, all the objects are in their final states, ensuring required method calls are not forgotten, and that resources are freed, for example, that we close all sockets. Bravetti et al. present a formal treatment of these properties [19].

In session types approaches, objects with protocols are usually forced to be used in a linear way to avoid race conditions, which reduces concurrency and restricts what a programmer can do [32, 34]. Given that **sharing of objects** is very common, it should be naturally supported, without putting too much burden on the programmer. For example, pointer-based data structures, like linked-lists, usually rely on internal sharing (i.e. aliasing). Such collections may also be used to store an arbitrary number of objects in different states which need to be tracked. Developing these data-types, and applications using them, is often challenging. To our knowledge, there is no typestate-oriented support for tracking the states of objects in collections, while ensuring protocol compliance and completion. Given this, the present study has the objective of answering the following research question (in Section 3.4)

RQ: *Are current static verification tools capable of verifying protocol compliance and completion even when objects are shared in collections?*

To study the contributions and limitations of the state of the art, we report our experience in verifying protocol compliance and completion with four tools for Java: VeriFast [39, 38], VerCors [33, 13], Plural [10], and KeY [1]. We picked these because of their rich features for verification, and because they are actively maintained (with the exception of Plural). We believe these cover the most used static analysis techniques which can be instructed to perform typestate verification. *VeriFast* checks programs annotated with method contracts written in **separation logic** [51, 55]. *VerCors*, however, uses **permission-based concurrent separation logic** to check programs, inspired by Chalice [44, 45]. *Plural* verifies that the protocols of objects are respected with **typestates** [59]. It introduces **access permissions** which combine typestate and object aliasing information, allowing state to be tracked and modified even when objects are shared, allowing for more uses beyond the “single writer vs multiple readers” model of fractional permissions [17]. *KeY* verifies sequential Java programs with specifications written in JML [43], based on first-order Java **dynamic logic** (JavaDL) [27]. It supports a great number of Java features and provides an interactive theorem prover with a high degree of automation and useful tactics to guide proofs. OpenJML is another verification tool based on JML [22]. Given that the differences [16] are not significant for our use case, and since KeY has an interactive prover, we focus our study on KeY.

To our knowledge, no such comparison study was previously done that focused on protocol compliance and completion. As we will observe, the running examples may look simple but constitute real challenges to these tools, especially since three of them are based on contracts, not behavioral types. Our conclusions support advocating for *lightweight verification methods* directed at these protocol related properties. The contributions of this paper are:

- Code **implementations** and **examples** of using file readers, linked-lists, and iterators (when possible), similar in all four tools, and **specifications** appropriate to each tool to verify the desired properties;
- An assessment if the tools can check **protocol compliance**, and if they can guarantee **protocol completion**, even with objects **shared in collections**;
- An evaluation of the **programmer’s effort** in making the code examples acceptable to each tool, justifying the need for lightweight methods to verify these kinds of programs.

With regards to our level of experience, we are knowledgeable in the concepts used, having applied them in different settings, and have had practical experience with VeriFast before conducting this study. Regarding the other tools, we report our experience in using them for the first time. To validate this study, our assessments were shared with the development teams. From the responses we got, they found the examples to be interesting and challenging. All the received feedback was very valuable in helping us to refine and confirm our conclusions.

This paper is structured as follows: Section 2 provides an overview of each tool; Section 3 presents **code implementations and specifications**, and if they were **accepted**, thus reporting our experience and answering the **RQ** (Section 3.4); Section 4 discusses our **assessments**; Section 5 discusses relevant work; finally, Section 6 presents our **conclusions**.

2 Background

2.1 VeriFast

VeriFast is a modular verifier for (subsets of) C and Java programs annotated with method contracts (pre- and post-conditions) written in **separation logic** [39, 38, 51, 55]. Besides the points-to assertions from separation logic, specifications support the definition of inductive data types, predicates, and fixpoint functions. Additionally, **deductive reasoning** [5] is supported via the definition of lemmas and the insertion of assertions in key program points to guide verification. Furthermore, it comes with an IDE allowing one to observe each step of a proof when an error is encountered. VeriFast is then able to statically check that contracts are respected during execution and that programs will not raise errors such as null pointer exceptions or perform incorrect actions such as accessing illegal memory. Nonetheless, VeriFast’s support for generics is still limited.¹

When declaring predicates, one may also specify **output parameters**. These appear after input parameters separated with a semicolon. Output parameters need to be precisely defined in the predicate definition and allow its user to “extract” them. In Listing 1, the parameter `b` is defined as an output parameter of the `account` predicate (line 1). It is precisely defined to be the value of the `balance` field of the account object. The `|->` symbol represents the points-to assertion while `&*&` represents the separating conjunction binary operator. This balance can then be “extracted” using the `?` symbol in a pre-condition (line 5), existentially quantifying the name `b`, which can then be mentioned in the post-condition (line 6), indicating the effect of a deposit given the current balance `b`.

■ **Listing 1** Output parameters example.

```

1 //@ predicate account(Account a; int b) = a.balance |-> b &*& b >= 0;
2 class Account {
3     int balance;
4     void deposit(int value)

```

¹ <https://github.com/verifast/verifast/issues/271>

40:4 On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage

```
5     //@ requires account(this, ?b) &*& 0 < value;
6     //@ ensures account(this, b + value);
7     {
8         balance += value;
9     }
10 }
```

For the sharing of memory locations, VeriFast has built-in support for **fractional permissions**, associating a number coefficient between 0 (exclusive) and 1 (inclusive) to each heap chunk [17]. By default, the coefficient is 1, which allows reads from and writes to a memory location. A number less than 1 allows only for reads. The programmer may provide coefficient patterns in the form of expressions, such as literal numbers or variables, or in the form of existentially quantified names (like *f* in line 2 of Listing 2). These patterns may be applied to points-to assertions but also to predicates. Applying a coefficient to a predicate is equivalent to multiplying it by each coefficient of each heap chunk mentioned in the predicate's body. Additionally, VeriFast supports the automatic splitting and merging of fractional permissions. Counting permissions are also supported via a trusted library [17].

■ Listing 2 Coefficient pattern example.

```
1 int getBalance()
2     //@ requires [?f]account(this, _);
3     //@ ensures [f]account(this, result);
4     { return balance; }
```

For C programs, VeriFast also supports leak checking: after consuming post-conditions, the heap must be empty. However, the programmer can leak certain resources with the `leak` command. For Java programs, leaking is always allowed.

2.2 VerCors

VerCors is a verifier for concurrent programs written in Java, C, OpenCL and PVL (Prototypal Verification Language), and annotated with method contracts [33, 13]. The specifications employ a logic based on **permission-based concurrent separation logic** [50]. The verification procedure is modular, checking each method in isolation given a contract with pre- and post-conditions. As in VeriFast, lemmas can be defined and assertions introduced to guide verification. Although there are other tools that perform static verification on annotated programs, VerCors focuses on supporting different concurrency patterns of high-level languages, and is designed to be language-independent. Support for inheritance and exceptions is still being worked upon based on theoretical work by Rubbens [56].² Internally, VerCors uses the Viper backend [48], which in turn uses Z3 [23].

VerCors supports two styles for specifying access to memory locations: **permission annotations**, following the approach of Chalice [44, 45]; and **points-to assertions** of separation logic, as in VeriFast. Both styles of specification have been shown to be equivalent by Parkinson and Summers [53]. The equivalence is presented in Figure 1. On the left-hand-side it is shown the use of a permission annotation, `Perm`, to request access to variable `var`, with fractional permission `p`, and storing a value equal to `val`. The `**` symbol represents the separating conjunction operator. On the right-hand-side it is shown the equivalent `PointsTo` assertion. Permission annotations are very useful because they allow us to refer to values in variables without the need to use new names for them.

² <https://vercors.ewi.utwente.nl/wiki/#inheritance-1>

```
Perm(var, p) ** var == val ≡ PointsTo(var, p, val)
```

■ **Figure 1** Permission annotations equivalent to points-to assertions.

As an example, List. 3 shows a method contract which requires exclusive permission to write in field `val` (line 2), and ensures that the new value is equal to the old one incremented by one (line 3).

■ **Listing 3** Permissions example.

```
1  /*@
2   requires Perm(val, 1);
3   ensures Perm(val, 1) ** val == \old(val) + 1;
4  */
5  void increment(){
6   val = val + 1;
7  }
```

VerCors also has support for **ghost code**, including ghost parameters and results in methods. These are declared in methods' contracts with the `given` and `yields` keywords, respectively. When calling a method, one uses the `with` and `then` keywords to assign ghost parameters and retrieve return values, respectively. These features are exemplified in Listing 4 where a `sum` method yields a ghost result given two ghost parameters, `x` and `y`. Line 13 shows how this method may be used. Ghost code is useful to keep track of intermediate results, which only exist for the purpose of verification.

■ **Listing 4** Ghost code example.

```
1  /*@
2   given int x;
3   given int y;
4   yields int res;
5   ensures res == x + y;
6  */
7  void sum() {
8   /*@ ghost res = x + y;
9  }
10
11 void main() {
12   sum() /*@ with {x=3; y=2;} then {result=res;} @*/;
13 }
14 }
```

2.3 Plural

Bierhoff and Aldrich addressed the problem of substitutability of subtypes while guaranteeing **behavioral subtyping** in a object-oriented language [9]. The specification technique models protocols using abstract states, incorporating *state refinements* (allowing the definition of substates, thus supporting substitutability of subtypes), *state dimensions* (which define orthogonal states corresponding to AND-states in Statecharts [28]), and *method refinements* (allowing methods in subclasses to accept more inputs and return more specific results). The approach is similar to pre- and post-condition based ones but provides better information hiding thanks to the **typestate** abstraction [59].

Bierhoff and Aldrich then built on previous work and developed a sound modular protocol checking approach, based on typestates, to ensure at compile-time that clients follow the usage protocols of objects even in the presence of aliasing [10]. For that, they developed the

40:6 On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage

notion of **access permissions** which combine typestate and object aliasing information. The approach was realized in Plural, a static verifier they developed for Java, as a plugin for Eclipse. As far as we know, not all Java's features are supported, such as exceptions. Although it is not maintained any longer, one can install it in Eclipse Juno (an old version from 2012) from its source. Given its support for rich access permissions, and direct application of the typestate abstraction, we believe its study is still very relevant.

An *access permission* tracks how a reference is allowed to read and/or modify the referenced object, how the object might be accessed through other references, and what is currently known about the object's typestate. To increase the precision of access permissions, Bierhoff and Aldrich introduced *weak permissions* (such as *share* and *pure*), where an object can be modified through other permissions. The proposed permissions include a *state guarantee* which ensures that an object remains in that state even in the face of interference. Additionally, they track *temporary state assumptions* which are discarded when they become outdated. All kinds of permissions are described in Table 1. A comprehensive survey on permission-based specifications was presented by Sadiq et al. [57].

■ **Table 1** Permissions in Plural.

Kind	Access to the referenced object	Access other aliases may have
Full	read and write	read-only
Pure	read-only	read and write
Immutable	read-only	read-only
Unique	read and write	none
Shared	read and write	read and write

In Listing 5 is an example of an iterator. In lines 1-3, it is stated that this object may be in two distinct states, **available** or **end**. These are defined as refinements, or subtypes, of the root state **alive**, a state common to all objects. Then it is specified that the **hasNext** method may be called in the **alive** state with just **pure** permission (line 5). If the method returns **true**, we further know that the iterator is in the **available** state, allowing us to refine our knowledge (line 6). Otherwise, the iterator is in the **end** state (line 7). The **next** method requires **full** permission and that the object be in the **available** state, and then it can only ensure it is in the **alive** state (line 10).

■ **Listing 5** Iterator example.

```
1 @Refine({
2   @States(value={"available", "end"}, refined="alive")
3 })
4 interface Iterator<E> {
5   @Pure("alive")
6   @TrueIndicates("available")
7   @FalseIndicates("end")
8   boolean hasNext();
9
10  @Full(requires="available", ensures="alive")
11  E next();
12 }
```

These kinds of permissions may be split to allow sharing of an object, and joined back together to allow one to potentially restore *unique* permission. **Fractional permissions** are used to track how much a permission was split [18]. Furthermore, different fractions can be mapped to different state guarantees through a *fraction function*, thus tracking for each state guarantee separately how many other permissions rely on it.

Beckman et al. extended the approach to verify the correctness of usage protocols in concurrent programs, statically preventing races on the abstract state of an object as well as preventing violations of state invariants [7]. This approach uses atomic blocks and was also realized in Plural. In this solution, access permissions are used as an approximation of the thread-sharedness of objects. For example, if *pure* or *share* permissions are used, it means that other references can modify the object, and it is assumed that this includes concurrent modifications. In this scenario, temporary state assumptions are discarded, unless the access is synchronized. Furthermore, accessing fields of an object with *share*, *pure*, or *full* permissions, must be performed inside atomic blocks.

Beckman later presented a similar approach which uses synchronization blocks instead of atomic blocks as the mutual exclusion primitive, given that the former are in more wide use [6]. Since programmers are required to synchronize on the receiver object, it becomes implicit to the analysis which parts of the memory are exclusively available, so programmers are not required to specify which parts of the memory are protected by which locks. However, this also implies that private objects cannot be used for the purposes of mutual exclusion.

2.4 KeY

KeY is a verifier for sequential Java programs [1]. Specifications are provided in Java comments in JML*, an extension of the Java Modeling Language (JML) [43]. JML is based on the design by contract paradigm with class invariants and method contracts [46]. Class invariants describe properties that must be preserved by all methods. Method contracts are composed by pre-conditions, post-conditions, and frame conditions, indicating the heap locations which a method may modify. With this, KeY can employ modular verification.

The example in Listing 6 uses a specification technique based on **dynamic frames** [40] and is adapted from the *Cell* example by Smans et al. [58]. The cell's specification starts by declaring a set of locations called `footprint` (line 4) composed only by the `x` field (line 6). The `accessible` annotation (line 5) specifies that the set `footprint` will only change if a location in the set mentioned on the right-side of the colon changes. In this case, `footprint` is constant. Then an invariant is stated (line 9) and it is specified that it only depends on locations in `footprint`. The `setX` method will not throw exceptions (indicated with the `normal_behavior` annotation in line 12), it assigns only to locations in the `footprint` (line 13), requires the parameter to be positive (line 14), and ensures the next call to `getX` will return the given value (line 15). Since it does not perform reads from heap locations, the `accessible` annotation is omitted.

■ Listing 6 JML specification example.

```

1  class Cell {
2      private int x;
3
4      /*@ model \locset footprint;
5         @ accessible footprint: \nothing;
6         @ represents footprint = x;
7         @*/
8
9      //@ invariant x > 0;
10     //@ accessible \inv: footprint;
11
12     /*@ normal_behavior
13        @ assignable footprint;
14        @ requires value > 0;
15        @ ensures getX() == value;
16        @*/

```

```

17 void setX(int value) {
18     x = value;
19 }
20 }

```

As far as we know, KeY is the verification tool that supports the greatest number of Java features among the other static verification tools for Java, allowing one to verify real programs considering the actual Java runtime semantics. This includes reasoning about inheritance, dynamic method lookup, runtime exceptions, and static initialization. A consequence of this is that, as the members of the KeY team point out, KeY is not overly suitable for the verification of algorithms that require abstracting away from the code since KeY's main goal is the verification of Java programs [20].

KeY's is based on an interactive theorem prover for first-order Java dynamic logic (JavaDL) [27], which can be seen as a generalization of Hoare logic [30]. An important part in the construction of proofs in KeY is symbolic execution. This process takes every possible execution branch and transforms the program leading to a set of constraints, which can then be verified against the specification. KeY provides a semi-automated environment where the user may choose to apply every step of the proof, apply a strategy macro, combining several deductive steps, or execute an automated proof search strategy. As well as offering a high degree of automation, KeY supports SMT solvers, such as Z3 [23], which are often useful to solve arithmetical problems [20]. More details on how to use KeY may be found online.³

The most common strategy macros, which we have significantly used in our experiments, are: propositional expansion (to apply propositional rules); finish symbolic execution (to apply only rules for modal operators of dynamic logic, thus executing Java programs symbolically); close provable goals (automatically close all goals that are provable, but do not apply any rules to goals which cannot be closed).

3 Experiments

In this section, we start by giving an overview of the examples that are going to be used, showing the object usage protocols and their implementations, as well as, client code using the presented objects (in Section 3.1). The code is in Java, a language supported by all the aforementioned tools, which given its object-oriented nature, is well-suited for building objects with protocol where method calls act like transitions of a state-machine.

Then in Sections 3.2 and 3.3, the common Java code for the classes is annotated with the appropriate specification for each tool capturing the intended object protocols.

Finally, in Section 3.4, we present annotated client code which uses the object code defined before, and answer the **RQ**: can the tools check protocol compliance and completion, even when objects are shared in a collection?

All code implemented is available online. Throughout the text, hyperlinks in blue point directly to the lines of code relevant to what is being discussed in order to help the reader and to avoid the need to download code. Nonetheless, crucial code parts are presented in listings and discussed in detail. Additionally, a thorough discussion of the implementation is also online for the interested reader.

³ <https://www.key-project.org/docs/UsingKeyBook/>

3.1 Running examples

In this study, the main objects with protocol we consider are file readers. Their usage protocol is shown in Figure 2. Circles represent states, arrows denote transitions performed by method calls, and diamonds represent a decision based on the return value of the preceding call. The initial state is marked with an incoming arrow without an outgoing state. The final state is marked with a thicker border. We refer the reader to [60, 61] for more information about this kind of automata, called *Deterministic Object Automata*, and a tool generating those.

■ **Figure 2** File reader's protocol.

According to the file reader's protocol, the `open` method must be initially called. Then, one must call the `eof` method to check if the end of the file was reached. While it returns `false`, `read` calls are allowed. Otherwise, the whole file was read and the `close` method needs to be called to terminate the protocol. A usage example of a file reader exhibiting protocol compliance and completion is shown in Listing 7.

■ **Listing 7** FileReader's usage example.

```

1 FileReader f = new FileReader("file.txt");
2 f.open();
3 while (!f.eof()) {
4   f.read();
5 }
6 f.close();

```

To track the number of bytes still available to be read, the reader has an internal `remaining` field. Additionally, we may use a `state` field to track the current state of the object. This may be seen as unnatural and superfluous, but when there is no primitive notion of `typestates` in the language, it is unavoidable. One example of this encoding of protocols being employed is in the `Casino` contract presented in the `VerifyThis` event.⁴ Exemplifying code is presented in Listing 8. Assume that methods prefixed with `file_` perform actions on the file system. Please note that in the tool specific implementations, files are not actually read, so as to simplify the code for demonstration purposes.

■ **Listing 8** FileReader's code.

```

1 class FileReader {
2   String filename; State state; int remaining;
3
4   FileReader(String name) {
5     filename = name;
6     state = INIT;
7   }

```

⁴ <https://verifythis.github.io/casino/>

40:10 On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage

```
8
9 void open() {
10     assert (state == INIT);
11     remaining = file_size(filename);
12     state = OPENED;
13 }
14
15 boolean eof() {
16     assert (state == OPENED);
17     return remaining == 0;
18 }
19
20 byte read() {
21     assert (state == OPENED && remaining > 0);
22     remaining--;
23     return file_byte_read(filename);
24 }
25
26 void close() {
27     assert (state == OPENED && remaining == 0);
28     file_close(filename);
29     state = CLOSED;
30 }
31 }
```

After implementing and specifying the file readers, we implement a collection to store these. The challenge is then to verify the collection and statically track the different states of the stored file readers, while ensuring protocol compliance and completion.

For our collection, we implement a singly-linked-list, meaning that each node has a reference only to the next node. This list has two fields: `head` and `tail`. The former points to the first node, the latter points to the last node, as it is commonly implemented in imperative languages. Items are added to the `tail` and removed from the `head`, following a FIFO discipline. Having a `tail` field is crucial for efficiency, avoiding the need to iterate all the nodes before adding a new node to the end. Code for it is presented in Listing 9.

■ Listing 9 Linked-list's code.

```
1 class Node<T> {
2     T value; Node next = null; Node(T v) { value = v; }
3 }
4
5 class LinkedList<T> {
6     Node<T> head = null; Node<T> tail = null;
7
8     void add(T value) {
9         if (head == null) {
10             head = tail = new Node(value);
11         } else {
12             tail.next = new Node(value);
13             tail = tail.next;
14         }
15     }
16
17     T remove() {
18         assert (head != null);
19         T value = head.value;
20         if (head == tail) {
21             head = tail = null;
22         } else {
23             head = head.next;
24         }
25         return value;
26     }
27 }
```

```

27
28   boolean isEmpty() { return head == null; }
29
30   LinkedListIterator<T> iterator() {
31       return new LinkedListIterator(head);
32   }
33 }

```

We believe implementing a linked-list is particularly relevant for a number of reasons. Besides being a very common data structure, and quite simple in nature, its use of pointers often creates challenges for type systems without support for *deductive reasoning*. For example, in a type system with a strict ownership discipline, it is difficult to deal with the aliasing between the `tail` field and the second to last node's `next` field.⁵ Additionally, matching the concrete structure of the collection (i.e. the linked nodes) with the abstract representation, to be able to track the states of the stored objects, usually requires ghost code and (again) deductive reasoning, as we will observe.

Although the number of values stored in the linked-list is arbitrary, we can define a finite protocol (Figure 3) that over-approximates the possible states: the list may be empty, which means that we are only allowed to add new values; or the list may be not empty, which means that we can also remove at least one value.⁶ With just these two states it is unknown if the list becomes empty or not after removing a value, so we need to encode this uncertainty with an additional state and use the `isEmpty` method to check the emptiness of the list.

■ **Figure 3** List's protocol.

Similarly, we can define a protocol for an iterator over the linked-list (Figure 4) with three states: one indicating that there are values to retrieve with the `next` method, another to specify that we reached the end of the list, and finally, a state to encode the uncertainty between the previous two, where the `hasNext` method may be used to check if there are still values to return. Code for the iterator is presented in Listing 10.

■ **Listing 10** Iterator's code.

```

1   class LinkedListIterator<T> {
2       Node<T> curr;
3       LinkedListIterator(Node head) { curr = head; }

```

⁵ For instance, in Rust, the ownership discipline prevents one from creating linked-lists, unless `unsafe` code is used. `GhostCell`, a recent solution to deal with this, allows for internal sharing but the collection itself still has to respect the discipline [62]. It uses `unsafe` code for its implementation but was proven safe with separation logic.

⁶ Context-free session types can be used to describe protocols which are not limited by the expressiveness of regular languages [2].

40:12 On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage

■ **Figure 4** Iterator's protocol.

```
4
5  boolean hasNext() {
6      return curr != null;
7  }
8
9  T next() {
10     assert (curr != null);
11     T value = curr.value;
12     curr = curr.next;
13     return value;
14 }
15 }
```

An example combining the three classes is shown in Listing 11. In this example, a number of file readers in their initial state is added to the list (line 6). This collection is then passed to the auxiliary method `useFiles` (line 7) which iterates through all the readers and, for each one, follows their protocol to the end. The properties of protocol compliance and completion hold for this program example.

■ **Listing 11** Usage example in code.

```
1  void main() {
2      LinkedList list = new LinkedList();
3      FileReader f1 = new FileReader("a");
4      FileReader f2 = new FileReader("b");
5      FileReader f3 = new FileReader("c");
6      list.add(f1); list.add(f2); list.add(f3);
7      useFiles(list);
8  }
9
10 void useFiles(LinkedList<FileReader> list) {
11     LinkedListIterator it = list.iterator();
12     while (it.hasNext()) {
13         FileReader f = it.next();
14         f.open();
15         while (!f.eof()) f.read();
16         f.close();
17     }
18 }
```

We will now report on our experience with each tool detailing the specification and proof effort required, keeping the issues of protocol compliance and completion in mind. In summary, we successfully verify the file reader class (Listing 8) and its use (Listing 7) in all four tools. The linked-list and iterator implementations (Listing 9 and 10), as well as their usages (Listing 11), are accepted by all except Plural. Protocol completion can be guaranteed with workarounds in all tools except Plural.

3.2 File reader specification

VeriFast

To implement the file reader, we use pre- and post-conditions in all public methods indicating the required and the ensured states after the call (example in List. 12). The fields of this object are `state` (to keep track of the current state), and `remaining` (to keep track of the number of bytes still to read). Every time the state needs to change, we assign to the `state` field. We use constants to identify different states, thus avoiding the use of literal numbers in specifications. To request access to the fields of the object, and to enforce that `remaining` is equal to or greater than zero, we define the `filereader` predicate.

■ **Listing 12** `close` method in VeriFast.

```

1 public void close()
2     //@ requires filereader(this, STATE_OPENED, 0);
3     //@ ensures filereader(this, STATE_CLOSED, 0);
4 {
5     this.state = STATE_CLOSED;
6 }

```

VerCors

The implementation in VerCors is very similar to the one in VeriFast, except for these differences: we do not define a predicate to abstract the contents of the object (instead we keep access to the fields exposed for practical reasons); and since VerCors supports ghost fields, we use one to track the state, using numbers to represent each state.

Plural

Given the support for tpestates, we directly define three states, *init*, *opened*, and *closed*, which refine (i.e. define a substate of) the root state `alive`, a state in which all objects are in. Additionally, we define two states, *eof* and *notEof*, refining *opened*, indicating if we have reached or not the end of the file, respectively. The file reader has a boolean field, `remaining`, indicating if there is something to read. To enforce the relation between the states *eof* and *notEof*, and the `remaining` field, we define invariants for these states. Due to a limitation, we had to simplify the `read` method, making it read the file all at once.⁷ To enforce the protocol, we declare for each method the required and ensured states as well as the permissions needed to perform each call. The `open`, `read`, and `close` methods require `unique` permission to the receiver object. *Full* permissions would be enough except for the possibility of concurrent accesses, which would require methods to be `synchronized`. The `eof` method only needs an *immutable* permission guaranteeing that we are in the *opened* state, and returns a boolean value indicating if the end of the file was reached.

KeY

We also model the protocol with pre- and post-conditions in methods. The state is tracked using an integer ghost field. As in VeriFast and VerCors, `remaining` stores the number of bytes left to read, and we enforce the value to be equal or greater than zero with an

⁷ Ideally, `remaining` would store an integer, but the syntax `remaining == 0` does not seem to be supported in the invariants. In consequence, we cannot model the arbitrary number of bytes to read.

40:14 On Using VeriFast, VerCors, Plural, and KeY to Check Object Usage

invariant. The file reader has a footprint, composed by the `state` and `remaining` fields, and each of its methods specifies which fields may be modified, according to the dynamic frames technique [40]. To verify this class, we have to prove each method correct, according to each specification, and the fact that nothing changes the footprint. Given its simplicity, all proofs were automatically done using KeY's default strategy.

Evaluation

As expected, we successfully modelled a protocol for a file reader in all four tools: in Plural, the implementation was mostly straightforward given the support for tpestates, but annotations were required in all methods; in VeriFast, VerCors, and KeY, we used method contracts, which also required some annotation burden. Thus, we motivate the need for more natural ways to specify protocols, for example, via automata, which helps the programmer visualize and design the protocol.

3.3 Linked-list and iterator specifications

VeriFast

The linked-list implementation is adapted and extended from a C implementation available online. One key difference from the aforementioned C code is that when the linked-list is empty, the `head` and `tail` fields have `null` values, instead of pointing to a dummy node. This matches common implementations and makes verification more challenging because we have to avoid null pointer errors.

To model the structure of the list, we define a predicate that holds access to the `head` and `tail` fields and of all the nodes in the list (List. 13). The only input parameter is the reference to the linked-list. The output parameters are the references to the head and tail, and a ghost list to reason about the values in the list in an abstract way (line 1). This ghost collection will be crucial to track the different states of the file readers stored in the list. Lines 3 and 4 ensure that if one of the fields is `null`, the other is also `null`, and the list is empty. To ease the addition of new elements to the list, we request access to the sequence of nodes between the head (inclusive) and the tail (exclusive), through the `lseg` predicate, and then keep access to the tail node separately (line 5). The `node` predicate holds the permissions to the `next` and `value` fields of a given node. Note that we do not hold permission to the fields of the values stored. This is to allow them to change independently of the linked-list.

■ **Listing 13** `l1ist` predicate in VeriFast.

```
1 predicate l1ist(LinkedList obj; Node h, Node t, list<FileReader> list) =
2   obj.head |-> h &&& obj.tail |-> t &&&
3     h == null ? t == null &&& list == nil :
4     t == null ? h == null &&& list == nil :
5     lseg(h, t, ?l) &&& node(t, null, ?value) &&&
6     list == append(l, cons(value, nil)) &&& list != nil;
```

The implementation of the `remove` and `isEmpty` methods is straightforward requiring only the unfolding and folding of the `l1ist` and `lseg` predicates a few times. The `add` method requires an auxiliary lemma (List. 14) stating that if we have a sequence of nodes plus the final node, and we append another node in the end, we get a new sequence with all the nodes from the previous sequence, the previous final node, and then the newly appended node.

■ **Listing 14** `add_lemma` lemma in VeriFast.

```
1 lemma void add_lemma(Node n1, Node n2, Node n3)
2   requires lseg(n1,n2,?l) &&& node(n2,n3,?value) &&& node(n3,?n4,?v);
3   ensures lseg(n1,n3,append(l,cons(value,nil))) &&& node(n3,n4,v);
```

To implement the iterator, we define a `iterator` predicate which holds access to the current node field and all the nodes in the linked-list. Then, we split the permissions to the nodes in two parts (List. 15): half of the permissions preserves the structure of the list (line 4), and the other half holds the view of the iterator (line 5): a sequence of nodes from the head (inclusive) to the current node (exclusive); and a sequence from the current node (inclusive) to the final one. Both parts allow us to reason on the values already seen, and the values still to be seen. This split occurs when the iterator is created. After iterating all the nodes, the full permission to the nodes needs to be restored to the list, which is done via an auxiliary lemma.

■ **Listing 15** `iterator_base` predicate in VeriFast.

```

1 predicate iterator_base(LinkedList javalist, Node n;
2   list<FileReader> list, list<FileReader> a, list<FileReader> b) =
3   [1/2] javalist.head |-> ?h &&& [1/2] javalist.tail |-> ?t &&&
4   [1/2] llist(javalist, h, t, list) &&&
5   [1/2] lseg(h, n, a) &&& [1/2] nodes(n, b) &&& list == append(a, b);

```

The implementation of the `hasNext` method is straightforward. The implementation of the `next` method requires unfolding and folding predicates, the use of a lemma showing that the `append` function is associative (result already available in VeriFast), and the `iterator_advance` lemma, which helps us advance the state of the iterator, moving the just retrieved value from the “to see” list to the “seen” list (List. 16).

■ **Listing 16** `iterator_advance` lemma in VeriFast.

```

1 lemma void iterator_advance(Node h, Node n, Node t)
2   requires [1/2] lseg(h, n, ?a) &&& [1/2] node(n, ?next, ?val1) &&&
3     [1/2] nodes(next, ?b) &&& [1/2] lseg(h, t, ?list) &&&
4     [1/2] node(t, null, ?val2);
5   ensures [1/2] lseg(h, next, append(a, cons(val1, nil))) &&&
6     [1/2] nodes(next, b) &&& [1/2] lseg(h, t, list) &&&
7     [1/2] node(t, null, val2);

```

VerCors

The implementations of the linked-list and iterator closely follow the VeriFast’s ones, with just some differences. Given that predicates in VerCors do not support output parameters, we have predicates to request access to the needed memory locations, and then methods to build the ghost lists that allow us to track the values. Additionally, we use `given` and `yields` clauses in the methods to receive and return the necessary lists (lines 1-2 of List. 17). Instead of using these clauses in methods, we would have preferred to rely on ghost fields storing those lists. Unfortunately, it seems one cannot reason about the old value of a field if its permission is inside a predicate. Using inline unfolding does not seem to work.

■ **Listing 17** `remove` method’s contract in VerCors.

```

1 given seq<FileReader> oldList;
2 yields seq<FileReader> newList;
3 requires state(oldList) ** |oldList| > 0;
4 ensures state(newList) ** newList == tail(oldList);

```

Linked-lists and iterators have been implemented before for VerCors [14] but, to our knowledge, there is no list implementation that uses a `tail` field, preferring instead a recursive approach, with the “head” being the first value, and the “tail” being the rest of the list.

Plural

For the linked-list, we adapt a stack example from Plural's repository.⁸ Naturally, we make the appropriate changes since our linked-list follows a FIFO discipline, while a stack follows a LIFO one. Since objects in Plural should be associated with tpestates, both our `Node` and `LinkedList` classes have protocols.

In the `Node` class, we define two orthogonal state dimensions, *dimValue* and *dimNext*, which handle the `value` and `next` fields, respectively. In *dimValue* there are two states, *withValue* and *withoutValue*, which indicate if the node has permission to the stored value or not. In *dimNext* we have states *withNext* and *withoutNext*, which say if the node has permission to the next node or if `next` is `null`. State dimensions avoid the need to reason about all the combinations of having (or not) a value and having (or not) a next node. Since direct field accesses are disallowed, we define getter and setter methods for both fields.

In the `LinkedList` class, we define two states: the empty and the non-empty. When it is empty, the `head` and `tail` fields are `null`. When it is not empty, `head` and `tail` are not `null` and there is unique permission to the first node, which is pointed by `head`. Since the `head` points to the next node, and so on, we should have the required chain of nodes that builds the linked-list. Adding and removing values from the list require *unique* permission to it.

Unfortunately, Plural did not accept either implementation. With regards to the `Node` class, we had errors in all the methods indicating that the receiver could not be packed (i.e. coerce from the concrete field view of the class to the abstract tpestate view [24]) to match the state specified by the `ensures` annotation parameter. Additionally, the invariant for the *withValue* state had an error stating that the parametric permission kind we specified was unknown, even though that was introduced with the appropriate annotation. In fact, we did the same for the `LinkedList` class and we did not get these kinds of errors.

With regards to `LinkedList`, the only errors reported were in the `add` method. To understand why, consider the case in which the list is not empty. In this case, the `tail` is non-null, and we must call `setNext` on it to append a new node (line 8 of List. 18). However, we do not have permission to do that. For this to work, we would need to have permission to the last node that is owned by the second to last node. Unfortunately, we could not perform such transferring of permissions. An alternative solution could be to use *share* permissions instead of *unique* ones in the nodes. But this would require locking when accessing them, because of the possibility of thread concurrency. Furthermore, we would lose track of the memory footprint used by the list (since *share* permissions allow for unrestricted aliasing). This can be an issue if we want to track all the references and ensure statically that all resources are freed at end. Given this, we did not attempt to implement the iterator.

■ Listing 18 `LinkedList`'s `add` method in Plural.

```

1 @Unique(requires="alive", ensures="notEmpty", use=Use.FIELDS)
2 public void add(@PolyVar(value="p", returned=false) T value) {
3     @Apply("p") Node<T> n = new Node<T>(value);
4     if (head == null) {
5         head = n;
6         tail = n;
7     } else {
8         tail.setNext(n);
9         tail = n;
10    }
11 }

```

KeY

The linked-list implementation is heavily inspired in a tutorial by Hiep et al. which implements a doubly-linked-list [29]. We declare several fields: `head` and `tail`; `size`, to count the number of values; `nodeList`, containing a sequence of nodes; and `values`, containing a sequence of values. The `nodeList` and `values` fields are ghost fields. As for the file reader, we define the linked-list's footprint, composed by its fields and the fields of all the nodes (line 5 of List. 19). We also specify that the footprint itself only changes if the nodes sequence changes (line 2), and that the list's invariant only depends on the locations in the footprint (line 3). The proof of the former was generated automatically by KeY using the default strategy. The proof of the latter required some interactivity to guide the proof. Note that the footprints of the values are not part of list's footprint.

■ Listing 19 List's footprint in KeY.

```

1 public model \locset footprint;
2 accessible footprint: nodeList;
3 accessible \inv: footprint;
4 represents footprint = size, head, tail, nodeList, values,
5   (\infinite_union \bigint i; 0 <= i < nodeList.length; ((Node)nodeList[i]
   ).*);

```

The list's invariant is the most verbose part of the specification. First, we specify that `size` is equal to the number of nodes, which is then equal to the number of values. Then we enforce that the values in the list are not null. We also use an existential quantifier, indicating that in each position of the sequences, elements exist (lines 1-2 of List. 20). This is necessary because KeY treats sequences in a way where they may occasionally contain not-yet-created objects. Additionally, since the sequence declarations do not enforce the type of their elements, we need to do it explicitly, either using an `instanceof` operator, or using an existential quantifier. Furthermore, we need to cast the result of accessing a position in a given sequence. Following that, we have to take into account that the list may be empty. So, we define that either the nodes sequence is empty, and the `head` and `tail` fields are null, or the nodes sequence is not empty, and the `head` points to the first node, and `tail` points to the last one (lines 3-6). To ensure we have a linked-list, we enforce that the `next` field of each node points to the following node in the sequence (lines 7-8). We also enforce that all the nodes are distinct (lines 9-12). Finally, we specify that each value in the values sequence corresponds to the value stored in each node in the same position.

■ Listing 20 List's invariant in KeY.

```

1 (\forallall \bigint i; 0 <= i < values.length;
2   (\exists FileReader f; f == values[i] && f != null)) &&
3 ((nodeList == \seq_empty && head == null && tail == null)
4   || (nodeList != \seq_empty && head != null && tail != null &&
5     tail.next == null && head == (Node)nodeList[0] &&
6     tail == (Node)nodeList[nodeList.length-1])) &&
7 (\forallall \bigint i; 0 <= i < nodeList.length-1;
8   ((Node)nodeList[i]).next == (Node)nodeList[i+1]) &&
9 (\forallall \bigint i; 0 <= i < nodeList.length;
10  (\forallall \bigint j; 0 <= j < nodeList.length;
11   (Node)nodeList[i] == (Node)nodeList[j] ==> i == j
12  )) && ...

```

The iterator has several fields: `list`, a reference to the list; `curr`, the current node; `index`, the position of the current node in the nodes sequence; `seen`, the sequence of values already iterated; and `to_see`, the sequence of values still to be iterated. The `index`, `seen`, and `to_see` fields are ghost fields. As usual, we define the iterator's footprint, composed only

by its fields (line 4 of List. 21). We also specify that the footprint itself does not change (line 2), and that the iterator’s invariant depends on its footprint and on the list’s footprint (line 3). The proof of the former was done automatically. For the proof of the latter, KeY’s default strategy was not enough. The reason for this was that KeY was applying multiple “cut” tactics to try to close the proof for each possible value of `size`. Nonetheless, it was mostly straightforward to guide the proof. We just had to use the “observerDependency” tactic to establish that the iterator’s invariant does not change in the presence of heap updates on locations that do not belong to its footprint or the list’s footprint.

■ **Listing 21** Iterator’s footprint in KeY.

```

1 public model \locset footprint;
2 accessible footprint: \nothing;
3 accessible \inv: footprint, list.footprint;
4 represents footprint = list, curr, index, seen, to_see;

```

In the iterator’s invariant we first specify that `index` is a value between zero and the number of values. This number may be equal to the number of values if and only if we have already iterated through all values. Then we enforce that the values in both sequences are not `null`. Following that, we define that the `seen` sequence corresponds to the values already seen, from position zero (inclusive) to `index` (exclusive), and that `to_see` corresponds to the values to see, from position `index` (inclusive) to the end. Since `curr` points to the current node, we map it to position `index` in the nodes sequence, or we specify that it is `null`, when iteration is done. Finally, we assert that the list’s invariant holds.

Regarding the linked-list, verifying the constructor, `add`, and `iterator` methods required only the default strategy, but for the `remove` method, some interactivity was needed, namely to show that the first value was the value of the `head`. Regarding the iterator, we had to guide the proof of the constructor, mostly to establish the invariants of the iterator and list, since KeY was applying “cut” multiple times, as before. The `hasNext` method was verified automatically with the default strategy. To verify the `next` method, we had to prove that: 1. only the list’s and iterator’s footprints are accessible; 2. the post-condition holds after execution; 3. and that only the iterator’s footprint is modified. These proof requirements required a lot of work, likely because of the relation between `index` and `curr`, which was probably not obvious to the default strategy. Examples of goals which required some effort to prove were: showing that the value of the current node was the first value in the “to see” sequence, proving that such a value was a file reader, and that the new sequences respected the invariant (after the current value was moved to the “seen” sequence).

Evaluation

In VeriFast, as well as in VerCors, the expressiveness of the logic allowed us to specify a linked-list and an iterator. However, deductive reasoning was often required. In our experience, we spent more time in proving results than in writing code, having to unfold and fold predicates very often, revealing their definitions, having to define multiple lemmas, and insert assertions to guide proofs. In VeriFast, we had to write about 160 lines of lemmas. In VerCors, we wrote about 100 lines. Some of the time spent in VerCors with the proofs was reduced because we could reuse the experience we had with VeriFast.

In Plural, we were not able to implement a linked-list. We believe the support for logical predicates would be necessary to be able to specify structures with recursive properties. Furthermore, as far as we can tell, there is no support for parametric tpestates, even though there is for fractional permissions, which could potentially allow one to model a list with objects in different states that evolve.

In KeY, we were able to implement and verify a linked-list and an iterator. Although KeY supports interactivity, together with useful macros and a high degree of automation, we spent some time proving properties about the heap. For example, we often had to prove that the footprints of two objects were disjoint, which means we also had to account for possible changes in the footprints themselves, which became very cumbersome. To do this, we had to make the footprints public so that they could be opened in proofs, otherwise we are not sure if we would have been able to finish the proofs. We believe this motivates the need to be able to prove heap and functional properties separately.

Given the differences between the approaches presented, we believe simply comparing lines of specification would not provide a meaningful comparison. Thus, we provide a qualitative evaluation. In summary, we observe that these methods require an important effort especially when one is learning the approaches. Not surprisingly, in VeriFast, VerCors, and KeY, the specification took more space than the code, and was usually verbose. VeriFast and VerCors also required a substantial amount of annotations to guide the proofs. With KeY, the space, usually needed for proofs in the other two tools, was replaced by the time spent proving results interactively. Even if it turns out that with training, it is not that hard to specify, implement, and verify the examples, it is certainly time consuming. We believe this motivates further study on what we can delegate to static analysis to ease this effort. Plural has less expressive power than the other tools, so it makes sense that the annotation effort was low.

3.4 RQ evaluation

We are able to produce examples of file readers usage, as presented in Section 3.1, where we successfully ensure that the protocol is followed (i.e. only the allowed methods in each state can be called), in all four tools: in VeriFast, VerCors, and KeY, thanks to the pre- and post-conditions; and in Plural, thanks to the tpestate abstraction directly supported. We can also ensure protocol compliance when different file readers are stored within a linked-list, in VeriFast (List. 22), VerCors, and KeY, but with significant annotation and proof effort, as observed in the examples produced.

■ **Listing 22** useFiles specification in VeriFast.

```

1 requires list != null &&& llist(list, _, _, ?1) &&& tracker(length(1))
   &&& foreachp(1, INV(FileReader.STATE_INIT));
2 ensures list != null &&& llist(list, _, _, 1) &&& tracker(0) &&& foreachp
   (1, INV(FileReader.STATE_CLOSED));

```

In the rest of this section, we focus our presentation on the crucial property of **protocol completion**, which guarantees that if and when the program terminates, all the objects are in the final states of their protocols.

VeriFast

To ensure that all file readers created through the lifetime of the program reach the end of their protocol, we define a **tracker** predicate in a *.javaspec* file which keeps hold of the number of open file readers (List. 23). This proposed solution is based on a private exchange with Jacobs [37]. Then, we augment the file reader's specification to increment this counter in the constructor, and decrement the counter in the **close** method. Finally, since we want to guarantee protocol completion for all created objects, we assert in the pre-condition and post-condition of the **main** method that the counter should be zero, given that **main** is the starting (and ending) point of Java programs.

■ **Listing 23** tracker.jvaspec file.

```

1 predicate tracker(int count);
2
3 lemma void increment_tracker();
4   requires tracker(?n);
5   ensures tracker(n + 1);
6
7 lemma void decrement_tracker();
8   requires tracker(?n);
9   ensures tracker(n - 1);

```

Unfortunately, it is possible to fail to ensure protocol completion if the programmer is not careful. Firstly, one could forget to increment and decrement the counter when the `typedstate-object` is initialized and when its protocol finishes, respectively. Secondly, if one forgets to include the post-condition in the `main` method, protocol completion will not be actually enforced. So, we can guarantee protocol completion but only if the programmer does not fall for these “traps”. Here we see that ghost code is useful to check properties, but if such code is not correctly connected with the “real” code, then the property we desired to establish is not actually guaranteed.

VerCors

To ensure protocol completion, we follow the previous idea, but instead of a “global counter” defined through a predicate written in a specification file, we create a `FileTracker` object which keeps hold of the number of open file readers using ghost code. When we augment the file reader’s implementation to increment and decrement the counter in the appropriate methods, we also have to pass the tracker using the `given` directive. Again, it is possible to fall for the same “traps”: forgetting to increment and decrement the counter, and forgetting to add the post-condition to the `main` method.

Since VerCors supports quantifiers, one could think of quantifying over all file readers and ensuring they are all closed. Unfortunately, we would be quantifying over all possible file readers, not just the ones actually allocated on the heap.

Plural

Although the `typedstate` abstraction is directly supported, protocol completion is not guaranteed since permissions may be “dropped”, as seen in List. 24, where a unique permission for an object is received but not used, without any error being reported. This was not an issue in other tools, even though leaking resources is permitted, because the support for deductive reasoning allowed us to count the number of active objects.

■ **Listing 24** Dropping file reader in Plural.

```

1 void droppingObject(
2   @Unique(requires="opened", returned=false) FileReader f) {}

```

As far as we can tell, Plural’s specification language is based on linear logic, which would imply that this would not be permitted. However, we understand why this is the case in Java, since it is common for one to stop using an object and letting the garbage collector reclaim memory. Nonetheless, we believe that ensuring protocol completion is crucial for `typedstate-objects`, to ensure that important method calls are not omitted and resources are freed (e.g. closing a socket).

KeY

To ensure that all file readers reach the end of their protocol, we define a contract for the `main` method such that for all file readers created at some point in the program, they are in the final state (line 2 of List. 25). Since KeY is not aware of the objects created or not before, we define as pre-condition that no file readers exist when `main` is called (line 1). This works because quantifiers in KeY only reason over objects in the heap. Given that `main` is the first method called in a Java program, this requirement is actually an assumption.

■ **Listing 25** `main` method’s contract with protocol completion in KeY.

```
1 requires !(\exists FileReader f; true);
2 ensures (\forallall FileReader f; f.state == FileReader.STATE_CLOSED);
```

Thanks to first-order dynamic logic, we can use quantifiers to specify that all existing file readers should have their protocol completed. Although this seems powerful, we have to adapt all other methods to specify that no new file readers are created inside. This is necessary because it would be possible for methods to create file readers only available in the scope of their execution, which would exist in the heap as created objects, but for which we would know nothing about. This post-condition, written as `!(\exists FileReader f; \fresh(f))`, was added in all needed methods. In the file reader’s constructor, we also had to say that `f` was different from `this`, since the newly created reference is fresh.

Evaluation

In the context of tpestates, checking for protocol completion is crucial to ensure that necessary method calls are not forgotten and that resources are freed, thus avoiding memory leaks. Unfortunately, that concept is not built-in in any of the logics employed by all four tools. We believe that protocol completion should be provided directly by the type system and the programmer should not be required to remember to add this property to the specification.

One workaround we found for VeriFast and VerCors was to have a counter that keeps track of all tpestated-objects which are not in the final state. This requires keeping hold of the aforementioned tracker in specifications, which can be a huge burden in bigger programs. Ensuring protocol completion could be embedded in separation logic and such a feature could even be possible in VeriFast. Given that VeriFast supports leak checking, one would just need to incorporate notions of tpestates and ensure that leaking would only be allowed when objects are in their final states. In C, one would also need to enforce that claimed memory is freed. In Java, leak checking would need to be enabled for tpestated-objects.

For Plural, we did not find a way to ensure protocol completion. This could be supported by asking the programmer to indicate which state of a given object is the final one and only allowing permissions for *ended* objects to be “dropped”.

In KeY, we made use of the support for universal quantifiers and reasoning on heap-dependent expressions. However, verifying the code against that specification can be cumbersome, and requires augmenting the specifications of all other methods, ensuring no untracked objects are added to the heap.

4 General assessment of the tools

In this section, we summarize our views about the tools, using the knowledge gained from our experiments, and provide suggestions of what could be improved.

VeriFast

Separation logic, fractional permissions, and predicates, allow for rich and expressive specifications that make it possible to verify complex programs. However, deductive reasoning is often required when the specifications are more elaborate, as we have seen when implementing the linked-list (Section 3.3). This is tedious and can be a barrier to less experienced users. Although VeriFast’s IDE provides a way for one to look at each step of a proof when an error is discovered, we believe that, at least in part, having a way to guide proofs (like one can do with proof assistants such as Coq), would improve the user experience even more by: (1) avoiding having to insert proof guiding assertions in the code implementation itself (allowing for more separation of concerns); and (2) avoiding the need to rerun the tool every time that occurs. In other words, when guiding the proofs, one would get immediate feedback. Nonetheless, the IDE experience was still very useful in helping us prove several results.

Checking for protocol completion is crucial to ensure that essential method calls are not omitted and that resources are freed. Unfortunately, that concept is not built-in in separation logic (Section 3.4). Given that VeriFast supports leak checking, one would just need to ensure that leaking would only be allowed when objects are in their final states.

VerCors

As in VeriFast, rich and expressive specifications are supported, but deductive reasoning is (again) required. As we noted before, this can be tedious, as highlighted by the time and lines of code we needed to prove results. Unfortunately, VerCors has no interactive experience so we had to practice “trial and error” more often, guessing what could be wrong and rerunning the tool every time we changed the code.

In terms of user experience, we think allowing for more separation between lemma and predicate functions from code, instead of forcing these to belong to classes as static methods, would help improve readability, as others have also noted [31]. We also believe the tool could be more efficient: since specifications are self-framing (i.e. only depend on memory locations that they themselves require to be accessible) and the checking process is modular, VerCors could cache some results to avoid re-checking parts of the code that were not modified. We also noticed that if we unfolded a predicate on which some truth depends on, that knowledge would be lost. For example, the knowledge of the values stored in a sequence of nodes depends on the permissions to those nodes, available in the `nodes_until` predicate. In principle, unfolding this predicate should not invalidate the available information, but it does. To workaround this, we had to use fractional permissions to keep hold of some fraction of the original predicate, and only unfold the other fractional part.

Comparison between VeriFast and VerCors

Given the similarities between VeriFast and VerCors, we believe it is very relevant to provide a comparison between both.

With respect to specifying access to memory locations, VeriFast only supports the points-to assertions of separation logic, while VerCors also supports permission annotations, inspired by Chalice [44, 45], allowing us to refer to values in variables without the need to use new names for them, which was very useful when writing the specifications. Furthermore, VerCors has built-in support for quantifiers, many different abstract data structures, and ghost code, which VeriFast does not. We used a fair amount of ghost code in VerCors. Nonetheless, VeriFast supports the definition of new inductive data types, fixpoint functions, higher-order predicates, and counting permissions, which VerCors does not. Unfortunately, VerCors does

not support generics in Java. Regarding VeriFast, as Bart Jacobs points out, at the time of writing, “support for Java generics in VeriFast is in its infancy”.

Both provide support for fractional permissions, which we have used. However, this model only allows for read-only access when data is shared. In consequence, either locks are required to mutate shared data (even in single-threaded code, where they are not really necessary, resulting in inefficient code), or a complex specification workaround is needed. We believe that the specifications and code should focus on the application’s logic, and the need to modify them to help the verifier should be avoided as much as possible. VerCors lacks support for counting permissions, which would allow permissions to be split in other ways.

Finally, we missed the support for output parameters which VeriFast has. To reproduce the same concept in VerCors, we had to add ghost parameters in many methods and explicitly pass values for those parameters when calling such methods. For example, when working with the linked-list, we kept track of the sequence of values in the list through ghost code, and always had to pass that sequence to each called method.

Plural

The rich set of access permissions allows objects’ state to be tracked even in the presence of aliasing, and permits read/write and write/write operations, thanks to state guarantees. Nonetheless, we could not specify structures such as the linked-list with double handle (i.e. with head and tail fields), likely because of the lack of support for logical predicates. Furthermore, to our knowledge, there is no support for parametric typestates.

The use of *share* permissions allows for unrestricted aliasing. Nonetheless, state assumptions need to be discarded because of the possibility that there might be other threads attempting to modify the same reference. Although this thread-sharedness approximation is sound, it forces the use of synchronization primitives even if a reference is only available in one thread. Beckman et al. discuss the possibility of distinguishing permissions for references that are only aliased locally from references that are shared between multiple threads, allowing access to thread-local ones without the need for synchronization [7]. But as far as we know, the idea was not realized.

Furthermore, there is no built-in guarantee of protocol completion. This could be provided by only permitting permissions for *ended* objects to be “dropped” (Section 3.4).

KeY

The use of JML for specifications, a language for formally specifying behavior of Java code, used by various tools, reduces the learning curve for those that already know JML. Furthermore, KeY supports a great number of Java features, allowing one to verify real programs considering the actual Java runtime semantics. Nonetheless, generics are not supported, although there is an automated tool to remove generics from Java programs, which can then be verified with KeY. Because of its focus on Java, KeY is not overly suitable for the verification of algorithms that require abstracting away from the code [20].

One important aspect that makes KeY stand out from other tools is the support for interactivity, which allows the programmer to guide the proofs. This is an aspect that we missed when experimenting with other tools. Additionally, KeY provides useful macros and a high degree of automation, as well as support for SMT solvers, such as Z3. We used Z3 often to more quickly close provable goals, specially those involving universal quantifiers.

Since KeY’s core is based on first-order dynamic logic, one can express heap-dependent expressions: the heap is an explicitly object in the logic. Although this allows for much expressiveness, it often becomes very difficult to verify programs, as our experience has shown

(Section 3.3). We think that a variant of KeY that would instead use separation logic, to abstract away the heaps and the notion of disjointness, would be very helpful, improving readability and reducing verbosity.

Nonetheless, there are probably other alternatives to separation logic that would help in solving the aforementioned issues. In a private conversation with KeY’s group leaders, they point out that the connectives of separation logic “would get in the way of automation”, a crucial feature of KeY. For example, it seems that “the heap separation rule tends to split proofs too early” [35]. Furthermore, they mention that the problems we encountered could be summarized in two main points: (1) insufficient abstract specification primitives; (2) inability to prove heap and functional properties separately, in a modular fashion. KeY’s team is aware of these issues and will address them in the future (at the time of writing).

As we pointed out above, we believe separation logic together with resource leaking prevention (except for objects with completed protocol), could be used to ensure protocol completion without the need for adding extraneous specifications. This would be another reason why we believe separation logic would be preferable over first-order dynamic logic, but it is possible there are other alternatives.

Finally, we enjoyed the user experience and appreciated that KeY comes with examples to experiment with. Nonetheless, at the moment of writing, we believe there is room for improvement. For more details, we refer the reader to a thorough discussion of the issues we found and suggestions for improvements, which we shared with KeY’s team.

5 Related work

Penninckx et al. develop an approach to verify input/output properties of programs [54]. They encode I/O behavior using abstract permission-based predicates implemented in VeriFast. The technique ensures that a program only performs the allowed I/O operations. Additionally, it guarantees a terminated program has performed all desired operations with a post-condition specifying the final state a program should be found in. Later, Jacobs presented an approach to verify liveness properties [36]. Blom et al. verify the functional behavior of concurrent software using histories, which record the actions taken by a concurrent program [15]. The technique has been integrated in VerCors and experimentally added to VeriFast. Similarly, Oortwijn integrated process algebra models [8] in VerCors to reason about functional properties of shared-memory concurrent programs, including non-terminating ones [52]. More recently, work has been developed to support the deductive verification of JavaBIP models in VerCors [12]. In these models, Java classes are considered as components where their behavior is described by finite state machines, and component interactions are specified with synchronization annotations [11]. Kim et al. propose a technique to specify protocols of Java classes by incorporating tpestates into JML [41]. When translating their extension to pure JML, multiple boolean fields for each state are declared which, when `true`, indicate the object is in that given state. Multiple fields are needed to support *state refinements* [9]. Cheon and Perumandla extend JML with a new specification clause containing a regular expression-like notation to specify the sequences of method calls allowed for a given class [21].

In this study, we focus on *sequential* examples and only present a simple protocol, which does not require a complex encoding, so the aforementioned techniques would either not be applicable or would introduce unnecessary verification overhead.

With respect to comparison studies, there are several that have been conducted. However, as far as we know, no study was previously done that focused on the verification of *protocol compliance and completion*. Nonetheless, we reference some works we found relevant to

us. Lathouwers and Huisman examine the annotation effort in several tools, including VeriFast and VerCors [42]. Hollander briefly discusses the differences between VeriFast and VerCors [31]. Boerman et al. study the way in which KeY and OpenJML treat JML specifications differently and the effort in switching between both tools [16].

6 Conclusions

In this paper, we address the **RQ** (Page 2) by reviewing four verification tools for Java. In particular, we evaluated their ability to check the correct use of objects with protocol, and if they were able to guarantee protocol completion, even when these were shared in collections (Section 3.4). Additionally, we evaluated the programmer’s effort in making the code acceptable to each, and provide suggestions for improvements (Section 4).

We were able to reach a general conclusion: stateful objects usually have protocols representing their intended usage. In the tools we have studied, protocols are not first-class entities; instead they need to be encoded with method contracts (even in Plural, annotations on methods are required). In contrast, approaches based on behavioral types, where protocols can be defined via automata [4, 47, 60], treat protocols as central, and provide a global view of the intended usage of each object. By having this model, reasoning on relevant properties becomes easier than on lower level encodings.

Now we summarize key points gathered from our experiments with each tool. Both VeriFast and VerCors support rich and expressive specifications based on separation logic: this allowed us to successfully address the **RQ**. However, deductive reasoning was often required. This is very demanding and can be a barrier to less experienced users. We believe improved interactive experiences for programmers are key to make these tools more approachable. Furthermore, fractional permissions only allow for read-only access when data is shared.

Plural is different from these tools in two major ways: it does not support logical predicates and so, specifications are less expressive in that regard, which prevented us from implementing a linked-list. Nevertheless, access permissions support more kinds of sharing, but access to thread-local shared data might require an unnatural use of locks.

KeY supports interactivity, automation, and the ability to reuse proofs. Nonetheless, the fact that heaps are mentioned explicitly in assertions made it difficult to read the hypothesis and proof goals. Additionally, we often had to show that certain footprints were disjoint. So, although we successfully answered the **RQ**, again the effort was substantial. To fully automate some proofs, KeY depends on finding the right specifications and proof search settings, which is not easy. More abstract specification primitives, and the ability to separate proofs of heap and functional properties, are crucial features to improve both readability and ease of proving results.

So, we proved protocol compliance with some effort, but protocol completion, crucial to ensure that necessary method calls are not forgotten and that resources are freed, is not directly supported by any of these tools. Although there are workarounds in some, we believe such guarantee should be supplied directly. This could be done by ensuring that no permission to an object is “dropped” unless it is in the final state.

In conclusion, this study motivates the need for lightweight methods to statically guarantee protocol compliance and completion in the presence of several patterns of sharing, like objects with protocol stored in collections, including the following features: usage protocols as the central entity defining objects’ behavior, more kinds of sharing beyond fractional permissions also avoiding the need for locks in sequential code, and better techniques to reason about permissions to heap locations.

For completion, this study could be complemented with OpenJML [22], and LiquidJava, a recent tool that integrates liquid types in Java [26].

The Dolorem Pattern: Growing a Language Through Compile-Time Function Execution

Simon Henniger ✉

Technische Universität München, Germany

Nada Amin ✉

Harvard University, Cambridge, MA, USA

Abstract

Programming languages are often designed as static, monolithic units. As a result, they are inflexible. We show a new mechanism of programming language design that allows to more flexible languages: by using compile-time function execution and metaprogramming, we implement a language mostly in itself. Our approach is usable for creating feature-rich, yet low-overhead system programming languages. We illustrate it on two systems, one that lowers to C and one that lowers to LLVM.

2012 ACM Subject Classification Software and its engineering → Compilers; Software and its engineering → Language features

Keywords and phrases extensible languages, meta programming, macros, program generation, compilation

1 Introduction

1.1 Motivation

Traditional macros serve mostly to create new syntax forms, expanding into a pre-defined core language. This means that the expressive power of macros is ultimately limited by the core language. For example, traditional macro systems could not add a “plus” macro to a language that does not have a concept of arithmetics.

This means that a language could never be fully built up from scratch with one of these macro systems. It also imposes a limit on the flexibility of macro systems: for example, they typically could not allow for supporting new features of a CPU chipset or a target language that are unsupported in the compiler.

We show a new pattern to design languages that can grow beyond their original definition. Our macros do not expand into a pre-defined core language, but rather into the target language itself. This allows us to build up a language of flexible zero- and low-cost abstractions in the form of macros.

1.2 Idea

We start with a low-level system (*the target system*), think the C environment. Using this system, we create a minimal programming language that compiles to the target system and allows for compile-time function execution. This language (which we will later call the *base language*), is barely any more high-level than the target system and just big enough to call and define functions.

We then give this language access to its own code generation functions. We also allow for certain functions defined in the language to be executed *as part of the compilation*.

As a result, we can define entirely new language features in the language and immediately use them after defining them, thereby *bootstrapping* a language from a low-level system.

This has a number of implications. First, we no longer implement a compiler as a monolithic unit. Rather, ours is an extensible system that consists of the implementation of the base language and any additional language features implemented in the base language.

Second, we effectively have heterogeneous staging from the high-level that targets the low-level system. The staging is realized by executing compiled functions at compile-time.

Our pattern provides abstractions within the high-level system to define new language features. Those are based on traditional macros, which allow adding commands to the language. In addition to macros, we allow for layers. A layer is a set of changes to the behavior of a set of existing macros, i.e. a change to the language semantics. Layers give rise to a language tower.

We show that our language provides facilities for very flexible metaprogramming and exhibits minimal overhead in many cases.

1.3 Structure

In this paper:

- We describe our design principles (Section 2).
- We describe the related concepts of heterogeneous staging and compile-time function execution (Section 3).
- Based on these design principles, we implement a small demonstration system that targets C, called *dolorem-c* (Section 4).
- We evaluate and demonstrate the flexibility by showing that we can implement examples (Section 5).
- Based on the result of our evaluation, we design, implement and evaluate a larger system called *dolorem-llvm* (Section 6), which we also evaluate (Section 7).

We discuss related work (Section 8) and conclude (Section 9).

2 Design

2.1 Definition

A language uses the *Dolorem pattern* if:

1. It provides the `lower` form to lower high-level source code to a low-level target language.
2. It provides the language user with the ability to define *macros*, which change the behavior of the `lower` form.
3. It exposes internal code generation functionality of the compiler to macros. Macro code can therefore explicitly control code generation, as though it were part of the compiler.

4. Its macros are defined in exactly the same language as any other code, rather than in a special language only available at compile-time. In particular, macros can call into regular code, allowing for compile-time function execution.
5. It is constructed through bootstrapping and staging.

We call a language a *Dolorem language* if it uses the Dolorem pattern.

Finally, we call a system that reads and interprets or compiles programs written in a Dolorem language a *Dolorem system*.

2.2 Two languages

This paper shows the design of two Dolorem languages. One of them, `dolorem-c`, lowers to C code, while the other lowers to LLVM IR.

2.3 Design Goals

The five parts of the Dolorem pattern definition will become primary design goals of the languages we will show. We now further elaborate on them and will then describe a set of secondary design goals that follow from the definition and help us reach our primary design goals.

2.3.1 Lower, don't evaluate

`eval` is commonly a function that takes an expression, evaluates it immediately, and returns another expression: the result of the evaluation. For example, the result of evaluating `(+ 1 1)` would be `2`, and the result of evaluating `(car '(a b c))` would be `'a`.

Dolorem systems call `lower` instead of `eval`.

`lower` takes an S-expression, parses it, lowers it into the system's target language, and returns a reference to the lowered code. The reference could be a pointer to an SSA in LLVM's Intermediate Representation, or just a string with C code. Calling `lower` on a function call, a variable name or an integer never actually calls the function, loads the variable content, or returns the value of that integer – with one exception: macros.

2.3.2 Macros are special cases of lowering

When the `lower` form is called on something that looks like a function call, it checks if the called function is marked as a macro.

If it is, it delegates to the macro which means it immediately (i.e. during compile time) calls it on its own argument and returns its result. This makes macros an example of compile-time function execution (see 3.1).

Hence, macro usages are one (and the only) instance in which the `lower` form behaves similar to the `eval` form.

Because macros have access to the entire language, the calling behavior is the only difference between macros and functions. Apart from it, they are both treated the same. This includes being compiled the same way.

2.3.3 Give macros explicit control over code generation

In Dolorem, macros can generate their own code. In order to do this, we give them explicit access to the code generation facilities in the compiler, so they can explicitly emit the target language.

2.3.4 Give macros access to the entire language

Unlike in other systems like C++'s “constexpr” functions, macros should not be restricted in which other functions they can call and what they can do.

First, this allows us to use macros in traditional metaprogramming cases, for example those where a metaprogram accesses and parses a file to use it as a basis for generating code. Second, since we use macros to directly generate backend code, it also improves the overall flexibility of the language.

Note that this requires us to consider each individual function to be its own translation unit. If we delayed compilation of a function, there could be a macro usage between the definition and compilation of it and then the function could not be used by the macro.

2.3.5 Keep the base language as small as possible

Because the Dolorem pattern uses staging, a Dolorem language is implemented in two parts: One part is implemented in some other language like C, while the rest is implemented in the Dolorem language itself (on top of the base language).

We refer to the first part as *the base language*. This part of the system should be kept minimal, i.e. just big enough to allow to bootstrap the rest of the language.

First, the Dolorem pattern aims for low overhead, so there is usually no reason not to implement something in a Dolorem language if we can.

Second, while we work to minimize it (see below), there is and will always be a barrier between a Dolorem language and its target language. So the behavior of any code that is written in a target language is a bit harder to change from within the Dolorem language.

2.4 Secondary principles

Based on this definition of the Dolorem pattern, we define a few secondary design goals that help us reach our primary goals:

2.4.1 Limit barriers

There should be as few barriers between the Dolorem language and the target environment as possible. For example, we should allow one to call the other directly, without using a *foreign function interface* or worrying too much about name mangling.

This not only makes it easier to interface Dolorem programs with existing programs written in the target environment, e.g. C (thereby increasing Dolorem's value as a systems programming language), but also allows to access the compiler's backend as seamlessly as possible.

2.4.2 Do not prescribe a model of execution

We let the language user decide about when to write code to disk/execute it rather than prescribing one model of execution. Unlike traditional language processors, Dolorem systems do not have a preferred mode of translation. Although we like to refer to them as compilers, they are neither compilers nor interpreters in the traditional sense.

Rather, a language user can decide to write and use a macro to execute code at compile-time, thereby using the Dolorem system as an interpreter, or write and use a macro to write generated code to disk, thereby using it as a compiler.

2.4.3 Layers are sets of overridden macros

We want to be able to change the behavior of macros even after their definition.

That is why we allow macros to be overridden. When we override a macro, we provide a new macro that replaces it. This new macro may call into the original macro (or an older override) as a fallback.

Since it is usually more useful to override several macros at once, Dolorem systems support layers – sets of macros that are overridden together. Layers are often used to provide new language features. For example, we will later show a “function overloading” layer that overrides the `lower` macro and the `defun` macro to allow for several functions with the same name and different numbers of arguments.

Since most macro overrides fall back on the last override, layers can stack to form a tower.

2.4.4 At global scope, everything is a macro

Similar to Lisp, there are no operators or keywords that are not also macros. This means that, at global scope, a Dolorem program is only a sequence of macros that are executed by the compiler in order of appearance.

Having nothing but macros is useful because it allows us to change every aspect of the language by overriding macros.

2.4.5 Use S-expressions

This paper is not about syntax. That said, the Dolorem pattern does place some unusual constraints on the syntax of the language it is used in:

1. The language itself is defined to be as flexible as possible and we do not want syntax to be a limiting factor.
2. We want macros to be able to read the syntax tree. Hence, the base language must provide facilities to do so. Any complexities in the syntax will therefore bloat the base language.

S-expressions are both flexible, and very easy to read and manipulate programmatically (using the famous `car`, `cdr`, `cons`), making them an ideal fit.

3 Concepts

3.1 Compile-time function execution

Compile-time function execution refers to a compiler’s ability to execute functions written in its target language at compile time.

Often, this is done to compute constant expressions at compile-time. An example is C++’s `constexpr` [2].

Depending on the language, functions that can be executed at compile time may only have access to a subset of the language. In C++, for example, `constexpr` functions are relatively limited: they can only call other functions marked `constexpr` and can not access the environment.

As explained above, languages with the Dolorem pattern use compile-time function execution to bootstrap the language. Macros, the functions executed at compile time, have access to the entire language. This includes the ability to call non-macro functions (principle (2.3.4)).

3.2 Heterogeneous staging

Multi-stage programming offers a principled way of generating code by working in a language with two stages: the first stage is a program generator which when executed yields the second-stage program. Whether a program belongs to the first stage (code generator) or second stage (generated code) can be determined by syntax quotations (MetaML [10]) or types (LMS [9]). Some multi-stage programming systems like LMS (Lightweight Modular Staging) support heterogeneous staging, where the code generator and the generated code can be in different languages.

Dolorem can be seen as a form of heterogeneous staging, where the `lower` facility acts as staging. Which stage a function belongs to is determined by whether it is marked as macro. Macros, being executed during code generation, form the code generator stage, while regular functions are the second stage.

4 dolorem-c: Implementation with C Target

dolorem-c is our first attempt at an implementation of the Dolorem pattern for a system. dolorem-c is intended as a proof of concept and simple demonstration. We want to distill the essence of the Dolorem pattern, rather than present a fully viable language¹.

To keep it as simple as possible, we target C and leave out some aspects of the language for now – for example, we rely on C for the type system and do not implement any type checks ourselves.

Since the dolorem-c system has no dependencies except for a working C compiler, it is easy to try it out².

4.1 The `lower` macro

After reading a file, dolorem-c calls `lower` on its content. `lower` takes a list and returns generated code. In our case, this means it has the following function signature:

`struct cexp* lower(struct val* e);`, where `struct cexp*` is a type that contains a piece of generated C code and `struct val*` is an S-expression.

Any C transpiler needs to implement its own representation of C code. The primary constraint for ours is that we want the resulting interface to be as simple as possible to use. That is why we keep our representation of a value in C code to only four syntactic categories (each stored as a separate string) that we use to track whether a statement should be at global or local scope, and to be able to differentiate between expressions and full statements that precede them. These are the four strings:

- `expression`, which stores the expression itself, e.g. `a+b`. It is later inserted into a statement.
- `context`, which stores a list of statements that need to precede whatever statement `expression` will be inserted into, e.g. `int a;`. If it is non-empty, this always ends in a closing curly parenthesis or a semicolon.
- `global`, which is a list of statements on global scope that should precede whatever function this `cexp` will be inserted into.
- `header`, which is a list of headers at global scope that need to be added to the environment after `cexp` has been compiled, e.g. `#include <stdio.h>` or a `cexp` that contains `printf`.

¹ The entire dolorem-c source code can be found in this GitHub repository: <https://github.com/metareflexion/dolorem-c>

² A version that runs in the browser can be found here: <https://shenniger.github.io/try-dolorem-c>

In the following, we will write `cexps` as tuples of strings in square braces separated by vertical lines, e.g. `[a+sqrt(b)||#include <math.h>]`.

For illustration, this is the behavior of `lower`:

- If `lower` is called on a number or string literal, it can directly lower that literal to C and prints that number or string literal as a `cexp` with empty local and global context (i.e. `4` evaluates to `[4|||]`).
- If `lower` is called on an identifier, it assumes it has found a reference to a variable and returns that as a `cexp` with empty local and global context (i.e. `myvariable` evaluates to `[myvariable|||]`). A more advanced Dolorem system (like `dolorem-llvm` which will be shown later) would try to find the variable in the current scope. `dolorem-c` leaves this to the C compiler.
- If `lower` finds a function call, it checks if the called function is a macro. If not, all the arguments to the call are recursively `lowered`, and code for the call is generated. If the called function is a macro, `lower` resolves the address of the macro function, and calls it.

4.2 Macros in the base language

We want to bootstrap as much of the language as possible. In order to be able to do that, we need to add a few more macros, just enough for the user to be able to define their own functions and macros:

- `progn` calls `lower` on each of a list of expressions and returns the result of the last (similar to `progn` in Lisp).
- `include` reads another file, and calls `progn` on its content.
- `funproto` creates a function prototype for a given function signature.
- `function` creates a function (including body).
- `mark-as-macro` marks a given function name as a macro.
- `compile` lowers its argument, then compiles the resulting C code to machine code, and stores the C headers. See below for more.

Note that `mark-as-macro` and `compile` are the only two macros in this list to have side effects. The others do not modify global state at all – for example, `function` only returns C code with a function definition, but does not register that function anywhere yet.

We need `progn` and `include` in the base language because, without them, we could not read any files of source code (but only individual macro calls), and we need the others to be able to define functions and macros.

In addition to those macros, there are a few functions that help with reading and processing S-expressions like `car`, `cdr`, `val-is-string`, `expect-ident`, or `make-int-val`.

The base language contains nothing else – most notably absent are any kind of control structures, local or global variable definitions, and arithmetic expressions.

In order to reduce barriers, the base language also does not introduce any new calling conventions. One example of that is that `dolorem-c`'s calling convention is the same as that of C and all `dolorem-c` symbols need to exist within the C environment. This is even true for macros: When a macro is called within `lower`, the address of the macro is being resolved by using a simple `dlsym(RTLD_DEFAULT, "macroname")`, i.e. we use the system's dynamic linker to resolve the symbol.

4.3 Marking a function as a macro

Any function that has the macro signature (`struct cexp* myfunction(struct val* e);`) can be marked as a macro. This does not change anything about the function's code or calling convention on the C side, however it has implications on how calls to the function are handled in `dolorem-c` code.

41:8 The Dolorem Pattern

If `myfunction` is not marked as a macro, `(myfunction myarg)` generates code to call the function and evaluate its argument `myarg`. Since we are assuming `myfunction` to take only one argument, a `struct val*`, `myarg` would thus be expected to be a pointer to a list argument.

If `myfunction` is marked as a macro, `(myfunction myarg)` resolves the macro `myfunction` and calls it on the unevaluated S-expression form of the argument (i.e. a list of only one element: the string `myarg`).

Note that macros can be overridden, functions cannot. Thus, a call to a function is resolved by the C environment, while a call to a macro is resolved first by Dolorem's own macro table (which might say that the macro `myfunction` was overridden by the macro `myfunction2`, so that macro would be called instead).

The `lower` function has the same signature as macros, and we also mark it as a macro. This may seem counterintuitive at first, because there is no point to ever calling it as a macro (as anything in `dolorem-c` is evaluated by `lower` anyway). Marking `lower` as a macro is still necessary, because that way, we can override it.

It is, however, useful to be able to call `lower` as a function from within `dolorem-c` code. For that, we define a function `lower-now`, which acts as an adaptor and calls the current `lower` override.

4.4 Implementing base language macros

Base language macros are implemented as simple C functions. As an example for how C code interfaces with S-expressions and macros, here is `progn`:

```
struct cexp *progn(struct val *e) {
    struct cexp *r = make_cexp("", "", "", "");
    // iterate through list
    for (struct val *args = e; !is_nil(args); args = cdr(args)) {
        // call lower on each element
        struct cexp *a = call_macro("lower", car(args));
        add_cexp(r, a);
        // if not the last element, add
        // expression to context
        if (a->E && *a->E && !is_nil(cdr(args))) {
            appendString(&r->Context, print_to_mem("%s;\n", a->E));
        }
        r->E = a->E;
    }
    return r;
}
```

We begin by calling `make_cexp` to create an empty C expression. Note that the four empty strings we pass to it correspond to the four syntactic categories described above.

Then we iterate through the list we were passed, lowering each element, and adding its context, global, and header to our `cexp`. The expression of the `cexp` we return will be that of the last element of the list (because that is the return value of the block); any expressions of the preceding elements will be appended to `context`.

Note that we do not directly call `lower`, but rather write `call_macro("lower", ...)`. While there is a C function called `lower` that we could use, the macro `lower` might have been overridden by Dolorem code by this point, so we need to look up the current version of `lower`.

4.5 Writing functions in the base language

In the base language, simply writing `(function ...)` is not enough to define a new function. That is because `function` merely generates the `cexp` for a function, but never actually invokes a C compiler.

Actually, we need to wrap any function definition into a `compile`, for example: `(compile (function hello-world ()void (puts "hello, world!")))`

The `compile` macro first `lowers` its argument, then appends the header portion of it to a global header store, and invokes a C compiler³ to compile it to a shared library⁴. The `compile` macro also loads this shared library.

4.6 Example macro 1: `defun`

To reduce this boilerplate, we first define `defun`, which provides us with a nicer function definition syntax and makes compilation implicit. `defun` is a good example for a simple macro that does not explicitly generate C code, but rather uses existing compiler facilities, for which it generates new input Dolorem code.

We call this kind of macro (that transforms Dolorem code to Dolorem code and then calls the `lower` macro on it for code generation) a *homogeneous transformation* (see 4.9).

In order to define a macro, we define a function that takes an S-expression and returns a `cexp`. The dolorem-c type system cannot handle either at this early stage of bootstrapping, so the actual function signature is `void* defun(void* args);`. We compile the resulting function, and then mark it as a macro.

`defun` should be just like `function`, except that it automatically compiles for us. Since all we want is this small syntactic change, it makes sense to implement the macro as a homogeneous transformation (from Dolorem code to Dolorem code):

```
(compile (function defun ((void* args)) void*
  (call-macro "lower" (cons
    (make-ident-val "compile")
    (cons (cons (make-ident-val "function") args) (make-nil-val))))
  ))
(mark-as-macro defun)
```

To define a macro, we first create a function, then explicitly compile it, and finally mark our function as a macro. Within the function, we create a new list (using standard Lisp macros like `cons`) composed of a call to `compile` and `function` on our argument.

We then `lower` this list. Note that, rather than directly calling `lower` in the macro, we need to `call-macro "lower"`. We need to do so because `lower` is a macro, but in this case, we do not want to call it during code generation of `defun`, but rather want to add a call to `lower`. We could also call `lower-now` (see 4.3) and will do so in later code examples.

After `defun`, we bootstrap a `defmacro` in a similar way, such that we no longer need to write down the function signature and explicitly `mark-as-macro` every time. Note that, because of the way in which we define `defmacro`, it automatically creates a parameter called `args` that contains the list the macro was called on.

³ Currently, both `tcc` and `gcc` have been tested. `tcc` is preferred on Linux because of its much faster compilation speed.

⁴ We use a shared library to make sure `libdl` can find all new symbols, and that newly compiled code can find and access all the symbols defined before. This is why the C compiler is asked to link the new code into a shared library (with dynamic symbol lookup enabled), which is then immediately loaded. `dolorem-llvm` uses a more complicated JIT-based approach for this, which we will discuss later.

4.7 Example macro 2: `var`

We will now show `var` as an example of a macro that generates its own C code.

These macros, which we will refer to as *lowering transformations* lower their Dolorem input to C code.

In the case of the `var` macro, we tap into C's ability to define local variables. We want to be able to write `(var int x)` to create a new int variable called `x`. For this, we define a primitive macro called `var`:

```
(defmacro var
  (make-cexp (expect-ident (car args))
    (print-to-mem
      "%s %s;\n"
      (expect-type (car (cdr args)))
      (expect-ident (car args)))
    ""
    ""))
```

We use the newly defined `defmacro` to define the macro in only one step (rather than defining a function, compiling it, and then marking it as a macro). Within the macro's body, we call `make-cexp`, whose four arguments correspond to the four syntactic categories defined above. Two of them (`header`, `global`) are empty, while the first one is simply the name of the variable, and the second is C syntax for its definition.

The base language gives us a range of functions like `char* expect_ident(struct val* e)`; and `long long expect_int(struct val* e)`; that check whether a given list expression is of a certain type and, if so, unpack and return its value (otherwise, the function outputs an appropriate error).

The macro uses `print_to_mem`⁵, a C function defined in the compiler that acts like `asprintf` (i.e. it formats a string and automatically allocates memory for it) to transform the dolorem-c code into C code and creates a `cexp` with the variable definition as context, only the variable name as expression, and empty `global` and `header` values.

In a similar way, we bootstrap (among others) `cond`, a Go-like `:=`, `and`, `equals`, `loop`, `add`, `sub`, and `assign`.

4.8 Language usage example: Hello, world in a loop

With the very primitive base language and our macros, we can now implement this example that prints "Hello, world!" ten times:

```
(include "def.dlr")
(defun main () void (progn
  (:= count 0)
  (while (sub count 10) (progn
    (puts "Hello, world!")
    (assign count (add count 1)))))
```

We assume that the file `"def.dlr"` contains all those macros and a function prototype for `puts`.

⁵ As a purely cosmetic improvement, any time an underscore appears in the C code, we can write a dash in dolorem-c. All dashes in function names are replaced by underscores when they are read.

Note that, while our program defines a `main` function, it currently does not do anything. As explained above, in order to execute code, we need to write a macro that either directly calls into the code, or writes it to disk.

We will show how to use Dolorem systems as compilers later. For now, let's execute our code directly:

```
(defmacro run (progn
  (main)
  (make-cexp "" "" "" ""))
(run))
```

We create a macro called `run` that calls into `main` and returns an empty `cexp`. Then, immediately after defining the macro, we call it.

4.9 Different types of transformations

As discussed above, there are two archetypes of Dolorem macros:

- *Homogeneous transformations*: These macros transform the S-expression they are given and then (at their very end) call `lower` to generate code for the transformed expression. Lisp can only work with this kind of macro.
- *Lowering transformations*: These macros parse the S-expression they are given and then call into the backend to generate code for it.

To demonstrate the difference, we will show two different implementations of the `quote` macro.

Most Lisps include a `quote` macro that, rather than evaluating an expression, passes its original S-expression along. Quoting is equally useful in Dolorem, but must be implemented differently. Rather than simply returning the original S-expression, we must generate code to create a given S-expression.

First, we will implement `quote` as a homogeneous transformation. We start with a function that, given a list, returns, as a list expression, a sequence of function calls to generate that list. For example, for `(1 2 3 test)`, our function should return `(cons (make-int-val 1)(cons (make-int-val 2)(cons (make-int-val 3)(cons (make-string-val "test")(make-nil-val))))))`. We call this function `lower-quote`. We can define the actual macro as simply `(defmacro quote (call-macro "lower" (lower-quote args)))` (i.e. call `lower-quote`, lower the result and return it).

`lower-quote` is defined as a series of `cond` statements⁶ that call a number of simple helper functions like `make-make-funcall` or `make-cons-funcall` that generate the actual calls. This is what the statements for lists and integers look like:

```
(defmacro quote (progn
  (var res void*)
  (cond (val-is-int args)
        (assign res (cons (make-ident-val "make-int-val") (cons args (
          make-nil-val))))))
  # ...
  (call-macro "lower" res)))
```

⁶ `dolorem-llvm` allows the implementation of a proper three-way if. In `dolorem-c`, this is hard due to the missing type system.

41:12 The Dolorem Pattern

This has several advantages. First, it is relatively easy to read (and, in fact, after `quote` has been defined, such functions are even more readable). It also does not require much advanced knowledge on the inner workings of the compiler or C. Furthermore, this macro is relatively forward-compatible and will continue to work with updated code generators, although future Dolorem syntax changes may break its compatibility.

Its primary issue is that it is not particularly fast. Creating a list expression that is then immediately parsed by the `lower` macro called in the last line is wasteful. We can write a faster version of it as a lowering transformation that directly generates C code:

```
(defmacro quote (progn
  (var res char*)
  (cond (val-is-int args)
        (assign res
                 (make-cexp (print-to-mem "make_int_val(%i)" (expect-int args))
                            "" "" "")))
  r))
```

While it is lower overhead, this way of implementation is also much more error-prone as we have to directly manipulate strings of C code.

There is no universal rule for when to use which of the two types of transformations. Both of them have their own advantages and disadvantages: lowering transformations are faster and more flexible, but error-prone, while homogeneous transformations are simpler, yet slower.

4.10 Example macro 3: Arithmetic operators

One of the traditionally more repetitive tasks within writing a compiler is to write the code for all the arithmetic operators. It is almost always the same code for each operator, which leads to code duplication within the compiler. We will show how to leverage dolorem-c's metaprogramming abilities to help us with bootstrapping the language and avoid having to write each operator separately.

An arithmetic operator needs to read the left-hand side and the right-hand side expression, then append the context of one to the other, and finally set the expression to something like "a+b". In order to save memory, we do not create a new expression value and instead reuse one of the arguments. Here is an example for `add`:

```
(defmacro add (progn
  (:= left (lower-now (car args)))
  (:= right (lower-now (car (cdr args))))
  (add-cexp left right)
  (set-expression left (print-to-mem "(%s) + (%s)" (get-expression
    left) (get-expression right)))
  left))
```

We see that almost all of this will be the same for all operators, apart from the name of the macro and the format string ("`(%s) + (%s)`").

Using a `quasiquote` implementation based on the `quote` macro shown above, we quote the entire macro, adding in the two changing parts via `quasiunquote`:

```
(quasiquote (defmacro (quasiunquote (car args)) (progn
  (:= left (lower-now (car args)))
  (:= right (lower-now (car (cdr args))))
  (add-cexp left right)
```

```
(set-expression left (print-to-mem (quasiunquote (car (cdr args)))
  (get-expression left) (get-expression right)))
left)))
```

Finally, we wrap this into a call to `lower` and add it into a macro:

```
(defmacro generate-arithmetic-operator
  (call-macro "lower" (quasiquote defmacro (quasiunquote (car args)) (
    progn
      (:= left (lower-now (car args)))
      (:= right (lower-now (car (cdr args))))
      (add-cexp left right)
      (set-expression left (print-to-mem (quasiunquote (car (cdr args)))
        ) (get-expression left) (get-expression right)))
    left))))
```

We have now defined a macro that defines macros.

To use it, we write the following (at global scope):

```
(generate-arithmetic-operator add "(%s) + (%s)")
(generate-arithmetic-operator sub "(%s) - (%s)")
(generate-arithmetic-operator mul "(%s) * (%s)")
(generate-arithmetic-operator divi "(%s) / (%s)")
```

4.11 Macro Overriding

With what we have shown so far, plenty of macros can be implemented into `dolorem-c`. However, there is currently no way to change a macro once it is defined.

Macro overriding changes that. We add a virtual table of macros to the base language. Now, whenever a function is marked as a macro, its address is stored in the virtual table, and whenever we call a macro, we take the address from the table rather than asking the dynamic linker for it.

We also define a new function `macrofunptr override_macro(const char* name, const char* newfun)`; that overrides the macro `name` by the replacement function `newfun` and returns a pointer to the old entry in the table.

With this, we can use the standard C pattern to change the behavior of existing macros:

1. We store the old function pointer from the virtual table in a global variable.
2. Then, we override the virtual table entry with a new function.
3. In the new function, we use the old pointer in the global variable as fallback.

4.12 Overriding Example: Location hints

A useful easy example is this overriding of `lower` that adds location hints to the C code so that the C compiler can emit correct debug information⁷. Any `dolorem-c` code compiled after a call to the function we are about to define (`load-csrchints`) can be stepped through line-by-line in GDB.

We start by creating a global variable to store the current `lower` function: `(compile (global-var csrchints_old_lower macrofunptr))`

⁷ gcc supports reading hint lines in the format of “# <filename> <line number>” to be able to tell where a piece of source code is originally from. We add these to the ‘context’ of the `cexp`.

41:14 The Dolorem Pattern

After this, we define a macro called `load-csrchints` that loads the C source hints override. This is where the overloading happens. The macro is supposed to be used at global scope, so we make it return an empty `cexp`:

```
(defmacro load-csrchints (progn
  (assign csrchints-old-lower
    (override-macro "lower" "lower-csrchints")))
  (make-cexp "" "" "" ""))
```

Finally, we define the new macro `lower-csrchints` that will replace `lower`:

```
(defmacro lower-csrchints (progn
  # Call lower-level 'lower'.
  (:= r (csrchints-old-lower args))
  (var filename char*)
  (var line long)
  (get-loc-info args (ptr-to filename) (ptr-to line) 0 0)
  (append-cexp r
    (get-expression r)
    (print-to-mem "# %li \"%s\"\n" line filename) "" ""))
  r))
```

Note that this implementation prints duplicated hint lines whenever many subexpressions are on the same C source line. It also currently does not handle blocks correctly, often giving only the number of the first line of a multi-line block. Although it is not entirely correct, it is good enough to be useful in many debugging scenarios.

4.13 Layers

As explained above, we want to be able to override multiple macros at once and use a convenient syntax that abstracts all the details (global variables, calls to the `override-macro` function, etc).

For example, we want to be able to write `(new-layer foo (lower (new-lower-code...))`) to override `lower` and to have all overrides, variables, and a function `load-layer-foo` automatically generated.

In `dolorem-c`, this higher-level layer syntax is defined as a homogeneous transformation macro, and it is not part of the base language, but rather defined in the language itself.

4.14 Layer Example: Function overloading

To demonstrate layers, we will add a very basic version of function overloading to `dolorem-c`.

`dolorem-c` does not have a type system, therefore function overloading by type is not possible. Hence, this example only overloads on the number of arguments, not the type.

To implement function overloading, we need to do two things. First, we need to change the `defun` macro such that it mangles the name of any newly created function name by adding the amount of arguments to the name. Second, we change `lower` such that it correctly resolves any overloaded function calls.

Note that one of the rather unusual features of this overloading layer is that we want mangled and non-mangled functions to coexist as seamlessly as possible. This is necessary because, otherwise, loading the layer would interfere with calling any functions defined before it was loaded. In order to achieve this goal, we add a hashmap that contains the names of any mangled functions. Whenever we find a function whose name is not in the hashmap, we do not change the call.

We will only change `defun`, not `function`. This means any functions that are defined using other means will not be mangled. This is useful because it avoids breaking macros or any other mechanism that might be defined and needs more low-level control over functions.

This is the entire source code of the layer:

```
(compile (global-var overloaded-fun void*)) # hashmap for names of
  mangled functions
(new-layer funoverload
  (init (assign overloaded-fun (hashmap-new)))
  (defun (progn
    (:= name (car args))
    (:= n-args (count-len (car (cdr args))))
    (hashmap-put overloaded-fun (expect-ident name) "")
    (val-set-string name (print-to-mem "%s__fo_%i" (expect-ident name)
      ) n-args))
    (fallback args)))
(lower (progn
  (cond (val-is-list args) (progn
    (var dummy char*)
    (cond (not
      (hashmap-get overloaded-fun
        (expect-ident (car args))
        (ptr-to dummy)))
      (val-set-string
        (car args)
        (print-to-mem "%s__fo_%i"
          (expect-ident (car args))
          (count-len (cdr args)))))))
    (fallback args))))))
```

We can now load the layer with `(load-layer-funoverload)`.

Within the layer implementation, we first add some initialization code for the hashmap, and then override the `defun` macro. Our new `defun` looks for the name of the function to be defined, saves it in the hashmap, and then mangles it by appending `"__fo_X"` (where `X` is the amount of parameters). Finally, it calls whichever `defun` implementation is in the tower before this layer on the newly changed definition.

We also override `lower`. If it finds a function call, our new implementation checks if the function name is in the hashmap. If it is, it mangles it based on the amount of arguments supplied. Finally, it delegates to the next layer.

4.15 Implementing optimizations

We want to be able to write code that transforms and optimizes already-generated code. To do so, we implement a transformation layer, similar in principle to the one implemented in section 4.12 (which adds location hints), except that our new layer will change the code.

As we implement our optimization, we will run into one major limitation, which is not related to the concept of the Dolorem pattern, but rather to a specific design decision we made for `dolorem-c`. Our representation of C code is purely textual, as opposed to using a syntax tree that is easier to change, making it a pain to read and transform once it has been generated. Using another representation for C code (such as some kind of syntax tree) would have made this easier. Unfortunately our textual representation will make our optimization more inelegant and inflexible than necessary.

41:16 The Dolorem Pattern

In section 4.10, we added a division operator to `dolorem-c`. It is common for compilers to transform integer divisions of a variable and a constant to a bit shift if the constant is a power of two. We will implement this optimization (except, since we are only showing this as an example and try to simplify as much as possible, we will only transform a division with two to a bitshift and ignore the other powers of two)⁸.

If we want to transform division code, we can either (1) change the `divi` macro by overriding it in a layer, or (2) look for divisions in the code after it has been fully generated, and then change the code. Only (2) is a transformation in the narrow sense, as (1) does not technically transform generated code, but rather changes the code generator. In the Dolorem context, both have a similar effect.

We will first implement a layer for (1):

```
(new-layer bitshift-instead-of-division
  (divi (progn
    (:= first-operand (car args))
    (:= second-operand (car (cdr args)))
    (:= result NULL)
    (cond (and
      (val-is-int second-operand)
      (equals (expect-int second-operand) 2)) (progn
        (:= c (lower-now first-operand))
        (assign result (make-cexp
          (print-to-mem "(%s) >> 1" (get-expression c))
          (get-context c)
          (get-global c)
          (get-header c))))))
    (cond (not result)
      (assign result (fallback args)))
    result)))
```

This overrides the `divi` macro itself, and adds a check for whether one of the operands is the number two.

Alternatively, we can implement option (2) and search and replace existing code for any divisions with two. Due to the limitations with the C code representation, we do this on a textual level.

All divisions will be within functions, so the easiest way to catch all of them is to override the function macro (used within `defun` as described above) and work with its output:

```
(new-layer bitshift-instead-of-divisions-2
  (function (progn
    (:= code (fallback args))
    (:= global-ptr (get-global code))
    (:= pointer global-ptr)
    (:= modified 0)
    (loop (assign pointer (strstr pointer "/" (2))) (progn
      (memcpy pointer ">> 1" 5)
      (assign modified 1)))
    (cond modified
      (set-global code global-ptr))
    code)))
```

⁸ Since all code is compiled (and optimized) by a C compiler which will most certainly do this optimization, our code does not actually yield a speed boost, but merely serves to illustrate how code transformations are implemented with the Dolorem pattern.

First, we call the overridden macro to generate the function code and then we search the `global` of its result (which is where the function body will be).

Note that this second implementation does not refer to the `divi` macro at all. In fact, it does not matter whether the division was created by that macro, some other macro, or even a combination of several macros. All that matters is that the generated code eventually shows up in a function, and once it does show up in the function, we have access to all other code in the function and can use this contextual information for our optimization. That is how we can also implement more complex optimizations that touch multiple macros.

As we discussed, the transformations themselves are implemented in a rather inelegant way, but still, this experiment shows the principles of how source code transformations can be implemented in Dolorem:

1. For simple optimizations, it often makes sense to change how the code is being created, as opposed to transforming it after it was already created.
2. To transform code, create a layer around a macro like `function` (or `compile`) that all code will pass through, and modify it there. Then, our optimization can even touch multiple macros and operate on an entire function (or even several functions).
3. The specific range of practical transformations depends on the design of the data structure generated code is stored in. The Dolorem pattern itself is not a limiting factor.
4. If an optimization is impractical to do, that does not mean it is impossible entirely. Dolorem systems use a target language and target compiler outside of Dolorem. Sometimes, it can make sense to optimize there.

More experimentation is needed to see whether this approach scales to more complex optimizations.

5 Discussion of the C implementation

We have successfully implemented a Dolorem system that targets C.

5.1 Code size

Minus header files, the hashmap implementation, the driver and the reader/parser, the entire compiler only has 377 lines of code. This shows that we were able to keep the base language very small. In an additional 284 lines of Dolorem code, we were able to bootstrap a relatively usable language. This confirms our original plan to keep the base language minimal and bootstrap the rest.

5.2 Scope

We have left out some important aspects of a language, most importantly the type system. This is certainly a major reason for why the implementation is so small in terms of code size. In the rest of the paper, we will show that the Dolorem pattern can scale and work for a more complicated language.

5.3 Generated code

When we output C code generated by `dolorem-c` and change the formatting a bit, it looks very similar to human-written C code (see Figure 1). Of course, this depends on the macros used. Macros may introduce additional complexities, and thus, additional overhead, if the abstraction they provide is costly or if they are badly written and introduce unnecessary cost – but none of the macros we have shown or used in examples do.

41:18 The Dolorem Pattern

■ **Figure 1** *left*: dolorem-c code for a non-recursive Fibonacci function, *middle*: generated C code (indentations added for readability), *right*: hand-written C code.

```
(defun
 fib ((int x)) int
 (progn
  (var i int)
  (var n1 int)
  (var n2 int)
  (var n3 int)
  (loop
   (less i x)
   (progn
    (assign n3 (add
              n1 n2))
    (assign n1 n2)
    (assign n2 n3)
    (assign i (add i
                  1)))
  ))
 n3
))
```

```
int fib__fo_1(int x) {
  int i = 2;
  i;
  int n1 = 0;
  n1;
  int n2 = 1;
  n2;
  int n3 = 0;
  n3;
  while((i) < (x)) {
    (n3) = ((n1) + (n2));
    (n1) = (n2);
    (n2) = (n3);
    (i) = ((i) + (1));
  }
  return n3;
}
```

```
int fib(int x) {
  int i = 2;
  int n1 = 0;
  int n2 = 1;
  int n3 = 0;
  while (i < x) {
    n3 = (n1 + n2);
    n1 = n2;
    n2 = n3;
    ++i;
  }
  return n3;
}
```

This also means we can compile it with a traditional C compiler, and the binary will be basically indistinguishable from that created from an equivalent program originally written in C.

5.4 Run-time overhead

The above already gives us a first indication that dolorem-c has no or very low overhead. Since the implementation is more of a proof-of-concept, we have not measured its performance, but have rather, in many cases including the one shown in Figure 1, seen that its C code is essentially equivalent to what we would have written by hand. We will later show a more detailed run-time analysis for dolorem-llvm.

5.5 Compile speed

Since dolorem-c can be used to directly execute code (rather than as a transpiler which code is exported from), compile speed is essential.

We expect most of the overall compile time to be spent in the C compiler. In order to verify, we implement a command line flag (-M) that instructs the compiler to measure the overall run-time and the time spent waiting for calls to the compiler, and output a percentage.

We test this while compiling several programs examples, including the definitions of the macros presented here (and more). None of our test cases does anything, they all compile and then terminate.

As expected, measurements show that 95-97 % (tcc) or more than 99 %⁹ of overall compile time is spent in the C compiler. The discrepancy is due to the fact that gcc is about 20 times slower than tcc, likely because its code generation is generally slower and also because it is not optimized to be invoked for each function separately.

Subtracting the time spent in the C compiler, dolorem-c takes between 5 and 10 milliseconds to compile the entire collection of standard macros (around 500 lines of dolorem-c code)¹⁰.

These measurements show that, while the dolorem-c compiler is comparatively fast given its flexibility, C compilation drastically slows it down. To improve speed, the implementation should implement some form of caching for the compilation. We will later show an example of this for dolorem-llvm.

6 Implementation with LLVM Target

We are now ready to implement the Dolorem pattern in an LLVM-based [7] system. While dolorem-c was intended as a proof of concept and simple demonstration, dolorem-llvm is intended to include more complex features like static typing, even if this makes it more complex¹¹.

The design of dolorem-llvm is similar to dolorem-c in many ways. We will not provide a full outline of the design, but rather describe the differences to dolorem-c, with a focus on providing some general discussion on how to apply the Dolorem pattern to a more complete compiler system.

Rather than generating code as a string, dolorem-llvm calls into LLVM directly to build LLVM IR.

LLVM's main interface is template-heavy C++ code. Since interfacing with that would drastically increase the size of the base language, we instead mostly interface with the C bindings (llvm-c).

6.1 The `lower` macro

Obviously, the most important difference is that there are no `cexps` anymore, because the new system does not translate to C.

Instead, `lower` returns a pointer to an `rtv` (*run-time value*) rather than a pointer to a `cexp`. An `rtv` wraps an `LLVMValue`, i.e. a reference to a value computed by a program. It also contains the type information the new type system needs.

6.2 Functions

`LLVMValue` works differently from a `cexp` in one key way: Because a dolorem-llvm `rtv` can hold only a value within a function, rather than an arbitrary piece of code, a dolorem-llvm macro can not return a full uncompiled function.

⁹ The results are very similar for all test cases and, while there is quite some variance between runs, it seems random and unrelated to the length or any other property of the test case. That is why we do not provide a detailed list of measurement values.

¹⁰ Measured on an Intel Xeon E3-1505M v5, when compiling the base language with gcc 12.2.

¹¹ The entire dolorem-llvm source code can be found in this GitHub repository: <https://github.com/shenniger/dolorem>

41:20 The Dolorem Pattern

Therefore, the `function` macro can not be implemented like in `dolorem-c`, and `dolorem-llvm` does not define one, but rather implements `defun`, and `defmacro` in its base language. There are separate macros to define lambdas.

In `dolorem-c`, the `defun` macro is essentially composed of two different macros, namely the `function` macro which generates C code for the function, and the `compile` macro which hands the generated code to a C compiler.

This shows that, while `dolorem-llvm` and `dolorem-c` both try to keep their base language minimal (principle (2.3.5)), LLVM's more complex API often causes macros to be moved into the base language.

6.3 Language usage: Compiling code

Above, we already showed how to execute Dolorem code directly during compile-time (see 4.8). However, principle (2.4.2) says that it should also be possible to compile Dolorem code.

In order to do that, we need to write LLVM IR code to disk, and then compile it:

1. LLVM only supports to write modules to disk, so by directly calling LLVM's `LLVMModuleCreateWithName`, we create a new LLVM module.
2. For each single function that is to be written to disk, we call `dolorem-llvm`'s `copy-symbol-to-module`. This function looks up a symbol in an array that `dolorem-llvm` copies all function modules to before they are JIT-compiled and copies it to the new module. Note that this works because, like `dolorem-c`, `dolorem-llvm` compiles each function separately and in its own `LLVMModule` (see principle (2.3.4)).
3. Call an LLVM function that exports a module, e.g. `LLVMWriteBitcodeToFile`.
4. Finally, we compile this module to machine code. The easiest way to do this is to invoke `clang` on the command line, but this could also be done using the LLVM library.

Here is a simple example that compiles a “Hello, world!” program to a Linux executable¹²:

```
(defun main () i32 (progn
  (puts "Hello, world!")
  0))
(defmacro compile (progn
  (:= mod (LLVMModuleCreateWithName "test"))
  (copy_symbol_to_module "main" mod)
  (LLVMWriteBitcodeToFile mod "tmp.bc")
  (system "clang tmp.bc -o hello-world";
  (empty-rtv)
  ))
(compile)
```

A program compiled in this way does not depend on the compiler in any way; it is a freestanding executable, quite similar to an executable a C compiler would have created for the same program.

6.4 Precompilation

We can use this mechanism for precompilation.

We compile all functions of a file (including macros) to a shared object. Next time we compile the same file, we still read it entirely and execute all macros, but do not compile any

¹² `(empty-rtv)`, like `dolorem-c`'s `(make-cexp "" "" "" "")`, creates an empty macro return value.

functions within the file if it is unchanged. Instead, we simply load the shared object from last time. This way, we continue to populate all internal data structures like function lists, but avoid calling into LLVM, which is the most time-consuming step.

We would typically use this on macros that define the language. Not having to recompile them every time we compile any `dolorem-llvm` code reduces compilation time.

This mechanism is important because it means that, unlike other staged languages, `dolorem-llvm` does not need to recompile the entire language with every translation unit.

6.5 Optimizations

In section 4.15, we discussed the implementation of code transformations and optimizations in the Dolorem system. We also already explained four basic principles of Dolorem source code transformations.

We will now attempt to use LLVM to optimize `dolorem-llvm` code. To do so, we use the four principles. Our attempt here differs from the attempt in section 4.15 in two main respects: First, since `dolorem-llvm` does not generate code as text, but instead constructs LLVM's data structure which is powerful and easy to modify, we will modify this data structure rather than text. Second, LLVM provides a number of facilities to implement and run optimizations which we can access because we have full access to LLVM (as part of 2.4.1).

That is why, unlike in `dolorem-c`, we will not implement our own layer for optimizing a function, but will instead show how to apply LLVM's `PassManager` to a `dolorem-llvm` function. To do so, we add a macro `optimize` that first lowers its argument, then calls into LLVM to run an optimization¹³:

```
(defmacro optimize (progn
  (:= result (lower (car args)))
  (LLVMBuildRetVoid bldr)
  (LLVMRunPasses mod # the current module
    "instcombine" # the pass name
    (GetThisMachineStdTargetRef) # a convenience function
    defined before
    (LLVMCreatePassBuilderOptions))
  result))
```

Note that we do not directly change the result of `(lower (car args))` before we return it. That is because it merely contains a pointer to an `LLVMValue` of the function return value (and the pointer will not change as part of the optimizations), while the actual sequence of commands is saved in the current `LLVMModule` as a side effect of lowering. This current `LLVMModule` is exposed to macros by the compiler through global variable `mod` and is guaranteed to only contain the currently compiled function (and any nested functions).

The idea of `optimize` is that we can wrap any function body in it to optimize that function, for example:

```
defun do-some-math () void (optimize (progn
  (:= i 10)
  (printf "10 * 16 = %i\n" (* i 16))
));
```

¹³ At the time when `optimize` is called, the final `ret` instruction is likely not yet generated, so we add it to the function before optimization by calling `LLVMBuildRetVoid`.

Since we chose "instcombine" above, LLVM will optimize arithmetic instructions, and thus (similar to the toy optimization we implemented for dolorem-c, but much more powerful) transform our multiplication into a bit shift.

Typically, optimization passes would be added by a flag or some other global compiler setting. Our solution is different: It is only applied to the specific function we want it applied on and also allows us more flexible control in other ways. Finally, our solution allows us to implement our own LLVM optimizer pass and then apply it using the method shown above. We do not show a full example for how, because there is nothing Dolorem-specific about the implementation. It is enough to write the LLVM optimizer function as a normal Dolorem function, then register it in LLVM's `PassManager` in the macro and use it (as shown above). The macro will be able to see the function definition because of principle 2.3.4 and get a pointer to the function, which LLVM can then call.

7 Discussion of the LLVM implementation

We will now evaluate four key factors of our implementation: more complex/powerful language, low code size, minimal/no run-time overhead, and fast compilation times.

7.1 More powerful language

dolorem-llvm is a more powerful and complete language than dolorem-c. It includes its own type system, can interface with C and enables a macro writer to access the full power of LLVM.

To show that we can implement nontrivial example programs in dolorem-llvm, we implemented a graphical Pong. The 192-line-long program uses the game library SDL2 to render graphics and receive inputs.

7.2 Code size

Using our own type system rather than piggybacking on C and emitting the more complex LLVM IR requires slightly more complexity in dolorem-llvm.

Minus header files, the hashmap implementation, the driver and the reader/parser, the entire compiler has about 1980 lines of code. Most of the increase compared to dolorem-c is due to the bigger base language, and also due to the higher complexity of LLVM code.

This shows that, while more complex targets do increase the size of the base language, the basic principle of bootstrapping most of the language still works.

7.3 Run-time overhead

Dolorem's design attempts to impose minimal inherent run-time overhead on programs.

It is challenging to evaluate this goal in general. Primarily, that is because the performance of a Dolorem program depends on the macros used to compile it more than on anything else. In C++, if someone writes a template that is wasteful, that leads to a slower program – just like a Dolorem macro that is badly written or implements a highly ambitious and high-overhead language feature will lead to a slower program.

While it is possible to write programs without complex templates in C++, it is not possible to write non-trivial Dolorem programs without using many macros (that is because we keep the base language minimal, see 2.3.5).

■ **Figure 2** Performance of a Fibonacci function (executed 10,000 times, milliseconds) implemented in C (black) and dolorem-llvm (yellow).

Therefore, in this section, we do not show that all Dolorem environments will be zero-overhead. We consider this to be not only impossible to show given the level afforded to macros, but also to be an undesirable goal: sometimes, using a macro that imposes a little bit of overhead might be a desirable choice, and that is fine, as long as it is a conscious, voluntary decision on the part of the developer.

Instead, we will show that, for our test cases, dolorem-llvm imposes no *inherent* run-time overhead, i.e. that dolorem-llvm allows the creation of a zero-overhead environment using macros and that it is possible to write non-trivial programs in it.

We will show this for two programs written using the default set of macros (i.e. the set of macros we have talked about in this paper). As part of our benchmark, we compile the generated code for a fibonacci function and compare it to an equivalent C implementation, using maximum LLVM optimization for both languages, i.e. `-O3` for C.

We see that the speed is exactly the same (Figure 2).

Another test shows the same result: When we compile the graphical Pong we implemented using the mechanism above and measure against an identical program written in C, we see that both are equally fast (in terms of frames per second).

Therefore, we conclude that, while additional tests are necessary to check this promise in the general case, we see that Dolorem exhibits no run-time overhead on the generated code in the cases we tested.

7.4 Compile speed

Many staged languages suffer from compile time problems, because the entire language needs to be recompiled with every translation unit. Dolorem has a unique strength that becomes relevant here: All language macros (like `if`, `add` etc.), after having been compiled, become part of the Dolorem environment, and, like any part of the Dolorem environment, can not only be JIT-compiled, but also exported as machine code (see “Do not prescribe a model of execution”, section 2.4.2). Therefore, unlike in other staged programming languages, it is trivial to precompile any part of the environment (see section 6.4) – including any macros that define the language. Once precompiled, all of those language macros are only a single `dlopen` away.

■ **Figure 3** Performance of dolorem-llvm’s compiler (seconds) for a program of size N lines of code.

That is why we do not include benchmarks on loading the basic environment: basic language macros only need to be compiled once when Dolorem is first installed and then the precompiled versions can be used.

However, we are still interested in the speed of dolorem-llvm’s compiler for new user code.

In order to benchmark this, we need a way of creating large amounts of code that is similar in structure to real-world dolorem-llvm code. We write a macro that duplicates existing code from a number of sources (including the standard library, the Pong implementation and a few other smaller test cases) while changing all names to avoid name clashes.

This way, we simulate how fast dolorem-llvm compiles large, real-world programs of a certain size (Figure 3).

In the case of the Pong example (which contains about 500 lines of Dolorem code in total), the compilation takes about 300 ms. Note that, because we do not use precompilation for this experiment, much of this is LLVM’s start-up time, so, unlike with dolorem-c, total start-up time does not scale proportionally to the amount of code.

We can see from Figure 3 that compilation/start-up times scale linearly with code size. Taking into account that general initialization takes about 200ms, every additional 1000 lines of code take about 12ms. This is competitive with modern C++ compilers.

Precompilation massively helps additionally reduce compile speed. With precompilation enabled, even mid-size examples like Pong start instantly (< 50 ms start-up time) in direct execution mode.

8 Related Work

We discuss various approaches to achieving extensible languages. Dolorem is distinct in that it is a heterogeneous metaprogramming system which gives its macros access to the entire language. Other approaches differ:

Ziggurat [3] is a language tower system to use Scheme-like macros for languages like C. While Ziggurat has a similar aim, namely to add layer-based metaprogramming to low-level languages, Ziggurat’s macros are different: they don’t have access to calling functions, and act more like a preprocessor, limited to generating code. In contrast, Dolorem adheres to the principle (2.3.4) that each macro has access to the full language: a macro can call into functions, for example.

McMicMac [6] is a macro-based system for generative programming in Scheme. It provides a standard way for writing syntax transformations. Dolorem is about expanding the scope of what macros can do, while McMicMac is about putting macros to use.

Converge [12] is a system to embed DSLs in a programming language with a compile-time meta-programming facility. Compared to Dolorem, the setting is homogeneous. The system can guarantee that these embeddings are safe and hygienic (in the sense of LISP macros [5]).

Like Dolorem, MetaOCaml [4] allows a developer to ask the run-time system to compile a piece of code, and link it back to the running program. However, unlike Dolorem, it is a homogeneous system. In practice, MetaOCaml can be seen as a two-stage language, where code is manually marked by quotations to ask the runtime system to compile it. The markings are not essential: inside and outside the markings, code is in the same language. They could even technically be erased yielding the same meaning with a different performance. In contrast, Dolorem is more of a metaprogramming system, where not only what is compiled can be controlled from within the language, but also *how* it is compiled.

Terra [1] and Dolorem share their aim to allow for generative low-level programming using staging. To do so, Terra is staged from within the popular scripting language Lua. Users can generate Terra code from within Lua. Terra and Dolorem also have similar mechanisms to export finished binaries programmatically. However, unlike Terra, Dolorem uses only one language and is mostly bootstrapped from within itself. Most importantly, this means that Dolorem macros have access to the entire language, while Terra and Lua are still separate, although they share the same lexical environment.

Racket [11], like Dolorem, allows macros to change the semantics of the language. Unlike Dolorem macros, Racket macros translate to standard Racket rather than directly generating code.

Metaphor [8] is an object-oriented multi-staging system that targets the .NET Runtime. Metaphor's primary design goal is to allow for type safety. While Metaphor's higher order functions have access to much of the .NET API, they mostly use it for reflection, rather than explicitly generating code.

9 Conclusion

We have described the Dolorem pattern for very flexible metaprogramming and have seen that it exhibits low overhead. Furthermore, we have shown and implemented two languages that make use of the pattern, one that lowers to C and one that lowers to LLVM.

We have discussed the design constraints that the pattern imposes on a language and presented a number of considerations, such as using S-expressions, allowing macros to call into the code generator, and compiling each function separately. We have explained the importance of the `lower` macro and how it compares to traditional `eval`-based approaches.

While `dolorem-c` mostly served as a proof of concept of the pattern, it could already show that our pattern can deliver on its promises of allowing easy language extensions. Its metaprogramming facilities were shown to be powerful enough to implement all arithmetic operators in less than twenty lines of code.

With `dolorem-llvm`, we have shown that the Dolorem pattern can work on a larger scale without losing its core advantages. To show that `dolorem-llvm` is fast and can interface well with existing libraries, we implemented a graphical Pong game.

Next steps

This paper showed a number of macro examples, but most of them were bootstrapping relatively standard language features. It would be interesting to create more complex layers and macros that leverage Dolorem systems to implement more advanced functionality, like instrumentation, data serialization, and borrow checking.

While we have seen in our experiments that Dolorem systems can exhibit low overhead, it would be interesting to conduct more and more methodical experiments on performance, especially those that help better understand how design choices made in macros impact overhead.

It could also be insightful to implement a Dolorem language that targets a more low-level language. For example, there could be a `dolorem-x86` that translates to x86 machine code (or x86 assembly). That would create a new use-case for macros: adding support for new instruction set extensions. It would also invite more experimentation with implementing custom optimization passes as macros.

Furthermore, an interesting topic of future research is to implement cross-compilation within a Dolorem system. `dolorem-c` particularly could be extended by a `cross-compile` form that acts similar to `compile`, except that it compiles for a different architecture. It might also be possible to stage an entirely new language from within a Dolorem language, e.g. to compile OpenGL shaders.

It should also be investigated whether `compile` speeds can be further improved by changing how the C compiler is invoked or by optimizing LLVM's JIT compiler.

Finally, neither `dolorem-c` and `dolorem-llvm` currently have a clearly defined memory model convention. There should be a design contract on where memory is allocated and freed within the compiler (and, by extension, within macros). By creating a design contract, more optimizations and more safety checks would be made possible.

Synthetic Behavioural Typing: Sound, Regular Multiparty Sessions via Implicit Local Types

Abstract

Programming distributed systems is difficult. Multiparty session typing (MPST) is a method to automatically prove safety and liveness of protocol implementations relative to protocol specifications.

In this paper, we introduce two new techniques to significantly improve the expressiveness of the MPST method: projection is based on *implicit* local types instead of explicit; type checking is based on the *operational semantics* of implicit local types instead of on the syntax. That is, the reduction relation on implicit local types is used not only “a posteriori” to prove type soundness (as usual), but also “a priori” to define the typing rules – *synthetically*.

Classes of protocols that can now be specified/implemented/verified for the first time using the MPST method include: recursive protocols in which different roles participate in different branches; protocols in which a receiver chooses the sender of the first communication; protocols in which multiple roles synchronously choose both the sender and the receiver of a next communication, implemented as mixed input/output processes. We present the theory of the new techniques, as well as their future potential, and we demonstrate their present capabilities to effectively support regular expressions as global types (not possible before).

1 Introduction

Programming distributed systems is difficult. One of the challenges is to prove that the implementation of *protocols* (message passing) is safe and live relative to the specification. Safety means that “bad” communications never happen: if a communication happens in the implementation, then it is allowed to happen by the specification. Liveness means that “good” communications eventually happen. *Multiparty session typing* (MPST), proposed by Honda et al. [39, 40], is a method to automatically prove safety and liveness of protocol implementations relative to protocol specifications. Figure 1 visualises the idea:

1. First, a *global type* G specifies a protocol among roles/participants r_1, \dots, r_n , while *processes* P_1, \dots, P_n implement it. A global type models the behaviour of all processes together (e.g., “first, a number from Alice to Bob; next, a boolean from Bob to Carol”).
2. Next, *local types* L_1, \dots, L_n are extracted from global type G by *projecting* G onto every role r_i . Each local type models the behaviour of one process alone (e.g., for Bob, “first, he receives a number from Alice; next, he sends a boolean to Carol”).

■ **Figure 1** MPST method.

■ **Figure 2** Two executions of the protocol in Example 1.

3. Last, the processes are verified by *type checking* every process P_i against its local type L_i .

Well-typedness at compile-time implies safety and liveness at run-time.

The following simple example further demonstrates the MPST method.

► **Example 1.** The *Summation* protocol consists of roles *Alice* (**a**), *Bob* (**b**), and *Carol* (**c**). First, zero or more numbers are communicated from Alice to Bob. Next, a token (**unit**) is communicated from Alice to Bob. Last, the sum of the numbers is communicated from Bob to Carol. Figure 2 visualises two executions of this protocol.

The following recursive global type specifies the protocol:

$$G = \mu X. \mathbf{a} \rightarrow \mathbf{b}: \begin{cases} \text{Nat}.X \\ \text{Unit}. \mathbf{b} \rightarrow \mathbf{c}: \text{Nat}. \checkmark \end{cases}$$

Informally, global type $p \rightarrow q: \{t_i.G_i\}_{1 \leq i \leq n}$ specifies the communication of a value of data type t_i from role p to role q , for some $1 \leq i \leq n$; we omit braces when $n = 1$.

The following recursive local types, projected from the global type, specify Alice and Bob:

$$L_{\mathbf{a}} = \mu X. \mathbf{b} \oplus \begin{cases} \text{Nat}.X \\ \text{Unit}. \checkmark \end{cases} \quad L_{\mathbf{b}} = \mu X. \mathbf{a} \& \begin{cases} \text{Nat}.X \\ \text{Unit}. \mathbf{c} \oplus \text{Nat}. \checkmark \end{cases}$$

Informally, local types $q \oplus \{t_i.L_i\}_{1 \leq i \leq n}$ and $p \& \{t_i.L_i\}_{1 \leq i \leq n}$ specify the send and the receive of a value of data type t_i from role p to role q , for some $1 \leq i \leq n$; we omit braces when $n = 1$.

The following processes, well-typed against the local types, implement Alice and Bob:

$$P_{\mathbf{a}} = \underbrace{\bar{\mathbf{b}}\langle 5 \rangle. \bar{\mathbf{b}}\langle 6 \rangle. \bar{\mathbf{b}}\langle \text{unit} \rangle. \mathbf{0}}_{\text{specifically, Figure 1b}} \quad P_{\mathbf{b}} = \text{loop}(\text{sum}: \text{Nat} = 0) \sum \begin{cases} \mathbf{a}(x: \text{Nat}). \text{recur}(\text{sum} + x) \\ \mathbf{a}(_ : \text{Unit}). \bar{\mathbf{c}}\langle \text{sum} \rangle. \mathbf{0} \end{cases}$$

Informally, process $\bar{q}\langle e \rangle.P$ implements the send of the value of expression e to role q , while process $\sum \{p(x_i: t_i). P_i\}_{1 \leq i \leq n}$ implements the receive of a value of data type t_i from role p into variable x_i , for some $1 \leq i \leq n$; we omit \sum and braces when $n = 1$. Well-typedness means that every action implemented in $P_{\mathbf{a}}$ (resp. $P_{\mathbf{b}}$) is also specified in $L_{\mathbf{a}}$ (resp. $L_{\mathbf{b}}$). \lrcorner

Over the past 10–15 years, substantial progress has been made both in MPST theory (e.g., extensions with advanced features, including time [10, 57], security [15–17, 24], and parametrisation [25, 33, 59]) and in MPST practice (e.g., tools for F# [58], F* [71], Go [25], Java [41, 42], OCaml [70], PureScript [46], Rust [48, 49], Scala [26, 61], and TypeScript [56]).

1.1 Open Question: Regular Expressions as Global/Local Types

The expressiveness of the grammar of global/local types determines which protocols can be specified. In turn, this determines which protocols can be implemented in a provably safe and live fashion: the higher the expressiveness, the higher the applicability of the MPST

method to program real(istic) distributed systems. For this reason, substantial research in the community has aimed to increase expressiveness. Doing so is not as simple as just adding new operators to the grammars; to be *effective*, these operators need to be supported by projection and type checking as well, which is actually complicated. As a result, regarding basic features, grammars of global types have effectively evolved as follows:

- In the original paper [39]:

$$G ::= p \rightarrow q : \{t_i . G_i\}_{1 \leq i \leq n} \mid \mu X . G \mid X \mid \checkmark$$

Thus, global types can specify that a sender chooses the data type *but not the receiver*.

- In recent papers [21–23, 54, 65]:

$$G ::= p \rightarrow \{q_i : t_i . G_i\}_{1 \leq i \leq n} \mid \mu X . G \mid X \mid \checkmark$$

Thus, global types can specify that a sender chooses the data type *and also the receiver*.

However, it remains an open question how to effectively generalise these *sub-regular* grammars to *regular* ones (e.g., global types that can specify that a receiver initially chooses the sender). This generalisation would enable the MPST-based verification of significantly more processes.

The notion of using regular expressions as global/local types, or *choreographies*, to specify protocols is intuitive, well-known, and actively studied. Early papers include those by Busi et al. [14], Bravetti–Zavattaro [12, 13], Lanese et al. [50], and Castagna et al. [20]; later papers include those by Guanciale–Tuosto et al. [27, 35, 64], Jongmans et al. [36, 37, 44], and De’Liguoro et al. [29]. Most of these many papers focus on projection, though, while *none* of them focus on type checking: typing rules to verify processes using regular expressions *do not yet exist* in the MPST literature. However, type checking is just as vital as projection in the MPST method (Figure 1). Thus, beyond the non-trivial achievements to *only project* regular expressions, the next elusive milestone is to *also type-check* processes against them.

In summary, the evolution of sub-regular grammars of global/local types has been hard and relatively slow; it also seems to remain relatively far from reaching an effective generalisation to regularity, despite considerable interest in the community. In contrast, for *binary* session typing, the state-of-the-art went beyond regularity already (including *mixed choice* [19]) and has started to explore *context-freeness* [2, 3, 45, 60, 63]. These observations suggest that the open question for multiparty must be significant, too, but apparently very hard to answer. In this paper, we rebuild the foundations of the MPST method using new techniques and answer the open question in the affirmative. For the first time, we effectively generalise the sub-regular grammar of global types to the following “open-ended” regular grammar:

$$G ::= p \rightarrow q : t \mid G_1 + G_2 \mid G_1 \cdot G_2 \mid G^* \mid \checkmark \mid \dots$$

1.2 Contributions of This Paper

In existing papers in the MPST literature, there is a tight correspondence between the structure of global/local types and the structure of processes, instrumental to define projection and type checking. For instance, the global/local types and the processes in Example 1 have essentially the same structure: cosmetics aside, the processes are just syntactic refinements of the global/local types (choices resolved; loops unrolled; values instead of data types).

However, the usage of regular expressions as global/local types breaks the tight correspondence. Generally speaking – deliberately unspecific to regular expressions – the foundational challenge is to define projection and type checking when the grammars are *so far apart* that structurally matching processes to global/local types is prohibitively complicated. *The idea of this paper is to abandon such structural matching and use two new techniques instead:*

- **Local types and projection:** Projection is based on *implicit* local types instead of explicit. To clarify the difference, consider the following projections of global type G in Example 1:

$$L_{\text{old}} = \mu X. \mathbf{a} \& \{ \text{Nat}.X, \text{Unit}.c \oplus \text{Nat}.\checkmark \} \quad L_{\text{new}} = G \upharpoonright \mathbf{b}$$

Explicit local type L_{old} is representative of existing techniques (same as $L_{\mathbf{b}}$ in Example 1): it has the same structure as G . In contrast, implicit local type L_{new} is representative of this paper’s new technique; essentially, it is just a role-indexed global type.

Notably, the concept of *merging*, shown to be problematic for session types [62] (i.e., published results based on merging turned out to be defective), is no longer needed.

- **Type checking:** Type checking is based on the *operational semantics* of implicit local types instead of on the syntax. That is, the reduction relation on implicit local types is used not only “a posteriori” to prove type soundness (as usual), but also “a priori” to define the typing rules. To clarify the difference, consider the following typing rules:

$$\frac{\Xi \vdash e : t_k \quad \Xi \vdash P : L_k}{\Xi \vdash \bar{q}_k \langle e \rangle . P : \sum \{ q_i ! t_i . L_i \}_{1 \leq i \leq n}} \text{[OLD]} \quad \frac{\Xi \vdash e : t \quad \Xi \vdash P : L' \quad L \xrightarrow{q!t} L'}{\Xi \vdash \bar{q} \langle e \rangle . P : L} \text{[NEW]}$$

Rule [OLD] is representative of existing techniques: it states that an output process is well-typed by an explicit local type if it matches the structure. In contrast, rule [NEW] is representative of this paper’s new technique: it states that an output process is well-typed by an implicit local type if it matches the behaviour.¹ As every local type is of the form $G \upharpoonright r$, its reduction relation is derivable from the reduction relation of G . The applicability of rule [NEW] is decidable as the reduction relations constitute finite state machines.

The programmer does not write implicit local types directly, but only global types; implicit local types are automatically extracted as role-indexed global types.

Our aim is to present the theory of the new techniques, as well as their future potential, and to demonstrate their present capabilities:

- X. Protocols that could already be specified/implemented using sub-regular grammars, but not yet verified (i.e., the MPST method is sound but incomplete), *can now be verified*. This includes recursive protocols in which *different roles participate in different branches*.
- Y. Protocols that could already be specified using sub-regular grammars, can now be specified *exponentially more succinct* using regular grammars.
- Z. Protocols that could not yet be specified/implemented/verified using sub-regular grammars, *can now be specified/implemented/verified* using regular grammars. This includes protocols in which *a receiver chooses the sender of the first communication*, and also protocols in which *multiple roles synchronously choose both the sender and the receiver of a next communication* (implemented as mixed input/output processes, similar to `select` for Go channels and POSIX sockets).

We note that the idea of this paper *also* improves the effectiveness of sub-regular grammars (item X). This is because the new techniques are deliberately unspecific to regular expressions, but general: the theory readily supports *any* model of behaviour directly as a global type – be it state-based (e.g., finite automata or labelled transition systems), or event-based (e.g.,

¹ Rule [OLD] is “analytic”: every process/type term that occurs in the premise of a rule *must* also occur as a subterm in the conclusion. In contrast, rule [NEW] is “synthetic” (the dual of “analytic”; e.g., [7, 38]): every process/type term that occurs in the premise of a rule *may* – but does not have to – occur as a subterm in the conclusion. That is, meta-variable L' occurs only in the premise, but not in the conclusion, so it needs to be synthesised to prove well-typedness (by computing the reduction relation).

pomsets or event structures), or logic-based (e.g., CTL or Hennessy–Milner logic) – so long as that model can be interpreted in our general format of operational semantics. Whether or not the usage of such models directly as global types is useful, or preferable over existing algebraic notation, is another research question. But, the future potential seems valuable.

In §2, we further detail the contributions of this paper. In §3, we apply the new techniques to sub-regular grammars. Thus, we introduce the main concepts and complications in a familiar setting. In §4, we apply the new techniques to regular grammars. This section is surprisingly short, which is evidence of the generality of the idea: all complications are addressed in the familiar setting of sub-regular grammars in §3, and those results are almost directly applicable to regular grammars in §4. A separate technical report contains proofs [43].

2 Overview of the Techniques

In this section, using several examples, we further detail the contributions of this paper. The examples follow the three steps of the MPST method (§1), adapted to the new techniques:

- 1a. The programmer writes a global type G and processes P_1, \dots, P_n for roles r_1, \dots, r_n .
- 1b. A tool computes the operational semantics of G and of the implicit local types $G \upharpoonright r_1, \dots, G \upharpoonright r_n$ in the form of a *termination predicate* and a *reduction relation* for every role. Every $G \upharpoonright r_i$ is an implicit local type; it does not compute an explicit one. That is, in this paper, projection is an operator for implicit local types instead of a function on global types.
2. A tool checks if every $G \upharpoonright r_i$ is *well-behaved*. If so, then G is *operationally equivalent* to $G \upharpoonright r_1, \dots, G \upharpoonright r_n$. That is, G mimics $G \upharpoonright r_1, \dots, G \upharpoonright r_n$, and vice versa. Well-behavedness of implicit local types is a new alternative to well-formedness of global types. Importantly, well-behavedness is fully *compositional*: it can be checked separately for every role.
3. A tool checks if every P_i is *well-typed* by $G \upharpoonright r_i$. If so, then $G \upharpoonright r_1, \dots, G \upharpoonright r_n$ is *operationally refined* by P_1, \dots, P_n . That is, $G \upharpoonright r_1, \dots, G \upharpoonright r_n$ mimics P_1, \dots, P_n , but not necessarily vice versa: $G \upharpoonright r_1, \dots, G \upharpoonright r_n$ may specify more behaviour than P_1, \dots, P_n must implement.

2.1 Sub-Regular Grammars

In §3, we apply the new techniques of this paper to the following sub-regular grammars of global types and processes; they are representative of existing ones in the MPST literature:

$$\begin{aligned}
 G &::= p \rightarrow q : \{t_i.G_i\}_{1 \leq i \leq n} \mid \mu X.G \mid X \mid \checkmark & \quad \text{output process} & \quad \text{input process} \\
 P &::= \sum \{O_1, \dots, O_n\} \mid \sum \{I_1, \dots, I_m\} \mid \dots & \quad O ::= \overline{q}(e).P & \quad I ::= p(x:t).P
 \end{aligned}$$

The informal meanings and notational conventions are the same as in Example 1 and further clarified in the examples in this subsection. The examples serve two purposes: to introduce the main concepts, and to demonstrate that the idea of this paper offers distinct expressive power, even in the familiar setting of sub-regular grammars (item **X** in §1.2).

► **Example 2.** We apply steps **1a**, **1b**, **2**, and **3** to the Summation protocol in Example 1:

- 1a. The following global type and processes specifies and implement the protocol (same as in Example 1, except the process for Carol, which is new here):

$$\begin{aligned}
 G &= \mu X. \mathbf{a} \rightarrow \mathbf{b} : \begin{cases} \text{Nat}.X \\ \text{Unit}.\mathbf{b} \rightarrow \mathbf{c}:\text{Nat}.\checkmark \end{cases} & \quad \begin{aligned} P_{\mathbf{a}} &= \overline{\mathbf{b}}(5).\overline{\mathbf{b}}(6).\overline{\mathbf{b}}(\text{unit}).\mathbf{0} \\ P_{\mathbf{b}} &= \text{loop}(\text{sum}:\text{Nat}=0) \sum \begin{cases} \mathbf{a}(x:\text{Nat}).\text{recur}(\text{sum}+x) \\ \mathbf{a}(_:\text{Unit}).\overline{\mathbf{c}}(x).\mathbf{0} \end{cases} \\ P_{\mathbf{c}} &= \mathbf{b}(_:\text{Nat}).\mathbf{0} \end{aligned}
 \end{aligned}$$

- 1b. In the style of process algebra, we define a termination predicate and a reduction relation on global/local types to formalise their operational semantics. The following graph visualises the operational semantics of G :

Every reduction is labelled with a *global action* of the form $pq?t$; it models a synchronous communication of a value of data type t from role p to role q . The following graphs visualise the operational semantics of $G\upharpoonright\mathbf{a}$, $G\upharpoonright\mathbf{b}$, and $G\upharpoonright\mathbf{c}$ (the *projections* of G):

Every reduction is labelled with a *local action* of the form $q!t$, $p?t$, or τ ; they model a send, a receive, or “idling” (passage of time in which a role internally waits). The operational semantics of $G\upharpoonright r$ is straightforwardly derived from the operational semantics of G , by replacing every global action $pq?t$ with the corresponding local action: $q!t$ when $p=r\neq q$ (i.e., r is the sender), or $p?t$ when $p\neq r\neq p$ (i.e., r is the receiver), or τ when $p\neq r\neq q$ (i.e., r does not participate in the communication). We note that two τ -reductions are superimposed in the visualisation for Carol; the details do not matter yet (see §3.2).

2. To assure that a global type is operationally equivalent to the family of projections, we define a predicate that analyses the operational semantics of implicit local types, called *well-behavedness*. An implicit local type is well-behaved when:
- **idling is neutral:** the same reductions are possible before and after a τ -reduction;
 - **sending is causal:** a $!$ -reduction is possible initially, or after a $!$ -reduction, or after a $?$ -reduction, or after a τ -reduction when it was possible already before that τ -reduction;
 - **receiving is deterministic:** multiple $?$ -reductions from the same source to different destinations must have different labels.

Thus: *every send must have at least one cause; every receive must have at most one effect*. Our first main result is that if every projection is well-behaved, then the global type is operationally equivalent to the family of projections (Theorem 23). It can be checked that $G\upharpoonright\mathbf{a}$, $G\upharpoonright\mathbf{b}$, and $G\upharpoonright\mathbf{c}$ are well-behaved, so G is operationally equivalent to $\{G\upharpoonright\mathbf{a}, G\upharpoonright\mathbf{b}, G\upharpoonright\mathbf{c}\}$.

3. To assure that a family of projections is operationally refined by a family of processes, we define a typing relation that compares the syntax of processes with the operational semantics of implicit local types. Roughly, $P = \sum\{O_1, \dots, O_n\}$ is well-typed by L when:
- for every O_i , if $O_i = \bar{q}(e)$, then L has a $q!t$ -reduction to L' (modulo τ -reductions);
 - for every $q!t$ -reduction of L (modulo τ -reductions), P has a subprocess O_i .

Furthermore, roughly, $P = \sum\{I_1, \dots, I_m\}$ is well-typed by L when:

- for every I_j , if $I_j = p(x:t)$, then L has a $p?t$ -reduction to L' (modulo τ -reductions);
- for every $p?t$ -reduction of L (modulo τ -reductions), P has a subprocess $I_j = p(x:t)$.

We note that, as usual in the MPST literature, there is asymmetry between well-typedness of selections of output processes and selections of input processes (see §3.6).

Our second main result is that if every process is well-typed by its projection, then the family of projections is operationally refined by the family of processes (Theorem 39). It can be checked that $P_{\mathbf{a}}$ is well-typed by $G \upharpoonright_{\mathbf{a}}$ (traverse the cycle in $G \upharpoonright_{\mathbf{a}}$ twice), $P_{\mathbf{b}}$ is well-typed by $G \upharpoonright_{\mathbf{b}}$, and $P_{\mathbf{c}}$ is well-typed by $G \upharpoonright_{\mathbf{c}}$ (traverse the downwards τ -reduction in $G \upharpoonright_{\mathbf{c}}$; this is sound), so $\{G \upharpoonright_{\mathbf{a}}, G \upharpoonright_{\mathbf{b}}, G \upharpoonright_{\mathbf{c}}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{c}}\}$.

Together, operational equivalence (step 2) and operational refinement (step 3) imply that $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{c}}\}$ is safe and live relative to G (Corollary 41). \square

The Summation protocol is simple. However, it is not yet supported by existing techniques based on global types and projection in the MPST literature. For instance, G in Example 2 is grammatical in the state-of-the-art papers of Majumdar et al. [54] and Van Glabbeek et al. [65], but the projection onto Carol is undefined by Majumdar et al. and ill-formed due to unguarded recursion by Van Glabbeek et al.; as a result, in those papers, G cannot be used to verify processes. The following example further demonstrates the expressive power of our development.

► **Example 3.** The *Recursive Two Buyer* protocol [62] (extension of the *Two Buyer* protocol [39]) consists of roles *Alice* (\mathbf{a}), *Bob* (\mathbf{b}), and *Seller* (\mathbf{s}). Sequentially, it has three subprotocols:

- **Alice and Seller (part 1):** First, the name of an item (**String**) is communicated from Alice to Seller. Next, the price (**Nat**) is communicated from Seller to Alice.
- **Alice and Bob:** When Alice wants to negotiate with Bob to split the price, an offer (**Nat**) is communicated from her to him. Next, an acceptance (**Acc**) is communicated from Bob to Alice and the subprotocol ends, or a rejection (**Rej**) and the subprotocol loops. When Alice wants not to negotiate, a rejection of the sale is communicated from her to him.
- **Alice and Seller (part 2):** When the negotiation between Alice and Bob succeeded (resp. failed), an acceptance (resp. rejection) of the sale is communicated from Alice to Seller.

We apply steps **1a**, **1b**, **2**, and **3** to the Recursive Two Buyer protocol:

1a. The following global type specifies the protocol:

$$G = \mathbf{a} \rightarrow \mathbf{s} : \text{String} . \mathbf{s} \rightarrow \mathbf{a} : \text{Nat} . \mu X . \mathbf{a} \rightarrow \mathbf{b} : \begin{cases} \text{Nat} . \mathbf{b} \rightarrow \mathbf{a} : \{ \text{Acc} . \mathbf{a} \rightarrow \mathbf{s} : \text{Acc} . \checkmark , \text{Rej} . X \} \\ \text{Rej} . \mathbf{a} \rightarrow \mathbf{s} : \text{Rej} . \checkmark \end{cases}$$

The following processes implement Alice, Bob, and Seller:

$$P_{\mathbf{a}} = \bar{\mathbf{s}} \langle \text{"foo"} \rangle . \mathbf{s} (x : \text{Nat}) . \bar{\mathbf{b}} \langle x/2 \rangle . \sum \begin{cases} \mathbf{b} (_ : \text{Acc}) . \bar{\mathbf{s}} \langle \text{acc} \rangle . \mathbf{0} \\ \mathbf{b} (_ : \text{Rej}) . \bar{\mathbf{b}} \langle x/3 \rangle . \sum \begin{cases} \mathbf{b} (_ : \text{Acc}) . \bar{\mathbf{s}} \langle \text{acc} \rangle . \mathbf{0} \\ \mathbf{b} (_ : \text{Rej}) . \bar{\mathbf{b}} \langle \text{rej} \rangle . \bar{\mathbf{s}} \langle \text{rej} \rangle . \mathbf{0} \end{cases} \end{cases}$$

$$P_{\mathbf{b}} = \text{loop} \sum \{ \mathbf{a} (y : \text{Nat}) . \text{if } y \leq 10 \text{ } (\bar{\mathbf{a}} \langle \text{acc} \rangle . \mathbf{0}) (\bar{\mathbf{a}} \langle \text{rej} \rangle . \text{recur}) , \mathbf{a} (_ : \text{Rej}) . \mathbf{0} \}$$

$$P_{\mathbf{s}} = \mathbf{a} (z : \text{String}) . \bar{\mathbf{a}} \langle \text{price}(z) \rangle . \sum \{ \mathbf{a} (_ : \text{Acc}) . \mathbf{0} , \mathbf{a} (_ : \text{Rej}) . \mathbf{0} \}$$

$P_{\mathbf{a}}$ implements that Alice offers Bob to contribute half the price; when Bob rejects, Alice offers Bob to contribute a third of the price; when Bob rejects again, Alice rejects the sale. $P_{\mathbf{b}}$ implements that Bob is willing to contribute at most ten units of currency.

1b. The following graphs visualise the operational semantics of G , $G \upharpoonright \mathbf{b}$, and $G \upharpoonright \mathbf{s}$:

2. It can be checked that $G \upharpoonright \mathbf{b}$ and $G \upharpoonright \mathbf{s}$ are well-behaved, in the same way as in Example 2. Furthermore, $G \upharpoonright \mathbf{a}$ is trivially well-behaved, as Alice participates in every communication, so the operational semantics of $G \upharpoonright \mathbf{a}$ has no τ -reductions. Thus, G is operationally equivalent to $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ (Theorem 23).
3. It can be checked that $P_{\mathbf{a}}$ is well-typed by $G \upharpoonright \mathbf{a}$ (by twice traversing the cycle in $G \upharpoonright \mathbf{a}$), $P_{\mathbf{b}}$ is well-typed by $G \upharpoonright \mathbf{b}$, and $P_{\mathbf{s}}$ is well-typed by $G \upharpoonright \mathbf{s}$. Thus, $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$ (Theorem 39).

Together, operational equivalence (step 2) and operational refinement (step 3) imply that $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$ is safe and live relative to G (Corollary 41). \lrcorner

The Recursive Two Buyer protocol was introduced by Scalas–Yoshida to demonstrate the limitations of previous papers based on global types and projection [62]: existing techniques do not support recursive protocols in which *different roles participate in different branches*. The solution proposed by Scalas–Yoshida is to remove global types and projection from the MPST method altogether and, instead, manually write explicit local types for Alice, Bob, and Seller (i.e., they effectively avoid the problem instead of solving it). In contrast, using the new techniques of this paper, we can specify such recursive protocols as global types, *and* automatically extract implicit local types from them, *and* automatically verify processes.

2.2 Regular Grammars

In §4, we apply the new techniques of this paper to the following regular grammars:

$$G ::= p \rightarrow q : t \mid G_1 + G_2 \mid G_1 \cdot G_2 \mid G^* \mid \checkmark \quad P ::= \sum \{O_1, \dots, O_n, I_1, \dots, I_m\} \mid \dots$$

The informal meanings are further clarified in the examples in this subsection. The examples serve two purposes: to evidence generality (i.e., no extra main concepts need to be introduced), and to demonstrate that the idea of this paper offers distinct expressive power. This power arises both in the “soft” sense (i.e., protocols that could already be specified, can now be specified exponentially more succinct; item **Y** in §1.2) and in the “hard” sense (i.e., protocols that could not yet be specified/implemented/verified, can now be; item **Z** in §1.2).

► **Example 4.** The Binomial_k protocol consists of roles *Alice* (**a**) and *Bob* (**b**). A choice between red (**Red**) and blue (**Blu**) is communicated from Alice to Bob, k times, independently. The following global types, which are equivalent, specify the protocol for $k = 3$:

$$G = \mathbf{a} \rightarrow \mathbf{b}: \left\{ \begin{array}{l} \text{Red.} \mathbf{a} \rightarrow \mathbf{b}: \left\{ \begin{array}{l} \text{Red.} \checkmark \\ \text{Blu.} \checkmark \end{array} \right. \\ \text{Blu.} \mathbf{a} \rightarrow \mathbf{b}: \left\{ \begin{array}{l} \text{Red.} \checkmark \\ \text{Blu.} \checkmark \end{array} \right. \\ \dots \text{ (similar to the subtree above)} \end{array} \right. \quad G = (\mathbf{a} \rightarrow \mathbf{b}: \text{Red} + \mathbf{a} \rightarrow \mathbf{b}: \text{Blu}) \cdot \\ (\mathbf{a} \rightarrow \mathbf{b}: \text{Red} + \mathbf{a} \rightarrow \mathbf{b}: \text{Blu}) \cdot \\ (\mathbf{a} \rightarrow \mathbf{b}: \text{Red} + \mathbf{a} \rightarrow \mathbf{b}: \text{Blu})$$

Informally, global types $G_1 + G_2$ and $G_1 \cdot G_2$ specify choice and sequencing. \lrcorner

The Binomial _{k} protocol could already be specified using existing sub-regular grammars of global types in the MPST literature. However, due to the usage of a prefixing operator, the size of G_1 in Example 4 is exponential in k . In contrast, due to the usage of a sequencing operator, the size of G_2 in Example 4 is linear in k . Thus, the Binomial _{k} protocol can now be specified exponentially more succinct. The following example demonstrates that another version of Binomial _{k} , which could not yet be specified/implemented/verified, can now be.

► **Example 5.** The *Role-based Binomial _{k}* protocol consists of roles *Alice* (\mathbf{a}) and *Bob* (\mathbf{b}). A unit is communicated from Alice to Bob, or from Bob to Alice, k times, independently. We apply steps **1a**, **1b**, **2**, and **3** to the Role-based Binomial _{k} protocol:

1a. The following global type specifies the protocol for $k = 3$:

$$G = (\mathbf{a} \rightarrow \mathbf{b}: \text{Unit} + \mathbf{b} \rightarrow \mathbf{a}: \text{Unit}) \cdot (\mathbf{a} \rightarrow \mathbf{b}: \text{Unit} + \mathbf{b} \rightarrow \mathbf{a}: \text{Unit}) \cdot (\mathbf{a} \rightarrow \mathbf{b}: \text{Unit} + \mathbf{b} \rightarrow \mathbf{a}: \text{Unit})$$

The following processes implement Alice and Bob:

$$P_{\mathbf{a}} = \sum \left\{ \begin{array}{l} \bar{\mathbf{b}} \langle \text{unit} \rangle. \sum \left\{ \begin{array}{l} \bar{\mathbf{b}} \langle \text{unit} \rangle. 0 \\ \mathbf{b}(_ : \text{Unit}). 0 \end{array} \right. \\ \mathbf{b}(_ : \text{Unit}). \sum \left\{ \begin{array}{l} \bar{\mathbf{b}} \langle \text{unit} \rangle. 0 \\ \mathbf{b}(_ : \text{Unit}). 0 \end{array} \right. \\ \dots \text{ (similar to the subtree above)} \end{array} \right. \quad P_{\mathbf{b}} = \dots \text{ (similar to } P_{\mathbf{a}})$$

1b. The following graphs visualise the operational semantics of G and $G \upharpoonright \mathbf{a}$:

2. It can be checked that $G \upharpoonright \mathbf{a}$ is well-behaved, in the same way as in Example 2. Similarly, $G \upharpoonright \mathbf{b}$ is well-behaved. Thus, G is operationally equivalent to $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}\}$ (Theorem 23). We note that we can use the same definition of well-behavedness as in §2.1, whereas the grammar differs: well-behavedness is independent of structure, so directly re-applicable.

3. Process $P = \sum \{O_1, \dots, O_n, I_1, \dots, I_m\}$ is well-typed by L when:

- $\sum \{O_1, \dots, O_n\}$ is well-typed by L , in the same way as in Example 2;
- $\sum \{I_1, \dots, I_m\}$ is well-typed by L , in the same way as in Example 2.

It can be checked that $P_{\mathbf{a}}$ is well-typed by $G|\mathbf{a}$. In particular, as $P_{\mathbf{a}}$ consists of only three unique subprocesses, no other subprocesses (duplicates) need to be type-checked when memoization is used. The three unique subprocesses are well-typed by the three non-final nodes in the visualisation of $G|\mathbf{a}$. Similarly, $P_{\mathbf{b}}$ is well-typed by $G|\mathbf{b}$. Thus, $\{G|\mathbf{a}, G|\mathbf{b}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}\}$ (Theorem 39).

Together, operational equivalence (step 2) and operational refinement (step 3) imply that $\{P_{\mathbf{a}}, P_{\mathbf{b}}\}$ is safe and live relative to G (Corollary 41). \dashv

The Role-based Binomial_k protocol could not yet be specified/implemented/verified in previous papers in the MPST literature: existing techniques do not support protocols in which *multiple roles synchronously choose both the sender and the receiver of a next communication*. In contrast, using the new techniques of this paper, we can specify such protocols (e.g., G in Example 5), implement them as *mixed input/output processes* (e.g., $P_{\mathbf{a}}$ and $P_{\mathbf{b}}$ in Example 5), and verify. The following example further demonstrates mixed input/output, and more.

► **Example 6.** The *Acquire–Use–Release* protocol consists of roles *Alice* (\mathbf{a}), *Bob* (\mathbf{b}), and *Server* (\mathbf{s}). Concurrently, it has three subprotocols:

- **Alice and Server (AS):** First, an “acquire” message (**Acq**) is communicated from Alice to Server. Next, a “permission” message (**Perm**) is communicated from Server to Alice. Next, zero or more “usage” messages (**Use**) are communicated from Alice to Server. Last, a “release” message (**Rel**) is communicated from Alice to Server.
 - **Bob and Server (BS):** Similar to **AS**.
 - **Mutual Exclusion (ME):** Between sending “permission” and receiving “release”, Server cannot send another “permission”, thereby constraining the interleaving of **AS** and **BS**.
- We apply steps 1a, 1b, 2, and 3 to the Acquire–Use–Release protocol:

1a. The following global type specifies the protocol:

$$G = + \left\{ \begin{array}{l} \mathbf{a} \rightarrow \mathbf{s} : \text{Acq} \cdot + \left\{ \begin{array}{l} \mathbf{s} \rightarrow \mathbf{a} : \text{Perm} \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Use}^* \cdot + \left\{ \begin{array}{l} \mathbf{a} \rightarrow \mathbf{s} : \text{Rel} \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Acq} \cdot G'_2 \\ \mathbf{b} \rightarrow \mathbf{s} : \text{Acq} \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Use}^* \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Rel} \cdot G'_2 \end{array} \right. \\ G'_1 \cdot G'_2 \\ G'_2 \cdot G'_1 \end{array} \right. \\ \mathbf{b} \rightarrow \mathbf{s} : \text{Acq} \cdot \dots \text{ (similar to the subtree above)} \end{array} \right.$$

$$G'_1 = \mathbf{s} \rightarrow \mathbf{a} : \text{Perm} \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Use}^* \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Rel} \quad G'_2 = \mathbf{s} \rightarrow \mathbf{b} : \text{Perm} \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Use}^* \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Rel}$$

The following processes implement Alice, Bob, and Server:

$$\begin{aligned} P_{\mathbf{a}} &= \bar{\mathbf{s}}\langle \text{acq} \rangle . \mathbf{s}\langle _ : \text{Perm} \rangle . \bar{\mathbf{s}}\langle \text{use} \rangle . \bar{\mathbf{s}}\langle \text{use} \rangle . \bar{\mathbf{s}}\langle \text{use} \rangle . \bar{\mathbf{s}}\langle \text{rel} \rangle . \mathbf{0} \\ P_{\mathbf{b}} &= \bar{\mathbf{s}}\langle \text{acq} \rangle . \mathbf{s}\langle _ : \text{Perm} \rangle . \bar{\mathbf{s}}\langle \text{use} \rangle . \bar{\mathbf{s}}\langle \text{rel} \rangle . \mathbf{0} \\ P_{\mathbf{s}} &= \sum \left\{ \begin{array}{l} \mathbf{a}(\text{acq1} : \text{Acq}) . \sum \left\{ \begin{array}{l} \bar{\mathbf{a}}\langle \text{perm} \rangle . \text{loop} \sum \left\{ \begin{array}{l} \mathbf{a}\langle _ : \text{Rel} \rangle . \mathbf{b}\langle _ : \text{Acq} \rangle . (\dots) \\ \mathbf{b}\langle _ : \text{Acq} \rangle . (\dots) \end{array} \right. \\ \mathbf{b}(\text{acq2} : \text{Acq}) . P_{\mathbf{s}}'' \end{array} \right. \\ \mathbf{b}\langle _ : \text{Acq} \rangle . (\dots) \end{array} \right. \end{array} \right. \\ \text{(version 1)} \quad P_{\mathbf{s}}'' &= \sum \{ \bar{\mathbf{a}}\langle \text{perm} \rangle . (\dots) , \bar{\mathbf{b}}\langle \text{perm} \rangle . (\dots) \} \\ \text{(version 2)} \quad P_{\mathbf{s}}'' &= \text{if } \text{alice_goes_first}(\text{acq1}, \text{acq2}) \text{ } (\bar{\mathbf{a}}\langle \text{perm} \rangle . (\dots)) (\bar{\mathbf{b}}\langle \text{perm} \rangle . (\dots)) \\ \text{(version 3)} \quad P_{\mathbf{s}}'' &= \bar{\mathbf{a}}\langle \text{perm} \rangle . (\dots) \end{aligned}$$

Version 1 of $P_{\mathbf{s}}''$ implements that, after receiving an “acquire” message from both Alice and Bob, Server chooses non-deterministically between sending a “permission” message to Alice or Bob. Versions 2 and 3 of $P_{\mathbf{s}}''$ implement that Server chooses deterministically. We note that the second choice in $P_{\mathbf{s}}$ is between a send and a receive (mixed input/output).

1b. The following graphs visualise the operational semantics of G and $G \upharpoonright \mathbf{a}$:

The dash pattern on the vertical edges is unimportant at this point (see Example 9).

2. It can be checked that $G \upharpoonright \mathbf{a}$ is well-behaved, in the same way as in Example 2. Similarly, $G \upharpoonright \mathbf{b}$ is well-behaved. Furthermore, $G \upharpoonright \mathbf{s}$ is trivially well-behaved, as Server participates in every communication, so the operational semantics of $G \upharpoonright \mathbf{s}$ has no τ -reductions. Thus, G is operationally equivalent to $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ (Theorem 23).
3. It can be checked that $P_{\mathbf{a}}$ is well-typed by $G \upharpoonright \mathbf{a}$, $P_{\mathbf{b}}$ is well-typed by $G \upharpoonright \mathbf{b}$, and $P_{\mathbf{s}}$ is well-typed by $G \upharpoonright \mathbf{s}$. Thus, $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$ (Theorem 39).

Together, operational equivalence (step 2) and operational refinement (step 3) imply that $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$ is safe and live relative to G (Corollary 41). \square

The Role-based Acquire–Use–Release protocol could not yet be specified/implemented/verified in previous papers in the MPST literature: existing techniques do not support protocols in which *a receiver chooses the sender of the first communication*. In contrast, using the new techniques of this paper, we can specify such protocols (e.g., G in Example 6), implement them as processes (e.g., $P_{\mathbf{a}}$, $P_{\mathbf{b}}$, and $P_{\mathbf{s}}$ in Example 5), and verify.

In this paper, projection (including well-behavedness) and type checking are independent of the syntax of global types; they are dependent only on the operational semantics. The formulations and proofs of our main results are similarly independent. As a result of this independence, our regular grammar of global types is actually “open ended”: it can be readily extended with additional global type operators (closed under regularity), intended to serve as higher-level abstractions to make the specification of protocols easier. As a first demonstration of this extensibility, we freely add the following operators:

$$G ::= \cdots \mid G_1 ; G_2 \mid G_1 \parallel G_2 \mid G_1 \bowtie G_2 \mid [G]_{\gamma_2}^{\gamma_1} \mid \cdots$$

► **Example 7.** The following global type specifies that units are communicated first between Alice, Bob1, and Carol1, and second between Alice, Bob2, and Carol2, in that order; the communication from Bob1 to Carol1, and the communication from Bob2 to Carol2, may happen out-of-order, though.

$$G = (\mathbf{a} \rightarrow \mathbf{b1}:\text{Unit} \cdot \mathbf{b1} \rightarrow \mathbf{c1}:\text{Unit}); \\ (\mathbf{a} \rightarrow \mathbf{b2}:\text{Unit} \cdot \mathbf{b2} \rightarrow \mathbf{c2}:\text{Unit})$$

42:12 Sound, Regular Multiparty Sessions via Implicit Local Types

Informally $G_1; G_2$ specifies a “weak” sequence: it is similar to $G_1 \cdot G_2$, except that *independent* communications in G_1 and G_2 (when disjoint roles participate) can happen out-of-order. \lrcorner

► **Example 8.** We re-apply steps **1a**, **1b**, **2**, and **3** to the Acquire–Use–Release protocol:

1a. The following global type, which is equivalent to G in Example 6, specifies the protocol:

$$\begin{aligned}
 G_{AS} &= \mathbf{a} \rightarrow \mathbf{s} : \text{Acq} \cdot \mathbf{s} \rightarrow \mathbf{a} : \text{Perm} \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Use}^* \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Rel} \\
 G_{BS} &= \mathbf{b} \rightarrow \mathbf{s} : \text{Acq} \cdot \mathbf{s} \rightarrow \mathbf{b} : \text{Perm} \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Use}^* \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Rel} \\
 G &= (G_{AS} \parallel G_{BS}) \bowtie G_{ME} \\
 G_{ME} &= + \begin{cases} \mathbf{s} \rightarrow \mathbf{a} : \text{Perm} \cdot \mathbf{a} \rightarrow \mathbf{s} : \text{Rel} \cdot \mathbf{s} \rightarrow \mathbf{b} : \text{Perm} \\ \mathbf{s} \rightarrow \mathbf{b} : \text{Perm} \cdot \mathbf{b} \rightarrow \mathbf{s} : \text{Rel} \cdot \mathbf{s} \rightarrow \mathbf{a} : \text{Perm} \end{cases}
 \end{aligned}$$

Informally, global types $G_1 \parallel G_2$ and $G_1 \bowtie G_2$ specify interleaving and join. In general, join demands that every role complies with both of its operands. In this example, join specifies that subprotocol **ME** in Example 6 constrains the interleaving of subprotocols **AS** and **BS**. That is, the three subprotocols are modularly specified as global types G_{AS} , G_{BS} , and G_{ME} , and composed as intended using \parallel and \bowtie ; the result is an exponentially more succinct – and arguably easier to write – specification than in Example 6.

The same processes $P_{\mathbf{a}}$, $P_{\mathbf{b}}$, and $P_{\mathbf{s}}$, with any version of $P_{\mathbf{s}}''$, as in Example 6 are used.

- 1b.** The same graphs as in Example 6 visualise the operational semantics of G and $G \upharpoonright \mathbf{a}$.
2. As in Example 6, G is operationally equivalent to $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$.
 3. As in Example 6, $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$. \lrcorner

► **Example 9.** We apply steps **1a**, **1b**, **2**, and **3** to a restricted version of the Acquire–Use–Release protocol in which, after receiving an “acquire” message from both Alice and Bob, Server must send a “permission” message *first* to Alice and *second* to Bob (static order):

1a. The following global type specifies the protocol:

$$G = [(G_{AS} \parallel G_{BS}) \bowtie G_{ME}]_{\mathbf{bs}^? \text{Perm}}^{\mathbf{as}^? \text{Perm}} \quad G_{AS}, G_{BS}, G_{ME} = \dots \text{ (same as in Example 8)}$$

Informally, global type $[G]_{\gamma_2}^{\gamma_1}$ specifies the prioritisation of global action γ_1 (superscript indicates “high” priority) over global action γ_2 (subscript indicates “low” priority) in G . The same processes $P_{\mathbf{a}}$, $P_{\mathbf{b}}$, and $P_{\mathbf{s}}$, with version 3 of $P_{\mathbf{s}}''$, as in Example 6 are used.

- 1b.** The same graphs as in Example 6 visualise the operational semantics of G and $G \upharpoonright \mathbf{a}$, but without the dashed edges.
2. As in Example 6, G is operationally equivalent to $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$.
 3. As in Example 6, $\{G \upharpoonright \mathbf{a}, G \upharpoonright \mathbf{b}, G \upharpoonright \mathbf{s}\}$ is operationally refined by $\{P_{\mathbf{a}}, P_{\mathbf{b}}, P_{\mathbf{s}}\}$. \lrcorner

► **Remark 10.** *Merging* has historically been crucial to support sufficiently expressive kinds of choice in the MPST literature, but it is not needed in this paper. Instead, the issues that merging-based well-formedness of global types address, are covered by well-behavedness of implicit local types. Example 2 and Example 3 already demonstrated this point. To further illustrate it, Table 1 lists global types for examples of Van Glabbeek et al. [65] and Scalas–Yoshida [62]: the examples of van Glabbeek et al. require merging; the examples of Scalas–Yoshida require a more advanced concept (i.e., they use these examples to demonstrate limitations of merging). Every projection of every global type in Table 1 is well-behaved. \lrcorner

■ **Table 1** Example protocols of Van Glabbeek et al. [65] and Scalas–Yoshida [62].

name	global type
Example 9 [vG21]	$G = (\mathbf{b} \rightarrow \mathbf{se}:\text{Talk})^* \cdot \mathbf{b} \rightarrow \mathbf{se}:\text{Buy} \cdot \mathbf{se} \rightarrow \mathbf{sh}:\text{Order}$
Example 13 [vG21]	$G = ((\mathbf{b1} \rightarrow \mathbf{s1}:\text{Wait})^* \cdot \mathbf{b1} \rightarrow \mathbf{s1}:\text{Order}) \parallel ((\mathbf{b2} \rightarrow \mathbf{s2}:\text{Wait})^* \cdot \mathbf{b2} \rightarrow \mathbf{s2}:\text{Order})$
Example 15 [vG21]	$G = (\mathbf{b} \rightarrow \mathbf{s1}:\text{Order1} \cdot \mathbf{b} \rightarrow \mathbf{s2}:\text{Wait})^* \cdot \mathbf{b} \rightarrow \mathbf{s2}:\text{Order2} \cdot \mathbf{b} \rightarrow \mathbf{s1}:\text{Done}$
OAuth2 [SY19]	$G = (\mathbf{s} \rightarrow \mathbf{c}:\text{Login} \cdot \mathbf{c} \rightarrow \mathbf{a}:\text{Passwd} \cdot \mathbf{a} \rightarrow \mathbf{s}:\text{Auth}) + (\mathbf{s} \rightarrow \mathbf{c}:\text{Cancel} \cdot \mathbf{c} \rightarrow \mathbf{a}:\text{Quit})$
Rec. map/reduce [SY19]	$G = G_1 \cdot (\mathbf{r} \rightarrow \mathbf{m}:\text{Continue} \cdot G_1)^* \cdot \mathbf{r} \rightarrow \mathbf{m}:\text{Stop} \cdot \mathbf{m} \rightarrow \mathbf{w1}:\text{Stop}$ $G_1 = \mathbf{m} \rightarrow \mathbf{w1}:\text{Datum} \cdot \mathbf{w1} \rightarrow \mathbf{r}:\text{Result}$
MP workers [SY19]	$G = \mathbf{s} \rightarrow \mathbf{wa1}:\text{Datum} \cdot (G_1 \parallel (\mathbf{s} \rightarrow \mathbf{wa2}:\text{Datum} \cdot G_2))$ $G_1 = (\mathbf{wa1} \rightarrow \mathbf{wb1} \rightarrow \mathbf{wc1}:\text{Datum} \cdot \mathbf{wc1} \rightarrow \mathbf{wa1}:\text{Result})^* \cdot \mathbf{wa1} \rightarrow \mathbf{wb1} \rightarrow \mathbf{wc1}:\text{Stop}$ $G_2 = (\mathbf{wa2} \rightarrow \mathbf{wb2} \rightarrow \mathbf{wc2}:\text{Datum} \cdot \mathbf{wc2} \rightarrow \mathbf{wa2}:\text{Result})^* \cdot \mathbf{wa2} \rightarrow \mathbf{wb2} \rightarrow \mathbf{wc2}:\text{Stop}$

3 Sub-Regular Grammars

In this section, we apply the new techniques for projection and type checking to sub-regular grammars of global types and processes; they are representative of existing ones in the MPST literature. Thus, we introduce the main concepts and complications in a familiar setting.

As this paper is about “processes that communicate” instead of “data that are communicated”, we leave the data language largely unspecified, except for some notation:

- **Syntax:** Let \mathbb{X} denote a set of *variables*, ranged over by x . Let $\mathbb{V} = \{\text{true}, \text{false}, 0, 1, 2, \dots\}$ denote a set of *values*, ranged over by v . Let $\mathbb{E} = \mathbb{X} \cup \mathbb{V} \cup \{\text{!false}, 2+3, \dots\}$ denote a set of *expressions*, ranged over by e . Let $e[v/x]$ denote *substitution* of v for x in e .
- **Static semantics:** Let $\mathbb{T} = \{\text{Bool}, \text{Nat}, \dots\}$ denote a set of *data types*, ranged over by t . Let $(\mathbb{X} \times \mathbb{T})^*$ denote the set of *data typing contexts* (i.e., lists of variable–type pairs), ranged over by Ξ . Let $\Xi \vdash e : t$ denote *well-typedness* of e by t in Ξ .
- **Dynamic semantics:** Let $\text{eval}(e)$ denote *evaluation* of e ; it can be undefined. For instance, $\text{eval}(2+3) = 5$, but $\text{eval}(2+\text{true})$ is undefined. Undefinedness of $\text{eval}(e)$ is a form of “going wrong” [55]; it can give rise to deadlock (Remark 33), prevented by well-typedness (§3.7).

3.1 Global Types – Syntax

Below, we define the grammar of global/local types and abstract global/local actions.

► **Definition 11.** Let \mathbb{R} denote a set of *roles*, ranged over by p, q, r . Let \mathbb{G} and \mathbb{L} denote the sets of *global types* and (*implicit*) *local types*, ranged over by G and L ; they are induced by the following grammar:

$$G ::= p \rightarrow q : \{t_i \cdot G_i\}_{1 \leq i \leq n} \mid \mu X. G \mid X \mid \checkmark \quad L ::= G \upharpoonright r$$

Let $\mathbb{R} \rightarrow \mathbb{L}$ denote the set of *role-indexed families of local types* (partial functions), ranged over by \mathcal{L} . Let $\mathbb{S} = \mathbb{G} \cup \mathbb{L} \cup (\mathbb{R} \rightarrow \mathbb{L})$ denote the set of *specifications*, ranged over by S . ◻

Global type $p \rightarrow q : \{t_i \cdot G_i\}_{1 \leq i \leq n}$ specifies the synchronous *communication* of a value of data type t_i from role p to role q , for some $1 \leq i \leq n$. Global types $\mu X. G$ and X specify a *recursive protocol*. Global type \checkmark specifies the *empty protocol*. Local type $G \upharpoonright r$ specifies the *projection* of G onto r . Thus, projection is a local type operator instead of a function on global types: $G \upharpoonright r$ does not compute an explicit local type; it is an implicit one. The programmer does not write implicit local types directly, but only global types.

► **Definition 12.** Let $\mathbf{\Gamma} = \{(pq!t, pq?t) \mid p \neq q\}$ and $\mathbf{\Lambda} = \bigcup \{(pq!t, pq?t) \mid p \neq q\} \cup \{\tau\}$ denote the sets of (*abstract*) *global actions* and (*abstract*) *local actions*, ranged over by γ and λ . Let $\mathbf{A} = \mathbf{\Gamma} \cup \mathbf{\Lambda}$ denote the set of (*abstract*) *actions*, ranged over by α . ◻

$$\begin{array}{c}
\frac{}{\checkmark \downarrow} [\downarrow\text{G-END}] \quad \frac{1 \leq i \leq n}{p \rightarrow q: \{t_i.G_i\}_{1 \leq i \leq n} \xrightarrow{pq!t_i} G_i} [\rightarrow\text{G-COM}] \quad \frac{G[\mu X.G/X] \xrightarrow{\gamma} G'}{\mu X.G \xrightarrow{\gamma} G'} [\rightarrow\text{G-REC}] \\
\frac{G \downarrow}{G \downarrow r \downarrow} [\downarrow\text{L-AT}] \quad \frac{G \xrightarrow{\gamma} G'}{G \downarrow r \xrightarrow{\gamma!r} G' \downarrow r} [\rightarrow\text{L-AT}] \quad pq?t|r = \begin{cases} pq!t & \text{if: } p = r \neq q \\ pq?t & \text{if: } q \neq r = q \\ \tau & \text{if: } p \neq r \neq q \end{cases} \quad \frac{L \xrightarrow{\tau} L' \not\downarrow}{L' \xrightarrow{\tau} L} [\rightarrow\text{L-REV}] \\
\frac{L_r \downarrow \text{ for every } r}{\{L_r\}_{r \in R} \downarrow} [\downarrow\text{L}] \quad \frac{L_p \xrightarrow{pq!t} L'_p \quad L_q \xrightarrow{pq?t} L'_q}{L_r = L'_r \text{ for every } r \notin \{p, q\}} [\rightarrow\text{L1}] \quad \frac{L_{\bar{r}} \xrightarrow{\tau} L'_{\bar{r}}}{L_r = L'_r \text{ for every } r \notin \{\bar{r}\}} [\rightarrow\text{L2}] \\
\{L_r\}_{r \in R} \xrightarrow{pq?t} \{L'_r\}_{r \in R} \quad \{L_r\}_{r \in R} \xrightarrow{\tau} \{L'_r\}_{r \in R}
\end{array}$$

(a) Termination (b) Reduction. Let $G[\mu X.G/X]$ denote unfolding of X into $\mu X.G$ in G .

■ **Figure 3** Operational semantics of sub-regular global/local types.

Local actions $pq!t$ and $pq?t$ model the *send* and the *receive* of a value of data type t from role p to role q ; we omit p or q when it is clear from the context. Local action τ models internal *idling*. Global action $(pq!t, pq?t)$ models a communication; we often write $pq?t$.

3.2 Global Types – Operational Semantics

Below, we define the termination predicate and reduction relation on global/local types.

► **Definition 13.** Let $G \downarrow$, $L \downarrow$, and $\mathcal{L} \downarrow$ denote termination of G , L , and \mathcal{L} . Formally, \downarrow is the predicate induced by the rules in Figure 3a, while $\not\downarrow$ is its complement (not derivable). ◻

► **Definition 14.** Let $G \xrightarrow{\gamma} G'$, $L \xrightarrow{\lambda} L'$, and $\mathcal{L} \xrightarrow{\lambda_p, \lambda_q} \mathcal{L}'$ denote reduction from G to G' with γ , from L to L' with λ alone, and from \mathcal{L} to \mathcal{L}' with λ_p and λ_q together (synchronously); we omit the label and/or the destination of a reduction if it does not matter. Formally, \rightarrow is the relation induced by the rules in Figure 3b, while $\not\rightarrow$ is its complement (not derivable). ◻

- Rule $[\rightarrow\text{G-COM}]$ states that a communication can reduce with a global action chosen from the alternatives. Following the recent paper of Gheri et al. [34], and for the same reason as them, we omit a reduction rule for out-of-order execution of independent global actions; its interplay with recursion may give rise to infinite reduction relations (e.g., [34, Exmp. 5.1]). We recover out-of-order execution in §4, as already demonstrated in Example 7.
- Rule $[\rightarrow\text{G-REC}]$ states that a recursive protocol can reduce when its body can.
- Rule $[\rightarrow\text{L-AT}]$ states that a projection can reduce when the global type can.
- Rule $[\rightarrow\text{L-REV}]$ states that a τ -reduction into a non-terminated branch can be *reversed*: after “doing nothing” (the τ -reduction from L to L'), a role is always permitted to backtrack by “doing more nothing” (the reverse). This rule ensures that a role r *cannot* commit – unilaterally and irrevocably – to a future communication with another role r' by internally “doing nothing” (i.e., morally, the decision to communicate cannot be made by r alone, but only together with r' , so r should not be able to make a premature commitment and get stuck). Conversely, it *can* commit to local termination by internally “doing nothing” (i.e., morally, the decision to locally terminate can be made by r alone).

► **Example 15.** The following global type specifies that either a number is communicated from Alice to Bob, and from Bob to Carol, or a boolean:

$$G = \mathbf{a} \rightarrow \mathbf{b}: \{ \text{Nat}. \mathbf{b} \rightarrow \mathbf{c}: \text{Nat}. \checkmark, \text{Bool}. \mathbf{b} \rightarrow \mathbf{c}: \text{Bool}. \checkmark \}$$

The following graph visualises the operational semantics of G and $G \downarrow \mathbf{c}$:

Dashed edges represent reductions induced by rule $[\rightarrow\text{L-REV}]$.

Without the τ -reductions of rule $[\rightarrow\text{L-REV}]$, for instance, Carol can commit to the receive of a number by internally “doing nothing” (τ -reduction leftwards). Morally, however, this decision cannot be made by Carol alone, but only together with Bob (depending, in turn, on his previous communication with Alice). *With* the τ -reductions of rule $[\rightarrow\text{L-REV}]$, in contrast, Carol cannot commit: after the τ -reduction leftwards, there is still a sequence of τ -reductions rightwards (which Carol can freely make, because they are internal to her, unobservable to Alice and Bob) to receive a boolean. \lrcorner

- Rules $[\rightarrow\text{L1}]$ and $[\rightarrow\text{L2}]$ state that a family can reduce, when two local types can reduce with a matching send/receive pair (synchronously), or when one can reduce by idling.

The following propositions state basic properties of the operational semantics.

► **Proposition 16** (type-level progress). $G \downarrow$, or $G \rightarrow$ (for every G). \lrcorner

► **Proposition 17** (type-level finiteness). $|\{G^\dagger \mid G \rightarrow \dots \rightarrow G^\dagger\}| \in \mathbb{N}$ (for every G). \lrcorner

Type-level progress and finiteness, which follow straightforwardly from Figure 3, will be used to assure liveness of families of well-typed processes and decidability of type checking.

Recall that S ranges over global types, local types, and families of local types (Definition 11), and α over global actions and local actions (Definition 12):

- Let $S \Rightarrow S^\dagger$ denote τ -reachability from S to S^\dagger : either $S = S^\dagger$, or $S \xrightarrow{\tau} \dots \xrightarrow{\tau} S^\dagger$.
- Let $S \Downarrow$ denote weak termination of S : $S \Rightarrow S^\dagger \downarrow$, for some S^\dagger .
- Let $S \xRightarrow{\alpha} S^\natural$ denote weak reduction from S to S^\natural with α : either $\alpha = \tau$ and $S \Rightarrow S^\natural$, or $S \Rightarrow S^\dagger \xrightarrow{\alpha} S^\ddagger \Rightarrow S^\natural$, for some S^\dagger, S^\ddagger .

As a notational convention, we use “ \prime ” to indicate destinations after 1 reduction, while we use “ \dagger ”, “ \ddagger ”, “ \natural ”, and “ \natural ” to indicate destinations after 0-or-more reductions.

3.3 Main Result 1: Well-Behavedness Implies Operational Equivalence

Intuition. The following global type specifies that a unit is communicated *first* from Alice to Bob, and *second* from Carol to Dave, in-order: $\mathbf{a} \rightarrow \mathbf{b}:\text{Unit}.\mathbf{c} \rightarrow \mathbf{d}:\text{Unit}.\checkmark$ (i.e., the independent actions of Alice–Bob and Carol–Dave cannot be executed out-of-order according to the operational semantics in Figure 3; we recover out-of-order execution in §4). However, this protocol is *unrealisable*: fundamentally, it cannot be implemented as a family of processes without additional covert synchronisation between Bob–Carol. This makes the global type effectively useless. Thus, we need a decision procedure to distinguish “bad” global types from “good” global types, to be able to rule out the bad ones from usage. To achieve this, we define sufficient conditions to ensure that a global type is *operationally equivalent* to the family of projections. That is, operational equivalence formalises protocol realisability.

Instead of defining the conditions on the syntax of global types in terms of *well-formedness* (as usual), we define the conditions on the operational semantics of implicit local types in terms of *well-behavedness*. If the operational semantics of every projection of a global type satisfies every condition, then operational equivalence is guaranteed. Conversely, if the operational semantics of any projection violates any condition, then the global type is ruled out. Well-behavedness is fully *compositional*: it can be checked separately for every role.

► **Remark 18.** A key advantage of well-behavedness of implicit local types over well-formedness of global types is that it allows us to prove the main results *independently of the set of global type operators*. Thus, the grammar can be extended with new global type operators (such that Propositions 16–17 continue to be valid) without reproving the theorems (§4). ◻

Before defining them formally, we informally introduce the main well-behavedness conditions:

- C1. Idling is neutral:** A local type must always have the same weak termination/reductions before τ -reductions as after them. This means that a role can neither increase nor decrease its behavioural alternatives by idling.
- C2. Sending is causal:** A local type must always have the same strong $!$ -reductions before τ -reductions as after them. This means that if a role can send after idling (later in the future), then it can also send immediately (already in the present). That is, the ability to send cannot arise out of “doing nothing”; there must be an observable cause.
- C3. Receiving is deterministic:** A local type must never have multiple weak $?$ -reductions with the same label but different destinations. This means that if a role receives, then its continuation is uniquely determined. Conditions **C2** and **C3** yield the following duality: *every send must have at least one cause; every receive must have at most one effect.*

► **Example 19.** We illustrate the conditions with three problematic cases, each of which demonstrates a different reason for operational inequivalence. In each case: first, we define a bad global type that specifies an unrealisable protocol; next, we visualise the operational semantics of it and the projections; next, we argue that they are indeed inequivalent; last, we state the well-behavedness condition that is violated by at least one projection.

- C1.** If $G_1 = \mathbf{a} \rightarrow \mathbf{b} : \{\text{Nat}.\mathbf{b} \rightarrow \mathbf{c} : \text{Nat}.\checkmark, \text{Unit}.\checkmark\}$, then:

The global type cannot be stuck after weak reduction $\xrightarrow{\mathbf{ab}^? \text{Nat}}$: it can always reduce onwards. In contrast, the family of projections can be stuck after weak reduction $\xrightarrow{\mathbf{ab}^? \text{Nat}}$, namely when $G_1 | \mathbf{c}$ weakly reduced rightwards instead of leftwards. In that case, $G_1 | \mathbf{b}$ neither can terminate, nor can reduce onwards (i.e., it needs to synchronise its $!$ -reduction with a $?$ -reduction of $G_1 | \mathbf{c}$, but $G_1 | \mathbf{c}$ has become unable to reciprocate). Thus, G_1 and $\{G_1 | r\}_{r \in \{\mathbf{a}, \mathbf{b}, \mathbf{c}\}}$ are inequivalent. This is caught by **C1**: $G_1 | \mathbf{c}$ has a weak $?$ -reduction before the rightwards τ -reduction, but not after it, which violates **C1** (i.e., idling is non-neutral), so G_1 is ruled out from usage.

- C2.** If $G_2 = \mathbf{a} \rightarrow \mathbf{b} : \text{Unit}.\mathbf{c} \rightarrow \mathbf{d} : \text{Unit}.\checkmark$, then:

The global type can terminate *only* after weak reductions $\xrightarrow{\mathbf{ab}^? \text{Unit}} \xrightarrow{\mathbf{cd}^? \text{Unit}}$. In contrast, the family of projections can terminate *also* after weak reductions $\xrightarrow{\mathbf{cd}^? \text{Unit}} \xrightarrow{\mathbf{ab}^? \text{Unit}}$, when

$G_2 \upharpoonright \mathbf{c}$ and $G_2 \upharpoonright \mathbf{d}$ begin with $\xrightarrow{\tau} \mathbf{d}!\mathbf{Unit}$ and $\xrightarrow{\tau} \mathbf{c}?\mathbf{Unit}$, and when $G_2 \upharpoonright \mathbf{a}$ and $G_2 \upharpoonright \mathbf{b}$ end with $\xrightarrow{\tau} \mathbf{b}!\mathbf{Unit}$ and $\xrightarrow{\tau} \mathbf{a}?\mathbf{Unit}$. Thus, G_2 and $\{G_2 \upharpoonright r\}_{r \in \{\mathbf{a}, \mathbf{b}, \mathbf{c}, \mathbf{d}\}}$ are inequivalent. This is caught by **C2**: $G_2 \upharpoonright \mathbf{c}$ does not have a $!$ -reduction before its τ -reduction, but it does have one after it, which violates **C2** (i.e., sending is non-causal), so G_2 is ruled out from usage. We note that if we allowed out-of-order execution of independent global actions, then G_2 would satisfy **C2**. We recover out-of-order execution in §4. The corresponding global type will be $\mathbf{a} \rightarrow \mathbf{b}:\mathbf{Unit}; \mathbf{c} \rightarrow \mathbf{d}:\mathbf{Unit}$, each of whose projections will be well-behaved.

C3. If $G_3 = \mathbf{a} \rightarrow \mathbf{b}:\{\mathbf{Bool}.\mathbf{b} \rightarrow \mathbf{c}:\mathbf{Unit}.\mathbf{c} \rightarrow \mathbf{b}:\mathbf{Bool}.\checkmark, \mathbf{Nat}.\mathbf{b} \rightarrow \mathbf{c}:\mathbf{Unit}.\mathbf{c} \rightarrow \mathbf{b}:\mathbf{Nat}.\checkmark\}$, then:

The global type cannot be stuck after weak reductions $\xrightarrow{\mathbf{ab}?\mathbf{Bool}} \xrightarrow{\mathbf{bc}?\mathbf{Unit}}$: it can always reduce onwards. In contrast, the family of projections can be stuck after weak reductions $\xrightarrow{\mathbf{ab}?\mathbf{Bool}} \xrightarrow{\mathbf{bc}?\mathbf{Unit}}$, namely when $G_1 \upharpoonright \mathbf{c}$ weakly reduced rightwards instead of leftwards. In that case, $G_3 \upharpoonright \mathbf{b}$ neither can terminate, nor can reduce onwards (i.e., it needs to synchronise its $\mathbf{c}?\mathbf{Bool}$ -reduction with a $\mathbf{b}!\mathbf{Bool}$ -reduction of $G_3 \upharpoonright \mathbf{c}$, but $G_3 \upharpoonright \mathbf{c}$ has become unable to reciprocate). Thus, G_3 and $\{G_3 \upharpoonright r\}_{r \in \{\mathbf{a}, \mathbf{b}, \mathbf{c}\}}$ are inequivalent. This is caught by condition **C3**: $G_3 \upharpoonright \mathbf{c}$ has two weak $?$ -reductions with the same label, but to different destinations, which violates **C3** (i.e., receiving is non-deterministic), so G_3 is ruled out from usage. \perp

We relate the well-behavedness conditions on implicit local types in this paper to well-formedness conditions on global types in the MPST literature in the terminology of Castagna et al. [20]. Condition **C1** is usually enforced through projection (i.e., projection determinises explicit local types as they are computed, without using τ -based operators). Condition **C2** is the *sequentiality* principle of Castagna et al.; it is usually enforced by allowing out-of-order execution of independent global actions. Condition **C3** is the *knowledge for choice* principle of Castagna et al. (i.e., a receiver must always be able to uniquely determine which branch the sender was in); it is usually enforced through merging. We note that well-behavedness is relatively permissive regarding branching (some non-directed and non-located choice patterns are allowed), whereas well-formedness is relatively restrictive (all such patterns are forbidden).

Technicalities. First, we define operational equivalence as a relation \approx on specifications (global types, local types, and families of local types). We derive the following requirements from Example 19: **(a)** \approx must be insensitive to idling (i.e., we argued in terms of weak reductions); **(b)** \approx must be sensitive to deadlock (i.e., we distinguished between termination and “being stuck”). Out of many candidates [66, 67], we adopt *weak bisimilarity* (e.g., [68]): it meets both requirements **a** and **b**; additionally, it is sensitive to branching, which is not a requirement, but which makes our proofs easier. Intuitively, two specifications are weak bisimilar when they can mimick each other’s termination/reductions modulo τ -reductions.

► **Definition 20.** Recall that \mathbb{S} denotes the set of all global types, local types, and families of local types, ranged over by S . A weak bisimulation $\heartsuit \subseteq \mathbb{S} \times \mathbb{S}$ is a relation that satisfies the following conditions, for every $(S_1, S_2) \in \heartsuit$, (and for every $S_1^\natural, S_2^\natural, \alpha$):

42:18 Sound, Regular Multiparty Sessions via Implicit Local Types

- If $S_1 \Downarrow$, then $S_2 \Downarrow$. – If $S_1 \xrightarrow{\alpha} S_1^\sharp$, then $S_1^\sharp \heartsuit S_2^\sharp$ and $S_2 \xrightarrow{\alpha} S_2^\sharp$, for some S_2^\sharp .
- If $S_2 \Downarrow$, then $S_1 \Downarrow$. – If $S_2 \xrightarrow{\alpha} S_2^\sharp$, then $S_1^\sharp \heartsuit S_2^\sharp$ and $S_1 \xrightarrow{\alpha} S_1^\sharp$, for some S_1^\sharp .

Let $S_1 \approx S_2$ denote weak bisimilarity. Formally, \approx is the largest weak bisimulation. \lrcorner

Next, we define well-behavedness by formalising the main conditions (plus two more).

► **Definition 21.** Let $\text{wb}(L)$ denote well-behavedness of L . Formally, it is the largest predicate that satisfies the following conditions, for every $L \in \text{wb}$ (and for every $L', L^\dagger, L_1^\dagger, L_2^\dagger, p, q, t$):

- C1.** If $L \Rightarrow L^\dagger$, then $L \approx L^\dagger$. [If L^\dagger is τ -reachable, then L and L^\dagger are weak bisimilar.]
- C2.** If $L \xrightarrow{pq!t} L^\dagger$, then $L \xrightarrow{pq!t} \approx L^\dagger$. [If L has a weak $!$ -reduction to L^\dagger , then it has the same strong $!$ -reduction to a weak bisimilar destination.]
- C3.** If $L \xrightarrow{pq?t} L_1^\dagger$ and $L \xrightarrow{pq?t} L_2^\dagger$, then $L_1^\dagger \approx L_2^\dagger$. [If L has the same weak $?$ -reductions to L_1^\dagger and L_2^\dagger , then L_1^\dagger and L_2^\dagger are weak bisimilar.]
- C4.** If $L \rightarrow$, then $L \not\Downarrow$. [If L can reduce, then it cannot terminate.]
- C5.** If $L \rightarrow L'$, then $\text{wb}(L')$. [Reduction preserves well-behavedness.] \lrcorner

Last, we prove that the conditions of well-behavedness are sufficient to ensure operational equivalence. The idea is to define a *correspondence relation* between global types and families of well-behaved local types. We can then show that correspondence is a weak bisimulation.

► **Definition 22.** Let $G \Leftarrow \{L_r\}_{r \in R}$ denote correspondence of G and $\{L_r\}_{r \in R}$. Formally:

$$\frac{[\text{wb}(G \upharpoonright r) \text{ and } \text{wb}(L_r) \text{ and } G \upharpoonright r \approx L_r]}{G \Leftarrow \{L_r\}_{r \in R}} \quad \lrcorner$$

► **Theorem 23 (equivalence).** If $\text{wb}(G \upharpoonright r)$, for every $r \in R$, then $G \approx \{G \upharpoonright r\}_{r \in R}$. \lrcorner

The proof of this main result is based on two auxiliary lemmas. They state that well-behavedness implies correspondence, and that correspondence implies weak bisimilarity.

► **Lemma 24.** If $\text{wb}(G \upharpoonright r)$, for every $r \in R$, then $G \Leftarrow \{G \upharpoonright r\}_{r \in R}$. \lrcorner

► **Lemma 25.** If $G \Leftarrow \{L_r\}_{r \in R}$, then $G \approx \{L_r\}_{r \in R}$. \lrcorner

The first lemma follows directly from the definition of correspondence and the reflexivity of weak bisimilarity. The proof of the second lemma relies on the definition of well-behavedness.

► **Remark 26.** Theorem 23 depends on premise $\text{wb}(G \upharpoonright r)$. To see that checking this premise is decidable, observe that the reduction relation of G is finite by Proposition 17. As the reduction relation of $G \upharpoonright r$ has exactly the same structure by rules $[\downarrow\text{L-AT}]$ and $[\rightarrow\text{L-AT}]$, and at most linearly many extra τ -transition by rule $[\rightarrow\text{L-REV}]$, it is finite as well. Consequently, checking well-behavedness (including weak bisimilarity [1]) of $G \upharpoonright r$ is trivially decidable. \lrcorner

► **Remark 27.** As an alternative to Theorem 23, of course, it is also possible to check weak bisimilarity between G and $\{G \upharpoonright r\}_{r \in R}$ directly. However, this would require one to compute the reduction relation of $\{G \upharpoonright r\}_{r \in R}$, which is exponentially large in the worst case. In contrast, as well-behavedness is fully compositional, such a computation is avoided. Thus, direct weak bisimilarity is of exponential complexity (in the size of the reduction relations), whereas well-behavedness is of linear complexity and, as a result, better scalable to many roles. \lrcorner

$$\begin{array}{c}

\end{array}$$

(a) Termination. (b) Reduction.

■ **Figure 4** Operational semantics of sub-regular processes. Let $P[v/x]$ denote capture-avoiding substitution of v for x in P . Let $P[\mathbf{loop} P/\mathbf{recur}]$ denote unfolding of **recur** into **loop** P in P .

3.4 Processes – Syntax

Below, we define the grammar of processes and concrete local actions.

► **Definition 28.** Let \mathbb{O} , \mathbb{I} , and \mathbb{P} denote the sets of output processes, input processes, and processes, ranged over by O , I , and P ; they are induced by the following grammar:

$$\begin{array}{l}
P ::= \sum\{O_1, \dots, O_n\} \mid \sum\{I_1, \dots, I_m\} \mid \quad O ::= \overline{pq}\langle e \rangle . P \quad I ::= p(x:t) . P \\
\text{if } e P_1 P_2 \mid \mathbf{loop} P \mid \mathbf{recur} \mid \mathbf{0}
\end{array}$$

Let $\mathbb{R} \rightarrow \mathbb{P}$ denote the set of role-indexed families of processes, ranged over by \mathcal{P} . ┘

Output process $\overline{pq}\langle e \rangle . P$ implements the *send* of the value of expression e from role p to role q ; we omit p when it is clear from the context. Input process $pq(x:t) . P$ implements the *receive* of a value of data type t into variable x from role p to role q ; we omit q when it is clear from the context; we omit “:t” when the data type does not matter. Processes $\sum\{O_1, \dots, O_n\}$ and $\sum\{I_1, \dots, I_m\}$ implement non-deterministic *selections* of n output processes (sends) and m input processes (receives); we omit “ \sum ” and braces when $n = m = 1$. Process **if** $e P_1 P_2$ implements a *conditional choice*. Processes **loop** P and **recur** implement a *loop*. Process **0** implements the *empty process*. We note that data parameters can be added to loops in the standard way (e.g., [62]). Process creation and session creation are orthogonal to the contributions of this paper and thus we omit them.

► **Remark 29.** We stipulate that every process is *guarded* (i.e., **recur** occurs only inside \sum -processes) and *closed* (i.e., **recur** occurs only inside **loop**-processes), while every family $\{P_r\}_{r \in R}$ is *well-formed* (i.e., for every $r \in R$, every output process that occurs in P_r is of the form $\overline{rq}\langle e \rangle . P'$, while every input process is of the form $pr(x:t) . P'$). ┘

► **Definition 30.** Let $\mathbb{II} = \bigcup\{pq!v, pq?v \mid p \neq q\}$ denote the set of (concrete) local actions, ranged over by π . ┘

3.5 Processes – Operational Semantics

Below, we define the termination predicate and reduction relation on processes.

► **Definition 31.** Let $P \downarrow$ and $\mathcal{P} \downarrow$ denote termination of P and \mathcal{P} . Formally, \downarrow is the predicate induced by the rules in Figure 4a. ┘

$$\begin{array}{c}
\frac{\Xi \vdash e : t \quad \Xi, \Upsilon \vdash P : L^\sharp \quad L \xrightarrow{pq!t} L^\sharp}{\Xi, \Upsilon \vdash \overline{pq}(e).P : L} [\vdash\text{-OUT}] \quad \frac{\Xi, x : t, \Upsilon \vdash P : L^\sharp \quad L \xrightarrow{pq?t} L^\sharp}{\Xi, \Upsilon \vdash pq(x:t).P : L} [\vdash\text{-IN}] \\
\frac{\Xi, \Upsilon \vdash O_i : L \text{ for every } 1 \leq i \leq n \quad [O_i = \overline{p}\langle \cdot \rangle. _ \text{ for some } 1 \leq i \leq n] \text{ for every } L \xrightarrow{pq!t}}{\Xi, \Upsilon \vdash \sum\{O_1, \dots, O_n\} : L} [\vdash\text{-SUM1}] \\
\frac{\Xi, \Upsilon \vdash I_j : L \text{ for every } 1 \leq j \leq m \quad [I_j = pq(_ : t). _ \text{ for some } 1 \leq j \leq m] \text{ for every } L \xrightarrow{pq?t}}{\Xi, \Upsilon \vdash \sum\{I_1, \dots, I_m\} : L} [\vdash\text{-SUM2}] \\
\frac{L \Downarrow}{\Xi, \Upsilon \vdash \mathbf{0} : L} [\vdash\text{-END}] \quad \frac{\Xi, \Upsilon, \mathbf{recur} : L \vdash P : L}{\Xi, \Upsilon \vdash \mathbf{loop} P : L} [\vdash\text{-LOOP}] \quad \frac{L_1 \approx L_2}{\Xi, \Upsilon, \mathbf{recur} : L_1 \vdash \mathbf{recur} : L_2} [\vdash\text{-RECUR}] \\
\frac{\Xi \vdash e : \mathbf{Bool} \quad \Xi, \Upsilon \vdash P_1 : L \quad \Xi, \Upsilon \vdash P_2 : L}{\Xi, \Upsilon \vdash \mathbf{if} e P_1 P_2 : L} [\vdash\text{-IF}] \quad \frac{[\vdash P_r : L_r \text{ and } \mathbf{wb}(L_r)] \text{ for every } r}{\vdash \{P_r\}_{r \in R} : \{L_r\}_{r \in R}} [\vdash]
\end{array}$$

■ **Figure 5** Well-typedness (“ $_$ ” is a meta-variable to indicate that the object does not matter).

► **Definition 32.** Let $P \xrightarrow{\pi} P'$ and $\mathcal{P} \xrightarrow{\pi_p, \pi_q} \mathcal{P}'$ denote reduction from P to P' with π alone, and from \mathcal{P} to \mathcal{P}' with π_p and π_q together (synchronously). Formally, \rightarrow is the relation induced by the rules in Figure 4b. \lrcorner

Rule $[\rightarrow\text{-SUM1}]$ (resp. $[\rightarrow\text{-SUM2}]$) states that a selection can reduce with a send (resp. receive) when there is a corresponding output process (resp. input process) among the alternatives and $\mathbf{eval}(e)$ is defined (resp. v is well-typed by t and bound to x). Rule $[\rightarrow\text{-IF}]$ states that a conditional choice can reduce when $\mathbf{eval}(e) \in \{\mathbf{true}, \mathbf{false}\}$ and the corresponding branch can reduce. Rule $[\rightarrow\text{-LOOP}]$ states that a recursive loop can reduce when its body can. Rule $[\rightarrow\text{-P}]$ states that a family can reduce when two processes can reduce with a matching send/receive pair (synchronously).

► **Remark 33.** Figure 4 contains no rules for communication errors: “going wrong” manifests as *deadlock*. There are three situations in which this can happen for a process P or family \mathcal{P} :

- If $P = \mathbf{if} e P_1 P_2$, but $\mathbf{eval}(e) \notin \{\mathbf{true}, \mathbf{false}\}$, then rules $[\downarrow\text{-IF}]/[\rightarrow\text{-IF}]$ are inapplicable.
- If $P = \sum\{\overline{p_1 q_1}(e_1).P_1, \dots, \overline{p_n q_n}(e_n).P_n\}$ and $n > 1$, but $\mathbf{eval}(e_i)$ is undefined for every $1 \leq i \leq n$, then rule $[\rightarrow\text{-SUM1}]$ is inapplicable.
- If not all processes in \mathcal{P} can terminate, while no two processes in \mathcal{P} can reduce with a matching send and receive, then rules $[\downarrow\text{-P}]/[\rightarrow\text{-P}]$ are inapplicable.

In each situation, P or \mathcal{P} cannot terminate/reduce. Well-typedness will prevent this. \lrcorner

3.6 Main Result 2: Well-Typedness Implies Operational Refinement

Now comes the pivotal concept among our contributions: the typing rules are based on the operational semantics of implicit local types instead of on their syntax. That is, the termination predicate and the reduction relation on local types are used not only “a posteriori” to prove type soundness (as usual), but also “a priori” to define the typing rules. This allows us to break the historically tight correspondence between the structure of global/local types and the structure of processes (§1.2).

► **Definition 34.** Recall that $(\mathbb{X} \times \mathbb{T})^*$ denotes the set of data typing contexts, ranged over by Ξ . Let $(\mathbf{recur} \times \mathbb{L})^*$ denote the set of process typing contexts, ranged over by Υ . Let $\Xi, \Upsilon \vdash O : L$, $\Xi, \Upsilon \vdash I : L$, $\Xi, \Upsilon \vdash P : L$ and $\vdash \mathcal{P} : \mathcal{L}$ denote well-typedness of O , I , P by L in Ξ, Υ , and of \mathcal{P} by \mathcal{L} . Formally, \vdash is the relation induced by the rules in Figure 5. \lrcorner

Rule $[\vdash\text{-END}]$ states that the empty process is well-typed when the local type can weakly terminate. Rule $[\vdash\text{-IF}]$ states that a conditional choice is well-typed when the condition and the branches are well-typed. Rules $[\vdash\text{-LOOP}]/[\vdash\text{-RECUR}]$ state that a loop is well-typed when the body and the recursive calls are well-typed. Rule $[\vdash]$ states that a family of processes is well-typed when every process is well-typed by a well-behaved local type.

Rule $[\vdash\text{-OUT}]$ states that an output process is well-typed when the local type has an *analogous* weak $!$ -reduction such that the expression and the continuation are well-typed; “analogous” means “same sender, same receiver, same data type”. Rule $[\vdash\text{-IN}]$ states that an input process is well-typed when the local type has an analogous weak $?$ -transition, and the continuation is well-typed. Rule $[\vdash\text{-SUM1}]$ states that a selection of output processes is well-typed when every subprocess is well-typed, and there is a *possibly non-analogous* subprocess for every weak $!$ -reduction of the local type. Rule $[\vdash\text{-SUM2}]$ states that a selection of input processes is well-typed when every subprocess is well-typed, and there is an *analogous* subprocess for every weak $?$ -reduction of the local type.

► **Remark 35.** As usual in the MPST literature, there is asymmetry between well-typedness of selections of output processes and selections of input processes: if the local type specifies ≥ 1 sends, then the process *may* implement *one* of them (i.e., the programmer statically chooses what/whereto the process sends); if it specifies ≥ 1 receives, then it *must* implement *all* of them (i.e., the environment dynamically chooses what/wherefrom the process receives). ◻

► **Example 36.** Let $G = \mathbf{a} \rightarrow \mathbf{b} : \{\mathbf{Nat}.\mathbf{b} \rightarrow \mathbf{c} : \mathbf{Nat}.\checkmark, \mathbf{Bool}.\mathbf{b} \rightarrow \mathbf{c} : \mathbf{Bool}.\checkmark\}$; the operational semantics of this global type was previously visualised in Example 15.

- **Alice:** Process $\bar{\mathbf{b}}\langle 5 \rangle.\mathbf{0}$, process $\bar{\mathbf{b}}\langle \mathbf{true} \rangle.\mathbf{0}$, and process $\mathbf{if\ cond}() (\bar{\mathbf{b}}\langle 5 \rangle.\mathbf{0}) (\bar{\mathbf{b}}\langle \mathbf{true} \rangle.\mathbf{0})$ are all well-typed by $G \upharpoonright \mathbf{a}$, because rule $[\vdash\text{-SUM1}]$ requires only one send specified to be implemented. Process $\bar{\mathbf{b}}\langle \mathbf{f}\mathbf{o}\mathbf{o} \rangle.\mathbf{0}$ is ill-typed, because rule $[\vdash\text{-SUM1}]$ requires every send implemented to be specified. Process $\mathbf{loop} (\bar{\mathbf{b}}\langle 5 \rangle.\mathbf{recur})$ is ill-typed by $G \upharpoonright \mathbf{a}$ as well, because rule $[\vdash\text{-LOOP}]$ adds $\mathbf{recur} : G \upharpoonright \mathbf{a}$ to the process typing context at the root of the derivation tree, but rule $[\vdash\text{-RECUR}]$ requires $\mathbf{recur} : \checkmark$ at the leaf, and $G \upharpoonright \mathbf{a} \not\approx \checkmark$.
- **Carol:** Process $\mathbf{b}(x:\mathbf{Nat}).\mathbf{0}$ and process $\mathbf{if\ cond}() (\mathbf{b}(x:\mathbf{Nat}).\mathbf{0}) (\mathbf{b}(x:\mathbf{Bool}).\mathbf{0})$ are both ill-typed by $G \upharpoonright \mathbf{c}$, because rule $[\vdash\text{-SUM2}]$ requires every receive specified to be implemented. Process $\sum \{\mathbf{b}(x:\mathbf{Nat}).\mathbf{0}, \mathbf{b}(x:\mathbf{Bool}).\mathbf{0}\}$ is well-typed by $G \upharpoonright \mathbf{c}$. ◻

The asymmetry between the right-sided premises of rules $[\vdash\text{-SUM1}]/[\vdash\text{-SUM2}]$ ensure that if a family of well-typed local types can reduce, then the family of well-typed processes can reduce, too, *but possibly with a non-analogous communication*. This is *progress*:

► **Lemma 37.** *If $G \rightleftharpoons \mathcal{L}$ and $\vdash \mathcal{P} : \mathcal{L}$, then $\mathcal{P} \downarrow$ or $\mathcal{P} \rightarrow$.* ◻

Complementary, the symmetry between the left-sided premises of rules $[\vdash\text{-SUM1}]/[\vdash\text{-SUM2}]$ (i.e., every subprocess of every selection needs to be well-typed) ensure that if a family of well-typed processes can reduce, then the family of well-behaved local types can reduce, too, *and necessarily with an analogous communication*. This is *preservation*:

► **Lemma 38.** *If $G \rightleftharpoons \mathcal{L}$ and $\vdash \mathcal{P} : \mathcal{L}$, then (for every \mathcal{P}', p, q, v):*

- *If $\mathcal{P} \downarrow$, then $G \downarrow$ and $\mathcal{L} \downarrow$.*
- *If $\mathcal{P} \xrightarrow{pq^?v} \mathcal{P}'$, then $G' \rightleftharpoons \mathcal{L}'$ and $\vdash \mathcal{P}' : \mathcal{L}'$ and $\vdash v : t$ and $G \xrightarrow{pq^?t} G'$ and $\mathcal{L} \xrightarrow{pq^?t} \mathcal{L}'$, for some t, G', \mathcal{L}' .* ◻

Progress and preservation entail *operational refinement*: every trace of the family of processes (with concrete actions) is also a trace of the family of projections (with analogous abstract actions); moreover, if the family of processes can terminate or deadlock, then also the family of projections can. We formalise this concept directly in the following theorem.

- **Theorem 39** (refinement). *If $\vdash \mathcal{P} : \{G \upharpoonright r\}_{r \in R}$, and $\mathcal{P} \xrightarrow{p_1 q_1 ? v_1} \dots \xrightarrow{p_n q_n ? v_n} \mathcal{P}^\dagger$, then:*
- $\{G \upharpoonright r\}_{r \in R} \xrightarrow{p_1 q_1 ? t_1} \dots \xrightarrow{p_n q_n ? t_n}$, and $\vdash v_1 : t_1$, and \dots , and $\vdash v_n : t_n$, for some t_1, \dots, t_n .
 - If $\mathcal{P}^\dagger \downarrow$, then $\mathcal{L}^\dagger \downarrow$.
 - If $\mathcal{P}^\dagger \not\downarrow$ and $\mathcal{P}^\dagger \not\rightarrow$, then $\mathcal{L}^\dagger \not\downarrow$ and $\mathcal{L}^\dagger \not\rightarrow$. ┘

► **Remark 40.** Theorem 39 depends on premise $\vdash \mathcal{P} : \{G \upharpoonright r\}_{r \in R}$. To see that checking this premise is decidable, observe that we need to check two sets of properties by rule $[\vdash]$: (1) well-typedness of the processes in \mathcal{P} by the local types in $\{G \upharpoonright r\}_{r \in R}$; (2) well-behavedness of the local types in $\{G \upharpoonright r\}_{r \in R}$. Regarding the first set, the typing rules for processes are defined inductively on the structure of processes. Consequently, the number of applications is finite. Furthermore, checking the premise of rule $[\vdash\text{-IN}]/[\vdash\text{-OUT}]/[\vdash\text{-SUM1}]/[\vdash\text{-SUM2}]$ is decidable because the reduction relation of every local type in $\{G \upharpoonright r\}_{r \in R}$ is finite (Remark 26). Thus, checking the first set of properties is decidable. Regarding the second set, see Remark 26. ┘

3.7 Safety and Liveness

We proved operational equivalence for projection (Theorem 23) and operational refinement for type checking (Theorem 39). Together, these main results entail type soundness.

- **Corollary 41** (type soundness). *If $\vdash \mathcal{P} : \{G \upharpoonright r\}_{r \in R}$ and $\mathcal{P} \xrightarrow{p_1 q_1 ? v_1} \dots \xrightarrow{p_n q_n ? v_n} \mathcal{P}^\dagger$, then:*
- **Safety:** $G \xrightarrow{p_1 q_1 ? t_1} \dots \xrightarrow{p_n q_n ? t_n}$, and $\vdash v_1 : t_1$, and \dots , and $\vdash v_n : t_n$, for some t_1, \dots, t_n .
 - **Liveness:** $\mathcal{P}^\dagger \downarrow$, or $\mathcal{P}^\dagger \rightarrow$. ┘

All communication errors that can give rise to deadlock (Remark 33) are ruled out when $\vdash \mathcal{P} : \{G \upharpoonright r\}_{r \in R}$ holds. Moreover, checking if $\vdash \mathcal{P} : \{G \upharpoonright r\}_{r \in R}$ holds, is decidable (Remark 40).

4 Regular Grammars

In this section, we apply the new techniques for projection and type checking to regular grammars of global types and processes for the first time. To achieve this, we need to revise and extend the definitions of the grammars in §3, termination/reduction rules, and typing rules. In contrast, the definitions of implicit local types, projection, and well-behavedness – as well as the main result of operational equivalence (Theorem 23) – can stay exactly the same as in §3: they were all formulated in general terms of termination and reduction, but not in specific terms of the rules that define them. Thus, only the following changes are needed:

- **Definition 42** (revision of Definition 11). $G ::= p \rightarrow q : t \mid G_1 + G_2 \mid G_1 \cdot G_2 \mid G^* \mid \checkmark$ ┘

Global type $p \rightarrow q : t$ specifies a synchronous communication. Global types $G_1 + G_2$ and $G_1 \cdot G_2$ specify the *choice* between, and the *sequence* of, G_1 and G_2 . Global type G^* specifies the *finite repetition* of G . Global type \checkmark specifies the *empty protocol*.

- **Definition 43** (revision of Definition 13 and Definition 14). *See Figure 6.* ┘

- **Definition 44** (extension of Definition 28). $P ::= \dots \mid \sum \{O_1, \dots, O_n, I_1, \dots, I_m\}$ ┘

Process $\sum \{O_1, \dots, O_n, I_1, \dots, I_m\}$ implements a non-deterministic *selection* of n output processes and m input processes, simultaneously (i.e., it is a *mixed input/output process*).

- **Definition 45** (extension of Definition 32). *See Figure 7.* ┘

$$\begin{array}{c}
\frac{}{\checkmark \downarrow} \quad \frac{G_i \downarrow}{G_1 + G_2 \downarrow} \\
\frac{G_1 \downarrow \quad G_2 \downarrow}{G_1 \cdot G_2 \downarrow} \quad \frac{}{G^* \downarrow}
\end{array}
\qquad
\begin{array}{c}
\frac{}{p \rightarrow q : t \xrightarrow{pq^*t} \checkmark} \quad \frac{G_i \xrightarrow{\gamma} G'}{G_1 + G_2 \xrightarrow{\gamma} G'} \\
\frac{G_1 \xrightarrow{\gamma} G'_1}{G_1 \cdot G_2 \xrightarrow{\gamma} G'_1 \cdot G_2} \quad \frac{G_1 \downarrow \quad G_2 \xrightarrow{\gamma} G'}{G_1 \cdot G_2 \xrightarrow{\gamma} G'} \quad \frac{G \xrightarrow{\gamma} G'}{G^* \xrightarrow{\gamma} G' \cdot G^*}
\end{array}$$

(a) Termination (b) Reduction

■ **Figure 6** Operational semantics of regular global types (standard for regular expressions; e.g., [4]).

$$\cdots \text{ (same as in Figure 4b)} \quad \frac{\sum\{O_1, \dots, O_n\} \xrightarrow{\pi} P'}{\sum\{O_1, \dots, O_n, I_1, \dots, I_m\} \xrightarrow{\pi} P'} \quad \frac{\sum\{I_1, \dots, I_m\} \xrightarrow{\pi} P'}{\sum\{O_1, \dots, O_n, I_1, \dots, I_m\} \xrightarrow{\pi} P'}$$

■ **Figure 7** Operational semantics of regular processes – Reduction rules.

► **Definition 46** (extension of Definition 34). *See Figure 8.* ┘

While Theorem 23 of operational equivalence is directly applicable to the regular grammar of global types in this section, Theorem 39 of operational refinement requires minor effort: we need to prove a new, yet simple, inductive case for the new typing rule in Figure 8. Then:

► **Corollary 47.** *Corollary 41 is applicable to the revisions and extensions in this section.* ┘

Extending the regular grammar of processes with new process operators (including typing rules) requires one to prove additional inductive cases. In contrast, extending the regular grammar of global types with new global type operators (such that Propositions 16–17 continue to be valid) is completely *free*. That is, in this paper, projection (including well-behavedness) and type checking are independent of the syntax of global types; they are dependent only on the operational semantics. The formulations and proofs of our main results are similarly independent. As a result of this independence, our regular grammar of global types is actually “open ended”. As a first demonstration of this extensibility, we freely add a few global type operators; they are intended to serve as higher-level abstractions to make the specification of protocols easier. See also Example 8 and Example 9 in §2.2.

► **Definition 48** (extension of Definition 42). $G ::= \cdots \mid G_1;G_2 \mid G_1 \parallel G_2 \mid G_1 \bowtie G_2 \mid [G]_{\gamma_2}^{\gamma_1}$ ┘

- Global type $G_1;G_2$ specifies the *weak sequence* of G_1 and G_2 . It is similar to $G_1 \cdot G_2$, except that independent communications in G_1 and G_2 can happen out-of-order. Communications are independent when they have disjoint sets of participating roles. By using G^* instead of $\mu X.G$ for loops (wlog for regularity), weak sequencing yields finite reduction relations.
- Global type $G_1 \parallel G_2$ specifies the *interleaving* of G_1 and G_2 . We note that interleaving was already present in the original paper on MPST [39], as well as in later papers (e.g., [20, 30, 31, 51]). However, in these papers, G_1 and G_2 need to have disjoint roles or disjoint channels, whereas in this paper, G_1 and G_2 need to have disjoint actions (as a result of well-behavedness); this is a weaker requirement. Interleaving allows us, for instance, to support the global types on rows “Example 13” and “MP workers” in Table 1.
- Global type $G_1 \bowtie G_2$ specifies the *join* of G_1 and G_2 : every “unconstrained” communication that occurs only in G_1 or only in G_2 is enabled in $G_1 \bowtie G_2$ if, and only if, it is enabled in G_1 or G_2 ; every “constrained” communication that occurs both in G_1 and in G_2 is enabled if, and only if, it is enabled in G_1 and G_2 . See also Example 49, below.
- Global type $[G]_{\gamma_2}^{\gamma_1}$ specifies the *prioritisation* of high-priority γ_1 over low-priority γ_2 in G .

$$\dots \text{ (same as in Figure 5)} \quad \frac{\Xi, \mathcal{Y} \vdash \sum\{O_1, \dots, O_n\} : L \quad \Xi, \mathcal{Y} \vdash \sum\{I_1, \dots, I_m\} : L}{\Xi, \mathcal{Y} \vdash \sum\{O_1, \dots, O_n, I_1, \dots, I_m\} : L}$$

■ **Figure 8** Well-typedness.

$$\begin{array}{c} \dots \text{ (same as in Figure 6a)} \qquad \dots \text{ (same as in Figure 6b)} \\ \frac{G_1 \downarrow \quad G_2 \downarrow}{G_1 ; G_2 \downarrow} \qquad \frac{G_1 \xrightarrow{\gamma} G'_1}{G_1 ; G_2 \xrightarrow{\gamma} G'_1 \cdot G_2} \quad \frac{r(G_1) \cap \{p, q\} = \emptyset \quad G_2 \xrightarrow{pq?t} G'_2}{G_1 ; G_2 \xrightarrow{pq?t} G_1 ; G'_2} \\ \frac{G_1 \downarrow \quad G_2 \downarrow}{G_1 \parallel G_2 \downarrow} \qquad \frac{G_1 \xrightarrow{\gamma} G'_1}{G_1 \parallel G_2 \xrightarrow{\gamma} G'_1 \parallel G_2} \quad \frac{G_2 \xrightarrow{\gamma} G'_2}{G_1 \parallel G_2 \xrightarrow{\gamma} G_1 \parallel G'_2} \\ \frac{G_1 \bowtie G_2 \not\downarrow}{G_1 \bowtie G_2 \downarrow} \quad \frac{G_1 \xrightarrow{\gamma} G'_1 \quad \gamma \notin \mathbf{a}(G_2)}{G_1 \bowtie G_2 \xrightarrow{\gamma} G'_1 \bowtie G_2} \quad \frac{G_2 \xrightarrow{\gamma} G'_2 \quad \gamma \notin \mathbf{a}(G_1)}{G_1 \bowtie G_2 \xrightarrow{\gamma} G_1 \bowtie G'_2} \quad \frac{G_1 \xrightarrow{\gamma} G'_1 \quad G_2 \xrightarrow{\gamma} G'_2}{G_1 \bowtie G_2 \xrightarrow{\gamma} G'_1 \bowtie G'_2} \\ \frac{[G]_{\gamma_2}^{\gamma_1} \not\downarrow}{[G]_{\gamma_2}^{\gamma_1} \downarrow} \quad \frac{G \xrightarrow{\gamma_1} G'}{[G]_{\gamma_2}^{\gamma_1} \xrightarrow{\gamma_1} [G']_{\gamma_2}^{\gamma_1}} \quad \frac{G \xrightarrow{\gamma_2} G' \quad G \xrightarrow{\gamma_1} G'}{[G]_{\gamma_2}^{\gamma_1} \xrightarrow{\gamma_2} [G']_{\gamma_2}^{\gamma_1}} \quad \frac{G \xrightarrow{\gamma} G' \quad \gamma \notin \{\gamma_1, \gamma_2\}}{[G]_{\gamma_2}^{\gamma_1} \xrightarrow{\gamma} [G']_{\gamma_2}^{\gamma_1}} \end{array}$$

(a) Termination (b) Reduction. Let $\mathbf{a}(G) = \{\gamma \mid G \rightarrow \dots \xrightarrow{\gamma}\}$ and $r(G) = \{p, q \mid pq?t \in \mathbf{a}(G)\}$.

■ **Figure 9** Operational semantics of regular global types, extended.

► **Example 49.** To exemplify join and prioritisation, let $G_1 = \mathbf{a} \rightarrow \mathbf{b} \cdot \mathbf{b} \rightarrow \mathbf{c}$ and $G_2 = \mathbf{a} \rightarrow \mathbf{b} \cdot \mathbf{b} \rightarrow \mathbf{d}$ (data types omitted). Unconstrained are $\mathbf{b} \rightarrow \mathbf{c}$ (only in G_1) and $\mathbf{b} \rightarrow \mathbf{d}$ (only in G_2); constrained is $\mathbf{a} \rightarrow \mathbf{b}$ (both in G_1 and in G_2). Thus, $G_1 \bowtie G_2$ is equivalent to $\mathbf{a} \rightarrow \mathbf{b} \cdot (\mathbf{b} \rightarrow \mathbf{c} \parallel \mathbf{b} \rightarrow \mathbf{d})$: after the constrained communication, the unconstrained communications are interleaved. Thus, $[G_1 \bowtie G_2]_{\mathbf{bd}^?}^{\mathbf{bc}^?}$ is equivalent to $[\mathbf{a} \rightarrow \mathbf{b} \cdot (\mathbf{b} \rightarrow \mathbf{c} \parallel \mathbf{b} \rightarrow \mathbf{d})]_{\mathbf{bd}^?}^{\mathbf{bc}^?}$, which is equivalent to $\mathbf{a} \rightarrow \mathbf{b} \cdot \mathbf{b} \rightarrow \mathbf{c} \cdot \mathbf{b} \rightarrow \mathbf{d}$: after $\mathbf{a} \rightarrow \mathbf{b}$ (no priority), $\mathbf{b} \rightarrow \mathbf{c}$ (high priority) must precede $\mathbf{b} \rightarrow \mathbf{d}$ (low priority). \lrcorner

► **Definition 50** (extension of Definition 43). *See Figure 9.* \lrcorner

- The termination rules for join and prioritisation state that they can terminate when they cannot reduce. This formalises the design decision that operators that constrain the behaviour of operands should be liberal: they should permit as much behaviour as possible within the constraints they impose (avoid premature termination when reductions are still possible); if less behaviour is required, more constraints can always be imposed.
- The second reduction rule for weak sequencing states that G_2 can start reducing before G_1 has finished reducing, when the roles that participate in the reduction of G_2 are disjoint from those that participate in reductions of G_1 (i.e., these reductions are independent).
- The first reduction rule (resp. second) for join states that it can γ -reduce when G_1 (resp. G_2) can, now, but G_2 (resp. G_1) cannot, ever (i.e., γ is unconstrained). The third reduction rule states that it can γ -reduce when G_1 and G_2 can (i.e., γ is constrained).
- The first reduction rule for prioritisation states that it can γ_1 -reduce (high priority) when G can. The second reduction rule states that it can γ_2 -reduce (low priority) when it cannot γ_1 -reduce. The third reduction rule states that it can γ -reduce when G can.

► **Example 51.** The following graphs visualise the operational semantics for Example 49:

We note that an evaluation of the usefulness of the added operators, as practical language primitives, is not really part of the present scope; here, our only aim was to give an impression of the future potential of the new techniques. Other possible global type primitives that may deserve future consideration include delayed choice [5], roles-as-ports composition [47], stateful global types (cf. stateful choreographies [28]), operators for higher-order protocols, and syntax for general models of behaviour (as mentioned towards the end of §1.2).

5 Related Work

This paper contributes to a line of research to increase the expressiveness of MPST [39]. Regarding basic features, previous works have focussed on two limitations of *directed choice* of the form $\sum\{p \rightarrow q : t_i . G_i\}_{1 \leq i \leq n}$: **(1)** every branch must start with the same sender and the same receiver as every other branch; **(2)** every “third role” that does not participate in the first communication of every branch must have the same behaviour in every branch.

- **Merging:** Honda et al. address limitation **2** by allowing “third roles” to have different behaviour in different branches when they are timely informed of the chosen branch [18]. The approach relies on a function to syntactically *merge* local types; it is adopted by many (e.g., [25, 33, 57]), but shown to be brittle [62]. In contrast, using our new projection and type checking techniques, we address limitation **2** without merging (Remark 10). Another approach that addresses limitation **2** without merging was developed by Scalas–Yoshida [62]. It works in three steps: first, every local type is interpreted as an automaton that specifies one role alone (similar to our operational semantics of implicit local types); next, the automata are composed into a product automaton – exponentially sized in the worse case – that specifies all roles together; last, the product automaton is checked for satisfaction of a special temporal logic formula φ , which entails type soundness. However, this method is non-compositional: the premise of the typing rule for families of processes (which depends on satisfaction of φ) cannot be checked separately for every role. Such non-compositional approaches to MPST have already been shown to have scalability issues [44]. Conversely, our typing rule for families is fully compositional (Remark 27).
- **Located/mixed choice:** Several teams of authors address limitation **1** by allowing every branch to start with a different receiver than every other branch. In earlier works that support such *located choice* of the form $\sum\{p \rightarrow q_i : t_i . G_i\}_{1 \leq i \leq n}$, communication races in the continuations are forbidden [9, 20, 31, 42, 51]; in later works, they are allowed [21–23, 54, 65]. We support them, too. However, the authors of these papers prove theorems for a closed set of global type operators, including $\sum\{p \rightarrow q_i : t_i . G_i\}_{1 \leq i \leq n}$. Instead, we prove theorems for an open set of global type operators, as demonstrated in §2.2 and §4. Verification of mixed input/output processes using session typing is a long-standing open problem. Progress was made by Casal et al. [19] (binary), Kouzapas–Yoshida (multiparty, but unpublished so far [69, ref. 24]), and Jongmans–Yoshida [44] (multiparty, but no type checking). We can verify multiparty non-deterministic mixed input/output processes for the first time (but not yet deterministic mixed choice), as demonstrated in §2.2.

The usage of the operational semantics of local types was first studied in the context of *multiparty compatibility* [32] and extensions [8, 51, 52]. The idea is to interpret local types as *communicating finite state machines* (CFSM) [11]. Multiparty compatibility, then, is a predicate on the joint state space of the CFSMs to ensure safety and liveness. As such, a key difference between multiparty compatibility (MC) and this paper’s well-behavedness (WB) is that MC is non-compositional (i.e., the joint state space must be computed, so MC cannot

be checked separately for every role), whereas WB is fully compositional (Remark 27). A rudimentary version of WB was studied by Jongmans–Yoshida [44], but it is less expressive (e.g., they do not support Example 15) and limited to projection (no type checking). A version of WB for global types was studied by Gheri et al. [34], in the context of choreography automata [6], but it is limited to projection (no type checking).

There are several non-traditional techniques for projection in the MPST literature. Lopez et al. [53] capture projection in a decidable type equivalence. Castellani et al. [22] and Hamers et al. [37] do not use projection at all, but type-check families of processes against global types (non-compositional). Last, the concept of implicit local types in this paper generalises an idea by Van Glabbeek et al. [65], who define merging as a local type operator.

6 Conclusion

We introduced two new techniques to significantly improve the expressiveness of the MPST method: projection is based on *implicit* local types instead of explicit; type checking is based on the *operational semantics* of implicit local types instead of on the syntax. Classes of protocols that can now be specified/implemented/verified for the first time using the MPST method include: recursive protocols in which different roles participate in different branches (Example 2, Example 3); protocols in which a receiver chooses the sender of the first communication (Example 6, Example 8, Example 9); protocols in which multiple roles synchronously choose both the sender and the receiver of a next communication (Example 5, Example 6), implemented as mixed input/output processes. We presented the theory of the new techniques, as well as their future potential, and we demonstrated their present capabilities to effectively support regular expressions as global types (not possible before).

As evidence that the new techniques are implementable, we implemented them; this implementation is available as a companion artefact (published in DARTS).

We aim to push the new techniques of this paper forward towards a new branch of research in MPST, centred around operational semantics of local types in typing rules; incidentally, it could be a natural path to explore for behavioural typing in general, too. In particular, we are keen to apply the new techniques for projection and type checking also to *asynchronous communication* and *parametrised protocols/indexed roles* [25, 33]. In both cases, the main challenge is how to ensure decidability (keep the reduction relations finite).

Abstract

Classical software documentation, as it was conceived and intended decades ago, is not the only reality anymore. Official documentation from authoritative and official sources is being replaced by real-time collaborative platforms and ecosystems that have seen a surge, influenced by changes in society, technology, and best practices. These modern tools influence the way developers document the conception, design, and implementation of software. As a by-product of these shifts, developers are changing their way of communicating about software. Where once official documentation stood as the only truth about a project, we now find a multitude of volatile and heterogeneous documentation sources, forming a complex and ever-changing *documentation landscape*.

Software projects often include a top-level README file with important information, which we leverage to identify their documentation landscape. Starting from ~12K GitHub repositories, we mine their README files to extract links to additional documentation sources. We present a qualitative analysis, revealing multiple dimensions of the documentation landscape (e.g., content type, source type), highlighting important insights. By analyzing instant messaging application links (e.g., Gitter, Slack, Discord) in the histories of README files, we show how this part of the landscape has grown and evolved in the last decade.

Our findings show that modern documentation encompasses communication platforms, which are exploding in popularity. This is not a passing phenomenon: On the contrary, it entails a number of unknowns and socio-technical problems the research community is currently ill-prepared to tackle.

2012 ACM Subject Classification Software and its engineering → Collaboration in software development; Human-centered computing → Collaborative and social computing

Keywords and phrases software documentation landscape, GitHub README, instant messaging

1 Introduction

Times are changing. This is even more true for software engineering. Major shifts have occurred, induced by the emergence of platforms like GitHub and StackOverflow, fundamentally changing how developers (and users) communicate about software projects: Mailing lists and forums are declining in favor of multi-media instant messaging platforms, such as Gitter, Slack, Discord, and GitHub Discussions, e.g., [9, 18, 27, 30, 33, 45, 46, 49, 50, 56, 58, 66, 67].

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Software documentation, a critical asset for developers [3], has been studied extensively with respect to its quality and usefulness [4, 10, 14, 19, 21, 54, 61, 79]. Nevertheless, the impact of the subtle but constant drift induced by new platforms is still to be evaluated. What are the implications for program comprehension if a tweet can influence how developers treat a bug [38]? Can the tweets on the usage of an API also serve as documentation? Classical software documentation, as we have known it, is being replaced by “communication”.

Documentation went from a clunky, and rather unloved, endeavor to becoming a fast-paced and volatile side dish. The utopia of “*on-demand documentation*” by Robillard et al. [55], is being replaced by a dystopia of an ever-changing landscape; documentation is waved away with sentences like “*check Discord*” or “*it’s in the pull request comments.*”

This change is more than just cosmetic, it is considerably affected by the richness of new media, influencing the cognitive processes that underlie communication [53]. Modern media-rich platforms offer vastly different mechanisms which are simply not there in classical electronic communication means. Moreover, developers do not only hold ephemeral discussions that they must be able to access now. They share knowledge (e.g., code examples, screenshots, howtos) that is important for them in the future, and they do not have (or rather: take) the time to persist it in a classical software documentation form (e.g., Wiki). Instant messaging is just too enticing for that. But, they will need long-term access to this knowledge and want to keep it searchable¹ [20] and organizable² [44]. They choose their platforms accordingly, for example, avoiding limitations in retrievable history [2], and are willing to pay significant sums for such services [12].

As the cards on documentation are being reshuffled, things seem murky: What happens to the body of knowledge contained in the repositories of classical communication platforms? What is the impact on standard software documentation? How do developers use modern platforms, and what does this imply?

The Spectrum Example. *Spectrum, a multi-forum community hosting platform, was hosting dozens of software related communities about frameworks (e.g., React, Laravel), UI design (e.g., Figma), front-end coding (e.g., CodePen), and developers’ networks in general (e.g., SpecFM). On Aug 24, 2021, to preserve history while pushing forward the adoption of new communication infrastructures, it was announced that “the time has come for the planned archival of Spectrum to focus our efforts on GitHub Discussions” [36]. Spectrum has become “read-only – no 404s or lost internet history.” The Spectrum team acknowledged the importance of conversations held on the platform and tried to avoid the limitations of relying on the Internet Archive for preservation [71]. Many Spectrum communities had already moved to GitHub Discussions, for reliability and flexibility reasons: Having code and the community in the same place outweighed other factors in the decision to change.*

We present an overview of the *documentation landscape* (i.e., a map of potential documentation sources) emerging from the analysis of ~12K GitHub projects. We explore current trends in documentation platforms and the relationship between documentation and communication platforms, exemplified by the tendency in a project’s README to include the latter as an indirect source of the former.

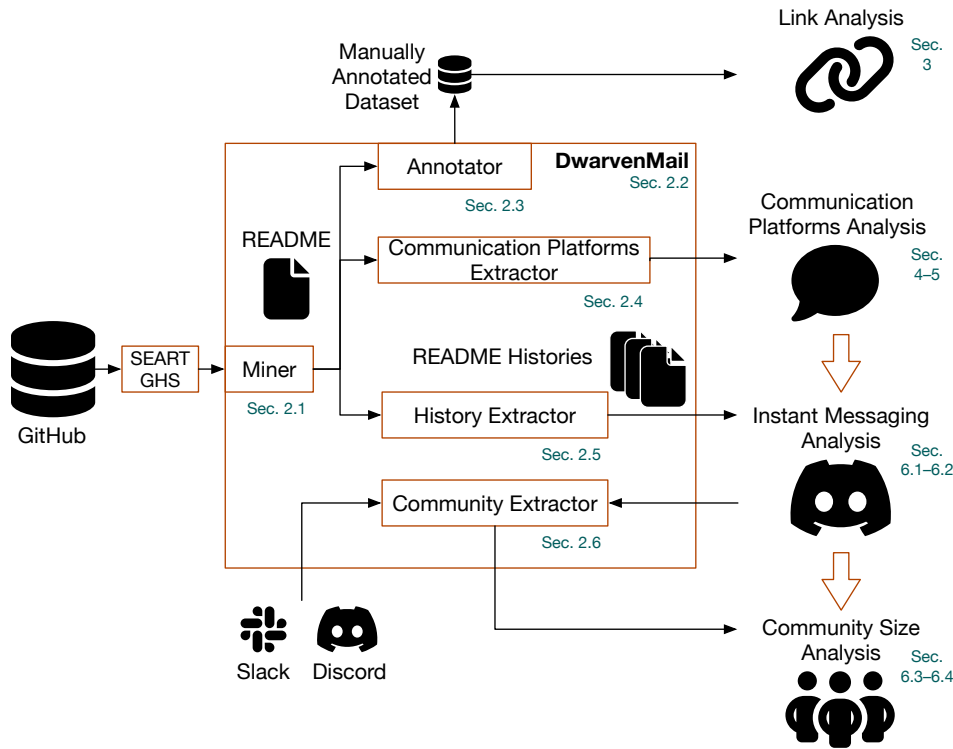

We show the most representative values in different dimensions characterizing the landscape. We then proceed more in-depth with the history of modern communication platforms. We show how some platforms have seen increasing adoption, reached a plateau, and finally started their decline. Our analysis provides insights into the many implications of this

¹ Especially for large communities, without limitations, as reported in this blog post.

² As demonstrated by the presence of an ecosystem built on top of instant messaging applications.

ongoing phenomenon for software documentation. Finally, we discuss possible features that future platforms should have to mitigate some of the perils introduced by these continuous shifts. We use the following icons to highlight salient points:

 Insight  Idea/Future Work  Threat

■ **Figure 1** DWARVENMAIL and Analyses Overview.

2 Dataset Creation and DWARVENMAIL

This section details the procedure and tool support (DWARVENMAIL) we implemented to collect the data for our analyses (Figure 1). We present the initial dataset, the mining procedure, our manual annotation, and details about the individual analyses we performed.

2.1 Project Mining

Starting from all repositories currently hosted on GitHub we used SEART-GHS [13] to compose a relevant dataset, applying the following filtering criteria: at least 2,000 commits (i.e., to eliminate toy projects), more than 10 contributors (i.e., to ensure that a certain number of people need to interact with each other to tackle the development effort), and more than 100 stars (i.e., to ensure that the projects are relevant to at least a handful of people). We only considered projects created before July 1, 2022 and excluded forks [22]. SEART-GHS currently monitors about 1.2M GitHub repositories. Projects excluded in SEART-GHS for having less than 10 stars [13] would have been excluded by the more restrictive criterion we applied, removing projects with less than 100 stars.

Filtering based on the number of stars might not be sufficient to select relevant projects. Nevertheless, starring can be important for project developers and managers [8]. We used this criterion as a common method for filtering out toy projects in GitHub (e.g., see [80]).

We performed the filtering on July 14, 2022, resulting in 12,461 projects exported as JSON input for DWARVENMAIL. After removing 374 aliases and 6 renamed forks, the final scraped dataset consists of 12,081 projects.

Table 1 presents an overview of the projects according to their languages. The *All* column shows the total number of projects, the *CP* column the projects where we could identify communication platforms (see Section 2.4), and the *IM* column the projects with instant messaging platforms. Percentages are derived with respect to the *All* column, while Δ percentages are relative to the *Total* row percentages.

Overall, 57.3% of the projects we analyzed feature at least one communication platform. An interesting observation is that systems written in “lower level / traditional” languages (C, PHP, Shell) tend to be below the overall average, while systems written in more “modern” languages (C#, Go, Rust, TypeScript) are more inclined to feature communication platforms. The difference is even more evident for recently popularized languages if we consider projects with instant messaging platforms (e.g., Go and Rust increase from +8.1% to +11.6% and from +9.5% to +16.7% respectively).

We performed multiple *One Proportion Z-Tests* (one for each language) and the difference in the proportion of projects using communication platforms for each language (r) and the overall dataset (r_0) is statistically significant for C, C#, Go, PHP, Rust, Shell, and TypeScript ($H_0 : r = r_0$, two-tailed Bonferroni corrected p-value < 0.0038). The same results hold for projects with instant messaging platforms.

■ **Table 1** Projects and Represented Languages.

Language	Projects						
	All	CP	CP %	$\Delta_{CP}\%$	IM	IM %	$\Delta_{IM}\%$
C	1,240	548	44.2%	-13.1%	248	20.0%	-9.2%
C#	543	378	69.6%	+12.3%	214	39.4%	+10.2%
C++	1,707	926	54.2%	-3.1%	469	27.5%	-1.7%
Go	677	443	65.4%	+8.1%	276	40.8%	+11.6%
Java	1,510	860	57.0%	-0.4%	432	28.6%	-0.6%
JavaScript	1,528	899	58.8%	+1.5%	440	28.8%	-0.4%
PHP	733	379	51.7%	-5.6%	165	22.5%	-6.7%
Python	1,806	1,094	60.6%	+3.3%	557	30.8%	+1.7%
Ruby	406	238	58.6%	+1.3%	103	25.4%	-3.8%
Rust	244	163	66.8%	+9.5%	112	45.9%	+16.7%
Shell	205	93	45.4%	-11.9%	35	17.1%	-12.1%
TypeScript	895	575	64.2%	+6.9%	314	35.1%	+5.9%
Other / Unspecified	587	328	55.9%	-1.4%	160	27.3%	-1.9%
Total	12,081	6,924	57.3%		3,525	29.2%	

2.2 Tool Support: DWARVENMAIL

To support our analyses, we developed DWARVENMAIL, a Python application to scrape GitHub and extract information about projects’ README files and their history. It features an object-oriented domain model to facilitate the extraction of insights from exploration.

DWARVENMAIL also supports manual inspection, link extraction, and classification from README files (see Section 2.3). DWARVENMAIL takes the list of projects in the dataset and uses the REST API of GitHub and web scraping [81] to extract the information needed to build its internal domain model. It is implemented as a multiprocessing application to speed up the scraping. Each process uses a different API key to access GitHub in parallel through

PyGitHub [23]. Parallelization is handled at project level: Each process gets a project from a queue and starts to fetch the data. Processes are also responsible for not exceeding GitHub rate limits associated with their API keys.

2.3 Manual Annotation

To examine the documentation sources and communication platforms of the projects, we performed a qualitative analysis of their README files. We relied on open card sorting, a well-established method for knowledge elicitation and classification [7, 41, 63, 76, 77], to incrementally refine the list of possible sources with flexible categories.

We manually reviewed the README files of the projects, extracted their links to documentation sources and organized them into categories. Given the considerable effort needed to annotate README files manually, we opted for a saturation approach [57]. We started with a sample set of 35 projects selected through stratified sampling, ensuring a balanced distribution among programming languages.

Two authors independently annotated each project README. Then we repeated the process in subsequent batches with 5 projects per batch until no new labels were added in two consecutive batches. We reached saturation after annotating 60 projects. In the end, we discussed conflicts and merged categories where needed. The process resulted in 2,349 links with 282 link types, which we discuss in Section 3. The creation of manually annotated datasets was supported by the *Annotator* module of DWARVENMAIL (Figure 2).

The screenshot shows the DWARVENMAIL Annotator interface. It features two side-by-side panes: 'Raw' and 'Rendered'. The 'Raw' pane displays the original Markdown text of a README file for 'The Bug Genie', including build status badges, social media links, and a list of features. The 'Rendered' pane shows a preview of the README as it would appear on GitHub, with the same content rendered into HTML. Below the panes, there are controls for adding and managing links, including a 'Link' input field, dropdown menus for 'Link Format', 'Content Type', 'Source Type', and 'Source Instance', and a table of existing links.

■ **Figure 2** DWARVENMAIL Annotator – Project Annotation Page.

An annotator ran the Flask application locally, pulled from Git the latest updates by other annotators, started a batch of annotations, committed, and pushed the modified files.

The Annotator's homepage shows a list of projects to annotate and the annotation status (i.e., who annotated what). Selecting a project opens the project annotation page (Figure 2) where one can browse the README of the selected project.

The project annotation page uses two side-by-side panes to present the README. The left one represents the raw Markdown version of the README. The right pane shows a partially rendered version (i.e., similar to what a user sees on GitHub).

2.4 Parsing Links: Strategy & Heuristics

We performed a quantitative analysis of communication platforms in README files (Sections 4 and 5). To support automatic platform extraction in such a large number of projects we used an approach based on Regular Expressions (RE).

For each communication platform that we discovered, we devised REs that would match the link as closely as possible, while retaining sufficient generality to abstract specific aspects (e.g., project name, internet domain, optional protocol). Possibly more than one RE has been associated with each platform. To fine-tune the REs, DWARVENMAIL features a detailed log generation for manual inspection of candidate and invalid links during the refinement.

DWARVENMAIL parses all the links in a README according to the set of identified REs. When a link is found, specific exclusion criteria are applied. A set of rules removes links to images, badge icons, platforms' generic homepages, and partial or invalid URLs (e.g., shorthands for Markdown sections captured by the REs).

The remaining links are normalized in a standard format and duplicates are removed. Platforms not directly linked in the README (e.g., collected in a list on the *Community* page of the project website) are omitted by the employed scraping algorithm. To reduce the false positive rate, DWARVENMAIL also verifies that links point to valid web pages (i.e., the server does not respond with an HTTP 404 Not Found). After this refinement, we obtain the final set of communication platforms referenced by the project READMEs.

2.5 Parsing README Histories

For projects referencing Gitter, Slack, and Discord as communication platforms, we analyzed the history of their READMEs to discover when those platforms appeared for the first time. In this case, the approach outlined above to exclude invalid links (Section 2.4) would not produce the desired results, because a link that is not valid today could have been valid in the past. This cannot be checked without an archive, or historical information. Hence, in our approach we assume that links with proper format were valid in the past. To reduce false positives, we used the most specific format able to capture the link.

2.6 Community Size

We include the Discord and Slack community size (i.e., number of members) in our domain model. The most popular way to add people to a Discord server is through an *invite link* [15]. Clicking on an invite link, brings the user to a page with metadata about the server (e.g., number of total members, number of online members). We gathered Discord community sizes by scraping the data from these invite pages. In the case of Slack, only 15% of the projects in our dataset have information about the community size on the invite page.

More effort is needed to explore communities that do not conform to a standard and/or customize their invite link to pursue specific goals (e.g., authorization workflow, authentication, spam prevention, analytics).

Extending the percentage of projects whose community size is correctly scraped could improve the reliability of results discussed in Sections 6.3 and 6.4.

2.7 Data Availability and Replication Package

We provide a replication package, publicly available on Figshare [51], containing the source code of DWARVENMAIL, the input dataset, the manually annotated projects, the serialized domain model of the scraped dataset, charts and tables exported from DWARVENMAIL.

3 Documentation Landscape

We define the documentation landscape of a software system as all the possible sources of information able to support design, implementation, comprehension, maintenance, and evolution of the system. Software documentation is a fundamental asset for developers and practitioners [3], when it is correct and up-to-date [10, 14, 19, 21, 54, 61], with its costs and benefits [79]. Modern software documentation is an ever expanding field. New sources include blogs [43], Twitter [72], StackOverflow [47], instant messaging applications [9, 18, 30, 33, 45, 46, 49, 50, 56, 58, 66, 67], news aggregators [6], and forums [27].

GitHub README files in Markdown (.md) format are a good starting point for a project from where all relevant documentation should be reachable.

Documentation sources in README files can either be directly referred to or behind multiple steps of indirection. An example of the former case is an invitation link that can be copy/pasted directly in Discord to access the community server of the project. In the latter case, the README could point to a community web page which in turn contains links to the mailing list, a Slack channel for Q&A, and potentially other communication and documentation sources.

The manual annotation presented in Section 2.3 produced 282 *single type* link tags. The links can come in many flavors thanks to the markdown format, ranging from pure textual hyperlinks to badges and images that link to external resources. We inspected them and identified three key dimensions of the documentation landscape: *content type*, *source type*, and *source instance*. We split single type tags into these three dimensions. We analyzed examples of each link type to disambiguate or enrich the classification when the original annotation had missing information.

Table 2 shows the top-15 most representative values for each dimension. The complete list of tags is available in the replication package [51].

The three key dimensions we propose to describe the documentation landscape of a software system are content type, source type, and source instance, exemplified as links in GitHub READMEs.

Source type, source instance, and content type could describe a link like: “This link is in the form of a *Badge*, it points to a *Wiki* on *Travis.com*, and contains information related to *CI / CD*.” Each dimension is instantiated with one of the possible tags for that category, forming a signature of the documentation source pointed by the link.

Exploring these dimensions could improve the automatic extraction of links and their features, to characterize and understand the (evolution of the) documentation landscape.

Link format. Link formats come in many flavors, also due to the fact that markdown files, while being textual, are usually inspected using a (multimedia capable) web browser. Badges, for example, are very common in GitHub README files, used to convey imminent information through iconic representation of a summary of the pointed resource (e.g., build status passing) where the link itself allows, if followed, to reach more extensive information (e.g., build process report). Masked links are another common practice to add links (not exclusively) to markdown documents.

Not all links in a raw README file are human readable links in the rendered README.

Content type. This is the primary dimension of the documentation landscape, denoting **what** kind of information is present in the landscape. There is a smooth gradient in content types regarding the number of links, but it is worth noting that there is no “standard”, but

■ **Table 2** Top-15 Most Relevant Tags, Number of Projects, and Links for Each Dimension. The percentage indicates the ratio of projects containing at least one link with the specified tag.

(a) Content Type.

Projects	Content Type	Links
36 (60%)	General Community Hub	141
29 (48%)	Official Documentation	97
28 (47%)	License	68
25 (42%)	Contributing	56
23 (38%)	Issues	52
23 (38%)	CI/CD	50
21 (35%)	Project Repository	76
20 (33%)	Relevant Projects	132
20 (33%)	Dependency/Environment	84
19 (32%)	Releases	60
16 (27%)	In-Repository Resource	67
16 (27%)	Package Repository	47
14 (23%)	CI/CD > Testing	24
13 (22%)	Installation Instructions	24
11 (18%)	Code Coverage	22

(b) Source Type.

Projects	Source Type	Links
55 (92%)	Homepage/Website	436
41 (68%)	Collaborative Platform	188
36 (60%)	Third Party Service	169
34 (57%)	Wiki	125
32 (53%)	Repository	166
28 (47%)	Sourcefile/Sourcefolder	151
25 (42%)	Instant Messaging	84
11 (18%)	Auxiliary README	21
10 (17%)	Readme Section/Anchor	44
9 (15%)	Mailing List	27
9 (15%)	Forum	20
8 (13%)	Image/GIF	21
8 (13%)	Blog	20
7 (12%)	Email Address	12
6 (10%)	Video	13

(c) Source Instance.

Projects	Source Instance	Links
33 (55%)	GitHub	179
16 (27%)	GitHub Workflows	50
13 (22%)	GitHub Releases	27
12 (20%)	Travis	22
11 (18%)	Gitter	34
9 (15%)	Google Groups	24
7 (12%)	Discord	18
7 (12%)	Codecov	14
7 (12%)	Python Package Index	13
6 (10%)	Twitter	12
6 (10%)	StackOverflow	9
5 (8%)	Slack	18
5 (8%)	Maven	11
5 (8%)	Read the Docs	5
4 (7%)	GitHub Profile	108

rather project-specific landscapes. Most relevant are *general community hubs*: Discord servers, Slack workspaces, Gitter rooms, IRC channels, mailing lists, and forums, with their internal structure for different topics, dedicated to a general community of users and practitioners.

Content type is relevant to interpret what a piece of documentation is about. There is no standard to the documentation landscape, each project develops its own. Even the top content types (community hubs, official documentation) are present in only half of the projects.

Source type. The *source type* dimension refers to the format of the content at the link's destination. This dimension is relevant for automatically extracting the documentation landscape since it determines how the content can be retrieved and parsed. *Homepage / websites*, the most relevant source type by a large margin, can be scraped with traditional web scraping techniques. *Collaborative platforms* like GitHub and Bugzilla could be addressed via their custom APIs. *Image / GIF > Screenshots*, further down in terms of relevance, would benefit from image segmentation and analysis approaches to extract, for example, documented user interface features. We also notice that links to mailing lists are fewer than those to IM applications, a trend we analyze in more detail in Section 4.

Source type captures *how* documentation is presented and how it can be accessed. Almost all projects feature a head quarters website, i.e., the go-to place to learn about a project. These starting points are then often complemented by a plethora of other sources, ranging from Wikis to forums and instant messaging platforms.

When analyzing the evolution through time of a README file we detect in many cases that the source types come and go, inducing “tectonic movements” in the landscape, as we can observe in the example depicted in Figure 3.

■ **Figure 3** Evolution of Communication Platforms in the “Scikit-learn” Project.

The Scikit-learn project, born in 2010, sees a mailing list as its initial documentation landscape, complemented shortly after by an IRC channel (which stopped existing a decade later). GitHub Issues is added within the project’s first year, while StackOverflow becomes part of the landscape in 2017. It is within the past 2 years that the landscape experiences an earthquake, with many new sources appearing, while the IRC channel is removed (it is worth noting that IRC and its successor, Gitter, co-exist for a year). At the time of writing the project in question features 11 different sources.

The documentation landscape of projects evolves together with the project. Especially in the past few years the source types have exploded in number, rendering the landscape highly dispersive.

The fact that there are more sources does not imply that the overall documentation of the system is better, on the contrary: We have observed an overall trend toward more volatile sources, mostly due to the rise of instant multimedia messaging platforms.

Source instance. The third dimension is a derivate of source type. For each type we can have multiple possible source instances, usually of a competing nature (see Section 5) with a similar purpose. Rather unsurprisingly for GitHub projects, GitHub itself with related instances of profiles, workflows, releases, and instant messaging (i.e., Gitter) takes top three, the 5th, and the 15th places. Services for package repositories (e.g., Python Package Index [48], Maven [62]) and CI/CD (e.g., Travis CI [73], Codecov [11]), messaging applications like Slack [60]/Discord [16], and also articles on the Medium platform [1] represent interesting research avenues.

Source instance can be seen as *where* (or by whom) documentation is “hosted.”

Source instances vary wildly, and new players constantly enter the stage. For example, recent changes in the pricing model of Slack might have influenced the ongoing mass migration toward other instant messaging platforms, of which there are dozens, with Discord quickly becoming the preferred alternative.

Tags in the three dimensions appear in different combinations, not all equally likely. Further research on the most common patterns could shed light on form and content interplay in software documentation.

4 Modern Communication Platforms

One of the recent major shifts in software development has been the emergence of various multimedia instant messaging platforms, such as Slack [60], Discord [16], and Gitter [39].

They not only experienced an increase in popularity but also seem to be a major suspect for the decline of other classical communication means, such as mailing lists and forums. We start by analyzing the platforms actually used by projects in our dataset. The scraping, based on regular expressions (see Section 2.4), took place between Aug 28 2022 at 21:01 and Aug 30 2022 at 02:12, leading to 12,081 scraped projects. Of those, 6,924 (57.3%) mention at least one such modern communication platform in their README files: 2,897 had 1 platform link, while 4,027 had 2 or more platform links. The remaining 5,157 projects had no platform links. The percentage is higher than the one reported by Käfer et al. [31] (57.3% vs. 46.7%), which can be explained by the fact that their analysis dates back 4 years.

We grouped communication platforms into three main categories: asynchronous, instant messaging, and social media.

Figure 4 summarizes number of links in READMEs (*Links*) and number of projects with at least one link (*Projects*) for each type of platform.

■ **Figure 4** Platform types.

■ **Figure 5** Number of projects linking to at least one platform.

There are Instant Messaging platforms (e.g., IRC, Slack, Discord), where communication can happen in real-time. In Asynchronous platforms (e.g., forum, mailing list, GitHub issues or discussions), communication usually takes some time to be processed and made available to other community members. The boundary between the two types has been blurred in the recent years by the technological improvements to the supporting infrastructure. We also considered Social Media platforms (e.g., Facebook, Twitter, Youtube). While their technical features can overlap with the other types, their huge user-base and ease of forming social connections make them stand out. Table 3 shows a complete list of the platforms we considered with a short description.

A project README can have multiple links to a single platform. This is particularly true for Social Media links where Twitter accounts of the main contributors or maintainers are all referenced.

■ **Table 3** Communication Platforms.

Platform	Description
Discord [16]	Voice, video, text messaging multimedia platform
Facebook [37]	Social media and social networking service
Forum	General category for web based discussion sites
GitHub [24]	GitHub infrastructure for project development
Gitter [39]	Voice, video, text messaging multimedia platform
IRC	Text-based instant messaging chat system
Linkedin [35]	Business social media & professional networking
Mailing List	E-mail based communication among recipients
Matrix [70]	Communication protocol implemented by clients
Medium [1]	Online publishing platform and social journalism
Reddit [52]	Social news aggregation, rating, discussion, and multimedia sharing
Slack [60]	Voice, video, text messaging multimedia platform
Spectrum [36]	Text-based web instant messaging chat system
StackOverflow [64]	Question and Answer website
Telegram [69]	Voice, video, text messaging multimedia platform
Twitter [75]	Social media and social networking service
Youtube [25]	Video hosting and sharing platform

In Figure 4, we see that the number of projects that use a specific platform is significantly lower than the number of links. For example, project *OpenAPITools/openapi-generator* [42] mentions 20 different Twitter accounts and 17 YouTube resources.

The identified categories are only a rough means to group similar platforms. In Figure 5 we show the number of projects having at least one reference to a specific platform.

Given our initial input set, it is not surprising to find GitHub to be the most referenced: The infrastructure is integrated enough to warrant support for the community with its own Issues and Discussions systems. This uniform consensus is followed by a more fragmented mix of Twitter, Discord, Gitter, Forums, Mailing Lists, and others in decreasing order of “popularity.” Far from being irrelevant, these platforms are used by hundreds of projects exclusively or in synergy. The next section sheds light on these synergies, complementarities, and on the competition between similar platforms.

5 Coexistence and Competition

Communication platforms can have different features and cater to different audiences. To cover development or users’ needs, projects can opt for using multiple media at the same time. What choices are made by core developers in terms of number and variety of platforms to include in a README?

Figure 6 depicts a non-exhaustive list of examples of overlaps between communication platforms (extracted with the REs presented in Section 2.4) used exclusively and side-by-side.

Around 38% of projects that use either Discord or Slack also include GitHub Issues in their READMEs (Figure 6a).

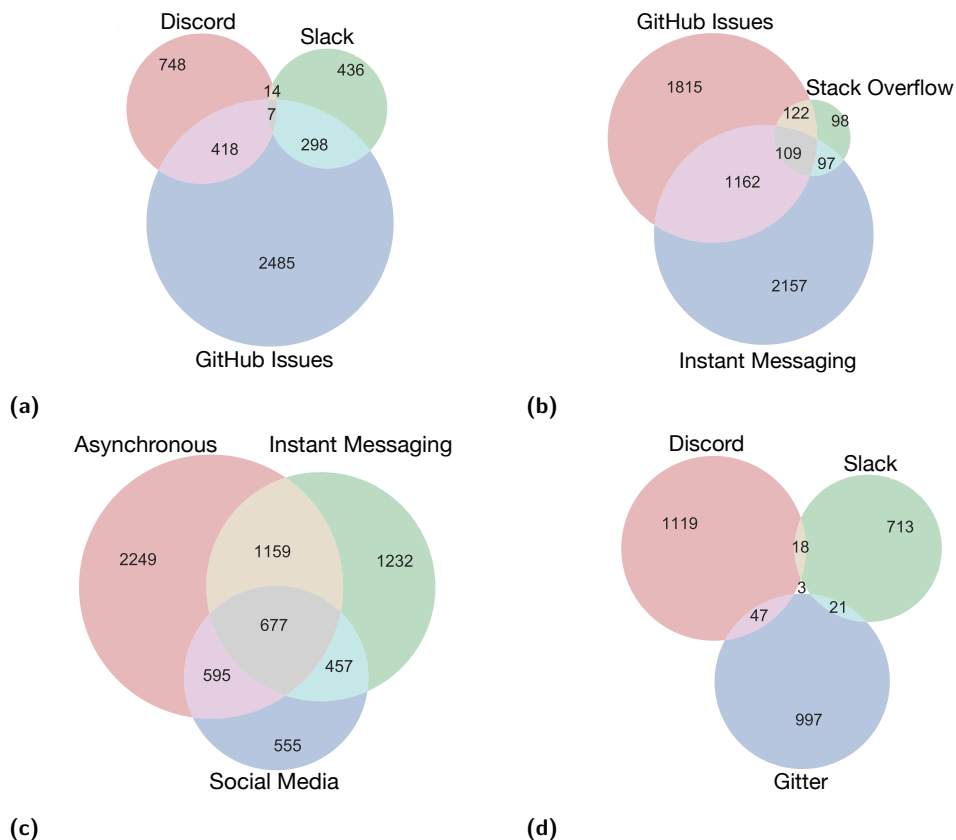

GitHub Issues can also be used without an explicit link in the README, as just a tab of the project, if enabled. Some platforms may be implicitly assumed to be available even if not present in the README.

Overall, 2,105 out of 3,208 projects (66%) using GitHub Issues, also have other communication platforms referenced in the README. Similar ratios are found, for example, for Discord with 801 out of 1,187 projects (67%).

Multiple communication platforms of different types can and do coexist.

■ **Figure 6** Communication Platforms Overlaps.

GitHub has significant overlaps with the whole category of instant messaging, and with specific asynchronous platforms (e.g., StackOverflow, see Figure 6b). However, 1,270 projects rely only on the integrated support provided by GitHub.

In general, if we consider the three main categories, we find that asynchronous platforms are used exclusively in 48% of projects, instant messaging follows with 35%, and social platforms seem the most frequently used as a complementary option (76%, see Figure 6c).

⚠️ | *It is not clear if different categories are mutually exclusive and why in a considerable amount of projects they tend to be used in conjunction.*

💡 | *This analysis should be complemented by how the user-base is distributed over these platforms.*

6 Instant Messaging: A Deep Dive

What makes instant messaging platforms appealing to developers? The steady growth in the number of projects including at least one platform of this kind is a piece of evidence supporting the need for fast and rich communication.

Instant messaging platforms fulfill a very specific role: Providing communication in real-time, possibly with rich media sharing capabilities (e.g., links, videos, files), and Voice over IP conferencing (i.e., VoIP). Two instances of these platforms are seldom found together. Similar characteristics, audiences, and usages make competition the prevailing paradigm.

Figure 6d shows that 97% of projects opting for these platforms choose between one of the three alternatives. Three projects include links (see Section 2.4) to all the platforms and also other instant messaging (e.g., Spectrum), but only *PowerShell/PowerShell* has a significant Discord community (more than 10k members).

Gitter, Discord, and Slack are selected by projects as alternatives, very seldom coexisting. This can be a possible strategy for successful projects not to spread their community too thin over multiple platforms with similar capabilities.

6.1 Gitter, Discord, and Slack: A Timeline

Based on README history and mining links for each version of the README as detailed in Section 2.5, for each project, we look for the first appearance date of Gitter, Discord, and Slack (Figure 7).

■ **Figure 7** Timeline of cumulative adoption date of Slack, Discord, and Gitter.

Gitter appeared for the first time at the end of 2013, followed one year later by Slack, and then Discord after 8 months. All three platforms show a “ramp-up” period of slightly more than one year after their first appearance, followed by a steady growth at different rates. Both Gitter (in mid-2020) and Slack (in 2022) reached a *plateau* where just a handful of projects added them to their communication platforms in the last year. Discord, on the other hand, is still growing significantly.

Since the beginning of 2020, Discord consistently outperformed Slack in terms of number of new projects adopting the platform for their community (Figure 8). The monthly growth rate has been higher than the highest for Slack in the previous years. It has also been at higher levels more consistently and for a longer period.

The comparison between additions of Gitter and Discord (Figure 9) shows a similar or even more evident tendency. The decline of the former and the growth of the latter are almost perfectly mirroring each other.

While one platform stops being added to projects, another is on the rise. This happened in the past and is bound to happen again in the future.

There is no guarantee that the example of the Spectrum platform we highlighted in Section 1 will be followed when Gitter goes out of fashion. It is also possible that the entire history of discussions, bug fixing sessions, and design decisions will just disappear.

■ **Figure 8** Monthly new projects adopting Discord and Slack.

■ **Figure 9** Monthly new projects adopting Gitter and Discord.

6.2 Throughput and Volatility

We investigated four Discord communities. Reactflux, Vue Land, and Angular.js are respectively tied to React, Vue, and Angular (web development frameworks). We compared them with each other and with the Discord.js community (Discord bot development).

In Figure 10, we show how the average number of messages per member in a sample period of three months (i.e., May–July, 2022) has high variability. While this might be due to a number of factors, we are interested in the sheer scale of the messages exchanged on those platforms every day.

Around 550 messages are exchanged per day in Vue Land and Angular.js. In Discord.js, instead, users exchange 305 messages *each hour*, totaling more than 7k messages a day.

The throughput of these servers means information is lost if one does not pay attention to notifications. Only a few messages are visible at a time and they scroll up quickly, putting full conversations behind the event horizon in a matter of minutes. Alert filters and community policies (e.g., forbidden mentioning of server wide tags) can only partially mitigate this problem. The trade-off between losing potentially interesting discussions and being constantly interrupted by notifications is the choice many modern developers face when dealing with these kinds of communities.

■ **Figure 10** Messages per day and average messages per day per member from May to July 2022 for four example Discord servers.

Application of summarization, visualization, and information retrieval techniques is fundamental to deal with scalability problems of these platforms.

6.3 Community Sizes

Discord communities in our dataset vary in size between 2 and 500,000 members. Figure 11 depicts Discord community size with respect to project age (i.e., days since creation).

■ **Figure 11** Discord community size with respect to project age (days from creation).

This should be investigated more in-depth to see if it is a breakpoint at which particular actions should be taken to keep the community growing.

Extraction of Slack community sizes has proven more difficult due to the high variance in invite page formats. Gitter does not even have an invite page to scrape, and, to the best of our knowledge, the community size cannot be automatically retrieved.

6.4 Different Projects, Same Community

Being in the same Discord community means sharing the same server (i.e., each project has a link in the README, possibly with different formats, but pointing to the same Discord server). We consider this a case of “different projects, same community”.

Figure 11 shows horizontal pairs in the top part of the scatterplot, suggesting that different projects might share the same community: Our initial hypothesis that “same size of the community means same community” might not apply, especially for smaller communities. Nevertheless, it is unlikely for two different large communities to have the same number of members at the same time. We manually inspected the projects in those pairs and they are indeed different projects referring to the same wider community. For Discord we could reliably use the community name to confirm our hypothesis, as parsed from the invitation metadata (Section 2.4).

Figure 12 shows how many projects share a community with respect to community size.

■ **Figure 12** Projects referencing the same community.

Further analysis can show if projects are tightly coupled (e.g., different projects from the same organization, new major versions of the same project) or if different projects have an underlying reason to cater to the same audience.

6.5 Technical, Social, and Ethical Challenges

Some community platforms are public, some allow anonymous access, some require a form of registration or access permission. We found communities with (automatic) procedures to accept new members but, in general, it is hard to devise a general automatic “agent” to explore all of them.

The sheer amount of customization that is possible, even in a simple invite landing page of Slack, has been an obstacle to getting reliable data about communities lying behind those pages. Exploring a larger and more varied sample could shed light on platform dependent similarities and differences.

Machine readable APIs for communities can greatly benefit not only research in this field, but also open new possibilities, e.g., the automatic migration of community-generated content to preserve the history of projects when the underlying technologies evolve.

Socio-ethical challenges. Communities usually are digital aggregations of people’s thoughts, ideas, rants, strengths, and weaknesses. Collecting such information can be seen as poking inside someone’s house. One can do it if having legitimate reasons to do so. One can be welcome if providing benefits for the community. But one can also be faced with concerns about privacy and legitimate use of collected information.

Companies owning the platform sometimes are more keen to share their data than administrators of communities they host. While Slack has a monetization policy tied to its history retrievability, Discord allows unlimited access to a wealth of historical information via its API.

A big role in the extensibility of our study is played by the attitude of administrators of interesting communities. While information might be public (i.e., anyone with a Discord account can automatically join a server and browse its entire content), to comply with Discord’s Terms of Service we need to ask for permission to add a bot to extract useful information for DWARVENMAIL. In this crucial step a fundamental role is played by personal beliefs and perceptions of the benefits of such a bot by the administrators and the community itself.

Accessibility of information is ever more beyond the fence of what is technically possible, towards the barrier of what is ethically and socially accepted.

7 Threats to Validity

Our analyses are based on a dataset of public GitHub projects as the only source. This poses a threat to the generalizability of our results with respect to the type of projects hosted on GitHub. Open source projects developed in this social coding style might differ significantly from closed source projects developed by a small team of hired developers. There are also no guarantees that the results presented can be generalized to projects hosted on other similar repositories (e.g., SourceForge).

The current study presents a limited generalizability with respect to the format of README files. Although our sampling procedure (Section 2.3) ensures generalizability with respect to the project’s main programming language, different README file formats could provide different link types and formats not fully captured by our analysis.

We found evidence of more than 15 different README formats. While most share a similar structure for external links, systematic analysis of these formats could improve the generalizability of the results.

Limiting the extraction of the documentation landscape to what is reachable from the main README file (i.e., ignoring links to other READMEs in submodules of a project) poses a threat to construct validity. This threat is partially mitigated by the magnitude of the phenomenon we highlighted, emerging despite the limited scope, and calling for discussion and further investigation (i.e., also considering auxiliary documentation sources as a starting point to map the landscape).

43:18 On the Rise of Modern Software Documentation

Our analysis benefits from verifying the validity of links whenever possible (i.e., if the resource referred by the link is still available we expect an HTTP 200 OK response). When mining GitHub we verified the links we found in a two step process. The time interval between the first pass for scraping and the second pass for verification was short enough to guarantee that most links were in their intended state. Obsolete links may be possible and are part of the present study.

The analysis lacks accuracy when links are redirected or reused. Moreover, in the effort to reconstruct link patterns for previous standard link formats of some platforms (e.g., Slack) we adopt a conservative approach where if the format follows reasonable patterns it is accepted as a valid link in the history of a README file. We have no guarantee nor a way to discover if the link was valid in the past.

The only possibility to study the evolution and validity of such links is to constantly monitor README files and their evolution over a period of time. Link validity can be checked as soon as the change in the README is triggered. This kind of study is outside of the scope of the presented work.

Semantic analysis of the pointed links could improve relatedness, reducing false positives in link validity. Automatic link validity and relatedness to the source topic should be investigated.

Links that are not visually represented in the rendered README are currently part of the analyses. This threat to the validity of our conclusions is partially mitigated by the low frequency of such occurrences. We found only 3 non-rendered links in 2 manually annotated projects (0.1% of links, 3.3% of projects).

We did not perform an analysis based on project types. Relationships between project type, intended audience, and the resulting documentation landscape could provide insights on how to leverage the landscape for projects of different natures and at different maturity stages.

8 Related Work

Communication channels, especially those tightly coupled with collaborative development platforms (e.g., GitHub), are fundamental for successful software development.

Hoegl et al. [29] and Lindsjrn et al. [34] found communication to be an essential subcontract of teamwork quality. Tantisuwankul et al. analyzed the communication channels of GitHub projects [68]. Studying 70k library projects in 7 ecosystems, they identified 13 communication channels as “a form of knowledge transfer or sharing” (e.g., licenses, change logs). They found that GitHub projects adopt multiple channels, which change over time, to capture new and update existing knowledge. Storey et al. [65] conducted a large-scale survey with 1,449 GitHub users to understand the communication channels developers find essential to their work. On average, developers indicated they use 11.7 channels across all their activities (e.g., email, chat, microblogging, Q&A websites). They concluded that “communication channels shape and challenge the participatory culture in software development.” Hata et al. [27] studied early adopters of GitHub Discussions, finding that developers considered them useful and important. Lima et al. [32] used NLP to detect related discussions of OSS communities in GitHub Discussions.

Treude and Storey [74] interviewed users of a community portal, finding that clients, developers, and end-users are involved in the process of externalizing developer knowledge.

Nugroho et al. [40] studied how Eclipse developers utilize project forums, concluding that forums are essential platforms for linking various resources in the Eclipse ecosystem besides representing an important source of expert knowledge.

Modern social media are becoming another information source for development activities. Mezouar et al. [38] studied how tweets can improve the bug fixing process. They observed how issues for Firefox and Chrome are usually reported earlier through Twitter than on tracking systems. This can potentially decrease the lifespan of a bug. Guzman et al. [26] analyzed the usage characteristics, content, and automatic classification of tweets about software applications. They found that tweets contain useful information for software companies but stressed the need for automatic filtering of irrelevant information.

Instant messaging platforms, from Internet Relay Chat (IRC) to Discord, went from simple text messages to rich multimedia support with integrated DevOps workflows (i.e., Slack integrations). Yu et al. [78] learned how real-time (i.e., IRC) and asynchronous (i.e., mailing lists) communications were used and balanced across the GNOME GTK+ project. Shihab et al. [59] analyzed IRC meeting logs and found that developers actively contributed through meeting channels.

Lin et al. [33] argued Slack played an increasingly significant role, sometimes replacing emails. They found various benefits of Slack over mailing lists. Developers use it for team-wide purposes (e.g., communicating with teammates, file and code sharing), community support (e.g., special interest groups), and personal benefits (e.g., networking, social activities). They also observed that developers commonly used bots to support their work. Chatterjee et al. [9] analyzed the conversations of developers from five Slack programming communities and developers' StackOverflow posts. They found prevalent useful information, including API mentions and code snippets with descriptions in both sources.

Alkadhi et al. [5] examined “rationale” elements (i.e., discussed issues, alternatives, pro-/con-arguments, decisions) in Atlassian HipChat messages of three software development teams. They found frequent, valuable discussions with elements of rationale. However, they also emphasized the need for automated tools due to the high volume of chat messages.

Shi et al. [58] conducted an empirical study on developers' Gitter chats. They manually analyzed 749 dialogs and performed an automated analysis of over 173K dialogs of OSS communities. Interestingly, developers tend to converse more on Wednesdays and Thursdays. They also found interaction patterns among conversations and noticed that developers tend to discuss topics such as API usage and errors. They argue the need for better utilization and mining of knowledge embedded in the massive chat history of OSS communities.

Hata et al. analyzed links in source code comments [28] in a large-scale study (~10 million links) extracted from files of the main language of the project. We focus on README file links, which are independent of the project language.

Ebert et al. [17] conducted an empirical study to understand which communication channels are used in GitHub projects and how they are presented to the audience, finding that the most common were chats, mail-related, social media, and GitHub channels. Käfer et al. [31] analyzed GitHub communication channels, finding that “Mailing lists are being replaced by modern enterprise chat systems in OSS development.” Our work broadens the scope beyond communication channels and adds details needed to identify the current status, understand how it has evolved, and obtain meaningful insights on why this is happening.

Each of the previously discussed studies focuses on a specific part of the documentation landscape, recognizing the importance of the sources for knowledge management and documentation. What is still missing is a higher level understanding of the phenomenon that shifts the relative importance of these sources over time, intra- and inter-project.

9 Conclusions and Future Work

Classical software documentation is being replaced by “communication”. At least in open source software on GitHub, it is supported by a plethora of platforms characterized by high throughput, volatility, and heterogeneity. The original vision of on-demand developer documentation [55] advocated for a paradigm shift. A shift did happen, but it was not in the direction foreseen by Robillard et al. five years ago. The new communication platforms bring new challenges and opportunities for modern software documentation. It is time to shed light on new forms of documentation. A comparison with classical documentation and where it survives, unscathed by the new media and the needs of modern software development, might help rethink the role of documentation itself. Research efforts in this direction can help maintain documentation useful for software comprehension, maintenance, and evolution, independently of the form it will take.

To achieve this we need a better understanding of the phenomenon occurring to software documentation sources. We regard the present work as scratching the surface of what has turned into an emerging heterogeneous, complex, and ever-changing documentation landscape, a *terra incognita* full of possibilities and threats.

Python Type Hints Are Turing Complete

Ori Roth   

Department of Computer Science, Technion, Haifa, Israel

Abstract

Grigore proved that Java generics are Turing complete by describing a reduction from Turing machines to Java subtyping. Furthermore, he demonstrated that his “subtyping machines” could have metaprogramming applications if not for their extremely high compilation times. The current work reexamines Grigore’s study in the context of another prominent programming language – Python. We show that the undecidable Java fragment used in Grigore’s construction is included in Python’s type system, making it Turing complete. In contrast to Java, Python type hints are checked by third-party static analyzers and run-time type checkers. The new undecidability result means that both kinds of type checkers cannot fully incorporate Python’s type system *and* guarantee termination. The paper includes a survey of infinite subtyping cycles in various type checkers and type reification in different Python distributions. In addition, we present an alternative reduction in which the Turing machines are simulated in real time, resulting in a significantly faster compilation. Our work is accompanied by a Python implementation of both reductions that compiles Turing machines into Python subtyping machines.

1 Introduction

Python enhancement proposal (PEP) 484 introduced optional type hints to the Python programming language, together with a full-blown gradual type system [16]. Tools such as Mypy [9] use type hints to type-check Python programs. Certain programs, however, cause Mypy to enter an infinite loop (we show an example below). We argue that the reason behind these failures is not a Mypy bug, but a deeper issue in the PEP 484 type system. We use Grigore’s reduction from Turing machines (TMs) to nominal subtyping with variance [6] to prove that Python type hints are, in fact, Turing complete. In other words, checking whether a Python program is correctly typed is as hard as the halting problem.

1.1 Nominal Subtyping With Variance

Subtyping is a type system decision problem. Given types t and s , the type system should decide whether type t is a subtype of s , $t <: s$, meaning that every t object is also a member of s . For example, every string is an object, `str <: object`, but not every object is a string, `object <: str`. Subtyping is needed, for example, for checking variable assignments:

44:2 Python Type Hints Are Turing Complete

```
x: t = ...
y: s = x # t<:s
```

The second assignment compiles if and only if $t <: s$.

Object-oriented languages such as Scala, C#, and Python use *nominal subtyping with variance* [7]. *Nominal* means that subtyping is guided by inheritance. Type t is a subtype of type s if class t is a descendant of s :

```
class s: ...
class t(s): ...
x: t = ...
y: s = x # ✓
```

Variance enables variability in type arguments. By default, type $t[u]$ is a subtype of $t[v]$ if and only if $u = v$. If t 's type parameter is covariant, u can be any subtype of v , $u <: v$; if it is contravariant, then $u >: v$. In Python, variance is specified in an argument to `TypeVar`, the constructor of type parameters. For example, the following Python program uses contravariance and is correctly typed:

```
x = TypeVar("x", contravariant=True)
class t(Generic[x]): ... # t has a contravariant type parameter x
x: t[str] = t[object]() # ✓ (str<:object)
```

Using a reduction from the Post correspondence problem (PCP) [13], Kennedy and Pierce showed that nominal subtyping with variance is undecidable [7]. Their work focused on three subtyping features (characteristics):

1. *Contravariance*: The presence of contravariant type parameters, as described above.
2. *Expansive-recursive inheritance*: The closure of types under the inheritance relation and type decomposition ($t[v] \rightarrow v$) is unbounded. Intuitively, expansive inheritance requires class t to recur in one of its supertypes:

```
class t(Generic[x], s[s["t[t[x]]"]]): ...
# note: forward references are put in string literals
```

A formal definition of expansive-recursive inheritance is provided in Section 2.

3. *Multiple instantiation inheritance*: Class t is allowed to derive class $s[·]$ multiple times using different type arguments:

```
class t(s[object], s[str]): ... # not legal in Python
```

Kennedy and Pierce proved that subtyping becomes decidable when contravariance or expansive inheritance are removed, but they were uncertain about the contribution of multiple instantiation inheritance to undecidability.

1.2 Subtyping Machines

Ten years after them, Grigore showed that Java subtyping is Turing complete using a direct reduction from TMs [6]. This reduction uses a subset of Java that conforms to Kennedy and Pierce's nominal subtyping with variance. Grigore's result settled Kennedy and Pierce's open problem since Java does not support multiple instantiation inheritance [12, §8.1.5]. Intuitively, multiple instantiation inheritance corresponds to non-deterministic subtyping [7, 14], so while it was useful in the PCP reduction, it is redundant in the TM reduction because deterministic TMs are as expressive as non-deterministic TMs.

Grigore's reduction can be described as a function

$$e(M, w) = \Delta \cdot q \quad (1)$$

that encodes TM M and input word w as program $P = \Delta \cdot q$ consisting of class table Δ and subtyping query q . The encoding ensures that TM M accepts w if and only if query q type-checks against Δ .

The idea behind the reduction is to encode the TM configuration (instantaneous description) in the subtyping query q . Recall that the configuration of TM M comprises (i) the content of the memory tape, (ii) the location of the machine head on the tape, and (iii) the current state of the machine's finite control. Figure 1 illustrates the initial configuration of M : The input word $w = a_1 a_2 \dots a_m$ is written on the tape, the machine head points to the first letter a_1 , and the current state is the initial state q_I .

■ **Figure 1** The initial configuration of a Turing machine.

To explain how configurations are encoded as subtyping queries, let us first introduce some syntax (adopted from Grigore's paper). We write a generic type $\mathbf{A}[\mathbf{B}[\mathbf{C}]]$ as ABC for short. The use of \blacktriangleleft instead of $<$: in a subtyping query means that the type on the left-hand side should be read in reverse (the same goes for \blacktriangleright and $>$), e.g., $ABC \blacktriangleleft DE$ is equivalent to $CBA <: DE$.

The initial TM configuration, depicted in Figure 1, is encoded by the following subtyping query:

$$ZEE L_{\perp} N M^L N L_{a_1} N L_{a_2} N \dots N L_{a_m} N L_{\perp} Q_I^{wR} \blacktriangleleft EEZ \quad (2)$$

Observe that the types in Equation (2) have the same colors as the machine configuration elements in Figure 1 that they encode. For example, the type L_{a_1} encodes the tape symbol a_1 , and both are purple. As the type on the left-hand side is written in reverse, the content of the encoded tape can be obtained by reading the L types from the left to the right. The full legend is listed in Table 1.

■ **Table 1** The components of Grigore's subtyping machine. All types use a single contravariant type parameter x , except Z , which is monomorphic. The superscripts vary.

Type	Corresponding TM component / purpose
$L_{\perp} x$	an infinite blank tail of the tape
$L_{\sigma} x$	a tape cell containing the symbol σ
$M^L x$	the location of the machine head
$Q_I^{wR} x$	the current TM state q_I
Z, Ex, Nx	utility types without corresponding TM components

Grigore referred to the subtyping query in Equation (2) as a *subtyping machine* because when the subtyping algorithm tries to resolve it, it simulates the computation steps of the original TM. The subtyping deduction preserves the general structure of the query, except that it steadily pushes the state type Q_I along the tape. When Q_I reaches the head type M^L , the subtyping algorithm simulates a single TM transition: It overwrites the current tape

44:4 Python Type Hints Are Turing Complete

cell ($L_{a_1} \Rightarrow L_\sigma$), moves the machine head (by repositioning M^L), and changes the machine state ($Q_I \Rightarrow Q_J$). The resulting subtyping query correctly encodes the next configuration in the TM run. This process continues until the machine accepts and the query is resolved, or the machine aborts and a compilation error is raised. If the machine runs indefinitely, the subtyping algorithm does not terminate.

While TMs move the machine head to the left or right freely, subtyping machines can change direction only when reaching the end of the type, *EEZ*. After simulating a TM transition, the subtyping machine must reach the end(s) of the tape, rotate, and then reach the location of the machine head M in the right orientation, before it can simulate the next transition. In general, Grigore’s subtyping machines can make $O(m)$ operations for every computation step of the TM they simulate, where m is the number of symbols on the tape, resulting in a substantial slowdown. For example, Grigore’s simulation of the CYK algorithm, which usually runs in $O(n^3)$, takes $O(n^9)$ subtyping deduction steps to be completed.

1.3 Subtyping Metaprogramming

Beyond the undecidability result, Grigore demonstrated metaprogramming applications for their subtyping machines. Although the computational power of subtyping machines is unlimited, harnessing this power for conducting meaningful type-level metaprogramming as done in, e.g., C++ [18], is not easy. To integrate subtyping machines into programs, Grigore proposed to wrap them in fluent APIs [2]. Fluent API methods are called in a stream (chain) of consecutive invocations, as demonstrated in Listing 1.

■ **Listing 1** Running a subtyping machine with a fluent API.

```
p: Palindrome = a().b().b().a().b().b().a()
```

In Grigore’s design, the fluent chain produces the tape of the subtyping machine. For example, the chain in Listing 1 produces a types tape containing the input word *abbabba*. We run the subtyping machine by assigning the chain to a variable, invoking a the subtyping query in Equation (2).

The purpose of the subtyping machine is to validate a property of the chain at compile time. For example, a subtyping machine that recognizes palindromes forces the fluent chain to encode a palindrome word, or else it would not compile. Since the chain in Listing 1 encodes a palindrome, the subtyping machine accepts and the assignment type-checks. This sort of type-level metaprogramming in fluent APIs is employed for embedding domain-specific languages (DSLs) and enforcing higher-level API protocols [3, 10, 4, 19, 14]. In theory, Grigore’s subtyping machines can encode any computable DSL or API protocol. Unfortunately, the slowdown ingrained into the design of the subtyping machines results in extremely high compilation times, making the technique impractical.

1.4 Contributions

This work revisits Grigore’s study of subtyping machines in the context of Python. We show that Python’s type system includes the Java fragment used in Grigore’s construction and is, therefore, Turing complete. We review the impact of undecidable subtyping on the Python ecosystem, covering compile-time and run-time type checkers and different Python distributions. Finally, we present a new subtyping machine design that avoids the inherent slowdown imposed by Grigore’s construction – an essential step towards practical subtyping machine applications. Our subtyping machines simulate TMs in real time, i.e., make $O(1)$ operations for each TM transition. The paper is accompanied by a Python implementation of Grigore’s and our reductions, producing subtyping machines on top of Python type hints.

Outline

The rest of the paper is organized as follows. In Section 2, we show that Python type hints are Turing complete and discuss possible ways to make them more tractable. Section 3 includes the survey of infinite subtyping and type reification in Python. Section 4 introduces our alternative design for subtyping machines that simulate TMs in real time. Section 5 presents our Python implementations of Grigore’s original reduction and the new reduction, and compares their performances. Section 6 concludes.

2 Python Subtyping is Undecidable

Type hints were introduced into the Python programming language with PEP 484 [16]. PEP 484 defines the syntax of type hints but only provides an informal description of their semantics, referring the reader to the supplementary PEP 483 [17] for an in-depth discussion. Type hints are used as annotations and are entirely optional:

```
def positive(x: int) -> bool:
    return x > 0
```

Static analysis on type hints is not performed by the Python interpreter but by third-party tools. For instance, Mypy [9] is a type checker for Python type hints; in fact, PEP 484 was originally inspired by Mypy [16].

The type system described in PEP 484 supports declaration-site nominal subtyping with variance, similar to the abstract type system studied by Kennedy and Pierce [7]. Although originally designed for Java, Grigore’s subtyping machines conform to Kennedy and Pierce’s type system. To implement subtyping machines with Python type hints, we need to show that Python’s type system includes the two subtyping features essential for Grigore’s construction: contravariance and expansive-recursive inheritance.

In Python, type variables are specified using a special constructor, `TypeVar`. Making a contravariant (or covariant) type variable is as simple as passing an argument to `TypeVar`:

```
z = TypeVar("z", contravariant=True)
class N(Generic[z]): ... # class N has a contravariant parameter z
```

Expansive-recursive inheritance is a more elusive aspect of nominal subtyping. Kennedy and Pierce [7] defined expansive inheritance using the *inheritance and decomposition closure* $\text{cl}(t)$ of type t . Here we provide a brief description of the closure; the full definition can be found in Kennedy and Pierce’s paper. Recall that we use a shorthand notation for generic types, $Cs = \mathcal{C}[s]$. If $\text{cl}(t)$ contains the type Cs , then by decomposition it also contains s :

$$\text{(DECOMPOSITION)} \quad \frac{Cs \in \text{cl}(t)}{s \in \text{cl}(t)} \quad (3)$$

If, in addition, class $\mathcal{C}[x]$ inherits from type u , denoted $Cx : u$, then $\text{cl}(t)$ also contains the type $u[x \leftarrow s]$, in which every occurrence of type parameter x is substituted by s :

$$\text{(INHERITANCE)} \quad \frac{Cs \in \text{cl}(t) \quad Cx : u}{u[x \leftarrow s] \in \text{cl}(t)} \quad (4)$$

Kennedy and Pierce proved that a class table is expansive-recursive if and only if the set $\text{cl}(t)$ is infinite for some type t . For example, consider the following class declaration:

```
x = TypeVar("x")
class C(Generic[x], N[N["C[C[x]]"]]): ... # Cx:NNCCx
```

44:6 Python Type Hints Are Turing Complete

The inheritance of class C is expansive-recursive since the set $\text{cl}(Ct)$ is infinite for any type t :

1. $Ct \in \text{cl}(Ct)$
 2. $NNCCt \in \text{cl}(Ct)$ (INHERITANCE)
 3. $NCCT \in \text{cl}(Ct)$ (DECOMPOSITION)
 4. $CCT \in \text{cl}(Ct)$ (DECOMPOSITION)
 5. $NNCCCT \in \text{cl}(Ct)$ (INHERITANCE)
- and so on...
- (5)

Between steps 1 and 4 the type Ct was transformed to CCT , increasing the size of the type by a single C . By continuing the deduction we get that the set $\text{cl}(Ct)$ contains the type $C^n t$ for any $n \geq 1$ and is, therefore, infinite.

As PEP 484 and the accompanying PEP 483 do not mention any restrictions on expansive-recursive inheritance (at least, that the author could find), we conclude that Python implicitly supports expansive inheritance. As evidence, the example above correctly compiles in Python and Mypy.

By enabling both contravariance and expansive-recursive inheritance, the designers of PEP 484 opened up Python type hints to the same pitfalls of nominal subtyping with variance studied by Kennedy, Pierce, and Grigore. For example, the code in Listing 2, adapted from Kennedy and Pierce [7], shows how contravariance and expansive inheritance can be combined to induce an infinite subtyping cycle.

■ **Listing 2** Contravariance, expansive inheritance, and infinite subtyping with Python type hints.

```
from typing import TypeVar, Generic, Any
z = TypeVar("z", contravariant=True)
class N(Generic[z]): ...
x = TypeVar("x")
class C(Generic[x], N[N["C[C[x]]"]]): ...
class T: ...
class U: ...
_: N[C[U]] = C[T]() # CT <: NCU ✗ infinite subtyping
```

The last line of Listing 2 contains a variable assignment that invokes the subtyping query $CT <: NCU$. The query is resolved using two subtyping rules [7]: SUPER, allowing us to replace a type with its supertype using an inheritance rule:

$$\text{(SUPER)} \quad \frac{Cx : u \quad u[x \leftarrow s] <: t}{Cs <: t} \quad (6)$$

And VAR, allowing us to remove a single type from both sides of the query:

$$\text{(VAR)} \quad \frac{C\text{'s type parameter } x \text{ is contravariant} \quad t <: s}{Cs <: Ct} \quad (7)$$

We use the rules SUPER and VAR to resolve the query as follows:

1. $CT <: NCU$
 2. $NNCCT <: NCU$ (SUPER)
 3. $CU <: NCCT$ (VAR)
 4. $NNCCU <: NCCT$ (SUPER)
 5. $CCT <: NCCU$ (VAR)
- and so on...
- (8)

Between steps 1 and 5, the subtyping query was not reduced but increased in size. This deductive process continues indefinitely. When Mypy checks this program, it throws a segmentation fault. In Section 5, we show that Mypy crashes because it gets stuck in an infinite recursion during the subtyping algorithm.

Since contravariance and expansive inheritance are enough to implement Grigore’s subtyping machines, we get that Python type hints are Turing complete. Section 5 presents our implementation of Grigore’s reduction with Python type hints. The resulting subtyping machines correctly run with Mypy.

2.1 Taming Python’s Type System

The source of undecidability in PEP 484 is the hazardous combination of contravariance and expansive-recursive inheritance, whose presence enables the construction of Grigore’s subtyping machines. Kennedy and Pierce proved that nominal subtyping with variance becomes decidable once either contravariance or expansive inheritance are removed [7]. Restrictions to expansive inheritance are implemented, for example, in the Scala programming language [11, §5.1.5] and the .NET framework [1, §II.9.2]. Removing expansive inheritance, however, might not be enough to make Python type hints decidable. A more thorough inspection of the various features of Python’s type system is required to determine this.

Greenman et al. [5] and Tate et al. [15] presented alternative subtyping algorithms for Java that are decidable. Besides the theoretical work, they surveyed extensive corpora of Java projects to show that their new algorithms do not break existing code and are thus backward compatible. Future attempts at making Python’s type hints decidable may follow a similar line.

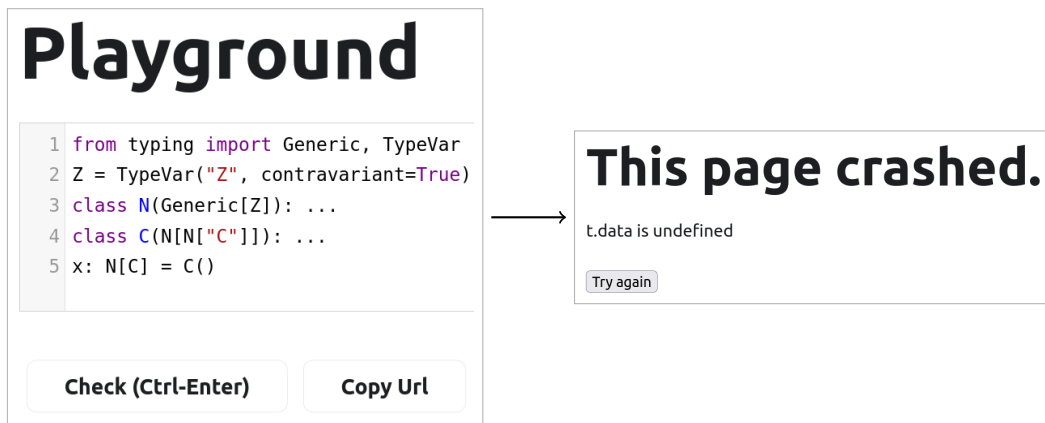

3 Type Reification and Infinite Subtyping in the Wild

A remote code execution vulnerability allows an attacker to run arbitrary *code* on a remote machine. Python type hints, on the other hand, can be used to run arbitrary *computations*. The distinction between code and computation is critical in the context of security: we can use type hints to compute prime numbers but not to access the file system or to open an SSH connection. Nevertheless, the fact that Python type hints are Turing complete does raise a few practical concerns. Type hints can induce infinite subtyping cycles, as demonstrated in Listing 2. These cycles cannot be detected by a “smart” type checker due to the undecidability of the halting problem. Thus, we can use infinite subtyping to attack Python type checkers and cause them to loop indefinitely or crash. For example, we managed to use infinite subtyping to crash the online playground of the Pyre Python type checker, as depicted in Figure 2. The playground is available at <https://pyre-check.org/play/>.

In Java, the compiler eliminates type arguments to generic types in a process called *type erasure*, making infinite subtyping a compile-time-only issue. Although PEP 484 mentions type erasure, it does not explicitly prohibit run-time type reification. The later PEP 585 [8] settles the matter, stating:

“The generic parameters are not preserved in instances created with parameterized types, in other words generic types erase type parameters during object creation.”

In practice, Python implementations *ignore* type erasure and keep records of generic types in run-time objects. Listing 3 demonstrates how to obtain information about type parameters and generic arguments at run time.

■ **Figure 2** Crashing the Pyre playground with an infinite subtyping cycle.

■ **Listing 3** Obtaining reified generic types in Python at run time.

```
from typing import TypeVar, Generic
x = TypeVar("x", contravariant=True)
class C(Generic[x]): ...
print(C.__parameters__) # (-x,)
y = C[int]()
print(y.__orig_class__) # __main__.C[int]
```

The field `__parameters__` of the generic class `C` reveals that the class uses a single contravariant type parameter `x`. The generic type of the parameterized instantiation `C[int]()` is retrieved using the `__orig_class__` field. We tested the code in Listing 3 on several Python distributions. The results are presented in Table 2.

■ **Table 2** Type reification in different Python distributions.

Python Distribution	Version	Type Reification	Notes
CPython	3.9.13	●	
PyPy	7.3.11	●	
RustPython	3.5.0alpha	●	
WinPython	3.0.20	●	
Brython	3.11.1	⊘	<code>__orig_class__</code> is bugged

Table 2 shows that all the Python implementations tested practice type reification. As an exception, Brython fails to retrieve the field `__orig_class__`. After inspecting the source code, the author believes it to be a bug. At the moment of writing these lines, an open issue¹ on CPython's GitHub project calls for a proper API wrapper for the `__orig_class__` field. This development indicates that the Python community sees type reification not as a mere implementation detail but as a desired feature that should be established further.

Although Python reifies generic types, it does not mean that run-time type checkers use them in subtyping checks. And while static analyzers have all the type hints available, there is no guarantee that they implement the complete Python type system described in

¹ <https://github.com/python/cpython/issues/101688>

PEP 484. Whether or not a type checker gets stuck on infinite subtyping or successfully runs a subtyping machine is determined by its support of type parameter variance. In particular, both cases depend on contravariant type parameters. We reviewed various static and dynamic Python type checkers and checked whether they support variance as described in PEP 484. The results are presented in Table 3.

■ **Table 3** Variance support in Python type checkers.

Type Checker	Version	Typing Discipline	Variance Support	Notes
Mypy	0.991	static	●	
Pyre	0.9.17	static	●	
Pyright	1.1.279	static	⦿	Pyright is unsound
Pytype	2022.11.10	static	○	
Pyanalyze	0.8.0	static	○	
Pydantic	1.10.2	dynamic	○	
Typeguard	2.13.3	dynamic	○	
Pytypes	1.0b10	dynamic	○	Delegates to <code>isinstance</code> (sometimes)
Typical	2.8.0	dynamic	○	Delegates to <code>isinstance</code>

We found that Mypy and Pyre are the only type checkers to fully support subtyping with variance. Pyright also acknowledges variant type parameters, but reports errors for correctly-typed programs, meaning that it is unsound. We showed this by running one of our (accepting) subtyping machines: Mypy and Pyre reported no errors while Pyright did report one. The code is found in the supplementary material. Pytype reported that it does not support contravariant parameters. For the rest of the type checkers, we had to search the source code for any mention of variance to conclude that they do not support it. Typical seems to delegate subtyping checks to `isinstance` or equivalent methods that reject generic types altogether. We observed similar behavior in Pytypes when using type forward references, i.e., types in string literals.

To fully support PEP 484, Python type checkers must support covariant and contravariant type parameters. Variance, however, introduces a security vulnerability in the form of unavoidable infinite subtyping cycles. Crashes of static type checkers may be forgiven, but for dynamic checkers, infinite subtyping poses a major concern. This also holds for Python’s `isinstance` check, if the designers of Python or one of its implementations ever consider adding run-time subtyping checks against generic types.

4 Real-Time Subtyping Machines

Grigore’s subtyping machines must scan the entire tape memory before they can simulate a single TM transition. This is because the subtyping machines can change their direction (from \blacktriangleleft to \blacktriangleright and vice versa) only when reaching the end of the tape. We now present an alternative design for subtyping machines that simulate TMs in real time, i.e., where a single TM computation step is simulated by $O(1)$ subtyping deductions.

Let $M = \langle Q, \Sigma, q_I, q_h, \delta \rangle$ be a TM where Q is the set of machine states, Σ is the set of tape symbols, q_I is the initial state, q_h is the termination state, and

$$\delta : Q \times (\Sigma \cup \{\perp\}) \rightarrow Q \times \Sigma \times \{L, R\}$$

is the transition function. In each computation step, the TM changes its state, overwrites the current tape cell, and moves the machine head to the left (L) or right (R). The TM accepts its input if and only if it reaches the termination state q_h . We use the symbol $\perp \notin \Sigma$ to denote blank tape cells.

44:10 Python Type Hints Are Turing Complete

The new encoding of subtyping machines is shown in Table 4. The encoding comprises ten inheritance rules (i) to (x) (recall that we use a colon to denote inheritance). To encode a TM M as a subtyping machine, fill in the inheritance rules' missing values using elements from M that satisfy the conditions on the right-hand side. For example, if M contains state $q_4 \in Q$ and tape symbol $p \in \Sigma$, then by rule (v),

$$Q_4^{LL}x : L_p N Q_4^L L_p N x.$$

When multiple rules apply to the same type, multiple inheritance is used. Symbol x is a contravariant type parameter and symbol $?$ denotes the wildcard type, i.e., the type that is consistent with (can be substituted by) any type. In Python, this is the `Any` type [16]. All the type parameters used in the encoding are contravariant. There are ten more inheritance rules in addition to those in Table 4, obtained by swapping L and R in each rule in the table.

■ **Table 4** Real-time subtyping machines. For each inheritance rule, swap L and R to get the symmetrical rule. The type parameter x is contravariant.

(i)	$Q_s^L x : L_a N Q_s^L L_b N x$	$\delta(q_s, a) = \langle q_{s'}, b, L \rangle$
(ii)	$Q_s^L x : L_a Q_s^{LRR} N L_b N x$	$\delta(q_s, a) = \langle q_{s'}, b, R \rangle$
(iii)	$Q_s^L x : L_{\perp} Q_s^{L\perp L} N L_b N x$	$\delta(q_s, \perp) = \langle q_{s'}, b, L \rangle$
(iv)	$Q_s^L x : L_{\perp} Q_s^{L\perp R} N L_b N x$	$\delta(q_s, \perp) = \langle q_{s'}, b, R \rangle$
(v)	$Q_s^{LL} x : L_a N Q_s^L L_a N x$	$\forall q_s \in Q, \forall a \in \Sigma$
(vi)	$N x : Q_s^{LRR} N Q_s^{RR} x$	$\forall q_s \in Q$
(vii)	$N x : Q_s^{L\perp L} Q_s^{RL} N L_{\perp} N x$	$\forall q_s \in Q$
(viii)	$N x : Q_s^{L\perp R} N Q_s^{RR} L_{\perp} N x$	$\forall q_s \in Q$
(ix)	$N x : Q_s^{LR} N Q_s^R x$	$\forall q_s \in Q$
(x)	$Q_h^L x : L_a ?$	$\forall a \in \Sigma \cup \{\perp\}$

The roles of the types in Table 4 are mostly the same as in Grigore's encoding (Table 1), i.e., L_a is a tape cell containing the symbol a , N is a buffer type, and Q_s is a state type. The new encoding, however, does not use a type for the machine head (M in Grigore's encoding) because the state type Q also indicates the location of the machine head. The superscripts of Q imply the head's movement direction; e.g., Q_s^{LL} means that the head is about to go two cells to the left, $Q_s^{L\perp R}$ means that the head is about to move left into a blank cell and then rotate, and so on.

The initial TM configuration is encoded by the following subtyping query:

$$Z N L_{\perp} Q_I^R \blacktriangleleft L_{a_1} N L_{a_2} N \cdots L_{a_{m-1}} N L_{a_m} N L_{\perp} N Z \quad (9)$$

The content of the tape is encoded by the L types, read from the left to the right. The current state and the position of the machine head are encoded by the type Q_I^R – the current cell is on the right (R) of the type, which is also the direction of the query (\blacktriangleleft). The infinite blank ends of the tape are encoded by the type L_{\perp} . Observe that the colors of the types in Equation (9) match the colors of the corresponding TM components in Figure 1. Type Q_s^R is half red and half orange because it represents both the current state *and* the head location.

To prove the correctness of the simulation, we show that the subtyping query in Equation (9) simulates the TM transitions while preserving the encoding of the machine tape, head, and state comprising the TM configuration. There are three variables to be considered:

the initial orientation of the head, whether or not the current cell is blank, and whether or not the machine head changes direction. For example, the machine head Q_I^R in Equation (9) points to the right (R) and reads a non-blank cell L_{a_1} . The next cell could be either L_{a_2} , if the head continues right, or blank L_\perp , if it rotates.

We now cover four cases, assuming that the initial orientation is *left* (this is the orientation used in Table 4). The other four cases are symmetrical. Next to each subtyping deduction step, we mention the subtyping rule used in this step. Recall that there are two subtyping rules, SUPER and VAR (Equations (6) and (7)). As all the type parameters are contravariant, the query changes direction (from \blacktriangleleft to \blacktriangleright and vice versa) after applying VAR a single time.

Case I. The head points to a *non-blank* cell a , replaces it with symbol b , and continues *left*. The relevant TM transition is

$$\delta(q_s, a) = \langle q_{s'}, b, L \rangle$$

and the resulting subtyping query is

$$\begin{aligned} \dots NL_a \blacktriangleright Q_s^L \dots & \\ \dots NL_a \blacktriangleright L_a N Q_{s'}^L L_b N \dots & \quad (i) + (\text{SUPER}) \\ \dots \blacktriangleright Q_{s'}^L L_b N \dots & \quad (\text{VAR}) \times 2 \end{aligned}$$

“(i) + SUPER” means applying rule SUPER with inheritance rule (i) from Table 4. “(VAR) $\times 2$ ” means applying rule VAR twice. Observe that the subtyping query simulates the TM transition while preserving the encoding: symbol L_a is replaced by L_b , state Q_s is replaced by $Q_{s'}$ (the next machine state), and the head moves to the cell on the left.

Case II. The head points to a *non-blank* cell a , replaces it with symbol b , and continues *right*. The relevant TM transition is

$$\delta(q_s, a) = \langle q_{s'}, b, R \rangle$$

and the resulting subtyping query is

$$\begin{aligned} \dots NL_a \blacktriangleright Q_s^L \dots & \\ \dots NL_a \blacktriangleright L_a Q_{s'}^{LRR} NL_b N \dots & \quad (ii) + (\text{SUPER}) \\ \dots N \blacktriangleleft Q_{s'}^{LRR} NL_b N \dots & \quad (\text{VAR}) \\ \dots Q_{s'}^{RR} N Q_{s'}^{LRR} \blacktriangleleft Q_{s'}^{LRR} NL_b N \dots & \quad (vi) + (\text{SUPER}) \\ \dots Q_{s'}^{RR} \blacktriangleleft L_b N \dots & \quad (\text{VAR}) \times 2 \\ \dots NL_b Q_{s'}^R NL_b \blacktriangleleft L_b N \dots & \quad (v) + (\text{SUPER}) \\ \dots NL_b Q_{s'}^R \blacktriangleleft \dots & \quad (\text{VAR}) \times 2 \end{aligned}$$

Case III. The head points to a *blank* cell (the end of the tape), replaces it with symbol b , and continues *left*. The relevant TM transition is

$$\delta(q_s, \perp) = \langle q_{s'}, b, L \rangle$$

and the resulting subtyping query is

$$\begin{aligned} ZNL_\perp \blacktriangleright Q_s^L \dots & \\ ZNL_\perp \blacktriangleright L_\perp Q_{s'}^{L\perp L} NL_b N \dots & \quad (iii) + (\text{SUPER}) \\ ZN \blacktriangleleft Q_{s'}^{L\perp L} NL_b N \dots & \quad (\text{VAR}) \\ ZNL_\perp N Q_{s'}^{RL} Q_{s'}^{L\perp L} \blacktriangleleft Q_{s'}^{L\perp L} NL_b N \dots & \quad (vii) + (\text{SUPER}) \\ ZNL_\perp N Q_{s'}^{RL} \blacktriangleright NL_b N \dots & \quad (\text{VAR}) \\ ZNL_\perp N Q_{s'}^{RL} \blacktriangleright Q_{s'}^{RL} N Q_{s'}^L L_b N \dots & \quad (ix) + (\text{SUPER}) \\ ZNL_\perp \blacktriangleright Q_{s'}^L L_b N \dots & \quad (\text{VAR}) \times 2 \end{aligned}$$

44:12 Python Type Hints Are Turing Complete

Case IV. The head points to a *blank* cell, replaces it with symbol b , and continues *right*. The relevant TM transition is

$$\delta(q_s, \perp) = \langle q_{s'}, b, R \rangle$$

and the resulting subtyping query is

$$\begin{aligned} ZNL_{\perp} &\blacktriangleright Q_s^L \dots && \\ ZNL_{\perp} &\blacktriangleright L_{\perp} Q_{s'}^{L\perp R} NL_b N \dots && (iv) + (\text{SUPER}) \\ ZN &\blacktriangleleft Q_s^{L\perp R} NL_b N \dots && (\text{VAR}) \\ ZNL_{\perp} Q_{s'}^{RR} N Q_{s'}^{L\perp R} &\blacktriangleleft Q_{s'}^{L\perp R} NL_b N \dots && (viii) + (\text{SUPER}) \\ ZNL_{\perp} Q_{s'}^{RR} &\blacktriangleleft L_b N \dots && (\text{VAR}) \times 2 \\ ZNL_{\perp} NL_b Q_{s'}^R NL_b &\blacktriangleleft L_b N \dots && (v) + (\text{SUPER}) \\ ZNL_{\perp} NL_b Q_{s'}^R &\blacktriangleleft \dots && (\text{VAR}) \times 2 \end{aligned}$$

The TM rejects its input when its current state is q_s , the current tape symbol is a , and the transition $\delta(q_s, a)$ is not defined. In this case, the subtyping query $L_a \blacktriangleright Q_s^L$ also rejects since there is no inheritance rule in Table 4 with which rule SUPER can be applied. On the other hand, if the TM reaches state q_h and accepts its input, the subtyping query $L_a \blacktriangleright Q_h^L$ is resolved by applying rule (x) .

Note that our simulation is clearly real-time. To simulate a single TM transition, the subtyping machine performs at most eight subtyping deductions (in cases II and IV).

The wildcard type used in rule (x) is not a part of Kennedy and Pierce's system of nominal subtyping with variance. Instead of using the wildcard, the subtyping machine could go to either side of the tape before resolving the query, as done in Grigore's simulation. This makes the subtyping machine design a bit more complicated, and its simulation of the TM returns to be non-real-time, but the computational complexity of the simulation is not increased.

5 Implementation and Performance Experiment

We present our Python implementation of Grigore's original reduction and our new real-time simulation introduced in Section 4 in the supplementary material. Our implementation compiles TMs into Python subtyping machines that use the type hints and generics described in PEP 484 [16]. Each subtyping machine comprises a class table (Table 4) and a variable assignment that invokes a subtyping query (Equation (9)). To run the subtyping machine, we use Mypy to type-check the generated Python code.

If the subtyping machine accepts its input, Mypy terminates successfully, and if the input is rejected, Mypy reports a typing error. But what happens when the subtyping machine runs indefinitely? When running Mypy on the code in Listing 2, containing an infinite subtyping cycle, Mypy crashes with a segmentation fault. To uncover the reason for the segmentation fault, we remove a call to `sys.setrecursionlimit` from Mypy's source code and run it again with the flag `--show-traceback`. Mypy reports the following error:

```
...
File "mypy/types.py", line 1283, in accept
File "mypy/subtypes.py", line 585, in visit_instance
File "mypy/subtypes.py", line 345, in check_type_parameter
File "mypy/subtypes.py", line 339, in check
File "mypy/subtypes.py", line 179, in is_subtype
File "mypy/subtypes.py", line 329, in _is_subtype
```

```

File "mypy/types.py", line 1283, in accept
File "mypy/subtypes.py", line 585, in visit_instance
File "mypy/subtypes.py", line 345, in check_type_parameter
File "mypy/subtypes.py", line 339, in check
File "mypy/subtypes.py", line 147, in is_subtype
RecursionError: maximum recursion depth exceeded while calling a Python object

```

The stack trace confirms that Mypy’s subtyping algorithm is implemented using recursion, causing it to crash with a segmentation fault on infinite subtyping. This observation makes it possible to measure the run time of the subtyping machine, i.e., the number of subtyping deductions it performs, by calculating the minimal size of the call stack required for Mypy to type-check the machine.

Figure 3 describes the results of our experiment, in which we measured the run times of subtyping machines accepting input words of various lengths. The TM used in the experiment recognizes palindromes over $\{a, b\}$ and runs in $O(n^2)$. We compiled the TM together with random palindromes of increasing lengths into subtyping machines, once using Grigore’s method and once with our construction. Then, binary search was used to find the minimal call stack size (in megabytes (MB)) required for Mypy to type-check the machine without getting a segmentation fault.

■ **Figure 3** Run times of the palindrome subtyping machines: Grigore’s reduction vs. the new reduction.

In theory, Grigore’s subtyping machines should run in $O(n^3)$ due to their inherent slow-down, while our machines are expected to run in $O(n^2)$ since they simulate the palindromes TM in real time. In practice, we see that our subtyping machines are much faster than Grigore’s and require significantly fewer resources to be type-checked.

6 Conclusions

Python type hints are Turing complete because PEP 484 supports nominal subtyping with variance, including contravariance and expansive-recursive inheritance. These two subtyping features are sufficient to implement Grigore’s subtyping machines that simulate TMs at compile time.

We demonstrated that infinite subtyping cause Python type checkers to crash with a stack overflow error. Due to the undecidability of the halting problem, fixing this problem requires changing the Python type system described in PEP 484. Even run-time type checkers are in danger because existing Python distributions reify generic types – in spite of the language specifications. In practice, we found that only two static analyzers (Mypy and Pyre) are vulnerable to infinite subtyping since they provide the most complete implementations of Python’s type system.

We described an alternative subtyping machine design that simulates TMs in real time, removing the inherent slowdown introduced in Grigore’s original design. Our experiment shows that the new subtyping machines compile significantly faster. Our design is an essential step towards practical subtyping machine applications. Nevertheless, such applications would most likely depend on the type checker’s implementation of the subtyping algorithm – specifically, that it is not recursive.
