## LIPICs – Leibniz International Proceedings in Informatics

LIPICs is a series of high-quality conference proceedings across all fields in informatics. LIPICs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

### *Editorial Board*

- Luca Aceto (*Chair*, Reykjavik University, IS and Gran Sasso Science Institute, IT)
- Christel Baier (TU Dresden, DE)
- Roberto Di Cosmo (Inria and Université de Paris, FR)
- Faith Ellen (University of Toronto, CA)
- Javier Esparza (TU München, DE)
- Daniel Král' (Masaryk University, Brno, CZ)
- Meena Mahajan (Institute of Mathematical Sciences, Chennai, IN)
- Anca Muscholl (University of Bordeaux, FR)
- Chih-Hao Luke Ong (University of Oxford, GB)
- Phillip Rogaway (University of California, Davis, US)
- Eva Rotenberg (Technical University of Denmark, Lyngby, DK)
- Raimund Seidel (Universität des Saarlandes, Saarbrücken, DE and Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Wadern, DE)
- Pierre Senellart (ENS, Université PSL, Paris, FR)

# ■ Contents

Preface	
<i>Jérôme Leroux, Sylvain Lombardy, and David Peleg</i> .....	0:xi
Organization	
.....	0:xiii

## Invited Talks

Exploring the Space of Colourings with Kempe Changes	
<i>Marthe Bonamy</i> .....	1:1–1:2
Online Algorithms with Predictions	
<i>Joan Boyar</i> .....	2:1–2:2
Modern Parallel Algorithms	
<i>Artur Czumaj</i> .....	3:1–3:2
Algebraic Reasoning for (Un)Solvable Loops	
<i>Laura Kovács</i> .....	4:1–4:2
Sliding into the Future: Investigating Sliding Windows in Temporal Graphs	
<i>Nina Klobas, George B. Mertzios, and Paul G. Spirakis</i> .....	5:1–5:12

## Regular Papers

Roman Census: Enumerating and Counting Roman Dominating Functions on Graph Classes	
<i>Faisal N. Abu-Khzam, Henning Fernau, and Kevin Mann</i> .....	6:1–6:15
Counting Computations with Formulae: Logical Characterisations of Counting Complexity Classes	
<i>Antonis Achilleos and Aggeliki Chalki</i> .....	7:1–7:15
Recognizing $H$ -Graphs – Beyond Circular-Arc Graphs	
<i>Deniz Aġaoġlu Çaġırıcı, Onur Çaġırıcı, Jan Derbisz, Tim A. Hartmann, Petr Hliněný, Jan Kratochvíl, Tomasz Krawczyk, and Peter Zeman</i> .....	8:1–8:14
Descriptive Complexity for Distributed Computing with Circuits	
<i>Veeti Ahvonen, Damian Heiman, Lauri Hella, and Antti Kuusisto</i> .....	9:1–9:15
Solving Irreducible Stochastic Mean-Payoff Games and Entropy Games by Relative Krasnoselskii–Mann Iteration	
<i>Marianne Akian, Stéphane Gaubert, Ulysse Naepels, and Basile Terver</i> .....	10:1–10:15
The Geometry of Reachability in Continuous Vector Addition Systems with States	
<i>Shaull Almagor, Arka Ghosh, Tim Leys, and Guillermo A. Pérez</i> .....	11:1–11:13
Competitive Search in the Line and the Star with Predictions	
<i>Spyros Angelopoulos</i> .....	12:1–12:15

48th International Symposium on Mathematical Foundations of Computer Science (MFCS 2023).

Editors: Jérôme Leroux, Sylvain Lombardy, and David Peleg

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Rényi-Ulam Games and Online Computation with Imperfect Advice <i>Spyros Angelopoulos and Shahin Kamali</i> .....	13:1–13:15
Multivariate to Bivariate Reduction for Noncommutative Polynomial Factorization <i>Vikraman Arvind and Pushkar S. Joglekar</i> .....	14:1–14:15
Entropic Risk for Turn-Based Stochastic Games <i>Christel Baier, Krishnendu Chatterjee, Tobias Meggendorfer, and Jakob Piribauer</i> .....	15:1–15:16
Speed Me up If You Can: Conditional Lower Bounds on Opacity Verification <i>Jiří Balun, Tomáš Masopust, and Petr Osíčka</i> .....	16:1–16:15
Separating Automatic Relations <i>Pablo Barceló, Diego Figueira, and Rémi Morvan</i> .....	17:1–17:15
On the Parameterized Complexity of Computing <i>st</i> -Orientations with Few Transitive Edges <i>Carla Binucci, Giuseppe Liotta, Fabrizio Montecchiani, Giacomo Ortali, and Tommaso Piselli</i> .....	18:1–18:15
Distributed CONGEST Algorithm for Finding Hamiltonian Paths in Dirac Graphs and Generalizations <i>Noy Biton, Reut Levi, and Moti Medina</i> .....	19:1–19:14
Locality Theorems in Semiring Semantics <i>Clotilde Bizière, Erich Grädel, and Matthias Naaf</i> .....	20:1–20:15
A Characterisation of Functions Computable in Polynomial Time and Space over the Reals with Discrete Ordinary Differential Equations: Simulation of Turing Machines with Analytic Discrete ODEs <i>Manon Blanc and Olivier Bournez</i> .....	21:1–21:15
MaxCut Above Guarantee <i>Ivan Bliznets and Vladislav Epifanov</i> .....	22:1–22:14
Cryptanalysis of a Generalized Subset-Sum Pseudorandom Generator <i>Charles Bouillaguet, Florette Martinez, and Damien Vergnaud</i> .....	23:1–23:15
The Compositional Structure of Bayesian Inference <i>Dylan Braithwaite, Jules Hedges, and Toby St Clere Smithe</i> .....	24:1–24:15
Deterministic Constrained Multilinear Detection <i>Cornelius Brand, Viktoriia Korchemna, and Michael Skotnica</i> .....	25:1–25:14
Rational Verification for Nash and Subgame-Perfect Equilibria in Graph Games <i>Léonard Brice, Jean-François Raskin, and Marie van den Bogaard</i> .....	26:1–26:15
On Property Testing of the Binary Rank <i>Nader H. Bshouty</i> .....	27:1–27:14
Short Definitions in Constraint Languages <i>Jakub Bulín and Michael Kompatscher</i> .....	28:1–28:15

The Online Simple Knapsack Problem with Reservation and Removability <i>Elisabet Burjons, Matthias Gehnen, Henri Lotze, Daniel Mock, and Peter Rossmanith</i> .....	29:1–29:12
Parikh One-Counter Automata <i>Michaël Cadilhac, Arka Ghosh, Guillermo A. Pérez, and Ritam Raha</i> .....	30:1–30:15
Modification Problems Toward Proper (Helly) Circular-Arc Graphs <i>Yixin Cao, Hanchun Yuan, and Jianxin Wang</i> .....	31:1–31:14
Isometric Path Complexity of Graphs <i>Dibyayan Chakraborty, Jérémie Chalopin, Florent Foucaud, and Yann Vaxès</i> .....	32:1–32:14
Support Size Estimation: The Power of Conditioning <i>Diptarka Chakraborty, Gunjan Kumar, and Kuldeep S. Meel</i> .....	33:1–33:13
Query Complexity of Search Problems <i>Arkadev Chattopadhyay, Yogesh Dahiya, and Meena Mahajan</i> .....	34:1–34:15
Tight Algorithmic Applications of Clique-Width Generalizations <i>Vera Chekan and Stefan Kratsch</i> .....	35:1–35:15
An Iterative Approach for Counting Reduced Ordered Binary Decision Diagrams <i>Julien Clément and Antoine Genitrini</i> .....	36:1–36:15
Inductive Continuity via Brouwer Trees <i>Liron Cohen, Bruno da Rocha Paiva, Vincent Rahli, and Ayberk Tosun</i> .....	37:1–37:16
Approximating the Value of Energy-Parity Objectives in Simple Stochastic Games <i>Mohan Dantam and Richard Mayr</i> .....	38:1–38:15
Dynamic Planar Embedding Is in DynFO <i>Samir Datta, Asif Khan, and Anish Mukherjee</i> .....	39:1–39:15
Universality and Forall-Exactness of Cost Register Automata with Few Registers <i>Laure Daviaud and Andrew Ryzhikov</i> .....	40:1–40:15
Relaxed Core Stability for Hedonic Games with Size-Dependent Utilities <i>Tom Demeulemeester and Jannik Peters</i> .....	41:1–41:14
Recontamination Helps a Lot to Hunt a Rabbit <i>Thomas Dissaux, Foivos Fioravantes, Harmender Gahlawat, and Nicolas Nisse</i> ...	42:1–42:14
String Diagrammatic Trace Theory <i>Matthew Earnshaw and Paweł Sobociński</i> .....	43:1–43:15
Upward Translation of Optimal and P-Optimal Proof Systems in the Boolean Hierarchy over NP <i>Fabian Egidy, Christian Glaßer, and Martin Herold</i> .....	44:1–44:15
Finding a Highly Connected Steiner Subgraph and its Applications <i>Eduard Eiben, Diptapriyo Majumdar, and M. S. Ramanujan</i> .....	45:1–45:15
FPT Approximation and Subexponential Algorithms for Covering Few or Many Edges <i>Fedor V. Fomin, Petr A. Golovach, Tanmay Inamdar, and Tomohiro Koana</i> .....	46:1–46:8

Graph Connectivity with Noisy Queries <i>Dimitris Fotakis, Evangelia Gergatsouli, Charilaos Pipis, Miltiadis Stouras, and Christos Tzamos</i> .....	47:1–47:14
Positive Data Languages <i>Florian Frank, Stefan Milius, and Henning Urbat</i> .....	48:1–48:15
Parameterized Analysis of the Cops and Robber Game <i>Harmender Gahlawat and Meirav Zehavi</i> .....	49:1–49:17
An FPT Algorithm for Spanning Trees with Few Branch Vertices Parameterized by Modular-Width <i>Luisa Gargano and Adele A. Rescigno</i> .....	50:1–50:15
Depth-3 Circuits for Inner Product <i>Mika Göös, Ziyi Guan, and Tiberiu Mosnoi</i> .....	51:1–51:12
On Polynomial-Time Decidability of $k$ -Negations Fragments of FO Theories (Extended Abstract) <i>Christoph Haase, Alessio Mansutti, and Amaury Pouly</i> .....	52:1–52:14
The Covering Canadian Traveller Problem Revisited <i>Niklas Hahn and Michalis Xeferis</i> .....	53:1–53:12
On the Complexity of Computing Time Series Medians Under the Move-Split-Merge Metric <i>Jana Holznigenkemper, Christian Komusiewicz, Nils Morawietz, and Bernhard Seeger</i> .....	54:1–54:15
Fixed-Parameter Algorithms for Fair Hitting Set Problems <i>Tanmay Inamdar, Lawqueen Kanesh, Madhumita Kundu, Nidhi Purohit, and Saket Saurabh</i> .....	55:1–55:14
Parameterized Approximation Scheme for Feedback Vertex Set <i>Satyabrata Jana, Daniel Lokshantov, Soumen Mandal, Ashutosh Rai, and Saket Saurabh</i> .....	56:1–56:15
Complexity Framework for Forbidden Subgraphs III: When Problems Are Tractable on Subcubic Graphs <i>Matthew Johnson, Barnaby Martin, Sukanya Pandey, Daniël Paulusma, Siani Smith, and Erik Jan van Leeuwen</i> .....	57:1–57:15
Polynomial-Delay Enumeration of Large Maximal Common Independent Sets in Two Matroids <i>Yasuaki Kobayashi, Kazuhiro Kurita, and Kunihiko Wasa</i> .....	58:1–58:14
Formalizing Hyperspaces for Extracting Efficient Exact Real Computation <i>Michal Konečný, Sewon Park, and Holger Thies</i> .....	59:1–59:16
Set Semantics for Asynchronous TeamLTL: Expressivity and Complexity <i>Juha Kontinen, Max Sandström, and Jonni Virtema</i> .....	60:1–60:14
Parameterized Complexity of Domination Problems Using Restricted Modular Partitions <i>Manuel Lafond and Weidong Luo</i> .....	61:1–61:14

Parameterized Max Min Feedback Vertex Set <i>Michael Lampis, Nikolaos Melissinos, and Manolis Vasilakis</i> .....	62:1–62:15
Distributed Merlin-Arthur Synthesis of Quantum States and Its Applications <i>François Le Gall, Masayuki Miyamoto, and Harumichi Nishimura</i> .....	63:1–63:15
Dichotomies for Maximum Matching Cut: $H$ -Freeness, Bounded Diameter, Bounded Radius <i>Felicia Lucke, Daniël Paulusma, and Bernard Ries</i> .....	64:1–64:15
A Weyl Criterion for Finite-State Dimension and Applications <i>Jack H. Lutz, Satyadev Nandakumar, and Subin Pulari</i> .....	65:1–65:16
On the Complexity Dichotomy for the Satisfiability of Systems of Term Equations over Finite Algebras <i>Peter Mayr</i> .....	66:1–66:12
Parallel Enumeration of Parse Trees <i>Margarita Mikhelson and Alexander Okhotin</i> .....	67:1–67:14
Spartan Bipartite Graphs Are Essentially Elementary <i>Neeldhara Misra and Saraswati Girish Nanoti</i> .....	68:1–68:15
On the Finite Variable-Occurrence Fragment of the Calculus of Relations with Bounded Dot-Dagger Alternation <i>Yoshiki Nakamura</i> .....	69:1–69:15
Effective Continued Fraction Dimension Versus Effective Hausdorff Dimension of Reals <i>Satyadev Nandakumar, Akhil S, and Prateek Vishnoi</i> .....	70:1–70:15
On the Expressive Power of Regular Expressions with Backreferences <i>Taisei Nogami and Tachio Terauchi</i> .....	71:1–71:15
OBDD(Join) Proofs Cannot Be Balanced <i>Sergei Ovcharov</i> .....	72:1–72:13
Lower Bounds for Choiceless Polynomial Time via Symmetric XOR-Circuits <i>Benedikt Pago</i> .....	73:1–73:15
A Super-Polynomial Separation Between Resolution and Cut-Free Sequent Calculus <i>Theodoros Papamakarios</i> .....	74:1–74:15
Realizing Finitely Presented Groups as Projective Fundamental Groups of SFTs <i>Léo Paviet Salomon and Pascal Vanier</i> .....	75:1–75:15
Deciding Predicate Logical Theories Of Real-Valued Functions <i>Stefan Ratschan</i> .....	76:1–76:15
A Polynomial-Time Algorithm for MCS Partial Search Order on Chordal Graphs <i>Guozhen Rong, Yongjie Yang, and Wenjun Li</i> .....	77:1–77:15
Probabilistic Input-Driven Pushdown Automata <i>Alex Rose and Alexander Okhotin</i> .....	78:1–78:14

Counting Homomorphisms from Hypergraphs of Bounded Generalised Hypertree Width: A Logical Characterisation <i>Benjamin Scheidt and Nicole Schweikardt</i> .....	79:1–79:15
Dynamic Constant Time Parallel Graph Algorithms with Sub-Linear Work <i>Jonas Schmidt and Thomas Schwentick</i> .....	80:1–80:15
On the Work of Dynamic Constant-Time Parallel Algorithms for Regular Tree Languages and Context-Free Languages <i>Jonas Schmidt, Thomas Schwentick, and Jennifer Todtenhoefer</i> .....	81:1–81:15
Logical Equivalences, Homomorphism Indistinguishability, and Forbidden Minors <i>Tim Seppelt</i> .....	82:1–82:15
Decomposing Finite Languages <i>Daniel Alexander Spenner</i> .....	83:1–83:14
Dependent $k$ -Set Packing on Polymoids <i>Meng-Tsung Tsai, Shi-Chun Tsai, and Tsung-Ta Wu</i> .....	84:1–84:15
Exponential Lower Bounds for Threshold Circuits of Sub-Linear Depth and Energy <i>Kei Uchizawa and Haruki Abe</i> .....	85:1–85:15
Exact and Approximation Algorithms for Routing a Convoy Through a Graph <i>Martijn van Ee, Tim Oosterwijk, René Sitters, and Andreas Wiese</i> .....	86:1–86:15
Ordinal Measures of the Set of Finite Multisets <i>Isa Vialard</i> .....	87:1–87:15
Checking Presence Reachability Properties on Parameterized Shared-Memory Systems <i>Nicolas Waldburger</i> .....	88:1–88:15

## ■ Preface

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a venue for high-quality original research in all branches of Theoretical Computer Science. MFCS is among the conferences with the longest history in the field – the first conference in the series was held already in 1972. For many years, the conference rotated between the Czech Republic, Slovakia, and Poland, but since 2013 it has expanded its realm and traveled around different countries in Europe. In 2023, at its 48th edition, MFCS was held in Bordeaux, France, on August 28th – September 1st.

This volume contains the invited contributions and the 84 contributed talks. The invited speakers were Marthe Bonamy (University of Bordeaux, France), Joan Boyar (University of Southern Denmark), Artur Czumaj (University of Warwick, UK), Laura Kovacs (TU Wien, Austria), and Paul Spirakis (university of Liverpool, UK).

The program committee of MFCS 2023 selected 84 papers out of the 209 submissions, with the authors of the submitted papers representing 38 countries. We express our deep gratitude to all the members of the program committee and the reviewers for their extensive reports and thorough discussions on the submissions' merits. We also warmly thank the invited speakers, as well as the authors of the submitted papers. MFCS proceedings have been published in the Dagstuhl/LIPIcs series since 2016. We thank Michael Wagner and the LIPIcs team for their kind help and support.

Jérôme Leroux  
Sylvain Lombardy  
David Peleg

# ■ Organization

## Program Committee

- Parosh Aziz Abdulla (Uppsala University)
- Akanksha Agrawal (Indian Institute of Technology Madras)
- Susanne Albers (Technical University of Munich)
- Josh Alman (Columbia University)
- Christel Baier (Technische Universität Dresden)
- Laurent Bienvenu (University of Bordeaux)
- Hans Bodlaender (Utrecht University)
- Olivier Bournez (Ecole Polytechnique)
- Véronique Bruyère (University of Mons)
- Ioannis Caragiannis (Aarhus University)
- Keerti Choudhary (Indian Institute of Technology Delhi)
- Thierry Coquand (University of Gothenburg)
- Stéphanie Delaune (Univiversité Rennes, CNRS, IRISA)
- Javier Esparza (Technische Universität München)
- Piotr Faliszewski (AGH University of Science and Technology)
- Michal Feldman (Tel-Aviv University)
- Paola Flocchini (University of Ottawa)
- Luisa Gargano (Università di Salerno)
- Leszek Gąsieniec (University of Liverpool)
- Jean Goubault-Larrecq (ENS Paris-Saclay)
- Petr Jancar (Palacky University)
- Lefteris M. Krousis (National and Kapodistrian University of Athens)
- Sándor Kisfaludi-Bak (Aalto University)
- Lukasz Kowalik (University of Warsaw)
- Daniel Král (Masaryk University)
- Rastislav Kráľovič (Comenius University)
- Ranko Lazic (University of Warwick)
- Jérôme Leroux, **co-Chair** (LaBRI, CNRS, Université de Bordeaux)
- Christof Löding (RWTH Aachen University)
- Pinyan Lu (Shanghai University of Finance and Economics)
- Elvira Mayordomo (Universidad de Zaragoza)
- Paolo Milazzo (University of Pisa)
- David Peleg, **co-Chair** (Weizmann Institute of Science)
- Simon Perdrix (Inria, Loria)
- Sophie Pinchinat (Université de Rennes)
- Jörg Rothe (Heinrich-Heine-Universität Düsseldorf)

48th International Symposium on Mathematical Foundations of Computer Science (MFCS 2023).  
Editors: Jérôme Leroux, Sylvain Lombardy, and David Peleg

Leibniz International Proceedings in Informatics  
LIPICIS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

- David Saulpic (IST Austria)
- Jiri Sgall (Charles University)
- Mahsa Shirmohammadi (CNRS, IRIF, Université Paris Cité)
- Michał Skrzypczak (University of Warsaw)
- Shay Solomon (Tel Aviv University)
- Dimitrios Thilikos (CNRS, LRIMM, Université de Montpellier)
- Patrick Totzke (University of Liverpool)
- Ashutosh Trivedi (University of Colorado Boulder)
- James Worrell (University of Oxford)
- Xiaoming Sun (Chinese Academy of Sciences)
- Meirav Zehavi (Ben-Gurion University)
- Marius Zimand (Towson University)
- Martin Zimmermann (Aalborg University)

## Abstract

Kempe changes were introduced in 1879 in an attempt to prove the 4-colour theorem. They are a convenient if not crucial tool to prove various colouring theorems. Here, we consider how to navigate from a colouring to another through Kempe changes. When is it possible? How fast?

**2012 ACM Subject Classification** Mathematics of computing → Graph coloring

**Keywords and phrases** Graph theory, graph coloring, reconfiguration

**Digital Object Identifier** 10.4230/LIPIcs.MFCS.2023.1

**Category** Invited Talk

Kempe changes were introduced in 1879 in an attempt to prove the 4-colour theorem [4]. They are a convenient if not crucial tool to prove various colouring theorems, most notably the 4-colour theorem [1] (every planar graph is 4-colourable) and Vizing’s edge colouring theorem [7] (the edges of any graph can be partitioned into at most  $\Delta + 1$  matchings, where  $\Delta$  is the maximum degree of a vertex in the graph). Given a coloured graph, a Kempe change consists in considering two colours  $a$  and  $b$  and a vertex coloured  $a$ , then swapping colours  $a$  and  $b$  in the maximal  $(a, b)$ -coloured component containing the specified vertex. Here, we consider how to navigate from a colouring to another through a series of Kempe changes. When is it possible? How fast? A seminal conjecture of Vizing from 1965 [8] states that in any graph, from any edge-colouring we can reach an optimal one through a well-chosen series of Kempe changes. While this remained a major challenge for decades, being only proved for graphs with maximum degree 3 or 4 [5, 2], then last year for triangle-free graphs [3], Narboni recently provided a full proof of the conjecture [6]. This notably implies that given at least one more colour than the optimal number, one can navigate from any edge-colouring to any other. The extra colour is necessary. How these results extend to the context of multigraphs remains widely open.

We will also discuss the number of steps necessary to navigate from any vertex-colouring of a  $k$ -degenerate graph to any other, when the number of colours is sufficiently large compared to the degeneracy, as well as the Kempe equivalent of Hadwiger’s conjecture and whether Kempe changes can be useful in the context of graphs with a forbidden minor. If time permits, we will see how this tool can be used for efficient sampling of random colourings of a graph and for counting the number of distinct colourings.

## 1 Extended Abstract

We begin with an introduction to online algorithms with predictions, where the online algorithm is given additional information, some predictions, which should, presumably, improve its performance. The seminal papers in this area, by Lykouris and Vassilvitskii [9, 10] and Purohit, Svitkina and Kumar [11], appeared at conferences in 2018 and have since inspired many other researchers to work in this area. A current list of related publications can be found on a dedicated website [1], which listed 145 articles as of July 10, 2023.

Online algorithms are those that as input receive a sequence of requests, each of which must be handled by the algorithm making an irrevocable decision, before the next request arrives. The research area, online algorithms with predictions, is related to an older line of research within online algorithms, advice complexity [5, 7, 4, 6], where the online algorithm is given “advice” which is assumed to be correct. In contrast, in the area of online algorithms with predictions, the predictions given to these online algorithms may come from machine learning and generally contain errors. In both of these models, the online algorithm receives extra information and the performance of an algorithm is measured using the competitive ratio (asymptotically, the worst-case ratio over all possible input sequences of the cost obtained by the algorithm compared to the cost of OPT, the optimal offline algorithm, on the same input). In advice complexity, the goal is to achieve a good competitive ratio with as few bits of advice as possible. In contrast, the goal in online algorithms with predictions is to achieve a good competitive ratio, despite errors in the predictions.

The amount of error in the predictions,  $\hat{p}$ , for an input sequence  $I$  with correct values,  $p$ , is given by some error measure,  $\eta(I, \hat{p}, p)$ . This is typically normalized as  $\eta(I, \hat{p}, p) / \text{OPT}(I)$ , where  $\text{OPT}(I)$  is the cost achieved by an optimal offline algorithm on input sequence  $I$ . An online algorithm with predictions should have a competitive ratio that degrades gracefully with increasing error (smoothness), performing near optimally if there is no error (consistency), but not performing too poorly, even if the predictions are terrible (robustness).

Results for two different minimization problems are presented, demonstrating

- the relevance of advice complexity for the paging problem with predictions [2] and
- the relevance of random order analysis [8] for a problem where, according to competitive analysis, no algorithm can be better than the trivial Follow-the-Predictions algorithm [3].

# Modern Parallel Algorithms

Artur Czumaj   

University of Warwick, Coventry, UK

---

## Abstract

---

Recent advances in the design of efficient parallel algorithms have been largely focusing on the nowadays classical model of parallel computing called *Massive Parallel Computation (MPC)*, which follows the framework of MapReduce systems. In this talk we will survey recent advances in the design of algorithms for graph problems for the MPC model and will mention some interesting open questions in this area.

## 1 Overview

Many modern computer applications require performing computations on massive amounts of data. Traditional models of computation, such as the RAM model or shared-memory parallel systems, are often inadequate for such computations, as the input do not fit into the available memory of even most advanced modern systems. The restrictions imposed by the limited memory in the available architectures and the requirement of fast processing of data has naturally led to the development of new models of parallel and distributed computation that are more suitable for processing massive amounts of data. On the basis of the successes of such massively parallel computation frameworks, such as MapReduce, Hadoop, Dryad, or Spark, Karloff, Suri, and Vassilvitskii (SODA 2010) introduced the *Massive Parallel Computation (MPC) model* that provides a clean abstraction of these frameworks and captures the modern needs of computation at a massive scale. After some later refinements, the MPC model has become the standard theoretical model of algorithmic study. At a very high-level, an MPC system consists of a collection of machines that can communicate with each other through indirect communication channels. The computation proceeds in synchronous rounds, where at each round the machines receive messages from other machines, perform arbitrarily complex local computations, and finally send appropriate messages to other machines so that the next round can start. The crucial factors in the analysis of algorithms in the MPC model are the number of rounds and the capacity of individual machines.

In the MPC model, there are  $m$  machines and each of them has  $s$  words of local space at its disposal. Initially, each machine receives its share of the input. For example, in the context of graph problems where the input is a collection  $V$  of nodes and  $E$  of edges, the input is arbitrarily distributed among the machines (and so  $s \cdot m \geq |V| + |E|$ ). The computation proceeds in synchronous *rounds* in which each machine processes its local data and performs an arbitrary complex local computation on its data. At the end of each round, machines exchange messages. Each message is sent only to a single machine specified by the machine

## 3:2 Modern Parallel Algorithms

that is sending the message. All messages sent and received by each machine in each round, as well as the output have to fit into the machine's local space  $\mathfrak{s}$  (in particular, in a single round, any machine can send at most  $\mathfrak{s}$  messages and be the recipient of at most  $\mathfrak{s}$  messages).

It has been quickly observed that the central parameter of the MPC is its local space  $\mathfrak{s}$ . While originally the main research has been frequently focused on the case when  $\mathfrak{s}$  is almost as large as the input size, most recent study has been concentrated on the *low-space regime* when  $\mathfrak{s} = N^\phi$  for some  $\phi \in (0, 1)$ , often  $\phi$  being arbitrarily small.

The talk will survey this topic, focusing on graph problems for the low-space regime. We will discuss recent advances in the design of algorithms for graph problems for the MPC model for fundamental problems like connectivity and matching. We will also study the relation between the MPC model and some other fundamental models of parallel and distributing computations, including the classical PRAM model and the distributed LOCAL and Congested Clique models. We will also list some interesting open questions in this area.

# Algebraic Reasoning for (Un)Solvable Loops

Laura Kovács  

TU Wien, Austria

---

## Abstract

---

Loop invariants describe valid program properties that hold before and after every loop iteration. As such, loop invariants are the workhorses in formalizing loop semantics and automating the formal analysis and verification of programs with loops.

While automatically synthesizing loop invariants is, in general, an uncomputable problem, when considering only single-path loops with linear updates (linear loops), the strongest polynomial invariant is in fact computable [5, 9, 6, 3]. Yet, already for loops with “only” polynomial updates, computing the strongest invariant has been an open challenge since 2004 [8].

In this invited talk, we first present computability results on polynomial invariant synthesis for restricted polynomial loops, called *solvable* loops [11]. Key to solvable loops is that one can automatically compute invariants from closed-form solutions of algebraic recurrence equations that model the loop behaviour [6, 4]. We also establish a technique for invariant synthesis for classes of loops that are not solvable, termed *unsolvable* loops [1].

We next study the limits of computability in deriving the (strongest) polynomial invariants for *arbitrary* polynomial loops. We prove that computing the strongest polynomial invariant of arbitrary, single-path polynomial loops is very hard [10] – namely, it is at least as hard as the Skolem problem [2, 12], a prominent algebraic problem in the theory of linear recurrences. Going beyond single-path loops, we show that the strongest polynomial invariant is uncomputable already for multi-path polynomial loops with arbitrary quadratic polynomial updates [7].

## Abstract

Graphs are fundamental tools for modelling relations among objects in various scientific fields. However, traditional static graphs have limitations when it comes to capturing the dynamic nature of real-world systems. To overcome this limitation, *temporal graphs* have been introduced as a framework to model graphs that change over time. In temporal graphs the edges among vertices appear and disappear at specific time steps, reflecting the temporal dynamics of the observed system, which allows us to analyse time dependent patterns and processes. In this paper we focus on the research related to *sliding time windows* in temporal graphs. Sliding time windows offer a way to analyse specific time intervals within the lifespan of a temporal graph. By sliding the window along the timeline, we can examine the graph's characteristics and properties within different time periods.

This paper provides an overview of the research on sliding time windows in temporal graphs. Although progress has been made in this field, there are still many interesting questions and challenges to be explored. We discuss some of the open problems and highlight their potential for future research.

## 1 Introduction

Graphs are used to model (binary) relations among different objects. They consist of a set of vertices, where two of them are connected together with an edge. They have become a fundamental tool for modelling diverse systems and real-world problems, steaming through the wide range of scientific fields. Let us mention just a few of them. In Social sciences they can be used to model different interactions among people (for example friendships, communications, etc.), in Chemistry they can model chemical compounds where the vertices represent different atoms of the compound and edges correspond to the chemical bonds among them, in molecular Biology they can model physical interactions between proteins, gene co-expression or biochemical reactions, in Physics they model interactions among particles, where nodes represent interactions where particles are created or destroyed and edges are particles traveling between the interactions. Having such a varied application and use, it is not surprising that the graph theory has been the subject of extensive research over the past centuries.

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

When studying real-life problems, it becomes evident that this ‘simple’ graph model is often insufficient. Many problems exhibit dynamic behavior, where the connections or interactions among their vertices change over time. For instance, in transportation networks, specific roads may be closed during certain intervals. In social networks, individuals may only interact at particular times of the day or month. Similarly, in information and communication networks, information or messages are transmitted from a source to a recipient through a set of connections at specific times. These graph models share a common attribute: their underlying graph topology or network structure undergoes discrete changes over time. This observation naturally gives rise to the concept of temporal graphs, which provide a straightforward and intuitive model for representing graphs that change over time, called *temporal graphs*.

► **Definition 1** (temporal graph [24]). *A temporal graph  $\mathcal{G}$  is a pair  $(G, \lambda)$ , where  $G = (V, E)$  is an underlying (static) graph and  $\lambda : E \rightarrow 2^{\mathbb{N}}$  is a time labeling function which assigns to every edge of  $G$  a set of discrete time labels.*

Due to their relevance and applicability in many areas, temporal graphs have been studied from various perspectives and under different names such as *dynamic* [9,19], *evolving* [7,12,16], *time-varying* [1,17,36], and *graphs over time* [27].

In most applications of temporal graphs, information can naturally only move along edges in a way that respects the ordering of their timestamps (i.e. time labels), that is, information can only flow along sequences of edges whose time labels are increasing (or non-decreasing). Motivated by this fact, most studies on temporal graphs have focused on “path-related” problems, such as e.g. temporal analogues of distance, diameter, reachability, exploration, and centrality [2,3,10,14,15,22,25,26,30,34,40]. In these problems, the most fundamental notion is that of a *temporal path* from a vertex  $u$  to a vertex  $v$ , which is a path from  $u$  to  $v$  such that the time labels of the edges are increasing (or at least non-decreasing) in the direction from  $u$  to  $v$ . To complement this direction, several attempts have been recently made to define meaningful “non-path” temporal graph problems which appropriately model specific applications. Some examples include temporal cliques, cluster editing, temporal vertex cover, temporal graph coloring, temporally transitive orientations of temporal graphs [4,6,11,18,21,23,32,33,37,39].

One of the main goals in temporal graphs’ research is to lift (algorithmic) graph theory models and results to a temporal/dynamic domain, in order to model natural, real world situations which are subject to discrete changes over time. The main challenge in this front is to find appropriate natural extensions and definitions of such problems. For instance, in static graphs, a *shortest path* between two vertices is a path connecting these two vertices with the smallest number of edges. On the other hand, in temporal graphs, there are at least three, equally natural, different analogues of a shortest path. First, a *shortest* temporal path from  $u$  to  $v$  is one that contains the smallest number of edges. Second, a *foremost* temporal path from  $u$  to  $v$  is one that arrives at  $v$  with the smallest time-stamp. Third, a *fastest* temporal path from  $u$  to  $v$  is one that has the smallest duration. These three types of temporal paths are illustrated in Figure 1.

What is common to most of the path-related problems is that their extension from static to temporal graphs often follows easily and quite naturally from their static counterparts. For example, requiring a graph to be (temporally) connected results in requiring the existence of a (temporal) path among each pair of vertices. In the case of non-path related problems, the exact definition and its application is not so straightforward. Let us consider the case of cliques. Defining cliques in a temporal graph as the set of vertices that interact at least once in the lifetime of the graph would be a bit counter intuitive, as two vertices may just interact

■ **Figure 1** In this temporal graph, the shortest path from  $s$  to  $t$  is  $(s, c, t)$  as it contains two edges; the foremost temporal path is  $(s, a, b, t)$  as it arrives at time 5; the fastest temporal path is  $(s, d, e, t)$  as it has duration  $9 - 7 + 1 = 3$ .

at the first time step and never again. To help with this problem, Viard et al. [37] introduced the idea of the *sliding time window* of some size  $\Delta$ , where they define a temporal clique as a set of vertices where in all  $\Delta$  consecutive time steps each pair of vertices interacts at least once. There is a natural motivation for this problem, namely to be able to find the contact patterns among high-school students. Following the idea of Viard et al. [37], many other problems on temporal graph were defined using sliding time windows. In this paper we present an overview of works on sliding windows in temporal graphs and at the end provide some open problems and further ideas with potential research topics.

## 2 Preliminaries and Notations

In the literature there are many (slightly) different notations and terminologies used for certain structures in temporal graph. For the purpose of this paper, we fix the following notation and definitions.

Given a (static) graph  $G = (V, E)$  with vertices in  $V$  and edges in  $E$ , an edge between two vertices  $u$  and  $v$  is denoted by  $uv$ , and in this case  $u$  and  $v$  are said to be *adjacent* in  $G$ . For every  $i, j \in \mathbb{N}$ , where  $i \leq j$ , we let  $[i, j] = \{i, i + 1, \dots, j\}$  and  $[j] = [1, j]$ . Throughout the paper we consider temporal graphs whose underlying graphs are finite and whose time labeling functions only map to finite sets. This implies that there is some  $t \in \mathbb{N}$  such that, for every  $t' > t$ , no edge of  $G$  is active at  $t'$  in  $(G, \lambda)$ . We denote the smallest such  $t$  by  $T$ , i.e.,  $T = \max\{t \in \lambda(e) \mid e \in E\}$ , and call  $T$  the *lifetime* of  $(G, \lambda)$ . Unless otherwise specified,  $n$  denotes the number of vertices in the underlying graph  $G$ , and  $T$  denotes the lifetime of the temporal graph  $\mathcal{G}$ . We refer to each integer  $t \in [T]$  as a *time step* of  $(G, \lambda)$ . The *instance* (or *snapshot*) of  $(G, \lambda)$  at time  $t$  is the static graph  $G_t = (V, E_t)$ , where  $E_t = \{e \in E : t \in \lambda(e)\}$ . Note that the *size* of a temporal graph  $\mathcal{G}$  is  $|\mathcal{G}| := |V| + \sum_{t=1}^T |E_t|$ .

For every  $t = 1, \dots, T - \Delta + 1$ , let  $W_t = [t, t + \Delta - 1]$  be the  $\Delta$ -*time window* that starts at time  $t$ . For every  $v \in V$  and every time step  $t$ , we denote the *appearance of vertex  $v$  at time  $t$*  by the pair  $(v, t)$  and the *edge appearance* (or *time-edge*) of  $e$  at time  $t$  by  $(e, t)$ . For  $t \in \lambda(e)$  we also say that  $e$  is *active* at time  $t$  in  $(G, \lambda)$ . That is, for every edge  $e \in E$ ,  $\lambda(e)$  denotes the set of time steps at which  $e$  is *active*.

A *temporal vertex subset* of  $(G, \lambda)$  is a set of vertex appearances in  $(G, \lambda)$ , i.e. a set of the form  $S \subseteq \{(v, t) \mid v \in V, t \in [T]\}$ . For a temporal vertex subset  $S$  and some  $\Delta$ -time window  $W_i$  within the lifetime  $T$  of  $(G, \lambda)$ , we denote by  $S[W_i] = \{(v, t) \in S \mid t \in W_i\}$  the subset of all vertex appearances in  $S$  in the  $\Delta$ -time window  $W_i$ . For a  $\Delta$ -time window  $W_i$  within the lifetime of a temporal graph  $(G, \lambda)$ , we denote by  $E[W_i] = \{e \in E \mid \lambda(e) \cap W_i \neq \emptyset\}$  the set of all edges which appear at some time step within  $W_i$ .

### 3 Known Results on Sliding Windows

In this section we present some of the known results on temporal graphs using sliding windows. As we discussed, the aim is to find a suitable definition for well motivated graph problems, that take in consideration also the changes that appear over time.

#### 3.1 Temporal Cliques

In a (static) graph  $G = (V, E)$ , a clique  $C \subseteq V$  is a collection of vertices, where every two of them are connected. We say that a clique  $C$  is maximal, if there exists no other vertex in  $V \setminus C$  that is connected to all of the vertices in  $C$ . There are many applications of (maximal) cliques for modeling real-world problems. For example, in their work Creamer et al. [13] calculate hierarchical structures in complex (communication) networks using cliques, and in [35] Samudrala and Moulton use cliques in the context of protein structure modeling.

Viard et al. [37] extended the notion of cliques to temporal graphs. Their work was motivated by the contact patterns among French high-school students. They studied the dataset with real-world contacts between individuals, captured with sensors. Where an edge  $e$  at time  $t$  was formed between two subjects if they were close enough to each other at time  $t$  for the detection to happen. The aim is to determine groups of students that were interacting more often. The obstacle in this case is how to naturally define such groups. If two students interacted only once and then never again, their interaction should not be considered as “valuable” as in the case when students interact more often, over certain period of time. With this in mind, the authors present the following natural definition of a  $\Delta$ -clique.

► **Definition 2.** *A  $\Delta$ -clique  $C$  in a temporal graph  $\mathcal{G} = (G, \lambda)$  with a life-time  $T$ , is a pair  $(X, I)$ , where  $X$  is a subset of vertices of  $G$  and  $I \subseteq [T]$ , such that for every two vertices  $u, v \in X$  there is a time-edge  $(uv, t)$  in  $\mathcal{G}$  in every  $\Delta$ -time window  $W_i \in I$ .*

Intuitively, among each pair of vertices in  $X$  there is a time-edge every  $\Delta$  time steps in the time interval  $I$ . The significance of the parameter  $\Delta$  is that it measures the level of interaction in  $\Delta$ -cliques. A small value of  $\Delta$  means that the interaction among vertices has to occur more often compared to the case of large  $\Delta$  values. The selection of  $\Delta$  depends on the data set and the purpose of the analysis.

The authors provide an algorithm that in  $O(2^n n^2 \bar{m}^3 + 2^n n^3 \bar{m}^2)$  time computes all maximal  $\Delta$ -cliques of a temporal graph  $(G, \lambda)$ , where  $n = V(G)$  and  $\bar{m} = \sum_{e \in E(G)} \lambda(e)$ . This result was further improved by Himmel et. al. [23] by providing an adaptation of the Bron-Kerbosch algorithm for enumerating maximal cliques, where they improve the running time to  $O(2^n T m)$ , where  $m = |E(G)|$ .

Cliques may not be always practical for modelling real-world situations as they can be too restrictive, for example some edges may not exist due to measurement errors or other reasons specific to the application. To overcome this issue, various relaxations of the clique concept have been developed. One popular approach is the use of  $k$ -plexes, a degree-based relaxation of cliques that requires every vertex to be connected to all but at most  $k - 1$  vertices in the  $k$ -plex, excluding itself. Extending this idea to temporal graphs, Bentert et al. [6] introduce the study of  $\Delta - k$ -plexes, where they relax the condition of  $\Delta$ -clique by allowing each vertex to have up to  $k - 1$  missing connections to other vertices in each  $\Delta$  consecutive time steps. They adapt the algorithm for  $\Delta$ -cliques to enumerate them, and provide some heuristic speed-up techniques that are useful when dealing with practical scenarios.

### 3.2 Temporal Vertex Cover

The vertex cover problem on a static graph  $G$  asks for a set of vertices  $S$  in  $V(G)$ , of a minimum size, such that each edge  $e \in E(G)$  has at least one endpoint in  $S$  (i. e., is covered by at least one vertex in the vertex cover). To extend the idea to temporal graphs one needs to first find a relevant and well motivated definition. For example, requiring that each edge is covered whenever it appears (i. e., there is a vertex cover in every snapshot of the temporal graph), may be a bit too restrictive. A well known motivation behind the vertex cover on static graphs is a problem of placing security guards throughout the airport, where corridors represent edges and two corridors meet in a vertex. Then a vertex cover is a collection of corridor intersections, where we place security guards such that the airport is fully observed by the security. Suppose now that during the day, for some reason, certain corridors are not in use (some gates may be open only during specific times). And suppose now also that a criminal needs a specific amount of time, without any supervision, to execute an illegal activity. Now, to prevent all such acts, we do not need to fully monitor each sector of the airport all the time, but we just have to make sure we check each part often enough. With this in mind, Akrida et al. [4] introduced the notion of sliding window temporal vertex cover.

► **Definition 3.** *A  $\Delta$ -sliding window temporal vertex cover  $S \subseteq V(G) \times [T]$  (or  $\Delta$ -TVC for short) in a temporal graph  $(G, \lambda)$ , with a lifetime  $T$ , is a collection of vertex appearances, such that each edge  $e \in E(G)$  is covered in every  $\Delta$ -time window  $W_i \subseteq [T]$ , if it appears.*

When determining  $\Delta$ -TVC of a given temporal graph, one wants to always find the one of minimum size. In their work Akrida et al. [4] first prove that a relaxed version of the problem (where  $\Delta = T$ , i. e., each edge has to be covered at least once in the whole lifetime  $T$  of the graph) is NP-hard already for the temporal graphs where the underlying graph is a star. For this sub-problem they prove also that the optimal solution cannot be obtained in  $O(2^{\epsilon T})$  time (for some small  $\epsilon$ ), assuming the Strong Exponential Time Hypothesis (SETH), as well as that it does not admit a Polynomial-Time Approximation Scheme (PTAS). For the general problem they provide an exact dynamic algorithm running in  $O(T\Delta(n+m) \cdot 2^{n\Delta(\Delta+1)})$  time on arbitrary temporal graphs, which cannot admit much more improvements (as it is almost at the lower complexity bound). They complement this result by providing an algorithm that, for graphs where each snapshot has a vertex cover number bounded by  $k$ , runs in an FPT time, when parameterized by  $\Delta$ . They investigate also the problem's approximability and prove that  $\Delta$ -TVC does not admit a PTAS, even when  $\Delta = 2$ , maximum degree of the underlying graph is 3 and every connected component of each snapshot is of size at most 7. In addition, they augment this result by providing approximation algorithms with ratios (i)  $\ln n + \ln \Delta + \frac{1}{2}$ , (ii)  $2k$ , where  $k$  is the maximum number of appearances of an edge in a sliding window, (iii)  $d$ , where  $d$  is the maximum vertex degree in every snapshot.

The study of  $\Delta$ -TVC problem was then further extended by Hamm et. al. [21]. The researchers studied the  $\Delta$ -sliding window vertex cover problem on sparse temporal graphs. They proved that the problem is NP-hard when  $\Delta \geq 2$  and the underlying graph  $G$  of the temporal graph  $(G, \lambda)$  is a path or a cycle. On the other hand, they developed a polynomial-time algorithm for solving  $T$ -TVC on paths and cycles, where  $T$  is the lifetime of the temporal graph. This raises the interesting question of whether there exists a boundary value for  $\Delta$  that distinguishes between the tractable and intractable categories on paths, thus determining the complete dichotomy of the problem. Moreover, for any  $\Delta \geq 2$  they augmented these results with a PTAS for  $\Delta$ -TVC on paths and cycles, which complements the hardness result. In addition, the authors presented three algorithms to counter the

hardness of the  $\Delta$ -TVC problem for arbitrary (non-restricted) temporal graphs. The first algorithm is an exact algorithm for  $\Delta$ -TVC with an exponential running time dependency on the number of edges in the underlying graph. Using this algorithm, they developed a polynomial-time  $(d - 1)$ -approximation algorithm for any  $d \geq 3$ , where  $d$  is the maximum vertex degree in any time step (which improved on  $d$ -approximation algorithm from Akrida et al.). Finally, the authors presented a simple fixed-parameter tractable algorithm with respect to the size of an optimum solution.

### 3.3 Temporal Coloring

In a static graph  $G$  a coloring problem asks for a minimum number of colors associated to vertices, such that two endpoints of each edge are not assigned the same color. A classical motivation behind this problem is allocating radio frequencies to radio towers at specific locations. Here the idea is to allocate different frequencies to towers that are located close enough to cause an overlap in transmission. In this case each tower is represented as a node of the graph, where two of them are connected if the towers are positioned so close that they interfere with each other, and each frequency represents a different color. Now, coloring the graph properly results in an assignment of frequencies, that causes no interference.

Let us consider a bit more evolved scenario, where instead of static radio towers, we observe mobile agents. Here every agent broadcasts information over a specific communication channel while it listens on all others. Therefore, when two agents are in close proximity, they exchange information only if they broadcast on different channels. We assume that agents can switch channels at any time. To ensure maximum information exchange, it is essential to find a schedule of assigning broadcasting channels to the agents over time that minimizes the number of required channels. This should allow each pair of agents to communicate at least once within every small time window when they are close to each other.

Following this motivation Mertzios et al. [33] introduce the study of temporal coloring using sliding windows. Where one wants to determine the coloring of vertex appearances, using the smallest possible number of colors, such that each edge is properly colored (incident vertices are of different color) at least once in every  $\Delta$  consecutive time steps, if the edge appears. For a formal definition see the following.

► **Definition 4.** *A  $\Delta$ -sliding window temporal coloring (or  $\Delta$ -TC for short) in a temporal graph  $(G, \lambda)$ , with a lifetime  $T$ , is a function  $\phi : V(G) \times [T] \rightarrow \mathbb{N}$ , that assigns one color  $\phi(v, t)$  to each vertex appearance, such that for every  $\Delta$ -time window  $W_i \subseteq [T]$ , and every edge  $e \in E[W_i]$  there is at least one time step  $t \in W_i$ , where  $e$  appears and its two endpoints  $u, v$  are colored using different colors, i. e.,  $(e, t)$  is a time-edge in  $(G, \lambda)$  and  $\phi(u, t) \neq \phi(v, t)$ .*

Mertzios et al. [32] start by studying a subcase of the problem, when  $\Delta = T$ . In this case the objective is to ensure that each edge is properly colored (its endpoints are of different color) at least once in the whole life time  $T$  of the temporal graph. Surprisingly, even the restricted subcase turns out to be NP-hard, already when one is asking if 2 colors are enough to color it properly. This presents a stark contrast to the static case, where identifying if a graph is 2-colorable (bipartite) can be accomplished in linear time. On the positive side they show that this subcase admits a polynomial kernel, when parameterized by the number of vertices in the input temporal graph. For the general case they prove that the problem is NP-hard, and provide two algorithms for it. One is an exponential-time algorithm, that asymptotically matches the running time lower bound (assuming ETH), and the second one is a linear time FPT algorithm, with respect to the number  $n$  of vertices.

In addition to the above mentioned work, some other variations of coloring temporal graphs have been explored (e.g. example [18, 29, 39]), however these studies do not use the approach with sliding windows.

### 3.4 Temporal Matching

Given a static graph  $G$  the problem of (maximum) matching asks for a (maximum) set of pairwise independent edges, that is, edges that share no endpoints. This problem has numerous applications in fields such as scheduling and planning, chemistry modeling, job allocation, and more. Once the time-dimension is added to the graph model, there can be different ways to carry over the definition to temporal graphs.

Following the idea of a sliding time window, Mertzios et al. [31] introduced the problem of  $\Delta$ -MAXIMUM TEMPORAL MATCHING ( $\Delta$ -TM), where one wants to determine a maximum set of time-edges that are pairwise  $\Delta$ -independent. Two time-edges  $(e, t), (f, t')$  are  $\Delta$ -independent if (i)  $e \cap f = \emptyset$ , or (ii)  $e \cap f \neq \emptyset$  and  $|t - t'| \geq \Delta$ . In other words, for any feasible solution of  $\Delta$ -TM, it is not possible to match a vertex more than once within any time interval of duration  $\Delta$ . This condition can represent scenarios where a short “recovery” period is needed for every vertex that participates in the matching, such as a brief period of rest after engaging in an energy-demanding activity.

In contrast to the Edmonds’ polynomial-time algorithm for finding a maximum matching in static graphs, Mertzios et al. [31] prove that  $\Delta$ -TM does not even admit an approximation algorithm, meaning it is APX hard, already in the case when  $\Delta = 2$  and the lifetime  $T$  of the temporal graph is 3. In addition, they show that the problem remains NP-hard even if the underlying graph, of the input temporal graph, is just a path. On the positive side, they provide an approximation algorithm for any constant  $\Delta$ , which achieves an approximation ratio of  $\frac{1}{2} + \epsilon$ , where  $\epsilon = \frac{1}{2(2\Delta-1)}$ . Besides that, they show that a problem admits two FPT algorithms, one when it is parameterized by the solution size, and the second one, when it is parameterized by the combined parameter  $\Delta$  and the size of a maximum matching of the underlying graph.

It is worth mentioning that another related variant of MAXIMUM TEMPORAL MATCHING has been studied (see Baste et al. [5]). In this model the authors do not use the  $\Delta$ -time windows, but instead require an edge to appear at least  $\Delta$  consecutive time steps, in order to be eligible for a matching. A temporal matching then consists of independent edge time-blocks of length at least  $\Delta$ .

## 4 Further Work

In the previous section we presented some already completed works on temporal graphs, that use the idea of sliding time windows. In this section we focus on problems that, to the best of our knowledge, have not yet been investigated using the sliding windows, and give rise to some interesting research questions.

### 4.1 Dominating Set

In a static graph  $G$ , a dominating set is a subset of vertices  $D \subseteq V(G)$ , such that each vertex  $V(G)$  is either in  $D$  or has a neighbor in  $D$ . The *Dominating set problem* asks for a dominating set of  $G$  of minimum size. One of the applications of the dominating set is in routing protocols for ad hoc wireless networks. The fundamental concept behind this approach involves identifying a dominating set within a network of devices and using these

dominating nodes for message routing. More specifically, when a user  $u$  wants to transmit a message to a user  $v$ , the routing process consists of determining the shortest path between the dominating neighbors of user  $u$  and user  $v$ . By ensuring that all devices admit at least one dominating neighbor, this method guarantees the delivery of messages.

In the world where these agents become mobile (i. e., they travel around the space), one can model this problem using temporal graph, where the aim is to find a *temporal dominating set*. Similarly as in other cases, we do not necessarily want to find a dominating set in every time step (as this would be too costly), therefore an approach with sliding time windows would be of use. We propose the following definition.

► **Definition 5.** A  $\Delta$ -sliding window temporal dominating set ( $\Delta$ -SWDS) is a subset of vertex appearances  $D \subseteq V(G) \times [T]$ , of a temporal graph  $(G, \lambda)$ , with the lifetime  $T$ , such that for any vertex appearance  $(v, t)$  the following holds:

1.  $(v, t') \in D$ , where  $|t - t'| \leq \Delta$  or
2.  $(u, t') \in D$ , where  $u$  is a neighbor of  $v$  in  $G$  and  $|t - t'| \leq \Delta$ .

Intuitively, any vertex of the underlying temporal graph is at any time step  $t$  either at most  $\Delta$  time-units away from being in  $D$ , or it has a neighbor that is at most  $\Delta$  time-units away from being in  $D$ . Since the Dominating set problem is already NP-hard on static graphs, it remains hard also for temporal graphs. So the interesting research question for the  $\Delta$ -SWDS would be if there exist any exact algorithms for it, i. e., some FPT algorithms, or maybe some approximation algorithms.

It is important to mention that there already exist some variations of the dominating set problems on temporal graphs. Casteigts and Flocchini [8] propose three different definitions of dominating sets on temporal graphs, namely temporal dominating set, evolving dominating set and permanent dominating set. In the temporal and evolving dominating set, one wants to determine the smallest set of vertices  $D$ , such that, in the temporal case, each vertex is dominated in at least one time step, and in the evolving case, each vertex is dominated in every time step. While the evolving dominating set  $D$  consists of vertex appearances, such that all vertex appearances are dominated in each time step. More specifically, in the first two cases, once a vertex is selected to be in  $D$  it is in  $D$  for all lifetime of the graph, while in the last case one vertex can be in  $D$  only at specific times. Some research has been done for aforementioned problems. For interested readers, we recommend exploring the following works [20, 28, 38], among others.

## 4.2 Edge Cover

The *minimum edge covering problem* on a static graph  $G$  asks for a minimum set  $E_C \subseteq E(G)$  of edges such that every vertex in  $V(G)$  is incident to at least one edge in  $E_C$ . Calculating a minimum edge cover can be done in polynomial time, by finding a maximum matching and then extending it greedily until all vertices are covered.

For the version of the edge covering problem on temporal graphs we propose the following definition.

► **Definition 6.** A  $\Delta$ -sliding window temporal edge covering ( $\Delta$ -SWECC) is a subset of edge appearances  $EC \subseteq E(G) \times [T]$ , of a temporal graph  $(G, \lambda)$ , with the lifetime  $T$ , such that every vertex appearance  $(v, t)$  is incident to at least one time-edge from the selected set  $EC \subseteq E \times T$ , in every time window  $t \in W_t$ .

Since many problems become significantly more challenging when dealing with temporal graphs, it would be really interesting to explore whether the same holds true for the  $\Delta$ -SWECC problem. Applying the exact approach used for static graphs may not yield direct results, as

it requires to first find a (suitable definition of a) temporal maximum matching. It is worth noting that in Section 3.4 we presented a  $\Delta$ -MAXIMUM TEMPORAL MATCHING, which turns out to be NP-hard.

### 4.3 Periodic connectivity

We say that a temporal graph  $(G, \lambda)$  is *temporally connected* if there exists a temporal path among each pair of vertices. Some results regarding the connectivity of temporal graphs have already been established, for example [3, 26, 30]. However, what if we introduce additional constraints and require that each vertex can reach any other vertex within every  $\Delta$  time-window? In such cases, we refer to the temporal graph  $(G, \lambda)$  as being  $\Delta$ -*temporally connected*. It would be interesting to study, for example, what is the minimum number of labels needed to label a given graph  $G$  in such a way that ensures  $\Delta$ -temporal connectivity of  $(G, \lambda)$ ? We can further restrict this problem by allowing only limited number  $k$  of labels to be added per each edge.

### 4.4 (Temporal) Graph Classes

Based on the properties of the studied graphs, we can assign them into different graph classes. For instance there are graphs that are  $k$ -colorable (can be properly colored using  $k$  colors),  $k$ -regular (each vertex is of degree  $k$ ), or planar (can be drawn on a plane without any edges crossing), among others.

To extend the concept of graph classes to the temporal setting with sliding windows, we propose introducing temporal graph classes. One such class could be the  $\Delta$  *sliding window  $k$ -colorable temporal graphs*, which refers to temporal graphs that can be temporally colored using  $k$  colors. Another class would be the  $\Delta$  *sliding window  $k$ -regular temporal graphs*, where each vertex admits exactly  $k$  different neighbors in every  $\Delta$  time-window, or perhaps each vertex  $v$  admits exactly  $k$  different neighbors in a time step  $t' \in W_t$  for every time window  $W_t$ . Similarly, we can define  $\Delta$  *sliding window planar temporal graphs* as temporal graphs that are planar in some  $t' \in W_t$  for every time-window  $W_t$ . Further refinement of these classes is possible by imposing additional restrictions. For example, we can consider temporal graphs that are *3-colorable in every 5-time window*. In such graphs, every vertex appearance  $(v, t')$  is assigned one of three colors, ensuring that within each sliding window  $W_t$  of size 5, there is at least one time step where the edge  $e$ , that appears in  $W_t$  is properly colored.

Overall, these extensions allow for the classification of temporal graphs based on their temporal characteristics, enabling the exploration of various graph classes in the context of sliding windows.

## 5 Conclusion

The study of temporal graphs has emerged as an important area of research with significant implications for understanding and analyzing dynamic systems. In this paper, we have presented a short overview of the works on sliding windows in temporal graphs. The concept of a sliding time window allows us to focus on specific temporal intervals within the lifetime of a temporal graph, providing valuable insights into the changing behavior and patterns of interactions. Given that this research field is fairly young, there are still many intriguing questions and challenges to be addressed. We presented some of them here and hope that this work inspires further exploration and investigation into these intriguing problems.

## Abstract

---

The concept of Roman domination has recently been studied concerning enumerating and counting in F. N. Abu-Khzam et al. (WG 2022). More technically speaking, a function that assigns 0, 1, 2 to the vertices of an undirected graph is called a *Roman dominating function* if each vertex assigned zero has a neighbor assigned two. Such a function is called *minimal* if decreasing any assignment to any vertex would yield a function that is no longer a Roman dominating function. It has been shown that minimal Roman dominating functions can be enumerated with polynomial delay, i.e., between any two outputs of a solution, no more than polynomial time will elapse. This contrasts what is known about minimal dominating sets, where the question whether or not these can be enumerated with polynomial delay is open for more than 40 years. This makes the concept of Roman domination rather special and interesting among the many variants of domination problems studied in the literature, as it has been shown for several of these variants that the question of enumerating minimal solutions is tightly linked to that of enumerating minimal dominating sets, see M. Kanté et al. in SIAM J. Disc. Math., 2014. The running time of the mentioned enumeration algorithm for minimal Roman dominating functions (Abu-Khzam et al., WG 2022) could be estimated as  $\mathcal{O}(1.9332^n)$  on general graphs of order  $n$ . Here, we focus on special graph classes, as has been also done for enumerating minimal dominating sets before. More specifically, for chordal graphs, we present an enumeration algorithm running in time  $\mathcal{O}(1.8940^n)$ . It is unknown if this gives a tight bound on the maximum number of minimal Roman dominating functions in chordal graphs. For interval graphs, we can lower this time bound further to  $\mathcal{O}(1.7321^n)$ , which also matches the known lower bound concerning the maximum number of minimal Roman dominating functions. We can also provide a matching lower and upper bound for forests, which is (incidentally) the same, namely  $\mathcal{O}^*(\sqrt{3}^n)$ . Furthermore, we present an optimal enumeration algorithm running in time  $\mathcal{O}^*(\sqrt[3]{3}^n)$  for split graphs and for cobipartite graphs, i.e., we can also give a matching lower bound example for these graph classes. Hence, our enumeration algorithms for interval graphs, forests, split graphs and cobipartite graphs are all optimal. The importance of our results stems from the fact that, for other types of domination problems, optimal enumeration algorithms are not always found.

Interestingly, we use a different form of analysis for the running times of our different algorithms, and the branchings had to be tailored and tweaked to obtain the intended optimality results. Our Roman dominating functions enumeration algorithm for trees and forests is distinctively different from the one for minimal dominating sets by Rote (SODA 2019). Our approach also allows to give concrete formulas for counting minimal Roman dominating functions on more concrete graph families like paths.

## 1 Introduction

ROMAN DOMINATION comes with a nice (hi)story, on how to position armies on the various regions to secure the Roman Empire with the smallest cost, measured in the number of armies. “To secure” means that either (1) a region  $r$  has at least one army or (2) a region  $r'$  neighboring  $r$  contains two armies, so that it can afford sending one army to the region  $r$  without diminishing  $r'$ 's self-defense capabilities.

It is easy to view ROMAN DOMINATION as a graph-theoretic problem, where the map is modeled as a graph. ROMAN DOMINATION has received notable attention in the last two decades [7, 17, 23, 26, 40, 41, 44, 48, 49, 51]. Relevant to our work is the development of exact algorithms: ROMAN DOMINATION can be solved in  $\mathcal{O}(1.5014^n)$  time (and space), see [40, 52, 54]. More combinatorial studies can be found in [16, 18, 25, 35, 39, 42, 43, 47, 55, 56, 57] as well as in the more recent chapter on Roman domination of [34]. Although independently introduced in [46], the *differential* of a graph is tightly related, see also [1, 8, 9, 10]. To briefly summarize all these findings, in many ways concerning complexity, ROMAN DOMINATION and DOMINATING SET behave exactly the same. There are two notable and related exceptions, as delineated in [2], concerning *extension problems* and *output-sensitive enumeration*.

*Extension problems* often arise from search-tree algorithms for their optimization counterpart as follows. Assume that a search-tree node corresponds to a partial solution (or pre-solution)  $U$  and instead of proceeding with the search-tree algorithm (by exploring all the possible paths from this node onward) we ask whether we can extend  $U$  to a meaningful solution  $S$ . In the case of DOMINATING SET, this means that  $S$  is an inclusion-wise minimal dominating set that contains  $U$ . Unfortunately, this EXTENSION DOMINATING SET problem and many similar problems are NP-hard, see [6, 12, 14, 15, 37, 38, 45]. Even worse: when parameterized by the “pre-solution size,” EXTENSION DOMINATING SET is one of the few problems known to be complete for the parameterized complexity class  $W[3]$ , as shown in [11]. This blocks any progress on the HITTING SET TRANSVERSAL PROBLEM by using extension test algorithms, which is the question whether all minimal hitting sets of a hypergraph can be enumerated with polynomial delay (or even output-polynomial) only. This question is open for four decades by now and is equivalent to several enumeration problems in logic, database theory and also to enumerating minimal dominating sets in graphs, see [22, 24, 29, 36].

By way of contrast and quite surprisingly, with an appropriate definition of the notion of minimality, the extension variant of ROMAN DOMINATION is solvable in polynomial time [3]. This was the key observation to show that enumerating all minimal Roman dominating functions is possible with polynomial delay. This triggered further interest in looking into enumerating minimal Roman dominating functions on graph classes, as also done in the case of DOMINATING SET, see [5, 20, 21, 30, 32, 33]. The basis of the output-sensitive enumeration result of [2] was several combinatorial observations. Here, we find ways how to use the underlying combinatorial ideas for non-trivial enumeration algorithms for minimal Roman dominating functions in split graphs, cobipartite graphs, interval graphs, forests and chordal graphs and for counting these exactly for paths. All these graph classes will be explained in separate sections below. These exploits constitute the main results of this paper. More details can be found at the end of the next section. Due to lack of space, further technical details can be found in [4]. We summarize known bases of lower and upper bounds on the number of minimal (Roman) dominating sets (resp. functions) in the next table; new results are shown with boxes; for matching bounds, only one number is displayed; c.f. [2, 21, 27, 33]. Polynomial delay is achievable for the mentioned special graph classes for enumerating minimal dominating sets [36, 38], but it is unclear how to combine these

approaches with good input-sensitive enumeration, while all input-sensitive results concerning minimal Roman dominating functions can also be implemented with polynomial delay, by interleaving extension tests with branching.

graph class:	general	chordal	split	interval	forests	cobipartite
domination	1.5704 / 1.7159	$\sqrt[3]{3} / 1.5048$	$\sqrt[3]{3}$	$\sqrt[3]{3}$	$\sqrt[13]{95}$	1.3195 / 1.3674
Roman dom.	1.7441 / 1.9332	$\sqrt{3} / 1.8940$	$\sqrt[3]{3}$	$\sqrt{3}$	$\sqrt{3}$	$\sqrt[3]{3}$

## 2 Definitions and Known Results

Let  $\mathbb{N} = \{1, 2, 3, \dots\}$  be the set of positive integers. For  $n \in \mathbb{N}$ , let  $[n] = \{m \in \mathbb{N} \mid m \leq n\}$ . We only consider undirected simple graphs. Let  $G = (V, E)$  be a graph. For  $U \subseteq V$ ,  $G[U]$  denotes the graph induced by  $U$ . For  $v \in V$ ,  $N_G(v) := \{u \in V \mid \{u, v\} \in E\}$  denotes the *open neighborhood* of  $v$ , while  $N_G[v] := N_G(v) \cup \{v\}$  is the *closed neighborhood* of  $v$ .  $|N_G(v)|$  is called the *degree* of  $v$ ; a vertex of degree 1 is known as a *leaf*. We extend such set-valued functions  $X : V \rightarrow 2^V$  to  $X : 2^V \rightarrow 2^V$  by setting  $X(U) = \bigcup_{u \in U} X(u)$ . Subset  $D \subseteq V$  is a *dominating set*, or ds for short, if  $N_G[D] = V$ . For  $D \subseteq V$  and  $v \in D$ , define the *private neighborhood* of  $v \in V$  with respect to  $D$  as  $P_{G,D}(v) := N_G[v] \setminus N_G[D \setminus \{v\}]$ . A function  $f : V \rightarrow \{0, 1, 2\}$  is called a *Roman dominating function*, or rdf for short, if for each  $v \in V$  with  $f(v) = 0$ , there exists a  $u \in N_G(v)$  with  $f(u) = 2$ . Simplifying notation, we set  $V_i(f) := \{v \in V \mid f(v) = i\}$  for  $i \in \{0, 1, 2\}$ . The *weight*  $w_f$  of a function  $f : V \rightarrow \{0, 1, 2\}$  equals  $|V_1| + 2|V_2|$ . The ROMAN DOMINATION problem asks, given  $G$  and an integer  $k$ , if there exists an rdf of weight at most  $k$ . Connecting to the original motivation,  $G$  models a map of regions, and if the region vertex  $v$  belongs to  $V_i$ , then we place  $i$  armies on  $v$ .

For defining the problem EXTENSION ROMAN DOMINATION, we first need to define the order  $\leq$  on  $\{0, 1, 2\}^V$ : for  $f, g \in \{0, 1, 2\}^V$ , let  $f \leq g$  if and only if  $f(v) \leq g(v)$  for all  $v \in V$ . Thus, we extend the usual linear ordering  $\leq$  on  $\{0, 1, 2\}$  to functions mapping to  $\{0, 1, 2\}$  in a pointwise manner. We call a function  $f \in \{0, 1, 2\}^V$  a *minimal Roman dominating function* if and only if  $f$  is an rdf and there exists no rdf  $g$ ,  $g \neq f$ , with  $g \leq f$ . The weights of minimal rdFs can vary considerably. Consider for example a star  $K_{1,n}$  with center  $c$ . Then,  $f_1(c) = 2$ ,  $f_1(v) = 0$  otherwise;  $f_2(v) = 1$  for all vertices  $v$ ;  $f_3(c) = 0$ ,  $f_3(u) = 2$  for one  $u \neq c$ ,  $f_3(v) = 1$  otherwise, define three minimal rdFs with weights  $w_{f_1} = 2$ , and  $w_{f_2} = w_{f_3} = n + 1$ .

In [2], several combinatorial properties of minimal Roman dominating functions were derived that were central for obtaining a general algorithmic enumeration result and that are also important when studying special graph classes. This is summarized as follows.

► **Theorem 2.1.** *Let  $G = (V, E)$  be a graph,  $f : V \rightarrow \{0, 1, 2\}$  and abbreviate  $G' := G[V_0(f) \cup V_2(f)]$ . Then,  $f$  is a minimal rdf if and only if the following conditions hold:*

1.  $N_G[V_2(f)] \cap V_1(f) = \emptyset$ ,
2.  $\forall v \in V_2(f) : P_{G', V_2(f)}(v) \not\subseteq \{v\}$ , also called *privacy condition*, and
3.  $V_2(f)$  is a *minimal dominating set* of  $G'$ .

This combinatorial result has been the key to show a polynomial-time decision procedure for the extension problem (Given a graph  $G = (V, E)$ , a function  $f : V \rightarrow \{0, 1, 2\}$ , the question is if there is minimal rdf  $g$  with  $f \leq g$ ). It can also be used to design enumeration algorithms that are input-sensitive. The simplest exploit is to branch on all vertices whether or not a vertex should belong to  $V_2(f)$ . Once  $V_2(f)$  is fixed, its neighborhood will form  $V_0(f)$  and the remaining vertices will be  $V_1(f)$ . For better running times, this approach has to be refined, see Section 5. We obtain estimates of running times for branching algorithms as explained in [28], including an introduction into the Measure-and-Conquer analysis.

### 3 Enumerating Minimal RDFs in Split and in Cobipartite Graphs

A split graph  $G = (V, E)$  consists of a bipartition of  $V$  as  $C$  and  $I$ , such that  $C$  forms a clique and  $I$  is an independent set. Let  $f : V \rightarrow \{0, 1, 2\}$  be a minimal rdf of  $G$ . If  $V_2(f)$  contains both a vertex  $v_c$  from  $C$  and a vertex  $v_i$  from  $I$ , then  $v_i$  cannot find a private neighbor in  $G$ , contradicting the minimality of  $f$ . We can hence first branch to decide if  $V_2(f) \subseteq C$  or if  $V_2(f) \subseteq I$ . After dealing with the simple case that  $|V_2(f) \cap C| = 1$  separately, we can assume that all private neighbors of  $V_2(f) \subseteq C$  are in  $I$  and that all private neighbors of  $V_2(f) \subseteq I$  are in  $C$ . We will describe a simple branching algorithm in which we can assume to immediately delete vertices that are assigned the value 0, as they will be always dominated.

**Case 1.** One element of  $C$  is assigned a value of 2. We can guess this element in  $\mathcal{O}(n)$  and proceed as follows.

1. Elements of  $C$  with no neighbors in  $I$  are assigned a value of zero.
2. Pick  $v \in C$  with at least two neighbors in  $I$  and branch by either setting  $f(v) = 2$  and assign 0 to vertices in  $N(v) \cap I$  or  $f(v) = 0$  (this leads to the branching vector  $(3, 1)$ ).
3. When all elements of  $C$  have exactly one neighbor in  $I$ , pick some  $v \in C$  with  $N(v) \cap I = \{w\}$ . Distinguish two cases.
  - 3.1  $w$  has at least one other neighbor  $x \in C$ . Then either  $f(v) = 2, f(w) = f(x) = 0$  (in fact, all neighbors of  $w$  are assigned 0), or  $f(v) = 0$  (this leads to a  $(3, 1)$  branch).
  - 3.2  $N(w) = \{v\}$ : either  $f(v) = 2, f(w) = 0$  or  $f(v) = 0, f(w) = 1$  (this leads to the branching vector  $(2, 2)$ ).

**Case 2.** No element of  $C$  is assigned a value of 2.

1. Then any isolated element of  $I$  is automatically assigned a value of 1 and can be deleted. Moreover, any element of  $C$  with no neighbors in  $I$  is assigned a value of 1 and deleted.
2. Pick a vertex  $v$  of degree at least two in  $I$  and branch by either setting  $f(v) = 2$  and assigning 0 to all its neighbors or set  $f(v) = 1$  (this leads to the branching vector  $(3, 1)$ ).
3. When all elements of  $I$  are leaves, pick  $v \in I$  with  $N(v) \cap C = \{w\}$ . Distinguish 2 cases.
  - 3.1  $w$  has at least one more neighbor  $x \in I$ : either  $f(v) = 2, f(w) = 0, f(x) = 1$  or  $f(v) = 1$  (delete  $v$ ) (this leads to the branching vector  $(3, 1)$ ).
  - 3.2  $N(w) \cap I = \{v\}$ : either  $f(v) = 2, f(w) = 0$  or  $f(v) = f(w) = 1$  (this leads to the branching vector  $(2, 2)$ ).

Notice that the analysis of the recursion is very simple: an rdf  $f$  is gradually defined, and the branching vectors describe the number of newly defined vertices. The worst-case branching vector is  $(1, 3)$ , which leads to the following claim.

► **Proposition 3.1.** *All minimal rdfs in a split graph of order  $n$  are enumerable in  $\mathcal{O}^*(1.4656^n)$ .*

► **Remark 3.2.** For cobipartite graphs, a similar reasoning applies. Now, it could be possible that one vertex  $x$  of the bipartition side  $X$  finds its private neighbor  $p_x$  in  $X$  itself and that one vertex  $y$  of the other bipartition side  $Y$  finds its private neighbor  $p_y$  in  $Y$ , such that the edges  $xp_y$  and  $yp_x$  do not exist. If  $G$  contains no universal vertices, then irrespectively whether the  $V_2(f)$ -vertices lie only in  $X$  or in  $Y$ , there must be at least one other vertex in  $V_2(f)$  on the same side. But this means that they must find their private neighbors on the other side. The branching is hence analogous to the split graph case.

$$C_{P,2,n} = \begin{cases} n-1 & \text{if } n \in [2] \\ C_{P,\bar{2},n-2} & \text{if } n > 2 \end{cases} \quad C_{P,\bar{2},n} = \begin{cases} n & \text{if } n \in [3] \\ C_{P,\bar{2},n-1} + C_{P,2,n-2} + C_{P,2,n-3} + C_{P,\bar{2},n-3} & \text{if } n > 3 \end{cases}$$

■ **Figure 1** The mutual recurrences for determining the number of minimal rdfs on a path  $P_n$ .

The previous arguments are invalid in the case of bipartite graphs. Here, we conjecture that the general case is not really easier than the bipartite case, as with minimal ds enumeration.

However, we can boost our algorithm and its simple analysis to actually prove an optimal enumeration result. In order to do this, a rather straightforward refinement of the previous case analysis suffices. Together with Remark 3.2 as well as the trick of interleaving the branching with extension tests as described in [2], this refined branching algorithm proves:

► **Theorem 3.3.** *All minimal rdfs in a split graph or a cobipartite graph of order  $n$  can be enumerated in time  $\mathcal{O}^*(\sqrt[3]{3}^n)$ , using polynomial space and polynomial delay only.*

We can complement Theorem 3.3 by showing lower bound examples in the following that prove that our simple branching algorithm analysis is optimal for split and cobipartite graphs.

► **Theorem 3.4.** *There exist split and cobipartite graphs of order  $n$  with  $\Omega(\sqrt[3]{3}^n)$  many minimal rdfs.*

**Proof.** We consider the graph  $G_t = (C_t \cup I_t, E_t)$  with  $C_t = \{c_1, \dots, c_{2t}\}$ ,  $I_t = \{v_1, \dots, v_t\}$ ,  $3t = n = |C_t \cup I_t|$  and  $E_t = \binom{C_t}{2} \cup \{\{c_{2i-1}, v_i\}, \{c_{2i}, v_i\} \mid i \in [t]\}$  (for the cobipartite case,  $I_t$  is also a clique). Thus,  $v_i \in I_t$  has degree 2. If  $V_2(f) \subseteq C_t$ , there are three ways to Roman-dominate any  $v_i \in I_t$ ,  $c_{2i-1}, c_{2i} \in C_t$  with a minimal rdf  $f$ :  $f(c_{2i}) = 2$ ,  $f(c_{2i-1}) = f(v_i) = 0$  or  $f(c_{2i-1}) = 2$ ,  $f(c_{2i}) = f(v_i) = 0$  or  $f(v_i) = 1$ ,  $f(c_{2i-1}) = f(c_{2i}) = 0$  (resp.  $f(c_{2i-1}) = f(c_{2i}) = 1$ , if  $V_2(f) = \emptyset$ ). This yields  $3^t = \sqrt[3]{3}^n$  many minimal rdfs. There can be at most  $2^t = \sqrt[3]{2}^n$  minimal rdfs  $f$  on  $G_t$  with  $V_2(f) \subseteq I_t$ . Hence,  $G_t$  is a graph of order  $n = 3t$  that has  $\sqrt[3]{3}^n + \sqrt[3]{2}^n - 1 \in \Omega(\sqrt[3]{3}^n)$  many minimal rdfs. ◀

Minimal dominating sets in cobipartite graphs where all dominating set vertices belong to one clique only correspond to minimal rdfs with no vertex assigned 1. So, we can use our rdf enumeration algorithm to enumerate minimal dominating sets on cobipartite graphs. This improves on the hitherto best published algorithm from [19] but would be worse than [53].

## 4 Counting Minimal Roman Dominating Functions on Paths

The following is the main result of this section, devoted to counting.

► **Proposition 4.1.** *The number of minimal Roman dominating functions of a path  $P_n$  grows as  $\mathcal{O}^*(c_{RD,P}^n)$ , with  $c_{RD,P} \leq 1.6852$ .*

This should be compared with the recursion of Bród [13] that yields the following asymptotic behavior for the number of minimal dominating sets of a path with  $n$  vertices:

► **Corollary 4.2** (follows from [13]). *The number of minimal dominating sets of a path  $P_n$  grows as  $\mathcal{O}^*(c_{D,P}^n)$ , with  $c_{D,P} \leq 1.4013$ .*

As every minimal dominating set  $D \subseteq V$  of a graph  $G = (V, E)$  corresponds to the minimal rdf  $f : V \rightarrow \{0, 1, 2\}$  with  $V_2(f) = D$  and  $V_0(f) = V \setminus D$ , it is clear that  $c_{D,P} \leq c_{RD,P}$ .

**Proof of Proposition 4.1.** Let  $C_{P,n}$  count the number of minimal rdfs of a  $P_n$ . Furthermore, let  $C_{P,2,n}$  and  $C_{P,\bar{2},n}$  denote the number of minimal rdfs of a  $P_n$  where the first vertex is assigned 2, or where it is decided that the first vertex is not assigned 2, respectively. Clearly,  $C_{P,n} = C_{P,2,n} + C_{P,\bar{2},n}$ . Consider  $P_n = (V_n, E_n)$  with  $V_n = \{v_i \mid i \in [n]\}$  and  $E_n = \{v_i v_{i+1} \mid i \in [n-1]\}$ . Let  $n \geq 3$  and  $f : V_n \rightarrow \{0, 1, 2\}$  be a minimal rdf.

If  $f(v_1) = 2$ , then  $f(v_2) = 0$ . Also  $f(v_3) \neq 2$ , as  $v_1$  would not have a private neighbor but itself for  $f(v_3) = 2$ . This shows (including trivial initial cases) the left-hand side of Figure 1. If  $f(v_1) \neq 2$ , then we have two subcases: (a) if  $f(v_1) = 1$ , then we know  $f(v_2) \neq 2$ ; (b) if  $f(v_1) = 0$ , then  $f(v_2) = 2$  is enforced. But we know more compared to the initial situation:  $v_2$  has already a private neighbor, namely  $v_1$ . Thus, we have further possibilities for  $v_3$ :  $f(v_3) = 2$  or  $f(v_3) = 0$ . The first subcase is as before:  $v_3$  has no private neighbor. If  $f(v_3) = 0$ , then either  $f(v_4) = 2$  and  $v_4$  has no private neighbor, or  $f(v_4) \neq 2$ ; hence the recursions on the right-hand side of Figure 1. Keeping in mind that  $C_{P,n-3} = C_{P,2,n-3} + C_{P,\bar{2},n-3}$ , we see  $C_{P,n} = C_{P,2,n} + C_{P,\bar{2},n} = C_{P,\bar{2},n-2} + C_{P,\bar{2},n-1} + C_{P,2,n-2} + C_{P,n-3} = C_{P,\bar{2},n-1} + C_{P,n-2} + C_{P,n-3}$ . Conversely,  $C_{P,n} = C_{P,2,n} + C_{P,\bar{2},n} = C_{P,\bar{2},n-2} + C_{P,\bar{2},n}$ . Hence,

$$C_{P,n} = C_{P,\bar{2},n} + C_{P,\bar{2},n-2} = C_{P,\bar{2},n-1} + (C_{P,\bar{2},n-2} + C_{P,\bar{2},n-4}) + (C_{P,\bar{2},n-3} + C_{P,\bar{2},n-5}),$$

which gives, ignoring the cases for small values of  $n$ , the following single recursion:

$$C_{P,\bar{2},n} = C_{P,\bar{2},n-1} + C_{P,\bar{2},n-3} + C_{P,\bar{2},n-4} + C_{P,\bar{2},n-5} \approx 1.6852^n$$

As  $C_{P,n} = C_{P,\bar{2},n-2} + C_{P,\bar{2},n}$ , the same asymptotic behavior holds for  $C_{P,n}$ .  $\blacktriangleleft$

We will further extend this result towards forests and towards interval graphs in the next sections, starting with a more general description of such branching algorithms.

## 5 A General Approach to Branching for Minimal RDFs

In this section, we sketch the general strategy that we apply for enumerating minimal rdfs. In most cases, the branching will look for a yet undecided vertex  $v$  (that we will call *active* henceforth) and will decide to label it with 2 in one branch and not to label it with 2 in the other branch. Now, in the first branch, we can say something about the neighbors of  $v$  as well: according to Theorem 2.1, they cannot be finally labelled with 1. We express this and similar properties by (always) splitting the vertex set  $V$  of the current graph  $G = (V, E)$  into:

- $A$ : active vertices. In the very beginning of the branching, all vertices are active.
- $\bar{V}_i$ : vertices that cannot be assigned a value of  $i$ ,  $i \in \{1, 2\}$ , due to previous decisions.
- $V_0$ : set of vertices assigned a value of zero that are not yet dominated.

Sometimes, the branching also considers a vertex from  $\bar{V}_1$ , which will be assigned 0 (and hence is deleted) in the branch when it is not assigned 2. We can also call extendibility tests before doing the branching in order to achieve polynomial delay; see [2].

Possibly, we can also (temporarily) have (and speak of) vertex sets  $V_i$  (with  $i \in \{1, 2\}$ ) with the meaning that each vertex in  $V_i$  is assigned the value  $i$ . Our algorithms will preserve the invariant that a vertex  $v \in \bar{V}_1$  must have a neighbor put into  $V_2$  (in the original graph), i.e.,  $N(v) \cap V_2 \neq \emptyset$ , which is a property that can be exploited in our analysis. Namely, a vertex is put into  $\bar{V}_1$  only if one of its neighbors has been put into  $V_2$ . However, notice that once the effect (mostly implied by Theorem 2.1) of putting a vertex  $v$  into  $V_i$  on its neighborhood  $N(v)$  has been taken care of, such a vertex  $v$  can be deleted from the “current graph” to simplify the considerations. More precisely, for  $i \in \{1, 2\}$ , our algorithms automatically delete vertices assigned a value of  $i$  after making sure the neighbors are placed in  $\bar{V}_{3-i}$ . It could happen

that the neighbor of a vertex  $w \in \overline{V_2}$  is assigned the value 2. Then,  $w$  must be assigned 0; as it is dominated, it can and will be deleted. Similarly, if the neighbor of a vertex  $w \in \overline{V_1}$  is assigned the value 1,  $w$  must be assigned 0 and is hence deleted. Only finally, it should be checked if a function  $f : V \rightarrow \{0, 1, 2\}$  that is constructed during branching is indeed a minimal rdf, as possibly some vertices assigned 2 do not have a private neighbor. During the course of our algorithm, whenever we speak of the degree of a vertex (in the current graph) in the following, we only count in neighbors in  $A \cup \overline{V_1} \cup \overline{V_2}$ . In most stages of our algorithms, we can assume  $V_1 = \emptyset$ , as we will explain.

Reduction rules are an important ingredient of any branching algorithm, as also shown in [28]. We will make use of the following reduction rules. Similar rules appeared in [2].

- ▶ Reduction Rule 5.1. If  $v \in \overline{V_2}$  with  $N(v) \subseteq \overline{V_2}$ , then set  $f(v) = 1$  and delete  $v$ .
- ▶ Reduction Rule 5.2. If  $v \in \overline{V_1}$  with  $N(v) \subseteq \overline{V_1}$ , then set  $f(v) = 0$  and delete  $v$ .
- ▶ Reduction Rule 5.3. If  $v \in A$  with  $N(v) \subseteq \overline{V_1}$ , then put  $v$  into  $\overline{V_2}$ .

▶ **Lemma 5.1.** *The three presented reduction rules are sound.*

In contrast to our approach in Section 3, we will now perform a Measure-and-Conquer analysis of the branching algorithms that we will describe. As a measure, we take

$$\mu(A, \overline{V_1}, \overline{V_2}, V_0) = |A| + \omega_1 |\overline{V_1}| + \omega_2 |\overline{V_2}|$$

for the “current graph” with vertex set partitioned as  $A \cup \overline{V_1} \cup \overline{V_2} \cup V_0$ . Hence, whenever we measure our graph, we can assume  $V_1 = \emptyset$ . In the beginning of the algorithm,  $A = V$  and  $\overline{V_1} = \overline{V_2} = V_0 = V_1 = \emptyset$ . To explain the work of the reduction rules, consider an isolated vertex (in the very beginning). The reduction rules will first move it into  $\overline{V_2}$  and then into  $\overline{V_1}$  to finally delete it. We will choose the constants  $\omega_1, \omega_2 \in [0, 1]$  to assess the running times of our algorithms best possible, hence also delivering upper bounds on the number of minimal rdfs of graphs of order  $n$  belonging to a specific graph class.

Concerning the reduction rules, we can easily observe that their application will never increase the measure. We will list in the following several branching rules (for the different graph classes) and we always assume that the rules are carried out in the given order.

## 6 Enumerating Minimal RdFs on Interval Graphs and Forests

Recall that an *interval graph* can be described as the intersection graph of a collection of intervals on the real line. This means that the vertices correspond to intervals and that there is an edge between two such vertices if the intervals have a non-empty intersection. We assume in the following that  $G = (V, E)$  is an interval graph with the interval representation  $\mathcal{I} = \{I_v := [l_v, r_v]\}_{v \in V}$ , i.e.,  $l_v$  is the left border and  $r_v$  is the right border of the interval representing the vertex  $v$ . We call  $v \in U$  *leftmost in*  $U \subseteq V$  if it is a vertex from  $U$  that has the smallest value of  $r_u$  among all vertices in  $U$ . A vertex leftmost in  $V$  is simply called *leftmost*. Notice that this notion of a leftmost vertex will be used in many places in the rules exhibited in the following and is not available in the setting of general graphs as investigated in [3] but relies on the interval graph structure. Our algorithm always branches on the leftmost vertex. Then, it simply considers all cases. We now present more details.

The reduction rules from Section 5 imply that each vertex in  $v \in A$  has at least one neighbor in  $A \cup \overline{V_2}$ . Concerning the measure, we will have  $\omega_1 = 1$  and set  $\omega_2 = \omega = 0.57$ . We will present the branching rules that constitute the backbone of our algorithm for enumerating minimal rdfs on interval graphs. We often provide illustrations of the different branching scenarios. In our figures, we adhere to the following drawing conventions:

(a)  $v$  is already dominated.(b)  $v \in A$  has neighbors in  $\overline{V}_2$ .

■ **Figure 2** Branching Rules 6.1 and 6.2. Here (and elsewhere in these illustrations) we only sketch important parts of a subgraph, not necessarily covering all cases of the rules within the drawings.

(a)  $v \in A$  has neighbors in  $A$ .(b)  $v \in A$  has neighbors in  $\overline{V}_2$  and in  $A$ .

■ **Figure 3** Branching Rules 6.3 and 6.4.

- ○ are vertices in  $A$ , ● are vertices in  $\overline{V}_1$ , ⊙ are vertices in  $A \cup \overline{V}_1$ .
- □ are vertices in  $\overline{V}_2$ .
- ◇ are vertices in  $A \cup \overline{V}_2$ , for which the exact set is not further defined.
- ◆ are vertices in  $A \cup \overline{V}_1 \cup \overline{V}_2$ , for which the exact set is not further defined.

► **Branching Rule 6.1.** Let  $v$  be the leftmost vertex in  $\overline{V}_1$  and let  $u$  be the leftmost vertex in  $N(v) \cap (A \cup \overline{V}_2)$  and branch as follows: (1) Put  $v$  in  $V_0$ . (2) Put  $v$  in  $V_2$  and  $u$  in  $V_0$ .

► **Lemma 6.1.** *The branching of Branching Rule 6.1 is a complete case distinction. Moreover, it leads at worst to the following branching vector:  $(1, 1 + \omega)$ .*

One can formulate and prove similar lemmas for the other branching rules that we present; see [4]. The branching vectors and branching numbers are summarized in Table 1.

► **Branching Rule 6.2.** Let  $v$  be the leftmost vertex in  $(A \cup \overline{V}_2)$ . If  $v \in A$  and  $N(v) \cap A = \emptyset$  hold, branch as follows: (1) Put  $v$  in  $V_2$  and  $N(v) \cap \overline{V}_2$  in  $V_0$ . (2) Put  $v$  in  $V_1$ .

► **Branching Rule 6.3.** Let  $v$  be leftmost in  $(A \cup \overline{V}_2)$ . If  $v \in A$  and  $|N(v) \cap A| \geq 2$  hold, branch as follows: (1) Put  $v$  in  $V_2$  and all vertices in  $N(v) \cap A$  into  $V_0$ . (2) Put  $v$  in  $\overline{V}_2$ .

► **Branching Rule 6.4.** Let  $v$  be the leftmost vertex in  $(A \cup \overline{V}_2)$ . If  $v \in A$ ,  $|N(v) \cap \overline{V}_2| \geq 1$  and  $|N(v) \cap A| = 1$  with  $u \in N(v) \cap A$  hold, then branch: (1) Put  $v$  in  $V_2$ ,  $N(v) \cap (\{u\} \cup \overline{V}_2)$  in  $V_0$ . (2) Put  $u$  in  $V_2$  and  $\{v\} \cup (N(v) \cap \overline{V}_2)$  in  $V_0$ . (3) Put  $v$  in  $V_0$  and  $u$  in  $\overline{V}_2$ .

► **Branching Rule 6.5.** Let  $v$  be the leftmost vertex in  $(A \cup \overline{V}_2)$ . If  $N[v] \cap A = \{v, u\}$  with  $N[v] \cap \overline{V}_2 = \emptyset$  and  $|N(u) \cap A| \geq 3$ , branch as follows:  
(1) Put  $v$  in  $V_2$ ,  $u$  in  $V_0$  and  $N(u) \setminus \{v\}$  in  $\overline{V}_2$ . (2) Put  $v$  in  $\overline{V}_2$ .

► **Branching Rule 6.6.** Let  $v_1$  be the leftmost vertex in  $(A \cup \overline{V}_2)$ . If  $N[v_1] \cap A = \{v_1, v_2\}$  with  $N[v_1] \cap \overline{V}_2 = \emptyset$ ,  $N(v_2) \cap A = \{v_1, v_3\}$  and if there exists a  $u \in N(v_3)$  such that  $N(u) = \{v_3\}$ , then branch as follows: (1) Put  $v_1$  in  $V_2$ ,  $v_2$  in  $V_0$  and  $v_3$  in  $\overline{V}_2$ . (2) Put  $v_1$  in  $V_1$ ,  $v_2$  in  $\overline{V}_2$ . (3) Put  $v_2$  in  $V_2$  and  $v_1, v_3$  in  $V_0$  and  $u$  in  $V_1$ . (4) Put  $v_2, v_3$  in  $V_2$  and  $v_1, u$  in  $V_0$ .

► **Branching Rule 6.7.** Let  $v_1$  be the leftmost vertex in  $(A \cup \overline{V}_2)$ , such that  $N[v_1] \cap A = \{v_1, v_2\}$ , with  $N[v_2] \cap \overline{V}_2 = \emptyset$  and  $N(v_2) \cap (A \cup \overline{V}_2) = \{v_1, v_3\}$ . If there is a  $u$  leftmost in  $A \setminus \{v_1, v_2, v_3\}$ , with  $\{v_3\} \subsetneq N(u)$ , then branch as follows: (1) Put  $v_1$  in  $V_2$  and  $v_2$  in  $V_0$  and  $v_3$  in  $\overline{V}_2$ . (2) Put  $v_1$  in  $V_1$ ,  $v_2$  in  $\overline{V}_2$ . (3) Put  $v_1$  in  $V_0$ ,  $v_2$  in  $V_2$  and  $v_3$  in  $\overline{V}_2$ . (4) Put  $v_2, v_3$  in  $V_2$  and  $v_1, u$  in  $V_0$  and  $N(u) \setminus \{v_3\}$  in  $\overline{V}_2$ .

(a)  $v_1 \in A$  has only one neighbor in  $A$  which has degree bigger than 2. (b)  $v_1, v_2, v_3 \in A$  is a path and  $v_3$  has a leaf neighbor.

■ **Figure 4** Branching Rules 6.5 and 6.6.

(a)  $v_1, v_2, v_3 \in A$  is a path and there exists a  $u \in A \cap N(v_3)$  with one more neighbor. (b)  $v \in \overline{V_2}$  is the leftmost vertex.

■ **Figure 5** Rules 6.7 and 6.8.

► **Branching Rule 6.8.** Let  $v$  be the leftmost vertex in  $(A \cup \overline{V_2})$ . If  $v \in \overline{V_2}$ , branch like: (1) For each  $u \in N(v) \cap A$ :  $u$  in  $V_2$  and  $N[v] \setminus \{u\}$  into  $V_0$ . (2) Put  $v$  in  $V_1$  and  $N(v) \cap A$  in  $\overline{V_2}$ .

► **Theorem 6.2.** All minimal rdfs of an interval graph of order  $n$  can be enumerated in time  $\mathcal{O}^*(\sqrt{3}^n)$ , with polynomial delay and in polynomial space.

This result is optimal, as there are interval graphs that have  $\sqrt{3}^n$  many minimal rdfs, namely collections of paths on two vertices:  $x - y$  can be Roman-dominated by  $f(x) = f(y) = 1$  or by assigning two to one vertex and zero to the other one, i.e., we get three possibilities per two vertices. For optimally enumerating minimal ds in interval graphs, see [31].

Recall that a forest is an acyclic undirected graph. A branching scenario that is similar to, but slightly more complex than, that of interval graphs can be used for forests (see [4]).

► **Theorem 6.3.** A forest of order  $n$  has at most  $\sqrt{3}^n$  many minimal rdfs. They can also be enumerated in time  $\mathcal{O}^*(\sqrt{3}^n)$ , with polynomial delay and in polynomial space.

■ **Table 1** Branching scenarios on interval graphs.

rule	branching vector	branching number
6.1 & 6.2	$(1, 1 + \omega)$	1.7314
6.3	$(3, 1 - \omega)$	1.6992
6.4	$(2 + \omega, 2 + \omega, 2 - \omega)$	1.6829
6.5	$(4 - 2\omega, 1 - \omega)$	1.7274
6.6	$(3 - \omega, 2 - \omega, 4, 4)$	1.6877
6.7	$(3 - \omega, 2 - \omega, 3, 5 - \omega)$	1.7315
6.8	$(\underbrace{\omega +  N(v) \cap A , \dots, \omega +  N(v) \cap A }_{ N(v) \cap A  \text{ many times}}, \omega + (1 - \omega) \cdot  N(v) \cap A )$	$\leq \sqrt{3} \leq 1.7321$

■ **Table 2** Branching rules and their vectors and numbers for chordal graphs; **worst cases in red.**

Rule	branching vector	branching number
7.1	$(1 - \omega_2, 1 + 3 \min(1 - \omega_1, \omega_2))$	<b>1.8940</b>
7.2	$(1 + \omega_1 + \omega_2, 1 - \omega_2)$	1.8014
7.3	$(\omega_1, \omega_1 + 2\omega_2)$	<b>1.8940</b>
7.4	$(\omega_1, 2 - \omega_1 + \min(1 - \omega_1, \omega_2))$	<b>1.8940</b>
7.5 & 7.16	$(\omega_1, 2\omega_1 + \omega_2)$	1.7915
7.6	$(\omega_1 + \omega_2, \omega_1 + \omega_2)$	1.8321
7.7 & 7.14	$(1 + \omega_2, 1 + \omega_2)$	never worse than Branching Rule 7.6
7.8	$(1 + \omega_2 + \min(1 - \omega_2, \omega_1), 1)$	1.6181
7.9	$(2, 1 - \omega_2)$	1.8471
7.10	$(1 + \omega_2, 1)$	1.779
7.11	$(1 + \omega_1 + 2(1 - \omega_2), \omega_1)$	1.5743
7.12	$(1 + 2\omega_2, 1)$	never worse than Branching Rule 7.10
7.13	$(2 + \omega_2, 1 - \omega_2)$	1.7249
7.15 & 7.17	$(2 - \omega_1 + \omega_2, 2 + \omega_2, 2 - \omega_2)$	1.8005

(a)  $v \in A$  has at least 3 neighbors in  $A \cup \overline{V_2}$ .

(b)  $v \in A$  has one neighbor  $w \in \overline{V_2}$  and at least one neighbor in  $\overline{V_1}$  that has only further neighbors in  $\overline{V_1}$ .

■ **Figure 6** Branching Rules 7.1 and 7.2.

This result is again optimal, as there are forests that have  $\sqrt{3}^n$  many minimal rdfs, namely collections of  $P_2$ . A similar optimality result was obtained by Rote [50] for enumerating minimal dominating sets in forests by using different techniques: there are (at most)  $\sqrt[13]{95}^n$  many of them in forests of order  $n$ .

## 7 Enumerating Minimal RDFs in Chordal Graphs

Recall that a graph is *chordal* if the only induced cycles it might contain have length three. In this quite technical section, we explain the following result whose optimality is open.

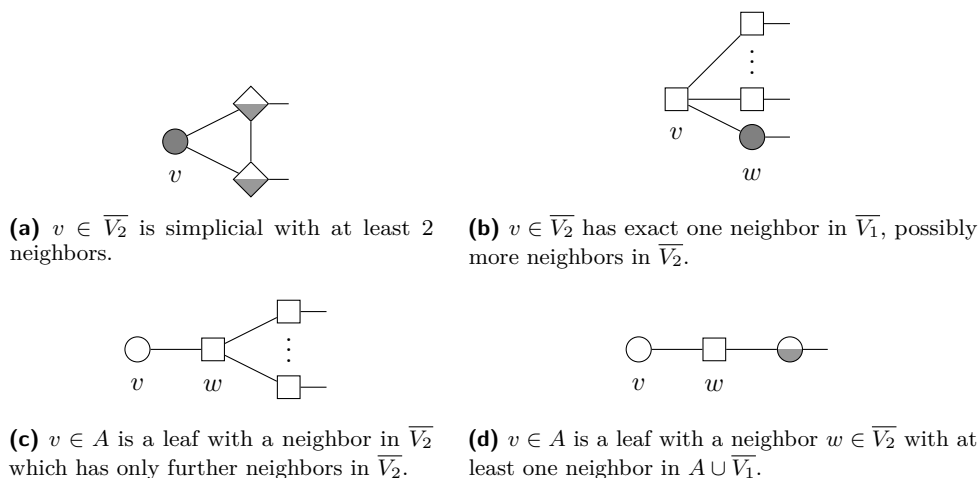

► **Theorem 7.1.** *All minimal Roman dominating functions of a chordal graph of order  $n$  can be enumerated with polynomial delay and in polynomial space in time  $\mathcal{O}(1.8940^n)$ .*

We are following the general approach sketched in Section 5. We adopt as a measure  $\mu = |A| + \omega_1 |\overline{V_1}| + \omega_2 |\overline{V_2}|$ . To obtain our result, we set  $\omega_1 = 0.710134$  and  $\omega_2 = 0.434799$ .

Initially, all vertices are in  $A$ . Each branching rule assumes the preceding rules have been applied exhaustively and none of their conditions is applicable anymore. We omit stating correctness lemmas and lemmas concerning branching vectors but refer to Table 2. These lemmas are in general quite simple.

► **Branching Rule 7.1.** If  $v \in A$  has at least three neighbors in  $A \cup \overline{V_2}$ , then we branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Add  $v$  to  $\overline{V_2}$ .

■ **Figure 7** Branching Rules 7.5, 7.6, 7.7 and 7.8.

From now on, we can assume that a vertex from  $A$  of degree at least 3 has a neighbor in  $\overline{V}_1$ .

► **Branching Rule 7.2.** If  $v \in A$  has at least one neighbor  $w$  in  $\overline{V}_2$  and at least one neighbor  $u$  in  $\overline{V}_1$  such that all neighbors of  $u$  (but  $v$  and possibly  $w$ ) are in  $\overline{V}_1$ , then we branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Add  $v$  to  $\overline{V}_2$ .

Knowing (by our invariants) that elements of  $\overline{V}_1$  are guaranteed to have neighbors in  $V_2$ , the next two branching rules apply to some elements of  $\overline{V}_1$  (illustration can be found in [4]):

► **Branching Rule 7.3.** If  $v \in \overline{V}_1$  has at least two neighbors in  $\overline{V}_2$ , then we branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Set  $f(v) = 0$  and delete  $v$ .

► **Branching Rule 7.4.** If  $v \in \overline{V}_1$  has at least three neighbors in  $A \cup \overline{V}_2$  then we branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Set  $f(v) = 0$  and delete  $v$ .

From now on, we discuss branching on simplicial vertices (or sometimes on vertices in the neighborhood of simplicial vertices as in [5]).

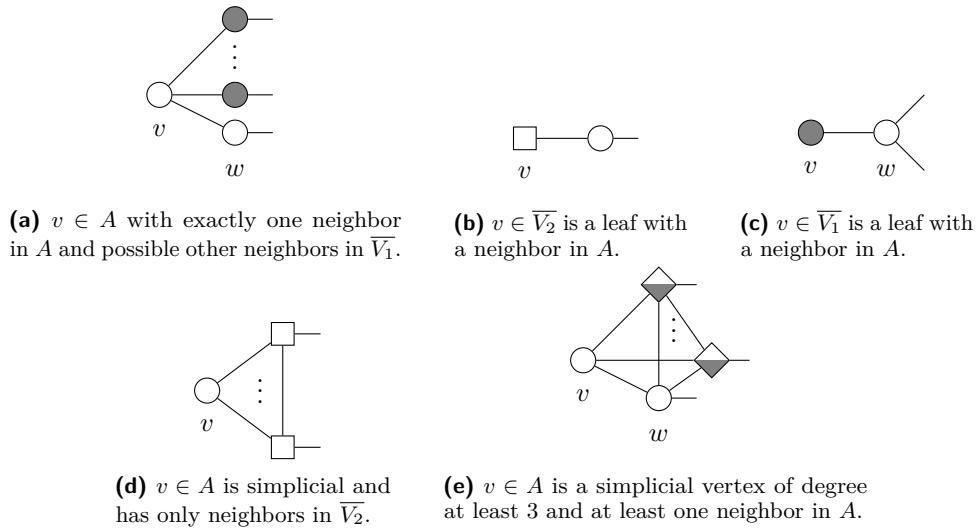

► **Observation 7.2.** *Simplicial vertices in  $\overline{V}_1$  can only have neighbors in  $A \cup \overline{V}_2 \cup \overline{V}_1$ . As we already considered vertices in  $\overline{V}_1$  with  $\geq 3$  neighbors in  $A \cup \overline{V}_2$ , in the following branchings, a vertex in  $\overline{V}_1$  has  $\leq 2$  neighbors in  $A \cup \overline{V}_2$ , not both of them in  $\overline{V}_2$  due to Branching Rule 7.3.*

► **Branching Rule 7.5.** If  $v \in \overline{V}_1$  is simplicial and of degree at least two, then branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Set  $f(v) = 0$  and delete  $v$ .

► **Observation 7.3.** *We note that an isolated pair of adjacent leaves, say  $v, w$ , give rise to a path, which has already been studied. However, assuming previous branching rules have resulted in such a path, the worst case is when  $v \in \overline{V}_2$  and  $w \in \overline{V}_1$ . To see this, note that if both  $v$  and  $w$  are in  $\overline{V}_2$  or both in  $\overline{V}_1$ , they would be deleted by Reduction Rules 5.1 or 5.2.*

► **Branching Rule 7.6.** If  $v \in \overline{V}_2$  is a vertex with exactly one neighbor  $w \in \overline{V}_1$  and possibly more neighbors in  $\overline{V}_2$ , then we branch as follows: (1) Set  $f(w) = 2$ ,  $f(v) = 0$  and update the neighbors of  $w$  accordingly. (2) Set  $f(w) = 0$  and  $f(v) = 1$  and delete  $v, w$ .

► **Branching Rule 7.7.** Let  $v \in A$  with  $N(v) = \{w\}$ ,  $w \in \overline{V}_2$ , with  $N(w) \setminus \{v\} \subseteq \overline{V}_2$ . Then, branch as follows: (1) Set  $f(v) = 2$  and  $f(w) = 0$ . (2) Set  $f(v) = f(w) = 1$  and delete  $v, w$ .

■ **Figure 8** Branching Rules 7.9, 7.10,7.11, 7.12 and 7.13.

► **Branching Rule 7.8.** If  $v \in A$  with  $N(v) = \{w\}$  and  $w \in \overline{V_2}$  and if there is at least one further neighbor of  $w$  that belongs to  $A \cup \overline{V_1}$ , then we branch as follows: (1) Set  $f(v) = 2$  and  $f(w) = 0$  and update all neighbors of  $w$  to  $\overline{V_2}$  or to  $V_0$ . (2) Set  $f(v) = 1$  and delete  $v$ .

The following rule again deals with a leaf vertex as a special case.

► **Branching Rule 7.9.** Let  $v \in A$  with  $N(v) \cap A = \{w\}$  and  $N(v) \setminus \{w\} \subseteq \overline{V_1}$ . Then, branch: (1) Set  $f(v) = 2$  and  $f(w) = 0$ , update all neighbors of  $w$  to  $\overline{V_2}$  or to  $V_0$ . (2) Add  $v$  to  $\overline{V_2}$ .

► **Branching Rule 7.10.** If  $v \in \overline{V_2}$  with  $N(v) = \{w\}$ ,  $w \in A$ , then we branch as follows: (1) Set  $f(w) = 2$  and  $f(v) = 0$ ; update  $N(w)$  accordingly. (2) Add  $w$  to  $\overline{V_2}$  and set  $f(v) = 1$ .

► **Branching Rule 7.11.** If  $v \in \overline{V_1}$  with  $N(v) = \{w\}$ ,  $w \in A$  and  $|N(w) \cap A| = 2$ , then branch: (1) Set  $f(v) = 2$ ,  $f(w) = 0$  and put the neighbors of  $w$  into  $\overline{V_2}$ . (2) Set  $f(v) = 0$  and delete  $v$ .

► **Branching Rule 7.12.** If  $v \in A$  is simplicial, of degree  $\geq 2$  with  $N(v) \subset \overline{V_2}$ , then branch: (1) Set  $f(v) = 2$  and assign zero to all its neighbors (delete  $N[v]$ ). (2) Set  $f(v) = 1$  and delete  $v$ .

► **Branching Rule 7.13.** If  $v \in A$  is simplicial, with  $|N(v)| \geq 2$  and  $N(v) \cap A \neq \emptyset$ , then we branch as follows: (1) Set  $f(v) = 2$  and update the neighbors accordingly. (2) Add  $v$  to  $\overline{V_2}$ .

Finally, we consider simplicial vertices in  $\overline{V_2}$  of degree  $\geq 2$ , now covering the remaining cases.

► **Branching Rule 7.14.** Let  $v \in \overline{V_2}$  be a simplicial vertex of degree two with a neighbor  $w \in A$ . If the other neighbor  $w'$  of  $v$  is in  $\overline{V_2}$ , then we branch as follows: (1) Set  $f(w) = 2$  and  $f(v) = f(w') = 0$ . (2) Add  $w$  to  $\overline{V_2}$ , set  $f(v) = 1$  and delete  $v$ .

► **Branching Rule 7.15.** If  $v \in \overline{V_2}$  is simplicial with two neighbors  $w, w' \in A$ , then we branch as follows: (1) Set  $f(w) = 2$ ,  $f(v) = 0$  and add  $w'$  to  $\overline{V_1}$ . (2) Set  $f(w') = 2$  and  $f(w) = f(v) = 0$ . (3) Add  $w$  and  $w'$  to  $\overline{V_2}$  and set  $f(v) = 1$ .

► **Branching Rule 7.16.** If  $v \in \overline{V_2}$  is simplicial, of degree at least two, with a neighbor  $w$  such that  $N[w] \setminus \{v\} \subseteq \overline{V_1}$ , then we branch as follows: (1) Set  $f(w) = 2$ ,  $f(v) = 0$  and delete  $N[v]$ . (2) Set  $f(w) = 0$  and delete it.

► **Branching Rule 7.17.** If  $v \in \overline{V_2}$  is simplicial, with neighbors  $w, w' \in \overline{V_1}$  s.t.  $N[w] \subset N[w']$ , then branch: (1) Set  $f(w') = 2$ ,  $f(v) = f(w) = 0$ . (2) Set  $f(w') = 0$  and delete it.

► **Lemma 7.4.** *Our rules cover all possible cases for chordal graphs.*

It remains open whether enumeration on chordal graphs can be improved further, so we hereby pose it as an open problem, or whether one can obtain a higher lower bound, which might also be a gap-improvement on general graphs. So far, the best lower bound for general graphs is a collection of  $C_5$ 's [2], which is clearly not a chordal graph. The worst-case example for chordal graphs is a collection of  $P_2$ 's, see Section 4 and our discussions on interval graphs.

## Abstract

We present quantitative logics with two-step semantics based on the framework of quantitative logics introduced by Arenas et al. (2020) and the two-step semantics defined in the context of weighted logics by Gastin & Monmege (2018). We show that some of the fragments of our logics augmented with a least fixed point operator capture interesting classes of counting problems. Specifically, we answer an open question in the area of descriptive complexity of counting problems by providing logical characterisations of two subclasses of  $\#P$ , namely  $\text{SpanL}$  and  $\text{TotP}$ , that play a significant role in the study of approximable counting problems. Moreover, we define logics that capture  $\text{FPSPACE}$  and  $\text{SpanPSPACE}$ , which are counting versions of  $\text{PSPACE}$ .

## 1 Introduction

We examine counting problems from the viewpoint of descriptive complexity. We present a quantitative logic with a least fixed point operator and two-step semantics. In the first step, given a structure, a formula generates a set. In the second step, a quantitative interpretation results from the cardinality of that set. These semantics allow us to use a uniform approach to identify logical fragments that capture several counting complexity classes.

In 1979, Valiant introduced the complexity class  $\#P$  in his seminal paper [32] and used it to characterise the complexity of computing the permanent function.  $\#P$  is the class of functions that count accepting paths of non-deterministic poly-time Turing machines, or, equivalently, the number of solutions to problems in NP. For example,  $\#\text{SAT}$  is the function that, on input a formula  $\varphi$  in CNF, returns the number of satisfying assignments of  $\varphi$ . Since then, counting complexity has played an important role in computational complexity theory.

Descriptive complexity provides characterisations of complexity classes in terms of the logic needed to express their problems. The Büchi–Elgot–Trakhtenbrot theorem [9, 15, 31] characterising regular languages in terms of Monadic Second-Order logic and Fagin’s theorem [17], which states that Existential Second-Order logic captures NP, are two fundamental results in this area. Another prominent result was the introduction of the class  $\text{MaxSNP}$  [29],

which has played a central role in the study of the hardness of approximation for optimization problems [6]. Moreover, descriptive complexity is an interesting and active research field with more recent results in the logical characterisation of the class  $P$  [20], dynamic complexity [33], symmetric linear programs [7], and counting complexity [5, 12], among others.

As in the case of optimization problems, an interesting, long-standing question is the logical characterisation of approximable counting problems. This is also a meaningful line of research since very few counting problems can be computed exactly in polynomial time. In the case of counting problems, the appropriate notion of approximability is the existence of a fully polynomial randomized approximation scheme (fpras). We denote the class of approximable counting problems by  $FPRAS$  [13, 8].

A counting class is considered *robust* if it has either natural complete problems or nice closure properties. Two robust subclasses of  $\#P$  defined in terms of Turing Machines (TMs), are of great significance in the quest for a characterisation of approximable counting problems. The first one is  $TotP$ , which contains all self-reducible counting problems whose decision version is in  $P$ . It is noteworthy that  $TotP$  is not contained in  $FPRAS$ , unless  $RP = NP$  [8], but almost all known approximable counting problems belong to  $TotP$  (see e.g. [23, 22, 27]). The second class, namely  $SpanL$  [2], is contained in  $TotP$ , and it consists of the functions that count different outputs of non-deterministic log-space *transducers*, i.e. TMs with output. To the best of our knowledge,  $SpanL$  is the only counting class so far defined in terms of TMs, that, despite containing  $\#P$ -complete problems [2], contains only approximable problems [4].

**Our contribution.** Our main objective is to provide logical characterisations of the classes  $SpanL$  and  $TotP$ , which was posed as an open question in [5]. To this end, we introduce a variant of the quantitative logics from [5]. Our two-step semantic definition is the key difference between our approach and that in [5]. The first step is an *intermediate semantics*, where the meaning of a formula is given as a set of strings that, intuitively, represent computation paths. In the second step, a concrete semantics associates with each formula the size of the set resulting from the intermediate semantics. Gastin et al. follow an analogous approach for weighted logics in [18], to give a connection to weighted automata.

In Section 4, we introduce logics equipped with least fixed point formulae that capture “span-classes” of restricted space, namely  $SpanL$  and  $SpanPSPACE$ , in a natural way (Theorems 4.7 and 4.13). When we consider such classes, we are interested in counting the number of different outputs produced by a transducer. Semantics that map the set of quantitative formulae to  $\mathbb{N}$  interpret every accepting path as a contributing unit. Then, by evaluating the sum of formulae as the sum of natural numbers, one can sum up the accepting paths of a TM. On the other hand, when a formula is evaluated as a set of output strings and the sum of formulae as the union of sets, they can count the number of different TM outputs.

We also consider two classes, namely  $\#PSPACE$  and  $TotP$ , which contain functions that count the accepting or all paths of TMs with restricted resources, respectively. Using our alternative semantics, a computation path can be encoded as a sequence of configurations visited by the TM along that path – in other words, its computation history – so that different paths are mapped to different sequences. In Section 5, we provide a logical characterisation of the class of functions that count the number of accepting paths of poly-space TMs, namely  $\#PSPACE$  [25] (Theorem 5.3), which coincides with  $FSPACE$ , i.e. the class of poly-space computable functions.  $FSPACE$  has already been characterised by a logic with a partial fixed point [5]. Interestingly, the logic we define here uses a least fixed point. In Section 6, we introduce a quantitative logic that captures  $TotP$  (Theorem 6.6). In Section 7, we discuss how to obtain two least fixed point logics that capture  $NL$  and  $PSPACE$  by specialising the semantics. We believe that the semantics we propose in this paper can contribute insight to the study of counting complexity classes.

**Related work.** Arenas et al. and Saluja et al. give logical characterisations of  $\#P$  in [30, 5]. The authors of [30] substitute existential quantification over second-order variables of  $\exists SO$  with counting second-order variables. The work in [5] incorporated counting into the syntax of the logic by introducing Quantitative Second-Order logic (QSO), a logic for quantitative functions, which is based on the framework of weighted logics [11, 18, 1]. There has been progress in characterising counting classes with respect to their approximability in the context of descriptive complexity. Saluja et al. defined the classes  $\#\Sigma_1$  and  $\#\Sigma_2$  in [30], and proved that they contain only problems that admit an fpras. A more recent variant of  $\#\Sigma_1$  [12] is also a subclass of FPRAS. The class  $\#\mathsf{R}\Pi_1$  [13] is conjectured to contain problems which are neither as hard to approximate as  $\#\mathsf{SAT}$  nor admit an fpras, and it was used to classify Boolean  $\#\mathsf{CSP}$  with respect to their approximability [14]. Since NP-complete problems cannot have approximable counting versions unless  $\mathsf{RP} = \mathsf{NP}$  [13], Arenas et al. suggested in [5] to examine robust classes of counting problems with an easy decision version. The papers [5, 8] defined such counting classes and examined them with respect to the approximability of their problems. There is also work on logics that capture superclasses of  $\#P$ , namely  $\mathsf{SpanP}$  [24] and  $\mathsf{FPSPACE}$  [25]. Compton and Grädel were the first to characterise  $\mathsf{SpanP}$  in [10], followed by Arenas et al. in [5], where they also introduced a logic that captures  $\mathsf{FPSPACE}$ . Finally, in [12], Durand et al. introduced a framework for the descriptive complexity of arithmetic circuit classes.

## 2 Preliminaries

**Turing machines.** A (*two-tape non-deterministic*) Turing machine (TM)  $N$  is a quintuple  $N = (\mathcal{Q}, \Sigma, \delta, q_0, q_F)$ , where  $\mathcal{Q}$  is a set of states,  $\Sigma = \{0, 1\}$  is the alphabet,  $\delta \subseteq (\mathcal{Q} \times (\Sigma \cup \{-\})^2) \times (\mathcal{Q} \times (\Sigma \cup \{-\})) \times \{L, R\}^2$  is the transition relation,  $q_0$  is the initial state, and  $q_F$  is the final accepting state. We assume the TM  $N$  has a read-only input tape and a work tape that it can read and write on.  $L$  and  $R$  in a transition designate that the respective tape head moves to the left or right. A *configuration*  $c$  of  $N$  encodes a snapshot of the computation of  $N$  and is defined in the usual way (see e.g. [28]). We can apply a compatible transition to a configuration to result in a new configuration in the expected way. W.l.o.g. we assume that every TM has a binary computation tree: any configuration is compatible with zero, one or two transitions. In the latter case, we call these transitions, the *left* and *right* non-deterministic transition. A *transducer*  $M$  is a TM with a write-only output tape, on which a string over  $\Sigma$  is written from left to right. The output of a computation is *valid* if  $M$  stops in the accepting state. A TM or transducer is called *deterministic* if at every configuration at most one transition can be applied. By restricting the time or space resources of a TM or transducer in the usual way, we can obtain an NPTM (non-deterministic poly-time TM), an NL-transducer (non-deterministic log-space transducer) etc.

We say that  $f$  is *computable in polynomial time* (resp. logarithmic/polynomial space), if there is a deterministic polynomial-time (resp. log-space/poly-space) transducer  $M$ , such that for every  $x \in \Sigma^*$ ,  $f(x)$  is the valid output of  $M$  on input  $x$ . We define the functions that count paths (resp. outputs) of a TM (resp. transducer) as follows.

► **Definition 2.1.** Let  $M$  be a Turing machine and  $T$  a transducer. We define functions  $acc_M, tot_M, span_T : \Sigma^* \rightarrow \mathbb{N} \cup \{+\infty\}$ , such that for every  $x \in \Sigma^*$ :

- (a)  $acc_M(x) = \#(\text{accepting computation paths of } M \text{ on input } x)$ ,
- (b)  $tot_M(x) = \#(\text{computation paths of } M \text{ on input } x) - 1$ ,
- (c)  $span_T(x) = \#(\text{different valid outputs of } T \text{ on input } x)$ .

**Classes of counting problems.** The classes defined in Definition 2.2 are already known, except for SpanPSPACE, which is presently defined.

- **Definition 2.2** ([2, 27, 25]). (a)  $\text{SpanL} = \{\text{span}_M : \Sigma^* \rightarrow \mathbb{N} \mid M \text{ is an NL-transducer}\}$ ,
- (b)  $\text{TotP} = \{\text{tot}_M : \Sigma^* \rightarrow \mathbb{N} \mid M \text{ is an NPTM}\}$ ,
- (c)  $\text{FPSPACE} = \{f : \Sigma^* \rightarrow \mathbb{N} \mid f \text{ is computable in polynomial space}\}$ ,
- (d)  $\#\text{PSPACE} = \{\text{acc}_M : \Sigma^* \rightarrow \mathbb{N} \mid M \text{ is a non-deterministic poly-space TM}\}$ .
- (e)  $\text{SpanPSPACE} = \{\text{span}_M : \Sigma^* \rightarrow \mathbb{N} \mid M \text{ is a non-deterministic poly-space transducer}\}$ .

► **Remark 2.3.** Note that in the definition of TotP, one is subtracted from the total number of paths so that a function can take the zero value. Since a TotP function  $f$  can be associated with an NPTM  $M$  that has a binary computation tree,  $f(x) = \text{tot}_M(x) = \#(\text{branchings of } M \text{ on input } x)$ , where a branching is an occurrence of a configuration on the computation tree, where  $M$  makes a non-deterministic choice.

► **Remark 2.4.** For the class SpanL, note that, by the pigeonhole principle, an NL-transducer has infinitely many accepting paths if and only if the length of its accepting runs is not bounded by a polynomial. It then makes sense to attach a clock that imposes a polynomial-time bound to each NLTM, as suggested in [2]. In this way, every NLTM is also an NPTM with a finite number of computation paths. Similarly, we assume that a clock that imposes an exponential-time bound can be attached to a non-deterministic poly-space TM.

► **Proposition 2.5** ([2, 27, 25]).  $\text{SpanL} \subseteq \text{TotP} \subseteq \#\text{P} \subsetneq \text{FPSPACE} = \#\text{PSPACE} \subseteq \text{SpanPSPACE}$ . The first two inclusions are proper unless  $\text{P} = \text{NP}$ .

The *decision version* of a function  $f : \Sigma^* \rightarrow \mathbb{N}$  is  $\{x \mid f(x) > 0\}$ . We say that a function  $f : \Sigma^* \rightarrow \mathbb{N}$  is *self-reducible* if its value on an instance can be recursively computed by evaluating  $f$  on a polynomial number of smaller instances. A formal definition of self-reducibility can be found in [3]. TotP can be characterised as the closure under parsimonious reductions of the class of self-reducible  $\#\text{P}$  functions whose decision version is in P [27].

► **Example 2.6.** Consider the problem of counting independent sets of all sizes in a graph  $G$ , denoted by  $\#\text{IS}$ . Let  $M$  be the NPTM that makes the following computation: given  $G_{i-1}$  and  $v_i, \dots, v_n$ ,  $M$  non-deterministically chooses to add vertex  $v_i$  to the independent set or not, and defines  $G_i$  to be either  $G_{i-1}$  where  $v_i$ , all its neighbours, and all edges adjacent to them have been removed, or  $G_{i-1}$  where  $v_i$  and its adjacent edges have been removed, respectively. Then,  $M$  recursively continues on  $G_i$  and  $v_{i+1}, \dots, v_n$ . Consider  $M'$  that on input  $G = \langle V = \{v_1, \dots, v_n\}, E \rangle$  simulates  $M$  on  $G$  and  $v_1, \dots, v_n$ , and has also an additional dummy path. Then,  $\#\text{IS}(G) = \#(\text{paths of } M' \text{ on input } G) - 1$ .

**Logics.** A relational vocabulary  $\sigma = \{\mathcal{R}_1^{k_1}, \dots, \mathcal{R}_m^{k_m}\}$  is a finite set of relation symbols. Each relation symbol  $\mathcal{R}_i$  has a positive integer  $k_i$  as its designated arity. A *finite structure*  $\mathcal{A} = \langle A, R_1, \dots, R_m \rangle$  over  $\sigma$  consists of a finite set  $A$ , which is called the *universe* of  $\mathcal{A}$  and relations  $R_1, \dots, R_m$  of arities  $k_1, \dots, k_m$  on  $A$ , which are interpretations of the corresponding relation symbols. We may write that  $\text{arity}(R_i) = k_i$  or that  $R_i$  is a  $k_i$ -ary relation. The *size of the structure*, denoted by  $|\mathcal{A}|$  or  $|A|$ , is the size of its universe. A *finite ordered structure* is a finite structure with an extra relation  $\leq$ , which is interpreted as a total order on the elements of the universe. In sequel,  $\mathcal{A}$  denotes a finite ordered structure unless otherwise specified. For convenience we use letters  $B, C, R, S$ , and so on, to denote both relation symbols and their interpretations. For example, the vocabulary of binary strings is  $\sigma_{bs} = \{\leq^2, B^1\}$ . Binary string  $x = 00101$  corresponds to the structure  $\mathcal{A} = \langle \{0, 1, \dots, 4\}, \leq, B = \{2, 4\} \rangle$ , where relation  $B$  represents the positions where  $x$  is one. Moreover,  $|\mathcal{A}| = 5$ .

First-order formulae over  $\sigma$  are defined in the usual way, using first-order variables that range over the universe of a structure, the relation symbols from  $\sigma$ , equality, the logical operators  $\wedge, \vee, \neg, \rightarrow$ , and first-order quantifiers  $\forall x$  and  $\exists x$ . For convenience and clarity, we omit function and constant symbols from the syntax of **FO**, but we include  $\top$ , which is the logical constant for truth. A first-order formula with no free variable occurrences is called a first-order *sentence*, where an occurrence of  $x$  is free if it does not lie in the scope of either  $\exists x$  or  $\forall x$ . In addition to the syntax of **FO**, **S0** includes and quantifies over second-order variables that range over relations, are denoted by uppercase letters, and each of them has an arity. **S0** includes formulae of the form  $X(x_1, \dots, x_k)$ , where  $X$  is a second-order variable of arity  $k$ , and  $x_1, \dots, x_k$  are first-order variables. The fragment of **S0** consisting only of existential second-order formulae is called existential second-order logic and is abbreviated as  $\exists\text{S0}$ . We use the usual  $\mathcal{A}, v, V \models \varphi$  interpretation of an **S0**-formula  $\varphi$ , given a structure  $\mathcal{A}$  and first- and second-order assignments  $v$  and  $V$ , respectively. If  $\varphi$  has no free first- or second-order variables,  $v$  or  $V$ , respectively, can be omitted. We refer the reader to [16] for a more extensive presentation of **FO** and **S0**.

The logical symbols of Quantitative Second-Order logic, denoted by **QSO**, include all the logical symbols of **S0** and the quantitative quantifiers  $\Sigma$  and  $\Pi$  for sum and product quantification, respectively. The arity of a second-order variable  $X$  is denoted by  $\text{arity}(X)$ . When we write logic  $\Lambda$  over  $\sigma$ , we mean the set of  $\Lambda$  formulae over  $\sigma$ . The set of **QSO** formulae over  $\sigma$  are defined by the following grammar:

$$\alpha ::= \varphi \mid s \mid (\alpha + \alpha) \mid (\alpha \cdot \alpha) \mid \Sigma x.\alpha \mid \Pi x.\alpha \mid \Sigma X.\alpha \mid \Pi X.\alpha \quad (1)$$

where  $\varphi$  is an **S0** formula over  $\sigma$ ,  $s \in \mathbb{N}$ ,  $x$  is a first-order and  $X$  a second-order variable. A formula  $\alpha$  in **QSO** is a sentence if every variable occurrence in  $\alpha$  is bound by a first-order, second-order, or quantitative quantifier. The evaluation of a **QSO** formula  $\alpha$  is a function  $\llbracket \alpha \rrbracket$  that on input  $\mathcal{A}, v$ , and  $V$  returns a number in  $\mathbb{N}$ . We refer the reader to [5, p. 5] for the definition of the semantics of **QSO** formulae. When  $\alpha$  is a sentence,  $\llbracket \alpha \rrbracket(\mathcal{A})$  is used to denote  $\llbracket \alpha \rrbracket(\mathcal{A}, v, V)$  for any  $v, V$ . We say that  $f \in \text{QSO}$  if there exists  $\alpha \in \text{QSO}$  such that  $f(\text{enc}(\mathcal{A})) = \llbracket \alpha \rrbracket(\mathcal{A})$ , for every  $\mathcal{A}$ . Note that **QSO** is a set of logical formulae, whereas  $\text{QSO}$  is a class of functions. For every logic  $\Lambda$ , we can define a corresponding class of functions as above, and we denote it by  $\Lambda$ .

► **Definition 2.7.** *A logic  $\Lambda$  captures a complexity class  $\mathcal{C}$ , and equivalently  $\mathcal{C} = \Lambda$ , over finite ordered structures over  $\sigma$ , if the following two conditions hold:*

1. *For every  $f \in \mathcal{C}$ , there is a sentence  $\alpha \in \Lambda$ , such that  $f(\text{enc}(\mathcal{A})) = \llbracket \alpha \rrbracket(\mathcal{A})$  for every finite ordered structure  $\mathcal{A}$  over  $\sigma$ .*
2. *For every sentence  $\alpha \in \Lambda$ , there is a function  $f \in \mathcal{C}$ , such that  $\llbracket \alpha \rrbracket(\mathcal{A}) = f(\text{enc}(\mathcal{A}))$  for every finite ordered structure  $\mathcal{A}$  over  $\sigma$ .*

*Moreover,  $\Lambda$  captures  $\mathcal{C}$  over finite ordered structures if  $\Lambda$  captures  $\mathcal{C}$  over finite ordered structures over  $\sigma$ , for every  $\sigma$ .*

For example,  $\Sigma\text{QSO}(\text{FO}) = \#\text{P}$  over finite ordered structures [5], where  $\Sigma\text{QSO}(\text{FO})$  is the set of **QSO** formulae that  $\Pi$  is not allowed and  $\varphi$  in (1) is restricted to be an **FO** formula.

Triples  $(\mathcal{A}, v, V)$  can be encoded in space polynomial in  $|A|$  using a standard mapping from finite ordered structures to strings over  $\{0, 1\}$  (see for example [26, Chapter 6]). We assume that a TM  $M$  takes as input the encoding of  $\mathcal{A}$  (or  $(\mathcal{A}, v, V)$ ), denoted by  $\text{enc}(\mathcal{A})$  (resp.  $\text{enc}(\mathcal{A}, v, V)$ ), even if we write  $M(\mathcal{A})$  (resp.  $M(\mathcal{A}, v, V)$ ) for the sake of brevity.

In all cases that we consider in this paper, the initial configuration of a TM is **FO** definable [21] and therefore, to prove that  $\Lambda$  captures  $\mathcal{C}$ , it suffices to verify conditions 1 and 2 in Definition 2.7 for  $f(\text{enc}(\mathcal{A}, v, V)) = \llbracket \alpha \rrbracket(\mathcal{A}, v, V)$ , where  $v, V$  encode the initial

## 7:6 Counting Computations with Formulae

$$\begin{aligned}
\text{Expl}[x](\mathcal{A}, v, V) &= \{v(x)\} \\
\text{Expl}[X](\mathcal{A}, v, V) &= \{V(X)\} \\
\text{Expl}[\varphi](\mathcal{A}, v, V) &= \begin{cases} \{\varepsilon\}, & \text{if } \mathcal{A}, v, V \models \varphi \\ \emptyset, & \text{otherwise} \end{cases} \\
\text{Expl}[\alpha_1 + \alpha_2](\mathcal{A}, v, V) &= \text{Expl}[\alpha_1](\mathcal{A}, v, V) \cup \text{Expl}[\alpha_2](\mathcal{A}, v, V) \\
\text{Expl}[\alpha_1 \cdot \alpha_2](\mathcal{A}, v, V) &= \text{Expl}[\alpha_1](\mathcal{A}, v, V) \circ \text{Expl}[\alpha_2](\mathcal{A}, v, V) \\
\text{Expl}[\Sigma y.\alpha](\mathcal{A}, v, V) &= \bigcup_{a \in A} \text{Expl}[\alpha](\mathcal{A}, v[a/y], V) \\
\text{Expl}[\Sigma Y.\alpha](\mathcal{A}, v, V) &= \bigcup_{B \subseteq A^k} \text{Expl}[\alpha](\mathcal{A}, v, V[B/Y])
\end{aligned}$$

■ **Table 1** Intermediate semantics of  $\Sigma\text{SO}(\underline{\Lambda})$  formulae.

configuration of a TM that corresponds to  $f$ . Finally, we often use that (a)  $\mathcal{A}, v, V \models \varphi$  can be decided in deterministic logarithmic space, if  $\varphi$  is an FO formula, and in deterministic polynomial space, if  $\varphi \in \text{SO}$ , for every finite structure  $\mathcal{A}$  [21], and (b) given  $\mathcal{A}$ , the lexicographic order on  $k$ -tuples over  $A$  induced by  $\leq$  is FO expressible and is also denoted by  $\leq$ .

### 3 The quantitative logic $\Sigma\text{SO}(\underline{\Lambda})$

The logic  $\Sigma\text{SO}(\underline{\Lambda})$  over  $\sigma$ , where  $\Lambda \in \{\text{FO}, \text{SO}\}$ , is defined by the following grammar:

$$\alpha ::= x \mid X \mid \varphi \mid (\alpha + \alpha) \mid (\alpha \cdot \alpha) \mid \Sigma y.\alpha \mid \Sigma Y.\alpha \quad (2)$$

where  $\varphi$  is in  $\Lambda$ ,  $x, y$  are first-order variables, and  $X, Y$  are second-order variables. The syntax of logic  $\Sigma\text{SO}(\underline{\Lambda})$  is the same as that of  $\Sigma\text{QSO}(\underline{\Lambda})$ , where a formula can also be a first- and second-order variable, but not a number  $s \in \mathbb{N}$ .  $\Sigma\text{FO}(\underline{\Lambda})$  is the fragment of  $\Sigma\text{SO}(\underline{\Lambda})$  in which  $\Sigma$  is not allowed over second-order variables. We say that a  $\Sigma\text{SO}(\underline{\Lambda})$  formula is  $x$ -free (resp.  $X$ -free) if it is given by grammar (2) without  $x$  (resp.  $X$ ).

► **Notation Remark 3.1.** We denote  $X \cdot \varphi(X)$  (or  $\varphi(X) \cdot X$ ) by  $\varphi(\underline{X})$ .

We define the semantics of the logic  $\Sigma\text{SO}(\underline{\Lambda})$  in two phases: a formula  $\alpha$  is mapped to a set of strings. Then, the semantic interpretation of formula  $\alpha$  is defined to be the size of this set. Formally,  $\llbracket \alpha \rrbracket(\mathcal{A}, v, V) = |\text{Expl}[\alpha](\mathcal{A}, v, V)|$ , where  $\text{Expl}[\alpha](\mathcal{A}, v, V)$  is recursively defined in Table 1. Expl stands for Explicit and we call  $\text{Expl}[\alpha](\mathcal{A}, v, V)$  the *intermediate semantic interpretation* of formula  $\alpha$ . Note that  $\cup$  and  $\circ$  between sets of strings have replaced sum and multiplication of natural numbers, respectively, in the semantics of QSO.  $S_1 \cup S_2$  is the union of  $S_1$  and  $S_2$ , whereas  $S_1 \circ S_2$  is *concatenation* of sets of strings lifted from the concatenation operation on strings, that is  $S_1 \circ S_2 = \{x \circ y \mid x \in S_1, y \in S_2\}$ . For example,  $\{\varepsilon, a_1, a_2a_3\} \circ \{\varepsilon, a_2a_3\} = \{\varepsilon, a_2a_3, a_1, a_1a_2a_3, a_2a_3a_2a_3\}$ , where  $\varepsilon$  denotes the empty string. In specific, if one of  $S_1, S_2$  is  $\emptyset$ , then  $S_1 \circ S_2 = \emptyset$ .

► **Notation Remark 3.2.** For a finite set  $K$ ,  $K^* := \bigcup_{n \in \mathbb{N}} K^n$  denotes the set of strings over  $K$ ,  $\mathcal{P}(K^*)$  the powerset of  $K^*$ , and  $\varepsilon$  the empty string. For an  $\mathcal{A}$  over  $\sigma$ ,  $\mathcal{R}_k := \mathcal{P}(A^k)$  denotes the set of relations on  $A$  of arity  $k$ .

► **Remark 3.3.** Note that for a formula  $\alpha \in \Sigma\text{SO}(\underline{\Lambda})$  and  $s \in \text{Expl}[\alpha](\mathcal{A}, v, V)$ , we have that  $s \in (A \cup \bigcup_{i \in \mathbb{N}} \mathcal{R}_i)^*$ . In this paper, we consider logics that are either  $X$ -free or  $x$ -free, and so for a formula  $\alpha$  in some of these logics and  $s \in \text{Expl}[\alpha](\mathcal{A}, v, V)$ , either  $s \in A^*$  or  $s \in (\bigcup_{i \in \mathbb{N}} \mathcal{R}_i)^*$ , respectively.

The length of  $\alpha$ , denoted by  $|\alpha|$ , is defined as the length of  $\alpha$  as a string of symbols, boolean formulae and sum operators are treated as one symbol. The length of  $s \in A^* \cup (\bigcup_{i \in \mathbb{N}} \mathcal{R}_i)^*$ , denoted by  $|s|$ , is the standard length of strings. It is not hard to define an *encoding*  $\text{enc}(s)$  of  $s$ , such that  $|\text{enc}(s)| \leq |s| \cdot \log |A|$ , if  $s \in A^*$ , and  $|\text{enc}(s)| \leq |s| \cdot |A|^k$ , if  $s \in (\bigcup_{1 \leq i \leq k} \mathcal{R}_i)^*$ .

► **Lemma 3.4.** *Let  $\alpha$  be a  $\Sigma\text{SO}(\underline{\Lambda})$  formula over  $\sigma$ . For every finite ordered structure  $\mathcal{A}$  over  $\sigma$ ,  $v$ , and  $V$ , and every  $s \in \text{Expl}[\alpha](\mathcal{A}, v, V)$ ,  $|s| \leq |\alpha|$ . Moreover, (a) if  $\alpha$  is an  $X$ -free formula, then  $|\text{enc}(s)| \leq |\alpha| \cdot \log |A|$ , and (b) if  $\alpha$  is an  $x$ -free formula, then  $|\text{enc}(s)| \leq |\alpha| \cdot \text{poly}(|A|)$ .*

### 3.1 The logic $\Sigma\text{SO}(\underline{\Lambda})$ with recursion

By adding a function symbol  $f$  to the syntax of  $\Sigma\text{SO}(\underline{\Lambda})$ , we obtain formulae defined below:

$$\beta ::= x \mid X \mid \varphi \mid f(x_1, \dots, x_k) \mid (\beta + \beta) \mid (\beta \cdot \beta) \mid \Sigma y. \beta \mid \Sigma Y. \beta \quad (3)$$

where  $f$  is a *first-order function symbol* with  $\text{arity}(f) = k$ , and  $x_1, \dots, x_k$  are first-order variables, also denoted by  $\vec{x}$ . In like manner, we can add a *second-order function symbol* to  $\Sigma\text{SO}(\underline{\Lambda})$ . In particular, we consider only second-order function symbols of arity 1, i.e. of the form  $f(X)$ , where  $X$  is a second-order variable. A  $\Sigma\text{SO}(\underline{\Lambda})$  formula  $\beta(X, f)$  with a second-order function symbol  $f(Y)$  is called *arity-consistent* when it has at most one free second-order variable  $X$ , where  $X$  has the same arity as  $Y$ . We fix an arity  $k$  for the first-order function symbol, or the argument of the second-order function symbol.

To extend the semantics of  $\Sigma\text{SO}(\underline{\Lambda})$  to the case of formula  $f(x_1, \dots, x_k)$ , we say that  $F$  is a *first-order function assignment* for  $\mathcal{A}$ , if  $F(f) : A^k \rightarrow \mathcal{P}(A^*)$ . In the case of formula  $f(X)$ , we say that  $F$  is a *second-order function assignment* for  $\mathcal{A}$ , if  $F(f) : \mathcal{R}_k \rightarrow \mathcal{P}(K^*)$ , where  $K$  can be either  $A$  or  $\bigcup_{i \in \mathbb{N}} \mathcal{R}_i$ . We define  $\mathcal{FOF}$  to be the set of functions  $h : A^k \rightarrow \mathcal{P}(A^*)$ ,  $\mathcal{SOF}$  the set of functions  $h : \mathcal{R}_k \rightarrow \mathcal{P}(A^*)$ , and  $\mathcal{RSOF}$  the set of functions  $h : \mathcal{R}_k \rightarrow \mathcal{P}((\bigcup_{i \in \mathbb{N}} \mathcal{R}_i)^*)$ .

Given  $v$  and  $V$ , we define  $\text{Expl}[f(\vec{x})](\mathcal{A}, v, V, F) := F(f)(v(\vec{x}))$  and  $\llbracket f(\vec{x}) \rrbracket(\mathcal{A}, v, V, F) := |F(f)(v(\vec{x}))|$ . The semantics of  $f(X)$  are defined in an analogous way. Now we can add to the syntax of  $\Sigma\text{SO}(\underline{\Lambda})$ , formulae of the form  $[\text{lfp}_f \beta](\vec{x})$  (resp.  $[\text{lfp}_f \beta](X)$ ), where  $\beta$  is a (resp. arity-consistent)  $\Sigma\text{SO}(\underline{\Lambda})$  formula equipped with a first-order (resp. second-order) function symbol  $f$ . To define the semantics of  $[\text{lfp}_f \beta](\vec{x})$ , we first define two lattices. The first lattice is  $(\mathcal{P}(A^*), \subseteq)$ , i.e. it contains all sets of strings over  $A$ . The bottom element is  $\emptyset$  and the top element is the set  $A^*$ . The second lattice is  $(\mathcal{FOF}, \leq_F)$ : for  $g, h \in \mathcal{FOF}$ ,  $g \leq_F h$  iff  $g(\vec{x}) \subseteq h(\vec{x})$ , for every  $\vec{x}$ . The bottom element is  $g_0$  which takes the value  $\emptyset$  for every  $\vec{x}$ , and the top element is  $g_{max}$ , which is equal to  $A^*$  for every  $\vec{x}$ . For an infinite increasing sequence of functions  $h_1 \leq_F h_2 \leq_F h_3 \leq_F \dots$  from  $\mathcal{FOF}$ , we define  $\lim_{n \rightarrow +\infty} h_n := h$ , where for every  $x \in A^k$ ,  $h(x) = \bigcup_{n \in \mathbb{N}} h_n(x)$ .

We interpret  $\beta(\vec{x}, f)$  as an operator  $T_\beta$  on  $\mathcal{FOF}$ . For every  $h \in \mathcal{FOF}$  and  $\vec{a} \in A^k$ ,  $T_\beta(h)(\vec{a}) = \text{Expl}[\beta(\vec{x}, f)](\mathcal{A}, v, V, F)$ , where  $v$  is a first-order assignment for  $\mathcal{A}$  such that  $v(\vec{x}) = \vec{a}$  and  $F$  is a first-order function assignment for  $\mathcal{A}$  such that  $F(f) = h$ . The following propositions state that  $T_\beta$  is monotone on  $(\mathcal{FOF}, \leq_F)$ .

► **Proposition 3.5.** *Let  $f$  be a first-order function symbol with  $\text{arity}(f) = k$  and  $\beta$  be a formula over  $\sigma$  defined by grammar (3), such that if  $\beta$  contains a function symbol, then this function symbol is  $f$ . Let also  $\mathcal{A}$  be a finite ordered structure over  $\sigma$ ,  $h, g : A^k \rightarrow \mathcal{P}(A^*)$  and*

$H, G$  be function assignments such that  $H(f) = h$  and  $G(f) = g$ . If  $h \leq_F g$ , then for every first- and second-order assignments  $v$  and  $V$ , respectively:

$$\text{Expl}[\beta](\mathcal{A}, v, V, H) \subseteq \text{Expl}[\beta](\mathcal{A}, v, V, G).$$

► **Proposition 3.6.** For every formula  $[\text{lfp}_f \beta](\vec{x})$ , where  $\beta$  is in  $\Sigma\text{SO}(\underline{A})$  equipped with a first-order function symbol, operator  $T_\beta$  is monotone on the complete lattice  $(\mathcal{FOF}, \leq_F)$ . In other words, for every  $h, g \in \mathcal{FOF}$ , if  $h \leq_F g$ , then  $T_\beta(h) \leq_F T_\beta(g)$ .

Thus, by the Knaster–Tarski theorem,  $T_\beta$  has a least fixed point. To compute the least fixed point of  $T_\beta$ , let us consider the sequence of functions  $\{h_i\}_{i \in \mathbb{N}}$ ,  $h_i : A^k \rightarrow \mathcal{P}(A^*)$ , where  $h_0(\vec{a}) = \emptyset$  for every  $\vec{a} \in A^k$ , and  $h_{i+1} := T_\beta(h_i)$ , for every  $i \in \mathbb{N}$ . We define  $\text{lfp}(T_\beta) := \lim_{n \rightarrow +\infty} h_n$ . Finally,  $\text{Expl}[\text{lfp}_f \beta](\vec{x})(\mathcal{A}, v, V) := \text{lfp}(T_\beta)(v(\vec{x})) = \lim_{n \rightarrow +\infty} h_n(v(\vec{x}))$  and  $\llbracket [\text{lfp}_f \beta](\vec{x}) \rrbracket(\mathcal{A}, v, V) = |\lim_{n \rightarrow +\infty} h_n(v(\vec{x}))|$ . The semantics of  $[\text{lfp}_f \beta](X)$  are defined in a completely analogous way. Examples 4.3, 4.8, and 4.9 make clear how formulae of the form  $[\text{lfp}_f \beta](\vec{x})$  are interpreted.

The logics we define below are fragments of  $\Sigma\text{SO}(\underline{\text{SO}})$  with recursion. Given a formula  $[\text{lfp}_f \beta](\vec{x})$  or  $[\text{lfp}_f \beta](X)$  in any of them, operator  $T_\beta$  is monotone on the complete lattice  $(\mathcal{F}, \leq_F)$ , where  $\mathcal{F}$  can be  $\mathcal{FOF}$ ,  $\mathcal{SOF}$ , or  $\mathcal{RSOF}$ .

► **Remark 3.7.** The name of a logic with recursion will be of the form  $\mathbf{R}_{L_1} \Sigma_{L_2}(\mathbf{L}_3)$ , where  $L_1 \in \{\mathbf{fo}, \mathbf{so}\}$  indicates that function symbol  $f$  is over first- or second-order variables, respectively,  $L_2 \in \{\mathbf{fo}, \mathbf{so}\}$  means that quantifier  $\Sigma$  is over first- or second-order variables, respectively, and  $L_3 \in \{\mathbf{FO}, \mathbf{SO}\}$  means that  $\varphi$  in (2) is in  $L_3$ .

## 4 Logics that capture SpanL and SpanPSPACE

► **Definition 4.1.**  $\mathbf{R}_{\mathbf{fo}} \Sigma_{\mathbf{fo}}(\mathbf{FO})$  over  $\sigma$  is the set of formulae  $[\text{lfp}_f \beta](\vec{x})$ , where  $\beta$  is defined by:

$$\beta ::= \alpha \mid f(x_1, \dots, x_k) \mid (\beta + \beta) \mid (\alpha \cdot \beta) \mid \Sigma y. \beta \quad (4)$$

where  $\alpha$  is an  $X$ -free  $\Sigma\mathbf{FO}(\underline{\mathbf{FO}})$  formula over  $\sigma$ ,  $x_1, \dots, x_k, y$  are first-order variables, and  $f$  is a first-order function symbol.

► **Remark 4.2.** Notice that for a formula  $[\text{lfp}_f \beta](\vec{x}) \in \mathbf{R}_{\mathbf{fo}} \Sigma_{\mathbf{fo}}(\mathbf{FO})$ , it may be the case that  $\llbracket [\text{lfp}_f \beta](\vec{x}) \rrbracket(\mathcal{A}, v, V) = +\infty$  analogously to the fact that the computation of an NLTM may contain cycles. For the sake of simplicity, we assume that an NL-transducer  $M$  can have infinitely many accepting paths and  $\text{SpanL}$  contains functions from  $\Sigma^*$  to  $\mathbb{N} \cup \{+\infty\}$ . To be in accordance with the literature, we can adjust the syntax of  $\mathbf{R}_{\mathbf{fo}} \Sigma_{\mathbf{fo}}(\mathbf{FO})$  formulae to express the operation of the clock attached to NLTM as discussed in Remark 2.4.

Let  $N$  be an NL-transducer and  $\mathcal{A}$  be over  $\sigma$  with  $|A| = n$ . The number of different configurations of  $N$  is at most  $n^k - 1$  for some  $k \in \mathbb{N}$ . To encode them, we use  $k$ -tuples over  $A$ . To encode the output symbol, if any, that is produced at some configuration, it suffices to use two distinct elements of  $A$ , since the output alphabet is  $\Sigma = \{0, 1\}$ ; we use the minimum element and the successor of the minimum element, which are both  $\mathbf{FO}$  expressible. Below, we informally write  $\varphi(c)$  to denote  $\varphi(x)$  interpreted in  $\mathcal{A}$  where first-order variable  $x$  is assigned  $c \in A$ . Formula  $[\text{lfp}_f \text{span}_L](\vec{x})$  counts the different valid outputs of  $N$ , where  $\text{span}_L(\vec{x}, f)$  is:

$$\text{acc}(\vec{x}) + \Sigma \vec{y}. \Sigma z. (\text{output}_0(\vec{x}, \vec{y}, z) + \text{output}_1(\vec{x}, \vec{y}, z) + \text{next}_0(\vec{x}, \vec{y}) + \text{next}_1(\vec{x}, \vec{y})) \cdot f(\vec{y}).$$

■ **Algorithm 1** NLTM  $MSp_{\beta}^{sub}$ .

---

**Input:**  $\gamma, \mathcal{A}, v, V$ , where  $\gamma$  is a subformula of  $\beta$

- 1 **if**  $\gamma == \alpha$  has no function symbol **then** simulate the transducer from Proposition 4.5
- 2 **if**  $\gamma == f(\vec{y})$  **then** simulate  $MSp_{\beta}^{sub}(\beta, \mathcal{A}, v[v(\vec{y})/\vec{x}], V)$
- 3 **if**  $\gamma == \gamma_1 + \gamma_2$  **then**
- 4 |   non-deterministically choose  $\gamma' \in \{\gamma_1, \gamma_2\}$
- 5 |   simulate  $MSp_{\beta}^{sub}(\gamma', \mathcal{A}, v, V)$
- 6 **if**  $\gamma == \alpha \cdot \gamma'$  **then**
- 7 |   **for**  $s \in A^*$  where  $|s| \leq |\alpha|$  **do**
- 8 |   |   **if**  $s \in \text{Expl}[\alpha](\mathcal{A}, v, V)$  **then** simulate  $MSp_{\beta}^{sub}(\gamma', \mathcal{A}, v, V)$
- 9 **if**  $\gamma == \sum y.\gamma'$  **then**
- 10 |   non-deterministically choose  $a \in A$
- 11 |   simulate  $MSp_{\beta}^{sub}(\gamma', \mathcal{A}, v[a/y], V)$

---

Interpretations of  $z$  and  $\vec{x}, \vec{y}$  encode a bit of the output, and configurations of  $N$ , respectively. Formulae  $\text{next}_i(\vec{c}, \vec{c}')$ ,  $i = 0, 1$ , say that if  $N$  is in configuration  $\vec{c}$  and makes non-deterministic choice  $i$ , then it is in  $\vec{c}'$ , and no output symbol is produced. Formulae  $\text{output}_i(\vec{c}, \vec{c}', b)$ ,  $i = 0, 1$ , state that  $N$  makes choice  $i$  and so it transitions from configuration  $\vec{c}$  to  $\vec{c}'$  and writes the bit encoded by  $b$  on the next output cell. When  $N$  is in some  $\vec{c}$  that only a deterministic transition can be made, then exactly one of  $\text{next}_i(\vec{c}, \vec{c}')$ ,  $\text{output}_i(\vec{c}, \vec{c}', b)$ ,  $i = 0, 1$ , is satisfied in  $\mathcal{A}$  for a  $\vec{c}' \in A^k$  (and a  $b \in A$ ). Formula  $\text{acc}(\vec{c})$  states that  $\vec{c}$  is the accepting configuration. All aforementioned formulae can be expressed in **F0**. Note that for any  $\mathcal{A}, v$ , and  $V$ ,  $\text{Expl}[\text{lf}_f \text{span}_{\perp}](\vec{x})(\mathcal{A}, v, V)$  is a set of strings in  $A^*$  that encode the outputs of  $N$ .

■ **Figure 1** The computation tree of a transducer  $N$  on some input  $\text{enc}(\mathcal{A})$ .  $\vec{c}/b$  represents that  $N$  enters configuration encoded by  $\vec{c}$  and writes bit  $b$  on the output tape.

► **Example 4.3.** Consider the computation tree shown in Figure 1 which corresponds to a transducer  $N$  that on input  $\text{enc}(\mathcal{A})$  has three outputs, and  $\text{span}_N(\text{enc}(\mathcal{A})) = 1$ . Let  $\mathbf{0}, \mathbf{1}$  denote the minimum and the successor of the minimum element of  $A$ , respectively. Then,

- $\text{Expl}[\text{lf}_f \text{span}_{\perp}](\vec{x})(\mathcal{A}, v[\vec{c}_{acc}/\vec{x}]) = \{\varepsilon\}$ , and  
 $\text{Expl}[\text{lf}_f \text{span}_{\perp}](\vec{x})(\mathcal{A}, v[\vec{c}_{rej}/\vec{x}]) = \emptyset$ ,
- $\text{Expl}[\text{lf}_f \text{span}_{\perp}](\vec{x})(\mathcal{A}, v[\vec{c}_1/\vec{x}]) = \emptyset \cup \{\mathbf{1}\} \circ f(\vec{c}_3) \cup f(\vec{c}_4) = \{\mathbf{1}\} \circ (\mathbf{0} \circ \emptyset) \cup \{\mathbf{1}\} \circ \{\varepsilon\} = \{\mathbf{1}\}$ ,
- $\text{Expl}[\text{lf}_f \text{span}_{\perp}](\vec{x})(\mathcal{A}, v[\vec{c}_{init}/\vec{x}]) = \emptyset \cup \{\mathbf{0}\} \circ f(\vec{c}_1) = \{\mathbf{01}\}$ .

Intuitively, the intermediate interpretation of  $\text{lf}_f \text{span}_{\perp}(\vec{c})$  is the set of the different valid outputs  $N$  produces during its computation starting from the configuration encoded by  $\vec{c}$ .

► **Proposition 4.4.** *Given an NL-transducer  $N$ ,  $\text{span}_N(\text{enc}(\mathcal{A})) = \llbracket [\text{lfp}_f \text{span}_L](\vec{x}) \rrbracket(\mathcal{A}, v, V)$ , for every  $\mathcal{A}$ ,  $v$ , and  $V$ , such that  $v(\vec{x})$  encodes the starting configuration of  $N$ .*

To prove that  $\text{R}_{\text{fo}}\Sigma_{\text{fo}}(\text{FO}) \subseteq \text{SpanL}$ , first note that  $X$ -free  $\Sigma\text{FO}(\text{FO})$  formulae can be easily evaluated by NLTMs as Proposition 4.5 states.

► **Proposition 4.5.** *For every  $X$ -free  $\Sigma\text{FO}(\text{FO})$  formula  $\alpha$  over  $\sigma$ , there is an NL-transducer  $M$ , that on input  $\text{enc}(\mathcal{A}, v, V)$  has exactly one accepting run for each  $s \in \text{Expl}[\alpha](\mathcal{A}, v, V)$ , on which it outputs  $\text{enc}(s)$ , and no other accepting runs.*

► **Proposition 4.6.** *Let  $[\text{lfp}_f \beta](\vec{x})$  be an  $\text{R}_{\text{fo}}\Sigma_{\text{fo}}(\text{FO})$  formula over  $\sigma$ . There is an NL-transducer  $M_\beta$ , such that  $\text{span}_{M_\beta}(\text{enc}(\mathcal{A}, v, V)) = \llbracket [\text{lfp}_f \beta](\vec{x}) \rrbracket(\mathcal{A}, v, V)$ , for every  $\mathcal{A}$ ,  $v$  and  $V$ .*

**Proof.** Let  $[\text{lfp}_f \beta](\vec{x}) \in \text{R}_{\text{fo}}\Sigma_{\text{fo}}(\text{FO})$ . The NL-transducer  $M_\beta(\mathcal{A}, v, V)$  calls  $M\text{Sp}_\beta^{\text{sub}}(\beta, \mathcal{A}, v, V)$  from Algorithm 1. If  $\beta$  does not contain a function symbol, then  $\llbracket [\text{lfp}_f \beta](\vec{x}) \rrbracket(\mathcal{A}, v, V) = \llbracket \beta \rrbracket(\mathcal{A}, v, V)$ . By Proposition 4.5, there is an NL-transducer  $M$ , such that  $\text{span}_M(\text{enc}(\mathcal{A}, v, V)) = \llbracket \beta \rrbracket(\mathcal{A}, v, V)$ . In this case, let  $M_\beta$  be  $M$ . Similarly, for any sub-formula  $\alpha$  of  $\beta$  without function symbols,  $M_\alpha$  is the NL-transducer associated with  $\alpha$  from Proposition 4.5. ◀

► **Theorem 4.7.**  $\text{R}_{\text{fo}}\Sigma_{\text{fo}}(\text{FO}) = \text{SpanL}$  over finite ordered structures.

The following are examples of specific SpanL problems expressed in  $\text{R}_{\text{fo}}\Sigma_{\text{fo}}(\text{FO})$ .

► **Example 4.8.** Let  $\mathcal{G} = \langle V, E, \leq \rangle$  represent a directed graph with a source. Then,  $\llbracket [\text{lfp}_f \beta](x) \rrbracket(\mathcal{G}, v, V)$  is the number of sinks in the graph, where  $\beta(x, f) := \forall y \neg E(x, y) \cdot x + \Sigma y. E(x, y) \cdot f(y)$ , and  $v(x)$  is the source of the graph.

► **Example 4.9.** Let  $\mathcal{N} = \langle Q = \{q_0, \dots, q_{n-1}, \ell_0, \dots, \ell_m\}, L, E_0, E_1, \leq \rangle$  represent an NFA  $N$  over the input alphabet  $\{0, 1\}$ , together with  $1^m$ ;  $Q$  is the universe,  $L = \{\ell_0, \dots, \ell_m\}$  is a relation that distinguishes states of  $N$  from the encoding of  $1^m$ , and  $E_i$ ,  $i = 0, 1$ , is the set of  $i$ -transitions of  $N$ . Let  $\beta(x, y, f) := \text{acc}(x) + (y < \max) \cdot \Sigma x'. \Sigma y'. (y' = y + 1) \cdot (E_0(x, x') \cdot \min_0 + E_1(x, x') \cdot \min_1) \cdot f(x', y')$ , where  $\min_0$  and  $\min_1$ , and  $\max$  express the minimum, the successor of the minimum, and the maximum element of  $Q$ , respectively,  $\text{acc}(x)$  expresses that  $x$  is an accepting state of  $N$ , and  $y' = y + 1$  is defined so that  $y'$  is the successor of  $y$ . Then,  $\llbracket [\text{lfp}_f \beta](x, y) \rrbracket(\mathcal{N}, v, V)$  is the number of strings of length at most  $m$  accepted by  $N$ , where  $v(x)$  encodes the starting state of  $N$ , and  $v(y)$  encodes the minimum element of  $L$ . This problem is SpanL-complete and was defined in [2] as the *census function* of an NFA.

We now introduce the logic  $\text{R}_{\text{so}}\Sigma_{\text{so}}(\text{SO})$ , which captures SpanPSPACE.

► **Definition 4.10.**  $\text{R}_{\text{so}}\Sigma_{\text{so}}(\text{SO})$  over  $\sigma$  is the set of formulae  $[\text{lfp}_f \beta](X)$ , where  $\beta$  is defined by:

$$\beta ::= \alpha \mid f(X) \mid (\beta + \beta) \mid (\alpha \cdot \beta) \mid \Sigma y. \beta \mid \Sigma Y. \beta \quad (5)$$

where  $\alpha$  is an  $X$ -free  $\Sigma\text{SO}(\text{SO})$  formula over  $\sigma$ ,  $y$  is a first-order variable,  $X, Y$  are second-order variables, and  $f$  is a second-order function symbol.

► **Remark 4.11.** Relations  $R_1, \dots, R_m$  on  $A$  with  $\text{arity}(R_j) = k$ ,  $1 \leq j \leq m$ , can be encoded by one relation  $R$  on  $A$  of arity  $k + \lceil \log m \rceil$ , by defining  $R(\vec{i}, \vec{a})$  iff  $R_i(\vec{a})$ , for every  $\vec{a} \in A^k$ , where  $\vec{i}$  is the  $i$ -th smallest  $\lceil \log m \rceil$ -tuple over  $A$ . We use this observation to show that a second-order function symbol  $f$  with  $\text{arity}(f) = 1$ , suffices to capture SpanPSPACE.

► **Remark 4.12.** To avoid formulae  $[\text{lf}_f \beta](X) \in \mathbf{R}_{\text{so}}\Sigma_{\text{so}}(\mathbf{SO})$  with  $\llbracket [\text{lf}_f \beta](X) \rrbracket(\mathcal{A}, v, V) = +\infty$ , we can adjust the syntax of  $\mathbf{R}_{\text{so}}\Sigma_{\text{so}}(\mathbf{SO})$  similarly to Remark 4.2. The only difference is that now the clock imposes an exponential-time bound.

Let  $\mathcal{A}$  over  $\sigma$  with  $|A| = n$  and  $M = (\mathcal{Q}, \Sigma, \delta, q_0, q_F)$  be a non-deterministic poly-space transducer that uses  $n^d - 1$  space. Let also  $k = \max\{d, \lceil \log |\mathcal{Q}| \rceil\}$ . We can use  $k$ -tuples over  $A$ , to encode  $n^d - 1$  tape cells and  $|\mathcal{Q}|$  states. W.l.o.g. assume that  $M$  has a single tape. A configuration of  $M$  can be encoded by the tuple of  $k$ -ary relations  $\vec{C} = (T, E, P, Q)$ :  $T(\vec{c})$  iff cell  $c$  encoded by  $\vec{c}$  contains symbol 1 (tape contents),  $E(\vec{c})$  denotes that all cells greater than  $c$  contain the symbol  $\_$  (end of zeros and ones on the tape),  $P(\vec{c})$  indicates that the head is on cell  $c$  (head's position), and  $Q(\vec{c})$  means that  $N$  is in state  $q$  that is encoded by  $\vec{c}$ . As in the case of **SpanL**, a bit that  $M$  outputs at some time step is encoded using two elements of  $A$ . Formulae  $\text{Next}_i(\vec{X}, \vec{Y})$ ,  $\text{Output}_i(\vec{X}, \vec{Y}, x)$ ,  $i = 0, 1$ , and  $\text{Acc}(\vec{X})$  express similar facts for the computation of  $M$  as the respective formulae defined for **SpanL**. They can be expressed in **F0** as the formulae that describe the computation of an NPTM in the proof of Fagin's theorem [21]. By Remark 4.11, the aforementioned formulae can be replaced by first-order formulae such that a unique relation is used to encode the configuration of  $M$ . Therefore, we abuse notation and write  $\text{Next}_i(X, Y)$ ,  $\text{Output}_i(X, Y, x)$ , and  $\text{Acc}(X)$ .

► **Theorem 4.13.**  $\mathbf{R}_{\text{so}}\Sigma_{\text{so}}(\mathbf{SO}) = \text{SpanPSPACE}$  over finite ordered structures.

**Proof.** The proof of  $\mathbf{R}_{\text{so}}\Sigma_{\text{so}}(\mathbf{SO}) \subseteq \text{SpanPSPACE}$  is analogous to that of Proposition 4.6. For the inclusion  $\text{SpanPSPACE} \subseteq \mathbf{R}_{\text{so}}\Sigma_{\text{so}}(\mathbf{SO})$ , given a non-deterministic poly-space transducer  $M$ , consider the formula  $\text{span}_{\text{pspace}}(X, f) := \text{Acc}(X) + \Sigma Y. \Sigma x. (\text{Output}_0(X, Y, \underline{x}) + \text{Output}_1(X, Y, \underline{x}) + \text{Next}_0(X, Y) + \text{Next}_1(X, Y)) \cdot f(Y)$ . Then,  $\llbracket [\text{lf}_f \text{span}_{\text{pspace}}](X) \rrbracket(\mathcal{A}, v, V) = \text{span}_M(\text{enc}(\mathcal{A}))$ , for every  $\mathcal{A}, v, V$ , such that  $V(X)$  encodes the initial configuration of  $M$ . ◀

## 5 $\mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO})$ captures $\#PSPACE$

In this section, we prove that the logic  $\Sigma\mathbf{SO}(\underline{\mathbf{SO}})$  equipped with a second-order function symbol and a restricted form of recursion captures  $\#PSPACE$  over finite ordered structures. Superscript **r** in the name of the logic stands for the fact that recursion is restricted.

► **Definition 5.1.**  $\mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO})$  over  $\sigma$  is the set of formulae  $[\text{lf}_f \beta](X)$ , where  $\beta$  is defined by:

$$\beta ::= \alpha \mid (\alpha + \beta) \mid \Sigma Y. \varphi(X, \underline{Y}) \cdot f(Y) \quad (6)$$

where  $X, Y$  are second-order variables,  $\varphi$  is an **SO** formula over  $\sigma$ ,  $\alpha$  is an  $x$ -free  $\Sigma\mathbf{SO}(\underline{\mathbf{SO}})$  formula over  $\sigma$ , and  $f$  is a second-order function symbol.

► **Remark 5.2.** In the case of  $\#PSPACE$ , we can attach a clock to non-deterministic poly-space TMs, and restrict the syntax of  $\mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO})$  accordingly, as in Section 4. An alternative approach is the following: it can be proven that for every  $\beta \in \mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO})$ ,  $\llbracket \beta \rrbracket$  is in **FPSPACE** in the sense that there is a deterministic poly-space TM  $N$  such that on input  $\text{enc}(\mathcal{A}, v, V)$  outputs  $\llbracket \beta \rrbracket(\mathcal{A}, v, V)$ , if  $\llbracket \beta \rrbracket(\mathcal{A}, v, V) \in \mathbb{N}$ , and the symbol  $\perp$ , if  $\llbracket \beta \rrbracket(\mathcal{A}, v, V) = +\infty$ . By Proposition 2.5,  $\mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO}) \subseteq \#PSPACE$ , where we consider a slightly different kind of a non-deterministic poly-space TM which on input  $x$ , if  $f(x) = +\infty$ , it outputs  $\perp$  and halts, and if  $f(x) = m \in \mathbb{N}$ , it generates  $m$  accepting paths.

► **Theorem 5.3.**  $\mathbf{R}_{\text{so}}^r \Sigma_{\text{so}}(\mathbf{SO}) = \#PSPACE$  over finite ordered structures.

## 6

 $R_{\text{so}}^r \Sigma_{\text{so}}^r(\text{FO})$  captures TotP

We define a fragment of  $\Sigma\text{SO}(\text{FO})$  with recursion, which we call  $R_{\text{so}}^r \Sigma_{\text{so}}^r(\text{FO})$ . Definitions 6.1 and 6.2 will be used to restrict the use of  $\Sigma$  operator.

► **Definition 6.1.** We say that a formula  $\varphi(Y)$  syntactically defines  $Y$  if  $\varphi(Y)$  is of the form  $\forall \vec{y} Y(\vec{y}) \leftrightarrow \psi(\vec{y})$ , for some formula  $\psi$ .

► **Definition 6.2.** We say that a formula  $\varphi(X, Y)$  (a) extends  $X$  to  $Y$  if it is of the form  $\forall \vec{y} Y(\vec{y}) \leftrightarrow X(\vec{y}) \vee \psi(X, \vec{y})$ , and (b) strictly extends  $X$  to  $Y$  if it is of the form  $\forall \vec{y} (Y(\vec{y}) \leftrightarrow X(\vec{y}) \vee \psi(X, \vec{y})) \wedge \exists \vec{y} (\neg X(\vec{y}) \wedge Y(\vec{y}))$ , for some formula  $\psi$  and  $\text{arity}(X) = \text{arity}(Y)$ .

► **Notation Remark 6.3.** (a)  $Y := \varphi \cdot \alpha$  denotes  $\Sigma Y. \varphi(Y) \cdot \alpha$ , where  $\varphi$  syntactically defines  $Y$ , and (b)  $\underline{Y} := \varphi(X) \cdot f(Y)$  denotes  $\Sigma Y. \varphi(X, Y) \cdot Y \cdot f(Y)$ , where  $\varphi$  (strictly) extends  $X$  to  $Y$ .

► **Definition 6.4.**

- (a) The  $\Sigma\text{SO}^r(\text{FO})$  formulae over  $\sigma$  are the  $x$ -free  $\Sigma\text{SO}(\text{FO})$  formulae with the restriction that the second-order sum operator only appears as  $Y := \varphi \cdot \alpha$ ,  $\varphi \in \text{FO}$ .  
 (b)  $R_{\text{so}}^r \Sigma_{\text{so}}^r(\text{FO})$  over  $\sigma$  is the set of formulae  $[\text{lfp}_f \beta](X)$ , where  $\beta$  is defined by:

$$\beta ::= \alpha \mid \underline{Y} := \psi(X) \cdot f(Y) \mid \alpha + \beta \mid \varphi \cdot \beta \mid \beta + \beta + \top \mid \varphi \cdot \beta + \neg \varphi \cdot \beta \quad (7)$$

where  $\alpha$  is a  $\Sigma\text{SO}^r(\text{FO})$  formula,  $\varphi, \psi \in \text{FO}$ ,  $\psi$  strictly extends  $X$  to  $Y$ , and  $f$  is a second-order function symbol.

To express the generic TotP problem in  $R_{\text{so}}^r \Sigma_{\text{so}}^r(\text{FO})$ , we first describe how an NPTM run can be encoded. Let  $\mathcal{A}$  be of size  $n$  and  $N = (\mathcal{Q}, \Sigma, \delta, q_0, q_F)$  be an NPTM that uses at most  $n^d - 1$  time. W.l.o.g. assume that  $N$  has a single tape. We define  $\Gamma = \Sigma \cup \{\_ \} = \{0, 1, \_ \}$ ,  $\Gamma_{\mathcal{Q}} = \Gamma \times \mathcal{Q}$ , and  $k = \max\{d, \lceil \log(3 + 3|\mathcal{Q}|) \rceil\}$ . To encode cells, time steps, and symbols in  $\Gamma \cup \Gamma_{\mathcal{Q}}$ , we use  $k$ -tuples over  $A$ . Let  $S$  be a relation of arity  $3k$ , such that, if  $\vec{r}$  represents the symbol  $\gamma \in \Gamma$ , then  $S(\vec{c}, \vec{t}, \vec{r})$  signifies that cell  $\vec{c}$  contains symbol  $\gamma$  at time step  $\vec{t}$ . If  $\vec{r}$  represents the symbol-state pair  $(\gamma, q) \in \Gamma_{\mathcal{Q}}$ , then  $S(\vec{c}, \vec{t}, \vec{r})$  signifies that  $\vec{c}$  contains symbol  $\gamma$ , the head is at cell  $\vec{c}$ , and  $N$  is in state  $q$  at time step  $\vec{t}$ . We use the FO expressible formulae  $\vec{x} + 1$  and  $\text{min}$  to describe the successor of  $\vec{x}$  and the minimum  $k$ -tuple, respectively.

We say that a relation  $S$  of arity  $3k$  on  $\mathcal{A}$  describes a partial run  $c_0 c_1 \dots c_m$  of  $N$ , when (a) there is some  $\vec{t} \in A^k$ , such that for every  $\vec{t}' \leq \vec{t}$ , there are  $\vec{c}, \vec{r} \in A^k$ , such that  $S(\vec{c}, \vec{t}', \vec{r})$ , and for every  $\vec{t}' > \vec{t}$  and  $\vec{c}, \vec{r} \in A^k$ , not  $S(\vec{c}, \vec{t}', \vec{r})$ , (b)  $S(-, \text{min}, -)$  describes the encoding of the starting configuration  $c_0$ , and (c) if  $S(-, \vec{t}, -)$  describes the encoding of  $c_i$ , then  $S(-, \vec{t} + 1, -)$  either describes the encoding of  $c_{i+1}$  or is empty. We say that formula  $\varphi(\vec{c}, \vec{t}, \vec{r})$  describes a partial run  $c_0 c_1 \dots c_m$ , when  $\varphi$  defines in  $\mathcal{A}$  a relation that does so. We use the standard notion of definability, where  $\varphi(\vec{x})$  defines  $R$  in  $\mathcal{A}$ , if for every  $\vec{a} \in A^k$ ,  $R(\vec{a})$  iff  $\mathcal{A}, v[\vec{a}/\vec{x}] \models \varphi(\vec{x})$ . For example, let  $S_0$  be a relation of arity  $3k$  that describes the beginning of a run by  $N$  on  $\text{enc}(\mathcal{A})$ .  $S_0$  can be defined in FO by  $\vec{y} = \text{min} \wedge \varphi_{c_0}(\vec{x}, \vec{z})$ , where  $\varphi_{c_0}$  encodes the starting configuration, as, for instance, in [21].

Below we define formula  $\text{tot}(X, f)$ , the least fixed point of which applied on  $S_0$  is equal to the number of branchings of  $N$  on input  $\text{enc}(\mathcal{A})$ :

$$\text{branch}(X) \left( \sum_{i=0,1} \underline{Y} := \text{ndet}_i(X) \cdot f(Y) + \top \right) + \neg \text{branch}(X) (\text{nfinal}(X) \cdot \underline{Y} := \text{det}(X) \cdot f(Y)).$$

Let  $X$  be interpreted as a relation  $S_p$  that describes a partial run  $c_0 \dots c_m$  of  $N$ . Formula  $\text{branch}$  checks whether the current configuration  $c_m$  creates a branching. Formulae  $\text{ndet}_i$ ,  $i = 0, 1$ , and  $\text{det}$  extend  $S_p$  to a relation  $S_{\text{new}}$ , that describes the run  $c_0 \dots c_m c_{m+1}$ , where

$c_{m+1}$  is the configuration that  $N$  reaches from  $c_m$  by making non-deterministic choice  $i$  or a deterministic transition, respectively. The evaluation continues recursively on  $S_{new}$ . Finally, if  $c_m$  is a configuration where  $N$  halts,  $\mathbf{nfinal}$  becomes false and recursion stops. Moreover,  $\mathbf{ndet}_i(X, Y)$ ,  $i = 0, 1$ , and  $\mathbf{det}(X, Y)$  are  $\mathbf{FO}$  formulae that strictly extend  $X$  to  $Y$ . As a result, there is a bijection between the strings in  $\text{Expl}[\llbracket \text{lf}_f \text{tot} \rrbracket(X)](\mathcal{A}, v, V)$  and branchings of  $N(\text{enc}(\mathcal{A}))$ . Assume that  $c_m$  is a configuration that is not the initial configuration  $c_0$  and leads to a non-deterministic choice. Then,  $c_m$  can be mapped to a string  $S_1 \circ \dots \circ S_i \in (\mathcal{R}_{3k})^*$  in  $\text{Expl}[\llbracket \text{lf}_f \text{tot} \rrbracket(X)](\mathcal{A}, v, V)$ , where  $S_j$  extends  $S_{j-1}$ , for every  $2 \leq j \leq i$ , and  $S_i$  describes  $c_0 \dots c_m$ . If  $c_0$  leads to a non-deterministic choice, it is mapped to string  $\varepsilon$ .

► **Proposition 6.5.** *Given an NPTM  $N$ ,  $\llbracket \llbracket \text{lf}_f \text{tot} \rrbracket(X) \rrbracket(\mathcal{A}, v, V) = \#(\text{branchings of } N(\text{enc}(\mathcal{A}))),$  where  $V(X)$  encodes the initial configuration of  $N$ .*

The specific form of any  $\llbracket \text{lf}_f \beta \rrbracket(X) \in \mathbf{R}_{\mathbf{so}}^r \Sigma_{\mathbf{so}}^r(\mathbf{FO})$  guarantees that there is an NPTM that generates a number of paths equal to  $\llbracket \llbracket \text{lf}_f \beta \rrbracket(X) \rrbracket(\mathcal{A}, v, V) + 1$ .

► **Theorem 6.6.**  $\mathbf{R}_{\mathbf{so}}^r \Sigma_{\mathbf{so}}^r(\text{LFP}) = \text{TotP}$  over finite ordered structures.

## 7 Conclusions and open questions

Inspired by the two-step semantics developed in the context of weighted logics, we introduced two-step semantics that enriches the existing framework of quantitative logics, i.e. logics for expressing counting problems. We provided logical characterisations of  $\text{SpanL}$  and  $\text{TotP}$ , answering an open question of [5]. Furthermore, we determined logics that capture  $\text{SpanPSPACE}$  and  $\text{FPSPACE}$ . Compared to the other classes, the logic that captures  $\text{TotP}$  was defined in a more complicated way that is related to the properties of  $\text{TotP}$  problems: recursion of the logic expresses self-reducibility and the restricted form of the recursion captures the easy-decision property. It is worth investigating whether  $\text{TotP}$  is captured by a simpler, more elegant logic. The intermediate semantics can express sets of computation paths of TMs, different valid outputs of transducers, or solutions to computational problems. In particular, in the case of  $\text{SpanL}$  and  $\text{SpanPSPACE}$ , union and concatenation of sets are more suitable than addition and multiplication of  $\mathbf{QS0}$ ; when the union (resp. concatenation) of two sets of strings is computed, identical outputs will contribute one string to the resulting set. In general, using the intermediate semantics, it becomes possible to keep track of paths, outputs, and solutions, apply operations on them, and then count them. Another difference between our logics and quantitative logics from [5], is that in [5], only first-order function symbols were considered and interpreted as functions  $h : A^k \rightarrow \mathbb{N}$ . Then, the respective second lattice  $(\mathcal{F}, \leq_F)$  is not complete and the least fixed point was defined by considering the supports of functions in  $\mathcal{F}$  [5, Section 6]. By defining here, functions whose values are sets of strings, the lattice  $(\mathcal{F}, \leq_F)$ , where  $\mathcal{F}$  is one of  $\mathcal{FOF}$ ,  $\mathcal{SOF}$ , or  $\mathcal{RSOF}$ , becomes complete, and the definition of the least fixed point is straightforward.

The two-step semantics we propose in this work is noteworthy for reasons beyond its primary objective. For instance, by specifying the concrete semantics such that any non-empty set maps to 1 and the empty set to 0, our results yield least-fixed-point logical characterisations of  $\text{NL}$  and  $\text{PSPACE}$ , the decision variants of  $\text{SpanL}$  and  $\text{FPSPACE}$ , respectively. It is known that these two classes are captured by  $\mathbf{FO}$  and  $\mathbf{S0}$ , equipped with the transitive closure operator, respectively [21]. Our logics combine the least fixed point with quite natural syntactic definitions, without resorting to different fixed-point operators for each logic.

We believe that the logical characterisation of  $\text{SpanL}$  can yield more direct ways to approximate its problems.  $\mathbf{R}_{\mathbf{fo}} \Sigma_{\mathbf{fo}}(\mathbf{FO})$  formulae bear some resemblance to regular grammars, (or, equivalently, to NFAs), since the syntax of the logic, at each recursive call, concatenates

a string of fixed length from the left with  $f(\vec{x})$ . An interesting question is whether one can adjust the fpras for #NFA and apply it directly to the syntax of  $R_{\text{FO}}\Sigma_{\text{FO}}(\text{FO})$ , giving an fpras metatheorem for the logic. Moreover, it is only natural to investigate the class that results from allowing arbitrary concatenations of recursive calls, and to expect a natural connection to context-free languages. Note that the problem of counting the strings of a specific length accepted by a context-free grammar admits a quasi-polynomial randomized approximation algorithm [19] and it is open whether it has an fpras.

Another interesting question remains the logical characterisation of a class for which computing the permanent of a matrix is complete under parsimonious reductions. This was the first problem shown in [32] to be #P-complete under Turing reductions, and it has an fpras [22]. Therefore, such a result would provide a new subclass of FPRAS and refine the complexity of the well-studied PERMANENT problem.

## Abstract

In 1992 Biró, Hujter and Tuza introduced, for every fixed connected graph  $H$ , the class of  $H$ -graphs, defined as the intersection graphs of connected subgraphs of some subdivision of  $H$ . Such classes of graphs are related to many known graph classes: for example,  $K_2$ -graphs coincide with interval graphs,  $K_3$ -graphs with circular-arc graphs, the union of  $T$ -graphs, where  $T$  ranges over all trees, coincides with chordal graphs. Recently, quite a lot of research has been devoted to understanding the tractability border for various computational problems, such as recognition or isomorphism testing, in classes of  $H$ -graphs for different graphs  $H$ .

In this work we undertake this research topic, focusing on the recognition problem. Chaplick, Töpfer, Voborník, and Zeman showed an XP-algorithm testing whether a given graph is a  $T$ -graph, where the parameter is the size of the tree  $T$ . In particular, for every fixed tree  $T$  the recognition of  $T$ -graphs can be solved in polynomial time. Tucker showed a polynomial time algorithm recognizing  $K_3$ -graphs (circular-arc graphs). On the other hand, Chaplick et al. showed also that for every fixed graph  $H$  containing two distinct cycles sharing an edge, the recognition of  $H$ -graphs is NP-hard.

The main two results of this work narrow the gap between the NP-hard and P cases of  $H$ -graph recognition. First, we show that the recognition of  $H$ -graphs is NP-hard when  $H$  contains two distinct cycles. On the other hand, we show a polynomial-time algorithm recognizing  $L$ -graphs, where  $L$  is a graph containing a cycle and an edge attached to it (which we call *lollipop graphs*). Our work leaves open the recognition problems of  $M$ -graphs for every unicyclic graph  $M$  different from a cycle and a lollipop.

## 1 Introduction

One of the most important and most widely studied types of graph representations is an *intersection model*, in which the vertices are represented by sets and the edges by the pairs of intersecting sets. Due to practical and theoretical applications, intersection graphs of simple geometric objects are among the most intensively studied. In this paper, we consider a special kind of intersection graphs, called  *$H$ -graphs*, introduced by Biró, Hujter and Tuza [5]. Since  *$H$ -graphs* generalize many known geometric intersection graph classes, they form a good background that allows to study basic computational problems in some systematic way. We first define  *$H$ -graphs* formally using the terminology we adapt throughout the paper.

Let  $H$  be a connected graph. An  *$H$ -model* of a graph  $G$  is a pair  $(H^\phi, \phi)$ , where  $H^\phi$  is a subdivision of  $H$  and  $\phi$  is a mapping from  $V(G)$  to the subsets of  $V(H^\phi)$ , such that:

- for every  $v \in V(G)$ , the subgraph of  $H^\phi$  induced by the set  $\phi(v)$  is connected,
- for every distinct  $u, v \in V(G)$  we have  $uv \in E(G)$  iff  $\phi(u) \cap \phi(v) \neq \emptyset$ .

A graph  $G$  is an  *$H$ -graph* if  $G$  admits an  *$H$ -model*. In particular, every graph  $G$  is an  *$H$ -graph* for some graph  $H$ , e.g., for  $H = G$ .

Many known geometric intersection graph classes are  *$H$ -graphs* for an appropriately chosen graph  $H$  or are  *$\mathcal{H}$ -graphs* for some simpler class of graphs  $\mathcal{H}$ , where by  *$\mathcal{H}$ -graphs* we mean the union of the classes of  *$H$ -graphs* over  $H \in \mathcal{H}$ :

- $K_2$ -graphs coincide with the class of *interval graphs*, which are defined as the intersection graphs of intervals on the line,
- $K_3$ -graphs coincide with the class of *circular-arc graphs*, which are defined as the intersection graphs of arcs of a fixed circle,
- $\mathcal{T}$ -graphs, where  $\mathcal{T}$  contains all trees, coincide with the class of *chordal graphs*, which are defined as graphs containing no induced cycles of size  $\geq 4$  [14],
- $\mathcal{P}$ -graphs, where  $\mathcal{P}$  contains all planar graphs, coincide with the class of *string graphs*, which are defined as the intersection graphs of curves in the plane.

The recent research on  *$H$ -graphs*, initiated by Chaplick et al. [10], aims to generalize efficient optimization algorithms from simple classes of graphs on wider families of  *$H$ -graphs*, as well as to determine the boundary of “polynomial tractability” for such computational problems as recognition or isomorphism testing. Here we aim for efficient *parameterized algorithms*, whose running time depends on the size  $n$  of the input graph and the parameter  $|H|$ , where  $|H|$  is the size of the graph  $H$ . First, we search for algorithms that work in polynomial time in  $n$  and  $|H|$ , then for FPT *algorithms* working in time  $f(|H|)n^{O(1)}$  for some computable function  $f$ , and finally for XP *algorithms* working in time  $O(n^{f(|H|)})$  for some computable function  $f$ . Various NP-complete problems on  *$H$ -graphs* were studied in the parameterized setting and shown to admit FPT and XP algorithms, e.g., [1, 2, 4, 8, 10, 11, 13, 16]. Some recent research is also focused on studying the combinatorial properties of  *$H$ -graphs*, which can be later used to construct efficient algorithms in these classes of graphs (see e.g. [11, 13]).

In this work we are focusing on the recognition problem. For a graph class  $\mathcal{G}$ , the *recognition problem* for  $\mathcal{G}$  is to decide whether an input graph  $G$  belongs to  $\mathcal{G}$ . For a graph class  $\mathcal{G}$  defined in a geometrical way, the recognition problem of  $\mathcal{G}$  usually boils down to testing whether the input graph has a representation appropriate for the class  $\mathcal{G}$ . There are known linear time recognition algorithms for interval graphs [6] and chordal graphs [21].

In the context of our research, circular-arc graphs form an important class of graphs. The recognition problem for circular-arc graphs was initially thought to be NP-hard [7], but since the 1980s we already know that it admits a polynomial time algorithm [22]. Currently, two linear-time algorithms recognizing circular-arc graph are known [17,20], but both of them are rather lengthy and non-trivial. No simple polynomial-time algorithm recognizing circular-arc graphs is known.

Although the recognition of chordal graphs takes linear time, with a tree  $T$  on the input deciding whether a graph  $G$  is a  $T$ -graph is NP-complete [18]. On the other hand, Chaplick et al. [10] gave an XP algorithm parameterized by  $|T|$  recognizing  $T$ -graphs. It is open whether the problem can be solved by an FPT algorithm (in [9] it is shown that proper  $T$ -graphs can be recognized in FPT, where a  $T$ -graph  $G$  is called *proper* if there exists a  $T$ -model  $(T_\phi, \phi)$  of  $G$  such that for no pair  $u, v \in V(G)$  we have  $\phi(u) \subseteq \phi(v)$ ). Moreover, Chaplick et al. [10] showed that recognition of  $H$ -graphs is NP-complete if  $H$  contains a diamond (a cycle on four vertices with a chord) as a minor [10]. That is, recognition of  $H$ -graphs is NP-complete for every fixed  $H$  which contains two distinct cycles sharing an edge.

## 1.1 Our results

Our first result states the following, which extends the hardness result from [10]:

► **Theorem 1.1.** *For every fixed graph  $H$  containing two distinct cycles, the recognition of  $H$ -graphs is NP-complete.*

Theorem 1.1 raises interests in  $M$ -graphs, where  $M$  is a *unicyclic* graph (a connected graph containing exactly one cycle). In particular, we are focusing on:

- the recognition problem for the class of  $M$ -graphs, where  $M$  is any fixed graph that consists of a cycle and some trees attached to it,
- the recognition problem for the class of *medusa graphs*, which are defined as  $\mathcal{M}$ -graphs, where  $\mathcal{M}$  is the class that contains all unicyclic graphs. Note that medusa graphs extend both circular-arc graphs and chordal graphs.

■ **Figure 1.1** From left to right: a unicyclic graph  $M$ , an  $M$ -graph  $G$ , an  $M$ -model  $(M^\phi, \phi)$  of  $G$ .

An  $\mathcal{M}$ -model of a graph  $G$  is an  $M$ -model of  $G$  where  $M \in \mathcal{M}$ . Suppose  $G$  is a medusa graph and suppose  $G$  admits an  $\mathcal{M}$ -model  $(M^\phi, \phi)$  for some  $M \in \mathcal{M}$ . A clique  $C$  in  $G$  satisfies the *Helly property* in  $(M^\phi, \phi)$  if  $\bigcap_{c \in C} \phi(c) \neq \emptyset$ , and the model  $(M^\phi, \phi)$  of  $G$  satisfies the *Helly property* if every clique of  $G$  satisfies the Helly property in  $(M^\phi, \phi)$ . A medusa graph  $G$  is *Helly* if  $G$  admits an  $\mathcal{M}$ -model that satisfies the Helly property. Figure 1.1 shows a fixed unicyclic graph  $M$ , another graph  $G$  which is an  $M$ -graph, and an  $M$ -model  $(M^\phi, \phi)$  of  $G$ . Since  $(M^\phi, \phi)$  satisfies the Helly property,  $G$  is a Helly medusa graph. We show the following regarding medusa graph:

► **Theorem 1.2.**

1. *The problem of recognizing medusa graphs is NP-complete.*
2. *The problem of recognizing Helly medusa graphs is polynomial time solvable.*

Our most important (and perhaps most difficult) result concerns the class of  $L$ -graphs (which we call *lollipop graphs*), where  $L$  is a unicyclic graph that consists of a cycle with an edge attached. Note that  $L$ -graphs extend the class of circular-arc graphs.

► **Theorem 1.3.** *The problem of recognizing  $L$ -graphs is polynomial time solvable.*

Our research reveals connections between problems we consider and certain problems related to the Helly property studied in the class of circular-arc graphs. In particular, we introduce the *Helly Cliques* problem, in which for a given circular-arc graph  $G$  and its cliques  $C_1, \dots, C_k$  we need to decide whether  $G$  has a circular-arc model in which all the cliques  $C_1, \dots, C_k$  satisfy the Helly property. We show that the recognition of medusa graphs is polynomial time equivalent to the Helly Cliques problem. We refer to [3, 12] for two different proofs that the Helly Cliques problem is NP-complete. Also, to devise a polynomial algorithm recognizing  $L$ -graphs, we exploit an FPT algorithm for the Helly Cliques problem (for  $k = 1$ ) devised in [12].

## 2 Preliminaries

We refer to the full version of this paper for the full version of this section.

### 2.1 Graphs and posets

All graphs considered in this paper are *simple*, that is, they have no multiedges and no loops. We denote a complete graph and a cycle on  $n$  vertices by  $K_n$  and  $C_n$ , respectively. A *hole* in a graph is an induced cycle on at least four vertices.

A *unicyclic* graph is a connected graph that has exactly one cycle. For a unicyclic graph  $M$ , we denote by  $M_O$  the set of vertices of the unique cycle of  $M$ .

We assume that the reader has some basic knowledge on partially ordered sets (*posets*).

### 2.2 $M$ -graphs

Suppose  $M$  is a fixed unicyclic graph. Let  $(M^\phi, \phi)$  be an  $M$ -model of a graph  $G$ . If the subdivision  $M^\phi$  of  $M$  is not relevant for our considerations, we denote the model  $(M^\phi, \phi)$  simply by  $(M, \phi)$  or even by  $\phi$  (if  $M$  is clear from the context). In this case we treat  $(M, \phi)$  as the intersection model of  $G$  in which every set  $\phi(v)$  forms an arcwise connected subset of some fixed plane drawing of the unicyclic graph  $M$ . Then  $M_O$  is the part of the drawing which contains the points of the drawing corresponding to the vertices and contained in the curves representing the edges from the unique cycle of  $M$ .

Let  $M$  be a unicyclic graph. We say that a graph  $G$  is a *saturated  $M$ -graph* if  $G$  has an  $M$ -model and has no  $M^*$ -model for any proper minor  $M^*$  of  $M$ .

► **Observation 2.1.** *Suppose  $M^*$  is a minor of  $M$ . If  $G$  has an  $M^*$ -model, then  $G$  has an  $M$ -model.*

### 2.3 Interval and Circular-Arc Graphs

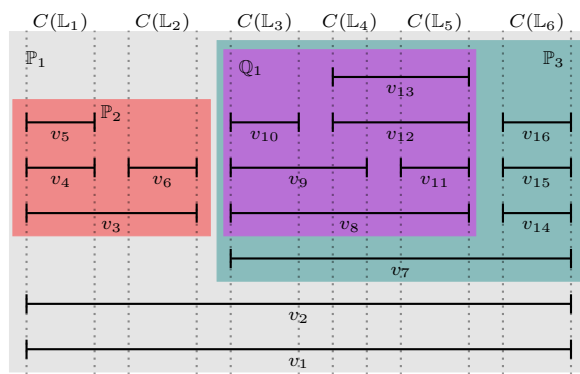

We assume that the reader has some basic knowledge of interval and circular-arc graphs. In our context we can define them as  $K_2$ -graphs and  $K_3$ -graphs.

Given an interval graph  $H$  and an interval model  $\phi$  of  $H$ , for every  $x \in \mathbb{R}$  we denote by  $C(x)$  the set  $\{v \in V(H) : x \in \phi(v)\}$ . A *sector*  $S$  of  $\phi$  is a maximal interval in  $\mathbb{R}$  such that  $C(x) = C(y)$  holds for every  $x, y \in S$ . Given a sector  $S$  of  $\phi$ , the *clique set*  $C(S)$  of  $S$  is

equal to  $C(x)$ , where  $x$  is any point inside  $S$ . Clearly, every two sectors of  $\phi$  are disjoint and the union of all sectors of  $\phi$  covers  $\mathbb{R}$  (note that  $\phi$  has at least two sectors  $S$  such that  $C(S) = \emptyset$ ). We say that a sector  $S$  of  $\phi$  is:

- *maximal* if  $C(S)$  is a maximal clique in  $H$ ,
- *minimal* if  $C(S) \subsetneq C(S')$  for any sector  $S'$  adjacent to  $S$ .

An interval model  $\phi$  of  $H$  is *normalized* if  $\phi$  has exactly  $2c + 1$  sectors (we count also the sectors with the empty clique set), where  $c$  is the number of maximal cliques in  $H$ . We refer to the full version of this paper for more details on the relations between normalized interval models of  $H$  and *consecutive orderings* of maximal cliques of  $H$  represented by the *PQ-tree* of  $H$  (see Figure 2.1).

(a) A normalized interval model  $\phi$  of  $H$ . Sectors of  $\phi$  are separated by dashed lines.

(b) *PQ*-tree  $T$  of  $H$  with leaf order  $L_1, L_2, L_3, L_4, L_5, L_6$  corresponding to consecutive clique ordering  $C_1, C_2, C_3, C_4, C_5, C_6$ .

■ **Figure 2.1**

Observe that we can obtain any interval model of  $H$  in the following way: first we choose a normalized model  $\phi$  of  $H$  (which is equivalent to picking a consecutive ordering of maximal cliques of  $H$ ) and then for each maximal sector  $S$  of  $\phi$  we shift (by a little) the endpoints of the intervals of  $\phi$  that lie on the borders of  $S$  (see Figure 2.2).

Since the definition of normalized models for circular-arc graphs is technical, we refer to the full version of this paper for the details. Here we only mention that in such models the relative relation between intersecting arcs (containment, covering the circle, or overlapping) depends on the relative relation between the closed neighbourhoods of the corresponding vertices of the graph.

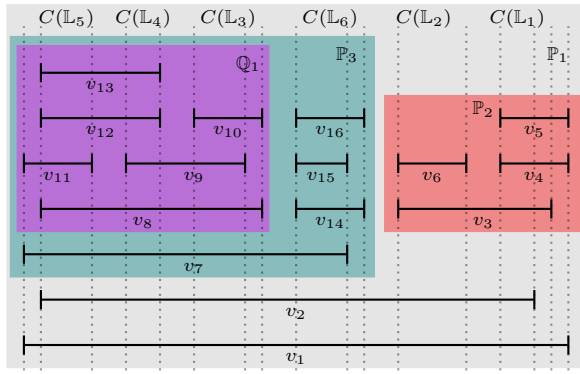

### 3 (Helly) Medusa Graphs

We refer to the full version of this paper for the full version of this section.

Recall that an  $\mathcal{M}$ -model of a graph  $G$  is an  $M$ -model of  $G$  where  $M \in \mathcal{M}$ . We introduce *normalized*  $\mathcal{M}$ -models, based on the following partition of  $V(G)$  into the *circle part*  $V_C$  and the *tree part*  $V_T$ . Start with  $V_C = \emptyset$  and repeatedly add to  $V_C$ :

- $V(C)$ , if  $C$  is a hole in  $G$ ,
- $V(P)$ , if  $P$  is an induced path in  $G$  joining two non-adjacent vertices from  $V_C$ .

Finally, let  $V_T = V \setminus V_C$ . Such a partition  $V_C \cup V_T$  of  $V(G)$  is unique and polynomial time computable. We call an  $\mathcal{M}$ -model  $(M, \phi)$  of  $G$  *normalized* if:

(a) An interval model  $\phi$  of  $H$ . Sectors of  $\phi$  are separated by dashed lines.

(b) PQ-tree  $T$  of  $H$  with leaf order  $L_5, L_4, L_3, L_6, L_2, L_1$  corresponding to clique ordering  $C_5, C_4, C_3, C_6, C_2, C_1$ .

■ Figure 2.2

- $\phi(v) \cap M_O \neq \emptyset$  for every  $v \in V_C$ ,
- $\phi(v) \cap M_O = \emptyset$  for every  $v \in V_T$ ,
- $\{\phi(v) \cap M_O : v \in V_C\}$  is a normalized circular-arc model of  $G[V_C]$ .

► **Lemma 3.1.** *Every  $\mathcal{M}$ -graph  $G$  has a normalized  $\mathcal{M}$ -model  $\psi$ .*

**Sketch of the proof:** Let  $V_C \cup V_T$  be a partition of  $V(G)$  into the circle part  $V_C$  and the tree part  $V_T$  of  $G$ . Let  $(M, \psi)$  be an  $\mathcal{M}$ -model of  $G$ . The model  $(M, \psi)$  already satisfies  $\psi(v) \cap M_O \neq \emptyset$  for every  $v \in V_C$ . Let  $T_1, \dots, T_k$  be a partition of  $V_T$  into connected components of  $G[V_T]$ . Let  $N_C(T_i)$  be the neighbourhood of  $T_i$  in the cycle part of  $G$ , i.e.  $N_C(T_i) = N(T_i) \cap V_C$ . First we prove that for every  $i \in [k]$  the graph  $G[T_i \cup N_C(T_i)]$  is chordal and the set  $N_C(T_i)$  forms a clique in  $G[V_C]$ . In particular, each  $G[T_i \cup N_C(T_i)]$  has an  $F_i$ -model  $\psi_i$  for some tree  $F_i$ . Next, we note that  $\psi|_{V_C}$  restricted to  $M_O$  forms a circular arc model of  $G[V_C]$  in which each clique  $N_C(T_i)$  is Helly. We normalize this model. Finally, we obtain a normalized  $\mathcal{M}$ -model  $(M', \phi)$  of  $G$  by joining a point of  $F_i$  contained in  $\bigcap \psi_i(N_C(T_i))$  to a point of  $M_O$  contained in  $\bigcap \phi(N_C(T_i))$  and then by merging the models  $\psi$  and  $\psi_i$  for  $i \in [k]$  appropriately. ◀

This yields our main theorem characterizing medusa graphs.

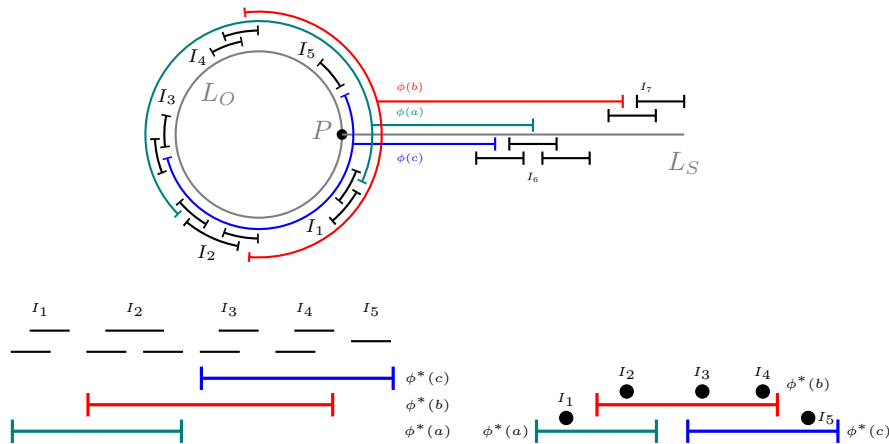

► **Theorem 3.2.** *(see the full version of this paper for the full proof) Let  $G$  be a graph, let  $V(G) = V_C \cup V_T$  be a partition of  $V(G)$  into the circle part  $V_C$  and the tree part  $V_T$  of  $G$ , and let  $T_1, \dots, T_k$  be a partition of  $V_T$  into connected components of  $G[V_T]$ . Then:*

1.  $G$  is a medusa graph if and only if  $G[V_C]$  is a circular arc graph in which for every  $i \in [k]$  the set  $N_C(T_i)$  induces a clique in  $G[V_C]$ , and  $G[V_C]$  admits a normalized circular-arc model in which every clique  $N_C(T_i)$  is Helly.
2.  $G$  is a Helly medusa graph if and only if  $G[V_C]$  is a Helly circular arc graph.

The conclusions of Theorem 3.2 bring our attention to the Helly Cliques problem.

► **Lemma 3.3.** *(see the full version of this paper for the full proof) Recognition of medusa graphs is poly-time equivalent to the Helly Cliques problem.*

We can summarize the section with the following theorem (which extends Theorem 1.2).

■ **Figure 4.1** Above:  $\{a, b, c\}$ -centered  $L$ -model  $\phi$  of  $G$ . Below left: Intervals  $\phi^*(a), \phi^*(b), \phi^*(c)$ : for  $x \in \{a, b, c\}$ ,  $\phi^*(x)$  is the shortest interval in  $L_O \setminus P$  that contains  $(L_O \setminus \phi(x))$  and every interval  $\bigcup \phi(I)$  which has a non-empty intersection with  $(L_O \setminus \phi(x))$ . Below right: schematic view of  $\phi^*$  with the components  $I_1, \dots, I_5$ . Our second key step should output  $\mathcal{H}$  containing  $H$  such that  $V(H) = \{a, b, c\}$  and  $E(H) = \{ab, bc\}$ .

► **Theorem 3.4.**

1. *The problem of recognizing medusa graphs is NP-complete.*
2. *The problem of recognizing medusa graphs parameterized by the number  $k$  of components in the tree part  $G[V_T]$  of the input graph is FPT.*
3. *The problem of recognizing Helly medusa graphs is polynomial time solvable.*

**Proof.** The statements of the theorem follow from Lemma 3.3, from the fact that the Helly Cliques problem is NP-complete [3,12] and can be solved in time  $2^{O(k \log k)} \text{poly}(n)$  [12], and from the fact that Helly circular-arc graphs recognition can be solved in linear-time [19]. ◀

**4 Lollipop Graphs**

In this section we derive a polynomial time algorithm for recognizing  $L$ -graphs, where  $L$  is the graph which consists of the clique  $K_3$  and an edge attached to one vertex of  $K_3$  ( $L$  is called a *lollipop* and  $L$ -graphs are called *lollipop graphs*). Since there are known polynomial-time algorithms recognizing  $K_{1,3}$ -graphs [10] and  $K_3$ -graphs [17, 20], we assume that an input graph  $G = (V, E)$  is not an  $L^*$ -graph for any proper minor  $L^*$  of  $L$ . Hence our goal is to test whether  $G$  is a saturated  $L$ -graph.

We fix a plane drawing of  $L$  which consists of the circle  $L_O$  and the stick  $L_S$  attached to  $L_O$  in the point  $P$  (see Figure 4.1 for an illustration). Then we treat an  $L$ -model  $\phi$  of  $G$  as the intersection model of  $G$  in which every set  $\phi(v)$  forms an arcwise connected subset of the drawing of  $L$ . We call the arcs contained in  $L_O \setminus P$  as *intervals* and we introduce *left-right* orders of the points in  $L_O \setminus P$  (consistent with the clockwise order) and in  $L_S \setminus P$ .

Let  $C$  be a clique of  $G$ . An  $L$ -model  $\phi$  of  $G$  is  $C$ -centered if  $C = \{v \in V : P \in \phi(v)\}$  and  $G$  is  $C$ -centered if  $G$  admits a  $C$ -centered  $L$ -model. For example, the model  $\phi$  shown in Figure 4.1 is  $\{a, b, c\}$ -centered.

Our approach consists of three key steps. The first step is summarized as follows.

► **Theorem 4.1.** *There is a polynomial time algorithm that, given a graph  $G$ , either decides that  $G$  is a saturated  $L$ -graph, or outputs a set of cliques  $\mathcal{C}$  of  $G$  such that, if  $G$  is a saturated  $L$ -graph then  $G$  is a  $C$ -centered  $L$ -graph for some  $C \in \mathcal{C}$ .*

Given the above theorem it remains to efficiently decide whether  $G$  is a  $C$ -centered graph for some fixed clique  $C$  of  $G$ . Let  $\mathcal{I}$  denote the set of components of  $G[V \setminus C]$ . Note that for every  $I \in \mathcal{I}$  the set  $I$  induces an interval graph in  $G$  if  $G$  is  $C$ -centered.

Suppose  $\phi$  is a  $C$ -centered model of  $G$ . To describe our second step, for every  $c \in C$  let  $\phi^*(c)$  denote the shortest interval in  $L_O \setminus P$  containing the interval  $L_O \setminus \phi(c)$  and every interval  $\bigcup \phi(I)$  whenever  $L_O \setminus \phi(c)$  intersects  $\bigcup \phi(I)$ , for  $I \in \mathcal{I}$ . Let  $H_\phi$  be an interval graph with the vertex set  $C' = \{c \in C : \phi^*(c) \neq \emptyset\}$  and with the intersection model given by the intervals  $\{\phi^*(c) : c \in C'\}$ .

Let  $C' \subseteq C$  and let  $H$  be an interval graph on the vertex set  $C'$ . A  $C$ -centered  $L$ -model  $\phi$  of  $G$  is  $(C, H)$ -centered if  $H_\phi = H$  and  $G$  is  $(C, H)$ -centered if  $G$  admits a  $(C, H)$ -centered model. For example, the model  $\phi$  from Figure 4.1 is  $(\{a, b, c\}, H)$ -centered, where  $H$  is such that  $V(H) = \{a, b, c\}$  and  $E(H) = \{ab, bc\}$ . Our second step comes down to the following.

► **Theorem 4.2.** *There is a polynomial time algorithm that, given a graph  $G$  and a clique  $C \subseteq V(G)$ , outputs a set of interval graphs  $\mathcal{H}$  such that, if  $G$  is a  $C$ -centered  $L$ -graph, then  $G$  is a  $(C, H)$ -centered  $L$ -graph for some  $H \in \mathcal{H}$ .*

Our final step, which is the most technical and probably most difficult, can be summarized as follows:

► **Theorem 4.3.** *There is a polynomial time algorithm that, given a graph  $G$ , a clique  $C \subseteq V(G)$ , and an interval graph  $H$  on a subset  $C'$  of  $C$ , decides whether  $G$  is a  $(C, H)$ -centered graph.*

The algorithm from Theorem 4.3 exploits dynamic programming along the PQ-tree of  $H$  to test whether there is a partition  $(\mathcal{J}, \mathcal{J}')$  of the components of  $\mathcal{I}$  together with a total ordering  $\prec$  of  $\mathcal{J}$  such that there is a  $(C, H)$ -centered model  $\phi$  of  $G$  that places the interval graphs of  $\mathcal{J}$  on  $L_O \setminus P$  in the order  $\prec$  and the interval graphs of  $\mathcal{J}'$  on the stick  $L_S$ .

#### 4.1 Sketch of the proof of Theorem 4.1 (the first key step)

We refer to the full version of this paper for the full proof.

Let  $G$  be a graph which is neither  $K_{1,3}$ -graph nor  $K_3$ -graph. Let  $V_C \cup V_T$  be the partition of  $V(G)$  into the circle part  $V_C$  and the tree part  $V_T$  of  $G$ , and let  $\mathcal{T}$  be the set of all maximal cliques of the chordal graphs  $G[T \cup N_C(T)]$ , where  $T$  runs over the components of  $G[V_T]$  (see Section 3). The algorithm for Theorem 4.1 works as follows. For every  $C^* \in \mathcal{T}$ :

- output  $C^*$  and denote by  $\mathcal{I}^*$  the components of  $G[V \setminus C^*]$ ,
- for every component  $I \in \mathcal{I}^*$  let  $C' = \{v \in C^* : v \text{ has a neighbour in } I\}$ ,
  - accept  $G$  as saturated  $L$ -graph if  $G[I \cup C']$  admits a circular arc model with  $C'$  Helly (we use a poly-time algorithm for the Helly Cliques problem with  $k = 1$ ) and  $G[V \setminus I]$  admits an interval model with  $C^*$  as the leftmost maximal clique,
  - if  $G[I]$  is an interval graph, then for every maximal clique  $D$  of  $G[I]$  output the clique  $C(D) = C' \cup \{v \in D : C' \subseteq N(v)\}$ .

Now we give a sketch of the proof that this algorithm is correct. Assuming  $G$  is a saturated  $L$ -graph, we first argue  $G$  admits an  $L$ -model  $\phi$  such that:

- there is a clique  $C^*$  from  $\mathcal{T}$  such that the set  $\bigcap \phi(C^*)$  is contained in  $L_S \setminus P$  and  $\bigcap \phi(C^*)$  is as close to  $P$  as possible,

- for every component  $I \in \mathcal{I}^*$  we have either  $\bigcup \phi(I) \subseteq L_O$  or  $\bigcup \phi(I) \subseteq (L_S \setminus P)$ .

As we show in the full version of this paper, such properties are satisfied by so-called *saturated*  $L$ -models of  $G$ . Given such  $\phi$ , we fall into one of the following cases:

- $P$  is not covered by  $\bigcup \phi(I)$  for any  $I \in \mathcal{I}^*$ . Then  $\phi$  can be easily turned into  $C^*$ -centered  $L$ -model of  $G$  (since the algorithm adds  $C^*$  to  $\mathcal{C}$ , Theorem 4.1 is satisfied).
- $P$  is covered by  $\bigcup \phi(I)$  for some  $I \in \mathcal{I}^*$ . The algorithm accepts  $G$  if  $I$  is the only component on  $L_O$  (which possibly induces a circular-arc graph and covers the whole circle  $L_O$ ). Otherwise, if two components from  $\mathcal{I}^*$  are represented on  $L_O$ , then all the components in  $\mathcal{I}^*$  induce interval graphs in  $G$ . In this case we argue that  $\phi$  can be turned into a  $C(D)$ -centered model, where  $D$  is a maximal clique in  $G[I]$  with  $\bigcap \phi(D)$  next to  $P$  (since the algorithm adds  $C(D)$  to  $\mathcal{C}$ , Theorem 4.1 is satisfied).

Given the previous, the algorithm for Theorem 4.1 either accepts  $G$ , or outputs  $\mathcal{C}$  of size at most  $O(n^2)$  ( $\mathcal{T}$  has size  $O(n)$  and for every  $C^* \in \mathcal{T}$  the total number of maximal cliques in the interval components of  $G[V \setminus C^*]$  is  $O(n)$ ).

## 4.2 Sketch of the proof of Theorem 4.2 (the second key step)

We refer to the full version of this paper for the full proof.

Consider a graph  $G$  and a clique  $C$  of  $G$ . Let  $\mathcal{I}$  be the set of components of  $G[V \setminus C]$ . For now, consider a  $C$ -centered model  $\phi$ . Then every  $I \in \mathcal{I}$  induces an interval graph and  $\{\phi(v) \mid v \in I\}$  is an interval model for  $G[I]$ . We partition  $I \in \mathcal{I}$  according to the intersection with  $L_O$  and  $L_S$  in the model  $\phi$ :

$$\mathcal{I}_O^\phi = \left\{ I \in \mathcal{I} : \bigcup \phi(I) \subseteq L_O \right\} \quad \text{and} \quad \mathcal{I}_S^\phi = \left\{ I \in \mathcal{I} : \bigcup \phi(I) \subseteq L_S \right\}.$$

For  $I \in \mathcal{I}$ , let  $C(I) = \{c \in C : c \text{ is not adjacent to some vertex in } I\}$ . Let  $\phi$  be a  $C$ -centered model of  $G$ . Note that the graph  $H_\phi$ , defined in Section 4, can be equivalently defined such that

$$C' = V(H_\phi) = \bigcup_{I \in \mathcal{I}_O^\phi} C(I) \quad \text{and} \quad E(H_\phi) = \{\{c, c'\} : \text{there is } I \in \mathcal{I}_O^\phi \text{ such that } c, c' \in C(I)\}.$$

Similarly, the model  $\phi^*$  of  $H_\phi$  can be equivalently defined such that for every  $c \in C'$  the set  $\phi^*(c)$  is the shortest interval that contains  $\bigcup \phi(I)$  for every  $I \in \mathcal{I}_O^\phi$  such that  $c \in C(I)$  – see Figure 4.1 for an illustration. Note that every non-minimal sector of  $\phi^*$  contains at least one component from  $\mathcal{I}_O^\phi$  and every  $I \in \mathcal{I}_O^\phi$  occupies a sector of  $\phi^*$  with the clique set  $C(I)$ .

We distinguish the interval graphs  $I \in \mathcal{I}$  as follows:

- $I \in \mathcal{I}$  is called *ambiguous* if  $G[C \cup I]$  has an interval model with  $C$  as its left-most clique (hence,  $I$  might be placed on the stick); otherwise  $I$  is called *circle*.
- An ambiguous component  $I \in \mathcal{I}$  is *simple* if  $N(u) \cap C = N(v) \cap C$  for all  $u, v \in I$ .

We denote the sets of the circle, ambiguous, ambiguous simple, and ambiguous non-simple components by  $\mathcal{I}_c$ ,  $\mathcal{I}_a$ ,  $\mathcal{I}_{as}$ , and  $\mathcal{I}_{ans}$ , respectively. Clearly,  $\mathcal{I}_c \subseteq \mathcal{I}_O^\phi$ , for every  $C$ -centered model  $\phi$ . Moreover, we show that for every  $I \in \mathcal{I}_c$  and every  $C$ -centered model  $\phi$  of  $G$  the component  $I$  occupies a maximal sector of  $\phi^*$  and no other component occupies this sector – see the circle component  $I_2$  in Figure 4.1. We additionally assume that  $C(I) \neq C(J)$  for every two simple components  $I \neq J$  since otherwise we may simply consider the input without  $J$ .

## 8:10 Recognizing $H$ -Graphs – Beyond Circular-Arc Graphs

We order  $\mathcal{I}$  based on their subset relation on  $\{C(I) : I \in \mathcal{I}\}$  and their classification into  $\mathcal{I}_a$ ,  $\mathcal{I}_{as}$ , and  $\mathcal{I}_{ans}$ . We define  $\subset_t$  for  $I, J \in \mathcal{I}$  as

$$I \subset_t J \text{ if } \begin{aligned} & (C(I) \subsetneq C(J)) \text{ or} \\ & (C(I) = C(J) \text{ and } I \in \mathcal{I}_c \text{ and } J \in \mathcal{I}_a) \text{ or} \\ & (C(I) = C(J) \text{ and } I \in \mathcal{I}_{ans} \text{ and } J \in \mathcal{I}_{as}). \end{aligned}$$

Then  $(\mathcal{I}, \subseteq_t)$  is a poset, where  $\subseteq_t$  is the reflexive closure of  $\subset_t$ .

▷ **Claim 4.4.** For every  $C$ -centered model  $\phi$  we have  $\mathcal{I}_S^\phi \subseteq \mathcal{I}_a$ , the components from  $\mathcal{I}_S^\phi$  form a chain in  $(\mathcal{I}, \subseteq_t)$ , and the left-right order of the components on  $L_S$  coincides with  $(\mathcal{I}_S^\phi, \subseteq_t)$ .

Let  $\mathcal{D} \subseteq \mathcal{I}$  be defined as follows. For every  $J \in \mathcal{I}_a$ ,

**(D1)** if  $C(I) \subseteq C(J)$  for some  $I \in \mathcal{I}_c$ , add  $J$  to  $\mathcal{D}$ .

**(D2)** if  $J \in \mathcal{I}$  is such that the downset of  $J$  has the width at least 4 in  $(\mathcal{I}, \subseteq_t)$ , add  $J$  to  $\mathcal{D}$ . We show that the components from  $\mathcal{D}$  need to be represented on the stick in any  $C$ -centered model of  $G$ .

Since every maximal sector of  $\phi^*$  contains a component from  $\mathcal{A}^\phi$  and the components from  $\mathcal{A}^\phi$  occupy maximal sectors of  $\phi^*$ , the set  $\mathcal{A}^\phi$  determines the set of all maximal cliques of  $H_\phi$ . Hence, the interval graph  $H_\phi$  is uniquely determined by the antichain  $\mathcal{A}^\phi$  containing the maximal components from  $(\mathcal{I}_O^\phi, \subseteq_t)$ . Therefore, we refer to  $H_\phi$  as to  $H(\mathcal{A}^\phi)$ .

Let  $\mathcal{I}' = \mathcal{I} \setminus \mathcal{D}$ . Let  $\mathcal{A}$  be the set of the maximal components in  $(\mathcal{I}', \subseteq_t)$ . Let  $\phi$  be a  $C$ -centered  $L$ -model of  $G$ . Since  $\mathcal{A}$  forms an antichain and  $\mathcal{I}_S^\phi$  forms a chain, their intersection contains at most one element. If  $\mathcal{A} \cap \mathcal{I}_S^\phi = \emptyset$ , then  $\mathcal{A}^\phi = \mathcal{A}$  and we output  $H(\mathcal{A})$  as a candidate. If  $|\mathcal{A} \cap \mathcal{I}_S^\phi| = \{A\}$ , then  $\mathcal{A}^\phi = (\mathcal{A} \setminus \{A\}) \cup \mathcal{A}_3$ , where  $\mathcal{A}_3$  is an antichain in the downset of  $A$ . Hence we try all of the  $O(n)$  maximal components in  $A \in \mathcal{A}$  combined with all antichains in  $DS(A)$ . Since  $A \notin \mathcal{D}$ , its downset has the width at most 3 and there are  $O(n^3)$  antichains in  $DS(A)$  which can be enumerated in polynomial time.

### 4.3 Sketch of the proof of Theorem 4.3 (the third key step)

We refer to the full version of this paper for the full proof.

First, we reduce the input instance  $G, C, H$ , so as there is no component  $I \in \mathcal{I}$  such that  $C(I)$  is the clique set of a minimal sector of an interval model of  $H$  (the set of cliques of minimal sectors of an interval model of  $H$  is independent on the model of  $H$ ).

Let  $\mathbb{T}$  be the PQ-tree of  $H$ , let  $V(\mathbb{T})$  be the nodes of  $\mathbb{T}$ , and let  $\mathbb{R}$  be the root of  $\mathbb{T}$ . For  $\mathbb{N} \in V(\mathbb{T})$ , let  $\mathcal{L}(\mathbb{N})$  denote the set of all leaves of  $\mathbb{T}$  which descend  $\mathbb{N}$  in  $\mathbb{T}$ . We set  $\mathcal{L} = \mathcal{L}(\mathbb{R})$ . For  $\mathbb{L} \in \mathcal{L}$  let  $C(\mathbb{L})$  denote the clique of  $H$  represented by  $\mathbb{L}$ . We refer to the full version of this paper for more about PQ-trees.

Our main task is to find a partition  $(\mathcal{J}, \mathcal{J}')$  of  $\mathcal{I}' = \mathcal{I} \setminus \mathcal{D}$  together with a total ordering  $\prec$  of  $\mathcal{J}$  such that there is a model  $\phi$  that places the interval graphs of  $\mathcal{J}$  on the circle  $L_O$  in the order  $\prec$  and the interval graphs of  $\mathcal{J}'$  on the stick  $L_S$ .

The easy part is to check whether  $\mathcal{J}' \subseteq \mathcal{I}'$  can be placed on the stick. We need to check whether  $(\mathcal{J}' \cup \mathcal{D})$  forms a chain in the poset  $(\mathcal{I}_a, \sqsubseteq)$ , with  $\sqsubseteq$  being the reflexive closure of the following binary relation  $\sqsubset$ , defined for distinct  $I, J \in \mathcal{I}_a$ :

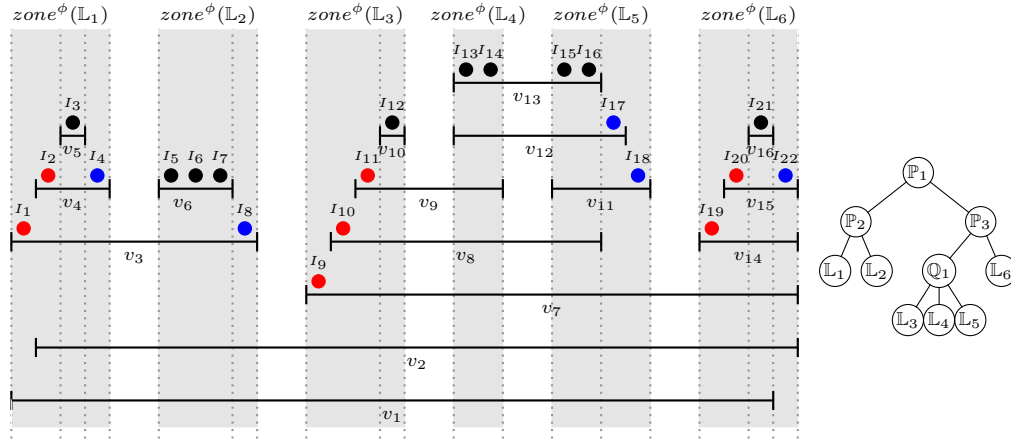

$$I \sqsubset J \text{ if } C(I) \subseteq C^s(J), \text{ where} \\ C^s(J) = \{c \in C : c \text{ is not adjacent to every vertex in } J\}.$$

Now, let us consider how to test whether  $\mathcal{J} \subseteq \mathcal{I}'$  together with an ordering  $\prec$  allows a model that places the interval graphs of  $\mathcal{J}$  in the order of  $\prec$  on the circle. We will denote such an ordering  $(\mathcal{J}, \prec)$  as a *good order* for  $\mathbb{R}$ . Our final dynamic program then determines the

good orderings in a bottom up fashion. Hence we will define a *good order*  $(\mathcal{K}, \prec)$  with respect to some node  $\mathbb{N}$  of  $\mathbb{T}$  and with respect to some left and right *borders*,  $(B_L, B_R)$ , which are cliques in  $H$ . Since this definition is technical (see the full version of this paper), we describe some properties of good orderings that occur in  $(\mathcal{I}_O^\phi, \prec_\phi)$ , where  $\phi$  is a  $(C, H)$ -centered model of  $G$  and  $(\mathcal{I}_O^\phi, \prec_\phi)$  is the left-right order of the components from  $\mathcal{I}_O^\phi$  on  $L_O \setminus P$ .

Let  $\phi$  be a  $(C, H)$ -centered model of  $G$ . For  $\mathbb{L} \in \mathcal{L}$  let  $\text{inner}(\mathbb{L}) = \{I \in \mathcal{I}' : C(I) = C(\mathbb{L})\}$  and let  $\text{inner}_O^\phi(\mathbb{L}) = \text{inner}(\mathbb{L}) \cap \mathcal{I}_O^\phi$ , and  $\text{inner}_S^\phi(\mathbb{L}) = \text{inner}(\mathbb{L}) \cap \mathcal{I}_S^\phi$ . Additionally, assume the maximal cliques of  $H$  appear in  $\phi^*$  in the order  $C(\mathbb{L}_1), \dots, C(\mathbb{L}_n)$ . For every  $\mathbb{L}_i \in \mathcal{L}$  we define the *left zone*  $\text{zone}_L^\phi(\mathbb{L}_i)$  of  $\mathbb{L}_i$  as an interval of  $(\mathcal{I}_O^\phi, \prec_\phi)$  including the components from the sectors of  $\phi^*$  contained strictly between the maximal sector  $S(\mathbb{L}_i)$  with the clique set  $C(\mathbb{L}_i)$  and the minimal sector of  $\phi^*$  preceding  $S(\mathbb{L}_i)$  in  $\phi^*$ . We define the *right zone*  $\text{zone}_R^\phi(\mathbb{L}_i)$  of  $\mathbb{L}_i$  analogously and we set  $\text{zone}^\phi(\mathbb{L}_i) = \text{zone}_L^\phi(\mathbb{L}_i) \cup \text{inner}_O^\phi(\mathbb{L}_i) \cup \text{zone}_R^\phi(\mathbb{L}_i)$ . For a non-leaf node  $\mathbb{N}$ , let  $\text{zone}^\phi(\mathbb{N}) = \bigcup_{\mathbb{L} \in \mathcal{L}(\mathbb{N})} \text{zone}^\phi(\mathbb{L})$ . Figure 4.2 shows the zones for some example model  $\phi^*$ . Components from the sets  $\text{zone}_L^\phi(\mathbb{L}_i)$ ,  $\text{inner}_O^\phi(\mathbb{L}_i)$ , and  $\text{zone}_R^\phi(\mathbb{L}_i)$  are illustrated as red, black, and blue dots, respectively. We have, for example,  $\text{zone}_L^\phi(\mathbb{L}_3) = \{I_9, I_{10}, I_{11}\}$ ,  $\text{zone}_R^\phi(\mathbb{L}_2) = \{I_8\}$ , and  $\text{inner}_O^\phi(\mathbb{L}_2) = \{I_5, I_6, I_7\}$ . We have  $\text{zone}^\phi(\mathbb{Q}_1) = \{I_9, \dots, I_{18}\}$  as  $\mathcal{L}(\mathbb{Q}_1) = \{\mathbb{L}_3, \mathbb{L}_4, \mathbb{L}_5\}$ .

■ **Figure 4.2** Zones in  $\phi^*$ .

- Among others, we show that for every  $i \in [n]$  (below we assume  $C(\mathbb{L}_0) = C(\mathbb{L}_{n+1}) = \emptyset$ ):
- the set  $\text{zone}_L^\phi(\mathbb{L}_i)$  forms a chain in  $(\mathcal{I}_a, \sqsubseteq)$ ,  $(\text{zone}_L^\phi(\mathbb{L}_i), \sqsubseteq)$  is equal to  $(\text{zone}_L^\phi(\mathbb{L}_i), \prec_\phi)$  and  $\text{zone}_L^\phi(\mathbb{L}_i)$  respects the border  $C(\mathbb{L}_{i-1}) \cap C(\mathbb{L}_i)$ , which means  $C(\mathbb{L}_{i-1}) \cap C(\mathbb{L}_i) \sqsubseteq \text{zone}_L^\phi(\mathbb{L}_i)$ ,
- the set  $\text{zone}_R^\phi(\mathbb{L}_i)$  forms a chain in  $(\mathcal{I}_a, \sqsubseteq)$ , we have  $(\text{zone}_R^\phi(\mathbb{L}_i), \sqsubseteq)$  is equal to the reverse of  $(\text{zone}_R^\phi(\mathbb{L}_i), \prec_\phi)$  and  $\text{zone}_R^\phi(\mathbb{L}_i)$  respects the border  $C(\mathbb{L}_i) \cap C(\mathbb{L}_{i+1})$ , which means  $C(\mathbb{L}_i) \cap C(\mathbb{L}_{i+1}) \sqsubseteq \text{zone}_R^\phi(\mathbb{L}_i)$ .

The next step is to define when  $(\mathcal{K}, \prec)$  is a *good order* for  $\mathbb{N}$  and borders  $(B_L, B_R)$ . Roughly speaking,  $(\mathcal{K}, \prec)$  is defined such that it allows to derive an admissible order  $\mathbb{L}_1, \dots, \mathbb{L}_m$  of the leaves from  $\mathcal{L}(\mathbb{N})$  and to define the zones for  $\mathbb{L}_i$  in  $(\mathcal{K}, \prec)$  for all  $i \in [m]$ . Moreover, it is required that the left zone of  $\mathbb{L}_1$  respects the border  $B_L$ , the right zone of  $\mathbb{L}_m$  respects the border  $B_R$ , and the right zone of  $\mathbb{L}_i$  and the left zone of  $\mathbb{L}_{i+1}$  respect the border  $C(\mathbb{L}_i) \cap C(\mathbb{L}_{i+1})$  for  $i \in [m-1]$ . For example, in Figure 4.2  $(\text{zone}^\phi(\mathbb{L}_3), \prec_\phi)$  is a good order for  $\mathbb{L}_3$  and the borders  $(\{v_1, v_2\}, \{v_1, v_2, v_7, v_8, v_9\})$ ,  $(\text{zone}^\phi(\mathbb{Q}_1), \prec_\phi) = (I_9, \dots, I_{18})$  is a good order for  $\mathbb{Q}_1$  and for the borders  $(\{v_1, v_2\}, \{v_1, v_2, v_7\})$ . Finally, the full definition of good orders allows us to prove Theorem 4.6, which boils down the problem of searching for a  $(C, H)$ -centered model of  $G$  to the problem of testing whether there is a “good triple” for the set  $\mathcal{I}'$  and the node  $\mathbb{R}$ .

► **Definition 4.5.** Let  $\mathbb{N}$  be a node of  $\mathbb{T}$  and  $\mathcal{I}^* \subseteq \mathcal{I}'$ . A triple  $(\mathcal{J}, \mathcal{J}', \prec)$  is good for the set  $\mathcal{I}^*$ , the node  $\mathbb{N}$ , and the borders  $(B_L, B_R)$ , if:

- $\{\mathcal{J}, \mathcal{J}'\}$  is a partition of  $\mathcal{I}^*$ .
- $(\mathcal{J}, \prec)$  is a good order for the node  $\mathbb{N}$  and the borders  $(B_L, B_R)$ ,
- $\mathcal{J}' \cup \mathcal{D}$  is a chain in  $(\mathcal{I}_a, \sqsubseteq)$ .

If  $(B_L, B_R) = (\emptyset, \emptyset)$ , we simply say  $(\mathcal{J}, \mathcal{J}', \prec)$  is good for the set  $\mathcal{I}^*$  and the node  $\mathbb{N}$ .

With the notion of a good triple we obtain the following theorem that characterizes all  $(C, H)$ -centered models of  $G$ .

► **Theorem 4.6** (see the full version of this paper for the full proof). Let  $G$  be a graph.

1. For every  $(C, H)$ -centered model  $\phi$  of  $G$  the triple  $(\mathcal{I}_O^\phi, \mathcal{I}_S^\phi \setminus \mathcal{D}, \prec_\phi)$  is good for  $\mathcal{I}'$  and the node  $\mathbb{R}$ .
2. For every triple  $(\mathcal{J}, \mathcal{J}', \prec)$  that is good for  $\mathcal{I}'$  and the node  $\mathbb{R}$ , there is a  $(C, H)$ -centered model  $\phi$  of  $G$  such that  $(\mathcal{J}, \prec) = (\mathcal{I}_O^\phi, \prec_\phi)$  and  $\mathcal{J}' \cup \mathcal{D} = \mathcal{I}_S^\phi$ .

Our algorithm needs to test whether there exists a good triple for the set  $\mathcal{I}' = \text{comp}(\mathbb{R})$ . Roughly speaking, this technical part is done as follows: first, we carefully define the sets  $\text{comp}(\mathbb{N}) \subseteq \mathcal{I}'$  for every node  $\mathbb{N} \in V(\mathbb{T})$  and then we compute good triples<sup>1</sup> for every set  $\text{comp}(\mathbb{N})$  using dynamic programming over  $\mathbb{T}$ .

## 5 Butterfly-Graphs

Here we sketch an approach to proving Theorem 1.1. The main task is to show NP-hardness of recognizing butterfly-graphs, where a butterfly is the graph consisting of two  $K_3$ 's joined on one vertex.

► **Theorem 5.1.** *BUTTERFLY-GRAPH RECOGNITION is NP-complete.*

It is easy to see NP-membership [10]. To show NP-hardness, we reduce from the BIPARTITE 2-TRACK; that is to decide whether a given bipartite graph  $G$  is 2-track. A graph  $G$  is 2-track if there are sets  $E_1, E_2$  whose union is  $E(G)$  such that  $(V(G), E_1)$  and  $(V(G), E_2)$  are interval graphs. Gonçalves & Ochem proved NP-hardness of this problem [15].

*Construction:* For a given bipartite graph  $G$  we construct a graph  $G'$  that is a butterfly-graph if and only if  $G$  is 2-track. Let  $S$  be a star  $K_{1,4}$  where every edge is subdivided once. The vertex set  $V(G')$  consists of  $V(S)$ , a vertex  $w_v$  for every vertex  $v \in V(G)$ , an edge-vertex  $w_{uv}$  for every edge  $uv \in E(G)$  and  $V(S)$ . The edge set  $E(G')$  consists of  $\binom{V(G)}{2}$ ,  $E(S)$  and the edges of making  $w_{uv}$  adjacent to  $w \in V(G) \setminus \{u, v\}$  for every edge  $uv \in E(G)$ . Finally, we add every edge between  $V(G)$  and  $V(S)$ .

Given  $G$  the graph  $G'$  can be constructed in polynomial time. It remains to show that  $G$  is 2-track if and only if  $G'$  is a butterfly-graph. For the formal proof we refer to the full version of this paper. Here we only sketch how we construct a butterfly-model of  $G'$  provided  $G$  is a bipartite 2-track (witnessed by interval models  $\phi_1$  and  $\phi_2$  of  $(V(G), E_1)$  and  $(V(G), E_2)$ ). A butterfly-model of  $G'$  is obtained as follows (see Figure 5.1 for an illustration):

- we embed  $\phi_1$  and  $\phi_2$  into a subdivision  $H^\phi$  of the butterfly as shown in Figure 5.1,
- we represent the vertices of  $S$  in the center of  $H^\phi$ ,
- for  $v \in V(G)$  we represent  $w_v$  by the set  $V(H^\phi) \setminus (\phi_1(v) \cup \phi_2(v))$  (see green set  $w_2$ )
- for  $uv \in E(G)$ , we represent  $w_{uv}$  by the set  $\phi_i(u) \cap \phi_i(v)$  if  $uv \in E_i$  (see red set  $w_{23}$ ).

<sup>1</sup> Since these sets might have exponential size, the algorithm calculates only their “fingerprints”.

■ **Figure 5.1** A bipartite graph  $G$  (to the left) as a 2-track (red and blue edges) witnessed by interval models  $\phi_1$  and  $\phi_2$  (in the middle), and a *butterfly*-model of  $G'$  (to the right).

## 6 Conclusions

The question whether for a fixed graph  $H$  the class of  $H$ -graphs can be recognized in polynomial time was posed by Biro, Hujter, and Tuza over 30 years ago [5]. The main results of our work show that the boundary between polynomial and NP-hard cases of  $H$ -graphs recognition lies somewhere between unicyclic graphs  $H$ , strictly above the class of circular-arc graphs. The research carried out so far reveals connections between the  $H$ -graphs recognition problems for unicyclic graphs  $H$  and certain problems related to the Helly property of circular-arc graphs. The latter problems are now intensively studied [12] and the positive results achieved so far allow us to state the following conjecture.

► **Conjecture 6.1.** *The recognition of  $H$ -graphs is polynomial-time solvable if and only if  $H$  is a unicyclic graph or  $H$  is a tree.*

In particular, we believe that the techniques introduced in our work, suitably extended, can be used to devise polynomial algorithms for the cases where  $H$  consists of a cycle and some edges attached to it. The situation might be different when we allow to have trees attached to the cycle in  $H$ . The difficulty might be caused by the lack of a data structure maintaining all representations of a  $T$ -graph, where  $T$  is a tree different than a path (counterparts of PQ-trees for interval graphs).

## Abstract

We consider distributed algorithms in the realistic scenario where distributed message passing is operated by circuits. We show that within this setting, modal substitution calculus MSC precisely captures the expressive power of circuits. The result is established via constructing translations that are highly efficient in relation to size. We also observe that the coloring algorithm based on Cole-Vishkin can be specified by logarithmic size programs (and thus also logarithmic size circuits) in the bounded-degree scenario.

## 1 Introduction

Distributed computing concerns computation in networks and relates directly to various fields of study including, inter alia, cellular automata and neural networks. In this paper we study distributed systems based on circuits. A distributed system is a labeled directed graph (with self-loops allowed) where nodes communicate by sending messages to each other. In each communication round a node sends a message to its neighbours and updates its state based on (1) its own previous state and (2) the messages received from the neighbours.

Descriptive complexity of distributed computing was initiated in [8], [11] and [9]. The articles [8] and [9] characterized classes of constant-time distributed algorithms via modal logics. The constant-time assumption was lifted in [11] which showed that the expressive power of *finite message passing automata* (FMPAs) is captured by *modal substitution calculus* MSC, which is an extension of modal logic by Datalog-style rules. The papers [8], [11] and [9] did not consider *identifiers*, i.e., ID-numbers roughly analogous to IP-addresses. It is worth noting that identifiers are, for various reasons, a key concept in much of the literature on distributed computing.

In this paper we study distributed computing based on circuits in a scenario with unique identifiers. Each node runs a copy of the same circuit  $C$ . In each communication round, the node sends its current bit string  $s$  to its neighbours and updates to a new string  $s'$  by feeding  $s$  and the strings  $s_1, \dots, s_m$  sent by the neighbours to  $C$  (letting  $s'$  be the output of  $C$ ). This is a realistic model of distributed computing which also takes *local computation* – the computation steps of the circuit – into account. Typically in distributed computing, only communication steps count. Since we study distributed systems, we call our circuits *message passing circuits*, or MPCs, although formally they are just plain circuits.

We establish an exact match between this circuit-based model and the logic MSC. Unlike earlier works on descriptive complexity of distributed computing, we work in the circuit-style paradigm where an algorithm is specified via an *allocation function*  $F$  that produces, in the simplest case, for each input  $n \in \mathbb{Z}_+$ , a circuit  $F(n)$  that operates on all distributed systems (i.e., labeled directed graphs, or Kripke models) of size  $n$ . As one of our main results, we prove that programs of the MSC-logic and constant fan-in message passing circuits translate to each other with only a *linear* blow-up in size. Thus, we can work interchangeably with circuit allocation functions and MSC-program allocation functions. The related formal statements are as follows, with  $\Pi$  denoting the set of proposition symbols considered (including ones for ID-bits) while  $\Delta$  is a degree bound for graphs.

► **Theorem 12.** *Given an MPC of size  $m$  for  $(\Pi, \Delta)$ , we can construct an equivalent  $\Pi$ -program of MSC. For a constant bound  $c$  for the fan-in of MPCs, the size of the program is  $\mathcal{O}(m)$ .*

► **Theorem 13.** *Given  $\Pi$ ,  $\Delta$  and a  $\Pi$ -program of MSC of size  $m$ , we can construct an equivalent MPC for  $(\Pi, \Delta)$  of size  $\mathcal{O}(\Delta m + |\Pi|)$  when  $\Delta > 0$  and  $\mathcal{O}(m + |\Pi|)$  when  $\Delta = 0$ .*

We are especially interested in the feasible scenario where  $F(n)$  is a circuit of size  $\mathcal{O}(\log n)$ . From the above results we can prove that, for a constant  $\Delta$  and constant fan-in bound, if we have an allocation function producing log-size circuits, we also have an allocation function for log-size programs, and vice versa. We put this into use by demonstrating that for graphs of degree bound  $\Delta$ , we can produce programs of size  $\mathcal{O}(\log n)$  that compute a  $(\Delta + 1)$ -coloring via a *Cole-Vishkin* [6] style approach – implying also an analogous result for circuits.

Generally, the circuit-based approach suits well for studying the *interplay of local computation and message passing*. While important, such effects have received relatively little attention in studies on distributed computing. We provide a range of related results.

**Related work.** As already mentioned, descriptive complexity of distributed computing has been largely initiated in [9], which characterizes a range of related complexity classes via modal logics. It is shown, for example, that graded modal logic captures the class MB(1) containing problems solvable in constant time by algorithms whose recognition capacity is sufficient all the way up to distinguishing between multisets of incoming messages but no further. In the paper, the link to logic helps also in *separating* some of the studied classes. The constant-time limitation is lifted in [11], which shows that finite distributed message passing automata (FMPAs) correspond to modal substitution calculus MSC, which is the logic studied also in the current paper. The work on MSC is extended in [15], which proves that while MSC corresponds to synchronized automata, the  $\mu$ -fragment of the modal  $\mu$ -calculus similarly captures asynchronous distributed automata.

Distributed computing with identifiers has been studied from the point of view of logic earlier in [4]. The paper [4] approaches identifiers via a uniform logical characterization of a certain class of algorithms using IDs, while our work is based on the circuit-style paradigm with formulas and circuits being given based on model size. Thus the two approaches are

not comparable in any uniquely obvious way. Nevertheless, one simple difference between our work and [4] is that we treat IDs bit by bit as concrete bit strings. Thus we can express, e.g., that the current ID has a bit 1 without implying that the current node cannot have the smallest ID in the system. This is because there is no guarantee on what the set of IDs in the current graph (or distributed system) is, and in a directed graph, we cannot even scan through the graph to find out. On the other hand, the logic in [4] can express, e.g., that the current node has the largest ID, which we cannot do. Of course, with a non-uniform formula allocation function, the circuit-style paradigm can even specify non-computable properties.

The closest work to the current article is [11] which gives the already mentioned characterization of finite message passing automata via MSC. The paper does not work within the circuit-style paradigm. Furthermore, we cannot turn our circuit to an FMPA and then use the translation of [11], as this leads to an exponential blow-up in size. Also, the converse translation is non-polynomial in [11]. Furthermore, that paper does not discuss identifiers, or the Cole-Vishkin algorithm, and the work in the paper is based on the paradigm of relating properties directly with single formulae rather than our circuit-style approach. Concerning further related and *very timely* work, [2] studies graph neural networks (or GNNs) and establishes a match between *aggregate-combine* GNNs and graded modal logic. For further related work on GNNs and logic, see, e.g., [7]. Concerning yet further work on logical characterizations of distributed computing models, we mention the theses [12, 16]. For unique identifiers in graph neural networks, see [14, 17, 10].

## 2 Preliminaries

We let  $\mathbb{Z}_+$  denote the set of positive integers. For every  $n \in \mathbb{Z}_+$ , we let  $[n]$  denote the set  $\{1, \dots, n\}$  and  $[n]_0$  the set  $\{0, \dots, n\}$ . For any set  $S$ , we let  $|S|$  denote the size (or cardinality) of  $S$ . Let  $\text{PROP}$  be a countably infinite set of proposition symbols. We suppose  $\text{PROP}$  partitions into two infinite sets  $\text{PROP}_0$  and  $\text{PROP}_1$ , with the intuition that  $\text{PROP}_0$  contains ordinary proposition symbols while  $\text{PROP}_1$  consists of distinguished proposition symbols reserved for encoding ID-numbers. We denote finite sets of proposition symbols by  $\Pi \subseteq \text{PROP}$ . By  $\Pi_0$  (respectively,  $\Pi_1$ ), we mean the subset of  $\Pi$  containing ordinary (respectively, distinguished) propositions. The set  $\text{PROP}$  is associated with a linear order  $<^{\text{PROP}}$  which also induces a linear order  $<^S$  over any set  $S \subseteq \text{PROP}$ .

Let  $\Pi$  be a finite set of proposition symbols. A **Kripke model** over  $\Pi$  is a structure  $(W, R, V)$  with a non-empty domain  $W$ , an **accessibility relation**  $R \subseteq W \times W$  and a **valuation function**  $V : \Pi \rightarrow \mathcal{P}(W)$  giving each  $p \in \Pi$  a set  $V(p)$  of nodes where  $p$  is considered true. A **pointed Kripke model** is a pair  $(M, w)$  where  $M$  is a Kripke model and  $w$  a node in the domain of  $M$ . We let  $\text{succ}(w)$  denote the set  $\{v \in W \mid (w, v) \in R\}$ .

As in [9, 11], we model distributed systems by Kripke models. An edge  $(w, u) \in R$  linking the node  $w$  to  $u$  via the accessibility relation  $R$  means that  $w$  can see messages sent by  $u$ . Thereby we adopt the convention of [9, 11] that messages travel in the direction *opposite* to the edges of  $R$ . An alternative to this would be to consider modal logics with only inverse modalities, i.e., modalities based on the inverse accessibility relation  $R^{-1}$ .

We next define general notions concerning acceptance of infinite sequences of bit strings. Let  $k \in \mathbb{N}$  and consider an infinite sequence  $S = (\bar{b}_j)_{j \in \mathbb{N}}$  of  $k$ -bit strings  $\bar{b}_j$ . Let  $A \subseteq [k]$  and  $P \subseteq [k]$  be subsets, called **attention** bits and **print** bits (or bit positions, strictly speaking). Let  $(\bar{a}_j)_{j \in \mathbb{N}}$  and  $(\bar{p}_j)_{j \in \mathbb{N}}$  be the corresponding sequences of substrings of the strings in  $S$ , that is,  $(\bar{a}_j)_{j \in \mathbb{N}}$  records the substrings with positions in  $A$ , and analogously for  $(\bar{p}_j)_{j \in \mathbb{N}}$ . Let  $(\bar{r}_j)_{j \in \mathbb{N}}$  be the sequence of substrings with positions in  $A \cup P$ . We say that  $S$  **accepts** in

round  $n$  if at least one bit in  $\bar{a}_n$  is 1 and all bits in each  $\bar{a}_m$  for  $m < n$  are zero. Then also  $S$  **outputs**  $\bar{p}_n$ . More precisely,  $S$  **accepts in round  $n$  with respect to  $(k, A, P)$** , and  $\bar{p}_n$  is the **output of  $S$  with respect to  $(k, A, P)$** . The sequence  $(\bar{r}_j)_{j \in \mathbb{N}}$  is the **appointed sequence** w.r.t.  $(k, A, P)$ , and the vector  $\bar{r}_j$  the **appointed string** of round  $j$ .

We then define some logics relevant to this article. For a finite set  $\Pi$  of proposition symbols, the set of **ML( $\Pi$ )-formulas** is given by the grammar  $\varphi ::= \top \mid p \mid \neg\varphi \mid (\varphi \wedge \varphi) \mid \diamond\varphi$  where  $p \in \Pi$  and  $\top$  is a logical constant symbol. The truth of a formula  $\varphi$  in a pointed Kripke model  $(M, w)$  is defined as follows:  $(M, w) \models p \Leftrightarrow w \in V(p)$  and  $(M, w) \models \diamond\varphi \Leftrightarrow (M, v) \models \varphi$  for some  $v \in W$  such that  $(w, v) \in R$ . The semantics for  $\top, \neg, \wedge$  is the usual one.

Now, let us fix a set  $\text{VAR} := \{V_i \mid i \in \mathbb{N}\}$  of **schema variables**. We will mostly use meta variables  $X, Y, Z$ , and so on to denote symbols in  $\text{VAR}$ . The set  $\text{VAR}$  is associated with a linear order  $<^{\text{VAR}}$  inducing a corresponding linear order  $<^{\mathcal{T}}$  over any  $\mathcal{T} \subseteq \text{VAR}$ . Given a set  $\mathcal{T} \subseteq \text{VAR}$  and a set  $\Pi \subseteq \text{PROP}$ , the set of **( $\Pi, \mathcal{T}$ )-schemata** of **modal substitution calculus** (or MSC) is the set generated by the grammar  $\varphi ::= \top \mid p \mid V_i \mid \neg\varphi \mid (\varphi \wedge \varphi) \mid \diamond\varphi$ , where  $p \in \Pi$  and  $V_i \in \mathcal{T}$ . A **terminal clause** of MSC (over  $\Pi$ ) is a string of the form  $V_i(0) :- \varphi$ , where  $V_i \in \text{VAR}$  and  $\varphi \in \text{ML}(\Pi)$ . An **iteration clause** of MSC (over  $\Pi$ ) is a string of the form  $V_i :- \psi$  where  $V_i \in \text{VAR}$  and  $\psi$  is a  $(\Pi, \mathcal{T})$ -schema for some set  $\mathcal{T} \subseteq \text{VAR}$ . In a terminal clause  $V_i(0) :- \varphi$ , the symbol  $V_i$  is the **head predicate** and  $\varphi$  the **body** of the clause. Similarly,  $V_i$  is the head predicate of the iteration clause  $V_i :- \psi$  while  $\psi$  is the body.

Let  $\mathcal{T} = \{Y_1, \dots, Y_k\} \subseteq \text{VAR}$  be a finite, nonempty set of  $k$  distinct schema variables. A **( $\Pi, \mathcal{T}$ )-program**  $\Lambda$  of MSC consists of two lists

$$\begin{array}{ll} Y_1(0) :- \varphi_1 & Y_1 :- \psi_1 \\ \vdots & \vdots \\ Y_k(0) :- \varphi_k & Y_k :- \psi_k \end{array}$$

of clauses (or rules) and two sets of predicates  $\mathcal{P} \subseteq \mathcal{T}$  and  $\mathcal{A} \subseteq \mathcal{T}$ , namely **print predicates** and respectively **attention predicates** of  $\Lambda$ . The first list contains  $k$  terminal clauses over  $\Pi$  and the second contains  $k$  iteration clauses whose bodies are  $(\Pi, \mathcal{T})$ -schemata. The set  $\mathcal{P} \cup \mathcal{A}$  is the set of **appointed predicates** of  $\Lambda$ . We call  $\Lambda$  a  **$\Pi$ -program** if it is a  $(\Pi, \mathcal{T})$ -program for some  $\mathcal{T} \subseteq \text{VAR}$ . The set of head predicates of  $\Lambda$  is denoted by  $\text{HEAD}(\Lambda)$ . For each variable  $Y_i \in \text{HEAD}(\Lambda)$ , we define that  $Y_i^0 := \varphi_i$ . Recursively, assume we have defined an  $\text{ML}(\Pi)$ -formula  $Y_i^n$  for each  $Y_i \in \text{HEAD}(\Lambda)$ . The formula  $Y_i^{n+1}$  is obtained by replacing each  $Y_j$  in  $\psi_j$  by  $Y_j^n$ . Then  $Y_i^n$  is the  $n$ th **iteration formula of  $Y_i$** . More generally, if  $\varphi$  is a  $(\Pi, \mathcal{T})$ -schema, then we let  $\varphi^{n+1}$  denote the  $\text{ML}(\Pi)$ -formula obtained from the schema  $\varphi$  by simultaneously replacing each  $Y_i \in \text{HEAD}(\Lambda)$  with  $Y_i^n$ . Now, let  $(M, w)$  be a pointed  $\Pi$ -model. We define that  $(M, w) \models \Lambda$  if for some  $n$  and some attention predicate  $Y$  of  $\Lambda$ , we have  $(M, w) \models Y^n$ . In Section 3, we will also define output conditions for MSC using print predicates.

For every  $(\Pi, \mathcal{T})$ -schema  $\psi$ , we let  $\text{md}(\psi)$  denote the **modal depth** of  $\psi$  (i.e., the maximum nesting depth of diamonds  $\diamond$  in  $\psi$ ). We let  $\text{mdt}(\Lambda)$  (respectively,  $\text{mdi}(\Lambda)$ ) denote the maximum modal depth of the bodies of the terminal clauses (resp., of the iteration clauses) of  $\Lambda$ . By  $\text{SUBS}(\Lambda)$  we denote the set of all subschemata of  $\Lambda$ , including head predicates and bodies of iteration and terminal clauses. If  $S$  is a set of schemata,  $\text{SUBS}(S)$  is the set of all subschemata of all schemata in  $S$ .

► **Example 1.** Given a proposition symbol  $p$  and a pointed Kripke model  $(M, w)$ , we say that  $p$  is *reachable* from  $w$  if there exists a directed path from  $w$  to a node  $v$  in  $M$  such that  $(M, v) \models p$ . Now, consider the program  $X(0) :- p, \quad X :- \diamond X$  where  $X$  is the appointed predicate. It is easy to show that  $(M, w) \models X^j$  for some  $j < n$  if and only if  $p$  is reachable from  $w$ , where  $n$  is the domain size of  $M$ .

Next we define a class of Kripke models which includes identifiers that are encoded by proposition symbols. Assume that  $p_1, \dots, p_\ell$  enumerate all the distinguished propositions in  $\Pi$  in the order  $<^{\text{PROP}}$ . For each node  $w$  of a Kripke model  $M$  over  $\Pi$ , we let  $\text{ID}(w)$  denote the **identifier** of  $w$ , that is, the  $|\Pi_1|$ -bit string such that the  $i$ th bit of  $\text{ID}(w)$  is 1 if and only if  $(M, w) \models p_i$ . The model  $M$  is a Kripke model **with identifiers** if  $\text{ID}(w) \neq \text{ID}(w')$  for each pair of distinct nodes  $w$  and  $w'$  of  $M$ . We let  $\mathcal{K}(\Pi, \Delta)$  denote the class of finite Kripke models  $(W, R, V)$  over  $\Pi$  with identifiers such that the out-degree of each node is at most  $\Delta \in \mathbb{N}$ . For a node  $w$ , let  $s_1, \dots, s_d$  be the identifiers of the members of  $\text{succ}(w)$  in the lexicographic order. A node  $v \in \text{succ}(w)$  is the  **$i$ th neighbour** of  $w$  iff  $\text{ID}(v) = s_i$ . Analogously to  $\text{ID}(w)$ , if  $p_1, \dots, p_m$  enumerate all the propositions in  $\Pi$  in the order  $<^{\text{PROP}}$ , then the **local input** of a node  $w$  of a Kripke model  $M$  over  $\Pi$  is the  $m$ -bit string  $t$  such that the  $i$ th bit of  $t$  is 1 if and only if  $(M, w) \models p_i$ .

## 2.1 Circuits and distributed computation

Here we first recall some basics related to circuits and then define a related distributed computation model. A **Boolean circuit** is a directed acyclic graph where each node of non-zero in-degree is labeled by one of the symbols  $\wedge, \vee, \neg$ . The nodes of a circuit are called **gates**. The in-degree of a gate  $u$  is called the **fan-in** of  $u$ , and the out-degree of  $u$  is **fan-out**. The **input gates** of a circuit are precisely the gates that have zero fan-in; these gates are not labeled by  $\wedge, \vee, \neg$ . The **output-gates** are the ones with fan-out zero; we allow multiple output gates in a circuit. Note that gates with  $\wedge, \vee$  can have any positive fan-in (also 1). The fan-in of every gate labeled with  $\neg$  is 1. The **size**  $|C|$  of a circuit  $C$  is the number of gates in  $C$ . The **depth**  $d(C)$  of  $C$  is the longest path length (number of edges) from an input gate to an output gate. The **height**  $h(G)$  of a gate  $G$  in  $C$  is the longest path length from an input gate to the gate  $G$ . Thus the height of an input gate is zero. Both the input gates and output gates of a circuit are linearly ordered. A circuit with  $n$  input gates and  $k$  output gates then computes a function of type  $\{0, 1\}^n \rightarrow \{0, 1\}^k$ . This is done in the natural way, analogously to the Boolean operators corresponding to  $\wedge, \vee, \neg$ , see for example [13] for the formal definition. The output of the circuit is the *binary string* determined by the output bits of the output gates.

From a Boolean formula it is easy to define a corresponding circuit by considering its *inverse tree representation*, meaning the tree representation with edges pointing in the inverse direction (toward the root). A node  $v$  in the inverse tree representation is the **parent** of  $w$  if there is an edge from  $w$  to  $v$ . Then  $w$  is a **child** of  $v$ . Note that input gates do not have any children and output gates have no parents. The **descendants** of  $w$  are defined such that every child of  $w$  is a descendant of  $w$  and also every child of a descendant of  $w$  is a descendant of  $w$ .

► **Definition 2.** Let  $\Pi$  be a set of propositions and  $\Delta \in \mathbb{N}$ . A **circuit for  $(\Pi, \Delta)$**  is a circuit  $C$  that specifies a function  $f : \{0, 1\}^{|\Pi|+k(\Delta+1)} \rightarrow \{0, 1\}^k$  for some  $k \in \mathbb{N}$ . The number  $k$  is called the **state length** of  $C$ . The circuit  $C$  is also associated with sets  $A \subseteq [k]$  and  $P \subseteq [k]$  of **attention bits** and **print bits**, respectively. For convenience, we may also call a circuit  $C$  for  $(\Pi, \Delta)$  a **message passing circuit** (or MPC) for  $(\Pi, \Delta)$ . The set  $A \cup P$  is called the **set of appointed bits** of the circuit.

A circuit  $C$  is **suitable** for a Kripke model  $M \in \mathcal{K}(\Pi, \Delta')$  with identifiers if  $C$  is a message passing circuit for  $(\Pi, \Delta)$  for some  $\Delta \geq \Delta'$ . A circuit  $C$  for  $(\Pi, \Delta)$  with  $|\Pi_1| = m$  is referred to as a **circuit for  $m$  ID-bits**. We let  $\text{CIRC}(\Pi_0, \Delta)$  denote the set of all circuits  $C$  such

that, for some  $\Pi$  with  $\Pi \cap \text{PROP}_0 = \Pi_0$ , the circuit  $C$  is a circuit for  $(\Pi, \Delta)$ . We stress that strictly speaking, when specifying an MPC, we should always specify (together with a circuit) the sets  $\Pi$ ,  $\Delta$ , the attention and print bits, and an ordering of the input and output gates.

Before giving a formal definition of distributed computation in a Kripke model  $M \in \mathcal{K}(\Pi, \Delta)$  with a circuit  $C$  for  $(\Pi, \Delta)$ , we describe the process informally. Each node  $u$  of  $M$  runs a copy of the circuit  $C$ . The node  $u$  is associated with a local input, which is the binary string that corresponds to the set of propositions true at  $u$ . In the beginning of computation, the circuit at  $u$  reads the string  $\bar{s} \cdot 0^\ell$  at  $u$ , where  $\bar{s}$  is the local input at  $u$  and  $\ell = k(\Delta + 1)$ , so  $0^\ell$  is simply the part of the input to  $C$  that does not correspond to proposition symbols. Then the circuit enters a *state* which is the  $k$ -bit output string of  $C$ . Let  $s(0, u)$  denote this string and call it the **state in communication round 0** at the node  $u$ . Now, recursively, suppose we know the state  $s(n, u)$  in communication round  $n \in \mathbb{N}$  for each node  $u$ . The state  $s(n+1, u)$  for round  $n+1$  at  $u$  is then computed as follows.

1. At each node  $u$ , the circuit sends  $s(n, u)$  to the nodes  $w$  such that  $R(w, u)$ . Note here that messages flow opposite to the direction of  $R$ -edges.
2. The circuit at  $u$  *updates* its state to  $s(n+1, u)$  which is the  $k$ -bit string obtained as the output of the circuit with the input  $\bar{s} \cdot \bar{s}_0 \cdots \bar{s}_\Delta$  which is the concatenation of the  $k$ -bit strings  $s_i$  (for  $i \in \{0, \dots, \Delta\}$ ) specified as follows. The string  $\bar{s}$  is the local input at  $u$ . The string  $\bar{s}_0$  is the state  $s(n, u)$ . Let  $i \in \{1, \dots, m\}$ , where  $m \leq \Delta$  is the out-degree of  $u$ . Then  $\bar{s}_i$  is the state  $s(n, v_i)$  of the  $i$ th neighbour  $v_i$  of  $u$ . For  $i > m$ , we have  $\bar{s}_i = 0^k$ .

We then define computation of MPCs formally. An MPC  $C$  for  $(\Pi, \Delta)$  of state length  $k$  and a Kripke model  $M = (W, R, V) \in \mathcal{K}(\Pi, \Delta)$  define a *synchronized distributed system* which executes an  $\omega$ -sequence of rounds defined as follows. Each round  $n \in \mathbb{N}$  defines a **global configuration**  $f_n: W \rightarrow \{0, 1\}^k$ . Let  $\bar{t}_w$  denote the binary string corresponding to the set of propositions true at  $w$  (i.e., local input). The configuration of round 0 is the function  $f_0$  such that  $f_0(w)$  is the  $k$ -bit binary string produced by  $C$  with the input  $\bar{t}_w \cdot 0^{k(\Delta+1)}$ . Recursively, assume we have defined  $f_n$ . Let  $v_1, \dots, v_m \in \text{succ}(w)$  be the neighbours of  $w$  ( $m \leq \Delta$ ) given in the order of their IDs. Let  $\bar{s}_w$  be the concatenation  $\bar{t}_w \cdot \bar{s}_0 \cdots \bar{s}_\Delta$  of  $k$ -bit binary strings such that **(1)**  $\bar{s}_0 = f_n(w)$ , **(2)**  $\bar{s}_i = f_n(v_i)$  for each  $i \in \{1, \dots, m\}$ , **(3)**  $\bar{s}_j = 0^k$  for  $j \in \{m+1, \dots, \Delta\}$ . Then  $f_{n+1}(w)$  is the output string of  $C$  with input  $\bar{s}_w$ . Now, consider the sequence  $(f_n(w))_{n \in \mathbb{N}}$  of  $k$ -bit strings that  $C$  produces at  $w$ . Suppose the sequence  $(f_n(w))_{n \in \mathbb{N}}$  accepts (resp. outputs  $\bar{p}$ ) in round  $n$  w.r.t.  $(k, A, P)$ . Then  $w$  **accepts** (resp., **outputs**  $\bar{p}$ ) in round  $n$ . Note that the circuit at  $w$  keeps executing after round  $n$ .

Given a Kripke model  $M = (W, R, V)$ , a **solution labeling** is a function  $W \rightarrow \{0, 1\}^*$  associating nodes with strings. The strings represent outputs of the nodes on distributed computation. We could, e.g., label the nodes with strings corresponding to “yes” and “no”. A **partial solution labeling** for  $M$  is a partial function from  $W$  to  $\{0, 1\}^*$ , that is, a function of type  $U \rightarrow \{0, 1\}^*$  for some  $U \subseteq W$ . Partial solution labelings allow for “divergent computations” on some nodes in  $W$ . The **global output** of a circuit  $C$  over a model  $M = (W, R, V)$  is a function  $g: U \rightarrow \{0, 1\}^*$  such that **(1)**  $U \subseteq W$ , **(2)** for all  $w \in U$ , the circuit  $C$  outputs  $g(w)$  in some round  $n$ , and **(3)**  $C$  does not produce an output for any  $v \in W \setminus U$ . Now, fix a finite set  $\Pi_0 \subseteq \text{PROP}_0$  of proposition symbols. Intuitively, these are the “actual” propositions in models, while the set of ID-propositions will grow with model size. Let  $\mathcal{M}(\Pi_0)$  denote the class of all finite Kripke models  $M$  with IDs and having a set  $\Pi$  of proposition symbols such that  $\Pi \cap \text{PROP}_0 = \Pi_0$ . Thus  $\Pi_0$  is the same for all models in  $\mathcal{M}(\Pi_0)$  but the symbols for IDs vary. Consider a subclass  $\mathcal{M} \subseteq \mathcal{M}(\Pi_0)$ . Now, a distributed computing **problem** over  $\mathcal{M}$  is a mapping  $p$  with domain  $\mathcal{M}$  that associates to each input  $M$  a (possibly infinite) set  $p(M)$  of partial solution labelings for  $M$ . The set  $p(M)$  represents the set of acceptable answers to the problem  $p$  over  $M$ . Many graph problems (e.g., colorings) naturally involve a set of such answer labelings.

For  $\Delta \in \mathbb{N}$ , we let  $\mathcal{M}(\Pi_0, \Delta)$  denote the restriction of  $\mathcal{M}(\Pi_0)$  to models with maximum out-degree  $\Delta$ . A **circuit sequence** for  $\mathcal{M}(\Pi_0, \Delta)$  is a function  $F : \mathbb{Z}_+ \rightarrow \text{CIRC}(\Pi_0, \Delta)$  such that  $F(n)$  is a circuit for  $\lceil \log n \rceil$  ID-bits. Now,  $F$  **solves** a problem  $p$  over  $\mathcal{M}(\Pi_0, \Delta)$  if the global output of  $F(n)$  belongs to  $p(M)$  for each  $M \in \mathcal{M}(\Pi_0, \Delta)$  of domain size  $n$ . Let  $c \in \mathbb{N}$ . We define  $\text{DCC}_\Delta^c[\log n]$  to be the class of distributed computing problems solvable by a circuit sequence  $F$  for some  $M \in \mathcal{M}(\Pi_0, \Delta)$  of maximum fan-in  $c$  circuits such that the size of  $F(n)$  is  $\mathcal{O}(\log n)$ . The related LOGSPACE uniform class requires that each  $F$  can be computed in LOGSPACE. DCC stands for *distributed computing by circuits*. Note that circuit sequences for  $\text{DCC}_\Delta^c[\log n]$  are trivially sequences for  $\text{NC}^1$ .

### 3 Extensions of MSC

The rest of this article is basically a proof of the expressive equivalence of MSC and MPCs over distributed systems, with a small blow-up in the respective sizes of programs and circuits. The argument is long, but we have divided it into suitably short lemmas to improve readability. The argument splits into the following two main parts:

1. equivalence of MPCs and **message passing MSC**, or MPMSC, an auxiliary logic to be defined below,
2. equivalence of MPMSC and MSC.

MPMSC is mainly used as a tool, and indeed, MPMSC and the related notions greatly help shorten and organize our arguments.

We define MPMSC via two further auxiliary logics. Let  $\Pi$  be a set of propositions and  $\mathcal{T}$  a set of schema variables. Let  $\Delta \in \mathbb{N}$ . In **Multimodal MSC** (or MMSC), instead of  $\diamond$ , we have the operators  $\diamond_1, \dots, \diamond_\Delta$ , and otherwise the syntax is as in MSC. The schema  $\diamond_i \varphi$  simply asks if  $\varphi$  is true at the  $i$ th neighbour. More formally, if  $(M, w)$  is a pointed Kripke model with identifiers, then  $(M, w) \models \diamond_i \varphi \Leftrightarrow (M, v_i) \models \varphi$  such that  $(w, v_i) \in R$  and  $v_i$  is the  $i$ th neighbour of  $w$ , noting that if the out-degree of  $w$  is less than  $i$ , then  $\diamond_i \varphi$  is false at  $w$ . A  $(\Pi, \Delta)$ -**program** of MMSC is exactly like a  $\Pi$ -program of MSC but we are only allowed to use operators  $\diamond_1, \dots, \diamond_\Delta$  instead of  $\diamond$ . A  $\Pi$ -**program**  $\Lambda$  of MMSC is a  $(\Pi, \Delta)$ -program for any  $\Delta \geq d$ , where  $d$  is the maximum subindex in any diamond in  $\Lambda$ . We also fix print and attention predicates for programs of MMSC. Note that MMSC is not a logic in the usual sense as the operators  $\diamond_i$  require information about the predicates defining IDs. This could be remedied via signature changes and limiting attention to multimodal models with relations having out-degree at most one. This approach would be a bit messy, and the current approach suffices for this article.

We next define MSC **with conditional rules** (or CMSC). Here we allow “if-else” rules as iteration clauses. Let  $\varphi_1, \dots, \varphi_n$  and  $\psi_1, \dots, \psi_n$  and also  $\chi$  be  $(\Pi, \mathcal{T})$ -schemata of basic MSC. A **conditional iteration clause** is a rule of the form  $X :=_{\varphi_1, \dots, \varphi_n} \psi_1; \dots; \psi_n; \chi$ . The schemata  $\varphi_i$  are **conditions** for the head predicate  $X$  and the schemata  $\psi_i$  are the related **consequences**. The last schema  $\chi$  is called the **backup**. Note that when  $n = 0$ , we have a standard MSC clause.  $\Pi$ -**programs** of CMSC are exactly as for MSC, but we are allowed to use conditional iteration clauses. Thus a program  $\Lambda$  of CMSC consists of  $k$  terminal clauses,  $k' \leq k$  conditional iteration clauses and  $k - k'$  standard iteration clauses for some  $k \in \mathbb{Z}_+$ . Again we also fix some sets of schema variables as print and attention predicates.

To fix the semantics, we will specify – as in MSC – the  $n$ th iteration formula of each head predicate. Informally, we always use the first (from the left) condition  $\varphi_i$  that holds and thus evaluate the corresponding consequence  $\psi_i$  as the body of our rule. If none of the conditions hold, then we use the backup. Let  $\Lambda$  be a  $\Pi$ -program of CMSC. First, we let

the zeroth iteration clause  $Y_i^0$  of a head predicate  $Y_i \in \text{HEAD}(\Lambda)$  be the terminal clause of  $Y_i$ . Recursively, assume we have defined an ML( $\Pi$ )-formula  $Y_i^n$  for each  $Y_i \in \text{HEAD}(\Lambda)$ . Now, consider the rule  $Y_i : -\varphi_1, \dots, \varphi_m \ \psi_1; \dots; \psi_m; \chi$ . Let  $\varphi_j^{n+1}$  be the formula obtained by replacing each schema variable  $Y_k$  in the condition  $\varphi_j$  by  $Y_k^n$ . The formulae  $\chi^{n+1}$  and  $\psi_k^{n+1}$  are obtained analogously. Then, the formula  $Y_i^{n+1}$  is

$$\bigvee_{k \leq m} \left( \left( \bigwedge_{j < k} \neg \varphi_j^{n+1} \right) \wedge \varphi_k^{n+1} \wedge \psi_k^{n+1} \right) \vee \left( \left( \bigwedge_{j \leq m} \neg \varphi_j^{n+1} \right) \wedge \chi^{n+1} \right).$$

Often the backup schema  $\chi$  is just the head predicate  $X$  of the rule. This means the truth value of the head predicate does not change if none of the conditions hold. We say that a condition  $\varphi_k$  is **hot** at  $w$  in round  $n \geq 1$  if the formula  $\varphi_k^n$  is true at  $w$  and none of the “earlier” formulas  $\varphi_j^n$  for conditions of the same rule (so  $j < k$ ) are true. Otherwise the backup is hot. We call a conditional iteration clause (or the corresponding head predicate) **active** in round  $n \geq 1$  at node  $w$  if one of the condition formulas of the rule is hot.

We finally specify **message passing** MSC (or MPMSC) essentially as multimodal MSC with conditional rules. The  $(\Pi, \Delta)$ -**programs** are exactly like  $(\Pi, \Delta)$ -programs of MMSC with conditional rules and the following restrictions. **(1)** The modal depth of terminal clauses and conditions of rules is zero. **(2)** The consequences, backups and bodies of standard iteration clauses all have modal depth at most one. As in MMSC, operators  $\diamond$  are not allowed. A  $\Pi$ -program of MPMSC is defined analogously to a  $\Pi$ -program MMSC. Thus a program of MPMSC contains  $k$  terminal clauses,  $k' \leq k$  conditional iteration clauses and  $k - k'$  standard iteration clauses for some  $k \in \mathbb{Z}_+$ . We also fix sets of attention and print predicates. The semantics is defined as for CMSC, noting that now diamonds  $\diamond_i$  are used. A non-terminal clause of a program of MPMSC is a **communication clause** if it contains at least one diamond. A communication clause is **listening** in round  $n \in \mathbb{Z}_+$  if one of the following holds. **(1)** A condition  $\varphi_i$  is hot and the corresponding consequence has a diamond. **(2)** A backup is hot and has a diamond. **(3)** The rule is not conditional but has a diamond.

### 3.1 Notions of equivalence and acceptance

Here we introduce useful acceptance and output conditions for programs of all variants of MSC, including standard MSC. The acceptance conditions will be consistent with the already given conditions for standard MSC.

Let  $\Lambda$  be a program and  $\mathcal{A}$  and  $\mathcal{P}$  the sets of attention and print predicates. Let  $Y_1, \dots, Y_k$  enumerate the head predicates in  $\Lambda$  in the order  $<^{\text{VAR}}$ . Let  $M = (W, R, V)$  be a Kripke model. Each round  $n \in \mathbb{N}$  defines a **global configuration**  $g_n : W \rightarrow \{0, 1\}^k$  given as follows. The configuration of the  $n$ th round is the function  $g_n$  such that the  $i$ th bit of  $g_n(w)$  is 1 if and only if  $(M, w) \models Y_i^n$ . If the sequence  $(g_n(w))_{n \in \mathbb{N}}$  accepts (respectively outputs  $\bar{p}$ ) in round  $n$  with respect to  $(k, \mathcal{A}, \mathcal{P})$ , then we say that the node  $w$  **accepts** (respectively **outputs**  $\bar{p}$ ) in round  $n$ . Then  $n$  is the **output round** (also called the **computation time**) of  $\Lambda$  at  $w$ . Note that the output round is a unique round since the accepting round is unique by the definition of infinite bit sequences where print and attention bits are fixed. We write  $(M, w) \models \Lambda$  if node  $w$  accepts in some round  $n$ . For a program  $\Lambda$  of message passing MSC and model  $M$ , a **global communication round** is a computation round  $n$  where at least one communication clause is listening in at least one node of  $M$ . A program  $\Lambda$  **outputs**  $\bar{p}$  **at**  $w$  **in global communication time**  $m$  if the output round of  $\Lambda$  at  $w$  is  $n$  and  $m \leq n$  is the number of global communication rounds in the set  $\{0, \dots, n\}$  of rounds in the computation.

Now, let  $\mathcal{L}$  denote the set of all programs of all of our variants of MSC. Let  $\mathcal{C}$  denote the set of all MPCs. For each  $\Lambda \in \mathcal{L}$ , we say that a Kripke model  $M$  is **suitable** for  $\Lambda$  if  $M$  interprets (at least) all the proposition symbols that occur in  $\Lambda$ . For a message passing

circuit for  $(\Pi, \Delta)$ , we say that  $M$  is **suitable** for the circuit if the set of proposition symbols interpreted by  $M$  is precisely  $\Pi$  and the maximum out-degree of  $M$  is at most  $\Delta$ . Now, let  $x$  and  $y$  be any members of  $\mathcal{C} \cup \mathcal{L}$ . We say that  $x$  and  $y$  are (acceptance) **equivalent** if for each Kripke model  $M$  that is suitable for both  $x$  and  $y$  and for each node  $w$  in the model,  $x$  and  $y$  produce the same output at  $w$  or neither produce any output at all at  $w$ . We say that  $x$  and  $y$  are **strongly equivalent**, if for each  $M$  suitable for  $x$  and  $y$  and for each node  $w$  in the model and in every round  $n$ , the objects  $x$  and  $y$  produce the same appointed string  $\bar{r}_n$  at  $w$ . We also define a special *weakened equivalence* notion for MPMSC and MPC. We say that a program  $\Lambda$  of MPMSC and a circuit  $C$  are **strongly communication equivalent**, if for each  $M$  suitable for both  $\Lambda$  and  $C$  and for each node  $w$  in the model, the appointed sequence  $S$  of the circuit is precisely the sequence  $(\bar{r}_j)_{j \in G}$  of appointed strings of the program, where  $G \subseteq \mathbb{Z}_+$  is the set of global communication rounds  $n$  of the program. Moreover, the MPMSC must not accept in any non-communication round. Finally, the **length** or **size** of a program (respectively, a schema) of any variant of MSC is the number of *occurrences* of proposition symbols, head predicates, and operators  $\top$ ,  $\neg$ ,  $\wedge$ ,  $\diamond$ ,  $\diamond_i$ . The modal depth  $\text{md}(\Lambda)$  of a program  $\Lambda$  is the maximum modal depth of its rule bodies (iteration and terminal).

#### 4 Linking MPMSC to message passing circuits

To obtain the desired descriptive characterizations, we begin by translating MPCs to MPMSC.

##### 4.1 From MPC to MPMSC

To ultimately translate MPCs to MPMSC, we will first show how to simulate the evaluation of a standard Boolean circuit with a diamond-free program of MSC. Let  $C$  be a circuit of depth  $d$  with  $\ell$  input and  $k$  output gates. Let  $L$  denote any of the variants of MSC. Fix schema variables  $I_1, \dots, I_\ell$  and  $O_1, \dots, O_k$ , with both sequences given here in the order  $<^{\text{VAR}}$ . Consider a program  $\Lambda$  of  $L$  with the following properties.

1. The set of schema variables of  $\Lambda$  contains (at least) the variables  $I_1, \dots, I_\ell, O_1, \dots, O_k$ .
2. The program has no diamond operators ( $\diamond$  or  $\diamond_i$ ) and contains no proposition symbols.
3. The terminal clause for each schema variable  $X$  is  $X(0) :- \perp$ .

Let  $P: \{\perp, \top\}^\ell \rightarrow \{\perp, \top\}^k$  be the function defined as follows. For each input  $(x_1, \dots, x_\ell) \in \{\perp, \top\}^\ell$  to  $P$ , modify  $\Lambda$  to a new program  $\Lambda(x_1, \dots, x_\ell)$  by changing each terminal clause  $I_i(0) :- \perp$  to  $I_i(0) :- x_i$ . Let  $(y_1, \dots, y_k) \in \{\perp, \top\}^k$  be the tuple of truth values of the  $d$ th iteration formulas  $O_1^d, \dots, O_k^d$ , where we recall that  $d$  is the depth of our circuit  $C$ . Then we define  $P(x_1, \dots, x_\ell) := (y_1, \dots, y_k)$ . Now, if  $P$  defined this way is identical to the function computed by  $C$ , then  $\Lambda$  **simulates** the circuit  $C$  (w.r.t.  $I_1, \dots, I_\ell$  and  $O_1, \dots, O_k$ ).

► **Lemma 3.** *For each circuit  $C$  of size  $m$  and with  $n$  edges, there exists a program of  $L$  of size  $\mathcal{O}(m+n)$  that simulates  $C$ , where  $L$  is any of the variants of MSC. Furthermore, with constant fan-in, the size of the program is  $\mathcal{O}(m)$ .*

**Proof.** Assume first that the depth  $d$  of  $C$  is at least 1. Next we modify  $C$  so that we obtain a circuit  $C'$  with the following properties: **(1)** The height of each output gate is the same, **(2)** the depth of  $C'$  is  $\mathcal{O}(d)$ , **(3)** the size of  $C'$  is  $\mathcal{O}(|C|)$  and **(4)**  $C'$  specifies the same function as  $C$ . The formal construction of  $C'$  is given in [1]. Then we define a schema variable for each gate of  $C'$ . The variables for the input gates are  $I_1, \dots, I_\ell$  while those for the output gates are  $O_1, \dots, O_k$ . Let  $X$  be a schema variable for a  $\wedge$ -gate  $G$  of  $C'$ . We define a corresponding terminal clause  $X(0) :- \perp$  and iteration clause  $X :- Y_1 \wedge \dots \wedge Y_j$ , where  $Y_1, \dots, Y_j$  are the variables for the gates that connect to  $G$ . With constant fan-in we have a constant amount of

connecting gates and therefore the length of each rule is  $\mathcal{O}(1)$ . Similarly, for a variable  $X'$  for a disjunction gate  $G'$ , we define the rules  $X'(0) :- \perp$  and  $X' :- Y'_1 \vee \dots \vee Y'_j$  where  $Y'_1, \dots, Y'_j$  are the variables for the gates connecting to  $G'$ . For negation, we define  $X''(0) :- \perp$  and  $X'' :- \neg Y$ , where  $Y$  is the variable for the connecting gate. We let the terminal clauses for the head predicates  $I_i$  relating to input gates be  $I_i(0) :- \perp$ . This choice of rules is irrelevant, as when checking if a program simulates a circuit, we modify the terminal rules to match input strings. The related iteration clause is  $I_i :- I_i$ .

Finally, in the extreme case where the depth of  $C$  is 0 (each input gate is also an output gate), we define the program with the head predicate sequence  $(I_1, \dots, I_\ell) = (O_1, \dots, O_k)$  and such that the (terminal and iteration) clause for each head predicate  $I_i = O_i$  is  $I_i :- \perp$ . ◀

► **Theorem 4.** *Given an MPC for  $(\Pi, \Delta)$  of size  $m$ , we can construct a strongly communication equivalent  $(\Pi, \Delta)$ -program of MPMSC. Supposing a constant bound  $c$  for the fan-in of MPCs, the size of the program is linear in the size of the circuit. Moreover, the computation time is  $\mathcal{O}(d)$  times the computation time of the MPC, where  $d$  is the depth of the MPC.*

**Proof.** Let  $C$  be an MPC for  $(\Pi, \Delta)$  of state length  $k$ . We will first explain informally how our program  $\Lambda_C$  for the circuit  $C$  will work. The program  $\Lambda_C$  uses  $k$  head predicates to simulate the state of the circuit. We will use Lemma 3 to build our program, and the operators  $\diamond_i$  will be used to simulate receiving messages of neighbours. The program  $\Lambda_C$  computes in repeated periods of  $d + 1$  rounds, where  $d = d(C)$  is the depth of  $C$ . Simulating the reception of neighbours' messages takes one round, and the remaining  $d$  rounds go to simulating the evaluation of the circuit.

Now we define our program formally. First we define a clock; the idea is for  $\Lambda_C$  to simulate the computation of  $C$  once per each cycle of the clock. We assume that the depth of  $C$  is at least 1, because if it is 0 then the clock is omitted and the rules of the program are trivial to construct. The clock consists of the head predicates  $T_0, T_1, \dots, T_{d(C)}$  and the following rules:  $T_0(0) :- \perp$ ,  $T_0 :- T_{d(C)}$ ,  $T_1(0) :- \top$ ,  $T_1 :- T_0$  and for  $i \in [d(C) - 1]$ , we have  $T_{i+1}(0) :- \perp$  and  $T_{i+1} :- T_i$ . In every round, precisely one of the head predicates  $T_i$  is true and the others are false. In round 0, the only true predicate is  $T_1$ , and in round  $i \in [d(C) - 1]$ , the only true predicate is  $T_{i+1}$ . After  $d(C)$  rounds the predicate  $T_0$  is true, and in the next round the clock starts over again.

Let  $\Gamma_C$  be a program simulating the internal evaluation of the circuit  $C$  as given in the proof of Lemma 3. We will obtain  $\Lambda_C$  by using the clock and rewriting some of the iteration clauses of  $\Gamma_C$  as follows. If  $X_G$  is a head predicate corresponding to a non-input gate  $G$  in  $\Gamma_C$ , then we rewrite the corresponding iteration clause  $X_G :- \varphi$  to  $X_G :-_{T_{h(G)}} \varphi; X_G$ , where  $h(G)$  is the height of the gate  $G$ .

For every  $\ell \in [|\Pi|]$ , we let  $I_\ell^\Pi$  refer to the head predicate of  $\Gamma_C$  that corresponds to the input gate of  $C$  that reads the truth value of proposition  $p_\ell$ . For every  $i \in [k]$  and  $j \in [\Delta]_0$  we let  $I_{(i,j)}$  refer to a head predicate of  $\Gamma_C$  that corresponds to the input gate of  $C$  that reads the  $i$ th value of the state string of the  $j$ th neighbour. The “neighbour 0” refers to the home node. Next, we will rewrite the clauses with head predicates corresponding to input gates. For every  $i \in [k]$ , we let  $O_i$  refer to the head predicate of  $\Gamma_C$  that corresponds to the  $i$ th output gate of  $C$ . The terminal (respectively, iteration) clause for  $I_i^\Pi$  is rewritten to be  $I_i^\Pi(0) :- p_i$  (resp.,  $I_i^\Pi :-_{T_0} p_i; I_i^\Pi$ ). If  $j \neq 0$ , then the terminal (resp., iteration) clause for every  $I_{(i,j)}$  is rewritten to be  $I_{(i,j)}(0) :- \perp$  (resp.,  $I_{(i,j)} :-_{T_0} \diamond_j O_i; I_{(i,j)}$ ). The terminal (resp., iteration) clause for every  $I_{(i,0)}$  is rewritten to be  $I_{(i,0)}(0) :- \perp$  (resp.,  $I_{(i,0)} :-_{T_0} O_i; I_{(i,0)}$ ). Now, we have obtained the iteration and terminal clauses of  $\Lambda_C$ .

The attention and print predicates of  $\Lambda_C$  are defined as follows. Let  $A \subseteq [k]$  (resp.  $P \subseteq [k]$ ) be the set of the attention (resp., print) bit positions in  $C$ . The print predicates of  $\Lambda_C$  are precisely the head predicates  $O_j$ , where  $j \in P$ . If the depth of  $C$  is 0, then the attention predicates of  $\Lambda_C$  are precisely the head predicates  $O_j$ , where  $j \in A$ . If the depth of  $C$  is greater than 0, then we add a fresh attention predicate  $A'$  whose terminal clause is  $A'(0) :- \perp$  and whose iteration clause is the disjunction of the head predicates  $O_j$  where  $j \in A$ . This is done to ensure that our program accepts during a communication round.

We analyze how  $\Lambda_C$  works. The program executes in a periodic fashion in cycles with  $d(C) + 1$  rounds in each cycle. In round 0, the program  $\Lambda_C$  reads the proposition symbols and records the local input with the head predicates  $I_i^{\Pi}$  whose truth values will remain constant for the rest of the computation. Also,  $T_1$  evaluates to true in round 0. In round 1, the head predicates corresponding to gates at height one are active and thus updated. (Note that the predicates  $I_{(i,j)}$  for input gates are inactive because  $T_0$  is false, so they stay false in round 1, because in round 0 they evaluate to false and the backup has no effect on the truth value.) From height one, the execution then continues to predicates for gates at height two, and so on. In round  $d(C)$ , the head predicates for output gates  $O_i$  are active. The program also outputs if an attention predicate is true. In round  $d(C) + 1$ , the predicate  $T_0$  is true and thus the input gate predicates  $I_{(i,j)}$  are active, and thereby the program starts again by updating them using diamonds  $\diamond_i$ . They obtain truth values that correspond to an input string to our circuit. The program then proceeds to simulate height one in round  $d(C) + 2$ , continuing in further rounds all the way up to height  $d(C)$  gates and finishing the second cycle of the execution of  $\Lambda_C$ . The subsequent cycles are analogous. Thus our program  $\Lambda_C$  simulates  $C$  in a periodic fashion.

It is easy to check that the program  $\Lambda_C$  is strongly communication equivalent to  $C$ . The communication clauses in  $\Lambda_C$  are synchronous, i.e., all nodes are listening in the same rounds. This is because simulating the circuit takes the same amount of time at every node. The translation is clearly linear in the size of  $C$  (for constant fan-in  $C$ ) due to Lemma 3. ◀

## 4.2 From MPMSC to MPC

Converting an MPMSC-program to a circuit is, perhaps, easier. The state string of the constructed MPC essentially stores the values of the head predicates and proposition symbols used by the program and computes a new state string by simulating the program clauses. We begin with the following lemma that shows how to get rid of conditional rules.

► **Lemma 5.** *Given a  $\Pi$ -program of CMSC, we can construct a strongly equivalent  $\Pi$ -program of MSC of size linear in the size of the CMSC-program and with the same maximum modal depth in relation to both terminal and iteration clauses.*

**Proof.** The full proof – given in [1] – is based on expressing the conditions of conditional clauses within a standard clause. The non-trivial part is to keep the translation linear. This can be achieved by using the conditions as “flags”. For example, consider a conditional iteration clause  $X :-_{\varphi_1, \varphi_2} \psi_1; \psi_2; \chi$ . The corresponding standard iteration clause is

$$X :- (\varphi_1 \wedge \psi_1) \vee (\neg\varphi_1 \wedge ((\varphi_2 \wedge \psi_2) \vee (\neg\varphi_2 \wedge \chi))),$$

which is clearly equivalent and linear in size to the original conditional iteration clause. This translation can be easily generalized for arbitrary conditional iteration clauses. ◀

It is easy to get the following corresponding result for MPMSC from the proof of the previous lemma, recalling that terminal clauses in MPMSC are always of modal depth zero.

► **Corollary 6.** *Given a  $\Pi$ -program of MPMSC of size  $m$ , we can construct a strongly equivalent  $\Pi$ -program of MMSC of size  $\mathcal{O}(m)$  and with the same maximum modal depth of iteration clauses and with terminal clauses of modal depth zero. All diamond operators in the constructed program also appear in the original one.*

We are now ready to prove the following.

► **Theorem 7.** *Given  $\Pi$ ,  $\Delta$  and a  $\Pi$ -program of MPMSC of size  $m$ , we can build a strongly equivalent MPC for  $(\Pi, \Delta)$  of size  $\mathcal{O}(\Delta m + |\Pi|)$  when  $\Delta > 0$  and  $\mathcal{O}(m + |\Pi|)$  when  $\Delta = 0$ .*

**Proof.** We give the proof idea; the full proof is in [1]. We first transform the MPMSC-program to a strongly equivalent MMSC-program (Corollary 6). From that program, we construct an MPC whose state string stores the truth values of head predicates and proposition symbols. The circuit is essentially constructed directly from the inverse tree representations of clauses. Head predicates and proposition symbols in the scope of a diamond will correspond to input gates for bits sent by neighbouring nodes. Moreover, head predicates and propositions not in the scope of a diamond relate to input gates for the home node. In communication round zero, the circuit uses a subcircuit constructed from terminal clauses, and in later rounds, it uses a subcircuit constructed from iteration clauses. ◀

## 5 Linking standard MSC to MPC and MPMSC

To simulate MPMSC (and MMSC) in MSC, we will need to simulate each  $\diamond_i$  with  $\diamond$  only. The following lemma is the key step in the process. In the lemma, note that while the computation time may seem large at first,  $|\Pi_1|$  is typically logarithmic.

► **Lemma 8.** *Given  $\Pi$  and a  $\Pi$ -program of MPMSC of size  $m$  where the maximum subindex of a diamond is  $I$ , we can construct an equivalent  $\Pi$ -program of CMSC of size  $\mathcal{O}(I + |\Pi_1| + m)$ . The computation time is  $\mathcal{O}(2^{|\Pi_1|})$  times the computation time of the MPMSC-program.*

**Proof.** Let us first discuss the key ideas of the proof. The key idea of simulating diamonds  $\diamond_i$  with  $\diamond$  is to scan through the neighbours one by one, in the order given by the IDs. To keep the outputs of our translation small in size, different diamonds  $\diamond_i$  will be “read” in different rounds. For this, we will use, together with IDs, the notion of a *clock*.

Clocks are an essential part in the proof, so let us discuss how they operate. A clock is basically a subprogram controlling head predicates  $M_1, \dots, M_\ell$ , where  $\ell = |\Pi_1|$ . At each node and in each iteration round of a CMSC-program, the truth values of the head predicates  $M_1, \dots, M_\ell$  always define a binary string  $s$  with  $\ell$  bits. While  $s$  changes during computation, different nodes have the same  $s$  at any given time instant. More formally, letting  $s_u(i)$  denote  $s$  at node  $u$  at iteration step  $i$ , we have  $s_u(i) = s_v(i)$  for all  $u$  and  $v$ . In the first iteration step, we have  $s = 0^\ell$ , and then, the string  $s$  goes through all the  $\ell$ -bit strings in lexicographic order. After that, the process starts again from  $0^\ell$ .

The clock string  $s$  is constant for more than a single iteration round of the CMSC-program. There are two reasons for this. Firstly, updating the clock string  $s$  to the lexicographically next string takes some time (and uses some auxiliary head predicates). Secondly, the clock has been designed to help the main program simulate multimodal diamonds  $\diamond_i$  with the single diamond  $\diamond$  of CMSC, and this requires some time. Let us next discuss how the clock string is indeed used.

For each string  $s$ , the main CMSC-program scans through all neighbours at each node. The goal is to find a neighbour whose ID is a precise match with  $s$ . Let  $X_{\text{ID}}$  be a head predicate that becomes true at each node  $u$  precisely at those rounds where the ID of  $u$  matches with  $s$ . Then, at node  $v$ , checking whether some neighbour has an ID matching the current string  $s$  is reduced to checking if  $\diamond X_{\text{ID}}$  holds.

Using the value of  $X_{ID}$  at neighbouring nodes, it is easy to simulate each  $\diamond_i$  with  $\diamond$ , as long as we reserve enough time for scanning through all neighbours of each node. For the full formal details, see [1]. ◀

The next theorem follows immediately from the above Lemma and Lemma 5.

► **Theorem 9.** *Given  $\Pi$  and a  $\Pi$ -program of MPMSC of size  $m$  where the maximum subindex in a diamond is  $I$ , we can construct an equivalent  $\Pi$ -program of MSC of size  $\mathcal{O}(I + |\Pi_1| + m)$ . The computation time is  $2^{\mathcal{O}(|\Pi_1|)}$  times the computation time of the MPMSC-program.*

## 5.1 A normal form for MSC

A program of MSC[1] is a program of MSC where the modal depth of terminal (respectively, iteration) clauses is zero (resp., at most one). This normal form of MSC is essentially used as the tool when translating a program of MSC to MPMSC and ultimately to MPC. We begin with the following lemma that shows we can force the modal depth of each terminal clause to zero.

► **Lemma 10.** *For every  $\Pi$ -program  $\Lambda$  of MSC, there exists an equivalent  $\Pi$ -program of MSC where the modal depth of terminal clauses is zero. The size of the program is linear in the size of  $\Lambda$  and the computation time is linear in the computation time of  $\Lambda$ .*

**Proof.** We sketch the proof; for the full proof, see [1]. The proof is based on (1) using CMSC suitably in order to modify terminal clauses so that their diamonds become part of iteration clauses and (2) then translating CMSC to MSC. ◀

We then show that the modal depth of iteration clauses can be reduced to one.

► **Theorem 11.** *For every  $\Pi$ -program  $\Lambda$  of MSC, there exists an equivalent  $\Pi$ -program of MSC[1]. The size of the MSC[1]-program is linear in the size of  $\Lambda$  and the computation time of the program is  $\mathcal{O}(\max(1, \text{md}(\Lambda)))$  times the computation time of  $\Lambda$ .*

**Proof.** We sketch the proof; for the full proof, see [1]. We first transform the original MSC-program to one where the modal depth of the terminal clauses is zero by Lemma 10. Then we use CMSC to replace each subschema of type  $\diamond\psi$  with a fresh head predicate  $X_{\diamond\psi}$  such that in the thereby obtained program, the modal depth of each iteration clause is at most 1. Finally, we translate CMSC to MSC by Lemma 5. ◀

## 5.2 Linking MSC and MPCs

We are now ready to link MSC to MPCs. In Section 4.1 we proved Theorem 4 that shows we can translate MPCs to strongly communication equivalent MPMSC-programs of size linear in the size of the MPC. On the other hand, Theorem 9 shows that we can translate any MPMSC-program to an equivalent program of MSC. We get the following theorem.

► **Theorem 12.** *Given an MPC for  $(\Pi, \Delta)$ , we can construct an equivalent  $\Pi$ -program of MSC. For a constant bound  $c$  for the fan-in of MPCs, the size of the program is linear in the size of the circuit. The computation time is  $\mathcal{O}(d + 2^{|\Pi_1|})$  times the computation time of the MPC, where  $d$  is the depth of the MPC.*

Theorem 7 showed that we can translate an MPMSC-program to a strongly equivalent MPC. Theorem 11 showed how to translate an MSC-program to a strongly equivalent MSC[1]-program, implying that translating an MSC-program to an MPMSC-program can be done without blowing up program size too much. These results directly imply the following.

► **Theorem 13.** *Given  $\Pi$ ,  $\Delta$  and a  $\Pi$ -program of MSC of size  $m$ , there exists an equivalent MPC for  $(\Pi, \Delta)$  of size  $\mathcal{O}(\Delta m + |\Pi|)$  when  $\Delta > 0$  and  $\mathcal{O}(m + |\Pi|)$  when  $\Delta = 0$ . The computation time is  $\mathcal{O}(\max(1, d))$  times the computation time of the MSC-program, where  $d$  is the modal depth of the MSC-program.*

By the above results, we observe that problems in  $\text{DCC}_{\Delta}^c[\log n]$  can be alternatively described with sequences of MSC-programs.

Finally, we note that Theorem 4 is one of our main results. It reminds us that communication time is indeed a different concept than computation time.

## 6 Brief notes on graph coloring

As proof-of-concept for this article, we briefly and informally discuss the Cole-Vishkin algorithm [5], a fundamental method used in distributed graph coloring. The CV-algorithm takes advantage of a phenomenon whereby it is possible to logarithmically reduce the size of a binary string by replacing it with a binary encoding of one of its positions. By iterating this technique, it is possible to reduce the size of an  $n$ -size string down to three in  $\mathcal{O}(\log^*(n))$  iterations. Applied as a distributed algorithm to an  $n$ -coloring in an oriented tree or forest, it is possible to reduce the number of colors to single digits in  $\mathcal{O}(\log^*(n))$  communication rounds [6]. By extension, Barenboim and Elkin [3] show a number of ways this can be combined with other simpler iterative algorithms to produce fast  $(\Delta + 1)$ -color reduction algorithms, i.e. algorithms that reduce the number of colors from the size of a graph down to its maximum degree plus one, which is optimal in the worst-case scenario.

While the communication time of these algorithms has been studied before, little is generally understood about the duration of their local (node-internal) computation and the necessary program length required to formally express them.

In the full preprint version of this paper [1] (available online), we prove that given a bound for the degree  $\Delta$  of a graph, the CV-algorithm and a broader simple  $(\Delta + 1)$ -color reduction algorithm can be expressed with a program of MPMSC with size logarithmic in the number of nodes. Additionally, the expression is uniform for all degree bounds. In other words, for any  $\Delta$ , the Cole-Vishkin algorithm (and the associated  $(\Delta + 1)$ -color reduction algorithm) can be expressed in a compact way in MSC and thus also in the related distributed computing class where MPCs are from  $\text{NC}^1$ . The following theorem is obtained as a result.

► **Theorem 14.** *Given a bounded-degree graph with at most  $n$  nodes, there exists an MPMSC-program of size  $\mathcal{O}(\log(n))$  that defines a  $(\Delta + 1)$ -coloring for the graph. The computation time is  $\mathcal{O}(\log(n) \log(\log(n)) \log^*(n))$  of which  $\log^*(n) + \mathcal{O}(1)$  are global communication rounds.*

By Theorems 14 and 9, we get a program of MSC of size  $\mathcal{O}(|\Pi_1| + \log(n))$  with an increase in computation time by a factor of  $2^{\mathcal{O}(|\Pi_1|)}$ . While the computation time may seem large, note that  $|\Pi_1|$  is typically logarithmic. We emphasize that the computation and communication times of a program are very different concepts and the former will usually dwarf the latter.

## 7 Conclusion

We have characterized distributed computation via circuits in terms of the logic MSC. The translations lead to only polynomial increase in size, and in the constant-degree scenario, the increase is only linear. In the future, we aim to expand these studies to concern models with weights, pushing the approach closer to work on neural networks.

## Abstract

We analyse an algorithm solving stochastic mean-payoff games, combining the ideas of relative value iteration and of Krasnoselskii–Mann damping. We derive parameterized complexity bounds for several classes of games satisfying irreducibility conditions. We show in particular that an  $\epsilon$ -approximation of the value of an irreducible concurrent stochastic game can be computed in a number of iterations in  $O(|\log \epsilon|)$  where the constant in the  $O(\cdot)$  is explicit, depending on the smallest non-zero transition probabilities. This should be compared with a bound in  $O(\epsilon^{-1}|\log(\epsilon)|)$  obtained by Chatterjee and Ibsen-Jensen (ICALP 2014) for the same class of games, and to a  $O(\epsilon^{-1})$  bound by Allamigeon, Gaubert, Katz and Skomra (ICALP 2022) for turn-based games. We also establish parameterized complexity bounds for entropy games, a class of matrix multiplication games introduced by Asarin, Cervelle, Degorre, Dima, Horn and Kozyakin. We derive these results by methods of variational analysis, establishing contraction properties of the relative Krasnoselskii–Mann iteration with respect to Hilbert’s semi-norm.

## 1 Introduction

### 1.1 Motivation and context

Stochastic mean-payoff games are a fundamental class of zero-sum games, appearing in various guises. In *turn-based* games, two players play sequentially, alternating moves, or choices of an action, being aware of the previous decision of the other player. Turn-based games with mean-payoff and finite state and action spaces are among the unsettled problems in complexity theory: they belong to the complexity class  $\text{NP} \cap \text{coNP}$  [14, 40] but are not known to be polynomial-time solvable. We refer the reader to the survey [7] for more information on the different classes of turn-based games. In contrast, in *concurrent games*, at each stage, the two players choose simultaneously one action, being unaware of the choice of the other player at the same stage. Turn-based games are equivalent to a subclass of concurrent games (in which in each state, one of the two players is a dummy). The existence

of the value for concurrent stochastic mean-payoff games is a celebrated result of Mertens and Neyman [28]. This builds on earlier results by Bewley and Kohlberg, connecting mean-payoff concurrent games with discounted concurrent games, by making the discount factor tend to 1, see [11]. Concurrent games are hard to solve exactly: the value is an algebraic number whose degree may be exponential in the number of states [21]. Moreover, concurrent reachability games are square-root sum hard [16].

Another class consists of *entropy games*, introduced by Asarin, Cervelle, Degorre, Dima, Horn and Kozyakin as an interesting category of “matrix multiplication games” [8]. Entropy games capture a variety of applications, arising in risk sensitive control [23, 6], portfolio optimization [3], growth maximization and population dynamics [36, 33, 32, 39]. Asarin et al. showed that entropy games belong to the class  $\text{NP} \cap \text{coNP}$ , showing an analogy with turn based games. In [1], Akian, Gaubert, Grand-Clément and Guillaud showed that entropy games are actually special cases of stochastic mean-payoff games, in which action spaces are infinite sets (simplices), and payments are given by Kullback-Leibler divergences.

A remarkable subclass of stochastic mean-payoff games arises when imposing *ergodicity* or *irreducibility* conditions. Such conditions entail that the value of the game is independent of the initial state. The simplest condition of this type requires that every pair of policies (Markovian stationary strategies) of the two players induces an irreducible Markov chain. Then, the solution of the game reduces to solving a nonlinear eigenproblem of the form  $T(u) = \lambda e + u$ , in which  $u \in \mathbb{R}^n$  is a non-linear eigenvector,  $\lambda$  is a non-linear eigenvalue, which provides the value of the mean-payoff game,  $e$  is the unit vector of  $\mathbb{R}^n$ , and  $T$  is a self-map of  $\mathbb{R}^n$ , the dynamic programming operator of the game, which we shall refer to as the “Shapley” operator. In fact, Shapley originally introduced a variant of this operator, adapted to the discounted case [34]. The undiscounted mean-payoff case was subsequently considered by Gillette [20]. We refer the reader to [29, 31] for background on Shapley operators and on the “operator approach” to games, and to [2] for a discussion of the non-linear eigenproblem.

In the one-player case, White [38] introduced *relative value iteration*, which consist in fixed point iterations up to additive constants  $\lambda_k \in \mathbb{R}$ , i.e.  $x_{k+1} = T(x_k) - \lambda_k e$ . This solves the non-linear eigenproblem  $T(u) = \lambda e + u$  under a primitivity assumption. However, this assumption appears to be too restrictive in the light of the classical Krasnoselskii–Mann algorithm [25, 27], which allows one to find a fixed point of a nonexpansive self-map  $T$  of a finite dimensional normed space, by constructing the “damped” sequence  $x_{k+1} = (1 - \theta)T(x_k) + \theta x_k$ , where  $0 < \theta < 1$ . Indeed, it was proposed in [19] to apply this algorithm to the non-linear eigenproblem  $T(u) = \lambda e + u$ , thought of as a fixed point problem in the quotient vector space  $\mathbb{R}^n / \mathbb{R}e$ . We will refer to this algorithm as the *relative Krasnoselskii–Mann value iteration*. An error bound in  $O(1/\sqrt{k})$  was derived in [19] for this algorithm, as a consequence of a general theorem of Baillon and Bruck [10], and the existence of an asymptotic geometric convergence rate was established in a special case. This left open the question of obtaining stronger iteration complexity bounds, in a “white box model”, for specific classes of stochastic mean-payoff games.

## 1.2 Contribution

We apply the relative Krasnoselskii–Mann value iteration algorithm to deduce complexity bounds for several classes of stochastic games. We consider in particular *unichain* concurrent stochastic mean-payoff games, in which every pair of policies of the two players induces a unichain transition matrix (i.e., a stochastic matrix with a unique final class). We define  $p_{\min}$  to be the smallest non-zero off-diagonal transition probability in the model. Corollary 20 shows that the relative Krasnoselskii–Mann iteration yields an  $\epsilon$ -approximation of the value

of the game, after  $C|\log \epsilon|$  iterations. The factor  $C$  is exponential in the bit-size of the input, it has an essential term of the form  $k\theta^{-k}$ , in which  $k \leq n$  is a certain “unichain index”, which is equal to 1 if all the transition probabilities are positive,  $\theta = p_{\min}/(1 + p_{\min})$ , and  $n$  denotes the number of states. Then, we consider the special case of unichain turn-based games, with rational transition probabilities whose denominator divides  $M$ . Theorem 23 shows that optimal policies can be obtained after a number of iterations of order  $M^k$ . The main tool is Theorem 19, which shows that a suitable iterate of the Shapley operator of a unichain concurrent game is a contraction in Hilbert’s seminorm. This theorem is proved using techniques of variational analysis, in particular we use a classical result of Mills [30], characterizing the directional derivative of the value of a matrix game, and properties of nonsmooth semidifferentiable maps.

Finally, we introduce a variant of the relative Krasnoselkii–Mann algorithm, adapted to entropy games. Theorem 26 shows that an irreducible entropy game can be solved exactly in a time of order  $(1 + \mathcal{A}/\underline{m})^k$  where  $k \leq n$  is a certain “irreducibility index”,  $\underline{m} \geq 1$  is the smallest multiplicity of an off-diagonal transition, and  $\mathcal{A}$  is a measure of the *ambiguity* of the game. In particular, we have  $W \leq \mathcal{A} \leq n^{1-1/n}W$  where  $W$  is the maximal multiplicity of a transition. The proof exploits the Birkhoff–Hopf theorem, which states that a positive matrix is a contraction in Hilbert’s projective metric.

The proofs of the present results can be found in the extended version of this article [4].

### 1.3 Related work

The algorithmic approach of stochastic mean-payoff games satisfying irreducibility conditions goes back to the work of Hoffman and Karp [22], applying policy iteration. Chatterjee and Ibsen-Jensen [13] studied concurrent stochastic mean-payoff games, under appropriate conditions of ergodicity. They showed in particular that the problem of approximation of the value is in FNP, and that this approximation problem, restricted to turn-based ergodic games, is at least as hard as the decision problem for simple stochastic games. They also showed that value iteration provides an  $\epsilon$ -approximation of the value of a concurrent stochastic game satisfying an irreducibility condition in  $O(\tau\epsilon^{-1}|\log \epsilon|)$  iterations, where  $\tau$  denotes a bound of the passage time between any two states under an arbitrary strategy, see Theorem 18, *ibid.* A recent “universal bound” on value iteration by Allamigeon, Gaubert, Katz and Skomra [5, Th. 13] entails an improvement of this bound to  $O(\tau\epsilon^{-1})$ . Corollary 20 further improves this bound to get  $C|\log \epsilon|$ . However, the later result requires an unichain assumption, whereas the assumption of [5, Th. 13] is milder.

The question of computing the value of a concurrent discounted stochastic game has been studied by Hansen, Koucký, Lauritzen, Miltersen and Tsigaridas in [21], who showed, using semi-algebraic geometry techniques, that an  $\epsilon$ -approximation of the value of a general concurrent game can be obtained in polynomial time if the number  $n$  of states is fixed. The exponent of the polynomial is of order  $O(n)^{n^2}$  and it was remarked in [21] that “getting a better dependence on  $n$  is a very interesting open problem”. Boros, Gurvich, Elbassioni and Makino considered the notion of  $\epsilon$ -ergodicity of a concurrent mean-payoff game, requiring that the mean-payoff of two initial states differ by at most  $\epsilon$ . They provided a potential-reduction algorithm allowing one to decide  $\epsilon$ -ergodicity, and to get an  $\epsilon$ -approximation of the value, with a dependence in  $\epsilon$  of order  $\epsilon^{-O(2^{2n}n \max(|A|, |B|))}$ , see [12]. Attia and Oliu-Barton developed in [9] a bisection algorithm, with a complexity bound polynomial in  $|\log \epsilon|$  and in  $|A|^n$  and  $|B|^n$  where  $A, B$  are the action spaces. In contrast to these three works, our approach only applies to the subclass of *unichain* concurrent games, but its complexity has a better dependence in the number of states; in particular, the exponents in our bound is at

most  $n$ , and the execution time grows only polynomially with the numbers of actions  $|A|$  and  $|B|$ . Moreover, our approach applies more generally to infinite (compact) action spaces (we only need an oracle evaluating the value of a possibly infinite matrix game up to a given accuracy).

The analysis of relative value iteration, using contraction techniques, goes back to the work of Federguen, Schweitzer and Tijms [17], dealing with the one-player and finite action spaces case, under a primitivity condition. The novelty here is the analysis of the concurrent two-player case, as well as the analysis of the effect of the Krasnoselskii–Mann damping, allowing one to replace earlier primitivity conditions by a milder unichain condition. Moreover, even in the one-player case, our formula for the contraction rate given in Theorem 19 improves the one of [17].

Our results of Section 9 dealing with entropy games are inspired by the series of works [8, 1, 5]. The subclass of “Despot-free” entropy games can be solved in polynomial time [1], and it is an open question whether general entropy games can be solved in polynomial time. The approach of [5] entails that one can get an  $\epsilon$ -approximation of the value of an entropy game in  $O(\epsilon^{-1})$  iterations, where the factor in the  $O(\cdot)$  is exponential in the parameters of the game. This bound is refined here to  $O(|\log \epsilon|)$ , in which the factor in the  $O(\cdot)$  depends on a measure of “ambiguity” – but our approach requires an irreducibility assumption.

## 2 Preliminary results on Shapley operators

Let  $n$  be an integer. A map  $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$  is said to be *order-preserving* when:  $\forall x, y \in \mathbb{R}^n, x \leq y \implies T(x) \leq T(y)$ , where  $\leq$  denotes the standard partial order of  $\mathbb{R}^n$ . It is *additively homogeneous* when:  $\forall x \in \mathbb{R}^n, \forall \lambda \in \mathbb{R}, T(x + \lambda e) = T(x) + \lambda e$  where  $e$  is the vector of  $\mathbb{R}^n$  having 1 in each coordinate.

► **Definition 1.** *A map  $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$  is an (abstract) Shapley operator if it is order-preserving and additively homogeneous.*

We will justify the terminology “Shapley operator” in the next section, where we give concrete examples, arising as dynamic programming operators of different classes of zero-sum repeated games. We set  $[n] := \{1, \dots, n\}$ . For any  $x \in \mathbb{R}^n$ , we denote  $\mathbf{t}(x) := \max_{i \in [n]} x_i$  and  $\mathbf{b}(x) := \min_{i \in [n]} x_i$  (read “top” and “bottom”). We define the *Hilbert’s seminorm* of  $x$  by:  $\|x\|_H = \mathbf{t}(x) - \mathbf{b}(x)$ . Since  $\|x\|_H = 0$  iff  $x \in \mathbb{R}e$ , we get that  $\|\cdot\|_H$  is actually a norm on the quotient vector space  $\mathbb{R}^n/\mathbb{R}e$ . We also notice that  $\|x\|_\infty = \inf\{\lambda \in \mathbb{R}_+ \mid -\lambda e \leq x \leq \lambda e\}$  and  $\|x\|_H = \inf\{\beta - \alpha \in \mathbb{R}_+ \mid \alpha, \beta \in \mathbb{R}, \alpha e \leq x \leq \beta e\}$ . It is easy to show, thanks to these expressions, that a Shapley operator  $T$  is non-expansive (i.e., 1-Lipschitz) for  $\|\cdot\|_H$  and for  $\|\cdot\|_\infty$ . Then, it induces a self-map  $\bar{T}$  on the quotient vector space  $\mathbb{R}^n/\mathbb{R}e$ , sending the equivalence class  $x + \mathbb{R}e$  to  $T(x) + \mathbb{R}e$ , and which is non-expansive.

► **Definition 2.** *We define the escape rate  $\chi(T)$  of a Shapley operator  $T$  as  $\lim_{k \rightarrow \infty} k^{-1}T^k(v)$ , where  $v$  is an arbitrary vector in  $\mathbb{R}^n$ . The lower and upper escape rates are defined respectively by  $\underline{\chi}(T) = \lim_{k \rightarrow \infty} k^{-1}\mathbf{b}(T^k(v))$  and  $\bar{\chi}(T) = \lim_{k \rightarrow \infty} k^{-1}\mathbf{t}(T^k(v))$ .*

Since  $T$  is nonexpansive in the sup-norm, the existence and the values of these limits are independent of the choice of  $v \in \mathbb{R}^n$ . In general, the escape rate  $\chi(T) = \lim_{k \rightarrow \infty} k^{-1}T^k(v)$  may not exist, but a subadditive argument shows that the lower and upper escape rates always exist, see e.g. [18]. A fundamental tool to establish the existence of the escape rate is to consider the following ergodic equation.

► **Definition 3.** *We say that the ergodic equation has a solution when there exists  $\lambda \in \mathbb{R}$  and  $u \in \mathbb{R}^n$  such that  $T(u) = \lambda e + u$ .*

► **Observation 4.** *If the above ergodic equation is solvable, then  $\chi(T) = \lambda e$ . More generally, if  $\alpha e + v \leq T(v) \leq \beta e + v$  for some  $v \in \mathbb{R}^n$  and  $\alpha, \beta \in \mathbb{R}$ , then  $\alpha \leq \underline{\chi}(T) \leq \bar{\chi}(T) \leq \beta$ .*

**Proof.** By an immediate induction, and as  $T$  is order-preserving and additively homogeneous we have :  $k\alpha e + v \leq T^k(v) \leq k\beta e + v$ . Then,  $k\alpha + \mathbf{b}(v) \leq \mathbf{b}(T^k(v)) \leq \mathbf{t}(T^k(v)) \leq k\beta + \mathbf{t}(v)$ . Dividing by  $k$  and letting  $k$  tend to infinity, we obtain the second statement. ◀

We are inspired by the following observation from fixed point theory.

► **Observation 5.** *Suppose now that  $T^q$  is  $\gamma$ -contraction in Hilbert's seminorm  $\|\cdot\|_H$ , for some  $q \geq 1$  and  $0 < \gamma < 1$ . Then, the ergodic equation is solvable.*

Shapley operators include (finite dimensional) Markov operators, which are of the form  $T(x) = Mx$ , where  $M$  is a  $n \times n$  stochastic matrix (meaning that  $M$  has nonnegative entries and row sums one). In this case, an exact formula is known for the contraction rate. In fact, one can consider the operator norm of  $M$ , thought of as a linear map acting on the quotient vector space  $\mathbb{R}^n / \mathbb{R}e$ ,  $\|M\|_H = \sup_{u \notin \mathbb{R}e} \frac{\|Mu\|_H}{\|u\|_H}$ .

► **Theorem 6** (Corollary of [15]).  $\|M\|_H = \delta(M) := 1 - \min_{1 \leq i < j \leq n} \left\{ \sum_{k \in [n]} \min(M_{ik}, M_{jk}) \right\}$ .

The term  $\delta(M)$  is known as *Dobrushin ergodicity coefficient*.

### 3 Two classes of zero-sum two-player repeated games

We next recall the definition and basic properties of two classes of zero-sum two-player games with finite state spaces. More details can be found in [29] for stochastic games and in [8, 1] for entropy games.

#### 3.1 Concurrent repeated zero-sum stochastic two-player games

We assume that the state space is equal to  $[n] = \{1, \dots, n\}$ . We call the two players “Min” and “Max”. The game is specified by the following data. For every state  $i \in [n]$ , we are given two non-empty compact sets  $A(i)$  and  $B(i)$ , representing the admissible actions of players Min and Max, respectively. For every  $i \in [n]$  and every choice of actions  $(a, b) \in A(i) \times B(i)$ , we are given a real number  $r_i^{ab}$ , representing an instantaneous payment, and a stochastic vector  $P_i^{a,b} = (P_{ij}^{a,b})_{j \in [n]}$ , meaning that  $P_{ij}^{a,b} \geq 0$  and that  $\sum_{j \in [n]} P_{ij}^{a,b} = 1$ . We assume that the functions  $(a, b) \mapsto r_i^{ab}$  and  $(a, b) \mapsto P_i^{a,b}$  are continuous.

The concurrent game is played in successive stages, starting from a known initial state  $i_0$  at stage 0. We denote by  $a_k$  and  $b_k$  the actions selected by Players Min and Max at stage  $k$ , respectively, and by  $i_k$  the state at this stage. The history until stage  $k$  consists of the sequence  $H_k = ((i_\ell, a_\ell, b_\ell)_{0 \leq \ell < k}, i_k)$ . A randomized strategy of Player Min (resp. Max) is a collection of measurable functions assigning to every history  $H_k$  a probability measure  $\alpha_k$  (resp.  $\beta_k$ ) on the compact set  $A(i_k)$  (resp.  $B(i_k)$ ). At stage  $k$ , being informed of the history  $H_k$  up to this stage, Player Min draws a random action  $a_k$  according to the probability measure  $\alpha_k$ , and similarly, Player Max draws a random action  $b_k$  according to the probability measure  $\beta_k$ . Then, Player Min makes to Player Max an instantaneous payment of  $r_{i_k}^{a_k, b_k}$ , and the next state  $i_{k+1}$  is drawn randomly according to the probability measure  $(P_{i_k, j}^{a_k, b_k})_{j \in [n]}$  on the state space  $[n]$ , i.e., the conditional probability that  $i_{k+1} = j$ , given the history  $H_k$  and actions  $a_k, b_k$ , is given by  $P_{i_k, j}^{a_k, b_k}$ . We shall say that a strategy is *pure* or *deterministic* if the action of the player is chosen as a deterministic function of the history. We denote by  $\sigma_k$  (resp.  $\tau_k$ ) the strategy of Player Min (resp. Max) at stage  $k$ , and denote by  $\sigma$  and  $\tau$

the sequences  $(\sigma_k)_{k \geq 0}$  and  $(\tau_k)_{k \geq 0}$ . In this way, to any initial state  $i_0 \in [n]$  and any pair of strategies  $(\sigma, \tau)$  of the two players is associated the infinite random sequence  $(i_k, a_k, b_k)_{k \geq 0}$ . We denote by  $\mathbb{E}_{i_0}^{\sigma, \tau}$  the expectation operator with respect to this process.

We shall consider special classes of strategies. We denote by  $\Delta_X$  the set of probability measures on a compact set  $X$ . A *randomized policy* of Player Min is a map  $\alpha : [n] \rightarrow \cup_{i \in [n]} \Delta_{A(i)}$ ,  $i \mapsto \alpha_i$ . For each  $i \in [n]$ ,  $d\alpha_i(a)$  determines the probability an action  $a \in A_i$  is chosen, according to this policy. Thus, the set of randomized policies of Min,  $\Pi_{\mathbb{R}}^{\text{Min}}$ , can be identified to  $\prod_{i \in [n]} \Delta_{A(i)}$ . A policy of Min is said to be *pure* if for all  $i \in [n]$ ,  $\alpha_i$  is a Dirac measure, so that  $d\alpha_i = \delta_{a_i}$  for some  $a_i \in A_i$ . Such a policy prescribes to play the deterministic action  $a_i$  when in state  $i$ . Therefore, a pure policy is uniquely specified by the map  $i \mapsto a_i$ . This allows us to identify the set of pure policies, denoted by  $\Pi_{\mathbb{P}}^{\text{Min}}$ , to the product  $\prod_{i \in [n]} A_i$ . A randomized *Markovian* strategy  $\sigma$  of Player Min is a strategy such that the decision prescribed by  $\sigma_k$  depends only on the current state  $i_k$ . In other words, it is obtained by selecting, at each time step, a randomized policy of Player Min, and playing the action according to this policy. A Markovian strategy is *pure* if only pure policies are selected. It is *stationary* if the same policy is applied at every time step  $k$ . In this way, a pure (resp. randomized) Markovian stationary strategy can be identified to a pure (resp. randomized) policy. We shall use the same notation and terminology for Player Max, mutatis mutandis. In particular, we denote by  $\Pi_{\mathbb{R}}^{\text{Max}}$  and  $\Pi_{\mathbb{P}}^{\text{Max}}$  the sets of randomized and pure policies of Player Max. We shall also denote by  $\Pi_{\mathbb{P}} = \Pi_{\mathbb{P}}^{\text{Min}} \times \Pi_{\mathbb{P}}^{\text{Max}}$  and  $\Pi_{\mathbb{R}} = \Pi_{\mathbb{R}}^{\text{Min}} \times \Pi_{\mathbb{R}}^{\text{Max}}$  the spaces of pairs of policies.

Given an initial state  $i_0$  and a pair of strategies  $(\sigma, \tau)$  of the two players, the expected payment received by Player Max in horizon  $N$  is defined by

$$J_{i_0}^N(\sigma, \tau) := \mathbb{E}_{i_0}^{\sigma, \tau} \left[ \sum_{k=0}^{N-1} r_{i_k}^{a_k, b_k} \right].$$

We shall denote by  $J^N(\sigma, \tau)$  the vector of  $\mathbb{R}^n$  with the above  $i_0$  entry, for each  $i_0 \in [n]$ . The finite horizon game has a value  $v^N \in \mathbb{R}^n$  and has a pair of optimal (randomized) strategies  $(\sigma^*, \tau^*)$ , meaning that

$$J^N(\sigma^*, \tau) \leq v^N = J^N(\sigma^*, \tau^*) \leq J^N(\sigma, \tau^*), \quad (1)$$

for all pairs  $(\sigma, \tau)$  of strategies, see [29]. Moreover, one can choose the pair of optimal strategies  $(\sigma^*, \tau^*)$  to be Markovian, that is  $(\sigma_k^*, \tau_k^*) \in \Pi_{\mathbb{R}}$  for all  $k \leq N$  (but it generally depends on  $k$  and  $N$ ). These optimal strategies can be obtained by using the dynamic programming equation of the game, as follows.

For any  $i, j \in [n]$ ,  $\alpha_i \in \Delta_{A(i)}$  and  $\beta_i \in \Delta_{B(i)}$ , let us denote

$$r_i^{\alpha_i, \beta_i} = \int_{A(i) \times B(i)} r_i^{a, b} d\alpha_i(a) d\beta_i(b) \quad \text{and} \quad P_{i, j}^{\alpha_i, \beta_i} = \int_{A(i) \times B(i)} P_{i, j}^{a, b} d\alpha_i(a) d\beta_i(b). \quad (2)$$

This extends the functions  $(a, b) \mapsto r_i^{a, b}$  and  $(a, b) \mapsto P_{i, j}^{a, b}$  from  $A(i) \times B(i)$  to  $\Delta_{A(i)} \times \Delta_{B(i)}$ . We then define the Shapley operator  $T$  of the concurrent game as the map  $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$  such that

$$T_i(v) = \min_{\alpha_i \in \Delta_{A(i)}} \max_{\beta_i \in \Delta_{B(i)}} \left( r_i^{\alpha_i, \beta_i} + \sum_{j \in [n]} P_{i, j}^{\alpha_i, \beta_i} v_j \right), \quad \text{for } i \in [n], v \in \mathbb{R}^n. \quad (3)$$

Note that in the above expression the infimum and supremum commute, owing to the compactness of action spaces, and continuity assumptions on the functions  $(a, b) \mapsto r_i^{a, b}$  and  $(a, b) \mapsto P_{i, j}^{a, b}$  (this follows from Sion's minimax theorem). Moreover, the operator  $T$  satisfies the properties of Definition 1.

Then, the value of the concurrent game in finite horizon is obtained from the recurrence equations:  $v^0 = 0$ ,  $v^N = T(v^{N-1})$ . Moreover, optimal strategies of the game when the remaining time is  $k < N$  (or at stage  $N - k$ ) are obtained by choosing optimal policies  $\alpha$  and  $\beta$  with respect to the vectors  $v^k$ , that is such that  $\alpha_i$  and  $\beta_i$  are optimal in the expression of  $T_i(v^k)$  in (3).

We now describe the *mean-payoff game*, which is obtained by considering the Cesaro limit of the payoff as the horizon  $N$  tends to infinity. More precisely, we set:

$$\chi_{i_0}^+(\sigma, \tau) := \limsup_{N \rightarrow \infty} N^{-1} J_{i_0}^N(\sigma, \tau) \quad \chi_{i_0}^-(\sigma, \tau) := \liminf_{N \rightarrow \infty} N^{-1} J_{i_0}^N(\sigma, \tau) .$$

We shall say that the game with mean-payoff has a value  $\chi^* \in \mathbb{R}^n$  if for all  $\varepsilon > 0$ , there exists strategies  $\sigma^\varepsilon, \tau^\varepsilon$  of the two players which are  $\varepsilon$ -optimal, meaning that for every strategies  $\sigma$  and  $\tau$ ,  $-\varepsilon e + \chi^+(\sigma^\varepsilon, \tau) \leq \chi^* \leq \chi^-(\sigma, \tau^\varepsilon) + \varepsilon e$ . Mertens and Neyman [28], building on a result of Bewley and Kohlberg [11], showed that when the action spaces  $A(i)$  and  $B(i)$  are finite, the mean-payoff game has a value (actually, in a stronger *uniform* sense). Moreover, the value coincides with the escape rate of the Shapley operator, i.e.,  $\chi^* = \lim_k T^k(0)/k$ . A counter-example of Vigerál shows that these properties do not carry over to the case of general compact action spaces [37].

One particular case that will interest us is when the ergodic equation is solvable, that is when there exists  $\lambda \in \mathbb{R}$  and  $v \in \mathbb{R}^n$  such that  $T(v) = \lambda e + v$ . In that case,  $\chi^* = \lambda e$  and there exists optimal randomized strategies for the two players which are both Markovian and stationary. Such a pair of strategies is obtained by choosing a pair  $(\alpha, \beta)$  of policies such that  $\alpha$  and  $\beta$  achieve the minimum and the maximum, respectively, in the expression of  $T(v)$  in (3). We shall see that the ergodic equation is always solvable under a unichain condition, even in the case of compact action spaces (Theorem 11).

A remarkable subclass of concurrent games consists of *turn-based* games. Then, the actions spaces  $A(i)$  and  $B(i)$  are required to be *finite*, and for every state  $i \in [n]$ , we assume that either  $A(i)$  or  $B(i)$  is a singleton. In other words, there is a bipartition  $[n] = I_{\text{Min}} \uplus I_{\text{Max}}$  of the set of states, so that in every state  $i \in I_{\text{Min}}$  (resp.  $I_{\text{Max}}$ ), Min (resp. Max) is the only player who has to take a decision. Then, the Shapley operator of the game reduces to  $T_i(x) = \min_{a \in A(i)} \max_{b \in B(i)} (r_i^{a,b} + \sum_j P_{i,j}^{a,b} x_j)$ , for  $i \in [n]$ , where again the min and max commute, because in every  $i \in [n]$ , either the min or the max is taken over a set reduced to a singleton. When the ergodic equation  $T(v) = \lambda e + v$  of a turn-based game is solvable, one obtains *pure* optimal policies in the mean-payoff game, by selecting actions that achieve the minimum and the maximum in each coordinate  $[T(v)]_i$  with  $i \in [n]$ . More generally, the existence of pure optimal policies for turn-based mean-payoff stochastic games was shown by Liggett and Lippman [26]. An illustrative example is given in Appendix A.

### 3.2 Entropy games

Entropy games were introduced in [8]. We use here the slightly more general model of [1, 5], to which we refer for background. An *entropy game* is a turn-based game played on a (finite) digraph  $(\mathcal{V}, \mathcal{E})$ , with two players, called “Despot” and “Tribune”, and an additional non-deterministic player, called “People”. We assume the set of vertices  $\mathcal{V}$  has a non-trivial partition:  $\mathcal{V} = \mathcal{V}_D \uplus \mathcal{V}_T \uplus \mathcal{V}_P$ . Players Despot, Tribune, and People control the states in  $\mathcal{V}_D$ ,  $\mathcal{V}_T$  and  $\mathcal{V}_P$  respectively, and they alternate their moves, i.e.,  $\mathcal{E} \subset (\mathcal{V}_D \times \mathcal{V}_T) \cup (\mathcal{V}_T \times \mathcal{V}_P) \cup (\mathcal{V}_P \times \mathcal{V}_D)$ . We suppose that every edge  $(p, d) \in \mathcal{E}$  with  $p \in \mathcal{V}_P$  and  $d \in \mathcal{V}_D$  is equipped with a *multiplicity*  $m_{pd}$  which is a (positive) natural number. For simplicity of exposition, we shall define here the value of an entropy game using only pure policies. More precisely, a

(pure) policy  $\sigma$  of Despot is a map which assigns to every node  $d \in \mathcal{V}_D$  a node  $t$  such that  $(d, t) \in \mathcal{E}$ . Similarly, a policy  $\tau$  of Tribune is a map which assigns to every node  $t \in \mathcal{V}_T$  a node  $p \in \mathcal{V}_P$ . We denote by  $n$  the cardinality of  $\mathcal{V}_D$ . Such a pair of policies determine a  $n \times n$  matrix  $M^{\sigma, \tau}$ , such that  $M_{d, d'}^{\sigma, \tau} = m_{\tau(\sigma(d)), d'}$ . Given an initial state  $\bar{d} \in \mathcal{V}_D$ , we measure the “freedom” of Player People by the limit  $R(\sigma, \tau) := \lim_{k \rightarrow \infty} [(M^{\sigma, \tau})^k e_{\bar{d}}]^{1/k}$ . A pair of (pure) policies determine a subgraph  $\mathcal{G}^{\sigma, \tau}$ , obtained by keeping only the successor prescribed by  $\sigma$  for every node of  $\mathcal{V}_D$ , and similarly for  $\tau$  and  $\mathcal{V}_T$ . Then, the “freedom” of player People is precisely the geometric growth rate of the number of paths of length  $3k$  starting from node  $\bar{d}$ , counted with multiplicities, as  $k \rightarrow \infty$ . In general, the graph  $\mathcal{G}^{\sigma, \tau}$  may have several strongly connected components, and it is observed in [5] that  $R(\sigma, \tau)$  coincides with the maximal spectral radii of the diagonal blocks of the matrix  $M^{\sigma, \tau}$  corresponding to the strongly connected components to which the initial state  $\bar{d}$  has access in  $\mathcal{G}^{\sigma, \tau}$ . In an entropy game, Despot wishes to minimize the freedom of People, whereas Tribune (a reference to the magistrate of Roman republic) wishes to maximize it. It is shown in [1] that the entropy game has a value in the space of pure policies, meaning that there exists pure policies  $\sigma^*, \tau^*$ , such that  $R(\sigma^*, \tau) \leq R(\sigma^*, \tau^*) \leq R(\sigma, \tau^*)$  for all pure policies  $\sigma, \tau$ . (Actually, more general, history dependent, strategies are considered in [1], and it is shown there that pure policies are optimal).

The dynamic programming operator of an entropy game is the self-map  $F$  of  $\mathbb{R}_{>0}^n$  given by  $F_d(x) = \min_{t \in \mathcal{V}_T, (d, t) \in \mathcal{E}} \max_{p \in \mathcal{V}_P, (t, p) \in \mathcal{E}} \sum_{d' \in \mathcal{V}_D, (p, d') \in \mathcal{E}} m_{p, d'} x_{d'}$ , for  $d \in \mathcal{V}_D$ . Then, the operator  $T := \log \circ F \circ \exp$  is a Shapley operator. It is shown in [1] that the value of the entropy game with initial state  $\bar{d}$  is given by the limit  $\lim_{k \rightarrow \infty} [(F^k(e))_{\bar{d}}]^{1/k}$ .

#### 4 The unichain property

Recall that to every  $n \times n$  nonnegative matrix  $M$  is associated a digraph with set of nodes  $[n]$ , such that there is an arc from  $i$  to  $j$  if  $M_{ij} > 0$ . The matrix is *irreducible* if this digraph is strongly connected. It is *unichain* if this digraph has a unique final strongly connected component (a strongly components is *final* if any path starting from this component stays in this component). The property of unichainedness is sometimes referred to as *ergodicity* since a stochastic matrix is unichain iff it has only one invariant measure, or equivalently, if the only *harmonic vectors* (i.e. the solutions  $v$  of  $Mv = v$ ) are the constant vectors, see the discussion in Theorem 1.1 of [2], and the references therein.

Given a pair  $(\sigma, \tau) \in \Pi_P$  of pure policies, we define the stochastic matrix:  $P^{\sigma, \tau} = (P_{i, j}^{\sigma(i), \tau(i)})_{i, j \in [n]}$ .

► **Definition 7.** We say that a game is unichain (resp. irreducible) if for all pairs of pure policies  $\sigma, \tau$ , the matrix  $P^{\sigma, \tau}$  is unichain (resp. irreducible).

► **Definition 8.** We say that a subset  $S$  of the states is closed under the action of a matrix  $P^{\sigma, \tau}$  if, starting from a state  $s \in S$  and playing according to the policies  $\sigma$  and  $\tau$ , the next state is still in  $S$ .

► **Remark 9.** If  $S$  is a set closed under the action of an unichain matrix  $P^{\sigma, \tau}$ , then  $S$  contains the final class of this matrix.

► **Remark 10.** The final class does not have to be the same for all pairs  $\sigma, \tau$  of policies in our definition of unichain games.

The following theorem addresses the issue of the existence of a solution to the ergodic equation in the case of a unichain game.

► **Theorem 11.** *Let  $T$  be the Shapley operator of a unichain concurrent stochastic game. Then, there exists a vector  $v \in \mathbb{R}^n$  and  $\lambda \in \mathbb{R}$  such that  $T(v) = \lambda e + v$ . Moreover, there exists a pair of optimal (randomized) Markovian stationary strategies, obtained by selecting actions that achieve the minimum and maximum in the expression of  $[T(v)]_i$ , for each state  $i \in [n]$ .*

## 5 Relative value iteration

Relative value iteration was introduced in [38] to solve one player stochastic mean-payoff games (i.e., average cost Markov decision processes). The “vanilla” value iteration algorithm consists in computing the sequence  $x_{k+1} = T(x_k)$ , starting from  $x_0 = 0$ . Then,  $x_k$  yields the value vector of the game in horizon  $k$ , and so, we expect  $x_k$  to go to infinity as  $k \rightarrow \infty$ . The idea of *relative* value is to renormalize the sequence by additive constants. We state in Algorithm 1 a general version of relative value iteration, allowing for *approximate* dynamic programming oracles. This will allow us to obtain complexity results in the Turing model of computation, by computing a rational approximation of the value of the Shapley operator  $T(x)$  at a given rational vector  $x$  up to a given accuracy.

■ **Algorithm 1** Relative value iteration in approximate arithmetics.

- 
- 1: **input:** A final requested numerical precision  $\epsilon > 0$  and a parameter  $0 < \eta \leq \epsilon/3$ . An oracle  $\tilde{T}$  which provides an  $\eta$ -approximation in the sup-norm of a Shapley operator  $T$ .
  - 2:  $x := 0 \in \mathbb{R}^n$
  - 3: **repeat**
  - 4:    $x := \tilde{T}(x) - \mathbf{t}(\tilde{T}(x))e$
  - 5: **until**  $\|x - \tilde{T}(x)\|_H \leq \epsilon/3$
  - 6:  $\alpha := \mathbf{b}(\tilde{T}(x) - x); \beta := \mathbf{t}(\tilde{T}(x) - x)$
  - 7: **return**  $x, \alpha, \beta$    ▷ The lower and upper escape rates of  $T$  are included in the interval  $[\alpha - \epsilon/3, \beta + \epsilon/3]$ , which is of width at most  $\epsilon$
- 

► **Theorem 12.** *Suppose that  $T$  is a Shapley operator. Then,*

1. *When it terminates, Algorithm 1 returns a valid interval of width at most  $\epsilon$  containing the lower and upper escape rates of  $T$ .*
  2. *If there is an integer  $q$  and a scalar  $0 < \gamma < 1$  such that  $T^q$  is a  $\gamma$ -contraction in Hilbert’s seminorm, and if  $\eta$  is chosen small enough, in such a way that  $\eta(12 + 24q/(1 - \gamma)) \leq \epsilon$ , then Algorithm 1 terminates in at most  $q(\log \|T(0)\|_H + \log 6 + |\log \epsilon|/|\log \gamma|)$  iterations.*
- The proof exploits the nonexpansiveness of the operator  $T$  in Hilbert’s seminorm.

## 6 Krasnoselskii–Mann damping

We shall see that for turn-based or concurrent games, it is useful to replace the original Shapley operator by a Krasnoselskii–Mann damped version of this operator. This will allow the relative-value iteration algorithm to converge under milder conditions.

► **Definition 13.** *If  $T$  is a Shapley operator, and  $0 < \theta < 1$ , we define  $T_\theta = \theta I + (1 - \theta)T$  where  $I$  is the identity operator.*

We will call *Krasnoselskii–Mann operator* the  $T_\theta$  operator. It is easy to show that it is also a Shapley operator. The following observation relates the ergodic constant of a damped Shapley operator with the ergodic constant of the original Shapley operator.

## 10:10 Relative Krasnoselskii–Mann Iteration

► **Lemma 14.** *Let  $T$  be a Shapley operator,  $u \in \mathbb{R}^n$  and  $\lambda \in \mathbb{R}$ . Then,  $T(u) = \lambda e + u$  if and only if  $T_\theta(u) = (1 - \theta)\lambda e + u$ . In particular,  $\chi(T) = (1 - \theta)^{-1}\chi(T_\theta)$  holds as soon as the ergodic equation  $T(u) = \lambda e + u$  is solvable.*

**Proof.** The equivalence is straightforward, and  $\chi(T) = (1 - \theta)^{-1}\chi(T_\theta)$  follows from Obs. 4. ◀

We consider the iteration  $x_{k+1} = T_\theta(x_k) - \mathbf{t}(T_\theta(x_k))e$ , obtained by applying relative value iteration (as in Algorithm 1) to the Krasnoselskii–Mann operator  $T_\theta$ , with an arbitrary initial condition  $x_0 \in \mathbb{R}^n$ . Ishikawa showed that the ordinary Krasnoselskii–Mann iteration applied to a nonexpansive self-map of a finite dimensional normed space does converge, as soon as a fixed point exists [24]. This entails the following result.

► **Theorem 15** (Compare with [19]). *Let  $T : \mathbb{R}^n \rightarrow \mathbb{R}^n$  be a Shapley operator, and  $0 < \theta < 1$ . Then, the sequence  $x_k$  obtained by applying relative value iteration to the Krasnoselskii–Mann operator  $T_\theta$  converges if and only if  $\exists u \in \mathbb{R}^n, \lambda \in \mathbb{R}, T(u) = \lambda e + u$ .*

A multiplicative variant of this result was proved in Theorem 11 of [19].

## 7 Contraction properties of unchain games under pure policies

We define the following parameter, representing the minimal value of a non-zero off-diagonal transition probability,  $p_{\min} = \min_{i,j \in [n], i \neq j, (a,b) \in A \times B} \{P_{i,j}^{a,b} : P_{i,j}^{a,b} > 0\}$ , and set  $\theta := p_{\min}/(1 + p_{\min})$ . For every pair of policies  $\sigma, \tau$  of the two players, we set  $Q^{\sigma,\tau} := \theta I + (1 - \theta)P^{\sigma,\tau}$ . For any sequence of pairs of pure policies  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$ , we define, for all  $i \in [n]$ ,  $S_i(\sigma_1, \tau_1, \dots, \sigma_k, \tau_k) := \{j \mid [Q^{\sigma_1, \tau_1} \dots Q^{\sigma_k, \tau_k}]_{ij} > 0\}$ .

► **Lemma 16.** *Suppose a concurrent game is unichain. Then, there is an integer  $k \leq n$  such that for all  $i_1, i_2 \in [n]$ , and for all sequences of pairs of pure policies  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$ ,  $S_{i_1}(\sigma_1, \tau_1, \dots, \sigma_k, \tau_k) \cap S_{i_2}(\sigma_1, \tau_1, \dots, \sigma_k, \tau_k) \neq \emptyset$ .*

We call the *unchain index* of the game, and denote by  $k_{\text{uni}}$  the smallest integer  $k$  satisfying the property of Lemma 16. Similarly, we call *irreducibility index* of an irreducible game, and denote by  $k_{\text{irr}}$ , the smallest integer  $k$  such that for every sequence of pure policies  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$ , the matrix  $Q^{\sigma_1, \tau_1} \dots Q^{\sigma_k, \tau_k}$  is positive. We have  $1 \leq k_{\text{uni}} \leq k_{\text{irr}}$ .

The following result will allow us to obtain a geometric contraction rate. The proofs of this theorem and of the next proposition show in particular that  $k_{\text{uni}} \leq n$  if the game is unichain and  $k_{\text{irr}} \leq n$  if the game is irreducible.

► **Theorem 17.** *Let us suppose that a concurrent game with  $n$  states is unichain, with unichain index  $k = k_{\text{uni}}$ . Then, for all sequences  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$  of pairs of pure policies of the two players,  $\|Q^{\sigma_1, \tau_1} \dots Q^{\sigma_k, \tau_k}\|_{\text{H}} \leq 1 - \theta^k$ .*

The following proposition improves the bound on the contraction rate provided by Theorem 17, in the special case of irreducible games.

► **Proposition 18.** *Let us suppose that a concurrent game with  $n$  states is irreducible, and let  $k = k_{\text{irr}}$  be the irreducibility index of the game. Then, for all sequences  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$  of pairs of pure policies of the two players,  $\|Q^{\sigma_1, \tau_1} \dots Q^{\sigma_k, \tau_k}\|_{\text{H}} \leq 1 - n\theta^k$ .*

## 8 Solving concurrent and turn-based games by relative Krasnoselskii–Mann iteration

We first establish a general bound for concurrent unichain games. Recall that  $\theta = p_{\min}/(1 + p_{\min})$ .

► **Theorem 19.** *Let  $T_\theta$  be the Krasnoselskii–Mann operator of a concurrent and unichain game. Then,  $T_\theta^{k_{\text{uni}}}$  is a contraction in Hilbert’s seminorm, with rate bounded by  $1 - \theta^{k_{\text{uni}}}$ . Moreover, if the game is irreducible,  $T_\theta^{k_{\text{irr}}}$  is a contraction in Hilbert’s seminorm, with rate bounded by  $1 - n\theta^{k_{\text{irr}}}$ .*

Combining this result with Theorem 12, we obtain the following result, in which we denote by  $\|r\|_\infty := \max_{i,a,b} |r_i^{ab}|$  the sup-norm of the payment function.

► **Corollary 20.** *Let  $T$  be the Shapley operator of a concurrent unichain game, and  $\epsilon \in (0, 1)$ . Algorithm 1, applied to the Krasnoselskii–Mann operator  $T_\theta$ , with the precision  $\eta$  prescribed in Theorem 12, provides an  $\epsilon$ -approximation of the value of the game in at most  $(|\log(\epsilon)| + \log 24 + \log \|r\|_\infty)k_{\text{uni}}\theta^{-k_{\text{uni}}}$  iterations.*

We now consider the special case of turn-based games. Then, the value is a rational number, and there are optimal pure policies. We now apply our approach to compute exactly the value and to find optimal pure policies.

► **Assumption 21.** *We now assume that the probabilities  $P_{i,j}^{a,b}$  are rational numbers with a common denominator denoted by  $M$ . We also assume that the payments  $r_i^{a,b}$  are integers.*

► **Lemma 22** (Coro. of [35]). *Let  $P$  be a  $n \times n$  unichain matrix whose entries are rational numbers with a common denominator  $M$ . Then, the entries of the unique invariant measure of  $P$  are rational numbers of denominator at most  $nM^{n-1}$ .*

When Algorithm 1 halts, returning a vector  $x \in \mathbb{R}^n$ , we select two pure policies  $\sigma^*$  and  $\tau^*$  that reach the minimum and maximum in the expression of  $T(x)$ , meaning that, for  $i \in [n]$ , we have:

$$T_i(x) = \max_{b \in B(i)} \left( r_i^{\sigma^*(i),b} + \sum_{j \in [n]} P_{ij}^{\sigma^*(i),b} x_j \right) = \min_{a \in A(i)} \left( r_i^{a,\tau^*(i)} + \sum_{j \in [n]} P_{ij}^{a,\tau^*(i)} x_j \right). \quad (4)$$

► **Theorem 23.** *Consider a unichain turn-based stochastic game satisfying Assumption 21. Let us choose  $\epsilon = (1 - \theta)(n^2 M^{2(n-1)})^{-1}$ , so that Algorithm 1 applied to  $T_\theta$  runs in at most*

$$(2 \log n + 2(n - 1) \log M + \log 24 + \log \|r\|_\infty) \theta^{-k_{\text{uni}}} k_{\text{uni}} \quad (5)$$

*iterations. Let  $x^*$  be the vector returned by the algorithm. Let us select pure policies  $\sigma^*$  and  $\tau^*$  reaching respectively the minimum and maximum in the expression of  $T(x^*)$ , as in (4). Then, these policies are optimal.*

## 9 Multiplicative Krasnoselskii–Mann Damping applied to Entropy Games

In the case of entropy games, the ergodic eigenproblem, for the operator  $F$  defined in Section 3.2, consists in finding  $u \in \mathbb{R}^n$  and  $\lambda \in \mathbb{R}$  such that  $\exp(\lambda) \exp(u) = F(u)$ . Equivalently,  $\lambda e + u = T(u)$  where  $T = \log \circ F \circ \exp$ . If this equation is solvable, then  $\exp(\lambda)$  is the value of the entropy game, for all initial states  $d \in \mathcal{V}_D$ . To solve this equation, we fix a positive number  $\vartheta > 0$ , and consider the following “multiplicative” variant of the Krasnoselskii–Mann operator:

## 10:12 Relative Krasnoselskii–Mann Iteration

$$[T_{m,\vartheta}(v)]_d = \log \min_{t \in \mathcal{V}_T, (d,t) \in \mathcal{E}} \max_{p \in \mathcal{V}_P, (t,p) \in \mathcal{E}} (\vartheta \exp(v_d) + \sum_{d' \in \mathcal{V}_D, (p,d') \in \mathcal{E}} m_{p,d'} \exp(v_{d'})) ,$$

recalling that  $m_{p,d'}$  denotes the multiplicity of the arc  $(p, d')$ . Unlike in the additive case, we do not perform a “convex combination” of the identity map and of the Shapley operator, but we only add the “diagonal term”  $\vartheta \exp(v_d)$ , where  $\vartheta$  can still be interpreted as a “damping intensity”, albeit in a multiplicative sense. If  $T(u) = \lambda e + u$ , then, one readily checks that  $T_{m,\vartheta}(u) = \mu e + u$ , where  $\mu = \log(\vartheta + \exp(\lambda))$ , and vice versa, so the non-linear eigenproblems for  $T$  and  $T_{m,\vartheta}$  are equivalent. As in the additive case, the damping intensity must be tuned to optimize the complexity bounds. We shall say that the multiplicity  $m_{p,d'}$  is *off-diagonal* if there is no path  $d' \rightarrow t \rightarrow p \rightarrow d'$  in the graph of the game. Equivalently, for any choices of policies  $\sigma, \tau$  of the two players, the entry  $m_{p,d'}$  does not appear on the diagonal of the matrix  $M^{\sigma,\tau}$ , defined in Section 3.2. Then, we denote by  $\underline{m}$  the minimum of off-diagonal multiplicities, observe that  $\underline{m}$  is precisely the minimum of all off-diagonal entries of the matrices  $M^{\sigma,\tau}$  associated to all pairs of policies. We set  $\vartheta := \underline{m}$ .

We shall say that an entropy game is *irreducible* if for every pair of policies  $\sigma, \tau$ , the matrix  $M^{\sigma,\tau}$  is irreducible. The *irreducibility index*  $k_{\text{irr}}$  of an irreducible entropy game is the smallest integer  $k$  such that for all policies  $\sigma_1, \tau_1, \dots, \sigma_k, \tau_k$ , the matrix  $M^{\sigma_1\tau_1} \dots M^{\sigma_k\tau_k}$  has positive entries. Arguing as in the case of stochastic concurrent games, we get that  $k_{\text{irr}} \leq n$  as soon as the game is irreducible. We define the *l-ambiguity* of the entropy game  $\mathcal{A}_l := \max_{d,d' \in \mathcal{V}_D} \max_{\sigma_1, \tau_1, \dots, \sigma_l, \tau_l} (M^{\sigma_1\tau_1} \dots M^{\sigma_l\tau_l})_{d,d'}$ . Observe that  $(M^{\sigma_1\tau_1} \dots M^{\sigma_l\tau_l})_{d,d'}$  is the number of paths from  $d$  to  $d'$  counted with multiplicities, in the finite horizon game induced by the policies  $\sigma_1, \tau_1, \dots, \sigma_l, \tau_l$  (this motivates the term “l-ambiguity”). If the game is irreducible, we define the *ambiguity* of the game  $\mathcal{A} := \max_{1 \leq l \leq k_{\text{irr}}} \mathcal{A}_l^{1/l}$ . We set  $W := \max_{(p,d) \in \mathcal{E} \cap (\mathcal{V}_P \times \mathcal{V}_D)} m_{p,d}$ , and observe that  $W \leq \mathcal{A} \leq n^{1-1/k_{\text{irr}}} W$ .

► **Theorem 24.** *Let  $T_{m,\vartheta}$  be the multiplicative Krasnoselskii–Mann operator of an irreducible entropy game. Then,  $T_{m,\vartheta}^{k_{\text{irr}}}$  is a contraction in Hilbert’s seminorm, with contraction rate bounded by  $\frac{\bar{\mathcal{M}}-1}{\bar{\mathcal{M}}+1}$ , where  $\bar{\mathcal{M}} := (1 + \mathcal{A}/\underline{m})^{k_{\text{irr}}}$ .*

We recall the following separation bound.

► **Theorem 25** (Coro. of [5]). *Suppose two pairs of (pure) policies yield distinct values in an entropy game with  $n$  Despot’s states. Then, these values differ at least by  $\nu_n^{-1}$  where*

$$\nu_n := 2^n (n+1)^{8n} n^{2n^2+n+1} e^{4n^2} \max(1, W/2)^{4n^2} .$$

Then, using Theorem 12, we deduce:

► **Theorem 26.** *Consider an irreducible entropy game, with irreducibility index  $k_{\text{irr}}$ . Let us choose  $\epsilon = (1 + (\underline{m} + W)\nu_n)^{-1}$ , so that Algorithm 1 applied to  $T_{m,\vartheta}$  runs in at most  $(\log(1 + (\underline{m} + W)\nu_n) + \log 6)k_{\text{irr}}\bar{\mathcal{M}}/2$  iterations. Moreover, let  $x^*$  be the vector returned by the algorithm. Let us select pure policies  $\sigma^*$  and  $\tau^*$  reaching respectively the minimum and maximum in the expression of  $T_{m,\vartheta}(x^*)$ . Then, these policies are optimal.*

## 10 Concluding Remarks

We have established parameterized complexity bounds for relative value iteration applied to several classes of stochastic games satisfying irreducibility conditions. These bounds rely on contraction properties in Hilbert’s seminorm. It would be interesting to see whether these contraction properties can also be exploited to derive complexity bounds for policy iteration, instead of value iteration.

## **A** Example of turn-based stochastic mean-payoff game

A turn-based stochastic mean-payoff game is represented below. Min states are represented by squares; Max states are represented by circles; Nature states are represented by small diamonds. The payments made by Min to Max are shown on the arcs. For every Nature state, the next state is chosen with the uniform distribution among the successors. The associated Shapley operator is the map  $T : \mathbb{R}^3 \rightarrow \mathbb{R}^3$  shown at right.

$$T_1(x) = 1 + \max\left(2 + \frac{x_2 + x_3}{2}, -3 + \frac{x_1 + x_3}{2}\right)$$

$$T_2(x) = \min\left(5 + \max\left(2 + \frac{x_2 + x_3}{2}, -3 + \frac{x_1 + x_3}{2}\right), 1 + 3 + \frac{x_1 + x_2}{2}\right)$$

$$T_3(x) = 4 + \max\left(\frac{x_2 + x_3}{2}, \frac{x_1 + x_2 + x_3}{3}\right)$$

The unichain index defined in Section 7 is  $k_{\text{uni}} = 1$ . Indeed, for all pairs of policies  $(\sigma_1, \tau_1)$ , we have  $S_1(\sigma_1, \tau_1) \supset \{1, 3\}$ ,  $S_3(\sigma_1, \tau_1) \supset \{2, 3\}$ , and  $S_2(\sigma_1, \tau_1) \supset \{2, 3\}$  if  $\sigma_1$  sends Min state 2 to Max state 3, and  $S_2(\sigma_1, \tau_1) = \{1, 2\}$  if  $\sigma_1$  sends Min state 2 to Max state 1. In all cases, we have  $S_i(\sigma_1, \tau_1) \cap S_j(\sigma_1, \tau_1) \neq \emptyset$  for  $i \neq j$ . We have  $p_{\min} = 1/3$ , and  $\theta = p_{\min}/(1 + p_{\min}) = 1/4$ . It follows from Theorem 19 that the damped Shapley operator  $T_\theta$  is a contraction of rate  $3/4$ . We know from Theorem 11 that the ergodic eigenproblem is solvable. By applying Algorithm 1, we find  $T(u) = \lambda e + u$  with  $(-1, -0.5, 0)$  and  $\lambda = 3.75$ . An approximation of  $u$  of precision  $< 10^{-8}$  in the sup norm is reached after only 15 iterations, to be compared with the precision of order  $(3/4)^{15} \simeq 10^{-2}$  given by the theoretical upper bound, for the same number of iterations. Thus, the convergence may be faster in practice than the one shown in Corollary 20. We deduce from  $T(u) = \lambda e + u$  that the value of the mean-payoff game is 3.75 regardless of the initial state. Optimal policies  $\sigma$  and  $\tau$  of both players are obtained by selecting the actions that achieve the minimum or the maximum in the expression of  $T(u)$ . The non-trivial actions of these optimal policies are as follows: from Min state 2 (square at bottom right), go to Max state 3 (circle at the top level), from Max state 2 (circle at the middle level), and also from Max state 3, got to the top right state (diamond) of Nature. These policies are shown on the figure above (red: policy of Min; blue: policy of Max). The stochastic matrix  $P^{\sigma, \tau}$  and payment vector  $r^{\sigma, \tau}$  associated to these policies are given by

$$r^{\sigma, \tau} = \begin{pmatrix} 3 \\ 4 \\ 4 \end{pmatrix}, \quad P^{\sigma, \tau} = \begin{pmatrix} 0 & 1/2 & 1/2 \\ 1/2 & 1/2 & 0 \\ 0 & 1/2 & 1/2 \end{pmatrix}.$$

The unique invariant measure of the matrix  $P^{\sigma, \tau}$  is  $\pi = (1/4, 1/2, 1/4)$ , and we have  $\pi r^{\sigma, \tau} = 15/4 = 3.75$ , consistently with the value of the mean-payoff already found.

## Abstract

We study the geometry of reachability sets of continuous vector addition systems with states (VASS). In particular we establish that they are “almost” Minkowski sums of convex cones and zonotopes generated by the vectors labelling the transitions of the VASS. We use the latter to prove that short so-called linear path schemes suffice as witnesses of reachability in continuous VASS. Then, we give new polynomial-time algorithms for the reachability problem for linear path schemes. Finally, we also establish that enriching the model with zero tests makes the reachability problem intractable already for linear path schemes of dimension two.

## 1 Introduction

Vector Addition Systems with States (VASS, for short) are rich mathematical models for the description of distributed systems, as well as chemical and biological processes, and more [19]. A VASS essentially consists of a finite-state machine whose transitions are labelled with integer vectors. Besides the current state, a configuration of the VASS also comprises the current values of a set of counters. When a transition is taken, the state of the machine changes and the values of the counters are updated by adding to them the vector that labels the transition. VASS arise naturally as an arguably-cleaner model than Petri nets, due to their reachability problem being polytime-interreducible with that of Petri nets.

While VASS are a very expressive model of concurrency that admits algorithmic analysis, the complexity of several associated decision problems is prohibitively high. For instance, the *reachability problem*, which asks “is a given target configuration reachable from a given initial configuration?”, was recently proved to be Ackermann-complete [6, 15, 14].

*Continuous VASS* were introduced by Blondin and Haase [2] as an alternative to *continuous Petri nets* [7] which trade off the ability to encode discrete information in favor of computational and practical benefits. Their only difference compared to VASS concerns how the counters are updated: In continuous VASS, when a transition is taken, the machine is

■ **Figure 1** From  $q_0$ , with initial counter values  $\mathbf{0}$ , the state  $q_2$  can be reached with counter values  $\{(3i + a, 6i + b) \mid (a, b) \in \{(0, 0), (1, 1)\}, i \in \mathbb{N}\}$ ; with continuous semantics, it can be reached with counter values  $\mathbf{x} + \mathbf{y}$  where  $\mathbf{x} \in \{(0, 0)\} \cup \{(a, b) \mid 0 < a, b \leq 1\}$  and  $\mathbf{y}$  lies on the ray  $\{(i, 2i) \mid i \in \mathbb{N}\}$ .

allowed to scale the update vector by some scalar  $0 < \alpha \leq 1$  before adding it to the current counter values (see Figure 1). In contrast to the situation with “discrete” VASS, the computational complexity of the reachability problem for continuous VASS is relatively low. Namely, in [2] the reachability problem for continuous VASS is shown to be **NP**-complete while the complexity of the same problem for discrete VASS is Ackermann-complete [6, 15, 14].

Despite the relatively low computational complexity, **NP** is not universally considered as tractable. The only subcase previously known to be in **P** was that of cyclic reachability when counters are allowed to hold negative values. It is also worth noting that the aforementioned **NP** upper bound is obtained by encoding the reachability problem into the existential fragment of the first-order theory of the reals with addition and order. It is natural to ask whether more efficient algorithms or encodings into “simpler” logics exist, e.g. linear programming, even if only for particular subcases.

**Fixed-dimension VASS.** The relatively new Ackermann lower bound for VASS reachability has renewed interest in what could be named the *Bordeaux-Warsaw program*: the study of the computational complexity of the reachability problem for low-dimensional VASS and extensions thereof (see, e.g., [4, 3, 5, 8]). In such cases, there may be efficient algorithms for the problem and, to quote Czerwiński and Orlikowski [6], “it is easier to [design] sophisticated techniques working in a simpler setting [that might] result in finding new techniques useful in much broader generality.” For dimensions 1 and 2 (and counter updates encoded in binary) the problem is **NP**-complete [12] and **PSPACE**-complete [1], respectively.

An important structural restriction on VASS which is often used as an intermediate step in establishing upper bounds is that of *flatness*, i.e. disallowing nested cycles. In fact, the upper bounds for dimensions 1 and 2 mentioned above can be seen as a consequence of such VASS being effectively flattable [16]. A further restriction consists of asking that the set of all runs of the VASS can be represented by a single regular expression  $\pi_0 \chi_1^+ \dots \pi_{n-1} \chi_n^+ \pi_n$  over the transitions. Such VASS are called *linear path schemes* (LPS, for short). Linear path schemes played an essential role in [1], where it is shown that for any path that witnesses reachability, there exists a linear path scheme that also witnesses reachability.

**VASS variants.** In this work we study continuous VASS. For complexity matters, we assume all counter updates are encoded in binary. As decision problems, we focus on reachability (via a path that might make the counters negative); nonnegative reachability, i.e. reachability via a path that keeps the counters nonnegative at all times; and zero-test reachability, corresponding to reachability with the added constraint that some states can only be visited with value zero for a designated counter. We summarize known and new results in Table 1. Below, we give a textual account of the complexity bounds from the table.

**(Discrete) Reachability.** The **NP**-hardness bound for LPS can be shown using a simple reduction from the SUBSETSUM problem with multiplicities, i.e. summands can be added more than once. The latter is known to be **NP**-complete, see e.g. [9, Proposition 4.1.1]. The upper bound for the general case is folklore and is proven in [11] even with *resets*.

**Continuous reachability.** The **NP**-hardness bound for flat VASS is stated in [2, Lemma 4.13(a)] for nonnegative reachability but the reduction establishes it for reachability as well. The upper bound for the general case follows from [2, Corollary 4.10]. Membership in **P** for LPS can be derived from [2, Theorem 4.15] which states that continuous cyclic reachability is in **P**. In this work, we give an alternative algorithm for continuous cyclic reachability and present a full decision procedure for continuous reachability for LPS.

**Nonnegative reachability.** For fixed dimension  $d$ , only an  $F_{d+O(1)}$  upper bound is known [15]. **NP**-hardness for LPS follows from the same proof as for reachability since the construction has no negative updates. Finally, the **NP** upper bound for flat VASS is folklore: (nonnegative) reachability in flat VASS can be encoded into existential Presburger Arithmetic (PA), a theory whose decidability is **NP**-complete (see, e.g., [10]).

**Continuous nonnegative reachability.** The **NP** upper and lower bounds for the general and flat cases follow from (the proofs of) the same results in the continuous reachability case. For the **P** upper bound, however, one cannot rely on [2, Theorem 4.15]. In fact, cyclic reachability (for general dimensions) is **NP**-hard in the continuous nonnegative case [2, Lemma 4.13(b)]. This is, thus, the first novel complexity bound we establish.

**Zero-test reachability.** The **NP**-hardness bound for LPS is a consequence of reachability being a subcase of zero-test reachability. The matching upper bound for flat VASS is an extension of the classical encoding into PA which accounts for linear constraints imposed by the zero tests on cycles. Finally, the general model is also known as Minsky machines and its reachability problem was proven undecidable by Minsky himself [17].

**Continuous zero-test reachability.** The **NP**-hardness for flat VASS is a consequence of reachability being a subcase of zero-test reachability. For LPS, the lower bound is novel and points to continuous zero-test reachability not being a suitable approximation of the discrete case. The general case is undecidable in dimension 4 or higher [2, Theorem 4.17].

**Our contributions.** Our main contribution is a geometrical understanding of the reachability sets of continuous VASS (see Theorem 1, Theorem 5, and Theorem 7). The latter allows us (1) to prove that short LPS suffice as witnesses of (nonnegative) reachability (see Theorem 11 and Theorem 18), and (2) to give new algorithms for the reachability problem for LPS (see Theorem 13 and Theorem 19) via encodings of their reachability sets into tractable theories. Namely, we stay within linear programming solutions to enable efficient implementation of our algorithms. Finally, we establish that zero-test reachability for LPS is **NP**-hard even in dimension 2 (Theorem 21).

■ **Table 1** Summary of computational complexity results for the reachability problem for VASS of fixed dimension. We write lower bounds for simpler cases and upper bounds for more general ones. New results are shown in green (upper) and red (lower bounds).

## 2 Preliminaries

In this work,  $\mathbb{Q}_{>0}$  denotes the set of all strictly positive rational numbers; and  $\mathbb{Q}_{\geq 0}$ , all nonnegative ones – including 0. Similarly,  $\mathbb{N}$ , i.e. the set of all natural numbers, includes 0, however  $\mathbb{N}_{>0}$  does not.

Let  $d$  be a positive integer. For any  $\mathbf{x} \in \mathbb{Q}^d$ , and  $r \in \mathbb{R}$ , we define the *open ball of radius  $r$  around  $\mathbf{x}$*  as usual:  $B_r(\mathbf{x}) = \{\mathbf{y} \in \mathbb{Q}^d : \|\mathbf{x} - \mathbf{y}\|_2 < r\}$ . Let  $X \subseteq \mathbb{Q}^d$ . Then, the *interior* of  $X$  is  $\text{int}(X) = \{\mathbf{x} \in X \mid \exists \varepsilon > 0, B_\varepsilon(\mathbf{x}) \subseteq X\}$ ; the *closure* of  $X$  is  $\text{cl}(X) = \{\mathbf{x} \in \mathbb{Q}^d \mid \forall \varepsilon > 0, B_\varepsilon(\mathbf{x}) \cap X \neq \emptyset\}$ ; and the *boundary* of  $X$  is  $\text{bd}(X) = \text{cl}(X) \setminus \text{int}(X)$ . Finally, we define the *relative interior* of  $X$ ,  $\text{relint}(X)$ , as its interior with respect to its embedding into its own affine hull as follows:  $\text{relint}(X) = \{\mathbf{x} \in X \mid \exists \varepsilon > 0, B_\varepsilon(\mathbf{x}) \cap \text{aff}(X) \subseteq X\}$ .

Let  $G \subseteq \mathbb{Q}^d$  be a set of (generating) vectors. We write  $\text{cone}(G)$  to denote the (*rational convex*) *cone*  $\{\sum_{i=0}^k a_i \mathbf{g}_i \mid k \in \mathbb{N}, \mathbf{g}_i \in G, a_i \in \mathbb{Q}_{\geq 0}\}$ . The (*linear*) *span* of  $G$  is defined as follows:  $\text{span}(G) = \{\sum_{i=0}^k a_i \mathbf{g}_i \mid k \in \mathbb{N}, \mathbf{g}_i \in G, a_i \in \mathbb{Q}\}$ . Finally, the *affine hull*  $\text{aff}(G)$  of  $G$  is the set  $\{\sum_{i=0}^k a_i \mathbf{g}_i \mid k \in \mathbb{N}, \mathbf{g}_i \in G, a_i \in \mathbb{Q}, \sum_{i=0}^k a_i = 1\}$ . (In particular, note that if  $\mathbf{0} \in G$  then  $\text{aff}(G) = \text{span}(G) = \text{span}(H)$ , for some  $H \subseteq G$  with cardinality at most  $d$ .)

### 2.1 Continuous VASS

Let  $d$  be a positive integer. A *continuous VASS*  $\mathcal{V}$  of dimension  $d$  is a tuple  $(Q, T, \ell)$  where  $Q$  is a finite set of states,  $T \subseteq Q \times Q$  is a finite set of transitions, and  $\ell : T \rightarrow \mathbb{Q}^d$  assigns an *update label* to every transition.

**Paths and runs.** A *configuration*  $c \in Q \times \mathbb{Q}^d$  is a tuple consisting of a state and the concrete values of the  $d$  *counters* of the VASS. We denote the configuration  $(p, \mathbf{x})$  by  $p(\mathbf{x})$ .

A *path*  $\pi$  is a sequence  $(p_1, p_2)(p_2, p_3) \dots (p_{n-1}, p_n) \in T^*$  of transitions. We write  $|\pi|$  to denote the length of the path, i.e.  $|\pi| = n - 1$ . A *run*  $\rho$  is a sequence  $q_1(\mathbf{x}_1)q_2(\mathbf{x}_2) \dots q_n(\mathbf{x}_n)$  of configurations such that for all  $1 \leq i < n$  we have:  $(q_i, q_{i+1}) \in T$  and  $\mathbf{x}_i + \alpha_i \cdot \ell(q_i, q_{i+1}) = \mathbf{x}_{i+1}$  for some  $\alpha_i \in \mathbb{Q}$  with  $0 < \alpha_i \leq 1$ . Often, we refer to the  $\alpha_i$  as the *coefficients of the run*. We say  $\rho$  *induces* the path  $(q_1, q_2) \dots (q_{n-1}, q_n)$ . Conversely, we sometimes say a run is *lifted* from a path. For instance,  $\pi$  can be lifted to a run  $p_1(\mathbf{y}_1) \dots p_n(\mathbf{y}_n)$  by fixing  $p_1(\mathbf{y}_1)$  as initial configuration and by choosing adequate coefficients  $\alpha_i$  for all transitions.

As a more concrete example, consider the path  $(q_0, q_1), (q_1, q_2), (q_2, q_3)$  in Figure 1, whose transitions are labelled by  $(1, 0)$  and  $(0, 1)$ . Starting from the configuration  $(0, 0)$  and using the coefficients  $\alpha_1 = 0.3$  and  $\alpha_2 = 0.5$  this path lifts to the run  $q_0(0, 0)q_1(0.3, 0)q_2(0.3, 0.5)$ .

We consider continuous VASS in a setting where only nonnegative counter values are allowed, denoted  $\mathbb{Q}_{\geq 0}$ VASS; and one which allows negative counters, denoted  $\mathbb{Q}$ VASS.

**Reachability.** Let  $p(\mathbf{x})$  and  $q(\mathbf{y})$  be two configurations. We say  $q(\mathbf{y})$  is *reachable* from  $p(\mathbf{x})$ , denoted  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$ , if there exists a run whose first and last configurations are  $p(\mathbf{x})$  and  $q(\mathbf{y})$  respectively. For a path  $\pi$ , we write  $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$  if, additionally, such a run exists which can be lifted from  $\pi$ . Given a configuration  $p_1(\mathbf{x})$  and a state  $q$ , we define the *reachability set* of a path  $\pi = (p_1, p_2) \dots (p_{n-1}, p_n)$  or a set  $P$  of paths below.

$$\text{Reach}^{\mathbf{x}}(\pi) = \{\mathbf{y} \in \mathbb{Q}^d \mid p_1(\mathbf{x}) \xrightarrow{\pi} p_n(\mathbf{y})\} \quad \text{Reach}^{\mathbf{x}}(P) = \bigcup_{\pi \in P} \text{Reach}^{\mathbf{x}}(\pi)$$

If  $\mathbf{x} = \mathbf{0}$  then we write simply  $\text{Reach}(\pi)$  and  $\text{Reach}(P)$ .

### 3 The Geometry of $\mathbb{Q}$ VASS Reachability Sets

In this section we discuss the geometry of the reachability sets in continuous VASS of dimension  $d$ . We first discuss paths and cycles separately. Then, we show that for solving the reachability problem, we only need to take short *linear path schemes* into consideration.

#### 3.1 The geometry of reachability sets for cycles

For this section, we fix a cycle  $\chi = (p_1, p_2) \dots (p_m, p_{m+1})$ , with  $p_1 = p_{m+1}$ . We study the geometry of the set  $\text{Reach}(\chi^+)$ , where  $\chi^+$  stands for  $\{\chi^k \mid k \in \mathbb{N}_{>0}\}$ .

Intuitively, following  $\chi$  allows us to add a scaled version of each transition vector along  $\chi$  arbitrarily many times, with the proviso that the scaling is strictly positive (the restriction to scale up to 1 disappears since we can repeatedly take the cycle). Thus, we can intuitively reach the interior of a cone, i.e. a positive linear combination of the vectors along  $\chi$ . For example, a cycle with vectors  $(1, 0)$  and  $(0, 1)$  will allow us to reach  $\{(x, y) \mid x > 0, y > 0\}$ . However, this intuition needs to be formalized carefully to account for linear dependencies between the vectors. This may render the cone not full-dimensional, i.e. its linear span may be a strict subspace of the vector space it is in. That would mean that the interior of the cone is empty. However, in such cases, the reachability set still is a “flattened” version of the interior, namely the relative interior of the cone.

##### 3.1.1 From cycles to cones

We formalize our intuition by proving that  $\text{Reach}(\chi^+)$  is the relative interior of the cone generated by  $G(\chi) = \{\ell(p_i, p_{i+1}) \mid 1 \leq i \leq m\}$ .

Indeed, all points  $\mathbf{x} \in \text{Reach}(\chi^+)$  can be obtained as positive linear combinations of generators. To any such  $\mathbf{x}$ , we can add or subtract any generating vector and stay within  $\text{cone}(G(\chi))$ , as long as it is sufficiently scaled down. Conversely, if one can add and subtract suitably scaled versions of all generating vectors to a point  $\mathbf{x} \in \text{cone}(G(\chi))$ , and remain within  $\text{cone}(G(\chi))$ , then it must be in the (relative) interior of  $\text{cone}(G(\chi))$ .

► **Theorem 1.** *Let  $G(\chi)$  be as defined above. Then,  $\text{Reach}(\chi^+) = \text{relint}(\text{cone}(G(\chi)))$ .*

Note that we consider the set  $G(\chi)$  of all labels of transitions from  $\chi$ , ignoring the fact that multiple transitions can have the same label. This is justified by the following lemma for the cycle  $\chi$  with generator  $G(\chi)$ .

► **Lemma 2.** *We have that  $\text{relint}(\text{cone}(\{\lambda_1 \ell(p_i, p_{i+1}) \mid 1 \leq i \leq m, \lambda_i \in \mathbb{Q}_{>0}\}))$  is equal to  $\{\sum_{i=1}^m a_i \mathbf{g}_i \mid a_i \in \mathbb{Q}_{>0}\}$ .*

**A concrete case: dimension 2.** For intuition, we state a consequence of Theorem 1 in dimension 2. For  $d = 2$ , a cone  $C$  is *trivial* if there exists  $\mathbf{v} \in \mathbb{Q}^d$  such that  $C$  is a subset of the line  $\{r \cdot \mathbf{v} \mid r \in \mathbb{Q}\}$ , and otherwise it is full-dimensional. For a trivial cone, its relative interior is either the entire cone (if the cone is the entire line), or the cone without  $\mathbf{0}$ , if the cone is a ray. It is easy to see that for a cycle  $\chi$  whose vector labellings  $G(\chi)$  are co-linear to  $\mathbf{v}$ , the reachability set of  $\chi^+$  in the continuous semantics is  $\text{cone}(G(\chi))$ , excluding any end-points (since the only possible end-point is  $\mathbf{0}$  if  $\text{cone}(G(\chi))$  is a ray). For full-dimensional cones, we can take any positive combination of the generators, but since no element of the generators can be taken zero times, the reachability set excludes the boundary. See Figure 2 (left) for a visualization. In the following statement we write  $\text{int}(G(\chi))$  and  $\text{bd}(G(\chi))$  for  $\text{int}(\text{cone}(G(\chi)))$  and  $\text{bd}(\text{cone}(G(\chi)))$  respectively.

■ **Figure 2** On the left: a cone with its boundary in blue; on the right: a zonotope with  $G = \{(1.5, 1), (1.5, -1), (0, 2)\}$ , where  $\text{adj}(G)$  is drawn in blue.

- **Corollary 3.** *Let  $G(\chi)$  be as above. In dimension  $d = 2$ , one of the following holds.*
- *Either  $\text{cone}(G(\chi))$  is trivial and  $\text{Reach}(\chi^+)$  is  $\text{cone}(G(\chi))$ , excluding any end-points;*
  - *or  $\text{cone}(G(\chi))$  is nontrivial and  $\text{Reach}(\chi^+) = \text{int}(G(\chi))$ .*

### 3.2 The geometry of reachability sets for paths

For this section, we fix a path  $\pi = (p_1, p_2) \dots (p_m, p_{m+1})$ . Similarly to the case of cycles, we establish a connection between  $\text{Reach}(\pi)$  and a type of polytope known as a zonotope.

Intuitively, since we now have a path that is taken once (rather than a cycle), the restriction that the scaling is at most 1 comes into play, and limits us. Moreover, multiplicities of linearly dependent vectors along the path also matter.

**Zonotopes.** Let  $G = \{\mathbf{g}_1, \dots, \mathbf{g}_k\} \subseteq \mathbb{Q}^d$  be a finite set of (generating) vectors. We write  $\text{zono}(G)$  to denote the *zonotope*<sup>1</sup>  $\{\sum_{j=1}^k a_j \mathbf{g}_j \mid a_j \in \mathbb{Q}, 0 \leq a_j \leq 1\}$ .

Following our interior-based approach for cycles, we study the reachable part of the boundary of a zonotope. We define  $s_G$  as the sum of all vectors in  $G$ , or  $s_G = \sum_{\mathbf{g} \in G} \mathbf{g}$ . Additionally, we define the set  $\text{adj}(G)$  of *faces* of  $\text{zono}(G)$  that are *adjacent to  $s_G$*  below. A face of  $\text{zono}(G)$  is any nonempty intersection of  $\text{zono}(G)$  with a half-space  $H$  such that none of the interior points of  $\text{zono}(G)$  lies on the boundary of  $H$ .

► **Definition 4 (Adjacent Sets).** *We define  $\text{adj}(G)$  as the union of  $\{s_G\}$  and all  $\mathbf{x} \in \mathbb{Q}^d$  on the relative interior of a face of  $\text{zono}(G)$  that contains  $s_G$ . (See Figure 2 for intuition.)*

Observe that  $\text{adj}(G) = \emptyset$  whenever  $s_G \in \text{int}(\text{zono}(G))$ .

#### 3.2.1 From paths to zonotopes

We show  $\text{Reach}(\pi)$  has a close relation with a zonotope whose generator is derived from the *multiset*  $M = [\ell(p_i, p_{i+1}) \mid 1 \leq i \leq m]$ . Intuitively, we obtain from  $M$  a generator  $G(\pi)$  by summing together co-linear vectors that are in the same “orientation”. For example, the vectors  $(1, 0)$  and  $(2, 0)$  along a single path have the same effect as  $(3, 0)$ , but  $(1, 0)$  and  $(-1, 0)$  have distinct effects. Technically, this is captured by grouping together vectors that are in the cones of each other. More formally, choose  $M' \subseteq M \setminus \{\mathbf{0}\}$  such that for all  $\mathbf{u} \in M \setminus \{\mathbf{0}\}$  there is a unique vector  $\mathbf{u}' \in M'$  such that  $\mathbf{u} \in \text{cone}(\mathbf{u}')$ . Then, define  $G(\pi)$  as follows:  $G(\pi) = \left\{ \sum_{\mathbf{u} \in M \cap \text{cone}(\mathbf{u}')} \mathbf{u} \mid \mathbf{u}' \in M' \right\}$ .

<sup>1</sup> Zonotope is the standard term, but since we do not use any of its special properties, the reader may view this as a standard polytope.

We show that the reachability set of  $\pi$  can be computed by taking  $\text{zono}(G(\pi))$ , and removing its boundary except for faces adjacent to  $s_G$ . The intuition behind this is similar to that of cycles: one can add strictly positive-scaled versions of the generating vectors, and therefore boundary elements that are obtained using 0-scales are unreachable. However, in zonotopes there are additional boundary faces that are obtained by capping the scale at 1 on some elements, and these are the faces adjacent to  $s_G$  (with  $s_G$  itself being the reachable vector where all elements are scaled to 1).

► **Theorem 5.** *Let  $G(\pi)$  be as above. Then,  $\text{Reach}(\pi) = \text{relint}(\text{cone}(G)) \cup \text{adj}(G(\pi))$ .*

As with cycles, compared to the multiset of all path labels, we restrict our attention to a simpler set  $G$  of vectors. The following result connecting them is almost immediate.

► **Lemma 6.** *Let  $\mathbf{x} \in \mathbb{Q}^d$ . Then, there exists  $(a_1, \dots, a_n) \in \mathbb{Q}^n$  such that  $\mathbf{x} = \sum_{i=1}^n a_i \mathbf{g}_i$  and  $0 < a_i \leq 1$ , for all  $1 \leq i \leq n$ , if and only if  $\mathbf{x} \in \text{Reach}(\pi)$ .*

### 3.3 The geometry of reachability sets for linear path schemes

A linear path scheme (LPS, for short) is a regular expression  $\pi_0 \chi_1^+ \pi_1 \dots \chi_n^+ \pi_n$  over the transitions. Importantly, the  $\pi_i$  are (possibly empty) paths; the  $\chi_i$  are cycles; and  $\pi_0 \chi_1 \pi_1 \dots \chi_n \pi_n$  is a valid path. Each LPS determines an infinite set  $\{\pi_0 \chi_1^{k_1} \dots \chi_n^{k_n} \pi_n \mid k_1, \dots, k_n \in \mathbb{N}_{>0}\}$  of paths that follows each of the paths exactly once and each of the cycles an arbitrary number of times. For this section, we fix a linear path scheme  $\sigma = \pi_0 \chi_1^+ \pi_1 \dots \chi_n^+ \pi_n$ .

#### 3.3.1 From LPS to cones and a zonotope

From previous developments in this work, the reader might already believe that the reachability set of an LPS can be shown to be the Minkowski sum of suitable subsets of convex cones and zonotopes. It transpires that one can further simplify this and obtain a characterization which involves a single zonotope and a single cone.

Below, we write  $G(\pi)$  to denote the generator of the zonotope for the path  $\pi_0 \pi_1 \dots \pi_n$  as defined in Subsubsection 3.2.1; for each  $1 \leq i \leq n$ , we write  $G(\chi_i)$  to denote the generator of the convex cone for the cycle  $\chi_i$  as defined in Subsubsection 3.1.1.

► **Theorem 7.**  $\text{Reach}(\sigma) \stackrel{is^2}{=} \text{relint}(\text{zono}(G(\pi))) \cup \text{adj}(G(\pi)) + \text{relint}(\text{cone}(\bigcup_{i=1}^n G(\chi_i)))$ .

To prove the theorem, we establish two intermediate results. The first one, together with Theorem 5, already yields the first (Minkowski) summand. The result below follows immediately from the definitions and commutativity of the Minkowski sum.

► **Lemma 8.** *We have that  $\text{Reach}(\sigma) = \text{Reach}(\pi_0 \pi_1 \dots \pi_n) + \sum_{i=1}^n \text{Reach}(\chi_i^+)$ .*

The next result allows us to group the sums of cycle reachability sets into a single convex cone. Indeed, Theorem 1 and an induction on the following lemma yield the last summand from Theorem 7.

► **Lemma 9.** *Let  $C$  and  $C'$  be cones with generators  $G$  and  $G'$  respectively. Then,  $C + C' = \text{cone}(G \cup G')$  and  $\text{relint}(C + C') = \text{relint}(C) + \text{relint}(C')$ .*

<sup>2</sup> To avoid clutter, we omit some parentheses: union has higher precedence than Minkowski sum.

## 4 The Complexity of QVASS Reachability

In this section, we use our results concerning the geometry of reachability sets to give an NP decision procedure for the reachability problem.

► **Theorem 10.** *Given a QVASS of dimension  $d$ , and two configurations  $p(\mathbf{x})$  and  $q(\mathbf{y})$ , determining whether  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$  is in NP.*

First, without loss of generality, we assume  $\mathbf{x} = \mathbf{0}$ . Indeed,  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$  if and only if  $p(\mathbf{0}) \xrightarrow{*} q(\mathbf{y} - \mathbf{x})$ . In the following we prove that if  $p(\mathbf{0}) \xrightarrow{*} q(\mathbf{x})$  then there is an LPS  $\sigma$  such that  $p(\mathbf{0}) \xrightarrow{\pi} q(\mathbf{x})$  for some  $\pi \in \sigma$  and  $\sigma$  has size polynomial on the number of transitions  $|T|$  and on the dimension  $d$ . Then, we show that checking whether  $p(\mathbf{0}) \xrightarrow{*} q(\mathbf{x})$  under a given linear path scheme is decidable in polynomial time. It follows that to check whether a configuration is reachable, in a general QVASS, one can guess a polynomial-sized LPS and check whether the corresponding configuration is reachable in it.

### 4.1 Short linear path schemes suffice

Presently, we argue that for any path we can find an LPS with a number of cycles that is polynomial in the number of transitions of the QVASS and the dimension such that all paths and cycles are simple, the set of transitions in the LPS is the same as that in the path, and the reachability set of the LPS includes that of the path.

For convenience, we define the *support* of a path  $\pi = t_1 \dots t_n$  as the set of all transitions that are present in the path:  $\llbracket \pi \rrbracket = \{t_i \mid 1 \leq i \leq n\}$ . For an LPS  $\sigma = \pi_0 \chi_1^+ \dots \chi_n^+ \pi_n$ , its support is  $\llbracket \sigma \rrbracket = \llbracket \pi_0 \rrbracket \cup \bigcup_{i=1}^n (\llbracket \chi_i \rrbracket \cup \llbracket \pi_i \rrbracket)$ .

► **Theorem 11.** *Let  $\pi$  be an arbitrary path. Then, there exists a linear path scheme  $\sigma = \pi_0 \chi_1^+ \pi_1 \dots \chi_n^+ \pi_n$ , with  $n \leq |T|$ , such that all  $\pi_i$  and  $\chi_i$  are simple paths and cycles, respectively,  $\llbracket \pi \rrbracket = \llbracket \sigma \rrbracket$ , and  $\text{Reach}(\pi) \subseteq \text{Reach}(\sigma)$ .*

Most properties of the LPS in the result above follow from considering an LPS with minimal length, with the length of an LPS defined as  $|\sigma| = |\pi_0| + \sum_{i=1}^n |\chi_i| + |\pi_n|$ . The main technical hurdle is thus the upper bound on the number of cycles. Our approach is to remove cycles whose support is covered by other cycles. The result below, which follows directly from Theorem 1 and Lemma 9, gives us that flexibility. As in Subsection 3.3, we write  $G(\chi)$  to denote the generator of the convex cone for  $\chi$ , i.e.  $G(\chi) = \{\ell(t) \mid t \in \llbracket \chi \rrbracket\}$ .

► **Lemma 12.** *Let  $\chi$  be a cycle and  $C$  be a set of cycles. If  $\llbracket \chi \rrbracket \subseteq \bigcup_{\theta \in C} \llbracket \theta \rrbracket$  then  $\text{Reach}(\chi^+) + \sum_{\theta \in C} \text{Reach}(\theta^+) = \sum_{\theta \in C} \text{Reach}(\theta^+)$ .*

Hence, to check whether a configuration is reachable in a general QVASS, one can guess a polynomial-sized LPS and check whether the corresponding configuration is reachable in it. To conclude membership in NP, it remains to argue that the latter check can be realized in polynomial time.

### 4.2 Reachability for linear path schemes is tractable

In this section, we show that determining whether a configuration is reachable via a linear path scheme is decidable in polynomial time.

► **Theorem 13.** *Given LPS  $\sigma$  and  $\mathbf{x}, \mathbf{y} \in \mathbb{Q}^d$ , determining whether  $\mathbf{y} \in \text{Reach}^{\mathbf{x}}(\sigma)$  is in P.*

Based on Theorem 7 and the geometric characterizations of the reachability sets of cycles and paths, it suffices to show how to determine whether there exist  $\mathbf{z}, \mathbf{c} \in \mathbb{Q}^d$  in a zonotope and a cone, respectively, such that  $\mathbf{y} = \mathbf{z} + \mathbf{c}$ . To do so, we make Lemma 6 and Lemma 2 effective by encoding them into systems of linear inequalities with *strict-inequality constraints*. It is known that the feasibility problem for linear programs is decidable in polynomial time even in the presence of strict inequalities (see, e.g., [18, Ch. 8.7.1]).

Henceforth, we fix an LPS  $\sigma = \pi_0 \chi_1^+ \pi_1 \dots \chi_n^+ \pi_n$ . We also adopt the notation from Subsection 3.3:  $G(\pi)$  denotes the generator of the zonotope for the path  $\pi_0 \pi_1 \dots \pi_n$ ; and  $G(\chi_i)$  the generator of the cone for  $\chi_i$  for each  $1 \leq i \leq n$ .

#### 4.2.1 Encoding the zonotope

Let  $G(\pi) = \{\mathbf{g}_1, \dots, \mathbf{g}_m\}$ . We now define the matrix  $\mathbf{A} \in \mathbb{Q}^{d \times (m+d)}$  and the vector  $\mathbf{a} \in \mathbb{Q}^d$ :

$$\mathbf{A} = \begin{pmatrix} (\mathbf{g}_1)_1 & (\mathbf{g}_2)_1 & \dots & (\mathbf{g}_m)_1 & -1 & 0 & \dots & 0 \\ (\mathbf{g}_1)_2 & (\mathbf{g}_2)_2 & \dots & (\mathbf{g}_m)_2 & 0 & -1 & 0 & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ (\mathbf{g}_1)_d & (\mathbf{g}_2)_d & \dots & (\mathbf{g}_m)_d & 0 & \dots & 0 & -1 \end{pmatrix} \text{ and } \mathbf{a} = (0, \dots, 0), \quad (1)$$

Further, we define the matrix  $\mathbf{B} \in \mathbb{Q}^{m \times (m+d)}$  and the vector  $\mathbf{b} \in \mathbb{Q}^m$  as:

$$\mathbf{B} = (\mathbf{I} \ \mathbf{0} \ \dots \ \mathbf{0}) \text{ and } \mathbf{b} = (1, 1, \dots, 1), \quad (2)$$

where  $\mathbf{I}$  is the  $m \times m$  identity matrix and  $\mathbf{0}$  is the  $m \times 1$  zero vector. Finally, we define  $\mathbf{C} \in \mathbb{Q}^{m \times (m+d)}$  and  $\mathbf{c} \in \mathbb{Q}^m$  as follows.

$$\mathbf{C} = (-\mathbf{I} \ \mathbf{0} \ \dots \ \mathbf{0}) \text{ and } \mathbf{c} = (0, 0, \dots, 0) \quad (3)$$

► **Lemma 14.**  $A\mathbf{z} = \mathbf{a} \wedge B\mathbf{z} \leq \mathbf{b} \wedge C\mathbf{z} < \mathbf{c}$  has a solution  $(\boldsymbol{\alpha}, \mathbf{y}) \in \mathbb{Q}^{m+d}$  iff  $\mathbf{y} \in \text{Reach}(\pi)$ .

This follows immediately from the fact that, by construction, the system has a solution if and only if there exists  $(\alpha_1, \dots, \alpha_m) \in (0, 1]$  such that  $\mathbf{y} = \sum_{i=1}^m \alpha_i \mathbf{g}_i$ , and Lemma 6.

#### 4.2.2 Encoding the cone

The encoding for the cone is even simpler, but requires we adapt our notation slightly.

Let  $\bigcup_{i=1}^n G(\chi_i) = \{\mathbf{g}_1, \dots, \mathbf{g}_m\}$ . We define the matrix  $\mathbf{A} \in \mathbb{Q}^{d \times (m+d)}$  and vector  $\mathbf{a} \in \mathbb{Q}^d$  as in Equation 1; and  $\mathbf{C} \in \mathbb{Q}^{m \times (m+d)}$  and  $\mathbf{c} \in \mathbb{Q}^d$  as in Equation 3.

► **Lemma 15.**  $A\mathbf{z} = \mathbf{a} \wedge C\mathbf{z} < \mathbf{c}$  has a solution  $(\boldsymbol{\alpha}, \mathbf{y}) \in \mathbb{Q}^{m+d}$  iff  $\mathbf{y} \in \sum_{i=1}^n \text{Reach}(\chi_i^+)$ .

This time the lemma follows from Lemma 2 and because, by construction, the system has a solution if and only if there are  $(\alpha_1, \dots, \alpha_m)$  nonnegative such that  $\mathbf{y} = \sum_{i=1}^m \alpha_i \mathbf{g}_i$ .

**Proof of Theorem 13.** The result follows from the fact that Lemma 8 can be made effective by encoding it into a master system of linear inequalities for the zonotope and the cycle. ◀

## 5 The Complexity of $\mathbb{Q}_{\geq 0}$ VASS Reachability

We now give an NP decision procedure for the reachability problem for  $\mathbb{Q}_{\geq 0}$  VASS.

► **Theorem 16.** Given a  $\mathbb{Q}_{\geq 0}$  VASS of dimension  $d$ , and configurations  $p(\mathbf{x})$  and  $q(\mathbf{y})$ , determining whether  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$  is in NP.

## 11:10 The Geometry of Continuous VASS

The structure of our argument is similar to the one in Section 4: we prove that short LPS suffice and then we prove reachability is tractable for LPS. The first part is considerably more complicated for  $\mathbb{Q}_{\geq 0}$ VASS and it is based on the fact that short LPS exist for  $\mathbb{Q}$ VASS. For this reason, we need additional notation: We write  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$  to denote that  $q(\mathbf{y})$  is reachable from  $p(\mathbf{x})$  in a  $\mathbb{Q}_{\geq 0}$ VASS and instead use  $p(\mathbf{x}) \xrightarrow{-*} q(\mathbf{y})$  to denote that  $q(\mathbf{y})$  is reachable from  $p(\mathbf{x})$  with respect to  $\mathbb{Q}$ VASS semantics (i.e. when allowing negative counter values). Similarly, we write  $\text{Reach}^{\mathbf{x}}(\cdot)$  for reachability sets w.r.t.  $\mathbb{Q}$ VASS and  $\text{Reach}_{\geq 0}^{\mathbf{x}}(\cdot)$  for that w.r.t.  $\mathbb{Q}_{\geq 0}$ VASS. We make repeated use of the following result by Blondin and Haase.

► **Lemma 17** (From [2, Proposition 4.5]). *There exists a path  $\pi$  such that  $q(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$  if and only if there exist paths  $\pi_1, \pi_2, \pi_3$  such that:*

1.  $q(\mathbf{x}) \xrightarrow{-*} q(\mathbf{y})$ ;
2.  $q(\mathbf{x}) \xrightarrow{\pi_1} q(\mathbf{x}')$ , for some  $\mathbf{x}' \in \mathbb{Q}_{\geq 0}^d$ ;
3.  $q(\mathbf{y}') \xrightarrow{\pi_3} q(\mathbf{y})$ , for some  $\mathbf{y}' \in \mathbb{Q}_{\geq 0}^d$ ; and
4.  $\llbracket \pi \rrbracket = \llbracket \pi_1 \rrbracket = \llbracket \pi_2 \rrbracket = \llbracket \pi_3 \rrbracket$ .

Moreover, if item 1–item 4 hold, then  $\mathbf{y} \in \text{Reach}_{\geq 0}^{\mathbf{x}}(\pi_1 \pi_2^+ \pi_3)$ .

Intuitively,  $q(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$  if the following conditions hold: first, we obviously need  $q(\mathbf{x}) \xrightarrow{-*} q(\mathbf{y})$ , and second, we need  $q(\mathbf{x})$  to allow some “wiggle room” using the same transitions as  $\pi$  and while keeping the counters nonnegative. Similarly, there should be wiggle room to reach  $q(\mathbf{y})$  with nonnegative counters. The lemma also shows that these conditions are necessary.

### 5.1 Short linear path schemes suffice

We start by proving that short LPS suffice.

► **Theorem 18.** *Let  $\pi$  be an arbitrary path such that  $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$ . Then, there exists a linear path scheme  $\sigma = \pi_0 \chi_1^+ \pi_1 \dots \chi_n^+ \pi_n$ , with:*

- $n \leq |Q|$ ,
- $\pi_i$  is a simple path for all  $0 \leq i \leq n$ ,
- $|\chi_i| \leq 4|Q|(|T| + d + 2)(|T| + 1)$  for all  $1 \leq i \leq n$ , and
- $\mathbf{y} \in \text{Reach}_{\geq 0}^{\mathbf{x}}(\sigma)$ .

Let us we outline our approach to prove this. Consider a path  $\pi$  such that  $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$ . We decompose  $\pi$  into  $\pi = \tau_0 \theta_1 \tau_1 \dots \theta_n \tau_n$  where the  $\tau_i$  are simple paths separated by at most  $|Q|$  (not necessarily simple) cycles  $\theta_i$ . We would now like to replace each cycle  $\theta$  with a short LPS  $\chi^+$ , as per the third item in Theorem 18. Note that we cannot readily do so using Theorem 11, as it does not guarantee nonnegative reachability. We thus take a more elaborate approach, as follows.

Consider a cycle  $\theta$ . By applying Lemma 17, we can replace  $\theta$  by an LPS  $\pi_1 \pi_2^+ \pi_3$ . We now apply Theorem 11 to  $\pi_2$ , thus obtaining an LPS  $\sigma = \mu_0 \zeta_1^+ \mu_1 \dots \zeta_m^+ \mu_m$  such that  $\text{Reach}^z(\pi_2) \subseteq \text{Reach}^z(\sigma)$  for all  $z$  (note that nonnegativity is no longer maintained). Recall that our goal is to represent  $\pi_2^+$  as an LPS, so we cannot use  $\sigma^+$ , as it is not an LPS. Instead, we show that by looking at the concrete path  $\bar{\sigma} = \mu_0 \zeta_1 \mu_1 \dots \zeta_m \mu_m$  we have  $\text{Reach}^z(\pi_2^+) \subseteq \text{Reach}^z(\bar{\sigma}^+)$ , and  $\bar{\sigma}^+$  is an LPS.

The next challenge is to plug back  $\bar{\sigma}^+$  as part of an LPS for  $\theta$ . To do so, we need to find LPS for  $\pi_1$  and  $\pi_3$ . We show that this is possible. We can now use Lemma 17 again, in the opposite direction, to conclude that  $\pi_1 \pi_2^+ \pi_3$  can be described by an LPS with appropriate bounds, retaining nonnegative reachability.

## 5.2 Reachability for linear path schemes is tractable

As in the QVASS case, here we are able to prove that determining whether a configuration is reachable via an LPS is decidable in polynomial time.

► **Theorem 19.** *Given LPS  $\sigma$  and  $\mathbf{x}, \mathbf{y} \in \mathbb{Q}_{\geq 0}^d$ , determining if  $\mathbf{y} \in \text{Reach}_{\geq 0}^{\mathbf{x}}(\sigma)$  is in  $\mathbf{P}$ .*

Once more, our argument relies on an encoding into a system of linear inequalities. However, in contrast to QVASS, the encoding is slightly less elegant. For each path  $\pi = (p_1, p_2) \dots (p_m, p_{m+1})$  occurring inside  $\sigma$ , instead of encoding an (affine) zonotope into a system of linear equalities, we focus directly on the  $m$  steps of the path.

Let  $\mathbf{b}_i = \ell(p_i, p_{i+1})$  for all  $1 \leq i \leq m$ . We will use the  $\mathbf{b}_i$  instead of the zonotope basis  $G(\pi)$  of Subsection 4.2. We now adapt the system from Subsection 4.2 to account for the nonnegativity of partial sums induced by the path prefixes. Recall  $\mathbf{A}, \mathbf{a}, \mathbf{B}, \mathbf{b}, \mathbf{C}$ , and  $\mathbf{c}$  as defined in Equation 1, Equation 2, and Equation 3. We introduce  $d + md$  new variables – the first  $d$  account for an initial vector  $\mathbf{x}$ , and the remaining  $md$  represent the intermediate values of the path after each transition.

Intuitively, we obtain from the above matrices new ones, denoted  $\mathbf{A}', \mathbf{a}', \mathbf{B}', \mathbf{b}', \mathbf{C}'$  so that  $\mathbf{A}'$  includes the constraints  $\bigwedge_{k=1}^d \bigwedge_{n=1}^m \left( \mathbf{x}_k + \sum_{j=1}^n (\mathbf{b}_j)_k z_j \right) = z_{m+2d+(n-1)d+k} \geq 0$ . We thus have the following.

► **Lemma 20.** *For a path  $\pi$ , the system  $\mathbf{A}'\mathbf{z} = \mathbf{a}' \wedge \mathbf{B}'\mathbf{z} \leq \mathbf{b}' \wedge \mathbf{C}'\mathbf{z} < \mathbf{c}'$  of linear inequalities has a solution  $(\boldsymbol{\alpha}, \mathbf{y}, \mathbf{x}, \boldsymbol{\iota}) \in \mathbb{Q}^{m+2d+md}$  if and only if  $p_1(\mathbf{x}) \xrightarrow{\pi} p_{m+1}(\mathbf{y})$ .*

**Proof of Theorem 19.** By Lemma 20, it suffices to argue that nonnegative reachability via a cycle  $\chi^+$  of  $\sigma$  can also be encoded into a system of linear inequalities. For this, we make use of the “if” direction of Lemma 17, which for  $\chi^+$  amounts to  $p(\mathbf{x}) \xrightarrow{\chi^+} p(\mathbf{y})$  iff (1)  $p(\mathbf{x}) \xrightarrow{\chi^+} p(\mathbf{y})$ , (2)  $p(\mathbf{x}) \xrightarrow{\chi} p(\mathbf{x}')$  for some  $\mathbf{x}' \in \mathbb{Q}_{\geq 0}$ , (3)  $p(\mathbf{y}') \xrightarrow{\chi} p(\mathbf{y})$  for some  $\mathbf{y}' \in \mathbb{Q}_{\geq 0}$ . Condition 1 can be encoded in a system of linear inequalities by Lemma 15, and conditions 2 and 3 can be encoded in such systems too as per Lemma 20. We can now conjoin the systems for the paths and cycles to obtain a master system of linear inequalities of polynomial size. ◀

## 6 The Complexity of Reachability with Zero Tests

We now argue that the reachability problem for continuous VASS with *zero tests* is **NP**-hard, already for LPS of dimension 2. For convenience, we state the result for QVASS. However, we note that the same proof establishes the result for  $\mathbb{Q}_{\geq 0}$ VASS.

We start by formally defining the model. A continuous VASS  $\mathcal{V}$  of dimension 2 with zero tests is a tuple  $(Q, t, \ell, Z_1, Z_2)$ , where  $\mathcal{V}' = (Q, t, \ell)$  is a continuous VASS and  $Z_i \subseteq Q$  for  $i = 1, 2$ . A run  $\rho = q_1(\mathbf{x}_1) \dots q_n(\mathbf{x}_n)$  of such a VASS is a run of  $\mathcal{V}'$  such that, additionally, for all  $1 \leq i \leq n$  we have that if  $q_i \in Z_j$ , for some  $j \in \{1, 2\}$ , then  $(\mathbf{x}_i)_j = 0$ . That is, any run that reaches a state in  $Z_j$  must be such that the value of the  $j$ -th counter is 0 then.

► **Theorem 21.** *For every  $d \in \mathbb{N}, d \geq 2$ , given a QVASS (or  $\mathbb{Q}_{\geq 0}$ VASS) of dimension  $d$ , and two configurations  $p(\mathbf{x})$  and  $q(\mathbf{y})$ , determining whether  $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$  is **NP**-hard, even for linear path schemes of dimension 2.*

We reduce from the PRIMECOVER problem: Given a set  $X$  of prime numbers and a collection  $S$  of subsets of  $X$ , with  $T \in \mathbb{N}$ , determine whether there is a subset  $S' \subseteq S$  such that  $\prod_{s' \in S'} \prod_{p \in s'} p = T$ . It is straightforward to prove PRIMECOVER is **NP**-hard by reduction from the the EXACTCOVER problem [13].

■ **Figure 3** In the dotted blue box, a multiplier gadget is shown: the state above is an element of  $Z_1$  (noted by  $x = 0$ ) while the state below is an element of  $Z_2$  (noted by  $y = 0$ ); The whole LPS encodes an instance of PRIMECOVER with  $S = \{s_1, s_2, \dots, s_n\}$  – recall that  $d_i = \prod_{p \in c_i} p$ .

Now, for each  $s \in S$  we create multiplier gadgets as depicted in Figure 3 where  $d = \prod_{p \in s} p$  and  $e = \lceil \log_2(\prod_{s \in S} \prod_{p \in s} p) \rceil + 1$ , and we link them in an LPS with transitions  $(q_i, q_{i+1})$ , for  $1 \leq i \leq |S|$ , labelled with  $(0, 0)$  updates (see Figure 3). We claim that PRIMECOVER has a positive answer if and only if  $q_1(1, 0) \xrightarrow{*} q_{|C|}(T, 0)$  in the constructed LPS.

## 7 Conclusion

We gave geometrical characterizations for the reachability sets of continuous VASS and their flat and LPS restrictions. Using these, we showed that polynomial-sized LPS suffice as witnesses of reachability and that reachability in linear path schemes is tractable. In addition, we sharpened hardness results in the presence of zero tests: it is **NP**-hard already for dimension two.

# Competitive Search in the Line and the Star with Predictions

Spyros Angelopoulos  

CNRS and LIP6, Sorbonne University, Paris, France

---

## Abstract

We study the classic problem of searching for a hidden target in the line and the  $m$ -ray star, in a setting in which the searcher has some *prediction* on the hider's position. We first focus on the main metric for comparing search strategies under predictions; namely, we give positive and negative results on the *consistency-robustness* tradeoff, where the performance of the strategy is evaluated at extreme situations in which the prediction is either error-free, or adversarially generated, respectively. For the line, we show tight bounds concerning this tradeoff, under the *untrusted advice* model, in which the prediction is in the form of a  $k$ -bit string which encodes the responses to  $k$  binary queries. For the star, we give tight, and near-tight tradeoffs in the *positional* and the *directional* models, in which the prediction is related to the position of the target within the star, and to the ray on which the target hides, respectively. Last, for all three prediction models, we show how to generalize our study to a setting in which the performance of the strategy is evaluated as a function of the searcher's desired tolerance to prediction errors, both in terms of positive and inapproximability results.

## 1 Introduction

Searching for a hidden target is one of the original disciplines within the field of Operations Research, but also a topic of significant study in Computer Science, both from the point of view of theoretical analysis and applications. This class of problems typically involves a mobile *searcher* that must locate an immobile *target* (often called *hider*) which hides in some unknown point of the search *environment*. Search problems provide natural formulations of real-life applications such as search-and-rescue missions [41], de-mining operations [2], and robot-based exploration [27].

Among the most well-studied search problems is *searching on the line*, in which the environment is the unbounded line, and its generalization, the  *$m$ -ray search*, or *star search* problem. In the  *$m$ -ray search* problem, the environment consists of  $m$  unbounded and concurrent rays, with a common point  $O$ , which is called the *origin*. Starting from  $O$ , the searcher must locate the target by following a *strategy*, defined as an infinite sequence of the form  $(x_i, u_i)_i$ , where  $x_i \in \mathbb{R}^+$  and  $u_i \in \{0, \dots, m-1\}$ , and with the following semantics: in iteration  $i$ , the searcher starts from  $O$ , traverses the ray  $u_i$  up to distance  $x_i$  from  $O$ , then returns back to  $O$ , before continuing with iteration  $i+1$ , until the target is eventually located. Note that for  $m=2$ , the star environment reduces to the infinite line.

Since the search environment is unbounded, the standard framework for evaluating the performance of a search strategy is *competitive analysis*, first introduced in [11]. Given a target  $t$  hiding at some unknown point of the star, define  $d(t)$  as the distance of  $t$  from  $O$ , and  $d(X, t)$  as the distance covered (or *cost* incurred) by a searcher that follows  $X$ , until  $t$  is located (i.e., the first time the searcher is reached, assuming a unit-speed searcher). The *competitive ratio* of  $X$  is formally defined as

$$\text{Cr}(X) = \sup_t \frac{d(X, t)}{d(t)}. \quad (1)$$

Searching on the line has a long history of study, going back to the work of Bellman [12] and Beck [10]. Beck and Newman [11] were the first to show that an optimal competitive ratio equal to 9 can be obtained by a simple doubling strategy, i.e., a strategy of the form  $x_i = 2^i$ . The  $m$ -ray search problem was first studied in the seminal works of Gal [24, 25] and independently by Baeza-Yates *et al.* [8]. Both problems have been extended in a variety of settings and generalizations related to TCS, AI and OR since the 1960s, due to their useful abstraction of resource allocation under uncertainty. For instance, linear and ray searching have connections to the design of *interruptible systems* in AI [4, 13], the design of *hybrid* algorithms [32], and pipelined *filter ordering* in databases [18]. They are also involved in the analysis of strategies for more complex search problems, such as *spiral* search on the plane [38]. There are numerous studies on variants of linear and star search; see, e.g., [31, 36, 29, 44, 33, 16, 20, 5, 19, 37, 15, 34, 46, 6, 43, 51, 36, 17] as well as the book [1] for a game-theoretic perspective of these problems. Note that the above are only some representative works, and that the problems have been studied under several other variants.

## 1.1 Searching with predictions

In this work, we study the power and limitations of search strategies with *predictions*, in which the searcher aims to improve the competitive ratio of its strategy by leveraging some inherently imperfect information on the target. This follows a very active line of research in online computation and algorithms with incomplete information, that was initiated with the works [45] and [49]. A very large number of problems have been studied under this model (see, e.g., the survey [47] and the online collection [42]).

In regards to the search problems we study, the nature of the prediction may vary according to the application at hand. We are interested in the following models, which were introduced in [3] in the context of linear search.

- (a) The prediction is a *k-bit string*. Here, the search is enhanced with a  $k$ -bit string that encodes some information on the target; alternatively, we may think of the prediction string as responses to binary *queries* given by  $k$  experts. For example, a single bit can provide a (potentially erroneous) response to queries such as “Is the target at distance at most  $d$  from  $O$ ”, or “Is the target on an even-indexed ray?”. This is a powerful model that generalizes the concept of *advice complexity* so as to allow for advice that may be erroneous. Note that search and exploration problems have been studied extensively under the standard advice complexity model (see, e.g., [21, 23, 28, 35, 48]), however all such studies rely crucially on advice that is error-free. Moreover, unlike works in which each query is *noisy* [14], i.e., the query responses are erroneous with some known probability, in our setting we do not rely on any probabilistic assumptions in regards to the quality of the advice.

- (b) The prediction is *directional*. Here, the prediction is an index in  $\{0, \dots, m - 1\}$  which describes the ray on which the target lies. This is a natural prediction can be useful, for example, in a search-and-rescue application, in which there is a hint about the direction a missing person may have taken when last seen.
- (c) The prediction is *positional*. Here, the prediction describes the position of the target within the environment, namely it is of the form  $(d, u)$ , where  $d$  corresponds to the predicted distance from the origin, and  $u$  corresponds to the predicted ray on which the target hides. This is, likewise, a very natural prediction (e.g., in a search-and-rescue mission, it provides a hint about the last reported whereabouts of the missing person).

We establish two objectives towards the evaluation of search strategies with predictions. The first objective is to find strategies of optimal, or near-optimal tradeoff between their *consistency* (namely, the competitive ratio assuming error-free prediction) and their *robustness* (namely, the competitive ratio assuming adversarially generated predictions). This is one of the standard methods of analyzing algorithms with predictions, since it establishes strong guarantees on worst-case (extreme) situations with respect to the quality of the prediction; see, e.g., [52, 40, 39, 3, 7] for applications to other online problems, and settings of incomplete information, more generally. Specifically, we are interested in showing both positive and negative results on the best-possible consistency that can be achieved by  $r$ -robust strategies, for any given  $r$ .

Our second objective goes beyond the consistency/robustness tradeoffs, and we evaluate the performance of the search strategy beyond the two extreme scenarios of error-free and adversarial error. Specifically, we study the novel setting in which the searcher defines an application-specific *tolerance* parameter  $H$  that determines its desired tolerance to errors or, equivalently, an anticipated upper bound on the prediction error (that may be known by historical data on previous searches). This parameter is defined appropriately for each of the three prediction models we study. Namely, in the untrusted advice model,  $H$  is related to the number of erroneous advice bits (or query responses); in the directional model  $H$  describes the distance of the predicted ray index to the one of the actual hiding target; and in the positional model,  $H$  is related to the distance between the predicted and the actual target position. The tolerance model is motivated by recent works in learning-enhanced online algorithms with *weak predictions*, in which the prediction is an upper bound of some pertinent parameter of the input (see e.g., online knapsack with frequency predictions [30], where the prediction is an upper bound on the size of items that appear online). Our objective is thus to quantify the tradeoff between the competitive ratio and the robustness as a function of the tolerance and other parameters of the problem (e.g., the number of queries, in the query-based model). Following [30], we will make use of the term *weak prediction* to refer to this setting.

The problems we study have applications in more general decision-making settings that go beyond the confines of search theory. This is since  $m$ -ray search, as discussed above, is an abstraction of resource allocation among  $m$  different tasks. To illustrate with an example, consider a researcher who has to allocate time among  $m$  different projects, without knowing ahead of time which project will be completed successfully. The researcher, however, may have some intuition about which of these tasks is the most likely to succeed. This problem fits the  $m$ -ray search abstraction with a directional prediction. In the weak prediction setting,  $H$  describes, more generally, the specific projects which the researcher believes are more likely to be successful.

Learning-augmented search has received attention in recent years. [3] studied consistency/robustness (Pareto) tradeoffs for linear search in the three prediction models described above. [9] studied a graph search setting where every node in the graph provides a prediction of its distance to the target vertex. [22] showed how to robustify graph exploration algorithms, where the prediction is related to the spanning tree of the explored graph.

## 1.2 Contribution

Our first results apply to the untrusted advice model (i.e, the  $k$ -query model). We prove tight upper and lower bounds on the best consistency that an  $r$ -robust strategy for linear search can achieve, for any  $r \geq 9$ , any size of advice  $k$ , and with no assumptions on the nature of the strategy. This improves upon both the upper and the lower bounds of [3], which gave a non-tight lower bound for  $k = 1$  and  $r = 9$ , and a non-tight lower bound for  $r > 9$  and  $k = 1$  for a restricted class of strategies called *asymptotic*. Here, the challenge is on the lower bound side. Specifically, we reduce the problem to a *parallel search* problem that involves  $2^k$  searchers, and we rely on a novel application of Gal’s functional theorem [26] to prove an information-theoretic tight lower bound. While this theorem has been previously applied in parallel search problems [44], its application in our setting is much more challenging, since we require that each of the  $2^k$  searchers must be individually  $r$ -robust. Specifically, unlike previous works, the proof requires an explicit *labeling* scheme that maps the search lengths of each parallel searcher to lengths of a “global” sequence. We also extend our upper bound to weak predictions, by applying tools from the theory of games with a *lying responder* [50], in order to bound the effect of erroneous query responses to the performance.

Our second class of results is on the directional prediction model of  $m$ -ray search. We give the first upper and lower bounds on the consistency-robustness tradeoffs, which extend those of [3] to star search. Here, the main challenge is again on the lower bound side, and specifically in the weak predictions setting. We show how a generalization of a biased search approach, in which the searcher allocates more time towards the predicted ray, allows us to prove an asymptotically tight bound on the competitive ratio as a function of the tolerance and the number of rays.

Last, we show tight (Pareto-optimal) consistency-robustness tradeoffs for  $m$ -ray search in the positional model. As with the directional model, the only previous known results applied to linear search [3]. The proof uses tools that circumvent the exact study of linear recurrence relations inherent in  $m$ -ray search problems. To our knowledge, this is a new approach towards impossibility results on this type of search games. As with the other models, we also provide tight upper and lower bounds on the competitive ratio under weak predictions. We emphasize that beyond the tight and near-tight results, the generalization to star search and the accompanied analysis under weak predictions are conceptually novel aspects of this work and extend the performance guarantees beyond the consistency/robustness tradeoffs.

Due to space limitations, we omit or sketch technical details in some of the proofs.

## 2 Preliminaries

We review some notation and known results concerning  $m$ -ray searching. Without predictions, a strategy is described by a sequence of the form  $X = (x_i, u_i)_{i \geq 0}$ ; we refer to  $i$  as the *iteration*<sup>1</sup> of the strategy, to  $x_i$  as the *length* of the  $i$ -th search *segment*, to  $u_i$  as the ray searched in iteration  $i$ , and to the point at which the searcher turns in the  $i$ -th iteration as the

---

<sup>1</sup> We will consider a numbering of iterations that starts either with 0, or with 1, depending on which simplifies the presentation.

corresponding *turn point*. Note that for linear search ( $m = 2$ ), we may assume, without loss of generality, that  $u_i = i \bmod m$ , and that  $x_{i+2} > x_i$ . We make the standing assumption that the target lies within distance at least a fixed value, otherwise every strategy has unbounded competitive ratio. It is well-known that the worst-case hiding positions of the target, i.e., the positions that maximize  $\text{Cr}(X)$ , are infinitesimally beyond the turn points of a searcher that follows  $X$ , namely, at distances  $x_i + \epsilon$  on rays  $u_i$ , for  $\epsilon > 0$ .

A strategy for  $m$ -ray search is called *cyclic*, if it explores the rays in a fixed permutation of  $\{0, \dots, m-1\}$ , e.g., if  $u_i = i \bmod m$ . The competitive ratio of a cyclic strategy of the form  $X = (x_i, i \bmod m)_i$  is easily shown to be equal to

$$\text{Cr}(X) = 1 + \sup_i \frac{2 \sum_{j=0}^{i+m-1} x_j}{x_i}. \quad (2)$$

In particular, a cyclic strategy is called *geometric* if  $x_i = b^i$ , for some fixed  $b > 1$  which is called the *base* of the strategy; we will denote such strategies by  $G_b$ . Geometric strategies are significant since they are often optimal for several variants of linear search. From (2), it follows that the competitive ratio of  $G_b$  is therefore equal to  $1 + 2b^m/(b-1)$ . This expression is minimized for  $b = m/(m-1)$ , and the resulting optimal competitive ratio, denoted by  $r_m^*$ , is equal to

$$1 + 2\rho_m^*, \quad \text{where } \rho_m^* = \frac{m^m}{(m-1)^{m-1}}.$$

Thus, given  $r \geq r_m^*$ , strategy  $G_b$  has competitive ratio at most  $r$  if  $b^m/(b-1) \leq \rho_r$ , where  $\rho_r$  is defined to be equal to  $(r-1)/2$ . We will denote by  $b_r$  the largest such  $b$  for which  $G_b$  is  $r$ -competitive, i.e., the largest real root of the function  $f(x) = x^m/(m-1) - \rho_r$ .

Under the prediction framework, the searcher is given some information  $h$  in regards to the target  $t$ , and determines a strategy  $X_h$  (we will often omit  $h$  when it is clear from context). Following [3], we define the *consistency* of a strategy as its competitive ratio assuming no prediction error, and its *robustness* as its competitive ratio assuming adversarial prediction error. Note, in particular, that the robustness of a strategy is equal to its competitive ratio without any prediction, and we will thus use these two terms interchangeably. We say that a strategy is  *$r$ -robust* if its robustness is at most  $r$  (similarly for the consistency), and that it is *Pareto-optimal* if its consistency and robustness are in an optimal tradeoff relation.

Let  $Y = (y_i)_{i=0}^\infty$  denote a sequence in  $\mathbb{R}^+$ . We define  $\alpha_Y$  as  $\alpha_Y = \limsup_{n \rightarrow \infty} y_n^{1/n}$ . This parameter appears prominently in Gal's theorem [26] which, informally, gives a lower bound on the supremum of a set of functionals by the supremum of these functionals over geometrically increasing sequences. From it, it follows that any  $m$ -ray search strategy  $Y$  with search lengths  $(y_i)_i$  has competitive ratio at least  $1 + 2 \frac{\alpha_Y^m}{\alpha_Y - 1}$ , hence if the strategy is  $r$ -competitive it must be that  $\alpha_Y \leq b_r$ .

### 3 Linear search with untrusted advice

In this section, we study linear search in a model in which the prediction is an untrusted advice string of size  $k$ . We first show optimal upper and lower bounds on the best consistency of  $r$ -robust strategies, then in Section 3.1 we study the extension to weak predictions.

Our results will show and exploit connections between a single-searcher strategy with  $k$ -bit advice, and a *multi-searcher* strategy with  $2^k$  parallel searchers, but no advice. Hence, we first present some definitions and notation concerning the setting of  $p > 1$  parallel searchers, labeled from the set  $\{0, \dots, p-1\}$ . In a  $p$ -searcher strategy, each searcher  $j$  defines its

own strategy of the form  $X_j = (x_{j,i}, u_{j,i})_{i=0}^\infty$ . We thus denote the  $p$ -searcher strategy as  $\mathcal{X} = \{X_j\}_{j=0}^{p-1}$ , or equivalently, we say that it is defined by the set  $\{X_j\}_{j=0}^{p-1}$ . The competitive ratio of a  $p$ -searcher strategy is the worst-case ratio of the first time one of the  $p$  searchers finds the target  $t$  (assuming unit-speed searchers) and the distance  $d(t)$  of the target from the origin [44].

Observe that the optimal consistency of an  $r$ -robust strategy with  $k$  advice bits is equal to the competitive ratio of a parallel search strategy that is defined by  $2^k$  searchers, each of which is individually  $r$ -robust. Namely, if the advice is error-free, it can be used to select the single-searcher strategy, among the  $2^k$  ones, that reaches the target at optimal cost. Note that, by construction, the robustness of this strategy is at most  $r$ , since each individual searcher is  $r$ -robust. This observation applies to both positive and negative results on the consistency/robustness tradeoffs.

We first show an upper bound on the consistency of  $r$ -robust strategies:

► **Theorem 1.** *For any  $r \geq 9$ , there is an  $r$ -robust strategy for searching on the line with  $k$ -bit advice that has consistency at most  $1 + 2 \frac{b_r^{1/q}}{b_r - 1}$ , where  $q = 2^{k-1}$ .*

**Proof sketch.** Let  $\mathcal{S}$  denote the  $2^k$ -parallel strategy as defined by the set  $S_0, \dots, S_{2^k-1}$  where

$$S_j = (b^{j+iq}, i \bmod 2), \text{ if } j \text{ is even and } S_j = (b^{j+iq}, (i+1) \bmod 2), \text{ if } j \text{ is odd,}$$

for some  $b > 1$  that will be specified later. That is, each individual strategy is near-geometric, and half of the searchers explore ray 0 in their first iteration, whereas the other half explore ray 1. We require that each strategy in  $\mathcal{S}$  is  $r$ -robust which implies, from the discussion in Section 2, that  $b$  must satisfy  $b^q \leq b_r$ , hence  $b \leq b_r^{1/q}$ . ◀

Note that this upper bound is not only of theoretical significance, but can be obtained in practice via a query-based implementation. This is because the  $i$ -th advice bit can be interpreted, equivalently, as a response to a subset query that asks whether the target is hiding within a specific subset of the infinite line. Informally, the theorem shows which questions to ask to  $k$  different experts<sup>2</sup> about the whereabouts of the target so as to maximize the efficiency of search, while remaining robust to adversarial responses.

We now move to the lower bound. We first show a useful property of parallel search. To illustrate the property, consider Figure 1, which shows the first segments of a  $p$ -parallel strategy defined by  $S_1, \dots, S_p$ . In this example, the first segment of strategies  $S_1, \dots, S_i$  is to the left ray of the line, whereas the first segment of  $S_{i+1}, \dots, S_p$  is to the right ray of the line. Furthermore, the lengths of these segments are in increasing order, in the left and the right ray, respectively, as illustrated. We observe that, without loss of generality, a target that hides infinitesimally beyond the first turnpoint in  $S_j$ , with  $j \in \{1, \dots, p-1\}$  is first discovered by  $S_{j+1}$ , and if  $j = p$ , it is first discovered by  $S_1$ . This is because, if this was not the case, then one of the strategies would mark its second turn before it had explored any new parts of the line, which would mean that the corresponding second segment would be redundant and thus could be omitted.

We can argue, inductively, that the same property extends not only to targets hiding infinitesimally beyond the first turn points, but beyond *every* turn point. To formalize this concept, let  $\mathcal{S}$  be a  $p$ -parallel strategy defined by single-searcher strategies  $S_1, \dots, S_p$ . We say that  $S_j$  is *responsible for the  $i$ -th turn point of  $S_i$*  if  $S_j$  is the first strategy in  $\mathcal{S}$  to discover a

<sup>2</sup> Experts may be inherently erroneous; in Theorem 4 we extend the result to account for query errors.

■ **Figure 1** A snapshot of the first iteration in a  $p$ -parallel strategy.

target hiding infinitesimally beyond the  $i$ -th turnpoint of  $S_i$ . The following lemma shows that it suffices to consider  $p$ -parallel strategies in which a “snapshot” of the first iteration of the  $p$  individual strategies provides a global picture about the relative turnpoints of all individual strategies, for all subsequent iterations. This will help us setup the lower bound.

► **Lemma 2.** *For any  $p$ -searcher strategy  $\mathcal{S}$ , there is a  $p$ -searcher strategy  $\mathcal{S}' = \{S'_1, \dots, S'_p\}$  such that there is a bijection  $\pi : \{1, \dots, p\} \rightarrow \{1, \dots, p\}$  with the property that for any  $j \in \{1, \dots, p\}$ ,  $S'_{\pi(j)}$  is responsible for the  $i$ -th turn point of  $S'_j$  for all  $i \in \mathbb{N}^+$ , and  $\mathcal{S}'$  has competitive ratio no worse than  $\mathcal{S}$ .*

We now show how to prove the lower bound.

► **Theorem 3.** *For any  $r \geq 9$ , every  $r$ -robust strategy for searching on the line with untrusted advice of size  $k$  has consistency at most  $1 + 2^{\frac{k^{1/q}}{r-1}}$ , where  $q = 2^{k-1}$ .*

**Proof sketch.** For convenience of notation, let  $n = 2^k$ , and let  $\mathcal{S}$  be an  $n$ -parallel strategy defined by  $S_1, \dots, S_n$ , and which satisfies the property of Lemma 2. Let  $i$  be such that strategies  $S_1, \dots, S_i$  start their first iteration to the left (in increasing order of this length), whereas  $S_{i+1}, \dots, S_n$  start their first iteration to the right (again in increasing length order). Thus, we have that  $S_j$  is responsible for  $S_{j-1}$ , for all  $j \in \{2, \dots, 2^k\}$ , whereas  $S_1$  is responsible for  $S_n$ . The situation is depicted in Figure 1, where  $p = n$ .

Let  $s_{j,m}$  denote the search length of the  $m$ -th iteration of  $S_j$ . For any fixed  $m$ , consider a target hiding infinitesimally beyond the  $m$ -th turn point of  $S_j$ , for each  $j$ . Since  $S_{j+1}$  is responsible for  $S_j$ , for all  $j \in \{1, \dots, i-1, i+1, \dots, n-1\}$ , we have

$$\text{Cr}(\mathcal{S}) \geq 1 + 2^{\frac{\sum_{l=1}^{m-1} s_{j+1,l}}{s_{j,m}}}, \quad \text{for all } j \in \{1, \dots, i-1, i+1, \dots, n-1\}. \quad (3)$$

In addition, since  $S_{i+1}$  and  $S_1$  are responsible for  $S_i$  and  $S_n$ , respectively, we have that

$$\text{Cr}(\mathcal{S}) \geq 1 + 2^{\frac{\sum_{l=1}^{m-1} s_{i+1,l}}{s_{i,m-1}}} \quad \text{and} \quad \text{Cr}(\mathcal{S}) \geq 1 + 2^{\frac{\sum_{l=1}^{m-1} s_{1,l}}{s_{n,m-1}}}, \quad (4)$$

and note the subtle, but important differences in the indexing of the denominators between (3) and (4). This motivates our next step, in which we *label* the lengths of all search segments of the  $2^k$  strategies in  $\mathcal{S}$  in a way that will allow us to use the above lower bounds. Let  $\{x_l\}_{l=1}^{\infty}$  denote the set of all segment lengths in the parallel strategy  $\mathcal{S}$ . We map bijectively each such length to a segment length of one of the strategies  $S_j$ , according to the following function.

$$s_{j,m} = \begin{cases} x_{j+mn}, & \text{if } j \in [1, \dots, i-1] \\ x_{j-1+mn} & \text{if } j \in [i+1, \dots, n-1] \\ x_{n-1+mn}, & \text{if } j = i \\ x_{n+mn}, & \text{if } j = n. \end{cases} \quad (5)$$

Combining (3), (4) and the mapping (5), we can show that

$$\text{Cr}(\mathcal{S}) \geq 1 + 2 \sup_m \frac{\sum_{l=1}^{mn} x_l}{\sum_{l=0}^{n-1} x_{mn-1+l}}. \quad (6)$$

Define the functional  $F_m$  to be  $F_m = \frac{\sum_{l=1}^{mn} x_l}{\sum_{l=0}^{n-1} x_{mn-1+l}}$ . It is easy to see that this functional satisfies the conditions of Gal's Theorem [26]. Therefore,

$$\text{Cr}(\mathcal{S}) \geq 1 + 2 \sup_m \frac{\sum_{l=1}^{mn} \alpha^l}{\sum_{l=0}^{n-1} \alpha^{mn-1+l}}, \quad \text{where } \alpha = \limsup_{l \rightarrow \infty} x_l^{1/l}. \quad (7)$$

If  $\alpha \leq 1$ , the RHS of (7) is unbounded. If  $\alpha > 1$ , (7) gives

$$\text{Cr}(\mathcal{S}) \geq 1 + 2 \sup_m \frac{\alpha^{mn+1} - \alpha}{(\alpha - 1)\alpha^{mn-1} \frac{\alpha^n - 1}{\alpha - 1}} \geq 1 + 2 \frac{\alpha^2}{\alpha^n - 1}. \quad (8)$$

We will now use the fact that each strategy in  $\mathcal{S}$  is individually  $r$ -robust, in order to bound  $\alpha$  from below, and thus  $\text{Cr}(\mathcal{S})$  as well. From [31] we know that any  $r$ -competitive single searcher strategy of the form  $Y = (y_j)_{j=1}^{\infty}$  satisfies  $y_j = O(b_r^j)$ . Given the labeling scheme (5), it follows that  $x_j = O(b_r^{j/n})$ , hence from the definition of  $\alpha$ ,  $\alpha \leq b_r^{1/n}$ . Therefore, (8) gives

$$\text{Cr}(\mathcal{S}) \geq 1 + 2 \frac{b_r^{2/n}}{b_r - 1} = 1 + 2 \frac{b_r^{1/q}}{b_r - 1},$$

which completes the proof.  $\blacktriangleleft$

We give some intuition behind the significance of the mapping (5) in the proof. The labeling accomplishes two goals: First, it leads to (6), whose sums in the numerator and the denominator contain summands with “contiguous” indices: this is an essential requirement for the application of Gal's theorem. Second, it implies that each strategy  $S_j$  is of the form  $(x_{\pi(j+nl)})_{l=0}^{\infty}$ , where  $\pi$  is a bijection over  $\{1, \dots, n\}$ , which allows us to argue that  $\alpha \leq b_r^{1/n}$ .

### 3.1 Extension to weak predictions

We show how to extend the upper bound to incorporate weak predictions. In this setting, as discussed in Section 1, given advice of size  $k$ , and robustness requirement  $r \geq 9$ , the searcher specifies a tolerance parameter  $H \leq k/2$ . The objective is to obtain an  $r$ -robust strategy of minimum competitive ratio assuming that at most  $H$  advice bits are erroneous.

To address this problem, we will make use of a result by Rivest *et al.* [50], who studied games with a *lying responder*. In their setting, given  $k \in \mathbb{N}^+$ ,  $H \leq k/2$ , and a domain  $\mathcal{D} = \{1, \dots, m\}$ , the objective is to find the index of an unknown  $x \in \mathcal{D}$ , using  $k$  queries, of which up to  $H$  may receive incorrect responses. A query can be a comparison query of the form “Is  $x \leq M$ ?”, for some given  $M \in [1, m]$ , or more generally, a subset query of the form “Is  $x$  in  $S$ ?”, where  $S$  is a subset of the domain  $\mathcal{D}$ . Define the sum of binomial coefficients  $\binom{N}{m} := \sum_{j=0}^m \binom{N}{j}$ , for  $m \leq N$ . In [50] it was shown that as long as  $m \leq 2^k / \binom{k}{H}$ ,  $k$  comparison queries suffice to find  $x$  in the above game, in the presence of at most  $H \leq k/2$  errors. This leads to the following extension of Theorem 1.

**► Theorem 4.** *For any  $r \geq 9$ , and any  $H \leq k/2$ , there is an  $r$ -robust strategy for searching on the line with  $k$ -bit advice that has competitive ratio at most  $1 + 2 \frac{b_r^{1/q}}{b_r - 1}$ , where  $q = 2^{k-1} / \binom{k}{H}$ .*

We can further show that

$$\frac{1}{q} \leq \frac{1}{2^{k(1-\mathcal{H}(\frac{H}{k}))}-1},$$

where  $\mathcal{H}$  denotes the *binary entropy* function. This allows for a direct comparison to the Pareto-optimal upper bound of Theorem 1. In particular, we observe that as  $k$  increases, the effect of the advice error in the competitive ratio becomes marginal, even if  $H$  is as high as linear in  $k$ .

#### 4 Ray search with directional prediction

In this section, we study  $m$ -ray search in the setting in which the prediction is the ray of the hiding target. Without loss of generality, we suppose that the prediction is the ray indexed 0.

For the upper bound, we consider the following strategy that generalizes the biased search approach of [20]. The searcher fixes some  $b > 1$  and  $\delta > 1$ , to be specified later, and explores the rays in the cyclic order  $0, 1, \dots, m-1$ . If the ray visited in the  $i$ -th iteration is ray 0, it explores it to a length equal to  $\delta b^i$ , otherwise, i.e., if the visited ray is in  $\{1, \dots, m-1\}$ , it explores it to a length equal to  $b^i$ . Thus the search combines elements of geometric search with a bias towards the predicted ray, as expressed by the parameter  $\delta$ .

► **Theorem 5.** *For every  $b > 1$ ,  $\delta > 1$ , the strategy described above has consistency at most  $1 + 2\frac{b^m}{b^m-1} + \frac{2}{\delta}\frac{b^m}{b^m-1}\frac{b^m-b}{b-1}$ , and robustness at most  $1 + 2\delta\frac{b^{m+1}}{b^m-1} + 2\frac{b^{m+1}}{b^m-1}\frac{b^m-b}{b-1} - 2b^m$ .*

Observe that if  $\delta = 1$ , then both the consistency and the robustness of the above strategy are equal to  $1 + 2\frac{b^m}{b^m-1}$ , as expected (i.e., the competitive ratio of a geometric strategy with base  $b$ ). For any fixed  $b$ , by increasing  $\delta$ , the consistency of the resulting strategy improves, at the expense of its robustness. We would like thus to optimize the robustness by choosing  $\delta$  as a function of  $b$ ,  $m$  and the desired consistency, however it is not obvious that this is possible analytically. Instead, suppose that we choose  $b = (m+1)/m$ , namely the base of the geometric strategy that results in an optimal competitive ratio for  $m$ -ray search equal to  $r_m^* = 1 + 2\rho_m^*$ . Then  $\frac{b^m}{b^m-1} \leq e/(e-1)$ , which implies that the consistency of the strategy is at most

$$1 + 2\frac{e}{e-1} + \frac{2}{\delta}\frac{e}{e-1}(\rho_m^* - m) = \frac{2}{\delta}\frac{e}{e-1}(\rho_m^* - m) + O(1).$$

On the other hand, the robustness of the strategy is at most

$$1 + 2\delta\frac{81}{36} + 2\frac{81}{36}(\rho_m^* - m) - 4 = \frac{9}{2}(\delta + \rho_m^* - m) + O(1).$$

Therefore, if we would like the strategy to be  $c$ -consistent, where  $c = O(1) + 2\tilde{c}$ , for some  $\tilde{c}$ , we can choose  $\delta$  to be equal to  $\frac{e}{(e-1)\tilde{c}}(\rho_m^* - m)$ , and the resulting robustness is then at most  $\frac{9}{2}(\rho_m^* - m)(1 + \frac{e}{(e-1)\tilde{c}}) + O(1)$ . We can also obtain more precise tradeoffs as  $m \rightarrow \infty$ , since in this case, it is known that  $r_m^* = 1 + 2\rho_m^* = 1 + 2em$ .

► **Corollary 6.** *For  $m \rightarrow \infty$ , the above strategy has consistency at most  $1 + 2\frac{e}{e-1} + \frac{2}{\delta}em$ , and robustness at most  $2e(m + \frac{\delta}{e-1})$ . In particular, given  $\tilde{c}$ , the strategy is  $(O(1) + 2\tilde{c})$ -consistent, and  $(O(1) + 2em(1 + \frac{e}{(e-1)\tilde{c}}))$ -robust.*

Next, we show a negative result on the tradeoff between the consistency and robustness that any strategy can achieve. The proof follows an approach that we generalize in the weak predictions setting (proof of the lower bound in Theorem 8).

► **Theorem 7.** *Any  $c$ -consistent strategy for searching with directional prediction, where  $c = 1 + 2\tilde{c}$ , has robustness at least  $1 + 2\rho_{m-1}^*(1 + \frac{1}{\tilde{c}-1})$ . In particular, for  $m \rightarrow \infty$ , its robustness is at least  $1 + 2e(m-1)(1 + \frac{1}{\tilde{c}-1})$ .*

#### 4.1 Extension to weak predictions

We consider the model in which if the predicted ray is  $h \in \{0, \dots, m-1\}$ , then the searcher would like to minimize its competitive ratio, assuming that the target hides in one of the rays in the interval  $[h - H \bmod m, h + H \bmod m]$ , where  $H \leq m/2$  is the tolerance parameter. This captures the case that the hiding ray is expected to be in a vicinity of the predicted ray, with respect to the tolerance of the searcher. We denote this set of rays by  $R_H$ , and its complement, by  $\bar{R}_H$ , and note that  $|R_H| = 2H + 1$  and  $|\bar{R}_H| = m - 2H - 1$ . Without loss of generality, we may assume that  $R_H = \{0, \dots, 2H\}$ .

We prove an asymptotically tight bound on the tradeoff between the competitive ratio and the robustness, that generalizes the error-free setting. Note that every strategy has competitive ratio at least  $1 + 2\rho_{2H+1}^*$ , since the weak prediction may incur a search in a  $(2H+1)$ -ray star. We also obtain an interesting corollary: as the competitive ratio approaches the optimal bound of  $1 + 2\rho_{2H+1}^*$ , the robustness increases dramatically.

► **Theorem 8.** *For every  $\tilde{c} > \rho_{2H-1}^*$  there exists a strategy with directional hint that has competitive ratio  $1 + 2\tilde{c}$ , and robustness at most  $O(\frac{\rho_{2H+1}^*}{\tilde{c} - \rho_{m-2H-1}^*}(m - 2H))$ . Furthermore, this bound is tight, i.e., every strategy of competitive ratio  $1 + 2\tilde{c}$  has robustness at least  $\Omega(\frac{\rho_{2H+1}^*}{\tilde{c} - \rho_{m-2H-1}^*}(m - 2H))$ .*

**Proof.** We first prove the upper bound, which generalizes the strategy we used in the context of consistency/robustness tradeoffs. Define  $b = \frac{2H+1}{2H}$ , i.e., the optimal base of a geometric strategy for searching in a  $(2H+1)$ -ray star, and  $\delta > 1$ , to be specified later. Consider a cyclic strategy which visits rays  $0, \dots, m-1$  in this order, and which works in rounds. Specifically, in round  $i$ , it explores ray  $j \in R_H$  to length  $\delta b^{(2H+1)i+j}$ , and every ray in  $\bar{R}_H$  to length  $b^{(2H+1)i+2H}$ . The competitive ratio of this strategy, assuming error at most  $H$ , is maximized for targets hiding infinitesimally beyond the turn points on ray  $2H$  in  $R_H$ . Simple calculations show that the competitive ratio is

$$1 + 2\rho_{2H+1}^* + \Theta\left(\frac{1}{\delta} \frac{b^{2H+1}}{b^{2H+1} - 1}(m - 2H - 1)\right),$$

and note that  $\frac{b^{2H+1}}{b^{2H+1} - 1}$  is at most  $e/(e-1)$ , by the choice of  $b$ . Thus, for the competitive ratio to be at most  $1 + 2\tilde{c}$ , it must be that

$$\delta \in \Omega\left(\frac{m - 2H}{\tilde{c} - \rho_{2H+1}^*}\right). \tag{9}$$

The robustness of the strategy is evaluated for a target hiding at distance infinitesimally beyond the turn points of the searcher on ray  $m-1$ . After simple calculations we obtain that the robustness is at most  $O(\delta \rho_{2H+1}^*(m - 2H + 1))$ , which from (9) is at most  $O(\frac{\rho_{2H+1}^*}{\tilde{c} - \rho_{2H+1}^*}(m - 2H))$ , and which proves the upper bound.

We now proceed with the lower bound. Any strategy for the problem consists of *phases*, which alternate between searching a subset of  $R_H$  and a subset of  $\bar{R}_H$ . Namely, every strategy  $X$  is of the form  $X = (x_i)_{i \geq 0}$ , in which  $x_i$ , for even  $i$ , describes the aggregate explored length of  $X$  on rays that belong exclusively in  $R_H$ , and  $x_i$  for  $i$  odd, describes the aggregate explored length on rays that belong exclusively in  $\bar{R}_H$ . Thus, in each phase  $i$ , the searcher incurs a cost of  $2x_i$ , for all  $i$  (except for the phase at which the target is found).

Define  $S_i = \sum_{j=0}^i x_{2j}$ , and  $S'_i = \sum_{j=0}^{i-1} x_{2j+1}$ . Then from the competitiveness of the strategy, for all even  $i$ , and for any target  $t_H$  hiding in  $R_H$  that is discovered in phase  $2(i+1)$ ,

$$1 + 2 \frac{S_i + S'_i}{d(t_H)} \leq c \Rightarrow \tilde{c} \geq \frac{S_i + S'_i}{d(t_H)}. \quad (10)$$

We know that searching in a  $(2H+1)$ -ray has competitive ratio at least  $1 + 2\rho_{2H+1}^*$ . This means that for all  $i$ , there exists a target  $d_i$  that is discovered in phase  $2(i+1)$  such that

$$1 + 2 \sup_i \frac{S_i}{d_i} \geq 1 + 2\rho_{2H+1}^*,$$

hence there exists some  $\bar{i}$  for which the above inequality gives  $1 + 2 \frac{S_{\bar{i}}}{d_{\bar{i}}} \geq 1 + 2\rho_{2H+1}^* - \epsilon$ , where  $\epsilon \rightarrow 0$ , as  $\bar{i}$  is allowed to be unbounded. To simplify the exposition, we can thus assume that  $\epsilon = 0$ , and obtain

$$d(t_{\bar{i}}) \leq \frac{S_{\bar{i}}}{\rho_{2H+1}^*}. \quad (11)$$

Moreover, for any  $i$ , there exists a hiding position for a target  $t'_i$  in  $\bar{R}_H$  that is first discovered in phase  $2i+1$  it must be that

$$1 + 2 \frac{S'_i}{d(t'_i)} \geq m - 2H - 1 \Rightarrow d(t'_i) = O\left(\frac{S'_i}{m - 2H - 1}\right), \quad (12)$$

since  $2S'_i$  describes the cost incurred by the searcher on rays in  $\bar{R}_H$ , right before phase  $2i+1$  starts. Note also that this inequality holds *for all*  $i$ , unlike (11), that holds only for  $\bar{i}$ .

To bound the robustness, consider the phase  $2\bar{i}+1$ , with  $\bar{i}$  as defined above, and the target  $t'_{\bar{i}}$ , again as defined above. Then we have that

$$\text{Robustness} \geq 1 + 2 \frac{S_{\bar{i}} + S'_{\bar{i}}}{d(t'_{\bar{i}})} = \Omega\left(\left(1 + \frac{S_{\bar{i}}}{S'_{\bar{i}}}\right)(m - 2H)\right), \quad (13)$$

from (12). Moreover, from (10) and (11) we have that

$$\frac{S_{\bar{i}} + S'_{\bar{i}}}{S'_{\bar{i}}} \leq \frac{\tilde{c}}{\rho_{2H+1}^*} \Rightarrow \frac{S_{\bar{i}}}{S'_{\bar{i}}} \geq \frac{\rho_{2H+1}^*}{\tilde{c} - \rho_{2H+1}^*},$$

and substituting the above inequality to (10) yields the result.  $\blacktriangleleft$

## 5 Ray search with positional prediction

In this section we study  $m$ -ray searching in the setting in which the prediction is the position of the target in the star environment. Namely, the prediction  $h$  is a pair  $(d_h, u_h)$ , where  $d_h$  is the predicted distance from  $O$  and  $u_h$  is the predicted ray. We first show the upper bound.

► **Theorem 9.** *For any  $r \geq r_m^*$ , there is an  $r$ -robust strategy of consistency at most  $1 + 2 \frac{1}{b_r - 1}$ .*

We will now show that the strategy of Theorem 9 is Pareto-optimal. The proof of the following theorem generalizes, but also simplifies the lower bound of [3] which applies only to linear search ( $m = 2$ ). The crux in the proof is to exploit the properties of the parameter  $\alpha_Y$ , where  $Y$  will be defined as the sequence of search lengths of a cyclic strategy defined by a linear recurrence relation. In particular, these properties allow us to bypass technical complications related to the study of such relations, by establishing appropriate lower bounds (as opposed to solving the recurrence relation).

## 12:12 Competitive Search in the Line and the Star with Predictions

► **Theorem 10.** For any  $r \geq r_m^*$ , no  $r$ -robust strategy for searching with positional prediction has consistency better than  $1 + 2\frac{1}{b_r - 1}$ .

**Proof sketch.** Using techniques rooted in previous studies of star search, we can show that there exists a *cyclic* strategy of the form

$$y_{j_h} = h, \text{ for some index } j_h \quad \text{and} \quad 1 + 2\frac{\sum_{i=0}^j y_i}{y_{j-m+1}} = r, \text{ for all } j \in [m-1, j_h],$$

which is  $r$ -robust and minimizes the consistency (among all  $r$ -robust strategies). It follows that for all  $j \leq j_h$ , the search length  $y_j$  is determined by the recurrence

$$y_j = r(y_{j-m+1} - y_{j-m}), \quad (14)$$

with some initial conditions  $y_0, \dots, y_{m-1}$ . We have that

$$d(Y, h) = \sum_{j=0}^{j_h} y_j = d_h + 2 \sum_{j=0}^{j_h-1} y_j = d_h + 2r(y_{j_h-m+1} - y_0) + \sum_{j=0}^{m-1} y_j, \quad (15)$$

where we used the fact that  $\sum_j y_j$  is telescoping, as seen by (14). From (15) we have  $\frac{d(Y, h)}{d_h} = 1 + 2\frac{ry_{j_h-m+1}}{d_h} + \frac{1}{d_h}(\sum_{j=0}^{m-1} y_j - y_0)$ . Since  $Y$  is cyclic, and  $d_h = y_{j_h}$ , we obtain that

$$\sup_h \frac{d(Y, h)}{d_h} \geq 1 + 2 \sup_{j_h} \frac{ry_{j_h-m+1}}{y_{j_h}} = 1 + 2r \sup_{j_h} \frac{y_{j_h-m+1}}{y_{j_h}}. \quad (16)$$

Define the functional  $F_j(Y) = \frac{y_{j-m+1}}{y_j}$ . This functional satisfies the conditions of Gal's functional theorem [26], hence  $\sup_j \frac{y_{j-m+1}}{y_j} \geq \frac{\alpha_Y^{j-m+1}}{\alpha_Y} = \alpha_Y^{-m}$ . Since  $Y$  is  $r$ -robust, as discussed in Section 2  $r \geq \text{Cr}(X) \geq \frac{\alpha_Y^m}{\alpha_Y - 1}$ , where it must be  $\alpha_Y \leq b_r$ , from the definition of  $b_r$ . Thus, (16) gives

$$\sup_h \frac{d(Y, h)}{d_h} \geq 1 + 2\frac{\alpha_Y^m}{\alpha_Y - 1}\alpha_Y^{-m} = 1 + 2\frac{1}{\alpha_Y - 1} \geq 1 + 2\frac{1}{b_r - 1}.$$

Hence, the consistency of  $Y$  is at least  $1 + 2\frac{1}{b_r - 1}$ , and thus so is the consistency of  $X$ . ◀

### 5.1 Extension to weak predictions

Given the prediction  $h$  related to a target  $t$ , we define the prediction *error* as the distance between  $t$  and  $h$  in the star, normalized by the distance  $d(h)$  of the prediction's position from the origin. Namely,  $\eta = \frac{|d(t) - d(h)|}{d(h)}$ . We distinguish between different types of the error: If  $d$  and  $h$  are in the same ray, but  $d(t) > d(h)$  we call the error *positive*, whereas if  $d$  and  $h$  are in the same ray, but  $d(t) < d(h)$  we call the error *negative*. If the error is neither positive or negative, then  $h$  and  $t$  are in different rays.

Let  $X_h$  denote the Pareto-optimal strategy of Theorem 9. Let  $H > 0$  denote the tolerance parameter that is specified by the searcher, and consider the strategy  $X_{h(1+H)}$ , i.e., the strategy that pretends that the prediction is at the same ray as  $h$ , but at distance  $d(h)(1+H)$  from  $O$ . The following result is a corollary of Theorem 9.

► **Corollary 11.** For any  $H > 0$  and  $r \geq r_m^*$ , strategy  $X_{h(1+H)}$  is  $r$ -robust and has competitive ratio at most  $\min\{1 + 2\frac{1+H}{b_r - 1}, r\}$ , if the error is either positive or negative, and at most  $H$ . Otherwise, its competitive ratio is at most  $r$ .

Last, we can show that the above tradeoffs are tight.

► **Theorem 12.** For any  $r$ -robust strategy with positional prediction, there exists  $q > 0$  such that its competitive ratio is no better than  $\min\{1 + 2\frac{1+q}{b_r - 1}, r\}$  for positive or negative error at most  $q$ . Otherwise, its competitive ratio is at least  $r$ .

## Abstract

We study the nascent setting of online computation with *imperfect* advice, in which the online algorithm is enhanced by some prediction encoded in the form of an imperfect, and possibly erroneous binary string. The algorithm is oblivious to the advice error, but defines a desired *tolerance*, namely an upper bound on the number of erroneous advice bits it can tolerate. This is a model that generalizes the *Pareto-based* advice model, in which the performance of the algorithm is only evaluated at the extreme values of error (namely, if the advice has either no errors, or if it is generated adversarially). It also subsumes the model in which the algorithm elicits a prediction on the online sequence, via imperfect responses to a number of *binary queries*.

In this work, we establish connections between games with a lying responder, also known as *Rényi-Ulam games*, and the design and analysis of online algorithms with imperfect advice. Specifically, we demonstrate how to obtain upper and lower bounds on the competitive ratio for important online problems such as time-series search, online bidding, and fractional knapsack. Our techniques provide the first lower bounds for online problems in this model. We also highlight and exploit connections between competitive analysis with imperfect advice and fault-tolerance in multiprocessor systems. Last, we show how to waive the dependence on the tolerance parameter, by means of resource augmentation and robustification.

## 1 Introduction

Online computation, and *competitive analysis*, in particular, have served as the definitive framework for the theoretical analysis of algorithms in a state of uncertainty. While the early, standard definition of online computation [37] assumes that the algorithm has no knowledge in regard to the request sequence, in practical situations, the algorithm may indeed have certain limited, but possibly inaccurate such information (e.g., some lookahead, or historical information on typical sequences). Hence, there is a clear need for more nuanced models that capture the power and limitations of online algorithms enhanced with external information.

One such approach, within Theoretical Computer Science, is the framework of *advice complexity*; see [18, 9, 20], the survey [10] and the book [25]. In the advice-complexity model (and in particular, the *tape* model [8, 9]), the online algorithm receives a string that encodes information concerning the request sequence, and which can help improve its performance. The objective is to quantify the tradeoffs between the size of the advice (in terms of the

number of bits) and the competitive ratio of the algorithm. This model places stringent requirements: the advice is assumed to be error-free, and may be provided by an omnipotent oracle. Thus, as noted in [34], this model is mostly of theoretical significance.

A different and more practical approach studies the effect of *predictions* towards improving the competitive ratio. In this model, the online algorithm is enhanced with some imperfect information concerning the request sequence, without restrictions on its size. One is interested in algorithms whose performance degrades gently as a function of the prediction *error*, and specifically perform well if the prediction is error-free (what is called the *consistency* of the algorithm), but also remain robust under any possible error (what is called the *robustness* of the algorithm). This line of research was initiated with the works [31] and [35], and a large number of online problems have been studied under this model (see, e.g., the survey [34] and the online collection [29]).

A combination of the advice complexity and prediction models is the *untrusted or Pareto-based advice* model, introduced in [5]. Here, parts of the advice may be erroneous, and the algorithm's performance is evaluated in two extreme situations, in regard to the advice error. At the one extreme, the advice is error-free, whereas, at the other extreme, the advice is generated by a (malicious) adversary who aims to maximize the performance degradation of the algorithm. Using the terminology of algorithms with predictions, these two competitive ratios are called consistency and robustness, respectively. The objective is to identify algorithms that are *Pareto-efficient*, and ideally *Pareto-optimal*, i.e., attain the best-possible tradeoffs between these two extreme measures. Several online problems have been studied recently within this framework of Pareto-optimality (both within the advice and the predictions models); see, e.g., [39, 28, 26, 4, 6].

## 1.1 Online computation with imperfect advice

The starting observation that motivates this work is that the Pareto-based framework of untrusted advice only focuses on extreme competitive ratios, namely the consistency and the robustness. A more general issue, instead, is to evaluate the impact of the advice error on the performance of the online algorithm. Given an advice string of size  $k$ , let us denote by  $\eta \leq k$  the number of erroneous bits. Naturally, the algorithm does not know the exact advice error ahead of time. Instead, the algorithm defines an application-specific parameter  $H \leq k$  which determines the desired *tolerance* to errors, or, equivalently, an anticipated upper bound on the advice error. This is motivated by recent works in learning-enhanced online algorithms with *weak predictions*, in which the prediction is an upper bound of some pertinent parameter of the input (see e.g., online knapsack with frequency predictions [23], where the prediction is an upper bound on the number of items of each value that appear online). Our objective is to quantify the tradeoffs between advice size, tolerance and competitive ratio, both from the point of upper and lower bounds.

A different interpretation of imperfect advice treats each advice bit as a (potentially erroneous) response to a *binary query* concerning the input. Hence, one may think of  $k$ -bit advice as a prediction elicited by means of  $k$  imperfect binary experts. Note that queries are known to help improve the performance of approximation algorithms in ML applications. For example, [33] studied clustering with noisy queries, where a query asks whether two points should belong in the same cluster, and where each query receives a correct response with probability  $p$  that is known to the algorithm. A different example is parsimonious learning-augmented caching [22], in which the system learns the predicted next-arrival time of certain appropriately queried pages.

In this work, we study the power, but also the limitations of online algorithms with adversarially erroneous queries. Unlike [33], we do not rely on any probabilistic assumptions concerning the query responses. To our knowledge, the imperfect advice model (in particular, its binary query-based interpretation) has only been applied to the problems of *contract scheduling* [6] and time-series search [7], from the point of view of upper bounds. While these works showed that binary queries help improve the algorithmic performance, both in terms of theoretical and empirical analysis, no principled methodology for obtaining lower bounds has been developed so far.

## 1.2 Contribution

We establish connections between games with a lying responder and the design and analysis of online algorithms with imperfect advice. Namely, we show how to leverage results from the analysis of *Rényi-Ulam* games, and obtain both positive and negative results on the competitive analysis. We apply these tools to three important and well-studied online problems, namely time-series search, online bidding, and online fractional knapsack. Our results improve the known upper bounds for these problems, where such results were already known, but also provide the first lower bounds on the competitive ratio of online problems in this setting, without any restrictive assumptions.

More precisely, we begin as a warm-up<sup>1</sup> with the time-series search problem in Section 3, which illustrates how these techniques can help us improve upon the results of [7]; we also show how to evaluate the competitive ratios, using approximations based on the binary entropy function. In Section 4, we study a more complex application, namely the online bidding problem, first studied in [5] in the context of untrusted advice. Here, the crucial part is establishing near-optimal lower bounds. We achieve this by formulating a multi-processor version of online bidding in  $l \leq 2^k$  processors, in which a certain number of processors may be faulty; we then relate the competitive ratio of this problem to the imperfect advice setting, by relating fault-tolerance in the processor level, to the inherent error in Rényi-Ulam games. In Section 5 we study the online fractional knapsack problem. Here, we present an algorithm whose competitive ratio converges to 1 at a rate exponential in  $k$ , as long as  $H < k/2$ . We also present a near-matching lower bound that shows that our algorithm is close-to-optimal. For the upper bound, the crux is to allocate queries so as to approximate two appropriately defined parameters of the instance. For the lower bound, we use an information theoretic argument. Specifically, we show a reduction from Rényi-Ulam games: if there existed an algorithm of competitive ratio better than a certain value, one could play the game beyond the theoretical performance bound, which is a contradiction.

As explained above, the parameter  $H$  expresses the algorithm's desired tolerance to errors, and is thus application-specific. In Section 6 we show how to waive the assumption that the precise tolerance is known ahead of time, in two different ways: First, by *resource-augmentation* arguments, i.e., by comparing the performance of an algorithm with perfect (error-free) advice of size  $k$  to that of an algorithm with  $l > k$  advice bits but potentially very high advice error. Second, by *robustifying* the algorithm, namely by requiring that the algorithm performs well even if the error happens to exceed the tolerance parameter.

The techniques we develop can be applicable to other online problems. Specifically, our approach to the online bidding problem defines the following general framework: For upper bounds, one would aim to define a collection of “candidate” algorithms that are closely

---

<sup>1</sup> For *ski rental*, which is another canonical warm-up problem, [5] showed that a single advice bit suffices to obtain optimal consistency/robustness. Hence, the problem is resolved under the imperfect advice model as well.

ranked in terms of their worst-case performance. Then the advice can be used so as to select a suitable candidate from this collection that is close to the best-possible. For lower bounds, one would aim to show that in any collection of candidate algorithms, the erroneous queries may have to always return a solution sufficiently far, in terms of “rank”, from the best one; then one needs to relate the concept of “rank” to performance, from a lower-bound point of view. This last part highlights connections between an online problem with adversarial advice and its fault-tolerant version in a parallel system (with no advice). On the other hand, our approach to the time-series and fractional knapsack problems illustrate another general technique: For upper bounds, one should identify some important parameters of the problem, then allocate the queries appropriately so as to approximate them in the presence of response errors. For lower bounds, information-theoretic arguments should establish a reduction from a Rényi-Ulam game to the online problem.

There are two additional observations concerning the results in this work. First, we allow *adaptive* queries, in that the response to the  $i$ -th query is a function of responses to the previous  $i - 1$  queries. Second, it is important to note that the results we present cannot be obtained straightforwardly by applying some error-correcting code. More precisely, one may be tempted to dedicate some advice bits towards error correction and use the remaining error-free bits in the spirit of classic advice complexity results. However, such an approach may very well be suboptimal since, depending on the problem at hand, an optimal algorithm may benefit more from a large number of somewhat erroneous advice bits than from a smaller number of perfect bits, and the analysis must take into account this possibility.

Due to space limitations, we omit or only sketch certain technical proofs. We refer to the full version on arXiv for the complete proofs.

## 2 Games with a lying responder

We review some core results related to games with a lying responder which will be in the heart of the analysis of online problems with imperfect advice. We are particularly interested in [36], which studied games between a *questioner* and a *responder*, related to an unknown value  $x$  drawn from a domain  $\mathcal{D}$ , where  $\mathcal{D}$  is a subset of reals or in general a totally ordered set. The questioner may ask general queries of the form “is  $x$  in  $S$ ”, where  $S$  is some subset of  $\mathcal{D}$ , and which are called *subset* queries. The upper bounds of [36] hold even if the questioner asks much simpler queries, namely *comparison* queries of the form “is  $x$  at most  $a$ ”, for some given  $a$ . Both the upper and lower bounds in [36] are expressed in terms of partial sums of binomial coefficients. Formally, we define:

$$\binom{N}{m} := \sum_{j=0}^m \binom{N}{j}, \text{ for } m \leq N.$$

We are interested, in particular, in the following game played over a continuous space:

**CONTINUOUSSEARCH( $k, H$ ) game.** In this game,  $x$  is a real number with  $x \in \mathcal{D} = (0, 1]$ , and the questioner asks  $k$  queries, at most  $H$  of which may receive erroneous responses. The objective of the questioner is to find an interval  $I_x$  such that  $x \in I_x$  and  $|I_x|$  is minimized.

► **Lemma 1** ([36]). *Any questioner’s strategy for CONTINUOUSSEARCH( $k, H$ ) with  $H \leq k/2$  is such that  $|I_x| \geq \binom{k}{H} / 2^k$ . Moreover, for  $H \leq k/2$ , there is a strategy, named C-WEIGHTING, that uses comparison queries and outputs an interval  $I_{W,x}$  with  $|I_{W,x}| \leq \binom{k-H}{H} / 2^{k-H}$ .*

The following game will be useful in our analysis of online time-series and fractional knapsack.

**FIND( $k, H$ ) game.** In this game, given  $k$  and  $H \leq k/2$ , and  $\mathcal{D} = \{1, \dots, m\}$ , the objective is to find an unknown  $x \in \mathcal{D}$ , using  $k$  queries, up to  $H$  of which may be answered incorrectly.

The proof of the following theorem is direct from Lemma 1:

► **Theorem 2.** *The largest positive integer  $\mu(k, H)$  such that a questioner can identify any number  $x \in \{1, 2, \dots, \mu(k, H)\}$  in the FIND( $k, H$ ) game is such that*

$$2^{k-H} / \binom{k-H}{H} \leq \mu(k, H) \leq 2^k / \binom{k}{H}.$$

We define two further games that will be of interest to our analysis. The first is related to searching in cyclic permutations, and will be useful in the upper-bound analysis of online bidding.

**MINCYCLIC( $n, k, H$ ) game.** Given an array  $A[0 \dots n-1]$  whose elements are an unknown cyclic permutation of  $\{0, \dots, n-1\}$ , the objective is to use  $k$  queries, at most  $H \leq k/2$  of which can be erroneous, so as to output an index of the array whose element is as small as possible.

► **Theorem 3.** *There is a questioner's strategy for MINCYCLIC( $n, k, H$ ) based on  $k$  comparison queries that outputs an index  $j$  such that  $A[j] \leq \lceil n \binom{k-H}{H} / 2^{k-H} \rceil$ , for all  $H \leq k/2$ .*

Last, we define a game that is related to searching in general permutations, and it will be useful in establishing lower bounds on the competitiveness of online bidding.

**SEARCH( $n, k, H$ ) game.** Given an array,  $A[0, \dots, n-1]$  whose elements are an unknown permutation of  $\{0, \dots, n-1\}$ , the objective is to use  $k$  queries, at most  $H$  of which can be erroneous, so as to output an index of the array whose element is as small as possible.

► **Theorem 4.** *For any questioner's strategy for the SEARCH( $n, k, H$ ) game, there is a responder's strategy such that if  $e$  is the element of  $A$  that is returned, then  $A[e] \geq \lfloor n \binom{k}{H} / 2^k \rfloor$ .*

### 3 A warm-up: Online time-series search

The *online (time series) search* problem formulates a simple, yet fundamental setting in decision-making under uncertainty. In this problem, a player must sell an indivisible asset within a certain time horizon, e.g., within a certain number of days  $d$ , that is unknown to the player. On each day  $i$ , a price  $p_i$  is revealed, and the player has two choices: either accept the price, and gain a profit  $p_i$  (at which point the game ends), or reject the price (at which point the game continues to day  $i+1$ ). If the player has not accepted a price by day  $d$ , then it accepts by default the last price  $p_d$ . The competitive ratio of the player's algorithm is the worst-case ratio, over all price sequences, of the maximum price in the sequence divided by the price accepted by the player.

The problem was introduced and studied in [19] that gave a simple, deterministic algorithm that achieves a competitive ratio equal to  $\sqrt{M/m}$ , where  $M, m$  are upper and lower bounds on the maximum and minimum price in the sequence, respectively, and which are assumed to be known to the algorithm. This bound is optimal for deterministic algorithms. Time-series search is a basic paradigm in online financial optimization, and several variants and

generalizations have been studied [17, 30, 40, 16]; see also the survey [27]. The problem has also been used as a case study for evaluating several performance measures of online algorithms, including measures alternative to competitive analysis [11, 1].

Time-series search was recently studied under the imperfect advice framework in [7], who showed an upper bound of  $(M/m)^{2^{2H-k/2}}$  on the competitive ratio with  $k$ -bit advice and tolerance  $H$ , under the assumption that  $H \leq k/4$ . Note that no upper bound is known for  $H \in (k/4, k/2]$ . If the advice is error-free, i.e., in the advice-complexity model, then a tight bound on the competitive ratio equal to  $(M/m)^{\frac{1}{2^{k+1}}}$  is due to [16].

We show the following result, as an application of the  $\text{FIND}(k, H)$  game discussed in Section 2.

► **Theorem 5.** *Consider the online time series search problem, with imperfect advice of size  $k$  and tolerance  $H \leq k/2$ . There is an algorithm that uses  $k$  comparison queries, and that has competitive ratio at most  $(M/m)^{\frac{1}{U+1}}$ , where  $U = \lfloor 2^{k-H} / \binom{k-H}{H} \rfloor$ , for any  $H \leq k/2$ . In contrast, no (deterministic) algorithm based on  $k$  subset queries has competitive ratio less than  $(M/m)^{\frac{1}{L+1}}$ , where  $L = \lceil 2^k / \binom{k}{H} \rceil$ .*

**Proof.** We first show the upper bound. Let  $a_1, \dots, a_U, r$  be defined such that  $r = \frac{a_1}{m} = \frac{a_2}{a_1} = \dots = \frac{a_U}{a_{U-1}} = \frac{M}{a_U}$ , hence  $r = (M/m)^{1/(U+1)}$ . The algorithm uses  $k$  comparison queries so as to find the best *reservation* price, in the set  $\{a_i\}_{i=1}^U$ , i.e., a threshold  $p$  above which the algorithm will always accept a price in the sequence. In particular, it can choose  $p$  to be the maximum value in  $\{a_i\}_{i=1}^U$  that does not exceed the maximum price in the sequence. This follows from Theorem 2, since  $U \leq 2^{k-H} / \binom{k-H}{H}$ . From the definition of the set  $\{a_i\}_{i=1}^U$ , it easily follows that this algorithm has competitive ratio at most  $r$ , which completes the proof of the upper bound.

We now show the lower bound. By way of contradiction, suppose that there is an algorithm  $A$  for time-series search with  $k$ -bit imperfect advice, and of competitive ratio less than  $C = (M/m)^{\frac{1}{L+1}}$ . We will show that  $A$  could then be used in the  $\text{FIND}(k, H)$  game so as to identify, using  $k$  queries, an unknown value in  $\{1, \dots, L+1\}$ , which is a contradiction to the upper bound of Theorem 2.

To arrive at the contradiction, define  $a_1, \dots, a_L$  and  $r'$  such that

$$r' = \frac{a_1}{m} = \frac{a_2}{a_1} = \dots = \frac{a_L}{a_{L-1}} = \frac{M}{a_L},$$

hence  $r' = (M/m)^{\frac{1}{L+1}} = C$ . Consider a game between the online algorithm  $A$  and the adversary, in which the request sequences consist of prices in  $\{m, a_1, \dots, a_L, M\}$ . More precisely, consider the set of request sequences of the form  $\sigma_i = m, a_1, \dots, a_i$ , for all  $i \in [1, L+1]$ , where  $a_{L+1}$  is defined to be equal to  $M$ . In  $\sigma_i$ ,  $A$  must accept price  $a_i$  to be strictly less than  $C$ -competitive. Equivalently,  $A$  uses  $k$  queries with at most  $H$  errors, and finds  $a_i$  in the set  $\{a_j\}_{j=1}^{L+1}$ , which contradicts Theorem 2. ◀

### 3.1 Comparison of the bounds

In order to compare the upper and lower bounds of Theorem 5, we need to be able to evaluate the partial sum of binomial coefficients. Since this partial sum does not have a closed form, we will rely on the following useful approximation from [32]. Let  $\mathcal{H}$  denote the *binary entropy* function. Then

$$\frac{2^{N\mathcal{H}(\frac{m}{N})}}{\sqrt{8m(1-\frac{m}{N})}} \leq \binom{N}{m} \leq 2^{N\mathcal{H}(\frac{m}{N})}, \quad \text{for } 0 < m < N/2. \quad (1)$$

We will also use the following property of the binary entropy function

$$4p(1-p) \leq \mathcal{H}(p) \leq (4p(1-p))^{1/\ln 4}, \quad \text{for all } p \in (0, 1). \quad (2)$$

We first show that the algorithm of Theorem 5 improves upon the one of [7]. First, note that [7] assumes that  $H \leq k/4$ , whereas Theorem 5 applies to all  $H \leq k/2$ . Furthermore, we improve on the competitive ratio for all values of  $H$  and  $k$ . For this, it suffices to show that  $\left(\binom{k-H}{H}\right)/2^{k-H} < 2^{2H-k/2}$ , which, from (1) holds if  $2^{(k-H)(\mathcal{H}(\frac{H}{k-H})-1)} < 2^{2H-k/2}$ , or equivalently  $(k-H)(\mathcal{H}(\frac{H}{k-H})-1) < 2H-k/2$ . Let  $\tau$  be such that  $\tau = H/k$  (hence  $\tau \leq 1/2$ ), then the latter is equivalent to showing that  $\mathcal{H}(\frac{\tau}{1-\tau}) < \frac{1+2\tau}{2-2\tau}$ . Using (2), it suffices to show that

$$\left(\frac{4\tau(1-2\tau)}{(1-\tau)^2}\right)^{1/\ln 4} < \frac{1+2\tau}{2-2\tau},$$

which holds for all  $\tau \leq 1/2$ .

Next, we investigate how close the upper and lower bounds of Theorem 5 are to each other. Recall that the bounds are of the form  $(M/m)^{1/(U+1)}$ , and  $(M/m)^{1/(L+1)}$ . Using (1), and ignoring for simplicity the floors and ceilings, we obtain that

$$U \geq 2^{k(1-\tau)(1-\mathcal{H}(\frac{\tau}{1-\tau}))} \quad \text{and} \quad L \leq \sqrt{8k\tau(1-\tau)}2^{k(1-\mathcal{H}(\tau))}.$$

The above inequalities, along with (2) show that the upper and lower bounds are very close to each other, since for any fixed value of  $\tau$ , we have that  $U \geq 2^{\Theta(k)}$  and  $L \leq 2^{\Theta(k)}$ .

## 4 Online bidding

Online bidding was introduced in [15] as a canonical problem for formalizing doubling-based strategies in online and offline optimization problems, such as searching for a target on the line, minimum latency, and hierarchical clustering. In this problem, a player wants to guess a hidden, unknown real value  $u \geq 1$ . To this end, the player defines an (infinite) sequence  $X = (x_i)$  of positive, increasing *bids*, which is called its *strategy*. The *cost of discovering* the hidden value  $u$  using the strategy  $X$ , denoted by  $c(X, u)$ , is defined to be equal to  $\sum_{i=1}^{j_u} x_i$ , where  $j_u$  is such that  $x_{j_u-1} < u \leq x_{j_u}$ . Hence one naturally defines the competitive ratio of the bidder's strategy  $X$  as  $\text{Cr}(X) = \sup_u \frac{c(X, u)}{u}$ .

In the standard version of the problem, i.e, assuming no advice, the doubling strategy  $x_i = 2^i$  achieves optimal competitive ratio equal to 4. Online bidding was studied under the untrusted advice model in [5], which gave bounds on the consistency/robustness tradeoffs. It was also studied under a model in which the prediction is the hidden value in [3, 5]. The problem is related to contract scheduling, studied in [6], see also the discussion in Section 4.1.3.

### 4.1 Online bidding with imperfect advice

#### 4.1.1 Upper bound

The idea behind the upper bound is as follows. We will consider bidding sequences from a space of  $2^k$  geometrically-increasing sequences (see Definition 6). In the ideal situation of perfect advice, the  $k$  advice bits could be used to identify the best strategy in this space. In the presence of advice errors, we will show how to exploit the cyclic structure of this space, in conjunction with our upper bound for the MINCYCLIC game (Theorem 3), so as to find a strategy that is not too far from the optimal.

We first define the space of geometrically-increasing bidding sequences.

► **Definition 6.** For given  $b > 1$ , and  $l \in \mathbb{N}^+$  define  $\mathcal{X}_{b,l}$  as the set of bidding sequences  $\{X_0, \dots, X_{l-1}\}$ , in which  $X_i = (b^{i+jl})_{j=0}^{\infty}$ , for all  $i \in [0, l-1]$ .

From the definition of  $\mathcal{X}_{b,l}$ , it is easy to see that for any potential target  $u$ , there is a cyclic permutation  $\pi$  of  $\{0, \dots, l-1\}$  which determines an ordering of the strategies in  $\mathcal{X}_{b,l}$  in terms of their performance. More precisely, suppose that  $X_{\pi(0)}$  is the best sequence that discovers  $u$  at least cost, say  $C$ . Then  $X_{\pi(i)}$  discovers  $u$  at cost at most  $b^i C$ . This property can help us show the following upper bound:

► **Theorem 7.** There is a bidding strategy based on  $k$  comparison queries of competitive ratio at most  $\frac{1+U}{2^k} \left(1 + \frac{2^k}{1+U}\right)^{1+\frac{1+U}{2^k}}$ , where  $U = \lceil 2^H \binom{k-H}{H} \rceil$ .

### 4.1.2 Lower bound

The idea behind the lower bound is as follows. With  $k$  advice bits, the best one can do is choose the best strategy from a set  $\mathcal{X}$  that consists of at most  $2^k$  strategies. Note that if the advice were error-free,  $|\mathcal{X}|$  could be as large as  $2^k$ ; however, in the presence of errors, the algorithm may choose to narrow  $|\mathcal{X}|$ .

Our approach combines two ideas. The first idea uses the abstraction of the SEARCH( $n, k, H$ ) game, and the lower bound of Theorem 4. This result will allow us to place a lower bound on the rank of the chosen strategy, where the best strategy has rank 0. The second idea is to define a *measure* that relates how much worse a strategy of rank  $j$  in  $\mathcal{X}$  has to be relative to the best strategy in  $\mathcal{X}$ . We will accomplish this by appealing to the concepts of *parallelism* and *fault tolerance*.

More precisely, given integers  $p$ , and  $\phi$ , with  $\phi < p$ , we define the *fault-tolerant parallel bidding* problem, denoted by FPB( $p, \phi$ ), as follows. The player is allowed to run, in parallel,  $p$  bidding strategies; however,  $\phi$  of these strategies can be *faulty*, in that they never discover the target; e.g., we can think of a fault strategy as one in which the player abruptly stops submitting bids, at some point in time, akin to a “byzantine” failure. The cost of discovering a target  $u$  is then defined as the minimum cost at which one of the  $p - \phi$  non-faulty strategies discovers the target, noting that the faults are dictated by an adversary that aims to maximize this cost. The competitive ratio is defined accordingly.

The next theorem is the main technical result for FPB( $p, \phi$ ), which gives a lower bound on the competitive ratio of any strategy for this problem, as a function of the parameters  $p$ ,  $\phi$  and  $\alpha_{\bar{X}}$ . Here,  $\bar{X}$  is defined as the sorted sequence of all bids in the  $p$ -parallel strategy  $X$ , in non-decreasing order. Moreover, given a sequence  $X$  of positive reals, we define  $\alpha_X$  to be equal to  $\limsup_{i \rightarrow \infty} x_i^{1/i}$ .

► **Theorem 8.** Every  $p$ -parallel strategy  $X$  for FPB( $p, \phi$ ) has competitive ratio  $Cr(X) \geq \frac{\alpha_{\bar{X}}^{p+1+\phi}}{\alpha_X^{\phi-1}}$ .

**Proof sketch.** We use properties of  $p$ -parallel strategies so as to show that any such strategy satisfies  $Cr(X) \geq \sup_q \frac{\sum_{i=0}^{q+\phi-1} \bar{x}_i}{\sum_{i=q}^{q-(p-1)} \bar{x}_i}$ . We then use Gal’s functional theorem [21] to obtain the result. We omit several technical details. ◀

We now show how to obtain a lower bound for the problem by combining the above ideas. We emphasize a subtle point: unlike error-free advice of size  $k$ , where one should always choose the best strategy out of a collection of exactly  $2^k$  strategies, it is conceivable that, in the presence of errors, this collection could very well be of size  $l < 2^k$ . This is because, as  $l$  decreases, so does the effect of errors on the competitive ratio. In other words, we need to establish the result for *all* values  $l \leq 2^k$ , and not only for  $l = 2^k$ .

► **Theorem 9.** For every bidding sequence  $X$  and  $k$  subset queries in the imperfect advice model, we have  $\text{Cr}(X) \geq \frac{1}{L}(1+L)^{1+1/L}$ , where  $L = 2^k / \binom{k}{H}$ .

**Proof.** Every bidding strategy will use the query responses so as to select a strategy from a set  $\mathcal{X} = \{X_0, \dots, X_{l-1}\}$  of candidate sequences, for some  $l \leq 2^k$ . For a given target value  $u$ , there is an ordering of the  $l$  sequences in  $\mathcal{X}$  such that  $X_{\pi(i)}$  has no worse competitive ratio than  $X_{\pi(i+1)}$ , namely the permutation orders the sequences in decreasing order of performance. From Theorem 4, it follows that the strategy will choose a sequence  $X_j$  such that  $\pi(j) \geq \lfloor l \binom{k}{H} / 2^k \rfloor$ . The competitive ratio of the selected sequence is at least the competitive ratio of the  $l$ -parallel strategy defined by  $\mathcal{X}$ , in which up to  $\phi_l = \lfloor l \binom{k}{H} / 2^k \rfloor$  sequences may be faulty. From Theorem 8,

$$\text{Cr}(X) \geq \frac{\alpha_{\bar{X}}^{l+1+\phi_l}}{\alpha_{\bar{X}}^l - 1}, \quad \text{with } \phi_l = \lfloor l \binom{k}{H} / 2^k \rfloor. \quad (3)$$

We now consider two cases. Suppose first that  $l < L$ . In this case, case  $\phi_l = 0$ , and therefore (3) implies that  $\text{Cr}(X) \geq \alpha_{\bar{X}}^{l+1} / (\alpha_{\bar{X}}^l - 1)$ , which is minimized for  $\alpha_{\bar{X}} = (l+1)^{1/l} > 1$ , therefore  $\text{Cr}(X) \geq \frac{1}{l}(l+1)^{1+1/l}$ . This function is decreasing in  $l$ , and since  $l < L$  we have  $\text{Cr}(X) \geq \frac{1}{L}(1+L)^{1+1/L}$ . Next, suppose that  $l \in [L, 2^k]$ . In this case, (3) gives  $\text{Cr}(X) \geq \frac{\alpha_{\bar{X}}^{l(1+1/L)}}{\alpha_{\bar{X}}^l - 1}$ . The above expression is minimized for  $\alpha_{\bar{X}} = (1+L)^{1/l}$ , and by substitution we obtain again  $\text{Cr}(X) \geq \frac{1}{L}(1+L)^{1+1/L}$ . ◀

### 4.1.3 Comparison of the bounds

We can prove that the ratio between the two bounds is approximately

$$\log \frac{\text{UB}}{\text{LB}} \leq \frac{\sqrt{8k\tau(1-\tau)}k(1-\tau)(1-\mathcal{H}(\frac{\tau}{1-\tau}))}{2^{k(1-\tau)(1-\mathcal{H}(\frac{\tau}{1-\tau}))}} - \frac{k(1-\mathcal{H}(\tau))}{2^{k(1-\mathcal{H}(\tau))}},$$

where  $\tau = H/k$ . We infer that as  $k$  increases, and for any fixed value of  $\tau$ , the upper and lower bounds become very close to each other.

Note that the techniques of [6] imply an online bidding strategy with imperfect advice of competitive ratio roughly equal to  $f(2k/H)$ , where  $f$  is the decreasing function  $f(x) = \frac{1}{x}(1+x)^{1+\frac{1}{x}}$ . Thus, if  $H = \Theta(k)$ , then the competitive ratio is independent of the number of queries  $k$ . In contrast, the competitive ratio of Theorem 7 is roughly equal to  $f(2^k/U)$ , which is smaller than  $f(2k/H)$ , and which rapidly decreases as the number of queries  $k$  increases.

We also note that our analysis implies a tight bound on the advice complexity of online bidding. No previous bounds on the advice complexity of this problem were known.

## 5 Online fractional knapsack

In the online fractional knapsack problem, the request sequence consists of *items*, where item  $i$  has a *value*  $v_i \in \mathbb{R}^+$  and a *size*  $s_i \in (0, 1]$ . The algorithm has a knapsack of unit capacity, and when considering item  $i$ , it can accept irrevocably a fraction  $f_i \in (0, 1]$  of the item, subject to capacity constraints. More precisely, the algorithm aims to maximize  $\sum_i (f_i \cdot v_i)$  subject to  $\sum_i (f_i \cdot s_i) \leq 1$ . Online fractional knapsack has important applications in sponsored search auctions, ad allocation and online trading, and has been studied in several settings, e.g., [2, 24, 38, 14]. In this section, we study this problem in the imperfect advice setting.

Let  $d_i = v_i/s_i$  denote the *density* of item  $i$ . While the offline version of the problem admits an optimal solution via a simple greedy algorithm (that sorts all items by non-decreasing order of density, and accepts items in this order until the knapsack is full), the online version is more challenging. Suppose that  $d_i \in [L, U]$ , for  $L, U$  known to the algorithm. [13, 12] gave matching  $O(\log(U/L))$  and  $\Omega(\log(U/L))$  upper and lower bounds on the competitive ratio of the problem, respectively, and [41] showed an optimal bound of  $\ln(U/L) + 1$  for deterministic algorithms.

## 5.1 Upper bound

As in all previous work, we assume that the density of all items is in  $[L, U]$  for known values of  $L$  and  $U$ . Let  $d^*$  denote the smallest density of an item included at a positive fraction in the optimal solution. That is, the optimal algorithm OPT accepts a fraction 1 of items with density larger than  $d^*$ , and fills the remaining space with a fraction of items of density  $d^*$ . Unfortunately, knowing  $d^*$  (even its exact value) is not sufficient for an online algorithm to be anywhere as efficient as OPT. For example, an algorithm that accepts a fraction 1 of items of density larger than  $d^*$  has unbounded competitive ratio in sequences that consist only of items of density  $d^*$ . Similarly, an algorithm that accepts a fraction 1 of items with density at least  $d^*$  has unbounded competitive ratio in sequences in which items of density  $d^*$  appear early in the sequence, and items of greater density later in the sequence. However, if we denote by  $c^* \in (0, 1)$  the fraction of the knapsack in the optimal solution that is either empty or occupied with items of density  $d^*$ , then knowing the exact value of both  $d^*$  and  $c^*$  suffices to achieve optimality. Our approach will then aim to use  $k$  comparison queries so as to approximate  $c^*$  and  $d^*$ , then use these approximations to choose fractional items.

### 5.1.1 Algorithm and analysis

We describe the online algorithm. We first define two types of partitions, related to the parameters  $d^*$  and  $c^*$ . In what concerns  $d^*$ , partition the interval  $[L, U]$  into  $s$  sub-intervals  $I_1, \dots, I_s$  such that  $I_i = [d_{i-1}, d_i]$ , for  $s$  that will be specified later. We also set  $L = d_0, U = d_s$ . The values  $d_i$  are defined so that:  $\beta = \frac{d_1}{d_0} = \frac{d_2}{d_1} = \dots = \frac{d_s}{d_{s-1}}$ . Thus, we have  $\beta = (U/L)^{1/s}$  and  $d_i = L \cdot \beta^i$ , and note that  $d^* \in I_x$  for some  $x \in [1, s]$ .

In what concerns the parameter  $c^*$ , we partition the interval  $[0, 1]$  into  $m$  sub-intervals  $I'_1, \dots, I'_m$  such that  $I'_i = [c_{i-1}, c_i]$ ; we have  $c_0 = 0$  and  $c_m = 1$ . The value of  $m$  will be determined later; the values  $c_i$  are defined so that  $c_1 = c_2 - \frac{c_1}{\beta} = c_3 - \frac{c_2}{\beta} = \dots = c_m - \frac{c_{m-1}}{\beta}$ .

It readily follows that for  $i \geq 1$ , we have  $c_i = \frac{\beta^{m+i-1} - \beta^{m+i-2}}{\beta^m - 1}$ . In particular,  $c_1 = \frac{\beta^m - \beta^{m-1}}{\beta^m - 1}$ , and  $\frac{1}{1-c_1} = \frac{\beta^m - 1}{\beta^{m-1} - 1}$ . Note also that  $c^* \in I'_y$  for some  $y \in [1, m]$ .

Provided that  $s \cdot m \leq \lfloor 2^{k-H} / \binom{k-H}{H} \rfloor$ , Theorem 2 shows that the algorithm can use  $k$  comparison queries so as to identify both  $x$  and  $y$ . Given these values, the algorithm reserves, in its knapsack, a capacity  $c = c_{y-1}$  for items with density in the range  $I_x = [d_{x-1}, d_x]$ , to which we refer as *critical items*. The algorithm uses the remaining capacity of  $1 - c$  for items of density larger than  $d_x$ , to which we refer as *heavy items*, and accepts a fraction 1 of all critical items, as long as the capacity  $c$  reserved for them allows. Similarly, the algorithm accepts a fraction 1 of heavy items and places them in their dedicated space of the knapsack. Given that  $c^* \in I'_y$ , we have  $1 - c > 1 - c^*$ ; that is, the reserved capacity for heavy items is at least equal to the total size of these items. In other words, the algorithm can afford to accept all heavy items. The algorithm rejects all items of density smaller than  $d_{x-1}$ .

► **Theorem 10.** *For any  $H \leq k/2$ , the above algorithm has competitive ratio*

$$\min_{s,m \in \mathbb{N}} f_m(\beta) \quad \text{where} \quad \beta = (U/L)^{1/s}, \quad \text{and} \quad f_m(\beta) = \frac{\beta^m - 1}{\beta^{m-1} - 1}$$

$$\text{subject to} \quad s \cdot m \leq \lfloor 2^{k-H} / \binom{k-H}{H} \rfloor.$$

## 5.2 Lower bound

We will show a lower bound  $C(k, H)$  on the competitive ratio of any algorithm with imperfect advice. For the sake of contradiction, suppose there is an algorithm  $A$  of competitive ratio better than  $C(k, H)$ . Our proof is based on a reduction from the  $\text{FIND}(k, H)$  game. Specifically, we prove that, based on  $A$ , we obtain a questioner's strategy for  $\text{FIND}(k, H)$  which can find a value  $z \in \{1, \dots, p\}$ , with  $p = \lceil 2^k / \binom{k}{H} \rceil + 1$ , which contradicts Theorem 2.

We give the intuition behind the proof. Let  $s$  and  $m$  be any two positive integers such that  $s \cdot m \leq p$  and  $s \cdot (m+1) > p$ . Define  $\beta = (U/L)^{1/s}$ , and  $d_i = U \cdot \beta^i$ , for  $i \in [1, s]$ . Given a pair  $(x, y)$  of integers, where  $x \in \{1, \dots, s\}$  and  $y \in \{1, \dots, m+1\}$ , define the sequence

$$\sigma_{x,y} = ((d_1, 1), (d_2, 1), \dots, (d_{x-1}, 1), (d_x, c_y)),$$

where  $(d_i, j)$  indicates a subsequence of  $j/\epsilon$  items, each of which has size  $\epsilon$  and density  $d_i$ , and where  $\epsilon$  is infinitesimally small.  $c_y \in [0, 1]$  is defined appropriately in the proof. For this sequence,  $\text{OPT}(\sigma_{x,y}) = (1 - c_y)d_{x-1} + c_y d_x$ . There are  $s \cdot (m+1) > p$  such sequences, and  $\sigma_{x,y}$  is a prefix sequence of  $\sigma_{x,y+1}$ , and  $\sigma_{x,m}$  is a prefix sequence of  $\sigma_{x+1,1}$ . In the proof, we consider request sequences of this form, and we show that if  $A$  is  $C(k, H)$ -competitive, its decisions can help find any given  $z \in \{1, \dots, p\}$ , which contradicts Theorem 2.

► **Theorem 11.** *For the fractional knapsack problem, where items densities are in  $[L, U]$ , no deterministic algorithm with  $k$  subset queries, out of which  $H \leq k/2$  may have erroneous responses, can achieve a competitive ratio better than*

$$C(k, H) = \min_{s,m \in \mathbb{N}} g_m(\beta) \quad \text{where} \quad \beta = (U/L)^{1/s}, \quad g_m(\beta) = \left( \frac{\beta^2 - \beta + 1}{2\beta + 1} \right)^{1/(m+1)}$$

$$\text{subject to} \quad s \cdot m \leq \lceil 2^k / \binom{k}{H} \rceil + 1.$$

### Comparison of the bounds

Let  $\tau = H/k$ . Since  $\frac{\beta^m - 1}{\beta^{m-1} - 1} \leq \beta$ , using (1), the upper bound of Theorem 10 is at most  $(U/L)^q$ , where  $q \leq 1/2^{k(1-\tau)(1-\mathcal{H}(\frac{\tau}{1-\tau}))}$ . Furthermore, since  $\frac{\beta^2 - \beta + 1}{2\beta + 1} \geq \frac{\beta}{3}$  (for all  $\beta \geq 3$ ), the lower bound of Theorem 11 is at least  $(U/L)^{q'} (1/3)^{q'}$ , where  $q' \geq 1/(2\sqrt{8k\tau(1-\tau)}2^{k(1-\mathcal{H}(\tau))} + 1)$ , for all  $U/L \geq 3$ . For simplicity, we omitted the floors and ceilings.

## 6 Waiving the assumption of the tolerance parameter

In the imperfect advice setting we have studied so far, the algorithm defines an application-specific tolerance parameter that measures its desired tolerance to errors (or equivalently, an anticipated upper bound on the error). This parameter is in a sense required, since the analysis of Rényi-Ulam games in [36] involves the extreme value of error (i.e.,  $H$ ) instead of the instance-specific error value (i.e.,  $\eta$ ). Nevertheless, in this section, we discuss how to mitigate the need for pre-determining a tolerance parameter. We propose two different

approaches, based on *resource-augmentation*, and *robustification*, which we discuss in what follows. We use the time-series search and online bidding problems as illustrations, even though our approach may carry through in other online problems, at the expense of more complex calculations.

## 6.1 Resource augmentation

In this setting, we compare an *oblivious* online algorithm  $A$  with  $l$  advice bits and no information on the error bound, to an online algorithm  $B$  that has  $k$  *ideal* (i.e. error-free) advice bits. Specifically, we are interested in finding the smallest  $l \geq k$  (as a function of  $k$ ) for which algorithm  $A$  is at least as good as algorithm  $B$ , regardless of the advice error of  $A$ .

The following theorem shows that  $O(1)$ -factor resource augmentation suffices to obtain an oblivious algorithm that is at least as efficient as any algorithm that operates in the ideal setting of error-free advice, and even if a fraction  $1/3 - c$  of the advice bits may be erroneous, for any constant  $c$ .

► **Theorem 12.** *Consider the time-series and the online bidding problems. For all sufficiently large  $k$ , and any  $c \in (0, 1/3)$ , there is an oblivious online algorithm  $A$  with advice of size  $l$ , whose competitive ratio is at least as good as that of any online algorithm  $B$  with  $k$  bits of perfect (i.e. error-free) advice, where  $l = \frac{1}{(\frac{2}{3}+c)(1-\mathcal{H}(\frac{\frac{1}{3}-c}{\frac{2}{3}+c}))}k + 1$ , for any error  $\eta \leq (1/3 - c)l$  in the advice of  $A$ .*

## 6.2 Robustification

In this setting, we augment the imperfect advice framework by requiring not only that the algorithm minimizes the competitive ratio assuming that the advice error is at most the tolerance  $H$ , but also that its competitive ratio does not exceed a *robustness* requirement  $r$ , for some specified  $r$ , if the error exceeds  $H$  (and in particular, if the advice is adversarially generated). We call such online algorithms  *$r$ -robust*. Thus, this model can be seen as an extension of both the imperfect advice and the untrusted advice model of [5].

For the time-series problem, we obtain the following result, which generalizes Theorem 5. In particular, note that Theorem 5 is a special case of Theorem 13 for  $\rho = 1$ .

► **Theorem 13.** *Consider the online time series search problem, with imperfect advice of size  $k$ , tolerance  $H \leq k/2$ , and robustness  $r = (M/m)^\rho$ , where  $\rho \in (1/2, 1]$ . There is an  $r$ -robust algorithm that uses  $k$  comparison queries, and has competitive ratio at most  $(M/m)^{\frac{2\rho-1}{\rho+1}}$ , where  $U = \lfloor 2^{k-H} / \binom{k-H}{H} \rfloor$ , for any  $H \leq k/2$ . Moreover, no (deterministic) algorithm based on  $k$  subset queries has competitive ratio better than  $(M/m)^{\frac{2\rho-1}{L+1}}$ , where  $L = \lceil 2^k / \binom{k-H}{H} \rceil$ .*

The analysis of  $r$ -robust algorithms for online bidding is more challenging, in particular in what concerns the impossibility results. We give an overview of the approach. For the upper bound, we can follow an analysis along the lines of Theorem 7, however, each bidding sequence in the collection  $\mathcal{X}_{b,2^k}$  must be individually  $r$ -robust. This is easy to enforce, and it requires that  $b$  must be such that  $b^2/(b-1) \leq r$ . The lower bound is more subtle: the proof follows the lines of Theorem 9, but uses the fact that if all the  $l$  sequences in  $X_0, \dots, X_{l-1}$  must be  $r$ -robust, then  $\alpha_{\bar{X}}^2/(\alpha_{\bar{X}} - 1) \leq r$ . We obtain the following:

► **Theorem 14.** *For every  $r \geq 4$  there is an  $r$ -robust bidding strategy with  $k$ -bit imperfect advice that has competitive ratio at most*

$$\min_{b>1} \frac{b^{2^k+U+1}}{b^{2^k}-1}, \quad \text{subject to } b^{2^{k+1}}/(b^{2^k}-1) \leq r, \quad \text{and where } U = \lceil 2^H \binom{k-H}{H} \rceil.$$

Furthermore, every  $r$ -robust bidding strategy has competitive ratio at least

$$\min_{\alpha>1} \frac{\alpha^{2^k+L+1}}{\alpha^{2^k}-1} \quad \text{subject to } \alpha^{2^k}/(\alpha^k-1) \leq r, \quad \text{and where } L = \lfloor \binom{k}{H} \rfloor.$$

---

## Abstract

---

Based on a theorem of Bergman [6, Theorem 4.5.3] we show that multivariate noncommutative polynomial factorization is deterministic polynomial-time reducible to the factorization of bivariate noncommutative polynomials. More precisely, we show the following:

1. In the white-box setting, given an  $n$ -variate noncommutative polynomial  $f \in \mathbb{F}\langle X \rangle$  over a field  $\mathbb{F}$  (either a finite field or the rationals) as an arithmetic circuit (or algebraic branching program), computing a complete factorization of  $f$  into irreducible factors is deterministic polynomial-time reducible to white-box factorization of a noncommutative bivariate polynomial  $g \in \mathbb{F}\langle x, y \rangle$ ; the reduction transforms  $f$  into a circuit for  $g$  (resp. ABP for  $g$ ), and given a complete factorization of  $g$  (namely, arithmetic circuits (resp. ABPs) for irreducible factors of  $g$ ) the reduction recovers a complete factorization of  $f$  in polynomial time.

We also obtain a similar deterministic polynomial-time reduction in the black-box setting.

2. Additionally, we show over the field of rationals that bivariate linear matrix factorization of  $4 \times 4$  matrices is at least as hard as factoring square-free integers. This indicates that reducing noncommutative polynomial factorization to linear matrix factorization (as done in [1]) is unlikely to succeed over the field of rationals even in the bivariate case. In contrast, multivariate linear matrix factorization for  $3 \times 3$  matrices over rationals is in polynomial time.

## 1 Introduction

The main aim of this paper is to show that multivariate polynomial factorization in the free noncommutative ring  $\mathbb{F}\langle x_1, x_2, \dots, x_n \rangle$  is polynomial-time reducible to *bivariate* noncommutative polynomial factorization in the bivariate ring  $\mathbb{F}\langle x, y \rangle$ . Such a result for commutative polynomial factorization is well-known due to Kaltofen's seminal work [9, 10] on multivariate polynomial factorization in the commutative polynomial ring  $\mathbb{F}[y_1, y_2, \dots, y_n]$ . However, this problem was open for noncommutative polynomials. Recently, a randomized polynomial-time algorithm was obtained for the factorization of noncommutative polynomials over finite fields, where the input polynomial is given by a noncommutative formula [1].<sup>1</sup> Broadly speaking, the algorithm of [1] works via Higman linearization ([8] [6] [7]) and reduces the problem to linear matrix factorization which turns out to have a randomized polynomial-time algorithm over finite fields.

---

<sup>1</sup> Factorization of *homogeneous* noncommutative polynomials is easier as it can be reduced to factorization of a special case of commutative polynomials. See [4] for details.

► **Problem 1** (Linear Matrix Factorization Problem). *The linear matrix factorization problem over a field  $\mathbb{F}$  takes as input a linear matrix:  $L = A_0 + \sum_{i=1}^n A_i x_i$ , where the  $A_i$  are  $d \times d$  scalar matrices (over  $\mathbb{F}$ ), the  $x_i, 1 \leq i \leq n$  are noncommuting variables, and  $A_0$  is assumed invertible for technical reasons. The problem is to compute a factorization of  $L$  as a product of irreducible linear matrices.*

The study of matrix factorization (linear matrix factorization, in particular) is an important part of Cohn's factorization theory over general free ideal rings. [6, 5].

Coming back to the polynomial factorization algorithm described in [1], the algorithm reduces polynomial factorization to linear matrix factorization which is, in turn, reducible to the problem of computing a common invariant subspace for a collection of  $n$  matrices. The common invariant subspace problem over finite fields can be efficiently solved using Ronyai's algorithm [12] which is based on the Artin-Wedderburn theorem for decomposition of algebras. This approach, however, runs into serious difficulties over rationals. Given a simple matrix algebra<sup>2</sup>  $\mathcal{A}$  over rationals, we do not know an efficient algorithm for checking if  $\mathcal{A}$  is a division algebra or whether it has zero divisors. This is one of our motivations for obtaining a reduction from multivariate polynomial factorization to bivariate factorization. Because Higman Linearization of a bivariate noncommutative polynomial given by a formula will yield a bivariate linear matrix. One could hope that factorization of a bivariate linear matrix is computationally easier than factorization of an  $n$ -variate linear matrix. Unfortunately, this is not the case. As we will see, even for 4-dimensional bivariate linear matrices the problem of factorization is at least as hard as factoring square-free integers.

### Multivariate to Bivariate

We start with some formal preliminaries. Let  $\mathbb{F}$  be any field and  $X = \{x_1, x_2, \dots, x_n\}$  be a set of  $n$  free noncommuting variables. Let  $X^*$  denote the set of all free words (which are monomials) over the alphabet  $X$  with concatenation of words as the monoid operation and the empty word  $\epsilon$  as identity element.

The *free noncommutative ring*  $\mathbb{F}\langle X \rangle$  consists of all finite  $\mathbb{F}$ -linear combinations of monomials in  $X^*$ , where the ring addition  $+$  is coefficient-wise addition and the ring multiplication  $*$  is the usual convolution product. More precisely, let  $f, g \in \mathbb{F}\langle X \rangle$  and let  $f(m) \in \mathbb{F}$  denote the coefficient of monomial  $m$  in polynomial  $f$ . Then we can write  $f = \sum_m f(m)m$  and  $g = \sum_m g(m)m$ , and in the product polynomial  $fg$  for each monomial  $m$  we have  $fg(m) = \sum_{m_1 m_2 = m} f(m_1)g(m_2)$ . The *degree* of a monomial  $m \in X^*$  is the length of the monomial  $m$ , and the degree  $\deg f$  of a polynomial  $f \in \mathbb{F}\langle X \rangle$  is the degree of a largest degree monomial in  $f$  with nonzero coefficient. For polynomials  $f, g \in \mathbb{F}\langle X \rangle$  we clearly have  $\deg(fg) = \deg f + \deg g$ .

A *nontrivial factorization* of a polynomial  $f \in \mathbb{F}\langle X \rangle$  is an expression of  $f$  as a product  $f = gh$  of polynomials  $g, h \in \mathbb{F}\langle X \rangle$  such that  $\deg g > 0$  and  $\deg h > 0$ . A polynomial  $f \in \mathbb{F}\langle X \rangle$  is *irreducible* if it has no nontrivial factorization and is *reducible* otherwise. For instance, all degree 1 polynomials in  $\mathbb{F}\langle X \rangle$  are irreducible. Clearly, by repeated factorization every polynomial in  $\mathbb{F}\langle X \rangle$  can be expressed as a product of irreducibles.

The problem of *noncommutative polynomial identity testing* (PIT) for multivariate polynomials is known to easily reduce to noncommutative PIT for bivariate polynomials: the reduction is given by the  $x_i \rightarrow xy^i, 1 \leq i \leq n$ , which transforms a given arithmetic circuit (or formula or algebraic branching program) computing a polynomial  $f(x_1, x_2, \dots, x_n)$  to the

<sup>2</sup> i.e. the algebra has no nontrivial two-sided ideals.

bivariate polynomial  $g(x, y) = f(xy, xy^2, \dots, xy^n)$ . As this substitution map ensures that every monomial of  $f$  is mapped to a distinct monomial of  $g(x, y)$ ,  $f$  is the zero polynomial if and only if  $g(x, y)$  is the zero polynomial. Indeed, this map even gives an injective homomorphism from the ring  $\mathbb{F}\langle x_1, x_2, \dots, x_n \rangle$  to  $\mathbb{F}\langle x, y \rangle$  [6, Problem 14, Exercises 2.5]. However, it does not preserve factorizations. For example, the polynomial  $f = x_3x_1 + x_4x_2 + x_4x_1 + x_5x_2 \in \mathbb{F}\langle X \rangle$  is clearly irreducible. But the image of  $f$  under this map has the nontrivial factorization  $(xy^2 + xy^3)(yxy + y^2xy^2)$ . Thus, it cannot be used to obtain a reduction from noncommutative multivariate polynomial factorization to bivariate polynomial factorization.

### Bergman's 1-inert embedding

However, based on a theorem of Bergman [6, Theorem 4.5.3], we can obtain a polynomial-time reduction from factorization of multivariate noncommutative polynomials in  $\mathbb{F}\langle x_1, x_2, \dots, x_n \rangle$  given by arithmetic circuits (resp. noncommutative algebraic branching programs (ABP)) to factorization of bivariate noncommutative polynomials in  $\mathbb{F}\langle x, y \rangle$ , again given by arithmetic circuit (resp. an ABP). This reduction is polynomial-time bounded for both finite fields and rationals. In the case of rationals we need to ensure that the bit complexities of all numbers involved are polynomially bounded. Furthermore, we show that essentially the same reduction works in the black-box setting as well.

The notion of 1-inert embeddings is defined below for free noncommutative polynomials.

► **Definition 2 (1-inert embedding).** [5] *Let  $X_\infty = \{x_1, x_2, \dots\}$  be a countably infinite set of free noncommuting variables and  $\{x, y\}$  be two free noncommuting variables. A 1-inert embedding of  $\mathbb{F}\langle X_\infty \rangle$  into  $\mathbb{F}\langle x, y \rangle$  is an injective homomorphism  $\varphi : \mathbb{F}\langle X \rangle \rightarrow \mathbb{F}\langle x, y \rangle$  such that for each polynomial  $f \in \mathbb{F}\langle X \rangle$ , if its image  $\varphi(f)$  factorizes nontrivially in  $\mathbb{F}\langle x, y \rangle$  as  $\varphi(f) = g_1 \cdot g_2$  then their preimages  $\varphi^{-1}(g_1)$  and  $\varphi^{-1}(g_2)$  exist and, since  $\varphi$  is a homomorphism, it gives a nontrivial factorization  $f = \varphi^{-1}(g_1)\varphi^{-1}(g_2)$  of  $f$  in  $\mathbb{F}\langle X \rangle$ .*

► **Remark 3.** The above definition implies that for all factorizations  $\varphi(f) = g_1g_2$ , the polynomials  $g_1$  and  $g_2$  are in the range of  $\varphi$ . Cohn [6, 5] treats 1-inert embeddings  $\varphi : R_1 \rightarrow R_2$  for general noncommutative integral domains  $R_1$  and  $R_2$ , which we do not require for our results.

► **Definition 4.** *A complete factorization of noncommutative polynomial  $f \in \mathbb{F}\langle X \rangle$  is a factorization  $f = f_1 \cdot f_2 \cdot \dots \cdot f_r$  into a product of irreducible polynomials  $f_i \in \mathbb{F}\langle X \rangle$ .*

Given an algebraic branching program (resp. Arithmetic Circuit) for  $f$ , we can efficiently obtain an algebraic branching program (resp. Arithmetic Circuit) for  $\varphi(f)$  and then we use idea of running a substitution automata on ABPs or circuits (see e.g. [4], [2], [3]) to construct a complete factorization of  $f$  given a complete factorization of  $\varphi(f)$ . In the next section we will elaborate and expand upon Bergman's embedding theorem [5] and show how to get an effective algorithmic version which is useful for our purpose of reconstruction of factors of  $f$  from factors of  $\varphi(f)$ .

The rest of the paper is organized as follows: In Section 2 we give necessary details of Bergman's result. In Section 3 we present the reductions. Motivated by the connection between noncommutative polynomial factorization and linear matrix factorization, in Section 4 we show a hardness result for bivariate linear matrix factorization for  $4 \times 4$  linear matrices over rationals. In contrast we obtain an efficient linear matrix factorization algorithm for  $3 \times 3$  linear matrices over rationals.

## 2

 Bergman's embedding

We recall the *graded lexicographic ordering*  $\prec$  on monomials in  $\{x, y\}^*$ , which is a total ordering on  $\{x, y\}^*$  defined as follows:

For monomials  $m_1, m_2 \in \{x, y\}^*$ ,  $m_1 \neq m_2$ , we say  $m_1 \prec m_2$  if either  $\deg(m_1) < \deg(m_2)$  or  $\deg(m_1) = \deg(m_2)$  and in the leftmost position  $i$  where they differ we have  $m_1[i] = y$  and  $m_2[i] = x$ .

For any polynomial  $g$ , let  $\text{supp}(g)$  denote the set of all monomials of  $g$  with non-zero coefficient. When  $m_1 \prec m_2$  we say that monomial  $m_1$  is *smaller* than monomial  $m_2$ . Equivalently, we say  $m_2$  is *larger* than  $m_1$ . The *leading monomial* of a polynomial  $g \in \mathbb{F}\langle x, y \rangle$  is the monomial  $m \in \text{supp}(g)$  (denoted by  $\text{lm}(g)$ ) such that  $w \prec m$  for all  $w \in \text{supp}(g)$ . That is, the leading monomial of  $g$  is the largest monomial in  $\text{supp}(g)$ .

For a monomial  $m \in \{x, y\}^*$  let  $d_x(m)$  (resp.  $d_y(m)$ ) denote the number of occurrences of  $x$  (resp.  $y$ ) in  $m$ . The *imbalance*  $i(m)$  of the monomial  $m$  is defined as

$$i(m) = d_x(m) - d_y(m).$$

Let  $B \subset \mathbb{F}\langle x, y \rangle$  be the set of all polynomials  $f$  such that every monomial  $m \in \text{supp}(f)$  has imbalance zero, i.e.  $i(m) = 0$  for all  $m \in \text{supp}(f)$ . Clearly,  $B$  is a subalgebra of  $\mathbb{F}\langle x, y \rangle$ . Let  $T$  be the set of all *minimally balanced* monomials. That is, for  $m \in T$  either  $m = \epsilon$  or  $i(m) = 0$  and for any proper prefix  $m'$  of  $m$  such that  $m' \neq \epsilon$ ,  $i(m') > 0$ . Notice that for all monomials  $m \in T \setminus \{\epsilon\}$  its leftmost symbol  $m[1]$  is  $x$ . We arrange the nontrivial monomials in  $T$  in increasing  $\prec$ -ordering. Let  $u_i$  denote the  $i^{\text{th}}$  monomial in this ordering. Let  $\bar{u}_i$  be the monomial obtained from  $u_i$  by replacing every occurrence of  $x$  by  $y$  and  $y$  by  $x$ . Let  $\bar{T} = \{\bar{u}_i \mid i \geq 1\}$ . It is easy to see that the monomials in  $T \cup \bar{T}$  generate the algebra  $B$ . In fact, every monomial  $m \in B$  is *uniquely* expressible as a product  $g_1 g_2 \dots g_\ell$ , where each  $g_j \in T \cup \bar{T}$ . If  $g_j \in T$  it is a  $T$ -factor of  $m$  and if  $g_j \in \bar{T}$  it is a  $\bar{T}$ -factor of  $m$ . Let  $C$  be the subalgebra of  $B$  generated by  $\{u_i + \bar{u}_i \mid i \geq 1\}$ .

► **Lemma 5.** *Let  $B$  and  $C$  be the subalgebras of  $\mathbb{F}\langle x, y \rangle$  as defined above.*

- *The leading monomial  $m$  of any polynomial in  $C$  has the form  $m = u_{i_1} u_{i_2} \dots u_{i_\ell}$ , where each  $u_{i_j}$  is a  $T$ -factor. That is,  $m$  does not have any  $\bar{T}$ -factor.*
- *Every polynomial  $f \in B \setminus C$  can be written as  $f = g + h$  for some  $g \in C$  and  $h \in B$ , such that the leading monomial of  $h$  has a  $\bar{T}$ -factor.*

**Proof.** By definition, each  $g \in C$  is a linear combination of products of the form  $\prod_{k=1}^\ell (u_{i_k} + \bar{u}_{i_k})$ . Hence, if  $\text{supp}(g)$  contains the monomial  $v_1 v_2 \dots v_\ell$ , where  $v_k \in \{u_{j_k}, \bar{u}_{j_k}\}$  for  $k \in [\ell]$ , then  $\text{supp}(g)$  also contains the degree- $d$  monomial  $u_{j_1} u_{j_2} \dots u_{j_\ell}$  (in fact, with the same coefficient as  $v_1 v_2 \dots v_\ell$ ). If  $u_{j_1} u_{j_2} \dots u_{j_\ell} \neq v_1 v_2 \dots v_\ell$  then, by definition of  $\prec$ , the monomial  $u_{j_1} u_{j_2} \dots u_{j_\ell}$  is larger than  $v_1 v_2 \dots v_\ell$ . Therefore, the leading monomial of any polynomial  $g \in C$  has the form claimed.

Next, let  $f \in B \setminus C$ . We will show the second part of the lemma by induction on the leading monomial of  $f$  w.r.t. the  $\prec$ -ordering (which is a well ordering on monomials).

The base case of the induction is when the leading monomial of  $f$  has a  $\bar{T}$ -factor then the claim follows as  $f = 0 + f$  and  $0 \in C$ . Suppose the leading monomial of  $f$  is  $m = u_{j_1} u_{j_2} \dots u_{j_\ell}$ . If the coefficient of  $m$  in  $f$  is  $\alpha \neq 0$ , let

$$f_1 = f - \alpha(u_{j_1} + \bar{u}_{j_1})(u_{j_2} + \bar{u}_{j_2}) \dots (u_{j_\ell} + \bar{u}_{j_\ell}). \quad (1)$$

If  $m_1$  is the leading monomial of  $f_1$  then clearly  $m_1 \prec m$ . Furthermore,  $f_1 \in B \setminus C$  as  $f - f_1 \in C$ . By induction hypothesis, we have  $f_1 = g' + h$  such that  $g' \in C$  and the leading monomial of  $h$  has a  $\bar{T}$ -factor. Since  $f = (f - f_1) + g' + h$  and  $g = (f - f_1) + g' \in C$ , this completes the induction and the proof. ◀

Let  $X_\infty = \{x_1, x_2, \dots\}$  be a countably infinite set of free noncommuting indeterminates. Consider the mapping  $\varphi : \mathbb{F}\langle X_\infty \rangle \mapsto \mathbb{F}\langle x, y \rangle$  defined as follows:

- Let  $\varphi(x_i) = u_i + \bar{u}_i$  for all  $x_i \in X_\infty$ .
- Extend  $\varphi$  to all monomials by multiplication. That is,  $\varphi(x_{i_1}x_{i_2}\dots x_{i_k}) = \prod_{j=1}^k \varphi(x_{i_j})$ .
- Further, extend  $\varphi$  to the ring  $\mathbb{F}\langle X_\infty \rangle$  by linearity:  $\varphi(\sum_{i=1}^t \alpha_i m_i) = \sum_{i=1}^t \alpha_i \varphi(m_i)$ , for monomials  $m_i \in X_\infty^*$  and scalars  $\alpha_i \in \mathbb{F}$  for  $i = 1$  to  $t$ .

► **Lemma 6.** *The map  $\varphi$  defined above is an injective homomorphism (i.e. a homomorphic embedding) from the ring  $\mathbb{F}\langle X_\infty \rangle$  to  $\mathbb{F}\langle x, y \rangle$ .*

**Proof.** To see that  $\varphi$  is a homomorphism, we first note that, by linearity, we have  $\varphi(f + g) = \varphi(f) + \varphi(g)$  for  $f, g \in \mathbb{F}\langle X_\infty \rangle$ . To verify that  $\varphi(fg) = \varphi(f)\varphi(g)$ , let  $f = \sum_m f_m m$  and  $g = \sum_m g_m m$  where  $f_m, g_m \in \mathbb{F}$  are the coefficients of monomial  $m$  in  $f$  and  $g$ , respectively. Then  $\varphi(fg) = \varphi((\sum_m f_m m)(\sum_w g_w w)) = \varphi(\sum_{m,w} f_m g_w m w)$ . Which, by linearity of  $\varphi$ , equals  $\sum_{m,w} f_m g_w \varphi(m)\varphi(w) = \varphi(f)\varphi(g)$ .

In order to show  $\varphi$  is injective, it suffices to show  $\varphi(f) \neq 0$  for  $f \neq 0$ . Suppose  $m \in \text{supp}(f)$ . Then  $\varphi(m) \neq 0$ , by the definition of  $\varphi$ . Hence, if  $m$  is the only monomial in  $\text{supp}(f)$  it follows that  $\varphi(f) \neq 0$ .

Otherwise, suppose  $m' \in \text{supp}(f)$  and  $m' \neq m$ . Let  $u$  be largest common prefix of  $m$  and  $m'$ . Then  $m = ux_i v$  and  $m' = ux_j w$ , for monomials  $u, v, w \in X_\infty^*$  and  $x_i \neq x_j$ . Noting that  $\varphi(x_i) = u_i + \bar{u}_i$  and  $\varphi(x_j) = u_j + \bar{u}_j$  we have  $\varphi(m) = \varphi(u)(u_i + \bar{u}_i)\varphi(v)$  and  $\varphi(m') = \varphi(u)(u_j + \bar{u}_j)\varphi(w)$ . From the definition of  $\varphi$ , clearly  $\varphi(u)$  is a homogeneous polynomial in  $\mathbb{F}\langle x, y \rangle$ . Let  $\deg(\varphi(u)) = D$ . Suppose  $\ell = |u_i| = |\bar{u}_i|$  and  $\ell' = |u_j| = |\bar{u}_j|$ . Without loss of generality suppose that  $u_i \prec u_j$ . Hence  $\ell \leq \ell'$ . As  $u_i$  and  $u_j$  are minimally balanced,  $u_i$  cannot be a prefix of  $u_j$ . Also, as  $u_i[1] = x$  and  $\bar{u}_j[1] = y$ ,  $u_i$  cannot be a prefix of  $\bar{u}_j$ . Therefore, for any monomials  $w_1 \in \text{supp}(\varphi(m))$  and  $w_2 \in \text{supp}(\varphi(m'))$ ,  $w_1$  and  $w_2$  will differ in the length  $\ell$  subword starting at location  $D + 1$ . It follows that  $\text{supp}(\varphi(m)) \cap \text{supp}(\varphi(m')) = \emptyset$ . Hence,  $\varphi(f) \neq 0$  implying that  $\varphi$  is injective. ◀

The subalgebra  $C$  has the important property that if  $f \in C$  then all factors of  $f$  are in  $C$  as well. In order to keep our presentation self-contained we include a complete proof with more details than are given in [5].

► **Theorem 7** (Bergman; [5, Chapter 4, Theorem 5.2]). *Let  $f \in C$ . For any factorization  $f = g \cdot h$  the polynomials  $g$  and  $h$  are in  $C$ .*

**Proof.** First we show that all monomials of  $g$  have the same imbalance. Likewise, all monomials of  $h$  have the same imbalance. Suppose  $a_{min}$  and  $a_{max}$  are the minimum and the maximum imbalances of monomials of  $g$ . Let  $b_{min}$  and  $b_{max}$  be the minimum and the maximum imbalance of monomials of  $h$ . Let  $m_{min}$  be a smallest monomial (with respect to  $\prec$ ) in  $\text{supp}(g)$  with imbalance  $a_{min}$ , and  $m_{max}$  be a largest monomial (with respect to  $\prec$ ) in  $\text{supp}(g)$  with imbalance  $a_{max}$ . Let  $w_{min}, w_{max}$  be monomials similarly defined for polynomial  $h$  corresponding to  $b_{min}$  and  $b_{max}$ . Now consider the product monomial  $u = m_{max}w_{max}$ . We claim that  $u$  is uniquely expressible as a product of a monomial of  $g$  and a monomial of  $h$ . To see this, suppose  $u = m'w'$  where  $m' \in \text{supp}(g)$ ,  $w' \in \text{supp}(h)$  and  $m_{max} \neq m'$  or  $w_{max} \neq w'$ . Now, as  $i(u) = i(m_{max}) + i(w_{max}) = i(m') + i(w')$  and  $m_{max}, w_{max}$  are the monomials with highest imbalance of  $g$  and  $h$  respectively, we must have  $i(m') = i(m_{max})$  and  $i(w') = i(w_{max})$ . So we get,  $m' \prec m_{max}$  and  $w' \prec w_{max}$  by the choice of  $m_{max}$  and  $w_{max}$ . But as  $u = m_{max}w_{max} = m'w'$ , clearly either  $m_{max}$  is a strict prefix of  $m'$  or  $w_{max}$  is a strict prefix of  $w'$ . In the former case we have  $m_{max} \prec m'$ , and in the later case  $w_{max} \prec w'$ .

These contradict the fact that  $m' \prec m_{max}$  and  $w' \prec w_{max}$ . Hence,  $u = m_{max}w_{max}$  is the unique expression of  $u$  as a product of a monomial of  $g$  and a monomial of  $h$ . Consequently,  $u$  has non-zero coefficient in  $f = g.h$ . Clearly  $u$  has imbalance  $a_{max} + b_{max}$ . Similarly, monomial  $v = m_{min}w_{min}$  is non-zero in  $f$  and has imbalance  $a_{min} + b_{min}$ . As  $f \in C$ , each monomial of  $f$  has imbalance 0. Hence,  $a_{max} + b_{max} = 0$  and  $a_{min} + b_{min} = 0$ . It follows that  $a_{max} = -b_{max} \leq -b_{min} = a_{min}$ , implying  $a_{min} = a_{max} = a$  and  $b_{min} = b_{max} = -a$ . Thus, all monomials of  $g$  have imbalance  $a$  and all monomials of  $h$  have imbalance  $-a$ .

Let  $m$  be the leading monomial of  $f$ . Clearly,  $m$  is a maximum degree monomial of  $f$ . Moreover,  $m$  is largest among the max-degree monomials of  $f$ . Let  $m = m_1m_2$  with  $m_1 \in \text{supp}(g)$  and  $m_2 \in \text{supp}(h)$ . We have  $i(m_1) = a$ ,  $i(m_2) = -a$ . As  $f \in C$ , the monomial  $\bar{m}$  obtained by replacing every occurrence of  $x$  by  $y$ , and  $y$  by  $x$  in  $m$  is also in  $\text{supp}(f)$ . Moreover,  $\bar{m}$  is the smallest monomial among the max-degree monomials of  $f$ . This forces that the monomial  $\bar{m}_1$  (obtained by interchanging  $x, y$  in  $m_1$ ) is in  $\text{supp}(g)$ . Similarly, monomial  $\bar{m}_2$  (obtained by swapping  $x, y$  in  $m_2$ ) is in  $\text{supp}(h)$ . We have  $i(\bar{m}_1) = -a$  and  $i(\bar{m}_2) = a$ . Now, all monomials of  $g$  have the same imbalance, and  $m_1, \bar{m}_1 \in \text{supp}(g)$ . This forces  $a = -a = 0$ . Consequently, all monomials in  $\text{supp}(g) \cup \text{supp}(h)$  have imbalance zero which implies  $g, h \in B$ . Now, applying Lemma 5 to  $g$  and  $h$  we have:

1.  $g = g_1 + g_2$ ,  $h = h_1 + h_2$ ,  $g_1, h_1 \in C$ , such that  $\text{lm}(g_2)$  has a  $\bar{T}$ -factor  $\bar{u}$ , and  $\text{lm}(h_2)$  has a  $\bar{T}$ -factor  $\bar{v}$ .
2. Consequently, the  $\text{deg}(g_2)$  prefix of  $\text{lm}(g_2h_1)$  contains the  $\bar{T}$ -factor  $\bar{u}$  and the  $\text{deg}(h_2)$  suffix of  $\text{lm}(g_1h_2)$  contains the  $\bar{T}$ -factor  $\bar{v}$ .
3. Finally, the  $\text{deg}(g_2)$  prefix and the  $\text{deg}(h_2)$  suffix of  $\text{lm}(g_2 \cdot h_2)$  contain, respectively, the  $\bar{T}$ -factors  $\bar{u}$  and  $\bar{v}$ .

Hence the leading monomials  $\text{lm}(g_2 \cdot h_1)$ ,  $\text{lm}(g_1 \cdot h_2)$ , and  $\text{lm}(g_2 \cdot h_2)$  are all distinct and cannot mutually cancel. Therefore, the leading monomial of  $\hat{f} = g_2 \cdot h_1 + g_1 \cdot h_2 + g_2 \cdot h_2$  contains a  $\bar{T}$ -factor unless both  $g_2 = 0$  and  $h_2 = 0$ . Now,  $\hat{f} = g_2 \cdot h_1 + g_1 \cdot h_2 + g_2 \cdot h_2 = f - g_1h_1$ . As  $f \in C$  and  $g_1, h_1 \in C$  it implies  $\hat{f} \in C$ . However, by Lemma 5, the leading monomial of  $\hat{f}$  cannot have a  $\bar{T}$ -factor. It forces  $g_2 = 0$  and  $h_2 = 0$  which implies  $g, h \in C$ .  $\blacktriangleleft$

Theorem 7 implies that  $\varphi$  is a 1-inert embedding (Definition 2).

► **Theorem 8.** *Let  $f \in \mathbb{F}\langle X \rangle$ , where  $X = \{x_1, \dots, x_n\}$ . Suppose  $f' = \varphi(f) = g' \cdot h'$  is a non-trivial factorization of  $\varphi(f)$  in  $\mathbb{F}\langle x, y \rangle$ . Then there is a non-trivial factorization  $f = g \cdot h$  for  $g, h \in \mathbb{F}\langle X \rangle$ , such that  $\varphi(g) = g'$  and  $\varphi(h) = h'$ .*

**Proof.** As  $\mathbb{F}\langle X \rangle \subset \mathbb{F}\langle X_\infty \rangle$ , the embedding  $\varphi$  maps  $f \in \mathbb{F}\langle X \rangle$  to some  $f' = \varphi(f) \in C$ . Suppose  $f' = g' \cdot h'$  is a nontrivial factorization of  $f'$  in  $\mathbb{F}\langle x, y \rangle$ . By Theorem 7, as  $f' \in C$ , its factors  $g', h' \in C$ . Since  $g' \in C$ , it is an  $\mathbb{F}$ -linear combination of products of the form  $(u_{t_1} + \bar{u}_{t_1})(u_{t_2} + \bar{u}_{t_2}) \dots (u_{t_\ell} + \bar{u}_{t_\ell})$ . By definition of  $\varphi$ ,

$$(u_{t_1} + \bar{u}_{t_1})(u_{t_2} + \bar{u}_{t_2}) \dots (u_{t_\ell} + \bar{u}_{t_\ell}) = \varphi(x_{t_1}x_{t_2} \dots x_{t_\ell}).$$

Hence, by linearity, it follows that  $g' = \varphi(g)$  for some nontrivial polynomial  $g \in \mathbb{F}\langle X_\infty \rangle$ , similarly there is a nontrivial polynomial  $h \in \mathbb{F}\langle X_\infty \rangle$  such that  $h' = \varphi(h)$ . Since  $\varphi$  is a homomorphism, we have

$$\varphi(f) = f' = g' \cdot h' = \varphi(g) \cdot \varphi(h) = \varphi(g \cdot h).$$

As  $\varphi$  is injective, we have  $f = g \cdot h$ . To complete the proof we need to argue that  $g, h \in \mathbb{F}\langle X \rangle$ . Let  $\text{Var}(g)$  be the subset of variables that occur in some non-zero monomial of  $g$ . We claim that  $\text{Var}(g) \subseteq X$ . Suppose  $\text{Var}(g)$  contains some  $x_i \notin X$ . Let  $m \in \text{supp}(g)$  be the largest

monomial (in  $\prec$ -ordering) in which  $x_i$  occurs. Then the monomial  $m \cdot \text{lm}(h)$  contains the variable  $x_i$  and has a non-zero coefficient in  $f = gh$ . This is a contradiction as  $f \in \mathbb{F}\langle X \rangle$  and  $X$  does not contain  $x_i$ . Hence  $\text{Var}(g) \subseteq X$ . Similarly,  $\text{Var}(h) \subseteq X$ .  $\blacktriangleleft$

### 3 Multivariate to Bivariate reduction

We now apply Bergman's theorem (Theorem 7) to show that multivariate noncommutative polynomial factorization is reducible to bivariate noncommutative polynomial factorization. We require some preparatory observations.

Let  $X = \{x_1, x_2, \dots, x_n\}$ , and  $v_1, v_2, \dots, v_n$  be any  $n$  distinct and minimally balanced monomials in  $\{x, y\}^*$ . We define  $\varphi : \mathbb{F}\langle X \rangle \rightarrow \mathbb{F}\langle x, y \rangle$ :  $\varphi(x_i) = v_i + \bar{v}_i$  for all  $i$ , which extends by multiplication, i.e.  $\varphi(x_{i_1}x_{i_2}\dots x_{i_k}) = \prod_{j=1}^k \varphi(x_{i_j})$ , to monomials, and by linearity to  $\mathbb{F}\langle X \rangle$ . The definition of  $\varphi$  is essentially like in the proof of Bergman's theorem, except that  $X$  is finite and the  $v_i, 1 \leq i \leq n$  are any  $n$  distinct minimally balanced monomials. The following lemma is on the same lines as Theorem 7 and Theorem 8. The straightforward proof is by a suitable renaming of the variables  $x_1, \dots, x_n$  before and after application of Theorem 7 in the proof of Theorem 8.

► **Lemma 9.** *Let  $X = \{x_1, \dots, x_n\}$  and  $f \in \mathbb{F}\langle X \rangle$ . Suppose  $v_1, v_2, \dots, v_n \in \{x, y\}^*$  are distinct minimally balanced monomials. If  $f' = \varphi(f) = g' \cdot h'$  is a non-trivial factorization of  $f'$  in  $\mathbb{F}\langle x, y \rangle$  then there are polynomials  $g, h \in \mathbb{F}\langle X \rangle$  such that  $g' = \varphi(g)$ ,  $h' = \varphi(h)$  and  $f = g \cdot h$ .*

In order to obtain a polynomial-time computable reduction it is convenient to choose  $v_1, v_2, \dots, v_n$  such that each  $v_i$  has the same length. The next lemma ensures that  $\ell = O(\log n)$  suffices. This follows from the fact that the number of minimally balanced monomials of length  $2\ell$  is at least as large as the  $(\ell - 2)^{\text{th}}$  Catalan number, and well-known asymptotic lower bounds on Catalan numbers.

► **Lemma 10.** *There are at least  $n$  minimally balanced monomials of length  $2\ell$  in  $\{x, y\}^*$  for  $\ell \geq \max(\lceil \log 2n \rceil, 6)$ . Furthermore, the lexicographically first  $n$  minimally balanced monomials of length  $2\ell$  can be computed in time polynomial in  $n$ .*

**Proof.** Consider monomials  $v$  of the form  $v = x \cdot w \cdot y$ , where  $w$  is a Dyck monomial.<sup>3</sup> That is,  $w$  is a balanced monomial such that every prefix of  $w$  has at most as many  $y$ 's as  $x$ 's. Notice that  $w \in \{x, y\}^{2\ell-2}$ . It follows that any nontrivial prefix of  $v$  has strictly more  $x$  than  $y$ . So any such monomial is minimally balanced of length  $2\ell$ . The number of Dyck monomials of length  $2\ell - 2$  is  $C_{\ell-1}$  (the  $(\ell - 1)^{\text{th}}$  Catalan number). A standard estimate yields  $C_k \sim \frac{4^k}{k^{3/2}\sqrt{\pi}}$ , which implies that  $C_k$  is  $2^{\Omega(k)}$ . Specifically,  $C_k > 2^k$  for  $k \geq 5$ . If  $n < 2^{\ell-1}$  and  $\ell \geq 6$  then there are at least  $n$  minimally balanced monomials of length  $2\ell$ , for  $\ell = \max(\lceil \log 2n \rceil, 6)$ . Clearly, we can compute the  $v_i, 1 \leq i \leq n$  by enumeration in  $\text{poly}(n)$  time.  $\blacktriangleleft$

#### 3.1 White-box reduction

We first describe the reduction in the white-box case for input polynomial  $f \in \mathbb{F}\langle X \rangle$  given by a noncommutative arithmetic circuit.

<sup>3</sup> Essentially a balanced parenthesis string with  $x$  as left and  $y$  as right parenthesis, respectively.

► **Lemma 11.** *Let  $X = \{x_1, \dots, x_n\}$  and  $f \in \mathbb{F}\langle X \rangle$  be a noncommutative polynomial given by arithmetic circuit  $C$  of size  $s$ . Then there is a deterministic polynomial time algorithm that outputs an arithmetic circuit computing the polynomial  $\varphi(f) \in \mathbb{F}\langle x, y \rangle$ , where the minimally balanced monomials  $v_i, 1 \leq i \leq n$  defining the map  $\varphi$  are as described by Lemma 10.*

**Proof.** For  $1 \leq i \leq n$ , we note that the sum of two monomials  $v_i + \bar{v}_i$  can be computed by a noncommutative arithmetic formula  $F_i$  of size  $O(\log n)$ . Let  $C'$  be the arithmetic circuit obtained from circuit  $C$  by replacing input variable  $x_i$  with the formula  $F_i$ . Clearly,  $C'$  computes  $\varphi(f)$  and its size is polynomially bounded. ◀

► **Lemma 12.** *For  $f \in \mathbb{F}\langle X \rangle$  suppose  $\varphi(f) = f'_1 \cdot f'_2 \cdots f'_r$  is a complete factorization of  $\varphi(f)$  in  $\mathbb{F}\langle x, y \rangle$  into irreducible factors  $f'_i \in \mathbb{F}\langle x, y \rangle$ . Then there are irreducible polynomials  $f_1, f_2, \dots, f_r \in \mathbb{F}\langle X \rangle$  such that  $f = f_1 f_2 \dots f_r$  and  $\varphi(f_i) = f'_i$  for each  $i$ .*

**Proof.** It follows by repeated application of Lemma 9 that if  $\varphi(f) = f'_1 \cdot f'_2 \cdots f'_r$ , is a factorization into irreducible factors  $f'_i \in \mathbb{F}\langle x, y \rangle$ , then there are polynomials  $f_1, f_2, \dots, f_r \in \mathbb{F}\langle X \rangle$  such that  $f = f_1 f_2 \dots f_r$  and  $\varphi(f_i) = f'_i$  for each  $i$ . We claim each  $f_i$  is irreducible. For, if  $f_i = g \cdot h$  is a nontrivial factorization of  $f_i$  in  $\mathbb{F}\langle X \rangle$  then clearly  $f'_i = \varphi(f_i) = \varphi(g)\varphi(h)$  is a nontrivial factorization of  $f'_i$ , which contradicts its irreducibility. ◀

Suppose  $C'_i$  is an arithmetic circuit of size  $s'_i$  for  $f'_i$  for  $i \in [r]$ . We will construct a circuit of size  $\text{poly}(s'_i, n)$  for  $f_i$  efficiently for each  $i \in [r]$ , which is the crucial part of our multivariate to bivariate reduction. The next lemma describes the algorithm crucial to the white-box reduction.

► **Lemma 13.** *Given as input a noncommutative arithmetic circuit  $C$  for the polynomial  $\varphi(g) \in \mathbb{F}\langle x, y \rangle$ , where  $g \in \mathbb{F}\langle X \rangle$  is a degree  $d$  polynomial,  $X = \{x_1, x_2, \dots, x_n\}$ , there is a deterministic polynomial-time algorithm, running in time  $\text{poly}(d, \text{size}(C), n)$  that computes a noncommutative arithmetic circuit  $C'$  for the polynomial  $g$ . Furthermore, if  $\varphi(g)$  is given by an algebraic branching program then the algorithm computes an algebraic branching program for  $g$ .*

**Proof.** The proof is based on the idea of evaluating a noncommutative arithmetic circuit on an automaton (specifically, a substitution automaton) described in [4] (see e.g., for related applications [2],[3]).

Let  $g' = \varphi(g)$ . Let  $g = \sum_m \alpha_m m$  where  $m \in X^*$  and  $\alpha_m$  is the coefficient of  $m$  in  $g$ . As noted before, the map  $\varphi$  has the property that  $\text{supp}(\varphi(m)) \cap \text{supp}(\varphi(m')) = \emptyset$  for monomials  $m \neq m'$  in  $X^*$ . Moreover if  $m = x_{i_1} x_{i_2} \dots x_{i_\ell}$  has nonzero coefficient  $\alpha_m$  in  $g$  then  $g'$  has a monomial  $m' = v_{i_1} v_{i_2} \dots v_{i_\ell}$  with coefficient  $\alpha_m$ . Hence, to retrieve an arithmetic circuit for  $g$  from the given circuit  $C'$  for  $g'$  our aim is to carry out the following transformation of the polynomial  $g'$  given by the circuit  $C'$ :

- Get rid of the monomials of  $g'$  containing of all  $\bar{v}_j \in \bar{T}$  for  $j \in [n]$ .
- For each remaining monomial  $m'$  of  $g'$  substitute  $x_i$  wherever the monomial  $v_i$  occurs as substring in  $m'$  for  $i \in [n]$ .

We will accomplish this transformation by evaluating the circuit  $C'$  at suitably chosen matrix substitutions  $x \leftarrow M_x$  and  $y \leftarrow M_y$ , where  $M_x$  and  $M_y$  will be  $N \times N$  matrices for polynomially bounded  $N$ . The resulting evaluation  $C'(M_x, M_y)$  will be an  $N \times N$  matrix. A designated entry of this matrix will contain the polynomial  $g$ . Clearly, if we can efficiently compute the claimed matrices  $M_x$  and  $M_y$  it will yield an arithmetic circuit  $C$  for the polynomial  $g$ . These matrices  $M_x$  and  $M_y$  will be obtained as transition matrices of a substitution automaton that will carry out the above transformation steps on the polynomial  $g'$ .

A finite substitution automaton  $\mathcal{A}$  is a deterministic finite automata  $\mathcal{A}$  along with a substitution map  $\delta : Q \times \{x, y\} \rightarrow Q \times (X \cup \mathbb{F})$  where  $Q$  is a set of states and  $X = \{x_1, x_2, \dots, x_n\}$  are noncommuting variables. For  $i, j \in Q$ ,  $a \in \{x, y\}$ ,  $u \in X \cup \mathbb{F}$ , if  $\delta(i, a) = (j, u)$ , it means that when automata  $\mathcal{A}$  in state  $i$  reads  $a$ , it replaces  $a$  by  $u$  and transitions to state  $j$ . For each  $a \in \{x, y\}$  we can define a  $|Q| \times |Q|$  transition matrix  $M_a$  such that  $M_a(i, j) = u$  if  $\delta(i, a) = (j, u)$  and 0 otherwise.

With  $\delta$  we associate projections  $\delta_1 : Q \times \{x, y\} \rightarrow Q$  and  $\delta_2 : Q \times \{x, y\} \rightarrow X \cup \mathbb{F}$  defined as  $\delta_1(i, a) = j$  and  $\delta_2(i, a) = u$  if  $\delta(i, a) = (j, u)$ . The functions  $\delta_1$  and  $\delta_2$  extend naturally to monomials: For  $w \in \{x, y\}^*$ ,  $\delta_1(i, w) = j$  means the automaton  $\mathcal{A}$  goes from state  $i$  to  $j$  on reading  $w$ . Let  $\tilde{w}_\ell$  denotes length  $\ell$  prefix of  $w$  and  $w_\ell$  denotes  $\ell^{\text{th}}$  symbol of  $w$  from left.  $\delta_2(i, w) = p$  means  $p = \prod_{\ell=0}^{|w|-1} \delta_2(\delta_1(i, \tilde{w}_\ell), w_{\ell+1})$ . Note that  $\delta_2(i, w)$  has the form  $\beta \cdot w'$  where  $\beta \in \mathbb{F}$ ,  $w' \in X^*$ . For  $\alpha \in \mathbb{F}$  define  $\delta_2(i, \alpha \cdot w)$  as  $\alpha \cdot \delta_2(i, w)$ .

Let  $g'(x, y) = \sum_m \alpha_m m \in \mathbb{F}\langle x, y \rangle$ . Then, the  $(s, t)^{\text{th}}$  entry of the  $|Q| \times |Q|$  matrix  $g'(M_x, M_y)$  is a polynomial  $g \in \mathbb{F}\langle X \rangle$  such that  $g = \sum_{m \in W_t} \alpha_m \delta_2(s, m)$ , where  $W_t$  is the set of all monomials that take the automaton  $\mathcal{A}$  from state  $s$  to state  $t$ .

Clearly, if  $g'$  has an arithmetic circuit of size  $s$  then we can construct an arithmetic circuit of size  $\text{poly}(s, n, |Q|)$  for  $g$  in deterministic time  $\text{poly}(s, n, |Q|)$ .

Turning back to the reduction, consider the input circuit  $C$  for  $g' = \varphi(g) \in \mathbb{F}\langle x, y \rangle$ . We will construct a substitution automaton  $\mathcal{A}$  such that the polynomial  $g$  is the  $(s, t)^{\text{th}}$  entry of the matrix  $g'(M_x, M_y)$ .

### Description of the Substitution Automata

As each  $v_i$  is minimally balanced it must begin with symbol  $x$  and end with symbol  $y$ . As  $|v_i| > 2$ , the second symbol of  $v_i$  is also  $x$  (if it was  $y$ , then the balanced monomial  $xy$  would be a strict prefix of a minimally balanced monomial  $v_i$ , which is a contradiction). So clearly each  $v_i$  is of the form  $xxw_iyy$ , where  $w_i$  is a Dyck monomial. Let  $v'_i = xw_iy$  for  $i \in [n]$ . We can easily design a deterministic finite automaton  $A'$  with  $O(mn)$  states such that the language accepted by  $A'$  is precisely the finite set  $\{v'_1, v'_2, \dots, v'_n\}$ , where  $m$  is the length of  $v_i$  for  $i \in [n]$ . Let  $\delta'$  denote the transition function and  $Q'$  be the set of states of  $A'$ , where  $q_1$  is the initial state and  $q_{f_i}$  is the final state associated with acceptance of string  $v'_i$  for  $i \in [n]$ .  $A'$  has a tree structure with root  $q_1$  and leaves  $q_{f_i}$  for  $i \in [n]$ , and any root to leaf path has length exactly  $2\ell - 2$ . We now define the substitution automaton  $\mathcal{A}$ . Its state set is  $Q = Q' \cup \{q_0, q_f, q_r\}$ . The transition function  $\delta : Q \times \{x, y\} \rightarrow Q \times (X \cup \mathbb{F})$  is defined as follows:

1.  $\delta(q_0, x) = (q_1, 1); \delta(q_0, y) = (q_r, 0)$ .
2. for  $q \in Q' \setminus \{q_{f_i} | 1 \leq i \leq n\}$ . and  $a \in \{x, y\}$ , let  $\delta(q, a) = (\delta'(q, a), 1)$ .
3.  $\delta(q_{f_i}, x) = (q_r, 0); \delta(q_{f_i}, y) = (q_f, x_i)$  for each  $i \in [n]$ .
4.  $\delta(q_f, x) = (q_1, 1)$  and  $\delta(q_f, y) = (q_r, 0)$ .
5.  $\delta(q_r, a) = (q_r, 0)$  for  $a \in \{x, y\}$ .

The final state of  $\mathcal{A}$  is  $q_f$ . For a monomial  $w \in \{x, y\}^*$ , starting at state  $q_0$  the automaton  $\mathcal{A}$  substitutes all the variables with 1 as long as it matches with a prefix of  $v_i$  for  $i \in [n]$  (given by transitions in 1,2 above). When the monomial matches with  $v_i$  for some  $i$  (which will happen while reading symbol  $y$  as each string  $v_i$  ends with  $y$ ),  $\mathcal{A}$  substitutes  $y$  by  $x_i$  and moves to state  $q_f$ . If it reads  $x$  instead of  $y$  then  $\mathcal{A}$  enters a rejecting state  $q_r$  (given by transition in 3 above). Hence, if  $\mathcal{A}$  finds substring  $v_i$  in  $w$  it replaces it with  $x_i$ . Whenever  $\mathcal{A}$  is in state  $q_f$ , it means the monomial read so far is of the form  $v_{i_1}v_{i_2} \dots v_{i_t}$ , and it has replaced it with  $x_{i_1}x_{i_2} \dots x_{i_t}$ . If in the state  $q_f$  symbol  $y$  is encountered, it means the next

## 14:10 Multivariate to Bivariate Reduction for Noncommutative Polynomial Factorization

substring cannot match with a minimally balanced monomial (as these start with  $x$ ) and the automaton goes to the rejecting state  $q_r$ . If in state  $q_f$  variable  $x$  is read the automaton goes to state  $q_1$  and restarts the search for a new substring that matches with some  $v_i$  (transition in 4 above).

In conclusion  $\mathcal{A}$  replaces all the monomials of the form  $v_{i_1}v_{i_2}\dots v_{i_t}$  by  $x_{i_1}x_{i_2}\dots x_{i_t}$ . If the monomial contains an occurrence of  $\bar{v}_i$ , or it is not of the form  $v_{i_1}v_{i_2}\dots v_{i_t}$ , then  $\mathcal{A}$  zeros out that monomial by suitably setting an occurrence of  $y$  to zero or enters the reject state  $q_r$ .<sup>4</sup>

It follows that the  $(q_0, q_f)^{th}$  entry of the  $|Q| \times |Q|$  matrix  $g'(M_x, M_y)$  is the polynomial  $g$ , where  $g' = \varphi(g)$ , and  $M_x, M_y$  are the transition matrices for the substitution automaton  $\mathcal{A}$ . This completes the proof.

Finally, if  $\varphi(g)$  is given by an algebraic branching program  $P$  then it is easy to see that the above construction with the substitution automaton  $\mathcal{A}$  yields  $P(M_x, M_y)$  which is an algebraic branching program. ◀

The main theorem of this section, stated below, summarizes the discussion in this section.

► **Theorem 14.** *In the white-box setting, factorization of multivariate noncommutative polynomials into irreducible factors is deterministic polynomial-time reducible to factorization of bivariate noncommutative polynomials into irreducible factors. More precisely, given as input  $f \in \mathbb{F}\langle X \rangle$  by an arithmetic circuit (resp. algebraic branching program), the problem of computing a complete factorization  $f = f_1 \cdot f_2 \cdots f_r$  where each  $f_i$  is output as an arithmetic circuit (resp. algebraic branching program) is deterministic polynomial-time reducible to the same problem for bivariate polynomials in  $\mathbb{F}\langle x, y \rangle$ .*

**Proof.** We describe the reduction:

1. Input  $f \in \mathbb{F}\langle X \rangle$  (as a circuit or ABP).
2. Transform  $f$  to  $f' = \varphi(f) \in \mathbb{F}\langle x, y \rangle$  as a circuit (resp. ABP) by the algorithm of Lemma 10.
3. Compute a complete factorization of  $f' = f'_1 \cdot f'_2 \cdots f'_r$ , where each  $f'_i \in \mathbb{F}\langle x, y \rangle$  is irreducible and is computed as a circuit (resp. ABP).
4. Apply the algorithm of Lemma 13 to obtain a complete factorization of  $f = f_1 \cdot f_2 \cdots f_r$ , where each  $f_i$  is irreducible and is output as a circuit (resp. ABP).

The correctness of the reduction and its polynomial time bound follow from Lemmas 9, 10 and 13. ◀

► **Remark 15.** We note that in the case  $\mathbb{F}$  is the field  $\mathbb{Q}$  (of rationals), we need to take into account the bit complexity of the rational numbers involved and argue that the reduction is still polynomial time computable. The main point to note here is that the reduction guarantees the size of the factor  $f_i$  is polynomially bounded in the size of  $g_i, 1 \leq i \leq r$ , where the size of  $g_i$  includes the sizes of any rational numbers that might be involved in the description of the arithmetic circuit (or ABP) for  $g_i$ .

► **Remark 16.** We note here that the ring  $\mathbb{F}\langle X \rangle$  is not a unique factorization domain. That is, a polynomial  $f \in \mathbb{F}\langle X \rangle$  may have, in general, multiple factorizations into irreducibles [6]. A standard example is the polynomial  $x + xyx$  which factorizes as  $x(1 + yx)$  as well as  $(1 + xy)x$ , where  $x, y, 1 + yx, 1 + xy$  are irreducible. As the map  $\varphi$  is an injective homomorphism, there is a 1-1 correspondence between factorizations of  $\varphi(f)$  and factorizations of  $f$ . More specifically, our reduction takes as input any complete factorization  $\varphi(f) = f'_1 f'_2 \cdots f'_r$  and computes the corresponding complete factorization  $f = f_1 f_2 \cdots f_r$  of  $f$ .

<sup>4</sup> We can dispense with the reject state  $q_r$ , as suitably setting an occurrence of  $y$  to 0 would also suffice. We have transitions to the reject state  $q_r$  for exposition.

► **Remark 17.** We note that the embedding  $\varphi$  does not preserve sparsity<sup>5</sup> of the polynomial  $f$ . More precisely, if the sparsity of the  $n$ -variate degree  $d$  polynomial  $f$  is  $s$  then the sparsity of the bivariate polynomial  $\varphi(f)$  is  $O(2^d s)$ . Thus, using this embedding map we do not get a reduction from sparse  $n$ -variate degree  $d$  polynomial factorization to sparse bivariate polynomial factorization, where  $s, d$  are allowed to be part of the running time. This problem remains unanswered.

### 3.2 Black-box reduction

The reduction in the black-box case is essentially identical. The only point to note, which is easy to see, is that the analogue of Lemma 13 holds in the black-box setting. We state that below. We recall what a black-box means in the noncommutative setting.

► **Definition 18.** A noncommutative polynomial  $f \in \mathbb{F}\langle X \rangle$  given by black-box essentially means we can evaluate  $f$  at any matrix substitution  $x_i \leftarrow M_i$ ,  $M_i \in \mathbb{F}^{N \times N}$ , where the cost of each evaluation is the matrix dimension  $N$ .

In the black-box setting, suppose we have an efficient algorithm for bivariate noncommutative polynomial factorization of degree  $D$  polynomials  $g \in \mathbb{F}\langle x, y \rangle$ , where the algorithm takes a black-box for  $g$  and outputs black-boxes for the irreducible factors of some factorization of  $g$  in time  $\text{poly}(D)$ . Then, given a black-box for a degree  $D$   $n$ -variate polynomial  $f \in \mathbb{F}\langle X \rangle$  as input, we require that the reduction transforms it into a black-box of a bivariate polynomial  $g \in \mathbb{F}\langle x, y \rangle$ , and from the output black-boxes of  $g$ 's irreducible factors, the reduction has to efficiently recover black-boxes for the corresponding irreducible factors of  $f$ .

► **Lemma 19.** Given as input a black-box for the polynomial  $\varphi(g) \in \mathbb{F}\{x, y\}$ , where  $g \in \mathbb{F}\langle X \rangle$  is a degree  $d$  polynomial,  $X = \{x_1, x_2, \dots, x_n\}$ , with matrix substitutions for  $x$  and  $y$  computed in deterministic polynomial-time we can obtain a black-box for the polynomial  $g \in \mathbb{F}\langle X \rangle$ .

**Proof.** The proof of Lemma 13 already implies this because the matrices  $M_x$  and  $M_y$  described there do not require  $\varphi(g)$  to be given in white-box as circuit or ABP. Thus, the black-box for  $\varphi(g)$  yields a black-box for  $g$  by accessing the  $(q_0, q_f)^{\text{th}}$  entry of the matrix output  $\varphi(g)(M_x, M_y)$ . ◀

As a consequence we obtain the claimed reduction from multivariate factorization to bivariate factorization in the black-box setting as well.

► **Theorem 20.** The problem of computing a complete factorization of  $f \in \mathbb{F}\langle X \rangle$  given by black-box is deterministic polynomial-time reducible to the problem of black-box computation of a complete factorization of polynomials in  $\mathbb{F}\langle x, y \rangle$ .

**Proof.** Given a black-box for  $f$  we obtain a black-box for  $\varphi(f)$  applying Lemma 10. Then, given a complete factorization  $\varphi(f) = f'_1 \cdot f'_2 \cdots f'_r$  where each factor  $f'_i$  is output by a black-box for it, by Lemma 19 we can obtain black-boxes for each  $f_i$ . This yields a complete factorization  $f = f_1 \cdot f_2 \cdots f_r$  of  $f$  where the factors are given by black-box. ◀

<sup>5</sup> The sparsity of a polynomial  $f$  is the number of monomials in  $\text{supp}(f)$ .

#### 4 Factorizing $4 \times 4$ linear matrices over $\mathbb{Q}$

We have shown in Section 3 that multivariate noncommutative polynomial factorization is efficiently reducible to the bivariate case. Suppose  $f \in \mathbb{F}\langle x, y \rangle$  is a bivariate polynomial given by a formula of size  $s$ . Applying Higman linearization [6], as done in [1], we can transform the problem to the factorization of bivariate linear matrices  $A_0 + A_1x + A_2y$ , where the matrices have size bounded by  $2s$ . In [1] the problem of factorizing an  $n$ -variate polynomial  $f \in \mathbb{F}\langle X \rangle$  given by a formula was solved in two steps when  $\mathbb{F}$  is a finite field: (i) Transform  $f$  to a linear matrix  $L$  and factorize  $L$  into irreducible factors by reducing it to the common invariant subspace problem, and (ii) extract the factors of  $f$  from the factors of  $L$ . This approach fails for  $\mathbb{F} = \mathbb{Q}$  because the common invariant subspace problem for matrices over  $\mathbb{Q}$  is at least as hard as factoring square-free integers [12]. In this section, we show that linear matrix factorization over  $\mathbb{Q}$ , even for  $4 \times 4$  bivariate linear matrices, remains at least as hard as factoring square-free integers. Thus, efficient polynomial factorization over  $\mathbb{Q}$  remains elusive even for bivariate polynomials. Our proof is based on ideas from Ronyai's work [12].

Let  $\alpha, \beta \in \mathbb{Q}$  be nonzero rationals. The *generalized quaternion algebra*  $H(\alpha, \beta)$  is the 4-dimensional algebra over  $\mathbb{Q}$  generated by elements  $1, u, v, uv$  where the rules for multiplication in  $H(\alpha, \beta)$  are given by  $u^2 = \alpha$ ,  $v^2 = \beta$ , and  $uv = -vu$ . A *simple algebra*  $\mathcal{A}$  over a field  $\mathbb{F}$  is an algebra that has no nontrivial two-sided ideal. The *center*  $C$  of algebra  $\mathcal{A}$  is the subalgebra consisting of all elements of  $\mathcal{A}$  that commute with every element of  $\mathcal{A}$ . Furthermore, it follows from some general theory [11, Chapter 1.6] that:

► **Fact 21.** *For any nonzero  $\alpha, \beta \in \mathbb{Q}$ , the algebra  $H(\alpha, \beta)$  is a simple algebra with center  $\mathbb{Q}$ . The algebra  $H(\alpha, \beta)$  is either a division algebra (which means no zero divisors in it) or is isomorphic to the algebra of  $2 \times 2$  matrices over  $\mathbb{Q}$  (which means it has zero divisors).*

The 4-dimensional algebra  $H(\alpha, \beta)$  can be represented as an algebra of  $4 \times 4$  matrices over  $\mathbb{Q}$ , which is the *regular representation*. The matrix corresponding to 1 is  $I_4$ , and the

matrices corresponding to  $u$  and  $v$  are  $M_u = \begin{bmatrix} 0 & 1 & 0 & 0 \\ \alpha & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & \alpha & 0 \end{bmatrix}$  and  $M_v = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \\ \beta & 0 & 0 & 0 \\ 0 & -\beta & 0 & 0 \end{bmatrix}$ .

We next show that factorizing  $4 \times 4$  bivariate linear matrices is at least as hard as finding zero divisors in generalized quaternion algebras.

► **Theorem 22.** *Finding zero divisors in an input quaternion algebra  $H(\alpha, \beta)$  is polynomial-time reducible to factorizing  $4 \times 4$  bivariate linear matrices  $A_0 + A_1x + A_2y$ , where each scalar matrix  $A_i$  is in  $\mathcal{M}_4(\mathbb{Q})$ .*

**Proof.** Let  $H(\alpha, \beta)$  be the given generalized quaternion algebra. Then  $H(\alpha, \beta) = \{a_0 + a_1u + a_2v + a_3uv \mid a_i \in \mathbb{Q}\}$ , where  $u^2 = \alpha$ ,  $v^2 = \beta$ , and  $uv = -vu$  defines the algebra multiplication.

We now consider factorizations of the  $4 \times 4$  linear matrix  $I_4 + M_u x + M_v y$ .

▷ **Claim 23.** The linear matrix  $I_4 + M_u x + M_v y$  is irreducible if and only if the quaternion algebra  $H(\alpha, \beta)$  is a division algebra.

**Proof of Claim.** Suppose the linear matrix  $L = I_4 + M_u x + M_v y$  has a nontrivial factorization  $L = I_4 + M_u x + M_v y = FG$ . That means neither  $F$  nor  $G$  is a scalar matrix. By a theorem of Cohn [6, Theorem 5.8.8], there are invertible scalar matrices  $P$  and  $Q$  in  $\mathcal{M}_4(\mathbb{Q})$  such that

$$PLQ = \begin{bmatrix} A & 0 \\ D & B \end{bmatrix}.$$

► **Remark 24.** To apply Cohn’s theorem the matrix  $L$  needs to be monic. That is, the matrix  $[M_u \mid M_v]$  must have full row rank and  $[M_u^T \mid M_v^T]^T$  must have full column rank. This is ensured as matrices  $M_u$  and  $M_v$  are full rank.

Putting  $x = y = 0$  we observe that  $PQ = \begin{bmatrix} A_0 & 0 \\ D_0 & B_0 \end{bmatrix}$ , where  $A_0, B_0$  and  $D_0$  are scalar matrices. As  $P$  and  $Q$  are invertible, both  $A_0$  and  $B_0$  are invertible. Hence  $PLP^{-1} = \begin{bmatrix} A & 0 \\ D & B \end{bmatrix} \cdot \begin{bmatrix} A_0 & 0 \\ D_0 & B_0 \end{bmatrix}^{-1} = \begin{bmatrix} A' & 0 \\ D' & B' \end{bmatrix}$ , where  $A', B'$  and  $D'$  are also linear matrices. Recall that  $I_4, M_u$  and  $M_v$  are the matrix representations of the elements  $1, u,$  and  $v$  in the basis  $\{1, u, v, uv\}$  of  $H(\alpha, \beta)$ . Treating  $P$  as a basis change matrix, the above equation yields a new basis  $\{w_1, w_2, w_3, w_4\}$  of  $H(\alpha, \beta)$ . Let  $\dim(A') = k$ . Then  $1 \leq \dim(A') \leq 3$  and the vectors  $w_1, \dots, w_k$  spans a  $k$ -dimensional subspace  $W \subset H(\alpha, \beta)$  that is a common invariant subspace for the matrices  $I_4, M_u, M_v$  and  $M_{uv}$ . In other words, the subspace  $W$  is preserved under left multiplication by  $u$  and  $v$ . We can assume, without loss of generality, that  $w_1 \neq 1$ : if  $k > 1$  then clearly we can assume this. If  $k = 1$  notice that  $w_1 = 1$  is impossible because the subspace  $W$  is not preserved under left multiplication by  $u$  or  $v$ . Then the four elements  $w_1, uw_1, vw_1, uvw_1$  are all in  $W$  and hence linearly dependent. Thus, some nontrivial linear combination  $\gamma_0 w_1 + \gamma_1 u w_1 + \gamma_2 v w_1 + \gamma_3 uv w_1 = 0$ . which means  $(\gamma_0 + \gamma_1 u + \gamma_2 v + \gamma_3 uv) \times w_1 = 0$ . Hence  $w_1$  is a zero divisor in  $H(\alpha, \beta)$ . Conversely, if  $z \in H(\alpha, \beta)$  is a zero divisor then the left ideal  $J = \{xz \mid x \in H(\alpha, \beta)\}$  is a proper subspace of  $H(\alpha, \beta)$  that is invariant under  $M_u$  and  $M_v$ . Applying Cohn’s theorem [6, Theorem 5.8.8], we obtain invertible scalar matrices  $P$  and  $Q$  such that  $PLQ = \begin{bmatrix} A & 0 \\ D & B \end{bmatrix} = \begin{bmatrix} A & 0 \\ 0 & I \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ D & I \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & B \end{bmatrix}$ . ◁

To complete the reduction, notice that if  $I_4 + M_u x + M_v y$  is irreducible then  $H(\alpha, \beta)$  is a division algebra. On the other hand, if we are given a nontrivial factorization  $I_4 + M_u x + M_v y = FG$  then, analyzing the proof of Cohn’s theorem [6, Theorem 5.8.8] (also see [1] for details), by suitable row and column operations we can compute in polynomial time the invertible scalar matrices  $P$  and  $Q$  from the factors  $F$  and  $G$ . Hence, by the proof of the above claim, we can efficiently compute a zero divisor  $w_1$  in  $H(\alpha, \beta)$ . ◀

As finding zero-divisors in the quaternion algebra  $H(\alpha, \beta)$  is known to be at least as hard as square-free integer factorization [12] we have the following.

► **Corollary 25.** *Factorizing  $4 \times 4$  bivariate linear matrices over  $\mathbb{Q}$  is at least as hard as factorizing square-free integers.*

## 5 Factorizing $3 \times 3$ linear matrices over $\mathbb{Q}$

In this section we present a deterministic polynomial-time algorithm for factorization of  $3 \times 3$  multivariate linear matrices over  $\mathbb{Q}$ . We start with a simple observation about linear matrix factorization in general.

► **Lemma 26.** *Suppose  $L = I_d + \sum_{i=1}^n A_i x_i$  is a linear matrix where each  $A_i, 0 \leq i \leq d$  is a  $d \times d$  matrix over  $\mathbb{Q}$ . Then  $L$  is irreducible if the characteristic polynomial of  $A_i$  is irreducible over  $\mathbb{Q}$  for any  $i$ .*

**Proof.** For if  $L$  is reducible then there is an invertible scalar matrix  $P$  such that  $PLP^{-1} = \begin{bmatrix} A & 0 \\ D & B \end{bmatrix}$ , which implies that  $PA_i P^{-1} = \begin{bmatrix} A'_i & 0 \\ D'_i & B'_i \end{bmatrix}$ , for scalar matrices  $A'_i, B'_i,$  and  $D'_i$ . Thus, the characteristic polynomial of  $A_i$  is the product of the characteristic polynomials of  $A'_i$  and  $B'_i$  which is a nontrivial factorization. ◀

The proof of the following theorem is based on linear algebra and Cohn's theorem [6, Theorem 5.8.8].

► **Theorem 27.** *There is a deterministic polynomial-time algorithm for factorization of  $3 \times 3$  multivariate linear matrices over  $\mathbb{Q}$ .*

**Proof.** We will first consider linear matrices of the form  $L = I_3 + \sum_{i=1}^n A_i x_i$ , where each  $A_i \in \mathcal{M}_3(\mathbb{Q})$  and the  $x_i$  are noncommuting variables. The algorithm computes a complete factorization of  $L$  into (at most three) irreducible linear matrix factors. By Cohn's theorem [6, Theorem 5.8.8], either  $L$  is irreducible or there is an invertible scalar matrix  $P$  such that  $PLP^{-1} = \begin{bmatrix} A & 0 \\ D & B \end{bmatrix}$ . Either  $A$  or  $B$  is a  $1 \times 1$  matrix. If  $A$  is a  $1 \times 1$  matrix then corresponding to it there is a 1-dimensional common invariant subspace spanned by a vector, say  $v$ , for the matrices  $A_i$ ,  $1 \leq i \leq n$ . More precisely, the row vector  $v^T$  is an eigenvector for each matrix  $A_i$ , and  $v^T A_i = \lambda_i v^T$  where  $\lambda_i \in \mathbb{Q}$  is the corresponding eigenvalue of matrix  $A_i$  for each  $i$ . Likewise, if  $B$  is a  $1 \times 1$  matrix then there is a corresponding 1-dimensional common invariant subspace spanned by a (column) vector  $u$  such that  $A_i u = \mu_i u$  for eigenvalues  $\mu_i$  of  $A_i$ . In either case, the common eigenspace is easy to compute from the characteristic polynomial of say  $A_1$  and then verifying that it is an eigenspace for the remaining  $A_i$  as well. This will yield the factorization  $PLP^{-1} = \begin{bmatrix} A & 0 \\ 0 & I \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ D & I \end{bmatrix} \cdot \begin{bmatrix} I & 0 \\ 0 & B \end{bmatrix}$ , where  $B$  is a  $2 \times 2$  linear matrix. The problem now reduces to factorizing the linear matrix  $B = I_2 + \sum_{i=1}^n B_i x_i$ , where  $B_i \in \mathcal{M}_2(\mathbb{Q})$ . A simple case analysis described below yields a polynomial-time algorithm for factorization of  $B$ .

1. If the characteristic polynomial of any  $B_i$  is irreducible over  $\mathbb{Q}$  then the linear matrix  $B$  is clearly irreducible.
2. If some  $B_i$  has two distinct eigenvalues  $\lambda \neq \lambda' \in \mathbb{Q}$  then the corresponding eigenspaces are 1-dimensional, spanned by their eigenvectors  $u \neq u'$ . Then either  $u$  or  $u'$  has to be an eigenvector for every  $B_j$  (otherwise  $B$  is irreducible), in which case we have a factorization of  $B$ .
3. Suppose each  $B_i$  has only one eigenvalue  $\lambda_i$ . Then, by linear algebra, after a basis change  $B_i$  is either of the form  $\begin{bmatrix} \lambda_i & 1 \\ 0 & \lambda_i \end{bmatrix}$  in which case the eigenspace is 1-dimensional with eigenvector  $(10)^T$ . We can check if this eigenspace is invariant for each  $B_j$  or not as before. Otherwise, after basis change each  $B_i = \begin{bmatrix} \lambda_i & 0 \\ 0 & \lambda_i \end{bmatrix} = \lambda_i I_2$  and the factorization is

$$B = \begin{bmatrix} 1 + \sum_{i=1}^n \lambda_i x_i & 0 \\ 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} 1 & 0 \\ 0 & 1 + \sum_{i=1}^n \lambda_i x_i \end{bmatrix}. \quad \blacktriangleleft$$

## Abstract

*Entropic risk (ERisk)* is an established risk measure in finance, quantifying risk by an exponential re-weighting of rewards. We study ERisk for the first time in the context of turn-based stochastic games with the total reward objective. This gives rise to an objective function that demands the control of systems in a risk-averse manner. We show that the resulting games are determined and, in particular, admit optimal memoryless deterministic strategies. This contrasts risk measures that previously have been considered in the special case of Markov decision processes and that require randomization and/or memory. We provide several results on the decidability and the computational complexity of the threshold problem, i.e. whether the optimal value of ERisk exceeds a given threshold. In the most general case, the problem is decidable subject to Shaniel’s conjecture. If all inputs are rational, the resulting threshold problem can be solved using algebraic numbers, leading to decidability via a polynomial-time reduction to the existential theory of the reals. Further restrictions on the encoding of the input allow the solution of the threshold problem in  $\text{NP} \cap \text{coNP}$ . Finally, an approximation algorithm for the optimal value of ERisk is provided.

## 1 Introduction

**Stochastic Models.** Formal analysis of stochastic models is ubiquitous across disciplines of science, such as computer science [4], biology [43], epidemiology [29], and chemistry [28], to name a few. In computer science, a fundamental stochastic model are Markov decision processes (MDPs) [46], which extend purely stochastic Markov chains (MCs) with non-determinism to represent an agent interacting with a stochastic environment. Stochastic games (SGs) [49, 18, 19] in turn generalize MDPs by introducing an adversary, modelling the case where two agents engage in adversarial interaction in the presence of a stochastic environment. Notably, SGs can also be used to conservatively model MDPs where transition probabilities are not known precisely [15, 53]. See also [46] and [14, 21] for further applications of MDPs and SGs.

## 15:2 Entropic Risk for Turn-Based Stochastic Games

■ **Figure 1** Illustration of the entropic risk measure. The random variable  $X$  takes values  $x_1$  to  $x_4$  uniformly with probability  $\frac{1}{4}$  each. Expectation considers the average of  $x_i$ , while entropic risk yields the (normalized logarithm of the) average of  $y_i = e^{-\gamma x_i}$ .

**Strategies and Objectives.** In MDPs and SGs, the recipes to resolve choices are called strategies. The objective of the agent is to optimize a payoff function against all possible strategies of the adversary. One of the most fundamental problems studied in the context of MDPs and SGs is the optimization of total reward (and the related *stochastic shortest path* problem [7]). Here, every state (or, equivalently, transition) of the stochastic model is assigned a cost or reward and the payoff of a trajectory is the total sum of rewards appearing along the path. MDPs and SGs with total reward objectives provide an appropriate model to study a wide range of applications, such as traffic optimization [27], verification of stochastic systems [26, 47], or navigation / probabilistic planning [50].

**Risk-Ignorance of Expectation.** Typically, the expectation of the obtained total reward is optimized. However, the expectation measure is ignorant towards aspects of risk; an expectation maximizing agent accepts a one-in-a-million chance of extremely high rewards over a slightly worse, but guaranteed outcome. Such a behaviour might be undesirable in a lot of situations: Consider a one-shot lottery where with a chance of  $10^{-6}$  we win  $2 \cdot 10^6$  times our stake and otherwise lose everything – a two-times increase in expectation. The optimal strategy w.r.t. expectation would bet all available assets, ending up broke in nearly all outcomes.

**Risk-Aware Alternatives.** To address this issue, *risk-aware* objectives create incentives to prefer slightly smaller performance in terms of expectation in exchange for a more “stable” behaviour. To this end, several variants have been studied in the verification literature, such as (a) variance-penalized expected payoff [45, 22] that combines the expected value with a penalty for the variance of the resulting probability distribution; (b) trade-off of the expectation and variance for various notions of variance [40, 11]; (c) quantiles and conditional value-at-risk (CVaR) [47, 42, 35]; to name a few.

**Drawbacks.** The current approaches suffer from the following three drawbacks:

1. The above studies focus on the second moment (variance) along with the first moment (mean), but do not incorporate other moments of the payoff distribution.
2. All approaches are studied only for MDPs; none of them have been extended to SGs.
3. Even in MDPs, the above problems require complicated strategies. For example, trade-offs between expectation and variance require memory and randomization [11, 40], while optimizing variance-penalized expected payoffs, quantiles, or the CVaR of the total reward require exponential memory [45, 30, 44, 42].

**Entropic Risk.** The notion of entropic risk [24] has been widely studied in finance and operation research, see e.g. [23, 10]. Informally, instead of weighing each outcome uniformly and then aggregating it (as in the case for regular expectation), entropic risk re-weighs outcomes by an exponential function, then computes the expectation, and finally re-normalizes the value. We illustrate this in Figure 1. The exact definition of entropic risk is introduced later on.

**Advantages.** Aside from satisfying many desirable properties of risk measures established in finance, entropic risk brings several crucial advantages in our specific setting, of which we list a few: Compared to expectation, “bad” outcomes are penalized more than “good” outcomes add value. Thus, an agent optimizing entropic risk seeks to reduce the chances of particularly bad outcomes while also being interested in a good overall performance. In contrast to variance minimization, it is beneficial to increase the probability of extremely good outcomes (which would increase variance). Moreover, the entropic risk incorporates *all* moments of the distribution. In particular, even if the expectation is infinite, entropic risk still provides meaningful values (opposed to both expectation and variance). Note that the expected total reward objective is often addressed under additional assumptions excluding this case [8, 26]. Additionally, entropic risk is a *time-consistent* risk measure. In our situation, this means that the risk evaluation at a state is the same for *any history*. This is in stark contrast to, e.g., quantile and CVaR optimal strategies, which after a series of unfortunate events start behaving recklessly (e.g. expectation optimal). Due to these advantages, ERisk has already been studied in the context of MDPs [33, 5]. However, to the best of our knowledge, neither the arising computational problems nor the more general setting of SGs have been addressed.

## 1.1 Our results

In this work we consider the notion of entropic risk in the context of SGs as well as the special cases of MCs and MDPs. For an overview of our complexity results, see Table 1.

1. *Determinacy and Strategy Complexity.* We establish several basic results, in particular that SGs with the entropic risk objective are determined and that pure memoryless optimal strategies exist for both players. This stands in contrast to other notions of risk, where even in MDPs strategies require memory and/or randomization.
2. *Exact Computation.* When allowing Euler’s number  $e$  as the basis of exponentiation, the threshold problem whether the optimal entropic risk lies above a given bound is decidable subject to Shaniel’s conjecture. If the basis of exponentiation and all other numbers in the input are rational, then all numbers resulting from the involved exponentiation are shown to be algebraic. We obtain a reduction to the existential theory of the reals and thus a PSPACE upper bound in this case.

Furthermore, we identify a notion of *small algebraic instance* in which all occurring numbers are not only algebraic, but have a small representation and are contained in an algebraic extensions of  $\mathbb{Q}$  of low degree. The threshold problem for small algebraic instances of MCs and MDPs can efficiently be solved by explicit computations in an algebraic extension of  $\mathbb{Q}$ . We obtain polynomial-time algorithms for MCs and MDPs, and conclude that the threshold problem lies in  $\text{NP} \cap \text{co-NP}$  for SGs in this case. For small algebraic instances, we furthermore show that an explicit closed form of the optimal value can be computed (a) in polynomial time for MCs; and consequently (b) in polynomial space for SGs.

3. *Approximate Computation.* We provide an effective way to compute an approximation, i.e. determine the optimal entropic risk up to a given precision of  $\varepsilon > 0$ . To this end, we show that in the general case, by considering enough bits of arising irrational numbers, we can

■ **Table 1** Overview of the decidability and complexity results for SGs, MDPs and MCs.

	threshold problem			optimal value	
	general instances (Thm. 14)	algebraic instances (Thm. 16)	small algebraic instances (Thm. 19)	computation for small algebraic instances (Thm. 20)	approximation with small rewards and risk aversion factor (Thm. 21)

bound the incurred error. In MDPs and MCs, the optimal value can be approximated in time polynomial in the size of the model, in  $-\log(\varepsilon)$ , and in the magnitude of the rewards. For SGs, this implies the existence of a polynomial-space approximation algorithm.

## 1.2 Related Work

The entropic risk objective has been studied before in MDPs: An early formulation can be found in [33] under the name *risk-sensitive MDPs* focusing on the finite-horizon setting. The paper [34] considers an exponential utility function applied to discounted rewards and optimal strategies are shown to exist, but not to be memoryless in general. In [20], the entropic risk objective is considered for MDPs with a general Borel state space and in [5] a generalization of this objective is studied on such MDPs. To the best of our knowledge, however, all previous work in the context of MDPs focuses on optimality equations and general convergence results of value iteration, while the resulting algorithmic problems for finite-state MDPs have not been investigated. Furthermore, we are not aware of work on the entropic risk objective in SGs.

For other objectives capturing risk-aversion, algorithmic problems have been analyzed on finite-state MDPs: Variance-penalized expectation has been studied for finite-horizon MDPs with terminal rewards in [17] and for infinite-horizon MDPs with discounted rewards and mean payoffs [22], and total rewards [45]. For total rewards, optimal strategies require exponential memory and the threshold problem is in NEXPTIME and EXPTIME-hard [45].

In [40], the optimization of expected accumulated rewards under constraints on the variance are studied for finite-horizon MDPs. Possible tradeoffs between expected value and variance of mean payoffs and other notions of variability have been studied in [11].

To control the chance of bad outcomes, the problem to maximize or minimize the probability that the accumulated weight lies below a given bound  $w$  has been addressed in MDPs [30, 31]. Similarly, quantile queries ask for the minimal weight  $w$  such that the weight of a path stays below  $w$  with probability at least  $p$  for the given value  $p$  under some or all schedulers [51, 48]. Both of these problems have been addressed for MDPs with non-negative weights and are solvable in exponential time in this setting [51, 30]. Optimal strategies require exponential memory and the decision version of these problems is PSPACE-hard [30].

The conditional value-at-risk (CVaR), a prominent risk-measure, has been investigated for mean payoff and weighted reachability in MDPs in [35] as well as for total rewards in MDPs [44, 42]. The optimal CVaR of the total reward in MDPs with non-negative weights can be computed in exponential time and optimal strategies require exponential memory [44, 42]. The threshold problem for optimal CVaR of total reward in MDPs with integer weights is at least as hard as the Positivity-problem for linear recurrence sequences, a well-known problem in analytic number theory whose decidability status is, since many decades, open [44].

For all these objectives capturing risk-aversion in some sense, we are not aware of any work addressing the resulting algorithmic problems on SGs.

## 2 Preliminaries

In this section, we recall the basics of (turn-based) SGs and relevant objectives. For further details, see, e.g., [46, 4, 26, 21]. We assume familiarity with basic notions of probability theory (see, e.g., [9]). We write  $\mathcal{D}(X)$  to denote the set of all *probability distributions* over a countable set  $X$ , i.e. mappings  $d : X \rightarrow [0, 1]$  such that  $\sum_{x \in X} d(x) = 1$ . The support of a distribution  $d$  is  $\text{supp}(d) := \{x \in X \mid d(x) > 0\}$ . For a set  $S$ ,  $S^*$  and  $S^\omega$  refer to the set of finite and infinite sequences of elements of  $S$ , respectively.

### Markov Chains, MDPs, and Stochastic Games

A *Markov chain (MC)* (e.g. [4]), is a tuple  $M = (S, \delta)$ , where  $S$  is a set of *states*, and  $\delta : S \rightarrow \mathcal{D}(S)$  is a *transition function* that for each state  $s$  yields a probability distribution over successor states. We write  $\delta(s, s')$  instead of  $\delta(s)(s')$  for the probability to move from  $s$  to  $s'$  for  $s, s' \in S$ . A (*infinite*) *path* in an MC is an infinite sequence  $s_0, s_1, \dots$  of states such that for all  $i$ , we have  $\delta(s_i, s_{i+1}) > 0$ . We denote the set of infinite paths by  $\text{Paths}_M$ . Together with a state  $s$ , an MC  $M$  induces a unique probability distribution  $\text{Pr}_{M,s}$  over the set of all infinite paths  $\text{Paths}_M$  starting in  $s$ . For a random variable  $f : \text{Paths}_M \rightarrow \mathbb{R}$ , we write  $\mathbb{E}_{M,s}(f)$  for the expected value of  $f$  under the probability measure  $\text{Pr}_{M,s}$ .

A *turn-based stochastic game (SG)* (e.g. [18]) is a tuple  $(S_{\max}, S_{\min}, A, \Delta)$ , where  $S_{\max}$  and  $S_{\min}$  are disjoint sets of *Maximizer* and *Minimizer* states, inducing the set of states  $S = S_{\max} \cup S_{\min}$ ,  $A$  denotes a finite set of *actions*, furthermore overloading  $A$  to also act as a function assigning to each state  $s$  a set of non-empty *available actions*  $A(s) \subseteq A$ , and  $\Delta : S \times A \rightarrow \mathcal{D}(S)$  is the *transition function* that for each state  $s$  and (available) action  $a \in A(s)$  yields a distribution over successor states. For convenience, we write  $\Delta(s, a, s')$  instead of  $\Delta(s, a)(s')$ . Moreover,  $\text{opt}_{a \in A(s)}^s$  refers to  $\max_{a \in A(s)}$  if  $s \in S_{\max}$  and  $\min_{a \in A(s)}$  if  $s \in S_{\min}$ , i.e. the preference of either player in a state  $s$ . We omit the superscript  $s$  where clear from context. Given a function  $f : S \rightarrow \mathbb{R}$  assigning values to states, we write  $\Delta(s, a)\langle f \rangle := \sum_{s' \in S} \Delta(s, a, s') \cdot f(s')$  for the weighted sum over the successors of  $s$  under  $a \in A(s)$ . A *Markov decision process (MDP)* (e.g. [46]) can be seen as an SG with only one player, i.e.  $S_{\max} = \emptyset$  or  $S_{\min} = \emptyset$ .

The semantics of SGs is given in terms of resolving choices by strategies inducing an MC with the respective probability space over infinite paths. Intuitively, a stochastic game is played in turns: In every state  $s$ , the player to whom it belongs chooses an action  $a$  from the set of available actions  $A(s)$  and the play advances to a successor state  $s'$  according to the probability distribution given by  $\Delta(s, a)$ . Starting in a state  $s_0$  and repeating this process indefinitely yields an infinite sequence  $\rho = s_0 a_0 s_1 a_1 \dots \in (S \times A)^\omega$  such that for every  $i \in \mathbb{N}_0$  we have  $a_i \in A(s_i)$  and  $\Delta(s_i, a_i, s_{i+1}) > 0$ . We refer to such sequences as (*infinite*) *paths* or *plays* and denote the set of all infinite paths in a given game  $G$  by  $\text{Paths}_G$ . Furthermore, we write  $\rho_i$  to denote the  $i$ -th state in the path  $\rho$ . *Finite paths* or *histories*  $\text{FPaths}_G$  are finite prefixes of a play, i.e. elements of  $(S \times A)^* \times S$  consistent with  $A$  and  $\Delta$ .

The decision-making of the players is captured by the notion of *strategies*. Strategies are functions mapping a given history to a distribution over the actions available in the current state. For this paper, *memoryless deterministic* strategies (abbreviated *MD strategies*, also called positional strategies) are of particular interest. These strategies choose a single action in each state, irrespective of the history, and can be identified with functions  $\sigma : S \rightarrow A$ . Since we show that these strategies are sufficient for the discussed notions, we define the semantics of games only for these strategies and refer the interested reader to the mentioned

## 15:6 Entropic Risk for Turn-Based Stochastic Games

literature for further details. We write  $\Pi_G$  for the set of all strategies and  $\Pi_G^{\text{MD}}$  for memoryless deterministic ones. We call a pair of strategies a *strategy profile*, written  $\pi = (\sigma, \tau)$ . We identify a profile with the induced joint strategy  $\pi(s) := \sigma(s)$  if  $s \in S_{\max}$  and  $\tau(s)$  otherwise.

Given a profile  $\pi = (\sigma, \tau)$  of MD strategies for a game  $G$ , we write  $G^\pi$  for the MC obtained by fixing both strategies. So,  $G^\pi = (S, \hat{\delta})$ , where  $\hat{\delta}(s) := \Delta(s, \pi(s))$ . Together with a state  $s$ , the MC  $G^\pi$  induces a unique probability distribution  $\Pr_{G,s}^\pi$  over the set of all infinite paths  $\text{Paths}_G$ . For a random variable over paths  $f : \text{Paths}_G \rightarrow \mathbb{R}$ , we write  $\mathbb{E}_{G,s}^\pi[f]$  for the expected value of  $f$  under the probability measure  $\Pr_{G,s}^\pi$ .

### Objectives

Usually, we are interested in finding strategies that optimize the value obtained for a particular *objective*. We introduce some objectives of interest.

**Reachability.** A reachability objective is specified by a set of *target states*  $T \subseteq S$ . We define  $\diamond T = \{\rho \mid \exists i. \rho_i \in T\}$  the set of all paths eventually reaching a target state. Given a strategy profile  $\pi$  and a state  $s$ , the probability for this event is given by  $\Pr_{G,s}^\pi[\diamond T]$ . On games, we are interested in determining the *value*  $\text{Val}_{G, \diamond T}(s) := \max_{\sigma \in \Pi_G^{\text{MD}}} \min_{\tau \in \Pi_G^{\text{MD}}} \Pr_{G,s}^{\sigma, \tau}[\diamond T]$  of a state  $s$ , which intuitively is the best probability we can ensure against an optimal opponent. Generally, one would consider supremum and infimum over strategies instead maximum and minimum over MD strategies. However, for reachability we know that these value coincide and the game is *determined*, i.e. the order of max and min does not matter [19]. Finally, we know that the value  $\text{Val}_{G, \diamond T}$  is a solution of the following set of equations

$$v(s) = 0 \text{ for } s \in S_0, \quad v(s) = 1 \text{ for } s \in T, \quad \text{and } v(s) = \text{opt}_{a \in A(s)} \Delta(s, a) \langle v \rangle \text{ otherwise, (1)}$$

where  $S_0$  is the set of states that cannot reach  $T$  against an optimal Minimizer strategy [13].

**Total Reward.** The total reward objective is specified by a reward function  $r : S \rightarrow \mathbb{R}_{\geq 0}$ , assigning non-negative rewards to every state. The total reward obtained by a particular path is defined as the sum of all rewards seen along this path,  $\text{TR}(\rho) := \sum_{i=1}^{\infty} r(\rho_i)$ . Note that since we assume  $r(s) \geq 0$ , this sum is always well-defined. Classically, we want to optimize the expected total reward, i.e. determine  $\text{Val}_{G, \mathbb{E} \text{TR}}(s) := \max_{\sigma \in \Pi_G^{\text{MD}}} \min_{\tau \in \Pi_G^{\text{MD}}} \mathbb{E}_{G,s}^{\sigma, \tau}[\text{TR}]$ . This game is determined and MD strategies suffice [16]. (To be precise, that work considers a more general formulation of total reward, our case is equivalent to the case  $\star = c$  and  $T = \emptyset$  (Def. 3) and the quantitative rPATL formula  $\langle\langle\{1\}\rangle\rangle \mathbf{R}_{\max=?}^r[\mathbf{F}^c \mathbf{f} \mathbf{f}]$ .)

### 3 Entropic Risk

As hinted in the introduction, for classical total reward we optimize the expectation and disregard other properties of the actual distribution of obtained rewards. This means that an optimal strategy may accept arbitrary risks if they yield minimal improvements in terms of expectation. To overcome this downside, we consider the entropic risk:

► **Definition 1.** Let  $b > 1$  a basis,  $X$  a random variable, and  $\gamma > 0$  a risk aversion factor. The entropic risk (of  $X$  with base  $b$  and factor  $\gamma$ ) (see, e.g., [25]) is defined as

$$\text{ERisk}_\gamma(X) := -\frac{1}{\gamma} \log_b(\mathbb{E}[b^{-\gamma X}]).$$

One often chooses  $b = e$ . Nevertheless, we also consider rational values for  $b$ , which allows us to apply techniques from algebraic number theory to arising computational problems.

► **Example 2.** Consider a random variable  $X$  that takes values  $x_1 = 1$ ,  $x_2 = 2$ ,  $x_3 = 4$ , and  $x_4 = 5$  with probability  $1/4$  each. Figure 1 illustrates how the entropic risk measure of  $X$  with base  $e$  is obtained for some risk aversion factor  $\gamma$ : The values  $x_i$  are depicted on the  $x$ -axis. We now map the values  $x_i$  to values  $y_i = e^{-\gamma x_i}$  on the  $y$ -axis. Then, the expected value of  $e^{-\gamma X}$  can be obtained as the arithmetic mean of the values  $y_i$ . The result is mapped back to the  $x$ -axis via  $y \mapsto -\frac{1}{\gamma} \log(y)$ , the inverse of  $x \mapsto e^{-\gamma x}$ , and we obtain  $\text{ERisk}_\gamma(X)$ .

The example shows that deviations to lower values are penalized, i.e. taken into consideration more strongly, by this risk measure. For a different perspective, we can also consider the Taylor expansion of  $\text{ERisk}$  w.r.t.  $\gamma$ , which is  $\text{ERisk}_\gamma(X) = \mathbb{E}[X] - \frac{\gamma}{2} \cdot \text{Var}[X] + \mathcal{O}(\gamma^2)$  (see, e.g., [2]). The terms hidden in  $\mathcal{O}(\gamma^2)$  comprise all moments of  $X$  and exhibit an asymmetry such that  $\text{ERisk}$  is roughly the expected value minus a penalty for deviations to lower values.

### 3.1 Entropic Risk in SGs

We are interested in the case  $X = \text{TR}$ , i.e. optimizing the risk for total rewards. We write

$$\text{ERisk}_{\mathbb{G}, \hat{s}}^\gamma(\pi) := -\frac{1}{\gamma} \log_b(\mathbb{E}_{\mathbb{G}, \hat{s}}^\pi[b^{-\gamma X}])$$

to denote the entropic risk of the total reward achieved by the strategy profile  $\pi$  when starting in state  $\hat{s}$ , omitting sub- and superscripts where clear from context. Clearly, this is well defined for any profile: We have that  $b^{-\gamma \text{TR}(\rho)} = b^{-\gamma \sum_{i=1}^{\infty} r(\rho_i)} = \prod_{i=1}^{\infty} b^{-\gamma r(\rho_i)}$  and each factor lies between 0 and 1, thus the product converges (possibly with limit 0).

We also give an insightful characterization for integer rewards. If  $r(s) \in \mathbb{N}$ , we have

$$\text{ERisk}_{\mathbb{G}, \hat{s}}^\gamma(\pi) = -\frac{1}{\gamma} \log_b \left( \sum_{n=0}^{\infty} \Pr_{\mathbb{G}, \hat{s}}^\pi[\text{TR} = n] \cdot b^{-\gamma n} \right). \quad (2)$$

Naturally, our goal is to optimize the entropic risk. In this work, we mainly consider the corresponding decision variant, which we call the *entropic risk threshold problem*:

**Entropic risk threshold problem:** Given an SG  $\mathbb{G}$ , state  $\hat{s}$ , reward function  $r$ , risk parameter  $\gamma$ , risk basis  $b$ , and threshold  $t$ , decide whether there exists a Maximizer strategy  $\sigma$  such that for all Minimizer strategies  $\tau$  we have  $\text{ERisk}_{\mathbb{G}, \hat{s}}^\gamma((\sigma, \tau)) \geq t$ .

Note that (for now) we do not assume any particular encoding of the input. For example, the reward function  $r$  could be given symbolically, describing irrational numbers. A second variant of the threshold problem asks whether the optimal value

$$\text{ERisk}_{\mathbb{G}, \hat{s}}^{\gamma*} := \sup_{\sigma \in \Pi_{\mathbb{G}}} \inf_{\tau \in \Pi_{\mathbb{G}}} \text{ERisk}_{\mathbb{G}, \hat{s}}^\gamma((\sigma, \tau)) \quad (3)$$

is at least  $t$  for a given threshold  $t$ . We will see that SGs with the entropic risk as objective function are determined and hence the two variants are equivalent. Before proceeding with our solution approaches, we provide an illustrative example.

► **Example 3.** Consider the MDP of Figure 2. The optimal total reward is obtained by choosing action **risk** in state  $s_1$ : Then, we actually obtain an infinite total reward through state  $s_2$ . In comparison, choosing action **safe** would yield a reward of 6 in total. Now, consider the entropic risk. When choosing action **risk**, we obtain a total reward of 2 and  $\infty$  with probability  $\frac{1}{2}$  each, while action **safe** yields 6 with probability 1. Let  $b = 2$  and  $\gamma = 1$  for simplicity. Then, we obtain an entropic risk of  $-\log_2(\frac{1}{2}2^{-2} + \frac{1}{2}2^{-\infty}) = 3$  under action **risk** and  $-\log_2(2^{-6}) = 6$  for **safe**. Thus, action **safe** is preferable.

■ **Figure 2** Our running example to demonstrate several properties of entropic risk. For ease of presentation, the system actually is an MDP, where all states belong to Maximizer. States are denoted by boxes and their reward is written next to the state name. Transition probabilities are written next to the corresponding edges, omitting probability 1.

► **Remark 4.** As hinted above, entropic risk is finite whenever a finite reward is obtained with non-zero probability, i.e. for any strategy profile  $\pi$ ,  $\text{ERisk}_{\mathcal{G},s}^\gamma(\pi) = \infty$  iff  $\Pr_{\mathcal{G},s}^\pi[\text{TR} = \infty] = 1$ . In contrast, expectation is infinite whenever there is a non-zero chance of infinite reward, i.e.  $\mathbb{E}_{\mathcal{G},s}^\pi[\text{TR}] = \infty$  iff  $\Pr_{\mathcal{G},s}^\pi[\text{TR} = \infty] > 0$ . So, entropic risk allows us to meaningfully compare strategies which yield infinite total reward with some positive probability.

### 3.2 Exponential Utility

Observe that the essential part of the entropic risk is the inner expectation. Thus, we consider the *negative exponential utility*

$$\text{NegUtil}_{\mathcal{G},s}^\gamma(\pi) := \mathbb{E}_{\mathcal{G},s}^\pi[b^{-\gamma \text{TR}}].$$

We have  $\text{ERisk}_{\mathcal{G},s}^\gamma(\pi) = -\frac{1}{\gamma} \log_b(\text{NegUtil}_{\mathcal{G},s}^\gamma(\pi))$ . Observe that in our case  $0 \leq \text{NegUtil}_{\mathcal{G},s}^\gamma(\pi) \leq 1$  for any  $\pi$ , as  $0 \leq \text{TR} \leq \infty$ . Moreover,  $\text{ERisk}_{\mathcal{G},s}^\gamma(\pi) \geq t$  iff  $\text{NegUtil}_{\mathcal{G},s}^\gamma(\pi) \leq b^{-\gamma t}$ , thus, a risk-averse agent (in our case Maximizer) wants to minimize NegUtil. The optimal value is

$$\text{NegUtil}_{\mathcal{G},s}^{\gamma*} := \inf_{\sigma \in \Pi_{\mathcal{G}}} \sup_{\tau \in \Pi_{\mathcal{G}}} \mathbb{E}_{\mathcal{G},s}^{\sigma,\tau}[b^{-\gamma \text{TR}}]. \quad (4)$$

We again omit sub- and superscripts where clear from context. We show later that games with NegUtil or ERisk as payoff functions are determined. Thus, the order of sup and inf in the above definition does not matter. We call a Maximizer-strategy  $\sigma$  optimal if  $\text{ERisk}_{\mathcal{G},s}^{\gamma*} = \inf_{\tau \in \Pi_{\mathcal{G}}} \text{ERisk}_{\mathcal{G},s}^\gamma((\sigma, \tau))$  and analogously for Minimizer-strategies.

## 4 Basic Properties and Decidability

In this section, we establish several results for SGs with entropic risk as objective functions concerning determinacy, strategy complexity, and decidability in the general case. We mainly work on games with NegUtil as payoff function. As ERisk can be obtained from NegUtil via the monotone function  $-\frac{1}{\gamma} \log(\cdot)$ , most results, such as determinacy or strategy complexity, will transfer directly to games with ERisk as objective function.

First, we show that the games are determined, i.e. the order of sup and inf in Equation (3) and Equation (4) can be switched. Then, we show that games with NegUtil as payoff function can be seen as reachability games via a reduction that introduces irrational transition probabilities in general. We conclude that considering only MD strategies is sufficient to obtain the optimal value, i.e. sup and inf can be replaced with a max and min over MD strategies. From this, we derive a system of inequalities that has a solution if and only if the optimal value satisfies  $\text{ERisk}^* \geq t$  for a given threshold  $t$ . We conclude this section by observing that the satisfiability of this system of inequalities can be expressed as a sentence in the language of the reals with exponentiation. In this way, we obtain the conditional decidability of the entropic risk threshold problem in SGs subject to Shaniel's conjecture.

Throughout this section, fix a game  $G$ , reward function  $r$ , state  $\hat{s}$ , risk parameter  $\gamma$ , and risk basis  $b$ . Omitted proofs can be found in the extended version [3].

## 4.1 Determinacy and Optimality Equation

► **Lemma 5.** *Stochastic games with NegUtil as payoff function are determined, i.e.*

$$\inf_{\sigma \in \Pi_G} \sup_{\tau \in \Pi_G} \mathbb{E}_{G,s}^{\sigma,\tau}[b^{-\gamma \text{TR}}] = \sup_{\tau \in \Pi_G} \inf_{\sigma \in \Pi_G} \mathbb{E}_{G,s}^{\sigma,\tau}[b^{-\gamma \text{TR}}].$$

**Proof.** This follows from the classical result on determinacy of Borel games [41], see [39] for a concrete formulation for stochastic games. In particular, the game is zero-sum and NegUtil is a bounded, Borel-measurable function. ◀

As ERisk is obtained from NegUtil via a monotone function, also games with ERisk as payoff function are determined. While ERisk\* is difficult to tackle directly due to its non-linearity, we can derive the following optimality equation for NegUtil\*:

► **Lemma 6.** *The optimal utility NegUtil\* is a solution of the following system of constraints:*

$$v(s) = b^{-\gamma r(s)} \cdot \overline{\text{opt}}_{a \in A(s)}^s \cdot \sum_{s' \in S} \Delta(s, a, s') \cdot v(s'), \quad (5)$$

where  $\overline{\text{opt}}^s$  is min for a Maximizer state  $s$  and max for a Minimizer state.

Unfortunately, NegUtil is not the unique or, at least, the pointwise smallest or largest fixed point of this equation system. Consider the case where  $r \equiv 0$ , i.e.  $b^{-\gamma r(s)} = 1$ . Here, every constant vector is a fixed point, however NegUtil\*  $\equiv 1$ . More generally, as the equations are purely multiplicative, for any fixed point  $v$ , every multiple  $\lambda \cdot v$  is a fixed point, too.

► **Example 7.** Again consider the example of Figure 2 with  $b = 2$  and  $\gamma = 1$ . The (simplified) equations we get are:

$$v_1 = 2^{-2} \cdot \min\{\frac{1}{2}v_2 + \frac{1}{2}v_3, v_4\} \quad v_2 = 2^{-2} \cdot v_2 \quad v_3 = v_3 \quad v_4 = 2^{-4} \cdot v_3,$$

where  $v_i$  corresponds to the value of  $s_i$ . First, for  $v_2$ , we observe that  $v_2 = 0$  is the only valid assignment. Then, we have that  $v_1 = 2^{-2} \cdot \min\{\frac{1}{2}0 + \frac{1}{2}v_3, 2^{-4}v_3\} = 2^{-3} \cdot \min\{v_3, 2^{-3}v_3\}$ . Clearly, this system is underdetermined and we obtain a distinct solution for any value of  $v_3$ .

To solve these issues, we need to define “anchors” of the equation. We observe the resemblance of classical fixed point equations for stochastic systems. In particular, for  $r \equiv 0$ , Equation (5) is the same as for reachability, Equation (1).

## 4.2 Reduction to Reachability

We define  $S_0 = \{s \mid \max_{\sigma} \min_{\tau} \Pr_{G,s}^{\sigma,\tau}[\text{TR} > 0] = 0\}$  and  $S_{\infty} = \{s \mid \max_{\sigma} \min_{\tau} \Pr_{G,s}^{\sigma,\tau}[\text{TR} = \infty] = 1\}$  the set of states in which Maximizer cannot obtain a total reward of more than 0 with positive probability against an optimal opponent strategy or ensure infinite reward with probability 1, respectively. We show later on that these sets are simple to compute and MD strategies are sufficient. Since  $r(s) \geq 0$ , all states in  $s \in S_0$  necessarily have  $r(s) = 0$ . Observe that  $S_0$  may be empty, but then  $S = S_{\infty}$  and so NegUtil\* = 0, ERisk\* =  $\infty$ . Through these sets, we can connect optimizing the utility to a reachability objective.

## 15:10 Entropic Risk for Turn-Based Stochastic Games

► **Lemma 8.** *For any state  $s$  in the game  $G$ , the optimal utility  $\text{NegUtil}^*$  is equal to the minimal probability of reaching the set  $S_0$  from  $s$  in game  $G_R$ , defined as follows: We add a designated sink state  $\underline{s}$  (which may belong to either player and only has a self-loop back to itself) and define  $\Delta_R(s, a, s') = b^{-\gamma r(s')} \cdot \Delta(s, a, s')$  for  $s, s' \in S$ ,  $a \in A(s)$  and  $\Delta_R(s, a, \underline{s}) = (1 - b^{-\gamma r(s)})$ . There is a direct correspondence between optimal strategies.*

We note that reachability games can also be reduced to our case:

► **Lemma 9.** *For any game  $G$  and (absorbing) reachability goal  $T$ , we have  $\text{Val}_{G, \diamond T}(s) = 1 - \text{NegUtil}_G^*(s)$  with reward  $r(s) = \mathbb{1}_T(s)$  and  $\gamma = 1$ .*

We highlight that this reduction from entropic risk games to reachability games is *not* an effective reduction in the computational sense, since  $G_R$  comprises *irrational* transition probabilities even for entirely rational inputs. We discuss how to tackle this in the next section and first proceed to derive some useful properties from this correspondence.

► **Lemma 10.** *The optimal utility  $\text{NegUtil}^*$  is the pointwise smallest solution of*

$$\begin{aligned} v(s) &= 0 \quad \text{for } s \in S_\infty, & v(s) &= 1 \quad \text{for } s \in S_0, \text{ and} \\ v(s) &= \overline{\text{opt}}_{a \in A(s)}^s b^{-\gamma r(s)} \cdot \Delta(s, a) \langle v \rangle & \text{otherwise} \end{aligned} \tag{6}$$

Yet, there might be multiple fixed points to the system of equations. This is to be expected, since already reachability on MDPs exhibits this problem [32]. We provide a discussion of these issues together with a sufficient condition for uniqueness in the extended version [3].

### 4.3 Strategy Complexity

By Lemma 8, the optimal negative exponential utility is achieved by reachability-optimal strategies in  $G_R$ . With the known results on reachability [18], this yields:

► **Theorem 11.** *MD strategies are sufficient to optimize the negative exponential utility and thus also entropic risk. More precisely, for all SGs  $G$ , there is an MD strategy  $\sigma$  for the Maximizer such that  $\text{ERisk}_{G,s}^{\gamma*} = \inf_{\tau \in \Pi_G} \text{ERisk}_{G,s}^\gamma((\sigma, \tau))$  and analogously for the Minimizer.*

► **Remark 12.** We highlight that this means that this notion of risk is history independent: Which actions are optimal does not depend on what has already “gone wrong”, but purely on the potential future consequences. This is in stark contrast to, e.g., conditional value-at-risk optimal strategies for total reward, which require exponential memory and switch to a purely expectation maximizing (i.e. risk-ignorant) behaviour after “enough” went wrong [42].

### 4.4 System of Inequalities

The problem we want to solve is deciding whether the Maximizer can ensure an entropic risk of at least  $t$ . Unfortunately, the reachability game  $G_R$  is not directly computable, since even for rational rewards  $b^{-\gamma r(s)}$  may be irrational. As such, we cannot use this transformation directly to prove decidability or complexity results and need to take a different route. Analogous to the classical solution to reachability, we first convert the problem to a system of inequalities. Intuitively, we replace every max with  $\geq$  for all options and dually min with  $\leq$  (again, recalling that Maximizer wants to minimize the value in  $G_R$ ). Formally, we consider the following:

$$\begin{aligned}
v(\hat{s}) &\leq b^{-\gamma t}, & v(s) &= 0 \quad \text{for } s \in S_\infty, & v(s) &= 1 \quad \text{for } s \in S_0, \\
v(s) &\leq b^{-\gamma r(s)} \cdot \Delta(s, a)\langle v \rangle & \text{for } s \in S_{\max}, a \in A(s), \\
v(s) &\geq b^{-\gamma r(s)} \cdot \Delta(s, a)\langle v \rangle & \text{for } s \in S_{\min}, a \in A(s), \text{ and} \\
\bigvee_{a \in A(s)} v(s) &= b^{-\gamma r(s)} \cdot \Delta(s, a)\langle v \rangle & \text{for } s \in S
\end{aligned} \tag{7}$$

Observe that this essentially is the decision variant to the standard quadratic program for reachability applied to  $G_R$  [19].

► **Lemma 13.** *The system of equations 7 has a solution if and only if  $\text{ERisk}^* \geq t$ .*

## 4.5 Decidability Subject to Schanuel’s Conjecture

From Equation (7), we obtain a conditional decidability result for the general case:

► **Theorem 14.** *Let all quantities, i.e. rewards, transition probabilities, the risk-aversion factor  $\gamma$ , and the basis  $b$  be given as formulas in the language of reals with exponentiation (i.e. with functions  $+$ ,  $\cdot$ , and  $\exp: x \mapsto e^x$ ). Then, the entropic risk threshold problem for SGs is decidable subject to Schanuel’s conjecture.*

**Proof.** In this case, the existence of a solution to Equation (7) can also be expressed as a sentence in the language of the reals with exponentiation. The corresponding theory is known to be decidable subject to Schanuel’s conjecture (see e.g. [37]) as shown by [38], and decidability of this theory is equivalent to the so-called “weak Schanuel’s conjecture”. ◀

In particular, this allows us to treat instances with basis  $b = e$ . Yet, even if all rewards, transition probabilities, and  $\gamma$  are given as rational values, but the basis  $b$  equals  $e$ , we do not know how to check the satisfiability of Equation (7) without relying on the theory of the reals with exponentiation. Note, however, that we do not need the “full power” of the exponential function: All values appearing in an exponent in Equation (7) are constants. So, the restricted exponential function that agrees with  $\exp$  on a closed interval  $[a_1, a_2]$  and is zero outside of this interval is sufficient. The theory of the reals with restricted exponentiation has some additional nice properties compared to the theory of the reals with full exponentiation: For example, it allows for quantifier elimination by [52] and related works. Nevertheless, this does not allow us to immediately obtain an unconditional decidability result.

## 5 The Algebraic Case

If all occurring values are rational, then all numbers of the system of inequalities Equation (7) are algebraic. The results of this section establish that the threshold problem for such instances is decidable. A detailed exposition of the results can be found in the extended version [3]; an overview of the complexity results can also be found in Table 1. Formally, we define:

► **Definition 15.** *An algebraic instance of the entropic risk threshold problem is an instance where all occurring values, i.e. the transition probabilities of the game  $G$ , all rewards assigned by the reward function  $r$ , the risk-aversion parameter  $\gamma$ , the basis  $b$ , and the threshold  $t$ , are rational and encoded as the fraction of co-prime integers in binary.*

## 15:12 Entropic Risk for Turn-Based Stochastic Games

In general, for algebraic instances, there is a reduction of our problem to the existential theory of the reals, leading to the following result where  $\exists\mathbb{R}$  denotes the complexity class of problems that are polynomial-time reducible to the existential theory of the reals:

► **Theorem 16.** *For algebraic instances, the entropic risk threshold problem is decidable in  $\exists\mathbb{R}$  and thus in PSPACE.*

Already for Markov chains, it is unclear whether the upper complexity bound can be improved. For a discussion on this issue, see also the extended version [3].

For Theorem 16, we use the standard decision procedure for the existential theory of the reals as a “black box” and do not make use of the special form of our problem. To exploit the specific structure of the system of inequalities, we note that for explicit computations on algebraic numbers the following two quantities are relevant for the resulting computational complexity: Firstly, the degree of the field extension of  $\mathbb{Q}$  in which the computation can be carried out. Secondly, the bitsize of the coefficients of the minimal polynomials of the involved algebraic numbers (see, e.g., [1, 6]). Alternatively, the bitsize of the representations of the algebraic numbers in a fixed basis of the field extension in which the computations can be carried out can be used. Note that the size of the basis is precisely the degree of that field extension. Motivated by these observations, we consider *small algebraic instances*, which allow us to prove that all occurring algebraic numbers have a sufficiently small representation.

► **Definition 17.** *A small algebraic instance of the entropic risk threshold problem consists of a SG  $G$  with rational transition probabilities, an integer reward function  $r$ , a rational risk-aversion parameter  $\gamma$ , a rational basis  $b$ , and a rational threshold  $t$ . Moreover, the rewards,  $\gamma$ , and  $t$  are encoded in unary, and as the fraction of co-prime integers encoded in unary, respectively. The remaining rational numbers are encoded as the fraction of co-prime integers in binary. If  $G$  is an MDP or a MC, we call the instance a small algebraic instance of an MDP or a MC.*

► **Remark 18.** For simplicity, we assume for small algebraic instances that all rewards are in  $\mathbb{N}$ . If this is not the case, we can multiply all rewards with the least common multiple  $D$  of the denominators of the rewards and use a new risk-aversion parameter  $\gamma' = \gamma/D$ . The resulting negative exponential utility is not affected by this transformation. The change of the optimal entropic risk by a factor of  $D$  can be addressed by also rescaling the threshold  $t' = t \cdot D$ . Nevertheless, note that this affects the encoding size of the risk-aversion factor  $\gamma$ . Relying on algorithms for explicit computations in algebraic numbers [1, 6], we obtain:

► **Theorem 19.** *For small algebraic instances, the entropic risk threshold problem: (a) belongs to  $\text{NP} \cap \text{coNP}$  for SGs; and (b) can be solved in polynomial time for MDPs or MCs.*

While the mentioned results concern the threshold problem, we can even go a step further in small algebraic instances of MCs. Here, the system of inequalities simplifies to a linear system of equations, which we can solve *explicitly* in the algebraic numbers. For small algebraic instances, this is possible in polynomial time yielding the following result.

► **Theorem 20.** *For small algebraic instances, an explicit representation of  $\text{NegUtil}^*$  can be computed in: (a) polynomial time for MCs; and (b) in polynomial space for SGs and MDPs.*

## 6 Approximation Algorithms

The results of the previous section suggest, depending on the form of the input, a polynomial-space algorithm or even worse in the general case. Clearly, this is somewhat unsatisfactory for practical applications. Recall that the difficulties are due to the occurring irrational

transition probabilities. In the hope that we can work with approximations of these numbers, we now aim to identify an approach which allows us to approximate the correct answer, i.e. compute a value close to the optimal entropic risk that the Maximizer can ensure. Again, fix an SG  $G$ , reward function  $r$ , risk parameter  $\gamma$ , and risk basis  $b$  throughout this section. Then, given a precision  $\varepsilon > 0$ , we aim to compute a value  $v$  such that  $|\text{ERisk}^* - v| < \varepsilon$ , i.e. an approximation with small absolute error.

Since entropic risk is the logarithm of utility, we need to obtain an approximation of  $\text{NegUtil}^*$  to a sufficiently small *relative* error. Concretely, we need to compute a value  $v_U$  such that  $b^{-\gamma\varepsilon} \leq v_U / \text{NegUtil}^* \leq b^{\gamma\varepsilon}$ . Then,  $v = -\frac{1}{\gamma} \log_b(v_U)$  yields an approximation, since

$$\begin{aligned} \text{ERisk}^* - v &= -\frac{1}{\gamma} \log_b(\text{NegUtil}^*) + \frac{1}{\gamma} \log_b(v_U) = \frac{1}{\gamma} \log_b(v_U / \text{NegUtil}^*) = (*) \\ (*) &\geq \frac{1}{\gamma} \log_b(b^{-\gamma\varepsilon}) = -\varepsilon \quad \text{and} \quad (*) \leq \frac{1}{\gamma} \log_b(b^{\gamma\varepsilon}) = \varepsilon. \end{aligned}$$

(When we are interested in a concrete value for  $v$ , we need to determine  $v_U$  with a slightly higher precision and then approximate  $\log_b(v_U)$  sufficiently.) Now, in order to approximate  $\text{NegUtil}^*$ , we still need to deal with a system comprising potentially irrational transition probabilities. We argue that the occurring values  $b^{-\gamma r(s)}$  can be “rounded” to a sufficient precision while keeping the overall relative error small. Using techniques from [12], we provide an effective way to compute a game  $G_{\approx}$ , which behaves “similarly” to the reachability game  $G_R$  from Lemma 8, in the extended version [3]. Once  $G_{\approx}$  is computed, we can employ classical solution methods, such as linear equation solving for MCs, linear programming for MDPs, or, e.g., quadratic programming for SGs leading to an algorithm in polynomial space for SGs.

► **Theorem 21.** *In MCs and MDPs, the optimal value  $\text{ERisk}^*$  can be approximated up to an absolute error of  $\varepsilon$  in time polynomial in the size of the system,  $-\log(\varepsilon)$ ,  $\log b$ ,  $\gamma \cdot r_{\max}$ , and  $1/(\gamma \cdot r_{\min})$ , where  $r_{\max}$  and  $r_{\min}$  are the largest and smallest occurring non-zero rewards, respectively. For SGs, this is possible in polynomial space.*

In particular, for fixed  $b$  and  $\gamma$ , and bounded rewards (both from above and below), we obtain a PTIME solution for MC and MDP. In general, the procedure is exponential for SG. Alternatively, we can also apply different approaches such as value iteration [36].

► **Remark 22.** We note the connection to the small algebraic case: The “limiting factor” in both cases is the (size of the) product of  $\gamma$  and the state rewards. If these are fixed or given in unary, respectively, the complexity of our proposed algorithms is significantly reduced.

As a final note, recall that we do not assume  $\gamma$  or the transition probabilities to be rational. We only require that we can expand their binary representation to arbitrary precision. Then, we can conservatively approximate their logarithm to evaluate the required rounding precision and approximate the transition probabilities of  $G_{\approx}$  in the same way.

## 7 Conclusion

We applied the entropic risk to total rewards in SGs to capture risk-averse behavior in these games. The objective forces agents to achieve a good overall performance while keeping the chance of particularly bad outcomes small. We showed that SGs with the entropic risk as payoff function are determined and admit optimal MD-strategies. This reflects the time-consistency of entropic risk and makes entropic risk an appealing objective as, in contrast, the optimization of other risk-averse objective functions that have been studied on MDPs in the literature require strategies with large memory or complicated randomization.

Computationally, difficulties arise due to the involved exponentiation leading to irrational or even transcendental numbers. For the general case, we obtained decidability of the threshold problem only subject to Shanuel’s conjecture while for purely rational inputs, the problem can be solved via a reduction to the existential theory of the reals. Additional restrictions on the encoding of the input allowed us to obtain better upper bounds. Further, we provided an approximation algorithm for the optimal value. For an overview of the results, see Table 1.

A question that is left open is whether the entropic risk threshold problem for algebraic instances of MCs can be solved more efficiently than by the polynomial-time reduction to the existential theory of the reals. This case constitutes a bottleneck in the complexity. Furthermore, we worked with non-negative rewards, which made a reduction from games with the entropic risk objective to reachability games possible. Dropping the restriction to non-negative rewards constitutes an interesting direction of future research, in which additional difficulties arise and a reduction to reachability is not possible anymore. A further direction for future work is the experimental evaluation of the proposed algorithms to assess their practical applicability as well as to investigate the behavior of the resulting optimal strategies. In particular, it might be interesting to investigate the “cost” of risk-awareness, namely how much the expected total reward of a risk-aware strategy differs from a purely expectation maximizing one on realistic systems.

## Abstract

Opacity is a property of privacy and security applications asking whether, given a system model, a passive intruder that makes online observations of system's behaviour can ascertain some “secret” information of the system. Deciding opacity is a PSPACE-complete problem, and hence there are no polynomial-time algorithms to verify opacity under the assumption that PSPACE differs from PTIME. This assumption, however, gives rise to a question whether the existing exponential-time algorithms are the best possible or whether there are faster, sub-exponential-time algorithms. We show that under the (Strong) Exponential Time Hypothesis, there are no algorithms that would be significantly faster than the existing algorithms. As a by-product, we obtained a new conditional lower bound on the time complexity of deciding universality (and therefore also inclusion and equivalence) for nondeterministic finite automata.

## 1 Introduction

In privacy and security applications and communication protocols, it is desirable to keep some information about the system or its behaviour secret. Such requirements put additional restrictions on the information flow of the system and have widely been discussed in the literature as various properties, including *anonymity* [14, 32, 38], *non-interference* [8, 12, 19, 33], *secrecy* [1, 3, 10], *security* [17], *perfect security* [46], and *opacity* [20, 30]. *Anonymity* is the property to preserve secrecy of identity of actions; for instance, web servers should not be able to learn the true source of a request. *Non-interference* asks whether, given two input states of the system that share the same values of specified variables, the behaviors of the system started from these states are indistinguishable by the observer under the observation of the specified variables. *Secrecy* expresses whether an observer can ever find out that a trajectory of the system belongs to a set of secret trajectories, and *perfect security* requires that an observer that knows the set of all trajectories of the system cannot deduce any information about occurrences of high-security events by observing low-security events.

In this paper, we are interested in (various types of) opacity, which in a sense generalizes the other mentioned properties; namely, the properties above can be verified by reduction to opacity. More specifically, Alur et al. [1] have shown that *secrecy* captures *non-interference*

and *perfect security*, and Lin [26] has provided an extensive discussion and comparison of all these properties. He has in particular shown that *anonymity* and *secrecy*, and the properties of *observability* [27], *diagnosability* [25, 37], and *detectability* [28, 29, 39] of discrete-event systems are special cases of opacity. Wu et al. [44] and Góes et al. [18] discuss applications of opacity in location privacy, and Wintenberg et al. [42] apply opacity in contact tracing.

Given a system model, *opacity* asks whether a malicious passive observer (an intruder) with a complete knowledge of the structure of the model can ascertain some “secret” information of the system by making online incomplete observations of system’s behaviour. The secret information is modeled either as a set of states or as a set of behaviours of the system. Based on the incomplete observations, the intruder estimates the state/behaviour of the system, and the system is opaque if for every secret state/behaviour of the system, there is a non-secret state/behaviour of the system that looks the same to the intruder. If the secret information is given as a set of states, we talk about state-based opacity [9, 11], whereas if the secret information is given as a set of secret behaviours (a language), we talk about language-based opacity [3, 15]. Several notions of opacity have been discussed in the literature for systems modeled by automata and Petri nets; see Jacob et al. [24] for an overview. In this paper, we focus on finite automata models and on the notions of opacity that we review in Section 3.

The fastest existing algorithms verifying the notions of opacity under consideration have exponential-time complexity with respect to the number of states of the automaton. In fact, the verification of opacity is a PSPACE-complete problem [4, 5, 24], and hence we may conclude that there are no polynomial-time algorithms deciding opacity unless PTIME = PSPACE. Although the assumption that PTIME  $\neq$  PSPACE excludes the existence of polynomial-time algorithms, the question whether there is a significantly faster (i. e., sub-exponential-time) algorithm remains open.

To achieve stronger lower bounds (although still conditional), we use the *Exponential Time Hypothesis* (ETH) and its strong version – the *Strong Exponential Time Hypothesis* (SETH). Both hypotheses were formulated by Impagliazzo and Paturi [23] and are based on the observation that (so far) we were not able to find algorithms that would, in the worst case, solve SAT significantly faster than the algorithms trying all possible truth assignments. In particular, ETH states that 3-SAT cannot be solved in time  $2^{o(n)}$  where  $n$  is the number of variables. However, it admits algorithms solving 3-SAT in time  $O(c^n)$  where  $c < 2$ . In fact, the current fastest 3-SAT algorithm of Paturi et al. [31], improved by Hertli [21], runs in time  $O^*(1.30704^n)$ . With increasing  $k$ , the current fastest  $k$ -SAT algorithms are getting slower; for instance, the best 4-SAT algorithm of Hertli [21] runs in time  $O^*(1.46899^n)$ . This observation motivated the formulation of SETH that claims that, for any constant  $c < 2$ , there is always a sufficiently large  $k$  such that  $k$ -SAT cannot be solved in time  $O(c^n)$  [23]. Both hypotheses imply that the complexity classes PTIME and NP are separated; moreover, SETH implies ETH.

In this paper, we show that under (S)ETH, there are no significantly faster algorithms verifying opacity. In particular, we show that unless SETH fails, there is no algorithm that decides whether a given  $n$ -state automaton satisfies the considered notions of opacity and runs in time  $O^*(2^{n/c})$ , for any  $c > 2$  (Theorem 8 and Corollary 15). Since the number of symbols in the alphabet of our construction is unbounded and the standard binary encoding of symbols does not work under SETH, it is not clear whether this result also holds for automata with a fixed size (binary) alphabet. We partially explore this question under ETH rather than SETH. We show that unless ETH fails, there is no algorithm that decides whether a given  $n$ -state automaton (over a binary alphabet) satisfies the considered notions of opacity and runs in time  $O^*(2^{o(n)})$ . Our results are summarized in Table 1; for the complexity upper bounds, we refer the reader to the literature [5, 34].

■ **Table 1** An overview of the algorithmic complexity of deciding opacity under the projection  $P: \Sigma^* \rightarrow \Gamma^*$ , where  $n$  is the number of states of the automaton and  $\varepsilon > 0$ .

	Lower bound		Upper bound
	$\Gamma$ not fixed	$ \Gamma  = 2$	
LBO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$O^*(2^n)$
CSO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$O^*(2^n)$
ISO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$O^*(2^n)$
IFO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$\begin{cases} O^*(2^n) & \text{if } IQ_{NS} = I_{NS} \times F_{NS} \\ O^*(2^{n^2}) & \text{otherwise} \end{cases}$
$k$ -SO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$O^*(2^n)$
INSO	$O^*(2^{n/(2+\varepsilon)})$	$O^*(2^{o(n)})$	$O^*(2^n)$

As a by-product, we obtain a new conditional lower bound for deciding universality (and hence inclusion and equivalence) for nondeterministic automata (NFA): Unless SETH fails, there is no  $c > 2$  such that the universality of an  $n$ -state NFA can be decided in time  $O^*(2^{n/c})$  (Corollary 18). This result strengthens the result of Fernau and Krebs [16] showing that if ETH is true, the universality of an  $n$ -state NFA cannot be decided in time  $O^*(2^{o(n)})$ .

## 2 Preliminaries

We assume that the reader is familiar with automata theory [22]. For a set  $S$ , the cardinality of  $S$  is denoted by  $|S|$  and the power set of  $S$  by  $2^S$ . If  $S$  is a singleton,  $S = \{x\}$ , we often simply write  $x$  instead of  $\{x\}$ . The set of all non-negative integers is denoted by  $\mathbb{N}$ .

An alphabet  $\Sigma$  is a finite nonempty set of symbols. A string over  $\Sigma$  is a finite sequence of symbols from  $\Sigma$ . The set of all strings over  $\Sigma$  is denoted by  $\Sigma^*$ ; the empty string is denoted by  $\varepsilon$ . A language  $L$  over  $\Sigma$  is a subset of  $\Sigma^*$ . For a string  $u \in \Sigma^*$ , the length of  $u$  is denoted by  $|u|$ . With every pair of alphabets  $(\Sigma, \Gamma)$  with  $\Gamma \subseteq \Sigma$ , we associate the morphism  $P: \Sigma^* \rightarrow \Gamma^*$  defined by  $P(a) = \varepsilon$ , for  $a \in \Sigma - \Gamma$ , and  $P(a) = a$ , for  $a \in \Gamma$ ; such morphisms are usually called *projections*. Intuitively, the action of the projection  $P$  is to erase all symbols that do not belong to  $\Gamma$ ; the symbols of  $\Gamma$  are usually called *observable symbols of  $\Sigma$  under the projection  $P$* . We lift the projection  $P$  from strings to languages in the usual way. The inverse projection of  $P$  is the function  $P^{-1}: \Gamma^* \rightarrow 2^{\Sigma^*}$  defined by  $P^{-1}(w) = \{w' \in \Sigma^* \mid P(w') = w\}$ .

A *nondeterministic finite automaton* (NFA) is a structure  $\mathcal{A} = (Q, \Sigma, \delta, I, F)$ , where  $Q$  is a finite set of states,  $\Sigma$  is an input alphabet,  $I \subseteq Q$  is a set of initial states,  $F \subseteq Q$  is a set of accepting states, and  $\delta: Q \times \Sigma \rightarrow 2^Q$  is a transition function that can be extended to the domain  $2^Q \times \Sigma^*$  by induction. If the accepting states are irrelevant, we omit them and simply write  $\mathcal{A} = (Q, \Sigma, \delta, I)$ . The language accepted by  $\mathcal{A}$  from the states of  $Q_0 \subseteq Q$  by the states of  $F_0 \subseteq F$  is the set  $L_m(\mathcal{A}, Q_0, F_0) = \{w \in \Sigma^* \mid \delta(Q_0, w) \cap F_0 \neq \emptyset\}$  and the language generated by  $\mathcal{A}$  from the states of  $Q_0$  is the set  $L(\mathcal{A}, Q_0) = L_m(\mathcal{A}, Q_0, Q)$ ; in particular, the language accepted by  $\mathcal{A}$  is  $L_m(\mathcal{A}) = L_m(\mathcal{A}, I, F)$  and the language generated by  $\mathcal{A}$  is  $L(\mathcal{A}) = L(\mathcal{A}, I)$ . The NFA  $\mathcal{A}$  is *deterministic* (DFA) if  $|I| = 1$  and  $|\delta(q, a)| \leq 1$  for every state  $q \in Q$  and every symbol  $a \in \Sigma$ .

For an alphabet  $\Gamma \subseteq \Sigma$ , we define the *projected automaton* of  $\mathcal{A}$ , denoted by  $P(\mathcal{A})$ , as the reachable part of a DFA obtained from  $\mathcal{A}$  by replacing every transition  $(q, a, r)$  with the transition  $(q, P(a), r)$ , followed by the standard subset construction [22]. The projected automaton of  $\mathcal{A}$  is also known as the *observer* of  $\mathcal{A}$  in the literature.

We define the *configuration of  $\mathcal{A}$*  as the state of the projected automaton  $P(\mathcal{A})$  of  $\mathcal{A}$ .

A (*Boolean*) *formula* consists of variables, symbols for logical connectives: conjunction, disjunction, negation; and parentheses. A *literal* is a variable or its negation. A *clause* is a disjunction of literals. A formula is in *conjunctive normal form* (CNF) if it is a conjunction of clauses. If each clause has at most  $k$  literals, the formula is in  $k$ -CNF. A formula is *satisfiable* if there is an assignment of 1 and 0 to the variables evaluating the formula to 1. Given a  $k \geq 3$  and a formula in  $k$ -CNF, the  $k$ -CNF *Boolean satisfiability problem* ( $k$ -SAT) is to decide whether the formula is satisfiable. If the formula in  $k$ -CNF has  $n$  variables, enumerating all the  $2^n$  possible truth assignments results in an  $O(2^n n^k)$ -time algorithm for  $k$ -SAT; the polynomial part  $O(n^k)$  comes from checking up to  $n^k$  clauses. We use the notation  $O^*$  to hide polynomial factors, that is,  $O^*(g(n)) = O(g(n) \cdot \text{poly}(n))$ .

The exponential time hypothesis states that 3-SAT cannot be solved in sub-exponential time  $2^{o(n)}$ , where  $n$  is the number of variables in the 3-CNF formula [23].

► **Hypothesis 1** (Exponential Time Hypothesis (ETH)). *There is some  $\varepsilon > 0$  such that 3-SAT cannot be solved in time  $O(2^{\varepsilon n})$ , where  $n$  is the number of variables in the formula.*

The strong ETH states that deciding  $k$ -SAT needs  $O^*(2^n)$  time for large  $k$  [23].

► **Hypothesis 2** (Strong ETH (SETH)). *For every  $\varepsilon > 0$ , there is some  $k \geq 3$  such that  $k$ -SAT cannot be solved in time  $O(2^{(1-\varepsilon)n})$ .*

### 3 Opacity Definitions

We now review the notions of opacity considered in this paper. We distinguish two types of opacity: those representing the secret by strings and those representing the secret by states.

Language-based opacity is a property asking whether for every secret behaviour, there is a non-secret behaviour that is the same under a considered projection; in this case, an intruder cannot distinguish the secret behaviour from a non-secret behaviour.

► **Definition 3.** *An NFA  $\mathcal{A} = (Q, \Sigma, \delta, I)$  is language-based opaque (LBO) with respect to disjoint languages  $L_S, L_{NS} \subseteq L(\mathcal{A})$ , called secret and non-secret languages, respectively, and a projection  $P: \Sigma^* \rightarrow \Gamma^*$  for  $\Gamma \subseteq \Sigma$ , if  $L_S \subseteq P^{-1}P(L_{NS})$ .*

*The LBO problem is to decide whether  $\mathcal{A}$  is LBO with respect to  $L_S, L_{NS}$ , and  $P$ .*

Although this definition is a special case of the most general notion of *trace opacity* of Bryans et al. [9], it is general enough to capture other notions, such as *strong nondeterministic non-interference* or *non-deducibility on composition* of Best et al. [8] and Busi and Gorrieri [12]. The secret and non-secret languages are often considered to be regular to ensure that the inclusion problem is decidable [2].

State-based opacity hides the secret information into states. In this paper, we consider five notions of state-based opacity. Current-state opacity requires that an intruder cannot identify, at any instance of time, whether the system is currently in a secret state.

► **Definition 4.** *An NFA  $\mathcal{A} = (Q, \Sigma, \delta, I)$  is current-state opaque (CSO) with respect to two disjoint sets  $Q_S, Q_{NS} \subseteq Q$  of secret and non-secret states, respectively, and a projection  $P: \Sigma^* \rightarrow \Gamma^*$  for  $\Gamma \subseteq \Sigma$ , if for every string  $w \in \Sigma^*$  such that  $\delta(I, w) \cap Q_S \neq \emptyset$ , there exists a string  $w' \in \Sigma^*$  such that  $P(w) = P(w')$  and  $\delta(I, w') \cap Q_{NS} \neq \emptyset$ .*

*The CSO problem is to decide whether  $\mathcal{A}$  is CSO with respect to  $Q_S, Q_{NS}$ , and  $P$ .*

Initial-state opacity requires that an intruder can never ascertain whether the computation started in a secret state.

► **Definition 5.** An NFA  $\mathcal{A} = (Q, \Sigma, \delta, I)$  is initial-state opaque (ISO) with respect to two disjoint sets  $I_S, I_{NS} \subseteq I$  of secret and non-secret initial states, respectively, and a projection  $P: \Sigma^* \rightarrow \Gamma^*$  for  $\Gamma \subseteq \Sigma$ , if for every  $w \in L(\mathcal{A}, I_S)$ , there exists  $w' \in L(\mathcal{A}, I_{NS})$  such that  $P(w) = P(w')$ .

The ISO problem is to decide whether  $\mathcal{A}$  is ISO with respect to  $I_S, I_{NS}$ , and  $P$ .

Initial-and-final-state opacity [43] generalizes both CSO and ISO. The secret is represented as a set of pairs of an initial state and of an accepting state. Therefore, ISO is a special case of initial-and-final-state opacity where the accepting states do not play a role, while CSO is a special case where the initial states do not play a role.

► **Definition 6.** An NFA  $\mathcal{A} = (Q, \Sigma, \delta, I, F)$  is initial-and-final-state opaque (IFO) with respect to two disjoint sets  $IQ_S, IQ_{NS} \subseteq I \times F$  of secret and non-secret pairs of states, respectively, and a projection  $P: \Sigma^* \rightarrow \Gamma^*$  for  $\Gamma \subseteq \Sigma$ , if for every secret pair  $(q_0, q_f) \in IQ_S$  and every string  $w \in L_m(\mathcal{A}, q_0, q_f)$ , there exists a non-secret pair  $(q'_0, q'_f) \in IQ_{NS}$  and a string  $w' \in L_m(\mathcal{A}, q'_0, q'_f)$  such that  $P(w) = P(w')$ .

The IFO problem is to decide whether  $\mathcal{A}$  is IFO with respect to  $IQ_S, IQ_{NS}$ , and  $P$ .

The algorithmic time complexity of deciding IFO is known to be  $O^*(2^{n^2})$  in general, and  $O(2^{2n})$  if  $IQ_S = I_S \times F_S$  and  $IQ_{NS} = I_{NS} \times F_{NS}$ , for some  $I_S, I_{NS} \subseteq I$  and  $F_S, F_{NS} \subseteq F$  [43]. Our complexity in Table 1 is based on the following observations.

Consider an NFA  $\mathcal{A} = (Q, \Sigma, \delta, I, F)$  and two sets  $IQ_S, IQ_{NS} \subseteq I \times F$ . The IFO property of  $\mathcal{A}$  is unchanged if all pairs  $(s, f_1), (s, f_2), \dots, (s, f_k)$  with a common left component are replaced by a single pair of the form  $(s, \{f_1, f_2, \dots, f_k\})$ . This reduces the number of pairs to be considered to  $n$ , where  $n$  is the number of states of  $\mathcal{A}$ . For every pair  $(s_i, F_i) \in I \times 2^F$ , we define the language  $L_i = L_m(\mathcal{A}, s_i, F_i)$  and the languages

$$L_S = \bigcup_{(s_i, F_i) \in IQ_S} L_i \quad \text{and} \quad L_{NS} = \bigcup_{(s_i, F_i) \in IQ_{NS}} L_i.$$

Then, deciding whether  $\mathcal{A}$  is IFO with respect to  $IQ_S, IQ_{NS}$ , and  $P$  is equivalent to deciding whether the inclusion  $P(L_S) \subseteq P(L_{NS})$  holds true. Since both  $L_S$  and  $L_{NS}$  can be represented by NFAs consisting of at most  $n$  copies of  $\mathcal{A}$ , they have  $O(n^2)$  states. The inclusion  $P(L_S) \subseteq P(L_{NS})$  of languages of two NFAs can be tested in time  $O(n^2 2^{n^2}) = O^*(2^{n^2})$ , which is a complexity upper bound that coincides with the bound of Saboori and Hadjicostis [36], who used trellis automata.

If  $IQ_{NS} = I_{NS} \times F_{NS} \subseteq I \times F$ , then the NFA for  $L_{NS}$  coincides with  $\mathcal{A}$  where the initial states are  $I_{NS}$  and the final states are  $F_{NS}$ . In particular, this automaton has  $n$  states, and therefore the inclusion  $P(L_S) \subseteq P(L_{NS})$  can be tested in time  $O(n^2 2^n) = O^*(2^n)$ .

The notion of  $k$ -step opacity generalizes CSO by requiring that the intruder cannot ascertain the secret in the current and  $k$  subsequent states. By definition, CSO is equivalent to 0-step opacity. We use a slight generalisation of a definition of Saboori and Hadjicostis [35] that was formulated by Balun and Masopust [5].

► **Definition 7.** An NFA  $\mathcal{A} = (Q, \Sigma, \delta, I)$  is  $k$ -step opaque ( $k$ -SO), for a given  $k \in \mathbb{N} \cup \{\infty\}$ , with respect to two disjoint sets  $Q_S, Q_{NS} \subseteq Q$  of secret and non-secret states, respectively, and a projection  $P: \Sigma^* \rightarrow \Gamma^*$  for  $\Gamma \subseteq \Sigma$ , if for every string  $st \in L(\mathcal{A})$  such that  $|P(t)| \leq k$  and  $\delta(\delta(I, s) \cap Q_S, t) \neq \emptyset$ , there exists a string  $s't' \in L(\mathcal{A})$  such that  $P(s) = P(s')$ ,  $P(t) = P(t')$ , and  $\delta(\delta(I, s') \cap Q_{NS}, t') \neq \emptyset$ .

The  $k$ -SO problem is to decide whether  $\mathcal{A}$  is  $k$ -SO with respect to  $Q_S, Q_{NS}$ , and  $P$ .

A special case of  $k$ -SO for  $k$  being infinity is called infinite-step opacity (INSO). These two notions are closely related for finite automata, because an  $n$ -state automaton is infinite-step opaque if and only if it is  $(2^n - 2)$ -step opaque [45].

For the state-based opacity notions, we may assume, without loss of generality, that the projection  $P$  is an identity; indeed, the transitions labeled by symbols from  $\Sigma - \Gamma$  can be seen as  $\varepsilon$ -transitions, and hence they can be removed by the classical algorithm eliminating  $\varepsilon$ -transitions [22]. This algorithm does not change the number of states but can quadratically increase the number of transitions. In the sequel, we omit the projection if it is an identity.

#### 4 Lower Bounds under Strong Exponential Time Hypothesis

We now show that under the strong exponential time hypothesis, there is no algorithm deciding current-state opacity that would be significantly faster than the best known algorithm.

► **Theorem 8.** *Unless SETH fails, there is no algorithm deciding whether a given  $n$ -state NFA is CSO that runs in time  $O^*(2^{n/(2+\varepsilon)})$ , for any  $\varepsilon > 0$ .*

**Proof.** For a given formula  $\varphi$  in  $k$ -CNF with  $n$  variables  $X = \{x_1, \dots, x_n\}$  and  $m$  clauses  $C = \{c_1, \dots, c_m\}$ , we construct, in polynomial time, an instance of CSO consisting of an NFA  $\mathcal{A}_\varphi$  with  $N = 2n + 2$  states and of sets of secret and non-secret states  $Q_S$  and  $Q_{NS}$ , respectively, such that  $\mathcal{A}_\varphi$  is CSO with respect to  $Q_S$  and  $Q_{NS}$  if and only if  $\varphi$  is satisfiable. As a result, if there was an algorithm solving CSO in time  $O^*(2^{N/(2+\varepsilon)})$ , then there would be an algorithm solving  $k$ -SAT in time  $O(\text{poly}(n)) + O^*(2^{(2n+2)/(2+\varepsilon)}) = O^*(2^{(1-\delta)n})$ , for  $\delta = \varepsilon/(2+\varepsilon) > 0$ , which contradicts SETH, and proves the theorem.

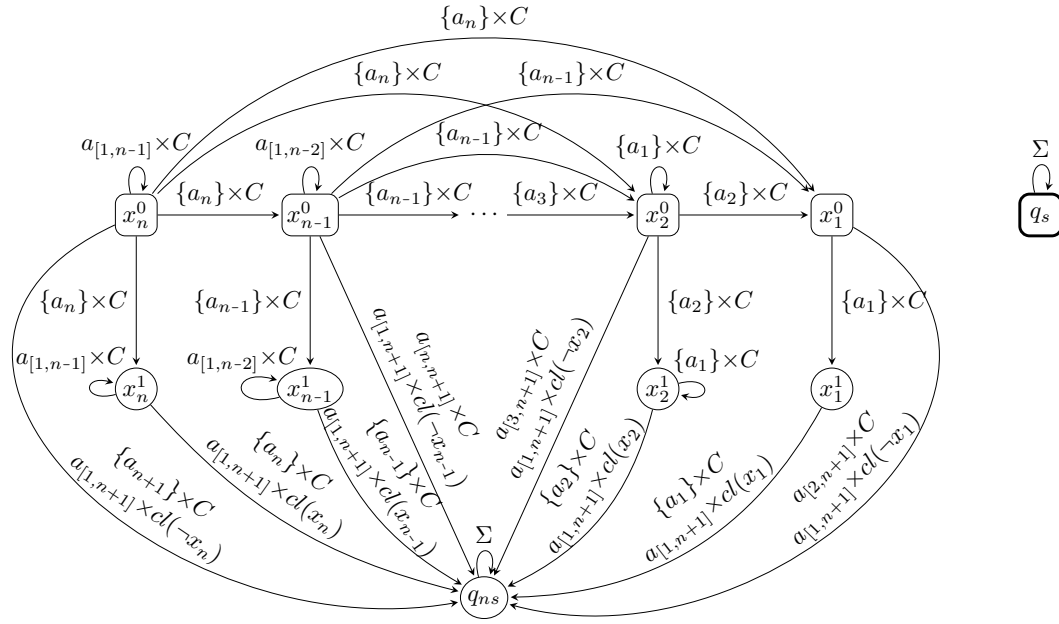

Intuitively, we construct the NFA  $\mathcal{A}_\varphi$  such that when  $\mathcal{A}_\varphi$  reads a string of a particular type (based on Zimin words), it is forced to examine all possible assignments to the variables  $x_1, \dots, x_n$ . If none of the assignments satisfies  $\varphi$ , then, after reading the whole string, the automaton  $\mathcal{A}_\varphi$  ends up in a configuration that contains only secret states, rendering thus  $\mathcal{A}_\varphi$  not CSO. On the other hand, when a satisfying assignment is encountered (or the string is not of the particular type), a non-secret state is permanently added to the configuration of  $\mathcal{A}_\varphi$ , and hence  $\mathcal{A}_\varphi$  is CSO.

Formally, the NFA  $\mathcal{A}_\varphi = (Q, \Sigma, \delta, I)$ , where the set of states is  $Q = \{q_s, q_{ns}\} \cup \{x_i^0, x_i^1 \mid x_i \in X\}$  with  $x_i^r$  representing the assignment of  $r \in \{0, 1\}$  to the variable  $x_i$ , the alphabet  $\Sigma = \Gamma = \{a_1, \dots, a_{n+1}\} \times C$ , that is, the projection  $P$  is an identity, and the set of secret states is  $Q_S = \{q_s\}$ , that is, the state  $q_s$  is the only secret state, the remaining states are non-secret. For an illustration of the construction, the reader may follow Example 14 together with the rest of the proof.

Let  $L$  be the set of literals of  $\varphi$ . We use the function  $cl: L \rightarrow 2^C$  that assigns to a literal  $\ell$  the set  $cl(\ell) = \{c \in C \mid \ell \in c\}$  of clauses containing  $\ell$ , and define the transition function  $\delta$  as follows, see Figure 1 for an illustration:

- The self-loops  $(q_s, \sigma, q_s)$  and  $(q_{ns}, \sigma, q_{ns})$  belong to  $\delta$  for every  $\sigma \in \Sigma$ ;
- For every state  $x_i^0$  and every  $c \in C$ ,
  - the transition  $(x_i^0, (a_i, c), x_i^1) \in \delta$ ;
  - the self-loop  $(x_i^0, (a_j, c), x_i^0) \in \delta$  for  $1 \leq j \leq i - 1$ ;
  - the transition  $(x_i^0, (a_i, c), x_j^0) \in \delta$  for  $1 \leq j \leq i - 1$ ;
  - the transition  $(x_i^0, (a_j, c), q_{ns}) \in \delta$  for  $i + 1 \leq j \leq n + 1$ ;
  - the transition  $(x_i^0, (a_j, c), q_{ns}) \in \delta$  for  $1 \leq j \leq n + 1$  and  $c \in cl(\neg x_i)$ ;
- For every state  $x_i^1$  and  $c \in C$ ,
  - the transition  $(x_i^1, (a_i, c), q_{ns}) \in \delta$ ;
  - the self-loop  $(x_i^1, (a_j, c), x_i^1) \in \delta$ , for  $1 \leq j \leq i - 1$ ;
  - the transition  $(x_i^1, (a_j, c), q_{ns}) \in \delta$  for  $1 \leq j \leq n + 1$  and  $c \in cl(x_i)$ .

■ **Figure 1** The NFA  $A_\varphi$  of Theorem 8, where the initial states are squared, the single secret state  $q_s$  is in bold, and for positive integers  $i \leq j$ ,  $[i, j] = \{i, i + 1, \dots, j\}$  and  $a_{[i,j]} = \{a_r \mid r \in [i, j]\}$ .

Finally, the set of initial states is  $I = \{q_s\} \cup \{x_1^0, \dots, x_n^0\}$ , corresponding to the assignment of 0 to all variables of  $\varphi$ .

We now define a language  $W_\varphi = Z_n \cdot (\{a_{n+1}\} \times C)$ , where  $Z_n$  is a language over the alphabet  $\{a_1, a_2, \dots, a_n\} \times C$  recursively defined as follows:

$$Z_1 = \{a_1\} \times C \quad \text{and} \quad Z_i = Z_{i-1} \cdot (\{a_i\} \times C) \cdot Z_{i-1}, \quad \text{for } 1 < i \leq n.$$

Such strings are known as *Zimin words* and it is well known that any string of  $Z_n$  is of length  $2^n - 1$  [40] and that

$$\text{the symbol on the } \ell\text{th position of any string from } Z_n \text{ is of the form } \{a_j\} \times C, \text{ where } j - 1 \text{ is the number of trailing zeros in the binary representation of } \ell \text{ [41].} \quad (1)$$

We finish the proof in a series of claims. The first claim shows that along any string of  $Z_n$ , the states  $\{x_i^0, x_i^1 \mid x_i \in X\}$  of  $A_\varphi$  encode all possible assignments to the variables.

▷ **Claim 9.** Let  $A_\varphi^X$  denote  $A_\varphi$  without the states  $q_s$  and  $q_{ns}$  and the corresponding transitions. For every  $w \in Z_n$ , after reading the prefix of  $w$  of length  $\ell \leq 2^n - 1$ , the configuration of  $A_\varphi^X$  is  $\{x_n^{r_n}, x_{n-1}^{r_{n-1}}, \dots, x_1^{r_1}\}$ , where  $r_n r_{n-1} \dots r_1$  represents  $\ell$  in binary.

▷ **Claim 10.** Every configuration of  $A_\varphi$  contains the secret state  $q_s$ .

By Claims 9 and 10, and because only the state  $q_s$  itself is reachable from  $q_s$  and only the state  $q_{ns}$  itself is reachable from  $q_{ns}$ , we have the following observation specifying the computation of  $A_\varphi$  along the strings of  $Z_n$ .

▷ **Claim 11.** After reading the prefix of  $w \in Z_n$  of length  $\ell \leq 2^n - 1$ , the configuration of  $A_\varphi$  is either  $\{x_n^{r_n}, x_{n-1}^{r_{n-1}}, \dots, x_1^{r_1}\} \cup \{q_s\}$  or  $\{x_n^{r_n}, x_{n-1}^{r_{n-1}}, \dots, x_1^{r_1}\} \cup \{q_s, q_{ns}\}$ , where  $r_n r_{n-1} \dots r_1$  represents  $\ell$  in binary. ◁

If there is a satisfying assignment, then the non-secret state  $q_{ns}$  is reached by  $\mathcal{A}_\varphi$ .

▷ **Claim 12.** For every prefix  $w$  of a string in  $Z_n$ , if the configuration of  $\mathcal{A}_\varphi$  after reading  $w$  satisfies  $\varphi$ , then after reading any further symbol in  $\Sigma$ , the configuration of  $\mathcal{A}_\varphi$  contains  $q_{ns}$ .

We now show that if  $\varphi$  is satisfiable, then  $\mathcal{A}_\varphi$  is CSO. To this end, we consider an arbitrary string  $w$  over  $\Sigma$ , and we denote by  $u$  the longest prefix of  $w$  that is a prefix of a string in  $Z_n$ . Let  $\ell$  be the minimal number such that its binary representation  $r_n r_{n-1} \cdots r_1$  is a satisfying assignment to the variables of  $\varphi$ .

If  $\ell \leq |u|$ , then, by Claim 11, the configuration of  $\mathcal{A}_\varphi$  after reading any prefix of  $u$  of length  $\ell' \leq \ell$  contains non-secret states  $x_n^{r_n}, x_{n-1}^{r_{n-1}}, \dots, x_1^{r_1}$ , where  $r_n r_{n-1} \cdots r_1$  represents  $\ell'$  in binary, and, by Claim 12, the  $(\ell + 1)$ st symbol of  $w$  moves  $\mathcal{A}_\varphi$  to a configuration that contains  $q_{ns}$ ; that is,  $\mathcal{A}_\varphi$  is CSO.

If  $\ell > |u|$ , we have  $w = u(a_s, c)v$  for  $(a_s, c) \in \Sigma$  and  $v \in \Sigma^*$ . Because  $\varphi$  is satisfiable, we have  $|u| < 2^n - 1$ . By Claim 11, the configuration of  $\mathcal{A}_\varphi$  after reading  $u$  contains  $x_n^{r_n}, \dots, x_1^{r_1}$ , where  $r_n r_{n-1} \cdots r_1$  represents  $|u|$  in binary. Let  $r_t$  be the rightmost zero of  $r_n r_{n-1} \cdots r_1$ , that is,  $r_n r_{n-1} \cdots r_1 = r_n r_{n-1} \cdots r_{t+1} 0 1 \cdots 1$ . Then,  $|u| + 1$  is  $r_n r_{n-1} \cdots r_{t+1} 1 0 \cdots 0$  in binary and, by (1), the symbol  $(a_s, c) \notin \{a_t\} \times C$ . However, if  $s < t$ , then  $x_s^1$  goes to state  $q_{ns}$  under  $\{a_s\} \times C$ , while if  $s > t$ , then  $x_t^0$  goes to state  $q_{ns}$  under  $\{a_s\} \times C$ . In both cases, the non-secret state  $q_{ns}$  is in the next configuration of  $\mathcal{A}_\varphi$ , and hence  $\mathcal{A}_\varphi$  is CSO.

To prove that if  $\varphi$  is not satisfiable, then  $\mathcal{A}_\varphi$  is not CSO, we use the following claim.

▷ **Claim 13.** If  $\varphi$  is not satisfiable, there is a string  $w_\varphi \in Z_n$  such that the configuration of  $\mathcal{A}_\varphi$  after reading  $w_\varphi$  is  $\{x_n^1, x_{n-1}^1, \dots, x_1^1\} \cup \{q_s\}$ .

We now show that if  $\varphi$  is not satisfiable, then  $\mathcal{A}_\varphi$  is not CSO. To this end, we consider the string  $w_\varphi$  constructed in Claim 13, which we extend to a string from  $W_\varphi = Z_n \cdot (\{a_{n+1}\} \times C)$  by adding a symbol of the form  $\{a_{n+1}\} \times C$ . Since  $\varphi$  is not satisfiable, there is a clause  $c \in C$  that is not satisfied by the assignment of 1 to the variables; that is, there is  $c \notin \bigcup_{i=1}^n cl(x_i)$ . Then, the string  $w_\varphi(a_{n+1}, c)$  moves the automaton  $\mathcal{A}_\varphi$  from the configuration  $\{x_n^1, x_{n-1}^1, \dots, x_1^1\} \cup \{q_s\}$  to the configuration  $\{q_s\}$ , and hence  $\mathcal{A}_\varphi$  is not CSO. ◀

We now illustrate the construction.

► **Example 14.** For simplicity, we consider a 2-CNF formula

$$\varphi = (x_2 \vee x_2) \wedge (x_1 \vee x_2) \wedge (\neg x_1 \vee x_3) \wedge (\neg x_2 \vee \neg x_3) \wedge (x_3)$$

with three variables  $x_1, x_2, x_3$  and five clauses  $c_1 = \{x_2, x_2\}$ ,  $c_2 = \{x_1, x_2\}$ ,  $c_3 = \{\neg x_1, x_3\}$ ,  $c_4 = \{\neg x_2, \neg x_3\}$ , and  $c_5 = \{x_3\}$ . The automaton  $\mathcal{A}_\varphi = (Q, \Sigma, \delta, \{q_s, x_1^0, x_2^0, x_3^0\})$  is depicted in Figure 2, where  $Q = \{q_s, q_{ns}\} \cup \{x_1^0, x_1^1, x_2^0, x_2^1, x_3^0, x_3^1\}$ ,  $\Sigma = \Gamma = \{a_1, a_2, a_3, a_4\} \times \{c_1, c_2, c_3, c_4, c_5\}$ , and  $q_s$  is the only secret state. Since  $\varphi$  is not satisfiable,  $\mathcal{A}_\varphi$  is not CSO; indeed, the string  $w = (a_1, c_1)(a_2, c_2)(a_1, c_5)(a_3, c_3)(a_1, c_1)(a_2, c_1)(a_1, c_4)(a_4, c_4)$  moves  $\mathcal{A}_\varphi$  to the configuration  $\{q_s\}$  consisting solely of the secret state, cf. Figure 3 depicting the reachable configurations of  $\mathcal{A}_\varphi$ .

On the other hand, if we consider the formula  $\varphi' = c_1 \wedge c_2 \wedge c_3 \wedge c_4$ , then  $\varphi'$  is satisfiable, and hence the NFA  $\mathcal{A}_{\varphi'}$  obtained from  $\mathcal{A}_\varphi$  by removing all transitions under symbols containing  $c_5$ , is CSO; it is visible from the reachable configurations of  $\mathcal{A}_{\varphi'}$  depicted in Figure 4.

The considered problems are all PSPACE-complete, and hence reducible to each other in polynomial time. However, this fact does not provide us with much information about the reductions. Even though some particular reductions have been discussed in the literature by Wu and Lafortune [43] and Balun and Masopust [5, 6], they are in most cases not suitable to prove lower bounds.

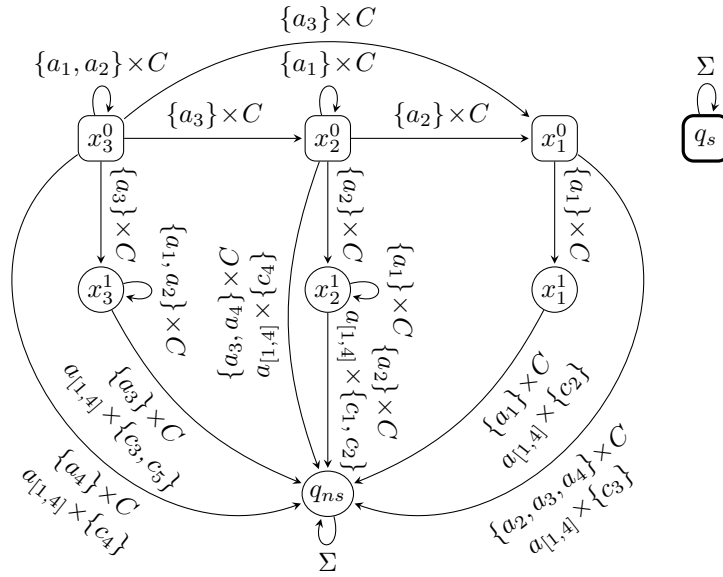

Figure 2 The NFA  $A_\varphi$  illustrating Theorem 8; the initial states are squared.

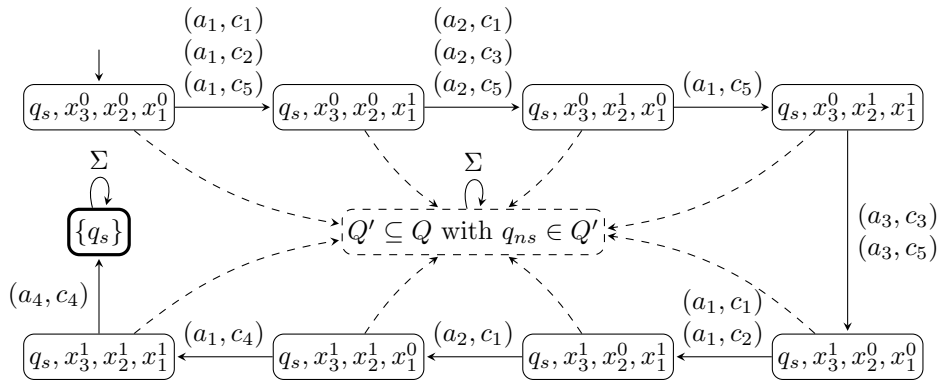

Figure 3 The configurations of  $A_\varphi$  – all undefined transitions go to the dashed middle state.

Figure 4 The configurations of  $A_{\varphi'}$ .

We now discuss the case of other types of opacity.

► **Corollary 15.** *Unless SETH fails, there is no algorithm deciding if a given  $n$ -state NFA is LBO/ISO/IFO/ $k$ -SO/INSO that runs in time  $O^*(2^{n/(2+\varepsilon)})$ , for any  $\varepsilon > 0$ .*

**Proof.** Consider the instance of CSO given by the NFA  $\mathcal{A}$  and the sets  $Q_S$  and  $Q_{NS}$  constructed in the proof of Theorem 8. Then,  $\mathcal{A}$  is CSO with respect to  $Q_S = \{q_s\}$  and  $Q_{NS} = Q - Q_S$  if and only if  $\mathcal{A}$  is LBO with respect to  $L_S = L_m(\mathcal{A}, q_s, q_s) = \Sigma^*$  and  $L_{NS} = L_m(\mathcal{A}, \{x_1^0, \dots, x_n^0\}, Q - \{q_s\})$ . Since the parts of  $\mathcal{A}$  corresponding to languages  $L_S$  and  $L_{NS}$  are disjoint, the instance of LBO may be encoded directly into  $\mathcal{A}$  by defining the corresponding states accepting the languages  $L_S$  and  $L_{NS}$ . Hence, the instance of LBO is of the same size as the instance of CSO. Therefore, if we solved the instance of LBO in time  $O^*(2^{(1-\delta)n})$ , we would also solve the instance of CSO in time  $O^*(2^{(1-\delta)n})$ .

Since there is no transition in  $\mathcal{A}$  from the sole secret state  $q_s$  to another state, the NFA  $\mathcal{A}$  is CSO if and only if  $\mathcal{A}$  is  $k$ -SO, for any  $k \in \mathbb{N} \cup \{\infty\}$ , and hence the result holds for  $k$ -SO as well as for INSO.

Furthermore, the NFA  $\mathcal{A}$  is CSO with respect to the sets  $Q_S$  and  $Q_{NS}$  if and only if  $\mathcal{A}$  is ISO with respect to the secret initial state  $I_S = \{q_s\}$  and non-secret initial states  $I_{NS} = \{x_1^0, \dots, x_n^0\}$ . Indeed, since  $L(\mathcal{A}, I_S) = \Sigma^*$ , the NFA  $\mathcal{A}$  is not CSO if and only if there is a string  $w \in \Sigma^*$  that moves  $\mathcal{A}$  from the initial configuration  $I_{NS}$  to the configuration  $\emptyset$ , which is if and only if  $\mathcal{A}$  is not ISO. As a result, solving ISO in time  $O^*(2^{(1-\delta)n})$  would solve CSO in time  $O^*(2^{(1-\delta)n})$ .

Finally, if all states of  $\mathcal{A}$  are accepting, then  $\mathcal{A}$  is ISO with respect to  $I_S = \{q_s\}$  and  $I_{NS} = \{x_1^0, \dots, x_n^0\}$  if and only if  $\mathcal{A}$  is IFO with respect to  $IQ_S = \{(q_s, q_s)\}$  and  $IQ_{NS} = I_{NS} \times Q$ ; hence, solving IFO in time  $O^*(2^{(1-\delta)n})$  would solve ISO in time  $O^*(2^{(1-\delta)n})$ . ◀

## 5 Lower Bounds under Exponential Time Hypothesis

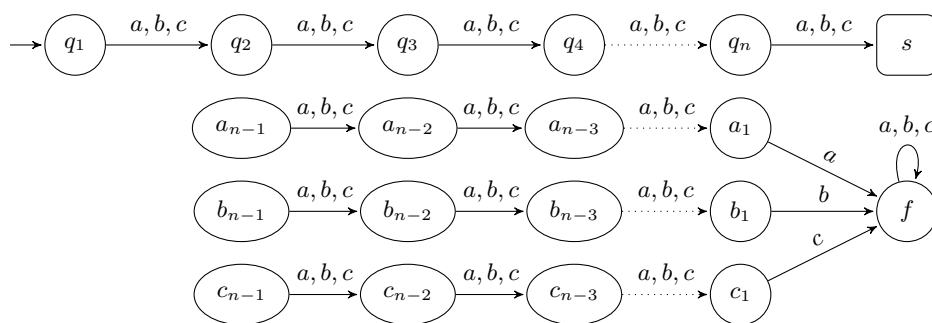

The number of symbols in the NFA constructed in Theorem 8 depends on the number of clauses in the instance of SAT. Since the standard binary encoding of symbols does not work under SETH, it is an open problem whether the results of Theorem 8 and Corollary 15 also hold for a fixed-sized alphabet.

Although we do not answer this question, we provide a lower bound for NFAs over a binary alphabet under ETH. Namely, we show that there is no algorithm solving the considered notions of opacity for such  $n$ -state NFAs that runs in time  $O^*(2^{o(n)})$ . We obtain the result by adjusting the construction of Fernau and Krebs [16], who showed that there is no algorithm solving the universality problem for  $n$ -state NFAs over a binary alphabet that runs in time  $O^*(2^{o(n)})$  unless ETH fails, and by using the observation of Cassez et al. [13] that universality can be reduced to opacity.

► **Theorem 16.** *Unless ETH fails, there is no algorithm deciding whether a given  $n$ -state NFA (over a binary alphabet) is CSO that runs in time  $O^*(2^{o(n)})$ .*

**Proof.** A 3-coloring of a graph  $G = (V, E)$  is a function  $\mu: V \rightarrow \{a, b, c\}$ . The coloring is proper if  $\mu(u) \neq \mu(v)$  whenever  $uv \in E$ . The 3-COLORING problem is to decide, given a graph  $G$ , whether there is a proper 3-coloring of  $G$ .

For a graph  $G$  with  $n$  vertices,  $V = \{v_1, v_2, \dots, v_n\}$ , and  $m$  edges, we construct an NFA  $\mathcal{A} = (Q, \Sigma, \delta, I)$ , where the states are  $Q = \{s, f\} \cup \{q_1, \dots, q_n\} \cup \{x_1, \dots, x_{n-1} \mid x \in \{a, b, c\}\}$ , the alphabet is  $\Sigma = \Gamma = \{a, b, c\}$ , the initial state is  $I = \{q_1\}$ , the secret state is  $Q_S = \{s\}$ , and the non-secret states are  $Q_{NS} = Q - Q_S$ . We define the transition function  $\delta$  as shown in Figure 5, and further extended it by adding three transitions  $(q_i, a, a_{j-i})$ ,  $(q_i, b, b_{j-i})$ , and  $(q_i, c, c_{j-i})$  for every edge  $v_i v_j \in E$  with  $i < j$ .

■ **Figure 5** The main part of the NFA  $\mathcal{A}$  resulting from the reduction of Theorem 16 without the transitions corresponding to the edges of  $G$ . The secret state is state  $s$ .

Intuitively, the coloring of  $G$  is encoded as a string  $w = c_1 \cdots c_n$  of length  $n$ , where  $c_i$  is the color of vertex  $i$ , and  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$  if and only if the non-secret state  $f$  is reachable under  $w$ ; indeed, the secret state  $s$  is reachable under every string of length  $n$ .

Fernau and Krebs [16] showed that  $\mathcal{A}$  ends up in state  $f$  under  $w$  if and only if  $w$  encodes a coloring that is not proper. Therefore, if  $w$  is a proper 3-coloring of  $G$ , then  $w$  does not move  $\mathcal{A}$  to state  $f$ ; that is, only the secret state  $s$  is reached under  $w$ , and hence  $\mathcal{A}$  is not CSO with respect to  $\{s\}$  and  $Q - \{s\}$ . On the other hand, if  $G$  does not have a proper 3-coloring, then every string of length  $n$  moves  $\mathcal{A}$  to both secret state  $s$  and non-secret state  $f$ ; that is,  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$ .

If  $G$  has  $n$  vertices and  $m$  edges, then  $\mathcal{A}$  has  $N = 4n - 1$  states and  $M = 12n + 3m - 12$  transitions. If there was an  $O^*(2^{o(N)})$ -time algorithm deciding CSO, we could reduce the instance of 3-COLORING to an instance of CSO in time  $O(N + M)$ , and solve CSO in time  $O^*(2^{o(N)})$ . Altogether, we could solve 3-COLORING in time  $O(N + M) + O^*(2^{o(N)}) = O^*(2^{o(n)})$ , which contradicts ETH. ◀

Similarly to the discussion in the previous section, to prove the lower bound for the other notions of opacity, it seems natural to combine the construction of the previous proof with the existing reductions among the notions [5, 6, 43]. However, most of the reductions result in too large, though polynomial, instances, and hence they are not suitable for our purposes. Therefore, new reductions are needed.

► **Corollary 17.** *Unless ETH fails, there is no algorithm deciding if a given  $n$ -state NFA (over a binary alphabet) is LBO/ISO/IFO/ $k$ -SO/INSO that runs in time  $O^*(2^{o(n)})$ .*

**Proof.** For the NFA  $\mathcal{A}$  of Theorem 16, we have  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$  if and only if  $\mathcal{A}$  is LBO with respect to  $L_S = L_m(\mathcal{A}, q_1, s)$  and  $L_{NS} = L_m(\mathcal{A}, q_1, Q - \{s\})$  [43]. If we could solve LBO in time  $O^*(2^{o(n)})$ , we could solve 3-COLORING in time  $O^*(2^{o(n)})$ .

Furthermore, since there is no transition from the sole secret state  $s$ , the automaton  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$  if and only if  $\mathcal{A}$  is  $k$ -SO with respect to  $\{s\}$  and  $Q - \{s\}$ , for any  $k \in \mathbb{N} \cup \{\infty\}$ . Therefore, the result holds for  $k$ -SO as well as for INSO.

Now, we take the NFA  $\mathcal{A}$  and add a copy of states  $q_1, q_2, \dots, q_n$ , denoted by  $q'_1, q'_2, \dots, q'_n$ , together with all transitions to states different from  $s$ , that is, we add  $(q'_i, x, p)$  for every transition  $(q_i, x, p)$  with  $p \neq s$ . We set the states  $q_1$  and  $q'_1$  initial, and denote the result by  $\mathcal{A}'$ . Then, the NFA  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$  if and only if  $\mathcal{A}'$  is ISO with respect to  $I_S = \{q_1\}$  and  $I_{NS} = \{q'_1\}$ . Indeed, if  $\mathcal{A}$  is CSO with respect to  $\{s\}$  and  $Q - \{s\}$ , then for every  $w$  moving  $\mathcal{A}$  to state  $s$ , there is  $w'$  moving  $\mathcal{A}$  to state  $f$ ; and so do the strings

$w$  and  $w'$  in  $\mathcal{A}'$ , which shows that  $\mathcal{A}'$  is ISO with respect to  $I_S = \{q_1\}$  and  $I_{NS} = \{q'_1\}$ . On the other hand, if  $\mathcal{A}$  is not CSO with respect to  $\{s\}$  and  $Q - \{s\}$ , then there is  $w$  moving  $\mathcal{A}$  only to state  $s$ , and hence  $w$  cannot be read by  $\mathcal{A}'$  from state  $q'_1$ , which shows that  $\mathcal{A}'$  is not ISO with respect to  $I_S = \{q_1\}$  and  $I_{NS} = \{q'_1\}$ . If we could solve ISO in time  $O^*(2^{o(n)})$ , we could solve 3-COLORING in time  $O^*(2^{o(n)})$  by reducing it to ISO and solving ISO in time  $O^*(2^{o(N+n)}) = O^*(2^{o(n)})$ , for  $N = 4n - 1$ .

If we in addition set the states  $s$  and  $f$  accepting, then  $\mathcal{A}'$  is ISO with respect to  $I_S = \{q_1\}$  and  $I_{NS} = \{q'_1\}$  if and only if  $\mathcal{A}'$  is IFO with respect to  $IQ_S = \{(q_1, s)\}$  and  $IQ_{NS} = \{(q'_1, f)\}$ , and hence if we could solve IFO in time  $O^*(2^{o(n)})$ , we could solve 3-COLORING in time  $O^*(2^{o(n)})$ . ◀

## 6 Discussion and Conclusions

We showed that if the strong exponential time hypothesis holds true, then, for any  $c > 2$ , there are no algorithms deciding various types of opacity in time  $O^*(2^{n/c})$ . Therefore, the current algorithms cannot be significantly improved.

More precisely, the results say that there are no algorithms deciding various types of opacity in time  $O^*(\sqrt{2}^n) = O^*(1.414213562^n)$ . However, the results admit the existence of algorithms deciding opacity in time  $O^*(1.5^n)$ . Whether such algorithms exist or whether the current lower bounds can be strengthened remains an open problem.

The construction used in the proof of Theorem 8 can be utilized to improve the conditional lower bound of deciding universality for NFAs. The universality problem for NFAs asks whether, given an NFA, the NFA accepts all strings over its alphabet. If we set the only secret state  $q_s$  of the NFA  $\mathcal{A}$  of Theorem 8 to be non-accepting and all the other states to be accepting, we obtain an NFA that is universal if and only if the automaton  $\mathcal{A}$  is CSO with respect to  $\{q_s\}$  and  $Q - \{q_s\}$ . We thus have the following consequence improving the result of Fernau and Krebs [16].

► **Corollary 18.** *Unless SETH fails, there is no algorithm deciding whether a given  $n$ -state NFA is universal that runs in time  $O^*(2^{n/(2+\varepsilon)})$ , for any  $\varepsilon > 0$ .* ◀

Consequently, we immediately have the following result.

► **Corollary 19.** *Given two NFAs  $\mathcal{A}_1$  and  $\mathcal{A}_2$  with  $n_1$  and  $n_2$  states, respectively, let  $n = \max(n_1, n_2)$ . Unless SETH fails, there is no algorithm deciding whether  $L_m(\mathcal{A}_1) \subseteq L_m(\mathcal{A}_2)$  in time  $O^*(2^{n/(2+\varepsilon)})$ , and there is no algorithm deciding whether  $L_m(\mathcal{A}_1) = L_m(\mathcal{A}_2)$  in time  $O^*(2^{n/(2+\varepsilon)})$ , for any  $\varepsilon > 0$ .* ◀

We left the question whether Theorem 8 also holds for NFAs over a fixed-size alphabet open. Although we did not answer this question, we showed that ETH implies the non-existence of sub-exponential-time algorithms deciding various types of opacity over a binary alphabet.

Inspecting Table 1, the reader may notice quite a large gap between the lower and upper bounds for the verification of IFO without any restrictions on the form of non-secret pairs. To improve the upper bound or to (conditionally) show that no such improvements are possible is a challenging open problem.

It is worth noticing that the construction in the proof of Corollary 15 produces an instance of a special case of the problem where the non-secret pairs are of the form  $IQ_{NS} = I_{NS} \times F_{NS}$ , and hence the special case is tight under the strong exponential time hypothesis.

## Abstract

We study the separability problem for automatic relations (i.e., relations on finite words definable by synchronous automata) in terms of recognizable relations (i.e., finite unions of products of regular languages). This problem takes as input two automatic relations  $R$  and  $R'$ , and asks if there exists a recognizable relation  $S$  that contains  $R$  and does not intersect  $R'$ . We show this problem to be undecidable when the number of products allowed in the recognizable relation is fixed. In particular, checking if there exists a recognizable relation  $S$  with at most  $k$  products of regular languages that separates  $R$  from  $R'$  is undecidable, for each fixed  $k \geq 2$ . Our proofs reveal tight connections, of independent interest, between the separability problem and the finite coloring problem for automatic graphs, where colors are regular languages.

## 1 Introduction

**Context.** The study of classes of relations on words has become an important topic in language theory [12, 23, 5, 13, 9], and also in areas such as databases and verification where they are used to build expressive languages. For instance, classes of relations of this kind are relevant for querying strings over relational databases [3], comparing paths in graph databases [2], or defining string constraints for model checking [20]. The most studied such classes include *recognizable*, *automatic*, and *rational* relations, each one of the latter two strictly extending the previous one. *Rational relations* are those definable by multi-head automata, with heads possibly moving asynchronously; automatic relations are rational relations that are accepted by multi-head automata whose heads are forced to move synchronously; and recognizable relations correspond to finite unions of products of regular languages (or, equivalently, to languages recognized via finite monoids, by Mezei’s Theorem). By definition, all of these classes coincide with the class of regular languages when restricted to unary relations.

---

<sup>1</sup> This result was achieved by using the `knowledge` package and its companion tool `knowledge-clustering`.

Prior work has focused on the *REC-DEFINABILITY PROBLEM*, which takes as input an  $n$ -ary rational relation  $R$  and asks whether it is equivalent to a recognizable relation  $\bigcup_i L_{i,1} \times \cdots \times L_{i,n}$ , where each  $L_{i,j}$  is a regular language. Intuitively, the problem asks whether the different components of the rational relation  $R$  are almost independent of one another. The study of REC-DEFINABILITY is relevant since relations enjoying this property are often amenable to some analysis including, e.g., abstract interpretations in program verification, variable elimination in constraint logic programming, and query processing over constraint databases (see the introduction of [1] for a thorough discussion on this topic).

In general, REC-DEFINABILITY of rational relations is undecidable, but it becomes decidable for two important subclasses: deterministic rational relations and automatic relations. For deterministic rational relations, REC-DEFINABILITY has been shown to be decidable in double-exponential time for binary relations by Valiant [27] – improving Stearns’s triple-exponential bound [25]. The decidability result was later extended to relations of arbitrary arity by Carton, Choffrut and Grigorieff [8, Theorem 3.7]. For automatic relations, the decidability of REC-DEFINABILITY can be obtained by a simple reduction to the problem of checking whether a finite automaton recognizes an infinite language [21] – which is decidable via a standard reachability argument. The precise complexity of the problem, however, was only recently pinned down. By applying techniques based on Ramsey Theorem over infinite graphs, it was shown that REC-DEFINABILITY of automatic relations is PSPACE-complete when relations are specified by non-deterministic automata [1, Theorem 1] [4, Corollary 2.9].

On the other hand, much less is known about the *REC-SEPARABILITY PROBLEM*, which takes two  $n$ -ary rational relations  $R, R' \subseteq \mathbb{A}^* \times \mathbb{A}^*$  and checks whether there is a recognizable relation  $S = \bigcup_i L_{i,1} \times \cdots \times L_{i,n}$  with  $R \subseteq S$  and  $R' \cap S = \emptyset$ . In other words, this problem asks whether we can *overapproximate*  $R$  with a recognizable relation  $S$  that is constrained not to intersect with  $R'$ . Separability problems of this kind abound in theoretical computer science, in particular in formal language theory where they have gained a lot of attention over the last few years – see, e.g., [24, 16, 11, 10].

As for definability, the REC-SEPARABILITY PROBLEM for rational relations is in general undecidable. In this paper we focus on the separability problem for automatic relations, that is, the restriction of the REC-SEPARABILITY PROBLEM defined above to the case when both  $R$  and  $R'$  are automatic relations. Notice that when  $R'$  is the complement of  $R$  this problem boils down to REC-DEFINABILITY. However, REC-SEPARABILITY for automatic relations is more general than REC-DEFINABILITY, and to this day it is unknown whether it is decidable.

**Main contributions and technical approach.** While we do not solve the separability problem for automatic relations, we report on some significant progress in our understanding of the problem. We start by establishing a tight connection between REC-SEPARABILITY and the colorability problem for “automatic graphs”, which may shed some light on the difficulty of the former problem. An automatic graph [7, 14, 17, 18] is an infinite graph defined on a regular set of finite words, whose edge set is described by a binary automatic relation. The REGULAR COLORABILITY PROBLEM is then the problem of checking if a given automatic graph is finitely colorable, with the restriction that each color forms a regular language. Concretely, we show that the REC-SEPARABILITY PROBLEM for binary automatic relations is equivalent, under polynomial time reductions, to the REGULAR COLORABILITY PROBLEM. Moreover, we introduce a hierarchy  $(k\text{-REC})_{k>0}$  of recognizable relations so that the coloring problem, when restricted to  $k > 0$  colors – called  $k$ -REGULAR COLORABILITY PROBLEM – reduces to the separability problem by relations of  $k$ -REC. Concretely:

► **Theorem 3.1.** *There are polynomial-time reductions:*

1. from the REC-SEPARABILITY PROBLEM to the REGULAR COLORABILITY PROBLEM;
2. from the REGULAR COLORABILITY PROBLEM to the REC-SEPARABILITY PROBLEM; and
3. from the  $k$ -REGULAR COLORABILITY PROBLEM to the  $k$ -REC-SEPARABILITY PROBLEM, for every  $k > 0$ .

Further, the last two reductions are so that the second relation in the instance of the SEPARABILITY PROBLEM is the identity  $Id$ .

The REGULAR COLORABILITY PROBLEM seems challenging, and in particular we lack tools for establishing that an automatic graph is finitely colorable; let alone checking that said colors define regular sets. On the other hand, it is easy to see that the  $k$ -REGULAR COLORABILITY PROBLEM is undecidable for each fixed  $k > 1$  if we lift the restriction that colors define regular sets, i.e., checking if an automatic graph admits a  $k$ -coloring – this has been proved in an unpublished thesis by Köcher [15, Proposition 6.5]. To be more precise, the problem is even co-recursively enumerable-complete<sup>2</sup>. We establish that this undecidability holds even with the restriction on colors being regular sets:

► **Theorem 4.4.** *The  $k$ -REGULAR COLORABILITY PROBLEM on automatic graphs is undecidable, for every  $k \geq 2$ . More precisely, the problem is recursively enumerable-complete. This holds also for connected automatic graphs.*

Note that the definitions of  $k$ -REGULAR COLORABILITY PROBLEM and  $k$ -COLORABILITY PROBLEM look similar, and are both undecidable, but the former is RE-complete while the latter is CORE-complete.

By reduction from the  $k$ -REGULAR COLORABILITY PROBLEM we obtain an important consequence for our separability problem: It is undecidable to check if two automatic relations can be separated by a recognizable relation defined by a *fixed* number of unions of products of regular languages. More specifically, fix  $k > 0$  and define  $k$ -PROD as the class of recognizable relations of the form  $S = \bigcup_{1 \leq i \leq k} L_{i,1} \times \cdots \times L_{i,n}$  – this hierarchy is intertwined with the  $(k\text{-REC})_{k>0}$  hierarchy introduced previously. We show that the  $k$ -PROD-SEPARABILITY PROBLEM, i.e., the problem of checking separability for binary automatic relations  $R$  and  $R'$  in terms of a recognizable relation  $S$  in the class  $k$ -PROD, is undecidable for any  $k \geq 2$ .

► **Theorem 5.6.** *The  $k$ -PROD-SEPARABILITY PROBLEM is undecidable, for every  $k \geq 2$ .*

At this point, a natural question is whether our choice of restricting the study to the class  $k$ -PROD, for fixed  $k > 1$ , is not too strong, in the sense that it turns undecidable not only the separability but also the *definability* problem for automatic relations. We show that this is not the case; in fact, by using a simple adaptation of the proof techniques in [1] we can show that the problem of checking if an automatic relation can be expressed as a relation in  $k$ -PROD, for any fixed  $k > 0$ , is decidable in single-exponential time:

► **Corollary 6.4.** *The  $k$ -PROD-DEFINABILITY PROBLEM is decidable, for every  $k > 0$ .*

**Remark.** For simplicity, we focus on binary automatic relations only. Extending the decidability results to  $n$ -ary automatic relations, for  $n > 2$  is direct by applying tools in [1].

---

<sup>2</sup> The upper bound follows from De Bruijn–Erdős Theorem.

## 2 Preliminaries

**Automatic and recognizable relations.** Let  $\mathbb{A}$  be a finite alphabet. We write  $\mathbb{A}_\perp$  for the extension of  $\mathbb{A}$  with a fresh symbol  $\perp$ . Given a pair  $(w_1, w_2) \in \mathbb{A}^* \times \mathbb{A}^*$ , we write  $w_1 \otimes w_2$  for the word over alphabet  $\mathbb{A}_\perp \times \mathbb{A}_\perp$  that is obtained as follows: first, padding the shorter word with  $\perp$ 's until both words are of the same length, and then reading the two words synchronously as if they were a single word over a binary alphabet. For example, if  $w_1 = aaba$  and  $w_2 = aa$ , then  $w_1 \otimes w_2 = (a, a)(a, a)(b, \perp)(a, \perp)$ . For any relation  $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ , let us write  $\otimes R$  to denote the set

$$\otimes R \hat{=} \{u \otimes v \mid (u, v) \in R\} \subseteq (\mathbb{A}_\perp \times \mathbb{A}_\perp)^*.$$

We then have the following:

- $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$  is an *automatic relation* iff  $\otimes R$  is a regular language;
- $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$  is a *recognizable relation* iff  $R = \bigcup_{i=1}^n A_i \times B_i$ , where  $n \in \mathbb{N}$  and all the  $A_i$ 's and  $B_i$ 's are regular languages over  $\mathbb{A}$ .

We denote by REC the class of all recognizable relations.

► **Example 2.1.** For any fixed constant  $c > 0$ , the relation  $R$  composed by all pairs of words of the form  $(a^n, a^{n+c})$ , for  $n \geq 0$ , is automatic. In turn,  $R$  is not recognizable. An example of a non-automatic relation is the one consisting of all pairs of the form  $(a^n, a^{d \cdot n})$ , for  $n > 0$ , for any constant  $d > 1$ . ◀

**Separability.** Let  $R$  and  $R'$  be automatic relations over an alphabet  $\mathbb{A}$ . A recognizable relation  $S$  over  $\mathbb{A}$  *separates*  $R$  from  $R'$  if  $R \subseteq S$  and  $R' \cap S = \emptyset$ .

► **Example 2.2.** Consider the automatic relations  $R = \{(a^n, a^{n+1}) \mid n \geq 0\}$  and  $R' = \{(a^n, a^{n+2}) \mid n \geq 0\}$ . They are separable by the recognizable relation

$$S = (A_{\text{even}} \times A_{\text{odd}}) \cup (A_{\text{odd}} \times A_{\text{even}}),$$

where  $A_{\text{even}}$  and  $A_{\text{odd}}$  are the regular languages  $(aa)^*$  and  $a(aa)^*$ , respectively. ◀

We study the following separability problem, for a class  $\mathcal{C}$  of recognizable relations.

**Problem:**  $\mathcal{C}$ -SEPARABILITY PROBLEM  
**Input:** Automatic relations  $R$  and  $R'$  over  $\mathbb{A}$   
**Question:** Is there a recognizable relation in  $\mathcal{C}$  over  $\mathbb{A}$  that separates  $R$  from  $R'$ ?

We also consider the  $\mathcal{C}$ -DEFINABILITY PROBLEM, which takes as input an automatic relation  $R$  and asks if there is a recognizable relation  $S$  in  $\mathcal{C}$  with  $S = R$ . It is easy to see that the  $\mathcal{C}$ -DEFINABILITY PROBLEM corresponds to an instance of the  $\mathcal{C}$ -SEPARABILITY PROBLEM.

▷ **Fact 2.3.** For any class  $\mathcal{C}$  of recognizable relations, the  $\mathcal{C}$ -DEFINABILITY PROBLEM is Turing-reducible to the  $\mathcal{C}$ -SEPARABILITY PROBLEM.

**Proof.** Reduce an instance  $R$  of the DEFINABILITY PROBLEM to the instance  $(R, (\mathbb{A}^* \times \mathbb{A}^*) \setminus R)$  of the SEPARABILITY PROBLEM. ◀

The following is known regarding the complexity of the REC-definability problem.

► **Proposition 2.4** ([1, Theorem 1]). *The REC-DEFINABILITY PROBLEM for automatic relations specified by non-deterministic automata is PSPACE-complete.*

**Automatic graphs.** Let  $L$  be a language of finite words over  $\mathbb{A}$ , and  $R \subseteq L \times L$  binary relation over  $\mathbb{A}$ . They naturally define a directed graph  $G = \langle L, R \rangle$ , *i.e.*, the nodes of  $G$  are the words over  $L$  and there is an edge in  $G$  from word  $u$  to word  $v$  iff  $(u, v) \in R$ . An *automatic graph* is a graph of the form  $\langle L, R \rangle$ , for  $R$  an automatic relation and  $L$  a regular language<sup>3</sup>. A  $k$ -*coloring* of  $\langle L, R \rangle$  is a partition of  $L$  into  $k$  sets  $V_1, \dots, V_k$  such that  $(V_i \times V_i) \cap E = \emptyset$  for every  $i$ .

► **Example 2.5.** Consider again the automatic relation  $R = \{(a^n, a^{n+c}) \mid n \geq 0\}$ , where  $c > 0$  is a fixed constant. The graph  $\langle a^*, R \rangle$  is formed by a disjoint union of  $c$  infinite directed paths, and thus it is 2-colorable. ◻

A  $k$ -*regular coloring* of an automatic graph is a  $k$ -coloring whose colors  $(V_i)_{1 \leq i \leq k}$  are regular languages. A *regular coloring* is a  $k$ -regular coloring for some  $k$ .

► **Example 2.6.** The automatic graph  $\langle a^*, R \rangle$  from Example 2.5 is 2-regular colorable. In fact, it suffices to define color  $V_1$  as having every word of the form  $a^n$  with  $n \equiv i \pmod{2c}$ , for  $i \in [0, c-1]$ , and  $V_2 = \mathbb{A}^* \setminus V_1$ . ◻

The  $k$ -REGULAR COLORABILITY PROBLEM is the problem of whether a given automatic graph has a  $k$ -regular coloring. The REGULAR COLORABILITY PROBLEM is the problem of whether a given automatic graph has a regular coloring.

### 3 Separability is Equivalent to Regular Colorability

We start by showing that the SEPARABILITY PROBLEM in terms of arbitrary recognizable relations is equivalent, under polynomial time reductions, to the REGULAR COLORABILITY PROBLEM. To make our statement precise, we need some terminology introduced below. Let  $k$ -REC be the class of languages expressed by unions of products of  $k$  regular languages which form a partition, that is (in the binary case), relations of the form  $(L_{i_1} \times L_{j_1}) \cup \dots \cup (L_{i_\ell} \times L_{j_\ell})$ , with  $i_1, j_1, \dots, i_\ell, j_\ell \in [1, k]$ , for some regular partition  $L_1, \dots, L_k$  of  $\mathbb{A}^*$  and  $\ell \in \mathbb{N}$ . Note that  $\text{REC} = \bigcup_k k\text{-REC}$ . Let us denote by  $Id$  the identity relation (on any implicit alphabet). Observe that  $Id$  is automatic but not recognizable.

► **Theorem 3.1.** *There are polynomial-time reductions:*

1. from the REC-SEPARABILITY PROBLEM to the REGULAR COLORABILITY PROBLEM;
2. from the REGULAR COLORABILITY PROBLEM to the REC-SEPARABILITY PROBLEM; and
3. from the  $k$ -REGULAR COLORABILITY PROBLEM to the  $k$ -REC-SEPARABILITY PROBLEM, for every  $k > 0$ .

Further, the last two reductions are so that the second relation in the instance of the SEPARABILITY PROBLEM is the identity  $Id$ .

**Proof.** We start with the last two reductions. Given an automatic graph  $\langle L, E \rangle$  over an alphabet  $\mathbb{A}$ , consider the instance  $R_1, R_2$  for the REC-SEPARABILITY PROBLEM, where  $R_1 = E$  and  $R_2 = Id$ . If  $\langle L, E \rangle$  is  $k$ -regular colorable via the coloring  $V_1, \dots, V_k$  then the  $k$ -REC relation  $\bigcup_{i \neq j} V_i \times V_j$  separates  $R_1$  and  $R_2$ . Conversely, if a  $k$ -REC relation  $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$  on the partition  $V_1 \dot{\cup} \dots \dot{\cup} V_k = \mathbb{A}^*$  separates  $R_1$  and  $R_2$ , then  $\bigcup_{i \neq j} V_i \times V_j$  also separates  $R_1$  and  $R_2$ , and this implies that  $V_1, \dots, V_k$  is a  $k$ -coloring for  $\langle \mathbb{A}^*, E \rangle$ .

<sup>3</sup> Note that an automatic graph can contain self-loops. However, since the presence of such an edge prevent the graph from being  $k$ -colorable for any  $k \geq 0$ , all our examples will be self-loop-free.

## 17:6 Separating Automatic Relations

For the first reduction, let us introduce some terminology. Given two relations  $R_1, R_2$  over  $\mathbb{A}^*$ , say that  $u \in \mathbb{A}^*$  is *compatible* with  $u' \in \mathbb{A}^*$  when for all words  $v \in \mathbb{A}^*$ :

$$\begin{aligned} (\text{COMP}_\ell): (u, v) \in R_1 \Rightarrow (u', v) \notin R_2, & \quad (\text{COMP}_r): (v, u) \in R_1 \Rightarrow (v, u') \notin R_2, \\ (\text{COMP}'_\ell): (u', v) \in R_1 \Rightarrow (u, v) \notin R_2 & \quad \text{and} \quad (\text{COMP}'_r): (v, u') \in R_1 \Rightarrow (v, u) \notin R_2. \end{aligned}$$

Define the *incompatibility graph*  $\mathcal{I}nc_{R_1, R_2}$  as the graph whose vertices are all words of  $\mathbb{A}^*$ , and with an edge from  $u$  to  $v$  whenever  $u$  is not compatible with  $v$ . Note that  $\mathcal{I}nc_{R, Id}$  is exactly the graph  $\langle \mathbb{A}^*, R \rangle$ . For a less trivial example of an incompatibility graph, see the full version.

► **Lemma 3.2.** *If  $R_1$  and  $R_2$  are automatic, then so is  $\mathcal{I}nc_{R_1, R_2}$ . Moreover, we can build an automaton for  $\mathcal{I}nc_{R_1, R_2}$  in polynomial time in the size of the automata for  $R_1$  and  $R_2$ .*

Given an instance  $(R_1, R_2)$  of the SEPARABILITY PROBLEM, we reduce it to the REGULAR COLORABILITY PROBLEM on its incompatibility graph  $\mathcal{I}nc_{R_1, R_2}$ .

**Left-to-right implication:** Assume that there exists  $S$  in  $k$ -REC that separates  $R_1$  from  $R_2$ . Then  $S$  can be written as  $(A_{i_1} \times A_{j_1}) \cup \dots \cup (A_{i_\ell} \times A_{j_\ell})$ , where  $(A_1, \dots, A_k)$  is a partition of  $\mathbb{A}^*$  in  $k$  regular languages. We define the color of a word  $u \in \mathbb{A}^*$  as the unique  $i \in \llbracket 1, k \rrbracket$  s.t.  $u \in A_i$ . In other words, the coloring is simply  $(A_1, \dots, A_k)$ .

This is indeed a proper coloring: if  $u$  and  $u'$  have the same color, we claim that  $u$  is compatible with  $u'$ . Indeed, take any  $v \in \mathbb{A}^*$ : if  $(u, v) \in R_1$ , then  $(u, v) \in S$ , so  $(u, v) \in A_{i_m} \times A_{j_m}$  for some  $m$ . But since  $u$  has the same color as  $u'$ , the fact that  $u \in A_{i_m}$  implies  $u' \in A_{i_m}$ , and hence  $(u', v) \in A_{i_m} \times A_{j_m} \subseteq S$ . But  $S$  separates  $R_1$  from  $R_2$ , and therefore  $(u', v) \notin R_2$ . This tells us that  $(\text{COMP}_\ell)$  holds. The other conditions hold by symmetry. We conclude that  $(A_1, \dots, A_k)$  defines a proper coloring of  $\mathcal{I}nc_{R_1, R_2}$ , and this coloring, with  $k$  colors, is regular since the  $A_i$ 's are regular languages by definition.

**Right-to-left implication:** Assume that  $\mathcal{I}nc_{R_1, R_2}$  is finitely colorable, say by  $(A_1, \dots, A_k)$ . Then let  $S$  be the union of all  $S_i$ 's where

$$\begin{aligned} S_i \triangleq \{ & (u, v) \mid u \in A_i \text{ and } (u', v) \in R_1 \text{ for some } u' \in A_i \} \\ & \cup \{ (u, v) \mid v \in A_i \text{ and } (u, v') \in R_1 \text{ for some } v' \in A_i \}. \end{aligned}$$

Since  $(A_1, \dots, A_k)$  covers every node of  $\mathcal{I}nc_{R_1, R_2}$ , we get  $R_1 \subseteq S$ . Moreover, we claim that  $R_2 \cap S = \emptyset$ . Indeed, if  $(u, v) \in S$ , then  $(u, v) \in S_i$  for some  $i, j$ . It either means that **1**  $(u', v) \in R_1$  for some  $u' \in A_i$ , or **2**  $(u, v') \in R_1$  for some  $v' \in A_i$ . In case **1**, the fact that  $u \in A_i$  implies that  $u$  and  $u'$  have the same color. Thus,  $u$  must be compatible with  $u'$  and hence  $(u, v) \notin R_2$  using  $(\text{COMP}'_\ell)$ . The other case is symmetric. Therefore,  $(u, v) \notin R_2$ , and thus  $S$  separates  $R_1$  from  $R_2$ .

Finally,  $S$  is recognizable; in fact,  $S = \bigcup_{i=1}^k (A_i \times R_1[A_i]) \cup (R_1^{-1}[A_i] \times A_i)$ , where for any set  $X \subseteq \mathbb{A}^*$  we define  $R_1[X]$  (resp.  $R_1^{-1}[X]$ ) as the set of  $v \in \mathbb{A}^*$  (resp.  $u \in \mathbb{A}^*$ ) such that  $(u, v) \in R_1$  for some  $u \in X$  (resp.  $v \in X$ ). Hence,  $R_1$  and  $R_2$  are REC-separable. ◀

It is not known to date whether the REGULAR COLORABILITY PROBLEM is decidable, and hence the same holds for the REC-SEPARABILITY PROBLEM in light of the previous theorem. This is due to the fact that there are no known characterizations of when an automatic graph is finitely colorable. In spite of this, we believe that the connection between separability and finite colorability is of interest, as it provides us with a way to define and study meaningful restrictions of our problems. The first such restriction corresponds to the  $k$ -REGULAR COLORABILITY PROBLEM for automatic graphs, which we study in the next section.

## 4 $k$ -Regular Colorability Problem

While we do not know how to approach the REGULAR COLORABILITY PROBLEM, we show that as soon as we add the restriction that the number of colors is bounded, the problem becomes undecidable; i.e., the  $k$ -REGULAR COLORABILITY PROBLEM is undecidable for  $k \geq 2$ . Using this, we obtain in the next section the undecidability for the SEPARABILITY PROBLEM on two natural classes of recognizable relations. This is proven by a reduction from a suitable problem on reversible Turing Machines with certain restrictions, which we call “well-founded”.

### 4.1 Regularity of Reachability for Turing Machines

We use the standard notation  $u[i..j]$  to denote the factor of a word  $u$  between (and including) positions  $i$  and  $j$ , and  $u[i]$  to denote  $u[i..i]$ . Consider any deterministic Turing Machine (TM)  $T = \langle Q, \Gamma, \perp, \delta, q_0, F \rangle$ , where  $Q$  is the set of states,  $\Gamma$  is tape alphabet,  $\perp$  is the blank symbol,  $\delta : (Q \setminus F) \times \Gamma_{\perp} \rightarrow Q \times \Gamma \times \{L, R\}$  is the transition (partial) function, where  $\Gamma_{\perp} = \Gamma \cup \{\perp\}$ , and  $q_0$  and  $F$  is the initial and set of final states, respectively. We represent a configuration with tape content  $w \cdot \perp^{\omega}$  (where  $w \in \Gamma^* \cdot \{\perp\}$ ), in state  $q$  and with the head pointing to the cell number  $1 \leq i \leq |w|$ , as the string

$$w[1..i-1] \cdot (w[i], q) \cdot w[i+1..|w|]$$

over the alphabet  $\mathbb{A}_T = \Gamma \cup (\Gamma_{\perp} \times Q)$ . In light of this representation, we will henceforth denote by “configuration” any string from the set  $\text{Conf}_T \hat{=} (\Gamma^* \cdot (\Gamma_{\perp} \times Q)) \cup (\Gamma^* \cdot (\Gamma \times Q) \cdot \Gamma^*)$ . The *initial configuration* is  $(\perp, q_0)$ . The *configuration graph* of  $T$  is the infinite graph  $\mathcal{G}^T$  having  $\text{Conf}_T$  as set of vertices and an edge from  $c$  to  $c'$ , denoted  $c \rightarrow c'$ , if  $c'$  is the configuration of the next step of  $T$  starting from  $c$ . Observe that the configuration graph  $\mathcal{G}^T$  of any TM  $T$  is an effective automatic graph (see, e.g., [18]).

We say that a deterministic TM  $T$  is *reversible* if every node of  $\mathcal{G}^T$  has in-degree at most 1, in other words if the machine is co-deterministic<sup>4</sup>. We say that a TM  $T$  is a *well-founded Reversible Turing Machine (wf-RTM)* if its configuration graph is such that (1) the initial configuration has in-degree 0 (2) every node has in-degree and out-degree at most one (3) there are no infinite backward paths  $c_1 \leftarrow c_2 \leftarrow \dots$  in  $\mathcal{G}^T$ .

Note that every well-founded Reversible Turing Machine is deterministic and reversible and, moreover, its configuration graph is a (possibly infinite) disjoint union of directed paths, which are all finite, or isomorphic to  $(\mathbb{N}, +1)$ . The set of *reachable configurations*, denoted by  $\text{Reach}$ , is the set of all configurations that admit a path from the initial configuration in  $\mathcal{G}^T$ , for a given TM  $T$ . Such a configuration graph is depicted on Figure 2a.

The *REACHABLE REGULARITY PROBLEM* is the problem of, given a wf-RTM  $T$ , whether its set of reachable configurations is a regular language. To show that it is undecidable, we exhibit a reduction from the halting problem on deterministic reversible Turing machines.

► **Proposition 4.1** ([19, Theorem 1]). *The halting problem on deterministic reversible Turing machines is undecidable.*

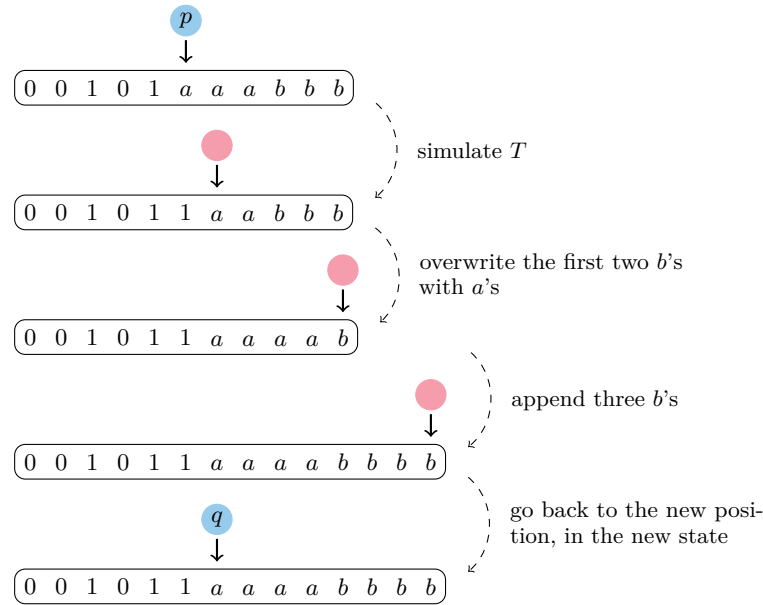

For more details and pointers on reversible Turing machines, see [22, Chapter 5].

► **Lemma 4.2.** *The REACHABLE REGULARITY PROBLEM is undecidable.*

<sup>4</sup> Note that a modern proof of undecidability of the isomorphism problem for automatic structures by Blumensath [6, §VIII. Theorem 4.3, p. 396 & second claim, p. 398] also relies on the use of reversible Turing machines.

## 17:8 Separating Automatic Relations

**Proof sketch.** By reducing the halting problem on deterministic reversible Turing machines, in such a way that the reachable configurations whose state  $q$  coincide with the state of the original machine are of the form  $(uqva^n b^n)$  where  $(uqv)$  is a configuration of the original machine,  $a$  and  $b$  are new symbols, and  $n \in \mathbb{N}$ . Transitions are defined in such a way that the new machine is a wf-RTM: this is implemented by having, for every transition  $uqv \rightarrow u'q'v'$  of the original machine and every  $n \in \mathbb{N}$ , a (multi-step) transition  $(uqva^n b^n) \rightarrow^* (u'q'v'a^{n+1}b^{n+1})$  – and is illustrated in Figure 1. Moreover:

■ **Figure 1** Encoding of a single transition of the form “when reading a blank in state  $p$ , write a 1, go in state  $q$  and move right” of the machine  $T$  in the machine  $T'$  in the proof of Lemma 4.2. Red unlabelled states represent states of  $T'$  that are not originally present in  $T$ .

- if the original machine was halting, then the reachable configurations of the new one are finite and hence regular;
- otherwise, the set of reachable configurations is not regular, which follows from the non-regularity of any infinite subset of  $\{a^n b^n \mid n \in \mathbb{N}\}$ .

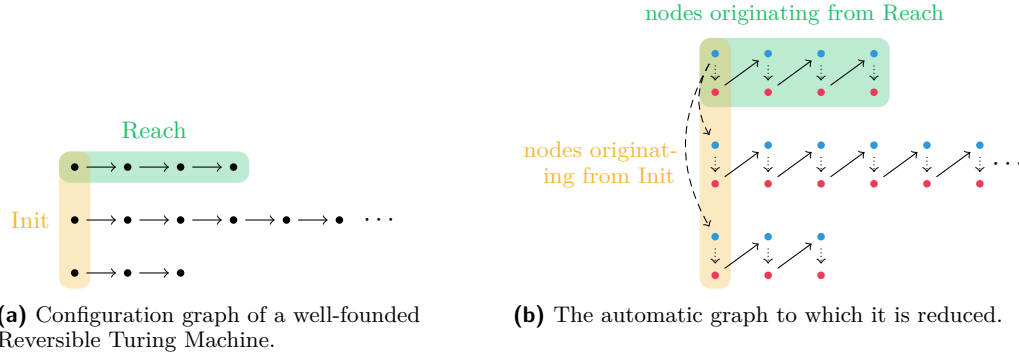

See the full version for more details. ◀

## 4.2 Undecidability of the $k$ -Regular Colorability Problem

We can now show undecidability for the  $k$ -REGULAR COLORABILITY PROBLEM by reduction from the REACHABLE REGULARITY PROBLEM as defined before.

▷ **Fact 4.3.** Given an automatic graph, the set of nodes with no predecessor is effectively a regular language.

► **Theorem 4.4.** *The  $k$ -REGULAR COLORABILITY PROBLEM on automatic graphs is undecidable, for every  $k \geq 2$ . More precisely, the problem is recursively enumerable-complete. This holds also for connected automatic graphs.*

■ **Figure 2** Reduction used in the proof of Theorem 4.4.

**Proof.** Lower bound. By reduction from the REACHABLE REGULARITY PROBLEM for wf-RTMs (Lemma 4.2). We first show it for  $k = 2$ . Given a wf-RTM  $T$ , let  $c_{init}$  be its initial configuration. Observe that the set  $Init$  of all vertices of  $\mathcal{G}^T$  with in-degree 0 is an effective regular language (by Fact 4.3), and that  $c_{init} \in Init$ . Let  $B$  and  $R$  be fresh symbols. Consider the automatic graph  $\langle L, E \rangle$  for  $L = \{B, R\} \times Confs_T$ , having an edge from  $(z, c) \in \{B, R\} \times Confs_T$  to  $(z', c') \in \{B, R\} \times Confs_T$  if either

1.  $(z, z') = (B, R)$  and  $c = c'$ ;
2.  $(z, z') = (R, B)$  and there is an edge from  $c$  to  $c'$  in  $\mathcal{G}^T$ ; or
3.  $(z, z') = (B, B)$ ,  $c = c_{init}$  and  $c' \in Init \setminus \{c_{init}\}$ .

Fresh symbols  $B$  and  $R$  are utilized to represent two versions of each configuration - one in Blue and one in Red. This graph is depicted on Figure 2. Note that  $\langle L, E \rangle$  is connected and 2-colorable: in fact, it is a directed (possibly infinite) tree with root  $(B, c_{init})$ .

We claim that  $\langle L, E \rangle$  is 2-regular colorable if, and only if, the set of reachable configurations of  $T$  is a regular language. In fact, up to permuting the two-colors,  $\langle L, E \rangle$  admits a unique 2-coloring, defined by:

$$C_1 \hat{=} \{B\} \times Reach \cup \{R\} \times (Confs_T \setminus Reach)$$

and  $C_2$  is the complement of  $C_1$ . If  $Reach$  is regular, then so is  $C_1$ . Dually, if  $C_1$  is regular, then  $Reach$  is the set of configurations  $c$  such that  $(B, c) \in C_1$  and hence is regular. It follows that  $\langle \mathbb{A}^*, E \rangle$  is 2-regular colorable if and only if the reachable configurations of  $T$  are regular, which concludes the proof for  $k = 2$ .

To prove the statement for any  $k > 2$ , we define  $\langle L, E_k \rangle$  as the result of adding a  $(k - 2)$ -clique to  $\langle L, E \rangle$  and adding an edge from every vertex of the clique to every vertex incident to an edge of  $E$ . This forces the clique to use  $k - 2$  colors that cannot be used in the remaining part of the graph and the proof is then analogous.

**Upper-bound.** We show that the problem is recursively enumerable. Let us define a  $k$ -colored automaton like a regular (complete) DFA, except that instead of having a set of final states, it has a partition  $\langle C_1, \dots, C_k \rangle$  of its states. Such an automaton recognizes a regular coloring  $\mathbb{A}^* \rightarrow \{1, \dots, k\}$ . Given an automatic graph  $\langle L, R \rangle$  – specified by NFA's  $\mathcal{A}_1$  and  $\mathcal{A}_2$  recognizing  $L$  and  $\otimes R$  respectively – and a  $k$ -colored automaton  $\mathcal{B}$ , we can build, by a product construction, an NFA  $\mathcal{A}'_2$  which accepts all  $u \otimes v \in \otimes R$  such that the color of  $u$  is

## 17:10 Separating Automatic Relations

distinct from the color of  $v$ . Then,  $\mathcal{A}'_2$  is equivalent to  $\mathcal{A}_2$  if, and only if,  $\mathcal{B}$  describes a proper  $k$ -coloring of  $\langle L, R \rangle$ . The RE upper-bound of the  $k$ -REGULAR COLORABILITY PROBLEM follows: it suffices to enumerate all  $k$ -colored automata and check for equivalence. ◀

Note that this reduction provides an easy way of building graphs in the shape of Figure 2b that are 2-colorable (in fact, they are trees) but not 2-regular colorable. In fact, we can provide a slightly more direct construction.

► **Example 4.5.** On the alphabet  $\mathbb{A} = \{a, b\}$ , the tree  $\mathcal{T}$  depicted in Figure 3 whose set of vertices is  $V = a^*b^*$  and whose set of edges is  $E = E_{\text{incr}} \cup E_{\text{init}}$ , with

$$E_{\text{incr}} = \{(a^p b^q, a^{p+1} b^{q+1}) \mid p, q \in \mathbb{N}\}$$

$$E_{\text{init}} = \{(\varepsilon, a^p) \mid p \in \mathbb{N}\} \cup \{(\varepsilon, b^q) \mid q \in \mathbb{N}\},$$

is automatic but not 2-regular colorable. Indeed, its only 2-coloring consists in partitioning the vertices of  $\mathcal{T}$  into

$$C = \{a^n b^n \mid n \in 2\mathbb{N}\} \cup \{a^p b^q \mid p > q \text{ and } q \text{ is odd}\} \cup \{a^p b^q \mid p < q \text{ and } p \text{ is odd}\}$$

and its complement  $V \setminus C$ . Let  $P = \{a^p b^q \mid p, q \in 2\mathbb{N}\} = (aa)^*(bb)^*$ :  $P$  is regular, yet  $C \cap P = \{a^n b^n \mid n \in 2\mathbb{N}\}$  is not. Hence,  $C$  is not regular, and thus  $\mathcal{T}$  is not 2-regular colorable. ◻

■ **Figure 3** The automatic tree  $\mathcal{T}$  of Example 4.5, and its unique 2-coloring  $(C, V \setminus C)$ , which is not regular.

## 5 Separability for Bounded Recognizable Relations

In this section we capitalize on the undecidability result of the previous section, showing how this implies the undecidability for the SEPARABILITY PROBLEM on two natural classes of bounded recognizable relations, namely:  $k$ -REC, and  $k$ -PROD. Remember that, for any  $k$ ,  $k$ -PROD is the subclass of REC consisting of unions of  $k$  cross-products of regular languages (which is a subclass of  $2^{2k}$ -REC).

**$k$ -Rec-separability.** First, observe that the 1-REC-SEPARABILITY PROBLEM is trivially decidable, since the only possible separator is  $\mathbb{A}^* \times \mathbb{A}^*$ . However, for any other  $k > 1$ , the problem is undecidable.

► **Proposition 5.1.** *The  $k$ -REC-SEPARABILITY PROBLEM is undecidable, for every  $k > 1$ .*

**Proof.** A consequence of the reduction from the  $k$ -REGULAR COLORABILITY PROBLEM of Theorem 3.1, combined with the undecidability of the latter for every  $k > 1$  (Theorem 4.4). ◀

**$k$ -Prod-separability.** On the  $k$ -PROD hierarchy we will find the same phenomenon. In particular the case  $k = 1$  is also trivially decidable.

► **Proposition 5.2.** *The 1-PROD-SEPARABILITY PROBLEM is decidable.*

**Proof.** Given two automatic relations  $R_1, R_2$ , there exists  $S \in 1\text{-PROD}$  that separates  $R_1$  from  $R_2$  if and only if  $\pi_1(R_1) \times \pi_2(R_1)$  separates  $R_1$  from  $R_2$ . ◀

As soon as  $k > 1$ , the  $k$ -PROD SEPARABILITY PROBLEM becomes undecidable. This is a consequence of the following simple lemma.

► **Lemma 5.3.** *A symmetric automatic relation  $R$  and the identity  $Id$  are separable by a relation in 2-PROD iff they have a separator of the form  $(A \times B) \cup (B \times A)$ .*

**Proof.** Assume that  $S \in 2\text{-PROD}$  separates  $R$  from  $Id$ . Then  $R \subseteq S$ , but since  $R$  is symmetric,  $R = R^{-1} \subseteq S^{-1}$  so  $R \subseteq S \cap S^{-1}$ , and hence  $R \subseteq S \cap S^{-1}$ . Moreover, since  $S$  has a trivial intersection with  $Id$ , so does  $S \cap S^{-1}$ . Hence,  $S \cap S^{-1}$  separates  $R$  from  $Id$ .

Since  $S \in 2\text{-PROD}$ , there exists  $A_1, A_2, B_1, B_2 \subseteq \mathbb{A}^*$  such that  $S = A_1 \times B_1 \cup B_2 \times A_2$ . Note that  $S \cap Id = \emptyset$  yields  $A_i \cap B_i = \emptyset$  for each  $i \in \{1, 2\}$ . Finally:

$$\begin{aligned}
 S \cap S^{-1} &= (A_1 \times B_1 \cup B_2 \times A_2) \cap (B_1 \times A_1 \cup A_2 \times B_2) \\
 &= ((A_1 \times B_1) \cap (B_1 \times A_1)) \cup ((A_1 \times B_1) \cap (A_2 \times B_2)) \\
 &\quad \cup ((B_2 \times A_2) \cap (B_1 \times A_1)) \cup ((B_2 \times A_2) \cap (A_2 \times B_2)) \\
 &= \overbrace{((A_1 \cap B_1) \times (A_1 \cap B_1))}^{=\emptyset} \cup ((A_1 \cap A_2) \times (B_1 \cap B_2)) \\
 &\quad \cup ((B_1 \cap B_2) \times (A_1 \cap A_2)) \cup \underbrace{((A_2 \cap B_2) \times (A_2 \cap B_2))}_{=\emptyset} \\
 &= ((A_1 \cap A_2) \times (B_1 \cap B_2)) \cup ((B_1 \cap B_2) \times (A_1 \cap A_2)). \quad \blacktriangleleft
 \end{aligned}$$

We can then establish the following:

► **Corollary 5.4.** *A symmetric automatic relation  $R$  and  $Id$  are separable by a relation in 2-PROD iff  $\langle \mathbb{A}^*, R \rangle$  is 2-regular colorable.*

**Proof.** By observing that for any symmetric relation  $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ , we have that  $A, B \subseteq \mathbb{A}^*$  is a coloring of  $\langle \mathbb{A}^*, R \rangle$  if, and only if,  $(A \times B) \cup (B \times A)$  separates  $R$  from  $Id$ . ◀

We can now easily show undecidability for the 2-PROD SEPARABILITY PROBLEM by reduction from the 2-REGULAR COLORABILITY PROBLEM.

► **Lemma 5.5.** *The 2-PROD-SEPARABILITY PROBLEM is undecidable.*

**Proof.** By reduction from the 2-REGULAR COLORABILITY PROBLEM on automatic graphs, which is undecidable by Theorem 4.4. Let  $\langle L, R \rangle$  be an automatic graph and  $\langle L, R' \rangle$  the symmetric closure of  $\langle L, R \rangle$ . It follows that  $\langle L, R' \rangle$  is still automatic and that there is a 2-regular coloring for  $\langle L, R' \rangle$  iff there is a 2-regular coloring for  $\langle L, R \rangle$  (the same coloring in fact). Thus, by Corollary 5.4,  $\langle L, R \rangle$  is 2-regular colorable iff there is a 2-PROD relation that separates  $R'$  from  $Id$ . ◀

Further, this implies undecidability for every larger  $k$ :

► **Theorem 5.6.** *The  $k$ -PROD-SEPARABILITY PROBLEM is undecidable, for every  $k \geq 2$ .*

■ **Figure 4** Construction in the proof of Theorem 5.6 for  $k = 5$ .  $S$  is depicted as the union of two (gray) rectangles since  $S \in 2\text{-PROD}$ . The relation  $R'_1$  is obtained from  $R_1$  (blue shape) by adding all blue edges, namely  $(a_i, b_i)$  for  $1 \leq i \leq k - 2$ . The relation  $R'_2$  is obtained from  $R_2$  (red shape) by adding all red edges, namely every other edge involving a vertex  $a_i$  or  $b_i$ . Finally,  $S'$  (five gray rectangles) is obtained from  $S$  by adding each  $\{a_i\} \times \{b_i\}$ .

**Proof.** The case  $k = 2$  is shown in Lemma 5.5, so suppose  $k > 2$ . The proof goes by reduction from the  $2\text{-PROD-SEPARABILITY PROBLEM}$ . Let  $R_1, R_2$  be a pair of automatic relations over an alphabet  $\mathbb{A}$ . Consider the alphabet extended with  $2(k - 2)$  fresh symbols  $\mathbb{A}' = \mathbb{A} \dot{\cup} \{a_1, \dots, a_{k-2}, b_1, \dots, b_{k-2}\}$ . We build automatic relations  $R'_1, R'_2$  over  $\mathbb{A}'$  such that  $(R_1, R_2)$  are  $2\text{-PROD}$  separable over  $\mathbb{A}$  iff  $(R'_1, R'_2)$  are  $k\text{-PROD}$  separable over  $\mathbb{A}'$ .

Let  $R'_1 = R_1 \dot{\cup} \{(a_i, b_i) : 1 \leq i \leq k - 2\}$  and

$$\begin{aligned}
 R'_2 = R_2 \dot{\cup} & \{(a_i, w) : w \in \mathbb{A}^*, 1 \leq i \leq k - 2\} \dot{\cup} \\
 & \{(w, b_i) : w \in \mathbb{A}^*, 1 \leq i \leq k - 2\} \dot{\cup} \\
 & \{(a_i, b_j) : 1 \leq i, j \leq k - 2, i \neq j\} \dot{\cup} \\
 & \{(b_i, a_j) : 1 \leq i, j \leq k - 2\}
 \end{aligned}$$

If  $(R_1, R_2)$  has a  $2\text{-PROD}$  separator  $S$ , then  $\tilde{S} \dot{\cup} \{(a_i, b_i) : 1 \leq i \leq k - 2\}$  is a  $k\text{-PROD}$  separator of  $(R'_1, R'_2)$ .

Conversely, if  $S' = (A_1 \times B_1) \cup \dots \cup (A_k \times B_k)$  is a  $k\text{-PROD}$  separator of  $(R'_1, R'_2)$ , then for every  $i$  there must be some  $j_i$  such that  $A_{j_i} \times B_{j_i}$  contains  $(a_i, b_i)$ . Observe that

- $A_{j_i} \cup B_{j_i}$  cannot contain any  $a_{i'}$  or  $b_{i'}$  for  $i' \neq i$ , and
- $A_{j_i} \cup B_{j_i}$  cannot contain any  $w \in \mathbb{A}^*$ ;

since otherwise we would have  $(A_{j_i} \times B_{j_i}) \cap R'_2 \neq \emptyset$ . Hence,  $\{i \mapsto j_i\}_i$  is injective, and thus  $S'$  is of the form  $S' = (A_1 \times B_1) \cup (A_2 \times B_2) \cup (\{a_1\} \times \{b_1\}) \cup \dots \cup (\{a_{k-2}\} \times \{b_{k-2}\})$ . We can further assume that  $A_1, B_1, A_2, B_2$  do not contain any  $a_i$  or  $b_i$  since otherwise we can remove them preserving the property of being a  $k\text{-PROD}$  separator of  $R'_1$  and  $R'_2$ . Hence,  $S \doteq (A_1 \times B_1) \cup (A_2 \times B_2)$  must cover  $R_1$  and be disjoint from  $R_2$ , obtaining that  $S$  is a  $2\text{-PROD}$  separator of  $R_1$  and  $R_2$ . ◀

## 6 Definability for Bounded Recognizable Relations

Up until now, we have examined two hierarchies of bounded recognizable relations, namely  $k\text{-PROD}$  and  $k\text{-REC}$ . Our previous analysis demonstrated that, for any element in these hierarchies (where  $k > 1$ ), the  $\text{SEPARABILITY PROBLEM}$  is undecidable. Nevertheless, we will now establish that the  $\text{DEFINABILITY PROBLEM}$  is decidable.

Given an automatic relation  $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ , consider the automatic equivalence relation  $\sim_R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ , defined as  $w \sim_R w'$  if for every  $v \in \mathbb{A}^*$  we have

1.  $(w, v) \in R$  iff  $(w', v) \in R$ , and
2.  $(v, w) \in R$  iff  $(v, w') \in R$ .

It turns out that equivalence classes of  $\sim_R$  define the coarsest partition onto which  $R$  can be recognized in terms of  $k$ -REC:

► **Lemma 6.1.** *For every automatic  $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ ,  $\sim_R$  has index at most  $k$  if, and only if,  $R$  is in  $k$ -REC.*

**Proof.** **Left-to-right** Assume that  $\sim_R$  has the equivalence classes  $E_1, \dots, E_k$ . Consider the set  $P \subseteq \{1, \dots, k\}^2$  of all pairs  $(i, j)$  such that there are  $u_i \in E_i$  and  $u_j \in E_j$  with  $(u_i, u_j) \in R$ . Define the  $k$ -REC relation  $R' = \bigcup_{(i,j) \in P} E_i \times E_j$ . We claim that  $R = R'$ . In fact, by definition of  $\sim_R$ , note that if there are  $u_i \in E_i$  and  $u_j \in E_j$  with  $(u_i, u_j) \in R$ , then  $E_i \times E_j \subseteq R$ . Hence,  $R' \subseteq R$ . On the other hand, for every pair  $(u, v) \in R$  there is  $(i, j) \in P$  such that  $u \in E_i, v \in E_j$  implying  $(u, v) \in R'$ . Hence,  $R \subseteq R'$ .

**Right-to-left** If  $R$  is a union of products of sets from the partition  $E_1 \dot{\cup} \dots \dot{\cup} E_k = \mathbb{A}^*$ , then every two elements of each  $E_i$  are  $\sim_R$ -related, and thus  $\sim_R$  has index at most  $k$ . ◀

We can then conclude that the definability problem for  $k$ -REC is decidable.

► **Corollary 6.2.** *The  $k$ -REC-DEFINABILITY PROBLEM is decidable, for every  $k > 0$ .*

**Proof.** An automatic relation  $R$  is in  $k$ -REC iff  $\sim_R$  has at most  $k$  equivalence classes by Lemma 6.1. In other words, an automatic relation  $R$  is not in  $k$ -REC iff the complement of  $\sim_R$  contains a  $(k+1)$ -clique, which can be easily tested. ◀

The relation  $\sim_R$  can also be used to characterize which automatic relations are definable in the class  $k$ -PROD.

► **Lemma 6.3.** *An automatic relation  $R$  is in  $k$ -PROD if, and only if,  $R = (A_1 \times B_1) \cup \dots \cup (A_k \times B_k)$  where each  $A_i$  and  $B_i$  is a union of equivalence classes of  $\sim_R$ .*

**Proof.** It suffices to show that for every equivalence class  $E$  from  $\sim_R$ , if  $A_1 \cap E \neq \emptyset$  then  $R = ((A_1 \cup E) \times B_1) \cup \dots \cup (A_k \times B_k)$ , and similarly for  $B_1$ . Assume  $w \in A_1 \cap E$  and take any pair  $(u, v) \in E \times B_1$ . We show that  $(u, v) \in R$ . By definition of  $\sim_R$ , since  $(w, v) \in R$  and  $w \sim_R u$ , we have that  $(u, v) \in R$ . ◀

Again, this characterization allows us to show that definability in the class  $k$ -PROD is decidable.

► **Corollary 6.4.** *The  $k$ -PROD-DEFINABILITY PROBLEM is decidable, for every  $k > 0$ .*

**Proof.** By brute force testing whether the automatic relation  $R$  is equivalent to  $(A_1 \times B_1) \cup \dots \cup (A_k \times B_k)$  for every possible  $A_i, B_i$  which is a union of equivalence classes of  $\sim_R$ . ◀

## 7 Discussion

We have established, among other things, the undecidability of the  $k$ -REGULAR COLORABILITY PROBLEM for  $k \geq 2$ . Yet, little is known about the REGULAR COLORABILITY PROBLEM.

► **Conjecture 7.1.** *The REC-SEPARABILITY PROBLEM – or, equivalently, the REGULAR COLORABILITY PROBLEM – is undecidable.*

Beyond its decidability status, the structural properties of regular colorability evades us:

► **Conjecture 7.2.** *Over automatic graphs, the following notions are pairwise disjoint:*

1. *to be finitely regular colorable,*
2. *to be finitely colorable,*
3. *not to contain unbounded cliques.*

Note that the implications (1)  $\Rightarrow$  (2)  $\Rightarrow$  (3) trivially hold. Moreover, recall that while the automatic tree of Example 4.5 is not 2-regular colorable, it is 3-regular colorable (it suffices to color  $\varepsilon$  with a new color, and then color  $a^p b^q$  by looking at the parity of  $p - q$ ). Hence, it does not prove that (2)  $\not\Rightarrow$  (1). Likewise, on arbitrary infinite graphs, we know that there exists triangle-free graphs that are not finitely colorable [26] – but we believe these graphs not to be automatic, and hence they would not prove that (3)  $\not\Rightarrow$  (2).

Finally, observe that it is decidable to test whether an automatic graph has *infinite* cliques [18, Corollary 5.5]. We conjecture that this property generalizes to unbounded cliques.

► **Conjecture 7.3.** *The problem of whether an automatic graph has bounded cliques is decidable.*

## Abstract

Orienting the edges of an undirected graph such that the resulting digraph satisfies some given constraints is a classical problem in graph theory, with multiple algorithmic applications. In particular, an  $st$ -orientation orients each edge of the input graph such that the resulting digraph is acyclic, and it contains a single source  $s$  and a single sink  $t$ . Computing an  $st$ -orientation of a graph can be done efficiently, and it finds notable applications in graph algorithms and in particular in graph drawing. On the other hand, finding an  $st$ -orientation with at most  $k$  transitive edges is more challenging and it was recently proven to be NP-hard already when  $k = 0$ . We strengthen this result by showing that the problem remains NP-hard even for graphs of bounded diameter, and for graphs of bounded vertex degree. These computational lower bounds naturally raise the question about which structural parameters can lead to tractable parameterizations of the problem. Our main result is a fixed-parameter tractable algorithm parameterized by treewidth.

## 1 Introduction

An orientation of an undirected graph is an assignment of a direction to each edge, turning the initial graph into a directed graph (or *digraph* for short). Notable examples of orientations are acyclic orientations, which guarantee the resulting digraph to be acyclic; transitive orientations, which make the resulting digraph its own transitive closure; and Eulerian orientations, in which each vertex has equal in-degree and out-degree. Of particular interest for our research are certain constrained acyclic orientations, which find applications in several domains, including graph planarity and graph drawing. More specifically, given a graph  $G = (V, E)$  and two vertices  $s, t \in V$ , an  $st$ -orientation of  $G$ , also known as *bipolar*

■ **Figure 1** (a): An undirected graph  $G$  with randomly labeled vertices. (b)-(c): Two polyline drawings of  $G$  computed by using different  $st$ -orientations. The drawing in (b) uses an  $st$ -orientation without transitive edges and it has smaller area and number of bends than the drawing in (c).

*orientation*, is an orientation of its edges such that the corresponding digraph is acyclic and contains a single source  $s$  and a single sink  $t$ . It is well-known that  $G$  admits an  $st$ -orientation if and only if it is biconnected after the addition of the edge  $st$  (if not already present). The computation of an  $st$ -numbering (an equivalent concept defined on the vertices of the graph) is for instance part of the quadratic-time planarity testing algorithm by Lempel, Even and Cederbaum [11]. Later, Even and Tarjan [8] showed how to compute an  $st$ -numbering in linear time, and used this result to derive a linear-time planarity testing algorithm. In the field of graph drawing, bipolar orientations are a central algorithmic tool to compute different types of layouts, including visibility representations, polyline drawings, dominance drawings, and orthogonal drawings (see [5, 9] for references). On a similar note, a notable result states that a planar digraph admits an upward planar drawing if and only if it is the subgraph of a planar  $st$ -graph, that is, a planar digraph with a bipolar orientation [6].

Recently, Binucci, Didimo and Patrignani [1] focused on  $st$ -orientations with no transitive edges. We recall that an edge  $uv$  is *transitive* if the digraph contains a path directed from  $u$  to  $v$ ; for example, the bold (red) edges in Figure 1c are transitive, see also Section 2 for formal definitions. Besides being of theoretical interest, such orientations, when they exist, can be used to compute readable and compact drawings of graphs [1]. For example, a classical graph drawing algorithm relies on  $st$ -orientations to compute polyline representations of planar graphs. The algorithm is such that both the height and the number of bends of the representations can be reduced by computing  $st$ -orientations with few transitive edges. See Algorithm `PolyLine` in [5] for details and Figure 1 for an example.

Unfortunately, while an  $st$ -orientation of an  $n$ -vertex graph can be computed in  $O(n)$  time, computing one that has the minimum number of transitive edges is much more challenging from a computational perspective. Namely, Binucci et al. [1] prove that the problem of deciding whether an  $st$ -orientation with no transitive edges exists is NP-complete, and provide an ILP model for planar graphs.

■ **Figure 2** The complexity landscape of the ST-ORIENTATION problem. The symbols  $tw$ ,  $\delta$ , and  $\sigma$  denote the treewidth, the maximum vertex degree, and the diameter of the graph, respectively. The boxes with red boundaries denote the new results presented in this paper.

**Contribution.** We study the parameterized complexity of finding  $st$ -orientations with few transitive edges. More formally, given a graph  $G$  and an integer  $k$ , the ST-ORIENTATION problem asks for an  $st$ -orientation of  $G$  with at most  $k$  transitive edges (see also Section 2). As already discussed, ST-ORIENTATION is para-NP-hard by the natural parameter  $k$  [1]. We strengthen this result by showing that, for  $k = 0$ , ST-ORIENTATION remains NP-hard even for graphs of diameter at most six, and for graphs of vertex degree at most four. In light of these computational lower bounds, we seek for structural parameters that can lead to tractable parameterizations of the problem. Our main result is a fixed-parameter tractable algorithm for ST-ORIENTATION parameterized by treewidth, a central parameter in the parameterized complexity analysis (see [7, 12]). Figure 2 depicts a summary of the computational complexity results known for the ST-ORIENTATION problem.

It is worth remarking that by Courcelle’s theorem one can derive an (implicit) FPT algorithm parameterized by treewidth and  $k$ , while we provide an explicit algorithm parameterized by treewidth only. The main challenge in applying dynamic programming over a tree decomposition is that the algorithm must know if adding an edge to the graph may cause previously forgotten non-transitive edges to become transitive, and, if so, how many of them. To tackle this difficulty, we describe an approach that avoids storing information about all edges that may potentially become transitive; instead, the algorithm guesses the edges that will be transitive in a candidate solution and ensures that no other edge will become transitive in the course of the algorithm. Our technique can be easily adapted to handle more general constraints on the sought orientation, for instance the presence of multiple sources and sinks.

**Paper structure.** We begin with preliminary definitions and basic tools, which can be found in Section 2. In Section 3 we describe our main result, an FPT algorithm for the ST-ORIENTATION problem parameterized by treewidth. Section 4 contains our second contribution, namely we adapt the NP-hardness proof in [1] to prove that the result holds also for graphs that have bounded diameter and for graphs with bounded vertex degree. In the latter case, the graphs used in the reduction not only have bounded vertex degree (at most four), but are also subdivisions of triconnected graphs. In Section 5 we list some interesting open problems that stem from our research.

For space reasons, some proofs have been omitted, and the corresponding statements are marked with  $(\star)$ .

## 2 Preliminaries

**Edge orientations.** Let  $G = (V, E)$  be an undirected graph. An *orientation*  $O$  of  $G$  is an assignment of a *direction*, also called *orientation*, to each edge of  $G$ . We denote by  $D_O(G)$  the digraph obtained from  $G$  by applying the orientation  $O$ . For each undirected pair  $(u, v) \in E$ , we write  $uv$  if  $(u, v)$  is oriented from  $u$  to  $v$  in  $D_O(G)$ , and we write  $vu$  otherwise. A directed

## 18:4 On the Parameterized Complexity of Computing $st$ -Orientations

path from a vertex  $u$  to a vertex  $v$  is denoted by  $u \rightsquigarrow v$ . A vertex of  $D_O(G)$  is a *source* (*sink*) if all its edges are outgoing (incoming). An edge  $uv$  of  $D_O(G)$  is *transitive* if  $D_O(G)$  contains a directed path  $u \rightsquigarrow v$  distinct from the edge  $uv$ . A digraph  $D_O(G)$  is an  *$st$ -graph* if: (i) it contains a single source  $s$  and a single sink  $t$ , and (ii) it is acyclic. An orientation  $O$  such that  $D_O(G)$  is an  *$st$ -graph* is called an  *$st$ -orientation*.

ST-ORIENTATION

**Input:** An undirected graph  $G = (V, E)$ , two vertices  $s, t \in V$ , and an integer  $k \geq 1$ .

**Output:** An  $st$ -orientation  $O$  of  $G$  such that the resulting digraph  $D_O(G)$  contains at most  $k$  transitive edges.

We recall that ST-ORIENTATION is NP-complete already for  $k = 0$  [1], which hinders tractability in the parameter  $k$ . Also, in what follows, we always assume that the input graph  $G$  is connected, otherwise we can immediately reject the instance as any orientation would give rise to at least one source and one sink for each connected component of  $G$ .

**Tree-decompositions.** Let  $(\mathcal{X}, T)$  be a pair such that  $\mathcal{X} = \{X_i\}_{i \in [\ell]}$  is a collection of subsets of vertices of a graph  $G = (V, E)$ , called *bags*, and  $T$  is a tree whose nodes are in one-to-one correspondence with the elements of  $\mathcal{X}$ . When this creates no ambiguity,  $X_i$  will denote both a bag of  $\mathcal{X}$  and the node of  $T$  whose corresponding bag is  $X_i$ . The pair  $(\mathcal{X}, T)$  is a *tree-decomposition* of  $G$  if:

1.  $\bigcup_{i \in [\ell]} X_i = V$ ,
2. For every edge  $uv$  of  $G$ , there exists a bag  $X_i$  that contains both  $u$  and  $v$ , and
3. For every vertex  $v$  of  $G$ , the set of nodes of  $T$  whose bags contain  $v$  induces a non-empty (connected) subtree of  $T$ .

The *width* of  $(\mathcal{X}, T)$  is  $\max_{i=1}^{\ell} |X_i| - 1$ , while the *treewidth* of  $G$ , denoted by  $\text{tw}(G)$ , is the minimum width over all tree-decompositions of  $G$ . The problem of computing a tree-decomposition of width  $\text{tw}(G)$  is fixed-parameter tractable in  $\text{tw}(G)$  [3]. A tree-decomposition  $(\mathcal{X}, T)$  of a graph  $G$  is *nice* if  $T$  is a rooted binary tree with the following additional properties [4]:

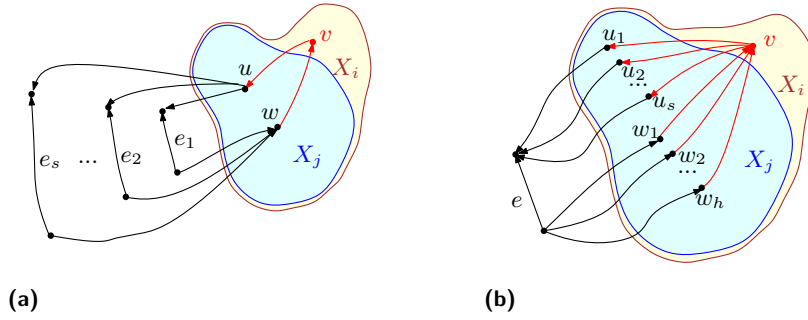

1. If a node  $X_i$  of  $T$  has two children whose bags are  $X_j$  and  $X_{j'}$ , then  $X_i = X_j = X_{j'}$ . In this case,  $X_i$  is a *join bag*.
2. If a node  $X_i$  of  $T$  has only one child  $X_j$ , then  $X_i \neq X_j$  and there exists a vertex  $v \in G$  such that either  $X_i = X_j \cup \{v\}$  or  $X_i \cup \{v\} = X_j$ . In the former case  $X_i$  is an *introduce bag*, while in the latter case  $X_i$  is a *forget bag*.
3. If a node  $X_i$  is the root or a leaf of  $T$ , then  $X_i = \emptyset$ . In this case,  $X_i$  is a *leaf bag*.

Given a tree-decomposition of width  $\omega$  of  $G$ , a nice tree-decomposition of  $G$  with the same width can be computed in  $O(\omega \cdot n)$  time [10].

### 3 The $st$ -Orientation Problem Parameterized by Treewidth

In this section, we describe a fixed-parameter tractable algorithm for ST-ORIENTATION parameterized by treewidth. In fact, the algorithm we propose can solve a slightly more general problem. Namely, it does not assume that  $s$  and  $t$  are part of the input, but it looks for an  $st$ -orientation in which the source and the sink can be any pair of vertices of the input graph. However, if  $s$  and  $t$  are prescribed, a simple check can be added to the algorithm (we will highlight the crucial point in which the check is needed) to ensure this property.

Let  $G = (V, E)$  be an undirected graph. A *solution* of the ST-ORIENTATION problem is an orientation  $O$  of  $G$  such that  $D_O(G)$  is an  *$st$ -graph* with at most  $k$  transitive edges. Let  $(\mathcal{X}, T)$  be a tree-decomposition of  $G$  of width  $\omega$ . For a bag  $X_i \in \mathcal{X}$ , we denote by  $G[X_i]$  the

■ **Figure 3** (a) The directed edges  $wv$  and  $vu$  make all edges  $e_1, \dots, e_s$  transitive. (b) Each pair of directed edges  $w_p v$  and  $v_q u$ , for  $p \in [1, h]$  and  $q \in [1, s]$ , makes  $e$  transitive.

subgraph of  $G$  induced by the vertices of  $X_i$ , and by  $T_i$  the subtree of  $T$  rooted at  $X_i$ . Also, we denote by  $G_i$  the subgraph of  $G$  induced by all the vertices in the bags of  $T_i$ . We adopt a dynamic-programming approach performing a bottom-up traversal of  $T$ . The solution space is encoded into records associated with the bags of  $T$ , which we describe in the next section.

### 3.1 Encoding solutions

Before describing the records stored for each bag, we highlight the main challenges about how to encode the partial solutions computed throughout the course of the algorithm. Let  $v$  be a vertex introduced in a bag  $X_i$ . Adding  $v$  and its incident edges to a partial solution may either turn many (possibly linearly many) forgotten edges into transitive edges and/or it may make the same forgotten edge transitive with respect to arbitrarily many different paths. This is schematically illustrated in Figure 3, where  $X_i$  and its child bag  $X_j$  are highlighted by shaded regions. In Figure 3a,  $e_1, \dots, e_s$  are forgotten edges, i.e., edges in  $G_i$  but not in  $G[X_i]$ ; if we orient edge  $(u, v)$  from  $v$  to  $u$  and edge  $(v, w)$  from  $w$  to  $v$  all edges  $e_1, \dots, e_s$  become transitive. In Figure 3b,  $e$  is a forgotten edge, while  $u_1, \dots, u_s$  and  $w_1, \dots, w_h$  are vertices of bag  $X_j$ ; orienting the edges  $(w_p, v)$  from  $w_p$  to  $v$  ( $1 \leq p \leq h$ ) and the edges  $(v, u_q)$  from  $v$  to  $u_q$ , turns  $e$  into a transitive edge with respect to  $h \times s$  different paths. In case of Figure 3a the algorithm cannot afford reconsidering the forgotten edges as they can be arbitrarily many. In case of Figure 3b the algorithm should avoid counting  $e$  multiple times (for each newly created path). To overcome these issues, the algorithm guesses the edges that are transitive in a candidate solution and verifies that no other edge can become transitive during the bottom-up visit of  $T$ . This is done by suitable records, describe below.

Let  $O$  be a solution and consider a bag  $X_i \in \mathcal{X}$ . The *record*  $R_i$  of  $X_i$  that *encodes*  $O$  represents the interface of the solution  $O$  with respect to  $X_i$ . For ease of notation, the restriction of  $D_O(G)$  to  $G_i$  is denoted by  $D_i$ , and similarly the restriction to  $G[X_i]$  is  $D[X_i]$ . Record  $R_i$  stores the following information.

- $\mathcal{O}_i$  which is the orientation of  $D[X_i]$ .
- $\mathcal{A}_i$  which is the subset of the edges of  $D[X_i]$  that are transitive in  $D_O(G)$ . We call such edges *admissible transitive edges* or simply *admissible edges*. The edges of  $G_i$  not in  $\mathcal{A}_i$  are called *non-admissible*. We remark that an edge of  $\mathcal{A}_i$  may not be transitive in  $D_i$ .
- $\mathcal{P}_i$  which is the set of ordered pairs of vertices  $(a, b)$  such that: (i)  $a, b \in X_i$ , and (ii)  $D_i$  contains the path  $a \rightsquigarrow b$ .

- $\mathcal{F}_i$  which is the set of ordered pairs of vertices  $(a, b)$  such that: (i)  $a, b \in X_i$ , and (ii) connecting  $a$  to  $b$  with a directed path makes a non-admissible edge of  $D_i$  to become transitive.
- $c_i$  which is the *cost* of  $R_i$ , that is, the number of transitive edges in  $D_i$ . Note that  $c_i \geq |\mathcal{A}_i|$ .
- $\mathcal{S}_i$  which maps each vertex  $v \in X_i$  to a Boolean value  $\mathcal{S}_i(v)$  that is true if and only if  $v$  is a source in  $D_i$ . Analogously,  $\mathcal{T}_i$  maps each vertex  $v \in X_i$  to a Boolean value  $\mathcal{T}_i(v)$  that is true if and only if  $v$  is a sink in  $D_i$ .
- $\sigma_i$  which is a flag that indicates whether  $D_O(G)$  contains a source that belongs to  $G_i$  but not to  $X_i$ . Analogously,  $\tau_i$  is a flag that indicates whether  $D_O(G)$  contains a sink that belongs to  $G_i$  but not to  $X_i$ .

Observe that, for a bag  $X_i$ , different solutions  $O$  and  $O'$  of  $G$  may be encoded by the same record  $R_i$ . In this case,  $O$  and  $O'$  are *equivalent*. Clearly, this defines an equivalent relation on the set of solutions for  $G$ , and each record represents an equivalence class. The goal of the algorithm is to incrementally construct the set of records (i.e., the quotient set) for each bag rather than the whole set of solutions. More formally, for each bag  $X_i \in \mathcal{X}$ , we associate a set of records  $\mathcal{R}_i = \{R_i^1, \dots, R_i^h\}$ . While this is not essential for establishing fixed-parameter tractability, we further observe that if more records are equal except for their costs, it suffices to keep in  $\mathcal{R}_i$  the one whose cost is no larger than any other record. The next lemma easily follows.

► **Lemma 1** ( $\star$ ). *For a bag  $X_i$ , the cardinality of  $\mathcal{R}_i$  is  $2^{O(\omega^2)}$ . Also, each record of  $\mathcal{R}_i$  has size  $O(\omega^2)$ .*

### 3.2 Description of the algorithm

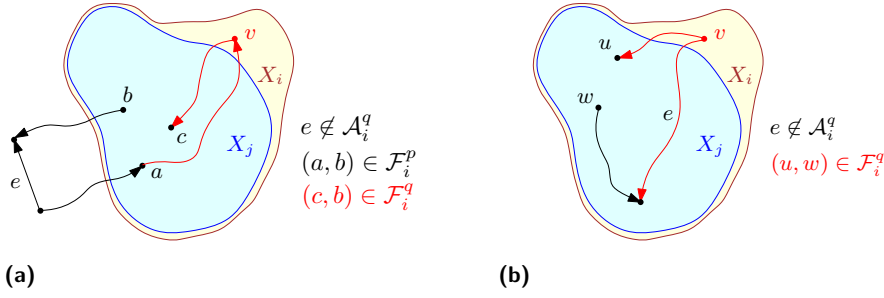

We are now ready to describe our dynamic-programming algorithm over a nice tree-decomposition  $(\mathcal{X}, T)$  of the input graph  $G$ . Let  $X_i$  be the current bag visited by the algorithm. We compute the records of  $X_i$  based on the records computed for its child or children (if any). If the set of records of a bag is empty, the algorithm halts and returns a negative answer. We distinguish four cases based on the type of the bag  $X_i$ . Observe that, to index the records within  $\mathcal{R}_i$ , we added a superscript  $q \in [h]$  to each record, and we will do the same for all the record's elements.

**$X_i$  is a leaf bag.** We have that  $X_i$  is the empty set and  $\mathcal{R}_i$  consists of only one record, i.e.,  $\mathcal{R}_i = \{R_i^1 = \langle \emptyset, \emptyset, \emptyset, \emptyset, 0, \emptyset, \emptyset, \text{false}, \text{false} \rangle\}$ .

**$X_i$  is an introduce bag.** Let  $X_j = X_i \setminus \{v\}$  be the child of  $X_i$ . Initially,  $\mathcal{R}_i = \emptyset$ . Next, the algorithm exhaustively extends each record  $R_j^p \in \mathcal{R}_j$  to a set of records of  $\mathcal{R}_i$  as follows. Let  $\mathcal{O}_v$  be the set of all the possible orientations of the edges incident to  $v$  in  $G[X_i]$ , and similarly let  $\mathcal{A}_v$  be the set of all the possible subsets of the edges incident to  $v$  in  $G[X_i]$ . The algorithm considers all possible pairs  $(o, t)$  such that  $o \in \mathcal{O}_v$  and  $t \in \mathcal{A}_v$ . For each pair  $(o, t)$ , we proceed as follows.

1. Let  $q = |\mathcal{R}_i| + 1$ , the algorithm computes a candidate orientation  $\mathcal{O}_i^q$  of  $G[X_i]$  starting from  $\mathcal{O}_j^p$  and orienting the edges of  $v$  according to  $o$ .
2. Similarly, it computes the candidate set of admissible edges  $\mathcal{A}_i^q$  starting from  $\mathcal{A}_j^p$  and adding to it the edges in  $t$ .
3. Next, it sets the candidate cost  $c_i^q = c_j^p + |t|$ .

■ **Figure 4** Illustration of Step 5c of the algorithm when  $X_i$  is an introduce bag.

4. Let the *extension*  $\langle \mathcal{O}_i^q, \mathcal{A}_i^q, c_i^q \rangle$  be *valid* if:

- a.  $c_i^q \leq k$ ;
- b. there is no pair  $(a, b) \in \mathcal{P}_j^p$  so that  $bv, va \in D[X_i^q]$ ;
- c. there is no pair  $(a, b) \in \mathcal{F}_j^p$  so that  $av, vb \in D[X_i^q]$ .

Clearly, if an extension is not valid, the corresponding record cannot encode any solution; namely, condition (a) ensures that the candidate cost does not exceed  $k$ , condition (b) guarantees the absence of cycles, condition (c) guarantees that no non-admissible edge becomes transitive. Hence, if an extension is not valid, the algorithm discards it and continues with the next pair  $(o, t)$ .

5. Instead, if the extension is valid, the algorithm computes the record  $R_i^q = \langle \mathcal{O}_i^q, \mathcal{A}_i^q, \mathcal{P}_i^q, \mathcal{F}_i^q, c_i^q, \mathcal{S}_i^q, \mathcal{T}_i^q, \sigma_i^q, \tau_i^q \rangle$  of  $\mathcal{R}_i$ , where  $\sigma_i^q = \sigma_j^p$ ,  $\tau_i^q = \tau_j^p$  (recall that  $X_j \subset X_i$ ). To complete the record  $R_i^q$ , it remains to compute  $\mathcal{S}_i^q, \mathcal{T}_i^q, \mathcal{P}_i^q$  and  $\mathcal{F}_i^q$ .

- a. For each vertex  $w \in X_j$ , we set  $\mathcal{S}_i^q(w) = \text{true}$  if and only if  $\mathcal{S}_j^p(w) = \text{true}$  and there is no edge of  $v$  oriented from  $v$  to  $w$  in  $D[X_i^q]$  (which would make  $w$  not a source anymore). Similarly, for each vertex  $w \in X_j$ , we set  $\mathcal{T}_i^q(w) = \text{true}$  if and only if  $\mathcal{T}_j^p(w) = \text{true}$  and there is no edge of  $v$  oriented from  $w$  to  $v$  in  $D[X_i^q]$ . Finally, we set  $\mathcal{S}_i^q(v) = \text{true}$  if and only if  $v$  is a source in  $D[X_i^q]$  (as by the definition), and we set  $\mathcal{T}_i^q(v) = \text{true}$  if and only if  $v$  is a sink in  $D[X_i^q]$ .
- b. We initially set  $\mathcal{P}_i^q = \emptyset$ . We recompute the paths from scratch as follows. We build an auxiliary digraph  $D^*$  which we initialize with  $D[X_i^q]$ . We then add to  $D^*$  the information about paths in  $\mathcal{P}_j^p$ . Namely, for each  $(a, b) \in \mathcal{P}_j^p$ , we add an edge  $ab$  to  $D^*$  (if it does not already exist). Once this is done, for each pair  $u, w \in X_i \times X_i$  for which there is a path  $u \rightsquigarrow w$  in  $D^*$ , we add the pair  $(u, w)$  to  $\mathcal{P}_i^q$ .
- c. Consider now  $\mathcal{F}_i^q$ . We initially set  $\mathcal{F}_i^q = \mathcal{F}_j^p$ . Observe that the addition of  $v$  might have created new pairs of vertices that should belong to  $\mathcal{F}_i^q$ . Namely, for each pair  $(a, b) \in \mathcal{F}_j^p$ , we verify what are the vertices  $c$  such that  $D[X_i^q]$  contains a path  $a \rightsquigarrow c$  while  $D[X_j^p]$  does not (observe that  $a \rightsquigarrow c$  contains  $v$ , possibly  $c = v$ ); for each such vertex, we add  $(c, b)$  to  $\mathcal{F}_i^q$ . See Figure 4a for an illustration. Similarly, we verify what are the vertices  $d$  such that  $D[X_i^q]$  contains a path  $d \rightsquigarrow b$  while  $D[X_j^p]$  does not (again  $d \rightsquigarrow b$  contains  $v$ , possibly  $d = v$ ); for each such vertex, we add  $(a, d)$  to  $\mathcal{F}_i^q$ . Finally, we consider all the edges incident to  $v$  and that are not in  $\mathcal{A}_i^q$ . These edges are not admissible and we should further update  $\mathcal{F}_i^q$  accordingly. This can be done as follows: we consider each edge  $e$  incident to  $v$  not in  $\mathcal{A}_i^q$ , for each such an edge  $e$  we verify what are the pairs of vertices in  $X_i$  (including  $e$ 's endpoints) such that connecting them with a path makes  $e$  transitive, we add such pairs to  $\mathcal{F}_i^q$  if not already present. See Figure 4b for an illustration.

## 18:8 On the Parameterized Complexity of Computing $st$ -Orientations

**$X_i$  is a forget bag.** Let  $X_j = X_i \cup \{v\}$  be the child of  $X_i$ . The algorithm computes  $\mathcal{R}_i$  by exhaustively merging records of  $\mathcal{R}_j$  as follow.

1. For each  $R_j^p \in \mathcal{R}_j$ , we remove from  $\mathcal{O}_j^p$  and  $\mathcal{A}_j^p$  all the edges incident to  $v$  and from  $\mathcal{P}_j^p$  and  $\mathcal{F}_j^p$  all the pairs where one of the vertices is  $v$ . Observe that due to this operation, there might now be records that are identical except possibly for their costs. Among them, we only keep one record whose cost is no larger than any other record.
2. Let  $R_j^p$  be a record of  $\mathcal{R}_j$  that was not discarded by the procedure above. If  $\mathcal{S}_j^p(v) \wedge \sigma_j^p$ , we discard  $R_j^p$  (because the encoded orientation would contain two sources), else we set  $\sigma_j^p = \text{true}$  (because  $v$  is a source). Similarly, if  $\mathcal{T}_j^p(v) \wedge \tau_j^p$ , we discard  $R_j^p$ , else we set  $\tau_j^p = \text{true}$ . At this point, if the record has not been discarded yet and vertices  $s$  and  $t$  are prescribed, we can add the following check. If  $\mathcal{S}_j^p(v) \wedge \sigma_j^p$ , then  $v$  is a source, hence if  $v \neq s$ , we discard the record. Analogously, if  $\mathcal{T}_j^p(v) \wedge \tau_j^p$ , then  $v$  is a sink, hence if  $v \neq t$ , we discard the record.
3. Finally, we remove from  $\mathcal{S}_j^p$  and  $\mathcal{T}_j^p$  the values  $\mathcal{S}_j^p(v)$  and  $\mathcal{T}_j^p(v)$ .
4. All the records that have not been discarded and have been updated according to the above procedure are added to  $\mathcal{R}_i$ .

**$X_i$  is a join bag.** Let  $X_j = X_{j'}$  be the two children of  $X_i$ . The algorithm computes  $\mathcal{R}_i$  by exhaustively checking if a pair of records, one from  $X_j$  and one from  $X_{j'}$ , can be merged together. For each pair  $R_j^p$  and  $R_{j'}^{p'}$ , we proceed as follows.

1. We initially set  $\mathcal{R}_i = \emptyset$ . The two records  $R_j^p$  and  $R_{j'}^{p'}$  are *mergeable* if:
  - a.  $\mathcal{O}_j^p = \mathcal{O}_{j'}^{p'}$ ;
  - b.  $\mathcal{A}_j^p = \mathcal{A}_{j'}^{p'}$ ;
  - c.  $c_j^p + c_{j'}^{p'} - |\mathcal{A}_j^p| \leq k$ ;
  - d. there is no pair  $(a, b) \in \mathcal{P}_j^p$  such that  $(b, a) \in \mathcal{P}_{j'}^{p'}$ ;
  - e. there is no pair  $(a, b) \in \mathcal{P}_j^p$  such that  $(a, b) \in \mathcal{F}_{j'}^{p'}$ ;
  - f. there is no pair  $(a, b) \in \mathcal{P}_{j'}^{p'}$  such that  $(a, b) \in \mathcal{F}_j^p$ ;
  - g.  $\neg(\sigma_j^p \wedge \sigma_{j'}^{p'})$ ;
  - h.  $\neg(\tau_j^p \wedge \tau_{j'}^{p'})$ .

Conditions **a-b** are obviously necessary to merge the records. Condition **c** guarantees that the number of transitive edges (avoiding double counting the admissible edges in  $X_i$ ) is at most  $k$ . Condition **d** guarantees the absence of cycles. Conditions **e-f** guarantee that no non-admissible edge becomes transitive. Conditions **g-h** guarantee that the resulting orientation contains at most one source and one sink. If the two records are not mergeable, we discard the pair and proceed with the next one. Otherwise we create a new record  $R_i^q$ , with  $q = |\mathcal{R}_i| + 1$ , and continue to the next step.

2. Based on the previous discussion, we can now compute  $R_i^q$  as follows:
  - a.  $\mathcal{O}_i^q = \mathcal{O}_j^p$ ;
  - b.  $\mathcal{A}_i^q = \mathcal{A}_j^p$ ;
  - c.  $c_i^q = c_j^p + c_{j'}^{p'} - |\mathcal{A}_j^p|$ ;
  - d. For each pair  $(a, b)$  of vertices of  $X_i$ , we add it to  $\mathcal{P}_i^q$  if it is contained in  $\mathcal{P}_j^p$  or in  $\mathcal{P}_{j'}^{p'}$ .
  - e. For each pair  $(a, b)$  of vertices of  $X_i$ , we add it to  $\mathcal{F}_i^q$  if  $\mathcal{F}_j^p(a, b) \vee \mathcal{F}_{j'}^{p'}(a, b)$ .
  - f. For each vertex  $v$  of  $X_i$ , we set  $\mathcal{S}_i^q(v) = \mathcal{S}_j^p(v) \wedge \mathcal{S}_{j'}^{p'}(v)$ ;
  - g. For each vertex  $v$  of  $X_i$ , we set  $\mathcal{T}_i^q(v) = \mathcal{T}_j^p(v) \wedge \mathcal{T}_{j'}^{p'}(v)$ ;
  - h.  $\sigma_i^q = \sigma_j^p \vee \sigma_{j'}^{p'}$ ;
  - i.  $\tau_i^q = \tau_j^p \vee \tau_{j'}^{p'}$ .

The next lemma establishes the correctness of the algorithm.

► **Lemma 2.** *Graph  $G$  admits a solution for ST-ORIENTATION if and only if the algorithm terminates after visiting the root of  $T$ . Also, the algorithm outputs a solution, if any.*

**Proof.** ( $\rightarrow$ ) Suppose that the algorithm terminates after visiting the root bag  $X_\rho$  of  $T$ . We reconstruct a solution  $O$  of  $G$  as follows. We can assume that our algorithm stores additional pointers for each record (a common practice in dynamic programming), such that each record has a single outgoing pointer (and potentially many incoming pointers). Consider a record  $R_i^q$  of a bag  $X_i$ . If  $X_i$  is an introduce bag, there is only one record  $R_j^p$  of the child bag  $X_j$  from which  $R_i^q$  was generated and the pointer links  $R_i^q$  and  $R_j^p$ . If  $X_i$  is forget bag, there might be multiple records that have been merged into  $R_i^q$  and in this case the pointer link  $R_i^q$  with one of these records with minimum cost. If  $X_i$  is a join bag, there are two mergeable records  $R_j^p$  and  $R_{j'}^{p'}$  that have been merged together, and the pointer links  $R_i^q$  to  $R_j^p$  and  $R_{j'}^{p'}$ . With these pointers at hand, we can apply a top-down traversal of  $T$ , starting from the single (empty) record of the root bag  $X_\rho$  and reconstruct the corresponding orientation  $O$ . Namely, when visiting an introduce bag and the corresponding record, we orient the edges of the introduced vertex  $v$  according to the orientation  $O_v$  defined by the record.

We now claim that  $D_O(G)$  is an *st*-graph with at most  $k$  transitive edges. Suppose first, for a contradiction, that  $D_O(G)$  contains more than one source. Let  $s$  and  $s'$  be two sources of  $D_O(G)$ . Then  $S_i^q(s) = \text{false}$  in the bag  $X_i$  in which  $s$  has been forgotten, and similarly for  $S_i^q(s')$ . This is however not possible by construction of  $S_i^q$ . Thus, either the record  $R_i^q$  has been discarded because  $S_j^p(v) \wedge \sigma_j^p$  (see item **2** when  $X_i$  is a forget bag) or  $\sigma_j^p = \text{false}$ . The first case contradicts the fact that  $R_i^q$  is a record used to reconstruct  $O$ . The second case implies that  $s'$  has not been encountered; however, in this latter case the algorithm sets  $\sigma_j^p = \text{true}$ , hence some descendant record will be discarded as soon as  $s'$  is forgotten, again contradicting the fact that we are considering records with pointers up to the root bag. A symmetric argument shows that  $D_O(G)$  contains a single sink. We next argue that  $D_O(G)$  is acyclic. Suppose, again for a contradiction, that  $D_O(G)$  contains a cycle. In particular, the cycle was created either in an introduce bag or in a join bag. In the former case, let  $v$  be the last vertex of this cycle that has been introduced in a bag  $X_i$ . Let  $a, b$  be the neighbors of  $v$  that are part of the cycle, and w.l.o.g. assume that the edges are  $va$  and  $bv$ . It must be  $\mathcal{P}_i^q$  does not contain the pair  $(a, b)$ , otherwise we would have discarded this particular orientation for the edges incident to  $v$  (see item **4.b** when  $X_i$  is an introduce bag). On the other hand, one easily verifies that when introducing a vertex  $v$ , all the new paths involving  $v$  are computed from scratch (see item **5.b** when  $X_i$  is an introduce bag), and, similarly, when joining two bags, the existence of a path in one of the two bags is correctly reported in the new record (see item **2.d** when  $X_i$  is a join bag). If the cycle was created in a join bag the argument is analogous, in particular, observe that we verify that there is no path contained in the record of one of the child bags such that the same path with reversed direction exists in the record of the other child bag (see item **1.d** when  $X_i$  is a join bag). We conclude this direction of the proof by showing that  $D_O(G)$  contains at most  $k$  transitive edges. Observe first that the cost of the record ensures that at most  $k$  edges of  $G$  are part of some set of admissible edges. Suppose, for a contradiction, that  $D_O(G)$  contains more than  $k$  transitive edges. Then there is a bag  $X_i$  and a record  $R_i^q$  in which a non-admissible edge became transitive. Also,  $X_i$  is either an introduce or a join bag. If  $X_i$  introduced a vertex  $v$ , observe that all the newly introduced edges are incident to  $v$ . On the other hand, the algorithm discarded the orientations of the edges of  $v$  for which there is a pair  $(a, b) \in \mathcal{F}_j^p$  (with  $X_j$  being the child of  $X_i$ ) so that  $av, vb \in D[X_i^q]$  (see item **4.c** when

## 18:10 On the Parameterized Complexity of Computing $st$ -Orientations

$X_i$  is an introduce bag). Then either the orientation was discarded, which contradicts the fact that we are considering a record used to build the solution, or  $\mathcal{F}_j^p$  missed the pair  $(a, b)$ . Again one verifies this second case is not possible, because the new pairs that are formed in an introduce bag are correctly identified (see item 5.c when  $X_i$  is an introduce bag) by the algorithm and similarly for join bags (see item 2.e when  $X_i$  is a join bag). If  $X_i$  is a join bag, the argument is analogous, in particular, we verified that there is no path in one of the two child records that makes transitive a non-admissible edge in the other child record (see items 1.e and 1.f when  $X_i$  is a join bag). This concludes the first part of the proof.

( $\leftarrow$ ) It remains to prove that, if  $G$  admits a solution  $O$ , then the algorithm terminates after visiting the root  $X_\rho$  of  $T$ . If this were not the case, there would be a bag  $X_i$  of  $T$  and a candidate record that encodes  $O$ , such that the record has been incorrectly discarded by the algorithm; we show that this is not possible. Suppose first that  $X_i$  is an introduce bag. Then a candidate record is discarded if the cost exceeds  $k$ , or if a cycle is created, or if a non-admissible edge becomes transitive (see the conditions of item 4 when  $X_i$  is an introduce bag). In all cases the candidate record does not encode a solution. If  $X_i$  is a forget bag, we may discard a candidate record if it is identical to another but has a non-smaller cost (see item 1 when  $X_i$  is a forget bag). Hence we always keep a record that either encodes the solution at hand or a solution with fewer transitive edges but with exactly the same interface at  $X_i$ . Also, we may discard a record if the forgotten vertex  $v$  is a source and  $G_i$  already contains a source (see item 2 when  $X_i$  is a forget bag). This is correct, because no further edge can be added to  $v$  after it is forgotten. A symmetric argument holds for the case in which a record is discarded due to  $v$  being a sink. Finally, if  $X_i$  is a join bag, pairs of records of its children bags are discarded if not mergeable (see the conditions of item 1 when  $X_i$  is a join bag). One easily verifies that failing one of the conditions for mergeability implies that the record does not encode a solution (see also the discussion after item 1).  $\blacktriangleleft$

The next theorem summarizes our contribution.

► **Theorem 3** ( $\star$ ). *Given an input graph  $G = (V, E)$  of treewidth  $\omega$  and an integer  $k \geq 0$ , there is an algorithm that either finds a solution of ST-ORIENTATION or reject the input in time  $2^{O(\omega^2)} \cdot n$ .*

### 4 The Complexity of the Non-Transitive $st$ -Orientation Problem for Graphs of Bounded Diameter and Bounded Degree

We begin by recalling the special case of ST-ORIENTATION considered in [1]. An  $st$ -orientation  $O$  of a graph  $G$  is *non-transitive* if  $D_O(G)$  does not contain transitive edges.

NON-TRANSITIVE ST-ORIENTATION (NT-ST-ORIENTATION)

**Input:** An undirected graph  $G = (V, E)$ , and two vertices  $s, t \in V$ .

**Output:** An non-transitive  $st$ -orientation  $O$  of  $G$  such that vertices  $s$  and  $t$  are the source and sink of  $D_O(G)$ , respectively.

The hardness proof of NT-ST-ORIENTATION in [1] exploits a reduction from NOT-ALL-EQUAL 3-SAT (NAE-3-SAT) [13]. Recall that the input of NAE-3-SAT is a pair  $\langle X, \varphi \rangle$  where  $X$  is a set of boolean variables and  $\varphi$  is a set of clauses, each composed of three literals out of  $X$ , and the problem asks for an assignment of the variables in  $X$  so that each clause in  $\varphi$  is composed of at least one true variable and one false variable.

In this section, we show that NT-ST-ORIENTATION is NP-hard even for graphs of bounded diameter and for graphs of bounded vertex degree that are subdivisions of triconnected graphs. To prove our results, we first summarize the construction used in [1].

#### 4.1 A Glimpse into the Hardness Proof of NT-st-Orientability

The construction in [1] adopts three types of gadgets, which we recall below. Given an edge  $e$  of a digraph  $D$  such that  $e$  has an end-vertex  $v$  of degree 1, we say that  $e$  *enters*  $D$  if it is outgoing with respect to  $v$ , and we say that  $e$  *exits*  $D$  otherwise. Similarly, given a directed edge  $e = uv$ , we say that  $e$  *exits*  $u$  and that  $e$  *enters*  $v$ .

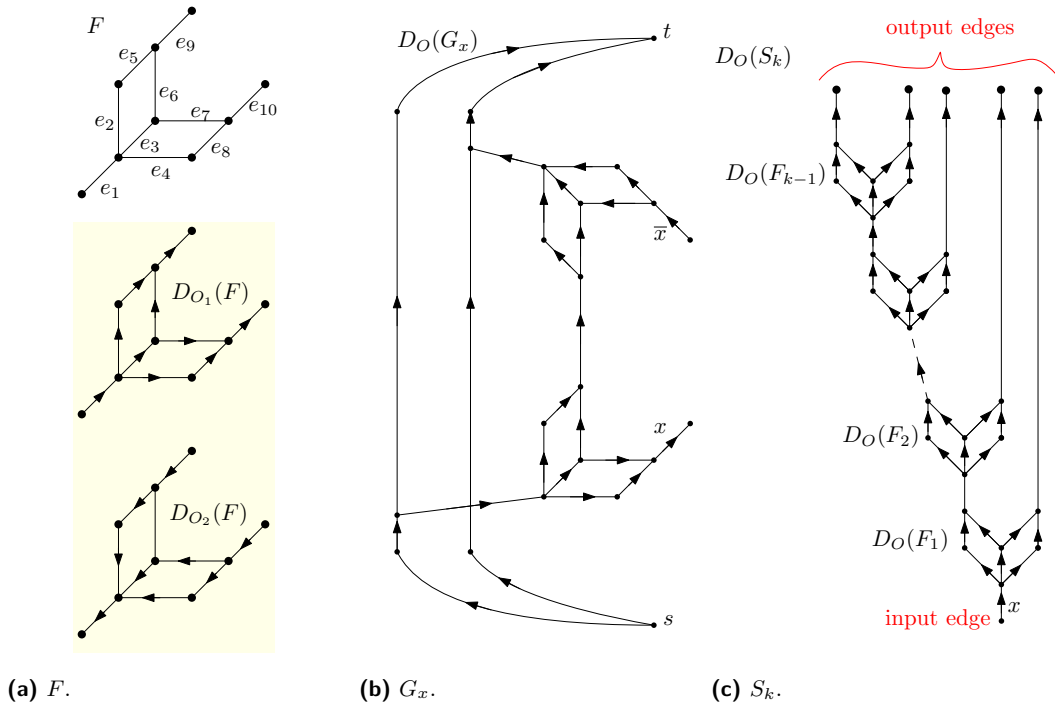

- The *fork gadget*  $F$  is depicted in Figure 5a. See Lemma 1 of [1]. Namely, if  $F$  does not contain  $s$  or  $t$  (the source and sink prescribed in the input), then in any non-transitive orientation  $O$  of a graph  $G$  containing  $F$ , either  $e_1$  enters  $F$  and  $e_9, e_{10}$  exit  $F$ , or vice versa. Figure 5a depicts  $F, D_{O_1}(F)$  and  $D_{O_2}(F)$ , where  $O_1$  and  $O_2$  are the two  $st$ -orientations admitted by  $F$ .
- The *variable gadget*  $G_x$  associated to a variable  $x \in X$  is shown in Figure 5b; observe it contains the designated vertices  $s$  and  $t$ . Its crucial property is stated in Lemma 2 of [1]. Namely, in any non-transitive  $st$ -orientation  $O$  of a graph  $G$  containing  $G_x$ , either  $x$  exists  $G_x$  and  $\bar{x}$  enters  $G_x$ , or vice-versa.
- The *split gadget*  $S_k$  is shown in Figure 5c; it consists of  $k-1$  fork gadgets chained together, for some fixed  $k > 0$ . The crucial property of this gadget is described in Lemma 3 of [1]. Namely, in any non-transitive  $st$ -orientation  $O$  of a graph  $G$  containing  $S_k$ , either  $x$  (the *input edge* of  $S_k$ ) enters  $S_k$  and the edges  $e_9$  and  $e_{10}$  of the fork gadgets  $F_1, \dots, F_{k-1}$  incident to one degree-1 vertex (the *outgoing edges* of  $S_k$ ) exit  $S_k$ , or vice-versa.

Given an instance  $\langle X, \varphi \rangle$  of NAE-3-SAT, the instance  $\langle G_\varphi, s, t \rangle$  of NT-ST-ORIENTATION is constructed as follow. For each  $x \in X$  we add  $G_x$  and two split gadgets  $S_k$  and  $S_{\bar{k}}$ , where  $k$  (resp.  $\bar{k}$ ) is the number of clauses where  $x$  appears in its non-negated (resp. negated) form (edges  $x$  and  $\bar{x}$  are the input edges of  $S_k$  and  $S_{\bar{k}}$ , respectively). Finally, for each clause  $c = (x_1, x_2, x_3) \in \varphi$ , we add a vertex  $c$  that is incident to an output edge of the split gadget of each of its variables. See Figure 6b, where the non-dashed edges and all the vertices with the exception of  $g$  define  $G_\varphi$ . It can be shown that  $\langle X, \varphi \rangle$  is a yes-instance of NAE-3-SAT if and only if  $\langle G_\varphi, s, t \rangle$  is a yes-instance of NT-ST-ORIENTATION [1].

#### 4.2 Hardness for Graphs of Bounded Diameter

Given an undirected graph  $G$ , the *distance* between two vertices of  $G$  is the length of any shortest path connecting them. The *diameter* of  $G$  is the maximum distance over all pairs of vertices of the graph. We now adapt the construction in Section 4.1 to show that NT-ST-ORIENTATION remains NP-hard also for graphs of bounded diameter. We define the *extended fork gadget* by adding an edge  $e_{11}$  to the fork gadget (see Figure 6a).

**Construction of  $H_\varphi$ .** Given an instance  $\langle X, \varphi \rangle$  of NAE-3-SAT and the instance  $\langle G_\varphi, s, t \rangle$  of NT-ST-ORIENTATION computed as described in Section 4.1, we define  $\langle H_\varphi, s, t \rangle$  as follows. We first set  $H_\varphi = G_\varphi$ . Then, we add a vertex  $g$  to  $H_\varphi$  and an edge  $(g, f)$  for each vertex  $f$  belonging to a fork  $F$  of  $H_\varphi$  and incident to the corresponding edges  $e_3, e_6$ , and  $e_7$ . Also, we add edges  $(g, t)$  and  $(s, g)$ , and we subdivide each of them once. See Figure 6b (the non-dashed edges and all the vertices with the exception of  $g$  define  $G_\varphi$ ).

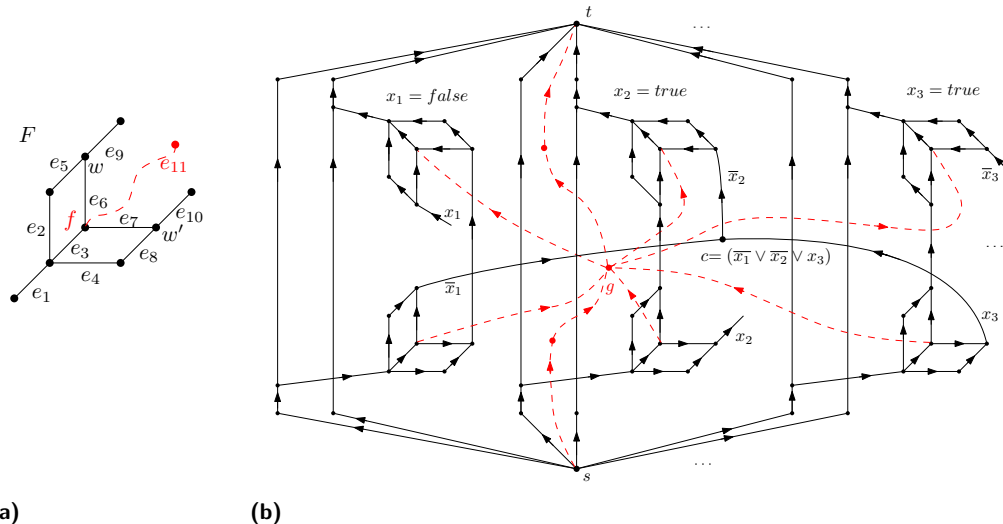

■ **Figure 5** (a) The fork gadget  $F$  and its two possible non-transitive  $st$ -orientations. (b) The variable gadget  $D_O(G_x)$  associated to  $x \in X$ , where  $O$  is one of its two possible orientations. (c) The split gadget  $D_O(S_k)$  associated to  $x$ , where  $O$  is one of its two possible orientations.

► **Theorem 4** ( $\star$ ). *NT-ST-ORIENTATION is NP-hard for graphs of diameter at most 6.*

**Proof sketch.** We construct  $H_\varphi$  as described above. Observe that any vertex of  $G$  is at distance at most 3 to  $g$ , hence  $H_\varphi$  has diameter at most 6. We show that a non-transitive  $st$ -orientation of  $G_\varphi$  corresponds to a non-transitive  $st$ -orientation of  $H_\varphi$  ( $\rightarrow$ ) and vice versa ( $\leftarrow$ ).

$(\rightarrow)$  Given a non-transitive  $st$ -orientation  $O'$  of  $G_\varphi$ , we construct an  $st$ -orientation  $O$  of  $H_\varphi$  by extending  $O'$  as follow. We orient the four edges of  $H_\varphi \setminus G_\varphi$  connecting  $s$  to  $t$  such that the path is directed from  $s$  to  $g$ . For each other edge  $e$ , which is incident to  $g$ , we orient it so that  $e$  enters  $g$  if and only if  $e$  is the edge incident to an extended fork gadget whose corresponding edge  $e_1$  is an entering edge. See Figure 6b. For each two vertices  $a, b \in D_O(H_\varphi)$ , there is no path  $a \rightsquigarrow b$  so that  $ag, gb \in D_O(H_\varphi)$ . Hence, since  $D_{O'}(G_\varphi)$  has no cycle, also  $D_O(H_\varphi)$  has no cycle. Consequently,  $O$  is an acyclic orientation with  $s$  and  $t$  being its single source and sink, respectively. We now show that it does not contain transitive edges. Let  $e = ab$  be any edge of  $D_O(H_\varphi)$ . We have that any path from  $s \rightsquigarrow t$  containing  $g$  either contains edges incident to degree-2 vertices or edges  $e_1, e_3$ , and  $e_{11}$  of an extended fork gadget. All these edges have endpoints which are not adjacent by construction. Hence, there is no path  $a \rightsquigarrow b$  containing  $g$  and, since  $O'$  is non-transitive,  $e$  is not transitive in  $D_O(H_\varphi)$ .

$(\leftarrow)$  This direction is based on the observation that, given an extended fork gadget  $F$ , in any non-transitive  $st$ -orientation  $O$  of  $G$ , either  $e_3$  enters  $f$  and  $e_6, e_7$  exit  $f$  or vice versa.  $\blacktriangleleft$

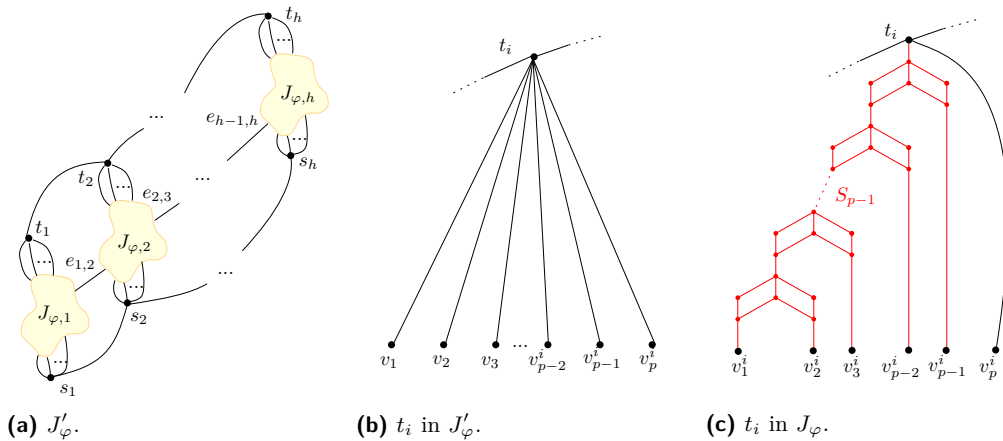

■ **Figure 6** (a) A fork gadget  $F$  extended with edge  $e_{11}$ . (b) Graphs  $D_{O'}(G_\varphi)$ , defined by the non-dashed edges, and graph  $D_O(H_\varphi)$ , obtained from  $G$  by adding  $g$  and the dashed edges.  $O'$  and  $O$  are non-transitive  $st$ -orientations of  $G_\varphi$  and  $H_\varphi$ , respectively.  $O$  is obtained by extending  $O'$ .

### 4.3 Hardness Subdivisions of Triconnected Graphs with Bounded Degree

We prove now that NT-ST-ORIENTATION is NP-hard even if  $G$  is a 4-graph, i.e., the degree of each vertex is at most 4, and, in addition, it is a subdivision of a triconnected graph.

**Construction of  $J_\varphi$ .** Given an instance  $\langle X, \varphi \rangle$  of NAE-3-SAT and the instance  $\langle G_\varphi, s, t \rangle$  of NT-ST-ORIENTATION computed as described in Section 4.1, we compute  $\langle J_\varphi, s, t \rangle$  as follows. We remove  $s$  and  $t$  from  $J''_\varphi = G_\varphi$ . We obtain a disconnected graph whose connected components are  $J_{\varphi,1}, \dots, J_{\varphi,h}$ . We add a vertex  $s_i$  and a vertex  $t_i$  to each  $J_{\varphi,i}$  (which will play the role of local sources and sinks for each component). Next, for each  $i \in [1, h - 1]$ : (i) We add the edge  $(s_i, s_{i+1})$  and  $(t_{i+1}, t_i)$ ; (ii) We add an edge  $e_{i+1,i}$  incident to a vertex identified as the  $f$ -vertex of a fork gadget of  $J_{\varphi,i+1}$  and to a vertex identified as the  $f$ -vertex of a fork gadget of  $J_{\varphi,i}$ . We denote by  $J'_\varphi$  the obtained graph; see Figure 7a for a schematic illustration. For each  $J_{\varphi,i}$  ( $i \in [1, h]$ ) of  $J'_\varphi$ , the only vertices having degree higher than 4 are  $s_i$  and  $t_i$ . For each  $i \in [1, h]$ , we proceed as follow. We first consider  $t_i$ . If  $t_i$  has degree  $p \leq 4$ , we do nothing. Otherwise, if  $p \geq 5$ , we proceed as follows: (i) We consider  $p - 1$  edges incident to  $t_i$  and to vertices of  $J_{\varphi,i}$  and we remove them; (ii) We connect the endpoints  $v_1^i, \dots, v_p^i$  of the removed edges that are not  $t_i$  to a split gadget  $S_{p-1}$  and  $t_i$  to the input edge of  $S_{p-1}$ . Figure 7b depicts  $t_i$  ( $i \in [1, h]$ ) and its neighborhood  $\{v_1^i, \dots, v_p^i\}$  in  $J'_\varphi$  and Figure 7c depicts how  $t_i$  is connected to the vertices  $v_1^i, \dots, v_p^i$  after the above operation. We perform a symmetric operation on  $s_i$ . The resulting graph is denoted by  $J_\varphi$ , and it has vertex degree at most four by construction.

► **Theorem 5** ( $\star$ ). *NT-ST-ORIENTATION is NP-hard for 4-graphs that are subdivisions of triconnected graphs.*

■ **Figure 7** (a) Schematic representation of graph  $J'_\varphi$ . (b-c) How vertex  $t_i$  is connected to its neighbourhood in (b)  $J'_\varphi$  and (c)  $J_\varphi$ .

## 5 Open Problems

Several interesting open problems stem from our research. Among them:

- Is there an FPT-algorithm for the ST-ORIENTATION problem parameterized by treewidth running in  $2^{o(\omega^2)} \cdot \text{poly}(n)$  time?
- Does ST-ORIENTATION parameterized by treedepth admit a polynomial kernel?
- We have shown that finding non-transitive  $st$ -orientations is NP-hard for graphs of vertex degree at most four. On the other hand, the problem is trivial for graphs of vertex degree at most two. What is the complexity of the problem for vertex degree at most three? Similarly, one can observe that the problem is easy for graphs of diameter at most two, while it remains open the complexity for diameter in the range  $[3, 5]$ .

## Abstract

We study the problem of finding a Hamiltonian cycle under the promise that the input graph has a minimum degree of at least  $n/2$ , where  $n$  denotes the number of vertices in the graph. The classical theorem of Dirac states that such graphs (a.k.a. Dirac graphs) are Hamiltonian, i.e., contain a Hamiltonian cycle. Moreover, finding a Hamiltonian cycle in Dirac graphs can be done in polynomial time in the classical centralized model.

This paper presents a randomized distributed CONGEST algorithm that finds w.h.p. a Hamiltonian cycle (as well as maximum matching) within  $O(\log n)$  rounds under the promise that the input graph is a Dirac graph. This upper bound is in contrast to general graphs in which both the decision and search variants of Hamiltonicity require  $\tilde{\Omega}(n^2)$  rounds, as shown by Bachrach et al. [PODC'19].

In addition, we consider two generalizations of Dirac graphs: Ore graphs and Rahman-Kaykobad graphs [IPL'05]. In Ore graphs, the sum of the degrees of every pair of non-adjacent vertices is at least  $n$ , and in Rahman-Kaykobad graphs, the sum of the degrees of every pair of non-adjacent vertices plus their distance is at least  $n + 1$ . We show how our algorithm for Dirac graphs can be adapted to work for these more general families of graphs.

## 1 Introduction

The Hamiltonian path and Hamiltonian cycle problems are fundamental in computer science and appeared in Karp's 21 NP-complete problems [15]. A Hamiltonian path is a path that visits every vertex in the graph exactly once and a Hamiltonian cycle is a cycle that visits every vertex in the graph exactly once. We say that a graph is *Hamiltonian* if it contains a Hamiltonian cycle.

While the problem is hard in general (assuming  $P \neq NP$ ), for some classes of graphs, it is guaranteed that all their members are Hamiltonian. In particular, the classical theorem of Dirac states that every graph in which the minimum degree is at least  $n/2$  is Hamiltonian

(we refer to graphs that satisfy this condition as DIRAC graphs). This condition is tight in the sense that if we are only guaranteed that the minimum degree is at least  $\alpha n$  for any  $0 < \alpha < 1/2$ , then the problem remains NP-complete [10].

In FOCS'87 Goldberg proposed the question of whether there is an NC-algorithm for finding a Hamiltonian cycle in DIRAC graphs.<sup>1</sup> This question was answered affirmatively by Dahlhaus et al. [9, 10], who gave a fast parallel algorithm on CREW-PRAM to find a Hamiltonian cycle in Dirac graphs. Their algorithm works in  $O(\log^4 n)$  parallel time and uses  $O(n + m)$  number of processors where  $m$  denotes the number of edges of the graphs.

Aside from the theoretical appeal of the problem, finding a Hamiltonian cycle in a graph also provides us with a maximum matching of the graph (and even perfect matching when  $n$  is even). Therefore, it is natural to ask whether the algorithm of Dahlhaus et al. [10] can be translated to the CONGEST model. To this end, one may attempt to use the PRAM simulation of Lotker, Patt-Shamir, and Peleg [19] for diameter-2 graphs (which applies for DIRAC graphs). However, this simulation is only valid when the number of processors is linear in the number of vertices in the graph. Another attempt is to use the more general transformation of Ghaffari and Li [13] that provide a randomized CONGEST algorithm that simulates any CRCW-PRAM algorithm that uses  $2m$  processors, runs in  $T$  parallel rounds, and operates on the input graph  $G$  that is stored in the PRAM's shared memory. The round complexity of the attained CONGEST algorithm is  $T \cdot \tau_{\text{mix}}(G) \cdot 2^{O(\sqrt{\log n})}$ , where  $\tau_{\text{mix}}(G)$  is the mixing-time of  $G$ . Thus even for constant mixing time, this yields a simulation of the algorithm of [10] in CONGEST with  $2^{O(\sqrt{\log n})}$  rounds. Moreover, since the mixing time of Dirac's graph can be  $\Theta(n)^2$ , the round complexity of this simulation can be super-linear in  $n$ . Consequently, our goal is to improve upon this round complexity by directly designing an algorithm for the CONGEST model. Indeed we provide an algorithm with an exponential improvement in the round complexity. Specifically, our algorithm for finding a Hamiltonian cycle in Dirac graphs runs in  $O(\log n)$  rounds. When the algorithm terminates, each vertex outputs the identifier of the vertex that is before it and the vertex that is after it on the cycle<sup>3</sup>.

In the CONGEST model, it is standard to assume that the processors have unbounded computational power. Therefore, one may wonder whether finding a Hamiltonian cycle in general graphs in  $o(n^2)$  rounds is possible. It was recently shown by Bachrach et al. [1] that even the problem of testing Hamiltonicity in the CONGEST model [21] requires  $\tilde{\Omega}(n^2)$  rounds. Therefore, it is natural to focus on restricted families of graphs such as DIRAC graphs and their generalizations. Since the classical result of Dirac, there have been many generalizations of Dirac's theorem (see [17] and references therein), e.g., graph families that are defined by sufficient conditions on degrees, neighborhoods, and other graph parameters [20, 2, 5, 18, 6, 7, 12, 11]. The first important generalization of Dirac's theorem is by Ore [20] who proved that every graph in which the sum of degrees of each pair of non-adjacent vertices is at least  $n$  is Hamiltonian. A more recent generalization, which also generalizes Ore's theorem, and allows graphs with less edges, is by Rahman and Kaykobad [22] who proved that every graph in which the sum of degrees of each pair of non-adjacent vertices plus their distance is at least  $n + 1$  has a Hamiltonian path. We refer to graphs that satisfy these conditions as ORE

<sup>1</sup> See [10] and [23] for more details.

<sup>2</sup> Consider a Dirac graph, over  $n$  vertices, which is composed of two cliques of size  $n/2$  with a perfect matching between the cliques.

<sup>3</sup> We note that although the input graph is undirected, the outputs of the vertices yield an oriented Hamiltonian cycle (or path).

graphs and RK graphs, respectively. We prove that our distributed CONGEST algorithm and its analysis can be adapted (without changing the round complexity asymptotically) for these generalizations of DIRAC graphs as well.

## Our Results

Our main result is stated in the following theorem.

► **Theorem 1.** *There exists a distributed algorithm for computing a Hamiltonian cycle in DIRAC graphs that runs in  $O(\log n)$  rounds in the CONGEST model. The algorithm succeeds with high probability.<sup>4</sup>*

We also prove the following, more general, theorem in the full version.

► **Theorem 2.** *There exists a distributed algorithm for computing a Hamiltonian cycle in ORE graphs and a Hamiltonian path in RK graphs that runs in  $O(\log n)$  rounds in the CONGEST model. The algorithm succeeds with high probability.*

A nice outcome of Theorem 2 is that a sequential simulation of the CONGEST algorithm for the RK graphs yields a polynomial time sequential algorithm for finding a Hamiltonian path in these graphs as well.

## 1.1 High-level Description of the Algorithm

Our algorithm maintains a path-cover of the graph, where a path-cover is a set of paths in the graph such that each vertex of the graph belongs to exactly one of the paths in the set.

Initially, the path-cover consists of paths of constant length. Hence the size of the initial path-cover is linear in  $n$ . Then the algorithm proceeds in iterations, where in each iteration, the size of the path-cover decreases by a constant factor, with constant probability. Consequently, after  $\Theta(\log n)$  iteration, the size of the path-cover is 1. Namely, a Hamiltonian path is found. The decrease in the size of the path-cover occurs as in each iteration (with constant probability) a constant fraction of the paths are merged into other paths, as we describe next.

We consider three types of merges. An *elementary merge* occurs when a path  $P$  is merged into a path  $Q$  by connecting the endpoints of  $P$  to the endpoints of an edge of  $Q$ . A *concatenation merge* occurs when two paths are merged by connecting their endpoints. Finally, a *cycle merge* occurs when merging two cycles that are connected with an edge into a single path.

In each iteration, the algorithm proceeds as follows. First, the paths of the path-cover are paired. Now, two phases are performed, as follows. In the first phase of each iteration, only pairs of paths for which a special condition (which we describe momentarily) holds are merged. The special condition guarantees that each one of these pairs can be merged into a single path. Specifically, a pair of paths,  $(P, Q)$  satisfy this special condition if the subgraph induced on the vertices of each one of them has a Hamiltonian cycle and additionally  $P$  and  $Q$  are connected with an edge to each other.

In the second phase of each iteration, concatenations and elementary merges are performed. The merges that are performed in this phase are selected as follows. Let  $P$  be a path in the path cover. The *elements* of  $P$  consists of its edges and its endpoints. Initially, each element

<sup>4</sup> We say that an event occurs *with high probability (w.h.p.)* if it occurs with probability at least  $1 - 1/\text{poly}(n)$ .

of  $P$  reserves itself to at most a single path,  $Q$ . The path  $Q$  is selected as follows. If the (reserved) element is an endpoint of  $P$ ,  $v$ , then  $Q$  is a path with an endpoint incident to  $v$ , chosen uniformly at random from the set of such paths. Otherwise, if the (reserved) element is an edge <sup>5</sup> of  $P$ ,  $(u, v)$ , then  $Q$  is a path with an endpoint incident to  $u$ , chosen uniformly at random from the set of such paths. A reservation of an element of  $P$  to a path  $Q$  grants  $Q$  the exclusive right to be merged into  $P$  using this element. The purpose of these reservations is to avoid a scenario in which two different paths are trying to merge into another path by using the same element.

We say that a reservation of an element is *useful* for a path  $Q$  if  $Q$  can be merged into another path via this element. By construction, all reservations of endpoints are useful. However, a reservation of an edge may be non-useful since the decision to reserve an edge to a path,  $Q$ , is done only by one of the endpoints of  $e$ . Hence, it might be the case that the other endpoint of  $e$  is not adjacent to the other endpoint of  $Q$ . Nonetheless, we show that on expectation, a constant fraction of the paths will have at least one useful reservation. After setting the reservations, each path is notified of the set of its useful reservations (if any). This can be carried out without congestion because of the exclusivity of the reservations. Then each path arbitrarily selects one of its useful reservations.

At this point, each path that has a useful reservation can be merged into another path via the respective reserved element exclusively. However, there are two problems with executing these merges. The first problem is that we want to avoid lengthy sequences of merges as this blows up the round complexity of the algorithm. Roughly speaking, this comes from the fact that when we merge paths (possibly many) into a single new path, all vertices of the corresponding (old) paths are updated about the identity of the new path. Moreover, for each new path (which is an outcome of possibly many merging operations), the algorithm constructs a spanning tree, of depth 2, which spans the vertices of the path. See more details in the full version on the role of these spanning trees in our algorithm.

The second problem is that these sequences of merges may be conflicting. A simple example of a conflict is when a graph  $P$  tries to merge into  $Q$  via an edge of  $Q$ , and  $Q$  tries to merge into  $P$  via an edge of  $P$ . Clearly, these two merges cannot be carried out simultaneously. Moreover, this example can be extended into arbitrarily long cycles.

Fortunately, these two problems can be remedied by the following simple idea. Each path tosses a fair coin. Then each path,  $P$ , is merged via its selected (reserved) element only if  $P$  tossed **tails** and  $Q$  tossed **heads**, where  $Q$  is the path of the respective element. On expectation  $1/4$  of the merges will be in the “right” orientation. In our analysis, we prove that this suffices for our needs (see more details on Subsection 4.3). This completes the description of the second phase of each iteration and concludes the description of the algorithm.

## 1.2 Correctness and Analysis of the Algorithm

The analysis of the algorithm has two ingredients. The first and main ingredient is showing that for any fixed iteration, the size of the path cover decreases by a constant fraction on expectation. The second ingredient is showing that after  $\Theta(\log n)$  iterations, with high probability, all paths are merged into a single Hamiltonian path.

---

<sup>5</sup> We note that although the graph is undirected, we keep an orientation on the edges of the paths of the path cover (so the obtained paths are directed).

For the first ingredient of the analysis, we define the notion of being a *good path*. Roughly speaking, a path is good if there are sufficiently many edges connecting its endpoints to vertices of other paths (the actual definition is more cumbersome than this, but this is essentially the property that we need). This property guarantees that any good path has many options for merging into other paths. In particular, the number of options is linear in the size of the current path cover (Lemma 14). We use this fact to show that, on any fixed iteration, a good path receives a useful reservation with constant probability (Claim 15).

Finally, we prove that there are sufficiently many good paths. Recall that at the beginning of each iteration, the paths are paired. In the algorithm analysis, we prove that for each one of the pairs of paths,  $(P, Q)$ , that were not merged in the first phase, either  $P$  or  $Q$  are good with respect to the current path-cover. We then show that consequently, this guarantees that with constant probability, a constant fraction of these paths will be merged into other paths in the second phase of the algorithm.

### 1.3 Adaptation of the Algorithm for ORE and RK Graphs

Since the family of RK graphs contains ORE graphs we, from now on, focus on RK graphs. We begin by proving some structural properties of RK graphs. One of these properties is that the vertices in RK graphs can be partitioned into 3 sets  $A$ ,  $C$ , and  $H$  where all the vertices in  $H$  satisfy Dirac's condition and the subgraph induced on each one of the sets  $A$  and  $C$ , form a clique. This structure allows us to perform as in the algorithm for DIRAC graphs with the only difference that at the beginning of each iteration, we get rid of (almost) all the paths in which one endpoint is not in  $H$ . Another technicality that we need to handle is the fact that our algorithm for DIRAC graphs uses spanning trees to manage the communication within the different paths in the path cover. In RK graphs these spanning trees may not span the entire respective paths. However, we show that with a slight adaptation, it is possible to maintain communication within the paths while adding only a constant factor blow-up in the round complexity.

### 1.4 Related Work

#### Parallel Algorithms

As mentioned above, Dahlhaus et al. [10] gave a  $O(\log^4 n)$  CREW-PRAM algorithm that uses a linear number of processors to find a Hamiltonian cycle in Dirac graphs. Another generalization of Dirac graphs are *Chvátal graphs*. A graph is called a Chvátal graph if its degree sequence  $d_1 \leq d_2 \leq \dots \leq d_n$  satisfies that for every  $k < n/2$ ,  $d_k \leq k$  implies that  $d_{n-k} \geq n - k$ . Chvátal proved (see e.g., [3]) that Chvátal graphs are also Hamiltonian. In [6] a sequential polynomial time algorithm that finds Hamiltonian cycles in Chvátal graphs has been shown. Sárközy [23] proved that a deterministic  $O(\log^4 n)$  time EREW-PRAM algorithm with a polynomial number of processors that finds a Hamiltonian cycle in a  $\eta$ -Chvátal graphs exists. A graph is called  $\eta$ -Chvátal graphs if for every  $k < n/2$ ,  $d_k \leq \min\{k + \eta n, n/2\}$ , it holds that  $d_{n-k-\eta n} \geq n - k$ , where  $0 < \eta < 1$ .

#### Distributed Algorithms with a Promise

It is known that a random  $G(n, p)$  graph contains w.h.p. a Hamiltonian cycle if  $p$  is at least  $(\log n + \log \log n + t(n))/n$ , for any divergent function  $t(n)$  [4]. Thus for any such  $p$ , the problem of deciding whether the graph is Hamiltonian becomes trivial; however, finding the Hamiltonian path or cycle, in this case, is still non-trivial. The problem of

finding a Hamiltonian cycle in the distributed setting was initially studied by Levy et al. [16] that provided an upper bound whose round complexity is  $O(n^{3/4+\epsilon})$  that w.h.p. finds a Hamiltonian cycle given that  $p = \omega(\sqrt{\log n}/n^{1/4})$ . Thereafter, other upper bounds were designed in the CONGEST model (in which the message size is bounded) for dealing with various ranges of  $p$ , as described next. The algorithm of Chatterjee et al. [8] works for  $p \leq \frac{c \ln n}{n^\delta}$ , ( $0 < \delta \leq 1$ ) and finds a Hamiltonian cycle w.h.p. in  $\tilde{O}(n^\delta)$  rounds. For  $p$  in  $\tilde{\Omega}(1/\sqrt{n})$ , Turau [24], provides an algorithm that finds w.h.p. a Hamiltonian cycle in  $O(\log n)$  rounds. More recently, Ghaffari and Li [13] showed the existence of a distributed algorithm for finding a Hamiltonian cycle, w.h.p., in  $G(n, d)$  for  $d = C \log n$  whose round complexity is  $2^{O(\sqrt{\log n})}$ , where  $C$  is a sufficiently large constant.

### Lower Bounds in the CONGEST Model

It is well known that certain properties can not be decided in the CONGEST model in a number of rounds which is  $o(n^2)$  [21]. As mentioned above, Bachrach et al. [1] proved a lower bound of  $\tilde{\Omega}(n^2)$  rounds for various problems in the CONGEST model, including Testing Hamiltonicity in general graphs.

## 1.5 Comparison with the Algorithm of Dahlhaus et al. [10]

As mentioned above, our algorithm builds on ideas from the algorithm of Dahlhaus et al. [10] for finding a Hamiltonian path in Dirac's graphs. Their algorithm also proceeds in iterations such that at each iteration it first performs cycle merges, then it performs concatenation merges and finally, it performs elementary merges. However, the specific structure of their algorithm and how these merges are selected are quite different from our algorithm.

We shall demonstrate several structural differences without going into all the details of their algorithm (which is more involved than our algorithm). These differences serve us in obtaining an improved round complexity and a simpler algorithm. Thereafter we shall emphasize the specific differences that arise from the fact that our algorithm works in the CONGEST model rather than the PRAM model.

The first structural difference is that on each iteration, before their algorithm turns into performing elementary merges it first has to exhaust most of the cycle merges, which requires an inner loop of  $\Theta(\log n)$  steps and thereafter it exhausts most of the concatenation merges by executing a special subroutine of Israeli and Shiloach [14] which returns both a vertex cover and an approximated maximum matching.

This subroutine is executed twice. One time on the subgraph induced on the endpoints of the paths in the path cover and another time on an auxiliary graph where on one side we have the set of paths and on the other side we have the set of edges composing the paths.

The reason that their algorithm exhausts the three types of merges in phases is that the progress of each phase relies on the exhaustion of the merges of the previous step.

For comparison, per iteration, our algorithm performs only one step of cycle merges and then one step in which both concatenation and elementary merges are performed simultaneously. We prove that this is sufficient to make enough progress per iteration.

Another difference is that in their algorithm, at the beginning of each iteration, every path is classified into one of two types. We are able to avoid this classification altogether and use a somewhat different classification only in the analysis.

We next list several challenges that arise specifically in the CONGEST model and in particular do not allow us to easily translate the algorithm of [10] into the CONGEST model.

The first problem is that we do not have shared memory among the processors so how can we efficiently merge even a pair of paths? To this end, our algorithm maintains spanning trees, of depth 2, on each one of the paths in the constructed path cover. Therefore, initially, we have a linear (in  $n$ ) number of spanning trees (and this number decreases as the algorithm progresses). We show that each edge participates in at most 2 different spanning trees and so communication within vertices of the same path can be maintained without causing congestion.

Another problem is concerned with elementary merges. Consider a path cover  $\mathcal{P}$  and an edge  $(u, v)$  on a path  $P \in \mathcal{P}$ . An elementary merge of a path  $Q$  into  $P$  can be performed via  $(u, v)$  only if one endpoint of  $Q$  is adjacent to  $u$  and the other is adjacent to  $v$ . However, there might be many endpoints that are adjacent to  $u$  or  $v$ , so how can we find the set of paths that can be merged via  $(u, v)$  into  $P$  without communicating too much between  $u$  and  $v$ ? As mentioned above, we show that we don't have to find this set. Specifically, we show that when  $u$  reserves the edge  $(u, v)$  to an endpoint that is adjacent to  $u$ , picked uniformly at random, then every path receives a useful reservation with constant probability. We remark that in this case, we rely on the randomness of our algorithm while the algorithm of [10] is deterministic.

Finally, we want to avoid long sequences of merges so we won't have to deal with long sequences of updates. To this end, we use the coin tosses of the vertices and perform merge operations only if they agree with the orientation defined by the coin tosses. As described above, this is also useful for avoiding conflicting merges. Consequently, the merges can be carried out simultaneously with very little and local coordination.

## 2 Paths-Merge Types and Paths Classification

### Notation

Let  $G = (V, E)$  be an undirected simple graph, where  $V$  is the vertex set, and  $E \subseteq \{\{u, v\} \mid u, v \in V\}$  is the edge set. Let  $n$  denote  $|V|$  and let  $m$  denote  $|E|$ . For a path  $P = (u_1, \dots, u_\ell)$ , we denote by  $V(P)$  the vertex set of  $P$ , i.e.,  $V(P) \triangleq \{u_1, \dots, u_\ell\}$ . For  $v \in V$ , let  $N(v)$  denote the neighbors set of  $v$  in  $G$ , that is  $N(v) = \{u \in V \mid \{v, u\} \in E\}$ . Let  $d(v)$  denote the degree of  $v$ , i.e.,  $d(v) = |N(v)|$ . For a pair of vertices  $u$  and  $v$ , let  $\delta(u, v)$  denote the length of a shortest path between  $u$  and  $v$ . We say that a set of paths in  $G$ ,  $\{P_i\}_{i=0}^{k-1}$ , is a *path-cover* of  $G$  if its union covers the vertex set of  $G$ , that is, if  $\bigcup_{i=0}^{k-1} V(P_i) = V(G)$ . For a path  $P$  in  $G$ , let  $d_P(v)$  denote the number of neighbours of  $v$  in  $P$ . For a path  $P = (u, \dots, v)$ , we refer to the vertices  $u$  and  $v$  as the *endpoints* of  $P$ .

### Path Merging Types

Through the course of the algorithm's execution, the algorithm performs three kinds of path merging depending on the paths at hand: an elementary merge, a concatenation, and cycle merging (see Figure 1). These merge operations are defined as follows.

► **Definition 3** (Elementary merge [10]). *Let  $P = (u_1, \dots, u_\ell)$  and  $Q = (v_1, \dots, v_m)$  be two disjoint paths. If  $\{u_1, v_i\}, \{u_\ell, v_{i+1}\} \in E$ , then  $(v_1, \dots, v_i, u_1, \dots, u_\ell, v_{i+1}, \dots, v_m)$  is a path. If  $\{u_1, v_{i+1}\}, \{u_\ell, v_i\} \in E$ , then  $(v_1, \dots, v_i, u_\ell, \dots, u_1, v_{i+1}, \dots, v_m)$  is a path. In either case, we say that we merged  $P$  into  $Q$  along the edge  $\{v_i, v_{i+1}\}$ . We call this step an elementary merging operation.*

■ **Figure 1** Path merging types.

► **Definition 4** (Concatenation [10]). Let  $P = (u_1, \dots, u_\ell)$  and  $Q = (v_1, \dots, v_m)$  be two disjoint paths. If there is an edge connecting an endpoint of  $P$  (either  $u_1$ , or  $u_\ell$ ) and an endpoint  $v \in \{v_1, v_m\}$  of  $Q$ , then we can use any of these edges to concatenate  $P$  and  $Q$  and say that we concatenated  $P$  to  $Q$  along vertex  $v$ . We call this operation a concatenation.

► **Definition 5** (Cycle Merging [10]). Let  $C$  and  $D$  be two disjoint cycles. If there is an edge connecting a vertex from  $C$  and a vertex from  $D$ , we can use this edge to get a path that passes through all the vertices of  $C$  and  $D$ . We call this operation a cycle merging.

### Paths Classification

For the sake of the analysis of the algorithm we classify the paths that the algorithm maintains as *sociable paths* (à la Dahlhaus et al. [10]) or as *cycled paths*, as follows.

► **Definition 6** ([10]). Let  $P = (u, \dots, v)$  be a path in a graph  $G$ . We say that the path  $P$  is sociable if  $d_P(u) + d_P(v) + 1 \leq |V(P)|$ .

► **Definition 7** (Cycled Path). Let  $P = (u_1, \dots, u_\ell)$  be a path in a graph  $G$ . We say that the path  $P$  is cycled if  $\{u_1, u_\ell\} \in E$  or if there exists an edge of  $P$ ,  $\{u_i, u_{i+1}\}$  such that both  $\{u_1, u_{i+1}\}, \{u_i, u_\ell\} \in E$ .

It is easy to see that if a path  $P$  is cycled, then the subgraph induced on  $V(P)$  is Hamiltonian. We shall use the following basic claim, the proof of which is deferred to the full version.

▷ **Claim 8.** Let  $P = (u_1, \dots, u_\ell)$  be a path that is not cycled. Then  $P$  is sociable.

## 3 The Algorithm

In this section, we list our distributed algorithm (see Algorithm 1) without giving all the details of implementation. We then prove its correctness in Section 4 and in the full version we discuss in more detail how the algorithm is implemented in the CONGEST model. We establish the following theorem.

► **Theorem 1.** *There exists a distributed algorithm for computing a Hamiltonian cycle in DIRAC graphs that runs in  $O(\log n)$  rounds in the CONGEST model. The algorithm succeeds with high probability.*

### 3.1 Listing of the Distributed Algorithm

Our algorithm begins with finding an initial path-cover of the graph in which each path is of length at least 2, denoted by  $\mathcal{P}_0$ . Then the algorithm proceeds in  $\Theta(\log n)$  iterations (in which the size of the path-cover decreases by a constant fraction with constant probability).

■ **Figure 2** Useful versus non-useful reservations.

We denote the path-cover at the beginning of the  $i$ -th iteration by  $\mathcal{P}_i$ . At the beginning of each iteration, the paths in  $\mathcal{P}_i$  are partitioned into pairs. Each pair of paths  $(P, Q)$  such that  $P$  and  $Q$  are connected with an edge, and both  $P$  and  $Q$  are cycled are merged (Step 5). We denote by  $\mathcal{P}_i^a$  the resulting path-cover.

Thereafter, each edge and endpoint of a path in  $\mathcal{P}_i^a$  reserves itself to an endpoint of another path in  $\mathcal{P}_i^a$ , which is picked uniformly at random.

Then, each path  $P$  in the path-cover selects out of the elements that were reserved to it (i.e., either an edge or an endpoint) a single element,  $\ell$ , such that  $P$  can be merged to another path via  $\ell$  (we refer such elements as *useful* for  $P$ ).

Each path,  $P$ , tosses a random fair coin,  $y_P$ . Next, all the merges are performed simultaneously where a path  $P$  is merged via its selected element,  $\ell$ , to a path  $Q$  only if  $y_P = \text{tails}$  and  $y_Q = \text{heads}$ .

► **Remark 9.** When a path  $P$  is merged to a path  $Q$  where  $y_P = \text{tails}$  and  $y_Q = \text{heads}$ , the orientation of  $Q$  is kept, and the orientation of  $P$  may be reversed to maintain consistency with the orientation of  $Q$ . For example, if  $P = (y_1, \dots, y_\ell)$  is merged to  $Q$  via  $\{u, v\}$  where the orientation of  $\{u, v\}$  is from  $u$  to  $v$  and  $y_1$  is connected to  $v$  and  $y_\ell$  is connected to  $u$  then the orientation of  $P$  is reversed after the merge.

## 4 Correctness of the Algorithm

In this section, we prove the correctness of our algorithm.

We begin by giving a lower bound on the number of possible merges for each path in the path-cover. We then use this bound to give a lower bound on the expected number of merges carried out in each iteration. Finally, we prove that with high probability after  $\Theta(\log n)$  iterations, all paths are merged into a single path. Some of the proofs are deferred to the full version.

### 4.1 Number of Possible Merges for Good Paths

In this section, we provide the proof of Lemma 11 which gives a lower bound on the number of possible ways a path  $P$  can be merged into a path  $Q$ . We then define the notion of *good* paths (Definition 13). Roughly speaking, a path is good if its endpoints are neighbors of sufficiently many vertices that belong to other paths in the path cover. Thereafter, we use Lemma 11 to give a lower bound on the total number of ways a good path,  $P$ , can be merged into any other path in the path-cover (Lemma 14).

■ **Algorithm 1** Finding a Hamiltonian path in a Dirac graph.

---

**Input:** A Dirac graph  $G = (V, E)$ .  
**Invariant:** The algorithm maintains a path-cover  $\mathcal{P}_i$  for every  $i \geq 0$ . The path-cover  $\mathcal{P}_{i+1}$  is computed from  $\mathcal{P}_i$  via elementary merges, cycle merges and concatenation merges operations.  
**Output:**  $\mathcal{P}_{\Theta(\log n)}$  is a Hamiltonian path. w.h.p. // For the exact constant within the  $\Theta$  notation we refer the reader to Lemma 18.

---

- 1 Compute a path-cover,  $\mathcal{P}_0$  in the graph such that each path is of size at least 2.
- 2 **for**  $i \leftarrow 0$  **to**  $\ell = \Theta(\log n)$  **do**
- 3     Pair all paths (except for at most one) and let  $\mathcal{I}_i$  denote the set of these pairs of paths.
- 4     Let  $\mathcal{L}_i \subseteq \mathcal{I}_i$  denote the set of paired paths that have an edge between them and for which both paths are cycled.
- 5     Perform cycle merges on all pairs in  $\mathcal{L}_i$ . // see Definition 5
- 6     Let  $\mathcal{P}_i^a$  denote the current path-cover
- 7     For every  $v \in V$  let  $D_i(v)$  denote the subset of endpoints of paths in  $\mathcal{P}_i^a$ ,  $u$ , such that  $\{u, v\} \in E$
- 8     **for every**  $P \in \mathcal{P}_i^a$  where  $P = (u_1, \dots, u_\ell)$  **do**
- 9         Every  $u_j$  for  $j \in \{1, \dots, \ell - 1\}$  picks an endpoint  $v$  u.a.r. from  $D_i(u_j)$  and reserves the edge  $(u_j, u_{j+1})$  for  $v$ .
- 10         Additionally, each endpoint of  $P$ ,  $v$ , reserves itself to an endpoint which is picked u.a.r. from  $D_i(v)$ .
- 11          $y_P \leftarrow \begin{cases} \text{heads,} & \text{w.p. } 1/2, \\ \text{tails,} & \text{o.w.} \end{cases}$ .
- 12          $M_i \leftarrow \emptyset$
- 13         **for every**  $P \in \mathcal{P}_i^a$  **do**
- 14             We say that an endpoint or an edge,  $x$ , is useful for  $P$  (w.r.t.  $\mathcal{P}_i^a$ ) if  $P$  can be concatenated or merged along  $x$  to another path in  $\mathcal{P}_i^a$ .
- 15             Let  $S_i(P)$  denote the set of elements reserved for the endpoints of  $P$  in Steps 8-10 which are also *useful* for  $P$ .
- 16              $P$  picks arbitrarily one of the elements in  $S_i(P)$  (assuming it is not empty) and adds it to  $M_i$ .
- 17     Perform concatenation merges and elementary merges with accordance to  $M_i$  and the  $y_P$  variables: a path  $P_1$  merges into a path  $P_2$  if there is a corresponding merge operation in  $M_i$  and if  $y_{P_1} = \text{tails}$  and  $y_{P_2} = \text{heads}$ . // see Definitions 3, 4
- 18 **return**  $\mathcal{P}_\ell$ .

---

Let  $P = (u, \dots, v)$  and  $Q = (a, \dots, b)$  be disjoint paths in  $G$ . Let  $M(P, Q)$  denote the number of edges along which one can merge  $P$  into  $Q$  via elementary merging plus the number of vertices along which one can concatenate  $P$  to  $Q$  (see Definitions 3 and 4, respectively). Let  $d(P, Q)$  denote the number of endpoints of  $Q$  connected with an edge to an endpoint of  $P$ .

We begin with extending the following lemma from [10].

► **Lemma 10** (Lemma. 5.2.5 [10], restated). *Let  $P = (u, \dots, v)$  and  $Q$  be disjoint paths in  $G$ . If  $d(P, Q) = 0$ , then the number of edges along which one can merge  $P$  into  $Q$  via elementary merging operations is at least  $d_Q(u) + d_Q(v) - |V(Q)| + 1$ .*

To achieve better round complexity, our algorithm performs concatenation and elementary merges simultaneously. To this end, we prove the following lemma, which extends Lemma 10 so that it also applies to cases where  $d(P, Q) > 0$ .

► **Lemma 11.** *Let  $P = (u, \dots, v)$  and  $Q = (a, \dots, b)$  be disjoint paths in  $G$  such that  $|V(P)|, |V(Q)| \geq 2$ . Then,*

$$M(P, Q) \geq d_Q(u) + d_Q(v) - |V(Q)| + 1. \quad (1)$$

We next give a lower bound on the number of merging operations which applies for a subset of paths in the path cover. We shall use the following definition.

► **Definition 12.** *Let  $\mathcal{P}$  be a path cover and let  $A(\mathcal{P})$  denote the set of paths,  $P = (u, \dots, v)$ , in  $\mathcal{P}$  such that there exists a path  $P' \in \mathcal{P}$  for which  $|V(P')| \geq |V(P)|$  and  $d_{P'}(u) + d_{P'}(v) = 0$ .*

In words,  $A(\mathcal{P})$  is the set of paths,  $P \in \mathcal{P}$  for which there exists another path,  $P' \in \mathcal{P}$ , which is not shorter than  $P$  and for which the endpoints of  $P$  are not adjacent to any of the vertices composing  $P'$ . We next define the notion of *good path*.

► **Definition 13 (good path).** *Let  $\mathcal{P}$  be a path cover. A path  $P \in \mathcal{P}$  is good (w.r.t.  $\mathcal{P}$ ) if it is sociable or in  $A(\mathcal{P})$ .*

The following lemma gives a lower bound on the number of merging operations for any path which is good. In the proof of the lemma, we extend ideas from Corollary 5.2.6 and Lemma 5.2.7 of Dahlhaus et al. [10]. Our extension allows us to drop the stringent requirement of Dahlhaus et al. [10] that the endpoints of  $P$  are not adjacent to endpoints of any other path in the path cover. This allows us to support the execution of both concatenations and elementary merging operations simultaneously.

► **Lemma 14.** *Let  $\mathcal{P}$  be a path-cover of  $G$ . For  $P \in \mathcal{P}$  define  $M(P) \stackrel{\text{def}}{=} \sum_{Q \in \mathcal{P} \setminus \{P\}} M(P, Q)$ . Then, for every good path,  $P \in \mathcal{P}$  it holds that  $M(P) \geq |\mathcal{P}|$ .*

## 4.2 Expected Number of Merges

In this section, we prove Claim 16 which states that the expected number of merges of each iteration is sufficiently large.

More specifically, for a fixed iteration  $i$ , we prove that if the number of cycle-merges performed at Step 5 is below some threshold (specifically if  $|\mathcal{L}_i| \leq |\mathcal{P}_i|/12$ ), then the expected size of  $M_i$  (the set of concatenation merges and elementary merges added in Step 16) is a constant fraction of the size of  $\mathcal{P}_i$ . We first prove the following claim which gives a lower bound on the probability that a good path receives a useful reservation.

▷ **Claim 15.** Fix an iteration  $i$ . For any  $P$  which is good with respect to  $A(\mathcal{P}_i^a)$ , it holds that  $P$  receives a useful reservation for at least one element with probability at least  $1/3$ .

*Proof.* Fix an iteration  $i$  and let  $P$  be a good path with respect to  $A(\mathcal{P}_i^a)$ . Let  $F$  denote the set of edges and endpoints that  $P$  can be merged to (see Definitions 3, 4) in  $\mathcal{P}_i^a$ . By Lemma 14, it holds that  $|F| \geq |\mathcal{P}_i^a|$ . Let  $x = 2|\mathcal{P}_i^a|$  denote the total number of endpoints of paths in  $\mathcal{P}_i^a$ . Since every edge and endpoint in  $F$  is reserved for  $P$  with a probability of at least  $1/x$ , the probability that  $P$  received at least one reservation of an element in  $F$  is at least  $1 - (1 - 1/x)^{|F|}$ . since  $(1 - 1/x)^{|F|} \leq (1 - 1/(2|\mathcal{P}_i^a|))^{|\mathcal{P}_i^a|} \leq 1/\sqrt{e}$ , it holds that this probability is at least  $1/3$ . ◁

▷ **Claim 16.** If  $\mathcal{L}_i \leq |\mathcal{P}_i|/12$  then  $\mathbb{E}(|M_i| \mid \mathcal{P}_i) \geq |\mathcal{P}_i|/36$ .

*Proof.* We first observe that in every pair  $(P, Q) \in \mathcal{I}_i \setminus \mathcal{L}_i$  at least one path is good with respect to  $\mathcal{P}_i^a$ . To see this, observe that there are two cases. The first case is that  $P$  and  $Q$  are not connected with an edge. This implies that at least one of them is in  $A(\mathcal{P}_i^a)$ . The second case is that at least one of them is not cycled, which by Claim 8 implies that at least one of them is sociable, as desired. We next lower bound the number of pairs in  $\mathcal{I}_i \setminus \mathcal{L}_i$ . Since the number of pairs is at least  $(|\mathcal{P}_i| - 1)/2 \geq |\mathcal{P}_i|/4$  and  $|\mathcal{L}_i| < |\mathcal{P}_i|/12$  it holds that  $|\mathcal{I}_i \setminus \mathcal{L}_i| \geq |\mathcal{P}_i|/4 - |\mathcal{P}_i|/12 = |\mathcal{P}_i|/6$ .

Therefore, by Claim 15, the expected size of merges that are added to  $M_i$  is at least  $|\mathcal{I}_i \setminus \mathcal{L}_i|/2 \cdot (1/3) \geq |\mathcal{P}_i|/36$ , as required. ◀

### 4.3 The Progress of Each Iteration

In this section, we prove the following lemma.

► **Lemma 17.** For any iteration  $i$  of Algorithm 1 it holds that  $\mathbb{E}(|\mathcal{P}_{i+1}|) \leq (1 - 1/144) \cdot \mathbb{E}(|\mathcal{P}_i|)$ .

*Proof.* Fix an iteration  $i$ . If  $\mathcal{L}_i \geq |\mathcal{P}_i|/12$  then at least  $|\mathcal{P}_i|/12$  paths of  $\mathcal{P}_i$  are merged and so  $|\mathcal{P}_{i+1}| \leq (1 - 1/12)|\mathcal{P}_i|$ , as desired.

Otherwise, by Claim 16,  $\mathbb{E}(|M_i|) \geq |\mathcal{P}_i|/36$ . Consider a merge operation in  $M_i$  in which path  $P$  is merged into path  $Q$ . This merge is carried in Step 17 only if  $y_P = \mathbf{tails}$  and  $y_Q = \mathbf{heads}$ , which happens with probability  $1/4$ . We denote these merge operations by  $M'_i$ , hence  $\mathbb{E}(|M'_i|) \geq |\mathcal{P}_i|/(36 \cdot 4) = |\mathcal{P}_i|/144$ . Moreover, since  $|\mathcal{P}_{i+1}| \leq |\mathcal{P}_i| - |M'_i|$  (recall that merges can occur before Step 17), it follows that  $\mathbb{E}(|\mathcal{P}_{i+1}| \mid \mathcal{P}_i) \leq |\mathcal{P}_i| - \mathbb{E}(|M'_i| \mid \mathcal{P}_i) \leq (1 - 1/144) \cdot |\mathcal{P}_i|$ .

The lemma follows since

$$\mathbb{E}(|\mathcal{P}_{i+1}|) = \sum_{\mathcal{P}_i} \Pr(\mathcal{P}_i) \cdot \mathbb{E}(|M'_i| \mid \mathcal{P}_i) \leq \sum_{\mathcal{P}_i} \Pr(\mathcal{P}_i) \cdot (1 - 1/144) \cdot |\mathcal{P}_i| = (1 - 1/144) \cdot \mathbb{E}(|\mathcal{P}_i|),$$

as required. ◀

#### 4.3.1 Number of Iterations

In this section, we prove that if the for-loop in Step 2 of Algorithm 1 performs  $\Theta(\log n)$  iterations, then the path that is returned at the end of the algorithm is Hamiltonian w.h.p.

We note that, although the algorithm uses independent coin tosses between different iterations, the success of two different iterations are random variables that may be dependent. Therefore we cannot use concentration bounds that assume the independence of the random variables (such as Chernoff's bound). Roughly speaking, the dependence comes from the fact that the constructed path cover depends on the coin tosses of previous iterations. Nonetheless, we can show that  $\Theta(\log n)$  iterations are sufficient.

The proof of our main theorem (Theorem 1) follows directly from the following lemma.

► **Lemma 18.** The path returned in Step 18 is Hamiltonian w.h.p.

*Proof.* Lemma 17 and the fact that  $|\mathcal{P}_0| \leq n$  imply that

$$\mathbb{E}(|\mathcal{P}_\ell|) \leq (1 - 1/144)^\ell \cdot \mathbb{E}(|\mathcal{P}_0|) \leq (1 - 1/144)^\ell \cdot n.$$

It follows that for  $\ell \geq \frac{2}{\log_2(144/143)} \cdot \log_2 n$ , it holds that  $\mathbb{E}(|\mathcal{P}_\ell|) \leq \frac{1}{n}$ .

Thus, by Markov's Inequality, it follows that the probability that the Algorithm fails is

$$\Pr(|\mathcal{P}_\ell| > 1) \leq \frac{\mathbb{E}(|\mathcal{P}_\ell|)}{1} \leq \frac{1}{n},$$

as required. ◀

## Abstract

Semiring semantics of first-order logic generalises classical Boolean semantics by permitting truth values from a commutative semiring, which can model information such as costs or access restrictions. This raises the question to what extent classical model-theoretic properties still apply, and how this depends on the algebraic properties of the semiring.

In this paper, we study this question for the classical locality theorems due to Hanf and Gaifman. We prove that Hanf’s locality theorem generalises to all semirings with idempotent operations, but fails for many non-idempotent semirings. We then consider Gaifman normal forms and show that for formulae with free variables, Gaifman’s theorem does not generalise beyond the Boolean semiring. Also for sentences, it fails in the natural semiring and the tropical semiring. Our main result, however, is a constructive proof of the existence of Gaifman normal forms for min-max and lattice semirings. The proof implies a stronger version of Gaifman’s classical theorem in Boolean semantics: every sentence has a Gaifman normal form which does not add negations.

## 1 Introduction

Originally motivated by *provenance analysis in databases* (see e.g. [18, 12] for surveys), semiring semantics is based on the idea to evaluate logical statements not just by *true* or *false*, but by values in some commutative semiring  $(K, +, \cdot, 0, 1)$ . In this context, the standard semantics appears as the special case when the Boolean semiring  $\mathbb{B} = (\{\perp, \top\}, \vee, \wedge, \perp, \top)$  is used. Valuations in other semirings provide additional information, beyond truth or falsity: the tropical semiring  $\mathbb{T} = (\mathbb{R}_+^\infty, \min, +, \infty, 0)$  is used for *cost analysis*, the natural semiring  $\mathbb{N} = (\mathbb{N}, +, \cdot, 0, 1)$  for counting evaluation strategies and proofs, and the Viterbi-semiring  $\mathbb{V} = ([0, 1]_{\mathbb{R}}, \max, \cdot, 0, 1)$  models *confidence scores*. Finite or infinite min-max semirings  $(K, \max, \min, a, b)$  can model, for instance, different *access levels* to atomic data (see e.g. [10]); valuations of a first-order sentence  $\psi$  in such *security semirings* determine the required clearance level that is necessary to access enough information to determine the truth of  $\psi$ . Further, semirings of polynomials or formal power series permit us to *track* which atomic facts are used (and how often) to establish the truth of a sentence in a given structure, and this has applications for database repairs [26] and also for the strategy analysis of games [17, 14]. Semiring semantics replaces structures by *K-interpretations*, which are functions  $\pi: \text{Lit}_A(\tau) \rightarrow K$ , mapping fully instantiated  $\tau$ -literals  $\varphi(\bar{a})$  over a universe  $A$  to values in a commutative semiring  $K$ . The value  $0 \in K$  is interpreted as *false*, while all other values in  $K$  are viewed as nuances of *true* or, perhaps more accurately, as *true, with some*

*additional information*. In provenance analysis, this is sometimes referred to as *annotated facts*. The value  $1 \in K$  is used to represent *untracked information* and is used in particular to evaluate true equalities and inequalities.

The development of semiring semantics raises the question to what extent classical techniques and results of logic extend to semiring semantics, and how this depends on the algebraic properties of the underlying semirings. Previous investigations in this direction have studied, for instance, the relationship between elementary equivalence and isomorphism for finite semiring interpretations and their definability up to isomorphism [15], Ehrenfeucht-Fraïssé games [7], and 0-1 laws [13].

The purpose of this paper is to study *locality* in semiring semantics. Locality is a fundamental property of first-order logic in classical semantics and an important limitation of its expressive power. It means that the truth of a first-order formula  $\psi(\bar{x})$  in a given structure only depends on a neighbourhood of bounded radius around  $\bar{x}$ , and on the existence of a bounded number of local substructures. Consequently, first-order logic cannot express global properties such as connectivity or acyclicity of graphs. On graphs there are natural and canonical notions of the distance between two points and of a neighbourhood of a given radius around a point. To define these notions for an arbitrary relational structure  $\mathfrak{A}$  one associates with it its *Gaifman graph*  $G(\mathfrak{A}) = (A, E)$  where two points  $a \neq b$  are adjacent if, and only if, they coexist in some atomic fact. There exist several notions of locality; the most common ones are *Hanf locality* and *Gaifman locality*, and the fundamental locality theorems for first-order logic are *Hanf's locality theorem* and *Gaifman's normal form theorem*. In a nutshell, Hanf's theorem gives a criterion for the  $m$ -equivalence (i.e. indistinguishability by sentences of quantifier rank up to  $m$ ) of two structures based on the number of local substructures of any given isomorphism type, while Gaifman's theorem states that every first-order formula is equivalent to a Boolean combination of local formulae and basic local sentences, which has many model-theoretic and algorithmic consequences. We shall present precise statements of these results in Sect. 3 and Sect. 4.

Locality thus provides powerful techniques, also for logics that go beyond first-order logic by counting properties, generalised quantifiers, or aggregate functions, [1, 21, 22, 23]. It has applications in different areas including low-complexity model-checking algorithms [19, 20], approximation schemes for logically defined optimisation problems [8], automata theory [25], computational issues on database transactions [2], and most recently also in learning theory, for the efficient learning of logical concepts [3, 5, 4]. This motivates the question, whether locality is also applicable in semiring semantics. The relevant semiring interpretations in this context are *model-defining*, which means that for any pair of complementary literals  $R\bar{a}, \neg R\bar{a}$  precisely one of the values  $\pi(R\bar{a}), \pi(\neg R\bar{a})$  is 0, and *track only positive information* which means that  $\pi(\neg R\bar{a})$  can only take the values 0 or 1. Model defining interpretations  $\pi$  define a unique structure  $\mathfrak{A}_\pi$  and we thus obtain a well-defined Gaifman graph  $G(\pi) := G(\mathfrak{A}_\pi)$ , with the associated notions of distance and neighbourhoods. The assumption that only positive information is tracked is necessary to get meaningful locality properties (see Sect. 2).

We clearly cannot generalise all known locality properties of first-order logic to semiring semantics in arbitrary commutative semirings. On semirings whose operations are not idempotent, we cannot expect a Gaifman normal form, since for computing the value of a quantified statement, we have to add or multiply values of subformulae for *all* elements of the structure, which gives an inherent source of non-locality. As a consequence, some of the locality results that we prove hold only under certain algebraic assumptions on the semiring, and further there turns out to be a difference of the locality properties of sentences and those of formulae with free variables. We shall establish the following results.

- (1) First-order formulae are Hanf-local for all semirings.
- (2) Hanf's locality theorem generalises to all fully idempotent semirings (in which both addition and multiplication are idempotent).
- (3) For formulae with free variables, Gaifman's normal form theorem does not generalise beyond the Boolean semiring.
- (4) For sentences, Gaifman's normal form theorem also fails in certain important semirings such as the natural semiring and the tropical semiring.
- (5) Over min-max semirings (and even lattice semirings), every first-order sentence has a Gaifman normal form.
- (6) In classical Boolean semantics, every sentence has a Gaifman normal form which does not introduce new negations.

The results (1), (2) on Hanf locality (Sect. 3) are proved by adaptations of the arguments for the Boolean case. The results (3) and (4) are established in Sect. 5 via specific examples of formulae that defeat locality, using simple algebraic arguments. The most ambitious result and the core of our paper is (5), a version of Gaifman's theorem for min-max semirings (Sect. 6), which we later generalise to lattice semirings (Sect. 7). It requires a careful choice of the right syntactical definitions for local sentences and, since the classical proofs in [11, 9] do not seem to generalise to semiring semantics, a new approach for the proof, based on quantifier elimination. This new approach also leads to a stronger version of Gaifman's theorem in Boolean semantics (6), which might be of independent interest.

## 2 Semiring Semantics

This section gives a brief overview on semiring semantics of first-order logic (see [16] for more details) and the relevant algebraic properties of semirings. A commutative<sup>1</sup> semiring is an algebraic structure  $(K, +, \cdot, 0, 1)$  with  $0 \neq 1$ , such that  $(K, +, 0)$  and  $(K, \cdot, 1)$  are commutative monoids,  $\cdot$  distributes over  $+$ , and  $0 \cdot a = a \cdot 0 = 0$ . We focus on semirings that are *naturally ordered*, in the sense that  $a \leq b \Leftrightarrow \exists c(a + c = b)$  is a partial order. For the study of locality properties, an important subclass are the *fully idempotent* semirings, in which both operations are idempotent (i.e.,  $a + a = a$  and  $a \cdot a = a$ ). Among these, we consider in particular all *min-max* semirings  $(K, \max, \min, 0, 1)$  induced by a total order  $(K, \leq)$  with minimal element 0 and maximal element 1, and the more general *lattice* semirings  $(K, \sqcup, \sqcap, 0, 1)$  induced by a bounded distributive lattice  $(K, \leq)$ .

For a finite relational vocabulary  $\tau$  and a finite universe  $A$ , we write  $\text{Lit}_A(\tau)$  for the set of *instantiated*  $\tau$ -literals  $R\bar{a}$  and  $\neg R\bar{a}$  with  $\bar{a} \in A^{\text{arity}(R)}$ . Given a commutative semiring  $K$ , a  $K$ -*interpretation* (of vocabulary  $\tau$  and universe  $A$ ) is a function  $\pi: \text{Lit}_A(\tau) \rightarrow K$ . It is *model-defining* if for any pair of complementary literals  $L, \neg L$  precisely one of the values  $\pi(L), \pi(\neg L)$  is 0. In this case,  $\pi$  induces a unique (Boolean)  $\tau$ -structure  $\mathfrak{A}_\pi$  with universe  $A$  such that, for every literal  $L \in \text{Lit}_A(\tau)$ , we have that  $\mathfrak{A}_\pi \models L$  if, and only if,  $\pi(L) \neq 0$ .

A  $K$ -interpretation  $\pi: \text{Lit}_A(\tau) \rightarrow K$  extends in a straightforward way to a valuation  $\pi[\![\varphi(\bar{a})]\!]$  of any instantiation of a formula  $\varphi(\bar{x}) \in \text{FO}(\tau)$ , assumed to be written in negation normal form, by a tuple  $\bar{a} \subseteq A$ . The semiring semantics  $\pi[\![\varphi(\bar{a})]\!]$  is defined by induction. We first extend  $\pi$  by mapping equalities and inequalities to their truth values, by setting  $\pi[\![a = a]\!] := 1$  and  $\pi[\![a = b]\!] := 0$  for  $a \neq b$  (and analogously for inequalities). Further, disjunctions and existential quantifiers are interpreted as sums, and conjunctions and universal quantifiers as products:

<sup>1</sup> In the following, *semiring* always refers to a commutative semiring.

$$\begin{aligned} \pi[\psi(\bar{a}) \vee \vartheta(\bar{a})] &:= \pi[\psi(\bar{a})] + \pi[\vartheta(\bar{a})] & \pi[\psi(\bar{a}) \wedge \vartheta(\bar{a})] &:= \pi[\psi(\bar{a})] \cdot \pi[\vartheta(\bar{a})] \\ \pi[\exists x \vartheta(\bar{a}, x)] &:= \sum_{a \in A} \pi[\vartheta(\bar{a}, a)] & \pi[\forall x \vartheta(\bar{a}, x)] &:= \prod_{a \in A} \pi[\vartheta(\bar{a}, a)]. \end{aligned}$$

Since negation does not correspond to a semiring operation, we insist on writing all formulae in negation normal form. This is a standard approach in semiring semantics (cf. [16]). Equivalence of formulae now takes into account the semiring values and is thus more fine-grained than Boolean equivalence.

► **Definition 1** ( $\equiv_K$ ). *Two formulae  $\psi(\bar{x})$ ,  $\varphi(\bar{x})$  are  $K$ -equivalent (denoted  $\psi \equiv_K \varphi$ ) if  $\pi[\psi(\bar{a})] = \pi[\varphi(\bar{a})]$  for every model-defining  $K$ -interpretation  $\pi$  (over finite universe) and every tuple  $\bar{a}$ . For a class  $\mathcal{S}$  of semirings, we write  $\psi \equiv_{\mathcal{S}} \varphi$  if  $\psi \equiv_K \varphi$  holds for all  $K \in \mathcal{S}$ .*

Towards locality properties, we define distances between two elements  $a, b$  in a  $K$ -interpretation  $\pi$  based on the induced structure  $\mathfrak{A}_\pi$ .

► **Definition 2** (Gaifman graph). *The Gaifman graph  $G(\pi)$  of a model-defining  $K$ -interpretation  $\pi: \text{Lit}_A(\tau) \rightarrow K$  is defined as the Gaifman graph  $G(\mathfrak{A}_\pi)$  of the induced  $\tau$ -structure. That is, two elements  $a \neq b$  of  $A$  are adjacent in  $G(\mathfrak{A}_\pi)$  if, and only if, there exists a positive literal  $L = Rc_1 \dots c_r \in \text{Lit}_A(\tau)$  such that  $\pi(L) \neq 0$  and  $a, b \in \{c_1, \dots, c_r\}$ .*

We write  $d(a, b) \in \mathbb{N}$  for the distance of  $a$  and  $b$  in  $G(\pi)$ . We further define the  $r$ -neighbourhood of an element  $a$  in  $\pi$  as  $B_r^\pi(a) := \{b \in A : d(a, b) \leq r\}$ . For a tuple  $\bar{a} \in A^k$  we put  $B_r^\pi(\bar{a}) := \bigcup_{i \leq k} B_r^\pi(a_i)$ .

Locality properties are really meaningful only for semiring interpretations  $\pi: \text{Lit}_A(\tau) \rightarrow K$  that *track only positive information*, which means that  $\pi(\neg L) \in \{0, 1\}$  for each negative literal  $\neg L$ . Indeed, if also negative literals carry non-trivial information, then either these must be taken into account in the definition of what “local” means, which will trivialise the Gaifman graph (making it a clique) so locality would become meaningless, or otherwise local information no longer suffices to determine values of even very simple sentences involving negative literals, such as  $\exists x \exists y \neg Rxy$ . We therefore consider here only  $K$ -interpretations over finite universes which are model-defining and track only positive information.

### 3 Hanf Locality

The first formalisation of locality that we consider is Hanf locality. We present generalisations of both the Hanf locality rank and of Hanf’s locality theorem, where the latter is conditional on algebraic properties of the semirings. One point that requires care in the adaptation of the classical proofs (cf. [9, 24]) is the combination of partial isomorphisms on disjoint and non-adjacent neighbourhoods. In the setting of semiring semantics, this depends on the assumption that  $K$ -interpretations only track positive information.

► **Lemma 3.** *Let  $\pi_A$  and  $\pi_B$  be model-defining  $K$ -interpretations that track only positive information. Let  $\sigma: B_r^{\pi_A}(\bar{a}) \rightarrow B_r^{\pi_B}(\bar{b})$  and  $\sigma': B_r^{\pi_A}(\bar{a}') \rightarrow B_r^{\pi_B}(\bar{b}')$  be two partial isomorphisms between disjoint  $r$ -neighbourhoods in  $\pi_A$  and  $\pi_B$ . If  $d(\bar{a}, \bar{a}') > 2r + 1$  and  $d(\bar{b}, \bar{b}') > 2r + 1$ , then  $(\sigma \cup \sigma'): B_r^{\pi_A}(\bar{a}, \bar{a}') \rightarrow B_r^{\pi_B}(\bar{b}, \bar{b}')$  is also a partial isomorphism.*

In classical Boolean semantics, a formula  $\psi(\bar{x})$  is *Hanf-local with Hanf locality rank  $r$* , if for any two tuples  $\bar{a}$  in  $\mathfrak{A}$  and  $\bar{b}$  in  $\mathfrak{B}$  we have the equivalence that  $\mathfrak{A} \models \psi(\bar{a}) \Leftrightarrow \mathfrak{B} \models \psi(\bar{b})$  whenever there is a bijection  $f: A \rightarrow B$  such that the  $r$ -neighbourhoods  $B_r^{\mathfrak{A}}(\bar{a}, c)$  and

$B_r^{\mathfrak{A}}(\bar{b}, f(c))$  are isomorphic for all  $c \in A$ . It is known that every first-order formula is Hanf-local, with locality rank depending only on the quantifier rank. The proof of this fact [24] relies on an inductive argument which, from given bijections between  $(3r+1)$ -neighbourhoods of  $k$ -tuples, builds bijections between  $r$ -neighbourhoods of  $(k+1)$ -tuples. Based on Lemma 3, the inductive argument can be adapted to semiring semantics to get the following result, which does not assume any specific properties of the underlying semiring (for details, see [6]).

► **Proposition 4** (Hanf locality in semiring semantics). *Let  $K$  be an arbitrary semiring. For every first-order formula  $\varphi(\bar{x})$ , there exists  $r \in \mathbb{N}$ , depending only on the quantifier rank of  $\varphi$ , such that for all model-defining  $K$ -interpretations  $\pi_A, \pi_B$  that track only positive information, and all tuples  $\bar{a}, \bar{b}$  we have that  $\pi_A[\varphi(\bar{a})] = \pi_B[\varphi(\bar{b})]$  whenever there is a bijection  $f: A \rightarrow B$  such that  $B_r^{\pi_A}(\bar{a}, c) \cong B_r^{\pi_B}(\bar{b}, f(c))$  for all  $c \in A$ .*

A much more fundamental result is *Hanf's locality theorem* which provides a sufficient combinatorial criterion for the  $m$ -equivalence of two structures, i.e. for their indistinguishability by sentences of quantifier rank up to  $m$ . We follow the classical proof in [9], which proceeds by showing that Hanf's criterion admits the construction of a back-and-forth system  $(I_j)_{j \leq m}$  which, by the Ehrenfeucht-Fraïssé theorem, implies the  $m$ -equivalence of the two structures. It turns out that this method carries over to  $K$ -interpretations precisely in the case that the semiring  $K$  is fully idempotent. We further show that for semirings that are not fully idempotent, there actually are counterexamples to Hanf's locality theorem.

To define back-and-forth systems between  $K$ -interpretations, first notice that the notion of partial isomorphisms generalises in an obvious way to  $K$ -interpretations (cf. [6]).

► **Definition 5** (Back-and-forth system). *Let  $\pi_A$  and  $\pi_B$  be two  $K$ -interpretations and let  $k \geq 0$ . A  $m$ -back-and-forth system for  $\pi_A$  and  $\pi_B$  is a sequence  $(I_j)_{j \leq m}$  of finite sets of partial isomorphisms between  $\pi_A$  and  $\pi_B$  such that*

- $\emptyset \in I_m$ , and
- for all  $j < m$ , the set  $I_{j+1}$  has back-and-forth extensions in  $I_j$ , i.e., whenever  $\bar{a} \mapsto \bar{b} \in I_{j+1}$  then for every  $c \in A$  there exists  $d \in B$ , and vice versa, such that  $(\bar{a}c) \mapsto (\bar{b}d)$  is in  $I_j$ .

We write  $(I_j)_{j \leq m}: \pi_A \cong_m \pi_B$  if  $(I_j)_{j \leq m}$  is a  $m$ -back-and-forth system for  $\pi_A$  and  $\pi_B$ .

Back-and-forth systems can be seen as algebraic descriptions of winning strategies in Ehrenfeucht-Fraïssé games, and in classical semantics, an  $m$ -back-and-forth system between two structures exists if, and only if, the structures are  $m$ -equivalent. However, in semiring semantics this equivalence may, in general, fail in both directions [7]. A detailed investigation of the relationship between elementary equivalence, Ehrenfeucht-Fraïssé games, and back-and-forth-systems in semiring semantics is outside the scope of this paper, and will be presented in forthcoming work. For the purpose of studying Hanf locality, we shall need just the fact that in the specific case of fully idempotent semirings,  $m$ -back-and-forth systems do indeed provide a sufficient criterion for  $m$ -equivalence.

► **Proposition 6.** *Let  $\pi_A$  and  $\pi_B$  be  $K$ -interpretations into a fully idempotent semiring  $K$ . If there is an  $m$ -back-and-forth system  $(I_j)_{j \leq m}$  for  $\pi_A$  and  $\pi_B$ , then  $\pi_A \equiv_m \pi_B$ .*

**Proof.** We show by induction that for every first-order formula  $\psi(\bar{x})$  of quantifier rank  $j \leq m$  and every partial isomorphism  $\bar{a} \mapsto \bar{b} \in I_j$  we have that  $\pi_A[\psi(\bar{a})] = \pi_B[\psi(\bar{b})]$ . For  $j = 0$  this is trivial. For the inductive case it suffices to consider formulae  $\psi(\bar{x}) = \exists y \varphi(\bar{x}, y)$  and  $\psi(\bar{x}) = \forall y \varphi(\bar{x}, y)$ , and a map  $\bar{a} \mapsto \bar{b} \in I_{j+1}$ . We have that

$$\begin{aligned} \pi_A[\exists y \varphi(\bar{a}, y)] &= \sum_{c \in A} \pi_A[\varphi(\bar{a}, c)] & \text{and} & & \pi_B[\exists y \psi(\bar{b}, y)] &= \sum_{d \in B} \pi_B[\varphi(\bar{b}, d)], \\ \pi_A[\forall y \varphi(\bar{a}, y)] &= \prod_{c \in A} \pi_A[\varphi(\bar{a}, c)] & \text{and} & & \pi_B[\forall y \psi(\bar{b}, y)] &= \prod_{d \in B} \pi_B[\varphi(\bar{b}, d)]. \end{aligned}$$

Since the semiring is fully idempotent, the valuations  $\pi_A[\exists y \varphi(\bar{a}, y)]$  and  $\pi_A[\forall y \varphi(\bar{a}, y)]$  only depend on the *set* of all values  $\pi_A[\varphi(\bar{a}, c)]$  for  $c \in A$ , and not on their multiplicities. It thus suffices to prove that the sets of values are identical for  $(\pi_A, \bar{a})$  and  $(\pi_B, \bar{b})$ , i.e.

$$\{\pi_A[\varphi(\bar{a}, c)] : c \in A\} = \{\pi_B[\varphi(\bar{b}, d)] : d \in B\}.$$

But this follows immediately from the fact that  $\bar{a} \mapsto \bar{b}$  has back and forth extensions in  $I_j$ , and from the induction hypothesis: for each  $c \in A$  there exists some  $d \in B$ , and vice versa, such that the map  $(\bar{a}, c) \mapsto (\bar{b}, d)$  is in  $I_j$ , and therefore  $\pi_A[\varphi(\bar{a}, c)] = \pi_B[\varphi(\bar{b}, d)]$ .  $\blacktriangleleft$

To formulate Hanf's criterion for  $K$ -interpretations  $\pi_A, \pi_B$ , we write  $\pi_A \rightleftharpoons_{r,t} \pi_B$ , for  $r, t \in \mathbb{N}$ , if for every isomorphism type  $\iota$  of  $r$ -neighbourhoods, either  $\pi_A$  and  $\pi_B$  have the same number of realisations of  $\iota$ , or both have at least  $t$  realisations.

► **Theorem 7** (Hanf's theorem for fully idempotent semirings). *Let  $K$  be a fully idempotent semiring. For all  $m, \ell \in \mathbb{N}$  there exist  $r = r(m) \in \mathbb{N}$  and  $t = t(m, \ell) \in \mathbb{N}$  such that for all model-defining  $K$ -interpretations  $\pi_A$  and  $\pi_B$  that track only positive information and whose Gaifman graphs have maximal degree  $\leq \ell$ , we have that  $\pi_A \equiv_m \pi_B$  whenever  $\pi_A \rightleftharpoons_{r,t} \pi_B$ .*

**Proof.** Given  $m, \ell \in \mathbb{N}$ , let  $r_0 = 0$ , inductively define  $r_{i+1} = 3r_i + 1$ , and set  $r = r_{m-1}$ . Further, let  $t = m \cdot e + 1$ , where  $e := 1 + \ell + \ell^2 + \dots + \ell^r$  is the maximal number of elements in an  $r$ -neighbourhood of a point, in  $K$ -interpretations with Gaifman graphs with maximal degree  $\ell$ . Assume that  $\pi_A$  and  $\pi_B$  are  $K$ -interpretations with that property, such that  $\pi_A \rightleftharpoons_{r,t} \pi_B$ .

We construct an  $m$ -back-and-forth system  $(I_j)_{j \leq m}$  for  $(\pi_A, \pi_B)$  by setting

$$I_j := \{\bar{a} \mapsto \bar{b} : |\bar{a}| = |\bar{b}| = m - j \text{ and } B_{r_j}^{\pi_A}(\bar{a}) \cong B_{r_j}^{\pi_B}(\bar{b})\}.$$

We have  $I_m = \{\emptyset\}$ , and since  $\pi_A \rightleftharpoons_{r,t} \pi_B$ , we have for every  $a \in A$  some  $b \in B$ , and vice versa, such that  $B_r^{\pi_A}(a) \cong B_r^{\pi_B}(b)$ , so  $I_m$  has back-and-forth extensions in  $I_{m-1}$ . Consider now a partial isomorphism  $\bar{a} \mapsto \bar{b}$  in  $I_{j+1}$ . There is an isomorphism  $\rho: B_{3r_j+1}^{\pi_A}(\bar{a}) \cong B_{3r_j+1}^{\pi_B}(\bar{b})$ . By symmetry, it suffices to prove the forth-property: for every  $a \in A$  we must find some  $b \in B$  such that  $\bar{a}a \mapsto \bar{b}b \in I_j$  which means that  $B_{r_j}^{\pi_A}(\bar{a}a) \cong B_{r_j}^{\pi_B}(\bar{b}b)$ .

*Case 1 (a close to  $\bar{a}$ ).* If  $a \in B_{2r_j+1}^{\pi_A}(\bar{a})$ , then we choose  $b = \rho(a) \in B_{2r_j+1}^{\pi_B}(\bar{b})$ . This is a valid choice since  $B_{r_j}^{\pi_A}(\bar{a}a) \subseteq B_{3r_j+1}^{\pi_A}(\bar{a})$  so  $\rho$  also provides an isomorphism between  $B_{r_j}^{\pi_A}(\bar{a}a)$  and  $B_{r_j}^{\pi_B}(\bar{b}b)$ .

*Case 2 (a far from  $\bar{a}$ ).* If  $a \notin B_{2r_j+1}^{\pi_A}(\bar{a})$ , then  $B_{r_j}^{\pi_A}(a) \cap B_{r_j}^{\pi_A}(\bar{a}) = \emptyset$ . Hence, it suffices to find  $b \in B$  such that  $B_{r_j}^{\pi_B}(b)$  has the same isomorphism type as  $B_{r_j}^{\pi_A}(a)$  (call this  $\iota$ ) with the property that  $b$  has distance at least  $2r_j + 2$  to  $\bar{b}$ . Since  $\pi_A$  and  $\pi_B$  only track positive information the isomorphisms can be combined by Lemma 3 to show that  $B_{r_j}^{\pi_A}(\bar{a}a) \cong B_{r_j}^{\pi_B}(\bar{b}b)$ .

Assume that no such  $b$  exists. Let  $s$  be the number of elements realising  $\iota$  in  $\pi_B$ . Since all of them have distance at most  $2r_j + 1$  from  $\bar{b}$  and there are at most  $t$  elements in  $r$ -neighbourhoods around  $\bar{b}$ , we have that  $s \leq t$ . On the other side there are at least  $s + 1$  elements realising  $\iota$  in  $\pi_A$ , namely  $s$  elements in  $B_{2r_j+1}^{\pi_A}(\bar{a})$  (due to  $\rho$ ) and  $a$ . But this

contradicts the fact that  $\iota$  either has the same number of realisations in  $\pi_A$  and  $\pi_B$ , or more than  $t$  realisations in both interpretations. Hence such an element  $b$  exists, and we have proved that  $(I_j)_{j \leq m}$  is indeed a  $m$ -back-and-forth system for  $(\pi_A, \pi_B)$ .

By Proposition 6 this implies that  $\pi_A \equiv_m \pi_B$ .  $\blacktriangleleft$

On the other side, we observe that Hanf's locality theorem in general *fails* for semirings with non-idempotent operations.

► **Example 8 (Counterexample Hanf).** Consider the natural semiring  $(\mathbb{N}, +, \cdot, 0, 1)$  and  $\psi = \exists x Ux$  over signature  $\tau = \{U\}$ . For each  $n$ , we define a model-defining  $K$ -interpretation  $\pi_n$  with universe  $\{a_1, \dots, a_n\}$  by setting  $\pi(Ua_i) = 1$  for all  $i$ . Then  $\pi_n \llbracket \psi \rrbracket = \sum_i \pi(Ua_i) = n$ .

As we only have unary predicates, all neighbourhoods are trivial. That is, they consist of just one element and all of them have the same isomorphism type. Thus,  $\pi_n$  realises this single isomorphism type precisely  $n$  times, which means that  $\pi_n \rightleftharpoons_{r,t} \pi_t$  for all  $r, t$  with  $n \geq t$ . But  $\pi_n \llbracket \psi \rrbracket \neq \pi_t \llbracket \psi \rrbracket$  for  $n \neq t$ , so Hanf's theorem fails for the natural semiring.

This example readily generalises to all semirings containing an element  $s \in K$  for which there are arbitrarily large numbers  $n, m \in \mathbb{N}$  with  $m \cdot s \neq n \cdot s$  or  $s^m \neq s^n$  ( $m \cdot s$  and  $s^m$  refer to the  $m$ -fold addition and multiplication of  $s$ , respectively). Indeed, we can map all atoms  $Ua_i$  to  $s$  and observe that Hanf's theorem fails for either  $\psi = \exists x Ux$  or  $\psi = \forall x Ux$ .  $\blacktriangleright$

## 4 Gaifman Normal Forms in Semirings Semantics

We briefly recall the classical notion of Gaifman normal forms (cf. [11, 9]), which capture locality in a syntactic way. Gaifman normal forms are Boolean combinations of *local formulae*  $\varphi^{(r)}(x)$  and *basic local sentences*. A local formula  $\varphi^{(r)}(x)$  is a formula in which all quantifiers are *relativised* to the  $r$ -neighbourhood of  $x$ , for instance  $\exists y \vartheta(x, y)$  is relativised to  $\exists y (d(x, y) \leq r \wedge \vartheta(x, y))$ . Here,  $d(x, y) \leq r$  asserts that  $x$  and  $y$  have distance  $\leq r$  in the Gaifman graph, which can easily be expressed in first-order logic (in Boolean semantics). A basic local sentence asserts that there exist *scattered* elements, i.e., elements with distinct  $r$ -neighbourhoods, which all satisfy the same  $r$ -local formula:  $\exists x_1 \dots \exists x_m (\bigwedge_{i \neq j} d(x_i, x_j) > 2r \wedge \bigwedge_i \varphi^{(r)}(x_i))$ . By Gaifman's theorem, every formula has an equivalent Gaifman normal form, which intuitively means that it only makes statements about distinct local neighbourhoods.

Moving to semiring semantics, we keep the notion of Gaifman normal forms close to the original one, with two exceptions. First, we only consider formulae in negation normal form. This means that we restrict to *positive* Boolean combinations and, in turn, permit the duals of basic local sentences (i.e., the negations of basic local sentences, in negation normal form). Second and most importantly, we lose the ability to express relativised quantifiers<sup>2</sup> in our logic. Instead, we extend first-order logic by adding relativised quantifiers (*ball quantifiers*) of the form  $Qy \in B_r^\tau(x)$  for  $Q \in \{\exists, \forall\}$  with the following semantics: given a formula  $\varphi(x, y)$ , a  $K$ -interpretation  $\pi: \text{Lit}_A(\tau) \rightarrow K$ , and an element  $a$ , we define

$$\pi \llbracket \exists y \in B_r^\tau(a) \varphi(a, y) \rrbracket := \sum_{b \in B_r^\pi(a)} \pi \llbracket \varphi(a, b) \rrbracket, \quad \pi \llbracket \forall y \in B_r^\tau(a) \varphi(a, y) \rrbracket := \prod_{b \in B_r^\pi(a)} \pi \llbracket \varphi(a, b) \rrbracket.$$

We drop  $\tau$  and write  $\exists y \in B_r(a)$  or  $\forall y \in B_r(a)$  if the signature is clear from the context.

<sup>2</sup> We could use the same formula for  $d(x, y) \leq r$  as in the Boolean case. However, this formula would not just evaluate to 0 or 1, but would include the values of all edges around  $x$ , so each relativised quantifier would have the unintended side-effect of multiplying with the edge values in the neighbourhood. One can show that this side-effect would make Gaifman normal forms impossible (see [6] for details).

$$\varphi^{(r)}(x, y) =$$

$$\forall z_1 \in B_{r_1}(x) (\exists z_2 \in B_{r_2}(z_1) \forall z_3 \in B_{r_3}(z_1) \neg E z_2 z_3) \\ \vee \forall z_4 \in B_{r_4}(y) E x z_4$$

■ **Figure 1** Example of a local formula and the corresponding quantification dag  $D(\varphi)$ , with circles indicating  $B_r(xy)$ . In this example,  $\varphi^{(r)}(x, y)$  is  $r$ -local for all  $r \geq \max(r_1 + r_2, r_1 + r_3, r_4)$ .

This alone is not as expressive as the Boolean notion. For instance, consider  $\varphi^{(r)}(x) = \exists y(d(x, y) \leq \frac{r}{2} \wedge \exists z(d(x, z) \leq r \wedge d(y, z) \leq \frac{r}{2} \wedge \dots))$  which quantifies  $z$  local around  $y$ . Using ball quantifiers, we want to write this as  $\varphi^{(r)}(x) = \exists y \in B_{\frac{r}{2}}(x) (\exists z \in B_{\frac{r}{2}}(y) \dots)$ , so we also permit ball quantifiers around previously quantified variables (here  $y$ ), as long as they stay within the  $r$ -neighbourhood of  $x$  (here:  $\frac{r}{2} + \frac{r}{2} \leq r$ ).

To formalise this condition, we consider the *quantification dag*  $D(\varphi)$  of a formula  $\varphi(\bar{x})$  which contains nodes for all variables in  $\varphi$  and where for every quantifier  $Qz \in B_{r'}(y)$  in  $\varphi$ , we add an edge  $z \rightarrow y$  with distance label  $r'$  (see Figure 1). If the summed distance of any path ending in a free variable  $x \in \bar{x}$  is at most  $r$ , then  $\varphi$  is  $r$ -local.

► **Definition 9 (Local formula).** An  $r$ -local  $\tau$ -formula around  $\bar{x}$ , denoted  $\varphi^{(r)}(\bar{x})$ , is built from  $\tau$ -literals by means of  $\wedge$ ,  $\vee$  and ball quantifiers  $Qz \in B_{r'}(y)$  such that in the associated quantification dag  $D(\varphi)$ , all paths ending in a free variable  $x \in \bar{x}$  have total length at most  $r$ .

We emphasise that in the Boolean case, Definition 9 is equivalent to the standard notion, so we do not add expressive power. For convenience, we allow quantification  $Qz \in B_{r'}(\bar{y}) \varphi(\bar{y}, z)$  around a tuple  $\bar{y}$ , which can easily be simulated by regular ball quantifiers.

For basic local sentences, we further need to quantify over scattered tuples. To this end, we also add *scattered quantifiers*  $\exists^{r\text{-sc}}(\bar{y})$  and  $\forall^{r\text{-sc}}(\bar{y})$  with the following semantics:

$$\pi[\exists^{r\text{-sc}}(\bar{y}) \varphi(\bar{y})] = \sum_{\substack{\bar{a} \subseteq A \\ d(a_i, a_j) > 2r \text{ for } i \neq j}} \pi[\varphi(\bar{a})], \quad \pi[\forall^{r\text{-sc}}(\bar{y}) \varphi(\bar{y})] = \prod_{\substack{\bar{a} \subseteq A \\ d(a_i, a_j) > 2r \text{ for } i \neq j}} \pi[\varphi(\bar{a})].$$

We remark that in idempotent semirings, which will be the main focus of our positive results, the addition of ball quantifiers makes it possible to express  $d(x, y) \leq r$  by a formula that only assumes values 0 or 1, such as  $\exists x' \in B_{\frac{r}{2}}(x) \exists y' \in B_{\frac{r}{2}}(y) (x' = y')$ , which is  $\frac{r}{2}$ -local around  $xy$ , or alternatively  $\exists x' \in B_r(x) (x' = y)$ , which is  $r$ -local only around  $x$ . Analogously for  $d(x, y) > r$ , so we permit the use of distance formulae to simplify notation whenever we work in idempotent semirings. Scattered quantifiers can then easily be expressed as  $\exists^{r\text{-sc}}(y_1, \dots, y_m) \vartheta(\bar{y}) := \exists y_1 \dots \exists y_m (\bigwedge_{i < j} d(y_i, y_j) > 2r \wedge \vartheta(\bar{y}))$  and  $\forall^{r\text{-sc}}(y_1, \dots, y_m) \vartheta(\bar{y}) := \forall y_1 \dots \forall y_m (\bigvee_{i < j} d(y_i, y_j) \leq 2r \vee \vartheta(\bar{y}))$ .

► **Definition 10 (Local sentence).** A basic local sentence is a sentence of the form

$$\exists^{r\text{-sc}}(y_1, \dots, y_m) \bigwedge_{i \leq m} \varphi^{(r)}(y_i) \quad \text{or} \quad \forall^{r\text{-sc}}(y_1, \dots, y_m) \bigvee_{i \leq m} \varphi^{(r)}(y_i).$$

A local sentence is a positive Boolean combination of basic local sentences.

Based on these notions we can now formulate precisely the questions about Gaifman normal forms in semiring semantics:

- (1) For which semirings  $K$  does every first-order *sentence* have a  $K$ -equivalent local sentence?
- (2) For which semirings  $K$  is it the case that every first-order *formula* is  $K$ -equivalent to a positive Boolean combination of local formulae and basic local sentences?

## 5 Counterexamples Against Gaifman Normal Forms

This section presents two examples for which a Gaifman normal form does not exist. Both use the vocabulary  $\tau = \{U\}$  with only unary predicates, so that the Gaifman graph  $G(\pi)$  of any  $K$ -interpretation  $\pi: \text{Lit}_A(\tau) \rightarrow K$  is trivial and the  $r$ -neighbourhood of a point, for any  $r$ , consists only of the point itself. Thus, local formulae  $\varphi^{(r)}(x)$  around  $x$  can always be written as positive Boolean combinations of literals  $Ux$ ,  $\neg Ux$  and equalities  $x = x$ ,  $x \neq x$ . Scattered tuples are simply distinct tuples, so we write  $\exists^{\text{distinct}}(\bar{x})$  instead of  $\exists^{r\text{-sc}}(\bar{x})$ .

### 5.1 A Formula Without a Gaifman Normal Form

Consider the formula  $\psi(x) := \exists y(Uy \wedge y \neq x)$  which, in classical Boolean semantics, has the Gaifman normal form  $\varphi(x) := \exists^{\text{distinct}}(y, z)(Uy \wedge Uz) \vee (\neg Ux \wedge \exists y Uy)$ . However, in semiring semantics it is in general not the case that  $\psi(x) \equiv_K \varphi(x)$ . Here we consider the specific case of a universe with two elements  $A = \{a, b\}$  and  $K$ -interpretations  $\pi_{st}$  with  $\pi_{st}(Ua) = s$  and  $\pi_{st}(Ub) = t$ , where  $s, t \in K \setminus \{0\}$  and  $s \neq t$ . Then  $\pi_{st}[\psi(a)] = t$  but  $\pi_{st}[\varphi(a)] = st + ts$ . So, unless  $K$  is the Boolean semiring, we find elements  $s, t$  where  $\pi_{st}[\psi(a)] \neq \pi_{st}[\varphi(a)]$ .

Of course, it might still be the case that there is a different Gaifman normal form of  $\psi(x)$  for semiring interpretations in a specific semiring  $K$ . We prove that this is not the case.

► **Proposition 11.** *In any naturally ordered semiring with at least three elements, the formula  $\psi(x) = \exists y(Uy \wedge y \neq x)$  does not have a Gaifman normal form.*

For the proof, we describe the values that the building blocks of Gaifman normal forms may assume in  $\pi_{st}$ . Recall that a local formula  $\alpha(x)$  is equivalent to a positive Boolean combination of literals  $Ux$ ,  $\neg Ux$ , and equalities. Since  $\pi_{st}(\neg Ux) = 0$  for all  $x \in A$ , we can view the evaluation  $\pi_{st}[\alpha(a)]$  as an expression built from the semiring operations, the value  $\pi_{st}(Ua) = s$  and constants 0, 1. Analogously for  $\pi_{st}[\alpha(b)]$ , but using  $\pi_{st}(Ub) = t$  instead of  $s$ . Hence there is a polynomial  $p_\alpha(X) \in K[X]$  such that  $\pi_{st}[\alpha(a)] = p_\alpha(s)$  and  $\pi_{st}[\alpha(b)] = p_\alpha(t)$ , for all interpretations  $\pi_{st}$ . For the evaluation of a basic local sentence  $\beta = \exists^{\text{distinct}}(y, z)(\alpha(y) \wedge \alpha(z))$ , we then obtain  $\pi_{st}[\beta] = p_\alpha(s)p_\alpha(t) + p_\alpha(t)p_\alpha(s)$ . That is,  $\beta$  can be described by a polynomial  $p_\beta(X, Y) \in K[X, Y]$  such that  $\pi_{st}[\beta] = p_\beta(s, t)$  and  $p_\beta$  is *symmetric* (that is,  $p_\beta(X, Y) = p_\beta(Y, X)$ ). The same holds for universal basic local sentences  $\beta = \forall^{\text{distinct}}(y, z)(\alpha(y) \vee \alpha(z))$ .

Every Gaifman normal form  $\varphi(x)$  can thus be represented by a polynomial  $f_\varphi(X, Y) = \sum_i h_i(X)g_i(X, Y)$ , with symmetric  $g_i$ , such that  $\pi_{st}[\varphi(a)] = f_\varphi(s, t)$  for all  $s, t$ . Proposition 11 then follows from the following algebraic observation (see [6] for a proof).

► **Lemma 12.** *Let  $K$  be a naturally ordered semiring with at least three elements. For any polynomial  $f(X, Y) = \sum_i h_i(X)g_i(X, Y)$  where the  $g_i$  are symmetric polynomials, there exist values  $s, t \in K \setminus \{0\}$  such that  $f(s, t) \neq t$ .*

### 5.2 A Sentence Without a Gaifman Normal Form

While Gaifman normal forms need not exist for formulae, in all relevant semirings beyond the Boolean one, they might still exist for sentences. Indeed, we shall prove a positive result for min-max semirings. However, such a result seems only possible for semirings where both operations are idempotent, similar to Hanf's theorem. For other semirings one can find rather simple counterexamples, as we illustrate for the tropical semiring  $\mathbb{T} = (\mathbb{R}_+^\infty, \min, +, \infty, 0)$ .

► **Proposition 13.** *The sentence  $\psi := \exists z \forall x \exists y(Uy \vee x = z)$  has no Gaifman normal form in the tropical semiring.*

The proof again works by describing the values of basic local sentences, this time in  $\mathbb{T}$ -interpretations of increasingly large size. One can then show that these values are either constant or grow too fast, compared to the value of  $\psi$  (see [6] for details). A similar construction works for the natural semiring  $(\mathbb{N}, +, \cdot, 0, 1)$  and we conjecture that it can be adapted to any infinite semiring with operations that are not idempotent.

## 6 Gaifman's Theorem for Min-Max Semirings

In this section, we prove our main result: a version of Gaifman's theorem for sentences evaluated in min-max semirings (which can be lifted to lattice semirings, see Sect. 7). We write  $\mathcal{M}$  for the class of min-max semirings and refer to  $\equiv_{\mathcal{M}}$  as *minmax-equivalence*.

► **Theorem 14** (Gaifman normal form). *Let  $\tau$  be a finite relational signature. Every  $\text{FO}(\tau)$ -sentence  $\psi$  is minmax-equivalent ( $\equiv_{\mathcal{M}}$ ) to a local sentence.*

Contrary to Hanf's locality theorem, we cannot follow the classical proofs of Gaifman's theorem. For instance, the proof in [9] is based on the Ehrenfeucht-Fraïssé method and makes use of characteristic sentences, which in general do not exist in semiring semantics over min-max semirings (cf. [15]). Gaifman's original proof [11] is a constructive quantifier elimination argument (which is similar to our approach), but makes use of negation to encode case distinctions in the formula, which is not possible in semiring semantics. Another argument why Gaifman's proof does not go through is that it applies to formulae, whereas formulae need not have Gaifman normal forms in our setting (cf. Sect. 5.1).

Instead, we present a novel proof of Gaifman's theorem that applies to the Boolean case as well as to min-max semirings. While our strategy is similar to Gaifman's – a constructive elimination of quantifier alternations – we have to phrase all results in terms of sentences and need to be more careful to derive equivalences that hold in all min-max semirings. These restrictions lead to a slight strengthening of Gaifman's classical result (see Sect. 7).

### 6.1 Toolbox

The proof is rather technical, but is based on a few simple observations. First notice that min-max semirings share many algebraic properties with the Boolean semiring. As a consequence, many classical logical equivalences are also minmax-equivalences, such as distributivity or idempotence. In particular, we can make use of disjunctive normal forms, conjunctive normal forms and prenex normal forms. Moreover, we can exploit the inherent symmetry of min-max semirings to simplify our proofs: arguments for existential sentences can be dualised for universal sentences (see [6] for details). However, we still have to consider quantifier alternations, which pose the main challenge.

Concerning locality, we make two simple but crucial observations. For the first one, consider a local formula  $\varphi^{(r)}(x, y)$  around two variables  $x$  and  $y$ . Such a formula may assert that  $x$  and  $y$  are close to each other, for instance  $\varphi^{(r)}(x, y) = Exy$ . But if  $x$  and  $y$  do not occur together within one literal, then  $\varphi^{(r)}$  intuitively makes independent statements about the neighbourhood of  $x$ , and the neighbourhood of  $y$ , so we can split  $\varphi^{(r)}$  into two separate local formulae. For the general case  $\varphi^{(r)}(\bar{x})$  in several variables, we group  $\bar{x}$  into tuples  $\bar{x}^1, \dots, \bar{x}^n$  with the idea that  $\varphi^{(r)}$  makes independent statements about each group  $\bar{x}^i$ .

► **Lemma 15** (Separation). *Let  $\varphi^{(r)}(\bar{x}^1, \dots, \bar{x}^n)$  be a local formula around  $\bar{x}^1 \dots \bar{x}^n$  and define  $X_i$  as the set of variables connected to some  $x \in \bar{x}^i$  in  $D(\varphi)$ . If each literal of  $\varphi^{(r)}(\bar{x}^1, \dots, \bar{x}^n)$  uses only variables in  $\bar{x}^i \cup X_i$  for a single  $i$ , then  $\varphi^{(r)}(\bar{x}^1, \dots, \bar{x}^n)$  is minmax-equivalent to a positive Boolean combination of  $r$ -local formulae around a single group  $\bar{x}^i$ .*

The second observation is that we can perform a clustering of any tuple  $(a_1, \dots, a_n) \in A^n$  into classes  $I_1, \dots, I_k$  so that elements within one class have “small” distance to each other, whereas different classes are “far apart”. This simple combinatorial observation is a fruitful tool to construct Gaifman normal forms: it becomes easy to quantify elements with a known clustering, and by the following lemma we can then do a disjunction over all clusterings.

► **Definition 16** (Configuration). *Let  $\pi$  be a  $K$ -interpretation with universe  $A$ . Let  $P = \{I_1, \dots, I_k\}$  be a partition of  $\{1, \dots, n\}$  and define representatives  $i_l = \min I_l$  of each class. We say that a tuple  $(a_1, \dots, a_n) \in A^n$  is in configuration  $(P, r)$ , if*

- (a)  $d(a_{i_l}, a_{i_{l'}}) \leq 5^{n-k}r - r$ , for all  $i \in I_l, l \in \{1, \dots, k\}$ , and
- (b)  $d(a_{i_l}, a_{i_{l'}}) > 4 \cdot 5^{n-k}r$ , for all  $l \neq l'$  (representatives are  $(2 \cdot 5^{n-k}r)$ -scattered).

Such a partition always exists: condition (a) remains true if we merge two classes violating (b), so starting from  $P = \{\{1\}, \dots, \{n\}\}$  we can merge classes until (b) holds.

► **Lemma 17** (Clustering). *Let  $\pi$  be a  $K$ -interpretation on  $A$ . For all tuples  $(a_1, \dots, a_n) \in A^n$  and all  $r \geq 1$ , there is a partition  $P$  such that  $(a_1, \dots, a_n)$  is in configuration  $(P, r)$ .*

## 6.2 Proof Outline for Gaifman’s Theorem

The heart of our proof is the elimination of quantifier alternations. Due to space reasons, we refer to the full version [6] for detailed proofs. Here we present an overview of the main steps. Each step proves, building on the previous ones, that sentences of a certain fragment can be translated to minmax-equivalent local sentences. These fragments consist of

- (1) sentences of the form  $\exists^{r\text{-sc}}(x_1, \dots, x_m) \bigwedge_{i \leq m} \varphi_i^{(r)}(x_i)$ ;
- (2) existential sentences  $\exists \bar{x} \varphi^{(r)}(\bar{x})$ ;
- (3) existential-universal sentences  $\exists \bar{y} \forall \bar{x} \varphi^{(r)}(\bar{y}, \bar{x})$ ;
- (4) all first-order sentences (Theorem 14).

We first note that Theorem 14 (step (4)) is a rather simple consequence of (2) and (3). By applying (3) and putting the resulting local sentence in prenex normal form, we can bring  $\exists^* \forall^*$ -sentences into  $\forall^* \exists^*$ -form. We can thus inductively<sup>3</sup> eliminate quantifier alternations by swapping quantifiers, until at most one alternation remains and (2) or (3) apply directly.

For step (1), note that the difference to a basic local sentence is that we permit different local formulae  $\varphi_i^{(r)}$  for each  $x_i$  (such sentences have been called *asymmetric* in [20, 8]). Our proof is an inductive construction of the equivalent local sentence. This step is quite technical, but greatly simplifies the following constructions.

To prove (2), we have to rewrite the  $\exists^*$ -prefix as a scattered quantifier  $\exists^{r\text{-sc}}(\bar{x})$ . This essentially follows from the Clustering and Separation Lemmas: for a given partition  $P = \{I_1, \dots, I_k\}$  we can do a scattered quantification of the representatives  $x_{i_1}, \dots, x_{i_k}$ , and then quantify the elements of each class  $I_l$  locally around its representative  $x_{i_l}$ .

Step (3) is the core of the elimination argument and the most difficult step of the proof. We roughly follow the structure of Gaifman’s proof [11] and, for a sentence  $\exists \bar{y} \forall \bar{x} \varphi^{(r)}(\bar{y}, \bar{x})$ , first split  $\forall \bar{x}$  into those elements close to  $\bar{y}$  (which we can quantify locally within  $\varphi$ ) and those elements far from  $\bar{y}$ , using the Separation Lemma. Eventually, we arrive at a positive Boolean combination of sentences  $\exists \bar{y} (\varphi_{\text{close}}^{(r)}(\bar{y}) \wedge \forall x \notin B_s(\bar{y}) \varphi_{\text{far}}^{(s)}(x))$ . Here, the far elements

<sup>3</sup> An attentive reader may notice that we have to deal with formulae with free variables in the induction, but (2), (3) only apply to sentences. We resolve this issue by temporarily substituting atoms with free variables by fresh relation symbols, without affecting the Gaifman graph (see [6, Abstraction Lemma]).

are covered by the *outside quantifier*  $\forall x \notin B_s(\bar{y})$  with the obvious semantics. As in Gaifman’s proof, the main challenge is the elimination of this outside quantifier. Gaifman approaches this by using negation to encode case distinctions in the Gaifman normal form. Our proof instead consists of a series of surprisingly difficult syntactical transformations that avoid negation, eventually leading to a minmax-equivalent local sentence without outside quantifiers.

## 7 Strengthening Gaifman’s Theorem

In this section, we rephrase our main result in terms of Boolean semantics, which leads to a novel strengthening of Gaifman’s classical theorem. Interestingly, Theorem 14 can be regained from the Boolean result by algebraic techniques, and even lifted to lattice semirings. These insights suggest that the merit of our proof, and the reason why it is more complicated than Gaifman’s original proof, is the construction of a Gaifman normal form without the use of negation. Since our proof applies in particular to the Boolean semiring and hence to standard Boolean semantics (the only difference is that we use ball quantifiers instead of distance formulae, but these are interchangeable), we obtain the following corollary.

► **Corollary 18** (Gaifman normal form without negation). *Let  $\tau$  be a finite relational signature. In Boolean semantics, every  $\text{FO}(\tau)$ -sentence  $\psi$  has an equivalent local sentence  $\psi'$  such that every relation symbol occurring only positively (only negatively) in  $\psi$  also occurs only positively (only negatively) in  $\psi'$ , not counting occurrences within distance formulae.*

We believe that this result may be of independent interest. A similar adaptation of Gaifman’s theorem has been considered in [20], namely that *existential* sentences are equivalent to *positive* Boolean combinations of *existential* basic local sentences. Our proof of step (2) implies a similar result (cf. [6]), as we also construct a positive Boolean combination of existential basic local sentences. However, we permit distance formulae  $d(x, y) > 2r$  within local formulae (which are abbreviations for universal quantifiers), while [20] does not. Moreover, the approximation schemes of [8] are based on a version of Gaifman’s theorem for sentences positive in a single unary relation (i.e., no negations are added in front of this relation). Their proof uses a version of Ehrenfeucht-Fraïssé games, which is quite different from our syntactical approach. Since unary relations do not occur in distance formulae, Corollary 18 subsumes their result. Interestingly, [20, 8] both share our observation that the proof of the respective version of Gaifman’s theorem is surprisingly difficult.

To prove Theorem 14 from Corollary 18, one can show (cf. [6]) that with some preparation, Boolean equivalences  $\equiv_{\mathbb{B}}$  can be lifted to lattice-equivalences  $\equiv_{\mathcal{L}}$  (which subsume  $\equiv_{\mathcal{M}}$ ). This is done by applying *separating homomorphisms* of [15] to turn a falsifying  $K$ -interpretation  $\pi$ , witnessing  $\not\equiv_{\mathcal{L}}$ , into a falsifying Boolean structure  $h \circ \pi$ , witnessing  $\not\equiv_{\mathbb{B}}$ . Such homomorphisms  $h$  exist for all min-max semirings [15] and also for the more general lattice semirings [7, 6]. We obtain the following generalisation of Theorem 14 by lifting the Boolean result.

► **Corollary 19.** *Let  $\tau$  be a finite relational signature. Every  $\text{FO}(\tau)$ -sentence  $\psi$  is lattice-equivalent ( $\equiv_{\mathcal{L}}$ ) to a local sentence.*

We remark that the lifting argument implies that for many sentences (to be precise, those where no relation occurs both positively and negatively, cf. [6]), the Gaifman normal form in min-max and lattice semirings coincides with the one for Boolean semantics in Corollary 18 (but not necessarily with Gaifman’s original construction). A further consequence is that the counterexample for formulae in Sect. 5.1 also applies to Corollary 18.

## 8 Conclusion

Semiring semantics is a refinement of classical Boolean semantics, which provides more detailed information about a logical statement than just its truth or falsity. This leads to a finer distinction between formulae: statements that are equivalent in the Boolean sense may have different valuations in semiring interpretations, depending on the underlying semiring. It is an interesting and non-trivial question, which logical equivalences and, more generally, which model-theoretic methods, can be carried over from classical semantics to semiring semantics, and how this depends on the algebraic properties of the underlying semiring.

Here we have studied this question for locality properties of first-order logic, in particular for Hanf's locality theorem and for Gaifman normal forms. Our setting assumes semiring interpretations which are model-defining and track only positive information, since these are the conditions that provide well-defined and meaningful locality notions. However, from the outset, it has been clear that one cannot expect to transfer all locality properties of first-order logic to semiring semantics in arbitrary commutative semirings. Indeed, semiring semantics evaluates existential and universal quantifiers by sums and products over all elements of the universe, which gives an inherent source of non-locality if these operations are not idempotent.

Most positive locality results thus require that the underlying semirings are fully idempotent. Under this assumption, one can adapt the classical proof of Hanf's locality theorem to the semiring setting, relying on a back-and-forth argument that itself requires fully idempotent semirings. The question whether there exist Gaifman normal forms in semiring semantics turned out to be more subtle. Indeed, for formulae with free variables Gaifman normal forms need not exist once one goes beyond the Boolean semiring. Also for sentences, one can find examples that do not admit Gaifman normal forms in semirings that are not fully idempotent. We have presented such an example for the tropical semiring.

Our main result, however, is a positive one and establishes the existence of Gaifman normal forms over the class of all min-max and lattice semirings. Intuitively, it relies on the property that in min-max semirings, the value of a quantified statement  $\exists x \varphi(x)$  or  $\forall x \varphi(x)$  coincides with a value of  $\varphi(a)$ , for some witness  $a$ . This needs, for instance, not be the case in lattice semirings, and hence the generalisation to lattice semirings uses a different approach based on separating homomorphisms. It is still an open question whether, in analogy to Hanf's theorem, Gaifman normal forms exist over all fully idempotent semirings. The proof of our main result, which is based on quantifier elimination arguments, turned out to be surprisingly difficult; we identified the lack of a classical negation operator as the main reason for its complexity. An interesting consequence of this restriction is a stronger version of Gaifman's classical theorem in Boolean semantics: every sentence has a Gaifman normal form which, informally speaking, does not add negations.

For applications such as provenance analysis, min-max semirings are relevant, for instance, for studying access levels and security issues. A much larger interesting class of semirings with wider applications are the absorptive ones, including the tropical semiring, in which addition is idempotent, but multiplication in general is not. We have seen that Gaifman normal forms for such semirings need not exist for all sentences. The question arises whether one can establish weaker locality properties for absorptive semirings, applicable perhaps to just a relevant fragment of first-order logic.

# A Characterisation of Functions Computable in Polynomial Time and Space over the Reals with Discrete Ordinary Differential Equations

## Simulation of Turing Machines with Analytic Discrete ODEs

### Abstract

We prove that functions over the reals computable in polynomial time can be characterised using discrete ordinary differential equations (ODE), also known as finite differences. We also provide a characterisation of functions computable in polynomial space over the reals. In particular, this covers space complexity, while existing characterisations were only able to cover time complexity, and were restricted to functions over the integers, and we prove that no artificial sign or test function is needed even for time complexity. At a technical level, this is obtained by proving that Turing machines can be simulated with analytic discrete ordinary differential equations. We believe this result opens the way to many applications, as it opens the possibility of programming with ODEs, with an underlying well-understood time and space complexity.

## 1 Introduction

Recursion schemes constitute a major approach to classical computability theory and, to some extent, to complexity theory. The foundational characterisation of **FPTIME**, based on bounded primitive recursion on notations, due to Cobham [10] gave birth to the field of *implicit complexity* at the interplay of logic and theory of programming. Alternative characterizations, based on safe recursion [1] or on ramification ([16, 15]) or for other classes [17] followed: see [8, 9] for monographs.

Initially motivated to help understanding how analogue models of computations compare to classical digital ones, in an orthogonal way, various computability and complexity classes have been recently characterised using Ordinary Differential Equations (ODE). An unexpected side effect of these proofs is the possibility of programming with classical ODEs, over the continuum. It recently led to solving various open problems. This includes the proof of the existence of a universal ODE [6], the proof of the Turing-completeness of chemical reactions [11], or hardness of problems related to dynamical systems [12].

Discrete ODEs, that we consider in this article, are an approach in-between born from the attempt of [4, 5] to explain some of the constructions for continuous ODEs in an easier way. The basic principle is, for a function  $\mathbf{f}(x)$ , to consider its discrete derivative defined as  $\Delta\mathbf{f}(x) = \mathbf{f}(x+1) - \mathbf{f}(x)$  (also denoted  $\mathbf{f}'(x)$  in what follows to help analogy with classical continuous counterparts). A consequence of this attempt is the characterisation obtained

in [4, 5]. They provided a characterisation of **FPTIME** for functions over the integers that does not require the specification of an explicit bound in the recursion, in contrast to Cobham’s work [10], nor the assignment of a specific role or type to variables, in contrast to safe recursion or ramification [1, 14]. Instead, they only assume involved ODEs to be linear, a very classical natural concept for differential equations.

► **Remark 1.** Unfortunately, even if it was the original motivation, both approaches for characterising complexity classes for continuous and discrete ODEs are currently not directly connected. A key difference is that there is no simple expression (no analogue of the Leibniz rule) for the derivative of the composition of functions in the discrete settings. The Leibniz rule is a very basic tool for establishing results over the continuum, using various stability properties, but that cannot be used easily over discrete settings.

In the context of algebraic classes of functions, the following notation is classical: call *operation* an operator that takes finitely many functions and returns some new function defined from them. Then  $[f_1, f_2, \dots, f_k; op_1, op_2, \dots, op_\ell]$  denotes the smallest set of functions containing  $f_1, f_2, \dots, f_k$  that is closed under the operations  $op_1, op_2, \dots, op_\ell$ . Call *discrete function* a function of type  $f : S_1 \times \dots \times S_d \rightarrow S'_1 \times \dots \times S'_d$ , where each  $S_i, S'_i$  is either  $\mathbb{N}$  or  $\mathbb{Z}$ . Write **FPTIME** for the class of functions computable in polynomial time, and **FPSPACE** for the class of functions computable in polynomial space.

► **Remark 2.** The literature considers two possible definitions for **FPSPACE**, according to whether functions with non-polynomial size values are allowed or not. In our case, we should add “whose outputs remain of polynomial size”, to resolve the ambiguity<sup>1</sup>.

A main result of [4, 5] is the following (LDL stands for linear derivation on length):

► **Theorem 3 ([4]).** *For functions over the reals, we have  $\text{LDL} = \mathbf{FPTIME}$  where  $\text{LDL} = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \times, \text{sg}(x) ; \text{composition}, \text{linear length ODE}]$ .*

In particular, writing as usual  $B^A$  for functions from  $A$  to  $B$ , we deduce:

► **Corollary 4 (Functions over the integers).**  $\text{LDL} \cap \mathbb{N}^{\mathbb{N}} = \mathbf{FPTIME} \cap \mathbb{N}^{\mathbb{N}}$ .

That is to say, LDL (and hence **FPTIME** for functions over the integers) is the smallest class of functions that contains the constant functions  $\mathbf{0}$  and  $\mathbf{1}$ , the projections  $\pi_i^k$  of the  $i^e$  coordinate of a vector of size  $k$ , the length function  $\ell(x)$ , mapping an integer to the length of its binary representation, the addition  $x+y$ , the subtraction  $x-y$ , the multiplication  $x \times y$ , the **sign** function  $\text{sg}(x)$  and that is closed under composition (when defined) and linear length-ODE scheme: the linear length-ODE scheme, formally given by Definition 15, corresponds to defining a function from a linear ODEs with respect to derivation along the length of the argument, so of the form  $\frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \ell} = \mathbf{A}[\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}] \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}[\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}]$ .

Here, we use the notation  $\frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \ell}$  which corresponds to the derivation of  $\mathbf{f}$  along the length function: given some function  $\mathcal{L} : \mathbb{N}^{p+1} \rightarrow \mathbb{Z}$  and in particular for the case where  $\mathcal{L}(x, \mathbf{y}) = \ell(x)$ ,

$$\frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \mathcal{L}} = \frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \mathcal{L}(x, \mathbf{y})} = \mathbf{h}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}) \tag{1}$$

is a formal synonym for  $\mathbf{f}(x+1, \mathbf{y}) = \mathbf{f}(x, \mathbf{y}) + (\mathcal{L}(x+1, \mathbf{y}) - \mathcal{L}(x, \mathbf{y})) \cdot \mathbf{h}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y})$ .

---

<sup>1</sup> Otherwise, the class is not closed by composition: this may be considered as a basic requirement when talking about the complexity of functions. The issue is about the usage of not counting the output as part of the total space used. In this model, given  $f$  computable in polynomial space, and  $g$  in logarithmic space,  $f \circ g$  (and  $g \circ f$ ) is computable in polynomial space. But this is not true, if we assume only  $f$  and  $g$  to be computable in polynomial space, since the first might give an output of exponential size.

► **Remark 5.** This concept introduced in [4, 5], is motivated by the fact that the latter expression is similar to the classical formula for continuous ODEs:

$$\frac{\delta f(x, \mathbf{y})}{\delta x} = \frac{\delta \mathcal{L}(x, \mathbf{y})}{\delta x} \cdot \frac{\delta f(x, \mathbf{y})}{\delta \mathcal{L}(x, \mathbf{y})},$$

and hence is similar to a change of variable. Consequently, a linear length-ODE is basically a linear ODE over a variable  $t$  once the change of variable  $t = \ell(x)$  is done.

However, in the context of (classical) ODEs, considering functions over the reals is more natural than only functions over the integers. Call *real function* a function  $f : S_1 \times \dots \times S_d \rightarrow S'_1 \times \dots \times S'_d$ , where each  $S_i, S'_i$  is either  $\mathbb{R}, \mathbb{N}$  or  $\mathbb{Z}$ . A natural question about the characterisation of **FPTIME** for real functions arises, and not only discrete functions: we consider here computability over the reals in its most classical approach, namely computable analysis [19].

As a first step, the class  $\mathbb{LDDL}^\bullet = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \times, \overline{\text{cond}}(x), \frac{x}{2}; \text{composition, linear length ODE}]$  has been considered in [3, 2] where some characterisation of **P**TIME was obtained, but only for functions from the integers to the reals (i.e. sequences) while it would be more natural to characterise functions from the reals to the reals. More importantly, this was obtained by assuming that some **non-analytic exact function** is among the basic available functions to simulate a Turing machine:  $\overline{\text{cond}}$  valuing 1 for  $x > \frac{3}{4}$  and 0 for  $x < \frac{1}{4}$ .

We prove first this is not needed, and mainly, we extend all previous results to real functions, furthermore covering not only time complexity but also space complexity. Consider

$$\mathbb{LDDL}^\circ = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \tanh, \frac{x}{2}, \frac{x}{3}; \text{composition, linear length ODE}],$$

where  $\ell : \mathbb{N} \rightarrow \mathbb{N}$  is the length function, mapping some integer to the length of its binary representation,  $\frac{x}{2} : \mathbb{R} \rightarrow \mathbb{R}$  is the function dividing by 2 (similarly for  $\frac{x}{3}$ ) and all other basic functions defined exactly as for  $\mathbb{LDDL}$ , but considered here as functions from the reals to reals.

► **Remark 6.** This class is  $\mathbb{LDDL}$  but without the  $\text{sg}(x)$  function, nor the multiplication function, or  $\mathbb{LDDL}^\bullet$  but without the  $\overline{\text{cond}}$  function, nor the multiplication. This is done by adding the analytic  $\tanh$  functions as a substitute (and adding  $x/3$ ).

► **Remark 7.** We can consider  $\mathbb{N} \subset \mathbb{Z} \subset \mathbb{R}$  but as functions may have different types of outputs, the composition is an issue. We consider, as in [3, 2], that composition may not be defined in some cases: it is a partial operator. For example, given  $f : \mathbb{N} \rightarrow \mathbb{R}$  and  $g : \mathbb{R} \rightarrow \mathbb{R}$ , the composition of  $g$  and  $f$  is defined as expected, but  $f$  cannot be composed with a function such as  $h : \mathbb{N} \rightarrow \mathbb{N}$ .

First, we improve Theorem 3 by stating **FPTIME** over the integers can be characterised algebraically using linear length ODEs and only analytic functions (i.e. no need for sign function). Since  $\mathbb{LDDL}^\circ$  is about functions over the reals, and Theorem 3 is about functions over the integers, we need a way to compare these classes. Given a function  $\mathbf{f} : \mathbb{R}^d \rightarrow \mathbb{R}^d$  sending every integer  $\mathbf{n} \in \mathbb{N}^d$  to the vicinity of some integer of  $\mathbb{N}^d$ , say at distance less than  $1/4$ , we write  $\text{DP}(f)$  for its discrete part: this is the function from  $\mathbb{N}^d \rightarrow \mathbb{N}^d$  mapping  $\mathbf{n} \in \mathbb{N}^d$  to the integer rounding of  $\mathbf{f}(n)$ . Given a class  $\mathcal{C}$  of such functions, we write  $\text{DP}(\mathcal{C})$  for the class of the discrete parts of the functions of  $\mathcal{C}$ .

► **Theorem 8.**  $\text{DP}(\mathbb{LDDL}^\circ) = \mathbf{FPTIME} \cap \mathbb{N}^{\mathbb{N}}$ .

Write  $\overline{\mathbb{LDDL}^\circ}$  for the class obtained by adding some effective limit operation similar to the one considered in [3] to get  $\overline{\mathbb{LDDL}^\bullet}$ . We get a characterization of functions over the reals (and not only sequences as in [3]) computable in polynomial time.

► **Theorem 9** (Generic functions over the reals).  $\overline{\text{LDL}}^\circ \cap \mathbb{R}^{\mathbb{R}} = \mathbf{FPTIME} \cap \mathbb{R}^{\mathbb{R}}$   
 More generally:  $\overline{\text{LDL}}^\circ \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}} = \mathbf{FPTIME} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}}$ .

We also prove that, by adding a robust linear ODE scheme (Definition 18), we get a class  $\text{RLD}^\circ$  (this stands for robust linear derivation) with the similar statements but for  $\mathbf{FPSPACE}$ .

► **Theorem 10.**  $\text{DP}(\text{RLD}^\circ) = \mathbf{FPSPACE} \cap \mathbb{N}^{\mathbb{N}}$ .

► **Theorem 11** (Generic functions over the reals).  $\overline{\text{RLD}}^\circ \cap \mathbb{R}^{\mathbb{R}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{R}}$   
 More generally:  $\overline{\text{RLD}}^\circ \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}} = \mathbf{FPSPACE} \cap \mathbb{R}^{\mathbb{N}^d \times \mathbb{R}^{d'}}$ .

As far as we know, this is the first time a characterisation of  $\mathbf{FPSPACE}$  with discrete ODEs is provided. If we forget the context of discrete ODEs,  $\mathbf{FPSPACE}$  has been characterised in [18] but using a bounded recursion scheme, i.e. requiring some explicit bound in the spirit of Cobham's statement [10]. We avoid this issue by considering numerically stable schemes, which are very natural in the context of ODEs.

At a technical level, all our results are obtained by proving Turing machines can be simulated with analytic discrete ODEs in a suitable manner. We believe our constructions could be applied to many other situations, where programming with ODEs is needed.

In Section 2, we recall some basic statements about the theory of discrete ODEs. In Section 3, we establish some properties about particular functions required for our proofs. In Section 4 we prove our main technical result: Turing machines can be simulated using functions from  $\text{LDL}^\circ$ . Section 5 is about converting integers and reals (dyadic) to words of a specific form. Section 6 is about applications of our toolbox. We prove in particular all above theorems.

## 2 Some concepts related to discrete ODEs

In this section, we recall some concepts and definitions from discrete ODEs, either well-known or established in [4, 5, 3]. We consider here that  $\mathbf{tanh}$  is  $\tanh$ , the hyperbolic tangent. The papers [4, 5] use similar definitions with the sign function  $\text{sg}$  and [3] with the piecewise affine function  $\text{cond}$ , that values 1 for  $x > \frac{3}{4}$  and 0 for  $x < \frac{1}{4}$ , instead of  $\tanh$ .

► **Definition 12** ([3]). A  $\mathbf{tanh}$ -polynomial expression  $P(x_1, \dots, x_h)$  is an expression built on  $+$ ,  $-$ ,  $\times$  (often denoted  $\cdot$ ) and  $\mathbf{tanh}$  functions over a set of variables  $V = \{x_1, \dots, x_h\}$  and integer constants.

We need to measure the degree, similarly to the classical notion of degree in polynomial expression, but considering all subterms that are within the scope of a  $\mathbf{tanh}$  function contributes to 0 to the degree.

► **Definition 13** ([3]). The degree  $\text{deg}(x, P)$  of a term  $P$  in  $x \in V$  is defined inductively as follows:  $\text{deg}(x, x) = 1$  and for  $x' \in V \cup \mathbb{Z}$  such that  $x' \neq x$ ,  $\text{deg}(x, x') = 0$ ;  $\text{deg}(x, P + Q) = \max\{\text{deg}(x, P), \text{deg}(x, Q)\}$ ;  $\text{deg}(x, P \times Q) = \text{deg}(x, P) + \text{deg}(x, Q)$ ;  $\text{deg}(x, \mathbf{tanh}(P)) = 0$ . A  $\mathbf{tanh}$ -polynomial expression  $P$  is essentially constant in  $x$  if  $\text{deg}(x, P) = 0$ .

A vectorial function (resp. a matrix or a vector) is said to be a  $\mathbf{tanh}$ -polynomial expression if all its coordinates (resp. coefficients) are, and *essentially constant* if all its coefficients are.

► **Definition 14** ([4, 5, 3]). A  $\mathbf{tanh}$ -polynomial expression  $\mathbf{g}(\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y})$  is essentially linear in  $\mathbf{f}(x, \mathbf{y})$  if it is of the form:  $\mathbf{A}[\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}] \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}[\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}]$  where  $\mathbf{A}$  and  $\mathbf{B}$  are  $\mathbf{tanh}$ -polynomial expressions essentially constant in  $\mathbf{f}(x, \mathbf{y})$ .

For example, the expression  $P(x, y, z) = x \cdot \tanh(x^2 - z) \cdot y + y^3$  is essentially linear in  $x$ , essentially constant in  $z$  and not linear in  $y$ . The expression:  $z + (1 - \tanh(x)) \cdot (1 - \tanh(-x)) \cdot (y - z)$  is essentially constant in  $x$  and linear in  $y$  and  $z$ .

► **Definition 15** (Linear length ODE [4, 5]). *A function  $\mathbf{f}$  is linear length-ODE definable from  $\mathbf{u}$  essentially linear in  $\mathbf{f}(x, \mathbf{y})$ ,  $\mathbf{g}$  and  $\mathbf{h}$ , if it corresponds to the solution of*

$$f(0, \mathbf{y}) = \mathbf{g}(\mathbf{y}) \quad \text{and} \quad \frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial \ell} = \mathbf{u}(\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}). \quad (2)$$

A fundamental fact is that the derivation with respect to length provides a way to do some change of variables:

► **Lemma 16** ([4, 5]). *Assume that (2) holds. Then  $\mathbf{f}(x, \mathbf{y})$  is given by  $\mathbf{f}(x, \mathbf{y}) = \mathbf{F}(\ell(x), \mathbf{y})$  where  $\mathbf{F}$  is the solution of the initial value problem*

$$\mathbf{F}(1, \mathbf{y}) = \mathbf{g}(\mathbf{y}), \quad \text{and} \quad \frac{\partial \mathbf{F}(t, \mathbf{y})}{\partial t} = \mathbf{u}(\mathbf{F}(t, \mathbf{y}), \mathbf{h}(2^t - 1, \mathbf{y}), 2^t - 1, \mathbf{y}). \quad (3)$$

This means  $\mathbf{f}(x, \mathbf{y})$  depends only on the length of its first argument:  $\mathbf{f}(x, \mathbf{y}) = \mathbf{f}(2^{\ell(x)}, \mathbf{y})$ . Then (3) can be seen as defining a function (with this latter property) by a recurrence of type

$$\mathbf{f}(2^0, \mathbf{y}) = \mathbf{g}(\mathbf{y}), \quad \text{and} \quad \mathbf{f}(2^{t+1}, \mathbf{y}) = \bar{\mathbf{u}}(\mathbf{f}(2^t, \mathbf{y}), \mathbf{h}(2^t - 1, \mathbf{y}), 2^t, \mathbf{y}). \quad (4)$$

for some  $\bar{\mathbf{u}}$  is essentially linear in  $\mathbf{f}(2^t, \mathbf{y})$ . As recurrence (3) is basically equivalent to (2):

► **Corollary 17** (Linear length ODE presented with powers of 2). *A function  $\mathbf{f}$  is linear  $\mathcal{L}$ -ODE definable iff the value of  $\mathbf{f}(x, \mathbf{y})$  depends only on the length of its first argument and satisfies (4), for some  $\mathbf{g}$  and  $\mathbf{h}$ , and  $\bar{\mathbf{u}}$ , essentially linear in  $\mathbf{f}(2^t, \mathbf{y})$ .*

We assume it is easier for our reader to deal with recurrences of the form (4) than with ODEs of the form (2). Consequently, this is how we will describe many functions from now on, starting with some basic functions, authorising compositions, and the above schemes. As an example,  $n \mapsto 2^n$  can easily be defined that way (by  $2^0 = 1$ , and  $2^{n+1} = 2 \cdot 2^n = 2^n + 2^n$ ) and we can produce  $n \mapsto 2^{p(n)}$  for any polynomial  $p$ . For example,  $(n_1, \dots, n_k) \rightarrow 2^{n_1 n_2 \dots n_k}$  can be obtained, using  $k$  such schemes in turn, providing the case of the polynomial  $p(n) = n^k$ .

When talking about space complexity, we will also consider the case where the ODE is not derivated with respect to length but with classical derivation. For functions over the reals an important issue is numerical stability.

► **Definition 18** (Robust linear ODE [4, 5]). *A bounded function  $\mathbf{f}$  is robustly linear ODE definable from  $\mathbf{u}$  essentially linear in  $\mathbf{f}(x, \mathbf{y})$ ,  $\mathbf{g}$  and  $\mathbf{h}$  if:*

1. *it corresponds to the solution of*

$$\mathbf{f}(0, \mathbf{y}) = \mathbf{g}(\mathbf{y}) \quad \text{and} \quad \frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial x} = \mathbf{u}(\mathbf{f}(x, \mathbf{y}), \mathbf{h}(x, \mathbf{y}), x, \mathbf{y}), \quad (5)$$

2. *where the schema (5) is polynomially numerically stable.*

Here, writing  $a =_n b$  for  $\|a - b\| \leq 2^{-n}$  for conciseness, **2.** means formally there exists some polynomial  $p$  such that, for all integer  $n$ , writing  $\epsilon(n) = p(n + \ell(\mathbf{y}))$ , if you consider any solution of  $\tilde{\mathbf{y}} =_{\epsilon(n)} \mathbf{y}$  and  $\tilde{\mathbf{h}}(x, \tilde{\mathbf{y}}) =_{\epsilon(n)} \mathbf{h}(x, \tilde{\mathbf{y}})$ , and  $\tilde{\mathbf{f}}(0, \tilde{\mathbf{y}}) =_{\epsilon(n)} \mathbf{g}(\mathbf{y})$  and  $\frac{\partial \tilde{\mathbf{f}}(x, \tilde{\mathbf{y}})}{\partial x} =_{\epsilon(n)} \mathbf{u}(\tilde{\mathbf{f}}(x, \tilde{\mathbf{y}}), \tilde{\mathbf{h}}(x, \tilde{\mathbf{y}}), x, \tilde{\mathbf{y}})$  then  $\tilde{\mathbf{f}}(x, \tilde{\mathbf{y}}) =_{\epsilon(n)} \mathbf{f}(x, \mathbf{y})$ .

**3 Some results about various functions**

A key part of our proofs is the construction of very specific functions in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$ : we write  $\{x\}$  for the fractional part of the real  $x$ , i.e.  $\{x\} = x - \lfloor x \rfloor$ . We provide some graphical representations of some of them to show that these functions are sometimes highly non-trivial (see for e.g. Figures 3 or 6).

A first observation is that we can uniformly approximate the  $\text{ReLU}(x) = \max(0, x)$  function using a essentially constant function:

► **Lemma 19.** We denote by  $Y(x, 2^{m+2})$  the function  $Y(x, 2^{m+2}) = \frac{1+\tanh(2^{m+2}x)}{2}$  (illustrated by Figure 1). For all integer  $m$ , for all  $x \in \mathbb{R}$ ,  $|\text{ReLU}(x) - xY(x, 2^{m+2})| \leq 2^{-m}$ .

■ **Figure 1** Graphical representation of  $xY(x, 2^{2+2})$  obtained with maple.

We deduce we can uniformly approximate the continuous sigmoid functions (when  $1/(b-a)$  is in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$ ) defined as:  $\mathfrak{s}(a, b, x) = 0$  whenever  $w \leq a$ ,  $\frac{x-a}{b-a}$  whenever  $a \leq x \leq b$ , and 1 whenever  $b \leq x$ .

► **Lemma 20 (Uniform approximation of any piecewise continuous sigmoid).** Assume  $\frac{1}{b-a}$  is in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$ . Then there is some function  $\mathcal{C}\text{-}\mathfrak{s}(m, a, b, x) \in \mathbb{L}\mathbb{D}\mathbb{L}^\circ$  (illustrated by Figure 2) such that for all integer  $m$ ,  $|\mathcal{C}\text{-}\mathfrak{s}(m, a, b, x) - \mathfrak{s}(a, b, x)| \leq 2^{-m}$ .

■ **Figure 2** Graphical representation of  $\mathcal{C}\text{-}\mathfrak{s}(2, \frac{1}{2}, \frac{3}{4}, x)$  and  $\mathcal{C}\text{-}\mathfrak{s}(2^5, \frac{1}{2}, \frac{3}{4}, x)$  obtained with maple.

**Proof.** We can write  $\mathfrak{s}(a, b, x) = \frac{\text{ReLU}(x-a) - \text{ReLU}(x-b)}{b-a}$ . Thus,  $|\mathcal{C}\text{-}\mathfrak{s}(m+1+c, a, b, x) - \mathfrak{s}(a, b, x)| \leq \frac{2 \cdot 2^{-m-1-c}}{b-a}$ , using the triangle inequality. Take  $c$  such that  $\frac{1}{b-a} \leq 2^c$ . ◀

The existence of the following function will play an important role to obtain the various functions of the next corollary.

► **Theorem 21.** *There exists some function  $\xi : \mathbb{N}^2 \rightarrow \mathbb{R}$  in  $\text{LDL}^\circ$  (illustrated in Figure 3) such that for all  $n, m \in \mathbb{N}$  and  $x \in [-2^n, 2^n]$ , whenever  $x \in [\lfloor x \rfloor + \frac{1}{8}, \lfloor x \rfloor + \frac{7}{8}]$ ,  $|\xi(2^m, 2^n, x) - \{x - \frac{1}{8}\}| \leq 2^{-m}$ .*

■ **Figure 3** Graphical representations of  $\xi(2, 4, x)$  obtained with maple: some details on the right.

The main idea of the proof is, by parity, to reduce the problem to construct an auxiliary function  $\xi'$  that works for  $x \geq 0$ , writing  $\xi(2^m, N, x) = \xi'(2^{m+2}, N, x) - \xi'(2^{m+2}, N, -x) + \frac{3}{4} - \frac{3}{4} \mathcal{C}\text{-s}(2^{m+2}, 0, \frac{1}{8}, x)$ , and then proving that  $\xi'$  is definable in  $\text{LDL}^\circ$ , using an adhoc recursive (in  $n$ ) definition of it.

► **Corollary 22 (A bestiary of functions).** *There exist*

1.  $\xi_1, \xi_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto \mathbb{R} \in \text{LDL}^\circ$  such that, for all  $n, m \in \mathbb{N}$ ,  $\lfloor x \rfloor \in [-2^n + 1, 2^n]$ , whenever  $x \in [\lfloor x \rfloor - \frac{1}{2}, \lfloor x \rfloor + \frac{1}{4}]$ ,  $|\xi_1(2^m, 2^n, x) - \{x\}| \leq 2^{-m}$ , and whenever  $x \in [\lfloor x \rfloor, \lfloor x \rfloor + \frac{3}{4}]$ ,  $|\xi_2(2^m, 2^n, x) - \{x\}| \leq 2^{-m}$  (see Figure 4).
2.  $\sigma_1, \sigma_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto \mathbb{R} \in \text{LDL}^\circ$  such that, for all  $n, m \in \mathbb{N}$ ,  $\lfloor x \rfloor \in [-2^n + 1, 2^n]$ , whenever  $x \in [\lfloor x \rfloor - \frac{1}{2}, \lfloor x \rfloor + \frac{1}{4}]$ ,  $|\sigma_1(2^m, 2^n, x) - \lfloor x \rfloor| \leq 2^{-m}$ , and whenever  $x \in [\lfloor x \rfloor, \lfloor x \rfloor + \frac{3}{4}]$ ,  $|\sigma_2(2^m, 2^n, x) - \lfloor x \rfloor| \leq 2^{-m}$  (see Figure 5).
3.  $\lambda : \mathbb{N}^2 \times \mathbb{R} \mapsto [0, 1] \in \text{LDL}^\circ$  such that for all  $m, n \in \mathbb{N}$ ,  $\lfloor x \rfloor \in [-2^n + 1, 2^n]$ , whenever  $x \in [\lfloor x \rfloor + \frac{1}{4}, \lfloor x \rfloor + \frac{1}{2}]$ ,  $|\lambda(2^m, 2^n, x) - 0| \leq 2^{-m}$ , and whenever  $x \in [\lfloor x \rfloor + \frac{3}{4}, \lfloor x \rfloor + 1]$ ,  $|\lambda(2^m, 2^n, x) - 1| \leq 2^{-m}$ .
4.  $\text{mod}_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto [0, 1] \in \text{LDL}^\circ$  such that for all  $m, n \in \mathbb{N}$ ,  $\lfloor x \rfloor \in [-2^n + 1, 2^n]$ , whenever  $x \in [\lfloor x \rfloor - \frac{1}{4}, \lfloor x \rfloor + \frac{1}{4}]$ ,  $|\text{mod}_2(2^m, 2^n, x) - \lfloor x \rfloor \bmod 2| \leq 2^{-m}$ .

■ **Figure 4** Graphical representation of  $\xi_1(2, 4, x)$  and  $\xi_2(2, 4, x)$  obtained with maple.

■ **Figure 5** Graphical representation of  $\sigma_1(2, 4, x)$  and  $\sigma_2(2, 4, x)$  obtained with maple.

■ **Figure 6** Graphical representation of  $\div_2(2, 4, x)$  obtained with maple.

5.  $\div_2 : \mathbb{N}^2 \times \mathbb{R} \mapsto [0, 1] \in \text{LDL}^\circ$  such that for all  $m, n \in \mathbb{N}$ ,  $\lfloor x \rfloor \in [-2^n + 1, 2^n]$ , whenever  $x \in [\lfloor x \rfloor - \frac{1}{4}, \lfloor x \rfloor + \frac{1}{4}]$ ,  $|\div_2(2^m, 2^n, x) - \lfloor x \rfloor // 2| \leq 2^{-m}$ , with  $//$  the integer division (see Figure 6).

**Proof.** Take  $\xi_1(M, N, x) = \xi(M, N, x - \frac{3}{8}) - \frac{1}{2}$ ,  $\xi_2(M, N, x) = \xi(N, x - \frac{7}{8})$ ,  $\sigma_i(M, N, x) = x - \xi_i(M, N, x)$ ,  $\lambda(M, N, x) = \mathcal{C}\text{-}\mathfrak{s}(2M, 1/4, 1/2, \xi(2M, N, x - 9/8))$ ,  $\text{mod}_2(M, N, x) = 1 - \lambda(M, N/2, \frac{1}{2}x + \frac{7}{8})$ ,  $\div_2(M, N, x) = \frac{1}{2}(\sigma_1(M, N, x) - \text{mod}_2(M, N, x))$ . ◀

Observing that for  $\bar{\text{if}}(d, l) = 4 \mathfrak{s}(1, 2, 1/2 + d + l/4) - 2$ , for  $l \in [0, 1]$ , we have  $\bar{\text{if}}(0, l) = 0$ , and  $\bar{\text{if}}(1, l) = l$ , and using Lemma 20 on this sigmoid, we get:

► **Lemma 23.** *There exists  $\mathcal{C}\text{-if} \in \text{LDL}^\circ$  such that,  $l \in [0, 1]$ , if we take  $|d' - 0| \leq 1/4$ , then  $|\mathcal{C}\text{-if}(d', l) - 0| \leq 2^{-m}$ , and if we take  $|d' - 1| \leq 1/4$ , then  $|\mathcal{C}\text{-if}(d', l) - l| \leq 2^{-m}$ .*

► **Lemma 24.** *Let  $\alpha_1, \alpha_2, \dots, \alpha_n$  be some integers, and  $V_1, V_2, \dots, V_n$  some constants. We write  $\text{send}(\alpha_i \mapsto V_i)_{i \in \{1, \dots, n\}}$  for the function that maps any  $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$  to  $V_i$ , for all  $i \in \{1, \dots, n\}$ .*

*There is some function in  $\text{LDL}^\circ$ , that we write  $\mathcal{C}\text{-send}(2^m, \alpha_i \mapsto V_i)_{i \in \{1, \dots, n\}}$ , that maps any  $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$  to a real at distance at most  $2^{-m}$  of  $V_i$ , for all  $i \in \{1, \dots, n\}$ .*

► **Lemma 25.** *Let  $N$  be some integer. Let  $\alpha_1, \alpha_2, \dots, \alpha_n$  be some integers, and  $V_{i,j}$  for  $1 \leq i \leq n$  some constants, with  $0 \leq j < N$ . We write  $\text{send}((\alpha_i, j) \mapsto V_{i,j})_{i \in \{1, \dots, n\}, j \in \{0, \dots, N-1\}}$  for the function that maps any  $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$  and  $y \in [j - 1/4, j + 1/4]$  to  $V_{i,j}$ , for all  $i \in \{1, \dots, n\}$ ,  $j \in \{0, \dots, N-1\}$ .*

There is some function in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$ , that we write  $\mathcal{C}\text{-send}(2^m, (\alpha_i, j) \mapsto V_{i,j})_{i \in \{1, \dots, n\}, j \in \{0, \dots, N-1\}}$ , that maps any  $x \in [\alpha_i - 1/4, \alpha_i + 1/4]$  and  $y \in [j - 1/4, j + 1/4]$  to a real at distance at most  $2^{-m}$  of  $V_{i,j}$ , for all  $i \in \{1, \dots, n\}$ ,  $j \in \{0, \dots, N-1\}$ .

#### 4 Simulating Turing machines with functions of $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$

This section is devoted to the simulation of a Turing machine using some analytic functions, and in particular functions from  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$ . We use some ideas from [3] but with several improvements, as we need to deal with errors and avoid multiplications.

Consider without loss of generality some Turing machine  $M = (Q, \{0, 1, 3\}, q_{init}, \delta, F)$  using the symbols 0, 1, 3, where  $B = 0$  is the blank symbol.

► **Remark 26.** The reason of the choice of symbols 1 and 3 will be made clear later.

We assume  $Q = \{0, 1, \dots, |Q| - 1\}$ . Let  $\dots l_{-k}l_{-k+1} \dots l_{-1}l_0r_0r_1 \dots r_n \dots$  denote the content of the tape of the Turing machine  $M$ . In this representation, the head is in front of symbol  $r_0$ , and  $l_i, r_i \in \{0, 1, 3\}$  for all  $i$ . Such a configuration  $C$  can be denoted by  $C = (q, l, r)$ , where  $l, r \in \Sigma^\omega$  are words over alphabet  $\Sigma = \{0, 1, 3\}$  and  $q \in Q$  denotes the internal state of  $M$ . Write:  $\gamma_{word} : \Sigma^\omega \rightarrow \mathbb{R}$  for the function that maps a word  $w = w_0w_1w_2 \dots$  to the dyadic  $\gamma_{word}(w) = \sum_{n \geq 0} w_n 4^{-(n+1)}$ .

The idea is that such a configuration  $C$  can also be encoded by some element  $\bar{C} = (q, \bar{l}, \bar{r}) \in \mathbb{N} \times \mathbb{R}^2$ , by considering  $\bar{r} = \gamma_{word}(r)$  and  $\bar{l} = \gamma_{word}(l)$ . In other words, we encode the configuration of a bi-infinite tape Turing machine  $M$  by real numbers using their radix 4 encoding, but using only digits 1,3. Notice that this lives in  $Q \times [0, 1]^2$ . Denoting the image of  $\gamma_{word} : \Sigma^\omega \rightarrow \mathbb{R}$  by  $\mathcal{I}$ , this even lives in  $Q \times \mathcal{I}^2$ .

► **Remark 27.** Notice that  $\mathcal{I}$  is a Cantor-like set: it corresponds to the rational numbers that can be written using only 1 and 3 in base 4. We write  $\mathcal{I}_S$  for those with at most  $S$  digits after the point (i.e. of the form  $n/4^S$  for some integer  $n$ ).

► **Lemma 28.** We can construct some function  $\overline{Next}$  in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$  that simulates one step of  $M$ : given a configuration  $C$ , writing  $C'$  for the next configuration, we have for all integer  $m$ ,  $\|\overline{Next}(2^m, \bar{C}) - \bar{C}'\| \leq 2^{-m}$ .

**Proof.** We can write  $l = l_0l^\bullet$  and  $r = r_0r^\bullet$ , where  $l_0$  and  $r_0$  are the first letters of  $l$  and  $r$ , and  $l^\bullet$  and  $r^\bullet$  corresponding to the (possibly infinite) word  $l_{-1}l_{-2} \dots$  and  $r_1r_2 \dots$  respectively.

$$\begin{array}{ccccccc} \dots & l^\bullet & | & l_0 & | & r_0 & | & r^\bullet & \dots \\ \hline & & & \underbrace{\hspace{2cm}} & & \underbrace{\hspace{2cm}} & & & \\ & & & l & & r & & & \end{array}$$

The function  $Next$  is of the form  $Next(q, l, r) = Next(q, l^\bullet l_0, r_0 r^\bullet) = (q', l', r')$  defined as a definition by case of type:

$$(q', l', r') = \begin{cases} (q', l^\bullet l_0 x, r^\bullet) & \text{whenever } \delta(q, r_0) = (q', x, \rightarrow) \\ (q', l^\bullet, l_0 x r^\bullet) & \text{whenever } \delta(q, r_0) = (q', x, \leftarrow) \end{cases}$$

This can be rewritten as a first candidate for the function  $\overline{Next}$ . Consider the similar function working over the representation of the configurations as reals, considering  $r_0 = \lfloor 4\bar{r} \rfloor$

$$\begin{aligned} \overline{Next}(q, \bar{l}, \bar{r}) &= \overline{Next}(q, \bar{l}^\bullet \bar{l}_0, \bar{r}_0 \bar{r}^\bullet) = (q', \bar{l}', \bar{r}') \\ &= \begin{cases} (q', \bar{l}^\bullet \bar{l}_0 x, \bar{r}^\bullet) & \text{whenever } \delta(q, r_0) = (q', x, \rightarrow) \\ (q', \bar{l}^\bullet, \bar{l}_0 x \bar{r}^\bullet) & \text{whenever } \delta(q, r_0) = (q', x, \leftarrow) \end{cases} \end{aligned}$$

- in the first case “ $\rightarrow$ ” :  $\bar{l} = 4^{-1}\bar{l} + 4^{-1}x$  and  $\bar{r}' = \bar{r}^\bullet = \{4\bar{r}\}$
  - in the second case “ $\leftarrow$ ” :  $\bar{l} = \bar{l}^\bullet = \{4\bar{l}\}$  and  $\bar{r}' = 4^{-2}\{4\bar{r}\} + 4^{-2}x + \lfloor 4\bar{l} \rfloor / 4$
- (6)

We introduce the following functions:  $\rightarrow: Q \times \{0, 1, 3\} \mapsto \{0, 1\}$  and  $\leftarrow: Q \times \{0, 1, 3\} \mapsto \{0, 1\}$  such that  $\rightarrow(q, a)$  (respectively:  $\leftarrow(q, a)$ ) is 1 when  $\delta(q, a) = (\cdot, \cdot, \rightarrow)$  (resp.  $(\cdot, \cdot, \leftarrow)$ ), i.e. the head moves right (resp. left), and 0 otherwise. We define  $nextq_a^q = q'$  if  $\delta(q, a) = (q', \cdot, \cdot)$ , i.e. values  $(q', x, m)$  for some  $x$  and  $m \in \{\leftarrow, \rightarrow\}$ .

We can rewrite  $\overline{Next}(q, \bar{l}, \bar{r}) = (q', \bar{l}', \bar{r}')$  as  $\bar{l}' = \sum_{q, r_0} \left[ \rightarrow(q, r_0) \left( \frac{\bar{l}}{4} + \frac{x}{4} \right) + \leftarrow(q, r_0) \{4\bar{l}\} \right]$  and  $\bar{r}' = \sum_{q, r_0} \left[ \rightarrow(q, r_0) \{4\bar{r}\} + \leftarrow(q, r_0) \left( \frac{\{4r\}}{4^2} + \frac{x}{4^2} + \frac{\lfloor 4\bar{l} \rfloor}{4} \right) \right]$ , and, using notation of Lemma 25,  $q' = \text{send}((q, r) \mapsto nextq_a^q)_{q \in Q, r \in \{0, 1, 3\}}(q, \lfloor 4\bar{r} \rfloor)$ .

Our problem with such expressions is that they involve some discontinuous functions such as the integer part and the fractional part function, and we would rather have analytic (hence continuous) functions. A key point is that from our trick of using only symbols 1 and 3, we are sure that in an expression like  $\lfloor 4\bar{r} \rfloor$ , either it values 0 (this is the specific case where there remain only blanks in  $r$ ), or that  $4\bar{r}$  lives in an interval  $[1, 2]$  or in interval  $[3, 4]$ . That means that we could replace  $\lfloor 4\bar{r} \rfloor$  by  $\sigma(4\bar{r})$  if we take  $\sigma$  as some continuous function that would be affine and values respectively 0, 1 and 3 on  $\{0\} \cup [1, 2] \cup [3, 4]$  (that is to say matches  $\lfloor 4\bar{r} \rfloor$  on this domain). A possible candidate is  $\sigma(x) = \mathfrak{s}(1/4, 3/4, x) + \mathfrak{s}(9/4, 11/4, x)$ . Then considering  $\xi(x) = x - \sigma(x)$ , then  $\xi(4\bar{r})$  would be the same as  $\{4\bar{r}\}$ : that is, considering  $r_0 = \sigma(4\bar{r})$ , replacing in the above expression every  $\{4\cdot\}$  by  $\xi(\cdot)$ , and every  $\lfloor \cdot \rfloor$  by  $\sigma(\cdot)$ , and get something that would still work the same, but using only continuous functions.

But, we would like to go to some analytic functions and not only continuous functions, and it is well-known that an analytic function that equals some affine function on some interval (e.g. on  $[1, 2]$ ) must be affine, and hence cannot be 3 on  $[3, 4]$ . But the point is that we can try to tolerate errors, and replace  $\mathfrak{s}(\cdot, \cdot)$  by  $\mathcal{C}\text{-}\mathfrak{s}(2^{m+c}, \cdot, \cdot)$  in the expressions above for  $\sigma$  and  $\xi$ , taking  $c$  such that  $(3 + 1/4^2)3|Q| \leq 2^c$ . This would just introduce some error at most  $(3 + 1/4^2)3|Q|2^{-c}2^{-m} \leq 2^{-m}$ .

► **Remark 29.** We could also replace every  $\rightarrow(q, r)$  in above expressions for  $\bar{l}'$  and  $\bar{r}'$  by  $\mathcal{C}\text{-}\text{send}(k, (q, r) \mapsto \rightarrow(q, r))(q, \sigma(4\bar{r}))$ , for a suitable error bound  $k$ , and symmetrically for  $\leftarrow(q, r)$ . However, if we do so, we still might have some multiplications in the above expressions.

The key is to use Lemma 23: we can also write the above expressions as

$$\begin{aligned} \bar{l}' &= \sum_{q, r} \left[ \mathcal{C}\text{-if} \left( 2^{m+c}, \mathcal{C}\text{-send}(2^2, (q, r) \mapsto \rightarrow(q, r))(q, \sigma(4\bar{r})), \frac{\bar{l}}{4} + \frac{x}{4} \right) \right. \\ &\quad \left. + \mathcal{C}\text{-if} \left( 2^{m+c}, \mathcal{C}\text{-send}(2^2, (q, r) \mapsto \leftarrow(q, r))(q, \sigma(4\bar{r})), \xi(4\bar{l}) \right) \right] \\ \bar{r}' &= \sum_{q, r} \left[ \mathcal{C}\text{-if} \left( 2^{m+c}, \mathcal{C}\text{-send}(2^2, (q, r) \mapsto \rightarrow(q, r))(q, \sigma(4\bar{r})), \xi(4\bar{r}) \right) \right. \\ &\quad \left. + \mathcal{C}\text{-if} \left( 2^{m+c}, \mathcal{C}\text{-send}(2^2, (q, r) \mapsto \leftarrow(q, r))(q, \sigma(4\bar{r})), \frac{\xi(4r)}{4^2} + \frac{x}{4^2} + \frac{\sigma(4\bar{l})}{4} \right) \right] \end{aligned}$$

and still have the same bound on the error. ◀

Once we have one step, we would like to simulate some arbitrary computation of a Turing machine, by considering the iterations of function *Next*.

The problem of above construction, is that, even if we start from the exact encoding  $\bar{C}$  of a configuration, it introduces some error (even if at most  $2^{-m}$ ). If we want to apply again the function *Next*, then we will start not exactly from the encoding of a configuration.

Looking at the choice of the function  $\sigma$ , a small error can be tolerated (roughly if the process does not involve points at distance less than  $1/4$  of  $\mathcal{I}$ ), but this error is amplified (roughly multiplied by 4 on some component), before introducing some new errors (even if at most  $2^{-m}$ ). The point is that if we repeat the process, very soon it will be amplified, up to a level where we have no true idea or control about what becomes the value of above function.

However, if we know some bound on the space used by the Turing machine, we can correct it to get at most some fixed additive error: a Turing machine using a space  $S$  uses at most  $S$  cells to the right and to the left of the initial position of its head. Consequently, a configuration  $C = (q, l, r)$  of such a machine involves words  $l$  and  $r$  of length at most  $S$ . Their encoding  $\bar{l}$ , and  $\bar{r}$  are expected to remain in  $\mathcal{I}_{S+1}$ . Consider  $\text{round}_{S+1}(\bar{l}) = \lfloor 4^{S+1}\bar{l} \rfloor / 4^{S+1}$ . For a point  $\bar{l}$  of  $\mathcal{I}_{S+1}$ ,  $4^{S+1}\bar{l}$  is an integer, and  $\bar{l} = \text{round}_{S+1}(\bar{l})$ . But now, for a point  $\tilde{\bar{l}}$  at distance less than  $4^{-(S+2)}$  from a point  $\bar{l} \in \mathcal{I}_{S+1}$ ,  $\text{round}_{S+1}(\tilde{\bar{l}}) = \bar{l}$ . In other words,  $\text{round}_{S+1}$  “deletes” errors of order  $4^{-(S+2)}$ . Consequently, we can replace every  $\bar{l}$  in above expressions by  $\sigma_1(2^{2S+4}, 2^{2S+3}, 4^{S+1}\bar{l})/4^{S+1}$ , as this is close to  $\text{round}_{S+1}(\bar{l})$ , and the same for  $\bar{r}$ , where  $\sigma_1$  is the function from Corollary 22. We could also replace  $m$  by  $m + 2S + 4$  to guarantee that  $2^{-m} \leq 4^{-(S+2)}$ . We get the following important improvement of the previous lemma:

► **Lemma 30.** *We can construct some function  $\overline{\text{Next}}$  in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$  that simulates one step of  $M$ , i.e. that computes the Next function sending a configuration  $\bar{C}$  of Turing machine  $M$  to  $\bar{C}'$ , where  $C'$  is the next one:  $\|\text{Next}(2^m, 2^S, \bar{C}) - \bar{C}'\| \leq 2^{-m}$ . Furthermore, it is robust to errors on its input, up to space  $S$ : considering  $\|\tilde{C} - \bar{C}\| \leq 4^{-(S+2)}$ ,  $\|\text{Next}(2^m, 2^S, \tilde{C}) - \bar{C}'\| \leq 2^{-m}$  remains true.*

► **Proposition 31.** *Consider some Turing machine  $M$  that computes some function  $f : \Sigma^* \rightarrow \Sigma^*$  in some time  $T(\ell(\omega))$  on input  $\omega$ . One can construct some function  $\tilde{f} : \mathbb{N}^2 \times \mathbb{R} \rightarrow \mathbb{R}$  in  $\mathbb{L}\mathbb{D}\mathbb{L}^\circ$  that does the same:  $\tilde{f}(2^m, 2^{T(\ell(\omega))}, \gamma_{\text{word}}(\omega))$  that is at most  $2^{-m}$  far from  $\gamma_{\text{word}}(f(\omega))$ .*

**Proof.** The idea is to define the function  $\overline{\text{Exec}}$  that maps some time  $2^t$  and some initial configuration  $C$  to the configuration at time  $t$ . This can be obtained using previous lemma by  $\overline{\text{Exec}}(2^m, 0, 2^T, C) = C$  and  $\overline{\text{Exec}}(2^m, 2^{t+1}, 2^T, C) = \overline{\text{Next}}(2^m, 2^T, \overline{\text{Exec}}(2^m, 2^t, 2^T, C))$ .

We can then get the value of the computation as  $\overline{\text{Exec}}(2^m, 2^{T(\ell(\omega))}, 2^{T(\ell(\omega))}, C_{\text{init}})$  on input  $\omega$ , considering  $C_{\text{init}} = (q_0, 0, \gamma_{\text{word}}(\omega))$ . By applying some projection, we get the following function  $\tilde{f}(2^m, 2^T, y) = \pi_3^3(\overline{\text{Exec}}(2^m, 2^T, 2^T, (q_0, 0, y)))$  that satisfies the property. ◀

Actually, in order to get **FPSPACE**, observe that we can also replace the linear length ODE by a linear ODE.

► **Proposition 32.** *Consider some Turing machine  $M$  that computes some function  $f : \Sigma^* \rightarrow \Sigma^*$  in some polynomial space  $S(\ell(\omega))$  on input  $\omega$ . One can construct some function  $\tilde{f} : \mathbb{N}^2 \times \mathbb{R} \rightarrow \mathbb{R}$  in  $\mathbb{R}\mathbb{L}\mathbb{D}^\circ$  that does the same: we have  $\tilde{f}(2^m, 2^{S(\ell(\omega))}, \gamma_{\text{word}}(\omega))$  that is at most  $2^{-m}$  far from  $\gamma_{\text{word}}(f(\omega))$ .*

**Proof.** The idea is the same, but not working with powers of 2, and with linear ODE: define the function  $\overline{\text{Exec}}$  that maps some time  $t$  and some initial configuration  $C$  to the configuration at time  $t$ . This can be obtained using previous lemma by  $\overline{\text{Exec}}(2^m, 0, 2^S, C) = C$  and  $\overline{\text{Exec}}(2^m, t+1, 2^S, C) = \overline{\text{Next}}(2^m, 2^S, \overline{\text{Exec}}(2^m, t, 2^S, C))$ .

In order to claim this is a robust linear ODE, we need to state that  $\text{Exec}(2^m, t, 2^S, C)$  is polynomially numerically stable: but this holds, since to estimate this value at  $2^{-n}$  it is sufficient to work at precision  $4^{-\max(m, n, S+2)}$  (independently of  $t$ , from the rounding).

We can then get the value of the computation as  $\overline{\text{Exec}}(2^m, 2^{S(\ell(\omega))}, 2^{S(\ell(\omega))}, C_{\text{init}})$  on input  $\omega$ , considering  $C_{\text{init}} = (q_0, 0, \gamma_{\text{word}}(\omega))$ . By applying some projection, we get the following function  $\tilde{f}(2^m, 2^S, y) = \pi_3^3(\overline{\text{Exec}}(2^m, S, 2^S, (q_0, 0, y)))$  that satisfies the property. ◀

## 5 Converting integers and dyadics to words, and conversely

One point of our simulations of Turing machines is that they work over  $\mathcal{I}$ , through encoding  $\gamma_{word}$ , while we would like to talk about integers and real numbers: we need to be able to convert an integer (more generally a dyadic) into some encoding over  $\mathcal{I}$  and conversely.

Fix the following encoding: every digit in the binary expansion of  $d$  is encoded by a pair of symbols in the radix 4 expansion of  $\bar{d} \in \mathcal{I} \cap [0, 1]$ : digit 0 (respectively: 1) is encoded by 11 (resp. 13) if before the “decimal” point in  $d$ , and digit 0 (respectively: 1) is encoded by 31 (resp. 33) if after. For example, for  $d = 101.1$  in base 2,  $\bar{d} = 0.13111333$  in base 4.

By iterating  $\ell(n)$  times the function

$$F(\bar{r}_1, \bar{l}_2) = \begin{cases} (\div_2(\bar{r}_1), (\bar{l}_2 + 5)/4) & \text{whenever } \text{mod}_2(\bar{r}_1) = 0 \\ (\div_2(\bar{r}_1), (\bar{l}_2 + 7)/4) & \text{whenever } \text{mod}_2(\bar{r}_1) = 1. \end{cases}$$

over  $(n, 0)$ , and then projecting on the second argument, we can prove:

► **Lemma 33** (From  $\mathbb{N}$  to  $\mathcal{I}$ ). *We can construct some function  $Decode : \mathbb{N}^2 \rightarrow \mathbb{R}$  in  $\text{LDL}^\circ$  that maps  $m$  and  $n$  to some point at distance less than  $2^{-m}$  from  $\gamma_{word}(\bar{n})$ .*

This technique can be extended to consider decoding of tuples: there is a function  $Decode : \mathbb{N}^{d+1} \rightarrow \mathbb{R}$  in  $\text{LDL}^\circ$  that maps  $m$  and  $\mathbf{n}$  to some point at distance less than  $2^{-m}$  from  $\gamma_{word}(\bar{\mathbf{n}})$ , with  $\bar{\mathbf{n}}$  defined componentwise.

Conversely, given  $\bar{d}$ , we need a way to construct  $d$ . Actually, as we will need to avoid multiplications, we state that we can even do something stronger: given  $\bar{d}$ , and (some bounded)  $\lambda$  we can construct  $\lambda d$ .

► **Lemma 34** (From  $\mathcal{I}$  to  $\mathbb{R}$ , and multiplying in parallel). *We can construct some function  $EncodeMul : \mathbb{N}^2 \times [0, 1] \times \mathbb{R} \rightarrow \mathbb{R}$  in  $\text{LDL}^\circ$  that maps  $m$ ,  $2^S$ ,  $\gamma_{word}(\bar{d})$  and (bounded)  $\lambda$  to some real at distance at most  $2^{-m}$  from  $\lambda d$ , whenever  $\bar{d}$  is of length less than  $S$ .*

## 6 Proofs and applications

When we say that a function  $f : S_1 \times \cdots \times S_d \rightarrow \mathbb{R}^d$  is (respectively: polynomial time or space) computable this will always be in the sense of computable analysis: see e.g. [7, 19]. We actually follow the formalisation in [3] of required concepts from computable analysis, able to mix complexity issues dealing with integer and real arguments. Theorem 8 follows from point 1. of next Proposition for one inclusion, and previous simulation of Turing machines for the other.

► **Proposition 35.**

1. *All functions of  $\text{LDL}^\circ$  are computable (in the sense of computable analysis) in polynomial time.*
2. *All functions of  $\text{RLD}$  are computable (in the sense of computable analysis) in polynomial space.*

The proof of the proposition consists in observing this holds for the basic functions and that composition preserves polynomial time (respectively: space) computability and also by linear length ODEs. This latter fact is established by computable analysis arguments, reasoning on some explicit formula giving the solution of linear length ODE. Regarding space, the main issue is the need to prove the schema given by Definition 18 guarantees  $\mathbf{f}$  is in  $\text{FPSPACE}$ , when  $\mathbf{u}$ ,  $\mathbf{g}$ , and  $\mathbf{h}$  are. Assuming condition 1. of Definition 18 would not be

sufficient: the problem is  $\mathbf{f}(x, \mathbf{y})$  may polynomially grow too fast or have a modulus function that would grow too fast. The point is, in Definition 18, we assumed  $\mathbf{f}$  to be both bounded and satisfying **2.**, i.e. polynomial numerical robustness. With these hypotheses, it is sufficient to work with the precision given by this robustness condition and these conditions guarantee the validity of computing with such approximated values.

We now go to various applications of it and of our toolbox. First, we state a characterisation of **FPTIME** for general functions, covering both the case of a function  $\mathbf{f} : \mathbb{N}^d \rightarrow \mathbb{R}^{d'}$ ,  $\mathbf{f} : \mathbb{R}^d \rightarrow \mathbb{R}^{d'}$  as a special case: only the first type (sequences) was covered by [3].

► **Theorem 36** (Theorem 9). *A function  $\mathbf{f} : \mathbb{R}^d \times \mathbb{N}^{d''} \rightarrow \mathbb{R}^{d'}$  is computable in polynomial time iff there exists  $\tilde{\mathbf{f}} : \mathbb{R}^d \times \mathbb{N}^{d''+2} \rightarrow \mathbb{R}^{d'} \in \text{LDL}^\circ$  such that for all  $\mathbf{x} \in \mathbb{R}^d$ ,  $X \in \mathbb{N}$ ,  $\mathbf{m} \in \mathbb{N}^{d''}$ ,  $n \in \mathbb{N}$ ,  $\|\tilde{\mathbf{f}}(\mathbf{x}, \mathbf{m}, 2^X, 2^n) - \mathbf{f}(\mathbf{x}, \mathbf{m})\| \leq 2^{-n}$ .*

The reverse implication of Theorem 36 follows from Proposition 35, (1.) and arguments from computable analysis. For the direct implication, for sequences, that is to say, functions of type  $\mathbf{f} : \mathbb{N}^{d''} \rightarrow \mathbb{R}^{d'}$  (i.e.  $d = 0$ , the case considered in [3]) we are almost done: reasoning componentwise, we only need to consider  $f : \mathbb{N}^{d''} \rightarrow \mathbb{R}$  (i.e.  $d' = 1$ ). As the function is polynomial time computable, this means that there is a polynomial time computable function  $g : \mathbb{N}^{d''+1} \rightarrow \{1, 3\}^*$  so that on  $\mathbf{m}, 2^n$ , it provides the encoding  $\overline{\phi(\mathbf{m}, n)}$  of some dyadic  $\phi(\mathbf{m}, n)$  with  $\|\phi(\mathbf{m}, n) - \mathbf{f}(\mathbf{m})\| \leq 2^{-n}$  for all  $\mathbf{m}$ . The problem is then to decode, compute and encode the result to produce this dyadic, using our previous toolbox.

More precisely, from Proposition 31, we get  $\tilde{g}$  with  $|\tilde{g}(2^e, 2^{p(\max(\mathbf{m}, n))}, \text{Decode}(2^e, \mathbf{m}, n)) - \gamma_{\text{word}}(g(\mathbf{m}, n))| \leq 2^{-e}$  for some polynomial  $p$  corresponding to the time required to compute  $g$ , and  $e = \max(p(\max(\mathbf{m}, n)), n)$ . Then we need to transform the value to the correct dyadic: we mean  $\tilde{\mathbf{f}}(\mathbf{m}, n) = \text{EncodeMul}(2^e, 2^t, \tilde{g}(2^e, 2^t, \text{Decode}(2^e, \mathbf{m}, n)), 1)$ , where  $t = p(\max(\mathbf{m}, n))$ ,  $e = \max(p(\max(\mathbf{m}, n)), n)$  provides a solution such that  $\|\tilde{\mathbf{f}}(\mathbf{m}, 2^n) - \mathbf{f}(\mathbf{m})\| \leq 2^{-n}$ .

► **Remark 37.** This is basically what is done in [3], except that we do it here with analytic functions. However, as already observed in [3], this cannot be done for the case  $d \geq 1$ , i.e. for example for  $f : \mathbb{R} \rightarrow \mathbb{R}$ . The problem is that we used the fact that we can decode:  $\text{Decode}$  maps an integer  $n$  to its encoding  $\bar{n}$  (but is not guaranteed to do something valid on non-integers). There cannot exist such functions that would be valid over all reals, as such function must be continuous, and there is no way to map continuously real numbers to finite words. This is where the approach of the article [3] is stuck.

To solve this, we use an adaptive barycentric technique. By lack of space, we discuss only the case of a polynomial time computable function  $f : \mathbb{R} \times \mathbb{N} \rightarrow \mathbb{R}$ . From standard arguments from computable analysis (see e.g. [Corollary 2.21][13]), the following holds and the point is to be able to realise all this with functions from  $\text{LDL}^\circ$ .

► **Lemma 38.** *Assume  $f : \mathbb{R} \times \mathbb{N} \rightarrow \mathbb{R}$  is computable in polynomial time. There exists some polynomial  $m : \mathbb{N}^2 \rightarrow \mathbb{N}$  and some  $\tilde{f} : \mathbb{N}^4 \rightarrow \mathbb{Z}$  computable in polynomial time such that for all  $x \in \mathbb{R}$ ,  $\|2^{-n} \tilde{f}(\lfloor 2^{m(n, M)} x \rfloor, u, 2^M, 2^n) - f(x, u)\| \leq 2^{-n}$  whenever  $\frac{x}{2^{m(n, M)}} \in [-2^M, 2^M]$ .*

Assume we consider an approximation  $\sigma_i$  (with either  $i = 1$  or  $i = 2$ ) of the integer part function given by Lemma 22. Then, given  $n, M$ , when  $2^{m(n, M)} x$  falls in some suitable interval  $I_i$  for  $\sigma_i$  (see statement of Lemma 22), we are sure that  $\sigma_i(2^e, 2^{m(n, M)+X+1}, 2^{m(n, M)} x)$  is at some distance upon control from  $\lfloor 2^{m(n, M)} x \rfloor$ . Consequently,  $2^{-n} \tilde{f}(\sigma_i(2^{m(n, M)+X+1}, 2^{m(n, M)} x), u, 2^M, 2^n)$  provides some  $2^{-n}$ -approximation of  $f(x, u)$ , up to some error upon control. When this holds, we then use an argument similar to what we describe for sequences: using functions from  $\text{LDL}^\circ$ , we can decode, compute, and encode the result to provide this dyadic. It is provided by an expression  $\text{Formula}_i(x, u, M, n)$  of the form  $\text{EncodeMul}(2^e, 2^t, \tilde{f}(2^2, 2^t, \text{Decode}(2^e, \sigma_i(2^e, 2^M, 2^{m(n, M)} x))), 2^{-n})$ .

The problem is that it might also be the case that  $2^{m(n,M)}x$  falls in the complement of the intervals  $(I_i)_i$ . In that case, we have no clear idea of what could be the value of  $\sigma_i(2^e, 2^{m(n,M)+X+1}, 2^{m(n,M)}x)$ , and consequently of what might be the value of the above expression  $Formula_i(x, u, M, n)$ . But the point is that when it happens for an  $x$  for  $\sigma_1$ , we could have used  $\sigma_2$ , and this would work, as one can check that the intervals of type  $I_1$  covers the complements of the intervals of type  $I_2$  and conversely. They also overlap, but when  $x$  is both in some  $I_1$  and  $I_2$ ,  $Formula_1(x, u, M, n)$  and  $Formula_2(x, u, M, n)$  may differ, but they are both  $2^{-n}$  approximation of  $f(x)$ .

The key is to compute some suitable “adaptive” barycenter, using function  $\lambda$ , provided by Corollary 22. Writing  $\approx$  for the fact that two values are closed up to some controlled bounded error, observe from the statements of Lemma 22 that whenever  $\lambda(\cdot, 2^n, x) \approx 0$ , we know that  $\sigma_2(\cdot, 2^n, x) \approx [x]$ ; whenever  $\lambda(\cdot, 2^n, x) \approx 1$  we know that  $\sigma_1(\cdot, 2^n, x) \approx [x]$ ; whenever  $\lambda(\cdot, 2^n, x) \in (0, 1)$ , we know that  $\sigma_1(\cdot, 2^n, x) \approx [x] + 1$  and  $\sigma_2(\cdot, 2^n, x) \approx [x]$ . That means that if we consider  $\lambda(\cdot, 2^n, x)Formula_1(x, u, M, n) + (1 - \lambda(\cdot, 2^n, x))Formula_2(x, u, M, n)$  we are sure to be close (up to some bounded error) to some  $2^{-n}$  approximation of  $f(x)$ . There remains that this requires some multiplication with  $\lambda$ . But from the form of  $Formula_i(x, u, M, n)$ , this could be also be written as follows, ending the proof of Theorem 36.

$$\begin{aligned} & EncodeMul(2^e, 2^t, \tilde{f}(2^e, 2^t, Decode(2^e, \sigma_1(2^e, 2^M, 2^{m(n,M)}x))), \lambda(2^e, 2^M, 2^{m(n,M)}x)2^{-n}) + \\ & EncodeMul(2^e, 2^t, \tilde{f}(2^e, 2^t, Decode(2^e, \sigma_2(2^e, 2^M, 2^{m(n,M)}x))), (1 - \lambda(2^e, 2^M, 2^{m(n,M)}x))2^{-n}) \quad (7) \end{aligned}$$

From the fact that we have the reverse direction in Theorem 36, it is natural to consider the operation that maps  $\tilde{\mathbf{f}}$  to  $\mathbf{f}$ . Namely, we introduce the operation  $ELim$  ( $ELim$  stands for Effective Limit):

► **Definition 39** (Operation  $ELim$ ). *Given  $\tilde{\mathbf{f}} : \mathbb{R}^d \times \mathbb{N}^{d''} \times \mathbb{N} \rightarrow \mathbb{R}^{d'} \in \overline{\text{LDL}}^\circ$  such that for all  $\mathbf{x} \in \mathbb{R}^d$ ,  $X \in \mathbb{N}$ ,  $\mathbf{x} \in [-2^X, 2^X]$ ,  $\mathbf{m} \in \mathbb{N}^{d''}$ ,  $n \in \mathbb{N}$ ,  $\|\tilde{\mathbf{f}}(\mathbf{x}, \mathbf{m}, 2^X, 2^n) - \mathbf{f}(\mathbf{x}, \mathbf{m})\| \leq 2^{-n}$ , then  $ELim(\tilde{\mathbf{f}})$  is the (clearly uniquely defined) corresponding function  $\mathbf{f} : \mathbb{R}^d \rightarrow \mathbb{R}^{d'}$ .*

► **Theorem 40.** *A continuous function  $\mathbf{f}$  is computable in polynomial time if and only if all its components belong to  $\overline{\text{LDL}}^\circ$ , where  $\overline{\text{LDL}}^\circ = [\mathbf{0}, \mathbf{1}, \pi_i^k, \ell(x), +, -, \overline{\text{cond}}(x), \frac{x}{2}, \frac{x}{3}; \text{composition, linear length ODE, } ELim]$ .*

For the reverse direction, by induction, the only thing to prove is that the class of functions from to the integers computable in polynomial time is preserved by the operation  $ELim$ . Take such a function  $\tilde{\mathbf{f}}$ . By definition, given  $\mathbf{x}, \mathbf{m}, X$  we can compute  $\tilde{\mathbf{f}}(\mathbf{x}, \mathbf{m}, 2^X, 2^n)$  with precision  $2^{-n}$  in time polynomial in  $n$ . This must be, by definition of  $ELim$  schema, some approximation of  $\mathbf{f}(\mathbf{x}, \mathbf{m})$  over  $[-2^X, 2^X]$ , and hence  $\mathbf{f}$  is computable in polynomial time. This also gives directly Theorem 9 as a corollary.

We obtain the statements for polynomial space computability (Theorems 10 and 11) replacing  $\overline{\text{LDL}}^\circ$  by  $\overline{\text{RLD}}^\circ$ , using similar reasoning about space instead of time, considering point 2. instead of 1. of Proposition 35, and Proposition 32 instead of Proposition 31.

## Abstract

In this paper, we study the computational complexity of the Maximum Cut problem parameterized above guarantee. Our main result provides a linear kernel for the Maximum Cut problem in connected graphs parameterized above the spanning tree. This kernel significantly improves the previous  $O(k^5)$  kernel given by Madathil, Saurabh, and Zehavi [ToCS 2020]. We also provide subexponential running time algorithms for this problem in special classes of graphs: chordal, split, and co-bipartite. We complete the picture by lower bounds under the assumption of the ETH. Moreover, we initiate a study of the Maximum Cut problem above  $\frac{2}{3}|E|$  lower bound in tripartite graphs.

## 1 Introduction

The maximum cut problem, MAX-CUT for short, is a well-studied optimization problem in computer science and graph theory. In this problem, we need to split the vertices of a given graph into two parts, such that the sum of weights of edges going between two parts is maximum. The weighted version of the decision problem was one of Karp’s 21 NP-complete problems [14]. However, it is known that even unweighted MAXIMUM CUT is NP-complete [10]. It is easy to see that the problem admits an FPT-algorithm parameterized by the solution size, since the size of solution is relatively large. Specifically, if  $m$  is the number of edges in the input graph, then using a greedy argument we can construct a cut of size  $\frac{m}{2}$ . That is why it is natural to study parameterization above lower bounds. Under such parameterization [13], our goal is to find a solution of size  $k + l(I)$  where  $I$  is the input instance,  $l(I)$  is a polynomial time computable lower bound and  $k$  is our parameter. For more details about parameterizations of this type, we refer interested readers to a very nice survey written by Gutin and Mnich [13]. Mahajan and Raman were the first who studied the MAXIMUM CUT problem parameterized above lower bounds [16]. They showed that MAXIMUM CUT parameterized above lower bound  $\frac{m}{2}$  admits an FPT-algorithm. Later Crowston et al. [4, 5] presented a  $2^{O(k)}$  algorithm and a kernel with  $O(k^5)$  vertices for MAXIMUM CUT in the connected graph under more refined lower bound  $\frac{m}{2} + \frac{n-1}{4}$ . Subsequently, Crowston et al. [3] presented an  $O(k^3)$ -vertex kernel, and finally, Etscheid and Mnich [8] constructed an  $O(k)$ -vertex kernel. However, MAXIMUM CUT admits other lower bounds. One such lower bounds for a connected graph is  $n - 1$ . To construct a cut of this size, it is enough to find a spanning tree and then partition vertices such that all edges of the

tree appear in the cut. Note that lower bounds  $\frac{m}{2} + \frac{n-1}{4}$ ,  $n-1$  are incomparable. We denote MAXIMUM CUT parameterized above spanning tree by MAX-CUT-AST. Madathil et al. [15] presented an  $\mathcal{O}^*(8^k)$ -time algorithm and a kernel with  $\mathcal{O}(k^5)$  vertices for MAX-CUT-AST. Note that the lower bounds  $\frac{m}{2} + \frac{n-1}{4}$  and  $n-1$  are incomparable, since in very sparse graphs  $n-1 > \frac{m}{2} + \frac{n-1}{4}$  but in dense graphs  $\frac{m}{2} + \frac{n-1}{4} > n-1$ . So, the linear kernel designed by Etscheid and Mnich [9] does not provide a linear kernel for the parameterization above  $n-1$ .

In this paper, we continue the study of MAX-CUT-AST. Our main result establishes an  $\mathcal{O}(k)$ -vertex kernel for this problem. This result resolves an Open Problem 2 from the survey [13] and significantly improves upon the previous  $\mathcal{O}(k^5)$ -vertex kernel.

► **Theorem 1.** *MAX-CUT-AST has a kernel with  $\mathcal{O}(k)$  vertices and  $\mathcal{O}(k)$  edges.*

► **Theorem 2.** *There is no kernel with sublinear number of vertices for MAX-CUT-AST unless ETH fails.*

MAXIMUM CUT does not admit a  $2^{o(m)}$ -time algorithm unless the ETH fails [2]. Hence, MAX-CUT-AST also does not admit  $2^{o(k)}$ -time algorithm unless the ETH fails. However, we show that we can get a significant improvement if we restrict our input to special classes of graphs. Specifically, we proved the following theorems.

► **Theorem 3.** *MAX-CUT-AST can be solved in a connected co-bipartite graph  $G$  in  $2^{\mathcal{O}(\sqrt{k})}$  poly time.*

► **Theorem 4.** *MAX-CUT-AST on connected chordal graphs and split graphs admits a  $2^{\mathcal{O}(\sqrt{k})}$  poly-time algorithm.*

We complement these results with conditional lower bounds assuming the Exponential Time Hypothesis.

► **Theorem 5.** *MAX-CUT-AST does not admit  $2^{o(\sqrt{k})}$  poly or  $2^{o(\sqrt{n})}$  poly algorithms on split graphs and on chordal graphs unless the ETH is false.*

► **Theorem 6.** *MAX-CUT-AST does not admit  $2^{o(\sqrt[4]{k})}$  poly algorithm on co-bipartite graphs unless the ETH is false.*

We also initiate a new parameterization of MAXIMUM CUT on tripartite graphs. First, we show that MAX-CUT-AST on tripartite graphs is essentially as hard as MAX-CUT-AST on general graphs. Note that it is easy to see that a tripartite graph admits cut of size  $\frac{2}{3}m$  where  $m$  is the number of edges. However, it is not clear how to find such cut if the partition is not provided in the input. We prove that we can construct a randomized polynomial time algorithm that finds such cut. In order to design the algorithm we employ semidefinite programming and technique used to find a best known approximation of MAXIMUM CUT [12].

► **Theorem 7.** *There is a polynomial time randomized algorithm that finds an edge cut of size  $\frac{2}{3}|E(G)|$  on an input tripartite graph  $G$ .*

Note that the lower bound  $\frac{2}{3}m$  is essentially tight since disjoint union of  $k$  triangles is a tripartite graph and the maximum cut equals to  $2k$  while the total number of edges is  $3k$ . Therefore it is natural to ask whether MAXIMUM CUT above  $\frac{2}{3}|E(G)|$  admits an FPT algorithm in tripartite graphs. Unfortunately, we have not resolved the question and state it as an open problem. However, we show that finding cuts significantly bigger than  $\frac{2}{3}|E(G)|$  is hard even in tripartite graphs that contain such cuts. Formally, we proved the following theorem.

► **Theorem 8.** *Assuming  $P \neq NP$  for any  $0 < \varepsilon < \frac{1}{6}$  there is no polynomial time algorithm that finds cut of size  $\geq (\frac{2}{3} + \varepsilon)|E|$  in tripartite graph if such cut exists.*

## 2 Preliminaries

In this paper we work with undirected simple graphs. Only in very special cases we allow multigraphs and multi-edges. We explicitly mention situation when we start working with multi-edges. We use standard graph notations which can be found in [7]. As usual we denote by  $n$  or  $|V(G)|$  number of vertices in a graph  $G$ . Similarly by  $m$  or  $|E(G)|$  we denote number of edges in a graph  $G$ . Generally by  $k$  we denote value of parameter that is under consideration at the moment of discussion. Complement of the graph  $G$  we denote by  $\bar{G}$ . We recall that  $V(\bar{G}) = V(G)$  and  $e \in E(\bar{G})$  if and only if  $e \notin E(G)$ . Recall that in the MAXIMUM CUT problem we need to partition vertices of a given graph into two parts such the number of edges between two parts is the maximum possible. By  $E_G(A, B)$  we denote the set of edges going from the set  $A$  to the set  $B$  in the graph  $G$ . If the graph  $G$  is clear from the context we omit subscript  $G$ . Partition of vertices of graph into two disjoint parts  $A$  and  $B$  we denote by  $(A, B)$ . Slightly abusing notation in some cases we refer to cut as a set of edges  $E(A, B)$  and in other cases we refer to cut as a partition of vertices  $(A, B)$ .  $\text{mc}(G)$  denotes size of the maximum cut of the graph  $G$ . We call a vertex an *articulation point/vertex* if its removal increase number of connected components. Recall that *block* is a maximal 2-connected component.

*Chordal* graphs are graphs that do not contain induced cycles on  $\ell$  vertices for  $\ell \geq 4$ . *Co-bipartite* graphs are graphs whose complement graph is bipartite.

Many of our results concern the parameterized complexity of the problems, including fixed-parameter tractable algorithms, kernelization algorithms, and some hardness results for certain parameters. For a detailed survey in parameterized algorithms we refer to the book of Cygan et al [6]. Due to the space constraints, proofs of lemmas marked by  $(\star)$  are omitted.

## 3 Kernel

In this section we provide a linear kernel for MAX-CUT-AST. Recall that in this problem, we are given a connected graph  $G$ , integer  $k$ , and our goal is to determine if  $G$  has a maximum cut of size at least  $n - 1 + k$ . Before we proceed we formulate lemma by Mathadil et al. [15] that we are using in our algorithm.

► **Lemma 9** ([15]). *There exists a polynomial time algorithm that for  $(G, k)$  either concludes that graph  $G$  has a cut of size at least  $|V(G)| - 1 + k$  or finds a set  $S \subseteq V(G)$  such that  $|S| \leq 3k$  and each block of  $G - S$  is either a clique or a cycle.*

► **Theorem 1.** *MAX-CUT-AST has a kernel with  $\mathcal{O}(k)$  vertices and  $\mathcal{O}(k)$  edges.*

**Proof.** First of all we apply algorithm from Lemma 9. After this step either we conclude that input instance is Yes-instance and we can output a trivial kernel or we find a set  $S$  with properties described in Lemma 9. In the later case we proceed with an application of reduction rules. Our reduction rules maintain the following properties: (i) graph is connected; (ii) each block of  $G - S$  is either a cycle or a clique, however some of these cycles might become cycles of length 2 (our graph might become a multi-graph).

We call a vertex of  $G - S$  *special* if it has an edge to  $S$  or if it is an articulation point of  $G - S$ .

We are ready to present our first reduction rule.

<b>Rule 1:</b>	Let $U$ be a block in $G \setminus S$ , $v \in U$ is the only special vertex in $U$ and $U \neq \{v\}$
Remove:	Vertices $U \setminus \{v\}$
Parameter:	Reduce $k$ by $\text{mc}(U) - ( U  - 1)$

## 22:4 MaxCut Above Guarantee

**Proof of correctness.** Note that  $U$  has no other articulation points or vertices with edges to  $S$  except  $v$ . Therefore,  $v$  is an articulation point of the whole graph  $G$ . Hence, the maximum cut in  $G$  equals to the sum of the cut in  $U$  and  $G - (U \setminus \{v\})$ .

This reduction deletes all edges in  $U$ , so the maximum cut decreases by  $\text{mc}(U)$ . Besides we delete  $|U| - 1$  vertices. Hence, the parameter should be decreased by  $\text{mc}(U) - (|U| - 1)$ . ◀

**Rule 2:** Let  $v$  has no neighbors in  $G \setminus S$ , and exactly one neighbor in  $S$  i.e.  $N(v) = u \in S$   
 Remove:  $v$   
 Parameter: Reduce  $k$  by multiplicity of edge  $uv - 1$

**Proof of correctness.** Under this constrains  $v$  is either a pendant vertex in  $G$  or vertex connected with some other vertex  $u$  by multiple edges. Removal of  $v$  decreases the maximum cut by multiplicity of edge  $uv$  and number of vertices decreases by one. ◀

Since a block can consist of one vertex only in case this vertex is isolated, exhaustive application of these two rules leave every block with at least two special vertices or the whole connected component is a single vertex with at least two edges towards  $S$  and neighborhood of size at least 2.

► **Lemma 11.** *In a graph where Rules 1, 2 do not apply, every connected component of  $G - S$  has at least two edges to  $S$ .*

**Proof.** Let  $C$  be a connected component of  $G - S$  such that  $|E(S, C)| = 1$ . Therefore, at most one vertex from  $C$  is a special vertex but not an articulation point.

If  $C$  is composed of a single block then it has no articulation points and therefore has a block with only one special vertex. Hence, either Rule 1 or Rule 2 must be applicable.

Otherwise  $C$  has at least two leaf blocks, each of them having exactly one articulation point. At least one of these leaf blocks has no other special vertices and can be reduced by Rule 1. ◀

► **Lemma 12.** *Let  $f$  be the number of edges between  $S$  and those connected components of  $G - S$  which have at least 3 edges to  $S$ . If  $f \geq 24k$  then  $(G, k)$  is a YES-instance.*

**Proof.** Let  $U_1, \dots, U_m$  be a connected components of  $G - S$ . Without loss of generality we can assume that the first  $l$  of them have more than three edges to  $S$  and the other have only 2. Note that  $l \leq \frac{f}{3}$ .

If  $f \geq 24k$  we construct a cut of  $G$  with at least  $|V(G)| + k$  edges. First of all, in each connected component  $U_i$  we construct a cut of size at least  $|V(U_i)| - 1$  according to a spanning tree lower bound. After that we put the whole  $S$  into one of the parts so that at least half of edges between  $S$  and  $G - S$  is cut. Note that number of edges between  $S$  and  $G - S$  is at least  $2(m - l) + f$ .

So, the constructed cut has the following size:

$$\begin{aligned} \text{mc}(G) &\geq \sum_{i=1}^m (|V(U_i)| - 1) + (m - l) + \frac{f}{2} = \sum_{i=1}^m |V(U_i)| - l + \frac{f}{2} \geq \sum_{i=1}^m |V(U_i)| - \frac{f}{3} + \frac{f}{2} \\ &= \sum_{i=1}^m |V(U_i)| + \frac{f}{6} \geq \sum_{i=1}^m |V(U_i)| + 4k \geq \sum_{i=1}^m |V(U_i)| + |S| + k \geq V(G) + k \end{aligned}$$

Constructed cut has size at least  $\geq V(G) - 1 + k$  which means that  $(G, k)$  is a Yes-instance. ◀

Before we state the next reduction rule we prove the following auxiliary claim.

▷ **Claim 13.** Let  $M$  be a maximum cut in a graph  $G$ , and edge  $e$  is a bridge in  $G$  then  $e \in M$ .

Proof. If  $e \in M$  then there is nothing to prove. Otherwise,  $e \notin M$ . Let  $e = uv$ . The maximum cut  $M$  induces a partition of vertices in  $G$  into two parts  $V_1, V_2$ . Without loss of generality  $u, v \in V_1$ . The edge  $e$  also induces a partition of  $V(G)$  into two parts  $W_1, W_2$ , each part corresponds to a connected component in a graph  $G - e$ . Without loss of generality, we assume that  $u \in W_1, v \in W_2$ . Let us consider the following partitioning  $(A, B)$  where  $A = (V_1 \cap W_1) \cup (V_2 \cap W_2), B = (V_1 \cap W_2) \cup (V_2 \cap W_1)$ . Note that  $u \in A, v \in B$ . So the cut generated by partitioning  $(A, B)$  contains edge  $e$ . Moreover, if edge  $e' \neq e$  then either  $e'$  connects two vertices from  $W_1$  or two vertices from  $W_2$ . Hence, if  $e' \in M$  then  $e'$  has one endpoint in  $A$  and the other in  $B$ . So,  $M$  is not a maximum cut which leads to a contradiction. ◁

<b>Rule 3</b>	Let $U$ be a block in $G - S$ which is a clique, $W \subseteq U$ is the set of special vertices such that $ W  \leq \lceil  U /2 \rceil$
Remove:	Vertices $V(U) \setminus W$ and a maximal subset of edges $F$ in $G[W]$ such that $(G - (U - W)) \setminus F$ is connected
Parameter:	Reduce $k$ by $\text{mc}(U) -  V(U)  +  W  -  E(G[W] \setminus F) $

**Proof of correctness.** Let  $G'$  be a graph obtained from  $G$  by deletion of all edges from  $U$  and vertices  $V(U) \setminus W$ .

Since  $U$  is a clique, its maximum cut is achieved when its vertices are divided between partitions equally (or almost equally if  $|U|$  is odd). Since  $|W| \leq \lceil |U|/2 \rceil$ , any cut of  $G'$  can be extended to induced maximum cut of  $U$  (simply add vertices from  $U \setminus W$  to both parts such that they contain  $\lceil |U|/2 \rceil$  and  $\lfloor |U|/2 \rfloor$  vertices from  $U$ ). Therefore,  $\text{mc}(G') + \text{mc}(U) \leq \text{mc}(G)$ .

Since  $G'$  and  $U$  do not have common edges we have  $\text{mc}(G') + \text{mc}(U) \geq \text{mc}(G)$ . Combining the two inequalities we have  $\text{mc}(G') + \text{mc}(U) = \text{mc}(G)$ .

Let  $G''$  be a graph  $(G - (U - W)) \setminus F$ . Note that  $V(G'') = V(G')$  and  $E(G'') = E(G') \cup (E(G[W]) \setminus F)$ . Each edge from the set  $E(G[W]) \setminus F$  is a bridge in  $G''$ , otherwise  $F$  is not maximal. In any graph maximum cut contains all bridges, by Claim 13, so we have:  $\text{mc}(G'') = \text{mc}(G') + |E(G[W]) \setminus F| = \text{mc}(G) - \text{mc}(U) + |E(G[W]) \setminus F|$ . And this proves correctness of the reduction.

Note that the reduction preserves the clique-cycle-forest property of  $G - S$  as we delete the subset  $V(U) \setminus W$  and the clique  $W$  was replaced by a spanning tree. So each edge in the spanning tree of  $W$  can be seen as a clique on two vertices. ◀

<b>Rule 4</b>	Let $e = bc$ be an edge from $E(G - S)$ such that $\deg_G b = \deg_G c = 2$ , and $a, d$ be the other neighbours of $b$ and $c$ respectively (note that $a$ and $d$ may be the same vertex)
Remove:	vertices $b, c$ and add edge $ad$ if $a \neq d$
Parameter:	No changes applied

**Proof of correctness.** Let  $G'$  be graph obtained after application of the reduction rule. We prove that  $\text{mc}(G') = \text{mc}(G) - 2$ .

First, we show that  $\text{mc}(G') \geq \text{mc}(G) - 2$ . Let  $(A, B)$  be partition of  $G$  that produces the maximum cut. Induced partition in the subgraph  $G'$  has cut of size  $\geq \text{mc}(G) - 2$ . Indeed, if all 3 edges  $ab, bc, cd$  are in cut  $E(A, B)$ , then  $a, d$  are in different partitions. Hence, the

induced partition cuts an edge  $ad$  in  $G'$  having a cut of size  $\text{mc}(G) - 3 + 1 = \text{mc}(G) - 2$  in  $G'$ . If at most 2 edges from the set  $\{ab, bc, cd\}$  belong to the cut  $E(A, B)$  then obviously induced vertex partition has cut at least  $|E(A, B)| - 2 = \text{mc}(G) - 2$ .

To prove that  $\text{mc}(G) \geq \text{mc}(G') + 2$  we construct partitioning of vertices  $V(G)$  based on partitioning of vertices  $V(G')$ . Let  $(A', B')$  be the maximum cut in  $G'$ . We construct partition of  $V(G)$  simply by adding vertices  $b, c$  to partition  $(A', B')$ . We place  $c$  be in the same part as  $a$  and  $b$  be in the other. Let us call obtained partition  $(A, B)$ . In this case edges  $ab, bc$  belong to cut  $E(A, B)$ , edge  $cd$  is in the cut if and only if  $ad$  was in the cut of the graph  $G'$ . Hence,  $|E_G(A, B)| = |E_{G'}(A', B')| + 2$ .

Since the lower bound and the maximum cut size decrease by two, the parameter should not be changed.

Note that after application of the reduction rule  $G' - S$  is a clique-cycle-forest as  $G - S$ . However, the reduction can remove a cycle of length 3 or turn a cycle of size 4 into two multiple edges. ◀

► **Lemma 14.** *If none of the above rules is applicable to  $G$  then at least half of all vertices in every block of  $G - S$  are special.*

**Proof.** For cliques it is true since otherwise rule 3 is applicable. Cycles can not have 2 consecutive non-special vertices since otherwise we can apply reduction rule 4. ◀

**Rule 5** If there are at least  $k$  even cycles blocks in  $G - S$   
 Return: YES-instance.

**Proof of correctness.** Consider a subgraph  $H$  containing  $k$  even cycles of  $G - S$ . We construct a spanning forest in  $H$ , to do this we remove an arbitrary edge in each cycle. This forest can be extended to a spanning tree  $F$  of the whole  $G$ . If we add back previously deleted edges of the subgraph  $H$  we obtain a bipartite graph (all introduced cycle have even length). The bipartite subgraph has exactly  $|V(G)| - 1 + k$  edges, hence,  $G$  has a required cut and we can output YES. ◀

Now we can bound the total size of connected components in  $G - S$  that have at least 3 edges to  $S$  (note that here we are speaking about connected components and not blocks). We split blocks of these components into several types and bound the total number of vertices in block of each type. We consider the following types of blocks from connected components with at least 3 edges going to  $S$ :

1. Blocks with  $\geq 3$  articulation points;
2. Blocks with  $< 3$  articulation points and at least one special vertex that is not an articulate vertex;
3. Even cycles with exactly two special vertices which are articulation points;
4. Cliques and odd cycles with exactly two special vertices which are articulation points.

These types of blocks cover all possibilities, since in connected components with at least three edges towards  $S$  all blocks with only one special vertex were removed by rule 1. Below for each type we bound the total size of blocks of this type.

1. For the graph  $G - S$  we consider a bipartite forest of blocks and articulation points  $F$ : for every block  $X$  we introduce a vertex  $a_X$  and for every articulation point  $y$  we introduce a vertex  $b_y$ . Moreover,  $a_X b_y \in E(F)$  if and only if  $y \in V(X)$ . Each articulation point belong to at least two blocks. Therefore leaves and isolated vertices in  $F$  correspond to blocks with one and zero articulation points respectively. We recall, that we removed all

blocks with at most one special vertex except isolated vertices with at least two edges going to  $S$ . Hence, each block corresponding to isolated vertex or leaf in the forest  $F$  has an edge going to  $S$ , as every non-isolated block left has at least two special vertices each of these blocks has its own edge to  $S$ . Hence, by Lemma 12 we have that there are at most  $24k$  leaves and isolated vertices in  $F$ .

It is known that for any tree or forest  $T$  the following holds

$$\sum_{v \in T: \deg_T v > 2} (\deg(v) - 2) \leq \text{number of leaves in } T.$$

Hence, we have

$$\sum_{v \in F: \deg_F v > 2} (\deg_F(v) - 2) \leq 24k. \quad (1)$$

Moreover,  $\sum_{v \in F: \deg_F v > 2} \deg_F(v) \leq 3 \sum_{v \in F: \deg_F v > 2} (\deg_F(v) - 2) \leq 3 \cdot 24k = 72k$ .

Note that the total number of articulation points in blocks with at least 3 articulation points is bounded by  $\sum_{v \in F: \deg_F v > 2} \deg_F(v)$ . The total number of special vertices that are not articulation points in such blocks is bounded by  $24k$ , by Lemma 12. Therefore, the total number of special vertices in blocks with at least 3 articulation points is bounded by  $72k + 24k = 96k$ . Hence, by Lemma 14 these blocks have at most  $2 \cdot 96k = 192k$  vertices.

2. Each block of these type has at least one special vertex  $v$  that is not an articulation point. This vertex must have an edge to  $S$ . Therefore at least one third of special vertices in this type blocks are vertices with an edge to  $S$ . By Lemma 12, number of vertices with an edge to  $S$  is at most  $24k$ . Hence, blocks of this type have at most  $3 \cdot 24k = 72k$  special vertices. Moreover, by lemma 14 we conclude that the total number of vertices in these blocks is at most  $2 \cdot 72k = 144k$ .
3. There is at most  $k$  such blocks otherwise the reduction rule 5 is applicable. By Lemma 14 each of these blocks has at most 4 vertices, so their total size is at most  $4k$ .
4. We note, that the only blocks in this category are simple edge between two articulation points. Indeed, a clique having more vertices would be reduced by Rule 3. An odd cycle with only two special vertices must have size 3 by Lemma 14. However, a cycle on 3 vertices is also a clique, so it is also subject to reduction by rule 3.

To bound the number of vertices in these blocks we again use forest of blocks and articulation points  $F$  constructed before. Let us mark and count vertices in this forest that belong to one of the following classes:

- a. **vertices of degree  $\geq 3$** : there is at most  $24k$  of such vertices, follows from inequality 1
- b. **other vertices corresponding to blocks of type 2 and 3**: Note that blocks of first type have degree  $\geq 3$  and therefore are counted in previous point. Before we showed that there are at most  $24k$  blocks of the second type and at most  $k$  blocks of the third type, so there are at most  $25k$  vertices of these type.
- c. **vertices corresponding to articulation points with an edge to  $S$** : by Lemma 12 there is at most  $24k$  such vertices.

Recall that we mark all vertices from bullets  $a, b, c$ . Hence, in total there are at most  $24k + 25k + 24k = 73k$  marked vertices. Note that every block of type 4 corresponds to an unmarked vertex.

Unmarked vertices correspond to blocks of type 4 and articulation points that (i) does not have an edge to  $S$ , (ii) belongs to exactly two blocks. We cannot have a path of unmarked vertices of length 6 since otherwise Rule 4 is applicable.

Note that every unmarked vertex is of degree 2. We consider a forest  $F'$  obtained from  $F$  by contracting every path of unmarked vertices into an edge.  $F'$  is a forest with only marked vertices so it has at most  $73k$  vertices and at most  $\leq 73k - 1$  edges. No more than 6 unmarked vertices can be mapped to a single edge of  $F$ . Hence, there are at most  $6(73k - 1) = 438k - 6$  unmarked vertices in  $F$ . Recall that number of blocks of type 4 is at most the number of unmarked vertices. Moreover, each such block contains at most 2 vertices. Hence, number of vertices in such blocks is at most  $876k - 12$ .

We just have shown that number of vertices in connected components with at least three edges to  $S$  is at most  $O(k)$ . Now it is left to obtain a bound for the total size of connected components that have exactly 2 edges to  $S$  (one edge is not possible due to Rules 1, 2, zero edges is impossible due to connectivity of the graph). From now on we are considering only blocks of connected components that have exactly 2 edges to  $S$ . Since each leaf block has an edge to  $S$ , these components are either a single block with 2 edges to  $S$ , or a chain of blocks with two leaf blocks having exactly one edge to  $S$ , or a single vertex having two edges going to  $S$ .

Note that every block in these components has exactly 2 special vertices or the whole component is a single vertex with two edges going to  $S$ . Hence, each such block is a cycle  $C_4$ , or a cycle  $C_2$  (a double edge), or a single edge  $K_2$ , or the whole component is just one vertex.

**Rule 6** If the total number of vertices in the connected components of  $G - S$  with 2 edges to  $S$  is at least  $20k$   
 Return: YES.

**Proof of correctness.** Let  $S' = S \cup$  (even cycle blocks of connected components of  $G - S$  with 2 edges to  $S$ ) and  $U =$  other vertices of these components. Due to Rule 5 we have at most  $k$  even cycles in  $G - S$ . Moreover, we are considering blocks that have at most 4 vertices. Hence, at most  $4k$  vertices can belong to an even cycles. Therefore,  $|S'| \leq 3k + 4k = 7k$  and  $|U| \geq 20k - 4k \geq 16k$ .

Every vertex in  $U$  has a degree 2 in  $G$ . Hence, there are no edges between vertices in  $U$ , since otherwise to this edge Rule 4 is applicable. Therefore each vertex in  $U$  has 2 edges going to  $S'$ . We prove that in this case the graph contains a cut of size at least  $V(G) + k$ . To do this we consider the following procedure:

- take a spanning forest  $H$  in  $G$  such that each tree in the forest has exactly one vertex in  $S'$ ;
- uniformly randomly partition vertices in  $S'$  in two parts;
- place the rest of all vertices in the part so that all edges from trees in  $H$  are in cut.

Note that every two vertices from different trees are placed in parts randomly independently. Hence, each edge between trees can be in the constructed cut with probability  $\frac{1}{2}$ . Since  $|S'| \leq 7k$  and each tree has one vertex in  $S'$  there is at least  $|V(G)| - 7k$  edges in  $H$ . Every vertex in  $U$  has two edges to vertices in  $S'$ . Hence, one of the edges is an edge between two trees in  $H$ . Therefore, the expected number of edges in the cut is at least  $\geq |E(H)| + \frac{16k}{2} = |V(G)| - |S'| + \frac{16k}{2} \geq |V(G)| - 7k + \frac{16k}{2} = |V(G)| + k$ . Hence, we proved that a cut of size at least  $|V(G)| - 1 + k$  exists.

Note that this procedure can be derandomized using method of conditional probabilities [17] which allows to find a required cut deterministically, if needed. ◀

Now we are ready to bound the overall number of vertices. Recall that there are at most  $192k$  vertices in blocks of type 1, at most  $144k$  vertices in blocks of type 2, at most  $4k$  vertices in blocks of type 3, at most  $876k - 12$  vertices in blocks of type 4. Hence,

number of vertices in connected components with at least 3 edges going to  $S$  is at most  $192k + 144k + 4k + 876k - 12 = 1216k - 12$ . We also have at most  $20k$  vertices in other connected components of  $G - S$  and at most  $3k$  vertices in  $S$ . In total we have at most  $1216k - 12 + 20k + 3k = \mathcal{O}(k)$  vertices.

In order to bound number of edges we employ the final reduction rule.

**Rule 7** If graph contains at least  $2k + 2|V(G)|$  edges  
Return: YES-instance.

**Proof of correctness.** Every graph has a cut of size at least  $\frac{|E(G)|}{2}$ . Hence, in this case graph has a cut of size at least  $\frac{2k+2|V(G)|}{2} = |V(G)| + k$  which means that our input is a YES-instance. ◀

Taking into account that  $|V(G)| = \mathcal{O}(k)$  after application of Rule 7 we conclude that  $|E(G)| = \mathcal{O}(k)$ .

The algorithm either produces a graph with  $\mathcal{O}(k)$  vertices and edges or concludes that the graph has a required cut. In the latter we can output a trivial YES-instance. Hence, we constructed a linear kernel.

Note that the final graph might contain multi-edges. However, in this case we can apply reduction rule 4 backwards and replace every multi-edge with a cycle of length 4. It is easy to see that exhaustive application of this operations increase kernel size only linearly. ◀

The following theorem shows that the obtained kernel has asymptotically optimal size unless ETH fails.

► **Theorem 2.** *There is no kernel with sublinear number of vertices for MAX-CUT-AST unless ETH fails.*

**Proof.** A trivial brute force algorithm solves MAX-CUT in  $\mathcal{O}(2^{|V(G)|})$ . A kernel with  $o(k)$  vertices would imply that we can solve MAX-CUT in  $2^{o(k)} = 2^{o(|E(G)|)}$  which is impossible unless ETH fails. ◀

## 4 Subexponential Algorithms for Max-Cut-AST

In this section we present subexponential algorithms for MAX-CUT-AST in chordal and co-bipartite input graphs.

### 4.1 Co-bipartite Graphs

► **Theorem 3.** *MAX-CUT-AST can be solved in a connected co-bipartite graph  $G$  in  $2^{\mathcal{O}(\sqrt{k})}$  poly time.*

**Proof.** Note that co-bipartite graphs consist of two disjoint cliques and edges between them. At least one of the cliques contains at least half of the vertices. Therefore, each co-bipartite graph contains at least  $\frac{n}{2}(\frac{n}{2} - 1)/2$  edges. It is well known that a maximum edge cut in any graph contains at least half of all edges. Hence, in any co-bipartite graph maximum cut size is at least  $\frac{n}{2}(\frac{n}{2} - 1)/4$ . Therefore, if  $\frac{n}{2}(\frac{n}{2} - 1)/4 \geq n - 1 + k$  we can output Yes immediately. Otherwise,  $k = \Omega(n^2)$  and the simple brute-force algorithm with working time  $2^n n^{\mathcal{O}(1)}$  is actually  $2^{\mathcal{O}(\sqrt{k})}$  poly algorithm. ◀

## 4.2 Chordal Graphs

First of all we recall some well-known results and prove auxiliary lemma.

► **Lemma 17** ([11]). *For an input chordal graph  $G$  we can find a tree decomposition of minimum width in polynomial time. Moreover, in this tree decomposition all vertices of each bag induce a clique in the original input graph  $G$ .*

► **Lemma 18** ([1]). *Given an input graph  $G$  and its tree decomposition of width  $k$  one can find the size of maximum cut in  $2^{\mathcal{O}(k)}$  poly time.*

► **Lemma 19.** *Let  $H$  be an induced subgraph in a connected graph  $G$  and graph  $H$  has a cut with at least  $\ell$  edges then the graph  $G$  has a cut of size at least  $|V(G)| - |V(H)| + \ell$ .*

**Proof.** Assume that  $(A, B)$  is the partitioning of  $V(H)$  into two parts such that  $|E(A, B)| \geq \ell$ . We complete the partitioning  $(A, B)$  with vertices from  $G \setminus H$  such that we get a cut of size at least  $|V(G)| - |V(H)| + \ell$ .

Let us consider a spanning forest  $F$  of the graph  $G$  such that each tree  $T$  from the forest  $F$  has only one vertex from  $V(H)$  and the vertex is a root node of the tree. For each vertex  $v \in V(G)$  we assign a tree  $T_v$  such that  $v \in T_v$  and  $T_v \in F$ . Moreover, for each  $v \in V(G)$  we assign vertex  $r_v \in V(H)$  such that  $r_v \in T_v$  and  $r_v$  is a root vertex of  $T_v$ . Now we are ready to present the partitioning. If  $d_{T_v}(v, r_v)$  is even we place  $v$  in the same part as  $r_v$ , otherwise we place  $v$  in the opposite part of  $r_v$ . In the constructed partitioning each edge of forest  $F$  is in the cut, since for each vertex its ancestor belong to a different part. Since the graph  $G$  is connected we have that  $|E(F)| = |V(G)| - |V(H)|$ . Also the partitioning contains all edges from the initial cut of subgraph  $H$ . Therefore, we constructed a cut of size at least  $|V(G)| - |V(H)| + \ell$ . ◀

Now we have all ingredients to prove the main theorem of this subsection.

► **Theorem 4.** *MAX-CUT-AST on a connected chordal graphs admits a  $2^{\mathcal{O}(\sqrt{k})}$  poly-time algorithm.*

**Proof.** Using Lemma 17 we find tree decomposition of the input graph  $G$ . In this tree decomposition each bag is a clique. We denote by  $\ell - 1$  the treewidth of the input graph  $G$ . Hence, there is a bag of size  $\ell$ . It means that  $G$  contains a subgraph  $H$  such that  $H$  is a clique on  $\ell$  vertices. If  $\frac{\ell(\ell-1)}{4} \geq k + \ell - 1$  then by Lemma 19 we conclude that the graph  $G$  contains a cut of size at least  $n + k - 1$ .

Otherwise,  $\frac{\ell(\ell-1)}{4} < k + \ell - 1$  and we have  $\ell < 5 + 2\sqrt{k}$ . Hence,  $\ell = \mathcal{O}(\sqrt{k})$  and we can find an exact value of the maximum cut by standard dynamic programming using tree decomposition. The running time of this algorithm is  $2^{\mathcal{O}(\ell)}$  poly =  $2^{\mathcal{O}(\sqrt{k})}$  poly. ◀

► **Corollary 21.** *MAX-CUT-AST on a connected split graph admits a  $2^{\mathcal{O}(\sqrt{k})}$  poly algorithm.*

**Proof.** The statement immediately follows from the previous theorem since the class of all split graphs is a subclass of all chordal graphs. ◀

## 4.3 Lower Bounds

Under assumption of the Exponential Time Hypothesis we show that algorithms for chordal and split graphs are essentially tight.

► **Theorem 5.** *MAX-CUT-AST does not admit  $2^{\mathcal{O}(\sqrt{k})}$  poly or  $2^{\mathcal{O}(\sqrt{n})}$  poly algorithms on split graphs and on chordal graphs unless the ETH is false.*

**Proof.** Bodlaender and Jansen [1] presented a reduction of MAX-CUT on arbitrary graph  $G$  to MAX-CUT on split graph. This reduction transform graph  $G$  with a cut  $K$  into a graph  $G'$  on  $|V(G)| + |E(\bar{G})|$  vertices with  $|V(G)| \cdot (|V(G)| - 1)/2 + 2|E(\bar{G})|$  edges. Moreover,  $G$  has the maximum edge cut  $K$  if and only if  $G'$  has the maximum edge cut  $2|E(\bar{G})| + K$ . Note that  $2|E(\bar{G})| + K = O(n^2)$  and  $|V(G)| + |E(\bar{G})| = O(n^2)$ . Hence, by solving MAX-CUT-AST in  $2^{o(\sqrt{k})}$  poly time (or in  $2^{o(\sqrt{|V(G')|})}$  poly) on split graphs we can solve MAX-CUT on arbitrary graphs in  $2^{o(n)}$  poly time. However, it is known that under assumption of ETH MAX-CUT does not admit  $2^{o(n)}$  poly algorithm [6]. So we get a desired contradiction. ◀

► **Theorem 6.** *MAX-CUT-AST does not admit  $2^{o(\sqrt[4]{k})}$  poly algorithm on co-bipartite graphs unless the ETH is false.*

**Proof.** Bodlaender and Jansen [1] presented a reduction of MAX-CUT on split graphs to MAX-CUT on co-bipartite graph. If the initial split graph  $G$  contains  $n$  vertices then the obtained co-bipartite graph will contain  $O(n)$  vertices and  $O(n^2)$  edges. It means that  $k = O(n^2)$ . If MAX-CUT-AST admits  $2^{o(\sqrt[4]{k})}$  poly =  $2^{o(\sqrt[4]{n^2})}$  poly =  $2^{o(\sqrt{n})}$  poly algorithm on co-bipartite graphs then we can solve MAX-CUT on split graphs in  $2^{o(\sqrt[4]{k})}$  poly =  $2^{o(\sqrt[4]{n^2})}$  poly =  $2^{o(\sqrt{n})}$  poly which contradict the previous theorem. ◀

## 5 Tripartite Graphs

### 5.1 Parametrization Above a Spanning Tree

► **Lemma 24.** *Let us assume that MAX-CUT-AST on tripartite graphs with  $n$  vertices admits algorithm with running time  $T(k, n)$  where  $k$  is the parameter. Then MAX-CUT-AST on arbitrary graph  $G$  with  $n'$  vertices and  $m'$  edges can be solved in  $T(k, n' + 2m') + \text{poly}(n')$  time.*

**Proof.** To prove the statement we reduce MAX-CUT-AST on arbitrary graph  $G$  to MAX-CUT-AST on tripartite graph  $G'$  such that  $|V(G')| = |V(G)| + |2E(G)|$ . We construct  $G'$  in the following way, for each edge  $e = uv \in E(G)$ : (i) create two vertices  $e_u, e_v$ ; (ii) delete edge  $uv$ ; (iii) add edges  $ue_u, e_u e_v, e_v v$ . Essentially we subdivide each edge twice. It is easy to see that  $V(G)$  is an independent set in graph  $G'$  and  $G' \setminus G$  is a disjoint union of edges. Hence,  $G'$  is a tripartite graph.

Now we provide a connection between the size of maximum cut in the graph  $G$  and the size of maximum cut in  $G'$ . We claim that  $\text{mc}(G') = \text{mc}(G) + 2|E(G)|$ . Having partition  $(A', B')$  of vertices  $V(G')$  we construct partitioning  $(A, B)$  of  $V(G)$  such that  $|E(A, B)| \geq |E(A', B')| - 2|E(G)|$ . We take  $A = A' \cap V(G), B = B' \cap V(G)$ . All edges in  $E(G')$  we can partition in triples of the following type  $ue_u, e_u e_v, e_v v$ . It is easy to see that if cut  $E(A', B')$  contains all three edges  $ue_u, e_u e_v, e_v v$  then cut  $E(A, B)$  contains at least one edge. So it means that for each triple we lose at most 2 edges in  $E(A, B)$  compared to  $E(A', B')$ . Hence,  $|E(A, B)| \geq |E(A', B')| - 2|E(G)|$ .

Now, it is enough to prove that having a cut  $(A, B)$  of graph  $G$  we can construct a cut  $(A', B')$  of  $G'$  such that  $|E(A', B')| \geq |E(A, B)| + 2|E(G)|$ . In order to do this for each edge  $e = uv$  we place vertices  $e_u, e_v$  in the opposite part to vertices  $u, v$  correspondingly, i.e. if  $u \in A, v \in B$  then we put  $u, e_v$  to  $A'$  and  $v, e_u$  to  $B'$ , similarly, if  $u, v \in A$  then we put  $u, v$  to  $A'$  and  $e_u, e_v$  to  $B'$ . It is easy to see that for such cut  $(A', B')$  we have  $|E(A', B')| \geq |E(A, B)| + 2|E(G)|$ .

So we proved that  $\text{mc}(G') = \text{mc}(G) + 2|E(G)|$ . Recall that  $|V(G')| = |V(G)| + |2E(G)|$ . Hence,  $\text{mc}(G') - (|V(G')| - 1) = \text{mc}(G) - (|V(G)| - 1)$ . Therefore, answer for MAX-CUT-AST on graph  $G'$  is the same as the answer for MAX-CUT-AST on graph  $G$ . As  $G'$  is tripartite we have proved the desired result. ◀

Above lemma implies the following result.

► **Corollary 25.** *There is no  $2^{o(k)}$  poly algorithm for MAX-CUT-AST on tripartite graphs under assumption of the ETH.*

**Proof.** Such algorithm would imply that MAX-CUT-AST can be solved on arbitrary graph in  $2^{o(k)}$  poly time by lemma 24. However, existence of such algorithm contradict to the ETH [15]. ◀

## 5.2 Parameterization Above $\frac{2}{3}|E|$

First of all we show that any tripartite graph  $G$  has a maximum cut of size at least  $\frac{2}{3}|E|$ . Let assume that  $G$  has parts  $V_1, V_2, V_3$ . It is easy to see that  $|E(V_1, V_2 \cup V_3)| + |E(V_2, V_1 \cup V_3)| + |E(V_3, V_1 \cup V_2)| = 2|E(G)|$ . So at least one of the cuts  $(V_1, V_2 \cup V_3), (V_2, V_1 \cup V_3), (V_3, V_1 \cup V_2)$  has size  $\frac{2}{3}|E|$ . However, even knowing that a graph is tripartite we may not have a partition itself.

Below we show that we can find an edge cut of size  $\frac{2}{3}|E|$  in tripartite graphs even if partition on three parts is not provided in the input. To get this result we employ semi-definite programming.

► **Theorem 7.** *There is a polynomial time randomized algorithm that finds an edge cut of size  $\frac{2}{3}|E(G)|$  on an input tripartite graph  $G$ .*

**Proof.** First of all for each vertex  $v_i \in G$  we assign vector  $\vec{v}_i \in \mathbb{R}^n$  and formulate the following program:

$$\begin{aligned} \min \lambda \\ \forall i \in V(G) \quad \langle \vec{v}_i, \vec{v}_i \rangle = 1 \\ \forall ij \in E(G) \quad \langle \vec{v}_i, \vec{v}_j \rangle \leq \lambda \end{aligned}$$

Essentially we are looking for  $n$  unit vectors such that minimum angle between any two vectors that correspond to adjacent vertices is maximized. We know that the input graph is tripartite, hence there is a solution such that  $\lambda \leq -\frac{1}{2}$ . To achieve the value  $-\frac{1}{2}$  it is enough to map vertices of first part into  $(1, 0, \dots, 0)$ , vertices of second part into  $(-\frac{1}{2}, \frac{\sqrt{3}}{2}, 0, \dots, 0)$ , vertices of third part into  $(-\frac{1}{2}, -\frac{\sqrt{3}}{2}, 0, \dots, 0)$ . It means that in the optimum solution of the semidefinite program angle between two vectors corresponding to two adjacent vertices is at least  $\frac{2\pi}{3}$ . It is known [18] that for any  $\epsilon$  semidefinite programming can be solved with additive error of size  $\epsilon$  in polynomial time from the input and  $\log \frac{1}{\epsilon}$ . Therefore, we can find the optimum value of  $\lambda$  up to additive error  $\epsilon$ . After that we generate a random hyperplane and split vertices of graph into two parts. We put vertex  $v_i$  to the first part if the vector  $\vec{v}_i$  is lying on one side of the generated hyperplane or to the second if  $\vec{v}_i$  is lying on the other side of the hyperplane. The expected value of an edge  $e = v_i v_j$  being in the cut under such partitioning is equal to  $\arccos(\langle \vec{v}_i, \vec{v}_j \rangle) \geq \arccos(-\frac{1}{2} + \epsilon) = \frac{2}{3} - \delta(\epsilon)$  [18, Chapter 6]. Hence, the expected value of the cut is at least  $(\frac{2}{3} - \delta(\epsilon))|E|$ . We choose  $\epsilon$  in such way that  $\delta(\epsilon)|E| \leq \frac{1}{6}$ . Since derivative of  $\arccos(\cdot)$  is bounded in the neighborhood of  $-\frac{1}{2}$  we can take  $\epsilon = \frac{1}{1000|E|^2}$ . If we choose  $\epsilon$  in this way we obtain a polynomial time algorithm which output a cut of expected value at least  $\frac{2}{3}|E| - \frac{1}{6}$ . Note that the value  $\frac{2}{3}|E| - \frac{1}{6}$  is not integer and the size of a cut is an integer. So, the algorithm sometimes must output values of size at least  $\lceil \frac{2}{3}|E| \rceil - \frac{1}{6} = \lceil \frac{2}{3}|E| \rceil$ . Since the cut size is bounded by  $|E|$ , our algorithm output value of size  $\lceil \frac{2}{3}|E| \rceil$  with probability at least  $\Omega(\frac{1}{|E|})$ . Therefore it is enough to repeat the algorithm polynomial number of times, take the largest cut among all generated. The algorithm will not output cut of size at least  $\lceil \frac{2}{3}|E| \rceil$  only with exponentially small probability. ◀

► **Lemma 27** (\*). *Under the assumption  $P \neq NP$  there is no polynomial time algorithm that for each tripartite graph  $G$  finds a cut of size at least  $\frac{5}{6}|E|$  if it exists.*

In the following theorem we show that fraction  $\frac{5}{6}$  can be replaced with any fraction of the following type  $\frac{2}{3} + \epsilon$  where  $\epsilon \in (0, \frac{1}{6})$ . Informally speaking to achieve this results it is enough to add large number of disjoint subgraphs  $K_3$  to the construction in the previous theorem. Indeed, each partition of a triangle cuts at most 2 edges out of 3. Therefore, by adding triangles we make fraction of size of maximum cut to the total number of edges being close to  $\frac{2}{3}$ .

► **Theorem 8.** *Assuming  $P \neq NP$  for any  $0 < \epsilon < \frac{1}{6}$  there is no polynomial time algorithm that finds cut of size  $\geq (\frac{2}{3} + \epsilon)|E|$  in tripartite graph if such cut exists.*

**Proof.** In order to refute existence of such algorithm we show that using this algorithm we can construct a polynomial time algorithm that on tripartite graphs with the number of edges divisible by 6 outputs cut of size at least  $\frac{5}{6}|E|$ , if such cut exists.

Let us assume that tripartite graph  $G$  contains  $n$  vertices and  $m$  edges and we need to check existence of cut of size at least  $\frac{5}{6}m$ . If we add  $k$  disjoint triangles to the graph  $G$  then essentially we need to check if in the new graph exists a cut of size at least  $\geq \frac{5m}{6} + 2k$ , since in each triangle we can cut at most two edges. However, the number of edges in the new graph is  $m + 3k$ . Therefore the ratio between the cut and the overall number of edges becomes  $\frac{5m/6+2k}{m+3k}$ . This fraction tends to  $\frac{2}{3}$  as long as we increase  $k$ . Consider the maximum integer  $k$  such that the fraction is not smaller than  $\frac{2}{3} + \epsilon$ . Note that, for fixed  $\epsilon$  we have  $k = \mathcal{O}(m)$ . Since we chose the maximum  $k$  with such properties we have that:

$$\frac{5m/6 + 2(k+1)}{m + 3(k+1)} < \frac{2}{3} + \epsilon \quad (2)$$

Now it is left to show that cuts with  $\frac{5}{6}m - 1$  edges does not satisfy required equation, i.e. that:

$$\frac{5m/6 + 2k - 1}{m + 3k} < \frac{2}{3} + \epsilon$$

To do this it is enough to show that  $\frac{5m/6+2k-1}{m+3k} < \frac{5m/6+2(k+1)}{m+3(k+1)}$ . Below we provide detailed computations.

$$\begin{aligned} & \frac{5m/6 + 2k - 1}{m + 3k} < \frac{5m/6 + 2(k+1)}{m + 3(k+1)} \\ 0 & < \frac{5m/6 + 2k + 2}{m + 3k + 3} - \frac{5m/6 + 2k - 1}{m + 3k} \\ 0 & < \frac{(5m/6 + 2k + 2)(m + 3k) - (5m/6 + 2k - 1)(m + 3k + 3)}{(m + 3k + 3)(m + 3k)} \\ 0 & < \frac{(5m/6 + 2k)(m + 3k) + 2(m + 3k) - (5m/6 + 2k)(m + 3k + 3) + (m + 3k + 3)}{(m + 3k + 3)(m + 3k)} \\ 0 & < \frac{(5m/6 + 2k)(m + 3k) + 2(m + 3k) - (5m/6 + 2k)(m + 3k) - 3(5m/6 + 2k) + (m + 3k + 3)}{(m + 3k + 3)(m + 3k)} \\ 0 & < \frac{2(m + 3k) - 3(5m/6 + 2k) + (m + 3k + 3)}{(m + 3k + 3)(m + 3k)} \\ 0 & < \frac{m(2 - 5/2 + 1) + k(6 - 6 + 3) + 3}{(m + 3k + 3)(m + 3k)} \\ 0 & < \frac{m/2 + 3k + 3}{(m + 3k + 3)(m + 3k)} \end{aligned}$$

Hence, the constructed graph with disjoint triangles  $G'$  contains cut of size  $\frac{5m}{6} + 2k$  if and only if it contains at least  $(\frac{2}{3} + \epsilon)|E(G')|$ . Moreover, it happens if and only if initial graph contained a cut with at least  $\frac{5}{6}|E(G)|$  edges. ◀

## 6 Conclusion

In Section 5 we initiate study of MAXIMUM CUT problem on tripartite graphs parameterized above  $\frac{2}{3}|E|$  lower bound. We think that existence of an FPT algorithm for this problem is an interesting open question.

## Abstract

We present attacks on a generalized subset-sum pseudorandom generator, which was proposed by von zur Gathen and Shparlinski in 2004. Our attacks rely on a sub-quadratic algorithm for solving a vectorial variant of the 3SUM problem, which is of independent interest. The attacks presented have complexities well below the brute-force attack, making the generators vulnerable. We provide a thorough analysis of the attacks and their complexities and demonstrate their practicality through implementations and experiments.

## 1 Introduction

A pseudo-random number generator is a deterministic algorithm that runs in polynomial time using a short random seed as its input, and produces a long sequence that is indistinguishable from a truly random sequence in polynomial time. The versatile applications of pseudo-random numbers have been extensively explored in the literature, particularly in cryptography where they are employed for tasks such as key generation, encryption, and digital signatures.

In 1985, Rueppel and Massey introduced the *knapsack generator* (or *subset sum generator*) [16] whose security ultimately relies on the NP-hard *modular subset sum problem*: given integers  $\omega_0, \dots, \omega_{n-1}$ ,  $t$  and  $q$ , find a subset of the  $\omega_i$ ’s that sum to  $t$  modulo  $q$ , i.e. to find bits  $x_0, \dots, x_{n-1} \in \{0, 1\}$  such that

$$\sum_{i=0}^{n-1} x_i \omega_i = t \pmod{q}.$$

In the *knapsack generator*, the modulus  $q$  is usually taken as a power of 2,  $q = 2^n$ , the *weights*  $\omega_0, \dots, \omega_{n-1}$  are kept secret and given  $n$  secret *control bits*  $u_0, \dots, u_{n-1}$ , one extends them using a linear feedback generator (a fast but non-cryptographically secure pseudo-random number generator) to obtain a flow of pseudo-random bits  $(u_i)_{0 \leq i \leq N+n-2}$ . For  $i \in \{0, \dots, N-1\}$ , one then computes

$$v_i = \sum_{j=0}^{n-1} u_{i+j} \omega_j \bmod 2^n$$

and outputs  $y_i$  which are the  $\rho = n - \ell$  leading bits of  $v_i$  where  $\ell$  is a given parameter.

In 2011, Knellwolf and Meier [12] presented a cryptanalysis of this generator. They used a *guess-and-determine* strategy coupled with lattice-based techniques to recover most of the key in relevant instances of the generator. In order to run said attack, they needed to guess all the  $n$  initial control bits. Hence their attack had a time complexity  $\Omega(2^n)$ . In 2009, Von zur Gathen and Shparlinski [20] presented the *fast knapsack generator* that had a far smaller key and was sensibly faster but had not undergone a serious cryptanalysis until recently [14]. We consider another variant of the subset sum pseudorandom generator, suggested by von zur Gathen and Shparlinski in 2004 [19].

The family of generators proposed by von zur Gathen and Shparlinski can be described in an abstract way using two integer parameters  $\lambda$  and  $n$  and three independent components:

- a control-sequence generator  $\text{CSG} : \{0, 1\}^\lambda \times \mathbb{N} \rightarrow \{0, 1\}^n$ ;
- an Abelian cyclic group  $(\mathbb{G}, +)$  of order  $q$  where the group law is denoted additively;
- a deterministic and public conversion function  $\Psi : \mathbb{G} \rightarrow \{0, 1\}^\rho$  where  $\rho$  denotes the output length of the pseudo-random generator.

The seed of this generalized subset-sum generator consists in a bit-string  $\text{seed}_0 \in \{0, 1\}^\lambda$  and  $n$  group elements  $P_1, \dots, P_n \in \mathbb{G}$ . The bit size of the seed is thus equal to  $\lambda + n \cdot \lceil \log_2(q) \rceil$ . At each iteration  $i \in \mathbb{N}$ , the control-sequence generator generates an  $n$ -bit string  $\mathbf{v}_i = (v_i^1, \dots, v_i^n) = \text{CSG}(\text{seed}_0, i)$ , computes the group element  $Q_i$  defined by

$$Q_i = [v_i^1]P_1 + \dots + [v_i^n]P_n \in \mathbb{G}$$

and outputs  $s_i = \Psi(Q_i) \in \{0, 1\}^\rho$ .

In the Rueppel-Massey classical subset sum generator, the group  $\mathbb{G}$  is thus the group of modular residue  $\mathbb{G} = \mathbb{Z}_q$ , the control-sequence generator is defined by a linear feedback shift register and the conversion function is a truncation. In [19], von zur Gathen and Shparlinski proposed to use for  $\mathbb{G}$  the group of rational points of an elliptic curve defined over a (prime) finite field, a linear feedback shift register as the control-sequence generator and again a truncation for the conversion function (more precisely, truncation of the  $x$ -coordinate of the elliptic curve point  $Q_i$ ). They proposed to use  $\lambda = n$  and an elliptic curve defined over a finite field  $\mathbb{Z}_p$  where  $p$  is a  $n$ -bit prime number. By the Hasse-Weil theorem [9], the number of group elements  $q$  is around  $2^n$  and the total seed size is  $\simeq n + n \cdot n = n \cdot (n + 1)$ . They suggested that  $\Psi$  should discard  $\ell = \log_2(n)$  low-order bits of the  $x$ -coordinate of the point before using it as pseudo-random output.

Von zur Gathen and Shparlinski claimed that: “the only available attack on this generator is the brute force search over all parameters defining this generator” and thus using  $n$  as small as 12 should provide a 128-bit security level. The statistical properties of the sequences generated by this pseudo-random generator were analyzed in [4, 1, 8] but its cryptographic security has not been studied up to the present article. We present a simple attack against this generator and a lattice-based attack on another variant derived from this abstraction. In the instantiation suggested by von zur Gathen and Shparlinski, our attack

has complexity  $\mathcal{O}(2^{1.78n})$  well below the  $\mathcal{O}(2^{n(n+1)})$  brute-force attack. Our attacks rely on a sub-quadratic algorithm for solving a vectorial variant of the 3SUM problem, which is of independent interest. We provide a thorough analysis of the attacks and their complexities, and demonstrate their practicality through implementations and experiments.

## 2 High-level description of the attack

We consider the case where the control sequence generated by the CSG is known by the adversary. If this is not the case, they can simply try all possible values for  $\text{seed}_0 \in \{0, 1\}^\lambda$  which increases the complexity of the attack by a multiplicative factor  $2^\lambda$ .

We assume that the control sequence generator outputs uniform and independent  $n$ -bit strings  $\mathbf{v}_i = \text{CSG}(\text{seed}_0, i)$  for each  $i \in \mathbb{N}$ . Note that in the concrete schemes that we attack, this is obviously false; we nevertheless carry our analysis under this assumption and our experimental results will show that it actually holds in practice.

Let us suppose that an adversary finds three indices  $i, j, k$  such that  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$  as vectors of integers, i.e. where the addition is performed coordinate-wise over  $\mathbb{Z}$ . In this case, the adversary knows that the relation  $Q_i + Q_j = Q_k$  holds in the group  $\mathbb{G}$ . They are not given the actual values of the points  $Q_i, Q_j$  and  $Q_k$  but only the values  $\Psi(Q_i), \Psi(Q_j)$  and  $\Psi(Q_k)$ . Assume that the number of preimages through  $\Psi$  is limited and that the adversary can efficiently compute them; they can simply check if  $\Psi(X + Y) = \Psi(Q_k)$  for all  $(X, Y)$  such that  $\Psi(X) = \Psi(Q_i)$  and  $\Psi(Y) = \Psi(Q_j)$ . If there exists only one such pair  $(X, Y)$  then the adversary can safely assume that  $Q_i = X, Q_j = Y$  (and  $Q_k = X + Y$ ).

The number of pairs  $(X, Y)$ 's such that

$$\Psi(X + Y) = \Psi(Q_k) \tag{1}$$

is difficult to estimate and depends heavily on the group  $\mathbb{G}$  and the conversion function  $\Psi$ . In [17], Shoup studied the computational complexity of the discrete logarithm in Abelian groups in the context of algorithms which do not exploit any special properties of the encodings of group elements. Shoup introduced the *generic group model* where each group element is encoded as a unique and arbitrary binary string (picked uniformly at random and independent of the actual group structure). As a consequence, it is not possible for an algorithm in this model to exploit any special properties of the encodings and group elements can only be operated on using an oracle that provides access to the group operations. If we make a similar assumption on the group  $\mathbb{G}$  and the conversion function  $\Psi$  is a truncation of  $\ell$  bits out of the  $(\log_2 q)$ -bit encodings of group elements, then we can expect that the number of preimages is close to  $2^\ell$  and the number of pairs  $(X, Y)$  different from  $(Q_i, Q_j)$  for which (1) holds is expected to be

$$2^\ell \cdot 2^\ell / 2^{\log_2(q) - \ell} \simeq 2^{3\ell} / q. \tag{2}$$

In particular if  $\rho > 2 \cdot \log_2(q) / 3$ , one expects the number of candidates for  $(Q_i, Q_j, Q_k)$  to be constant in a “generic” group. It is worth mentioning that this assumption does not hold in the classical knapsack generator that uses the group  $\mathbb{G} = \mathbb{Z}_m$  since in this case, the number of candidates for a single equation will be about  $2^{2\ell}$ .

Each relation  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$  gives two relations in the group  $\mathbb{G}$ :

$$Q_i = v_i^1 P_1 + \dots + v_i^n P_n \quad \text{and} \quad Q_j = v_j^1 P_1 + \dots + v_j^n P_n$$

If the adversary collect sufficiently many linearly independent such relations, they would be able to retrieve all the weights used in the generalized knapsack generator.

■ **Table 1** Tabulating all solutions of  $x + y = z$  for  $x, y, z \in \{0, 1\}$ .

$x$	0	0	0	0	1	1	1	1
$y$	0	0	1	1	0	0	1	1
$z$	0	1	0	1	0	1	0	1
$x + y$	0	0	1	1	1	1	2	2

In the following, we describe and analyse an algorithm to find “good triplets” of indices  $(i, j, k)$  such that  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$  and show how to use it to attack the elliptic knapsack generator when  $\rho = n - \log_2(n)$  (as suggested by von zur Gathen and Shparlinski).

### 3 Finding “Good Triplets”

Assume that three lists  $A, B$ , and  $C$ , each of size  $N$ , are made of uniformly random  $n$ -bit strings. Let  $Y$  be the random variable that counts the number of triplets  $(x, y, z) \in A \times B \times C$  such that  $x + y = z$  when  $x, y$  and  $z$  are seen over  $\mathbb{Z}^n$  and not modulo 2. When this relation holds, we call  $(x, y, z)$  a “good triplet”. Our goals in this section are twofold: 1) lower-bound the probability that  $A, B$  and  $C$  contain a good triplet and 2) design an algorithm to find good triplets efficiently.

As a warm-up, examining the simplest case ( $n = 1$ ) is interesting (cf. Table 1). Looking at this table, we see that  $\Pr(x + y = z) = 3/8$ . We next prove the following

► **Theorem 1.**  $E(Y) = N^3 \left(\frac{3}{8}\right)^n$ , and  $\Pr(Y = 0) \leq \frac{1}{N^3} \left(\frac{8}{3}\right)^n + \frac{3}{N} \left(\frac{10}{9}\right)^n + \frac{3}{N^2} \left(\frac{4}{3}\right)^n$ .

The proof is given in Appendix A. It boils down to estimating the variance of  $Y$  and using the second-moment inequality. With  $N = \alpha(8/3)^{n/3}$ , Theorem 1 yields:

$$\Pr(Y = 0) \leq \frac{1}{\alpha^3} + \frac{3}{\alpha}(0.801\dots)^n + \frac{3}{\alpha^2}(0.69\dots)^n.$$

Therefore, setting  $\alpha = 10$  is sufficient to ensure that a good triplet exists with probability 99.9%. In addition, it follows from the theorem that

$$\Pr(Y = 0) \leq \frac{1}{E(Y)} + \frac{3}{(E(Y))^{2/3}} + \frac{3}{(E(Y))^{1/3}}. \tag{3}$$

#### 3.1 A Simple Sub-Quadratic Algorithm to Find Good Triplets

Finding a “good triplet” (such that  $x + y = z$ ) can be done using a naive quadratic algorithm: for all pairs  $(x, y)$  in  $A \times B$ , check if  $x + y \in C$ ; if so, return  $(x, y, x + y)$ ; after this loop, return  $\perp$  (to handle the case where the algorithm fails). This could potentially be sped up a little by exploiting the fact that  $x$  and  $y$  are necessarily disjoint.

In this section, we present a simple algorithm to find a good triplet more efficiently. We work under the assumption that the input lists have size  $N := \alpha(8/3)^{n/3}$  for some constant  $\alpha \geq 4$ . Under this condition, (3) ensures that there is a good triplet with probability at least  $\frac{3}{64}$ . This assumption will be relaxed in the next section.

Looking again at Table 1, we see that  $\Pr(x = 1 \mid x + y = z) = 1/3$  while  $\Pr(z = 1 \mid x + y = z) = 2/3$ . In other terms, even though  $x, y, z$  are sampled uniformly at random, if we restrict our attention to good triplets, then  $x$  and  $y$  are biased towards zero (sparse) while  $z$  is biased towards 1 (dense).

This observation suggests an algorithm to find good triplets efficiently: remove from  $A, B$  (resp.  $C$ ) input vectors of Hamming weight different from  $n/3$  (resp.  $2n/3$ ), then run the naive quadratic algorithm on what remains.

► **Theorem 2.** *This algorithm terminates in  $\mathcal{O}(N^e)$  with  $e = 2 \ln(9/4) / \ln(8/3) \approx 1.654$  and succeeds with probability  $\Omega(\frac{1}{n})$ .*

**Proof.** Let  $H$  denote the binary entropy function, meaning that  $H(x) = -x \log_2(x) - (1-x) \log_2(1-x)$ , for all  $0 < x < 1$ . The following standard bounds for the binomial coefficient can be derived from Stirling's formula:

$$\frac{2^{nH(x)}}{\sqrt{8nx(1-x)}} \leq \binom{n}{xn} \leq \frac{2^{nH(x)}}{\sqrt{2\pi nx(1-x)}}, \quad (0 < x < 1/2) \quad (4)$$

It follows from the discussion just before the statement of the theorem that there are  $3^n$  good triplets on  $n$  bits (out of  $8^n$  triplets in total). The number of good triplets that satisfy the weight condition imposed by the algorithm is

$$N = \binom{n}{n/3, n/3, n/3} = \binom{n}{2n/3} \binom{2n/3}{n/3} \geq \frac{2^{nH(2/3)}}{\sqrt{n}4/3} \frac{2^{2n/3}}{2\sqrt{n/3}} = \frac{3\sqrt{3}}{8n} 3^n.$$

If the input list contain a good triplet, then the algorithm described above returns it with probability greater than  $0.65/n$ . The claimed time complexity is in fact a consequence of the *next* theorem (Theorem 5), and we will therefore not prove it here. ◀

### 3.2 Sub-Quadratic Algorithm with Overwhelming Success Probability

We generalize the algorithm of the previous section by relaxing the weight condition. This yields Algorithm 1. It takes an additional argument  $w$  controlling the maximum allowed weight. In the sequel, all the stated complexities must be understood “up to a constant factor”. Let  $\epsilon$  denote a constant in the open interval  $(0; \frac{1}{6})$ . Let  $X \sim \mathcal{B}(n, p)$  be a binomial random variable. We will use the classical inequality (5) given below, a proof of which can be found in [2] amongst others. Here,  $D(a, p)$  is the Kullback-Leibler divergence between an  $a$ -coin and a  $p$ -coin:

$$\begin{aligned} \Pr(X \leq an) &\leq \exp(-nD(a, p)) && \text{if } a < p. \\ \Pr(X \geq an) &\leq \exp(-nD(a, p)) && \text{if } a > p, \\ D(a, p) &= a \ln \frac{a}{p} + (1-a) \ln \frac{1-a}{1-p}. \end{aligned} \quad (5)$$

We denote by  $\text{wt}(x)$  the Hamming weight of a bit string  $x$ .

■ **Algorithm 1** Find good triplets.

---

```

1: function FINDTRIPLET( $A, B, C, w$ )
2:    $A' \leftarrow \{x \in A \mid \text{wt}(x) \leq w\}$ 
3:    $B' \leftarrow \{y \in B \mid \text{wt}(y) \leq w\}$ 
4:   for all  $x, y \in A' \times B'$  do
5:     if  $x + y \in C$  then
6:       return  $(x, y, z)$ 
7:   return  $\perp$ 

```

---

► **Lemma 3.** *With  $w = n(\frac{1}{3} + \epsilon)$ , if the input contains a good triplet, then Algorithm 1 returns  $\perp$  with probability less than  $2 \exp(-2n\epsilon^2)$ .*

**Proof.** Assume that the input lists contain a good triplet  $(x^*, y^*, z^*)$ . It will be discarded if and only if the weight of either  $x^*, y^*$  is greater than  $w$ . We know that the weight of  $x^*$  and  $y^*$  follows a binomial distribution of parameters  $(n, 1/3)$ , therefore (5) shows that either has weight greater than  $n(1/3 + \epsilon)$  with probability less than  $\exp(-nD(1/3 + \epsilon, 1/3))$ .

The (“well-known”) fact that  $D(p + \epsilon, p) \geq 2\epsilon^2$  combined with union bound (for  $x^*$  and  $y^*$ ) then yields the announced result. ◀

► **Lemma 4.** *Let  $T$  denote the running time of Algorithm 1 with  $w = n(\frac{1}{3} + \epsilon)$ . Then  $E[T] \leq N + N^2 \exp[-2nD(\frac{1}{3} + \epsilon, \frac{1}{2})]$ .*

**Proof.** Filtering the input lists and keeping only low-weight vectors can be done in linear time. Given the complexity of the naive quadratic algorithm, the total time complexity is simply  $T = N + |A'| \cdot |B'|$ .

Let  $X \sim \mathcal{B}(n, 1/2)$  be a binomial random variable modeling the weight of a random  $n$ -bit vector. Such a vector belongs to  $A'$  or  $B'$  if its weight is less than or equal to  $w$ , and this happens with probability  $s := \Pr(X \leq w)$ . The binomial tail bound (5) yields  $s \leq \exp[-nD(\frac{1}{3} + \epsilon, \frac{1}{2})]$ .

The sizes of  $A'$  and  $B'$  are stochastically independent random variables following a binomial distribution of parameters  $(N, s)$  with expectation  $Ns$ . The expected running time of the quadratic algorithm on  $A'$  and  $B'$  is therefore  $E(|A'| \times |B'|) = E|A'| \times E|B'| = N^2 s^2$ . Combining this with the upper bound on  $s$  gives the announced result. ◀

► **Theorem 5.** *Write  $e = 2 \cdot \frac{\ln(9/4)}{\ln(8/3)} \approx 1.654$ . For all  $d > e$  there is an algorithm that runs in time  $\mathcal{O}(N^d)$ , where  $N$  denotes the size of the input list and fails to reveal a good triplet present in the input with negligible probability (in  $n$ ).*

**Proof.** Let  $e < d < 2$  be a complexity exponent greater than the bound  $e$  given in the statement of the theorem. There always exist  $\epsilon > 0$  such that

$$d = 2 - 6 \frac{D(\frac{1}{3} + \epsilon, \frac{1}{2})}{\frac{1}{3} \ln \frac{8}{3} + \epsilon \ln 2}.$$

Indeed, setting  $\epsilon = 0$  in this expression yields the lower-bound exponent  $e$  of the theorem, and the expression of  $d$  is increasing as a function of  $\epsilon$ ; it reaches  $d = 2$  for  $\epsilon = 1/6$ .

Let  $N_0 := (8/3)^{n/3}$ , so that input lists of size  $N_0$  contain a single good triplet in average. We distinguish two cases depending of the size of the input lists.

Suppose that  $N \leq 2^{\epsilon n} N_0$ , where  $N$  denotes the size of the input lists. In this case run Algorithm 1 with  $w = n(\frac{1}{3} + \epsilon)$ . Lemma 3 guarantees the exponentially small failure probability while lemma 4 tells us that the expected running time  $T$  is less than  $N + N^2 \exp[-2nD(\frac{1}{3} + \epsilon, \frac{1}{2})]$ .

A quick calculation shows that the algorithm then runs in time  $\mathcal{O}(N^d)$  – the value of  $d$  has been chosen for this purpose. The theorem is proved in this case.

If  $N > 2^{n\epsilon} N_0$ , then slice the input lists in chunks of size  $4N_0$  and run Algorithm 1 with  $w = n/3$  on each successive chunk until a solution is found. Each chunk contains a good triplet with probability at least  $\frac{3}{64}$  thanks to (3). The algorithm reveals this triplet, if it exists, with probability  $\Omega(\frac{1}{n})$ , because it always works if the algorithm of the previous section works.

There are  $2^{en}/4$  chunks (i.e., exponentially many). Because the chunks are disjoint parts of the input lists, success in a chunk is independent from the others. Therefore the probability that this process fails to reveal a good triplet is negligible. The running time of this procedure is  $\mathcal{O}(NN_0^{e-1})$ . Because  $N_0 \leq N$ , this is less than  $\mathcal{O}(N^e)$ . ◀

► **Remark 6.**  $A_b, B_b$  and  $C_b$  the subsets of strings of  $A, B$  and  $C$  whose first bit is equal to  $b$  (for  $b \in \{0, 1\}$ ), then a good triplet necessarily belongs to one of the three sets  $A_0 \times B_0 \times C_0$ ,  $A_0 \times B_1 \times C_1$  or  $A_1 \times B_0 \times C_1$  (and the search for a good triplet in  $A \times B \times C$  thus reduces to the search in those three sets). The expected cardinality of  $A_0, A_1, B_0, B_1, C_0$  and  $C_1$  is  $N/2$  and applying this idea recursively, one obtains (assuming the division is always done in a “balanced” manner) a time complexity  $T(N)$  which heuristically satisfies the recursion  $T(N) = 3T(N/2) + \mathcal{O}(N)$  (and thus  $T(N) = \mathcal{O}(N^{\log_2(3)}) = \mathcal{O}(N^{1.59})$ ). This improves a bit the complexity of our algorithm, but this “divide-and-conquer” approach is probably more complex to implement. It would be interesting to see if one can combine this approach with our filtering technique.

#### 4 Practical Key-recovery Attack on the von zur Gathen-Shparlinski Elliptic Subset Sum Generator

In this section, we consider the instantiation of the knapsack generator suggested by von zur Gathen and Shparlinski in [19]. In particular, the group  $\mathbb{G}$  is an elliptic curve  $E$  defined over a (prime) finite field  $\mathbb{F}_p$  (where  $p \geq 5$  is an  $n$ -bit prime number). It is a rational curve given by the following Weierstrass equation

$$E : y^2 = x^3 + ax + b$$

for some  $a, b \in \mathbb{F}_p$  with  $4a^3 + 27b^2 \neq 0$ . It is well known that the set  $E(\mathbb{F}_p)$  of  $\mathbb{F}_p$ -rational points (including the special point  $O$  at infinity) forms an Abelian group with an appropriate composition rule (denoted additively) where  $O$  is the neutral element – for more details on elliptic curves, we refer to [5, 21]. Von zur Gathen and Shparlinski suggested to use a conversion function  $\Psi : E \rightarrow \{0, 1\}^\rho$  that simply truncates  $\ell = \log_2(n)$  least significant bits of the x-coordinate of a point (with  $\rho = n - \ell$ ). An  $n$ -bit linear feedback shift register is used as the control-sequence generator (as in the Rueppel-Massy classical knapsack generator) and the overall seed length is thus  $n(n + 1)$  bits.

##### 4.1 Attack on the Elliptic Subset Sum Generator

The adversary first “guesses”  $\text{seed}_0$ . In other terms, all subsequent steps have to be repeated  $2^n$  times, one for each possible value of  $\text{seed}_0$ .

Following the analysis from Section 3, one needs to construct three sets  $A, B, C$  of independent  $n$ -bit strings size  $N = \alpha(8/3)^{n/3} \leq \alpha 2^{0.472n}$  in order to find a good triplet  $(i, j, k)$  such that  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$  time  $\mathcal{O}(N^{1.654\dots}) = \mathcal{O}(2^{0.78n})$  with probability at least  $1 - 7/\alpha$ . We need to have  $n/2$  such good triplets in order to find the  $n$  points  $P_1, \dots, P_n$  used as weights in this elliptic knapsack generator, and we can hope to obtain them with constant positive probability from an output sequence made of  $\Omega(n^2(8/3)^{n/3})$  output values in  $\{0, 1\}^\rho$ . In our implementation, we do not distinguish the sets  $A, B$ , and  $C$  and simply run the algorithm from the previous section with  $A = B = C$  the sets of all vectors  $\mathbf{v}_i$  corresponding to all known outputs  $s_i \in \{0, 1\}^\rho$ .

Note that, as in the classical knapsack generator, the control sequence is not made of independent  $n$ -bit strings since if one denotes  $(u_n)_{n \geq 0}$  the sequence output by the linear feedback shift register, we have

$$\mathbf{v}_i = (v_i^1, \dots, v_i^n) = (u_i, u_{i+1}, \dots, u_{i+n-1}) \in \{0, 1\}^n$$

for  $i \in \mathbb{N}$ . The analysis given in Section 3 does not apply to such sequences but we make the heuristic assumption that these  $n$ -bit tuples are “sufficiently” random and that our algorithm will succeed with a similar probability (this heuristic is validated by our experiments).

We then follow the general idea given above but for each good triplet  $(i, j, k)$  such that  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$ , if the adversary finds two points  $X$  and  $Y$  on the elliptic curve such that  $\Psi(X) = s_i$ ,  $\Psi(Y) = s_j$  and  $\Psi(X + Y) = s_k$ , then this gives rise to two possible relations:

1.  $X = Q_i$ ,  $Y = Q_j$  (and  $X + Y = Q_i + Q_j = Q_k$ ), but also
2.  $X = -Q_i$ ,  $Y = -Q_j$  (and  $X + Y = -(Q_i + Q_j) = -Q_k$ ).

This is due to the fact that on an elliptic curve, a point and its negative have representations with much in common since they share the same the x-coordinate (and the y-coordinates are opposites). This “non-genericness” of elliptic curves is well-known and has important consequences in cryptography<sup>1</sup>. However, with a truncation of  $\log_2(n)$  bits of the x-coordinate of the points, we expect the number of points triple compatible with  $(s_i, s_j, s_k)$  to be equal to only 2.

Note that for the first good triplet computed in the attack, the sign is not a problem since the generator parametrized with the  $n$  points  $P_1, \dots, P_n$  outputs the same sequence as the one parametrized with the  $n$  points  $-P_1, \dots, -P_n$ . The adversary can then pick up arbitrarily  $(Q_i, Q_j) = (X, Y)$  or  $(Q_i, Q_j) = (-X, -Y)$ . However, for the subsequent relations obtained from other good triplets, the sign choice may be incompatible with the first one and this will result in a system with no solutions. In order to be able to solve the system, we need to have  $n$  linear relations among the points  $P_1, \dots, P_n$  and each good triplet gives us two such relations (the third one is by construction is a linear combination of the two others and is useless in solving the linear system). Assuming that  $n$  is even, one needs to make  $n/2 - 1$  choices for the sign of each relation (after the first one), and the adversary can simply “guess” all such signs. This multiplies the running time of the algorithm by a factor  $2^{n/2-1}$ .

Once the  $n/2$  good triplets have been found, the algorithm can inverse the system and obtain the  $n$  points  $P_1, \dots, P_n$ . From these values, the points  $P_1, \dots, P_n$ . The overall complexity of the attack is thus

$$\mathcal{O}\left(2^n(2^{0.78n} + 2^{2\log(n)} + 2^{n/2-1}) + \text{poly}(n)\right) = \mathcal{O}\left(2^{1.78n}\right)$$

binary operations.

## 4.2 Experimental Results

We implement our attack using sagemath v.9.5 on a laptop. Our codes are available at <https://github.com/floretteM/Knapsack>. In our implementation, we did not need the exhaustive search on the signs mentioned above since we instead looked for good triplets that involve a point already found (and this sets up the sign with certainty). This makes the probability of finding such good triplets more complex to analyse but this trick works well in practice.

We first consider the elliptic curve defined by the equation  $y^2 = x^3 + 5x + 5$  over  $\mathbb{F}_p$  where  $p = 2^{16} - 15$ . This curve contains  $q = 65111$  points. We present the attack when the control sequence  $(\mathbf{v}_i)$  is known and we consider  $n = 16$  as suggested by von zur Gathen and Shparlinski. The key size in this setting is equal to 256 bits. We present in Table 2 the number  $m$  of outputs needed and the time necessary to recover the secret weights with probability at least 50% when  $\ell$  bits are missing.

<sup>1</sup> For instance, the ECDSA signature scheme is malleable in the sense that if the pair of integers  $(r, s)$  is

■ **Table 2** Key-recovery with exhaustive search and  $q$  a 16-bit integer.

$\ell$	1	2	3	4	5	6
$m$	1000	1000	1000	1000	1000	1885
time	6.9s	5.3s	5.6s	5.02s	5.7s	26.7s

When 7 bits are truncated we cannot recover the weights even with 3000 outputs. But we earlier observed that the algorithm would not work well if  $\ell > \log_2(q)/3$ , see (2). With the proposed choice of  $\ell = \log_2 n = 5$ , our results are coherent with the heuristic.

To test the limits of our attack, we also implement it for elliptic curves with larger group orders (*i.e.* for parameters larger than those suggested by von zur Gathen and Shparlinski). This gives an algorithm with overall complexity  $\mathcal{O}(2^n(2^{0.78n} + 2^{n/2}) \cdot \text{poly}(n, \log(p)))$ .

We consider the elliptic curve defined by the equation  $y^2 = x^3 + x + 14$  over  $\mathbb{F}_p$  where  $p = 2^{40} + 15$  but still  $n = 16$ . With this choice we can focus on recovering the points of the elliptic curves from the outputs without being bothered by finding the good triplets. This curve contains  $q = 1099510687747$  points. We present in Table 3 the number  $m$  of outputs needed and the time necessary to recover the secret weights with probability at least 50% when  $\ell$  bits are missing.

■ **Table 3** Key-recovery with exhaustive search and  $q$  a 40-bit integer.

$\ell$	1	2	3	4	5	6	7	8	9
$m$	1885	1885	1885	1885	1885	1885	1885	1885	1750
time	2.1s	2.1s	2.08s	2.5s	2.6s	2.1s	3.5s	8.3s	26.7s

## 5 Practical Key-recovery Attack on the Subset Product Generator

Following the generalization of the knapsack generator to elliptic curves proposed by von zur Gathen and Shparlinski, it is natural to consider other variants using Abelian groups of interest in cryptography. The most natural choice is to use (a subgroup of) the multiplicative group of a finite field  $\mathbb{Z}_p$  for some prime number  $p$ . This group is certainly not generic since there exist sub-exponential time discrete logarithm algorithms in these groups, but it seems that representation of group elements by the unique member of its class in  $\{0, \dots, p-1\}$  is sufficiently “generic” that using truncation of their bit-representation as a conversion function would permit an adversary to mount a lattice-based attack on this generator even if a quarter of the bits of each group elements is discarded when computing the output of the generator.

More precisely, in this section, we consider a multiplicative variant of the subset sum generator where:

- the control-sequence generator is a linear feedback shift register with a  $\lambda$ -bit seed;
- the Abelian cyclic group  $(\mathbb{G}, \cdot)$  is the multiplicative group of a (prime) finite field  $\mathbb{Z}_p$  (note that it is denoted multiplicatively);
- the public conversion function  $\Psi : \mathbb{G} \rightarrow \{0, 1\}^\rho$  where  $\rho = \lfloor \alpha \cdot \log_2(p) \rfloor$  is simply the truncation of  $\lceil (1 - \alpha) \log_2(p) \rceil$  bits of the unique member of its group element class in  $\{0, \dots, p-1\}$ . The notation  $\div$  denotes the euclidean division.

---

a valid signature of a given message then so is  $(r, -s)$  [18].

We call this generator the *subset product generator*.

### 5.1 Description of the Attack

In this setting, the seed consists in a bit-string  $\text{seed}_0 \in \{0, 1\}^\lambda$  and  $n$  group elements  $g_1, \dots, g_n \in \mathbb{Z}_p^*$ . The bit size of the seed is thus equal to  $\lambda + n \cdot \lceil \log_2(p) \rceil$ . At each iteration  $i \in \mathbb{N}$ , the control-sequence generator generates an  $n$ -bit string  $\mathbf{v}_i = (v_i^1, \dots, v_i^n) = \text{CSG}(\text{seed}_0, i)$ , computes the group element  $h_i$  defined by

$$h_i = g_1^{v_i^1} \cdots g_n^{v_i^n} \in \mathbb{Z}_p^*$$

and outputs  $s_i = \Psi(h_i) = h_i \text{div } 2^\ell \in \{0, 1\}^k$  where  $p$  is a  $(k + \ell)$ -bit long prime number (with  $k = \lfloor \alpha \cdot \log_2(p) \rfloor$ ).

A straightforward adaptation of the attack of the Section 4 gives an attack with complexity  $O(2^\lambda \cdot (2^{0.78n} + p^{2(1-\alpha)}))$  for  $\alpha \geq 2/3$ . Note that the complexity does not involve the  $O(2^{n/2})$  term that came from the indecision on the signs in the elliptic curve variant of the knapsack generator. We remark that one can improve the complexity of the attack by replacing the brute-force search on the missing bits with the use of Coppersmith technique to retrieve them.

**Coppersmith's method.** Coppersmith's method [7, 6] is a technique to find small integer zeroes of univariate or bivariate polynomials modulo a given integer. It has been generalized for finding small roots of (modular) multivariate polynomial equations with integer coefficients by several authors and notably used to attack algebraic pseudo-random generators (see [11, 10, 3, 14] and references therein). These techniques work by constructing a Euclidean lattice associated with the system of equations, and then finding short vectors in this lattice using lattice reduction algorithms. In its most basic variant, given a polynomial  $f(X_1, \dots, X_k)$  defined modulo an integer  $p$ , one can find a "small" root  $(x_1, \dots, x_k) \in \mathbb{Z}_p^k$  under the condition that  $|x_i| \leq B_i$  for some bounds  $(B_1, \dots, B_k)$ . The method succeeds (heuristically) in polynomial time when (up to small constant factors),

$$\prod_{i \in M} B_1^{i_1} \cdots B_k^{i_k} \leq p$$

when  $f$  can be written as a sum of monomials of the form

$$f(X_1, \dots, X_k) = \sum_{i \in M} a_i X_1^{i_1} \cdots X_k^{i_k}$$

for some  $a_i \in \mathbb{Z}_p^*$ . For this simple variant, the lattice is constructed using only the polynomial  $f$  but there exist variants – with better upper-bounds on the root  $(x_1, \dots, x_k)$  – using lattices of higher dimensions with shifts or powers of the polynomial  $f$  (see [11] for details).

**Description of the attack.** For a vector  $\mathbf{v}_i$  output by the control sequence generator, we have

$$h_i = g_1^{v_i^1} \cdots g_n^{v_i^n} \in \mathbb{Z}_p^*$$

with  $h_i = (2^\ell s_i + x_i)$  where  $x_i \in \{0, \dots, 2^\ell - 1\}$  is some value unknown to the adversary. Given a good triplet  $(i, j, k)$  with  $\mathbf{v}_i + \mathbf{v}_j = \mathbf{v}_k$ , we have  $h_i \cdot h_j = h_k \pmod p$  and thus:

$$(2^\ell s_i + x_i) \cdot (2^\ell s_j + x_j) = (2^\ell s_k + x_k) \pmod p.$$

The unknowns  $(x_i, x_j, x_k)$  are thus “small” roots of an equation of the form

$$Ax_i + Bx_j + x_ix_j - x_k + C = 0 \pmod{p}$$

where  $A = 2^\ell s_i$ ,  $B = 2^\ell s_j$  and  $C = (2^\ell s_i \cdot 2^\ell s_j - 2^\ell s_k) \pmod{p}$  are values known by the adversary. One can thus apply Coppersmith’s technique to this polynomial and the basic technique (without using shifts or powers of the polynomial) will succeed if  $|x_i|, |x_j|, |x_k| \leq p^{1/5}$ . A simple trick allows us to improve readily this bound by setting  $y = x_ix_j - x_k$  such that  $|y| \leq 2^{2\ell}$  and solving the equation

$$g(x_i, x_j, y) = Ax_i + Bx_j + y + C = 0 \pmod{p}$$

in  $(x_i, x_j, y)$  is sufficient to recover  $(x_i, x_j, x_k)$ . Using the basic Coppersmith’s technique (again without using shifts or powers of this polynomial), this attack will succeed (heuristically) in polynomial-time if  $|x_i|, |x_j|, |x_k| \leq p^{1/4}$ . For  $\alpha \geq 3/4$ , we thus obtain an attack with the overall complexity

$$\mathcal{O}(2^\lambda \cdot 2^{0.78n} + n \cdot \text{poly}(\log_2(p))) = \mathcal{O}(2^\lambda \cdot 2^{0.78n}).$$

► **Remark 7.** Note that we can improve the bound on the size of the “small” root by using shifts and powers of the polynomial  $g(x_i, x_j, y)$ . For instance, if one considers the family of four polynomials

$$\{g, x_i \cdot g, x_j \cdot g, g^2\}$$

that vanishes in  $(x_i, x_j, y)$  modulo  $p$  with total multiplicity  $(1 + 1 + 1 + 2) = 5$  and involve the following set of monomials:

$$\{x_i, x_j, y, x_i^2, x_ix_j, x_iy, x_j^2, x_jy, y^2\}$$

with a sum of degrees equal to  $(1 + 1 + 2 + 2 + 2 + 3 + 2 + 3 + 4) = 20$ , we obtain that the Coppersmith’s method succeeds (heuristically) if  $|x_i|, |x_j|, |x_k| \leq p^{5/20} = p^{1/4}$  (see [11]). This gives the same bound as above. However, if we reintroduce the variable  $x_k$  and replace the monomial  $x_ix_j$  by  $y + x_k$ , the total degree of the set of monomials decreases to 19 and this decreases the bound to  $p^{5/19}$ . It is possible to decrease a bit further the exponent of  $p$  in this bound, at the cost of using a lattice of higher dimension in Coppersmith’s technique using the technique of unravelled linearization from [10] (see also [3]).

## 5.2 Experimental Results

**Exhaustive search on the truncated bits.** We consider first the finite field  $\mathbb{F}_p$  with  $p = 2q + 1$  and  $q = 99839$ . We choose weights in the cyclic multiplicative group  $\mathbb{G}$  of order  $q$  made by the non-quadratic residues of  $K$  minus zero. We present the attack when the control sequence  $(\mathbf{v}_i)$  is known and we consider  $n = 16$  for which the key size is equal to 256 bits. We present in Table 4 the number  $m$  of outputs needed and the time necessary to recover the secret weights with probability at least 50% when  $\ell$  bits are missing.

When 7 bits are truncated we cannot recover the weights even with 1885 outputs.

Now we consider the finite field  $\mathbb{F}_p$  with  $p = 2q + 1$  and

$$q = 72536599031050480402372360602698911648481683373808860129469667649180998227293$$

a 256-bit number, but still  $n = 16$ . With this choice we can focus on recovering the points from the outputs without being bothered by finding the good triplets.

## 23:12 Cryptanalysis of a Generalized Subset-Sum Pseudorandom Generator

■ **Table 4** Key-recovery with exhaustive search and  $q$  a 16-bit integer.

$\ell$	1	2	3	4	5	6
$m$	1000	1000	1000	1000	1000	1885
time	0.51s	0.45s	0.44s	0.47s	0.58s	2.1s

■ **Table 5** Key-recovery with exhaustive search and  $q$  a 256-bit integer.

$\ell$	1	2	3	4	5	6	7	8	9
$m$	1000	1000	1000	1000	1000	1000	1000	1000	1000
time	0.46s	0.50s	0.48s	0.43s	0.55s	0.70s	0.87s	1.9s	6.6s

**Coppersmith method.** We consider the attack on the second group with  $p = 2q + 1$  and  $q$  a 256-bit number. First, we implement the attack with the single polynomial  $g = Ax_i + Bx_j + y + C$ . As the Coppersmith method is a bit more unpredictable, we present in Table 6 the number  $m$  of outputs needed and the time necessary to recover the weights with probability at least 50% when  $\ell$  bits are missing.

■ **Table 6** Key-recovery with Coppersmith method and  $q$  a 256-bit integer.

$\ell$	2	4	8	16	32	62	63
$m$	1000	1000	1000	1000	1000	1000	1000
time	0.71s	0.67s	0.68s	0.61s	0.63s	0.51s	0.55s

If we follow the heuristic in Coppersmith's method we should be able to retrieve the weights up to  $\ell = 64$  and  $\ell = 64$  is the first instance where the attack stops working. If we try to consider the family of polynomials  $\{g, x_i g, x_j g, y g, g^2\}$  instead the improvement on the upper-bound from  $p^{1/4}$  to  $p^{5/19}$  would not be significant for 256-bit integers.

**A Proof of Theorem 1**

We now proceed to prove theorem 1.

**Proof.** Let  $x, y, z, u, v$  denote five independent random bits, and set:

$$\begin{aligned} \rho &= \Pr(x + y = z) \\ \sigma &= \Pr(u + v = z \mid x + y = z) \\ \tau &= \Pr(u + y = v \mid x + y = z) \end{aligned}$$

We already know that  $\rho = 3/8$ . Building a simple table as above shows that  $\sigma = \tau = 5/12$  (see Table 7).

■ **Table 7** Tabulating  $u + v, x + y, u + y$  for  $x, y, z, u, v \in \{0, 1\}$ .

$u$	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
$v$	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1
$x$	0	0	0	0	1	1	1	1	0	0	0	0	1	1	1
$y$	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1
$z$	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0
$u + v$	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1
$x + y$	0	0	1	1	1	1	2	2	0	0	1	1	1	1	2
$u + y$	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1

$u$	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1
$v$	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1
$x$	0	0	0	0	1	1	1	1	0	0	0	0	1	1	1
$y$	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1
$z$	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0
$u + v$	1	1	1	1	1	1	1	2	2	2	2	2	2	2	2
$x + y$	0	0	1	1	1	1	2	2	0	0	1	1	1	1	2
$u + y$	1	1	2	2	1	1	2	2	1	1	2	2	1	1	2

Let  $X(i, j, k)$  denote the binary random variable that takes the value 1 if and only if  $A[i] + B[j] = C[k]$ , so that  $Y = \sum X(i, j, k)$ . Unless mentioned otherwise, all sums are taken over  $0 \leq i, j, k < N$ ; we omit the indices to alleviate notations.

The expected value of  $Y$  is easy to determine. Because the elements of the lists are identically distributed,  $\Pr(A[i] + B[j] = C[k])$  is independent of  $i, j$  and  $k$  and its value is  $\rho^n$ . We get:

$$E(Y) = E\left(\sum X(i, j, k)\right) = \sum E(X(i, j, k)) = \sum \Pr(A[i] + B[j] = C[k]) = N^3 \left(\frac{3}{8}\right)^n.$$

Because  $Y$  is the sum of binary random variables, we are entitled to use the “conditional expectation inequality” [15] (see also [13, MPR]):

$$\Pr(Y > 0) \geq \sum_{i=1}^n \frac{E(Y_i)}{E(Y \mid Y_i = 1)}. \tag{6}$$

Which, in our case, gives:

$$\Pr(Y > 0) \geq \sum \frac{E(X(i, j, k))}{E(Y \mid X(i, j, k) = 1)}.$$

As argued above, the value of the term under the sum is independent of  $i, j$  and  $k$ , so this boils down to:  $\Pr(Y > 0) \geq \left(\frac{3}{8}\right)^n / E(Y \mid X(0, 0, 0) = 1)$ . It remains to compute the expected number of good triplets under the assumption that there is at least one. This yields:

$$E(Y \mid X(0, 0, 0) = 1) = \sum \Pr(A[i] + B[j] = C[k] \mid A[0] + B[0] = C[0])$$

We split this sum into 8 parts by considering separately the situation where  $i = 0$ ,  $j = 0$  and  $k = 0$  (resp.  $\neq 0$  for each summation index). We introduce the shorthand  $p_{ijk} = \Pr(A[i] + B[j] = C[k] \mid A[0] + B[0] = C[0])$  and we assume that  $i, j, k > 0$ . Because  $A[i]$  is sampled independently from  $A[0]$  (resp.  $B, C$ ), the two events inside the conditional probability are in fact independent and therefore  $p_{ijk} = \left(\frac{3}{8}\right)^n$ . But when at least one index is zero, this is no longer the case. The extreme situation is  $p_{000} = 1$ .

When there is a single non-zero summation index, the situation is rather simple. If  $x + y = z$ , then  $x + U = z$  if and only if  $U = y$ , and this happens with probability  $2^{-n}$  because  $U$  is uniformly random. This shows that  $p_{i00} = p_{0j0} = p_{00k} = 2^{-n}$ .

It remains to deal with the case of two non-zero summation indices. In fact,  $p_{ij0}$  is simply  $\sigma^n$ , while both  $p_{i0k}$  and  $p_{0jk}$  are equal to  $\tau^n$  (by the symmetry between the role of the first two lists).

It follows that

$$\begin{aligned} E(Y \mid X(0, 0, 0) = 1) &= (N-1)^3 \left(\frac{3}{8}\right)^n + 3(N-1)^2 \left(\frac{5}{12}\right)^n + 3(N-1) \cdot 2^{-n} + 1 \\ &= N^3 \left(\frac{3}{8}\right)^n + 3N^2 \left(\frac{5}{12}\right)^n + 3N2^{-n} + 1 - \Delta \end{aligned}$$

$$\text{with } \Delta = (3N^2 - 3N + 1) \left(\frac{3}{8}\right)^n + 3(2N - 1) \left(\frac{5}{12}\right)^n + 3 \cdot 2^{-n}.$$

The “error term”  $\Delta$  is always positive for  $N \geq 1$ . Going back to the beginning, we have:

$$\begin{aligned} \Pr(Y > 0) &\geq \frac{N^3(3/8)^n}{N^3(3/8)^n + 3N^2(5/12)^n + 3N(1/2)^n + 1 - \Delta} \\ &\geq \frac{1}{1 + 3N^{-1}(10/9)^n + 3N^{-2}(4/3)^n + N^{-3}(8/3)^n} \end{aligned}$$

Using the convexity of  $x \mapsto 1/(1+x)$ , we obtain

$$\Pr(Y = 0) \leq 3N^{-1}(10/9)^n + 3N^{-2}(4/3)^n + N^{-3}(8/3)^n. \quad \blacktriangleleft$$

## Abstract

Bayes' rule tells us how to invert a causal process in order to update our beliefs in light of new evidence. If the process is believed to have a complex compositional structure, we may observe that the inversion of the whole can be computed piecewise in terms of the component processes. We study the structure of this compositional rule, noting that it relates to the lens pattern in functional programming. Working in a suitably general axiomatic presentation of a category of Markov kernels, we see how we can think of Bayesian inversion as a particular instance of a state-dependent morphism in a fibred category. We discuss the compositional nature of this, formulated as a functor on the underlying category and explore how this can be used for a more type-driven approach to statistical inference.

## 1 Introduction

A *Markov kernel*  $f$  is a function whose output is stochastic given the input. It can be thought of as a stateless device which, if supplied with inputs, will produce an output that depends probabilistically on the input. Mathematically speaking, this is nothing but a conditional distribution  $\mathbb{P}(y|x)$ . The problem of Bayesian inversion is that we observe the output of such a device but only have a probabilistic “prior” belief about the input, and we would like to update our beliefs about what the input was given the output. For example, suppose a process takes the roll of an unseen die and tells us whether it was even or odd, except with probability 10% it flips the result. If the process tells us that a specific roll resulted in “even” then Bayes' law tells us how we should update a prior belief that the die is uniformly random, to obtain a belief about what the specific roll was.

It is commonly the case that the process is not a black box, but is a composite process formed from simpler pieces. The conditional distribution formed by sequentially composing two such stochastic functions is given by forming their joint distribution and then marginalising over the middle variable. In the case of a long chain of sequentially composed functions, belief updating for the whole can be done “compositionally” in terms of belief updating for each individual part, in a process notably similar to backpropagation in neural networks. A process such as this underlies probabilistic programming languages, which are able to run programs “backwards” after conditioning on some output.

24:2 The Compositional Structure of Bayesian Inference

The goal of this paper is to study this process of compositional Bayesian inversion of Markov kernels in isolation, using a suitable axiomatisation of a category of Markov kernels. We provide a method to build categories whose morphisms are pairs of a Markov kernel and an associated “Bayesian inverter”, which is itself built compositionally.

Symmetric monoidal categories with compatible families of copy and delete morphisms have been identified as an expressive language for synthetically representing concepts from probability theory [5, 8]. The typical interpretation given is that the objects represent sets or measurable spaces, and morphisms are Markov kernels between them. Branded *Markov categories* [8] in this context, these categories have recently seen widespread use in applied category theory as a foundation of probability for two reasons: they allow working axiomatically while abstracting over the specific details of theories such as stochastic matrices, Gaussian kernels and Giry (measure-theoretic) kernels; and they provide a rich string-diagram calculus allowing for simple graphical presentations of many calculations and constructions in probability.

$\mathbb{P}_X(x)\mathbb{P}_Y(y)$		$\sum_{y \in Y} \mathbb{P}_{X \times Y}(-, y)$	
Product distributions	Parallel composition	Marginalisation	Deletion
$\mathbb{P}_X(x)\delta(x, x')$		$\sum_{y \in Y} \mathbb{P}_f(z y)\mathbb{P}_g(y x)$	
Diagonal distributions	Copying	Chapman-Kolmogorov	Sequential composition

■ **Figure 1** The graphical representation of common formulas for probability distributions.

A categorical translation of Bayes’ law allows for a general definition of a *Bayesian inverse* to a morphism in a Markov category. However, in contrast to many other contexts where we have a notion of dualising morphisms, Bayesian inverses depend on an extra piece of data: the prior distribution. This is abstracted in our definition as a *state* on an object  $X$ , or a morphism out of the monoidal unit,  $I \rightarrow X$ , which represents a (non-conditional) probability distribution on  $X$ . This leads us to the abstract definition of a Bayesian inverse [5]:

► **Definition 1** (Bayesian Inversion). *Let  $f : X \rightarrow Y$  and  $p : I \rightarrow X$ , a kernel  $f' : Y \rightarrow X$  is called a Bayesian inverse of  $f$  at  $p$  if the following equation holds:*

This categorical based approach to Bayes’ law naturally leads to a question of whether Bayesian inverses compose; that is, can we construct a Bayesian inverse of a composite kernel  $f \circ g$  as a composite of the separate Bayesian inverses of  $f$  and  $g$ ? Inspecting the relevant equation

(1)

we can observe that this is indeed true if  $f'$  and  $g'$  are Bayesian inverse to  $f$  and  $g$ , but we have to ask for  $f'$  not to be inverse to  $f$  at  $p$ , but rather at  $g \circ p$ : in some sense the type of this composition is dependent on the kernels that it is being applied to. In other words, assuming a hypothetical function  $\text{BayesInv}(f, p)$  which computes Bayesian inverses, the composite could be expressed as

$$\text{BayesInv}(f \circ g, p) = \text{BayesInv}(g, p) \circ \text{BayesInv}(f, g \circ p)$$

Notably this has a similar form to the reverse-mode chain rule for Jacobian matrices that underlies backpropagation,  $J_{g \circ f}^\top(x) = J_g^\top(f(x))J_f^\top(x)$ . As such we think of the composition rule as a *chain rule for Bayesian updating*. To formalise the compositionality of such a construction we would typically like to promote it to a functor on our Markov category, which we denote in general as  $\mathcal{C}$ . The fact that Bayesian inverses are indexed by  $p$  in this way makes choosing the target of such a a Bayesian inversion functor nontrivial however.

One approach to making Bayesian inversion functorial, taken by Cho and Jacobs [5], is to work instead in a category where the objects  $X$  are equipped with a choice of  $p : I \rightarrow X$ : in this case, there is always a canonical choice of inverse morphism, making Bayesian inversion into a “dagger” functor. Although such a setting is still a Markov category, this approach does depart from the operational interpretation of morphisms as stochastic kernels, because the distribution produced is already present in the type of the morphism. So the morphisms have more of a “relational” role.

In this paper we take an alternative approach and instead consider a category where the morphisms are indexed families of kernels. Consequently, we can represent the entire  $(I \rightarrow X)$ -indexed family of Bayesian inverses as a single morphism, resolving the problems faced previously. The morphisms of this category have a very similar structure to a *lens* from database theory and functional programming [7], but, instead of performing deterministic updates to data structures, this performs Bayesian updates to beliefs. We therefore call such pairs *Bayesian lenses*.

This category is however “too big” in the sense that it contains everything whose type matches that of the Bayesian inverse. Rather than a failure of the abstraction, we view this as a feature allowing us to encode not only exact Bayesian inversion, but also approximate updaters and other structures. To pick out the specific lenses corresponding to the actual Bayesian inverse of  $f$  we therefore use a functor  $\mathcal{C} \rightarrow \mathbf{BLens}$ , which encodes a choice of Bayesian inverse for each kernel.

The category of Bayesian lenses is constructed as a fibred category that is closely related to the families fibration, commonly used in the semantics of dependent types. We embrace this relationship by extending  $\mathbf{BLens}$  into a larger category constructed from a generalised families fibration which leads us to a category of *dependent Bayesian lenses*, which have not only indexed families as morphisms, but indexed objects as well. This construction admits Bayesian inverses whose domains are allowed to depend on the prior distribution at which the inverse is taken. In certain Markov categories this allows us to consider inverses as being restricted to the support of the prior, which puts the construction on a neater theoretical foundation, and which clarifies thinking about the Bayesian inversion of structure maps in the category. Since Bayes’ law does not define how beliefs should be updated after a zero-probability observation, this falls into the usual pattern in computer science of using a type system to “make illegal states unrepresentable”<sup>1</sup>.

<sup>1</sup> This phrase originated with Yaron Minsky in the blog post <https://blog.janestreet.com/effective-ml-revisited/>

**2 Preliminaries**

► **Definition 2** (Markov Categories [8]). A Markov category is a symmetric monoidal category  $\mathcal{C}$  with the structure of a commutative comonoid on each object, such that:

- the assignment of counits (“delete” or “discard” maps) to objects is natural; and
- comultiplications (“copy” maps) are compatible with the monoidal structure:

► **Example 3** (Stochastic Matrices, [8] example 2.5). There is a Markov category **FinStoch** whose objects are finite sets, and whose morphisms  $f : X \rightarrow Y$  are stochastic matrices  $f : X \times Y \rightarrow [0, 1]$ , i.e. satisfying  $\sum_{y \in Y} f(x, y) = 1$  for all  $x \in X$ . Identity morphisms are identity matrices, and composition of morphisms is by matrix multiplication, known in this context as the Chapman-Kolmogorov equation,  $(g \circ f)(x, z) = \sum_{y \in Y} f(x, y) \cdot g(y, z)$ . The symmetric monoidal structure of **FinStoch** is given on objects by cartesian product, and on morphisms by tensor product of stochastic matrices:  $(f \otimes g)((x, x'), (y, y')) = f(x, y) \cdot g(x', y')$ .

► **Example 4** (Gaussian Kernels, [8] section 6). There is a Markov category **Gauss** whose objects are Euclidean spaces  $\mathbb{R}^n$ , and whose morphisms  $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$  are triples of a matrix  $M \in \mathbb{R}^{m \times n}$ , a vector  $\mu \in \mathbb{R}^n$  and a positive semidefinite matrix  $\sigma \in \mathbb{R}^{n \times n}$ , considered to represent an affine function with independent Gaussian noise  $f(v) = Mv + \mathcal{N}(\mu, \sigma)$ . The definitions of categorical composition and monoidal product are slightly involved, but can be derived from laws of Gaussian probability.

► **Example 5** (Probability Kernels, [8] section 4). Giry [10] introduced a monad  $\mathcal{G}$  on the category of measurable spaces, now known as the Giry monad, taking each measurable space to the space of probability measures on it, equipped with an appropriate measurable structure. The Kleisli category  $\text{Kl}(\mathcal{G})$  is a Markov category, also known as **Stoch**, which allows working with arbitrary measure-theoretic probability and contains many other important Markov categories as subcategories, including the previous two examples. Although this category is in a sense canonical, it suffers from many undesirable properties due to extremely general nature of measure theory. One example which is relevant in the later sections is the spaces representing the support of certain distributions.

Keeping these examples in mind, we refer to the morphisms of such a category as *Markov kernels* or more simply as *kernels*.

► **Definition 6** (Almost-Sure Equality [5]). A pair of kernels  $f, g : X \rightarrow Y$  are *p-almost-surely equal* for some  $p : I \rightarrow X$ , if the following equality holds

In this case we write  $f \simeq_p g$ .

We note that this equation is similar in shape to that which defines a Bayesian inverse. Indeed this pattern of considering a kernel composed onto one branch of a copy is a standard way to consider a kernel in the context of a distribution on its domain. The appearance of this pattern in the definition of the Bayesian inverse means exactly that we are defining the concept only up to almost-sure equality.

► **Proposition 7** (Bayesian inverses are almost-surely equal). *For any kernel  $f : X \rightarrow Y$  and state  $p : I \rightarrow X$ , if two kernels  $g, g' : Y \rightarrow X$  both satisfy the conditions of a Bayesian inverse to  $f$ , then  $g \simeq_{f \circ p} g'$ .* ◀

Considering the interpretation of these equations, this result makes intuitive sense. It essentially says that Bayesian inversion is uniquely defined only on the points where Bayes' law would not have you divide by zero. This allows us to be mindful of the partiality of Bayes' law without requiring the added complication of considering partial maps. However, this will complicate matters later when we establish the functoriality of Bayes' law. In fact, as we will see, we will need some extra coherence assumptions to ensure that Bayesian inversion is functorial, rather than only almost-surely functorial.

### 3 Bayesian Updates Compose Optically

The Bayesian inverse of a kernel is defined with respect to a prior state on the domain of the kernel. We want to consider the general inverse of a kernel  $A \rightarrow B$  as a function which assigns to each prior  $p : I \rightarrow A$ , a  $p$ -inverse  $B \rightarrow A$ . However the space of priors with respect to which a kernel can be inverted depends on the domain of the kernel: it is the set of states  $\mathcal{C}(I, \text{dom}(f))$ . To formalise this dependence we construct an *indexed category*. Just as indexed sets  $(X_i)_{i \in I}$  can be thought of as functions  $I \rightarrow \mathbf{Set}$ , we define indexed categories as (pseudo)functors into  $\mathbf{Cat}$ . We consider Bayesian inverses in the context of an indexed category  $\mathcal{C} \rightarrow \mathbf{Cat}$  sending  $X$  to a category of  $\mathcal{C}(I, X)$ -indexed kernels.

► **Definition 8** (The **Stat** construction). *We define the indexed category of  $\mathcal{C}$ -state-indexed kernels,  $\mathbf{Stat} : \mathcal{C}^{op} \rightarrow \mathbf{Cat}$ , as follows.*

For each  $X$ ,  $\mathbf{Stat}(X)$  is the category of  $\mathcal{C}(I, X)$ -indexed kernels, where

- objects are the objects of  $\mathcal{C}$ ;
- morphisms  $A \rightarrow B$  are functions  $\mathcal{C}(I, X) \rightarrow \mathcal{C}(A, B)$ ; and
- composition and identities are pointwise given by the corresponding structure in  $\mathcal{C}$ .

For  $f : X \rightarrow Y$  in  $\mathcal{C}$  we obtain a reindexing functor  $f^* : \mathbf{Stat}(Y) \rightarrow \mathbf{Stat}(X)$  which

- acts as the identity on objects; and
- reindexes functions by sending  $\sigma : \mathcal{C}(I, Y) \rightarrow \mathcal{C}(A, B)$  to  $f^* \sigma$  defined by:

$$\begin{array}{ccc} \mathcal{C}(I, X) & \longrightarrow & \mathcal{C}(I, Y) \longrightarrow \mathcal{C}(A, B) \\ p & \longmapsto & f \circ p \longmapsto \sigma(f \circ p) \end{array}$$

Since the reindexing functors are defined by pre-composition it is easy to verify that **Stat** is indeed a functor.

This provides sufficient expressive power to represent general Bayesian inverses. For a kernel  $f : X \rightarrow Y$ , the general Bayesian inverse of  $f$  is a morphism  $Y \rightarrow X$  in  $\mathbf{Stat}(X)$ . However it is awkward to have to work across a large collection of categories in order to represent the inverses for every kernel. Really we would like to assemble the collection of

## 24:6 The Compositional Structure of Bayesian Inference

categories into a single category containing all of the inverses. Fortunately this category is described exactly by the *Grothendieck construction* [2, §8.3]. The Grothendieck construction realises an equivalence between indexed categories and *fibrations* – functors with a property of being suitably projection-like. The core of the construction is a disjoint union of the constituent categories, equipped with morphisms induced by the reindexing functors that connect each of the otherwise disjoint components.

$$\frac{\text{Indexed categories} \quad F : \mathcal{C} \rightarrow \mathbf{Cat}}{\text{Fibrations} \quad P_F : \left( \coprod_{C \in \mathcal{C}} F(C) \right) \rightarrow \mathcal{C}}$$

We proceed to construct the category of all state-indexed kernels in this way, which we will call the category of *Bayesian lenses*.

► **Definition 9** (Bayesian Lenses). *We define the category of Bayesian lenses as the Grothendieck construction  $\mathbf{BLens}(\mathcal{C}) = \coprod_{X \in \mathcal{C}} \mathbf{Stat}(X)^{op}$ .*

Explicitly this is a category whose objects are pairs  $\begin{pmatrix} X \\ A \end{pmatrix}$  of objects from  $\mathcal{C}$ , and whose morphisms are of the form  $(f, f^\#) : \begin{pmatrix} X \\ A \end{pmatrix} \rightarrow \begin{pmatrix} Y \\ B \end{pmatrix}$  where  $f$  is a kernel  $X \rightarrow Y$ , and  $f^\#$  is a family of “backward” kernels,  $\mathcal{C}(I, X) \rightarrow \mathcal{C}(B, A)$ . The composition of two such morphisms

$$\begin{pmatrix} X \\ A \end{pmatrix} \xrightarrow{(f, f^\#)} \begin{pmatrix} Y \\ B \end{pmatrix} \xrightarrow{(g, g^\#)} \begin{pmatrix} Z \\ C \end{pmatrix}$$

is  $(g \circ f, (g \circ f)^\#)$  where  $(g \circ f)^\#$  is a function  $\mathcal{C}(I, X) \rightarrow \mathcal{C}(C, A)$ , sending  $p : I \rightarrow X$  to the composition

$$C \xrightarrow{g^\#(f \circ p)} B \xrightarrow{f^\#(p)} A.$$

We call the morphisms of this category *Bayesian lenses*.

► **Remark 10.** Contrary to our general description of the Grothendieck construction, we in fact used the “fibrewise” opposite of  $\mathbf{Stat}$ , taking  $\mathbf{Stat}(X)^{op}$  for each  $X$  in  $\mathcal{C}$ . Ultimately this does not change the space of functions we can represent, but it provides a neater type signature for the morphisms we care about. Namely this means the Bayesian inverse of a kernel will be a morphism  $\begin{pmatrix} X \\ X \end{pmatrix} \rightarrow \begin{pmatrix} Y \\ Y \end{pmatrix}$ , rather than  $\begin{pmatrix} X \\ Y \end{pmatrix} \rightarrow \begin{pmatrix} Y \\ X \end{pmatrix}$ . We think of the appearance of the opposite here as signalling that we are working with a kind of bidirectional process.

Spivak [19] proposes that the fibrewise opposite of a fibration be considered as a generalisation of the lens construction from database theory and functional programming [7]. More clearly, if  $\mathcal{C}$  is the category of sets (which is degenerately a Markov category), then  $f^\# : \mathcal{C}(I, X) \rightarrow \mathcal{C}(B, A)$  can be equivalently written  $f^\# : X \times B \rightarrow A$ , and we recover the standard definition of a lens. This motivates our use of the term “Bayesian lens” for these morphisms.

► **Proposition 11** (Bayesian inversion is almost functorial). *If  $\mathcal{C}$  has Bayesian inverses for ever kernel at every prior, then Bayesian inversion defines a functor  $T : \mathcal{C} \rightarrow \mathbf{BLens}(\mathcal{C})$  up to almost-sure equality.*

**Proof.** Because Bayesian inverses are only unique up to almost-equality,  $T$  is only almost surely functorial: it maps each object  $X$  to  $\begin{pmatrix} X \\ X \end{pmatrix}$ , and each kernel  $f : X \rightarrow Y$  to a lens  $(f, f^\#) : \begin{pmatrix} X \\ X \end{pmatrix} \rightarrow \begin{pmatrix} Y \\ Y \end{pmatrix}$  whose inverse component is given by a representative of the almost-surely unique family of Bayesian inversions of  $f$ .

Given a pair of composable kernels  $X \xrightarrow{f} Y \xrightarrow{g} Z$ , we need to check that this mapping is almost surely functorial. Following equation (1), we note that the state with respect to which this functoriality is almost sure is  $g \circ f \circ p$ , for every state  $p$  on  $X$ . We therefore need to verify that

$$\begin{pmatrix} X \\ X \end{pmatrix} \xrightarrow{(f, f^\#)} \begin{pmatrix} Y \\ Y \end{pmatrix} \xrightarrow{(g, g^\#)} \begin{pmatrix} Z \\ Z \end{pmatrix} \simeq_{g \circ f} \begin{pmatrix} X \\ X \end{pmatrix} \xrightarrow{(g \circ f, (g \circ f)^\#)} \begin{pmatrix} Z \\ Z \end{pmatrix}.$$

This follows from three applications of Definition 1:

Note that although Markov categories in general may not admit all Bayesian inverses, we can always restrict to a wide subcategory  $\mathcal{C}^\dagger$  consisting of only those kernels which admit inverses.

#### 4 Dependent Bayesian Lenses

Those familiar with categorical semantics of type theory might observe that the construction of Bayesian lenses is similar to that of the *families fibration* [12, §1.2]. This construction, commonly used in the interpretation of dependent types, constructs a category whose objects and morphisms are set-indexed families of objects and morphisms from another underlying category. As a fibration this category projects onto the category of sets, by picking out the indexing set or reindexing function under each family.

► **Definition 12** (The families fibration [12, §1.2]). *The indexed category of families over a category  $\mathcal{C}$  is the functor  $\mathbf{Fam}_{\mathcal{C}} : \mathbf{Set}^{op} \rightarrow \mathbf{Cat}$  defined as so:*

- For a set  $X$ ,  $\mathbf{Fam}_{\mathcal{C}}(X)$  is the category whose objects are  $X$ -indexed families of objects  $X \rightarrow \text{Ob}(\mathcal{C})$  and whose morphisms  $A \rightarrow B$  are families of morphisms  $\phi : \{x \in X\} \rightarrow \mathcal{C}(A_x, B_x)$ .
- For a function  $\alpha : Y \rightarrow X$ , the induced reindexing functor  $\alpha^* : \mathbf{Fam}_{\mathcal{C}}(X) \rightarrow \mathbf{Fam}_{\mathcal{C}}(Y)$  is given by pre-composition with alpha:

$$\alpha^*(A) : X \xrightarrow{\alpha} Y \xrightarrow{A} \text{Ob}(\mathcal{C})$$

$$\alpha^*(\phi) : \{y \in Y\} \xrightarrow{\alpha} \{\alpha(x) \in X\} \xrightarrow{\phi} \mathcal{C}(A_{\alpha(y)}, B_{\alpha(y)})$$

Alternatively, viewing sets as discrete categories,  $\mathbf{Fam}_{\mathcal{C}}$  is the functor that sends  $X$  to the functor category  $\mathbf{Cat}(X, \mathcal{C})$  and reindexes by precomposition with the function viewed as a functor between discrete categories.

A crucial difference between this and the indexed category in Definition 8 is that the latter is indexed only by sets of the form  $\mathcal{C}(I, X)$  whereas  $\mathbf{Fam}_{\mathcal{C}}(-)$  allows for arbitrary indexing sets. Having the indexing sets take the form  $\mathcal{C}(I, -)$  allows us to additionally restrict the reindexing functors to those represented by kernels of  $\mathcal{C}$ . Formally we can see this as the result of reindexing  $\mathbf{Fam}_{\mathcal{C}}(-)$  itself with the state functor:

## 24:8 The Compositional Structure of Bayesian Inference

► **Definition 13** (State-indexed families). *The indexed category  $\mathbf{StFam}_{\mathcal{C}} : \mathcal{C}^{op} \rightarrow \mathbf{Cat}$  is given by the composite of functors:*

$$\mathcal{C}^{op} \xrightarrow{\mathcal{C}(I, -)^{op}} \mathbf{Set}^{op} \xrightarrow{\mathbf{Fam}_{\mathcal{C}}} \mathbf{Cat}$$

$$\begin{array}{ccc} A & \mathcal{C}(I, A) & \mathcal{C}^{\mathcal{C}(I, A)} \\ f \downarrow & \downarrow f \circ - & \uparrow \alpha \mapsto \alpha(f \circ -) \\ B & \mathcal{C}(I, B) & \mathcal{C}^{\mathcal{C}(I, B)} \end{array}$$

*This has as objects  $\mathcal{C}(I, X)$ -indexed families of objects from  $\mathcal{C}$  and as morphisms  $\mathcal{C}(I, X)$ -indexed families of kernels from  $\mathcal{C}$ .*

Note that the categories indexed by  $\mathbf{StFam}$  are more general than those indexed by  $\mathbf{Stat}$ : the objects of  $\mathbf{StFam}_{\mathcal{C}}(X)$  are whole functions  $\mathcal{C}(I, X) \rightarrow \mathbf{Ob}(\mathcal{C})$ , whereas an object of  $\mathbf{Stat}_{\mathcal{C}}(X)$  is merely a single object of  $\mathcal{C}$ .

► **Proposition 14.**  *$\mathbf{Stat}_{\mathcal{C}}$  is a subfunctor of  $\mathbf{StFam}_{\mathcal{C}}$  given by restricting to subcategories which consist only of constantly-indexed families of objects i.e. those families  $\mathcal{C}(I, X) \rightarrow \mathbf{Ob}(\mathcal{C})$  which are constant functions.* ◀

Observing that  $\mathbf{StFam}$  is a generalisation of  $\mathbf{Stat}$ , we are led to consider whether the fibration constructed from  $\mathbf{StFam}$  could profitably be considered as a generalised category of lenses. By analogy with the use of  $\mathbf{Fam}$  in dependent type theory we refer to these as *dependent Bayesian lenses*.

► **Definition 15** (Dependent Bayesian Lenses). *We define the category of dependent Bayesian lenses over  $\mathcal{C}$  to be the Grothendieck construction of the fibrewise opposite of  $\mathbf{StFam}$ ,*

$$\mathbf{DBLens}(\mathcal{C}) = \coprod_{X \in \mathcal{C}} \mathbf{StFam}_{\mathcal{C}}(X)^{op}.$$

Unpacking this definition we have that:

- Objects of  $\mathbf{DBLens}(\mathcal{C})$  are pairs  $\binom{X}{A}$  where  $X \in \mathcal{C}$  and  $A : \mathcal{C}(I, X) \rightarrow \mathbf{Ob}(\mathcal{C})$ . We think of this as representing a set of dependent pairs, whose elements are  $\langle p, a \rangle \in \mathcal{C}(I, X) \times A(p)$ .
- Morphisms  $\binom{X}{A} \rightarrow \binom{Y}{B}$  are pairs  $(f, f^{\#})$  of a kernel  $f : X \rightarrow Y$  and a family of kernels  $f^{\#} : \{p \in \mathcal{C}(I, X)\} \rightarrow \mathcal{C}(B(f \circ p), A(p))$ .
- The composition is as with the non-dependent version in Definition 9. Aside from the fact that  $f^{\#}$  is here considered as a dependent function, the data of a morphism is the same. It is straightforward to verify that the extra dependent typing data still aligns where appropriate.

► **Remark 16.** The functor  $\mathcal{C}(I, -)^{op} : \mathcal{C}^{op} \rightarrow \mathbf{Set}^{op}$  can be made into a lax monoidal functor with structure maps induced by functions  $\mathcal{C}(I, X \otimes Y) \rightarrow \mathcal{C}(I, X) \times \mathcal{C}(I, Y)$  which map states to pairs of states obtained by deleting either variable. Then it follows by results in [14] that  $\mathbf{StFam}$  is the composition of lax monoidal functors, and so its Grothendieck construction inherits a monoidal structure.

### 5 Support Objects

Giving an abstract account of Bayes' law, Definition 1 promises to be very important in studying Bayesian statistics synthetically, but it is in some way unsatisfying because it only specifies a morphism up to almost-sure equality. For example, considering  $\mathbf{FinStoch}$ , if a

distribution  $p : I \rightarrow X$  is not fully supported, then the inverse of a kernel  $X \rightarrow Y$  is only specified by the above definition at the points in the support of  $p$ . We can work around this ambiguity however by instead considering inverses as kernels between objects representing the supports of distributions.

Fritz [8] proposes a definition for support objects in a Markov category, but does not develop the idea further. Here we investigate some properties of support objects and explain how they can be used to enhance the theory of abstract Bayesian inversion.

► **Definition 17.** Fix a state  $p : I \rightarrow X$ . An object  $X_p$  is called a support of  $p$  if  $X_p$  represents the covariant functor  $(\mathcal{C}(X, -)/\simeq_p) : \mathcal{C} \rightarrow \mathbf{Set}$ .

This definition succinctly captures the essential properties of the support of a distribution, but it is quite opaque and does not encourage intuition. If an object is a support of another object, intuitively it should behave as a subspace, having an inclusion map which satisfies some extra properties. We state this formally in terms of the existence of certain section-retraction kernels representing this inclusion.

► **Proposition 18.**  $X_p$  is a support of  $p : I \rightarrow X$  if and only if there is a section-retraction pair  $X_p \xrightarrow{i} X \xrightarrow{r} X_p$  such that for any kernels  $f, g : X \rightarrow Y$  we have  $f \simeq_p g \iff f \circ i = g \circ i$ .

**Proof.** Assume  $X_p$  is a support. This means we have a natural isomorphism  $\Phi : (\mathcal{C}(X, -)/\simeq_p) \rightarrow \mathcal{C}(X_p, -)$ . We take  $i = \Phi_X(\text{id}_X)$ , then we see from the following naturality square that the action of  $\Phi$  must be to pre-compose representative morphisms with  $i$ :

$$\begin{array}{ccc}
 i & \longleftarrow & [\text{id}_X]_{\simeq_p} \\
 \downarrow & & \downarrow \\
 \mathcal{C}(X_p, X) & \xleftarrow{\Phi_X} & \mathcal{C}(X, X)/\simeq_p \\
 \mathcal{C}(X_p, f) \downarrow & & \downarrow \mathcal{C}(X, f)/\simeq_p \\
 \mathcal{C}(X_p, Y) & \xleftarrow{\Phi_Y} & \mathcal{C}(X, Y)/\simeq_p \\
 \downarrow & & \downarrow \\
 f \circ i & \longleftarrow & [f]_{\simeq_p}
 \end{array}$$

Hence we establish the property that pre-composition by  $i$  is an isomorphism between kernels from  $X$  and  $\simeq_p$ -equivalences classes of kernels from  $X_p$ . We further have that  $\text{id}_{X_p} = \Phi(\Phi^{-1}(\text{id}_{X_p})) = \Phi^{-1}(\text{id}_X) \circ i$ , so we can take the retract to be  $r = \Phi^{-1}(\text{id})$ .

Conversely, given such an  $i$  and  $r$ , it is clear that pre-composition by  $i$  defines a function  $\mathcal{C}(X, Y) \rightarrow \mathcal{C}(X_p, Y)$  natural in  $Y$  and the assumed property of  $i$  guarantees that this is a bijection from  $\simeq_p$ -equivalence classes. Finally we have that  $i \circ r \circ i = i$ , so  $i \circ r \simeq_p \text{id}_{X_p}$ . Hence pre-composition by  $r$  is an inverse to  $(-)\circ i : (\mathcal{C}(X, -)/\simeq_p) \rightarrow \mathcal{C}(X_p, -)$ . ◀

While support objects are not necessarily unique, they must be unique up to isomorphism, since two support objects for the same distribution must by definition represent the same presheaf. When we discuss a given support object we therefore really mean a given support object along with a choice of section and retraction.

Now, if we have a distribution on  $X$ ,  $p : I \rightarrow X$ , and a kernel  $f : X \rightarrow Y$  we can push  $p$  forward to a distribution  $f \circ p$  on  $Y$ . So  $f$  restricts to a kernel  $f|_p = r \circ f \circ i : X_p \rightarrow Y_{f \circ p}$ . Dually we have an inclusion of kernels  $g : X_p \rightarrow Y_q$  into  $\langle g \rangle = i \circ g \circ r : X \rightarrow Y$ . Using these there is an obvious adjustment to the definition of Bayesian inversion in order to capture Bayesian inverses between supports:

## 24:10 The Compositional Structure of Bayesian Inference

► **Definition 19** (Bayesian-inverse-with-support). *Fix kernels  $p : I \rightarrow X$  and  $f : X \rightarrow Y$  with support objects  $X_p$  and  $Y_{f \circ p}$ . We call a kernel  $f_p^\# : Y_{f \circ p} \rightarrow X_p$  a Bayesian inverse with support if  $\langle f_p^\# \rangle$  is an ordinary Bayesian inverse for  $f$  at  $p$ .*

This is very similar to the previous definition. However the presence of support objects in  $f_p^\#$ 's domain and codomain mean that the kernel is more canonical than an ordinary Bayesian inverse. In fact for any ordinary inverse  $f_p^\#$ , its restriction to the distribution  $f \circ p$  is an inverse-with-support.

► **Theorem 20** (Unique Bayesian Inversion). *Fix kernels  $f : X \rightarrow Y$  and  $p : I \rightarrow X$ , and support objects  $X_p$  and  $Y_{f \circ p}$ . If  $f$  has an ordinary Bayesian inverse at  $p$ , then there is a unique inverse-with-support to  $f$  at  $p$ .*

**Proof.** See Appendix A. ◀

This final result suggests that we can now define a functor that picks out the canonical inverse for a given kernel. Recall that in Proposition 11 we were almost able to show that Bayesian inversion defines a functor  $\mathcal{C} \rightarrow \mathbf{BLens}(\mathcal{C})$  except that the functoriality constraint only holds up to almost-equality. Using support objects we improve this into strict functoriality between kernels. Bayesian inversion with supports departs from the previous situation slightly in that the domain and codomain of the inverse kernels vary as the indexing distribution varies. Fortunately this is exactly the extra level of generality afforded us by dependent Bayesian lenses.

► **Proposition 21.** *If  $\mathcal{C}$  has Bayesian inverses for every kernel, and support objects for every distribution  $I \rightarrow X$  then the fibred category  $\mathbf{DBLens}(\mathcal{C})$  has a section  $T : \mathcal{C} \rightarrow \mathbf{DBLens}(\mathcal{C})$  sending kernels to families of their Bayesian inverses between support objects.*

**Proof.** We write explicitly the mapping defining  $T$ . On objects  $T(X) = \begin{pmatrix} X \\ S_X \end{pmatrix}$  where  $S_X : \mathcal{C}(I, X) \rightarrow \text{Ob}(\mathcal{C})$  maps  $p$  to a choice of support object  $X_p$ . On kernels  $f : X \rightarrow Y$ , we have  $T(X) = (f, f^\#) : \begin{pmatrix} X \\ S_X \end{pmatrix} \rightarrow \begin{pmatrix} Y \\ S_Y \end{pmatrix}$  where for each  $p \in \mathcal{C}(I, X)$ ,  $f_p^\# : Y_{f \circ p} \rightarrow X_p$  is given by the Bayesian inverse with support of  $f$  at  $p$ .

The functoriality of  $T$  follows similarly to in Proposition 11. Briefly, if  $f$  and  $g$  are composable Bayesian inverses with support, then  $\langle f \rangle$  and  $\langle g \rangle$  are composable ordinary inverses, so by Proposition 11 their composition must be an inverse. By the definition of the inclusions it is immediately that  $\langle f \rangle \circ \langle g \rangle = \langle f \circ g \rangle$ , so  $f \circ g$  is an inverse-with-support. Then by uniqueness, the fact that the composition  $f \circ g$  is a Bayesian inverse implies the strict equality required for functoriality. ◀

► **Remark 22.** Proposition 21 proves the compatibility of sequential composition in a Markov category with Bayesian inversion, however there is another axis for composition in our graphical notation. This is the parallel composition, or monoidal product of  $\mathcal{C}$ . To ask for this structure to be compatible with inversion is to ask for the functor  $T$  to respect the monoidal structure. Indeed as we noted in Remark 16, we may naturally define a monoidal product on  $\mathbf{DBLens}(\mathcal{C})$ , then  $T$  straightforwardly inherits the structure of a *lax monoidal functor* with respect to this.

► **Remark 23.** Most of the results developed in this section relied on the existence of support objects. Indeed this is satisfied for our first two examples Example 3 and Example 4, but this is quite a strong assumption in general. The approach to functorial Bayesian inversion taken in [5] and later expanded on in [8] is to work in a category  $\mathbf{ProbStoch}(\mathcal{C})$  whose objects are equipped with a choice of distribution and whose morphisms are quotiented by

almost-sure equality with respect to these chosen distributions. This makes exact functoriality straightforward to prove, but it detracts from the interpretation of morphisms as stochastic functions. Working in  $\mathbf{ProbStoch}(\mathcal{C})$  we are unable to think of Bayesian updating as a dynamic process which maps observations to new distributions, since the resultant distribution is already encoded in the codomain.

We could instead take a hybrid approach, using dependent Bayesian lenses where the forwards kernel is still valued in  $\mathcal{C}$  but the “backwards” mapping is in  $\mathbf{ProbStoch}(\mathcal{C})$ . This means the type of a general inverse can become a function  $\{p \in \mathcal{C}(I, X)\} \rightarrow \mathbf{ProbStoch}(\mathcal{C})((Y, f \circ p), (X, p))$ . This provides a lot of the same theoretical niceties of support objects, including exact functoriality, while still applying in a more general context. We leave the further investigation of this construction to future work.

## 6 Example: Estimating Transition Probabilities in Markov Chains

To illustrate the compositional nature of Bayesian inversion in practice we consider how to view a typical Bayesian inference problem in this framework. Namely we use as our example, the common problem of learning transition probabilities for a Markov chain from an observed sequence of states [21].

In the category  $\mathbf{FinStoch}$ , a Markov chain is nothing but an endomorphism  $t : S \rightarrow S$  for some finite set  $S$  of *states*, with an initial state distribution  $s : I \rightarrow S$ . Often we do not know the actual transition probabilities, but instead have a family of distributions dependent on another external parameter,  $t : S \otimes \Theta \rightarrow S$ . In such a situation we want to choose an optimal value of  $\Theta$  based on a sequence of observations of states in the past. A common technique for choosing this value is to consider the observed state sequence as an element of the space  $S \otimes \dots \otimes S$ , with which we can perform a Bayesian update. That is, given a state sequence  $(s_1, \dots, s_n)$  we would like to compute a posterior distribution  $\mathbb{P}(\Theta | s_1, \dots, s_n)$ .

From the data involved we can define a family of maps  $f_n : \Theta \rightarrow S^{\otimes n}$  describing the distribution over  $n$ -length state sequences corresponding to any value of  $\Theta$  (see Figure 2 for an example). Computing the Bayesian inverse of  $f_n$  we obtain kernels which map sequences  $S^{\otimes n}$  to posterior distributions over  $\Theta$ . Of course, as we have already discussed, in order to compute this all we need is the Bayesian inverse for the transition matrix  $t$ . Knowing the functorial relationship between “forward” models  $f_n$  and their corresponding inverse models, we can build an inverse for  $f_n$  out of many copies of the inverse for  $t$ .

■ **Figure 2** An example of a “state-trace” kernel obtained from a Markov chain, yielding state sequences of length 4.

Figure 2 depicts a typical composite which we may want to invert. It consists only of four kinds of non-trivial cell: the transition matrix  $t$ , the initial state distribution  $s$ , copy maps  $\text{copy}_S : S \rightarrow S \otimes S$  and  $\text{copy}_\Theta : \Theta \rightarrow \Theta \otimes \Theta$ , and a delete map  $\text{delete}_\Theta : \Theta \rightarrow I$ . As  $t$  is an arbitrary kernel there is little we can say about its Bayesian inverse, but we can fully characterise the inverses for the other kinds of cells. The inverse of  $s$  at  $p$  should have a type  $s_p^\# : S_p \rightarrow I$ , but by the uniqueness of the delete map this is equal to  $\text{delete}_{S_p} : S_p \rightarrow I$ . Dually, filling in the definition of Bayesian inversion for  $\text{delete}_\Theta$  at  $p$  requires that  $(\text{delete}_\Theta)_p^\#$  is exactly  $p : I \rightarrow \Theta$ .

Finally we consider the Bayesian inverse of  $\text{copy}_S$ . Of course the case for  $\text{copy}_\Theta$  is identical. In the case of non-dependent Bayesian lenses, without supports, it is difficult to understand what these copy maps do. The copy operation is supported on only a small subset of its domain. Intuitively this is the diagonal set  $\{(s, s) | s \in S\}$ , but in the abstract case this set notation is not valid. We may wonder if there is a way that we can describe this using only the axiomatic setting we have been working with so far. Indeed, we can show that there is in fact an isomorphism of the support object  $(S \otimes S)_{\text{copy}_\Theta \circ p} \cong S_p$  and moreover, the morphism witnessing this isomorphism is exactly the Bayesian inverse of  $\text{copy}$ .

This isomorphism is a very powerful fact. It enforces in the type of a morphism, using the notion of dependent typing present in  $\mathbf{DBLens}(\mathcal{C})$ , that the observations we make from a process involving copying should preserve the exact equalities expected given our knowledge about the generative processes from which the observations originated.

It is not difficult to derive an explicit formula for this with traditional probability theory, but our structural viewpoint can offer a more pedagogical approach to describing inference algorithms. Using a 2-dimensional syntax for kernels and understanding the compositional nature of Bayesian inversion, a lot of the apparent complexity of equations in statistics is clarified by applying operations piecewise on string diagrams. It additionally becomes straightforward to see how to extend this to more complicated scenarios. For example, a hidden Markov model is obtained from the above example simply by postcomposing each wire with an additional kernel  $o : S \rightarrow O$ . Then compositionality described exactly how to extend a solution to account for the additional mapping.

This approach provides not just additional pedagogy, but also is very amenable to algorithmic study: as future work, we hope to investigate ways in which, by isolating the basic repeated units and their compositional structure, we can automatically generate a lot of the additional data required and can perhaps facilitate certain optimisations.

## 7 Further work

Our work situates Bayesian inversion amongst a range of bidirectional processes observed in different contexts, each of which exhibit lens (or lens-like) structure and “cybernetic” application [4]: reverse-mode automatic differentiation (generalizing backpropagation of error) [6]; economic games [9]; reinforcement learning [11]; and database updating [7]. It was in this latter setting, in the context of functional programming, that lenses were first described, and generalizations of lenses remain in popular use in that setting. This points to a first avenue for future work: a new approach to probabilistic programming that incorporates both Bayesian and differential updating, extending the currently popular use of deterministic lenses, and with general application to cybernetic systems.

Probabilistic programming languages allow the programmer essentially to construct Markov kernels in a compositional way using a standard programming language syntax, and perform inference on the resulting models [20]. Typically, performing inference is not

transparently compositional, and so we hope that our results will lead to improvements here, for instance by allowing the programmer to “amortize” parts of an inference process. Perhaps more importantly, our approach could lead to the use of a dependent type system to statically rule out events of measure zero. Furthermore, in a generically bidirectional language of the kind we envisage, we expect that compilers will be able to share optimizations across differential and probabilistic parts.

We expect these ideas not only to be of use to language designers therefore, but also to users. In many applications of probabilistic inference, one first constructs a “joint model”: a joint state across all the variables of interest, which may factorise according to a Bayesian network or other graphical model. Because computing exact Bayesian inversions involves marginalization (normalization: the sum or integral in the Chapman-Kolmogorov equation), and such a computation is often intractable, one usually resorts to approximate methods, and this is where the “extra” morphisms in categories of Bayesian lenses come in: they can be understood as approximate inverses.

By parameterizing these lenses, one can associate to them *loss functions* that characterize “how far” a given inversion is from optimality<sup>2</sup>; like the inversions themselves, these losses depend on both the priors and the observations, and they again compose according to a lens pattern. The third author, in the unpublished works [17, 18], has begun developing this programme, based on ideas from compositional game theory [9]. It results in an account of approximate inference whose algorithms are “correct by construction”, which may be an advantage over traditional methods which simply start from a given joint distribution. Moreover, because the loss functions are “local” to each lens, the resulting framework captures the compositional structure seemingly exhibited by “predictive coding” neural circuits in the brain [1]. Similarly, by making use of the lens structure presented here, the framework suggests a formal unification of backprop and predictive coding, as sought by various authors [13, 15], and it reveals connections to the method of backward induction in reinforcement learning [11]. We hope that future developments make use of these relationships, so that we may build intelligent systems that are both efficient and well-understood.

## A Uniqueness of Bayesian Inversion

► **Notation 24.** *In the graphical language we denote the inclusion and restriction kernels for a support object respectively as follows:  $X_p \text{ } \leftarrow \vdash \text{ } X \text{ } \rightarrow \vdash \text{ } X_p$*

This is a convenient shorthand for indicating the section-retract relation between sections and restrictions, however care must be taken when calculating with these. Since we are not labelling the triangles, we should only pair inclusions and restrictions corresponding to the same states; the characterising equations only hold for such pairs. However in practice it is difficult to naturally arrive at a situation where this caveat can be an issue, so this is less of a shortcoming that it might seem.

We have strict equality of inclusions followed by restrictions, but in the converse we have almost-equality of restrictions followed by inclusions.

► **Lemma 25.** *Restriction is almost inverse to inclusion:*

$$X \xrightarrow{r} X_p \xrightarrow{i} X \simeq_p X \xrightarrow{id} X.$$

**Proof.** Note that  $i \circ r \circ i = i$  so by the quotienting property of  $(-)\circ i$  we have  $i \circ r \simeq_p \text{id}$ . ◀

► **Proposition 26.** *Fix kernels  $f : X \rightarrow Y$  and  $p : I \rightarrow X$ , and support objects  $X_p$  and  $Y_{fp}$ . Then inverses-with-support of  $f$  at  $p$  are in bijection with  $\simeq_{fp}$ -equivalence classes of ordinary Bayesian inverses.*

**Proof.** We first exhibit a map  $\Psi$  from inverses-with-support to ordinary inverses. Let  $g : Y_{fp} \rightarrow X_p$  be a Bayesian inverse with support of  $f$  at  $p$ . By the definition of inverses with support this means that  $\Psi(g) := \langle g \rangle$  is an ordinary Bayesian inverse.

Conversely if  $h : Y \rightarrow X$  is an ordinary Bayesian inverse to  $f$  at  $p$ , we want to define an inverse with support  $\tilde{\Psi}(h) : Y_{fp} \rightarrow X_p$ . As a first guess we might try the restriction  $h|_{fp}$  but we see that the codomain of this kernel does not match. Namely we have  $h|_{fp} : Y_{fp} \rightarrow X_{hfp}$  but require a codomain of  $X_p$ . In fact we can verify that  $hfp = p$ : since  $h$  is a Bayesian inverse of  $f$  at  $p$  we have that

and so by the naturality of the delete map:

So it is well defined to set  $\tilde{\Psi}(h) := h|_{fp}$ . We can see that this is an inverse-with-support: to show this we must show that  $\langle h|_{fp} \rangle$  is an ordinary Bayesian inverse. i.e. that

But this follows straightforwardly by two applications of Lemma 25 and the fact that  $h$  is a Bayesian inverse.

We finally have that  $\Psi(-)$  is inverse to  $\tilde{\Psi}$  when viewed as maps to/from equivalence classes:

$$\begin{aligned} \Psi(\tilde{\Psi}(h)) &= i_p \circ r_p \circ h \circ i_{fp} \circ r_{fp} \\ &\simeq_{fp} i_p \circ r_p \circ h \\ &\simeq_{fp} h \end{aligned}$$

where the final equivalence uses the fact that  $h$  is a Bayesian inverse to move it out of the way, similarly to the previous chain of equalities.  $\blacktriangleleft$

Noting that all Bayesian inverses to  $f$  at  $p$  must be  $(f \circ p)$ -almost equal we obtain Theorem 20 as a corollary, that Bayesian inverses with support are unique.

**► Theorem 20 (Unique Bayesian Inversion).** *Fix kernels  $f : X \rightarrow Y$  and  $p : I \rightarrow X$ , and support objects  $X_p$  and  $Y_{fp}$ . If  $f$  has an ordinary Bayesian inverse at  $p$ , then there is a unique inverse-with-support to  $f$  at  $p$ .*

# Deterministic Constrained Multilinear Detection

## Abstract

We extend the algebraic techniques of Brand and Pratt (ICALP'21) for deterministic detection of  $k$ -multilinear monomials in a given polynomial with non-negative coefficients to the more general situation of detecting *colored*  $k$ -multilinear monomials that satisfy additional constraints on the multiplicities of the colors appearing in them. Our techniques can be viewed as a characteristic-zero generalization of the algebraic tools developed by Guillemot and Sikora (MFCS'10) and Björklund, Kaski and Kowalik (STACS'13)

As applications, we recover the state-of-the-art deterministic algorithms for the GRAPH MOTIF problem due to Pinter, Schachnai and Zehavi (MFCS'14), and give new deterministic algorithms for generalizations of certain questions on colored directed spanning trees or bipartite planar matchings running in deterministic time  $O^*(4^k)$ , studied originally by Gutin, Reidl, Wahlström and Zehavi (J. Comp. Sys. Sci. 95, '18). Finally, we give improved randomized algorithms for intersecting three and four matroids of rank  $k$  in characteristic zero, improving the record bounds of Brand and Pratt (ICALP'21) from  $O^*(64^k)$  and  $O^*(256^k)$ , respectively, to  $O^*(4^k)$ .

## 1 Introduction

The area of fixed-parameter algorithms, sprung from the seminal work of Downey and Fellows (see e.g. their monograph [11]), has produced an enormous amount of tools and techniques to facilitate the design of algorithms that can solve NP-hard problems in running times of the form  $f(k) \cdot \text{poly}(n)$ , where  $n$  is the input size and  $k$  is some parameter that can be interpreted to quantify the difficulty of the instance at hand.

Two prominent and highly successful techniques contributing to this toolbox are, on the one hand, of *algebraic* nature, focusing on formulations of combinatorial problems in the language of polynomials, and then employing mathematical means to solve these reformulations. On the other hand, one of the earliest approaches known to produce fixed-parameter algorithms is the combinatorial method of *representative families*, with their first algorithmic applications dating back at least to work of Monien [25].

Both the algebraic as well as the representative-family based approach have received a considerable amount of attention in recent years, often focusing on the same application problems. This has resulted in a flurry of competing results on variants of e.g., the notorious longest path problem, subgraph isomorphism, set packing, network design as well as matroid problems, to name a few.

An important variation on the basic combinatorial problems studied in these lines of research concerns *colored* variants of the problems. One of the most well-studied problems of this kind is the *graph motif* problem, which was originally motivated from the analysis of biological networks, and has since been the subject of many parameterized algorithmic studies. As with the uncolored variants of these problems, the colored counterparts attracted attention from researchers from both the perspective of representative families, as well as the algebraic point of view, with both techniques contributing methods that have remained the state-of-the-art within their respective regime. A possibly sweeping generalization of the results that together form this body of work might perhaps conclude that algebraic methods seem more adapted to produce fast randomized algorithms, whereas the representative families tend to yield record bounds for deterministic algorithms.

On the side of algebraic algorithms, in the uncolored regime, a common technique for all of the combinatorial problems above is to formulate them as so-called *multilinear monomial detection* problems. In these problems, one is given an arithmetic circuit computing a polynomial, and the task is to decide whether this polynomial contains a product of  $k$  variables that are all pairwise distinct, and  $k$  is the parameter. Similarly, in the colored variants, these detection problems are generalized to so-called *constrained* multilinear monomial detection, where additional coloring constraints are imposed on the products of variables to be detected. This is also the technique that is considered in the present article.

## 1.1 Related Work

For general background on fixed-parameter algorithms, we refer the reader to the snapshot of the state-of-the-art of the field as captured by e.g. the textbook of Cygan et al. [9], in particular Chapters 10 and 12, where diverse applications of the tools mentioned above are developed.

### Algebraic Algorithms

One of the seminal works for algebraic methods in parameterized and exact algorithms is the work by Björklund et al. [2] on fast subset convolutions and its application for the parameterized Steiner tree problem. More specifically, for the problems considered in this article, the algorithms by Koutis and Williams on multilinear detection were highly influential [20, 22, 29]. These methods were first transported to the setting of constrained multilinear detection by Guillemot and Sikora [17] and subsequently improved by Koutis [21] as well as Björklund, Kowalik and Kaski [4, 5]. It is important to note that all their methods are inherently randomized, because they resort to a use of the DeMillo-Lipton-Schwartz-Zippel Lemma, which makes it seem hard to derandomize them in a black-box manner.

### Graph Problems

These randomized algebraic methods allow to design the state-of-the-art algorithms for e.g. the maximum graph motif problem, running time  $2^k \cdot \text{poly}(n)$  [4, 5]. On the side of deterministic algorithms, which is the focus of this article, the relevant techniques are more combinatorial in nature. Indeed, the method of representative families was first considered

explicitly in the context of fixed-parameter algorithms by Marx [24] and has since been extended into a most intricate machinery, in particular in the works of Fomin et al. [15, 16]. These methods were then refined by Pinter, Shachnai and Zehavi and applied to design the state-of-the-art deterministic algorithms for the graph motif problem [26], running in time  $2^{\omega k} \cdot \text{poly}(n)$ .

## Matroid Problems

Another area in which representative-families based methods have proven fruitful is the realm of *matroid problems*. In this article, we consider the problem of *matroid intersection*: Given  $q$  (representations of) matroids of rank  $k$ , decide whether they share a single common basis. This is a classic problem in combinatorial optimization, and the polynomial-time solvable special case of intersecting  $q = 2$  matroids is famously treated by Edmonds [13]. More generally, intersecting  $q > 2$  matroids becomes *NP*-hard, and fixed-parameter algorithms for this problem were given first (without using this term) by Barvinok [1]. In a later development, Marx [24] revived the interest in this problem by giving the first single-exponential (in  $q$  and  $k$ ) algorithm using representative families, which was superseded by the work of Fomin et al. [15]. The current state-of-the-art is  $4^{qk}$  [8]. A recent manuscript of Eiben, Koana and Wahlström [14] shows that this can be improved to  $4^{(q-2)k}$  using different algebraic methods.

## Our Contribution

The contribution of this paper is three-fold. First, we show how to extend the (deterministic) algebraic machinery of Brand and Pratt to the colored, that is, constrained-multilinear setting. This is noteworthy insofar as until now, the only known algebraic tools for this task were inherently randomized, and the only deterministic algorithms for the respective combinatorial application problems were of decidedly combinatorial nature.

Secondly, we show how to use these adapted methods to, on the one hand, reproduce the deterministic state-of-the-art for the graph motif problem without any additional problem-specific adaptation as a generic application of the algebraic methodology laid out here. In addition, we provide examples of natural colorful extensions of several combinatorial problems, involving e.g. spanning trees and planar perfect matchings, that are not known to admit deterministic algorithms by using only the known combinatorial techniques.

Finally, we improve the state-of-the-art for matroid intersection in the case  $q \leq 4$  by giving specialized polynomial formulations of these cases. It is worth noting that the speedup over the generic state-of-the-art technique is by a factor of 16 (or 4 with respect to [14]) in the exponential base.

## Organization

We continue with a formal introduction of notation and all problems considered in the article. We then prove our main theorem about constrained multilinear detection and give our applications for graph problems. We then conclude with the improved algorithms for matroid problems.

## 2 Preliminaries

Generally, we denote the set of integers  $\{1, \dots, t\}$  by  $[t]$ , and use  $[t]_0$  as a shorthand for  $[t] \cup \{0\}$ . We denote by  $\mathbb{N}$  the set of natural numbers excluding zero, and by  $\mathbb{Q}$  the set of rational numbers.

**Matrices and Matroids**

Let  $A$  be a matrix with row set  $X$  and column set  $Y$ , and let  $X_0$  and  $Y_0$  be subsets of  $X$  and  $Y$  correspondingly. We denote by  $A[X_0, Y_0]$  the submatrix of  $A$  restricted to the rows in  $X_0$  and the columns in  $Y_0$  (while in  $A[Y_0]$  the restriction is applied to columns alone). In particular,  $A[X, Y] = A[Y] = A$ . For two matrices  $A$  and  $B$ , we denote their direct sum by  $A \oplus B$ . For an arbitrary sequence  $r_1, \dots, r_N \in \mathbb{Q}$ , we write  $\text{Vand}_k(r_1, \dots, r_N)$  for the  $k \times N$  *Vandermonde* matrix defined through

$$\text{Vand}_k(r_1, \dots, r_N)_{l,j} = r_j^l, \quad l \in [k-1]_0, \quad j \in [N].$$

By convention, we let  $0^0 = 1$  in this definition, and we say  $\text{Vand}_k(r_1, \dots, r_N)$  is the Vandermonde matrix of the sequence  $r_1, \dots, r_N$ .

A *finite matroid*  $\mathcal{M}$  is a pair  $(E, \mathcal{I})$ , where  $E$  is a finite set (called the *ground set*) and  $\mathcal{I}$  is a family of subsets of  $E$  (called the *independent sets*) satisfying so-called independence axioms. In this article we only work with finite matroids that can be represented by matrices as follows. Any matrix  $M$  with entries in  $\mathbb{Q}$  gives rise to a matroid  $\mathcal{M}$  with the ground set being its set of columns. The independent sets of the matroid are those subsets of columns that are linearly independent as vectors. In particular, size of any *base* (i.e., maximal with respect to inclusion independent set) of  $\mathcal{M}$  is equal to the rank of  $M$ . We say that such a matroid  $\mathcal{M}$  is *represented* by  $M$ .

**Polynomials**

Let  $R$  be a commutative ring, and let  $x_1, \dots, x_n$  be formal indeterminates. Then  $R[x_1, \dots, x_n]$  is the ring of polynomials in  $x_1, \dots, x_n$  with coefficients in  $R$ , and we call the latter the *coefficient ring* of the polynomial ring.

Every polynomial  $f$  can be represented uniquely as a weighted, finite sum of monomials, that is, products of variables. We may therefore write

$$f = \sum_{a_1, \dots, a_n \in \mathbb{N}} c_{a_1, \dots, a_n} x_1^{a_1} \cdots x_n^{a_n},$$

where only finitely many of the coefficients  $c_{a_1, \dots, a_n} \in R$  are non-zero. When all monomials appearing in  $f_{\mathcal{M}}$  are of degree  $k$ , we call  $f$  itself *homogeneous of degree  $k$* . Furthermore, if for some choice of  $a_1, \dots, a_n \leq 1$  there is a coefficient  $c_{a_1, \dots, a_n} \neq 0$ , we say that  $f$  has a *multilinear* monomial  $x_1^{a_1} \cdots x_n^{a_n}$ .

Our algorithms are based on the algebraic techniques found in [8]. In this approach, as with similar algebraic methods [20], the combinatorial objects (matroid bases, subgraphs, subsets, and so on) over a universe of size  $n$  are modeled using (rational) multivariate polynomials over the indeterminates  $x_1, \dots, x_n$ . The crux of the approach in [8] is then to write down a polynomial whose coefficients encode some information about the combinatorial problem at hand, and evaluate algebraically some linear functional over this polynomial that reveals some sought-after combinatorial answers.

This functional is defined via the following inner product: Let  $f$  and  $g$  be any two such polynomials that are homogeneous of degree  $k$ , and say that  $f$  is as above and

$$g = \sum_{a_1, \dots, a_n \in \mathbb{N}} d_{a_1, \dots, a_n} x_1^{a_1} \cdots x_n^{a_n}.$$

Then we define their *apolar inner product*  $\langle f, g \rangle$  in an almost entirely straightforward way, by

$$\langle f, g \rangle = \sum_{a_1, \dots, a_n \in \mathbb{N}} a_1! \cdot a_2! \cdots a_n! \cdot c_{a_1, \dots, a_n} \cdot d_{a_1, \dots, a_n}. \quad (1)$$

Including the product of factorials serves the purpose of normalization, which allows to connect  $\langle f, g \rangle$  with the partial derivatives of  $f$  and  $g$ .

As an inner product, this mapping can be intuitively interpreted as a measure of similarity between  $f$  and  $g$ . In particular, when fixing  $g$  (or, equivalently,  $f$ ) to, for example, the  $k$ -th elementary symmetric polynomial

$$e_k(x_1, \dots, x_n) = \sum_{\substack{S \subseteq [n] \\ |S|=k}} \prod_{s \in S} x_s,$$

which has all, and only, multilinear monomials with coefficient one, it is easy to see that  $f \mapsto \langle f, e_k \rangle$  is a linear functional that yields the sum of coefficients of multilinear monomials of degree  $k$  of  $f$ . If  $f$  maps to a non-zero value under this functional, we may conclude that  $f$  has a multilinear monomial. As shown in [8], the complexity of evaluating this functional depends on certain algebraic properties of  $f$  and  $e_k$  (or  $g$ , in general).

### Arithmetic Circuits

Even before these algebraic properties, the complexity of this evaluation depends on the *encoding* of  $f$  and  $g$ . Indeed, if  $f$  and  $g$  are given by their list of coefficients, then all questions treated in this article become trivial. However, this would imply inputs that are of exponential size in  $n$ , making this *sparse* encoding a poor choice for polynomials enumerating e.g. combinatorial objects, as an algebraic analog to brute-force search. Instead, polynomials are encoded using *arithmetic circuits*, which are directed acyclic graphs with a single sink, labeled as follows: Every vertex of in-degree zero (*inputs*) is labeled with either an indeterminate or a constant from the coefficient ring. Every vertex with non-zero in-degree is labeled either  $+$  or  $\times$ . The labeled nodes of the arithmetic circuit are referred to as *gates*. An arithmetic circuit *computes* a polynomial in the obvious inductive manner. Finally, we call an arithmetic circuit *skew* if every  $\times$ -gate has at most one edge coming from a non-input gate.

### Constrained Monomials

In the context of this article, multilinear monomials that are not only multilinear, but satisfy additional constraints are relevant. More precisely, suppose  $C = \{1, \dots, q\}$  is a set of  $q$  colors with *multiplicities*  $\mu_1, \dots, \mu_q \in \mathbb{N}$ , and  $\chi : [n] \rightarrow C$  is a *coloring* of  $[n]$ . A multilinear monomial  $x_1^{a_1} \cdots x_n^{a_n}$  is called *well-colored* if  $\sum_{i: \chi(i)=c} a_i \leq \mu_c$  for all colors  $c \in C$ , that is, every color appears at most  $\mu_c$  times in the monomial.

### Problem Statements

Let us now formally introduce the problems studied in this article. The most prominent one, which will be used to reduce the combinatorial application problems to, is the following algebraic problem.

## 25:6 Deterministic Constrained Multilinear Detection

### CONSTRAINED $k$ -MULTILINEAR DETECTION

- Input: A number  $k$ , an arithmetic circuit computing a polynomial  $f$ , a coloring of the variables of  $f$ , together with multiplicity constraints on each color.
- Question: Does  $f$  have a well-colored multilinear monomial of degree  $k$ ?

In our algorithms, we will encounter the restriction that the computed polynomial  $f$  (but not necessarily the circuit itself) have non-negative coefficients in order to make them deterministic. This is a natural restriction when dealing with combinatorial problems in many cases.

### Graph Problems

In analogy to the definition of well-colored monomials, the notion of a vertex or edge coloring includes those mappings that are not necessarily *proper* colorings, that is, two neighboring vertices in a graph, or two edges sharing a vertex, may very well receive the same color. To be precise, given a coloring  $\chi : V(G) \rightarrow \{1, \dots, q\}$ , or analogously  $\chi : E(G) \rightarrow \{1, \dots, q\}$ , and multiplicities  $\mu_1, \dots, \mu_q$ , we call a set  $S$  of vertices (or edges, respectively) *well-colored* if  $\chi^{-1}(i) \cap S \leq \mu_i$  for all  $i = 1, \dots, q$ . With this in mind, the following problems can be defined:

### MAXIMUM GRAPH MOTIF

- Input: A vertex-colored undirected graph  $G$  together with multiplicity constraints on each color.
- Question: Does  $G$  have a well-colored set of  $k$  vertices that induce a connected subgraph of  $G$ ?

In algebraic terms, MAXIMUM GRAPH MOTIF, while amenable to our techniques, doesn't showcase their full strength, for reasons explained in the article. In contrast, the following problems share the important property that they can be expressed succinctly by computations of certain determinants, which allows us to give the first fixed-parameter algorithms for them that are probably hard to come by using other approaches. These are made in analogy to the non-well-colored graph problems studied by Gutin et al. [18].

### WELL-COLORED SPANNING TREE

- Input: A number  $k$  and an edge-colored directed graph  $G$  together with multiplicity constraints on each color.
- Question: Does  $G$  have a well-colored subset of  $k$  edges that can be extended to a directed spanning tree of  $G$ ?

### WELL-COLORED PLANAR PERFECT MATCHING

- Input: A number  $k$  and an edge-colored planar graph  $G$  together with multiplicity constraints on each color.
- Question: Does  $G$  have a well-colored subset of  $k$  edges that can be extended to a perfect matching?

### INTERNALLY WELL-COLORED SPANNING TREE

- Input: A number  $k$  and a vertex-colored planar graph  $G$  together with multiplicity constraints on each color.
- Question: Does  $G$  have a spanning tree such that its internal vertices contain a well-colored subset of at least  $k$  vertices?

### 3 Constrained Multilinear Detection

For any multiplicities  $\mu = (\mu_1, \dots, \mu_q)$  and natural numbers  $n, k$ , consider the polynomial ring  $\mathbb{Q}[y_{1,1}, \dots, y_{1,n}, \dots, y_{q,1}, \dots, y_{q,n}]$  in  $nq$  variables. Following the nomenclature from randomized algebraic methods by Björklund, Kaski and Kowalik [4, 5], we refer to the variables  $y_{i,1}, \dots, y_{i,n}$  as the *shades* of the color  $i$ . We call a multilinear monomial of degree  $k$  in  $y$ -variables *well-colored* if for every color  $i$ , at most  $\mu_i$  shades of the color  $i$  appear in the monomial. Furthermore, we associate with every subset  $M$  of  $[nq]$  of size  $k$  a multilinear monomial  $y_M$  of degree  $k$  in the obvious manner.

► **Lemma 1.** *There is an algorithm that, given  $\mu$ , constructs in time  $\text{poly}(n, k, q)$  a skew arithmetic circuit computing a polynomial  $\chi_\mu = \sum_{M \subseteq [nq], |M|=k} c_M y_M$  such that  $c_M \geq 0$  for all  $M$ , and strict inequality holds if and only if  $y_M$  is well-colored.*

**Proof.** For every  $i \in [q]$ , let

$$\mu_{\leq i} = \sum_{j=1}^i \mu_j$$

be the  $i$ -th partial sum of  $\mu$ . We set  $\mu_{\leq 0} = 0$ . Then, we define a matrix  $S \in \mathbb{Q}^{k \times nq}$  as follows:  $S = (S_1 | S_2 | \dots | S_q)$  is the concatenation of  $q$  blocks  $S_1, \dots, S_q \in \mathbb{Q}^{k \times n}$ , one for each color. Each block  $S_i$  is in turn defined as  $S_i = U_i \cdot V_i$ , where  $U_i \in \mathbb{Q}^{k \times \mu_i}$  is a Vandermonde matrix of dimension  $k \times \mu_i$ , and  $V_i \in \mathbb{Q}^{\mu_i \times n}$  is a Vandermonde matrix of dimension  $\mu_i \times n$ , namely

$$\begin{aligned} U_i &= \text{Vand}_k(\mu_{\leq i-1} + 1, \mu_{\leq i-1} + 2, \dots, \mu_{\leq i}), \\ V_i &= \text{Vand}_{\mu_i}(1, \dots, n). \end{aligned}$$

For a subset  $M \subseteq [nq]$  of size  $k$ , let  $\sigma_M = \det(S[M])$ . We claim that  $\sigma_M \geq 0$  holds, which can be seen as follows. Let  $m = \mu_{\leq q}$ , and consider the auxiliary matrices

$$\begin{aligned} U &= (U_1 | U_2 | \dots | U_q) = \text{Vand}_k(1, \dots, m) \in \mathbb{Q}^{k \times m}, \\ V &= V_1 \oplus \dots \oplus V_q \in \mathbb{Q}^{m \times nq}. \end{aligned}$$

Then per definition, we have  $S = UV$ , and moreover  $S[M] = U \cdot V[M]$ . Therefore, by the Cauchy-Binet formula,

$$\sigma_M = \sum_{\substack{L \subseteq [m] \\ |L|=k}} \det(U[L]) \cdot \det(V[L, M]). \quad (2)$$

Note now that  $U[L]$  is a Vandermonde matrix of an increasing sequence, hence  $\det(U[L])$  is strictly positive, as witnessed by the well-known formula for the Vandermonde determinant:

$$\det(\text{Vand}_k(r_1, \dots, r_N)) = \prod_{1 \leq i < j \leq N} (r_j - r_i).$$

On the other hand, we observe that  $V[L, M]$  is either a direct sum of submatrices of Vandermonde matrices of positive increasing sequences, or has determinant zero. In the former case,  $\det(V[L, M])$  is the product of the determinants of these submatrices. It is also well-known that Vandermonde matrices of positive, increasing sequences are *totally positive*, that is, *all* their minors, not just maximal minors, are positive. Hence, the determinant of

each submatrix is positive, and so is their product, i.e.,  $\det(V[L, M]) > 0$ . Consequently, since we already argued that  $\det(U[L]) > 0$  holds, we have shown that  $\det(V[L, M]) \cdot \det(U[L]) \geq 0$  holds for all  $L$  in (2), and thus in particular  $\sigma_M \geq 0$ .

Furthermore, if  $M$  contains more than  $\mu_i$  indices that belong to the  $i$ -th block of  $S$ , then  $\sigma_M = 0$ : The  $i$ -th block of  $S$  is defined as  $S_i = U_i V_i$  with  $U_i \in \mathbb{Q}^{k \times \mu_i}$  and  $V_i \in \mathbb{Q}^{\mu_i \times n}$ . Hence,  $S_i$  is of rank at most  $\mu_i$ , and any set of more than  $\mu_i$  columns from  $S_i$  will necessarily be linearly dependent. Conversely, if  $M$  contains  $\rho_i \leq \mu_i$  indices belonging to the  $i$ -th block of  $S$  for each  $i$ , pick arbitrary subset  $L$  of rows of  $V$  containing precisely  $\rho_i$  rows from each  $V_i$ . Then  $V[L, M]$  is a direct sum of square submatrices of Vandermonde matrices of increasing sequences, which makes the corresponding term  $\det(U[L]) \det(V[L, M])$  strictly positive. Since we have just argued that all summands in (2) are non-negative, this proves that in this case,  $\sigma_M > 0$ .

Overall, we have shown that  $\sigma_M \neq 0$  if and only if  $M$  contains no more than  $\mu_i$  indices from the same block of  $S$ , which is equivalent to the corresponding monomial  $y_M$  being well-colored. Another application of Cauchy-Binet then provides us with the sought circuit: Letting  $Y$  be the matrix with diagonal entries  $y_{1,1}, y_{1,2}, \dots, y_{n,q}$ , we observe that

$$\det(S \cdot Y \cdot S^T) = \sum_{M \subseteq [nq], |M|=k} \sigma_M^2 \cdot y_M.$$

By the preceding argument, this polynomial has the desired properties demanded in the statement, and the witnessing skew circuit can be written down in polynomial time, using the known constructions for skew determinant circuits [23]. ◀

► **Remark 2.** The proof of the preceding Lemma can also be seen as constructing an explicit representation of the  $k$ -truncation of the partition matroid corresponding to  $\mu$ .

► **Theorem 3.** *There is a deterministic algorithm that, given an  $n$ -variate homogeneous polynomial  $f$  of degree  $k$  with non-negative coefficients, represented as an arithmetic circuit of size  $s$ , as well as multiplicities  $\mu$ , decides in time  $2^{\omega k} \cdot \text{poly}(n, k, s)$  whether or not  $f$  contains a multilinear monomial that is well-colored with respect to  $\mu$ . Here  $\omega < 2.373$  denotes the exponent of matrix multiplication. This running time can be reduced to  $4^k \cdot \text{poly}(n, k, s)$  if the circuit computing  $f$  is skew.*

**Proof.** We invoke [8, Theorem 25] with  $f$  and  $\chi_\mu$  to compute  $\langle f, \chi_\mu \rangle$ . Since both  $f$  (by assumption) and  $\chi_\mu$  (by Lemma 1) have non-negative coefficients, this inner product is zero if and only if no well-colored multilinear monomial exists in  $f$ , and positive otherwise. The claim on the improved running time follows from [8, Theorem 7] and the fact that  $\chi_\mu$  is a determinant polynomial. ◀

## 4 Graph Problems

This theorem allows us to recover the best known bounds for deterministic detection of maximum graph motifs using an entirely different approach.

► **Corollary 4** ([26]). *There is a deterministic algorithm for MAXIMUM GRAPH MOTIF running in time  $2^{\omega k} \text{poly}(n, k)$ .*

**Proof.** All that is needed is a polynomial representation of the set of all  $k$ -vertex connected subgraphs of the input graph. This is possible due to a construction first employed by Guillemot and Sikora [17] on so-called *branching walks*. Consider the following sequence of polynomials:  $P_{i,0} = 1$  for all  $i$ , and

$$P_{i,s} = x_i \sum_{j \in N_G(i)} \sum_{t_1+t_2=s-1} P_{i,t_1} \cdot P_{j,t_2}.$$

The multilinear monomials in  $\beta_k = \sum_{i \in V} P_{i,k}$  can be shown to correspond bijectively to  $k$ -vertex connected subgraphs, and clearly all coefficients are non-negative. Hence, given a coloring  $\chi : [n] \rightarrow C$ , it suffices to evaluate  $\beta_k$  with  $x_j = y_{c,j}$  for all  $j$  such that  $\chi(j) = c$ , for all colors  $c \in C$ . Invoking Theorem 3 then answers whether or not there is a graph motif as sought. ◀

► **Remark 5.** If one were able to design a skew circuit computing  $\beta_k$ , the running time in the preceding theorem would drop immediately to  $4^k$ . From the perspective of algebraic complexity, it is an interesting problem whether such skew circuits for  $\beta_k$  exist, or whether one can rule out their existence under common complexity-theoretic assumptions. The latter could be accomplished e.g. by a completeness proof of  $\beta_k$  for the algebraic complexity class  $VP$ . However, despite heavy research efforts in the past (see e.g. [12] and references therein), very few natural  $VP$ -complete polynomials are known, and the family  $\beta_k$  is not among them.

One conspicuous property of the polynomial  $\beta_k$  is that its computation is *monotone*, that is, no cancellations can arise during its computation. However, the method described here is able to deal also with such cases where cancellations due to negations occur (but the resulting final coefficients are still non-negative). Indeed, this distinction is subtle but crucial: for instance, the determinant can only be computed without using cancellations by circuits of exponential size [19], whereas it is well-known to admit general arithmetic circuits with cancellations of polynomial size. A large number of polynomials that enumerate combinatorial objects can be expressed as determinants, which makes this situation particularly relevant. Moreover, determinants are the prototypical example for polynomials computable by skew circuits, which allows to use the faster running time mentioned in Theorem 3. For instance, this allows us to solve e.g. the following problems in deterministic time  $O^*(4^k)$ :

► **Theorem 6.** *There are deterministic algorithms running in time  $4^k \cdot \text{poly}(n, k)$  for each of the following problems:*

- *WELL-COLORED SPANNING TREE,*
- *WELL-COLORED PLANAR PERFECT MATCHING, and*
- *INTERNALLY WELL-COLORED SPANNING TREE.*

**Proof.** The algorithms for these three problems all follow the same basic principle and build upon the algorithms for the variants where *well-colored* monomials are replaced by monomials with at least  $k$  distinct colors, which is the special case of having multiplicities  $\mu_i = 1$  for all  $i$ . The core idea is to make use of determinantal generating functions for the sought objects in each case. These generating functions are provided by the directed Matrix-Tree theorem and the Pfaffian of planar graphs. Details on these formulations can be found in [6] and [3]. Once these generating functions are available, all that remains to check is that by a standard trick of substituting  $x_i \mapsto (1 + x_i)$  for every variable, these become generating functions for all subsets of solutions (that is, all subsets of edges of spanning trees, all subsets of perfect matchings, etc.), and the claim follows by applying Theorem 3. ◀

## 5 Intersecting Four Matroids

The general method for intersecting  $q$  matroids shown in [8] exploits a well-known connection to matroid parity, and solves the latter problem instead. Indeed, given  $q$  matroids each of rank  $k$  represented by matrices with entries in  $\mathbb{Q}$ , the algorithm in [8] runs in randomized

## 25:10 Deterministic Constrained Multilinear Detection

time  $O^*(4^{kq})$ . In particular, for the cases  $q = 3, 4$ , this specializes to algorithms running in time  $O^*(64^k)$  and  $O^*(256^k)$ , respectively, and [14] improve this to  $O^*(4^k)$  and  $O^*(16^k)$  (and  $O^*(4^{k(q-2)})$  in general). We will now show how to obtain a running time of  $O^*(4^k)$  in both cases, and examine the conditions under which the algorithms can be made deterministic. First, we define an extension of the apolar inner product to tensor products of polynomial rings, that is, polynomial rings that have themselves as a coefficient rings another ring of polynomials. For instance, consider  $f \in \mathbb{Q}[x_1, \dots, x_n] \otimes \mathbb{Q}[y_1, \dots, y_n] \cong \mathbb{Q}[x_1, \dots, x_n][y_1, \dots, y_n]$ . In general,  $f$  has the form

$$f = \sum_{a_1, \dots, a_n \in \mathbb{N}} \sum_{b_1, \dots, b_n \in \mathbb{N}} c_{a_1, \dots, a_n}^{b_1, \dots, b_n} \cdot x_1^{a_1} \cdots x_n^{a_n} \cdot y_1^{b_1} \cdots y_n^{b_n},$$

with only finitely many of the  $c_{a_1, \dots, a_n}^{b_1, \dots, b_n}$  non-zero. Moreover, for fixed  $a_1, \dots, a_n$ , we can collect all the corresponding terms into a single polynomial  $\hat{c}_{a_1, \dots, a_n} \in \mathbb{Q}[y_1, \dots, y_n]$  via

$$\hat{c}_{a_1, \dots, a_n} = \sum_{b_1, \dots, b_n \in \mathbb{N}} c_{a_1, \dots, a_n}^{b_1, \dots, b_n} \cdot y_1^{b_1} \cdots y_n^{b_n},$$

and then recover the familiar

$$f = \sum_{a_1, \dots, a_n \in \mathbb{N}} \hat{c}_{a_1, \dots, a_n} x_1^{a_1} \cdots x_n^{a_n}.$$

While it is true that

$$\mathbb{Q}[x_1, \dots, x_n][y_1, \dots, y_n] \cong \mathbb{Q}[x_1, \dots, x_n, y_1, \dots, y_n],$$

it is important that we distinguish these two ways of looking at  $f$ . In particular, there is nothing new to say about the inner product on the latter polynomial ring, which is well-defined already through Eq. (1). However, for our purposes, we extend the definition Eq. (1) to  $f, g \in \mathbb{Q}[x_1, \dots, x_n][y_1, \dots, y_n]$ , where  $f$  is as above and  $g = \sum_{a_1, \dots, a_n \in \mathbb{N}} \hat{d}_{a_1, \dots, a_n} x_1^{a_1} \cdots x_n^{a_n}$ , with  $\hat{d}_{a_1, \dots, a_n} \in \mathbb{Q}[y_1, \dots, y_n]$  defined analogously to  $\hat{c}_{a_1, \dots, a_n}$ . Then, we set

$$\alpha(f, g) := \sum_{a_1, \dots, a_n \in \mathbb{N}} a_1! \cdots a_n! \cdot \hat{c}_{a_1, \dots, a_n} \cdot \hat{d}_{a_1, \dots, a_n} \in \mathbb{Q}[y_1, \dots, y_n].$$

Note that such a mapping cannot possibly be an inner product anymore (after all, its codomain is not the field  $\mathbb{Q}$ , but  $\mathbb{Q}[y_1, \dots, y_n]$ ), and thus the need for a separate treatment arises. In particular, the algorithms for computing the apolar inner product from [8] do not extend, at least not within the same running time bound, to the case where  $\langle \cdot, \cdot \rangle$  is replaced by  $\alpha$ . However, we can use their results to obtain the following:

► **Lemma 7.** *Let  $f = \det(M_1)$  and  $g = \det(M_2)$ , where  $M_i$  for  $i = 1, 2$  are matrices of dimension  $k \times k$  having bilinear polynomials in  $x_1, \dots, x_n$  and  $y_1, \dots, y_n$  as entries. Then, there is an algorithm that, given  $\bar{y}_1, \dots, \bar{y}_n \in \mathbb{Q}$ , evaluates the polynomial  $\alpha(f, g) \in \mathbb{Q}[y_1, \dots, y_n]$  at  $\bar{y}_1, \dots, \bar{y}_n$  in  $O^*(4^k)$  arithmetic operations over  $\mathbb{Q}$ . Moreover, if the evaluation points  $\bar{y}_1, \dots, \bar{y}_n$  can be encoded using  $O^*(1)$  bits, then  $\alpha(f, g)$  can be evaluated in time  $O^*(4^k)$ .*

**Proof.** By substituting  $\bar{y}_1, \dots, \bar{y}_n$  into  $M_1$  and  $M_2$  and using the fact that evaluation of polynomials at a fixed point is a homomorphism, we find that  $\langle f(\bar{y}_1, \dots, \bar{y}_n), g(\bar{y}_1, \dots, \bar{y}_n) \rangle = \alpha(f, g)(\bar{y}_1, \dots, \bar{y}_n)$  for all  $\bar{y}_1, \dots, \bar{y}_n$ . Since the determinant is well-known to have skew circuits [23], we are in position to apply [8, Theorem 7] to evaluate  $\langle f(\bar{y}_1, \dots, \bar{y}_n), g(\bar{y}_1, \dots, \bar{y}_n) \rangle$  in the required time bound. ◀

► **Theorem 8.** *Let  $\mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3, \mathcal{M}_4$  be four matroids over a common ground set  $E$  of size  $n$ , each represented by a matrix  $R_i \in \mathbb{Q}^{k \times n}$ . Then, we can decide in randomized time  $O^*(4^k)$  whether these four matroids share a common basis.*

**Proof.** First, let us assume that  $E = [n]$  without loss of generality. We then begin by introducing  $n$  fresh indeterminates  $y_1, \dots, y_n$ . Let then  $Y$  be the diagonal matrix of dimension  $n \times n$  having  $y_i$  in its  $i$ -th diagonal entry. Observe that  $\hat{R}_i := R_i Y$  is the matrix  $R_i$  where the  $i$ -th column was scaled by a factor of  $y_i$ . Moreover, for any set  $S \subset [n]$  of  $k$  column indices, the maximal minor of  $\hat{R}_i$  corresponding to  $S$ , that is, the determinant of the matrix  $\hat{R}_i[S]$  obtained from  $\hat{R}_i$  by restricting to the columns in  $S$ , is a polynomial in  $y_1, \dots, y_n$ . Indeed, since the determinant is a multilinear functional in its columns, we have

$$\det(\hat{R}_i[S]) = \prod_{s \in S} y_s \cdot \det(R_i[S]). \quad (3)$$

In analogy to  $Y$ , let  $X$  be the diagonal matrix having  $x_i$  in its  $i$ -th diagonal entry. Now, the Cauchy-Binet formula gives the following expression for the determinant of the product  $\hat{R}_i \cdot X \cdot R_j^T$ , with a similar reasoning as in Eq. (3):

$$\begin{aligned} \det(\hat{R}_i \cdot X \cdot R_j^T) &= \\ & \sum_{S \subseteq [n], |S|=k} \det(\hat{R}_i[S]) \cdot \det(R_j[S]) \cdot \prod_{s \in S} x_s = \\ & \sum_{S \subseteq [n], |S|=k} \left( \prod_{s \in S} y_s \cdot \det(R_i[S]) \cdot \det(R_j[S]) \right) \cdot \prod_{s \in S} x_s. \end{aligned}$$

In the last line, we grouped the products in order to highlight that we consider this expression foremost as a polynomial in the variables  $x_i$ , that is, an element of  $\mathbb{Q}[y_1, \dots, y_n][x_1, \dots, x_n]$ . Of course, the analogous expression holds for  $\det(R_i \cdot X \cdot R_j^T)$  (note the missing hat on  $R_i$ ), namely

$$\det(R_i \cdot X \cdot R_j^T) = \sum_{S \subseteq [n], |S|=k} \det(R_i[S]) \cdot \det(R_j[S]) \cdot \prod_{s \in S} x_s,$$

which is a polynomial from  $\mathbb{Q}[x_1, \dots, x_n] \subset \mathbb{Q}[y_1, \dots, y_n][x_1, \dots, x_n]$ .

Since by assumption,  $\det(R_i[S]) \neq 0$  if and only if  $S$  is a basis of  $\mathcal{M}_i$ , it follows from the definition of  $\alpha(\cdot, \cdot)$  (and noting that all the  $x_i$  have exponent zero or one) that

$$\alpha(\det(\hat{R}_1 \cdot X \cdot R_2^T), \det(R_3 \cdot X \cdot R_4^T)) = \quad (4)$$

$$\sum_{S \subseteq [n], |S|=k} (\det(R_1[S]) \cdot \det(R_2[S])) \cdot \left( \prod_{s \in S} y_s \cdot \det(R_3[S]) \cdot \det(R_4[S]) \right) = \quad (5)$$

$$\sum_{\substack{S \text{ basis of} \\ \mathcal{M}_1, \dots, \mathcal{M}_4}} \underbrace{\det(R_1[S] R_2[S] R_3[S] R_4[S])}_{\neq 0} \cdot \prod_{s \in S} y_s. \quad (6)$$

As witnessed in the last line of the preceding calculation,  $\alpha(\det(\hat{R}_1 \cdot X \cdot R_2^T), \det(R_3 \cdot X \cdot R_4^T))$  is the zero polynomial if and only if the four input matroids share no common basis. Therefore, all that remains is to test the polynomial  $\alpha(\det(\hat{R}_1 \cdot X \cdot R_2^T), \det(R_3 \cdot X \cdot R_4^T))$  for zero, using the DeMillo–Lipton–Schwartz–Zippel Lemma [10, 30, 28] in combination with Lemma 7, we obtain the desired randomized algorithm: Choosing random evaluation points, we can ensure that  $\alpha(\det(\hat{R}_1 \cdot X \cdot R_2^T), \det(R_3 \cdot X \cdot R_4^T))$  evaluates to a non-zero value, in case

it truly is non-zero, with constant probability. Of course, if the polynomial is identically zero, so is every evaluation, and the algorithm will always correctly recognize this. As usual, repeating this procedure a polynomial number of times allows us to decrease the one-sided error probability exponentially. ◀

► **Corollary 9.** *Given three matroids  $\mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3$  as in Theorem 8, we can decide in randomized time  $O^*(4^k)$  whether they share a common basis.*

**Proof.** This follows from choosing  $\mathcal{M}_1 = \mathcal{M}_2$  in Theorem 8. ◀

► **Remark 1.** During the preparation of the present article, a manuscript by Eiben, Koana and Wahlström [14] appeared, where they give a different algebraic approach to some of the matroid problems considered here. In particular, their Theorem 4.6 coincides with Corollary 9, and they show how to use this as a base case to obtain an algorithm for intersecting  $q$  rank- $k$  matroids, running in time  $4^{k(q-2)} \cdot \text{poly}(n)$ . It would be interesting to see if our Theorem 8 can be expedited in a similar manner to obtain a running time of  $4^{k(q-3)} \cdot \text{poly}(n)$ . Their techniques are based on exterior algebra, which is related to the methods used in this article through a general algebraic connection [7].

## 5.1 Intersecting Positroids

Using the same strategy as for general matroids, we obtain deterministic algorithms for the following important class of matroids:

► **Definition 10.** Let  $k \leq n$ , and let  $\mathcal{M}$  be a matroid over a ground set of size  $n$  of rank  $k$ . Suppose  $\mathcal{M}$  is represented by a matrix  $M$  such that for each submatrix  $M[S]$  with  $S \subset [n]$  and  $|S| = k$  it holds that the corresponding maximal minor satisfies  $\det(M[S]) \geq 0$ . In this case,  $\mathcal{M}$  is called a *positroid*.

It is worth pointing out that while these objects seem not to have made any significant algorithmic appearances so far, they are of great importance in geometry, where they correspond to the so-called *totally non-negative Grassmannian*. They have many desirable properties that general matroids are lacking, most notably a beautiful combinatorial correspondence with certain planar bicolored (or *plabic*) graphs. We refer the reader to Postnikov’s groundbreaking work on the subject [27].<sup>1</sup>

Let us furthermore remark that the following results will only apply to the situation where the input matroids are *promised* to be positroids, since there doesn’t seem to be a way to decide efficiently whether a given matroid representation does indeed only have non-negative minors. While the aforementioned correspondence with plabic graphs does in principle allow for a full-fledged decision problem (by taking as an input not the matrix of the positroid, but its corresponding plabic graph, and then computing a representation from this graph), this is beyond the scope of the present article.

► **Theorem 11.** *Let  $\mathcal{M}_1, \mathcal{M}_2, \mathcal{M}_3, \mathcal{M}_4$  be four positroids over a common ground set  $E$  of size  $n$ , each represented by a matrix  $R_i \in \mathbb{Q}^{k \times n}$  with non-negative minors. Then, we can decide in deterministic time  $O^*(4^k)$  whether these four matroids share a common basis.*

**Proof.** The proof relies on the fact that all determinants in Eq. (6) are not only non-zero, but in fact positive. Therefore, it is not necessary to include the variables  $y_i$  in the calculation, and a direct application of [8, Theorem 7] to  $(\det(R_1 \cdot X \cdot R_2^T), \det(R_3 \cdot X \cdot R_4^T))$  is already enough. The resulting value is non-zero if and only if the four positroids share a common basis, and the running time bound follows directly from [8]. ◀

## Abstract

We study a natural problem about rational behaviors in multiplayer non-zero-sum sequential infinite duration games played on graphs: rational verification, that consists in deciding whether all the rational answers to a given strategy satisfy some specification. We give the complexities of that problem for two major concepts of rationality: Nash equilibria and subgame-perfect equilibria, and for three major classes of payoff functions: energy, discounted-sum, and mean-payoff.

**2012 ACM Subject Classification** Software and its engineering → Formal methods; Theory of computation → Logic and verification; Theory of computation → Solution concepts in game theory

**Keywords and phrases** Games on graphs, Nash equilibria, subgame-perfect equilibria

## 1 Introduction

Formal methods are essential to guarantee the correctness of safety critical computer systems. Techniques like model-checking [13] or automated theorem proving [15] are now routinely used to develop systematically hardware pieces as well as embedded control systems. Nevertheless, there are contexts in which formal methods have not yet been applied successfully large-scale: that is the case of multi-agent systems, which still represent a challenge for formal verification techniques, because they are usually composed of *heterogeneous* components, ranging from traditional pieces of reactive code to wholly autonomous robots or human users. Producing operational model abstractions for this diversity of sub-systems is often challenging.

While it may be inconvenient, to say the least, to produce an operational model of the behavior of a human or a complex autonomous robot, identifying the high level objectives of those components may be easier. Taking into account those objectives is often key for reasoning about the correctness of a system that interacts with those components. Indeed, a system is usually not supposed to be correct in all circumstances, but only when agents in its environment behave in a way that concurs with their own objectives. In *rational verification* (RV), a system needs to enforce some property, not in all possible executions, but only in those in which the environment agents behave rationally with regards to their own objectives.

Rationality is the focus point of game theory, and can be formalized in several ways: for instance, with the notion of *Nash equilibrium* (NE) [24]. NEs have been used in a few promising contributions, like in verification of non-repudiation and fair exchange protocols [12, 20, 21], or planning of self-driving cars interacting with human drivers [26], etc. Nevertheless, those works do not propose a general framework for RV and their contributions are rather specific to their application domains. There is thus a need for more systematic study of formal frameworks for RV. Such a study has been started recently: for instance, the authors of [18]

study the automatic verification of an LTL specification in multi-agent systems that behave according to an NE, and in [11], the authors study a setting in which the environment has multiple objectives and only produces behaviors that are Pareto-optimal with regards to them. This work contributes to that line of research by considering a notion of rationality formalized by *subgame-perfect equilibria* (SPEs), a refinement of NEs that is better suited to formalize rationality in sequential games, in which NEs suffer from non-credible threats [25].

More precisely, we consider here the *rational verification problem*, which takes as inputs: (i) a multiplayer game graph with a designated player called *Leader*, (ii) a finite state description of a (potentially infinite) set of strategies for Leader, (iii) a description of the objective for Leader, and (iv) a description of the objectives of all the other players. It asks whether for all possible fixed strategies  $\sigma_L$  of Leader (defined by the finite state description), for all possible rational responses of the other agents, the generated outcome satisfies Leader's objective. That problem is well-suited to formalize the verification of correctness of a controller interacting with an environment composed of rational agents.

**Contributions.** To solve the RV problems, we provide a general construction, called the *product game* (Definition 5): we show that, given a game and a finite-state description of a set of Leader's strategies, one can incorporate the memory states of that finite-state description in the arena of the game in a way that Leader is implicitly forced to follow some strategy in the set. Thus, we show that the RV problem reduces in polynomial time to the *universal threshold problem*, a problem that is easier to study algorithmically: given a game, does every equilibrium satisfy a given specification? Also, some game classes we analyze have been addressed with slightly different definitions in previous literature. Interestingly, we provide a reduction in the opposite direction as well (Cor. 6).

We use that tool to prove the undecidability of RV in energy games (Th. 9 and 10); in the case of subgame-perfect RV, we show that undecidability holds even when Leader plays against only two players. We show that Nash RV is co-recursively enumerable in those games, and leave that question open for subgame-perfect RV – but contrary to the Nash setting, SPEs may require infinite memory to reach some payoffs (Prop. 11). In discounted-sum (DS) games, we show that the RV problems are at least as hard as the *target discounted-sum problem* (Th. 13), whose decidability is an open question. However, we prove that those problems are recursively enumerable (Th. 14). In the case of mean-payoff (MP) games, Cor. 8, combined with older results, entails that the RV problems are coNP-complete. But that case highlights a subtlety in the definition of RV: if one wants to check that a strategy is such that *every* rational response satisfies the specification, then when no such response exists, the strategy will be accepted. In the case of MP games, that leads to results that can be considered as counter-intuitive. We thus propose a stronger definition of the RV problem, called *chaotic RV*, to avoid that weakness: it consists in deciding whether a strategy satisfies the specification against every response that is *as rational as it can be*, using the notions of  $\varepsilon$ -NE and  $\varepsilon$ -SPE, that are quantitative relaxations of NE and SPE. We show that such a problem is  $\text{P}^{\text{NP}}$ -complete in MP games (Th. 19), and that in every other setting (Nash or subgame-perfect RV in the two other game classes), it coincides with RV, since rational responses always exist (Prop. 17). A synopsis of those results can be found in Table 1.

**Related works.** During the last decade, multiplayer games and their applications to reactive synthesis have raised a growing attention: the reader may refer to [3, 9, 10, 16, 22], and their references. The concept of *rational verification* appears in [19], where Gutierrez, Najib, Perelli, and Wooldridge give the complexity of several related problems. They use a definition

■ **Table 1** Synopsis of our results.

	Nash RV	Ach. Nash RV	SP RV	Ach. SP RV
Energy	undecidable, co-RE		undecidable	
DS	TDS-hard, RE		TDS-hard, RE	
MP	coNP-complete		coNP-complete	P <sup>NP</sup> -complete

that is slightly different from ours: their problem consists in deciding, given a game and a specification, whether all NEs (or one of them) in that game satisfy the specification, without any player representing the system (Leader in our setting). Still, as we show with Cor. 8, that problem is strongly related to ours. In [27], they also study if  $\omega$ -regular properties are enforced by NEs induced by mean-payoff objectives. The objectives considered in those papers are only  $\omega$ -regular objectives. Moreover, both in [19] and in [27] only NEs are considered, while our main contributions are about SPEs, that are arguably better suited for reasoning about sequential games [25], but also require substantially more complex techniques. In [14], Filiot, Gentilini, and Raskin study *Stackelberg values* of mean-payoff and discounted-sum two-player non-zero sum games, i.e. the payoff that Leader gets when the other player, *Follower*, plays the *best response* that is available with regards to his own objective. This is a synthesis problem while we consider a verification problem. They consider only one player in the environment while we consider the more general case of  $n$  players.

In [28], and later in [29], Ummels studies SPEs in parity games. He proves that they always exist, and that deciding whether there exists an SPE in a given parity game that generates a payoff vector between two given thresholds (the *constrained existence problem*, very close to the *universal threshold problem* studied in this paper) is EXPTIME-easy and NP-hard. In [8], Brihaye, Bruyère, Goeminne, Raskin, and van den Bogaard, study the same problem in quantitative reachability games, and prove that it is PSPACE-complete.

In [17], Flesch and Predtetchinski give a general procedure to characterize SPEs. In [4], Brice, Raskin, and van den Bogaard introduce the *negotiation function*, a tool that turns Flesch and Predtetchinski's procedure into effective algorithms for a large class of games. In [6], they use it to close the gap left by Ummels, proving that the constrained existence problem is NP-complete in parity games, with methods that they use later in [5] to prove that the same problem is also NP-complete in mean-payoff games. An alternative procedure to solve such SPE problems is proposed in [23], where Meunier constructs a two-player zero-sum game in which one player has a winning strategy if and only if there exists an SPE satisfying the desired constraint in the input game. That technique is nevertheless often costly, because the size of the constructed game is proportional to the number of possible payoff vectors; and for the same reason, it cannot be applied to games with infinite payoff spaces.

Energy objectives have also been widely studied, in connection with the study of vector additions systems with states and Petri nets, but almost always in a two-player zero-sum setting: see for instance [2, 22, 30]. As for discounted-sum objectives, they are defined for instance by Zwick and Paterson in [31], again in a two-player zero-sum setting. They are strongly related to the target discounted-sum problem, which is a long-standing open problem, as shown in [1] by Boker, Henzinger, and Otop. To the best of our knowledge, no algorithmic results are known for those classes of objectives in a multiplayer non-zero sum setting.

**Structure of the paper.** In Sec. 2, we introduce the necessary background. In Sec. 3, we present the product game. In Sec. 4, we exploit it to study energy games; in Sec. 5, DS games; and in Sec. 6, MP games. The complete proofs of our results, and additional results, are given in the complete version of this paper [7].

## 2 Background

**Graphs, games and strategies.** We call *graph* a finite directed graph, i.e. a pair  $(V, E)$  where  $V$  is a finite set of *vertices* and  $E \subseteq V \times V$  is a set of *edges*. The edge  $(u, v)$ , written  $uv$ , is an *outgoing edge* of  $u$ . A *path* in  $(V, E)$  is a finite or infinite sequence  $\alpha = \alpha_0\alpha_1 \cdots \in V^* \cup V^\omega$  such that for every index  $k$ , we have  $\alpha_k\alpha_{k+1} \in E$ . We write  $\text{Occ}(\alpha)$  (resp.  $\text{Inf}(\alpha)$ ) for the set of vertices that occur (resp. that occur infinitely often) in  $\alpha$ . For a given index  $k$ , we write  $\alpha_{\leq k} = \alpha_{<k+1} = \alpha_0 \dots \alpha_k$ , and  $\alpha_{\geq k} = \alpha_{>k-1} = \alpha_k\alpha_{k+1} \dots$ . A *cycle* is a finite path  $c = c_0 \dots c_n$  with  $c_n c_0 \in E$ . A finite path  $\alpha$  is *simple* if for every two indices  $k \neq \ell$ , we have  $\alpha_k \neq \alpha_\ell$ .

We call *non-initialized game* a tuple  $\mathcal{G} = (\Pi, V, (V_i)_{i \in \Pi}, E, \mu)$ , where:

- $\Pi$  is a finite set of *players*;
- $(V, E)$  is a graph, in which every vertex has at least one outgoing edge;
- $(V_i)_{i \in \Pi}$  is a partition of  $V$ , in which  $V_i$  is the set of vertices *controlled* by player  $i$ ;
- a *play* (resp. *history*) in the game  $\mathcal{G}$  is an infinite (resp. finite) path in the graph  $(V, E)$ , and the set of plays (resp. histories) in  $\mathcal{G}$  is denoted by  $\text{Plays}\mathcal{G}$  (resp.  $\text{Hist}\mathcal{G}$ );
- the *payoff function*  $\mu : \text{Plays}\mathcal{G} \rightarrow \mathbb{R}^\Pi$  maps each play  $\pi$  to the tuple  $\mu(\pi) = (\mu_i(\pi))_{i \in \Pi}$ .

Given a set of players  $P \subseteq \Pi$ , we often write  $V_P = \bigcup_{i \in P} V_i$ . When  $i$  is a player and when the context is clear, we write  $-i$  for the set  $\Pi \setminus \{i\}$ . We often assume that a special player, called *Leader* and denoted by the symbol  $\mathbb{L}$ , belongs to the set  $\Pi$ . An *initialized game* is a pair  $(\mathcal{G}, v_0)$ , often written  $\mathcal{G}_{\uparrow v_0}$ , where  $\mathcal{G}$  is a non-initialized game and  $v_0 \in V$  is a vertex called *initial vertex*. When the context is clear, we use the word *game* for both initialized and non-initialized games. A play (resp. history) in the initialized game  $\mathcal{G}_{\uparrow v_0}$  is a play (resp. history) that has  $v_0$  as first vertex. The set of plays (resp. histories) in  $\mathcal{G}_{\uparrow v_0}$  is denoted by  $\text{Plays}\mathcal{G}_{\uparrow v_0}$  (resp.  $\text{Hist}\mathcal{G}_{\uparrow v_0}$ ). We also write  $\text{Hist}_i\mathcal{G}$  (resp.  $\text{Hist}_i\mathcal{G}_{\uparrow v_0}$ ) for the set of histories in  $\mathcal{G}$  (resp.  $\mathcal{G}_{\uparrow v_0}$ ) whose last vertex is controlled by player  $i$ .

A *strategy* for player  $i$  in the initialized game  $\mathcal{G}_{\uparrow v_0}$  is a mapping  $\sigma_i : \text{Hist}_i\mathcal{G}_{\uparrow v_0} \rightarrow V$ , such that  $v\sigma_i(hv)$  is an edge of  $(V, E)$  for every  $hv$ . A history  $h$  is *compatible* with a strategy  $\sigma_i$  if and only if  $h_{k+1} = \sigma_i(h_0 \dots h_k)$  for all  $k$  such that  $h_k \in V_i$ . This definition naturally extends to plays. A *strategy profile* for  $P \subseteq \Pi$  is a tuple  $\bar{\sigma}_P = (\sigma_i)_{i \in P}$ , where each  $\sigma_i$  is a strategy for player  $i$  in  $\mathcal{G}_{\uparrow v_0}$ . A play, or a history, is *compatible* with  $\bar{\sigma}_P$  if it is compatible with every  $\sigma_i$  for  $i \in P$ . Since the  $\sigma_i$ 's domains are pairwise disjoint, we sometimes consider  $\bar{\sigma}_P$  as one function: for  $hv \in \text{Hist}\mathcal{G}_{\uparrow v_0}$  such that  $v \in \bigcup_{i \in P} V_i$ , we liberally write  $\bar{\sigma}_P(hv)$  for  $\sigma_i(hv)$  with  $i$  such that  $v \in V_i$ . A *complete strategy profile*, usually written  $\bar{\sigma}$ , is a strategy profile for  $\Pi$ . Exactly one play is compatible with the strategy profile  $\bar{\sigma}$ : we call it its *outcome* and write  $\langle \bar{\sigma} \rangle$  for it. When  $\bar{\tau}_P$  and  $\bar{\tau}'_Q$  are two strategy profiles with  $P \cap Q = \emptyset$ , we write  $(\bar{\tau}_P, \bar{\tau}'_Q)$  for the strategy profile  $\bar{\sigma}_{P \cup Q}$  such that  $\sigma_i = \tau_i$  for  $i \in P$ , and  $\sigma_i = \tau'_i$  for  $i \in Q$ .

**Notable classes of games.** Here, we will focus on three game classes. In those classes, each player  $i$ 's payoff is based on a *reward mapping*  $r_i : E \rightarrow \mathbb{Q}$ . Intuitively, the reward mapping gives the (positive or negative) reward that player  $i$  gets for each action. The first class, energy games, is a class of *Boolean games*, i.e. games in which all payoffs are equal either to 0 or to 1. For such games, we say that player  $i$  *loses* the play  $\pi$  when  $\mu_i(\pi) = 0$ , and *wins* it when  $\mu_i(\pi) = 1$ . The other games are called *quantitative*. In energy games, the players seek to keep the aggregated sum of those rewards, their *energy level*, always nonnegative. That quantity symbolizes any resource that an agent could have to store: fuel, money, ...

■ **Figure 1** An example of mean-payoff game.

► **Definition 1** (Energy). *In a graph  $(V, E)$ , we associate to each reward mapping  $r$  the energy level function  $\text{EL}_r : \text{Hist}\mathcal{G} \rightarrow \mathbb{N} \cup \{\perp\}$  defined by:*

- $\text{EL}_r(h_0) = 0$ ;
- $\text{EL}_r(h_{\leq n+1}) = \text{EL}_r(h_{\leq n}) + r(h_n h_{n+1})$  if  $\text{EL}_r(h_{\leq n}) \neq \perp$ , and  $\text{EL}_r(h_{\leq n}) + r(h_n h_{n+1}) \geq 0$ ;
- $\text{EL}_r(h_{\leq n+1}) = \perp$  otherwise.

*The game  $\mathcal{G}$  is an energy game if there exists a tuple  $(r_i)_{i \in \Pi}$  of reward mappings such that for each  $i$  and every  $\pi$ , we have  $\mu_i(\pi) = 0$  if  $\text{EL}_{r_i}(\pi_{\leq n}) = \perp$  for some  $n$ , and  $\mu_i(\pi) = 1$  otherwise. When the context is clear, we write  $\text{EL}_i$  for  $\text{EL}_{r_i}$ .*

In discounted-sum games, each player's payoff is obtained by summing the rewards that the player obtains with some discount factor applied as the play goes along.

► **Definition 2** (Discounted-sum). *In a graph  $(V, E)$ , we define for each reward mapping  $r$  and each discount factor  $\lambda \in (0, 1)$  the discounted sum function  $\text{DS}_r^\lambda : h \mapsto \sum_k \lambda^k r(h_k h_{k+1})$ . Then, we write  $\text{DS}_r^\lambda(\pi) = \lim_n \text{DS}_r^\lambda(\pi_{\leq n})$ . The game  $\mathcal{G}$  is a discounted-sum game (or DS game for short) if there exists a discount factor  $\lambda \in (0, 1) \cap \mathbb{Q}$  and a tuple  $(r_i)_{i \in \Pi}$  of reward mappings such that for each  $i$  and every  $\pi$ , we have  $\mu_i(\pi) = \text{DS}_{r_i}^\lambda(\pi)$ . When the context is clear, we write  $\text{DS}_i$  for  $\text{DS}_{r_i}^\lambda$ .*

In mean-payoff games, a players' payoff is equal to their asymptotic average reward.

► **Definition 3** (Mean-payoff). *In a graph  $(V, E)$ , we define for each reward mapping  $r$  the mean-payoff function  $\text{MP}_r : h_0 \dots h_n \mapsto \frac{1}{n} \sum_k r(h_k h_{k+1})$ . Then, we write  $\underline{\text{MP}}_r(\pi) = \liminf_n \text{MP}_r(\pi_{\leq n})$ . The game  $\mathcal{G}$  is a mean-payoff game (or MP game for short) if there exists a tuple  $(r_i)_{i \in \Pi}$  of reward mappings, such that for each player  $i$ , we have  $\mu_i = \underline{\text{MP}}_{r_i}$ . When the context is clear, we write  $\text{MP}_i$  for  $\text{MP}_{r_i}$ , and  $\underline{\text{MP}}_i$  for  $\underline{\text{MP}}_{r_i}$ .*

Every game  $\mathcal{G}$  from one of those three classes can be encoded with a finite number of bits. We write  $\|\mathcal{G}\|$  for that number.

An example of MP game is given in Figure 1, with two players: player  $\circ$ , who controls the vertices  $a$  and  $c$ , and player  $\square$ , who controls the vertex  $b$ . The initial vertex is  $v_0 = a$ . We wrote above each edge the rewards that both players get when that edge is taken. Three types of plays are possible in that game: the one that loops on the vertex  $a$  gives both players the payoff 0; the ones that loop on the vertex  $b$  give both players the payoff 1; and the ones that loop on the vertex  $c$  give both players the payoff 0.

**Equilibria and rational responses.** In this paper, we study rational behaviors of players: we have, therefore, to define our rationality concepts. Let us start with the most classical one: *Nash equilibrium*. The strategy profile  $\bar{\sigma}$  is a *Nash equilibrium* (resp.  $\mathbb{L}$ -fixed Nash equilibrium) – or  $\mathbb{L}$ -fixed NE for short – in  $\mathcal{G}_{\uparrow v_0}$  if for each player  $i$  (resp. each player  $i \neq \mathbb{L}$ ) and every strategy  $\sigma'_i$ , called *deviation of  $\sigma_i$* , we have  $\mu_i(\langle \sigma'_i, \bar{\sigma}_{-i} \rangle) \leq \mu_i(\langle \bar{\sigma} \rangle)$ . When it is not the case, we call *profitable deviations* the deviations that do not satisfy that inequality.

As an example, in the game given in Figure 1, two types of NEs can be found: those that eventually loop on the vertex  $b$ , and give both players the payoff 1; and those that loop on  $a$ , but in which player  $\circ$  has no profitable deviation, because if she goes to the vertex  $b$ , player

□ threatens to go to the vertex  $c$  (and player □ has no profitable deviation, because he does never make any choice). However, player □'s threat is not *credible*, since going to the vertex  $c$  would give him the payoff 0, while he could stay on the vertex  $b$  and get the payoff 1. A stronger rationality concept, that avoids that phenomenon, is the one of *subgame-perfection*.

Let  $hv$  be a history in the game  $\mathcal{G}$ . The *subgame* of  $\mathcal{G}$  after  $hv$  is the game  $\mathcal{G}_{\uparrow hv} = (\Pi, V, (V_i)_i, E, \mu_{\uparrow hv})_{\uparrow v}$ , where  $\mu_{\uparrow hv}$  maps each play  $\pi$  to its payoff in  $\mathcal{G}$ , assuming that the history  $hv$  has already been played, i.e. to the payoff  $\mu_{\uparrow hv}(\pi) = \mu(h\pi)$ . If  $\sigma_i$  is a strategy in  $\mathcal{G}_{\uparrow v_0}$ , its *substrategy* after  $hv$  is the strategy  $\sigma_{i\uparrow hv} : h' \mapsto \sigma_i(hh')$  in the game  $\mathcal{G}_{\uparrow hv}$ .

The strategy profile  $\bar{\sigma}$  is a ( $\mathbb{L}$ -fixed) *subgame-perfect equilibrium* – or ( $\mathbb{L}$ -fixed) *SPE* for short – in  $\mathcal{G}_{\uparrow v_0}$  if and only if for every history  $h$  in  $\mathcal{G}_{\uparrow v_0}$  (resp. every history  $h$  compatible with  $\sigma_{\mathbb{L}}$ ), the strategy profile  $\bar{\sigma}_{\uparrow h}$  is a ( $\mathbb{L}$ -fixed) Nash equilibrium in the subgame  $\mathcal{G}_{\uparrow h}$ .

NEs and SPEs entail two notions of rationality for the environment's responses to a strategy  $\sigma_{\mathbb{L}}$  of Leader. A strategy profile  $\bar{\sigma}_{-\mathbb{L}}$  is a *Nash response* to  $\sigma_{\mathbb{L}}$  if the strategy profile  $\bar{\sigma} = (\sigma_{\mathbb{L}}, \bar{\sigma}_{-\mathbb{L}})$  is an  $\mathbb{L}$ -fixed NE, and a *subgame-perfect response* if it is an  $\mathbb{L}$ -fixed SPE. The set of Nash (resp. subgame-perfect) responses to  $\sigma_{\mathbb{L}}$  is written  $\text{NR}(\sigma_{\mathbb{L}})$  (resp.  $\text{SPR}(\sigma_{\mathbb{L}})$ ).

Finally, let  $\rho \in \{\text{Nash, subgame-perfect}\}$ . We call  $\rho$ -*equilibria* the NEs if  $\rho = \text{Nash}$ , and the SPEs if  $\rho = \text{subgame-perfect}$ . We will similarly talk about  $\mathbb{L}$ -fixed  $\rho$ -*equilibria*, and  $\rho$ -*responses*. We write  $\rho\text{R}(\sigma_{\mathbb{L}})$  for the set of  $\rho$ -responses to a strategy  $\sigma_{\mathbb{L}}$ .

**Mealy machines.** A *Mealy machine* for player  $i$  on a game  $\mathcal{G}$  is a tuple  $\mathcal{M} = (Q, q_0, \Delta)$ , where  $Q$  is a finite set of *states*, where  $q_0 \in Q$  is the *initial state*, and where  $\Delta \subseteq (Q \times V_{-i} \times Q) \cup (Q \times V_i \times Q \times V)$  is a finite set of *transitions*, such that for every  $(p, u, q, v) \in \Delta$ , we have  $uv \in E$ , and such that for every  $p \in Q$  and  $u \in V$ , there exists a transition  $(p, u, q)$  or  $(p, u, q, v) \in \Delta$ . Specialist readers will have noted that this definition is more general than the classical one, in which it is often assumed that for each  $p$  and  $u$ , there exists exactly one such transition: hereafter, such a machine will be called *deterministic*. Results about deterministic Mealy machines can be applied to *programs*, which are supposed to run deterministically; we chose to take a more general definition to capture also *protocols*, which may be given to an agent who would still have some room for manoeuvre in how they apply it.

A strategy  $\sigma_i$  in  $\mathcal{G}_{\uparrow v_0}$  is *compatible* with  $\mathcal{M}$  if there exists a mapping  $h \mapsto q_h$  that maps every history  $h$  in  $\mathcal{G}_{\uparrow v_0}$  to a state  $q_h \in Q$ , such that for every  $hv \in \text{Hist}_{-i}\mathcal{G}_{\uparrow v_0}$ , we have  $(q_h, v, q_{hv}) \in \Delta$ , and for every  $hv \in \text{Hist}_i\mathcal{G}_{\uparrow v_0}$ , we have  $(q_h, v, q_{hv}, \sigma_i(hv)) \in \Delta$ . The set of strategies in  $\mathcal{G}_{\uparrow v_0}$  compatible with  $\mathcal{M}$  is written  $\text{Comp}_{\uparrow v_0}(\mathcal{M})$ . If  $\mathcal{M}$  is deterministic, then there is exactly one strategy compatible with  $\mathcal{M}$ ; we call it a *finite-memory* strategy.

Note that one can define analogously Mealy machines that capture a set of strategy profiles for several players, and even for the whole set  $\Pi$ . Note also that every Mealy machine  $\mathcal{M}$  can be encoded with a finite number of bits: we write  $\|\mathcal{M}\|$  for that number.

Figure 2 depicts a Mealy machine on the game of Figure 1. Each arrow from a state  $p$  to a state  $q$  labeled  $u|v$  denotes the existence of a transition  $(p, u, q, v)$  (from the state  $p$ , the machine reads the vertex  $u$ , switches to the state  $q$  and outputs the vertex  $v$ ). Each arrow from a state  $p$  to a state  $q$  labeled  $u$  denotes the existence of a transition  $(p, u, q)$  (from  $p$ , the machine reads  $u$ , switches to  $q$  and outputs nothing). It is a machine for player □, that is not deterministic: from the state  $q_0$ , reading the vertex  $b$ , the machine stays in  $q_0$  but it can output either  $b$  or  $c$ . The strategies that are compatible with it can be described as follows: when player □ has to play, if the vertex  $a$  was seen an odd number of times, then he stays in  $b$ ; in the opposite case, he can either stay in  $b$  or eventually go to  $c$ .

■ **Figure 2** A non-deterministic one-player Mealy machine.

■ **Figure 3** A product game.

**Decision problem.** Let us now define rational verification (RV). We define it for each game class  $\mathcal{C}$ , for each  $\rho \in \{\text{Nash, subgame-perfect}\}$ , and in both the deterministic and the non-deterministic setting.

► **Problem 4** ((Deterministic)  $\rho$ -rational verification problem in the class  $\mathcal{C}$ ). *Given a game  $\mathcal{G}_{\uparrow v_0} \in \mathcal{C}$ , a threshold  $t \in \mathbb{Q}$  and a (deterministic) Mealy machine  $\mathcal{M}$  on  $\mathcal{G}$ , is every  $\mathbb{L}$ -fixed  $\rho$ -equilibrium  $\bar{\sigma}$  with  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$  such that  $\mu_{\mathbb{L}}(\langle \bar{\sigma} \rangle) > t$ ?*

### 3 The product game

Although very intuitive, the RV problems are quite hard to study as they are. Indeed, their instances include two graph structures: a game and a Mealy machine. However, responding rationally to Leader's strategies that are compatible with  $\mathcal{M}$  amounts to play rationally in a larger game, in which the machine  $\mathcal{M}$  has been incorporated.

► **Definition 5** (Product game). *Let  $\mathcal{G}_{\uparrow v_0}$  be a game, and let  $\mathcal{M}$  be a Mealy machine for Leader in  $\mathcal{G}$ . Their product game is the game  $\mathcal{G}_{\uparrow v_0} \otimes \mathcal{M} = (\Pi \cup \{\mathbb{D}\}, V', (V'_i)_i, E', \mu')_{\uparrow (v_0, q_0)}$  where the player  $\mathbb{D}$ , called Demon, chooses how the machine  $\mathcal{M}$  will run. Formally:*

- $V' = (V \times Q) \cup (V \times Q \times Q)$ ;
- $V'_{\mathbb{L}} = \emptyset$ ,  $V'_i = V_i \times Q \times Q$  for every  $i \in \Pi \setminus \{\mathbb{L}\}$ , and  $V'_{\mathbb{D}} = (V \times Q) \cup (V_{\mathbb{L}} \times Q \times Q)$ ;
- the set  $E'$  contains:
  - the edge  $(u, p)(u, p, q)$  for each  $(p, u, q) \in \Delta$  (if  $u \notin V_{\mathbb{L}}$ ), or  $(p, u, q, v) \in \Delta$  (if  $u \in V_{\mathbb{L}}$ );
  - the edge  $(u, p, q)(v, q)$  for each  $(p, u, q, v) \in \Delta$  (if  $u \in V_{\mathbb{L}}$ );
  - the edge  $(u, p, q)(v, q)$  for each  $(p, u, q) \in \Delta$ , and each  $uv \in E$  (if  $u \notin V_{\mathbb{L}}$ );
- each payoff function  $\mu'_i$  maps every play  $(\pi_0, q_0)(\pi_0, q_0, q_1)(\pi_1, q_1) \dots$  to the payoff  $\mu_i(\pi_0 \pi_1 \dots)$  if  $i \neq \mathbb{D}$ , and to the payoff 0 if  $i = \mathbb{D}$ .

Figure 3 depicts the game  $\mathcal{G}_{\uparrow v_0} \otimes \mathcal{M}$ , when  $\mathcal{G}_{\uparrow v_0}$  is the game of Figure 1 and  $\mathcal{M}$  the machine of Figure 2. Leader is then assimilated to player  $\square$ , and Demon's vertices are represented by dotted boxes. The unreachable vertices have been omitted, and we have given only the non-zero rewards. Since, from the vertex  $(a, q_0, q_1)$ , player  $\circ$  has always the possibility to go to the vertex  $(b, q_1)$  and to get the payoff 1, it can be shown that every NE and every SPE in that game gives player  $\square$  the payoff 1. As we will see now, that means that the strategies compatible with the machine  $\mathcal{M}$  guarantee the payoff 1 to player  $\square$  against Nash-rational or subgame-perfect rational responses, i.e. that  $\mathcal{G}_{\uparrow v_0}, 1 - \varepsilon$ , and  $\mathcal{M}$ , for every  $\varepsilon > 0$ , form a positive instance of the Nash and subgame-perfect RV problems.

► **Theorem 6.** *Let  $\rho \in \{\text{Nash, subgame-perfect}\}$ . Let  $\mathcal{G}_{\uparrow v_0}$  be a game, let  $\mathcal{M}$  be a Mealy machine for Leader in  $\mathcal{G}$ , and let  $t \in \mathbb{Q}$ . Then, every  $\rho$ -response  $\bar{\sigma}_{-\mathbb{L}}$  to every strategy  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$  satisfies  $\mu_{\mathbb{L}}(\langle \bar{\sigma} \rangle) > t$  if and only if every  $\rho$ -equilibrium  $\bar{\tau}$  in the game  $\mathcal{G}_{\uparrow v_0} \otimes \mathcal{M}$  satisfies  $\mu'_{\mathbb{L}}(\langle \bar{\tau} \rangle) > t$ .*

Thus, solving the  $\rho$ -RV problem in the game  $\mathcal{G}_{\uparrow v_0}$  amounts to solve the  $\rho$ -universal threshold problem ( $\rho$ -UT problem) in  $\mathcal{G}_{\uparrow v_0} \otimes \mathcal{M}$ .

► **Problem 7** ( $\rho$ -universal threshold problem in the class  $\mathcal{C}$ ). *Given a game  $\mathcal{G}_{\uparrow v_0} \in \mathcal{C}$ , a player  $i \in \Pi$ , and a threshold  $t \in \mathbb{Q}$ , is every  $\rho$ -equilibrium  $\bar{\sigma}$  in  $\mathcal{G}_{\uparrow v_0}$  such that  $\mu_i(\langle \bar{\sigma} \rangle) > t$ ?*

Moreover, the size of the product game is bounded by a polynomial function of  $\|\mathcal{G}\|$  and  $\|\mathcal{M}\|$ ; and when the game  $\mathcal{G}$  belongs to a class  $\mathcal{C}$  among the three classes defined in Section 2, then all product games constructed from it also belong to  $\mathcal{C}$ . Hence the following.

► **Corollary 8.** *Let  $\mathcal{C}$  be a game class among energy games, DS games, and MP games. Then, in the class  $\mathcal{C}$ , for a given  $\rho \in \{\text{Nash, subgame-perfect}\}$ , the  $\rho$ -UT problem, the  $\rho$ -RV problem, and the deterministic  $\rho$ -RV problem are reducible to each other in polynomial time.*

**Proof.**

■ *The deterministic  $\rho$ -RV problem reduces to the  $\rho$ -RV problem, because a non-deterministic Mealy machine is a Mealy machine.*

■ *The  $\rho$ -UT problem reduces to the deterministic  $\rho$ -RV problem.*

Let  $\mathcal{G}_{\uparrow v_0}$ ,  $i$  and  $t$  form an instance of the  $\rho$ -UT problem. We define the game  $\mathcal{G}'_{\uparrow v_0}$  as equal to the game  $\mathcal{G}_{\uparrow v_0}$ , where Leader has been added to the player set, but controls no vertex. We define  $\mu_{\mathbb{L}} = \mu_i$ . If  $\mathcal{G}$  belongs to the class  $\mathcal{C}$ , so does  $\mathcal{G}'$ . Let  $\mathcal{M}$  be the one-state deterministic Mealy machine on  $\mathcal{G}'$  that never outputs anything. Then, a strategy profile  $\bar{\sigma}$  in  $\mathcal{G}'_{\uparrow v_0}$  is an  $\mathbb{L}$ -fixed  $\rho$ -equilibrium, if and only if it is an  $\mathbb{L}$ -fixed  $\rho$ -equilibrium with  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$ , if and only if the strategy profile  $\bar{\sigma}_{-\mathbb{L}}$  is a  $\rho$ -equilibrium in the game  $\mathcal{G}_{\uparrow v_0}$ . As a consequence  $\mathcal{G}_{\uparrow v_0}$ ,  $i$ , and  $t$  form a positive instance of the  $\rho$ -UT problem, if and only if  $\mathcal{G}'_{\uparrow v_0}$ ,  $\mathcal{M}$ , and  $t$  form a positive instance of the deterministic  $\rho$ -RV problem. Moreover, the latter can be constructed from the former in polynomial time.

■ *The  $\rho$ -RV problem reduces to the  $\rho$ -UT problem, by Th. 6, and since the product game  $\mathcal{G}_{\uparrow v_0} \otimes \mathcal{M}$  can be constructed from  $\mathcal{G}_{\uparrow v_0}$  and  $\mathcal{M}$  in polynomial time. ◀*

## 4 Energy games

Let us now apply that result to our game classes: first, energy objectives.

**Nash rational verification.** RV problems are undecidable in this class, as we will show by reduction from the halting problem of two-counter machines (the reader who is not familiar with those machines may refer to [7]). However, Nash RV is co-recursively enumerable.

► **Theorem 9.** *In energy games, the Nash RV problem, deterministic or not, is undecidable and co-recursively enumerable.*

**Proof sketch.** We prove here that the Nash UT problem is undecidable and co-recursively enumerable. The theorem will follow by Cor. 8.

■ *Undecidability.* We show undecidability by reduction from the halting problem of a two-counter machine. Let  $\mathcal{K}$  be a two-counter machine. We define an energy game  $\mathcal{G}_{\uparrow q_0^1}$  with five players – players  $C_1^T$ ,  $C_1^+$ ,  $C_2^T$ ,  $C_2^+$ , and  $\mathbb{W}$ , called *Witness* – by assembling the

■ **Figure 4** Gadgets.

gadgets presented in Figure 4 – the rewards that are not presented are equal to 0, and the players controlling relevant vertices are written in blue. Then, a play in  $\mathcal{G}_{\uparrow v_0}$  that does not reach the vertex  $\blacktriangle$  simulates a sequence of transitions of  $\mathcal{K}$ , that can be a valid run or not: at each step, the counter  $C_i$  is captured by the energy level of player  $C_i^T$ , always equal to the energy level of player  $C_i^+$ . For each counter  $C_i$ , the player  $C_i^+$  will have a profitable deviation if that play fakes a test to 0, by going to the vertex  $\blacktriangle$ ; and the player  $C_i^T$  will lose, and therefore have a profitable deviation by staying in  $q_0^i$  if it fakes a positive test. Thus, as shown in the complete version of this proof, every NE outcome in the game  $\mathcal{G}_{\uparrow q_0^1}$  is won by Witness if and only if the machine  $\mathcal{K}$  does not terminate. As a consequence, the halting problem of two-counter machines reduces to the Nash UT problem in energy games, which is therefore undecidable.

- *Co-recursive enumerability.* As shown in the complete version of this proof, in an energy game  $\mathcal{G}_{\uparrow v_0}$ , if there exists an NE that makes some player  $i$  lose, then there exists a finite-memory one. Thus, a semi-algorithm that recognizes the negative instances of the UT problem consists in enumerating the finite-memory complete strategy profiles on  $\mathcal{G}_{\uparrow v_0}$ , and for each of them, to check (by diagonalization):
  - whether it is an NE: that is decidable (in polynomial time), by [7];
  - whether it makes player  $i$  lose: that is recursively enumerable, by constructing step by step its outcome and computing the energy levels on the fly.

We have a negative instance of the UT problem if and only if at least one finite-memory strategy profile satisfies those two conditions. The Nash UT problem is therefore co-recursively enumerable.  $\blacktriangleleft$

**Subgame-perfect rational verification.** In the subgame-perfect setting, the previous construction could also prove undecidability. But we choose to present a refinement of it, that proves a stronger result.

► **Theorem 10.** *In energy games, the subgame-perfect RV problem, deterministic or not, is undecidable, even when Leader plays against only two players.*

Again, the proof shows that, in particular, that problem is not recursively enumerable in energy games. It might still be the case that it is co-recursively enumerable. That would in particular be the case if finite memory was sufficient for an SPE to make any player  $i$  lose, when that is possible, as in the case of NEs. Unfortunately, one cannot follow this approach, because that statement is false: in order to be able to punish some player, without making another player lose, an SPE may have to memorize their energy levels, and therefore require infinite memory, as it will be the case in the example that follows. We leave therefore the question open.

► **Proposition 11.** *In the energy game presented in Figure 5, there exists an SPE that makes player  $\square$  lose, but no finite memory SPE can achieve that result.*

■ **Figure 5** A game where infinite memory is necessary to make player  $\square$  lose.

■ **Figure 6** A game constructed from an instance of TDS.

### 5 Discounted-sum games

We will now move to DS objectives. First, let us define the following decision problem.

► **Problem 12** (Target discounted-sum problem). *Given four quantities  $\lambda, a, b, t \in \mathbb{Q}$  with  $0 < \lambda < 1$ , is there a sequence  $(u_n)_{n \in \mathbb{N}} \in \{a, b\}^\omega$  such that  $\sum_{n \in \mathbb{N}} u_n \lambda^n = t$ ?*

Although it is a quite natural problem that appears in many different fields, the target discounted-sum (TDS) problem turns out to be surprisingly hard to solve, and its decidability status is still open. The interested reader may refer to [1] for more details. The following theorem shows that RV problems are at least as difficult.

► **Theorem 13.** *The TDS problem reduces to the complements of the (deterministic) Nash rational and subgame-perfect RV problems in discounted-sum games.*

**Proof.** We present here a reduction to the complements of the Nash universal and subgame-perfect UT problems; the result follows by Cor. 8. Let  $a, b, t \in \mathbb{Q}$ , let  $\lambda \in \mathbb{Q} \cap (0, 1)$ , and let  $\mathcal{G}_{\uparrow v_0}$  be the DS game of Figure 6, with discount factor  $\lambda$ . In that game, there exists an NE  $\bar{\sigma}$  with  $\mu_\circ(\langle \bar{\sigma} \rangle) < 0$ , if and only if there exists an SPE  $\bar{\sigma}$  with  $\mu_\circ(\langle \bar{\sigma} \rangle) < 0$ , if and only if  $a, b, t$ , and  $\lambda$  form a positive instance of the TDS problem.

Indeed, if such an NE or SPE exists, it necessarily reaches the vertex  $a$ . But then, player  $\square$  must get at least the payoff  $\mu_\square(v_0 v_1^\omega) = t\lambda^2$ , and player  $\diamond$  the payoff  $\mu_\diamond(v_0 v_2 v_3^\omega) = -t\lambda^2$ , otherwise they would have a profitable deviation. If such a play exists, then we have a positive instance of the TDS problem. Conversely, from such a positive instance, one can construct a play from  $v_0$  in which player  $\circ$  gets the payoff  $\frac{\lambda^2}{1-\lambda}$ , player  $\square$  the payoff  $t\lambda^2$ , and player  $\diamond$  the payoff  $-t\lambda^2$ , and none of them has a profitable deviation in any subgame. ◀

The previous theorem suggests that finding algorithms solving those problems is a very ambitious objective. However, in the sequel, we will show that like the TDS problem, the RV problems are recursively enumerable. The key idea is the following: a property of DS objectives is that when a play gives to some player a payoff that is strictly smaller than some threshold, that can be seen on finite prefixes of those plays. Therefore, although strategy profiles are in general infinite objects that exist in uncountable number, profitable deviations can be found by analyzing their behaviors on a finite (but unbounded) number of histories.

► **Theorem 14.** *In DS games, the Nash rational and the subgame-perfect RV problems, deterministic or not, are recursively enumerable.*

■ **Figure 7** The temptation of chaos: an illustration.

## 6 Mean-payoff games

**Classical rational verification.** Let us now end with MP games. The reduction from RV problems to UT problems enables us to apply results and methods that already exist in the literature.

► **Theorem 15.** *In the class of MP games, the Nash rational and the subgame-perfect RV problems, deterministic or not, are coNP-complete.*

**The temptation of chaos.** It is now worth noting that the definition we gave of RV entails, in the case of MP games, results that may be considered as counter-intuitive. For instance, consider the game of Figure 7, where Leader owns no vertex, and consider the only (vacuous) strategy available for Leader. Does that strategy guarantee a payoff greater than 1? Intuitively, it does not, since Leader always receives the payoff 0. But still, that strategy, that game, and that threshold form a positive instance of subgame-perfect RV, because no  $\mathbb{L}$ -fixed SPE exists in that game (see [4]). More generally, the definition we give of RV considers that a *good* strategy for Leader is a strategy such that for every response of the environment that is rational, the generated outcome observes some specification. But a strategy is then good, in that sense, if *no* rational response of the environment exists: that is the phenomenon that we can call *temptation of chaos*. While that case does never occur in energy and DS games, where rational responses are always guaranteed to exist (as we will see below), it must be considered in MP games.

**Achaotic rational verification.** To avoid such phenomena, we introduce an alternative definition of RV, *achaotic RV*: a good strategy for Leader will be a strategy that guarantees the given threshold against every response that is *as rational as possible*. To define that problem, we need quantitative relaxations to the notions of NEs and SPEs. Let  $\mathcal{G}_{\uparrow v_0}$  be a game. Let  $\varepsilon \geq 0$ . The strategy profile  $\bar{\sigma}$  is an  $\varepsilon$ -NE (resp.  $\mathbb{L}$ -fixed  $\varepsilon$ -NE) in  $\mathcal{G}_{\uparrow v_0}$  if and only if for each  $i \in \Pi$  (resp.  $\Pi \setminus \{\mathbb{L}\}$ ) and every deviation  $\sigma'_i$  of  $\sigma_i$ , the inequality  $\mu_i(\langle \sigma'_i, \bar{\sigma}_{-i} \rangle) \leq \mu_i(\langle \bar{\sigma} \rangle) + \varepsilon$  holds: no deviation is profitable *by more than*  $\varepsilon$ . Note that 0-NEs coincide with NEs. We derive from that notion, as expected, the notions of ( $\mathbb{L}$ -fixed)  $\varepsilon$ -SPEs,  $\varepsilon$ -Nash and  $\varepsilon$ -subgame-perfect responses, and the notations  $\varepsilon\text{NR}(\sigma_{\mathbb{L}})$ ,  $\varepsilon\text{SPR}(\sigma_{\mathbb{L}})$ , and  $\varepsilon\rho\text{R}(\sigma_{\mathbb{L}})$ . We can now define our decision problem.

► **Problem 16** (Achaotic (deterministic)  $\rho$ -RV in the class  $\mathcal{C}$ ). *Given a game  $\mathcal{G}_{\uparrow v_0} \in \mathcal{C}$ , a threshold  $t \in \mathbb{Q}$ , and a Mealy machine (resp. a deterministic Mealy machine)  $\mathcal{M}$  on  $\mathcal{G}$ , does there exist  $\varepsilon \geq 0$  satisfying:*

- $\varepsilon\rho\text{R}(\sigma_{\mathbb{L}}) \neq \emptyset$  for some strategy  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$ ;
- and  $\mu_{\mathbb{L}}(\langle \sigma_{\mathbb{L}}, \bar{\sigma}_{-\mathbb{L}} \rangle) > t$  for every  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$ , and every  $\bar{\sigma}_{-\mathbb{L}} \in \varepsilon\rho\text{R}(\sigma_{\mathbb{L}})$ ?

We will prove below that in mean-payoff games, there exists a least quantity  $\varepsilon_{\min}$  such that  $\varepsilon_{\min}\rho$ -responses to a given strategy  $\sigma_{\mathbb{L}}$  exist. For instance, in the example depicted by Figure 7, we have  $\varepsilon_{\min} = 1$ . Thus, we can rephrase the achaotic RV problems as follows: given a game  $\mathcal{G}_{\uparrow v_0}$ , a threshold  $t \in \mathbb{Q}$  and a Mealy machine  $\mathcal{M}$ , do we have  $\mu_{\mathbb{L}}(\langle \sigma_{\mathbb{L}}, \bar{\sigma}_{-\mathbb{L}} \rangle) > t$  for every  $\sigma_{\mathbb{L}} \in \text{Comp}_{\uparrow v_0}(\mathcal{M})$  and every  $\bar{\sigma}_{-\mathbb{L}} \in \varepsilon_{\min}\rho\text{R}(\sigma_{\mathbb{L}})$ ?

Among the problems we study here, this new definition is relevant in only one case: subgame-perfect RV in MP games. In all other cases, the RV problems are equivalent to their achaotic versions, because Nash and subgame-perfect responses are guaranteed to exist.

► **Proposition 17.** *Let  $C$  be a class of games, among the classes of energy games and DS games. Let  $\rho \in \{\text{Nash}, \text{subgame-perfect}\}$ . Then, the positive instances of the achaotic  $\rho$ -RV problem in  $C$  are exactly the positive instances of the  $\rho$ -RV problem. Similarly, the positive instances of the achaotic Nash-RV problem in MP games are exactly the positive instances of the  $\rho$ -RV problem.*

Now, an optimal algorithm for that problem in MP games requires the following lemma: in each game, there exists a least  $\varepsilon$  such that  $\varepsilon$ -SPEs exist, and it can be written with a polynomially bounded number of bits. To prove that, we need to use the notion of *negotiation function*, defined in [4]: a function from vertex labellings to vertex labellings whose least  $\varepsilon$ -fixed point (i.e., the least vertex labelling  $\lambda$  that is a fixed point of that function up to  $\varepsilon$ ) characterizes  $\varepsilon$ -SPEs. Our result can be obtained by revisiting a proof of [5], that was designed to bound the number of bits required to write that least  $\varepsilon$ -fixed point, for a fixed  $\varepsilon$ . Hereafter, we write  $\|\varepsilon\|$  for the number of bits required to write  $\varepsilon$  in a usual encoding.

► **Lemma 18.** *There exists a polynomial  $P_1$  such that in every mean-payoff game  $\mathcal{G}_{\uparrow v_0}$ , there exists  $\varepsilon_{\min}$  with  $\|\varepsilon_{\min}\| \leq P_1(\|\mathcal{G}\|)$  such that  $\varepsilon_{\min}$ -SPEs exist in  $\mathcal{G}_{\uparrow v_0}$ , and  $\varepsilon$ -SPEs, for every  $\varepsilon < \varepsilon_{\min}$ , do not.*

We are now equipped to prove the following theorem.

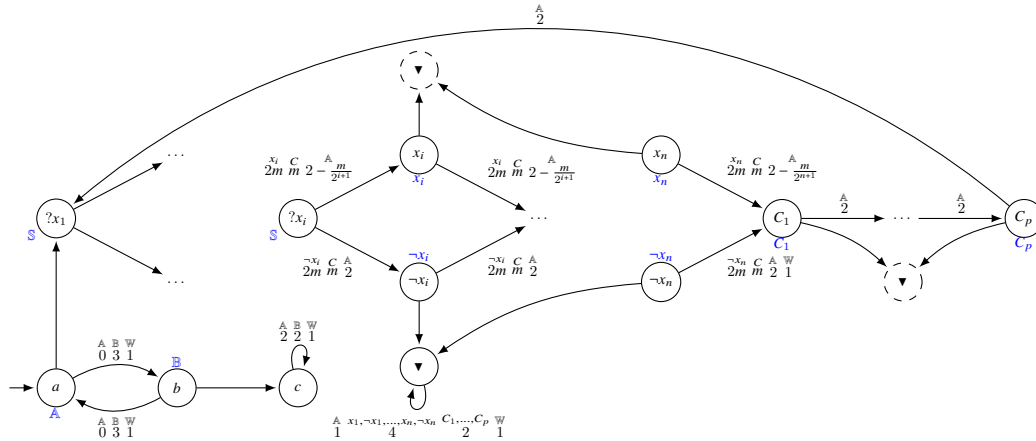

► **Theorem 19.** *In the class of mean-payoff games, the achaotic subgame-perfect RV problem, deterministic or not, is  $\text{P}^{\text{NP}}$ -complete.*

**Proof sketch.** Using Lem. 18 and the same arguments as in the proof of Th. 6, those two problems are interreducible with the following one: given  $\mathcal{G}_{\uparrow v_0}$  and a  $t \in \mathbb{Q}$ , does every  $\varepsilon_{\min}$ -SPE  $\bar{\sigma}$  in  $\mathcal{G}_{\uparrow v_0}$  satisfy  $\mu_{\mathbb{L}}(\langle \bar{\sigma} \rangle) > t$ ? Let us prove  $\text{P}^{\text{NP}}$ -completeness for that problem.

- *Easiness.* By [5], there is an NP algorithm deciding, given  $\varepsilon$  and  $\mathcal{G}_{\uparrow v_0}$ , whether there is an  $\varepsilon$ -SPE in  $\mathcal{G}_{\uparrow v_0}$ , i.e. whether  $\varepsilon \geq \varepsilon_{\min}$ . Using Lem. 18 and the inequality  $\varepsilon_{\min} \leq 2 \max_{i,uv} |r_i(uv)|$ , a dichotomous search can thus compute  $\varepsilon_{\min}$  using polynomially many calls to that algorithm. Then, one last call can decide whether there exists an  $\varepsilon_{\min}$ -SPE  $\bar{\sigma}$  such that  $\mu_i(\langle \bar{\sigma} \rangle) \leq t$ .
- *Hardness.* We proceed by reduction from the following  $\text{P}^{\text{NP}}$ -complete problem: given a Boolean formula  $\varphi$  in conjunctive normal form over the ordered variables  $x_1, \dots, x_n$ , is the lexicographically first valuation  $v_{\min}$  satisfying  $\varphi$  such that  $v_{\min}(x_n) = 1$ ? (and in particular, does such a valuation exist?) Let us write  $\varphi = \bigwedge_{j=1}^p C_j$ . We construct a game  $\mathcal{G}_{\uparrow a}$ , with a player called *Witness* and written  $\mathbb{W}$ , in which there exists an  $\varepsilon_{\min}$ -SPE  $\bar{\sigma}$  such that  $\mu_{\mathbb{W}}(\langle \bar{\sigma} \rangle) \leq 0$  if and only if  $\varphi$  is satisfiable and  $v_{\min}(x_n) = 1$ . That game, depicted in Figure 8 (unmentioned rewards are equal to 0, and we write  $m = 2n + p$ ), has  $2n + p + 4$  players: the literal players  $x_1, \neg x_1, \dots, x_n, \neg x_n$ ; the clause players  $C_1, \dots, C_p$ ; the player *Solver*, written  $\mathbb{S}$ ; the player *Witness*, written  $\mathbb{W}$ ; the player *Alice*, written  $\mathbb{A}$ ; and the player *Bob*, written  $\mathbb{B}$ .

This game is based on the classical example of MP game in which SPEs do not exist, already presented in Section 6. In the latter, from the vertex  $a$ , Alice can access a sink vertex, where Bob and her both get the payoff 1. Here, they access instead to a region where the choices of Solver define a valuation of  $x_1, \dots, x_n$  – unless one of the literal players chooses to go to the sink vertex  $\blacktriangledown$ , which will be a profitable deviation if Solver makes inconsistent choices (one literal and, later, its negation). That valuation  $v$

■ **Figure 8** The game  $\mathcal{G}_{\uparrow a}$ .

defines Alice's payoff  $\mu_A(\pi) = 2 - \sum_{i=1}^n \frac{v(x_i)}{2^i}$ , and therefore defines how much deviating and reaching  $c$  is profitable for her. Consequently, as we show in the complete version of this proof, the valuation  $v_{\min}$  is the binary encoding of the quantity  $\varepsilon_{\min}$ , and there is an  $\varepsilon_{\min}$ -SPE in which Witness gets the payoff 0 or less if and only if  $v_{\min}(x_n) = 1$ . ◀

# On Property Testing of the Binary Rank

---

## Abstract

---

Let  $M$  be an  $n \times m$   $(0, 1)$ -matrix. We define the  $s$ -binary rank, denoted as  $\text{br}_s(M)$ , of  $M$  as the minimum integer  $d$  such that there exist  $d$  monochromatic rectangles covering all the 1-entries in the matrix, with each 1-entry being covered by at most  $s$  rectangles. When  $s = 1$ , this corresponds to the binary rank, denoted as  $\text{br}(M)$ , which is well-known in the literature and has many applications.

Let  $R(M)$  and  $C(M)$  denote the sets of rows and columns of  $M$ , respectively. Using the result of Sgall [10], we establish that if  $M$  has an  $s$ -binary rank at most  $d$ , then  $|R(M)| \cdot |C(M)| \leq \binom{d}{\leq s} 2^d$ , where  $\binom{d}{\leq s} = \sum_{i=0}^s \binom{d}{i}$ . This bound is tight, meaning that there exists a matrix  $M'$  with an  $s$ -binary rank of  $d$ , for which  $|R(M')| \cdot |C(M')| = \binom{d}{\leq s} 2^d$ .

Using this result, we present novel one-sided adaptive and non-adaptive testers for  $(0, 1)$ -matrices with an  $s$ -binary rank at most  $d$  (and exactly  $d$ ). These testers require  $\tilde{O}\left(\binom{d}{\leq s} 2^d / \epsilon\right)$  and  $\tilde{O}\left(\binom{d}{\leq s} 2^d / \epsilon^2\right)$  queries, respectively.

For a fixed  $s$ , this improves upon the query complexity of the tester proposed by Parnas et al. in [9] by a factor of  $\tilde{\Theta}(2^d)$ .

## 1 Introduction

Let  $M$  be an  $n \times m$   $(0, 1)$ -matrix. We define the  $s$ -binary rank, denoted as  $\text{br}_s(M)$ , of  $M$  as the minimum integer  $d$  such that there exist  $d$  sets (rectangles)  $I_k \times J_k$ , where  $I_k \subseteq [n] := \{1, \dots, n\}$  and  $J_k \subseteq [m]$  for  $k \in [d]$  that satisfy the conditions: for every  $(i, j) \in [n] \times [m]$  where  $M[i, j] = 1$ , there is at least one and at most  $s$  integer  $t \in [d]$  such that  $(i, j) \in I_t \times J_t$  (each 1-entry in  $M$  is covered by at least one and at most  $s$  monochromatic rectangles). Additionally,  $M[i, j] = 1$  for all  $(i, j) \in I_k \times J_k$  for  $k \in [d]$  (monochromatic rectangles).

When  $s = 1$ , the  $s$ -binary rank  $\text{br}_1(M)$  is known as the binary rank, denoted as  $\text{br}(M)$ . When  $s = \infty$ , the  $s$ -binary rank  $\text{br}_\infty(M)$  is referred to as the Boolean rank. Both of these concepts are well-known in the literature. You can explore many applications of these concepts by referring to notable sources such as Amilhastre and Vigneron [1], Chalermsook et al. [3], and Gregory et al. [5]. These references, along with the internal citations, provide an extensive collection of related works with additional applications.

The binary rank can also be defined as follows: the binary rank of an  $n \times m$   $(0, 1)$ -matrix  $M$  is equal to the minimum  $d$  such that there exist an  $n \times d$   $(0, 1)$ -matrix  $N$  and a  $d \times m$   $(0, 1)$ -matrix  $L$  satisfying  $M = NL$ . The binary rank can also be interpreted as the minimum number of bipartite cliques required to partition all the edges of a bipartite graph with adjacency matrix  $M$ . Similarly, the  $s$ -binary rank of  $M$  is the minimum number of bipartite cliques needed to cover all the edges of a bipartite graph with adjacency matrix  $M$ , with each edge being covered by at most  $s$  bipartite cliques. In [3], Chalermsook et al. show that approximating the binary rank within a factor of  $n^{1-\delta}$  for any given  $\delta$  is NP-hard.

A *property-testing* algorithm, also known as a *tester*, for the  $s$ -binary rank [9], takes as input  $0 < \epsilon < 1$ , integers  $d$ ,  $n$ , and  $m$ , and has query access to the entries of an  $n \times m$   $(0, 1)$ -matrix  $M$ . If  $M$  has an  $s$ -binary rank at most  $d$  (or exactly  $d$ ), the tester accepts with

probability at least  $2/3$ . If  $M$  is  $\epsilon$ -far from having an  $s$ -binary rank at most  $d$  (or exactly  $d$ ), meaning that modifying more than an  $\epsilon$ -fraction of the entries of  $M$  is required to obtain a matrix with an  $s$ -binary rank at most  $d$  (or exactly  $d$ ), then the tester rejects with probability at least  $2/3$ . If the tester accepts matrices with an  $s$ -binary rank at most  $d$  (or exactly  $d$ ) with probability 1, it is referred to as a *one-sided error tester*. In *adaptive testing*, the queries can depend on the answers to previous queries, while in *non-adaptive testing*, all queries are predetermined by the tester in advance. The objective is to construct a tester that makes the fewest number of queries possible.

The testability of the  $s$ -binary rank at most  $d$  of  $(0,1)$ -matrices was studied in [8, 9]. In [8], Nakar and Ron presented a non-adaptive one-sided error tester for  $s = 1$  that makes  $\tilde{O}(2^{4d}/\epsilon^4)$  queries. In [9], Parnas et al. gave non-adaptive and adaptive one-sided error testers for  $s = 1$  that makes  $O(2^{2d}/\epsilon^2)$  and  $O(2^{2d}/\epsilon)$  queries, respectively. The results presented in [9] also hold to the  $s$ -binary rank at most  $d$ .

In this paper, we establish the following theorems for the testability of the  $s$ -binary rank at most  $d$  (or exactly  $d$ ):

► **Theorem 1.** *There exists an adaptive one-sided error tester for  $s$ -binary rank of  $n \times m$   $(0,1)$ -matrices that makes  $\tilde{O}\left(\binom{d}{\leq s} 2^d/\epsilon\right)$  queries.*

► **Theorem 2.** *There exists a non-adaptive one-sided error tester for  $s$ -binary rank of  $n \times m$   $(0,1)$ -matrices that makes  $\tilde{O}\left(\binom{d}{\leq s} 2^d/\epsilon^2\right)$  queries.*

For fixed  $s$ , this improves the query complexity of Parnas et al. in [9] by a factor of  $\tilde{O}(2^d)$ .

## 1.1 Our Approach

The tester of Parnas et al. [9] uses the fact that if  $M'$  is a  $k \times k$  sub-matrix of  $M$  and  $M'$  is of  $s$ -binary rank at most  $d$ , then the following properties hold:

1.  $M'$  has at most  $2^d$  distinct rows and at most  $2^d$  distinct columns.
2. If  $M$  is  $\epsilon$ -far from having  $s$ -binary rank at most  $d$ , then extending  $M'$  by one more uniformly at random row and column from  $M$  yields a  $(k+1) \times (k+1)$  sub-matrix  $M''$  of  $M$  that, with probability at least  $\Omega(\epsilon)$ , satisfies: either the number of distinct rows in  $M''$  is greater by one than the number of distinct rows in  $M'$ , or the number of distinct columns in  $M''$  is greater by one than the number of distinct columns in  $M'$ .

So, their adaptive tester starts from an empty matrix  $M' = ()$  and then runs  $O(2^d/\epsilon)$  iterations. At every iteration, if  $M'$  is of size  $(2^d + 1) \times (2^d + 1)$  it rejects. Otherwise, it extends  $M'$  by uniformly at random one row and one column. Let  $M''$  be the resulting sub-matrix. If the  $s$ -binary rank of  $M''$  is greater than  $d$ , the tester rejects. If the number of distinct rows or columns in  $M''$  is greater than the number in  $M'$ , then it continues to the next iteration with  $M' \leftarrow M''$ . Otherwise, it continues to the next iteration with  $M'$ . If, after  $O(2^d/\epsilon)$  iterations,  $M'$  has  $s$ -binary rank at most  $d$ , the tester accepts.

If the  $s$ -binary rank of  $M$  is at most  $d$ , then every sub-matrix of  $M$  has an  $s$ -binary rank at most  $d$ , and the tester accepts. If  $M$  is  $\epsilon$ -far from having  $s$ -binary rank at most  $d$ , then: since, at each iteration, with probability at least  $\Omega(\epsilon)$ , the number of distinct rows or columns of  $M'$  is increased by one, and since matrices of  $s$ -binary rank  $d$  have at most  $2^d$  distinct rows and at most  $2^d$  distinct columns, with high probability, we either obtain  $M'$  with an  $s$ -binary rank greater than  $d$ , or  $M'$  reaches to the dimension of  $(2^d + 1) \times (2^d + 1)$ . In both cases, the tester rejects. The query complexity of the tester is  $O(2^{2d}/\epsilon)$ , which is the worst-case number of the entries of the matrix  $M'$ ,  $O(2^{2d})$ , times the number of trials  $O(1/\epsilon)$  for extending  $M'$  by one row and one column.

We now give our approach. Call a sub-matrix  $M'$  of  $M$  *perfect* if it has distinct rows and distinct columns. Our adaptive tester uses the fact that if  $M'$  is a perfect  $k \times k'$  sub-matrix of  $M$  of  $s$ -binary rank  $d$ , then

1.  $kk' \leq \binom{d}{\leq s} 2^d$ .
2. If  $M$  is  $\epsilon$ -far from having  $s$ -binary rank at most  $d$ , then at least one of the following occurs<sup>1</sup>
  - a. With probability at least  $\Omega(\epsilon)$ , extending  $M'$  by one uniformly at random column of  $M$ , gives a perfect  $k \times (k' + 1)$  sub-matrix  $M''$  of  $M$ .
  - b. With probability at least  $\Omega(\epsilon)$ , extending  $M'$  by one uniformly at random row of  $M$ , gives a perfect  $(k + 1) \times k'$  sub-matrix  $M''$  of  $M$ .
  - c. With probability at least  $\Omega(\epsilon)$ , extending  $M'$  by one uniformly at random column and one uniformly at random row of  $M$ , gives a perfect<sup>2</sup>  $(k + 1) \times (k' + 1)$  sub-matrix  $M''$  of  $M$ .

Item 1 follows from Sgall's result in [10] (See Section 3), and item 2 is Claim 10 in Parnas et al [9]. Now, the tester's strategy is as follows. If  $k \leq k'$ , the tester first tries to extend  $M'$  with a new column. If it succeeds, it moves to the next iteration. Otherwise, it tries to extend  $M'$  with a new row. If it succeeds, it moves to the next iteration. Otherwise, it tries to extend  $M'$  with a new row and a new column. If it succeeds, it moves to the next iteration. If it fails, it accepts. If  $k' < k$ , it starts with the row, then the column, and then both.

Using this strategy, we show that the query complexity will be, at most, the order of the size  $kk' \leq \binom{d}{\leq s} 2^d$  of  $M'$  times the number of trials,  $\tilde{O}(1/\epsilon)$ , to find the new row, column, or both. This achieves the query complexity in Theorem 1.

For the non-adaptive tester, the tester, uniformly at random, chooses  $t = \tilde{O}\left(\binom{d}{\leq s} 2^d / \epsilon^2\right)$  rows  $r_1, \dots, r_t \in [n]$  and  $t$  columns  $c_1, \dots, c_t \in [m]$  and queries all  $M[r_i, c_j]$  for all  $i \cdot j \leq t$  and puts them in a table. Then it runs the above non-adaptive tester. When the non-adaptive tester asks for uniformly at random row or column, it provides the next element  $r_i$  or  $c_j$ , respectively. The queries are then answered from the table. We show that the adaptive algorithm does not need to make queries that are not in the table before it halts. This achieves the query complexity in Theorem 2.

## 1.2 Other Rank Problems

The *real rank* of a  $n \times m$ -matrix  $M$  over any field  $F$  is the minimal  $d$ , such that there is a  $n \times d$  matrix  $N$  over  $F$  and a  $d \times m$  matrix  $L$  over  $F$  such that  $M = NL$ . The testability of the real rank was studied in [2, 6, 7]. In [2], Balcan et al. gave a non-adaptive tester for the real rank that makes  $\tilde{O}(d^2/\epsilon)$  queries. They also show that this query complexity is optimal.

The Boolean rank ( $\infty$ -binary rank) was studied in [8, 9]. Parnas et al. in [9] gave a non-adaptive tester for the Boolean rank that makes  $\tilde{O}(d^4/\epsilon^4)$  queries<sup>3</sup>.

<sup>1</sup> Note that what we have in a-c is not precisely what we use in the algorithm and its proof of correctness. For the exact statement, please refer to Claim 13. It can be observed that both statements are equivalent, allowing for a change in the constant within the  $\Omega$  notation.

<sup>2</sup> It may happen that events (a) and (b) do not occur and (c) does

<sup>3</sup> The query complexity in [9] is  $\tilde{O}(d^4/\epsilon^6)$ . We've noticed that Lemma 3 in [9] is also true when we replace  $(\epsilon^2/64)n^2$  with  $(\epsilon/4)n^2$ . To prove that, in the proof of Lemma 3, replace Modification rules 1 and 2 with the following modification: Modify to 0 all beneficial entries. This gives the result stated here, [4].

## 2

 Definitions and Preliminary Results

Let  $M$  be a  $n \times m$   $(0, 1)$ -matrix. We denote by  $R(M)$  and  $C(M)$  the set of rows and columns of  $M$ , respectively. The number of distinct rows and columns of  $M$  are denoted by  $r(M) = |R(M)|$  and  $c(M) = |C(M)|$ , respectively. The *binary rank* of a  $n \times m$ -matrix  $M$ ,  $\text{br}(M)$ , is equal to the minimal  $d$ , where there is a  $n \times d$   $(0, 1)$ -matrix  $N$  and a  $d \times m$   $(0, 1)$ -matrix  $L$  such that  $M = NL$ .

We define the  $s$ -binary rank,  $\text{br}_s(M)$ , of  $M$  to be the minimal integer  $d$  such that there are  $d$  sets (rectangles)  $I_k \times J_k$  where  $I_k \subseteq [n] := \{1, \dots, n\}$ ,  $J_k \subseteq [m]$ ,  $k \in [d]$  such that  $M[i, j] = 1$  for all  $(i, j) \in I_k \times J_k$ ,  $k \in [d]$  (monochromatic rectangles) and for every  $(i, j) \in [n] \times [m]$  where  $M[i, j] = 1$  there are at least one and at most  $s$  integers  $t \in [d]$  such that  $(i, j) \in I_t \times J_t$  (each 1-entry in  $M$  is covered by at least one and at most  $s$  monochromatic rectangles).

We now prove.

► **Lemma 3.** *Let  $M$  be a  $n \times m$   $(0, 1)$ -matrix. The  $s$ -binary rank of  $M$ ,  $\text{br}_s(M)$ , is equal to the minimal integer  $d$ , where there is a  $n \times d$   $(0, 1)$ -matrix  $N$  and a  $d \times m$   $(0, 1)$ -matrix  $L$  such that: For  $P = NL$ ,*

1. *For every  $(i, j) \in [n] \times [m]$ ,  $M[i, j] = 0$  if and only if  $P[i, j] = 0$ .*
2. *For every  $(i, j) \in [n] \times [m]$ ,  $P[i, j] \leq s$ .*

**Proof.** If  $M$  is of  $s$ -binary rank  $d$ , then there are rectangles  $\{I_k \times J_k\}_{k \in [d]}$ ,  $I_k \subseteq [n]$ ,  $J_k \subseteq [m]$ ,  $k \in [d]$  such that  $M[i, j] = 1$  for all  $(i, j) \in I_k \times J_k$ ,  $k \in [d]$  and for every  $(i, j) \in [n] \times [m]$  where  $M[i, j] = 1$  there are at least one and at most  $s$  integers  $t \in [d]$  such that  $(i, j) \in I_t \times J_t$ . Define row vectors  $a^{(k)} \in \{0, 1\}^n$  and  $b^{(k)} \in \{0, 1\}^m$  where  $a_i^{(k)} = 1$  iff (if and only if)  $i \in I_k$ , and  $b_j^{(k)} = 1$  iff  $j \in J_k$ . Then define<sup>4</sup>  $P = a^{(1)'}b^{(1)} + \dots + a^{(d)'}b^{(d)}$ . It is easy to see that  $(a^{(k)'}b^{(k)})[i, j] = 1$  iff  $(i, j) \in I_k \times J_k$ . Therefore,  $P[i, j] = 0$  iff  $M[i, j] = 0$  and  $P[i, j] \leq s$  for all  $(i, j) \in [n] \times [m]$ . Define the  $n \times d$  matrix  $N = [a^{(1)'} | \dots | a^{(d)'}]$  and the  $d \times m$  matrix  $L = [b^{(1)} | \dots | b^{(d)}]'$ . It is again easy to see that  $P = NL$ .

The other direction can be easily seen by tracing backward in the above proof. ◀

We now prove the following,

► **Lemma 4.** *Let  $P$  be a  $n \times m$  matrix. Let  $N$  and  $L$  be  $n \times d$   $(0, 1)$ -matrix and  $d \times m$   $(0, 1)$ -matrix, respectively, such that  $P = NL$ . Then  $r(P) \leq r(N)$  and  $c(P) \leq c(L)$ .*

**Proof.** We prove the result for  $r$ . The proof for  $c$  is similar. Let  $r_1, \dots, r_n$  be the rows of  $N$  and  $p_1, \dots, p_n$  be the rows of  $P$ . Then  $p_i = r_i L$ . Therefore, if  $r_i = r_j$ , then  $p_i = p_j$ . Thus,  $r(P) \leq r(N)$ . ◀

Let  $M$  be a  $n \times m$  matrix. For  $x \in X \subseteq [n]$ ,  $y \in Y \subseteq [m]$ , we denote by  $M[X, Y]$  the  $|X| \times |Y|$  sub-matrix of  $M$ ,  $(M[x', y'])_{x' \in X, y' \in Y}$ . Denote by  $M[X, y]$  the column vector  $(M[x', y])_{x' \in X}$  and by  $M[x, Y]$  the row vector  $(M[x, y'])_{y' \in Y}$ .

For  $x \in [n]$  (resp.  $y \in [m]$ ) we say that  $M[X, y]$  is a *new column* (resp.  $M[x, Y]$  is a *new row*) to  $M[X, Y]$  if it is not equal to any of the columns (resp. rows) of  $M[X, Y]$ .

► **Lemma 5.** *Let  $M$  be a  $n \times m$  matrix,  $x \in [n]$ ,  $X \subseteq [n]$ ,  $y \in [m]$ , and  $Y \subseteq [m]$ . Suppose  $M[x, Y]$  is not a new row to  $M[X, Y]$ , and  $M[X, y]$  is not a new column to  $M[X, Y]$ . Then  $M[x, Y \cup \{y\}]$  is not a new row to  $M[X, Y \cup \{y\}]$  if and only if  $M[X \cup \{x\}, y]$  is not a new column to  $M[X \cup \{x\}, Y]$ .*

<sup>4</sup> Here  $x'$  is the transpose of  $x$ .

**Proof.** If  $M[x, Y \cup \{y\}]$  is not a new row to  $M[X, Y \cup \{y\}]$ , then there is  $x' \in X$  such that  $M[x, Y \cup \{y\}] = M[x', Y \cup \{y\}]$ . Since  $M[X, y]$  is not a new column to  $M[X, Y]$ , there is  $y' \in Y$  such that  $M[X, y] = M[X, y']$ . Since  $M[x, Y \cup \{y\}] = M[x', Y \cup \{y\}]$ , we have  $M[x', y'] = M[x, y']$  and  $M[x, y] = M[x', y]$ . Since  $M[X, y] = M[X, y']$ , we have  $M[x', y] = M[x', y']$ . Therefore,  $M[x, y] = M[x, y']$  and  $M[X \cup \{x\}, y] = M[X \cup \{x\}, y']$ . Thus,  $M[X \cup \{x\}, y]$  is not a new column to  $M[X \cup \{x\}, Y]$ .

Similarly, the other direction follows.  $\blacktriangleleft$

### 3 Matrices of $s$ -Binary Rank $d$

In this section, we prove the following two Lemmas.

► **Lemma 6.** For any  $n \times m$   $(0, 1)$ -matrix  $M$  of  $s$ -binary rank at most  $d$ , we have

$$r(M) \cdot c(M) \leq \binom{d}{\leq s} 2^d.$$

► **Lemma 7.** There is a  $(0, 1)$ -matrix  $M'$  of  $s$ -binary rank  $d$  that satisfies  $r(M') \cdot c(M') = \binom{d}{\leq s} 2^d$ .

To prove Lemma 6, we use the following Sgall's lemma.

► **Lemma 8.** [10]. Let  $\mathcal{A}, \mathcal{B} \subseteq 2^{[d]}$  be such that for every  $A \in \mathcal{A}$  and  $B \in \mathcal{B}$ ,  $|A \cap B| \leq s$ . Then  $|\mathcal{A}| \cdot |\mathcal{B}| \leq \binom{d}{\leq s} 2^d$ .

We now prove Lemma 6.

**Proof.** Since the  $s$ -binary rank of  $M$  is at most  $d$ , by Lemma 3, there is a  $n \times d$   $(0, 1)$ -matrix  $N$  and a  $d \times m$   $(0, 1)$ -matrix  $L$  such that, for  $P = NL$

1. For every  $(i, j) \in [n] \times [m]$ ,  $M[i, j] = 0$  if and only if  $P[i, j] = 0$ .
2. For every  $(i, j) \in [n] \times [m]$ ,  $P[i, j] \leq s$ .

Obviously,  $r(M) \leq r(P)$  and  $c(M) \leq c(P)$ . Consider  $\mathcal{A} = \{A_1, \dots, A_n\} \subseteq 2^{[d]}$  and  $\mathcal{B} = \{B_1, \dots, B_m\} \subseteq 2^{[d]}$ , where  $A_i = \{j | N_{i,j} = 1\}$  and  $B_k = \{j | L_{j,k} = 1\}$ . Since the entries of  $P = NL$  are at most  $s$ , for every  $i \in [n]$  and  $k \in [m]$ ,  $|A_i \cap B_k| \leq s$ .

By Lemma 4 and 8,

$$r(M) \cdot c(M) \leq r(P) \cdot c(P) \leq r(N) \cdot c(L) = |\mathcal{A}| \cdot |\mathcal{B}| \leq \binom{d}{\leq s} 2^d. \quad \blacktriangleleft$$

We now prove Lemma 7.

**Proof of Lemma 7.** Let  $N$  be a  $2^d \times d$   $(0, 1)$ -matrix where its rows contain all the vectors in  $\{0, 1\}^d$ . Let  $L$  be a  $d \times \binom{d}{\leq s}$  matrix where its columns contain all the vectors in  $\{0, 1\}^d$  of weight at most  $s$ . Obviously,  $P = NL$  is  $2^d \times \binom{d}{\leq s}$  with entries that are less than or equal to  $s$ . Define a  $2^d \times \binom{d}{\leq s}$   $(0, 1)$ -matrix  $M'$  where  $M'[i, j] = 0$  if and only if  $P[i, j] = 0$ . Then, by Lemma 3,  $M'$  is of  $s$ -binary rank at most  $d$ . We now show that  $r(M') \cdot c(M') = \binom{d}{\leq s} 2^d$ .

Since the identity  $d \times d$  matrix  $I_d$  is a sub-matrix of  $L$ , we have that  $NI_d = N$  is  $(0, 1)$ -matrix and a sub-matrix of  $P$  and therefore of  $M'$ . Therefore,  $r(M') \geq r(N) = 2^d$ . Since  $I_d$  is a sub-matrix of  $N$ , by the same argument,  $c(M') \geq c(L) = \binom{d}{\leq s}$ . Therefore  $r(M') \cdot c(M') \geq \binom{d}{\leq s} 2^d$ . Thus,  $r(M') \cdot c(M') = \binom{d}{\leq s} 2^d$ .

We now show that  $M'$  has  $s$ -binary rank  $d$ . Suppose the contrary, i.e.,  $M'$  has binary rank  $d' < d$ . Then there are  $2^d \times d'$   $(0, 1)$ -matrix  $N$  and  $d' \times \binom{d}{\leq s}$   $(0, 1)$ -matrix  $L$  such that  $P = NL$  and  $M'[i, j] = 0$  iff  $P[i, j] = 0$ . Now by Lemma 4,  $r(M') \leq r(P) \leq r(N) \leq 2^{d'} < 2^d$ , which gives a contradiction.  $\blacktriangleleft$

#### 4 Testing The $s$ -Binary Rank

In this section, we present the adaptive and non-adaptive testing algorithms for  $s$ -binary rank at most  $d$ . We first give the adaptive algorithm and prove Theorem 1.

##### 4.1 The Adaptive Tester

```

Adaptive-Test-Rank( $d, s, M, n, m, \epsilon$ )
Input: Oracle that accesses the entries of  $n \times m$  (0,1)-matrix  $M$ .
Output: Either “Accept” or “Reject”

1.  $X \leftarrow \{1\}; Y \leftarrow \{1\}; t = 9d/\epsilon$ .
2. While  $|X| \cdot |Y| \leq \binom{d}{\leq s} 2^d$  do
3.   If the  $s$ -binary rank of  $M[X, Y]$  is greater than  $d$ , then Reject.
4.    $Finish \leftarrow False; X' \leftarrow \emptyset; Y' \leftarrow \emptyset$ . /*  $X'$  and  $Y'$  are multi-sets.
5.   If  $|X| \geq |Y|$  then
6.     While (NOT  $Finish$ ) AND  $|X'| < t$ 
7.       Draw uniformly at random  $x \in [n] \setminus X; X' \leftarrow X' \cup \{x\};$ 
8.       If  $M[x, Y]$  is a new row to  $M[X, Y]$ 
9.         then  $X \leftarrow X \cup \{x\}; Finish \leftarrow True$ .
10.    If (NOT  $Finish$ ) then
11.      While (NOT  $Finish$ ) AND  $|Y'| < t$ 
12.        Draw uniformly at random  $y \in [m] \setminus Y; Y' \leftarrow Y' \cup \{y\}$ .
13.        If  $M[X, y]$  is new column to  $M[X, Y]$ 
14.          then  $Y \leftarrow Y \cup \{y\}; Finish \leftarrow True$ .
15.    Else ( $|X| < |Y|$ )
16.      While (NOT  $Finish$ ) AND  $|Y'| < t$ 
17.        Draw uniformly at random  $y \in [m] \setminus Y; Y' \leftarrow Y' \cup \{y\};$ 
18.        If  $M[X, y]$  is a new column to  $M[X, Y]$ 
19.          then  $Y \leftarrow Y \cup \{y\}; Finish \leftarrow True$ .
20.      If (NOT  $Finish$ ) then
21.        While (NOT  $Finish$ ) AND  $|X'| < t$ 
22.          Draw uniformly at random  $x \in [n] \setminus X; X' \leftarrow X' \cup \{x\}$ 
23.          If  $M[x, Y]$  is a new row to  $M[X, Y]$ 
24.            then  $X \leftarrow X \cup \{x\}; Finish \leftarrow True$ .
25.          While (NOT  $Finish$ ) AND  $X' \neq \emptyset$  do
26.            Draw uniformly at random  $x \in X'$  and  $y \in Y'$ 
27.            If  $M[x, Y \cup \{y\}]$  is a new row to  $M[X, Y \cup \{y\}]$  OR, equivalently,
28.               $M[X \cup \{x\}, y]$  is a new column to  $M[X \cup \{x\}, Y]$ 
29.                then  $X \leftarrow X \cup \{x\}; Y \leftarrow Y \cup \{y\}; Finish \leftarrow True$ .
30.                else  $X' \leftarrow X' \setminus \{x\}; Y' \leftarrow Y' \setminus \{y\}$ .
31.            If (NOT  $Finish$ ) then Accept
32.            else Reject

```

■ **Figure 1** An adaptive tester for  $s$ -binary rank at most  $d$ .

In this section, we prove Theorem 1.

Consider the tester **Adaptive-Test-Rank** in Figure 1. The tester, at every iteration of the main While-loop (step 2) has a set  $X$  of rows of  $M$  and a set  $Y$  of columns of  $M$ . If  $|X| \geq |Y|$  (step 5), the tester first tries to extend  $M[X, Y]$  with a new column (steps 6-8). If it succeeds, it moves to the next iteration. Otherwise, it tries to extend  $M[X, Y]$  with a new row (steps 9-12). If it succeeds, it moves to the next iteration. Otherwise, it tries to extend  $M[X, Y]$  with a new row and a new column (steps 21-26). If it succeeds, it moves to the next iteration. If it fails, it accepts (step 27). If  $|X| < |Y|$  (step 13), it starts with the row of  $M[X, Y]$  (steps 14-16), then the column (steps 18-20), and then both (steps 21-26). If it fails, it accepts (step 27).

If  $|X| \cdot |Y| > \binom{d}{\leq s} 2^d$  (step 2 and then step 28) or the  $s$ -binary rank of  $M[X, Y]$  is greater than  $d$  (step 3), then it rejects.

We first prove

► **Lemma 9.** *Let  $t = 9d/\epsilon$ . Tester **Adaptive-Test-Rank** makes at most  $2 \binom{d}{\leq s} 2^{dt} = \tilde{O} \left( \binom{d}{\leq s} 2^d \right) / \epsilon$  queries.*

**Proof.** We prove by induction that at every iteration of the main While-loop (step 2), the tester knows the entries of  $M[X, Y]$ , and the total number of queries,  $q_{X, Y}$ , is at most  $2|X||Y|t$ . Since the While-loop condition is  $|X||Y| \leq \binom{d}{\leq s} 2^d$ , the result follows.

At the beginning of the algorithm, no queries are made, and  $|X| = |Y| = 1$ . Then  $2|X||Y|t = 2t > 0 = q_{X, Y}$ . Suppose, at the  $k$ th iteration, the tester knows the entries of  $M[X, Y]$  and  $q_{X, Y} \leq 2|X||Y|t$ . We prove the result for the  $(k + 1)$ th iteration.

We have the following cases (at the  $(k + 1)$ th iteration)

**Case I.**  $|X| \geq |Y|$  (step 5) and, for some  $x$ ,  $M[x, Y]$  is a new row to  $M[X, Y]$  (step 8).

In that case, *Finish* becomes *true*, and no other sub-while-loop is executed. Therefore, the number of queries made at this iteration is at most  $|Y|t$  (to find all  $M[x, Y]$ ), and one element  $x$  is added to  $X$ . Then, the tester knows all the entries of  $M[X \cup \{x\}, Y]$  and

$$q_{X \cup \{x\}, Y} = q_{X, Y} + |Y|t \leq 2|X||Y|t + |Y|t \leq 2|X \cup \{x\}| \cdot |Y|t,$$

and the result follows.

**Case II.**  $|X| \geq |Y|$  (step 5), for all  $x' \in X'$ ,  $M[x', Y]$  is not a new row to  $M[X, Y]$  (step 8), and for some  $y$ ,  $M[X, y]$  is a new column to  $M[X, Y]$  (step 12).

In that case, *Finish* becomes *true*, and no other sub-while-loop is executed after the second sub-while-loop (step 10).

Therefore, in this case, the number of queries made at this iteration is at most  $|Y|t + |X|t$ .  $|X|t$  queries in the first sub-while-loop (to find  $M[x, Y]$  for all  $x \in X'$ ), and at most  $|Y|t$  queries in the second sub-while-loop (to find  $M[X, y']$  for all  $y' \in Y'$ ). Then one element  $y$  is added to  $Y$ . Therefore, the tester knows the entries of  $M[X, Y \cup \{y\}]$  and, since  $|Y| \leq |X|$ ,

$$q_{X, Y \cup \{y\}} = q_{X, Y} + |X|t + |Y|t \leq 2|X||Y|t + 2|X|t = 2|X| \cdot |Y \cup \{y\}|t,$$

and the result follows.

**Case III.**  $|X| \geq |Y|$ , for all  $x' \in X'$ ,  $M[x', Y]$  is not a new row to  $M[X, Y]$ , for all  $y' \in Y'$ ,  $M[X, y']$  is not a new column to  $M[X, Y]$ , and for some  $x \in X'$ ,  $y \in Y'$ ,  $M[x, Y \cup \{y\}]$  is a new row to  $M[X, Y \cup \{y\}]$  (step 23).

## 27:8 On Property Testing of the Binary Rank

In this case,  $|X'| = |Y'| = t$ , the number of queries is  $|X|t + |Y|t + t$ . Exactly  $|X|t$  queries in the first sub-while-loop,  $|Y|t$  queries in the second sub-while-loop, and at most<sup>5</sup>  $t$  queries in the sub-while-loop in step 21. Then one element  $x$  is added to  $X$ , and one element  $y$  is added to  $Y$ . Then the tester knows the entries of  $M[X \cup \{x\}, Y \cup \{y\}]$  and

$$q_{X \cup \{x\}, Y \cup \{y\}} = q_{X, Y} + |X|t + |Y|t + t \leq 2|X| \cdot |Y|t + |X|t + |Y|t + t \leq 2|X \cup \{x\}| \cdot |Y \cup \{y\}|t.$$

**Case IV.**  $|X| \geq |Y|$ , for all  $x' \in X'$ ,  $M[x', Y]$  is not a new row to  $M[X, Y]$ , for all  $y' \in Y'$ ,  $M[X, y']$  is not a new column to  $M[X, Y]$ , and for all the drawn pairs  $x \in X', y \in Y'$ ,  $M[x, Y \cup \{y\}]$  is not a new row to  $M[X, Y \cup \{y\}]$  (step 23).

In this case, *Finish* will have value *False*, and the tester accepts in step 27.

The analysis of the case when  $|X| < |Y|$  is similar to the above analysis. ◀

We now prove the completeness of the tester.

► **Lemma 10.** *If  $M$  is a  $n \times m$   $(0, 1)$ -matrix of  $s$ -binary rank at most  $d$ , then the tester **Adaptive-Test-Rank** accepts with probability 1.*

**Proof.** The tester rejects if and only if one of the following occurs,

1.  $M[X, Y]$  has  $s$ -binary rank greater than  $d$ .
2.  $|X| \cdot |Y| > \binom{d}{\leq s} 2^d$ .

If  $M[X, Y]$  has  $s$ -binary rank greater than  $d$ , then  $M$  has  $s$ -binary rank greater than  $d$ . This is because, if  $M = NL$ , then  $M[X, Y] = N[X, [d]] \cdot L[[d], Y]$ . So item 1 cannot occur.

Before we show that item 2 cannot occur, we prove the following:

► **Claim 11.** The rows (resp. columns) of  $M[X, Y]$  are distinct.

**Proof.** The steps in the tester where we add rows or columns are steps 8, 12 16, 20, and 23. In steps 8, 12 16, 20 it is clear that a row (resp. column) is added only if it is a new row (resp. column) to  $M[X, Y]$ . Consider step 23 and suppose, w.l.o.g  $|X| \geq |Y|$ . This step is executed only when *Finish* = *False*. This happens when  $|X'| = |Y'| = t$ , for every  $x \in X'$ ,  $M[x, Y]$  is not a new row to  $M[X, Y]$ , and for every  $y \in Y'$ ,  $M[X, y]$  is not a new column to  $M[X, Y]$ . Then  $x$  and  $y$  are added to  $X$  and  $Y$ , respectively, if  $M[x, Y \cup \{y\}]$  is a new row to  $M[X, Y \cup \{y\}]$ . Then, by Lemma 5,  $M[X \cup \{x\}, y]$  is a new column to  $M[X \cup \{x\}, Y]$ . So, the rows (and columns) in  $M[X \cup \{x\}, Y \cup \{y\}]$  are distinct. This implies the result. ◀

Suppose, to the contrary,  $|X| \cdot |Y| > \binom{d}{\leq s} 2^d$ . Since  $M' = M[X, Y]$  satisfies  $r(M')c(M') = |X| \cdot |Y| > \binom{d}{\leq s} 2^d$ , by Lemma 6, the  $s$ -binary rank of  $M'$ , and therefore of  $M$ , is greater than  $d$ . A contradiction. ◀

We now prove the soundness of the tester.

We first prove the following.

► **Claim 12.** Let  $M$  be a  $n \times m$   $(0, 1)$ -matrix,  $X \subseteq [n]$ , and  $Y \subseteq [m]$ . Suppose there are two functions,  $' : [n] \rightarrow X$  and  $'' : [m] \rightarrow Y$ , such that

1. For every  $x \in [n]$ ,  $M[x, Y] = M[x', Y]$ .
2. For every  $y \in [m]$ ,  $M[X, y] = M[X, y'']$ .
3. For every  $x \in [n]$  and  $y \in [m]$ ,  $M[x, y] = M[x', y'']$ .

Then  $M$  has at most  $|X|$  distinct rows and  $|Y|$  distinct columns, and its  $s$ -binary rank is the  $s$ -binary rank of  $M[X, Y]$ .

<sup>5</sup> This is because, for  $x \in X', y \in Y'$ , the tester already knows  $M[x, Y]$  and  $M[X, y]$  from the first and second sub-while-loop and only needs to query  $M[x, y]$ .

Proof. Let  $x \in [n] \setminus X$ . For every  $y$ ,  $M[x, y] = M[x', y''] = M[x', y]$ . Therefore, row  $x$  in  $M$  is equal to row  $x'$ . Similarly, column  $y$  in  $M$  is equal to column  $y''$ .

Since adding equal columns and rows to a matrix does not change the  $s$ -binary rank<sup>6</sup>, we have  $\text{br}_s(M[X, Y]) = \text{br}_s(M[X, [m]]) = \text{br}_s(M)$ .  $\triangleleft$

The following Claim is proved in [9] (Claim 10). Here, we give the proof for completeness.

$\triangleright$  **Claim 13.** Let  $M$  be a  $(0, 1)$ -matrix that is  $\epsilon$ -far from having  $s$ -binary rank at most  $d$ . Let  $X \subseteq [n]$  and  $Y \subseteq [m]$ , such that  $\text{br}_s(M[X, Y]) \leq d$ , the columns of  $M[X, Y]$  are distinct, and the rows of  $M[X, Y]$  are distinct. Then one of the following must hold:

1. The number of rows  $x \in [n]$  where  $M[x, Y]$  is a new row to  $M[X, Y]$  is at least  $n\epsilon/3$ .
2. The number of columns  $y \in [m]$  where  $M[X, y]$  is a new column to  $M[X, Y]$  is at least  $m\epsilon/3$ .
3. The number pairs  $(x, y)$ ,  $x \notin X$ ,  $y \notin Y$ , where,  $M[x, Y] = M[x', Y]$  for some  $x' \in X$ ,  $M[X, y] = M[X, y'']$  for some  $y'' \in Y$ , and  $M[x, y] \neq M[x', y'']$ , is at least  $mn\epsilon/3$ .

Proof. Assume, to the contrary, that none of the above statements holds. Change every row  $x$  in  $M$  where  $M[x, Y]$  is a new row to  $M[X, Y]$  to a zero row. Let  $X'$  be the set of such rows. Change every column  $y$  in  $M$  where  $M[X, y]$  is a new column to  $M[X, Y]$  to a zero column. Let  $Y'$  be the set of such columns. For every other entry  $(x, y)$ ,  $x \notin X$ ,  $y \notin Y$  that is not changed to zero and  $M[x, y] \neq M[x', y'']$ , change  $M[x, y]$  to  $M[x', y'']$ . Let  $M'$  be the matrix obtained from the above changes.

The number of entries  $(x, y)$  where  $M[x, y] \neq M'[x, y]$  is less than  $(n\epsilon/3)m + (m\epsilon/3)n + mn\epsilon/3 = \epsilon mn$ . Therefore,  $M'$  is  $\epsilon$ -close to  $M$ . By claim 13,  $\text{br}_s(M') = \text{br}_s(M[[n] \setminus X', [m] \setminus Y']) = \text{br}_s(M[X, Y]) \leq d$ . A contradiction.  $\triangleleft$

We now prove the soundness of the tester.

$\blacktriangleright$  **Lemma 14.** *If  $M$  is  $\epsilon$ -far from having  $s$ -binary rank  $d$ , then with probability at least  $2/3$ , **Adaptive-Test-Rank** rejects.*

**Proof.** Consider the while-loop in step 2 at some iteration  $i$ . If  $\text{br}_s(M[X, Y]) > d$ , then the tester rejects in step 3. We will now show that if  $\text{br}_s(M[X, Y]) \leq d$ , then, with probability at most  $3e^{-2d}$ , the tester accepts at iteration  $i$ .

To this end, let  $\text{br}_s(M[X, Y]) \leq d$ . Then, by Claim 13, one of the following holds.

1. The number of rows  $x \in [n]$  where  $M[x, Y]$  is a new row to  $M[X, Y]$  is at least  $n\epsilon/3$ .
2. The number of columns  $y \in [m]$  where  $M[X, y]$  is a new column to  $M[X, Y]$  is at least  $m\epsilon/3$ .
3. The number pairs  $(x, y)$ ,  $x \notin X$ ,  $y \notin Y$ , where,  $M[x, Y] = M[x', Y]$  for some  $x' \in X$ ,  $M[X, y] = M[X, y'']$  for some  $y'' \in Y$ , and  $M[x, y] \neq M[x', y'']$ , is at least  $mn\epsilon/3$ .

Now at the  $i$ th iteration, suppose w.l.o.g,  $|X| \geq |Y|$  (the other case  $|Y| < |X|$  is similar). If item 1 occurs, then with probability at least  $p = 1 - (1 - \epsilon/3)^t \geq 1 - e^{-2d}$ , the tester finds a new row to  $M[X, Y]$  and does not accept at iteration  $i$ . If item 2 occurs, then if it does not find a new row to  $M[X, Y]$ , with probability at least  $p$ , the tester finds a new column to  $M[X, Y]$  and does not accept. If item 3 occurs, and it does not find a new row or column to  $M[X, Y]$ , then with probability at least  $p$ , it finds such a pair and does not accept. Therefore, with probability at most  $3(1 - p) \leq 3e^{-2d}$ , the tester accepts at iteration  $i$ .

<sup>6</sup> If we add a column to a matrix that is equal to column  $y$ , then the rectangles that cover column  $y$  can be extended to cover the added column.

## 27:10 On Property Testing of the Binary Rank

Since the while-loop runs at most  $|X| + |Y| \leq 2|X||Y| \leq 2\binom{d}{\leq s}2^d \leq 2^{2d+1}$  iterations, with probability at most  $3e^{-2^d}2^{2d+1} \leq 1/3$ , the tester accepts in while-loop. Therefore, with probability at least  $2/3$ , the tester does not accept in the while-loop. Thus, it either rejects because  $\text{br}_s(M[X, Y]) > d$  or rejects in step 28. ◀

### 4.2 The Non-Adaptive Tester

In this section, we prove Theorem 2.

**Non-Adaptive-Test-Rank**( $d, s, M, n, m, \epsilon$ )

**Input:** Oracle that accesses the entries of  $(0, 1)$ -matrix  $M$ .

**Output:** Either “Accept” or “Reject”.

1.  $T \leftarrow \frac{324 \cdot d^2 \binom{d}{\leq s} 2^d}{\epsilon^2}$ .
2. Draw uniformly at random  $x^{(1)}, \dots, x^{(T)} \in [n]$ .
3. Draw uniformly at random  $y^{(1)}, \dots, y^{(T)} \in [m]$ .
4. For every  $i \in [T]$  and  $j \in [T]$  such that  $i \cdot j \leq T$
5.  $D[i, j] \leftarrow \text{Query } M[x^{(i)}, y^{(j)}]$
6.  $u = 1; w = 1$ .
7. Run **Adaptive-Test-Rank**( $d, s, M, n, m, \epsilon$ )
  - When the tester asks for a uniform at random  $x$  - return  $x^{(u)}$ ;  $u \leftarrow u + 1$
  - When the tester asks for a uniform at random  $y$  - return  $y^{(w)}$ ;  $w \leftarrow w + 1$
  - When the tester makes the Query  $M[x^{(i)}, y^{(j)}]$  - return  $D[i, j]$

■ **Figure 2** A non-adaptive tester for  $s$ -binary rank at most  $d$ .

First, consider **Adaptive-Test-Rank** in Figure 1. Consider steps 7, 11, 15, and 19, where it draws a new column or row. We prove.

► **Lemma 15.** *Let  $t = 9d/\epsilon$ . At each iteration of **Adaptive-Test-Rank**, the total number of uniformly at random rows  $x \in [n]$  drawn is at most  $(|X| + \min(|X|, |Y| - 1))t$ , and the number of uniformly at random rows  $y \in [m]$  drawn is at most  $(|Y| + \min(|X|, |Y|))t$ .*

**Proof.** We prove by induction that at every iteration of the main While-loop (step 2), the total number of random rows drawn by the tester,  $n_{X, Y}$ , is at most  $(|X| + \min(|X|, |Y| - 1))t$ , and the total number of random columns drawn,  $m_{X, Y}$ , is at most  $(|Y| + \min(|X|, |Y|))t$ .

At the beginning,  $|X| = |Y| = 1$ , and the number of columns and rows is 1. In that case,<sup>7</sup>  $n_{X, Y} = 1 \leq t$  and  $m_{X, Y} = 1 \leq 2t$ . Suppose, at the  $k$ th iteration, the induction statement is true. We prove the result for the  $(k + 1)$ th iteration.

At the  $(k + 1)$ th iteration, we have the following cases.

**Case I.**  $|X| \geq |Y|$  (step 5) and, for some  $x$ ,  $M[x, Y]$  is a new row to  $M[X, Y]$  (step 8).

In that case, *Finish* becomes *true*, and no other sub-while-loop is executed. Therefore, the number of rows drawn at this iteration is at most  $t$ , and one element  $x$  is added to  $X$ . No columns are drawn. Then,

$$n_{X \cup \{x\}, Y} \leq n_{X, Y} + t \leq (|X| + \min(|X|, |Y| - 1) + 1)t \leq (|X \cup \{x\}| + \min(|X \cup \{x\}|, |Y| - 1))t,$$

<sup>7</sup> We assume that the first column/row drawn is column/row one

and

$$m_{X \cup \{x\}, Y} = m_{X, Y} \leq (|Y| + \min(|X|, |Y|))t \leq (|Y| + \min(|X \cup \{x\}|, |Y|))t.$$

Thus, the result follows for this case.

**Case II.**  $|X| \geq |Y|$  (step 5), for all  $x' \in X'$ ,  $M[x', Y]$  is not a new row to  $M[X, Y]$  (step 8), and for some  $y$ ,  $M[X, y]$  is a new column to  $M[X, Y]$  (step 12).

In that case, *Finish* becomes *true*, and no other sub-while-loop is executed after the second sub-while-loop (step 10).

Therefore, in this case, the number of rows drawn at this iteration is  $t$ , one element  $y$  is added to  $Y$ , and the number of columns drawn is at most  $t$ . Then

$$\begin{aligned} n_{X, Y \cup \{y\}} = n_{X, Y} + t &\leq (|X| + \min(|X|, |Y| - 1) + 1)t \\ &= (|X| + |Y|)t = (|X| + \min(|X|, |Y \cup \{y\}| - 1))t, \end{aligned}$$

and

$$m_{X, Y \cup \{y\}} \leq m_{X, Y} + t \leq (|Y| + \min(|X|, |Y|) + 1)t \leq (|Y \cup \{y\}| + \min(|X|, |Y \cup \{y\}|))t.$$

Thus, the result follows for this case.

**Case III.**  $|X| < |Y|$  (step 13), and for some  $y$ ,  $M[X, y]$  is a new column to  $M[X, Y]$  (step 16).

In that case, *Finish* becomes *true*, and no other sub-while-loop is executed. Therefore, the number of columns drawn at this iteration is at most  $t$ , and one element  $y$  is added to  $Y$ . No rows are drawn. Then,

$$n_{X, Y \cup \{y\}} = n_{X, Y} \leq (|X| + \min(|X|, |Y| - 1))t \leq (|X| + \min(|X|, |Y \cup \{y\}| - 1))t,$$

and

$$m_{X, Y \cup \{y\}} \leq m_{X, Y} + t \leq (|Y| + \min(|X|, |Y|) + 1)t = (|Y \cup \{y\}| + \min(|X|, |Y \cup \{y\}|))t.$$

Thus, the result follows for this case.

**Case IV.**  $|X| < |Y|$  (step 13), for all  $y' \in Y'$ ,  $M[X, y']$  is not a new row to  $M[X, Y]$ , and for some  $x$ ,  $M[x, Y]$  is a new column to  $M[X, Y]$  (step 20). In that case, *Finish* becomes *true*, and no other sub-while-loop is executed after the fourth sub-while-loop (step 18).

In this case, the number of rows drawn at this iteration is  $t$ , one element  $x$  is added to  $X$ , and the number of columns drawn is at most  $t$ . Then

$$\begin{aligned} n_{X \cup \{x\}, Y} = n_{X, Y} + t &\leq (|X| + \min(|X|, |Y| - 1) + 1)t \\ &\leq (|X \cup \{x\}| + \min(|X \cup \{x\}|, |Y| - 1))t \\ m_{X \cup \{x\}, Y} &\leq m_{X, Y} + t \leq (|Y| + \min(|X|, |Y|) + 1)t = (|Y| + \min(|X \cup \{x\}|, |Y|))t. \end{aligned}$$

Thus, the result follows for this case.

**Case V.** For all  $x' \in X'$ ,  $M[x', Y]$  is not a new row to  $M[X, Y]$ , for all  $y' \in Y'$ ,  $M[X, y']$  is not a new column to  $M[X, Y]$ , and for some  $x \in X'$ ,  $y \in Y'$ ,  $M[x, Y \cup \{y\}]$  is a new row to  $M[X, Y \cup \{y\}]$  (step 23).

In this case, the number of rows drawn at this iteration is  $t$ , the number of columns drawn is  $t$ , one element  $x$  is added to  $X$ , and one element  $y$  is added to  $Y$ . Then

$$\begin{aligned} n_{X \cup \{x\}, Y \cup \{y\}} = n_{X, Y} + t &\leq (|X| + \min(|X|, |Y| - 1) + 1)t \\ &\leq (|X \cup \{x\}| + \min(|X \cup \{x\}|, |Y \cup \{y\}| - 1))t. \end{aligned}$$

$$\begin{aligned} m_{X \cup \{x\}, Y \cup \{y\}} = m_{X, Y} + t &\leq (|Y| + \min(|X|, |Y|) + 1)t \\ &\leq (|Y \cup \{y\}| + \min(|X \cup \{x\}|, |Y \cup \{y\}|))t. \end{aligned} \quad \blacktriangleleft$$

## 27:12 On Property Testing of the Binary Rank

We are now ready to prove Theorem 2.

**Proof.** By Lemma 15, the total number of rows and columns drawn in **Adaptive-Test-Rank** up to iteration  $t$  is at most  $n' := 9(|X| + \min(|X|, |Y| - 1))d/\epsilon \leq 18|X|d/\epsilon$  and  $m' := 9(|Y| + \min(|X|, |Y|))d/\epsilon \leq 18|Y|d/\epsilon$ , respectively. We also have  $|X| \cdot |Y| \leq \binom{d}{\leq s} 2^d$ . So

$$n' \cdot m' \leq 324|X||Y|d^2/\epsilon^2 \leq T := \frac{324 \cdot d^2 \binom{d}{\leq s} 2^d}{\epsilon^2}.$$

Consider the tester **Non-Adaptive-Test-Rank** in Figure 2. The tester draws  $T$  rows  $x^{(1)}, \dots, x^{(T)} \in [n]$ , and columns  $y^{(1)}, \dots, y^{(T)} \in [m]$  and queries all  $M[x^{(i)}, y^{(j)}]$  where  $ij \leq T$  and puts the result in the table  $D$ . Then it runs **Adaptive-Test-Random** using the above-drawn rows and columns. We now show that all the queries that **Adaptive-Test-Random** makes can be fetched from the table  $D$ .

At any iteration, the number of rows drawn is at most  $n'$ , and the number of rows drawn is at most  $m'$ . Therefore, the tester needs to know (in the worst case) all the entries  $M[x^{(i)}, y^{(j)}]$  where  $i \leq n'$  and  $j \leq m'$ . Since  $ij \leq n'm' \leq T$ , the result follows.

The number of queries that the tester makes is

$$\sum_{i=1}^T \frac{T}{i} = O(T \ln T) = \tilde{O}\left(\frac{\binom{d}{\leq s} 2^d}{\epsilon^2}\right). \quad \blacktriangleleft$$

### 5 Testing the Exact $s$ -Binary Rank

We first prove the following.

► **Lemma 16.** *Let  $M$  and  $M'$  be  $n \times m$   $(0, 1)$ -matrices that differ in one row (or column). Then  $|\text{br}_s(M) - \text{br}_s(M')| \leq 1$ .*

**Proof.** Suppose  $\text{br}_s(M) = d$  and  $M'$  differ from  $M$  in row  $k$ . Let  $N$  and  $L$  be  $n \times d$   $(0, 1)$ -matrix and  $d \times m$   $(0, 1)$ -matrix, respectively, such that  $P = NL$ , for every  $(i, j) \in [n] \times [m]$ ,  $P[i, j] \leq s$ , and  $P[i, j] = 0$  if and only if  $M[i, j] = 0$ . Add to  $N$  a column (as a  $(d + 1)$ th column) that all its entries are zero except the  $k$ -th entry, which equals 1. Then change  $N[k, j]$  to zero for all  $j \in [d]$ . Let  $N'$  be the resulting matrix. Add to  $L$  another row (as a  $(d + 1)$ th row) equal to the  $k$ -th row of  $M'$ . Let  $L'$  be the resulting matrix. Let  $P' = N'L'$ . It is easy to see that  $P'[i, j] = P[i, j]$  for all  $i \neq k$  and  $j$ , and the  $k$ th row of  $P'$  is equal to the  $k$ th row of  $M'$ . Then, for every  $(i, j) \in [n] \times [m]$ ,  $P'[i, j] \leq s$ , and  $P'[i, j] = 0$  if and only if  $M'[i, j] = 0$ . Therefore,  $\text{br}_s(M') \leq d + 1 = \text{br}_s(M) + 1$ . In the same way,  $\text{br}_s(M) \leq \text{br}_s(M') + 1$ . ◀

► **Lemma 17.** *Let  $\eta = d^2/(nm)$ . Let  $M$  be  $n \times m$   $(0, 1)$ -matrix. If  $M$  is  $\epsilon$ -close to having  $s$ -binary rank at most  $d$ , then  $M$  is  $(\epsilon + \eta)$ -close to having  $s$ -binary rank  $d$ .*

**Proof.** We will show that for every  $n \times m$   $(0, 1)$ -matrix  $H$  of  $s$ -binary rank at most  $d - 1$ , there is a  $n \times m$   $(0, 1)$ -matrix  $G$  of  $s$ -binary rank  $d$  that is  $\eta$ -close to  $H$ . Therefore, if  $M$  is  $\epsilon$ -close to having  $s$ -binary rank at most  $d$ , then it is  $(\epsilon + \eta)$ -close to having  $s$ -binary rank  $d$ .

Define the  $n \times m$   $(0, 1)$ -matrices  $G_k$ ,  $k \in [d] \cup \{0\}$ , where  $G_0 = H$  and for  $k \geq 1$ ,  $G_k[i, j] = H[i, j]$  if  $j > k$  or  $i > d$ , and  $G_k[[d], [k]] = I_d[[d], [k]]$  where  $I_d$  is the  $d \times d$  identity matrix. Since  $G_d[[d], [d]] = I_d$ , we have  $\text{br}_s(G_d) \geq d$ . It is clear that for every  $k \in [d] \cup \{0\}$ ,  $G_k$  is  $(d^2/nm)$ -close to  $H$ . If  $\text{br}_s(G_d) = d$ , then take  $G = G_d$ , and we are done. Otherwise, suppose  $\text{br}_s(G_d) > d$ .

Now consider a sequence  $H = G_0, G_1, G_2, \dots, G_d$ . By Lemma 16, we have  $\text{br}_s(G_{i-1}) - 1 \leq \text{br}_s(G_i) \leq \text{br}_s(G_{i-1}) + 1$ . Now since  $\text{br}_s(G_0) = \text{br}_s(H) \leq d - 1$  and  $\text{br}_s(G_d) > d$ , by the discrete intermediate value theorem, there must be  $k \in [d]$  such that  $\text{br}_s(G_k) = d$ . Then take  $G = G_k$ , and we are done. ◀

Now, the tester for testing the  $s$ -binary rank  $d$  runs as follows. If  $mn < 2d^2/\epsilon$ , then find all the entries of  $M$  with  $mn < 2d^2/\epsilon$  queries. If  $\text{br}_s(M) = d$ , then accept. Otherwise, reject. If  $mn \geq 2d^2/\epsilon$ , then run **Adaptive-Test-Rank**( $d, s, M, n, m, \epsilon/2$ ) (for the non-adaptive, we run **Non-Adaptive-Test-Rank**( $d, s, M, n, m, \epsilon/2$ )) and output its answer.

We now show the correctness of this algorithm. If  $M$  is of  $s$ -binary rank  $d$ , then it is of  $s$ -binary rank at most  $d$ , and the tester accepts.

Now, suppose  $f$  is  $\epsilon$ -far from having  $s$ -binary rank  $d$ . If  $mn < 2d^2/\epsilon$ , the tester rejects. If  $mn \geq 2d^2/\epsilon$ , then, by Lemma 17,  $f$  is  $(\epsilon - \eta)$ -far from having  $s$ -binary rank at most  $d$ , where  $\eta = d^2/(nm)$ . Since  $\eta = d^2/(nm) \leq \epsilon/2$ , the function  $f$  is  $(\epsilon/2)$ -far from having  $s$ -binary rank at most  $d$ , and therefore the tester, with probability at least  $2/3$ , rejects.

## 6 Conclusion and Open Problems

In this work, we introduced the notion of  $s$ -binary rank for  $(0, 1)$ -matrices, extending the concept of binary rank. We established a tight upper bound on the size of matrices with  $s$ -binary rank at most  $d$ , and showed the existence of matrices achieving this bound. Using this result, we presented novel one-sided adaptive and non-adaptive testers for  $(0, 1)$ -matrices with  $s$ -binary rank at most  $d$ , significantly improving the query complexity compared to prior work. The adaptive tester requires  $\tilde{O}\left(\binom{d}{\leq s} 2^d/\epsilon\right)$  queries, while the non-adaptive tester requires  $\tilde{O}\left(\binom{d}{\leq s} 2^d/\epsilon^2\right)$  queries.

The following are open problems that are worth investigating:

**Tighter Bounds on Query Complexity:** Investigate whether the query complexity of the testers for  $(0, 1)$ -matrices with  $s$ -binary rank at most  $d$  can be further improved. Specifically, explore alternative approaches or refinements that can reduce the dependence on  $\binom{d}{\leq s}$  and  $2^d$  in the query complexity bounds.

**Generalization Beyond  $(0, 1)$ -Matrices:** Extend the concept of  $s$ -binary rank to other types of matrices, such as integer-valued matrices or matrices with entries from a larger alphabet. Study the properties, computational aspects, and property testing of these generalizations.

Addressing these open problems will lead to a more profound understanding of the  $s$ -binary rank, provide further insights into the structure of matrices, and potentially lead to improved algorithmic techniques and applications in various fields.

## Abstract

A first-order formula is called *primitive positive* (*pp*) if it only admits the use of existential quantifiers and conjunction. Pp-formulas are a central concept in (fixed-template) constraint satisfaction since  $\text{CSP}(\Gamma)$  can be viewed as the problem of deciding the primitive positive theory of  $\Gamma$ , and pp-definability captures gadget reductions between CSPs.

An important class of tractable constraint languages  $\Gamma$  is characterized by having *few subpowers*, that is, the number of  $n$ -ary relations pp-definable from  $\Gamma$  is bounded by  $2^{p(n)}$  for some polynomial  $p(n)$ . In this paper we study a restriction of this property, stating that every pp-definable relation is definable by a pp-formula of polynomial length. We conjecture that the existence of such *short definitions* is actually equivalent to  $\Gamma$  having few subpowers, and verify this conjecture for a large subclass that, in particular, includes all constraint languages on three-element domains. We furthermore discuss how our conjecture imposes an upper complexity bound of co-NP on the subpower membership problem of algebras with few subpowers.

## 1 Introduction

Constraint satisfaction is a unifying framework for expressing a wide range of computational tasks coming from a smorgasbord of real-life applications and theoretical contexts. In a CSP instance, the goal is to assign values to variables subject to a list of *constraints* to be satisfied. In the most general setting, a constraint consists of a tuple of variables (its *scope*) and a list of admissible evaluations of the scope (i.e., tuples of values, forming the *constraint relation*). Usually, the set of variables, the sets of admissible values for every variable (its *domain*), and the list of input constraints are all finite. This simple formulation strikes a “perfect balance between generality and structure” [3].

In this general formulation, the CSP is an NP-complete problem: for example, SAT or graph 3-colorability are easily expressible in this framework. However, many problems subsumed by it are tractable, e.g., 2-SAT, Horn-SAT, or checking the consistency of a system of linear equations over  $\mathbb{Z}_p$ . A natural way to explore the complex landscape of the CSP,

justified by applications as well as theory [13], is to fix a finite domain  $A$  and a finite set of relations  $\Gamma$  on  $A$  that are allowed to appear as constraints (a *constraint language*) [25]; such fragment of the CSP is usually denoted by  $\text{CSP}(\Gamma)$ . (Sometimes, constraint languages on infinite domains, or with infinitely many relations are considered. But for simplicity, following, e.g., [3], we keep the two standard finiteness assumptions throughout the paper.)

The CSP dichotomy theorem [10, 27, 28] states that for every constraint language  $\Gamma$ ,  $\text{CSP}(\Gamma)$  is in P or NP-complete. To tame the vast landscape of constraint languages, it was immensely helpful to realize that various ad hoc “gadget” complexity reductions share a common explanation using the notion of *primitive positive (pp-) definability* (i.e., the usual first-order logic definability restricted to  $\{\exists, \wedge, =\}$ -formulas) [19, 18] and the more general notions of *pp-interpretability* and *pp-constructibility* [4]. In fact, the CSP dichotomy theorem implies that  $\text{CSP}(\Gamma)$  is NP-complete if and only if  $\Gamma$  pp-constructs *every* finite constraint language. Moreover, pp-definability and its generalizations have an external characterization via so-called *polymorphisms* (“multivariate homomorphisms”) [15, 7, 17]. For an introduction to the area, see [3].

Constraint languages  $\Gamma$  for which  $\text{CSP}(\Gamma)$  is solvable by a certain algorithmic approach involving computing with *compact representations* of solution sets (generalizing *bases* of vector spaces or *strong generating sets* from the Schreier-Sims algorithm for permutation groups [26]) were characterized in [6, 16] as those that have *few subpowers*, that is, the number of  $n$ -ary relations pp-definable from  $\Gamma$  is bounded by  $2^{p(n)}$  for some polynomial  $p(n)$ . This property, also called *polynomial expressiveness* [12], is equivalent to having either of the following two properties where *small* means of size bounded by a polynomial in the arity  $n$ :

- *small generating sets*, i.e., every relation pp-definable from  $\Gamma$  has a small subset that is not contained in any proper pp-definable subset,
- *small independent sets*, i.e., sets of tuples such that every tuple can be separated from the remaining tuples by a pp-formula, are small.

The equivalence of those properties was established in [6, Proposition 1.4].

In this paper, we study another measure of “smallness” of a constraint language, that we call *short pp-definitions*: every  $n$ -ary relation pp-definable from  $\Gamma$  is definable by some primitive positive formula of polynomial length. Examples include constraint languages encoding 2-SAT, or the consistency of linear systems over  $\mathbb{Z}_p$ .

A simple cardinality argument shows that a constraint language with short pp-definitions must have few subpowers. We conjecture that the converse is also true and thus the two properties are equivalent.

► **Conjecture 1.** *A constraint language has short pp-definitions, if and only if it has few subpowers.*

We remark that exponential-length pp-definitions are needed for constraint languages without few subpowers (cf. [6, Theorem 3.12]).

In Section 2 we give a formal definition of short pp-definitions, examples, and an exposition of related properties. An equivalent condition (definability by pp-formulas with polynomially many existential quantifiers) was studied in [23] for Boolean constraint languages (i.e., constraint languages on a two-element domain) under the name *polynomial closedness*. It can be easily seen that Conjecture 1 is true in the Boolean case, as stated in [23, Corollary 1].

In Section 4 we prove Theorem 21, the main result of our paper, which confirms the conjecture for a substantial class of constraint languages, namely those whose *polymorphism algebra* generates a *residually finite variety*. This, in particular, implies that Conjecture 1 also holds for constraint languages on three-element domains (Corollary 23). The proof

proceeds by first reducing to the case of *critical* relations (see [29]), and then employing structural theorems from universal algebra, in a similar fashion as in [9]. We explain some necessary background from universal algebra in Section 3.

Apart from being a natural property in constraint satisfaction, in Section 5 we argue that short pp-definitions have further applications in the study of the *subpower membership problem*  $\text{SMP}(\mathbf{A})$  over an algebraic structure  $\mathbf{A}$  (see [21, 24, 9]), i.e., the problem of deciding whether a given list of tuples over  $\mathbf{A}$  generates another tuple over  $\mathbf{A}$ . For algebras  $\mathbf{A}$  with few subpowers, *compact representations* provide a natural certificate for “Yes”-instances; this was used to show that  $\text{SMP}(\mathbf{A}) \in \text{NP}$  [20]. We argue that short pp-definitions can serve as a natural certificate for “No”-instances. In particular, we show how short pp-definitions impose an upper complexity bound of co-NP on the subpower membership problem. Thus, Conjecture 1 would imply that  $\text{SMP}(\mathbf{A}) \in \text{NP} \cap \text{co-NP}$ , for all algebras  $\mathbf{A}$  with few subpowers.

## 2 Preliminaries

Let  $A$  be a finite set. An  $n$ -ary relation  $R$  on  $A$  is any subset of  $n$ -tuples  $R \subseteq A^n$ . By a *constraint language* on  $A$  (its *domain*) we mean any finite set  $\Gamma = \{R_1, \dots, R_m\}$  of relations on  $A$  of arbitrary, but finite arities.

A relation  $R$  is *primitive positive definable* (or *pp-definable* for short) from  $\Gamma$ , if it is definable in first-order logic by a formula using only the relations from  $\Gamma$ , the equality relation, conjunction, and existential quantification. Equivalently, in prenex normal form:

$$R(x_1, \dots, x_n) \leftrightarrow \exists y_1 \exists y_2 \dots \exists y_k \bigwedge_{i \in \{1, \dots, C\}} S_i(z_1^i, \dots, z_{r_i}^i)$$

where  $S_i$  is an  $r_i$ -ary relational symbol representing a relation from  $\Gamma \cup \{=_A\}$  and  $z_j^i \in \{x_1, \dots, x_n, y_1, \dots, y_k\}$ . We remark that  $\text{CSP}(\Gamma)$  can be defined as the problem of deciding the primitive positive fragment of the first-order theory of  $\Gamma$ .

The set of all relations pp-definable from  $\Gamma$ , denoted by  $\langle \Gamma \rangle$ , forms a *relational clone*, i.e., a set of relations on  $A$  containing the identity relation and closed under intersections, direct products, projections, and permutations of coordinates. Any constraint language  $\Gamma$  that generates a relational clone  $\mathcal{R} = \langle \Gamma \rangle$  is called a *relational basis* of  $\mathcal{R}$ . Let us denote by  $\langle \Gamma \rangle_n$  the set of all  $n$ -ary relations pp-definable from  $\Gamma$ .

The usefulness of pp-definability for the CSPs is summarized in the following theorem going back to [19]. For a modern exposition as well as generalizations see [3] and [4].

► **Theorem 2.** *If  $\Gamma$  and  $\Delta$  are constraint languages such that  $\Delta \subseteq \langle \Gamma \rangle$ , then there is a logspace reduction from  $\text{CSP}(\Delta)$  to  $\text{CSP}(\Gamma)$ .*

In order to put Conjecture 1 on a firm footing, let us next formally define the notion of *few subpowers* [6, 16] and the central concept of the present paper, *short pp-definitions*.

► **Definition 3.** *A constraint language  $\Gamma$  has few subpowers, if there exists a polynomial  $p(n)$  such that  $|\langle \Gamma \rangle_n| \leq 2^{p(n)}$  for all  $n > 0$ .*

► **Definition 4.** *Let  $\Gamma$  be a constraint language. We say that  $\Gamma$  has:*

- pp-definitions of length [at most]  $f(n)$ , if for every  $n > 0$  and every  $R \in \langle \Gamma \rangle_n$ ,  $R$  is definable from  $\Gamma$  by a primitive positive formula  $\phi$  of length  $|\phi| \leq f(n)$ .
- short pp-definitions if  $\Gamma$  has pp-definitions of length  $p(n)$  for some polynomial  $p(n)$ .

Here we consider the length  $|\phi|$  to be simply the number of symbols in some syntactical representation of the formula. In the definition of *short pp-definitions*, one could alternatively bound the number of atomic formulas in  $\phi$ , or the number  $k$  of existentially quantified

variables by a polynomial  $p(n)$ . (The latter option was used in [23] in the notion of *polynomial closedness* of  $\langle \Gamma \rangle$ .) Note that, since  $\Gamma$  is fixed and finite, these three possible definitions coincide.

Clearly, having few subpowers is a property of the relational clone  $\langle \Gamma \rangle$ , independent of the choice of the relational basis  $\Gamma$ . We observe that the same is true for short pp-definitions. In fact, up to multiplication by a scalar, this is true for any bound  $f(n)$  on the length of pp-definitions:

► **Lemma 5.** *Let  $\Gamma$  and  $\Delta$  be constraint languages such that  $\langle \Gamma \rangle = \langle \Delta \rangle$ . If  $\Gamma$  has pp-definitions of length  $f(n)$ , then  $\Delta$  has pp-definitions of length  $O(f(n))$ . In particular,  $\Gamma$  has short pp-definitions if and only if  $\Delta$  does.*

**Proof.** Let  $R \in \langle \Delta \rangle_n = \langle \Gamma \rangle_n$ . By assumption,  $R$  has a pp-definition  $\phi_R$  from  $\Gamma$  of length at most  $f(n)$ . Since  $\Gamma \subseteq \langle \Gamma \rangle = \langle \Delta \rangle$ , every relation  $S \in \Gamma$  can be defined from  $\Delta$  by some pp-formula  $\psi_S$ . Let  $c = \max\{|\psi_S| : S \in \Gamma\}$ . If we replace every atomic formula  $S_i(z_1^i, \dots, z_{r_i}^i)$  in  $\phi_R$  by a suitable variant of the formula  $\psi_{S_i}$ , we obtain a pp-definition of  $R$  from  $\Delta$  of length at most  $c \cdot f(n)$ . ◀

Central to the algebraic approach to the CSP is the idea that constraint languages up to pp-definability (that is, relational clones) can be characterized by their *polymorphisms*. Following the terminology from [3], a  $k$ -ary operation  $f : A^k \rightarrow A$  is *compatible* with an  $n$ -ary relation  $R \subseteq A^n$ , and  $R$  is *invariant* under  $f$ , if  $f$  applied coordinate-wise to any  $k$   $n$ -tuples from  $R$  yields an  $n$ -tuple that is also in  $R$ . A *polymorphism* of a constraint language  $\Gamma$  is then any function on the domain that is compatible with all relations from  $\Gamma$ . As is usual, we write  $\text{Pol}(\Gamma)$  to denote the set of all polymorphisms of  $\Gamma$  and, similarly,  $\text{Inv}(\mathcal{F})$  for the set of all relations on the domain  $A$  invariant under a set of operations  $\mathcal{F}$ . The key connection between polymorphisms and pp-definability can be summarized in the following lemma.

► **Lemma 6** ([15, 7, 17]). *For any constraint language  $\Gamma$ ,  $\langle \Gamma \rangle = \text{Inv}(\text{Pol}(\Gamma))$ .*

Few subpowers can be characterized by the existence of an *edge polymorphism*, that is, a polymorphism satisfying certain algebraic identities (under all evaluations of variables in the domain). Such characterizations are typical in the algebraic approach to the CSP.

► **Theorem 7** ([6, 16]). *A constraint language  $\Gamma$  has few subpowers, if and only if for some  $k \geq 2$  there exists a  $k$ -edge polymorphism  $e \in \text{Pol}(\Gamma)$ , that is, a  $(k+1)$ -ary operation  $e : A^{k+1} \rightarrow A$  satisfying the following identities:*

$$\begin{aligned} e(y, y, x, x, x, \dots, x) &\approx x \\ e(y, x, y, x, x, \dots, x) &\approx x \\ e(x, x, x, y, x, \dots, x) &\approx x \\ e(x, x, x, x, y, \dots, x) &\approx x \\ &\vdots \\ e(x, x, x, x, x, \dots, y) &\approx x \end{aligned}$$

In this case  $\text{CSP}(\Gamma) \in \text{P}$ .

The following two special cases were important intermediate steps towards Theorem 7 (as well as the CSP dichotomy theorem) and, in particular, cover all *Boolean* (i.e., where  $A = \{0, 1\}$ ) constraint languages with few subpowers:

- A *Mal'tsev* operation is a ternary operation  $m: A^3 \rightarrow A$  satisfying the identities  $m(x, x, y) \approx m(y, x, x) \approx y$ . If  $m$  is a Mal'tsev operation, then  $e(x_1, x_2, x_3) = m(x_2, x_1, x_3)$  is a 2-edge term.
- A *near-unanimity* operation (of arity  $k \geq 3$ ) is an operation  $t$  satisfying the following identities:

$$x \approx t(y, x, \dots, x) \approx t(x, y, x, \dots, x) \approx t(x, \dots, x, y, x) \approx t(x, \dots, x, y)$$

Then  $e(x_1, x_2, \dots, x_{k+1}) = t(x_2, \dots, x_{k+1})$  is a  $k$ -edge term. A ternary near-unanimity is called a *majority*.

Let us now give two examples of constraint languages with short pp-definitions; Example 8 is invariant under a Mal'tsev operation, while Example 11 has a majority polymorphism.

► **Example 8.** The problem of checking consistency of a linear system over  $\mathbb{Z}_2$  can be encoded as CSP( $\Gamma$ ) for  $\Gamma = \{R_{\text{Lin}}, C_0, C_1\}$  where  $R_{\text{Lin}} = \{(0, 0, 0), (0, 1, 1), (1, 0, 1), (1, 1, 0)\}$  encodes “ $x_1 + x_2 = x_3$ ”,  $C_0 = \{0\}$ , and  $C_1 = \{1\}$ . Indeed, any linear equation  $x_1 + x_2 + \dots + x_n = b$  can be encoded using auxiliary variables  $y_1, \dots, y_{n-1}$  and three-variable equations

$$x_1 + x_2 = y_1, \quad y_1 + x_3 = y_2, \quad \dots, \quad y_{n-2} + x_n = y_{n-1}, \quad y_{n-1} = b$$

thus providing a pp-definition:

$$\exists y_1 \dots \exists y_{n-1} (R_{\text{Lin}}(x_1, x_2, y_1) \wedge \dots \wedge R_{\text{Lin}}(y_{n-2}, x_n, y_{n-1}) \wedge C_b(y_{n-1}))$$

The relational clone  $\langle \Gamma \rangle$  then consists of all affine subspaces of  $\mathbb{Z}_2^n$ , for any  $n > 0$ . The relations from the relational basis  $\Gamma$  are all affine and it is easy to see that relations pp-definable from affine subspaces are also affine subspaces. On the other hand, an affine subspace  $R$  of  $\mathbb{Z}_2^n$  can be described by at most  $n$  linear equations and the conjunction of the corresponding pp-formulas clearly defines  $R$ . The length of this conjunction is in  $O(n^2)$  and therefore  $\Gamma$  has not only few subpowers but also short (quadratic) pp-definitions.  $\Gamma$  is arguably one of the easiest examples of a constraint language with a Mal'tsev polymorphism; in fact  $\langle \Gamma \rangle = \text{Pol}(\{m\})$  for the Mal'tsev operation  $m(x, y, z) = x + y + z \pmod 2$ .

While Conjecture 1 is open even under the presence of a Mal'tsev polymorphism, the above example can be generalized to a *central* Mal'tsev polymorphism, that is, one which is compatible with its own function graph, i.e., the 4-ary relation  $R = \{(x, y, z, m(x, y, z)) \mid x, y, z \in A\}$ . (The reason is that the *polymorphism algebra* is then *affine*, i.e., polynomially equivalent to a module.)

For the second example, we need the following characterization of relations invariant under near-unanimity operations:

► **Theorem 9** ([2]). *If a relation  $R \subseteq A^n$  is invariant under a  $(k + 1)$ -ary near-unanimity operation  $t$ , then it is pp-definable from its projections to at most  $k$ -ary subsets of coordinates by the following formula:*

$$R(x_1, \dots, x_n) \leftrightarrow \bigwedge_{\substack{I = \{i_1, \dots, i_k\} \\ I \subseteq [n], |I| \leq k}} \text{proj}_I R(x_{i_1}, \dots, x_{i_k})$$

Here, for a relation  $R \subseteq A^n$  and a subset of coordinates  $I \subseteq \{1, 2, \dots, n\}$ , the *projection* of  $R$  to  $I = \{i_1, i_2, \dots, i_k\}$  (where  $i_1 < i_2 < \dots < i_k$ ) is the  $k$ -ary relation  $\text{proj}_I R = \{(a_{i_1}, \dots, a_{i_k}) \mid (a_1, \dots, a_n) \in R\} \in \langle \Gamma \rangle$ . Thus, if a constraint language  $\Gamma$  has a  $(k + 1)$ -ary near-unanimity polymorphism  $t$ , then every relation  $R \in \langle \Gamma \rangle_n$  can be written as the conjunction of  $\binom{n}{k}$  relations of arity  $k$  (for  $n \geq k$ ). As a direct corollary of Theorem 9 we obtain:

► **Corollary 10.** *Let  $\Gamma$  be a constraint language with a  $(k + 1)$ -ary near-unanimity polymorphism. Then  $\Gamma$  has pp-definitions of length  $O(n^k)$ .*

► **Example 11.** Corollary 10 can be exemplified by 2-SAT. The standard way to encode 2-SAT as a CSP is by using the constraint language  $\Gamma_{2\text{-SAT}} = \{R_{00}, R_{01}, R_{10}, R_{11}\}$  where  $R_{ij} = \{0, 1\}^2 \setminus \{(i, j)\}$  represent each clause type (see [3, Example 2.2]). It is well known that the relations pp-definable from  $\Gamma_{2\text{-SAT}}$  are exactly those invariant under the majority operation, i.e., the unique 3-ary near-unanimity operation on  $\{0, 1\}$ . By Corollary 10,  $\Gamma_{2\text{-SAT}}$  has quadratic pp-definitions.

► **Theorem 12** (see [23, Corollary 1]). *Let  $\Gamma$  be a Boolean constraint language with few subpowers, then  $\Gamma$  has quadratic pp-definitions. Thus Conjecture 1 holds for constraint languages  $\Gamma$  over Boolean domains.*

**Proof.** By the classification of Post's lattice, every Boolean constraint language with few subpowers has either the Mal'tsev polymorphism  $x + y + z \bmod 2$  or the (unique) majority polymorphism (this was observed, e.g., in [12]). In both cases, we obtain quadratic pp-definitions, as in Examples 8 and 11. ◀

We remark that, in general, the situation is much more complicated than in Theorem 12: Already in the 3-element case there are constraint languages that have few subpowers, but neither a Mal'tsev, nor a near-unanimity polymorphism (e.g. [8, Examples 2.1.1 and 2.1.2]).

### 3 Universal Algebra

In the following, we are going to introduce some basic notions from universal algebra that will allow us to state our main result (Theorem 21) in its full generality. In Section 3.1 we furthermore discuss how short pp-definitions behave with respect to basic algebraic constructions. For more background in universal algebra we refer to the textbooks [5, 11].

An *algebra*  $\mathbf{A} = (A; (f_i)_{i \in I}^{\mathbf{A}})$  is a first-order structure in a purely functional language  $(f_i)_{i \in I}$  (where each symbol  $f_i$  has an associated *arity*). We say  $\mathbf{A}$  is finite if its domain  $A$  is finite. A *subalgebra*  $\mathbf{B} = (B; (f_i)_{i \in I}^{\mathbf{B}})$  of an algebra  $\mathbf{A} = (A; (f_i)_{i \in I}^{\mathbf{A}})$  (denoted  $\mathbf{B} \leq \mathbf{A}$ ) is an algebra obtained by restricting all *basic operations*  $f_i^{\mathbf{A}}$  to an invariant subset  $B \subseteq A$ . The *product*  $\prod_{i \in I} \mathbf{A}_i$  of a family of algebras  $(\mathbf{A}_i)_{i \in I}$  in the same language is defined as the algebra with domain  $\prod_{i \in I} A_i$ , whose basic operations are defined coordinate-wise. A *homomorphism*  $h: \mathbf{A} \rightarrow \mathbf{B}$  between algebras is defined as a map that preserves all basic operations, i.e.,  $h(f_i^{\mathbf{A}}(a_1, \dots, a_n)) = f_i^{\mathbf{B}}(h(a_1), \dots, h(a_n))$  for all  $i \in I$ . The *kernel* of every homomorphism (i.e., the relation defined by  $(x, y) \in \theta \leftrightarrow h(x) = h(y)$ ) is a *congruence*, that is, an equivalence relation invariant under  $\mathbf{A}$ . Conversely, for every congruence  $\alpha$  of  $\mathbf{A}$ , it is easy to see, that one can construct a *quotient algebra*  $\mathbf{A}/\alpha$ , as the homomorphic image of the quotient mapping  $x \mapsto x/\alpha$ . Under the inclusion order, the set of all congruence of an algebra  $\mathbf{A}$  forms the *congruence lattice*  $\text{Con}(\mathbf{A})$ . The minimal element of this lattice is always the trivial congruence  $0_{\mathbf{A}} = \{(x, x) \mid x \in A\}$ . An algebra  $\mathbf{A}$  is called *subdirectly irreducible* if  $0_{\mathbf{A}}$  has a unique cover in  $\text{Con}(\mathbf{A})$ , i.e., there is a unique minimal non-trivial congruence.

By H, S, and P we denote the closure of a set of algebras under homomorphic images, subalgebras, and products respectively. It is well-known that the closure of any set of algebras under HSP is a *variety*, i.e., a class of algebras defined by a set of identities (by Birkhoff's theorem, see, e.g., [5]). A variety is called *residually finite* if (up to isomorphism) it only contains finitely many subdirectly irreducible algebras, all of which are finite.

### 3.1 Algebras with short pp-definitions

If we assign a function symbol to every element of  $\text{Pol}(\Gamma)$ , for a constraint language  $\Gamma$ , then we can also regard  $\text{Pol}(\Gamma)$  as an algebra (the *polymorphism algebra* of  $\Gamma$ ). On the other hand, for every algebra  $\mathbf{A}$ , its invariant relations  $\text{Inv}(\mathbf{A})$  form a relational clone. Thus, it makes sense to say that a finite algebra  $\mathbf{A}$  has *few subpowers* if  $\text{Inv}(\mathbf{A})$  has few subpowers.

Note that a relation  $R$  is invariant under  $\mathbf{A}$  if and only if  $R \leq \mathbf{A}^n$  for some  $n$ , i.e.,  $R$  is a subalgebra of some power of  $\mathbf{A}$  (such  $R$  is also called a *subpower of  $\mathbf{A}$* , which motivates the notion of having “few subpowers”).

By a (non-constructive) proof of Aichinger, Mayr and McKenzie [1], for every algebra  $\mathbf{A}$  with few subpowers there exists a finite relational basis  $\Gamma$  of  $\text{Inv}(\mathbf{A})$ , i.e., a constraint language, such that  $\text{Inv}(\mathbf{A}) = \langle \Gamma \rangle$  (for general algebras  $\mathbf{A}$  this is not the case). Thus, it makes sense to define the following:

► **Definition 13.** *An algebra  $\mathbf{A}$  has pp-definitions of length  $f(n)$ , if there exists a constraint language  $\Gamma$  such that  $\text{Inv}(\mathbf{A}) = \langle \Gamma \rangle$ , and  $\Gamma$  has pp-definitions of length  $f(n)$ . An algebra  $\mathbf{A}$  has short pp-definitions, if it has pp-definitions of length  $p(n)$ , for some polynomial  $p$ .*

Note that, by Lemma 5, having short pp-definitions is independent of the choice of the relational basis  $\Gamma$ . By the following lemma, having short pp-definitions is also preserved under forming finite powers of algebras. The proof is provided in Section A.1 in the Appendix.

► **Lemma 14.** *Let  $\mathbf{A}$  be an algebra and  $\mathbf{B} = \mathbf{A}^k$  for some  $k > 1$ . Then  $\mathbf{B}$  has pp-definitions of length  $O(f(n))$  if and only if  $\mathbf{A}$  has pp-definitions of length  $O(f(\lceil \frac{n}{k} \rceil))$ .*

In the following, we will also work with multi-sorted relations, as this provides a natural framework for our proof in Section 4. More specifically, if  $\mathcal{A}$  is a finite set of finite algebras of the same language, then it still makes to study the set of all invariant relations  $R \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  for  $\mathbf{A}_1, \dots, \mathbf{A}_n \in \mathcal{A}$ . In particular, the set of all such relations will still form a relational clone (where variables have possibly different domains  $A_i$ ). If, furthermore, all elements of  $\mathcal{A}$  have few subpowers, the finite relational basis result of Aichinger, Mayr and McKenzie [1] still applies, and it makes sense to define the property of having short pp-definitions for  $\mathcal{A}$  (we refrain from giving technical details here). We remark that studying constraint languages in which the variables can come from different domains is a fairly standard viewpoint in CSP; it was, for example, used in the proof of the CSP dichotomy theorem by Zhuk [28].

This multisorted approach allows us to consider relations over the closure  $\text{HS}(\mathbf{A})$  of  $\mathbf{A}$  under homomorphic images and subalgebras instead of only  $\mathbf{A}$  itself. This is justified by the following lemma; the proof is provided in Section A.2 of the Appendix.

► **Lemma 15.** *An algebra  $\mathbf{A}$  has pp-definitions of length  $O(f(n))$ , if and only if the family of algebras  $\text{HS}(\mathbf{A})$  has (multisorted) pp-definitions of length  $O(f(n))$ .*

In particular, Lemma 15 implies that  $\mathbf{A}$  has short pp-definitions, if and only if  $\text{HS}(\mathbf{A})$  has (multisorted) short pp-definitions. We remark that Lemma 15 does *not* imply that any *single* algebra  $\mathbf{B} \in \text{HS}(\mathbf{A})$  has short pp-definitions if  $\mathbf{A}$  does. In fact, we do not know if this is true (see Question 25 in the Discussion section).

## 4 Main result

In this section, we prove the main result of our paper. We first need to introduce some standard definitions that found prominent use in the universal algebraic approach to constraint satisfaction before (see, e.g., [8, Chapter 2]).

A relation  $R \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  is called *critical* if it is  $\wedge$ -irreducible, i.e., it cannot be written as the intersection of strictly bigger relations  $Q \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$ , and it has *no dummy variables*, i.e., it depends on all of its inputs.

A binary relation  $R \subseteq A \times B$  has the *parallelogram property* if  $(a, c), (a, d), (b, c) \in R$  implies  $(b, d) \in R$ . An  $n$ -ary relation  $R \subseteq A_1 \times A_2 \times \dots \times A_n$  has the *parallelogram property*, if for all subsets  $I \subset \{1, 2, \dots, n\}$  it has the parallelogram property when considered as a binary relation  $R \subseteq (\prod_{i \in I} A_i) \times (\prod_{j \notin I} A_j)$ . The *signature* of  $R$  is the following set of triples:

$$\text{Sig}(R) = \{(i, a, b) \in [n] \times A_i^2 \mid \exists \bar{x}, \bar{y} \in R \text{ with } x_j = y_j \text{ for } j = 1, \dots, i-1 \text{ and } x_i = a, y_i = b\}$$

In the proof of Lemma 17 below, we will need the following straightforward observation.

► **Observation 16.** *If  $R$  has the parallelogram property,  $R \subseteq S$ , and  $\text{Sig}(R) = \text{Sig}(S)$ , then  $R = S$ .*

Using these notions, we can reduce the problem of finding short pp-definitions to critical relations with the parallelogram property:

► **Lemma 17.** *Let  $\mathbf{A}$  be an algebra with a  $k$ -edge term. If all the critical relations  $R \leq \mathbf{A}^n$  with parallelogram property have pp-definitions of length at most  $f(n)$ , then  $\mathbf{A}$  has pp-definitions of length  $O(n^k + n \cdot f(n))$ .*

**Proof.** Clearly, every relation  $R \leq \mathbf{A}^n$  is the intersection of the  $\wedge$ -irreducible relations above it (in the inclusion order), thus it can be written as a conjunction of critical relations. Hence we only need to give an upper bound on the number of such critical relations.

By [20, Theorem 3.6], the presence of a  $k$ -edge term implies that every critical relation is either of arity  $\leq k$ , or has the parallelogram property. This further implies (see, e.g., [8, Corollary 2.3.5.]) that  $R = R' \wedge \bigwedge_{I \subseteq [n], |I| \leq k} \text{proj}_I(R)$ , where  $R' \leq \mathbf{A}^n$  is the minimal invariant relation containing  $R$  and having the parallelogram property. Clearly,  $\bigwedge_{I \subseteq [n], |I| \leq k} \text{proj}_I(R)$  can be written as the conjunction of at most  $c \cdot n^k$  many critical relations, for some  $c > 0$ .

The relation  $R'$ , if not already  $\wedge$ -irreducible itself, is given by the intersection of all  $\wedge$ -irreducible relations  $S > R'$  that have the parallelogram property. Denote by  $\mathcal{S}$  the set of all such relations. For every  $(i, a, b) \notin \text{Sig}(R')$  where  $a \in \text{proj}_i R'$  choose  $S_{(i,a,b)} \in \mathcal{S}$  such that  $(i, a, b) \notin \text{Sig}(S_{(i,a,b)})$ . Then by Observation 16,  $R' = \bigcap_{(i,a,b) \notin \text{Sig}(R')} S_{(i,a,b)}$  which is an intersection of at most  $n \cdot |A|^2$   $\wedge$ -irreducible relations. (To see that such  $S_{(i,a,b)}$  exists, let  $\bar{x} \in R'$  be such that  $x_i = a$  and let  $\bar{y}$  be such that  $y_i = b, y_j = x_j$  for  $j \neq i$ . We can choose  $S_{(i,a,b)}$  to be a maximal relation containing  $R$  but omitting  $\bar{y}$ .)

Consequently,  $R'$  can be defined as a conjunction of at most  $n \cdot |A|^2$  many critical relations with the parallelogram property which concludes the proof. ◀

We remark that an analogous statement to Lemma 17 also holds for multisorted relations  $R \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$ , such that the sorts  $\mathbf{A}_i$  come from a finite set of algebras that have a common  $k$ -edge term. In particular, this is the case for  $\mathbf{A}_i \in \text{HS}(\mathbf{A})$ , if  $\mathbf{A}$  has a  $k$ -edge term (cf. Lemma 15).

When dealing with multisorted relations  $R$  over  $\text{HS}(\mathbf{A})$ , we can furthermore always restrict the domain  $\mathbf{A}_i$  of the  $i$ -th variable of a relation  $R$  to its projection  $\text{proj}_i(R) \leq \mathbf{A}_i$ . So, without loss of generality, we can assume that  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  is *subdirect*, i.e., its projection to every coordinate  $i$  is the full domain  $\mathbf{A}_i$ .

For a subdirect relation  $R \leq_{sd} \mathbf{B} \times \mathbf{C}$  with the parallelogram property, let us define the *linkedness congruence*  $\theta_B$  on  $\mathbf{B}$  by  $(x, y) \in \theta_B \leftrightarrow (\exists c \in C)(R(x, c) \wedge R(y, c))$ . For a general relation  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with the parallelogram property, and any proper subset  $I \subset [n]$

of coordinates, we define the *linkedness congruence*  $\theta_I$  on  $\text{proj}_I(R)$  analogously, where we consider  $R$  as a binary relation between  $\text{proj}_I(R)$  and  $\text{proj}_{[n]\setminus I}(R)$  (we write  $\theta_i$  instead of  $\theta_{\{i\}}$ ). It follows from the parallelogram property that  $\theta_I$  is indeed a congruence of  $\text{proj}_I(R)$ . A subdirect relation  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  is called *reduced* if every tuple  $(a_1, \dots, a_n) \in R$  is already uniquely determined by  $(a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_n)$ , for any coordinate  $i$ ; in other words,  $\theta_i$  is trivial, for every  $i = 1, \dots, n$ . By the following lemma, we can reduce the quest for short pp-definitions to *reduced*, subdirect, critical relations with the parallelogram property:

► **Lemma 18.** *Let  $\mathbf{A}$  be an algebra with a  $k$ -edge term. Assume that all relations  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with  $\mathbf{A}_i \in \text{HS}(\mathbf{A})$  that are reduced, critical, and have the parallelogram property, have (multisorted) pp-definitions of length at most  $f(n)$ . Then  $\mathbf{A}$  has pp-definitions of length  $O(n^k + n \cdot f(n))$ .*

**Proof.** We first prove that we can pp-define all critical relations  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with  $\mathbf{A}_i \in \text{HS}(\mathbf{A})$  that have the parallelogram property (but are not necessarily reduced), by pp-definitions of length at most  $O(f(n))$ . Given such a relation, let us consider the linkedness congruence  $\theta_i \in \text{Con}(\mathbf{A}_i)$  for every coordinate  $i$ . Then let us define the quotient  $R' = R/(\theta_1, \dots, \theta_n)$ . It is not hard to see that  $R' \leq_{sd} \mathbf{A}_1/\theta_1 \times \dots \times \mathbf{A}_n/\theta_n$ , is also critical, and has the parallelogram property. Furthermore, by definition of  $\theta_i$ ,  $R'$  is reduced.

Since  $R$  has the parallelogram property, it is equal to the full preimage of  $R'$  under the quotient map  $(x_1, \dots, x_n) \mapsto (x_1/\theta_1, \dots, x_n/\theta_n)$ . Thus, every pp-definition  $\phi'(x_1, \dots, x_n)$  of  $R'$  gives rise to the pp-definition  $\exists y_1, \dots, y_n (\bigwedge_{i=1}^n (x_i/\theta_i = y_i) \wedge \phi'(y_1, \dots, y_n))$  of length  $O(f(n))$  which defines  $R$ ; this proves our claim. The statement of the lemma then follows directly from (the multi-sorted version of) Lemma 17, and Lemma 15. ◀

Any relation  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  as in Lemma 18 comes with several nice properties (in algebraic terms, it is a *graph of a joint similarity* between the algebras  $\mathbf{A}_i$ , cf. [8, Section 2.3.1]). We are mainly going to need the following property in Lemma 19, respectively its generalization in Lemma 20:

► **Lemma 19** ([20, Lemma 2.4]). *Let  $\mathbf{A}_1, \dots, \mathbf{A}_n$  be algebras with few subpowers, and let  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  be a reduced, critical relation with the parallelogram property. Then every  $\mathbf{A}_i$  is subdirectly irreducible.*

► **Lemma 20.** *Let  $\mathbf{A}_1, \dots, \mathbf{A}_n$  be algebras with few subpowers, and let  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  be a critical relation with the parallelogram property. For  $I \subset [n]$ , let  $\theta_I$  be the linkedness congruence on  $\text{proj}_I(R)$  with respect to  $R$ . Then  $\theta_I$  is  $\wedge$ -irreducible.*

**Proof.** Since  $R$  is  $\wedge$ -irreducible, there is a unique cover  $R^* > R$  in the lattice of all subalgebras of  $\mathbf{A}_1 \times \dots \times \mathbf{A}_n$ . A tuple  $\bar{a} = (a_1, \dots, a_n) \in R^* \setminus R$  is called a *key tuple* of  $R$  (cf. [29]). It follows from the criticality of  $R$  that for every  $j = 1, \dots, n$ , there is a tuple  $(a_1, \dots, b_j, \dots, a_n) \in R$  that only differs from  $\bar{a}$  at position  $j$ .

For simplicity, let us assume that  $I = \{1, 2, \dots, i\}$  with  $i < n$ . Then, the linkedness-congruence  $\theta_I$  has an equivalence class containing all elements of the form  $(a_1, \dots, b_j, \dots, a_i)$  for  $j = 1, \dots, i$ . Note that  $(a_1, a_2, \dots, a_i) \in \text{proj}_I(R)$  is not an element of this class.

To prove that  $\theta_I$  is  $\wedge$ -irreducible, let  $\theta'$  be a congruence strictly above  $\theta_I$ . We claim that then  $\theta'$  must also contain the pair  $((a_1, a_2, \dots, a_i), (b_1, a_2, \dots, a_i))$ . To prove the claim, let us define  $R'(\bar{x}) = \exists \bar{y}_I (\theta'(\bar{x}_I, \bar{y}_I) \wedge R(\bar{y}_I, \bar{x}_{[n]\setminus I}))$ . As  $R'$  properly contains  $R$ , it also must contain its cover  $R^*$ , and thus the key tuple  $(a_1, a_2, \dots, a_n)$ . Moreover, the linkedness congruence of  $R'$  on coordinates  $I$  is equal to  $\theta'$ , thus  $\theta'$  must contain the pair  $((a_1, a_2, \dots, a_i), (b_1, a_2, \dots, a_i))$ . So  $\theta_I$  has a unique cover  $\theta_I^*$ , which is the congruence generated by  $\theta_I \cup \{((a_1, a_2, \dots, a_i), (b_1, a_2, \dots, a_i))\}$ ; this finishes the proof. ◀

We are now ready to prove our main result:

► **Theorem 21.** *Let  $\mathbf{A}$  be an algebra with a  $k$ -edge term, and assume that  $\text{HSP}(\mathbf{A})$  is residually finite. Then  $\mathbf{A}$  has pp-definitions of length  $O(n^k)$ .*

**Proof.** Let  $\mathcal{V}_{SI}$  consist of all subdirectly irreducible elements of  $\text{HSP}(\mathbf{A})$ . Since  $\text{HSP}(\mathbf{A})$  is residually finite,  $\mathcal{V}_{SI}$  contains up to isomorphism only finitely many algebras, all of which are finite. In particular  $\mathcal{V}_{SI}$  is a subset of  $\text{HS}(\mathbf{A}^l)$ , for some finite power  $l$ .

By Lemma 14, it is enough to prove pp-definitions of length  $O(n^k)$  for  $\mathbf{A}^l$ . By Lemma 18, it suffices to prove that every reduced, critical relation  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with  $\mathbf{A}_i \in \text{HS}(\mathbf{A}^l)$  that has the parallelogram property, has a (multisorted) pp-definition of linear length.

Let  $\Gamma$  be the set of all at most ternary invariant relations over  $\text{HS}(\mathbf{A}^l)$ . We construct a pp-definition of  $R$  from  $\Gamma$  of length linear in  $n$ , by induction on  $n$ . For  $n \leq 3$ ,  $R$  itself is in  $\Gamma$ .

For general  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with the parallelogram property, recall the definition of the linkedness congruence  $\theta_I$ . We then define the algebra  $\mathbf{A}_{1,2} = \text{proj}_{\{1,2\}}(R)/\theta_{\{1,2\}}$ , and the relations  $Q = \{(x_1, x_2, y_{1,2}) \in A_1 \times A_2 \times A_{1,2} \mid y_{1,2} = (x_1, x_2)/\theta_{\{1,2\}}\}$  and  $R' = \{(y_{1,2}, x_3, \dots, x_n) \mid \exists x_1, x_2 (Q(x_1, x_2, y_{1,2}) \wedge R(x_1, x_2, x_3, \dots, x_n))\}$ . Note that  $Q \leq \mathbf{A}_1 \times \mathbf{A}_2 \times \mathbf{A}_{1,2}$ , and  $R' \leq \mathbf{A}_{1,2} \times \mathbf{A}_3 \times \dots \times \mathbf{A}_n$ . Since  $R$  has the parallelogram property,  $R$  can be defined by the pp-formula  $(\exists y_{1,2} \in \mathbf{A}_{1,2}) (Q(x_1, x_2, y_{1,2}) \wedge R'(y_{1,2}, x_3, \dots, x_n))$ .

By Lemma 20,  $\theta_{\{1,2\}}$  is  $\wedge$ -irreducible. This implies that  $\mathbf{A}_{1,2}$  is subdirectly irreducible and hence an element of  $\mathcal{V}_{SI} \subseteq \text{HS}(\mathbf{A}^l)$ . In particular, this means that  $Q$  is a relation from our relational basis  $\Gamma$ . The relation  $R'$  is of arity  $n - 1$ , and thus, by induction assumption, has a pp-definition of linear length. This finishes our proof. ◀

Note that, although in the proof of Theorem 21 we found a *ternary* constraint language  $\Gamma$  defining the reduced critical relations  $R \leq_{sd} \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with parallelogram property, the same may not be true for the original algebra  $\mathbf{A}$ . An explicit bound on the maximal required arity is given by  $3l$ , where  $l$  is such that all subdirectly irreducible elements of  $\text{HSP}(\mathbf{A})$  are contained in  $\text{HS}(\mathbf{A}^l)$ . We are not aware of any better bound than the double exponential  $l \leq |A|^{|A|^{|A|+1}+1}$  [14] (see also [8, Theorem A.5.27.]).

As an immediate consequence of Theorem 21 we get that every 3-element algebra with few subpowers has short pp-definitions, confirming Conjecture 1 for the 3-element case. It is well known that few subpowers imply *congruence modularity* [6, Theorem 4.2]; thus we can use the following fact:

► **Theorem 22** ([8, Corollary A.5.31.]). *Let  $\mathbf{A}$  be an algebra on a 3-element set, such that  $\text{HSP}(\mathbf{A})$  is congruence modular. Then  $\text{HSP}(\mathbf{A})$  is residually finite.*

► **Corollary 23.** *Let  $\Gamma$  be a constraint language on a 3-element domain. Then  $\Gamma$  has short pp-definitions if and only if  $\Gamma$  has few subpowers. More precisely,  $\Gamma$  has pp-definitions of length  $O(n^k)$ , where  $k$  is the minimal number such that  $\Gamma$  has a  $k$ -edge polymorphism.*

**Proof.** Let us assume that  $\Gamma$  is a constraint language with a  $k$ -edge polymorphism, and let  $\mathbf{A} = \text{Pol}(\Gamma)$  be its polymorphism algebra. Since the existence of an edge operation implies that  $\text{HSP}(\mathbf{A})$  is congruence modular [6, Theorem 4.2], by Theorem 22,  $\text{HSP}(\mathbf{A})$  is residually finite. By Theorem 21,  $\mathbf{A}$ , and thus also  $\Gamma$ , has pp-definitions of length  $O(n^k)$ .

If  $\Gamma$  has few subpowers, then by Theorem 7, it has a  $k$ -edge polymorphism for some  $k$ . Thus  $\Gamma$  has short pp-definitions if it has few subpowers. ◀

## 5 The Subpower Membership Problem

The *Subpower Membership Problem*  $\text{SMP}(\mathbf{A})$  of a finite algebra  $\mathbf{A}$  is the computational problem in which the input consists of a list of tuples  $\bar{b}, \bar{a}_1, \dots, \bar{a}_k \in A^n$ , for arbitrary  $n \geq 1$ , and one needs to decide whether  $\bar{b}$  lies in the subalgebra  $\text{Sg}_{\mathbf{A}^n}(\bar{a}_1, \dots, \bar{a}_k)$  generated by  $\bar{a}_1, \dots, \bar{a}_k$ , i.e., in the smallest  $R \leq \mathbf{A}^n$  that contains  $\bar{a}_1, \dots, \bar{a}_k$ .

The existence of an efficient algorithm for  $\text{SMP}(\mathbf{A})$  implies that it is feasible to represent the relations in  $\text{Inv}(\mathbf{A})$  by some generating set of tuples. In particular, in the context of constraint satisfaction, it was remarked by several authors (see, e.g., [9]) that a polynomial-time algorithm for  $\text{SMP}(\mathbf{A})$  would allow us to define constraint satisfaction problems over *infinite* constraint languages  $\Gamma \subseteq \text{Inv}(\mathbf{A})$ , where the constraint relations in  $\Gamma$  are encoded by generating tuples. In [16], any algebra  $\mathbf{A}$  with  $\text{SMP}(\mathbf{A})$  in P was referred to as *polynomially evaluable*.

While there are algebras for which  $\text{SMP}(\mathbf{A})$  is EXPTIME-complete [22], it was asked in [16, Question 3] whether all algebras with few subpowers are polynomially evaluable. An affirmative answer was given for several special cases [24, 9], but the question still remains open in general. The best general upper bound on the complexity of  $\text{SMP}(\mathbf{A})$  for algebras with few subpowers is NP [9]. This bound is based on the fact that membership of an element in a relation  $R \leq \mathbf{A}^n$  can always be witnessed by a *compact representation* of  $R$ , i.e., a small, canonical generating set. The difficulty in finding *deterministic* polynomial algorithms lies in efficiently computing such compact representations of  $R$  from an arbitrary generating set.

Note that for an algebra  $\mathbf{A}$  with  $\text{Inv}(\mathbf{A}) = \langle \Gamma \rangle$ , the *non-membership* of a tuple  $\bar{b}$  in a relation  $\text{Sg}_{\mathbf{A}^n}(\bar{a}_1, \dots, \bar{a}_k)$  can be witnessed by a pp-formula  $\phi(\bar{x})$  over  $\Gamma$ , such that  $\phi$  holds for all tuples  $\bar{a}_1, \dots, \bar{a}_k$ , but not for  $\bar{b}$ .

If  $\Gamma$  has short pp-definitions, we can guess such a certificate  $\phi$  for “No”-instances of  $\text{SMP}(\mathbf{A})$ , and verify it in polynomial time. As a direct consequence of this (and the fact that short pp-definitions imply few subpowers), we obtain the following:

► **Theorem 24.** *Let  $\mathbf{A}$  be an algebra with short pp-definitions. Then  $\text{SMP}(\mathbf{A}) \in \text{NP} \cap \text{co-NP}$ .*

In particular, Conjecture 1 would imply that  $\text{SMP}(\mathbf{A}) \in \text{NP} \cap \text{co-NP}$  for every algebra  $\mathbf{A}$  with few subpowers. Note, however, that in the setting of our main result (Theorem 21), this does not provide any progress on the subpower membership problem, since it was shown in [9] that  $\text{SMP}(\mathbf{A})$  is even in P for every algebra  $\mathbf{A}$  with few subpowers that generates a residually finite variety.

## 6 Discussion

By Theorem 21, constraint languages  $\Gamma$  with few subpowers, whose polymorphism algebra generates a residually finite variety, have short pp-definitions. While this confirms Conjecture 1 for a large subclass of constraint languages, much work remains to prove the conjecture in full generality.

The condition of residual finiteness does not bear much importance in constraint satisfaction, it is mainly used in purely algebraic contexts. Important steps to connect short pp-definitions closer to the theory of constraint satisfaction would be to extend our results to specific tractability classes (such as constraint languages with Mal'tsev polymorphisms), and to show invariance under *pp-interpretations*:

► **Question 25.** *Let  $\Gamma$  and  $\Delta$  be two constraint languages, such that  $\Delta$  is pp-interpretable in  $\Gamma$  and  $\Gamma$  has short pp-definitions. Then, does  $\Delta$  also have short pp-definitions?*

Pp-interpretations are a generalization of pp-definitions, that describe certain gadget reductions between constraint languages on different domains. All standard tractability classes (including few subpowers, Mal'tsev, near-unanimity) are closed under pp-interpretations, which motivates Question 25 (note that Conjecture 1 implies a positive answer). We remark that we do not know the answer to this question even for  $\Delta$  being *pp-definable* in  $\Gamma$  (as Lemma 5 assumes *pp-interdefinability*). In the special case of *pp bi-interpretable* structures, Question 25 has a positive answer by a straightforward generalization of the proof of Lemma 5, we thank the anonymous reviewer for this observation. In algebraic terms, Question 25 asks whether for  $\mathbf{A}$  with short pp-definitions, it is the case that also every *extension* of every algebra  $\mathbf{B} \in \text{HSP}^{\text{fin}}(\mathbf{A})$  has short pp-definitions; for finite powers  $\mathbf{P}^{\text{fin}}$ , we verified the statement in Lemma 14.

As discussed in Section 5, it is also essential for progress on the Subpower Membership Problem to extend our results to algebras  $\mathbf{A}$  that do not generate residually finite varieties. While we did not present any results on this in this paper, we are aware of singular examples of such algebras with short pp-definitions (such as the 4-element algebra, described by Brady in [8, Example 2.3.2.]; short pp-definitions follow directly from his analysis).

In order to improve the complexity result of Theorem 24 and put  $\text{SMP}(\mathbf{A})$  in the class P, we would need an explicit method of efficiently computing a short pp-definition for a relation  $R = \text{Sg}_{\mathbf{A}^n}(\bar{a}_1, \dots, \bar{a}_k)$  given by its generators  $\bar{a}_1, \dots, \bar{a}_k$ . This motivates the following question:

► **Question 26.** *Let  $\Gamma$  be a constraint language with short pp-definitions. Is there a polynomial-time algorithm that computes a (short) pp-definition of a relation  $R \leq \langle \Gamma \rangle_n$ , given by a set of generators  $\bar{a}_1, \dots, \bar{a}_k$ ?*

We remark that over Boolean domains, Question 26 has a positive answer (see Examples 8 and 11).

Finally, recall that the bound from Theorem 21 is a polynomial of degree  $k$  if  $\Gamma$  has a  $k$ -edge polymorphism. It is therefore tempting to conjecture that the same degree could be enough in general for Conjecture 1. Note that the number of  $n$ -ary pp-definable relations, for  $\Gamma$  with a  $k$ -edge polymorphism, is known to be in  $2^{O(n^k)}$  [16, Theorem 3.4].

## A Omitted proofs of technical lemmata

### A.1 Proof of Lemma 14

**Proof.** It is straightforward to see that any relation  $R \subseteq B^n$  is invariant under  $\mathbf{B}$  if and only if it is invariant under  $\mathbf{A}$ , when interpreted as an  $kn$ -ary relation on  $A$ .

We are first going to prove the “only if” direction. Let  $\Delta$  be a relational basis of  $\text{Inv}(\mathbf{B})$ . By interpreting every  $m$ -ary relation  $Q \in \Delta$  as a  $km$ -ary relation  $Q' \leq \mathbf{A}^{km}$ , we obtain a relational basis  $\Delta' = \{Q' \mid Q \in \Delta\}$  of  $\text{Inv}(\mathbf{A})$ .

Let  $R \leq \mathbf{A}^n$ . By adding dummy variables, we can assume without loss of generality that  $n = k\ell$  for  $\ell = \lceil \frac{n}{k} \rceil$ . Then by assumption,  $R$  considered as an  $\ell$ -ary relation over  $B$  has a pp-definition  $\phi(x_1, \dots, x_\ell)$  from  $\Delta$  of length in  $O(f(\ell))$ . If we substitute each ( $B$ -valued) variable in  $\phi$  by a  $k$ -tuple of ( $A$ -valued) variables, and each  $\Delta$ -predicate  $Q$  in  $\phi$  by the corresponding  $\Delta'$ -predicate  $Q'$ , then we obtain a pp-definition  $\phi'$  of  $R$  of length at most  $k \cdot f(\ell) = k \cdot f(\lceil \frac{n}{k} \rceil)$ . Note further that existentially quantifying all the additionally added dummy variables adds only constantly many symbols. Thus  $\mathbf{A}$  has pp-definitions of length  $O(k \cdot f(\lceil \frac{n}{k} \rceil)) = O(f(\lceil \frac{n}{k} \rceil))$ .

Now let us prove the “if” direction. Let  $\Gamma$  be a relational basis of  $\text{Inv}(\mathbf{A})$ . Let  $e: A \rightarrow A^k$  be the map  $x \mapsto (x, \dots, x)$ . For every  $Q \in \Gamma$ , we define  $Q' = \{(e(x_1), \dots, e(x_m)) \mid (x_1, \dots, x_m) \in Q\} \leq \mathbf{B}^m$ , and we define the binary relations  $P_i = \{((x_1, \dots, x_k), e(x_i)) \mid (x_1, \dots, x_k) \in B\} \leq \mathbf{B}^2$ , for  $i = 1, \dots, k$ . We construct the relational basis of  $\text{Inv}(\mathbf{B})$  as  $\Gamma' = \{Q' \mid Q \in \Gamma\} \cup \{P_1, \dots, P_k\}$ .

Let  $R' \leq \mathbf{B}^n$  and let  $R \leq \mathbf{A}^{kn}$  be the relation  $R'$  considered as a  $kn$ -ary relation over  $A$ . By assumption, there exists a pp-definition  $\phi(x_1, \dots, x_{nk})$  of  $R \leq \mathbf{A}^{kn}$  over  $\Gamma$  of length in  $O(f(\lceil \frac{kn}{k} \rceil)) = O(f(n))$ . Let  $z_1, \dots, z_\ell$  be its existentially quantified variables. Let us then define  $\phi'(y_1, y_2, \dots, y_n)$  as a pp-formula over  $\Gamma'$  with existentially quantified variables  $x'_1, \dots, x'_{nk}, z'_1, \dots, z'_\ell$  and predicates  $P_i(y_j, x'_{(j-1)(k+i)})$  for all  $i \in [k], j \in [n]$ , as well as  $Q'(u'_1, \dots, u'_m)$  for every predicate  $Q(u_1, \dots, u_m)$  in  $\phi$  with  $u_i \in \{x_1, \dots, x_{nk}, z_1, \dots, z_\ell\}$ . It is easy to check that  $\phi'$  defines  $R' \leq \mathbf{B}^n$  over  $\Gamma'$ . Clearly, the length of  $\phi'$  is in  $O(f(n))$ . ◀

### A.2 Proof of Lemma 15

**Proof.** Let  $\Gamma$  be a relational basis of  $\text{Inv}(\mathbf{A})$ , and let  $R \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with  $\mathbf{A}_i \in \text{HS}(\mathbf{A})$ . So  $\mathbf{A}_i = h_i(\mathbf{S}_i)$  for a subalgebra  $\mathbf{S}_i \leq \mathbf{A}$  and a homomorphism  $h_i: \mathbf{S}_i \rightarrow \mathbf{A}_i$ . Note that the graph of this homomorphism  $G_{h_i} = \{(a, h_i(a)) : a \in \mathbf{S}_i\} \leq \mathbf{S}_i \times \mathbf{A}_i$  is an invariant relation. We define  $\Gamma'$  to be the union of  $\Gamma$  and all binary relations  $G_h$ . It is not hard to see that  $R' = \{(a_1, \dots, a_n) \in \mathbf{S}_1 \times \dots \times \mathbf{S}_n \mid (h_1(a_1), \dots, h_n(a_n)) \in R\}$  is invariant under  $\mathbf{A}$ . By assumption,  $R'$  has a pp-definition  $\phi'(x_1, \dots, x_n)$  of length in  $O(f(n))$ . The relation  $R$  can then be defined by the pp-formula  $\exists y_1, \dots, y_n (\bigwedge_{i=1}^n G_{h_i}(y_i, x_i) \wedge \phi(y_1, \dots, y_n))$ , whose length is also in  $O(f(n))$ .

For the converse, let us consider relations  $R \leq \mathbf{A}_1 \times \dots \times \mathbf{A}_n$  with  $\mathbf{A}_i \in \text{HS}(\mathbf{A})$  from any relational basis  $\Gamma$  of  $\text{Inv}(\text{HS}(\mathbf{A}))$ . Then  $\mathbf{A}_i = h_i(\mathbf{S}_i)$ , for a subalgebra  $\mathbf{S}_i \leq \mathbf{A}$  and a homomorphism  $h_i: \mathbf{S}_i \rightarrow \mathbf{A}_i$ . As above,  $R' = \{(a_1, \dots, a_n) \in A^n \mid (h_1(a_1), \dots, h_n(a_n)) \in R\}$  is invariant under  $\mathbf{A}$ . It is not hard to see that  $\Gamma' = \{R' \mid R \in \Gamma\}$  is a relational basis of  $\text{Inv}(\mathbf{A})$ , and for any pp-definition  $\phi$  of a relation  $Q \leq \mathbf{A}^n$  over  $\Gamma$ , the formula  $\phi'$  obtained by replacing every occurrence of the symbol  $R$  by  $R'$  defines  $Q$  over  $\Gamma'$ . ◀

# The Online Simple Knapsack Problem with Reservation and Removability

## Abstract

In the *online simple knapsack problem*, a knapsack of unit size 1 is given and an algorithm is tasked to fill it using a set of items that are revealed one after another. Each item must be accepted or rejected at the time they are presented, and these decisions are irrevocable. No prior knowledge about the set and sequence of items is given. The goal is then to maximize the sum of the sizes of all packed items compared to an optimal packing of all items of the sequence.

In this paper, we combine two existing variants of the problem that each extend the range of possible actions for a newly presented item by a new option. The first is *removability*, in which an item that was previously packed into the knapsack may be finally discarded at any point. The second is *reservations*, which allows the algorithm to delay the decision on accepting or rejecting a new item indefinitely for a proportional fee relative to the size of the given item.

If both removability and reservations are permitted, we show that the competitive ratio of the *online simple knapsack problem* rises depending on the relative reservation costs. As soon as any nonzero fee has to be paid for a reservation, no online algorithm can be better than 1.5-competitive. With rising reservation costs, this competitive ratio increases up to the golden ratio ( $\phi \approx 1.618$ ) that is reached for relative reservation costs of  $1 - \frac{\sqrt{5}}{3} \approx 0.254$ . We provide a matching upper and lower bound for relative reservation costs up to this value. From this point onward, the tight bound by Iwama and Taketomi for the *removable knapsack problem* is the best possible competitive ratio, not using any reservations.

## 1 Introduction

Online problems model situations where an algorithm receives an input piece-wise. The analysis of online problems does not revolve around how much time and space is used when solving the problem, but how *good* the solution provided by an online algorithm is with respect to an optimal offline counterpart. In classical online models, an online algorithm receives a piece of input or *request* and must output some irrevocable part of the solution before the next request arrives, without room for changing the output later on.

---

<sup>1</sup> corresponding author

The *simple knapsack problem* is, as the name suggests, a simplification of the classical *knapsack problem*: Given a set of items  $I$ , a size function  $w : I \rightarrow \mathbf{R}$  and a gain function  $g : I \rightarrow \mathbf{R}$ , the task is to find a subset of items  $S \subseteq I$  such that  $\sum_{i \in S} w(i) \leq 1$  and  $\sum_{i \in S} g(i)$  is maximized. In the *simple knapsack problem*,  $w : I \rightarrow [0, 1]$  and  $w(i) = g(i)$  for all items  $i \in I$ . The offline knapsack problem is a classical hard optimization problem and has been shown to be NP-complete [14]. Both the knapsack problem and the simple knapsack problem admit fully polynomial time approximation schemes [11].

In this work we study the *online simple knapsack problem*. Given a knapsack with capacity 1, an algorithm receives a request sequence  $S = \{x_1, \dots, x_n\}$  consisting of items of size smaller than or equal to 1, and must decide at each step whether to take such an item or reject it. The length of the sequence is initially unknown to the algorithm and the decision on each item must be made before the next item arrives. The decisions are irrevocable, and once an item has been packed or rejected, the decision cannot be reversed in later steps.

Competitive analysis was introduced by Sleator and Tarjan [19] as a way to analyze the performance of online algorithms. The *strict competitive ratio* of an online algorithm for an online maximization problem, such as the *online simple knapsack problem*, is the ratio between the gain obtained by an optimal offline algorithm and the gain obtained by the online algorithm in the worst-case instance. For an introduction to online analysis, we refer the reader to the standard book by Borodin and El-Yaniv [4].

Several variants of online models have been introduced to discern which problems are truly complex, or have a high information content, and which problems are simple in general but contain some rare worst-case instances yielding large competitive ratios. Some of these approaches, such as randomized algorithms [1], advice complexity [7, 10, 15], randomization of the adversary [6, 16, 18], etc. have been applied to various online problems, including the *online simple knapsack problem*, with some success.

In the general online setting, it is well-known [17] that there cannot be an algorithm for the online simple knapsack problem – and thus also for the online knapsack problem – with a bounded competitive ratio. Thus, most research so far has been focused on analyzing some variants of the problem or of the online model. Iwama and Taketomi [12] introduced a variant that adds the possibility to remove previously packed items from the knapsack, without any additional costs. This can be done at any point during the run of an algorithm. They showed a tight competitive ratio of the golden ratio  $\phi \approx 1.618$  for this model.

Recently Böckenhauer et al. [2] introduced a model for the online simple knapsack that adds the possibility to reserve items for a fee proportional to their size. In this model, if an item is reserved, the decision whether the item should be added to the knapsack can be postponed to a later point. However, if an algorithm decides to reserve an item, it has to pay some reservation cost  $c = \alpha x$  that depends on a given parameter  $\alpha$  between 0 and 1, and the item size  $x$ . Surprisingly, in this case, even for arbitrarily small values of the reservation parameter  $\alpha$ , the competitive ratio is not better than 2.

In this paper, we consider a variant of the online simple knapsack problem where an algorithm is allowed to reserve items (reservation) or alternatively to remove items previously placed into the knapsack (removability). Both of these alternatives allow an algorithm to postpone or alter decisions on whether to pack an object. Our reason to choose this variant is that it is a variant of the online simple knapsack with bounded competitive ratio below 2, the best ratio that the reservation model allowed. Some of the questions we wanted to answer is whether the reservations would help at all, and if so, if it is possible to achieve a competitive ratio approaching 1 for low reservation costs. We also want to know if the model behaves similarly to the secretary problem with reservation [5], where for large reservation costs the competitive ratio is the same as without reservations.

■ **Figure 1** A schematic plot of the competitive ratio with respect to the reservation costs  $\alpha$  for the online simple knapsack problem with reservation and removability.

Other variants of the knapsack problem include the work by Böckenhauer et al. [3], who studied the online simple knapsack problem with advice and randomization, and concluded that with one single advice or random bit the problem becomes 2-competitive, whereas further additional random bits do not improve the competitive ratio. Iwama and Zhang [13] looked at the problem with resource augmentation, which means that the size of the knapsack for the online problem is slightly larger than the knapsack size of the offline algorithm. Han, Kawase and Makino [8] considered a version where the items may be removed from the knapsack at the cost of a factor of the item size, and showed that if the factor is smaller than  $1/2$ , the competitive ratio is 2, and otherwise it is a function depending on the factor itself. This is different from the variant we consider, as in this case one pays to remove items from the knapsack, whereas in our version the algorithm pays to reserve items, but not to remove them. Another variant of the problem allows for a buffer of constant size, in which items may be intermediately stored. Han et al. [9] studied the case where the buffer has at least as much capacity as the knapsack itself; the items presented may be allocated into the buffer or irrevocably rejected and only in the last step are the items selected for placement into the knapsack. The reservation model has also been recently applied to the secretary problem [5], where one can achieve a competitive ratio as close to 1 as possible with diminishing values of the reservation cost. For large reservation costs, the competitive ratio is the same as in the model without reservation.

For the online simple knapsack problem with both removability and reservation, we provide tight upper and lower bounds of  $\frac{3-1.5\alpha}{2-1.5\alpha}$  for  $0 < \alpha \leq 1 - \sqrt{5}/3 \approx 0.2546$ , which goes from 1.5 to  $\phi$ . For larger values of  $\alpha$ , the competitive ratio stays constant at  $\phi$ . These bounds are depicted in Figure 1. This means that, even if the reservation costs are arbitrarily small the competitive ratio is worse than 1.5, and for any  $\alpha > 0.2546$  the best achievable competitive ratio is the one that can be achieved without reserving any items. This is in contrast to the behavior of the competitive ratio for the reservation model without removability, where the competitive ratio is constant at value 2 on the small range, and grows until being unbounded for large values of  $\alpha$ .

## 1.1 Problem Definition

We now formally define the online simple knapsack problem with reservation and removability.

Just as in the standard online simple knapsack problem, defined in the introduction, an algorithm solving the problem with reservation and removability is given a knapsack with capacity 1, and receives a request sequence  $S = \{x_1, \dots, x_n\}$  of items. Every item  $x_i$  of the

## 29:4 The Online Simple Knapsack Problem with Reservation and Removability

request sequence only has one parameter, the size, thus it is possible to refer to the size of each item as  $x_i$  while keeping the context clear. At the beginning of the request sequence, the algorithm is also given a parameter  $0 \leq \alpha \leq 1$  for the reservation costs. After receiving an item of size  $x$  the algorithm has three options. It can either decide to pack this item – assuming the total size of already packed items together with the new item is smaller than 1 –, reserve this item at cost  $\alpha x$ , or reject this item. Moreover, the algorithm can also decide to remove and reject any item currently in the knapsack at any point. The decision to reject an item is irrevocable.

Once the whole request sequence  $S$  has been processed, an algorithm  $A$  can decide to pack any reserved items, removing any items in the knapsack accordingly if necessary, as long as they fit into the knapsack. The goal of an algorithm is to maximize its total size of items packed in the knapsack after the whole instance has been processed minus the reservation costs, that is,

$$\text{gain}_S(A, \alpha) = \sum_{x_i \text{ packed}} x_i - \sum_{x_i \text{ reserved}} \alpha x_i .$$

The performance of an algorithm is measured against the optimal solution in a worst-case manner. Thus, the competitive ratio of an algorithm  $A$  is the highest ratio between the size of an optimal solution  $OPT$  and the gain of  $A$ , over all instances

$$c(A, \alpha) = \sup_S \left\{ \frac{\text{gain}_S(OPT, \alpha)}{\text{gain}_S(A, \alpha)} \right\} .$$

We now present matching upper and lower bounds for the competitive ratio of any algorithm solving the online simple knapsack problem with reservation and removability.

### 2 Lower Bound

First note that no algorithm can be better than optimal, in particular we have a lower bound of 1 for  $\alpha = 0$ .

In this section we show that no algorithm can reach a competitive ratio smaller than  $\min\{\frac{3-1.5\alpha}{2-1.5\alpha}, \phi\}$  for all  $0 < \alpha < 1$ . The ratio  $\frac{3-1.5\alpha}{2-1.5\alpha}$  is equal to  $\phi$  at  $\alpha = 1 - \frac{\sqrt{5}}{3} \approx 0.2546$ . For any larger values of  $\alpha$ , we prove that it is not possible to construct an algorithm that performs better than the strategy of Iwama and Taketomi for the knapsack with removability and without reservation [12].

► **Theorem 1.** *Given a parameter  $0 < \alpha \leq 1 - \frac{\sqrt{5}}{3}$ , there exists no algorithm for online simple knapsack with reservation and removability achieving a competitive ratio better than  $\frac{3-1.5\alpha}{2-1.5\alpha}$ .*

**Proof.** We present an adversarial strategy to show that no algorithm can reach a competitive ratio of  $\frac{3-1.5\alpha}{2-1.5\alpha} - \varepsilon$  for any given  $\varepsilon > 0$ . For the following analysis, we will abbreviate  $\frac{2-1.5\alpha}{3-1.5\alpha}$  with  $k$ . Consider the following set of adversarial instances with  $0 < \delta \ll \varepsilon$ :

The adversary starts by presenting the first item  $x_1$  of size  $1 - k + \delta$ . In this situation an arbitrary algorithm  $A$  can choose between the following options:

**Case 1, Pack  $x_1$ .**  $A$  packs the first item of size  $1 - k + \delta$  into the knapsack. The adversary next presents the second item  $x_2$  of size  $k + \delta$  that barely does not fit together with the first item.

**Case 1.1, Remove  $x_1$  and pack  $x_2$ .**  $A$  discards the item of size  $1 - k + \delta$  and packs  $x_2$ .

The adversary then presents an item of size  $1 - x_1 = k - \delta$ . This would perfectly fit together with the discarded item  $x_1$ , so  $OPT$  has a solution of size 1. Since this item does not fit together with  $x_2$ ,  $A$  only holds  $x_2$  as the larger one of the two items, which results in the desired competitive ratio.

**Case 1.2, Reserve  $x_2$ .**  $A$  reserves the item of size  $k + \delta$ . The adversary presents the item  $x_3$  of size  $k + \delta^2$ .

**Case 1.2.1, Remove  $x_1$  and pack  $x_3$ .** Assuming  $A$  discards the first item that is still held in its knapsack to pack the item of size  $k + \delta^2$ . Similar to Case 1.1, the adversary then presents the counterpart to the discarded item of size  $1 - x_1 = k - \delta$ .  $A$  cannot pack its reserved item together with the newly packed item, since  $k - \delta + k + \delta^2 > 1$  for all  $\alpha \in (0, 1 - \frac{\sqrt{5}}{3})$ . The gain of  $A$  is even smaller than in Case 1.1, due to the costs of reserving an item.

**Case 1.2.2, Reserve  $x_3$ .**  $A$  reserves the item of size  $k + \delta^2$ . The adversary presents  $x_4$  of size  $k + \delta^3$  and will continue to present items  $x_{j+1}$  of size  $k + \delta^j$  as long as  $A$  reserves those items. At some point  $A$  must stop reserving these items due to the accumulating reservation costs exceeding any possible gain. As soon as  $A$  rejects an item, or discards the item in its knapsack to pack an item, the case can be handled analogously to 1.2.1 or 1.2.3. The gain of the algorithm will be lower than in these cases due to the added reservation costs.

**Case 1.2.3, Reject  $x_3$ .** The algorithm does not pack the item of size  $k + \delta^2$ . The adversary presents an item of size  $1 - x_3$ . So while  $OPT$  reaches 1,  $A$  can at the most pack  $x_1$  and the item of size  $1 - x_3$ . Together, with subtracted reservation costs, the algorithm then has a gain of  $2 - \frac{4-3\alpha}{3-1.5\alpha} - \alpha k$ . A simple analysis shows that this yields a ratio higher than  $\frac{3-1.5\alpha}{2-1.5\alpha}$ .

**Case 1.3, Reject  $x_2$ .**  $A$  does not pack or reserve the item of size  $k + \delta$ . No further items are presented. The algorithm thus only holds  $x_1$ , while an optimal solution would be to pack the item  $x_2$ . The ratio of  $k$  to  $1 - k$  is worse than  $\phi$  for every  $\alpha < 1 - \frac{\sqrt{5}}{3}$  and therefore, in particular, larger than the desired ratio.

**Case 2, Reserve  $x_1$ .**  $A$  reserves the first item of size  $1 - k + \delta$ . The adversary presents the item  $x'_2$  of size  $\frac{2}{3} + 2\delta$ .

**Case 2.1 Pack  $x'_2$ .** The algorithm packs the item of size  $\frac{2}{3} + 2\delta$ . The next item is  $x'_3$  of size  $\frac{1}{3} + 2\delta$ .

**Case 2.1.1 Remove  $x'_2$  and pack  $x'_3$ .** The algorithm discards the item of size  $\frac{2}{3} + 2\delta$  from its knapsack and instead packs the item of size  $\frac{1}{3} + 2\delta$ . The adversary next presents an item of size  $1 - x'_2$ .  $OPT$  then has a solution of size 1.  $A$  can at most reach a gain of  $x_1 + x'_3 - \alpha x_1 = \frac{1}{3} + 1 - k + 3\delta - \alpha(1 - k) = k$ .

**Case 2.1.2 Reserve  $x'_3$ .**  $A$  reserves the item of size  $\frac{1}{3} + 2\delta$ . The adversary continues to present items  $x'_{j+1}$  of size  $\frac{1}{3} + \delta + \delta^{j-1}$ , as long as  $A$  reserves those items. As soon as  $A$  rejects an item or discards the item already in its knapsack to pack an item, these cases can be handled analogously to 2.1.1 or 2.1.3. The gain of the algorithm will be lower than in these cases due to the added reservation costs.

**Case 2.1.3 Reject  $x'_3$ .** The algorithm does not pack the item of size  $\frac{1}{3} + 2\delta$ . The adversary then presents an item of size  $1 - x'_3$ . Since  $x'_3$  was the smallest item of all that have been presented so far, the counterpart will not fit together with any other item of  $A$ . Therefore  $OPT$  has a gain of 1, whereas the largest packing of  $A$  consists of the item  $x'_2$  which is of smaller size than  $k$ .

**Case 2.2 Reserve  $x'_2$ .**  $A$  reserves the item of size  $\frac{2}{3} + 2\delta$ . The adversary presents  $x''_2$  of size  $\frac{2}{3} + \delta + \delta^2$ .

**Case 2.2.1 Pack  $x''_2$ .**  $A$  packs the item of size  $\frac{2}{3} + \delta + \delta^2$  into the knapsack. The next item is  $x'_3$  of size  $\frac{1}{3} + 2\delta$ .

**Case 2.2.1.1 Remove  $x''_2$  and pack  $x'_3$ .** The algorithm discards the item of size  $\frac{2}{3} + \delta + \delta^2$  from its knapsack and instead packs the item of size  $\frac{1}{3} + 2\delta$ . The adversary next presents an item of size  $1 - x''_2$ .  $OPT$  then has a solution of size 1.  $A$  can at most reach a gain of  $x_1 + x'_3 - \alpha x_1 = \frac{1}{3} + 1 - k + 3\delta - \alpha(1 - k) = k$ .

**Case 2.2.1.2 Reserve  $x'_3$ .**  $A$  reserves the item of size  $\frac{1}{3} + 2\delta$ . The adversary continues to present items  $x'_{j+1}$  of the size  $\frac{1}{3} + \delta + \delta^{j-1}$ , as long as  $A$  reserves those. As soon as  $A$  rejects an item or discards the item already in its knapsack to pack an item, these cases can be handled analogously to 2.2.1.1 or 2.2.1.3. The gain of the algorithm will be lower than in these cases due to the added reservation costs.

**Case 2.2.1.3 Reject  $x'_3$ .** The algorithm does not pack the item of size  $\frac{1}{3} + 2\delta$ . The adversary then presents an item of size  $1 - x'_3$ . Since  $x'_3$  was the smallest item of all that have been presented so far, the counterpart will not fit together with any other item of  $A$ . Therefore  $OPT$  has a gain of 1, whereas the largest packing of  $A$  consists of the item  $x'_2 < k$ .

**Case 2.2.2 Reserve  $x''_2$ .** The algorithm reserves the item of size  $\frac{2}{3} + \delta + \delta^2$ . The adversary continues to present items  $x''_j$  of the size  $\frac{2}{3} + \delta + \delta^j$ , as long as  $A$  reserves these items. As soon as  $A$  rejects an item or discards the item already in its knapsack to pack an item, these cases can be handled analogously to 2.2.1 or 2.2.3. The gain of the algorithm will be lower than in these cases due to the added reservation costs.

**Case 2.2.3 Reject  $x''_2$ .**  $A$  does not pack the item of size  $\frac{2}{3} + \delta + \delta^2$ . The adversary then presents an item of size  $1 - x''_2$ . The gain of  $OPT$  is then 1. The maximum gain of  $A$  is then  $x_1 + 1 - x''_2 - \alpha(x_1 + x'_2) = 1 - k + \frac{1}{3} - \delta - \delta^2 - \alpha(1 - k + \frac{1}{3} - \delta - \delta^2)$  which is slightly smaller than the gain of  $A$  in Case 2.1.1 due to increased reservation costs and thus especially smaller than  $k$ .

**Case 2.3 Reject  $x'_2$ .** The algorithm does not pack the item of size  $\frac{2}{3} + 2\delta$ . No further items are presented. Similarly to Case 1.3, the algorithm only holds  $x_1$ , while an optimal packing would be  $x'_2$ . Since even  $x'_2 > x_2$ , the same argumentation from Case 1.3 concludes this case.

**Case 3, Reject  $x_1$ .** No further items are presented. Therefore the optimal solution is exactly the item  $x_1 = 1 - k$ , while  $A$  has packed no items. The competitive ratio is then unbounded.  $\blacktriangleleft$

It is not surprising that for increasing reservation costs, the competitive ratio is increasing, too. In particular, it is easy to see that the competitive ratio cannot decrease if the reservation costs increase.

**► Corollary 2.** For  $\alpha > 1 - \frac{\sqrt{5}}{3}$ , no algorithm can be better than  $\phi$ -competitive for the online simple knapsack problem with reservation and removability.

**Proof.** The competitive ratio of Theorem 1 reaches  $\phi$  at  $\alpha = 1 - \frac{\sqrt{5}}{3}$ . For every  $\alpha > 1 - \frac{\sqrt{5}}{3}$  it is possible to present the lower bound with exactly the same items as in Theorem 1 for  $\alpha = 1 - \frac{\sqrt{5}}{3}$ . The only difference are the higher costs for every reservation. Thus, in every case, the gain of an optimal offline solution stays the same, while the algorithm gets at most the gain of the case  $\alpha = 1 - \frac{\sqrt{5}}{3}$ .  $\blacktriangleleft$

### 3 Upper Bound

If  $\alpha = 0$ , then the problem becomes an offline problem, since an algorithm can reserve every item for free. Thus a competitive ratio of 1 is achievable. Trivially, this matches the lower bound.

However, as we will see now, as soon as the value of  $\alpha$  is positive, the best achievable competitive ratio is worse than 1.5-competitive.

To handle the range of  $0 < \alpha \leq 1 - \frac{\sqrt{5}}{3}$ , we present Algorithm 1 with a competitive ratio of  $\frac{3-1.5\alpha}{2-1.5\alpha}$ , matching the lower bound established in the previous subsection.

Algorithm 1, analyzed in this section, can be split in three phases. All of the phases work similarly: First, if small items arrive, they are packed since they will not cause harm (we can throw them out at any time).

Then there are two kind of interesting ranges for medium-sized items: A large-medium range, where the algorithm tries to keep the smallest items to maintain the possibility to get fitting counterparts (similar to [12]). And a small-medium range, where an item gets reserved, because otherwise the ratio between large and small items in the large-medium range, where only the smallest items are kept, gets too large by itself. After the first reservation, the algorithm continues in the second phase; after the second reservation in the third phase.

Finally, very large items, which are sufficiently large to guarantee the desired competitive ratio by themselves, are the easiest case since the algorithm can just pack these items to achieve the desired competitive ratio immediately.

The main difference between the three phases is, that the ranges for the different actions are shifted – due to the ability to use the reserved items, but also due to the paid reservation costs that need to be compensated. Due to these shifts, in the third phase there is no small-medium range, and there is no need to reserve any more items, thus Algorithm 1 reserves at most two items.

► **Theorem 3.** *For  $0 < \alpha \leq 1 - \frac{\sqrt{5}}{3}$ , there exists an algorithm solving the online simple knapsack problem with reservation and removability that is not worse than  $\frac{3-1.5\alpha}{2-1.5\alpha}$  competitive.*

**Proof.** We prove that Algorithm 1 achieves the competitive ratio on the statement. For ease of notation, we define  $c := \frac{3-1.5\alpha}{2-1.5\alpha}$ . If Algorithm 1 is at any point able to pack a knapsack such that, even when paying the reservation costs, the desired competitive ratio is reached, it stops afterwards. This is the case in lines 4, 9 and 16.

Depending on the instance, Algorithm 1 reserves zero, one or two items. In the following, we show that the algorithm yields the desired competitive ratio in those three cases.

**Case 1: Algorithm 1 ends in line 4 or 22, before the first reservation is made.** When presented with a new item, the algorithm first checks if this item together with a subset of its packed items already yields a packing of size  $\frac{1}{c}$ . In the following analysis, assume that this is not the case, since if this were the case, the algorithm would have achieved the desired competitive ratio anyways.

Items that are smaller than  $1 - \frac{1}{c}$  are packed by the algorithm in line 5. Items with sizes between  $1 - \frac{1}{c}$  and  $\frac{1}{c^2}$  will be reserved in line 7, if the condition in line 4 does not hold: We investigate this case as Case 2.

The first item of size between  $\frac{1}{c^2}$  and  $\frac{1}{c}$  is packed. If further items in this range arrive, only the smallest item of this range is packed (or kept) in the knapsack and the other items from this range are discarded. If an item  $x_k$  in this range, which should be kept in the knapsack according to line 6, does not fit, it must be due to the items already in the knapsack, which are each smaller than  $1 - \frac{1}{c}$ . Thus, in this case, it is possible to combine this item  $x_k$  with a subset of the small items in the knapsack to get a packing of size at least  $\frac{1}{c}$ , triggering the end of the packing in line 4.

■ **Algorithm 1** Upper bound Algorithm for  $0 < \alpha \leq 1 - \frac{\sqrt{5}}{3}$ .  $\text{OPT}(S)$  denotes the size of the optimal packing of the set  $S$ ,  $c := \frac{3-1.5\alpha}{2-1.5\alpha}$ .

21:       Keep  $x_k$  if  $x_k + x_g < \min(x_m \in M) \wedge x_k < \min(x_l \in L)$ ;  $L := L \cup x_k$ ;
22:   Pack  $\text{OPT}(K \cup R)$ 
    
```

---

On the other hand, if the instance ends before reserving the first item, the only possible difference between an optimal solution and a solution of the algorithm is that the algorithm only has the smallest item in the range between  $\frac{1}{c^2}$  and  $\frac{1}{c}$ , while the optimal solution might have a different item in this range. Since the smallest item in this range is at least of size  $\frac{1}{c^2}$  and the largest item is at most of size  $\frac{1}{c}$ , the ratio is smaller than  $\frac{1/c}{1/c^2} = c$ . Additional small items can be part of both the optimal solution and the solution provided by the algorithm, which only makes the ratio smaller.

Note that an optimal solution cannot contain two items in the range between  $\frac{1}{c^2}$  and  $\frac{1}{c}$ , since the algorithm would also be able to combine the two items in this range. The algorithm always keeps the smallest possible item within the range, a second item within the range that could fit into the knapsack would trigger the condition in line 4, since two items of size at least  $\frac{1}{c^2}$  are sufficient to reach  $\frac{1}{c}$  ( $\frac{2}{c^2} \geq \frac{1}{c}$  for  $c \leq 2$ ).

**Case 2: Algorithm ends in line 9 or 22 with one reserved item.** Assume one item  $x_f$  in the range  $1 - \frac{1}{c}$  to  $\frac{1}{c^2}$  was reserved. The reservation costs for this item are  $\alpha x_f$ . Thus, the algorithm needs to pack at least  $\frac{1}{c} + \alpha x_f$  to guarantee the desired competitive ratio independently to the gain achieved by an optimal solution.

For items smaller than  $1 - \frac{1}{c} - \alpha x_f$  the same argument for the small items in Case 1 holds: These items can be packed in a greedy manner until the threshold  $\frac{1}{c} + \alpha x_f$  is reached. An item of size between  $1 - \frac{1}{c} - \alpha x_f$  and  $\frac{1}{3}$  will be reserved in line 10, if the algorithm cannot pack a knapsack of size  $\frac{1}{c} + \alpha x_f$  at this point. This case is discussed in the next part of the proof, as Case 3.

■ **Figure 2** A schematic plot of the size ranges in the algorithm when two items have already been reserved. The targeted size for the items is  $t = \frac{1}{c} + \alpha(x_g + x_f)$ .

Note that it is sufficient to combine the first reserved item with a single item of size at least  $\frac{1}{3}$  to reach the desired competitive ratio, even after paying the reservation costs, as

$$\frac{1}{3} + (1 - \alpha)x_f \geq \frac{1}{3} + (1 - \alpha)\left(1 - \frac{1}{c}\right) = \frac{1}{c},$$

in the considered range of  $\alpha$ . In addition, any item that reaches  $\frac{1}{c} + \alpha x_f$  either by its own or together with small items is sufficient as well. Thus, with every item between  $\frac{1}{3}$  and  $1 - x_f$ , or larger than  $\frac{1}{c} + \alpha x_f$ , the threshold is reached already and the algorithm stops in line 9.

We are left to consider items of sizes between  $1 - x_f$  and  $\frac{1}{c} + \alpha x_f$ , which will reach line 12 in the algorithm. With the items in this range, we follow the same strategy as for the large-medium items before the first reservation: The smallest of those items will be kept in the knapsack. This works for the same reasons as in Case 1, as explained below.

Assume the instance stops here and the algorithm was not able to reach  $\frac{1}{c} + \alpha x_f$ : The only difference between the solution of the algorithm and an optimal solution is that the algorithm sticks to the smallest item in the range between  $1 - x_f$  and  $\frac{1}{c} + \alpha x_f$ , which gives us the worst possible case. Note that no item of size smaller than  $1 - x_f$  can be rejected before the first reservation, since it otherwise would have been packed in combination with  $f$ . The ratio between  $\frac{1}{c} + \alpha x_f$  and  $1 - x_f$  is less than  $c$ , since  $x_f$  is at most  $\frac{1}{c^2}$ . Again, additional small items can be added to both the optimal solution and the solution provided by the algorithm, only decreasing the ratio.

**Case 3: Algorithm ends in line 16 or 22 with two reservations made.** Assume two items were reserved, the first item  $x_f$  of size between  $1 - \frac{1}{c}$  and  $\frac{1}{c^2}$ , and the second item  $x_g$  of size between  $1 - \frac{1}{c} - \alpha x_f$  and  $\frac{1}{3}$ . Therefore, the algorithm has already paid  $\alpha(x_g + x_f)$  as reservation costs, and now needs a packing of size  $\frac{1}{c} + \alpha(x_g + x_f)$  to guarantee the competitive ratio of  $c$  independent of any optimal solution size.

First note that, an item or a subset of items is sufficient to reach  $\frac{1}{c} + \alpha(x_f + x_g)$  in three cases: it either reaches the threshold by its own, reaches the threshold together with one of the reserved items, or with the two reserved items combined.

To reach the threshold with one of the reserved items, a subset of items must have a size between  $\frac{1}{c} + \alpha(x_f + x_g) - x_f$  and  $1 - x_f$ , or between  $\frac{1}{c} + \alpha(x_f + x_g) - x_g$  and  $1 - x_g$  (depending on which of the reserved items will be used to combine this subset with). The subsets sizes, that combined with  $x_f$  are sufficient to reach the necessary threshold can obviously be smaller than the subsets that can be combined with  $x_g$ , since  $x_g < \frac{1}{3}$  and  $x_f > \frac{1}{3}$ . With simple analysis, it can be shown that for any  $\alpha$  between 0 and  $1 - \frac{\sqrt{5}}{3}$  and for every choice of  $x_g$  and  $x_f$  in the given ranges,  $1 - x_g$  must be larger than  $\frac{1}{c} + \alpha(x_f + x_g) - x_f$ . Therefore these intervals overlap, as displayed in Figure 2.

It follows that there are three intervals in which an item can be presented and the algorithm might not stop immediately:

1. Items smaller than  $\frac{1}{c} + \alpha(x_g + x_f) - x_g - x_f$  are too small to reach the necessary size in combination with both of the reserved items. Note that those are smaller than  $1 - \frac{1}{c} - \alpha(x_g + x_f)$ , thus they can be packed greedily. As soon as the knapsack is overfull due to those items a subset of the small items can be selected to reach  $\frac{1}{c} + \alpha(x_g + x_f)$ . This argumentation is analogous to the small items argument in the two previous cases.

## 29:10 The Online Simple Knapsack Problem with Reservation and Removability

2. Items between  $1 - x_g - x_f$  and  $\frac{1}{c} + \alpha(x_g + x_f) - x_f$ , which are too large to fit together with both reserved items, but too small to reach the threshold in combination with the largest reserved item. We will call those items *mid-sized*.
3. Items that cannot be combined any of the reserved items but also do not reach the threshold by themselves, i.e., items between  $1 - x_g > \frac{2}{3}$  and  $\frac{1}{c} + \alpha(x_f + x_g)$ . Those items will be called *large*.

As we have already justified, the small items in 1. are not a concern. We argue now that the desired competitive ratio is also achieved when mid-sized and large items appear in the request sequence after reserving two items.

The algorithm keeps either the smallest large item, or the smallest mid-sized item. This is dependent on the situation, as detailed in lines 18 to 21: If the smallest large item is smaller than the smallest mid-sized item in combination with  $x_g$ , the algorithm keeps the smallest large item. On the other hand, if the smallest mid-sized item in combination with  $x_g$  is smaller than the smallest large item, the algorithm keeps the smallest mid-sized item. Note that we can assume that every large item is larger than  $\frac{2}{3}$ , since otherwise it can be combined with  $x_g$ , reaching the threshold  $\frac{1}{c} + \alpha(x_g + x_f)$ .

Therefore the following crucial observation holds: If the algorithm is able to pack either one large item together with  $x_f$ ,  $x_g$  or a mid-sized item, or the algorithm is able to pack three items among  $x_f$ ,  $x_g$  and mid-sized items, the algorithm will also reach the desired threshold and competitive ratio.

To see this, first note that every mid-sized item of size smaller than or equal to  $\frac{1}{3}$  will be packed into the knapsack and will never be replaced by a large item. This is the case because every large item must be larger than  $\frac{2}{3}$ , and an item of size smaller than  $\frac{1}{3}$  in combination with  $x_g$  must be smaller or equal than  $\frac{2}{3}$ .

Assume that, at some point, an arbitrary algorithm is about to pack the last item of a combination of one large and one mid-sized or reserved item, or a combination of three mid-sized or reserved items. Due to the construction and the selection of items before, we are able to do so as well:

- If the last item is a large item, the algorithm is able to pack such a combination, since the smallest mid-sized item is in the knapsack if it is smaller than the reserved  $x_g$ . Otherwise the reserved  $x_g$  is available for a combination.
- If the last item is a mid-sized one, it fits together with the current combination of items selected by Algorithm 1 (either two mid-sized or one large item), since it is the smallest possible combination by construction.

A simple calculation then shows that every such combination of items (one large and one mid-sized/reserved item, or three mid-sized/reserved items) is of size at least  $\frac{1}{c} + \alpha(x_g + x_f)$ , even if chosen as small as possible.

The only thing left to prove is that even if there is no such combination, the algorithm still reaches the designated competitive ratio:

First note that large items are only rejected or removed from the knapsack in the first two phases. Those items had at most size  $\frac{1}{c} + \alpha x_f$ . Items that remained in the knapsack can be considered as either small items that can be packed in a greedy manner, or as large items. If there were an item that is not in the allowed range for large or small items in this phase, it would have been used to reach the threshold for a guaranteed competitive ratio immediately, just like it would have been possible if the item was presented in the third phase.

By using mid-sized and large items together with the reserved ones, every optimal solution can only reach  $\frac{1}{c} + \alpha(x_g + x_f)$ , while Algorithm 1 cannot be worse than  $x_g + x_f$  on any instance. An easy calculation shows that even for smallest possible sizes of  $x_g$  and  $x_f$ , their

combination is sufficient to reach the competitive ratio of  $c$ , since an optimal solution cannot be better than  $\frac{1}{c} + \alpha(x_g + x_f)$ . Since Algorithm 1 can use small items in the same manner as an optimal solution, the appearance of small items cannot worsen the ratio. ◀

This concludes the analysis for an upper bound that matches the lower bound for values of  $\alpha$  smaller than  $\alpha \geq 1 - \sqrt{5}/3$ .

For any  $\alpha \geq 1 - \sqrt{5}/3$ , note that the algorithm for knapsack with removable objects (without reservation) presented by Iwama and Taketomi [12] achieves a competitive ratio of  $\phi$ , thus matching our lower bound as well.

## 4 Concluding Remarks

The upper and lower bounds for the competitive ratio of the online simple knapsack with reservation and removability show that, as long as the value of  $\alpha$  is positive the competitive ratio is above 1.5. For large values of  $\alpha$  the competitive ratio stays the same as in the removability model without reservation, which is somehow intuitive, showing that at some point reserving items is not worth the costs. More surprising are the results for small values of  $\alpha$ . The algorithm with reservation that achieves the desired upper bound rarely makes use of the reservation, even in the case with very small  $\alpha$  only two items are reserved in total. This behavior is similar to that of online simple knapsack with reservations but without removability for small values of  $\alpha$ .

For future research, a natural variation of the problem would be to allow items to be reserved after they were added to the knapsack, i.e. to allow removing items from the knapsack and reserve them instead of only having the option to discard them (like we considered here).

It is known that the classic general online knapsack does not yield a finite competitive ratio and also the option to remove items of the knapsack does not help. Thus, it remains an interesting question if the reservation model changes the situation. We think that, at least for small reservation costs, it should be possible to achieve a constant competitive ratio, but this is still open and could also be a topic for further research.

## Abstract

Counting abilities in finite automata are traditionally provided by two orthogonal extensions: adding a single counter that can be tested for zeroness at any point, or adding  $\mathbb{Z}$ -valued counters that are tested for equality only at the end of runs. In this paper, finite automata extended with both types of counters are introduced. They are called Parikh One-Counter Automata (POCA): the “Parikh” part referring to the evaluation of counters at the end of runs, and the “One-Counter” part to the single counter that can be tested during runs.

Their expressiveness, in the deterministic and nondeterministic variants, is investigated; it is shown in particular that there are deterministic POCA languages that cannot be expressed without nondeterminism in the original models. The natural decision problems are also studied; strikingly, most of them are no harder than in the original models. A parametric version of nonemptiness is also considered.

## 1 Introduction

Extensions of finite automata abound in the literature, with a traditional common goal: To find computational models with good expressiveness for which relevant problems are decidable. The impetus lies in formal verification: Can I express my process using that new model, then formally check that it does not have “bad” behaviors? Typically, processes are thus implemented with expressive models, while bad behaviors can be represented using a regular language. To answer the verification question, the key computational problem is then *inclusion in a regular language* (are all the executions of my process not bad?).

A common approach to extending finite automata is to equip them with counters or some sort of counting abilities. The literature crystallizes around two main extensions:

- Adding a *single* counter which can be tested for zeroness throughout the run. A typical language that such an extension can recognize is  $L_1 = \{a^n b^n \mid n \geq 0\}^*$  (mind the star!).
- Adding any constant number of counters, but they can only be tested for zeroness or equality a bounded number of times (during the run or at the end only, these variants being equivalent for nondeterministic machines). This includes reversal-bounded counter machines [14, 6] and Parikh automata [16, 4, 5], which, incidentally, are equally expressive.

A typical language in these extensions is  $L_2 = \{a^n b^n c^n \mid n \geq 0\}$ .

Unsurprisingly,  $L_1$  cannot be recognized using the second extension, while  $L_2$  cannot be recognized with the first. A natural extension is, thus, to combine these two approaches to counting into a single model, prompting the questions: **1.** Is the expressiveness of the combined model more interesting than just the union of the two original models; and **2.** Are the good decidability properties of the original models retained in the combined one?

Here, we report on this extension. The model, called *Parikh One-Counter Automata* (POCA), consists in a finite automaton with one counter which can be tested for zeroness and any number of  $\mathbb{Z}$ -valued counters that are checked at the end of the run using a Presburger formula (an arithmetic formula of first-order logic with addition).<sup>1</sup> We contribute:

- A (de)pumping lemma allowing for the study of the limits of the expressiveness of POCA. Pumping in one-counter automata is fairly simple, as it follows standard arguments for pushdown automata. In Parikh automata (i.e., POCA without the unbounded counter), any cycle taken twice can be moved around without changing membership. However, combining these two properties for POCA proves to be a great technical challenge.
- A complete picture of the relationships between POCA, one-counter automata, and Parikh automata, in their nondeterministic and deterministic variants. In addition to separation of the classes of languages under consideration, we observe that some languages that are only *nondeterministic* for both Parikh automata and one-counter automata turn out to be *deterministic* for POCA. This is of special interest in the context of verification since many problems are undecidable for nondeterministic machines but decidable for deterministic ones. We also study how the base models of Parikh automata and one-counter automata are “embedded” in POCA (Theorem 15, the statement of which should be clear at this point of the Introduction).
- A study of the decision problems for POCA and its deterministic variant. Strikingly, emptiness and inclusion in a regular language are no more complex than with Parikh automata: coNP-complete. We also study *parametric* POCA, in which parameters  $x, y, \dots$  can be used in the counter updates (as  $+x, -y$ , for instance), and show that it is undecidable whether, for all parameter values, the language of the POCA is nonempty. We relate this problem to considerations on arithmetic theories since it is one of the main motivations behind the study of parametric models [1].

■ **Figure 1** Closure properties and complexity results. Results about Parikh automata (PA) and one-counter automata (OCA) are from the literature [7, 16, 5, 17, 21, 2]. The left side of the table lists closure properties;  $h$  and  $h^{-1}$  mean closure under morphisms and inverse morphisms.

<sup>1</sup> We rely on a slightly different but equivalent definition, in which the Presburger formula actually specifies a relation on the number of times each transition is taken in the run. This explains the use of Rohit Parikh’s name: a run is accepting if its Parikh image is accepted by the Presburger formula. Formal definitions appear in Section 2.

■ **Figure 2** Separations among deterministic and nondeterministic variants of PA, OCA & POCA. The arrows denote the strict subclass relation, e.g.,  $\text{DetPA} \subsetneq \text{PA}$ . All the classes not having a sequence of arrows between them are incomparable. The language in between classes belongs to the higher class but not to the lower.

**Organization of the paper.** We recall some classical notions and introduce our models in Section 2 then present some examples of POCA in Section 3. In Section 4, we state our (de)pumping lemma for POCA and rely on it to show that some languages are not expressible. We study the relationships between our classes of languages in Section 5, the closure properties of our models in Section 6, and the complexity of decision problems in Section 7.

## 2 Preliminaries

We assume the reader to be familiar with elementary automata theory.

**Sets.** We write  $\mathbb{N} = \{0, 1, 2, \dots\}$  and  $\mathbb{N}_{>0} = \{1, 2, \dots\}$ . Let  $d \in \mathbb{N}_{>0}$ . A set  $E \subseteq \mathbb{Z}^d$  is said to be *linear* if there exist vectors  $\mathbf{v}_0, \mathbf{v}_1, \dots, \mathbf{v}_k \in \mathbb{Z}^d$  such that  $E = \{\mathbf{v}_0 + \sum_{i=1}^k x_i \mathbf{v}_i \mid x_1, \dots, x_k \in \mathbb{N}\}$ . A set is *semilinear* if it is a finite union of linear sets. Equivalently, a set  $E \subseteq \mathbb{Z}^d$  is semilinear if it can be represented as the set of vectors satisfying a *Presburger formula* with  $d$  free variables, that is, a first-order formula over  $(\mathbb{N}, +)$ .

**Words, languages.** We usually use  $\Sigma$  for alphabets, write  $\varepsilon$  for the empty word, and let  $\Sigma^\varepsilon$  be  $\Sigma \cup \{\varepsilon\}$ , with the understanding that  $\varepsilon \notin \Sigma$ . Any alphabet in this paper is implicitly totally ordered, so that we can speak of the  $i$ -th letter of the alphabet. This is only useful in defining the *Parikh image*  $\Phi(w)$  of a word  $w \in \Sigma^*$ : this is the vector in  $\mathbb{N}^{|\Sigma|}$  whose  $i$ -th component is the number of times the  $i$ -th letter of  $\Sigma$  appears in  $w$ .

Given two alphabets  $\Sigma, \Gamma$ , any function  $\Sigma \rightarrow \Gamma^*$  can be uniquely extended to a function  $h: \Sigma^* \rightarrow \Gamma^*$ , called a *morphism*, in such a way that  $h(\varepsilon) = \varepsilon$  and  $h(u \cdot v) = h(u) \cdot h(v)$ . For a language  $L \subseteq \Sigma^*$ , we write  $h(L)$  for  $\{h(w) \mid w \in L\}$ .

Given a language  $L \subseteq \Sigma^*$ , two words  $u, v \in \Sigma^*$  are *Myhill-Nerode equivalent* if for any  $w \in \Sigma^*$ ,  $uw \in L \Leftrightarrow vw \in L$ . This is an equivalence relation, and we write  $[u]_L$  for the set of words Myhill-Nerode equivalent to  $u$ . We will be mostly interested in  $[\varepsilon]_L$ , the set of words that can be erased from or inserted at the beginning of any word without changing its membership to  $L$ .

**Parikh one-counter automata.** A *Parikh One-Counter Automaton* (POCA)  $\mathcal{A}$  is a tuple  $(Q, q_0, \Sigma, \Delta_0, \Delta_+, F, \varphi)$  where:

- $Q$  is a finite set of states and  $q_0 \in Q$  is the initial state,
- $\Sigma$  is an alphabet,

### 30:4 Parikh One-Counter Automata

- $\Delta_0 \subseteq Q \times \Sigma^\varepsilon \times \{0, 1\} \times Q$  is a *zero-value* transition relation,
- $\Delta_+ \subseteq Q \times \Sigma^\varepsilon \times \{-1, 0, 1\} \times Q$  is a *positive* transition relation,
- $F \subseteq Q$  is a set of final states, and
- $\varphi$  is an existential Presburger formula with  $(|\Delta_0| + |\Delta_+|)$  free variables.

A *run* in  $\mathcal{A}$  is a sequence of transitions:

$$\rho = (q_1, \ell_1, b_1, q_2)(q_2, \ell_2, b_2, q_3) \cdots (q_{n-1}, \ell_{n-1}, b_{n-1}, q_n) \in (\Delta_0 \uplus \Delta_+)^*.$$

We say that  $\rho$  *starts* in  $q_1$  and *ends* in  $q_n$ . Its *trace* is the sequence of partial sums of the  $b_i$ , representing the current value of the counter:

$$\text{trace}(\rho) = \left( \sum_{i<1} b_i, \sum_{i<2} b_i, \dots, \sum_{i<n} b_i \right),$$

with the understanding that the first term of that sequence is zero. The  $i$ -th element of the trace is simply written  $\text{trace}(\rho)_i$ . The run  $\rho$  is:

- *counter-correct* if for all  $i$ ,  $\text{trace}(\rho)_i = 0 \rightarrow \rho_i \in \Delta_0$  and  $\text{trace}(\rho)_i \neq 0 \rightarrow \rho_i \in \Delta_+$ . In other words, a transition from  $\Delta_0$  is taken if the current value of the counter is 0 and one from  $\Delta_+$  if the counter is nonzero.
- *initial* if it starts in  $q_0$ , *final* if it ends in a state in  $F$ .
- *constraint-correct* if  $\Phi(\rho)$  satisfies  $\varphi$ .
- *accepting* if it is initial, final, counter-correct, and constraint-correct.

The *label* of the run  $\rho$  is the concatenation of all the  $\ell_i$  and a word  $w$  is accepted by  $\mathcal{A}$  if it is the label of an accepting run. Finally, the *language recognized* by the POCA  $\mathcal{A}$  is the set  $\mathcal{L}(\mathcal{A})$  of words accepted by it.

A POCA  $\mathcal{A}$  is said to be *deterministic* (DetPOCA) if for all states  $q$  and for both  $\Delta \in \{\Delta_0, \Delta_+\}$ :

- There are no two transitions in  $\Delta$  from  $q$  having the same label; and
- If there is a transition in  $\Delta$  from  $q$  labeled  $\varepsilon$ , there is no other transition from  $q$  in  $\Delta$ .

**Parikh Automata & One-Counter Automata.** These two models are restrictions of POCA:

- A *Parikh Automaton* (PA) is a POCA in which  $\Delta_0 \subseteq Q \times \Sigma^\varepsilon \times \{0\} \times Q$ . In this case,  $\Delta_+$  is not useful, so we simply omit it from the tuple representation and do not write the 0 update of  $\Delta_0$ . We use DetPA for the deterministic variant.
- A *One-Counter Automaton* (OCA) is a POCA in which  $\varphi$  is a tautology; we then omit it from the tuple representation. We use DetOCA for the deterministic variant.

### 3 Examples

We start with a few examples of POCA languages, which will help in clarifying the relationship of POCA with PA and OCA.

► **Example 1.** Let  $T = \{a^n b^n \mid n > 0\}$  and define:

$$L = \{u_1 u_2 \cdots u_m c^m \mid m > 0 \wedge u_1, u_2, \dots, u_m \in T\}.$$

This language can be shown to be unrecognizable by PA or OCA. Intuitively, it is not a PA language since it has unbounded sequences of words from  $T$ , each of which necessitating an equality check, and it is not an OCA language since  $m$  and  $n$ , respectively the number of  $c$

and the number of  $a, b$ , require two separate counters. However,  $L$  is recognizable using a POCA. Indeed, the counter can be used to check that each subword in  $a^+b^+$  is in  $T$  and the semilinear constraint can be used to check that the number of words  $u_i$  is exactly the number of  $c$ . In fact, this process is deterministic, hence  $L$  is a DetPOCA language.

► **Example 2.** Let again  $T = \{a^n b^n \# \mid n > 0\}$  and  $K = \{a^n b^n c^n \# \mid n > 0\}$  and define:

$$L_T = \{a, b, \#\}^* T \{a, b, \#\}^* \quad \text{and} \quad L_K = \{a, b, c, \#\}^* K \{a, b, c, \#\}^*.$$

Using a single counter,  $L_T$  can be deterministically recognized: every time we switch from  $b$  to  $a$ , we can reset the counter in search for a subword in  $T$ . Thus  $L_T$  is a DetOCA (hence DetPOCA) language. However, it can be shown that  $L_T$  is a PA language, but not a DetPA language with tools from [4]. As for  $L_K$ , since  $K$  cannot be recognized by an OCA, we need to use the semilinear constraint to recognize it: a PA for  $L_K$  would simply guess the position of the word in  $K$ , read the next  $a^+b^+c^+$  using a separate part of the automaton, then check that there were as many  $a, b$ , and  $c$  in this subword using the semilinear constraint. Thus  $L_K$  is a PA (hence POCA) language. We can show, however, that it is not a DetPOCA language.

► **Example 3.** The previous example seems to indicate that a language that is expressible with both PA and OCA can only be deterministic if it is expressible with a DetPA or DetOCA. This is not the case. Take for instance  $B = \{a^i b^j c^k \mid i \neq j \vee j \neq k\}$  and define:

$$L = \{a^n \# u_1 \# u_2 \# \dots \# u_m \mid m > n > 0 \wedge u_1, u_2, \dots, u_m \in a^* b^* c^* \wedge u_n \in B\},$$

in words, the number of  $a$  at the beginning indicates where to find a block in  $B$ . This language is in OCA and PA but in neither DetOCA nor DetPA. It is, however, in DetPOCA: one would use the counter to find  $u_n$  (with  $n$  the number of  $a$  at the beginning), and check that  $u_n \in B$  using the semilinear constraint.

## 4 Pumping lemmas: Statements and Applications

Although pumping lemmas abound for context-free languages, and thus for OCA, there is no known technique in the PA world that takes any PA language  $L$  and a long enough word in  $L$ , and creates a word of different length in  $L$ . As mentioned in the introduction, the main expressiveness lemma for PA relies on the fact that any cycle taken twice can be moved around without changing membership. Relying on this and by carefully analyzing the behavior of the counter on long enough runs, we can show an expressiveness lemma reminiscent of a pumping property:

► **Lemma 4** (Depumping lemma). *Let  $L \subseteq \Sigma^*$  be a POCA (resp. DetPOCA) language. For any infinite language  $K \subseteq [\varepsilon]_L$  and  $N \in \mathbb{N}$ , there are words  $u, (u_i)_{i \leq n}, v, (v_j)_{j \leq m}$ , with  $m, n \geq N$ , such that all of the following hold:*

1.  $x = (u_1 u)(u_2 u) \dots (u_n u) \cdot (v_1 v)(v_2 v) \dots (v_{m-1} v)v_m$  is in  $K$ ,
2.  $uv \neq \varepsilon$ ,
3. There exist  $w_1, w_2 \in \Sigma^*$  such that, letting  $x' = u_1 \dots u_n v_1 \dots v_m$ , it holds that  $w_1 x' w_2$  is in  $L$  (resp. in  $[\varepsilon]_L$ ).

**Proof sketch.** Let  $\mathcal{A}$  be a POCA recognizing  $L$ . Now, let  $\{x_1, x_2, \dots\} \subseteq [\varepsilon]_L$  be an infinite set of words such that  $\text{length}(x_{i+1}) > \text{length}(x_i) > i$  for all  $i \geq 1$ . Since  $x_i \in [\varepsilon]_L$ , for all  $i \geq 1$ , we know that for any  $k$ , there is a run  $\rho_k$  of  $\mathcal{A}$  on  $x_1 \dots x_k$  which can be extended to an accepting run. Write  $\rho_k$  as  $\pi_1 \dots \pi_k$  with each  $\pi_i$  being the subrun corresponding to the subword  $x_i$ . (Note that  $\pi_i$  may be different for each value of  $k$ .)

For a word  $w$ , we say a (sub)run of  $\mathcal{A}$  on  $w$  that starts and ends in the same state is a  $w$ -cycle. Since the  $x_i$  are increasing in length, so are the  $\pi_i$ . If we take a large enough  $k \in \mathbb{N}$ , the pigeonhole principle will ensure the existence of a nonempty word  $u$  and an index  $i \in \mathbb{N}$  such that  $u$ -cycles appear more than  $N$  times in  $\pi_i$ . Note that it would suffice to argue that we can shift these  $u$ -cycles to the other subruns  $\pi_j$  with  $j \neq i$  while preserving the validity of the run. (The reason we want to shift cycles rather than just remove them is because we want to preserve the Parikh image.) In this case,  $w_1$  and  $w_2$  would be the words labelling the runs  $\pi'_1 \cdots \pi'_{i-1}$  and  $\pi'_{i+1} \cdots \pi'_p \sigma$  where:  $p$  is the maximal index  $j$  such that we shift some  $u$ -cycle to  $\pi_j$ ,  $\pi'_j$  is the run we get from  $\pi_j$  after shifting the  $u$ -cycles, and  $\sigma$  is any run such that  $\pi_1 \pi_2 \cdots \pi_p \sigma$  is accepting. The only obstruction in doing this is that, while shifting the  $u$ -cycles, we might invalidate the run by making the counter value nonzero at a zero-value transition. This is why we have to take a (possibly) larger  $k \in \mathbb{N}$  so that, again by the pigeonhole principle, we are ensured of the existence of another word  $v$  such that  $v$ -cycles can be shifted along with  $u$ -cycles to guarantee that the above does not happen. The technical aspect of the proof lies in formalising this idea. ◀

► **Remark 5.** Lemma 4 is a *depumping* lemma: it removes portions of the word  $x$  that appear often. We forego the statement for the *pumping* lemma as we will not need it, but the same proof shows that we can swap the roles of  $x$  and  $x'$  in the lemma, thus creating a longer word.

► **Remark 6.** The proof allows for some slightly stronger variations of this statement. For instance, we can assume that  $K^*$  is a set of prefixes of words in  $L$  instead of assuming that  $K \subseteq [\varepsilon]_L$ . In this case, the conclusion in the POCA case would not change and, for DetPOCA, the third conclusion would state that  $w_1 x' w_2$  is Myhill-Nerode equivalent to *some* word in  $K$ .

We now turn to examples of languages that we will show to be outside of DetPOCA and POCA. For the rest of this section, let  $\Sigma = \{a, b, c, \#\}$ . Our examples will rely on the following languages:

- $L_{ab} = \{\#a^n \#b^m \#c^m \# \mid n, m \in \mathbb{N}\}$ ,
- $L_{bc} = \{\#a^n \#b^m \#c^m \# \mid n, m \in \mathbb{N}\}$ ,
- $L_{abc} = \{\#a^n \#b^n \#c^n \# \mid n \in \mathbb{N}\} = L_{ab} \cap L_{bc}$ .

► **Proposition 7.**  $L_{ab}^* \cup L_{bc}^*$  is not recognizable by a DetPOCA.

**Proof.** We rely on Lemma 4. Assume that it is recognizable by a DetPOCA, pick  $L_{abc}$  as the language  $K$  in Lemma 4, and set  $N = 4$ . Note that we have indeed that any word of  $L_{abc}$  is Myhill-Nerode equivalent to  $\varepsilon$  in  $L_{ab}^* \cup L_{bc}^*$ . Using the notations of the lemma, we see that neither  $u$  nor  $v$  can contain  $\#$ , since they are both repeated at least 4 times in  $x$ . Thus, removing the repetitions of  $u$  and  $v$  from  $x$ , we obtain that  $x'$  is of the shape  $\#a^i \#b^j \#c^k \#$  but outside of  $L_{abc}$ ; note that  $x'$  has at least one letter from  $\{a, b, c\}$ . Assume that  $i \neq j$  (the case  $j \neq k$  is similar), and let  $z = \#a\#b\#cc\#$ , a word in  $L$ . For any words  $w_1, w_2$ , the word  $w_1 x' w_2 z$  cannot be in  $L$ , since  $x \notin L_{ab}$  and  $z \notin L_{bc}$ . This shows that  $w_1 x' w_2$  is not Myhill-Nerode equivalent to  $\varepsilon$ , a contradiction. ◀

► **Proposition 8.** Let  $B = \{\#a^i \#b^j \#c^k \# \mid i \neq j \vee j \neq k\}$  and  $C = (\#a^* \#b^* \#c^* \#)^*$ . The language  $C \cdot B \cdot C$  is not expressible with a DetPOCA.

**Proof.** Note that  $L_{abc} \subseteq [\varepsilon]_{CBC}$ : indeed, a word in  $L_{abc}$  is in  $C \setminus B$ . We can thus follow the proof of Proposition 7 and stop at the point where  $x'$  is seen to be of the shape  $\#a^i \#b^j \#c^k \#$  but not in  $L_{abc}$ . In fact,  $x' \in B$ . The conclusion of the pumping lemma now tells us that

there are words  $w_1, w_2$  such that  $w_1x'w_2 \in [\varepsilon]_{CBC}$ . Since  $\varepsilon \cdot x' \in CBC$ , we have that  $w_1x'w_2x' \in CBC$ , so certainly  $w_1x'w_2 \in C$  (recall that  $B \subseteq C$ ). But since  $x' \in B$ , we have that  $w_1x'w_2 \in CBC$  too, and thus that  $\varepsilon \in CBC$ , a contradiction. ◀

► **Remark 9.** The two previous languages happen to be expressible with POCA; let us investigate where the proof of inexpressibility breaks down when we rely on the conclusion in the POCA case of Lemma 4. In Proposition 7, we have the luxury of picking a  $z$ : this is not allowed in the POCA case, which simply guarantees that there are words  $w_1, w_2$  such that  $w_1x'w_2 \in L$ . And indeed, we only know that  $x'$  has an unbalanced number of  $a, b, c$ , leaving the possibility, that  $x' \in L_{ab} \cup L_{bc}$ , so  $w_1 = w_2 = \varepsilon$  would satisfy the conclusion of the Lemma. Similarly, in Lemma 4, there is no contradiction to be gained from  $x' \in B$  on its own, which is the case when  $w_1 = w_2 = \varepsilon$  in the Lemma.

► **Proposition 10.**  $L_{abc}^* = L_{ab}^* \cap L_{bc}^*$  is not recognizable by a POCA.

**Proof.** This follows the same process as the proof of Proposition 7, up to the point where  $x'$  is seen to be of the shape  $\#a^i\#b^j\#c^k\#$  but not in  $L_{abc}$ . Certainly, then, whichever words were to be put at the beginning and end of this word, we cannot reach a word in  $L$ . ◀

## 5 Expressiveness

### 5.1 Normal forms and inclusion in logarithmic space

We first note that cycles of  $\varepsilon$ -transitions, in which a POCA would guess a large number, are not needed. Additionally, we can complete the underlying automaton of a POCA so that:

► **Theorem 11.** For any (Det)POCA language  $L$ , there is a (Det)POCA  $A$  with language  $L$  and a constant  $c \in \mathbb{N}$  such that any word  $w \in L$  is accepted by  $A$  with a run of length at most  $c|w|$  that reads the whole input. In particular, all cycles of  $\varepsilon$ -transitions in  $A$  decrease the counter.

We will assume henceforth that all of our POCA are of the above type. From this, and noting that the Parikh constraint of a POCA can be made quantifier-free by adding “equality modulo  $m$ ” predicates, we immediately get:

► **Corollary 12.** Any DetPOCA language is in the class  $L$ . Any POCA language is in the class  $NL$ .

### 5.2 Separations

We compare the expressiveness of POCA with PA and OCA, in both their deterministic and nondeterministic variants; we obtain the following separations:

- **Theorem 13.** ■ *DetPA and DetOCA are strictly less expressive than DetPOCA;*  
 ■ *PA and OCA are strictly less expressive than POCA;*  
 ■ *The expressive power of DetPOCA is incomparable with that of PA and OCA.*

**Proof.** The inclusions in the first two statements are immediate and strictness was mentioned in Example 1. This example also shows that DetPOCA is not included in either PA or OCA.

What is left to show is that there are PA and OCA languages that are not in DetPOCA. The language  $CBC$  of Proposition 8 is such a language: it is not in DetPOCA, but it can be expressed with both a PA and an OCA (one simply guesses when the  $B$  word occurs and, within this word, guesses and checks which of the options  $i \neq j$  or  $j \neq k$  holds). ◀

In addition, we have exhibited (Propositions 7 and 8) languages expressible with POCA but not DetPOCA. Hence:

► **Theorem 14.** *DetPOCA are strictly less expressive than POCA.*

### 5.3 Rendering the OCA or Parikh part useless in a POCA

The wide disparity of expressive power between POCA and its base models OCA and Parikh automata stands in sharp contrast with the intuition that the two counting features of POCA are orthogonal. In this section, we explore how we can essentially “saturate” the abilities of one of the base models, in such a way that it cannot contribute meaningfully to recognizing a language. This is reminiscent of the work of [18], in which it is shown that if the shuffle of a nonregular context-free language and another language  $T$  is still context-free, then  $T$  has to be regular. In other words, the nonregular context-free language “saturates” the stack. See also [15] for a related notion of *simplest nonregular context-free language*.

Recall that the *shuffle* of two words  $u \sqcup v$  is the set  $\{u_1v_1 \cdots u_kv_k \mid u_i, v_i \in \Sigma^* \wedge u = u_1 \cdots u_k \wedge v = v_1 \cdots v_k\}$ . The shuffle of two languages is the set of shuffles of words from each language.

► **Theorem 15 (One-counter-stripping).** *Let  $L' \subseteq \Sigma^*$  and  $a, b \notin \Sigma$ . If  $L' \sqcup \{a^n b^n \mid n \geq 0\}^*$  is a (Det)POCA language, then  $L'$  is a (Det)PA language. The converse holds.*

**Proof sketch.** Let the POCA accepting  $L$  be  $\mathcal{A}$ . To prove the theorem above, we give a procedure of producing the intended Parikh automaton  $\mathcal{A}'$  accepting  $L'$ , using  $\mathcal{A}$  as a black box. The main idea is that  $\mathcal{A}'$  simulates  $\mathcal{A}$ , but along the accepting runs in  $\mathcal{A}'$ , the counter is only used in a bounded way that can be encoded in the state space; hence we can get rid of the counter while accepting  $L'$ . We formalize this idea as follows:

Let  $C, C_\varepsilon$  be the number of simple cycles with nonempty underlying word, and simple  $\varepsilon$ -cycles in  $\mathcal{A}$ . Let  $C' = C + C_\varepsilon + 1$ . Define a function  $\text{pad} : \Sigma^* \rightarrow (\Sigma \uplus \{a, b\})^*$  such that for any word  $w = c_1 \cdots c_n \in \Sigma^*$ ,  $\text{pad}(w)$  is of the form  $\text{pad}(w) = c_1 \cdot (a^{|Q|} b^{|Q|})^{C'} \cdots c_n \cdot (a^{|Q|} b^{|Q|})^{C'}$ . Note that, if  $w \in L'$ , then  $\text{pad}(w) \in L$ . We extend the function on the language  $L'$  naturally:  $\text{pad}(L) = \{\text{pad}(x) \mid x \in L\} \subset L'$ . The following lemma then holds.

► **Lemma 16.** *Let  $\text{Reach} = \{n \mid \exists (x \cdot y) \in \text{pad}(L'), \text{ and } q_f \in F, (q_0, 0) \xrightarrow{x} (q, n) \xrightarrow{y} q_f\}$  be the set of all counter values appearing in any accepting run in  $\mathcal{A}$  on reading a word from  $\text{pad}(L')$ . The set  $\text{Reach}$  is bounded, i.e., there exists a bound  $B \in \mathbb{N}$  such that, for every  $n \in \text{Reach}, n \leq B$ .*

Using the above lemma, we can already outline the procedure to construct the desired PA  $\mathcal{A}'$  such that  $L(\mathcal{A}') = L'$ . Let the POCA  $\mathcal{A}$  be of the form  $(Q, q_0, \Sigma \uplus \{a, b\}, \Delta, F, \varphi)$ . Then the PA  $\mathcal{A}'$  is of the form  $(Q', q'_0, \Sigma, \Delta', F', \varphi')$  such that,

- $Q' = Q \times \{0, 1, \dots, B\} \uplus \{r\}$ ,
- $q'_0 = (q_0, 0)$  and  $F' = F \times \{0, 1, \dots, B\}$ ,
- for every run of the form  $(q, i) \xrightarrow{l \cdot (a^{|Q|} b^{|Q|})^{C'}} (q', j) \in \Delta^*$ , where  $l \in \Sigma, q, q' \in Q$ , and  $i \leq B$ 
  - (i). if  $j \leq B$ , then  $((q, i) \xrightarrow{l} (q', j)) \in \Delta'$
  - (ii). otherwise  $((q, i) \xrightarrow{l} r) \in \Delta'$ .

Note that, for every configuration  $(q, i)$  in  $\mathcal{A}$  and  $l \in \Sigma$ , the number of runs on the word  $l \cdot (a^{|Q|} b^{|Q|})^{C'}$  is finite as  $\mathcal{A}$  does not contain any nonnegative  $\varepsilon$ -cycle.

- The construction of  $\Delta'$  from  $\Delta$  imposes a linear function  $f : \mathbb{Z}^{\Delta'} \rightarrow \mathbb{Z}^{\Delta}$ . Let the Parikh constraint for  $\mathcal{A}$  be  $\varphi$  with  $|\Delta|$  free variables. Then we define  $\varphi'$  with  $|\Delta'|$  free variables such that, a vector  $\mathbf{v} \in \mathbb{Z}^{\Delta'} \models \varphi'$  if and only if  $f(\mathbf{v}) \models \varphi$ .

It is easy to check that  $\mathcal{A}'$  accept  $w$  if and only if  $\mathcal{A}$  accepts  $\text{pad}(w)$ . This implies  $\mathcal{A}'$  recognises  $L'$ . The above procedure also preserves determinacy, i.e., if  $\mathcal{A}$  is deterministic, then  $\mathcal{A}'$  is also deterministic. ◀

Similarly, we expect that some operation would render the Parikh constraint useless. Specifically, assume that for some language  $L$ , the language  $(L\#)^*$  is recognized by a POCA  $A$ . Consider a long word  $w$  in  $L\#$ ; in the accepting run for it, we could move (pairs of) cycles *after* the  $\#$  symbol. Repeating this, we obtain a subword of  $w$  of constant length, appearing before  $\#$ , which must also be in  $L$ . Hence to recognize  $L$ , one only needs to simulate  $A$  for a counter-correct run and find the subword of constant length to check for constraint-correctness. The Parikh constraint can thus be hardcoded, and we thus conjecture:

► **Conjecture 17.** *Let  $L \subseteq \Sigma^*$  be a language and  $\# \notin L$ . If  $(L\#)^*$  is a POCA (resp. DetPOCA) language, then  $L$  is an OCA (resp. DetOCA) language.*

## 6 Closure Properties

We study in this section the closure properties of the POCA classes. We start with positive closure properties and then move to nonclosure claims. The results of this section are summarized in Figure 1, in the Introduction.

### 6.1 Positive closure properties

► **Theorem 18.** *The class of languages recognized by DetPOCA is closed under complement, inverse morphisms, and intersection/union with regular languages.*

**Proof.**

**Complement.** When there is no counter, i.e., in the DetPA case, this is fairly straightforward: the complement of a DetPA is the union of

1. the complement of the language of the underlying automaton; and
2. the language of the DetPA with the semilinear constraint negated.

For DetPOCA, this approach has multiple caveats: as we will see, DetPOCA is not closed under union, moreover, we need to take the complement of the underlying *DetOCA* which is slightly more technical. Let us sketch how to overcome these limitations. Consider a DetPOCA  $\mathcal{A}$ . We follow the standard first steps for complementing deterministic pushdown automata (e.g., [13, Chapter 10.2]):

1. Ensure that the automaton reads the input word in its entirety;
2. Mark as final any state that can reach a final state following only  $\varepsilon$ -transitions (possibly zeroing the counter along the way).

The language of  $\mathcal{A}$  is unchanged and a word is rejected iff after reading it, we reach a nonfinal state. Call  $F$  the set of final states at this point. Next, note that given the Parikh image of a run starting in the initial state, one can find, in first-order logic, which state is the last one in the run (this is the one state that has more incoming transitions taken than outgoing ones). Let us define a DetPOCA  $\mathcal{B}$  as  $\mathcal{A}$ , but with *all* states final. In addition, the constraint formula of  $\mathcal{B}$  accepts if either the last state of the run is *not* in  $F$  or if it is and the constraint

## 30:10 Parikh One-Counter Automata

formula of  $\mathcal{A}$  rejected the Parikh image. A word is accepted by  $\mathcal{B}$  if either the underlying DetOCA of  $\mathcal{A}$  rejected it or if it did accept it but the constraint set of  $\mathcal{A}$  was rejecting it. This is precisely the complement of  $\mathcal{L}(\mathcal{A})$ , concluding this proof.

**Intersection/union with regular languages, inverse morphism.** These are standard. ◀

► **Theorem 19.** *The class of languages recognized by POCA is closed under union, concatenation, morphisms, inverse morphisms, and intersection with regular languages.*

**Proof.**

**Concatenation.** This follows the classical construction for regular languages. The only complication is that the counter has to be reset after the jump (and the Parikh constraint has to undergo variable renaming as they speak about disjoint sets of variables arising from the original automata). This can be achieved using  $\varepsilon$ -transitions with decrements on the counter.

**Other closures.** These follow standard arguments. ◀

### 6.2 Nonclosure properties

► **Theorem 20.** *The class of languages recognized by DetPOCA is not closed under union, intersection, concatenation with regular languages, and morphisms.*

**Proof.**

**Union, intersection, concatenation with regular languages.** This is covered by Propositions 7, 8, and 10, respectively, noting that  $L_{ab}^*$ ,  $L_{bc}^*$ ,  $B$ , and  $C$  (using the notation therein) are all expressible using DetPOCA.

**Morphisms.** This is immediate from nonclosure under union. Indeed, take any two DetPOCA languages  $L_1, L_2$  over the same alphabet  $\Sigma$  and let  $\Gamma$  be a disjoint alphabet of the same size as  $\Sigma$ . Let  $h: \Gamma^* \rightarrow \Sigma^*$  be any bijective morphism. Certainly,  $T = L_1 \cup h^{-1}(L_2)$  is recognizable with a DetPOCA, since one can decide which language to test for by reading the first letter. Extending  $h$  so that it is the identity over  $\Sigma$ , we have, however, that  $h(T) = L_1 \cup L_2$ . Thus if DetPOCA were closed under morphism, it would be closed under union, a contradiction. ◀

► **Theorem 21.** *The class of languages recognized by POCA is not closed under intersection and complement.*

**Proof.** For intersection, this is the contents of Proposition 10. Nonclosure under complement is immediate from closure under union but not under intersection. ◀

## 7 Decision Problems

### 7.1 Classical decision problems

In this section, we study the computational complexity of some classical decision problems for automata: given one or two automata  $\mathcal{A}$  and  $\mathcal{B}$ , *nonemptiness* asks whether  $\mathcal{L}(\mathcal{A}) \neq \emptyset$ , *universality* whether  $\mathcal{L}(\mathcal{A}) = \Sigma^*$ , *inclusion* whether  $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}(\mathcal{B})$ , and *equivalence* whether  $\mathcal{L}(\mathcal{A}) = \mathcal{L}(\mathcal{B})$ . From the known results listed in Figure 1, we immediately get:

► **Corollary 22.** *Universality, inclusion, and equivalence are undecidable for POCA. Inclusion is undecidable for DetPOCA.*

► **Theorem 23.** *Nonemptiness is NP-complete for DetPOCA and POCA. Universality is coNP-complete for DetPOCA.*

**Proof.** For nonemptiness, hardness comes from the same property for DetPA and PA. In [7, Proposition III.2], this is shown by encoding instances of the SUBSETSUM problem into an instance of the nonemptiness problem for DetPA. NP-membership for nonemptiness for POCA can be shown in a way similar to [7, Proposition III.2]: we can construct an existential Presburger formula  $\varphi_\rho$  whose models form the set of Parikh images of accepting runs of the underlying OCA of a given POCA. The formula  $\varphi_\rho$  can be obtained in polynomial time using a construction from [22, Theorem 4].<sup>2</sup> We can then check whether  $\varphi \wedge \varphi_\rho$  is satisfiable, which is the case if and only if the language of the given POCA is nonempty. Since satisfiability of existential Presburger formulas is in NP (see, e.g., [10] and references therein), this concludes the proof.

For universality of DetPOCA, this is a direct consequence of the (effective!) closure of DetPOCA under complement (Theorem 18) and the previous discussion. ◀

► **Remark 24.** NP-hardness of nonemptiness has only little to do with the hardness of solving the constraint formula itself or from encoding numbers in that formula in binary. Indeed, the constraint formula obtained in the reduction from SUBSETSUM can be made quantifier-free and without constants besides 1, in which case checking that a tuple satisfies the formula is easy (in L). Let us make this reduction more explicit to see this. We build a partial PA (the counter is not needed) that either “takes” a number from the instance set or does not, in the sense that for each number  $n$  in the set, there will be a transition  $t$  that is either taken  $n$  times or 0 times. We present the construction through an example: The following partial PA will select whether  $n = 13$  gets into the candidate subset:

The constraint formula would assert (writing  $t_i$  for the number of times  $t_i$  is taken):

$$t_x = 1 \vee ((t_1 = 1) \wedge (t_2 = t_1 + t_1 + 1) \wedge (t_3 = t_2 + t_2) \wedge (t_4 = t_3 + t_3 + 1)),$$

corresponding to the binary encoding of 13, that is, 1101. Transition  $t_4$  is thus taken exactly 13 times or not at all, and the reduction is concluded by summing these selection transitions and checking if they are unequal to the target value.

► **Corollary 25.** *It is coNP-complete to decide, given a POCA  $\mathcal{A}$  and a regular language  $R$  as an NFA, whether  $\mathcal{L}(\mathcal{A}) \subseteq R$ .*

► **Open Question 26.** *Is equivalence decidable for DetPOCA? We conjecture that it is.*

## 7.2 Parametric decision problems

In the field of formal verification, computational models represent so-called *reactive systems* that communicate with and evolve based on their surrounding environment. To formalize the varying conditions provided by the environment, the models receive *parameters*, usually

<sup>2</sup> See [12] for a construction that fixes a small mistake in the proof of that theorem.

integer valued variables [1]. In [3], it is shown that reachability in parametric timed automata with two clocks correspond to parametric emptiness problem for certain classes of one-counter machines. In [8] and [19], the authors showed that parametric emptiness for OCA (“for any parameter value, the OCA is nonempty”) is decidable, where the parameters may appear on the updates of the counter. We study that problem for POCA; there are two natural places where parameters could appear: the counter updates and within the constraint formula.

- **Definition 27.** A parametric POCA is a tuple  $\mathcal{A} = (Q, q_0, \Sigma, X, \Delta_0, \Delta_+, F, \varphi)$  where:
- $Q, q_0, \Sigma,$  and  $F$  are as in POCA,
  - $X = \{x_1, \dots, x_n\}$  is a finite set of parameters that will take integer values,
  - $\Delta_0$  and  $\Delta_+$  are as in POCA but can also include tuples of the form  $(p, a, +x, q)$  and  $(p, a, -x, q)$  with  $a \in \Sigma^\varepsilon$  and  $x \in X,$
  - $\varphi$  has  $d + n$  free variables, where  $d = |\Delta_0| + |\Delta_+|,$  corresponding to the Parikh image of the run and the valuation of the parameters in  $X.$

Given a valuation  $\mu: X \rightarrow \mathbb{N},$   $\mathcal{A}$  induces a POCA  $\mathcal{A}_\mu$  with well-defined runs, language, etc. A POCA with parametric updates is a parametric POCA in which  $\varphi$  does not have occurrence of the parameters and a POCA with parametric constraint is a parametric POCA in which  $\Delta_0$  and  $\Delta_+$  only have nonparametric transitions.

Given a parametric POCA  $\mathcal{A}$  with parameter set  $X,$  the *parametric universal nonemptiness problem*, PUNE for short, asks whether it holds that, for all  $\mu: X \rightarrow \mathbb{N},$  we have  $\mathcal{L}(\mathcal{A}_\mu) \neq \emptyset.$

► **Theorem 28.** The PUNE problem for POCA with parametric updates is undecidable. It is decidable and complete for  $\text{coNEXP}^{\text{EXP}}$  for POCA with parametric constraint.

**Proof.**

**Parametric updates.** We present a reduction from Hilbert’s tenth Problem to the PUNE problem. Recall that Hilbert’s Tenth Problem asks, given a polynomial with integer coefficients, if it has a positive integer solution.

Let  $P(x_1, \dots, x_n)$  be such a polynomial and write  $P = c_1M_1 + \dots + c_kM_k$  with each  $c_i$  in  $\mathbb{Z}$  and each  $M_i$  a monomial with coefficient 1 (e.g.,  $x_1x_2^2$ ). We construct a POCA  $\mathcal{A}$  with parametric updates over the parameter set  $\{x_1, \dots, x_n\}$  that *evaluates*  $P.$  This is in the following sense: there are transitions  $t_1, \dots, t_k$  of  $\mathcal{A}$  such that for any valuation  $\mu$  of the parameters, there is a unique accepting run  $\rho$  in  $\mathcal{A}_\mu,$  and, writing  $|\rho|_{t_i}$  for the number of times  $t_i$  occurs in  $\rho:$

$$c_1|\rho|_{t_1} + \dots + c_k|\rho|_{t_k} = P(\mu(x_1), \dots, \mu(x_n)).$$

We start with the simplest case:  $P = x_i.$  Consider the following OCA (the labels are not important, so we assume that each transition has a unique label and do not write it):

Here, our transition  $t$  that evaluates to  $P(\mu(x_i))$  is simply the self-loop: if the run is counter-correct, this loop must have been taken  $\mu(x_i)$  times. Note that accepting runs end with a counter value of zero and that this POCA has a single final state – these are properties we will keep throughout this construction.

Next, assume  $P = Mx_i$  with  $M$  a monomial with coefficient 1. We assume that we have built a POCA  $\mathcal{A}_M$  with a transition  $t_M$  that is taken  $M(x_1, \dots, x_n)$  times on accepting runs. We then build the following POCA for  $P:$

As constraint, we combine the Parikh constraint of  $\mathcal{A}_M$  with the statement that the  $+x_i$  loop should be taken the same number of times as  $t_M$ ; consequently, for any accepting run  $\rho$  of this POCA with valuation  $\mu$ , the  $-1$  loop is taken  $|\rho|_{t_M} \mu(x_i)$  times, which is  $M(\mu(x_1), \dots, \mu(x_n)) \mu(x_i)$  by hypothesis. This  $-1$  loop is thus the transition that evaluates to  $P(\mu(x_1), \dots, \mu(x_n))$ .

For the general case, we can chain together our POCA for each monomial one after the other, and obtain our claimed POCA for any polynomial. The constraint formula can then compute the exact value of  $P(\mu(x_1), \dots, \mu(x_n))$  and accept if it is nonzero. Thus, there is no positive integer solution to  $P$  iff for any valuation  $\mu$ ,  $\mathcal{A}_\mu$  has a nonempty language.

**Parametric constraint.** This follows the same proof as decidability in the nonparametric case, but results in a formula of Presburger arithmetic with one alternation starting with  $\forall$ . Validity of such sentences is complete for the class mentioned in the statement of the theorem [9]. ◀

## 8 Conclusion

In the long tradition of combining computational means to obtain expressive models (e.g., [20]), we have equipped one-counter automata with a mechanism to count events *globally*. This mechanism, namely constraining the Parikh image of runs to fall within a semilinear set, always enables recognizing non-context-free languages (e.g.,  $\{a^n b^n c^n \mid n > 0\}$ ) while still preserving the decidability of emptiness for models with effective semilinear Parikh images. However, studying the expressiveness of the combined model is surprisingly difficult: techniques that apply to the original model usually do not preserve satisfaction of the semilinear constraint.

Here, we have obtained expressiveness lemmas that allowed us to study the closure properties and the class relationships of the models at play. In particular, we have shown that there are languages expressible with a combination of deterministic one-counter automata and semilinear constraint that cannot be obtained by any of the underlying mechanisms: the whole is greater than the sum of its parts.

We underline research directions stemming from this work:

- We left open two main questions: 1. Is equivalence decidable for DetPOCA? We conjecture that a refinement of the algorithms for DetOCA ([21, 2]) will lead to a positive answer. 2. Is it true that if  $L' = (L\#)^*$  is a POCA language, then  $L'$  doesn't use the semilinear constraint in any meaningful way, so that  $L$  is an OCA language?
- The undecidability of the parametric universality nonemptiness problem (Theorem 28) is rather unfortunate. Indeed, we had originally expected that this problem would be a natural automata counterpart of the validity of sentences in a fragment of Presburger arithmetic with divisibility called BIL (see [19, Conclusion]). Such sentences are naturally translated to POCA with parametric updates in such a way that validity corresponds to parametric nonemptiness, but alas, validity of the BIL fragment is decidable while the PUNE problem for POCA with parametric updates is not. For context, an elegant connection between another fragment of Presburger arithmetic with divisibility and OCA with parametric updates was established in [11]: the validity problem of the former is interreducible with the nonemptiness problem of the latter via nondeterministic polynomial-time reductions. This leaves open the problem of finding such a correspondence for BIL.

- A reviewer asked the following relevant question: Can a POCA for an OCA language be more succinct than the equivalent OCA (and similarly for a POCA for a PA language)? Some examples come to mind:  $\{w \in \{a, b\}^* \mid |w|_a = 18|w|_b\}$  requires an OCA with at least 18 states, but can be done with a PA with one state. A more interesting class of languages to study this trade-off is that of languages expressible with an OCA but not by a PA, or conversely.

## Abstract

We present a  $9^k \cdot n^{O(1)}$ -time algorithm for the proper circular-arc vertex deletion problem, resolving an open problem of van 't Hof and Villanger [Algorithmica 2013] and Crespelle et al. [Computer Science Review 2023]. Our structural study also implies parameterized algorithms for modification problems toward proper Helly circular-arc graphs.

## 1 Introduction

A graph is a *circular-arc graph* if its vertices can be assigned to arcs on a circle such that there is an edge between two vertices if and only if their corresponding arcs intersect. If none of the arcs properly contains another, then the graph is a *proper circular-arc graph*. See Figure 1 for two examples of proper circular-arc graphs. Proper circular-arc graphs “form an important subclass of the class of all claw-free graphs,” and their study has been an important step towards finding “a structural characterization of all claw-free graphs” [6]. The structures and recognition of proper circular-arc graphs have been well studied and well understood [19, 8].

Another and earlier motivation for studying (proper) circular-arc graphs is from their relation with (*proper*) *interval graphs*, i.e., intersection graphs of intervals on the real line. The *intersection graph* of a family of sets has a vertex for each set and an edge between two vertices if and only if their the sets they represent have a nonempty intersection. It is easy to see that each (proper) interval graph is a (proper) circular-arc graph, and the connection of these classes has been used in both structural and algorithmic studies of these classes. Indeed, the first linear-time recognition algorithm for proper circular-arc graphs is based on a general observation of both proper circular-arc graphs and proper interval graphs [8]. Neither graph in Figure 1 is a proper interval graph, but removing any vertex from Figure 1(a), or any vertex but  $v_5$  from Figure 1(b) leaves a proper interval graph.

Let  $\mathcal{G}$  be a hereditary (closed under taking induced subgraphs) graph class. Given a graph  $G$  and an integer  $k$ , the  $\mathcal{G}$  vertex deletion problem asks whether we can remove  $k$  vertices from  $G$  to make a graph in  $\mathcal{G}$ . It is known that the  $\mathcal{G}$  vertex deletion problem is NP-hard

■ **Figure 1** Two proper circular-arc graphs and their arc models.

when  $\mathcal{G}$  is nontrivial (i.e., having infinite members and infinite non-members) [15]. These problems have been intensively studied in the framework of parameterized computation. Suppose that the input graph has  $n$  vertices and  $m$  edges. We say that a graph problem is *fixed-parameter tractable (FPT)* if there is an algorithm solving it in time  $f(k) \cdot n^{O(1)}$ , where  $f$  is a computable function depending only on  $k$  [9]. For example, it is well known that the proper interval vertex deletion problem is FPT [20, 3]. In the algorithm of van 't Hof and Villanger [20], the kinship between proper circular-arc graphs and proper interval graphs plays a crucial role. They showed that it suffices to destroy all the small forbidden induced subgraphs, and then the graph is already a proper circular-arc graph, on which the proper interval vertex deletion problem can be solved in linear time. They asked whether the proper circular-arc vertex deletion problem is FPT as well, and this open problem was recently raised again by Crespelle et al. [7]. We answer this question affirmatively.

► **Theorem 1.** *The proper circular-arc vertex deletion problem can be solved in time  $9^k \cdot n^{O(1)}$ .*

A major difference between the class of proper interval graphs and the class of proper circular-arc graphs is that the later class is not closed under disjoint union. This can be easily observed from their models: while we can always put intervals for two different components side by side, no such accommodation is possible for two sets of arcs if one set of them covers the whole circle. As a matter of fact, if a proper circular-arc graph is not connected, it has to be a proper interval graph. (The same remark applies to the relation between circular-arc graphs and interval graphs.)

If a proper circular-arc graph contains a hole of length at least five, then its property is quite similar to a proper interval graph. What is difficult is when a few arcs cover the whole circle in an arc model. For such a graph, it is more convenient to study its complement. Indeed, when characterizing proper circular-arc graphs, Tucker [19] actually listed the forbidden induced subgraphs of the complement class. He also observed that if the complement  $\bar{G}$  of a proper circular-arc graph  $G$  is not connected, then  $\bar{G}$  is bipartite. *Permutation graphs* are the intersection graphs of line segments between two parallel lines, and *bipartite permutation graphs* are those permutation graphs that are bipartite. Bipartite

permutation graphs are also known as proper interval bigraphs and unit interval bigraphs [14]. It is well known that a co-bipartite graph  $H$  is a proper circular-arc graph if and only if  $\overline{H}$  is a bipartite permutation graph.

Let  $(G, k)$  be an instance to the proper circular-arc vertex deletion problem, and let  $V_-$  be a solution. If  $G - V_-$  is not connected, then it is a proper interval graph; if  $G - V_-$  is not co-connected, then it is the complement of a bipartite permutation graph. We can call the algorithm of Cao [3] and the algorithm of Bożyk et al. [1] to check whether such a set  $V_-$  exists, and we are done if it does. In the rest, we may assume that  $G - V_-$  is neither a proper interval graph nor the complement of a bipartite graph, hence both connected and co-connected. For this purpose we may assume that  $G$  itself is both connected and co-connected; otherwise, there is a unique component  $C$  of  $G$  or  $\overline{G}$  such that  $V(G) \setminus V(C) \subseteq V_-$ . Either the instance is trivially FPT, when  $n = O(k)$ , or it suffices to consider the largest component of  $G$  or  $\overline{G}$ .

The algorithm proceeds as follows. We can destroy all forbidden induced subgraphs of order at most seven by branching. Now  $G$  is free of small forbidden induced subgraphs and is both connected and co-connected. Our key observation is that if  $G$  is not already a proper circular-arc graph, then  $\overline{G}$  must be bipartite. Note that any induced subgraph of a bipartite graph is bipartite, but we have assumed that  $G - V_-$  is not the complement of a bipartite graph. Therefore, we are ready to directly return “yes” or “no.”

Since the parameterized algorithm branches on a small set of vertices that intersects every solution, we can easily turn it into an approximation algorithm for the maximum proper circular-arc induced subgraph problem.

► **Theorem 2.** *There is a polynomial-time approximation algorithm of approximation ratio 9 for the minimization version of the proper circular-arc vertex deletion problem.*

Proper circular-arc graphs also arise naturally when we consider the clique graph (the intersection graph of maximal cliques of a host graph) of a circular-arc graph. The complicated structures of circular-arc graphs are mainly due to the lack of the so-called *Helly* property: every set of pairwise intersecting arcs has a common intersection. For example, neither model in Figure 1 is Helly: the set  $\{v_1, v_2, v_3\}$  in (a) and the set  $\{v_3, v_4, v_5\}$  in (b) violate the Helly property. A graph is a *Helly circular-arc graph* if it admits an arc model that is Helly. Since every interval model is Helly, all interval graphs are Helly circular-arc graphs. It is well known that the clique graph of an interval graph, with at most  $n$  maximal cliques, is a proper interval graph [13]. The same upper bound holds for the number of maximal cliques in a Helly circular-arc graph, and the clique graph of a Helly circular-arc graph is always a proper circular-arc graph [10]. Let us remark parenthetically that a circular-arc graph may have an exponential number of maximal cliques, e.g., the complement of the union of  $p$  disjoint edges, which has  $2p$  vertices, each of degree  $2p - 2$ .

The class of proper Helly circular-arc graphs is sandwiched between proper circular-arc graphs and proper interval graphs. This observation has been crucial for the algorithms for modification problems toward proper interval graphs [3]. A graph is a *proper Helly circular-arc graph* if it has an arc model that is both proper and Helly. A word of caution is worth on the definition of proper Helly circular-arc graphs. One graph might admit two arc models, one being proper and the other Helly, but no arc model that is both proper and Helly. For example, both models in Figure 1 are proper but neither is Helly, and it is not difficult to make Helly arc models for  $S_3$  and  $W_4$ , but, as the reader may easily verify, neither of them admits an arc model that is both proper and Helly. Therefore, the class of proper Helly circular-arc graphs does not contain all those graphs being both proper circular-arc graphs and Helly circular-arc graphs, but a proper subclass of it. Indeed, a proper circular-arc

graph is a proper Helly circular-arc graph if and only if it is  $\{S_3, W_4\}$ -free [16]. Another characterization of proper Helly circular-arc graphs is that they are precisely those graphs whose clique matrices have the circular-ones property for both rows and columns [17].

We then consider modification problems toward proper Helly circular-arc graphs. For this class we also consider the edge deletion and completion problems (a proof of their NP-completeness was provided in the full version). The edge deletion (resp., completion) problem asks whether we can delete (resp., add) at most  $k$  edges to a graph to make it satisfy certain properties. Again, we start by destroying all small forbidden induced subgraphs, up to six vertices. We show that a connected graph free of such induced subgraphs is already a proper Helly circular-arc graph. For the vertex deletion problem, either we remove all but one component, or we remove vertices to get a proper interval graph. The edge deletion problem is even simpler: if the graph is not connected, we cannot make it connected by deleting edges. Thus, depending on whether the graph is connected, either we are already done, or we are solving the proper interval edge deletion problem. This idea can even solve the general deletion problem that allows  $k_1$  vertex deletions and  $k_2$  edge deletions. The situation is quite different for the completion problem. We are happy if we can add at most  $k$  edges to make the input graph a proper interval graph. Otherwise, we have to make a connected proper Helly circular-arc graph. After we have dealt with all the small forbidden induced subgraphs, the only nontrivial case is when there is a large component, which contains a long hole  $H$ , and several small components. We need to “attach” these small components to vertices on  $H$ . Since these operations are local, we can find a solution by dynamic programming. Thus, all three problems are FPT, and they can be done in linear FPT time. Again, the parameterized algorithm for the vertex deletion problem can be easily turned into an approximation algorithm.

- **Theorem 3.** *For modification problems toward proper Helly circular-arc graphs, there are*
- *an  $O(6^k \cdot (m + n))$ -time algorithm for the vertex deletion problem;*
  - *an  $O(8^k \cdot (m + n))$ -time algorithm for the edge deletion problem;*
  - *an  $O(14^{k_1+k_2} \cdot (m + n))$ -time algorithm for the deletion problem; and*
  - *a  $k^{O(k)} \cdot (m + n)$ -time algorithm for the completion problem.*

*Moreover, there is an  $O(nm + n^2)$ -time approximation algorithm of approximation ratio 6 for the minimization version of the proper Helly circular-arc vertex deletion problem.*

Somewhat surprisingly, modification problems toward circular-arc graphs and its subclasses have not received sufficient attention. We hope our work will inspire more study in this direction. Apart from the two classes in the present paper, the next interesting class is the class of normal Helly circular-arc graphs, a super class of proper Helly circular-arc graphs. They have played crucial roles in solving modification problems to interval graphs [5, 2]. Also related and probably simpler are the modification problems toward unit (Helly) circular-arc graphs. It is well known that a graph is a proper interval graph if and only if it is a unit interval graph. However, there are proper (Helly) circular-arc graphs that are not unit (Helly) circular-arc graphs, e.g., the graph obtained from an even hole of length at least eight by adding edges to connect consecutive even-numbered vertices.

## 2 Preliminaries

All graphs discussed in this paper are undirected, simple, and finite. The vertex set and edge set of a graph  $G$  is denoted by, respectively,  $V(G)$  and  $E(G)$ . Let  $n = |V(G)|$  and  $m = |E(G)|$ . A *walk* in a graph  $G$  is a sequence of vertices and edges in the form of  $v_0$ ,

$v_0v_1, v_1, v_1v_2, \dots, v_\ell$ . Since the edges are determined by the vertices, such a walk can be denoted by  $v_0v_1 \dots v_\ell$  unambiguously. We say that this walk *connects*  $v_0$  and  $v_\ell$ , which are the *ends* of this walk, and refer to it as a  $v_0$ - $v_\ell$  walk. The *length* of a walk is the number of occurrences of edges it contains, and  $\ell$  in the previous example. A walk is *closed* if  $\ell > 1$  and  $v_0 = v_\ell$ . A walk is a *path* if all its vertices are distinct. A path is *nontrivial* if it contains at least three vertices. A closed walk of length  $\ell$  is a *cycle* if it visits precisely  $\ell$  vertices; i.e., no repeated vertices except the two ends. The length of a cycle  $C$  is denoted as  $|C|$ . For simplicity, we denote a cycle of length  $\ell$  as  $v_1v_2 \dots v_\ell$  instead of  $v_1v_2 \dots v_\ell v_1$ . The indices are understood to be modulo  $\ell$ ; e.g.,  $v_0 = v_\ell$  and  $h_{-1} = h_{\ell-1}$ . A *hole* is an induced cycle of length at least four. A walk, path, cycle, or hole is *odd* (resp., *even*) if its length is odd (resp., even). For  $\ell \geq 3$ , we use  $C_\ell$  to denote an induced cycle on  $\ell$  vertices; if we add a new vertex to a  $C_\ell$  and make it adjacent to no or all vertices on the cycle, then we end with a  $C_\ell^*$  or  $W_\ell$ , respectively.

The complement graph  $\overline{G}$  of a graph  $G$  is defined on the same vertex set  $V(G)$ , where a pair of vertices  $u$  and  $v$  is adjacent in  $\overline{G}$  if and only if  $uv \notin E(G)$ ; e.g.,  $\overline{C_5^*}$  is  $W_5$ . The graph  $\overline{C_3^*}$  is also called a *claw*. A graph  $G$  is *connected* if every pair of vertices is connected by a path, and *co-connected* if  $\overline{G}$  is connected.

A *circular-arc graph* is the intersection graph of a set of arcs on a circle. The set of arcs is called an *arc model* of this graph. In this paper, all arcs are closed. An arc model is *proper* if no arc in it properly contains another arc. A graph is a *proper circular-arc graph* if it has a proper arc model. In case there is a point of the circle avoided by all the arcs in an arc model, we can cut the circle and straighten all the arcs into line segments. Such a graph is an *interval graph*, i.e., the intersection graph of a set of closed intervals on the real line, and the set of intervals is an *interval model* of this graph. Proper interval graphs are defined analogously. Clearly, any (proper) interval model can be viewed as a (proper) arc model leaving some point uncovered, and hence all (proper) interval graphs are always (proper) circular-arc graphs.

■ **Figure 2** Some small forbidden induced graphs.

Let  $F$  be a fixed graph. We say that a graph  $G$  is  $F$ -free if  $G$  does not contain  $F$  as an induced subgraph. For a set  $\mathcal{F}$  of graphs, a graph  $G$  is  $\mathcal{F}$ -free if  $G$  is  $F$ -free for every  $F \in \mathcal{F}$ . If every  $F \in \mathcal{F}$  is minimal, i.e., not containing any  $F' \in \mathcal{F}$  as a proper induced subgraph, then  $\mathcal{F}$  comprises the (minimal) *forbidden induced subgraphs* of this class. See Figure 2 for some of the forbidden induced subgraphs considered in the present paper. We use  $S_3^*$  to denote the graph obtained by adding an isolated vertex to  $S_3$ .

► **Theorem 4** ([19]). *A graph is a proper circular-arc graph if and only if it is free of  $S_3^*, C_\ell^*$  with  $\ell \geq 4$ , as well as the complements of  $S_3, F_1, F_2, F_3, F_4, C_{2\ell+2}$ , and  $C_{2\ell-1}^*$  with  $\ell \geq 2$ .*

Neither the class of circular-arc graphs nor the class of proper circular-arc graphs is closed under taking disjoint unions. Indeed, if a (proper) circular-arc graph  $G$  is not a (proper) interval graph, then in any model of  $G$ , the union of the arcs covers the whole circle. Such a graph is necessarily connected.

► **Proposition 5** (Folklore). *If a proper circular-arc graph  $G$  is not connected, then  $G$  is a proper interval graph.*

Proper circular-arc graphs have three infinite families of forbidden induced subgraphs, namely,  $\{C_\ell^* \mid \ell \geq 4\}$ ,  $\{\overline{C_{2\ell+2}} \mid \ell \geq 2\}$ , and  $\{\overline{C_{2\ell-1}^*} \mid \ell \geq 2\}$  by Theorem 4. The first of them can be ignored for connected graphs.

► **Lemma 6.** *Let  $G$  be a connected graph. If  $G$  does not contain the complement of  $C_3^*$  or the complement of  $S_3$ , then  $G$  is  $\{C_\ell^* \mid \ell \geq 5\}$ -free.*

**Proof.** Suppose for contradiction that there exist an induced cycle  $C$  and a vertex  $v$  in  $G$  with  $|C| \geq 5$  and  $V(C) \cap N(v) = \emptyset$ . Since  $G$  is connected, we can find a shortest path from  $v$  to  $C$ . Let the last three vertices on this path be  $x$ ,  $y$ , and  $z$ ; note that  $z$  is on  $C$  and  $x$  is nonadjacent to any vertex on  $C$ . We may number the vertices on  $C$  such that  $C = v_1 v_2 \cdots v_{|C|}$  and  $z = v_2$ . If  $y$  is adjacent to only  $v_2$  on  $C$ , then  $\{v_1, v_2, v_3, y\}$  induces a claw. If  $y$  is also adjacent to both  $v_1$  and  $v_3$ , then  $\{v_1, v_3, x, y\}$  induces a claw, and it is similar if  $y$  is adjacent to any three consecutive vertices on  $C$ . Otherwise,  $y$  is adjacent to precisely one of  $v_1$  and  $v_3$ . Without loss of generality, assume that  $y$  is adjacent to  $v_3$  but not  $v_1$ . Note that  $y$  is not adjacent to  $v_4$  either, and then  $\{v_1, v_2, v_3, v_4, x, y\}$  induces a copy of the complement of  $S_3$ . ◀

An arc model is *Helly* if every set of pairwise intersecting arcs has a nonempty common intersection. A circular-arc graph is *proper Helly* if it has an arc model that is both proper and Helly.

► **Theorem 7** ([17]). *A proper circular-arc graph is a proper Helly circular-arc graph if and only if it contains no  $W_4$  or  $S_3$ .*

Note that  $S_3^*$  contains  $S_3$ , while all the complements of  $F_1, F_2, F_3, F_4$ , and  $\{C_{2\ell}, C_{2\ell-1}^* \mid \ell \geq 4\}$  contain  $W_4$ . The following corollaries follow from Theorem 7, together with Theorem 4 and Lemma 6, respectively.

► **Corollary 8** ([17]). *A graph is a proper Helly circular-arc graph if and only if it contains no  $\overline{C_3^*}, S_3, \overline{S_3}, W_4, W_5, \overline{C_6}$ , or  $C_\ell^*$  for  $\ell \geq 4$ .*

► **Corollary 9.** *Let  $G$  be a connected graph. If  $G$  does not contain  $\overline{C_3^*}, C_4^*, S_3, \overline{S_3}, W_4, W_5$ , or  $\overline{C_6}$ , then  $G$  is a proper Helly circular-arc graph.*

Recall that proper interval graphs are precisely  $\{\overline{C_3^*}, S_3, \overline{S_3}, C_\ell \mid \ell \geq 4\}$ -free graphs [18, 21].

► **Corollary 10.** *Let  $G$  be a proper Helly circular-arc graph. Then  $G$  is a proper interval graph if and only if  $G$  does not contain any holes.*

The following can be viewed as a constructive version of Corollary 9.<sup>1</sup>

► **Proposition 11** (\*). *Let  $G$  be a connected graph. In  $O(m+n)$  time we can either detect an induced subgraph in  $\{\overline{C_3^*}, C_4^*, S_3, \overline{S_3}, W_4, W_5, \overline{C_6}\}$ , or build a proper and Helly arc model for  $G$ .*

A graph is a *permutation graph* if its vertices can be assigned to line segments between two parallel lines such that there is an edge between two vertices if and only if their corresponding segments intersect. The class of permutation graphs has a large number of forbidden induced subgraphs [11]. Fortunately, most of them contain an odd cycle, and thus the structures of forbidden induced subgraphs of bipartite permutation graphs are far simpler.

<sup>1</sup> Proofs of statements marked with \* are given in the full version (attached).

► **Theorem 12** ([11]). *A graph is a bipartite permutation graph if and only if it is free of  $F_1$ ,  $F_2$ ,  $F_3$ ,  $C_3$ , and  $C_\ell$  with  $\ell \geq 5$ .*

We correlate proper circular-arc graphs and bipartite permutation graphs.

► **Theorem 13** (Folklore). *The following are equivalent on a graph  $G$ :*

- i)  $G$  is a proper circular-arc graph and  $\overline{G}$  is bipartite; and
- ii)  $\overline{G}$  is a bipartite permutation graph.

The following is complement to Proposition 5 in a sense. Note that (proper) circular-arc graphs that are co-bipartite have played crucial roles in understanding these graph classes [19].

► **Proposition 14** ( $\star$ ). *Let  $G$  be a proper circular-arc graph. If  $\overline{G}$  is not connected, then  $\overline{G}$  is a bipartite permutation graph.*

### 3 Deletions to proper Helly circular-arc graphs

We first study the proper Helly circular-arc vertex deletion problem. We may assume without loss of generality that the input graph cannot be made a proper interval graph by removing  $k$  vertices. Therefore, the resulting graph after removing any  $k$ -solution is connected by Proposition 5. An FPT algorithm is immediate from Corollary 9: after destroying all the copies of  $\overline{C}_3^*$ ,  $C_4^*$ ,  $S_3$ ,  $\overline{S}_3$ ,  $W_4$ ,  $W_5$ , and  $\overline{C}_6$  in  $G$  by standard branching, we return all vertices except those in a maximum-order component. A similar (and simpler) approach works for the proper Helly circular-arc edge deletion problem. The focus of the following proof is thus on efficient implementations.

► **Theorem 15.** *The proper Helly circular-arc vertex deletion problem and the proper Helly circular-arc edge deletion problem can be solved in time  $O(6^k \cdot (m + n))$  and  $O(10^k \cdot (m + n))$ , respectively.*

**Proof.** Let  $(G, k)$  be an instance of proper Helly circular-arc vertex deletion. Our algorithm proceeds as follows. We start by calling the algorithm of Cao [3] to check whether there is a set  $V_-$  of at most  $k$  vertices such that  $G - V_-$  is a proper interval graph. If the set is found, then we return “yes.” In the rest, we look for a solution  $V_-$  such that  $G - V_-$  is *not* a proper interval graph. By Proposition 5, (note that a proper Helly circular-arc graph is a proper circular-arc graph,)  $G - V_-$  is connected.

For the general case, the algorithm solves the problem by making recursive calls to itself; we return “no” directly for a recursive call in which  $k < 0$ . For each component  $C$  of  $G$ , we call the algorithm of Proposition 11. If a subgraph induced by  $F \subseteq V(G)$  is found, then the algorithm calls itself  $|F|$  times, each with a new instance  $(G - v, k - 1)$  for some  $v \in F$ . Since we need to delete at least one vertex from  $F$ , the original instance  $(G, k)$  is a yes-instance if and only if at least one of the instances  $(G - v, k - 1)$  is a yes-instance. Now that  $G$  is free of  $\overline{C}_3^*$ ,  $C_4^*$ ,  $S_3$ ,  $\overline{S}_3$ ,  $W_4$ ,  $W_5$ , and  $\overline{C}_6$ , every component of  $G$  is a proper Helly circular-arc subgraph (Corollary 9). We find a component  $C$  of  $G$  that has the maximum order. We return “yes” if  $|V(C)| \geq n - k$ , when  $V(G) \setminus V(C)$  is a solution, or “no” otherwise. Since each of  $\overline{C}_3^*$ ,  $C_4^*$ ,  $S_3$ ,  $\overline{S}_3$ ,  $W_4$ ,  $W_5$ , and  $\overline{C}_6$  has at most 6 vertices, at most 6 recursive calls are made, all with parameter value  $k - 1$ . By Proposition 11, each recursive call can be made in  $O(m + n)$  time. Therefore, the total running time is  $O(6^k \cdot (m + n))$ .

The algorithm for the edge deletion problem is even simpler. Again, we start by calling the algorithm for proper interval edge deletion problem [3], which takes time  $O(4^k \cdot (m + n))$ . We proceed only when the answer is “no.” In the recursive calls for the general case, we always

return “no” whenever  $k$  is negative or  $G$  becomes disconnected; note that a disconnected graph cannot be made connected by edge deletions. We call the algorithm of Proposition 11, and return “yes” if  $G$  is already a proper Helly circular-arc graph. Otherwise, an induced subgraph  $F$  is found. The algorithm calls itself  $|E(F)|$  times, each with a new instance  $(G - uv, k - 1)$  for some edge  $uv$  in  $G[F]$ . By Proposition 11, each recursive call can be made in  $O(m + n)$  time. Therefore, the total running time is  $O(10^k \cdot (m + n))$ , where 10 is the number of edges in a  $W_5$ . ◀

It is straightforward to adapt an approximation algorithm for the proper Helly circular-arc vertex deletion problem from the parameterized algorithm in Theorem 15. From Theorem 15 we can easily derive an FPT algorithm for the combined deletion problem toward proper Helly circular-arc graphs, which allows  $k_1$  vertex deletions and  $k_2$  edge deletions. We can fill in the gap between the constants in Theorems 15 and 3. Only  $S_3$ ,  $W_5$ , and  $\overline{C_6}$  have more than eight edges. For an  $S_3$ , either we delete one edge between two degree-four vertices, or we have to delete both edges incident to a degree-2 vertex. For the other two cases, the ideas are similar. The details are deferred to the full version.

#### 4 Proper Helly circular-arc completion

Compared to the deletion problems, the completion problem toward proper Helly circular-arc graphs is significantly more difficult. For all the deletion problems, we can always assume that the graph is connected, and then by Corollary 9, we are only concerned with small forbidden induced subgraphs. Since adding edges may make a graph connected, we cannot assume connected input graphs for the completion problem.

Every hole in a proper Helly circular-arc graph is a dominating set of the graph, and we can be more specific on the intersection between a hole and the neighborhood of any vertex.

► **Proposition 16** ( $\star$ ). *Let  $H$  be a hole in a proper Helly circular-arc graph. Every vertex in this graph has at least two neighbors on  $H$ .*

It is well known that the maximal cliques of an interval graph can be arranged as a path. Gavril [12] showed that the maximal cliques of a Helly circular-arc graph can be arranged as a circle. This implies that a Helly circular-arc graph has a linear number of maximal cliques.

► **Theorem 17** ([12]). *A graph  $G$  is a Helly circular-arc graph if and only if its maximal cliques can be arranged as a circle so that for every vertex  $v$  in  $G$ , the maximal cliques containing  $v$  are consecutive.*

We use a *clique cycle* to denote the circular arrangement of maximal cliques specified in Theorem 17, and a *clique path* is defined analogously. In a clique path, we call the first and the last cliques *end cliques*. Note that a clique path can always be viewed as a clique cycle, while if two consecutive cliques of a clique cycle are disjoint, then it can be viewed as a clique path.

Proper interval graphs are precisely claw-free interval graphs, which can be restated as a graph is a proper interval graph if and only if it is claw-free and has a clique path. One may thus expect that a graph is a proper Helly circular-arc graph if and only if it is claw-free and has a clique cycle. As we have mentioned, however,  $S_3$  is a Helly circular-arc graph and hence has a clique cycle, but it is not a proper Helly circular-arc graph even though it is claw-free. The following statement can be directly observed from forbidden induced subgraphs of the class of proper Helly circular-arc graphs and of the class of normal Helly circular-arc graphs; see also Lin et al. [17, Theorem 9].<sup>2</sup>

<sup>2</sup> An arc model is known to be normal and Helly if no set of three or fewer arcs covers the circle [12, 4].

► **Lemma 18** ([17]). *A graph is a proper Helly circular-arc graph if and only if it is claw-free and it has an arc model in which no set of three or fewer arcs covers the circle.*

If a proper Helly circular-arc graph  $G$  is not an interval graph, then it has a hole (Corollary 10). The structure of every local part of  $G$  is very like a proper interval graph when the hole is long enough (the length at least six). With the removal of two maximal cliques with no edge in between from  $G$ , the hole is separated into two sub-paths. Since every remaining vertex is adjacent to one of the two sub-paths, the remaining graph has precisely two components.

► **Lemma 19** ( $\star$ ). *Let  $G$  be a proper Helly circular-arc graph that is not an interval graph. Let  $A_1$  and  $A_2$  be two maximal cliques of  $G$  with no edge between them, and let  $B_1$  and  $B_2$  be the vertex sets of the two components of  $G - (A_1 \cup A_2)$ . Let  $G_1$  be any proper interval graph on  $B_1 \cup A_1 \cup A_2$  in which  $A_1$  and  $A_2$  are the end cliques, and  $N_{G_1}(A_i) \cap B_1 = N_G(A_i) \cap B_1$  for  $i = 1, 2$ . Replacing  $G[B_1 \cup A_1 \cup A_2]$  with  $G_1$  gives another proper Helly circular-arc graph.*

For the completion problem, we may again assume that the input graph  $G$  is free of  $\overline{C}_3^*$ ,  $C_4^*$ ,  $S_3$ ,  $\overline{S}_3$ ,  $W_4$ ,  $W_5$ , and  $\overline{C}_6$ . We are done if  $G$  is already a proper Helly circular-arc graph. In particular, this is the case when  $G$  is a proper interval graph or when  $G$  is connected (Corollary 9). Thus, we may assume that  $G$  is not connected and it is not a proper interval graph. There must be a hole in  $G$  (Corollary 10), and we add either a chord of this hole, or an edge between this hole and every vertex in other components. If there is a hole of length of no more than  $16k + 16$ , then there are only  $O(k^2)$  such choices, and we can branch on adding one of them. In the rest, every hole is longer than  $16k + 16$  (hence at least half of the vertices on  $H$  have no neighbors incident to a  $k$ -solution). Let  $H$  be such a hole, and let  $G_0$  be the component of  $G$  that contains  $H$ . Note that  $G_0$  is a proper Helly circular-arc graph (Corollary 9). After adding  $k$  or fewer edges, if the resulting graph is a proper Helly circular-arc graph, then there must be a hole of length greater than  $k$  in the subgraph induced by  $V(H)$ . Thus, for every vertex  $x$  in  $V(G) \setminus V(G_0)$ , at least two edges must be added between  $x$  and  $H$  (Proposition 16). We can return “no” if  $|V(G_0)| < n - \frac{k}{2}$ . Other components have fewer than  $k$  vertices while any hole is longer than  $16k + 16$ , and thus they are already proper interval subgraphs. They are accordingly called *small components*.

We say that a vertex  $x$  is *touched* by a solution  $E_+$  if  $x$  is an endpoint of an edge in  $E_+$ , and a set  $X$  of vertices is *touched* if at least one vertex in  $X$  is touched. All vertices in  $V(G) \setminus V(G_0)$  are touched, and we are more concerned with touched vertices in  $G_0$ .

► **Proposition 20** ( $\star$ ). *Let  $E_+$  be a solution to  $G$ . If a maximal clique  $K$  of  $G$  is untouched by  $E_+$ , then  $K$  is a maximal clique of  $G + E_+$ .*

Recall that a clique cycle of a proper Helly circular-arc graph can be found in linear time [4]. We may fix a clique cycle  $\langle K_1, K_2, \dots, K_\ell \rangle$  of  $G_0$ , denoted by  $\mathcal{K}$ , and assume that  $H$  and  $\mathcal{K}$  are numbered such that no neighbor of  $v_1$  or  $v_{|H|}$  is touched, and  $\{v_1, v_{|H|}\} \subseteq K_1$ , which is untouched. Note that  $G_0$  has at least  $|H|$  maximal cliques. Since  $H$  is longer than  $16k + 16$ , few of them are touched by a  $k$ -solution  $E_+$ . By Lemma 19 and Proposition 20, these untouched maximal cliques serve as “isolators” of the modifications.

We can guess another untouched maximal clique  $K_p$  of  $G_0$  that is disjoint from and nonadjacent to  $K_1$ . By Proposition 20,  $K_1$  and  $K_p$  are both maximal cliques of a proper Helly circular-arc graph  $G + E_+$ . Since  $K_p$  is disjoint from and nonadjacent to  $K_1$ , it follows that  $G + E_+ - (K_1 \cup K_p)$  is not connected. Then  $H$  is broken into two paths in  $G - (K_1 \cup K_p)$ . Recall that every vertex in  $V(G) \setminus V(G_0)$  needs to be connected to a vertex on  $H$ . When the graph  $G + E_+$  is not a proper interval graph, every small component is connected to

## 31:10 Modification Problems Toward Proper (Helly) Circular-Arc Graphs

exactly one of the two sub-paths of  $H$ . But then the resulting graph remains connected after all vertices in  $K_1 \cup K_p$  removed, a contradiction. We can guess in  $2^k$  time to which side each small component is attached. Then we need to add edges to make two proper interval graphs. However, we cannot call the proper interval completion problem to solve this task. For example, the subgraph induced by  $\bigcup_{i=1}^p K_i$  together with the small components is already a proper interval graph. The trouble is how to make them connected while keeping  $K_1$  and  $K_p$  the end cliques of the final clique path. The same holds for the other part of the problem.

For each  $i$  with  $1 < i < |H|$ , let the maximal cliques containing  $v_i$  be  $K_{\text{from}(i)}, \dots, K_{\text{to}(i)}$ ; i.e.,  $\text{from}(i)$  and  $\text{to}(i)$  are the smallest and, respectively, the largest indices. We define  $K_{\text{to}(1)}$  and  $K_{\text{from}(|H|)}$  analogously. Let  $r$  be the number of small components, denoted as  $C_1, \dots, C_r$ . For each pair  $p, q$  of indices with  $1 \leq p < q \leq |H|$ , and each subset  $S$  of  $[1..r]$ , we check whether it is possible to add at most  $k$  edges to make  $G[\bigcup_{i=\text{to}(p)}^{\text{from}(q)} K_i \cup \bigcup_{j \in S} C_j]$  a proper interval graph, under the condition that  $K_{\text{to}(p)}$  and  $K_{\text{from}(q)}$  are the end cliques and remain untouched. Let  $\beta(S, p, q)$  denote the minimum cost if it is at most  $k$ , or  $\infty$ . We define  $\beta(S, p, q)$  to be  $\infty$  when  $K_{\text{to}(p)}$  and  $K_{\text{from}(q)}$  are not disjoint. Then  $\beta([1..r], 1, |H|)$  is the value we need, which can be calculated as follows.

► **Proposition 21.** *The value of  $\beta([1..r], 1, |H|)$  can be computed in  $k^{O(k)}(n+m)$  time.*

**Proof.** First, for  $a$  and  $b$  with  $a < b \leq a + 8k$  and  $S \subseteq [1..r]$ , we calculate  $\beta(S, a, b)$  as follows. From each component  $C_j$  with  $j \in S$ , we take a vertex  $x$ , guess a vertex  $v_i$  with  $a < i < b$ , and add the edge  $xv_i$ . After that, the subgraph induced by  $\bigcup_{i=\text{to}(a)}^{\text{from}(b)} K_i \cup \bigcup_{j \in S} C_j$  is connected. It will remain connected after adding edges. We then branch on adding edges to destroy induced subgraphs in  $\{\overline{C}_3^*, S_3, \overline{S}_3\}$  and holes in the subgraph induced by  $\bigcup_{i=\text{to}(a)}^{\text{from}(b)} K_i \cup \bigcup_{j \in S} C_j$ , without adding any edges incident to  $K_{\text{to}(a)}$  or  $K_{\text{from}(b)}$ .

Since  $G_0$  is a proper Helly circular-arc graph, a vertex is adjacent to at most four vertices on  $H$  (there is a claw otherwise). A solution is incident to at most  $2k$  vertices, and thus at most  $8k$  vertices on  $H$  have touched neighbors. If  $v_{b-1}$  has a touched neighbor, then for some  $i$  with  $2 \leq i \leq 8k + 2$ , the vertex  $v_{b-i}$  has no touched neighbor. For  $b - a > 8k$ , by Lemma 19, we have

$$\beta(S, a, b) = \min_{\substack{1 \leq i \leq 8k+1 \\ S' \subseteq S}} (\beta(S \setminus S', a, b-i) + \beta(S', b-i, b)). \quad (1)$$

We can then use dynamic programming to calculate  $\beta([1..r], 1, |H|)$  with (1). ◀

We are now ready to summarize the algorithm in Figure 3. The analysis is left to the full version.

### 5 Proper circular-arc vertex deletion

Since we will use properties of both the graph  $G$  and its complement, we beg the reader's attentiveness in reading this section. There are algorithms for the vertex deletion problem toward proper interval graphs and toward bipartite permutation graphs. We are henceforth focused on graphs that are both connected and co-connected. As usual, we can get rid of small forbidden induced subgraphs easily.

► **Definition 22.** *A graph is reduced if it is both connected and co-connected, and it contains no  $C_3^*$ ,  $C_5^*$ ,  $\overline{C}_4^*$ ,  $C_6^*$ ,  $S_3$ ,  $\overline{S}_3^*$ ,  $F_1$ ,  $F_2$ ,  $F_3$ , or  $F_4$ .*

- 
1. **if** there exists an induced subgraph  $X$  in  $\{\overline{C_3^*}, C_4^*, S_3, \overline{S_3}, W_4, W_5, \overline{C_6}\}$  **then**  
**branch** on adding missing edges of  $X$ ;  $\backslash\backslash$  returns “no” if  $k$  becomes negative.
  2. **if**  $G$  is a proper Helly circular-arc graph **then return** “yes”;
  3. find a hole  $H$  of  $G$  and let  $G_0$  be the component of  $G$  that contains  $H$ ;
  4. **if**  $|H| \leq 16k + 16$  **then**  
**branch** on adding chords of  $H$  or edges between  $H$  and other components;
  5. **if**  $|V(G_0)| < n - \frac{k}{2}$  **then return** “no”;
  6. **if**  $\beta([1..r], 1, |H|) \leq k$  **then return** “yes”;  
**else return** “no.”
- 

■ **Figure 3** The outline of the algorithm for the proper Helly circular-arc completion problem.

Similar to Proposition 11, one can make an algorithm for finding one of the subgraphs listed above when the input graph is not reduced. We omit details since it does not improve our main algorithm. The next lemma is complement and similar to Lemma 6.

► **Lemma 23.** *A reduced graph is  $\{C_\ell^* \mid \ell \geq 7\}$ -free.*

**Proof.** Let  $R$  be a reduced graph. Suppose for contradiction that there exist a hole  $H$  of length at least seven and a vertex that is nonadjacent to any vertex on  $H$ . Since  $R$  is connected, we can find a vertex  $x$  adjacent to  $H$ , and another vertex  $y$  that is adjacent to  $x$  but not to  $H$ . Let  $H = v_1v_2 \cdots v_{|H|}$ . We argue first that  $x$  cannot be adjacent to two consecutive vertices on  $H$ . Suppose for contradiction that  $x$  is adjacent to both  $v_1$  and  $v_2$ . Then  $v_1, v_2$ , and  $x$  form a triangle. Since  $R$  is free of  $C_3^*$ , it follows that  $x$  is adjacent to both  $v_4$  and  $v_5$ . But then  $v_1, v_2, v_4, v_5$ , and  $x$  induce a  $\overline{C_4^*}$  (note that  $v_5$  and  $v_1$  are nonadjacent because  $\ell \geq 7$ ).

Assume without loss of generality that  $x$  is adjacent to  $v_3$ . Note that  $x$  is adjacent to neither  $v_2$  nor  $v_4$ . If  $x$  is adjacent to  $v_5$  as well, then  $x$  is nonadjacent to  $v_6$ , and  $\{v_2, \dots, v_6, x, y\}$  induces an  $F_2$ . By symmetry,  $x$  cannot be adjacent to  $v_1$  either. But then  $\{v_1, \dots, v_5, x, y\}$  induces an  $F_1$ . ◀

By definition, a reduced graph is  $C_3^*$ - and  $C_5^*$ -free.

► **Corollary 24.** *A reduced graph is  $\{C_{2\ell+1}^* \mid \ell \geq 1\}$ -free.*

By Theorem 4, the definition of reduced graphs, and Lemma 6, a reduced graph is the complement of a proper circular-arc graph if and only if it does not contain any even hole of length at least eight. We will therefore be focused on long even holes. The main structural statement characterizes reduced graphs that contain long even holes.

► **Lemma 25.** *If a reduced graph contains an even hole of length at least eight, then it is bipartite.*

**Proof (sketch).** Let  $v_1v_2 \cdots v_\ell$  be an even hole with  $\ell \geq 8$  of a reduced graph  $R$ , and denote it by  $B$ . We prove the lemma with a sequence of claims.

1. No vertex on  $B$  participates in any triangle.
2. If some odd hole of  $R$  intersects  $B$ , then there exists an odd hole of  $R$  whose intersection with  $B$  is a nonempty sub-path of  $B$ .
3. If  $V(C) \cap V(B)$  is consecutive for an odd induced cycle  $C$ , then  $|V(C) \cap V(B)| \leq 4$ .
4. No odd induced cycle can intersect  $B$  (no vertex on  $B$  is contained in any odd induced cycle).

## 31:12 Modification Problems Toward Proper (Helly) Circular-Arc Graphs

Finally, we show that  $R$  does not contain any odd cycle at all. Let  $C$  be an odd induced cycle that is disjoint from  $B$ . First assume  $C = x_1x_2x_3$ . Since  $R$  is  $C_3^*$ -free, every vertex on  $B$  is adjacent to at least one vertex on  $C$ . Assume without loss of generality that  $x_1$  has the largest number of neighbors on  $B$ , and let their indices be  $i_1, i_2, \dots, i_p$ , sorted increasingly. Note that all of them have the same parity by the first claim. Since  $R$  is  $C_6$ -free,  $i_{j+1} - i_j$  is either two or at least six for all  $j = 1, \dots, p - 1$ . Since  $p \geq \lceil \frac{\ell}{3} \rceil$ , there must be three consecutive ones with differences two; assume without loss of generality, that they are  $v_1, v_3$ , and  $v_5$ . If  $\ell = 8$ , then  $x_1v_5v_6 \cdots v_8v_1$  has length six, and hence  $x_1$  must be adjacent to  $v_7$  as well; otherwise,  $x_1$  has another neighbor on  $B$  because  $p \geq \lceil \frac{\ell}{3} \rceil \geq 4$ . This neighbor forms an  $F_3$  with  $\{x_1, v_1, v_2, \dots, v_5\}$ . Now that  $|C| \geq 5$ ; let it be  $x_1x_2 \cdots x_{|C|}$ . We take  $v_i \in N(x_1) \cap V(B)$  and  $v_j \in N(x_3) \cap V(B)$ . The sub-path  $v_i v_{i+1} \cdots v_j$  forms an odd cycle with either  $x_1x_2x_3$  (when  $j - i$  is odd) or  $x_3x_4 \cdots x_{|C|}x_1$  (when  $j - i$  is even). From this odd cycle we can retrieve an induced odd cycle, which has to intersect both  $B$  and  $C$  (because both  $B$  and  $C$  themselves are induced cycles). This contradicts the fourth claim, and concludes the proof of this lemma.  $\blacktriangleleft$

The following is immediate from Theorem 4, Lemma 6, and Lemma 25.

► **Corollary 26.** *If a reduced graph  $R$  is not bipartite, then  $R$  is the complement of a proper circular-arc graph.*

We are now ready to present the algorithm for the proper circular-arc vertex deletion problem in Figure 4. Let  $(G, k)$  be an instance to the problem, and we may assume without loss of generality that  $G$  does not contain any small forbidden induced subgraphs on at most seven vertices. If there is a set  $V_-$  of  $k$  vertices such that  $G - V_-$  is a proper interval graph or  $\overline{G} - V_-$  is a bipartite permutation graph, then we are done. Hence, we will look for a solution  $V_-$  such that  $G - V_-$  is both connected and co-connected (Propositions 5 and 14).

For this purpose we may assume that  $G$  itself is connected and co-connected: if  $G$  is not connected, we can work on the components of  $G$  one by one, and it is similar for  $\overline{G}$ . Thus,  $\overline{G}$  is a reduced graph. If  $\overline{G}$  is not bipartite, then  $G$  is already a proper circular-arc graph (Corollary 26). Otherwise,  $\overline{G}$  is bipartite, of which any induced subgraph of it is bipartite. In other words, if there exists a solution  $V_-$ , then  $\overline{G} - V_-$  is a bipartite permutation graph, and this has been handled already.

- 
1. **if**  $(G, k)$  is a yes-instance of proper interval vertex deletion **then**  
    **return** “yes”;
  2. **if**  $(\overline{G}, k)$  is a yes-instance of bipartite permutation vertex deletion **then**  
    **return** “yes”;  
     $\parallel$  *We’re looking for a solution  $V_-$  with both  $G - V_-$  and  $\overline{G} - V_-$  connected.*
  3. **branch** on deleting vertices of small forbidden induced subgraphs;
  4.  $\mathcal{C} \leftarrow$  maximal vertex sets that are connected and co-connected;
  5. **if**  $G[C]$  is co-bipartite for all  $C \in \mathcal{C}$  **then return** “no”;
  6.  $C \leftarrow$  a maximum set from  $\mathcal{C}$  with  $G[C]$  not co-bipartite;
  7. **if**  $|V(G) \setminus V(C)| \leq k$  **then return** “yes”;  
    **else return** “no.”
- 

■ **Figure 4** The outline of the algorithm for proper circular-arc vertex deletion.

Again, it is quite straightforward to turn this algorithm into an approximation algorithm, and the proofs for Theorems 1 and 2 are left to the full version.

## Abstract

---

A set  $S$  of isometric paths of a graph  $G$  is “ $v$ -rooted”, where  $v$  is a vertex of  $G$ , if  $v$  is one of the end-vertices of all the isometric paths in  $S$ . The *isometric path complexity* of a graph  $G$ , denoted by  $ipco(G)$ , is the minimum integer  $k$  such that there exists a vertex  $v \in V(G)$  satisfying the following property: the vertices of any isometric path  $P$  of  $G$  can be covered by  $k$  many  $v$ -rooted isometric paths.

First, we provide an  $O(n^2m)$ -time algorithm to compute the isometric path complexity of a graph with  $n$  vertices and  $m$  edges. Then we show that the isometric path complexity remains bounded for graphs in three seemingly unrelated graph classes, namely, *hyperbolic graphs*, (*theta*, *prism*, *pyramid*)-*free graphs*, and *outerstring graphs*. Hyperbolic graphs are extensively studied in *Metric Graph Theory*. The class of (*theta*, *prism*, *pyramid*)-free graphs are extensively studied in *Structural Graph Theory*, e.g. in the context of the *Strong Perfect Graph Theorem*. The class of outerstring graphs is studied in *Geometric Graph Theory* and *Computational Geometry*. Our results also show that the distance functions of these (structurally) different graph classes are more similar than previously thought.

There is a direct algorithmic consequence of having small isometric path complexity. Specifically, using a result of Chakraborty et al. [ISAAC 2022], we show that if the isometric path complexity of a graph  $G$  is bounded by a constant  $k$ , then there exists a  $k$ -factor approximation algorithm for ISOMETRIC PATH COVER, whose objective is to cover all vertices of a graph with a minimum number of isometric paths.

## 1 Introduction

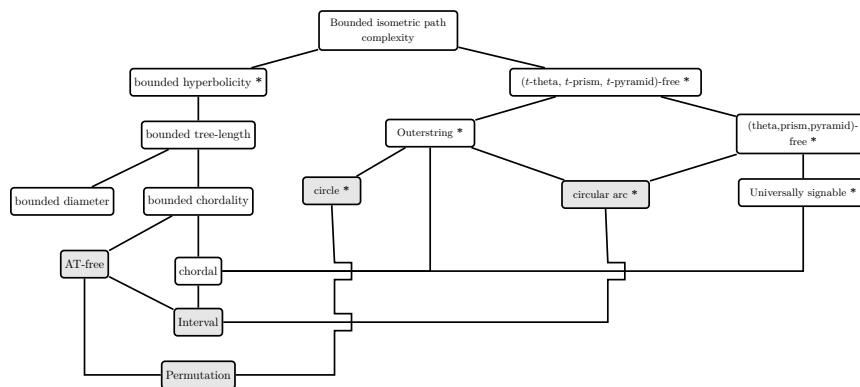

A path is *isometric* if it is a shortest path between its endpoints. An *isometric path cover* of a graph  $G$  is a set of isometric paths such that each vertex of  $G$  belongs to at least one of the paths. The *isometric path number* of  $G$  is the smallest size of an isometric path cover of  $G$ . Given a graph  $G$  and an integer  $k$ , the objective of the algorithmic problem ISOMETRIC PATH COVER is to decide if there exists an isometric path cover of cardinality at most  $k$ . ISOMETRIC PATH COVER has been introduced and studied in the context of pursuit-evasion games [2, 3]. However, until recently the algorithmic aspects of ISOMETRIC PATH COVER remained unexplored. After proving that ISOMETRIC PATH COVER remains NP-hard on *chordal graphs* (graphs without any induced cycle of length at least 4), Chakraborty et al. [7] provided constant-factor approximation algorithms for many graph classes, including *interval graphs*, chordal graphs, and more generally, graphs with bounded *treelength*. To prove the approximation ratio of their algorithm, the authors introduced a parameter called *isometric path antichain cover number* of a graph  $G$ , denoted as  $ipacc(G)$  (see Definition 6), and proved (i) when  $ipacc(G)$  is bounded by a constant, ISOMETRIC PATH COVER admits a constant-factor approximation algorithm on  $G$ ; and (ii) the isometric path antichain cover number of graphs with bounded *treelength* is bounded.

The objectives of this paper are three fold: **(A)** provide a more intuitive definition of isometric path antichain cover number; **(B)** provide a polynomial-time algorithm to compute  $ipacc(G)$ ; and **(C)** prove that it remains bounded for seemingly unrelated graph classes. Along the way, we also extend the horizon of approximability of ISOMETRIC PATH COVER. To achieve **(A)** we introduce the following new metric graph parameter, that we will show to be always equal to the isometric path antichain cover number, and whose definition is simpler.

► **Definition 1.** *Given a graph  $G$  and a vertex  $v$  of  $G$ , a set  $S$  of isometric paths of  $G$  is  $v$ -rooted if  $v$  is one of the end-vertices of all the isometric paths in  $S$ . The isometric path complexity of a graph  $G$ , denoted by  $ipco(G)$ , is the minimum integer  $k$  such that there exists a vertex  $v \in V(G)$  satisfying the following property: the vertices of any isometric path  $P$  of  $G$  can be covered by  $k$  many  $v$ -rooted isometric paths.*

A consequence of Dilworth’s theorem is that for any graph  $G$ ,  $ipacc(G) = ipco(G)$  (see Lemma 7). We will give a polynomial-time algorithm to compute  $ipco(G)$ , and therefore  $ipacc(G)$  for an arbitrary undirected graph  $G$ . This achieves **(B)**. Finally, to achieve **(C)**, we consider the following three seemingly unrelated graph classes, namely,  $\delta$ -*hyperbolic graphs*, (*theta, prism, pyramid*)-*free graphs* and *outerstring graphs*, and show that their isometric path complexity is bounded by a constant.

**$\delta$ -hyperbolic graphs.** A graph  $G$  is said to be  $\delta$ -*hyperbolic* [20] if for any four vertices  $u, v, x, y$ , the two larger of the three distance sums  $d(u, v) + d(x, y)$ ,  $d(u, x) + d(v, y)$  and  $d(u, y) + d(v, x)$  differ by at most  $2\delta$ . A graph class  $\mathcal{G}$  is *hyperbolic* if there exists a constant  $\delta$  such that every graph  $G \in \mathcal{G}$  is  $\delta$ -hyperbolic. This parameter comes from geometric group theory and was first introduced by Gromov [20] in order to study groups via their *Cayley graphs*. The hyperbolicity of a tree is 0, and in general, the hyperbolicity measures how much the distance function of a graph deviates from a tree metric. Many structurally defined graph classes like chordal graphs, *cocomparability graphs* [13], *asteroidal-triple free graphs* [14], graphs with bounded *chordality* or *treelength* are hyperbolic [8, 22]. Moreover, hyperbolicity has been found to capture important properties of several large practical graphs such as the Internet graph [25] or database relation graphs [30]. Due to its importance in discrete

■ **Figure 1** Inclusion diagram for graph classes. If a class  $A$  has an upward path to class  $B$ , then  $A$  is included in  $B$ . Constant bounds for the isometric path complexity on graph classes marked with  $*$  are contributions of this paper.

mathematics, algorithms, *metric graph theory*, researchers have studied various algorithmic aspects of hyperbolic graphs [8, 15, 10, 16]. Note that graphs with diameter 2 are hyperbolic, which may contain any graph as an induced subgraph.

**(theta, prism, pyramid)-free graphs.** A *theta* is a graph made of three vertex-disjoint induced paths  $P_1 = a \dots b$ ,  $P_2 = a \dots b$ ,  $P_3 = a \dots b$  of lengths at least 2, and such that no edges exist between the paths except the three edges incident to  $a$  and the three edges incident to  $b$ . A *pyramid* is a graph made of three induced paths  $P_1 = a \dots b_1$ ,  $P_2 = a \dots b_2$ ,  $P_3 = a \dots b_3$ , two of which have lengths at least 2, vertex-disjoint except at  $a$ , and such that  $b_1 b_2 b_3$  is a triangle and no edges exist between the paths except those of the triangle and the three edges incident to  $a$ . A *prism* is a graph made of three vertex-disjoint induced paths  $P_1 = a_1 \dots b_1$ ,  $P_2 = a_2 \dots b_2$ ,  $P_3 = a_3 \dots b_3$  of lengths at least 1, such that  $a_1 a_2 a_3$  and  $b_1 b_2 b_3$  are triangles and no edges exist between the paths except those of the two triangles. A graph  $G$  is *(theta, pyramid, prism)-free* if  $G$  does not contain any induced subgraph isomorphic to a theta, pyramid or prism. A graph is a *3-path configuration* if it is a theta, pyramid or prism. The study of 3-path configurations dates back to the works of Watkins and Meisner [31] in 1967 and plays “special roles” in the proof of the celebrated *Strong Perfect Graph Theorem* [11, 18, 27, 29]. Important graph classes like chordal graphs, *circular arc* graphs, *universally-signable* graphs [12] exclude all 3-path configurations. Popular graph classes like *perfect* graphs, *even hole-free* graphs exclude some of the 3-path configurations. Note that, (theta, prism, pyramid)-free graphs are not hyperbolic. To see this, consider a cycle  $C$  of order  $n$ . Clearly,  $C$  excludes all 3-path configurations and has hyperbolicity  $\Omega(n)$ .

**Outerstring graphs.** A set  $S$  of simple curves on the plane is *grounded* if there exists a horizontal line containing one endpoint of each of the curves in  $S$ . A graph  $G$  is an *outerstring* graph if there is a collection  $C$  of grounded simple curves and a bijection between  $V(G)$  and  $C$  such that two curves in  $S$  intersect if and only if the corresponding vertices are adjacent in  $G$ . The term “outerstring graph” was first used in the early 90’s [23] in the context of studying intersection graphs of simple curves on the plane. Many well-known graph classes like chordal graphs, *circular arc* graphs [19], *circle* graphs (intersection graphs of chords of a circle [17]), or cocomparability graphs [13] are also outerstring graphs and thus, motivated researchers from the *geometric graph theory* and *computational geometry* communities to study algorithmic

and structural aspects of outerstring graphs and its subclasses [4, 5, 6, 21, 24]. Note that, in general, outerstring graphs may contain a prism, pyramid or theta as an induced subgraph. Moreover, cycles of arbitrary order are outerstring graphs, implying that outerstring graphs are not hyperbolic.

It is clear from the above discussion that the classes of hyperbolic graphs, (theta, prism, pyramid)-free graphs, and outerstring graphs are pairwise incomparable (with respect to the containment relationship). We show that the isometric path complexities of all the above graph classes are small.

## 1.1 Our contributions

The main technical contributions of this paper are as follows. First we prove that the isometric path complexity can be computed in polynomial time.

► **Theorem 2.** *Given a graph  $G$  with  $n$  vertices and  $m$  edges, it is possible to compute  $ipco(G)$  in  $O(n^2m)$  time.*

Recall that, the above theorem and Lemma 7 imply that for any undirected graph  $G$ ,  $ipacc(G)$  can be computed in polynomial time. Then we show that the isometric path complexity remains bounded on hyperbolic graphs, (theta, pyramid, prism)-free graphs, and outerstring graphs. Specifically, we prove the following theorem.

► **Theorem 3.** *Let  $G$  be a graph.*

- (a) *If the hyperbolicity of  $G$  is at most  $\delta$ , then  $ipco(G) \leq 4\delta + 3$ .*
- (b) *If  $G$  is a (theta, pyramid, prism)-free graph, then  $ipco(G) \leq 71$ .*
- (c) *If  $G$  is an outerstring graph, then  $ipco(G) \leq 95$ .*

To the best of our knowledge, the isometric path complexity being bounded (by constant(s)) is the only known non-trivial property shared by any two or all three of these graph classes. Theorem 3 shows that isometric path complexity (equivalently isometric path antichain cover number), as recently introduced graph parameters, are general enough to unite these three graph classes by their metric properties. We hope that this definition will be useful for the field of metric graph theory, for example by enabling us to study (theta,prism,pyramid)-free graphs and outerstring graphs from the perspective of metric graph theory.

We provide a unified proof for Theorem 3b and 3c by proving that the isometric path complexity of ( $t$ -theta,  $t$ -pyramid,  $t$ -prism)-free graphs [28] (see Section 4 for a definition) is bounded by a linear function of  $t$ . Due to the above theorems, we also have as corollaries that there is a polynomial-time approximation algorithm for ISOMETRIC PATH COVER with approximation ratio

- (a)  $4\delta + 3$  on  $\delta$ -hyperbolic graphs,
- (b) 73 on (theta, prism, pyramid)-free graphs,
- (c) 95 on outerstring graphs, and
- (d)  $8t + 63$  on ( $t$ -theta,  $t$ -pyramid,  $t$ -prism)-free graphs.

To contrast with Theorem 3, we construct highly structured graphs with small *treewidth* and large isometric path complexity. A *wheel* consists of an induced cycle  $C$  of order at least 4 and a vertex  $w \notin V(C)$  adjacent to at least three vertices of  $C$ . The three path configurations introduced earlier and the wheel together are called *Truemper configurations* [29] and they are important objects of study in structural and algorithmic graph theory [1, 18].

► **Theorem 4.** For every  $k \geq 1$ ,

- (a) there exists a (pyramid, prism, wheel)-free graph  $G$  with tree-width 2, hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$  and  $\text{ipco}(G) \geq k$ .
- (b) there exists a (theta, prism, wheel)-free graph  $G$  with tree-width at most 3, hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$  and  $\text{ipco}(G) \geq k$ .
- (c) there exists a (theta, pyramid, wheel)-free graph  $G$  with hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$  and  $\text{ipco}(G) \geq k$ .

**Organisation.** In Section 2, we recall some definitions and some results. In Section 3, we present an algorithm to compute the isometric path complexity of a graph and prove Theorem 2. In Section 4, we prove Theorem 3. In Section 5, we prove Theorem 4. We conclude in Section 6. Proofs of lemma and observations marked with (\*) are provided in the main version of the paper.

## 2 Definitions and preliminary observations

In this section, we recall some definitions and some related observations. A sequence of distinct vertices forms a *path*  $P$  if any two consecutive vertices are adjacent. Whenever we fix a path  $P$  of  $G$ , we shall refer to the subgraph formed by the edges between the consecutive vertices of  $P$ . The *length* of a path  $P$ , denoted by  $|P|$ , is the number of its vertices minus one. A path is *induced* if there are no graph edges joining non-consecutive vertices. A path is *isometric* if it is a shortest path between its endpoints. For two vertices  $u, v$  of a graph  $G$ ,  $d(u, v)$  denotes the length of an isometric path between  $u$  and  $v$ .

In a directed graph, a *directed path* is a path in which all arcs are oriented in the same direction. For a path  $P$  of a graph  $G$  between two vertices  $u$  and  $v$ , the vertices  $V(P) \setminus \{u, v\}$  are *internal vertices* of  $P$ . A path between two vertices  $u$  and  $v$  is called a  $(u, v)$ -path. Similarly, we have the notions of *isometric  $(u, v)$ -path* and *induced  $(u, v)$ -path*. The interval  $I(u, v)$  between two vertices  $u$  and  $v$  consists of all vertices that belong to an isometric  $(u, v)$ -path. For a vertex  $r$  of  $G$  and a set  $S$  of vertices of  $G$ , the *distance of  $S$  from  $r$* , denoted as  $d(r, S)$ , is the minimum of the distance between any vertex of  $S$  and  $r$ . For a subgraph  $H$  of  $G$ , the *distance of  $H$  w.r.t.  $r$*  is  $d(r, V(H))$ . Formally, we have  $d(r, S) = \min\{d(r, v) : v \in S\}$  and  $d(r, H) = d(r, V(H))$ .

For a graph  $G$  and a vertex  $r \in V(G)$ , consider the following operations on  $G$ . First, remove all edges  $xy$  from  $G$  such that  $d(r, x) = d(r, y)$ . Let  $G'_r$  be the resulting graph. Then, for each edge  $e = xy \in E(G'_r)$  with  $d(r, x) = d(r, y) - 1$ , orient  $e$  from  $y$  to  $x$ . Let  $\overrightarrow{G}_r$  be the directed acyclic graph formed after applying the above operation on  $G'$ . Note that this digraph can easily be computed in linear time using a Breadth-First Search (BFS) traversal with starting vertex  $r$ . The following definition is inspired by the terminology of posets (as the graph  $\overrightarrow{G}_r$  can be seen as the Hasse diagram of a poset).

► **Definition 5.** For a graph  $G$  and a vertex  $r \in V(G)$ , two vertices  $x, y \in V(G)$  are *antichain vertices* if there are no directed paths from  $x$  to  $y$  or from  $y$  to  $x$  in  $\overrightarrow{G}_r$ . A set  $X$  of vertices of  $G$  is an *antichain set* if any two vertices in  $X$  are *antichain vertices*.

► **Definition 6** ([7]). Let  $r$  be a vertex of a graph  $G$ . For a subgraph  $H$ ,  $A_r(H)$  shall denote the maximum antichain set of  $H$  in  $\overrightarrow{G}_r$ . The *isometric path antichain cover number* of  $\overrightarrow{G}_r$ , denoted by  $\text{ipacc}(\overrightarrow{G}_r)$ , is defined as follows:

$$\text{ipacc}(\overrightarrow{G}_r) = \max\{|A_r(P)| : P \text{ is an isometric path}\}.$$

The isometric path antichain cover number of graph  $G$ , denoted as  $ipacc(G)$ , is defined as the minimum over all possible antichain covers of its associated directed acyclic graphs:

$$ipacc(G) = \min \left\{ ipacc(\vec{G}_r) : r \in V(G) \right\}.$$

For technical purposes, we also introduce the following definition. For a graph  $G$  and a vertex  $r$  of  $G$ , let  $ipco(\vec{G}_r)$  denote the minimum integer  $k$  such that any isometric path  $P$  of  $G$  can be covered by  $k$   $r$ -rooted isometric paths (The notation reflects that it is a dual notion of  $ipacc(\vec{G}_r)$ ). Using Dilworth's Theorem we prove the following important lemma.

► **Lemma 7.** For any graph  $G$  and vertex  $r$ ,  $ipco(\vec{G}_r) = ipacc(\vec{G}_r)$ . Therefore,  $ipco(G) = ipacc(G)$ .

**Proof.** Let  $r$  be a vertex of  $G$  such that any isometric path of  $G$  can be covered by  $ipco(\vec{G}_r)$   $r$ -rooted isometric paths. Let  $P$  be an arbitrary isometric path of  $G$ . Since two vertices of an antichain of  $\vec{G}_r$  cannot be covered by a single  $r$ -rooted path and  $P$  is covered by  $ipco(\vec{G}_r)$   $r$ -rooted paths, we deduce  $|A_r(P)| \leq ipco(\vec{G}_r)$ . This is true for any isometric path  $P$  of  $G$ . Hence,  $ipacc(\vec{G}_r) \leq ipco(\vec{G}_r)$ . Conversely, consider a vertex  $r \in V(G)$ . By definition of  $ipco(\vec{G}_r)$ , there is an isometric path  $P$  that cannot be covered by  $(ipco(\vec{G}_r) - 1)$   $r$ -rooted isometric paths. By Dilworth theorem,  $P$  contains an antichain of  $\vec{G}_r$  of size  $ipco(\vec{G}_r)$ . Hence  $|A_r(P)| \geq ipco(\vec{G}_r)$  and  $ipacc(\vec{G}_r) \geq ipco(\vec{G}_r)$ . The second part of the lemma follows immediately. ◀

We also recall the following theorem and proposition from [7].

► **Theorem 8 ([7]).** For a graph  $G$ , if  $ipacc(G) \leq c$ , then ISOMETRIC PATH COVER admits a polynomial-time  $c$ -approximation algorithm on  $G$ .

► **Proposition 9 ([7]).** Let  $G$  be a graph and  $r$ , an arbitrary vertex of  $G$ . Consider the directed acyclic graph  $\vec{G}_r$ , and let  $P$  be an isometric path between two vertices  $x$  and  $y$  in  $G$ . Then  $|P| \geq |d(r, x) - d(r, y)| + |A_r(P)| - 1$ .

**Proof.** Orient the edges of  $P$  from  $y$  to  $x$  in  $G$ . First, observe that  $P$  must contain a set  $E_1$  of oriented edges such that  $|E_1| = |d(r, y) - d(r, x)|$  and for any  $\vec{ab} \in E_1$ ,  $d(r, a) = d(r, b) + 1$ . Let the vertices of the largest antichain set of  $P$  in  $\vec{G}_r$ , i.e.,  $A_r(P)$ , be ordered as  $a_1, a_2, \dots, a_t$  according to their occurrence while traversing  $P$  from  $y$  to  $x$ . For  $i \in [2, t]$ , let  $P_i$  be the subpath of  $P$  between  $a_{i-1}$  and  $a_i$ . Observe that for any  $i \in [2, t]$ , since  $a_i$  and  $a_{i-1}$  are antichain vertices, there must exist an oriented edge  $\vec{b_i c_i} \in E(P_i)$  such that either  $d(r, b_i) = d(r, c_i)$  or  $d(r, b_i) = d(r, c_i) - 1$ . Let  $E_2 = \{\vec{b_i c_i}\}_{i \in [2, t]}$ . Observe that  $E_1 \cap E_2 = \emptyset$  and therefore  $|P| \geq |E_1| + |E_2| = |d(r, y) - d(r, x)| + |A_r(P)| - 1$ . ◀

### 3 Proof of Theorem 2

In this section we provide a polynomial-time algorithm to compute the isometric path complexity of a graph. Let  $G$  be a graph. In the following lemma, we provide a necessary and sufficient condition for two vertices of an isometric path to be covered by the same isometric  $r$ -rooted path in  $\vec{G}_r$  for some vertex  $r \in V(G)$ .

► **Lemma 10.** *Let  $r$  be a vertex of  $G$ . If  $P = (u = v_0, \dots, v_k = v)$  is an isometric  $(u, v)$ -path with  $d(r, u) \leq d(r, v)$  then there exists an isometric  $r$ -rooted path containing  $u, v$  in  $\overrightarrow{G}_r(P)$  if and only if  $d(v_{i+1}, r) = d(v_i, r) + 1$  for all  $i \in \{0, \dots, k - 1\}$ .*

**Proof.** If  $d(v_{i+1}, r) = d(v_i, r) + 1$  for every  $i \in \{0, \dots, k - 1\}$  then the path obtained by concatenating an isometric  $(r, u)$ -path and the path  $P$  is an isometric  $r$ -rooted  $(r, v)$ -path containing  $u, v$  in  $\overrightarrow{G}_r(P)$ . Now suppose that there exists an isometric  $r$ -rooted path containing  $u, v$  in  $\overrightarrow{G}_r(P)$ , i.e.,  $d(r, v) - d(r, u) = d(u, v)$ . Then, along any path from  $u$  to  $v$ , we need to traverse at least  $d(u, v)$  edges increasing the distance to  $r$ . Since  $P$  is an isometric  $(u, v)$ -path, it contains exactly  $d(u, v)$  edges. Hence,  $d(r, v_{i+1}) = d(r, v_i) + 1$  for every  $i \in \{0, \dots, k - 1\}$ . ◀

### 3.1 Notations and preliminary observations

We now introduce some notations that will be used to describe the algorithm and prove its correctness. Consider three vertices  $r, x, v$  of  $G$  such that  $x \neq v$ . Let  $\mathcal{P}_{\searrow}^r(x, v)$  denote the set of all isometric  $(x, v)$ -paths  $P$  containing a vertex  $u$  that is adjacent to  $v$  and satisfies  $d(r, u) = d(r, v) - 1$ . Analogously, let  $\mathcal{P}_{\rightarrow}^r(x, v)$  denote the set of all isometric  $(x, v)$ -paths  $P$  containing a vertex  $u$  that is adjacent to  $v$  and satisfies  $d(r, u) = d(r, v)$  and let  $\mathcal{P}_{\nearrow}^r(x, v)$  denote the set of all isometric  $(x, v)$ -paths  $P$  containing a vertex  $u$  that is adjacent to  $v$  and satisfies  $d(r, u) = d(r, v) + 1$ . Observe that the set of isometric  $(x, v)$ -paths is precisely  $\mathcal{P}_{\searrow}^r(x, v) \cup \mathcal{P}_{\rightarrow}^r(x, v) \cup \mathcal{P}_{\nearrow}^r(x, v)$  and that some of these sets may be empty.

Given a path  $P$ , we denote by  $|S_r(P)|$  the minimum size of a set of isometric  $r$ -rooted paths covering the vertices of  $P$ . We denote by  $\gamma_{\searrow}^r(x, v)$  and  $\beta_{\searrow}^r(x, v)$  respectively the minimum of  $|S_r(P)|$  and  $|S_r(P - \{v\})|$  over all paths  $P \in \mathcal{P}_{\searrow}^r(x, v)$ . More formally,

$$\begin{aligned} \gamma_{\searrow}^r(x, v) &= \max \{ |S_r(P)| : P \in \mathcal{P}_{\searrow}^r(x, v) \}, \\ \beta_{\searrow}^r(x, v) &= \max \{ |S_r(P - \{v\})| : P \in \mathcal{P}_{\searrow}^r(x, v) \}. \end{aligned}$$

Note that if  $\mathcal{P}_{\searrow}^r(x, v)$  is empty, we have  $\gamma_{\searrow}^r(x, v) = \beta_{\searrow}^r(x, v) = 0$ . We define similarly  $\gamma_{\nearrow}^r(x, v)$ ,  $\beta_{\nearrow}^r(x, v)$ , and  $\gamma_{\rightarrow}^r(x, v)$ :

$$\begin{aligned} \gamma_{\nearrow}^r(x, v) &= \max \{ |S_r(P)| : P \in \mathcal{P}_{\nearrow}^r(x, v) \}, \\ \beta_{\nearrow}^r(x, v) &= \max \{ |S_r(P - \{v\})| : P \in \mathcal{P}_{\nearrow}^r(x, v) \}, \\ \gamma_{\rightarrow}^r(x, v) &= \max \{ |S_r(P)| : P \in \mathcal{P}_{\rightarrow}^r(x, v) \}. \end{aligned}$$

Finally, let  $\gamma^r(x, v) = \max \{ \gamma_{\searrow}^r(x, v), \gamma_{\rightarrow}^r(x, v), \gamma_{\nearrow}^r(x, v) \}$  be the maximum of  $|S_r(P)|$  over all isometric  $(x, v)$ -paths  $P$ . In our algorithm, we will need also to consider the case where  $v = x$  as an initial case. For practical reasons, we let  $\gamma^r(x, x) = \gamma_{\searrow}^r(x, x) = \gamma_{\rightarrow}^r(x, x) = \gamma_{\nearrow}^r(x, x) = 1$  and  $\beta_{\searrow}^r(x, x) = \beta_{\nearrow}^r(x, x) = 0$ . Based on the above notations and Lemma 7, we have the following observation.

► **Observation 11.** *For any graph  $G$  and any vertex  $r$  of  $G$ , we have  $ipco(\overrightarrow{G}_r) = ipacc(\overrightarrow{G}_r) = \max_{x,v} \gamma^r(x, v)$  and  $ipco(G) = ipacc(G) = \min_r \max_{x,v} \gamma^r(x, v)$ .*

Observation 11 implies that to compute the isometric path complexity of a graph it is enough to compute the parameter  $\gamma^r(x, v)$  for all  $r, x, v \in V(G)$  in polynomial time. In the next section, we focus on achieving this goal without computing explicitly any of the sets  $\mathcal{P}_{\searrow}^r(x, v)$ ,  $\mathcal{P}_{\rightarrow}^r(x, v)$  or  $\mathcal{P}_{\nearrow}^r(x, v)$ . (Note that the size of these sets could be exponential in the number of vertices of the graph).

### 3.2 An algorithm to compute $\gamma^r(x, v)$

Throughout this section, let  $r$  and  $x$  be two fixed vertices of  $G$ . We shall call  $r$  as the “root” and  $x$  as the “source” vertex. The objective of this section is to compute the parameter  $\gamma^r(x, v)$  for all vertices  $v \in V(G)$ .

In the sequel, since we always refer to a fixed root  $r$  and source  $x$ , we omit  $r$  and  $x$  and use the shorthand  $\gamma(v)$  for  $\gamma^r(x, v)$ . We do the same with the notations  $\gamma_{\nearrow}(v)$ ,  $\gamma_{\rightarrow}(v)$ ,  $\gamma_{\searrow}(v)$ ,  $\beta_{\nearrow}(v)$ , and  $\beta_{\searrow}(v)$  that also refer to fixed vertices  $r$  and  $x$ . In the following lemmas, we shall provide explicit (recursive) formulas to compute  $\gamma_{\nearrow}(v)$ ,  $\gamma_{\rightarrow}(v)$ ,  $\gamma_{\searrow}(v)$ ,  $\beta_{\nearrow}(v)$ , and  $\beta_{\searrow}(v)$ . Using these formulas, we will show how to compute  $\gamma(v)$  for all  $v \in V(G)$  in a total of  $O(|E(G)|)$ -time.

► **Observation 12.** *If  $r$  is the root vertex,  $x$  the source vertex, and  $v$  is distinct from  $x$ , then*

$$\begin{aligned}\beta_{\searrow}(v) &= \max\{\gamma(u) : u \in I(x, v) \cap N(v); d(r, u) = d(r, v) - 1\}, \\ \beta_{\nearrow}(v) &= \max\{\gamma(u) : u \in I(x, v) \cap N(v); d(r, u) = d(r, v) + 1\}.\end{aligned}$$

► **Lemma 13 (\*)**. *If  $r$  is the root vertex,  $x$  the source vertex, and  $v$  is distinct from  $x$ , then  $\gamma_{\rightarrow}(v) = \max\{1 + \gamma(u) : u \in I(x, v) \cap N(v); d(r, u) = d(r, v)\}$ .*

► **Lemma 14 (\*)**. *If  $r$  is the root vertex,  $x$  the source vertex, and  $v$  is a vertex distinct from  $x$ , then  $\gamma_{\searrow}(v) = \max\{\max\{\gamma_{\searrow}(u), \gamma_{\rightarrow}(u), \beta_{\nearrow}(u) + 1\} : u \in I(x, v) \cap N(v); d(r, u) = d(r, v) - 1\}$*

► **Lemma 15 (\*)**. *If  $r$  is the root vertex,  $x$  the source vertex, and  $v$  is a vertex distinct from  $x$ , then  $\gamma_{\nearrow}(v) = \max\{\max\{\gamma_{\nearrow}(u), \gamma_{\rightarrow}(u), \beta_{\searrow}(u) + 1\} : u \in I(x, v) \cap N(v); d(r, u) = d(r, v) + 1\}$ .*

Now we provide a BFS based algorithm to compute the above parameters. Let  $r$  and  $x$  be fixed root and source vertices of  $G$ , respectively. For a vertex  $u \in V(G)$ , let  $\mathcal{D}(u) = \{\gamma(u), \gamma_{\nearrow}(u), \gamma_{\rightarrow}(u), \gamma_{\searrow}(u), \beta_{\nearrow}(u), \beta_{\searrow}(u)\}$ . Clearly, the set  $\mathcal{D}(x)$  can be computed in constant time. Now let  $X_i$  be the set of vertices at distance  $i$  from  $x$ . Clearly, the sets  $X_i$  can be computed in  $O(|E(G)|)$ -time (using a BFS) and  $X_0 = \{x\}$ . Let  $i \geq 1$  be an integer and assume that for all vertices  $u \in \bigcup_{j=0}^{i-1} X_j$ , the set  $\mathcal{D}(u)$  is already computed. Let  $v \in X_i$  be a vertex. Then due to the formulas given in Observation 12 and Lemmas 13–15, the set  $\mathcal{D}(v)$  can be computed by observing only the sets  $\mathcal{D}(u)$ ,  $u \in N(v) \cap X_{i-1}$ . Hence, for all vertices  $v \in V(G)$ , the sets  $\mathcal{D}(v)$  can be computed in a total of  $O(|E(G)|)$  time. Hence, we have the following lemma.

► **Lemma 16.** *For a root vertex  $r$  and source vertex  $x$ , for all vertices  $v \in V(G)$ , the value  $\gamma^r(x, v)$  can be computed in  $O(|E(G)|)$  time.*

We can now finish the proof of Theorem 2. Let  $G$  be a graph with  $n$  vertices and  $m$  edges. For a root vertex  $r$ , by applying Lemma 16, for every source  $x \in V(G)$ , it is possible to compute  $ipco\left(\overrightarrow{G}_r\right) = \max_{x,v} \gamma^r(x, v)$  in  $O(nm)$  time. By repeating this for every root  $r \in V(G)$ , it is possible to compute  $ipco(G) = \min_r ipco\left(\overrightarrow{G}_r\right)$  in  $O(n^2m)$  time.

## 4 Proof of Theorem 3

**First we prove Theorem 3a.** We recall the definition of Gromov products [20] and its relation with hyperbolicity. For three vertices  $r, x, y$  of a graph  $G$ , the Gromov product of  $x, y$  with respect to  $r$  is defined as  $(x|y)_r = \frac{1}{2}(d(x, r) + d(y, r) - d(x, y))$ . Then, a graph  $G$  is  $\delta$ -hyperbolic [9, 20] if and only if for any four vertices  $x, y, z, r$ , we have  $(x|y)_r \geq \min\{(x|z)_r, (y|z)_r\} - \delta$ .

■ **Figure 2** An example of a 4-fat turtle. Let  $C$  be the cycle induced by the black vertices,  $P$  be the path induced by the white vertices. Then the tuple  $(4, C, P, c, c')$  defines a 4-fat turtle.

Let  $G$  be a graph with hyperbolicity at most  $\delta$ . Due to Lemma 7, in order to prove Theorem 3a, it is enough to show that  $ipacc(G) \leq 4\delta + 3$ . Aiming for a contradiction, let  $r$  be a vertex of  $G$  and  $P$  be an isometric path such that  $|A_r(P)| \geq 4\delta + 4$ . Let  $a_1, a_2, \dots, a_{2\delta+2}, \dots, a_{4\delta+4}$  be the vertices of  $A_r(P)$  ordered as they are encountered while traversing  $P$  from one end-vertex to the other. Let  $x = a_1, z = a_{2\delta+2}, y = a_{4\delta+4}$ . Let  $Q$  denote the  $(y, z)$ -subpath of  $P$ . Observe that,  $|A_r(Q)| \geq 2\delta + 2$ . Then we have  $(x|y)_r \geq \min\{(x|z)_r, (y|z)_r\} - \delta$ . Without loss of generality, assume that  $(x|z)_r \leq (y|z)_r$ . Hence,

$$\begin{aligned} (x|y)_r &\geq (x|z)_r - \delta \\ d(x, r) + d(y, r) - d(x, y) &\geq d(x, r) + d(z, r) - d(x, z) - 2\delta \\ d(y, r) - d(x, y) &\geq d(z, r) - d(x, z) - 2\delta \\ d(y, r) - d(z, r) + 2\delta &\geq d(x, y) - d(x, z) \\ d(y, r) - d(z, r) + 2\delta &\geq d(y, z) \\ d(y, z) &\leq |d(y, r) - d(z, r)| + 2\delta. \end{aligned}$$

But this directly contradicts Proposition 9, which implies that  $d(y, z) \geq |d(y, r) - d(z, r)| + |A_r(Q)| - 1 \geq |d(y, r) - d(z, r)| + 2\delta + 1$ . This completes the proof of Theorem 3a.

**Now, we shall prove Theorems 3b and 3c.** First, we shall define the notions of  $t$ -theta,  $t$ -prism, and  $t$ -pyramid [28]. For an integer  $t \geq 1$ , a  $t$ -prism is a graph made of three vertex-disjoint induced paths  $P_1 = a_1 \dots b_1, P_2 = a_2 \dots b_2, P_3 = a_3 \dots b_3$  of lengths at least  $t$ , such that  $a_1 a_2 a_3$  and  $b_1 b_2 b_3$  are triangles and no edges exist between the paths except those of the two triangles. For an integer  $t \geq 1$ , a  $t$ -pyramid is a graph made of three induced paths  $P_1 = a \dots b_1, P_2 = a \dots b_2, P_3 = a \dots b_3$  of lengths at least  $t$ , two of which have lengths at least  $t + 1$ , they are pairwise vertex-disjoint except at  $a$ , such that  $b_1 b_2 b_3$  is a triangle and no edges exist between the paths except those of the triangle and the three edges incident to  $a$ . For an integer  $t \geq 1$ , a  $t$ -theta is a graph made of three internally vertex-disjoint induced paths  $P_1 = a \dots b, P_2 = a \dots b, P_3 = a \dots b$  of lengths at least  $t + 1$ , and such that no edges exist between the paths except the three edges incident to  $a$  and the three edges incident to  $b$ . A graph  $G$  is  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free if  $G$  does not contain any induced subgraph isomorphic to a  $t$ -theta,  $t$ -pyramid or  $t$ -prism. When  $t = 1$ ,  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free graphs are exactly  $(\theta$ , prism, pyramid)-free graphs.

Now, we shall show that the isometric path antichain cover number of  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free graphs are bounded above by a linear function on  $t$ . We shall show that, when the isometric path antichain cover number of a graph is large, the existence of a structure called “ $t$ -fat turtle” (defined below) as an induced subgraph is forced, which cannot be present in a  $((t - 1)$ -theta,  $(t - 1)$ -pyramid,  $(t - 1)$ -prism)-free graph.

► **Definition 17.** For an integer  $t \geq 1$ , a “ $t$ -fat turtle” consists of a cycle  $C$  and an induced  $(u, v)$ -path  $P$  of length at least  $t$  such that all of the following hold:

- (a)  $V(P) \cap V(C) = \emptyset$ ,

■ **Figure 3** Illustration of the notations used in the proof of Lemma 20.

- (b) For any vertex  $w \in (V(P) \setminus \{u, v\})$ ,  $N(w) \cap V(C) = \emptyset$  and both  $u$  and  $v$  have at least one neighbour in  $C$ ,
- (c) For any vertex  $w \in N(u) \cap V(C)$  and  $w' \in N(v) \cap V(C)$ , the distance between  $w$  and  $w'$  in  $C$  is at least  $t$ ,
- (d) There exist two vertices  $\{c, c'\} \subset V(C)$  and two distinct components  $C_u, C_v$  of  $C - \{c, c'\}$  such that  $N(u) \cap V(C) \subseteq V(C_u)$  and  $N(v) \cap V(C) \subseteq V(C_v)$ .

The tuple  $(t, C, P, c, c')$  defines the  $t$ -fat turtle. See Figure 2 for an example.

In the following observation, we show that any  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free graph cannot contain a  $(t + 1)$ -fat turtle as an induced subgraph.

► **Lemma 18 (\*)**. For some integer  $t \geq 1$ , let  $G$  be a graph containing a  $(t + 1)$ -fat turtle as an induced subgraph. Then  $G$  is not  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free.

In the remainder of this section, we shall prove that there exists a linear function  $f(t)$  such that if the isometric path antichain cover number of a graph is more than  $f(t)$ , then  $G$  is forced to contain a  $(t + 1)$ -fat turtle as an induced subgraph, and therefore is not  $(t$ -theta,  $t$ -pyramid,  $t$ -prism)-free. We shall use the following observation.

► **Observation 19 (\*)**. Let  $G$  be a graph,  $r$  be an arbitrary vertex,  $P$  be an isometric  $(u, v)$ -path in  $G$  and  $Q$  be a subpath of an isometric  $(v, r)$ -path in  $G$  such that one endpoint of  $Q$  is  $v$ . Let  $P'$  be the maximum  $(u, w)$ -subpath of  $P$  such that no internal vertex of  $P'$  is a neighbour of some vertex of  $Q$ . We have that  $|A_r(P')| \geq |A_r(P)| - 3$ .

► **Lemma 20**. For an integer  $t \geq 1$ , let  $G$  be a graph with  $\text{ipacc}(G) \geq 8t + 64$ . Then  $G$  has a  $(t + 1)$ -fat turtle as an induced subgraph.

**Proof.** Let  $r$  be a vertex of  $G$  such that  $\text{ipacc}(\vec{G}_r)$  is at least  $8t + 64$ . Then there exists an isometric path  $P$  such that  $|A_r(P)| \geq 8t + 64$ . Let the two endpoints of  $P$  be  $a$  and  $b$ . (See Figure 3.) Let  $u$  be a vertex of  $P$  such that  $d(r, u) = d(r, P)$ . Let  $P(a, u)$  be the  $(a, u)$ -subpath of  $P$  and  $P(b, u)$  be the  $(b, u)$ -subpath of  $P$ . Both  $P(a, u)$  and  $P(b, u)$  are isometric paths and observe that either  $|A_r(P(a, u))| \geq 4t + 32$  or  $|A_r(P(b, u))| \geq 4t + 32$ . Without loss of generality, assume that  $|A_r(P(b, u))| \geq 4t + 32$ . Let  $Q(r, b)$  be an isometric  $(b, r)$ -path in  $G$ . First observe that  $u$  is not adjacent to any vertex of  $Q(r, b)$ . Otherwise,  $d(u, b) \leq 2 + d(r, b) - d(r, u)$ , which contradicts Proposition 9. Let  $P(u, w)$  be the maximum  $(u, w)$ -subpath of  $P(b, u)$  such that no internal vertex of  $P(u, w)$  is a neighbour of  $Q(r, b)$ . Note that  $P(u, w)$  is an isometric path and  $w$  has a neighbour in  $Q(r, b)$ . Applying Observation 19, we have the following:

▷ Claim 21.  $|A_r(P(u, w))| \geq 4t + 29$ .

Let  $Q(r, u)$  be any isometric  $(u, r)$ -path of  $G$ . Observe that  $w$  is not adjacent to any vertex of  $Q(r, u)$ . Otherwise,  $d(u, w) \leq 2 + d(r, u) - d(r, w)$ , which contradicts Proposition 9. Let  $P(z, w)$  be the maximum  $(z, w)$ -subpath of  $P(u, w)$  such that no internal vertex of  $P(z, w)$  has a neighbour in  $Q(r, u)$ . Observe that  $P(z, w)$  is an isometric path, and  $z$  has a neighbour in  $Q(r, u)$ . Again applying Observation 19, we have the following:

▷ Claim 22.  $|A_r(P(z, w))| \geq 4t + 26$ .

Let  $a_1, a_2, \dots, a_k$  be the vertices of  $A_r(P(z, w))$  ordered according to their appearance while traversing  $P(z, w)$  from  $z$  to  $w$ . Due to Claim 22, we have that  $k \geq 4t + 26$ . Let  $c = a_{2t+13}$  and  $Q(r, c)$  denote an isometric  $(c, r)$ -path. Let  $T(r, c_1)$  be the maximum subpath of  $Q(r, c)$  such that no internal vertex of  $T(r, c_1)$  is adjacent to any vertex of  $P(z, w)$ . Observe that neither  $z$  nor  $w$  can be adjacent to  $c_1$  (due to Proposition 9). Moreover, if  $c_1$  is a vertex of  $P(z, w)$  then we must have  $c_1 = c$ .

▷ Claim 23 (\*). Let  $x$  be a neighbour of  $c_1$  in  $P(z, w)$ ,  $X$  be the  $(x, b)$ -subpath of  $P(u, b)$  and  $Y$  be the  $(x, u)$ -subpath of  $P(u, b)$ . Then  $|A_r(X)| \geq 2t + 11$  and  $|A_r(Y)| \geq 2t + 11$ .

Let  $T(c_1, c_2)$  be the maximum  $(c_1, c_2)$ -subpath of  $T(c_1, r)$  such that no internal vertex of  $T(c_1, c_2)$  is adjacent to a vertex of  $Q(r, b)$  or  $Q(r, u)$ . We have the following claim.

▷ Claim 24 (\*). The length of  $T(c_1, c_2)$  is at least  $t + 3$ .

The path  $T(c_1, c_2)$  forms the first ingredient to extract a  $(t + 1)$ -fat turtle. Let  $z_1$  be the neighbour of  $z$  in  $Q(r, u)$  and  $w_1$  be the neighbour of  $w$  in  $Q(r, b)$ . We have the following claim.

▷ Claim 25 (\*). The vertices  $w_1$  and  $z_1$  are non adjacent.

Now we shall construct a  $(w_1, z_1)$ -path as follows: Consider the maximum  $(w_1, w_2)$ -subpath, say  $T(w_1, w_2)$ , of  $Q(r, b)$  such that no internal vertex of  $T(w_1, w_2)$  has a neighbour in  $Q(r, u)$ . Similarly, consider the maximum  $(z_1, z_2)$ -subpath, say  $T(z_1, z_2)$ , of  $Q(r, u)$  such that no internal vertex of  $T(z_1, z_2)$  is a neighbour of  $w_2$ . (Note that it is possible that  $z_2 = w_2 = r$ .) Let  $T$  be the path obtained by taking the union of  $T(w_1, w_2)$  and  $T(z_1, z_2)$ . Observe that  $z_2$  must be a neighbour of  $w_2$  and  $T$  is an induced  $(w_1, z_1)$ -path. The definitions of  $T$  and  $P(z, w)$  imply that their union induces a cycle  $Z$ . Here we have the second and final ingredient to extract the  $(t + 1)$ -fat turtle.

Suppose that  $c_2$  has a neighbour in  $T$ . Let  $T'$  be the maximum subpath of  $T(c_1, c_2)$  which is vertex-disjoint from  $Z$ . (Note that if  $c_1 = c$  or  $c_2 \in \{w_2, z_2\}$  (e.g. when  $c_2 = w_2 = z_2 = r$ ),  $T(c_1, c_2)$  may share vertices with  $Z$ .) Due to Claim 24, the length of  $T'$  is at least  $t + 1$ . Let  $e_1$  and  $e_2$  be the end-vertices of  $T'$ . Observe the following.

- Each of  $e_1$  and  $e_2$  has at least one neighbour in  $Z$ .
- $Z - \{z, w\}$  contains two distinct components  $C_1, C_2$  such that for  $i \in \{1, 2\}$ ,  $N(e_i) \cap V(Z) \subseteq V(C_i)$ .
- For a vertex  $e'_1 \in N(e_1) \cap V(Z)$  and  $e'_2 \in N(e_2) \cap V(Z)$ , the distance between  $e'_1$  and  $e'_2$  is at least  $t + 1$ . This statement follows from Claim 23.

Hence, we have that the tuple  $(t + 1, Z, T', z, w)$  defines a  $(t + 1)$ -fat turtle. Now consider the case when  $c_2$  does not have a neighbour in  $T$ . By definition,  $c_2$  has at least one neighbour in  $Q(r, u)$  or  $Q(r, b)$ . Without loss of generality, assume that  $c_2$  has a neighbour  $c_3$  in  $Q(r, u)$  such that the  $(z_2, c_3)$ -subpath, say,  $T''$  of  $Q(r, u)$  has no neighbour of  $c_2$  other than  $c_3$ . Observe that the path  $T^* = (T' \cup (T'' - \{z_2\}))$  is vertex-disjoint from  $Z$  and has length at least  $t + 1$ . Let  $e_1, e_2$  be the two end-vertices of  $T^*$ . Observe the following.

■ **Figure 4** (a)  $X_4$  (b)  $Y_4$  (c)  $Z_4$ .

- Each of  $e_1$  and  $e_2$  has at least one neighbour in  $Z$ .
- $Z - \{z, w\}$  contains two distinct components  $C_1, C_2$  such that for  $i \in \{1, 2\}$ ,  $N(e_i) \cap V(Z) \subseteq V(C_i)$ .
- For a vertex  $e'_1 \in N(e_1) \cap V(Z)$  and  $e'_2 \in N(e_2) \cap V(Z)$ , the distance between  $e'_1$  and  $e'_2$  is at least  $t + 1$ . This statement follows from Claim 23.

Hence,  $(t + 1, Z, T^*, z, w)$  is a  $(t + 1)$ -fat turtle. ◀

**Proof of Theorem 3b.** Lemma 7, 18 and 20 together imply Theorem 3b.

► **Lemma 26** (\*). *Any outerstring graph is (4-theta, 4-prism, 4-pyramid)-free.*

**Proof of Theorem 3c.** Lemma 7, 18, 20, and 26 together imply Theorem 3c.

## 5 Proof of Theorem 4

We shall provide a construction for every  $k \geq 4$ , this implies the statement of Theorem 4 for any  $k \geq 1$ . First we shall prove Theorem 4a. For a fixed integer  $k \geq 4$ , first we describe the construction of a graph  $X_k$  as follows. Consider  $k + 1$  paths  $P_1, P_2, \dots, P_{k+1}$  each of length  $k$  and having a common endvertex  $a$ . For  $i \in [k + 1]$ , let the other endvertex of  $P_i$  be denoted as  $b_i$ . Moreover, for  $i \in [k + 1]$ , let the neighbours of  $a$  and  $b_i$  in  $P_i$  be denoted as  $a'_i$  and  $b'_i$ , respectively. For  $i \in [k]$ , introduce an edge between  $b_i$  and  $b_{i+1}$ . The resulting graph is denoted  $X_k$  and the special vertex  $a$  is the *apex* of  $X_k$ . See Figure 4(a). For a fixed integer  $k \geq 4$ , consider the graph  $X_k$  and for each  $i \in [k]$ , introduce an edge between  $b_i$  and  $b'_{i+1}$ . Let  $Y_k$  denote the resulting graph and the special vertex  $a$  is the *apex* of  $Y_k$ . See Figure 4(b). For a fixed integer  $k \geq 4$ , consider the graph  $Y_k$  and for each  $\{i, j\} \subseteq [k]$ , introduce an edge between  $a'_i$  and  $a'_j$ . Let  $Z_k$  denote the resulting graph and the special vertex  $a$  is the *apex* of  $Z_k$ . See Figure 4(c). We prove the following lemmas.

► **Lemma 27** (\*). *For  $k \geq 4$ , let  $G$  be the graph constructed by taking two distinct copies of  $X_k$  and identifying the two apex vertices. Then  $G$  is a wheel-free, (pyramid, prism)-free graph with treewidth 2, hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$  and  $\text{ipacc}(G) \geq k$ .*

► **Lemma 28** (\*). *For  $k \geq 4$ , let  $G$  be the graph constructed by taking two distinct copies of  $Y_k$  and identifying the two apex vertices. Then  $G$  is a wheel-free, (theta, prism)-free graph with treewidth 3, hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$ , and  $\text{ipacc}(G) \geq k$ .*

► **Lemma 29** (\*). *For  $k \geq 4$ , let  $G$  be the graph constructed by taking two distinct copies of  $Z_k$  and identifying the two apex vertices. Then  $G$  is a wheel-free, (theta, pyramid)-free graph with hyperbolicity at least  $\lceil \frac{k}{2} \rceil - 1$  and  $\text{ipacc}(G) \geq k$ .*

Lemma 7, 27, 28, 29 imply Theorem 4.

## 6 Conclusion

In this paper, we have introduced the new graph parameter *isometric path complexity*. We have shown that the isometric path complexity of a graph with  $n$  vertices and  $m$  edges can be computed in  $O(n^2m)$ -time. It would be interesting to provide a faster algorithm to compute the isometric path complexity of a graph. We have derived upper bounds on the isometric path complexity of three seemingly (structurally) different classes of graphs, namely hyperbolic graphs,  $(\theta, \text{pyramid, prism})$ -free graphs and outerstring graphs. An interesting direction of research is to generalise the properties of hyperbolic graphs or  $(\theta, \text{pyramid, prism})$ -free graphs to graphs with bounded isometric path complexity.

Note that, in our proofs we essentially show that, for any graph  $G$  that belongs to one of the above graph classes, any vertex  $v$  of  $G$ , and any isometric path  $P$  of  $G$ , the path  $P$  can be covered by a small number of  $v$ -rooted isometric paths. This implies our “choice of the root” is arbitrary. This motivates the following definition. The *strong isometric path complexity* of a graph  $G$  is the minimum integer  $k$  such that for each vertex  $v \in V(G)$  we have that the vertices of any isometric path  $P$  of  $G$  can be covered by  $k$  many  $v$ -rooted isometric paths. Our proofs imply that the strong isometric path complexity of graphs from all the graph classes addressed in this paper are bounded. We also wonder whether one can find other interesting graph classes with small (strong) isometric path complexity.

Our results imply a constant-factor approximation algorithm for ISOMETRIC PATH COVER on hyperbolic graphs,  $(\theta, \text{pyramid, prism})$ -free graphs and outerstring graphs. However, the existence of a constant-factor approximation algorithm for ISOMETRIC PATH COVER on general graphs is not known (an  $O(\log n)$ -factor approximation algorithm is designed in [26]).

## Abstract

We consider the problem of estimating the support size of a distribution  $D$ . Our investigations are pursued through the lens of distribution testing and seek to understand the power of conditional sampling (denoted as COND), wherein one is allowed to query the given distribution conditioned on an arbitrary subset  $S$ . The primary contribution of this work is to introduce a new approach to lower bounds for the COND model that relies on using powerful tools from information theory and communication complexity.

Our approach allows us to obtain surprisingly strong lower bounds for the COND model and its extensions.

- We bridge the longstanding gap between the upper bound  $O\left(\log \log n + \frac{1}{\epsilon^2}\right)$  and the lower bound  $\Omega\left(\sqrt{\log \log n}\right)$  for the COND model by providing a nearly matching lower bound. Surprisingly, we show that even if we get to know the actual probabilities along with COND samples, still  $\Omega\left(\log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)}\right)$  queries are necessary.
- We obtain the first non-trivial lower bound for the COND equipped with an additional oracle that reveals the actual as well as the conditional probabilities of the samples (to the best of our knowledge, this subsumes all of the models previously studied): in particular, we demonstrate that  $\Omega\left(\log \log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)}\right)$  queries are necessary.

## 1 Introduction

We consider the problem of estimating the support size of a distribution  $D$  over a domain  $\Omega$  (of size  $n$ ), which is defined as follows:

$$\text{SUPP}(D) := \{x \mid D(x) > 0\}.$$

We are interested in  $(\epsilon, \delta)$ -approximation<sup>1</sup> of the size of  $\text{SUPP}(D)$  (i.e.,  $|\text{SUPP}(D)|$ ). For simplicity in exposition, throughout this paper, we consider  $\delta$  to be a small constant (more specifically,  $1/3$ , which can be reduced to any arbitrary small constant.). The support size estimation is a fundamental problem in data science and finds a myriad of applications ranging from database management, biology, ecology, genetics, linguistics, neuroscience, and physics (see [30] and the references therein). Naturally, the distribution is not specified explicitly, and therefore, the complexity of the problem depends on the queries that one is allowed to the distribution. As such, the primary objective is to minimize the number of queries (aka *query complexity*).

Along with support size estimation, several other properties of distributions have attracted investigations over the past three decades (see [9]). As such, several query models have been considered by the research community. The simplest model SAMP only allows drawing independent and identically distributed samples from  $D$ . Valiant and Valiant [30] showed that to get an estimation up to an additive factor of  $\epsilon n$  (for any  $\epsilon > 0$ ),  $O(n/\epsilon^2 \log n)$  samples suffice, which was subsequently improved to  $O(\frac{n}{\log n} \log^2(1/\epsilon))$  by Wu and Yang [31]. Further, Wu and Yang proved that  $\Omega(\frac{n}{\log n} \log^2(1/\epsilon))$  samples are also necessary to get an estimate up to an additive error of  $\epsilon n$ . A natural extension to SAMP is called *probability-revealing sample* or PR-SAMP, due to Onak and Sun [27], wherein instead of just returning an independent sample  $x$  from  $D$  (as in SAMP), the oracle provides a pair  $(x, D(x))$  (i.e., a sample along with the probability assigned on it by  $D$ ). Onak and Sun showed that to estimate the support size up to an additive error of  $\epsilon n$ ,  $\Theta(1/\epsilon^2)$  samples are necessary and sufficient in the PR-SAMP model. The same upper bound for the PR-SAMP model was also implicit in the work by Canonne and Rubinfeld [8].

As we seek to explore more powerful models than PR-SAMP, a model of interest is DUAL [2, 22, 8] wherein we have access to two oracles: One is SAMP that provides a sample from  $D$ , and another is EVAL that given any  $x \in \Omega$ , outputs the value of  $D(x)$ . In the DUAL model, for any  $\epsilon_1, \epsilon_2 \in (0, 1]$ , distinguishing between whether the support size of  $D$  is at most  $\epsilon_1 n$  or at least  $\epsilon_2 n$  requires  $\Theta(1/(\epsilon_2 - \epsilon_1)^2)$  queries [8]. An extension of EVAL is CEVAL wherein for totally ordered domains, given  $x$ , CEVAL outputs  $\sum_{y \preceq x} D(x)$ . Similarly, CDUAL is an extension of DUAL where we have access to oracles SAMP and CEVAL. Caferov, Kaya, O'Donnell, and Say [7] showed that  $\Omega(\frac{1}{\epsilon^2})$  queries are needed in the CDUAL model to estimate the support size up to an additive factor of  $\epsilon n$ . However, to the best of our knowledge, no non-trivial result is known for the support size estimation problem with  $(1 + \epsilon)$  multiplicative error in the above models.

While SAMP, PR-SAMP, and DUAL are natural models, they are limiting in theory and practice as they fail to capture several scenarios wherein one is allowed more powerful access to the distribution under consideration. Accordingly, CFGM [13] and CRS [11]

<sup>1</sup> We want to estimate  $|\text{SUPP}(D)|$  by  $\hat{s}$  such that  $\frac{|\text{SUPP}(D)|}{(1+\epsilon)} \leq \hat{s} \leq (1+\epsilon)|\text{SUPP}(D)|$  with the success probability at least  $1 - \delta$ . This version is also referred to as  $(1 + \epsilon)$ -multiplicative factor estimation. Another interesting version to consider is the additive  $\epsilon n$ -estimation (where  $n$  denotes the size of the domain) which asks to output a  $\hat{s}$  such that  $|\text{SUPP}(D)| - \epsilon n \leq \hat{s} \leq |\text{SUPP}(D)| + \epsilon n$  with the success probability at least  $1 - \delta$ . Unless otherwise stated explicitly, we consider the multiplicative variant.

initiated the study of a more general sampling model COND, where we are allowed to draw samples conditioning on any arbitrary subsets of the domain  $\Omega$ . More specifically, the sampling oracle takes a subset  $S \subseteq \Omega$  chosen by the algorithm and returns an element  $x \in S$  with probability  $D(x)/D(S)$  if  $D(S) > 0$ . The models proposed by CFGM and CRS differ in their behavior for the case when  $D(S) = 0$ . The model proposed by CFGM [13] allows the oracle to return a uniformly random element from  $S$  when  $D(S) = 0$ . On the other hand, the COND model defined in CRS [11] assumes that the oracle (and hence the algorithm) returns “failure” and terminates if  $D(S) = 0^2$ . Note that the COND model of CRS is more powerful than that of CFGM since, when  $D(S) = 0$ , in the former case, we get to know that  $D(S) = 0$ , whereas in the latter case, we get a uniformly random element of  $S$ .

The relative power of the COND model of CRS over that of CFGM is also exhibited in the context of support size estimation. Acharya, Canonne, and Kamath [1] designed an algorithm with query complexity  $\tilde{O}(\log \log n/\epsilon^3)$  in the COND model of CFGM to estimate the support size up to  $(1 + \epsilon)$  multiplicative factor under the assumption that the probability of each element is at least  $\Omega(1/n)$ . They also note that the assumption of a lower bound on the probability of each element is required for their techniques to work. It is worth highlighting that for the problem of support size estimation in the SAMP model, one needs a lower bound of  $\Omega(1/n)$  on the minimum probability assigned to any element in the support. Otherwise, one can assign a negligible probability to certain elements which will never be observed. In the COND model, such an assumption is not necessary. Indeed, a result of Falahatgar, Jafarpour, Orlitsky, Pichapati, and Suresh [18] implies that  $O(\log \log n + \frac{1}{\epsilon^2})$  queries are sufficient in the COND model of CRS for any arbitrary probability distribution, i.e., there is no requirement for the assumption of lower bound on the probability of each element. The key idea behind this result is that it is possible to decide whether the support size is  $> 2t$  or  $\leq t$  for any integer  $t \geq 0$  (for any arbitrary probability distributions) with high probability using only  $O(1)$  queries, even with weaker oracle access in which, given any  $S \subseteq \Omega$ , it can be determined whether  $S \cap \text{SUPP}(D) = \emptyset$  or not. On the lower bound side, we only know that at least  $\Omega(\sqrt{\log \log n})$  COND queries are necessary [13].

The two models were introduced in the context of uniformity testing, wherein the choice of how to handle the case of  $D(S) = 0$  did not make any significant differences. We would like to emphasize that CRS’s model is more powerful than that of CFGM, and thus any lower bound shown in the first one also provides the same in the latter one. Moreover, the model of CRS closely approximates the behavior of modern probabilistic programming systems [21]. Therefore, throughout this paper, we consider the COND model of CRS.

Since its introduction, the COND model has attained significant attention both in theory and practice. From a theoretical perspective, various other distribution testing problems have been studied under the COND model [17, 24, 26] and its variant like *subcube conditioning model* [3, 10, 15]. Apart from that, the COND model and its variants find real-world applications in the areas like formal methods and machine learning (e.g., [14, 25, 20]). Also, the modern probabilistic programming systems extend classical programs with the addition of sampling and *observe*, where the semantics of the observe match that of CRS’s COND model [21].

---

<sup>2</sup> Note that analyzing each step of the algorithm makes it possible to determine the set, conditioning on which caused the algorithm to output “failure” and terminate. The rest of the algorithm can then execute with the information that  $D(S) = 0$  for the above set  $S$ . Therefore, for the simplicity of exposition, we will assume that the COND model defined in CRS returns “failure” when  $D(S) = 0$ , but the algorithm does not terminate.

### 33:4 Support Size Estimation: The Power of Conditioning

It is worth remarking that the COND model is incomparable with PR-SAMP. Therefore, it is quite natural, both from a theory and practical perspective, to consider a sampling model that inherits power from both COND and PR-SAMP. We consider a model where we are allowed to condition on any arbitrary subset  $S \subseteq \Omega$ , and if  $D(S) > 0$ , we receive a sample  $x \in S$  with probability  $D(x)/D(S)$  (as in COND) along with the probability assigned on it by  $D$  (i.e.,  $D(x)$ ); “failure” otherwise. We refer to this model as *probability-revealing conditional sample*<sup>3</sup> or in short COND-PR. To the best of our knowledge, Golia, Juba, and Meel [20] were the first ones to initiate the study of the COND-PR model. Their work focused on the multiplicative estimation of entropy on the COND-PR model. Golia et al. were primarily motivated to investigate the COND-PR model upon the observation that the usage of the model counter and a sampler can simulate the COND-PR model wherein a circuit specifies the distribution. Also, implicit in their study is that the availability of model counter and samplers [16] allows one to simulate generalization of COND-PR model wherein for a given input  $D$  and  $S$  in addition to  $D(x)$  for a sampled item  $x \in S$ , the oracle also returns the value of  $D(x)/D(S)$  (the conditional probability of  $x$  given  $S$ ). We refer to this model as *conditional sampling evaluation model*<sup>4</sup>, or in short COND-EVAL. To the best of our knowledge, the COND-EVAL subsumes all the previously studied variants of the COND model (see Figure 1).

■ **Figure 1** Relative power of different models: An edge  $u \rightarrow v$  means the model  $v$  is more powerful than the model  $u$ .

To summarize, there has been a long line of research that has relied on the usage of the COND model and its variants, resulting in significant improvements in the query complexity for several problems in distribution testing. While there has been a multitude of techniques for obtaining upper bounds for the COND model and its variants, such has not been the case for lower bounds. In particular, the prior techniques developed in the context of support size estimation for COND model have primarily relied on the observation that an algorithm  $\mathcal{A}$  that makes  $q$  COND queries can be simulated by a decision tree of  $O(q2^{q^2})$  nodes. Accordingly, the foregoing observation allows one to obtain  $\Omega(\sqrt{\log \log n})$  lower bound for

<sup>3</sup> The name is motivated from the PR-SAMP model [27].

<sup>4</sup> The name is motivated from the standard *evaluation* model EVAL [28] where given any  $x \in \Omega$ , we get the value of the probability density function of  $D$  at  $x$ .

COND, which leaves open a major gap with respect to the upper bound of  $O(\log \log n + \frac{1}{\epsilon^2})$ . The situation is even direr when considering models that augment COND with powerful oracles such as EVAL since the approach based on a decision tree fails due to additional information supplied by oracles such as EVAL, and accordingly, no non-trivial lower bounds are known for models such as CDUAL, COND-EVAL, and the like. Therefore, there is a desperate need for new lower bound techniques to fully understand the power of the COND model and its natural extensions.

## 1.1 Our Contribution

One of our primary contributions is to provide a seemingly new approach to proving lower bounds in the COND model and its more powerful variants. Our approach is based on information theory and reductions to problems in communication complexity. We note that the communication complexity-based approaches to lower bounds have been explored in prior work; such approaches are only limited to weaker models such as the SAMP and the PAIRCOND models [6, 5]. While we demonstrate the application of our approach in the context of support size estimation for different variants of COND, we believe our approach is of general interest and can be applied to other distribution testing problems.

For ease of exposition, here we situate the discussion in the context of the most general model, COND-EVAL. One of the inherent difficulties in proving any non-trivial lower bound for the COND-EVAL model arises from the fact that the different sets for conditioning can overlap in an arbitrary manner (and unlike in PAIRCOND model, these sets are of arbitrary size) and further be chosen in an adaptive way. The adaptivity and arbitrary size of sets make it extremely difficult to upper bound the conditional entropy at any step of the algorithm. Furthermore, the power of revealing the probability mass (on any set) by a COND-EVAL query risks licking “a lot of” information which makes it even more challenging. The key departure from earlier work is the choice of an infinite family of distributions, so the range of outcomes of an algorithm is continuous and so cannot be encoded with any finite (or even infinite) length message. To this end, we rely on Fano’s inequality, a fundamental tool in information theory, to show lower bounds for statistical estimation. In order to apply Fano’s inequality, we need to upper bound the information gain at every step of the algorithm. Our approach proceeds by relying on a restricted model of conditioning where the queried sets are *laminar*, i.e., either they do not intersect or are subsets/supersets of each other. Accordingly, we first obtain lower bounds for the restricted model and lift to the lower bounds for the COND-EVAL model.

Our approach is compelling enough to provide non-trivial lower bounds in the most potent COND-EVAL model, for which no lower bound was known before. However, before providing the usefulness of the general framework, let us demonstrate how a special instantiation of our approach can be applied to obtain strong lower bounds in the context of support size estimation for the COND model and its (simpler) variants. Our first result bridges the long-standing gap between the upper bound of  $O(\log \log n + \frac{1}{\epsilon^2})$  and the lower bound of  $\Omega(\sqrt{\log \log n})$  in case of COND model. In particular, we obtain an  $\Omega(\log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)})$  lower bound on the query complexity in the COND-PR model, which in turn provides the same lower bound for the PR-SAMP, DUAL, and COND model.

► **Theorem 1.** *Every algorithm that, given COND-PR access to a distribution  $D$  on  $[n]$  and  $\epsilon \in (0, 1]$ , estimates the support size  $|\text{SUPP}(D)|$  within a multiplicative  $(1 + \epsilon)$ -factor with probability at least  $\frac{2}{3}$ , must make  $\Omega\left(\log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)}\right)$  queries to the COND-PR oracle.*

## 33:6 Support Size Estimation: The Power of Conditioning

Recall the best-known upper bound for the support size estimation in COND is  $O(\log \log n + \frac{1}{\epsilon^2})$  and therefore, the above theorem achieves a near-matching lower bound in the context of COND and COND-PR. It is rather surprising that the combination of PR-SAMP and COND does not yield power in the context of the support size estimation. It is worth mentioning that we already know of a lower bound of  $\Omega(1/\epsilon^2)$  for the PR-SAMP and DUAL model due to [8]. Hence, our result along with [8] provides a lower bound of  $\Omega(\log \log n + \frac{1}{\epsilon^2})$  for these two models (i.e., we can get rid of the annoying  $\log(1/\epsilon)$  factor from the lower bound term of Theorem 1).

Our primary result is to establish the first non-trivial lower bound in the context of COND-EVAL, which in turn provides the first-known lower bound for many other previously studied models, such as CDUAL.

► **Theorem 2.** *Any algorithm that, given COND-EVAL access to a distribution  $D$  on  $[n]$  approximates the support size  $|\text{SUPP}(D)|$  within a multiplicative  $(1 + \epsilon)$ -factor with probability at least  $2/3$ , must make  $\Omega\left(\log \log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)}\right)$  queries.*

Since COND-EVAL subsumes COND-PR, we have the upper bound of  $O(\log \log n + \frac{1}{\epsilon^2})$ , and the ensuing gap leaves open an interesting question. It is worth remarking that it is not hard to see (by extending the proof of Theorem 1) that the upper bound is nearly tight if one were to replace COND-EVAL with approximate-COND-EVAL wherein, for a given  $D$  and  $S$ , the oracle essentially provides an estimate of  $D(S)$  up to a small multiplicative error (see the discussion in the full version). We conjecture that the upper bound is tight for COND-EVAL.

► **Conjecture 3.** *Any algorithm that, given COND-EVAL access to a distribution  $D$  on  $[n]$  approximates the support size  $|\text{SUPP}(D)|$  within a multiplicative  $(1 + \epsilon)$ -factor with probability at least  $2/3$ , must make  $\Omega\left(\log \log n + \frac{1}{\epsilon^2 \log(1/\epsilon)}\right)$  queries.*

The validity of the above conjecture would establish the significant power of the COND model in the context of support size estimation as COND-EVAL and COND-PR, despite being augmented with powerful oracles in addition to conditioning, do not yield better algorithms.

## 2 Preliminaries

### Notations

We use the notation  $[n]$  to denote the set of integers  $\{1, 2, \dots, n\}$ . For any probability distribution  $D$  defined over  $[n]$ , for any  $i \in [n]$ , let  $D(i)$  denote the probability of choosing  $i$  when sampling according to  $D$ . For any subset  $S \subseteq [n]$ , we use  $D(S)$  to denote the probability mass assigned on  $S$  by the distribution  $D$ , i.e.,  $D(S) := \sum_{i \in S} D(i)$ .

### Different access models

Let  $D$  be a distribution over  $[n]$ . Below we formally define the query models that we consider in this paper.

► **Definition 4 (COND Query Model).** *A conditional (in short, COND) oracle for  $D$  takes as input a set  $S \subseteq [n]$ , and if  $D(S) > 0$ , returns an element  $j \in S$  with probability  $D(j)/D(S)$ . If  $D(S) = 0$ , then the oracle returns “failure”.*

► **Definition 5** (COND-PR Query Model). A probability-revealing conditional sampling (in short, COND-PR) oracle for  $D$  takes as input a set  $S \subseteq [n]$ , and if  $D(S) > 0$ , returns a pair  $(j, D(j))$  (where  $j \in S$ ) with probability  $D(j)/D(S)$ . If  $D(S) = 0$ , then the oracle returns “failure”.

► **Definition 6** (COND-EVAL Query Model). A conditional evaluation (in short, COND-EVAL) oracle for  $D$  takes as input a set  $S \subseteq [n]$ , and if  $D(S) > 0$ , returns a tuple  $(j, D(j), D(j)/D(S))$  (where  $j \in S$ ) with probability  $D(j)/D(S)$ . If  $D(S) = 0$ , then the oracle returns “failure”.

► **Definition 7** (SET-EVAL Query Model). A set evaluation (in short, SET-EVAL) oracle for  $D$  takes as input a set  $S \subseteq [n]$ , and returns the value  $D(S)$ .

It is straightforward to observe that the COND-EVAL is at least as powerful as the COND-PR oracle which in turn is at least as powerful as the COND oracle. Further, the COND-EVAL oracle is at least as powerful as the SET-EVAL oracle.<sup>5</sup>

### Shannon entropy and source coding theorem

The *entropy* of a discrete random variable  $X$  taking values in  $\mathcal{X}$  is defined as  $H(X) := \sum_{x \in \mathcal{X}} p(x) \log \frac{1}{p(x)}$  where  $p(x) = \Pr[X = x]$ .

The seminal work of Shannon [29] establishes a connection between the entropy and the expected length of an optimal code that encodes a random variable.

► **Theorem 8** (Shannon's Source Coding Theorem [29]). Let  $X$  be a discrete random variable over domain  $\mathcal{X}$ . Then for every uniquely decodable code  $C : \mathcal{X} \rightarrow \{0, 1\}^*$ ,  $\mathbb{E}(|C(X)|) \geq H(X)$ . Moreover, there exists a uniquely decodable code  $C : \mathcal{X} \rightarrow \{0, 1\}^*$  such that  $\mathbb{E}(|C(X)|) \leq H(X) + 1$ .

## 3 Technical Overview

### Lower bound for COND-PR

We start with deriving the lower bound of Theorem 1. It consists of two parts – an  $\Omega(\log \log n)$  lower bound for a multiplicative  $4/3$ -factor estimation algorithm and an  $\Omega(\frac{1}{\epsilon^2 \log \frac{1}{\epsilon}})$  lower bound for an additive  $\epsilon n$ -factor algorithm. We first show an  $\Omega(\log \log n)$  lower bound for a multiplicative  $4/3$ -factor algorithm. For that purpose, we consider an *integer-guessing* game between Alice and Bob, where Alice uniformly at random chooses an integer  $x \in [\log n]$ . Then sends a message (binary string) to Bob. Upon receiving the message, Bob's task is to guess  $x$  correctly (with high probability). Since the entropy of the chosen integer is  $\log \log n$ , by Shannon's source coding theorem, the length of the message, on average, must be  $\Omega(\log \log n)$ . We show that if there exists an algorithm  $T$  that makes  $t$  COND-PR queries, then it suffices for Alice to send a message of length  $O(t)$ , and hence  $t = \Omega(\log \log n)$ .

To show the same, for each  $x \in [\log n]$ , Alice considers a distribution  $D_x$  with support  $[2^x]$ . The probability  $D_x(j)$  of an element  $j \in [2^x]$  in  $D_x$  decreases exponentially as  $j$  increases. Alice runs the algorithm  $T$  on the distribution  $D_x$  and would like to send an encoding of the run (i.e., the sampled element along with its probability for each step). Using a trivial

<sup>5</sup> Since on input  $S$ , the COND-EVAL oracle returns a tuple  $(j, D(j), D(j)/D(S))$  where  $j \in S$ , one can compute the value of  $D(S)$  whenever  $D(S) > 0$ ; otherwise (when  $D(S) = 0$ ) the COND-EVAL oracle returns “failure”, from which one can infer that  $D(S) = 0$ .

encoding, even to send a sampled element, requires  $\Theta(\log n)$  bits, which is already more than the Shannon entropy and thus would not give any lower bound. So Alice needs to use a slightly clever encoding. Roughly speaking, since the probabilities are exponentially decreasing, the conditional sampling from any set  $S \subseteq [n]$  returns an element from the first “few” smallest elements of  $S$  (with high probability). Thus even though  $|S|$  can be large, the sampled element (at each step) can be specified by only constantly many bits. Alice sends this encoding of the sampled element (along with its probability value which can again be encoded with constantly many bits due to the construction of  $D_x$ 's) at each of  $t$  steps to Bob. Hence Bob knows the complete run and thus can determine the index  $x$  using the algorithm  $T$ . We provide detailed proof in the full version.

Next, we turn our attention to showing the dependency of  $\epsilon$  in the lower bound. We show an  $\Omega\left(\frac{1}{\epsilon^2 \log \frac{1}{\epsilon}}\right)$  lower bound for an additive  $\epsilon n$ -factor algorithm. Since a multiplicative  $(1 + \epsilon)$ -factor algorithm also provides an additive  $\epsilon n$ -factor estimation, the above lower bound also works for  $(1 + \epsilon)$ -factor algorithms. We prove this bound by showing a reduction from a well-studied communication complexity problem, namely the *Gap-Hamming distance* problem, and then applying the known lower bound for the Gap-Hamming distance [12]. The proof argument (and the dependence on  $\epsilon$ ) also holds true for COND-EVAL model.

### Lower bound for COND-EVAL

The approach used to get an  $\Omega(\log \log n)$  lower bound in the COND-PR model cannot be used to show the same for the COND-EVAL model. One of the powers of COND-EVAL model (over the COND-PR) comes from its ability to compute  $D(S) := \sum_{j \in S} D(j)$  for any set  $S \subseteq [n]$ .

Recall the hard instance  $D_x$ 's used in the  $\Omega(\log \log n)$  lower bound proof for the COND-PR model. Let  $X^* := \{2^x \mid x \in [\log n]\}$ . It is easy to verify that  $D_x(X^*) \neq D_{x'}(X^*)$  for any  $x \neq x' \in [\log n]$ . So, the value of  $x$  (and hence the support of  $D_x$ ) can be determined using only one COND-EVAL query with the set  $X^*$ . Thus our lower bound argument fails in this model. For the sake of intuition about how we overcome the above issue, we want to point out that the above argument does not fail if we have an approximate COND-EVAL query instead of COND-EVAL query, i.e., if the oracle gives the estimate of  $D(S)$  up to a small additive error say  $\frac{3}{2^{n^{0.1}}}$ . This is because for  $x, x' \in [\frac{\log n}{10}, \log n]$ , we have  $|D_x(X^*) - D_{x'}(X^*)| \leq \frac{2}{2^{n^{0.1}}}$ . Hence, given that  $x, x' \in [\frac{\log n}{10}, \log n]$ , we can not distinguish between  $x$  and  $x'$  as the estimate could be the same for both  $x$  and  $x'$ .

To mitigate the above issue (for COND-EVAL), we construct a new set of hard distributions. Our objective is that for any set  $X^*$ , if the value of  $D_x(X^*)$  is in  $(0, 1)$ , then value of  $D_x(X^*)$  should not give information about  $x$ . One plausible approach could be to replace each distribution  $D_x$  with a finite set of distributions such that for any set  $S \subseteq [n]$ , there are many distributions in the instance with the same value of  $D(S)$ . Unfortunately, we do not know how to get such a set of distributions preserving other useful properties needed for our proof. Our key high-level idea is to replace the distribution  $D_x$  (for each  $x \in [\log n]$ ) with a distribution over an infinite number of distributions. This way, the value of  $D_x(X^*)$  cannot be used to determine the value of chosen  $x$  (as there can be infinite values of  $x$  having the same value  $D(X^*)$ ). However, one immediate issue that arises is if our instance has an infinite domain (here distributions), then how do we even get a distribution over an infinite space? Further, like before, we still want the probabilities to exponentially decrease so that the sampled element is always among the first few smallest elements of the conditioning set  $S$ . Fortunately, in statistics and compositional data analysis, there has been a study of

probability distributions on the set of all (infinite) distributions. Based on requirements, our choice is the well-studied Dirichlet distribution that satisfies a strong independence property which is necessary for our analysis.

A Dirichlet distribution on support  $[K]$  with parameters  $\alpha_1, \dots, \alpha_K > 0$  has a probability density function given by  $f(p_1, \dots, p_K) = \frac{\prod_{i \in [K]} p_i^{\alpha_i - 1}}{B(\alpha_1, \dots, \alpha_K)}$  where  $\{p_i\}_{i \in [K]}$  belongs to the standard  $K-1$  simplex, i.e.,  $\sum_{i \in [K]} p_i = 1$  and  $p_i \geq 0$  for all  $i \in [K]$  and  $B(\alpha_1, \dots, \alpha_K)$  is a normalizing constant. When  $\alpha_1 = \dots = \alpha_K = 1$ , the Dirichlet distribution is just the uniform distribution on  $K-1$  simplex. The higher the value of parameter  $\alpha_i$ , the higher the (expected) value of  $p_i$ . Since we want the probability value to be exponentially decreasing, we set the values of  $\alpha_1, \dots, \alpha_n$  exponentially decreasing. Then for each index  $x$  chosen uniformly at random from  $[\log n]$ , we sample a distribution  $D_x$  with support  $[2^x]$  from the Dirichlet distribution with parameters  $\alpha_1, \dots, \alpha_{2^x}$ . By the standard Yao's principle, it suffices to show a high error probability of any deterministic algorithm that correctly estimates the support size (and hence determines the index  $x$ ) of the distribution sampled as above. Note that the entropy of the index is still  $\log \log n$ , but the previous communication framework (between Alice and Bob) will not be useful here. This is because the range of the outcomes of the algorithm (the actual and the conditional probabilities) is continuous, and so cannot be encoded with any finite (or even infinite) length message. Instead, we apply Fano's inequality, a tool from information theory.

Roughly speaking, we show that the information gain (about the index) by the query's outcome at every step is  $O(1)$ . Since the initial entropy of the index is  $\log \log n$ , at least  $\log \log n$  steps of the algorithm are needed. The main technical challenge is to upper bound the information gain at every step. It is particularly challenging as it requires calculating the explicit density function (for the outcome) corresponding to each index. These density functions are conditioned on the previous outcomes and thus change at every step. Further, the set queried by the algorithms can be adaptive, which makes our task even more difficult. To ease our analysis, we first assume that the queried sets by the algorithm are *laminar*, i.e., either they do not intersect or are subsets/supersets of each other. Our  $\Omega(\log \log n)$  lower bound holds for COND-EVAL model for all the algorithms satisfying this laminar condition. It is not hard to observe that any algorithm that makes  $t$  general queries can be simulated by an algorithm that queries the laminar family of sets and makes at most  $2^t$  queries. This observation gives us  $\Omega(\log \log \log n)$  lower bound for the general case. We believe that  $\Omega(\log \log n)$  is the correct lower bound for the general case, but (perhaps it is an artifact of our analysis that) the laminar structure is necessary for applying the independence properties of Dirichlet distribution which leads to only an  $\Omega(\log \log \log n)$  lower bound. For the sake of simplicity, we first prove the lower bound for a weaker model called, SET-EVAL, and then extend to the general COND-EVAL model. We refer to the oracle that, given any  $S \subseteq [n]$ , just outputs the value of  $D(S)$ , as SET-EVAL oracle. Since using a COND-EVAL query, we can simulate a SET-EVAL query, the COND-EVAL model is at least as powerful as SET-EVAL. We now describe the proof of the lower bound for the SET-EVAL model in more detail.

For an index  $x$  chosen uniformly at random from  $[\log n]$ , we sample a distribution  $D_x$  with support  $[2^x]$  from the Dirichlet distribution with parameters  $\alpha_1, \dots, \alpha_{2^x}$  ( $\alpha_j = \frac{1}{2^j}$  for all  $j \in [x]$ ). By the standard Yao's principle, it suffices for us to show a high error probability of any deterministic algorithm that correctly estimates the support size (and hence determines the index  $x$ ) of the distribution sampled as above. Let  $T$  be any such deterministic algorithm that queries a laminar family of sets. We need to show that  $T$  must make  $\Omega(\log \log n)$  queries. The main technical ingredient in the proof is to show that the information gain (about

### 33:10 Support Size Estimation: The Power of Conditioning

the index  $x$ ) by the outcome of any query of the algorithm is  $O(1)$ . This implies that the total information gain is  $O(t)$ , where  $t$  is the number of queries. Then Fano's inequality immediately implies that  $t \geq \Omega(\log \log n)$ . Let the  $i$ -th query ( $i \in [t]$ ) be denoted by set  $A_i$ , and the outcome of the  $i$ -th query (sum of probabilities of elements in the set  $A_i$ ) be denoted by  $Z_i$ . The information gain (about the index  $x$ ) by the  $i$ -th query (for any  $i \in [t]$ ) is the conditional mutual information  $I(X; Z_i | Z^{i-1})$  where  $Z_i$  is the random variable denoting the outcome of  $i$ -th query,  $Z^{i-1} = (Z_1, \dots, Z_{i-1})$  is the random variable denoting the vector of previous outcomes and  $X$  is the random variable denoting the uniformly chosen index  $x$  from  $[\log n]$ . By definition, the conditional mutual information  $I(A; B|C)$  for random variables  $A, B, C$  is equal to the expectation (over  $C$ ) of the KL divergence between the joint distribution  $Q_{(A,B)|C}$  and the product distribution  $Q_{A|C} \times Q_{B|C}$ . The technical difficulty is to upper bound the conditional mutual information  $I(X; Z_i | Z^{i-1})$  by  $O(1)$ . This is particularly challenging since the joint and the product distributions are not explicitly given, and queries are adaptive. To overcome this difficulty, at any step  $i \in [t]$  (after  $(i-1)$ -th query), we first partition the  $[\log n]$  into four groups denoted by  $L_0^i, L_1^i, L_2^i, L_3^i$  such that for the first three groups, the outcome of the algorithm (i.e.,  $Z_i$ ) is (deterministically) determined by the previous outcomes of the algorithm (i.e.,  $Z^{i-1} = (Z_1, \dots, Z^{i-1})$ ) whereas for any  $x$  in the fourth group  $L_3^i$ , the outcome is not fixed (given previous outcomes) but comes from a distribution (which we show to be also Dirichlet). Let this distribution be denoted by  $Q_x$  for  $x \in L_3^i$ . The information gain by the  $i$ -th query is  $\log 3$  (because there are three groups for which outcome is deterministically determined) plus the information gain corresponding to the last group  $L_3^i$ . This term can be upper bounded by the maximum KL divergence between distributions  $Q_x$  and  $Q_{x'}$  for any  $x, x' \in L_3^i$ . Thus our goal is to show that KL divergence between  $Q_x$  and  $Q_{x'}$  for any  $x, x' \in L_3^i$  is  $O(1)$ . Using the independence property of Dirichlet distributions and the laminar structure of query sets, we show that the KL divergence between the distributions  $Q_x$  and  $Q_{x'}$  is equal to the KL divergence between two beta distributions with different parameters (beta distributions are a special case of Dirichlet distributions). The explicit formula for KL divergence between two beta distributions is well-known (e.g., see [23]), and we use this formula to upper bound the KL divergence by  $O(1)$ .

► **Remark 9.** Technically, the above lower bound for SET-EVAL (and COND-EVAL) does not hold if it is promised that the probabilities in the given distribution are rational numbers. This is because, in the lower bound instances above, the probability of an element can be any arbitrary real number in  $(0, 1)$ . However, we can use the following standard fact to show that the lower bound holds even with the rational probabilities.

A Polya urn is an urn containing  $\alpha_i$  balls of color  $i$ , for each  $i \in [K]$ . The urn evolves at each discrete time step – a ball is sampled uniformly at random. The ball's color is observed, and two balls of the observed color are returned to the urn. Let  $X_{i,m}$  be the number of balls of color  $i$  (for each  $i \in [K]$ ) added after  $m$  time steps. Clearly  $D_m = (\frac{X_{1,m}}{m}, \dots, \frac{X_{K,m}}{m})$  is a probability distribution over  $[K]$ . It can be shown that the distributions  $D_1, \dots, D_m$  converges to a Dirichlet distribution with parameters  $\alpha_1, \dots, \alpha_K$  when  $m$  tends to  $\infty$  [4].

Instead of using Dirichlet distribution in our lower bound proof, we can use the distribution  $D_m$  for sufficiently large  $m$ . Since for any  $m$ , the probabilities in  $D_m$  are rational numbers, we can get the lower bound even when the probabilities are rationals.

#### The power of COND-EVAL

We further demonstrate the power of the COND-EVAL model by showing an algorithm with constant query complexity for a number of distribution testing problems for which there are strong lower bounds known for the COND-PR and COND model. Our first

example is the well-studied *Equivalence testing* problem. Here, given two distributions  $D$  and  $D'$ , the goal is to accept if  $D = D'$  and reject if their *total variation distance*  $\|D - D'\|_{TV} = \sum_{i \in [n]} |D(i) - D'(i)| > \epsilon$  (both with high probability). It is known that  $\Omega(\sqrt{\log \log n})$  queries are necessary in the COND model [1]. On the other hand,  $\Omega(1/\epsilon)$  queries are required in the COND-PR model. (Consider a uniform distribution  $U$  on  $[n]$ . Now randomly choose  $i, j \in [n]$ . We modify  $U$  to construct another distribution  $U'$  by setting  $U'(i) = 2/n$ ,  $U'(j) = 0$ , and no changes in the probability mass of other elements. Note that  $\epsilon = \|U - U'\|_{TV} = 2/n$ . It is easy to see that  $\Omega(n) = \Omega(\frac{1}{\epsilon})$  queries are required to distinguish  $U$  and  $U'$  in the COND-PR model.) We show that Equivalence testing can be done in just two COND-EVAL queries. The above upper bound result extends to another unrelated problem for the COND-EVAL model – the problem of testing whether the given distribution is *m-grained*, i.e., the probability of each element is an integer multiple of  $1/m$ . Finally, we show that the multiplicative  $(1 + \epsilon)$ -approximation of square of the  $L_2$  norm  $(\sum_{j \in [n]} D(j)^2)$  of a distribution  $D$  can be computed using  $O(\frac{1}{\epsilon^2})$  queries of COND-EVAL. To the best of our knowledge, this problem has been studied previously only in the SAMP model [19], wherein it was shown that  $\Omega(\frac{\sqrt{n}}{\epsilon^2})$  queries are required.

### The power of bounded-set conditioning

We further study the support size estimation problem when we allow SAMP oracle access and conditioning on sets of size at most  $k$ . We show a lower bound of  $\Omega(n/k)$  and an upper bound of  $O(\frac{n \log \log n}{k})$  for constant factor approximation in this model. The upper bound holds for the COND oracle model, while our lower bound holds for the stronger COND-EVAL oracle model.

Both the upper and lower bounds are not difficult to establish. Falahatgar et al. [18] showed that  $O(\log \log n)$  queries are sufficient (with no restriction on the size of the set for conditioning) to get a constant approximation for oracle access which, given any  $S \subseteq [n]$ , returns whether  $S \cap \text{SUPP}(D) = \emptyset$  or not. Oracle access to a set of size  $s$  can be simulated by  $s/k$  oracle access when conditioning on at most  $k$ -sized sets is allowed. This gives an upper bound of  $O(\frac{n \log \log n}{k})$ . Interestingly, the hard instance for the bounded-set conditioning to estimate the support size is when the support size is constant. We refer the readers to the full version for all the detailed proofs.

## 4 Conclusion

We investigate the power of conditioning for estimating the support size up to a multiplicative  $(1 + \epsilon)$ -factor. To date, there is a gap between the upper bound of  $O(\log \log n + 1/\epsilon^2)$  and the lower bound of  $\Omega(\sqrt{\log \log n})$  in the standard COND model. In this paper, we close this gap by providing a lower bound of  $\Omega(\log \log n + \frac{1}{\epsilon^2 \log \frac{1}{\epsilon}})$ . We actually show the lower bound in even a more powerful model, namely COND-PR, where in addition to the conditioning, one is also allowed to get the actual probability of the sampled elements (i.e., a combination of COND and PR-SAMP). In the dependency of  $\epsilon$ , there is a small gap of  $\log(1/\epsilon)$  factor, and we want to leave the problem of removing this factor from the lower bound term as an open problem.

It is quite surprising that the combination of COND and PR-SAMP does not yield more power compared to only the COND model in the context of the support size estimation. We thus continue our investigation by appending the algorithms with an even more powerful oracle that could also get the conditional probabilities of the sampled elements (not just the actual probabilities). We call this model COND-EVAL. This model turns out to be

more powerful in the context of several other important distribution testing problems. For the support size estimation, we show a lower bound of  $\Omega(\log \log \log n + \frac{1}{\epsilon^2 \log \frac{1}{\epsilon}})$  in this COND-EVAL model. On the technical side, this paper introduces many new ideas, such as using continuous distribution (Dirichlet distribution) for constructing hard instances and applying information theory and communication complexity tools to conditional sampling models. We hope that such techniques could be useful for showing non-trivial lower bounds for other distribution testing problems as well.

For the support size estimation problem in the COND-EVAL model, currently, we only know of an  $O(\log \log n)$  upper bound, whereas we could only show a lower bound of  $\Omega(\log \log \log n)$ . We would like to pose the problem of closing this gap as an interesting open problem. Another interesting open problem is to determine if an upper bound of  $o(\log \log n)$  is possible in the COND-PR and COND-EVAL models, assuming a certain lower bound on the probability mass of each element in the support size (e.g., the probability of any element is either 0 or at least  $1/n$ ).

## Abstract

We relate various complexity measures like sensitivity, block sensitivity, certificate complexity for multi-output functions to the query complexities of such functions. Using these relations, we provide the following improvements upon the known relationship between pseudo-deterministic and deterministic query complexity for total search problems:

- We show that deterministic query complexity is at most the third power of its pseudo-deterministic query complexity. Previously, a fourth-power relation was shown by Goldreich, Goldwasser and Ron (ITCS'13).
- We improve the known separation between pseudo-deterministic and randomized decision tree size for total search problems in two ways: (1) we exhibit an  $\exp(\tilde{\Omega}(n^{1/4}))$  separation for the SEARCHCNF relation for random  $k$ -CNFs. This seems to be the first exponential lower bound on the pseudo-deterministic size complexity of SEARCHCNF associated with random  $k$ -CNFs. (2) we exhibit an  $\exp(\Omega(n))$  separation for the APPROXHAMWT relation. The previous best known separation for any relation was  $\exp(\Omega(n^{1/2}))$ .

We also separate pseudo-determinism from randomness in AND and (AND, OR) decision trees, and determinism from pseudo-determinism in PARITY decision trees. For a hypercube colouring problem, that was introduced by Goldwasser, Impagliazzo, Pitassi and Santhanam (CCC'21) to analyze the pseudo-deterministic complexity of a complete problem in TFNP<sup>dt</sup>, we prove that either the *monotone* block-sensitivity or the *anti-monotone* block sensitivity is  $\Omega(n^{1/3})$ ; Goldwasser et al. showed an  $\Omega(n^{1/2})$  bound for *general* block-sensitivity.

## 1 Introduction

The question of whether randomness adds computational power over determinism, and if so, how much, has been a question of great interest that is still not completely understood. Naturally, the answer depends on the computational model under consideration, but it also depends on the type of problems one hopes to solve. One may wish to compute some function of the input, a special case being decision problems where the function has just two possible values. There are also search problems, where for some fixed relation  $R \subseteq X \times Y$  and an input  $x \in X$ , one wishes to find a  $y \in Y$  that is related to  $x$ ; i.e.  $(x, y) \in R$ . If every  $x \in X$  has at least one such  $y$ , we have a total search problem defined by  $R$ , the  $R$ -search problem. In the context of (total) search problems, a nuanced usage of randomness led to the beautiful notion of pseudo-determinism; see [7]. A function  $f$  solves the  $R$ -search problem if for every  $x$ ,  $(x, f(x)) \in R$ . A randomized algorithm which computes such an  $f$

with high probability is said to be a pseudo-deterministic algorithm solving the  $R$ -search problem. Thus a pseudo-deterministic algorithm uses randomness to solve a search problem and almost always provides a canonical solution per input.

The original papers introducing pseudo-determinism examined both polynomial-time algorithms and sublinear-time algorithms; in the latter case, the computational resource measure is query complexity. In [8], a maximal separation was established between pseudo-deterministic and randomized query algorithms;  $\Omega(n)$  vs  $O(1)$ . Very recently, in [9], this separation was revisited. The separating problems in [8] do not lie in the query-complexity analogue of NP (nondeterministic polylog query complexity, or polylog query complexity to deterministically verify a solution,  $\text{TFNP}^{dt}$ ). This is a very natural class of search problems, and in [9], an almost-maximal separation between randomized and pseudo-deterministic search is established for a problem in this class. The problem in question is  $\text{SEARCHCNF}$ : given an assignment to the variables of a highly unsatisfiable  $k$ -CNF formula, to search for a falsified clause; this problem is very easy for randomized search ( $O(1)$  queries), and solutions are easily verifiable. Theorem 7 of [9] establishes that for unsatisfiable  $k$ -CNF formulas on  $n$  variables with sufficiently strong expansion in the clause-variable incidence graph (in particular, for most random  $k$ -CNF formulas), the corresponding search problem has pseudo-deterministic complexity  $\Omega(\sqrt{n})$ , even in the quantum query setting. In [9], the size measure of decision trees in the pseudo-deterministic setting was also studied. Lifting the query separation using a small gadget, a strong separation between randomized size and pseudo-deterministic size was obtained:  $\text{SEARCHCNF}$  problem on random  $k$ -CNFs lifted with 2-bit XOR has randomized size  $O(1)$  but require pseudo-deterministic size  $\exp(\Omega(\sqrt{n}))$ .

Taking this study further, Theorem 3 of [9] shows that the promise problem  $\text{PROMISEFIND1}$ , of finding a 1 in an  $n$ -bit string with Hamming weight at least  $n/2$ , is in a sense complete for the class of search problems that are in  $\text{TFNP}^{dt}$  and have efficient randomized query algorithms. By relating this search problem to a certain combinatorial problem concerning colourings of the hypercube, and by using the lower bound for  $\text{SEARCHCNF}$ , a lower bound of  $\Omega(\sqrt{n})$  on the pseudo-deterministic complexity of  $\text{PROMISEFIND1}$  is obtained (Theorem 14 and subsequent remark in [9]). The colouring problem on hypercubes states that any proper coloring of the hypercube contains a point with many 1s and with high block sensitivity. In [9], a point with block sensitivity  $\Omega(\sqrt{n})$  is proven to exist (Theorem 14), and a point with block sensitivity  $\Omega(n)$  is conjectured to exist (Conjecture 16).

### Our contributions

- (1) We improve upon the known relationship between pseudo-deterministic query complexity and deterministic query complexity for total search problems: We show that deterministic query complexity is at most the third power of its pseudo-deterministic query complexity. (Previously a fourth-power relation was shown in [8].)
- (2) We improve the known separations between pseudo-deterministic and randomized decision tree size in two ways: (1) an  $\exp(\tilde{\Omega}(n^{1/4}))$  separation for the  $\text{SEARCHCNF}$  relation for random  $k$ -CNFs (the  $\exp(\Omega(n^{1/2}))$  separation in [9] is only for the lifted formulas  $k$ -CNF composed with XOR), and (2) an  $\exp(\Omega(n))$  separation for the  $\text{APPROXHAMWT}$  relation (the previous best separation for any relation was  $\exp(\Omega(n^{1/2}))$ ).
- (3) We separate pseudo-deterministic and randomized query complexity in AND and (AND, OR) decision trees, and show that deterministic and pseudo-deterministic complexity are polynomially related in these models, upto polylog  $n$  factors. In the  $\text{PARITY}$  decision tree model, we observe that deterministic and pseudo-deterministic query complexities are well separated.

- (4) For the hypercube colouring problem posed in [9], we prove that either the monotone block-sensitivity or the anti-monotone block sensitivity is  $\Omega(n^{1/3})$ ; previously an  $\Omega(n^{1/2})$  bound was known but only for general block-sensitivity.

### Significance, context, and techniques

We now describe each of our contributions, with surrounding context, in more detail.

For Boolean functions, randomized and deterministic query complexities are known to be polynomially related by the classic result of Nisan [14]. Since deterministic query lower bounds are often easy to obtain using some kind of adversary argument, this provides a route to randomized query lower bounds for Boolean functions. For search problems, however, there is no such polynomial relation. Note that separating pseudo-determinism from randomness requires a lower bound against randomized query algorithms that provide canonical solutions. Such algorithms compute multi-output functions (following nomenclature from [9]) as opposed to Boolean functions. Thus what is required is randomized query lower bounds for multi-output functions. For such functions, too, lower bounds for deterministic querying are often relatively easy to obtain. And again, as for Boolean functions, deterministic and randomized query complexity for multi-output functions are known to be polynomially related; in [8] (Theorem 4.1(3)), the authors show that the deterministic query complexity is bounded above by the fourth power (as opposed to cubic power for Boolean functions) of the randomized complexity. They also show that it is bounded above by the cubic power times a factor that depends on the size of the search problem's range. We revisit these relations, and further tighten them to a cubic power relation. Thus for search problems, deterministic query complexity is bounded above by the cubic power of its pseudo-deterministic query complexity; Theorem 3.2. We show this by relating various complexity measures like sensitivity, block sensitivity, certificate complexity for multi-output functions to their query complexities; Theorem 3.1.

Using the recent result from [4] that derandomized the size measures for total Boolean functions, we establish a polynomial relationship between the log of pseudo-deterministic size and the log of deterministic size, ignoring polylog factors in the input dimension; Theorem 4.3. This gives us another way to separate randomized size from pseudo-deterministic size: any total search problem which is easy with randomization but difficult for deterministic search will lead to a separation between pseudo-deterministic size and randomized size; one such problem is SEARCHCNF on suitably expanding  $k$ -CNF formulas. In [9], it was shown that SEARCHCNF for such formulas *lifted* by small gadgets like XOR, has large pseudo-deterministic size complexity. There are known situations where the complexity of a formula and its lift by small gadgets widely vary in search problems. For instance, it was known that proving the unsatisfiability of formulas corresponding to Tseitin lifted by a small gadget should be hard in cutting planes proof system [6]. The popular belief was that such hardness extends to even unlifted Tseitin formulas. In a breakthrough work [5], this belief was proven false! However, we are able to obtain an  $\exp(\tilde{\Omega}(n^{1/4}))$  lower bound on the pseudo-deterministic size complexity for SEARCHCNF with unlifted random  $k$ -CNF formulas, in contrast to the bounds from [9]. As far as we know, this is the first exponential lower bound on the pseudo-deterministic size complexity of SEARCHCNF for random  $k$ -CNF formulas. Like Tseitin formulas, determining the complexity of random  $k$ -CNF formulas in various models remains an important theme of current research.

We also show, see Theorem 4.5, that any completion of the promise-problem APPROXMAJ by a total Boolean function, requires large randomized decision tree size. Observing that this promise-problem is “embedded” in the APPROXHAWWT search problem, we obtain an  $\exp(\Omega(n))$  separation between the pseudo-deterministic and randomized size complexity of APPROXHAWWT, in Theorem 4.6.

The more general query models we consider are those of AND (OR) decision trees, abbreviated as ADT's (ODT's), where each query is a conjunction of variables, (AND, OR) decision trees, where each query is either a conjunction or a disjunction of variables, and PARITY decision trees, where each query reports the parity of some subset of variables. These models obviously generalize decision trees, and are more powerful in the deterministic setting, appear naturally in contexts like combinatorial group testing and other contexts. More recently, they have been advocated by [11] as a meaningful intermediate model between query and communication complexity. For AND and (AND, OR) decision trees, we show that pseudo-determinism is still separated from randomness; Theorems 5.3 and 5.6. To show the former, we relate randomized query complexity for multi-output functions in this model to monotone block sensitivity. To show the latter, we note that a recently proved result from [4] relating depth in (AND, OR) trees and size in ordinary trees for Boolean functions, also holds for multi-output functions. Furthermore, using other results from [4] that derandomized the AND and (AND, OR) decision trees for total Boolean functions, we observe that pseudo-determinism and determinism are polynomially related in these settings, ignoring polylog $n$  factors; Theorems 5.4 and 5.7. For PARITY decision trees, in contrast, we observe that determinism is separated from pseudo-determinism; Theorem 5.8. There is no polynomial relation between these two complexity measures. In this setting, we do not know whether pseudo-determinism is separated from randomness.

Finally, we revisit the hypercube coloring problem from [9]. There, the existence of a point with large Hamming weight and block-sensitivity  $\Omega(\sqrt{n})$  is established, using the previously established lower bound for SEARCHCNF. We give a completely combinatorial and constructive argument to show that a point with large Hamming weight and block-sensitivity  $\Omega(n^{1/3})$  exists, Theorem 6.3. While we seemingly sacrifice stronger bounds in the quest for simplicity, our algorithm actually proves something that is stronger in a different way, and hence our result is perhaps incomparable with that of [9]. The difference is that we identify many sensitive blocks that are all 1's, or many sensitive blocks that are all 0's. In other words, we show that the monotone (or anti-monotone) block sensitivity is  $\Omega(n^{1/3})$ . Monotone block sensitivity was used recently, first by [12] and then by [4], to prove query complexity lower bounds for ADT's. In particular, our result implies that every function that solves PROMISEFIND1, requires large depth to be implemented by *either* randomized ADT's *or* by randomized ODT's. We believe that this could be strengthened to show that such solutions are always hard for randomized ADTs<sup>1</sup>. Proving such a result is an interesting open problem.

### Related work

For Boolean functions, the relations between many complexity measures and query complexity has been studied extensively in the literature. A consolidation of many known results appears in [2] as well as in [10].

### Organisation of the paper

In Section 3 we establish the relationships between various measures for multi-output functions, and establish the polynomial relation between pseudo-deterministic and deterministic query complexity for search problems. In Section 4 we establish relations between pseudo-deterministic size and deterministic size. Section 5 discusses the complexity of search problems

---

<sup>1</sup> Note that there are solutions that are easy for ODTs, even deterministically. For instance, a binary search can be implemented to find efficiently the first occurrence of a 1.

in AND, (AND, OR), and PARITY decision trees. Section 6 discusses the hypercube coloring problem. We refer the reader to the full version of our paper [3] for proofs omitted due to space constraints.

## 2 Preliminaries

We use standard notation and terminology in the paper, which we briefly explain here. For detailed definitions, we refer the reader to the full version of our paper [3]. For  $x \in \{0, 1\}^*$ , and  $b \in \{0, 1\}$ ,  $|x|$  is the length of  $x$  and  $|x|_b$  is the number of occurrences of  $b$  in  $x$ . We also write  $\text{wt}(x)$  for  $|x|_1$ . To sample uniformly from a set  $S$ , we write  $\sim_u S$ . For  $B \subseteq [n]$  and  $b \in \{0, 1\}$ ,  $b_B$  is the  $n$ -bit string that equals  $b$  at positions in  $B$  and  $1 - b$  elsewhere.

For a multi-output function  $f : \{0, 1\}^n \rightarrow [m]$  and input  $x \in \{0, 1\}^n$ , we use the following measures, which are natural extensions from the Boolean case, to capture different aspects of its complexity:  $s(f, x)$  counts the number of input bits at  $x$  that can be flipped to change the output of  $f(x)$ ;  $\text{bs}(f, x)$  is the maximum integer  $r$  for which there exist  $r$  disjoint sensitive blocks of  $f$  at  $x$  (where  $f$  is sensitive to block  $B$  on input  $x$  if  $f(x) \neq f(x \oplus 1_B)$ );  $C(f, x)$  is the minimum number of input bits required to uniquely identify the output of  $f(x)$ . Maximizing over all inputs gives  $s(f)$ ,  $\text{bs}(f)$ , and  $C(f)$ , the sensitivity, block sensitivity, and certificate complexity of  $f$ , respectively. We also use sensitivity and block sensitivity measures that only allow flipping either 0s or 1s. A set  $B \subseteq [n]$  is a *sensitive  $b$ -block* of  $f$  at input  $x$  if  $x_i = b$  for each  $i \in B$ , and  $f(x) \neq f(x \oplus 1_B)$ . The  *$b$ -block sensitivity* of  $f$  at  $x$ , denoted  $\text{bs}_b(f, x)$ , is the maximum integer  $r$  for which there exist  $r$  disjoint sensitive  $b$ -blocks of  $f$  at  $x$ . The  *$b$ -sensitivity* of  $f$  at  $x$ ,  $s_b(f, x)$ , is the number of sensitive  $b$ -bits of  $x$ . Maximizing over all inputs gives  $s_b(f)$ , and  $\text{bs}_b(f)$ , the  $b$ -sensitivity and  $b$ -block sensitivity of  $f$ , respectively. Note that  $s_0(f)$  and  $\text{bs}_0(f)$  are the same as the monotone sensitivity and monotone block sensitivity used in [12] to study AND-decision trees.

For a search problem  $\mathcal{S}$ , a (deterministic) decision tree  $T$  computing  $\mathcal{S}$  is a binary tree with internal nodes labelled by the variables and the leaves labelled by  $y \in \mathcal{Y}$ . It evaluates an unknown input  $x$  by traversing the tree based on variable queries. The label of the leaf reached must belong to  $\mathcal{S}(x)$ . The depth of a decision tree  $T$  is the length of the longest root-to-leaf path, and its size is the number of leaves. The deterministic query/size complexity of  $\mathcal{S}$ , denoted by  $D^{\text{dt}}(\mathcal{S})/D\text{Size}^{\text{dt}}(\mathcal{S})$ , is defined to be the minimum depth/size of a decision tree that computes  $\mathcal{S}$ .

A randomized query algorithm/decision tree  $\mathcal{A}$  is defined by a distribution  $\mathcal{D}_{\mathcal{A}}$  over deterministic decision trees. It evaluates an input  $x$  by randomly selecting a tree  $T$  from  $\mathcal{D}_{\mathcal{A}}$  and outputting the label of the leaf reached by  $T$  on  $x$ . The algorithm is considered to compute  $\mathcal{S}$  with error at most  $\epsilon$  if, for every  $x$ , the probability that  $\mathcal{A}(x)$  belongs to  $\mathcal{S}(x)$  is at least  $1 - \epsilon$ . The depth/size complexity of the randomized decision tree is determined by the maximum depth/size among all decision trees in the distribution's support. The randomized query/size complexity of  $\mathcal{S}$  with error  $\epsilon$ , denoted by  $R_{\epsilon}^{\text{dt}}(\mathcal{S})/R\text{Size}_{\epsilon}^{\text{dt}}(\mathcal{S})$ , is the minimum depth/size of a randomized decision tree that computes  $\mathcal{S}$  with error  $\epsilon$ . For a probability distribution  $\mathcal{D}$  over the domain of  $\mathcal{S}$ , the  $(\mathcal{D}, \epsilon)$ -distributional query/size complexity of  $\mathcal{S}$ , denoted by  $D_{\mathcal{D}, \epsilon}^{\text{dt}}(\mathcal{S})/D\text{Size}_{\mathcal{D}, \epsilon}^{\text{dt}}(\mathcal{S})$ , is the minimum depth/size of a deterministic decision tree that gives a correct answer on  $1 - \epsilon$  fraction of inputs weighted by  $\mathcal{D}$ . When we drop  $\epsilon$  from the subscript of a randomized/distributional query measures, we assume  $\epsilon = 1/3$ .

A multi-output function  $f : \{0, 1\}^n \rightarrow [m]$  solves  $\mathcal{S}$ , denoted by  $f \in_s \mathcal{S}$ , if for every  $x \in \{0, 1\}^n$ ,  $(x, f(x)) \in S$ . A pseudo-deterministic query algorithm for a search problem  $\mathcal{S}$ , with error  $1/3$ , is a randomized decision tree that computes some multi-output function

$f$  that solves  $\mathcal{S}$  with error at most  $1/3$ . The pseudo-deterministic query complexity of  $\mathcal{S}$ , denoted by  $\text{psD}^{\text{dt}}(\mathcal{S})$ , is equal to  $\min_{f \in_s \mathcal{S}} R^{\text{dt}}(f)$ , and pseudo-deterministic size complexity of  $\mathcal{S}$ , denoted by  $\text{psDSize}^{\text{dt}}(\mathcal{S})$ , is equal to  $\min_{f \in_s \mathcal{S}} \text{RSize}^{\text{dt}}(f)$ . Note that randomized query algorithms for  $\mathcal{S}$  do not necessarily output a canonical value with high probability, only a value  $y$  such that  $(x, y) \in \mathcal{S}$  with high probability.

### Known results that we use

► **Proposition 2.1** ([15]). *For a search relation  $\mathcal{S}$ ,*  
 $R_\epsilon^{\text{dt}}(\mathcal{S}) = \max_{\mathcal{D}} D_{\mathcal{D}, \epsilon}^{\text{dt}}(\mathcal{S})$  and  $\text{RSize}_\epsilon^{\text{dt}}(\mathcal{S}) = \max_{\mathcal{D}} \text{DSize}_{\mathcal{D}, \epsilon}^{\text{dt}}(\mathcal{S})$ .

► **Proposition 2.2** ([14, 10, 2]). *For any Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,*

1.  $s(f) \leq bs(f) \leq C(f) \leq s(f)bs(f)$ .
2.  $s(f) \leq bs(f) \leq 3R_{1/3}^{\text{dt}}$ .
3.  $C(f) \leq D^{\text{dt}}(f) \leq C(f)^2$ .
4.  $D^{\text{dt}}(f) \leq C(f)bs(f)$ .
5.  $D^{\text{dt}}(f) = O((R^{\text{dt}}(f))^3)$ .

► **Proposition 2.3** (restated from [8]). *For a search relation  $\mathcal{S}$ ,*

1.  $D^{\text{dt}}(\mathcal{S}) \leq \left(\text{psD}^{\text{dt}}(\mathcal{S})\right)^4$ . [Restated from Theorem 4.1(3) in [8]]
2.  $D^{\text{dt}}(\mathcal{S}) \leq \left(\text{psD}^{\text{dt}}(\mathcal{S})\right)^3 \ell_{\mathcal{S}}(n)$ , where  $\ell_{\mathcal{S}}(n)$  is the number of bits required to represent the range of  $\mathcal{S}$ . [Restated from Theorem 4.1(3) in [8]]

► **Proposition 2.4.**

1. (Corollary 4.2 in [8]) *For the relation*  
 $\text{APPROXHAWWT} = \{(x, v) : |wt(x) - v| \leq n/10\}$ ,  
 $\text{psD}^{\text{dt}}(\text{APPROXHAWWT}) \in \Omega(n)$  and  $R^{\text{dt}}(\text{APPROXHAWWT}) = O(1)$ .
2. (Theorem 4 in [9]) *For the relation*  $\text{PROMISEFIND1} = \{(x, i) : wt(x) \geq |x|/2 \wedge x_i = 1\}$ ,  
 $\text{psD}^{\text{dt}}(\text{PROMISEFIND1}) \in \Omega(\sqrt{n})$  and  $R^{\text{dt}}(\text{PROMISEFIND1}) = O(1)$ .

► **Proposition 2.5.** *For  $F$  a random 3-CNF formula on  $n$  variables with  $m = \Theta(n)$  clauses sampled from  $\mathcal{F}_m^{3,n}$ , with probability  $1 - o(1)$ ,  $F$  is unsatisfiable and furthermore,*

1.  $R^{\text{dt}}(\text{SEARCHCNF}(F)) = O(1)$ .
2.  $D^{\text{dt}}(\text{SEARCHCNF}(F)) = \Omega(n)$ . (From [13, 1])
3.  $\text{DSize}^{\text{dt}}(\text{SEARCHCNF}(F)) = \exp(\Omega(n))$ . (From [1])

## 3 Relating measures for multi-output functions

We show the analogs of Proposition 2.2 for multi-output functions. The idea is to do the necessary modifications to the analogous results in the Boolean function case. For the proof, we refer the reader to the full version of our paper [3].

► **Theorem 3.1.** *For a function  $f : \{0, 1\}^n \rightarrow [m]$ , the following relations hold.*

1.  $C(f) \leq s(f)bs(f)$ .
2.  $s(f) \leq bs(f) \leq 3R_{1/3}^{\text{dt}}(f)$
3.  $C(f) \leq D^{\text{dt}}(f) \leq C(f)^2$ .
4.  $D^{\text{dt}}(f) \leq 2C(f)bs(f)$ .
5.  $D^{\text{dt}}(f) = O((R^{\text{dt}}(f))^3)$ .

Using the above, we can now improve the bounds from Proposition 2.3 for search problems. One  $\text{psD}^{\text{dt}}(\mathcal{S})$  factor from item 1 there can be removed, as also the  $\ell_{\mathcal{S}}(n)$  factor in item 2.

► **Theorem 3.2.** For any total search problem  $\mathcal{S}$ ,  $D^{\text{dt}}(\mathcal{S}) = O((\text{psD}^{\text{dt}}(\mathcal{S}))^3)$ .

**Proof.** For total search problem  $\mathcal{S}$ , let  $\tilde{f}$  be a function solving  $\mathcal{S}$ , with  $\text{psD}^{\text{dt}}(\mathcal{S}) = R^{\text{dt}}(\tilde{f})$ . Then, using Theorem 3.1(5), we obtain  $D^{\text{dt}}(\mathcal{S}) = \min_{f \in_s \mathcal{S}} D^{\text{dt}}(f) \leq D^{\text{dt}}(\tilde{f}) \leq O((R_{1/3}^{\text{dt}}(\tilde{f}))^3) = O(\text{psD}^{\text{dt}}(\mathcal{S})^3)$ . ◀

## 4 Pseudo-deterministic size vs deterministic size

In this section, we establish a polynomial relationship, up to polylog  $n$  factors, between the logarithm of pseudo-deterministic size and the logarithm of deterministic size for total search problems, Theorem 4.3. We also improve the separation between pseudo-deterministic and randomized size, Theorem 4.6.

Before showing these results, we first examine an argument for extending results on Boolean functions to multi-output functions. We note that a relationship between randomized and deterministic complexity in a query model for Boolean functions yields an almost identical relationship between pseudo-deterministic complexity and deterministic complexity for search problems. The result follows from a straightforward application of a binary search argument and also appears in the work of [8] for making a similar claim for the ordinary query model. We give a proof sketch, for details refer to the full version of our paper [3].

► **Proposition 4.1.** In a query model  $M$ , let  $D^M$  ( $\text{DSize}^M$ ),  $R^M$  ( $\text{RSize}^M$ ) and  $\text{psD}^M$  ( $\text{psDSize}^M$ ) denote the query complexity (size complexity, respectively) in the deterministic, randomized and pseudo-deterministic settings. Then,

1. If for some monotonic function  $q : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$  and every total Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,  $D^M(f) \leq q(R^M(f), n)$ , then for any total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ ,  $D^M(\mathcal{S}) = O(q(\text{psD}^M(\mathcal{S}), n) \cdot \min(\log m, \text{psD}^M(\mathcal{S})))$ .
2. If for some monotonic function  $q : \mathbb{R} \times \mathbb{N} \rightarrow \mathbb{N}$  and every total Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,  $\log \text{DSize}^M(f) \leq q(\log \text{RSize}^M(f), n)$ , then for any total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ ,  $\log \text{DSize}^M(\mathcal{S}) = O(q(\log \text{psDSize}^M(\mathcal{S}), n) \cdot \min(\log m, \log \text{psDSize}^M(\mathcal{S})))$ .

**Proof Sketch.** We give a proof sketch for the second statement. For search problem  $\mathcal{S}$  with  $\text{psDSize}^M(\mathcal{S}) = s$ , let function  $\tilde{f}$  solve  $\mathcal{S}$  with  $\text{RSize}^M(\tilde{f}) = s$  witnessed by a randomized tree  $T$ . For  $k = \lceil \log m \rceil$ , define the Boolean functions  $f_1, f_2, \dots, f_k$  where  $f_i(x)$  extracts the  $i$ th bit in the  $k$ -bit representation of  $\tilde{f}(x)$ . Then for each  $i \in [k]$ ,  $\text{RSize}^M(f_i) \leq \text{RSize}^M(\tilde{f}) = s$ ; simply relabel the leaves of  $T$  appropriately. By the hypothesised relation for Boolean functions, for each  $i \in [\lceil \log m \rceil]$ ,  $\log \text{DSize}^M(f_i) \leq q(\log \text{RSize}^M(f_i), n) \leq q(\log s, n)$ . Let  $T_i$  be a deterministic tree achieving this size bound. By composing the trees  $T_1, T_2, \dots, T_k$  and suitably relabelling the leaves with elements from  $[m]$ , we obtain a deterministic tree for  $\tilde{f}$  of size  $(2^{q(\log s, n)})^k$ . With careful analysis, we can get  $\min(\log m, \log \text{psDSize}^M(\mathcal{S}))$  in place of  $k$  in the exponent. ◀

Recently it was shown in [4] that for total Boolean functions, the logarithms of deterministic and randomized size are polynomially related, ignoring a polylog factor in input size.

► **Proposition 4.2** ([4, Theorem 3.1(b)]). For a total Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,

$$\log \text{DSize}^{\text{dt}}(f) = O((\log \text{RSize}^{\text{dt}}(f))^4 \log^3(n)).$$

Using the relation from Proposition 4.2 as the “hypothesised function” in Proposition 4.1(2), we obtain the following result, relating the log of deterministic size and the log of pseudo-deterministic size for search problems.

► **Theorem 4.3.** *For a total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ , we have*

$$\log \text{RSize}^{\text{dt}}(\mathcal{S}) = O(\log^4 \text{psDSize}^{\text{dt}}(\mathcal{S}) \cdot \log^3(n) \cdot \min(\log m, \log \text{psDSize}^{\text{dt}}(\mathcal{S}))).$$

In [9] (Theorem 22), a separation was established between pseudo-deterministic and randomized size for a SearchCNF problem, defined on suitably expanding kCNF formulas *lifted* with 2-bit XOR gadgets. It was shown that the randomized size complexity of this problem is  $O(1)$ , while the pseudo-deterministic size complexity is  $\exp(\Omega(\sqrt{n}))$ . We obtain a similar (but weaker) separation for the SearchCNF problem *without any lifting*, by putting together Proposition 2.5(Item 3) and Theorem 4.3.

► **Corollary 4.4.** *For  $F$  a random 3-CNF formula on  $n$  variables with  $m = cn$  clauses sampled from  $\mathcal{F}_m^{3,n}$ , with probability  $1 - o(1)$ ,  $F$  is unsatisfiable and*

$$\text{psDSize}^{\text{dt}}(\text{SEARCHCNF}(F)) = \exp(\Omega(n^{1/4}/\log n)).$$

Since  $\text{RSize}^{\text{dt}}$  of SEARCHCNF on random 3-CNF formulas is  $O(1)$  w.h.p (see Proposition 2.5(Item 1)), we get a separation between  $\text{RSize}^{\text{dt}}$  and  $\text{psDSize}^{\text{dt}}$ , albeit not as strong as [9]. However, Theorem 4.3 allows us to conclude that any total search problem separating randomized and deterministic size will yield a separation between  $\text{RSize}^{\text{dt}}$  and  $\text{psDSize}^{\text{dt}}$ .

We now improve the separation between randomized and pseudo-deterministic sizes, from  $O(1)$  vs  $\exp(\Omega(\sqrt{n}))$  as shown in [9], to  $O(1)$  vs  $\exp(\Omega(n))$ . To achieve this, we focus on the APPROXHAWWT problem. For this problem, a linear depth separation between randomized and pseudo-deterministic algorithms is already known from [8] (see Proposition 2.4). By using a 1-bit indexing gadget, we can lift the depth separation in APPROXHAWWT to an exponential size separation, as was done in [9, Theorem 22]. (The 1-bit indexing gadget replaces each variable  $x$  by the function  $\text{SEL}(x^a, x^b, x^c) = \text{if } x^a = 1 \text{ then } x^b \text{ else } x^c$ .) In the rest of this section, we show that the exponential size separation between randomized and pseudo-deterministic algorithms can also be achieved using APPROXHAWWT itself *without the lift*. It is easy to see that the randomized size of APPROXHAWWT is  $O(1)$ . We show that its pseudo-deterministic size is  $\exp(\Omega(n))$ . To this end, we establish that every solution to APPROXHAWWT embeds a hard boolean function whose randomized decision tree size is exponential in the input size. This hard function is a completion of the promise problem Approximate Majority, APPROXMAJ.

APPROXMAJ is a promise problem (i.e. partial Boolean functions; certain bit strings are promised to never appear as inputs) where the task is to compute the majority of the given bit string. The promise is that the fraction of bits set to 1 in the input is either at least  $3/4$  or at most  $1/2$ . A completion of APPROXMAJ is a total Boolean function that extends APPROXMAJ arbitrarily on the non-promised inputs. We show that every solution to APPROXHAWWT embeds some completion of APPROXMAJ, and that the randomized decision tree size of every completion of APPROXMAJ is exponential in the input size.

► **Theorem 4.5.** *For the promise problem (partial boolean function) APPROXMAJ,*

$$\text{APPROXMAJ}(x) = \begin{cases} 0 & \text{if } |x| \leq n/2 \\ 1 & \text{if } |x| \geq 3n/4 \end{cases},$$

*every completion  $f$  of APPROXMAJ has  $\text{RSize}^{\text{dt}}(f) = \exp(\Omega(n))$ .*

The proof of Theorem 4.5 is based on a corruption argument and follows the template for proving randomized decision tree size lower bounds in [4, Theorem A.7]. This argument is essentially due to Swagato Sanyal, and we thank him for allowing us to include it here. Before we see its proof, let us use it to establish an exponential separation between randomized and pseudo-deterministic size for APPROXHAWWT.

► **Theorem 4.6.** *Let  $\mathcal{S}$  be the search problem  $\text{APPROXHAWWT} = \{(x, v) \in \{0, 1\}^n \times \{0, 1, \dots, n\} : |wt(x) - v| \leq n/10\}$ , where  $wt(x)$  is the Hamming weight of  $x$ . Then  $\text{RSize}^{\text{dt}}(\mathcal{S}) = O(1)$ , while  $\text{psDSize}^{\text{dt}}(\mathcal{S}) = \exp(\Omega(n))$ .*

**Proof.** The Hamming weight of a string can be estimated within a small ( $\theta(n)$ ) additive error by querying a constant number of variables uniformly at random and outputting the scaled-up fraction of 1's seen in the queried bits. Thus  $\text{RSize}^{\text{dt}}(\mathcal{S}) = O(1)$ .

To show a pseudo-deterministic size lower bound, we need to show that any function that solves the  $\text{APPROXHAWWT}$  problem must have randomized decision tree of size  $\exp(\Omega(n))$ . Let  $f$  be any function solving the  $\text{APPROXHAWWT}$  problem. The total Boolean function  $\bar{f} : \{0, 1\}^n \rightarrow \{0, 1\}$  defined as  $\bar{f}(x) = 1$  iff  $f(x) > 6n/10$  is a completion of  $\text{APPROXMAJ}$ . Given a randomized decision tree that computes  $f$ , we can relabel the leaves appropriately to obtain a randomized decision tree that computes  $\bar{f}$ . Using Theorem 4.5, we conclude that  $\text{RSize}^{\text{dt}}(f) \geq \text{RSize}^{\text{dt}}(\bar{f}) = \exp(\Omega(n))$ . ◀

**Proof of Theorem 4.5.** Let  $f$  be any completion of  $\text{APPROXMAJ}$ . Our strategy is to construct a hard distribution  $\mathcal{D}$  on the inputs  $\{0, 1\}^n$  such that  $\text{DSize}_{\mathcal{D}, 1/3}^{\text{dt}}(f) = \exp(\Omega(n))$ , and then use Yao's minmax principle (see Proposition 2.1) to conclude that  $\text{RSize}^{\text{dt}}(f) = \exp(\Omega(n))$ . To define the hard distribution, we start by introducing some terminology. For an input  $x \in \{0, 1\}^n$ , let  $S_x^1 = \{i : x_i = 1\}$  and  $S_x^0 = [n] \setminus S_x^1$ . We say that  $x$  is 0-sensitive if all the 0s in  $x$  are sensitive with respect to  $f$ . For  $x \in \{0, 1\}^n$ , we define the set of extreme upward neighbors of  $x$  as  $\text{EUN}(x) = \{y : S_x^1 \subseteq S_y^1, f(x) = f(y) \text{ and } y \text{ is 0-sensitive}\}$ . With this terminology in place, we can define the hard distribution as follows:

1. Let  $\text{rep} : \{0, 1\}^n \rightarrow \{0, 1\}^n$  be a function which maps  $x \in \{0, 1\}^n$  to an arbitrary input from  $\text{EUN}(x)$ . Define  $\mu_0$ , a distribution over  $f^{-1}(0)$  as follows: Sample an  $x$  of Hamming weight  $n/2$  uniformly at random, and output  $\text{rep}(x)$ .
2. Define  $\mu_1$ , a distribution over  $f^{-1}(1)$ , as follows: Sample an  $x$  according to  $\mu_0$ , an index  $i$  uniformly at random from  $S_x^0$ , and return  $x \oplus 1_{\{i\}}$ .
3. Our hard distribution  $\mathcal{D}$  is  $(\mu_0 + \mu_1)/2$  i.e. with probability  $1/2$  return a sample from  $\mu_0$ , and with probability  $1/2$  return a sample from  $\mu_1$ .

We show below that  $\text{DSize}_{\mathcal{D}, 1/10}^{\text{dt}}(f) = \exp(\Omega(n))$ . Let  $T$  be a deterministic decision tree computing  $f$  correctly on at least  $9/10$ -probability mass when the input is sampled according to  $\mathcal{D}$ . Since  $\mathcal{D}$  samples with probability  $1/2$  from  $\mu_0$  and with probability  $1/2$  from  $\mu_1$ ,  $T$  must be correct on at least  $4/5$ -th mass of  $\mu_0$  as well as at least  $4/5$  mass of  $\mu_1$ . Let  $L_0$  be set of all 0-labelled leaves (0-leaves) in  $T$ . Let  $\rho_0$  and  $\rho_1$  be the  $\mu_0$  and  $\mu_1$  mass captured by 0-leaves respectively; i.e.,

$$\rho_0 = \sum_{v \in L_0} \Pr_{x \sim \mu_0} [x \text{ reaches } v]; \quad \rho_1 = \sum_{v \in L_0} \Pr_{x \sim \mu_1} [x \text{ reaches } v].$$

As discussed above,  $\rho_0 \geq 4/5$  and  $\rho_1 \leq 1/5$ .

For a leaf  $v$ , let  $Z_v$  denote the set of indices of variables fixed to zero on the path leading to  $v$  and  $E_v(x)$  denote the event that the input  $x$  reaches leaf  $v$ . We will show that 0-paths with small  $|Z_v|$  together capture at most  $2/5$  of the  $\mu_0$  mass, and 0-paths with large  $|Z_v|$  individually capture exponentially small  $\mu_0$  mass. Thus to ensure that  $\rho_0$  is large enough, there must be many 0-leaves.

1. (0-paths with few 0's). Firstly, we show that 0-paths which see less than  $\lceil n/8 \rceil$  0's must capture no more than  $2/5$ -th mass of  $\mu_0$ , i.e.,

$$\rho_0^0 = \sum_{\substack{v \in L_0 \\ |Z_v| < \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [x \text{ reaches } v] \leq 2/5.$$

## 34:10 Query Complexity of Search Problems

This follows from the sensitivity property of  $\mu_0$ . Specifically, each  $y$  in the support of  $\mu_0$  has a Hamming weight less than  $3n/4$ , and since all the 0s in  $y$  are sensitive, each  $y$  in the support of  $\mu_0$  has 0-sensitivity of at least  $n/4$ . Therefore, if a 0-path has not observed many 0s, the corresponding leaf will also capture a significant amount of  $\mu_1$  mass. Formally, consider a subcube  $Q$  corresponding to a 0-leaf with less than  $\lceil n/8 \rceil$  variables fixed to 0. Due to the sensitivity property of  $\mu_0$ , each  $x$  supported by  $\mu_0$  has at least  $n/4$  sensitive 0s. Hence, any  $x$  supported by  $\mu_0$  that lies in  $Q$  has at least half of its total 0s unfixed. By flipping any of these 0s, we obtain an input supported by  $\mu_1$  that still lies in  $Q$ . Therefore,

$$\begin{aligned} 1/5 \geq \rho_1 &\geq \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{x \sim \mu_1} [E_v(x)] = \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{\substack{x \sim \mu_0 \\ i \sim_u S_x^0}} [E_v(x \oplus 1_{\{i\}})] \\ &\geq \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{\substack{x \sim \mu_0 \\ i \sim_u S_x^0}} [E_v(x) \text{ and } i \notin Z_v] = \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [E_v(x)] \Pr_{i \sim_u S_x^0} [i \notin Z_v | E_v(x)] \\ &\geq \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [E_v(x)] \cdot \left( \frac{|S_x^0| - n/8}{|S_x^0|} \right) \geq \frac{1}{2} \cdot \left( \sum_{\substack{v \in L_0 \\ |v|_0 < \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [E_v(x)] \right) = \frac{1}{2} \rho_0^0. \end{aligned}$$

(In the last inequality, we use the fact that  $|S_x^0| > n/4$ .) Hence  $\rho_0^0 \leq 2/5$ .

2. (0-paths with lots of 0's). Secondly, we show that a 0-path which sees more than  $\lceil n/8 \rceil$  0's can capture at most  $\kappa = \exp(-\Omega(n))$  of  $\mu_0$  mass. Consider a leaf  $v$  labelled 0 such that the path leading to  $v$  fixes  $t \geq \lceil n/8 \rceil$  variables to 0;  $|Z_v| = t \geq n/8$ . Let  $S_{n/2}$  be all strings of Hamming weight  $n/2$ . We have

$$\begin{aligned} \kappa &= \Pr_{y \sim \mu_0} [y \text{ reaches } v] = \Pr_{x \sim_u S_{n/2}} [rep(x) \text{ reaches } v] \\ &\leq \Pr_{x \sim_u S_{n/2}} [S_{rep(x)}^1 \cap Z_v = \emptyset] \leq \Pr_{x \sim_u S_{n/2}} [S_x^1 \cap Z_v = \emptyset] \quad (\text{because } S_x^1 \subseteq S_{rep(x)}^1) \\ &\leq \frac{\binom{n-t}{n/2}}{\binom{n}{n/2}} \leq \frac{\binom{7n/8}{n/2}}{\binom{n}{n/2}} = \prod_{i=0}^{n/2-1} \frac{7n/8 - i}{n - i} \leq \left( \frac{7}{8} \right)^{n/2} = 2^{-\Omega(n)}. \end{aligned}$$

With these two observations, we can now obtain the desired lower bound.

$$\begin{aligned} 4/5 \leq \rho_0 &= \sum_{v \in L_0} \Pr_{x \sim \mu_0} [E_v(x)] = \sum_{\substack{v \in L_0 \\ |Z_v| < \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [E_v(x)] + \sum_{\substack{v \in L_0 \\ |Z_v| \geq \lceil n/8 \rceil}} \Pr_{x \sim \mu_0} [E_v(x)] \\ &\leq 2/5 + \kappa \times (\text{number of 0-leaves}). \end{aligned}$$

Hence the number of 0-leaves is at least  $2/(5\kappa) = \exp(\Omega(n))$ . ◀

## 5 More general decision trees

A variable is queried at each node of a decision tree. Generalising the class of permitted queries gives rise to many variants of decision trees that have been considered in different contexts. In this section, we consider three such classes.

- *AND-decision trees (ADT)*: queries are restricted to AND of non-negated variables.
- *(AND, OR)-decision trees*: queries are restricted to AND or OR of variables.
- *PARITY-decision trees (PDT)*: queries are restricted to PARITY of variables.

We denote the deterministic, pseudo-deterministic and randomized query complexity in each of these types of trees as  $(D^{\wedge\text{-dt}}, \text{psD}^{\wedge\text{-dt}}, R^{\wedge\text{-dt}})$ ,  $(D^{(\wedge, \vee)\text{-dt}}, \text{psD}^{(\wedge, \vee)\text{-dt}}, R^{(\wedge, \vee)\text{-dt}})$ , and  $(D^{\oplus\text{-dt}}, \text{psD}^{\oplus\text{-dt}}, R^{\oplus\text{-dt}})$ , respectively.

AND, OR and PARITY are the most basic Boolean functions. It is thus natural to study the relationship between determinism, pseudo-determinism and randomization in these settings. We will use the following recently-proved results from [4].

► **Proposition 5.1** ([4]). *For every total Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ ,*

1.  $D^{\wedge\text{-dt}}(f) = O(R^{\wedge\text{-dt}}(f)^3 \log^4(n))$ . ([4, Theorem 4.5])
2.  $\log \text{DSize}^{\text{dt}}(f)/(2 \log n) \leq D^{(\wedge, \vee)\text{-dt}}(f) \leq 4 \log \text{DSize}^{\text{dt}}(f)$ . ([4, Lemma 4.2])
3.  $\log \text{RSize}^{\text{dt}}(f)/(2 \log n) \leq R^{(\wedge, \vee)\text{-dt}}(f) \leq 4 \log \text{RSize}^{\text{dt}}(f)$ . ([4, Lemma 4.2])
4.  $D^{(\wedge, \vee)\text{-dt}}(f) = O(R^{(\wedge, \vee)\text{-dt}}(f)^4 \log^7(n))$ . ([4, Theorem 4.1])

### AND-decision trees

Pseudo-determinism can be separated from randomness in AND decision trees. To establish the separation, we first give a technique to prove a pseudo-deterministic lower bound using 0-block sensitivity. The following theorem generalizes Theorem 3.1(2) to AND decision trees. The same relation is proved for Boolean functions in [12], by reduction to a hard communication problem; We give a more direct proof in the full version of our paper [3] for multi-output functions by constructing a hard distribution and using Yao's minimax principle.

► **Theorem 5.2.** *For a multi-output function  $f$ ,  $R_{1/3}^{\wedge\text{-dt}}(f) \geq bs_0(f)/3$ .*

*For a total search problem  $\mathcal{S}$ ,  $\text{psD}_{1/3}^{\wedge\text{-dt}}(\mathcal{S}) \geq \min_{f \in \mathcal{S}} bs_0(f)/3$ .*

Using this result, we can now separate randomized and pseudo-deterministic complexity.

► **Theorem 5.3.** *Let  $\mathcal{S}$  be the search problem  $\text{APPROXHAMWT} = \{(x, v) : |wt(x) - v| \leq n/10\}$ . Then  $R^{\wedge\text{-dt}}(\mathcal{S}) = R^{\text{dt}}(\mathcal{S}) = O(1)$ , while  $\text{psD}^{\wedge\text{-dt}}(\mathcal{S}) = \Omega(n)$ .*

**Proof.** It is easy to see, and already noted in Corollary 4.2 of [8], that  $R^{\text{dt}}(\mathcal{S}) = O(1)$ . To show  $\text{psD}^{\wedge\text{-dt}}(\mathcal{S}) = \Omega(n)$ , we will show that any  $f$  solving  $\mathcal{S}$  must have 0-sensitivity of at least  $4n/5$ . This too follows the proof outline from Corollary 4.2 of [8], where a lower bound on  $\text{psD}^{\text{dt}}$  was obtained. But using Theorem 5.2, we draw the stronger conclusion that  $\text{psD}^{\wedge\text{-dt}}(\mathcal{S}) \geq 4n/5$ . Suppose that for some  $f$  solving  $\mathcal{S}$ ,  $s_0(f) < 4n/5$ . We start with  $x^0 = 0^n$  and create a sequence of inputs  $\langle x^i \rangle$  such that  $wt(x^i) = i$  and  $f(x^i) = f(0^n)$ . Because  $f$  solves APPROXHAMWT,  $n/10 \geq f(0^n) = f(x^1) = f(x^2) = \dots = f(x^l) \geq l - n/10$ . Thus if we are able to create such a sequence of length at least  $l = n/5 + 1$ , then we already have a contradiction. The only thing left is to create the sequence  $x^i$ . For  $0 \leq i \leq n/5$ , given  $x^i$  with  $f(x^i) = f(0^n)$ , we need to find a suitable  $x^{i+1}$ . Note that  $x^i$  has exactly  $n - i$  0-bit positions, of which at most  $s_0(f)$  are sensitive, so at least  $s = n - i - s_0(f)$  0-bit positions are not sensitive. Since  $s_0(f) < 4n/5$  and  $i \leq n/5$ ,  $s > 0$ , so  $x^i$  has at least one non-sensitive 0-bit position. Pick any such position, say  $j$ , and define  $x^{i+1} = x^i \oplus 1_{\{j\}}$ . Note that  $x^{i+1}$  satisfies the desired properties i.e.  $f(x^{i+1}) = f(x^i) = f(0^n)$  and  $wt(x^{i+1}) = i + 1$ . ◀

On the other hand, using Proposition 5.1(1) with Proposition 4.1, we get a polynomial relationship between  $\text{psD}^{\wedge\text{-dt}}$  and  $D^{\wedge\text{-dt}}$ .

► **Theorem 5.4.** *For a total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ , we have*

$$D^{\wedge\text{-dt}}(\mathcal{S}) = O(\text{psD}^{\wedge\text{-dt}}(\mathcal{S})^3 \cdot \log^4(n) \cdot \min(\log m, \text{psD}^{\wedge\text{-dt}}(\mathcal{S}))).$$

**(AND, OR)-decision trees**

The results of Proposition 5.1(2),(3) are proved in [4] only for total Boolean functions. However, the proof there is based on a syntactic argument, where the upper bound relies on a tree-balancing argument and the lower bound is obtained by opening up AND and OR queries. Since the proof is syntactic, it naturally extends to multi-output functions and search problems as well. Using this extension to multi-output functions, we obtain the following relationship between  $\text{psDSize}^{\text{dt}}$  and  $\text{psD}^{(\wedge, \vee)\text{-dt}}$ .

► **Lemma 5.5.** *For a total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ , we have*

$$\log \text{psDSize}^{\text{dt}}(\mathcal{S}) / (2 \log n) \leq \text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) \leq 4 \log \text{psDSize}^{\text{dt}}(\mathcal{S}).$$

**Proof.** For  $\mathcal{S}$ , let  $f$  and  $g$  be multi-output function solving  $\mathcal{S}$ , with  $\text{psDSize}^{\text{dt}}(\mathcal{S}) = \text{RSize}^{\text{dt}}(f)$  and  $\text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) = \text{R}^{(\wedge, \vee)\text{-dt}}(g)$  respectively. Then

$$\begin{aligned} 4 \log \text{psDSize}^{\text{dt}}(\mathcal{S}) &= 4 \log \text{RSize}^{\text{dt}}(f) \stackrel{(*)}{\geq} \text{R}^{(\wedge, \vee)\text{-dt}}(f) \geq \text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) \\ &= \text{R}^{(\wedge, \vee)\text{-dt}}(g) \stackrel{(*)}{\geq} \log \text{RSize}^{\text{dt}}(g) / (2 \log n) \geq \log \text{psDSize}^{\text{dt}}(\mathcal{S}) / (2 \log n). \end{aligned}$$

The inequalities marked (\*) holds because of Proposition 5.1(3). ◀

This, along with the size separation from Theorem 4.6, gives us a separation between randomized and pseudo-deterministic query complexity in (AND, OR)-decision trees.

► **Theorem 5.6.** *Let  $\mathcal{S}$  be the search problem APPROXHAMWT. Then  $\text{R}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) = O(1)$  and  $\text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) = \Omega(n / \log n)$ .*

On the other hand, using Proposition 5.1(4) along with Proposition 4.1 gives a polynomial relation between pseudo-determinism and determinism, upto polylog  $n$  factors.

► **Theorem 5.7.** *For a total search problem  $\mathcal{S} \subseteq \{0, 1\}^n \times [m]$ , we have*

$$\text{D}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}) = O(\text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S})^4 \cdot \log^7(n) \cdot \min(\log m, \text{psD}^{(\wedge, \vee)\text{-dt}}(\mathcal{S}))).$$

**PARITY-decision trees**

For PARITY decision trees, for total Boolean functions, the randomized and deterministic PARITY query complexities are linearly separated: for the AND and OR functions, the deterministic PDT complexity is  $\Omega(n)$ , whereas the randomized PDT complexity is  $O(1)$ . The search analogue of the OR function gives an almost linear separation between determinism and pseudo-determinism in the PDT model. See the full version of our paper [3] for details.

► **Theorem 5.8.** *Let  $\mathcal{S}$  be the search problem SEARCHOR =  $\{(x, v) : (x_v = 1) \text{ or } (x = 0^n \wedge v = n + 1)\}$ . Then  $\text{D}^{\oplus\text{-dt}}(\mathcal{S}) = n$  whereas  $\text{psD}^{\oplus\text{-dt}}(\mathcal{S}) = O(\log n \log \log n)$ .*

Establishing a super-polynomial separation between randomness and pseudo-determinism remains open for PARITY decision trees.

**6 A combinatorial proof of a combinatorial problem**

In [9], the authors studied the pseudo-deterministic query complexity of a promise problem (PROMISEFIND1). Here the input bit string has 1s in at least half the positions, and the task is to find a 1. They observed that PROMISEFIND1 is a complete problem for easily-verifiable

search problems with randomized query algorithms (see Theorem 3 in [9]), and proved a  $\Omega(\sqrt{n})$  lower bound on its pseudo-deterministic query complexity. They conjectured that the pseudo-deterministic query lower bound for PROMISEFIND1 can be improved to  $\Omega(n)$ . Towards understanding the PROMISEFIND1 problem better, they introduced a natural colouring problem on hypercubes which states that any proper coloring of the hypercube contains a point with many 1s and with high block sensitivity.

► **Definition 6.1.** *A proper coloring of the  $n$ -dimensional hypercube  $H_n$  is any function  $\phi : \{0, 1\}^n - \{0^n\} \rightarrow [n]$  such that for all  $\beta \in \{0, 1\}^n - \{0^n\}$ ,  $\beta_{\phi(\beta)} = 1$ .*

We say a proper coloring  $\phi$  is  $d$ -sensitive if there exists a  $\beta \in \{0, 1\}^n$  such that  $|\beta|_1 \geq n/2$  and  $\beta$  has block sensitivity at least  $d$  with respect to  $\phi$ . That is, there are  $d$  disjoint blocks of inputs,  $B_1, \dots, B_d$  such that for all  $i \in [d]$ ,  $\phi(\beta) \neq \phi(\beta \oplus 1_{B_i})$ . The hypercube coloring problem is about proving lower bound on the (block) sensitivity of every proper coloring. In [9] it was shown that every proper coloring is  $\Omega(\sqrt{n})$ -sensitive.

► **Proposition 6.2** (Theorem 14 [9]). *Every proper coloring of  $H_n$  is  $\Omega(\sqrt{n})$ -sensitive.*

The hypercube coloring problem is closely related to the pseudodeterministic query complexity of PROMISEFIND1. It is a straightforward observation that showing every proper coloring is  $d$ -sensitive implies a lower bound of  $d$  on the pseudo-deterministic query complexity of PROMISEFIND1. To prove Proposition 6.2 in [9], the sensitivity lower bound for the search problem associated with a random unsat  $k$ -XOR formula was converted into a block sensitivity lower bound for the hypercube coloring problem.

We give a self-contained combinatorial solution to the coloring problem. Our solution shows that every proper coloring of hypercube has a  $\beta \in \{0, 1\}^n$  with Hamming weight  $\geq n/2$  and with block sensitivity  $\Omega(n^{1/3})$ . In fact, either the 1-block sensitivity or the 0-block sensitivity (or both) is  $\Omega(n^{1/3})$ . Thus this appears incomparable with the bound from [9]. Our solution is constructive: Algorithm 1 finds the required high-weight, high-block-sensitivity point, by querying  $\phi$  at various points.

► **Theorem 6.3.** *Every proper coloring  $\phi$  of the Boolean hypercube has a  $\beta \in \{0, 1\}^n$  with  $|\beta| \geq n/2$  satisfying  $bs_0(\phi, \beta) = \Omega(n^{1/3})$  or  $bs_1(\phi, \beta) = \Omega(n^{1/3})$ .*

**Proof.** In Algorithm 1, we describe a procedure to find the required point  $\beta$ . To prove that the algorithm is correct, we need to prove that if it returns  $\beta \in \{0, 1\}^n$  and blocks  $D_1, D_2, \dots, D_r$ , then

1.  $\beta \in \mathcal{X}$  (i.e.  $\beta$  has Hamming weight at least  $n/2$ ),
2.  $D_1, D_2, \dots, D_r$  are disjoint sensitive blocks of  $\phi$  at  $\beta$ , and
3. either all these blocks are 1-blocks of  $\beta$  or all these blocks are 0-blocks.
4.  $r = \Omega(n^{1/3})$ ,

Observe that by construction, for each  $i \in [t+1]$  where  $\beta^i$  is constructed by the algorithm,  $\beta^i$  has 0s in  $B_j$  for  $j < i$  and 1s in  $B_i$  (in fact, 1s elsewhere); hence the blocks  $B_1, \dots, B_{i-1}$  are disjoint.

Further, by construction, each complete iteration of the for loop adds fewer than  $t^2$  positions to  $C$ : there are fewer than  $t$  blocks (otherwise the algorithm would terminate at line 9) and each block has size less than  $t$  (otherwise the algorithm would terminate at line 13). Thus, since  $|C_0| = 0$ , if the algorithm reaches line 15 in iteration  $i$ , then  $C_i$  has size less than  $i \cdot t^2$ . Hence  $\beta^{i+1}$  has hamming weight  $n - |C_i| > n - it^2 \geq n - t^3 > n - n/2 \geq n/2$  and is in  $\mathcal{X}$ .

■ **Algorithm 1** Algorithm to find the sensitive point.

---

**Require:** A proper coloring  $\phi$ . i.e. For  $\mathcal{X} = \{x \in \{0, 1\}^n \mid \sum_i x_i \geq n/2\}$ ,  $\phi : \mathcal{X} \rightarrow [n]$  satisfying  $\forall x \in \mathcal{X}, x_{\phi(x)} = 1$ .

- 1:  $t \leftarrow \lfloor (n/2)^{1/3} \rfloor$ ;  $C_0 \leftarrow \emptyset$

---

If the algorithm terminates at line 9 in the  $i$ th iteration of the for loop, then by the choice in line 6 the returned blocks are disjoint 1-sensitive blocks of  $\beta = \beta^i$ , and there are at least  $t$  of them. Similarly, if the algorithm terminates at line 13 in the  $i$ th iteration of the for loop, then by minimality of the sensitive block  $B_{i,j}$  chosen in line 12, each position in  $B_{i,j}$  is a 0-sensitive location in  $\beta = \beta^i \oplus 1_{B_{i,j}}$ , and there are at least  $t$  of them.

If the algorithm terminates at line 18, then each  $B_i$  is a 0-block of  $\beta = \beta^{t+1}$  and there are  $t$  such blocks. It remains to prove that each  $B_i$  is sensitive for  $\beta = \beta^{t+1}$ . To show this, we will first show that each  $C_i$  is a certificate for  $\beta^i$ , and then show that this implies each  $B_i$  is sensitive for  $\beta$ .

For the first part, suppose for some  $i \in [t]$ ,  $C_i$  is not a certificate for  $\beta^i$ . Then there exists an  $\alpha \in \mathcal{X}$  such that  $\forall j \in C_i, \alpha_j = \beta_j^i$ , but  $\phi(\alpha) \neq \phi(\beta^i)$ . Let  $B$  be the set of positions where  $\alpha$  and  $\beta^i$  differ i.e.  $\alpha = \beta^i \oplus 1_B$ . Since  $\alpha$  and  $\beta^i$  agree on  $C_i$ ,  $B$  must be disjoint from  $C_i$ . Since  $\phi(\beta^i) \neq \phi(\alpha) = \phi(\beta^i \oplus 1_B)$ ,  $B$  is a 1-sensitive block of  $\phi$  at  $\beta^i$ . By the choice in line 6 at the  $i$ th iteration,  $\beta^i$  has no 1-sensitive blocks disjoint from the blocks  $B_{i,1}, \dots, B_{i,s}$ . But  $B_i$  is precisely the union of the these blocks, and is contained in  $C_i$ , so  $B$  is disjoint from  $B_i$ , a contradiction. Hence  $C_i$  is indeed a  $\phi$ -certificate for  $\beta^i$ .

For the second part, note that for each  $i \in [t]$ ,  $\beta$  and  $\beta^i$  agree on  $C_{i-1}$  and  $\beta \oplus B_i$  and  $\beta^i$  agree on  $C_i$ . Since  $C_i$  is a certificate for  $\beta^i$ ,  $\phi(\beta \oplus B_i) = \phi(\beta^i) = \ell$ , say. By the definition of proper coloring,  $\{\ell\}$  is a 1-sensitive block of  $\beta^i$ , and since the blocks chosen in line 6 are the maximum possible 1-sensitive blocks,  $\ell \in B_i$ . But  $\phi(\beta) \neq \ell$  because  $\beta = 0_{C_t}$  and has only 0s in  $B_i$ . Thus  $\phi(\beta) \neq \phi(\beta \oplus B_i)$ , and hence  $B_i$  is a 0-sensitive block for  $\beta$ .

Finally, by choice of  $t$ , we see that  $r = \Omega(n^{1/3})$ . This concludes the correctness proof. ◀

---

## Abstract

In this work, we study two natural generalizations of clique-width introduced by Martin Fürer. Multi-clique-width (mcw) allows every vertex to hold multiple labels [ITCS 2017], while for fusion-width (fw) we have a possibility to merge all vertices of a certain label [LATIN 2014]. Fürer has shown that both parameters are upper-bounded by treewidth thus making them more appealing from an algorithmic perspective than clique-width and asked for applications of these parameters for problem solving. First, we determine the relation between these two parameters by showing that  $mcw \leq fw + 1$ . Then we show that when parameterized by multi-clique-width, many problems (e.g., CONNECTED DOMINATING SET) admit algorithms with the same running time as for clique-width despite the exponential gap between these two parameters. For some problems (e.g., HAMILTONIAN CYCLE) we show an analogous result for fusion-width: For this we present an alternative view on fusion-width by introducing so-called glue-expressions which might be interesting on their own. All algorithms obtained in this work are tight up to (Strong) Exponential Time Hypothesis.

## 1 Introduction

In parameterized complexity apart from the input size we consider a so-called parameter and study the complexity of problems depending on both the input size and the parameter where the allowed dependency on the input size is polynomial. In a more fine-grained setting one is interested in the best possible dependency on the parameter under reasonable conjectures. A broad line of research is devoted to so-called *structural parameters* measuring how simple the graph structure is: different parameters quantify various notions of possibly useful input structure. Probably the most prominent structural parameter is treewidth, which reflects how well a graph can be decomposed using small vertex separators. For a variety of problems, the tight complexity parameterized by treewidth (or its path-like analogue pathwidth) has been determined under the so-called Strong Exponential Time Hypothesis (e.g., [33, 24, 32, 11, 28, 12, 16]). However, the main drawback of treewidth is that it is only bounded in sparse graphs: a graph on  $n$  vertices of treewidth  $k$  has no more than  $nk$  edges.

To capture the structure of dense graphs, several parameters have been introduced and considered. One of the most studied is clique-width. The clique-width of a graph is at most  $k$  if it can be constructed using the following four operations on  $k$ -labeled graphs: create a vertex with some label from  $1, \dots, k$ ; form a disjoint union of two already constructed graphs; give all vertices with label  $i$  label  $j$  instead; or create all edges between vertices

with labels  $i$  and  $j$ . It is known that if a graph has treewidth  $k$ , then it has clique-width at most  $3 \cdot 2^{k-1}$  and it is also known that an exponential dependence in this bound is necessary [9]. Conversely, cliques have clique-width at most 2 and unbounded treewidth. So on the one hand, clique-width is strictly more expressive than treewidth in the sense that if we can solve a problem efficiently on classes of graphs of bounded clique-width, then this is also true for classes of graphs of bounded treewidth. On the other hand, the exponential gap has the effect that as the price of solving the problem for larger graph classes we potentially obtain worse running times for some graph families.

Fürer introduced and studied two natural generalizations of clique-width, namely fusion-width (fw) [19] and multi-clique-width (mcw) [20]. For fusion-width, additionally to the clique-width operations, he allows an operator that fuses (i.e., merges) all vertices of label  $i$ . Originally, fusion-width (under a different name) was introduced by Courcelle and Makowsky [10]. However, they did not suggested studying it as a new width parameter since it is parametrically (i.e., up to some function) equivalent to clique-width. For multi-clique-width, the operations remain roughly the same as for clique-width but now every vertex is allowed to have multiple labels. For these parameters, Fürer showed the following relations to clique-width (cw) and treewidth (tw):

$$\text{fw} \leq \text{cw} \leq \text{fw} \cdot 2^{\text{fw}} \quad \text{mcw} \leq \text{cw} \leq 2^{\text{mcw}} \quad \text{fw} \leq \text{tw} + 2 \quad \text{mcw} \leq \text{tw} + 2 \quad (1)$$

Fürer also observed that the exponential gaps between clique-width and both fusion- and multi-clique-width are necessary. As our first result, we determine the relation between fusion-width and multi-clique-width:

► **Theorem 1.** *For every graph  $G$ , it holds that  $\text{mcw}(G) \leq \text{fw}(G) + 1$ . Moreover, given a fuse- $k$ -expression  $\phi$  of  $G$ , a multi-clique-width- $(k + 1)$ -expression of  $G$  can be created in time polynomial in  $|\phi|$  and  $k$ .*

The relations in (1) imply that a problem is FPT parameterized by fusion-width resp. multi-clique-width if and only if this is the case for clique-width. However, the running times of such algorithms might strongly differ. Fürer initiated a fine-grained study of problem complexities relative to multi-clique-width, starting with the INDEPENDENT SET problem. He showed that this problem can be solved in  $\mathcal{O}^*(2^{\text{mcw}})$  where  $\mathcal{O}^*$  hides factors polynomial in the input size. On the other hand, Lokshtanov et al. proved that under SETH no algorithm can solve this problem in  $\mathcal{O}^*((2 - \varepsilon)^{\text{pw}})$  where pw denotes the parameter called pathwidth [28]. Clique-width of a graph is at most its pathwidth plus two [15] so the same lower bound holds for clique-width and hence, multi-clique-width as well. Therefore, the tight dependence on both clique-width and multi-clique-width is the same, namely  $\mathcal{O}^*(2^k)$ . We show that this is the case for many further problems.

► **Theorem 2.** *Let  $G$  be a graph given together with a multi- $k$ -expression of  $G$ . Then:*

- *DOMINATING SET can be solved in time  $\mathcal{O}^*(4^k)$ ;*
- *$q$ -COLORING can be solved in time  $\mathcal{O}^*((2^q - 2)^k)$ ;*
- *CONNECTED VERTEX COVER can be solved in time  $\mathcal{O}^*(6^k)$ ;*
- *CONNECTED DOMINATING SET can be solved in time  $\mathcal{O}^*(5^k)$ .*

*And these results are tight under SETH.*

*Further, CHROMATIC NUMBER can be solved in time  $f(k) \cdot n^{2^{\mathcal{O}(k)}}$  and this is tight under ETH.*

We prove this by providing algorithms for multi-clique-width with the same running time as the known tight algorithms for clique-width. The lower bounds for clique-width known from the literature then apply to multi-clique-width as well proving the tightness of our results.

By Theorem 1, these results also apply to fusion-width. For the following three problems we obtain similar tight bounds relative to fusion-width as for clique-width, but it remains open whether the same is true relative to multi-clique-width:

► **Theorem 3.** *Let  $G$  be a graph given together with a fuse- $k$ -expression of  $G$ . Then:*

- *MAX CUT can be solved in time  $f(k) \cdot n^{\mathcal{O}(k)}$ ;*
- *EDGE DOMINATING SET can be solved in time  $f(k) \cdot n^{\mathcal{O}(k)}$ ;*
- *HAMILTONIAN CYCLE can be solved in time  $f(k) \cdot n^{\mathcal{O}(k)}$ .*

*And these results are tight under ETH.*

To prove these upper bounds, we provide an alternative view on fuse-expressions, called *glue-expressions*, interesting on its own. We show that a fuse- $k$ -expression can be transformed into a glue- $k$ -expression in polynomial time and then present dynamic-programming algorithms on glue-expressions. Due to the exponential gap between clique-width and both fusion- and multi-clique-width, our results provide exponentially faster algorithms on graphs witnessing these gaps.

**Related Work.** Two parameters related to both treewidth and clique-width are modular treewidth (mtw) [3, 22] and twinclass-treewidth [29, 31, 27] (unfortunately, sometimes also referred to as modular treewidth). It is known that  $\text{mcw} \leq \text{mtw} + 3$  (personal communication with Falko Hegerfeld). Further dense parameters have been widely studied in the literature. Rank-width (rw) was introduced by Oum and Seymour and it reflects the  $\mathbb{F}_2$ -rank of the adjacency matrices in the so-called branch decompositions. Originally, it was defined to obtain a fixed-parameter approximation of clique-width [30] by showing that  $\text{rw} \leq \text{cw} \leq 2^{\text{rw} + 1} - 1$ . Later, Bui-Xuan et al. started the study of algorithmic properties of rank-width [5]. Recently, Bergougnoux et al. proved the tightness of first ETH-tight lower bounds for this parameterization [2]. Another parameter defined via branch-decompositions and reflecting the number of different neighborhoods across certain cuts is boolean-width (boolw), introduced by Bui-Xuan et al. [6, 7]. Fürer [20] showed that  $\text{boolw} \leq \text{mcw} \leq 2^{\text{boolw}}$ . Recently, Eiben et al. presented a framework unifying the definitions and algorithms for computation of many graph parameters [13].

**Organization.** We start with some required definitions and notations in Section 2. In Section 3 we prove the relation between fusion-width and multi-clique-width from Theorem 1. After that, in Section 4 we introduce glue- $k$ -expressions and show how to obtain such an expression given a fuse- $k$ -expression of a graph. Then in Section 5 we employ these expressions to obtain algorithms parameterized by fusion-width. In Section 6 we present algorithms parameterized by multi-clique-width. We conclude with some open questions in Section 7. In this work some technical details have been omitted due to space constraints. We refer to the full version of the paper for all proofs [8].

## 2 Preliminaries

For  $k \in \mathbb{N}_0$ , we denote by  $[k]$  the set  $\{1, \dots, k\}$  and we denote by  $[k]_0$  the set  $[k] \cup \{0\}$ .

We use standard graph-theoretic notation. Our graphs are simple and undirected if not explicitly stated otherwise. For a graph  $H$  and a partition  $(V_1, V_2)$  of  $V(H)$ , by  $E_H(V_1, V_2) = \{\{v_1, v_2\} \mid v_1 \in V_1, v_2 \in V_2\}$  we denote the set of edges between  $V_1$  and  $V_2$ . For a set  $S$  of edges in a graph  $H$ , by  $V(S)$  we denote the set of vertices incident with the edges in  $S$ .

A  $k$ -labeled graph is a pair  $(H, \text{lab}_H)$  where  $\text{lab}_H: V(H) \rightarrow [k]$  is a *labeling function* of  $H$ . Sometimes to simplify the notation in our proofs we will allow the labeling function to map to some set of cardinality  $k$  instead of the set  $[k]$ . In the following, if the number  $k$  of labels does not matter, or it is clear from the context, we omit  $k$  from the notions (e.g., a labeled graph instead of a  $k$ -labeled graph). Also, if the labeling function is clear from the context, then we simply call  $H$  a labeled graph as well. Also we sometimes omit the subscript  $H$  of the labeling function  $\text{lab}_H$  for simplicity. For  $i \in [k]$ , by  $U_i^H = \text{lab}_H^{-1}(i)$  we denote the set of vertices of  $H$  with label  $i$ . We consider the following four operations on  $k$ -labeled graphs.

1. *Introduce*: For  $i \in [k]$ , the operator  $v\langle i \rangle$  creates a graph with a single vertex  $v$  that has label  $i$ . We call  $v$  the *title* of the vertex.
2. *Union*: The operator  $\oplus$  takes two vertex-disjoint  $k$ -labeled graphs and creates their disjoint union. The labels are preserved.
3. *Join*: For  $i \neq j \in [k]$ , the operator  $\eta_{i,j}$  takes a  $k$ -labeled graph  $H$  and creates the supergraph  $H'$  on the same vertex set with  $E(H') = E(H) \cup \{\{u, v\} \mid \text{lab}_H(u) = i, \text{lab}_H(v) = j\}$ . The labels are preserved.
4. *Relabel*: For  $i \neq j$ , the operator  $\rho_{i \rightarrow j}$  takes a  $k$ -labeled graph  $H$  and creates the same  $k$ -labeled graph  $H'$  apart from the fact that every vertex that with label  $i$  in  $H$  instead has label  $j$  in  $H'$ .

A well-formed sequence of such operations is called a  $k$ -*expression* or a *clique-expression*. With a  $k$ -expression  $\phi$  one can associate a rooted tree such that every node corresponds to an operator, this tree is called a *parse tree* of  $\phi$ . With a slight abuse of notation, we denote it by  $\phi$  as well. By  $G^\phi$  we denote the labeled graph arising in  $\phi$ . And for a node  $t$  of  $\phi$  by  $G_t^\phi$  we denote the labeled graph arising in the subtree (sometimes also called a *sub-expression*) rooted at  $t$ , this subtree is denoted by  $\phi_t$ . The graph  $G_t^\phi$  is then a subgraph of  $G^\phi$ . A graph  $H$  has *clique-width* of at most  $k$  if there is a labeling function  $\text{lab}_H$  of  $H$  and a  $k$ -expression  $\phi$  such that  $G^\phi$  is equal to  $(H, \text{lab}_H)$ . By  $\text{cw}(H)$  we denote the smallest integer  $k$  such that  $H$  has clique-width at most  $k$ . Fürer has studied two generalizations of  $k$ -expressions [19, 20].

*Fuse*: For  $i \in [k]$ , the operator  $\theta_i$  takes a  $k$ -labeled graph  $H$  with  $\text{lab}_H^{-1}(i) \neq \emptyset$  and *fuses* the vertices with label  $i$ , i.e., the arising graph  $H'$  has vertex set  $(V(H) - \text{lab}_H^{-1}(i)) \cup \{v\}$ , the edge relation in  $V(H) - \text{lab}_H^{-1}(i)$  is preserved, and  $N_{H'}(v) = N_H(\text{lab}_H^{-1}(i))$ . The labels of vertices in  $V(H') - v$  are preserved, and vertex  $v$  has label  $i$ . A *fuse- $k$ -expression* is a well-formed expression that additionally to the above four operations is allowed to use fuses. We adopt the above notations from  $k$ -expressions to fuse- $k$ -expressions. Let us only remark that for a node  $t$  of a fuse- $k$ -expression  $\phi$ , the graph  $G_t^\phi$  is not necessarily a subgraph of  $G^\phi$  since some vertices of  $G_t^\phi$  might be fused later in  $\phi$ .

► **Remark 4.** Originally, Fürer allows that a single introduce-node creates multiple, say  $q$ , vertices with the same label. However, we can eliminate such operations from a fuse-expression  $\phi$  as follows. If the vertices introduced at some node participate in some fuse later in the expression, then it suffices to introduce only one of them. Otherwise, we can replace this introduce-node by  $q$  nodes introducing single vertices combined using union-nodes. These vertices are then also the vertices of  $G^\phi$ . So in total, replacing all such introduce-nodes would increase the number of nodes of the parse tree by at most  $\mathcal{O}(|V(G^\phi)|)$ , which is not a problem for our algorithmic applications.

Another generalization of clique-width introduced by Fürer [20] is multi-clique-width (mcw). A multi- $k$ -labeled graph is a pair  $(H, \text{lab}_H)$  where  $\text{lab}_H: V(H) \rightarrow 2^{[k]}$  is a multi-labeling function. We consider the following four operations of multi- $k$ -labeled graphs.

1. *Introduce*: For  $q \in [k]$  and  $i_1, \dots, i_q \in [k]$ , the operator  $v\langle i_1, \dots, i_q \rangle$  creates a multi- $k$ -labeled graph with a single vertex that has label set  $\{i_1, \dots, i_q\}$ .
2. *Union*: The operator  $\oplus$  takes two vertex-disjoint multi- $k$ -labeled graphs and creates their disjoint union. The labels are preserved.
3. *Join*: For  $i \neq j \in [k]$ , the operator  $\eta_{i,j}$  takes a multi- $k$ -labeled graph  $H$  and creates its supergraph  $H'$  on the same vertex set with  $E(H') = E(H) \cup \{\{u, v\} \mid i \in \text{lab}_H(u), j \in \text{lab}_H(v)\}$ . This operation is only allowed when there is no vertex in  $H$  with labels  $i$  and  $j$  simultaneously, i.e., for every vertex  $v$  of  $H$  we have  $\{i, j\} \not\subseteq \text{lab}_H(v)$ . The labels are preserved.
4. *Relabel*: For  $i \in [k]$  and  $S \subseteq [k]$ , the operator  $\rho_{i \rightarrow S}$  takes a multi- $k$ -labeled graph  $H$  and creates the same multi-labeled graph apart from the fact that every vertex with label set  $L \subseteq [k]$  such that  $i \in L$  in  $H$  instead has label set  $(L \setminus \{i\}) \cup S$  in  $H'$ . Note that  $S = \emptyset$  is allowed.

A well-formed sequence of these four operations is called a *multi- $k$ -expression*. As for fuse-expressions, Fürer allows introduce-nodes to create multiple vertices but we can eliminate this by increasing the number of nodes in the expression by at most  $\mathcal{O}(|V(G^\phi)|)$ . We adopt the analogous notations from  $k$ -expressions to multi- $k$ -expressions.

**Complexity.** To the best of our knowledge, the only known way to approximate multi-clique-width and fusion-width is via clique-width, i.e., to employ the relation (1). The only known way to approximate clique-width is, in turn, via rank-width. This way we obtain a  $2^{2^k}$ -approximation of multi-clique-width and fusion-width running in FPT time. For this reason, to obtain tight running times in our algorithms we always assume that a fuse- or multi- $k$ -expression is provided. Let us emphasize that this is also the case for all tight results for clique-width in the literature (see e.g., [1, 27]). In this work, we will show that if a graph admits a multi- $k$ -expression resp. a fuse- $k$ -expression, then it also admits one whose size is polynomial in the size of the graph. Moreover, such a “compression” can be carried out in time polynomial in the size of the original expression. Therefore, we delegate this compression to a black-box algorithm computing or approximating multi-clique-width or fusion-width and assume that provided expressions have size polynomial in the graph size.

**(Strong) Exponential Time Hypothesis.** The algorithms in this work are tight under one of the following conjectures formulated by Impagliazzo et al. [23]. The Exponential Time Hypothesis (ETH) states that there is  $0 < \varepsilon < 1$  such that 3-SAT with  $n$  variables and  $m$  clauses cannot be solved in time  $\mathcal{O}^*(2^{\varepsilon n})$ . The Strong Exponential Time Hypothesis (SETH) states that for every  $0 < \varepsilon < 1$  there is an integer  $q$  such that  $q$ -SAT cannot be solved in time  $\mathcal{O}^*(2^{\varepsilon n})$ . In this work,  $\mathcal{O}^*$  hides factors polynomial in the input size.

**Simplifications.** If the graph is clear from the context, by  $n$  we denote the number of its vertices. If not stated otherwise, the number of labels is denoted by  $k$  and a label is a number from  $[k]$ .

### 3 Relation Between Fusion-Width and Multi-Clique-Width

In this section, we show that the multi-clique-width of a graph is at most as large as its fusion-width plus one. Fürer [20] has proven the following relation:

► **Theorem 5** ([20]). *For every graph  $H$ , it holds that  $\text{cw}(H) \leq \text{fw}(H) + 1$ .*

The proof is constructive: given a fuse- $k$ -expression it creates a  $k \cdot 2^k$ -expression of the same graph. We use ideas from this proof to prove our result.

► **Theorem 6.** *For every graph  $H$ , it holds that  $\text{mcw}(H) \leq \text{fw}(H) + 1$ . Moreover, given a fuse- $k$ -expression  $\phi$  of  $H$ , a multi- $(k + 1)$ -expression of  $H$  can be created in time polynomial in  $|\phi|$  and  $k$ .*

**Proof.** Here we sketch the intuition behind the proof and for all formalities we refer to the full version. We start by showing that  $\text{mcw}(H) \leq 2 \cdot \text{fw}(H)$  holds. To prove this, we will consider a fuse- $k$ -expression of  $H$  and from it, we will construct a multi- $2k$ -expression of  $H$  using labels  $\{1, \dots, k, \widehat{1}, \dots, \widehat{k}\}$ . For simplicity, let  $\widehat{[k]} = \{\widehat{1}, \dots, \widehat{k}\}$ . For this first step, we follow the construction of Fürer in his proof of Theorem 5. There he uses  $k \cdot 2^k$  labels from the set  $[k] \times 2^{[k]}$  so the second component of such a label is a subset of  $[k]$ . Multi-expressions allow vertices to hold multiple labels and we model the second component of a label via subsets of  $\widehat{[k]}$ . After that, we show that the labels  $i$  and  $\widehat{i}$  can be almost unified for every  $i \in [k]$ . Using just one additional label  $\star$ , we then obtain a multi- $(k + 1)$ -expression of  $H$ .

For simplicity of representation, in this proof sketch we assume that our fuse-expression contains no relabel-nodes (we refer to the full version for the complete proof). We may assume that our fuse-expression does not contain nodes that do not change the arising labeled graph. Also if a vertex arising in some fuse-operation participates in some later fuse-operation, then the earlier fuse can be removed. Now we assume that any vertex arising in a fuse-operation does not participate in later fuses. We say that  $v$  is a *fuse-vertex* at a node  $x$  of the expression if  $v$  *participates* in some fuse-operation above  $x$ . For the label  $i$  of  $v$  we then also say that  $i$  is a *fuse-label* at  $x$ . Instead of first creating the fuse-vertices via introduce-nodes and then fusing them, we will introduce only one vertex representing the result of the fusion. The creation of the edges incident with such a *new* vertex (originally incident with fuse-vertices) then needs to be *postponed* until the moment where this vertex is introduced. To remember that some vertex  $v$  is missing an edge to a new vertex with label  $i$ , we will add a label  $\widehat{i}$  to the label set of  $v$ . After the creation of this vertex, the edge will be reconstructed using a corresponding join.

Now we provide more details. First, we cut off every leaf of the expression introducing a fuse-vertex. Second, we replace every fuse-node  $\theta_i$  by a *new* introduce-node  $1\langle i \rangle$ . Since for every fuse-vertex we have kept only the latest fuse-node it participates in, the vertex set of the graph arising in the current expression is  $V(H)$ , and the edges incident with new vertices need to be created. For this, let  $x$  be a  $\eta_{i,j}$ -node. If both  $i$  and  $j$  are not fuse-labels at  $x$ , no additional work needs to be done. Next, assume that exactly one of the labels  $i$  and  $j$ , say  $i$ , is a fuse-label at  $x$ . The information about the created edges is stored in vertices of label  $j$ : for this, we replace this join with a relabel  $\rho_{j \rightarrow \{j, \widehat{i}\}}$ . Now assume that both  $i$  and  $j$  are fuse-labels at  $x$ . Then  $x$  creates only one edge of  $H$  since all vertices of label  $i$  (resp.  $j$ ) are fused into one vertex later. We may assume that in the original expression, the fuse of vertices with label  $j$  happens before the fuse of label  $i$ . We store the information about the postponed edge in  $j$  as follows. Let  $x_j$  be the new introduce-node that replaced the fuse-node for label  $j$ . And let  $S$  denote the set of labels of the new vertex created in this node: in the beginning,  $S$  consists of  $j$  only but after processing some join-nodes, it might contain further labels from  $\widehat{[k]}$ . Then we replace  $x_j$  with a  $1\langle S \cup \{\widehat{i}\} \rangle$ -node. Finally, we create the remembered edges as follows. Let  $x$  be a new  $1\langle S \rangle$ -node for some set  $S$  of labels. By construction, there exists a unique  $i \in S \cap [k]$ : this is the label of vertices originally fused at this node while  $S \setminus i \subseteq \widehat{[k]}$  remembers the edges to be created later in the expression. So right after  $x$ , we first add a  $\eta_{i, \widehat{i}}$ -node and second, a  $\rho_{i \rightarrow \emptyset}$ -node to reflect that the missing edges have been created.

This concludes the construction of a multi- $2k$ -expression of  $H$ . The crucial observation is that the labels  $i$  and  $\widehat{i}$  are almost never used at the same time. Indeed, if label  $\widehat{i}$  occurs in some vertex created by some sub-expression, then all leaves introducing the vertices of label  $i$  have been cut off from this sub-expression. So there are no vertices with label  $i$  now. The only moment to which both labels  $i$  and  $\widehat{i}$  occur simultaneously is right after a new  $1\langle S \rangle$ -node with  $i \in S$ : now the label  $\widehat{i}$  is used to create the postponed edges incident with the new vertex and then  $\widehat{i}$  is removed. So apart from these two operations, we can unify  $i$  and  $\widehat{i}$ : one additional label  $\star$  suffices to distinguish them during these operations. This results in a multi- $(k+1)$ -expression of  $H$ . ◀

#### 4 Reduced Glue-Expressions

► **Definition 7.** A glue- $k$ -expression is a well-formed expression constructed from introduce-, join-, relabel-, and glue-operations on  $k$ -labeled graphs. A glue-operation takes as input two  $k$ -labeled graphs  $(H_1, \text{lab}_1)$  and  $(H_2, \text{lab}_2)$  satisfying the following two properties:

- For every  $v \in V(H_1) \cap V(H_2)$ , the vertex  $v$  has the same label in  $H_1$  and  $H_2$ , i.e., we have  $\text{lab}_1(v) = \text{lab}_2(v)$ .
- For every  $v \in V(H_1) \cap V(H_2)$  and every  $j \in [2]$ , the vertex  $v$  is the unique vertex with its label in  $H_j$ , i.e., we have  $|\text{lab}_1^{-1}(\text{lab}_1(v))| = |\text{lab}_2^{-1}(\text{lab}_2(v))| = 1$ .

In this case, we call the graphs  $H_1$  and  $H_2$  glueable. The output of this operation is then the graph  $H_1 \sqcup H_2$  with  $V(H_1 \sqcup H_2) = V(H_1) \cup V(H_2)$  and  $E(H_1 \sqcup H_2) = E(H_1) \cup E(H_2)$  where the labels are preserved. The vertices in  $V(H_1) \cap V(H_2)$  are called glue-vertices.

Note that if  $H_1$  and  $H_2$  satisfy these properties, then the gluing is equivalent to a union followed by a sequence of fuses  $\theta_i$  where  $i$  is a label of a vertex shared by  $H_1$  and  $H_2$ .

► **Definition 8.** A glue- $k$ -expression  $\xi$  is called reduced if the following properties hold:

1. Let  $i, j \in [k]$ , let  $t$  be a  $\eta_{i,j}$ -node in  $\xi$ , and let  $t'$  be the child of  $t$  in  $\xi$ . Then  $G_v^\xi$  contains no edge  $\{v, w\}$  with  $\text{lab}_v^\xi(v) = i$  and  $\text{lab}_v^\xi(w) = j$ .
2. Let  $t$  be a glue-node in  $\xi$  and let  $t_1$  and  $t_2$  be its children. Then the graphs  $G_{t_1}^\xi$  and  $G_{t_2}^\xi$  are edge-disjoint.
3. Let  $t$  be a glue-node in  $\xi$ , let  $t_1$  and  $t_2$  be its children, and let  $v$  be a glue-vertex. Then for every  $j \in [2]$ , the vertex  $v$  has an incident edge in  $G_{t_j}^\xi$ .

As we will see in Section 5, such expressions are very useful for algorithmic applications.

In this section we sketch how to transform a fuse- $k$ -expression into a reduced glue- $k$ -expression of the same graph in polynomial time. Although the idea behind the construction of such expressions is quite natural, the realization is rather technical. For this reason, here we only provide a high-level idea of the required steps and refer to the full version for the extensive description.

In the first phase, we transform a fuse- $k$ -expression into a (not necessarily reduced) glue- $k$ -expression as follows. As the first step, we want to achieve that every fuse-node  $t$  is right above some union-node, i.e., there are only fuse-nodes on the path between  $t$  and the topmost union-node below  $t$ . For this, we shift every fuse-node down to the closest union-node (see Figure 1 (a)). We emphasize that this cannot be achieved simply by repetitive swapping of the fuse-node with its child: e.g., swapping  $\theta_i$  with  $\rho_{j \rightarrow i}$  would change the arising graph. In the second step, we want to achieve that every fuse-node  $t$  fuses exactly two vertices and these vertices come from different sides of the union right below it. In other words, we want that any two vertices, that are ever fused, are fused as early as possible. So if there is a node  $t$  fusing at least two vertices coming from the same side of the topmost union-node  $t_\oplus$

**Figure 1** The steps to transform a fuse-expression into a glue-expression. (a) Shifting fuse-nodes to union-nodes. (b) Creating copies of fuse-nodes to fuse vertices as early as possible. (c) Shifting the copied fuse-nodes to union-nodes.

below it, these vertices can actually be fused before  $t_{\oplus}$  already. To accomplish this, we add a new fuse-node  $t'$  below  $t_{\oplus}$  (see Figure 1 (b)). After that,  $t'$  is shifted down to the next union-node as in the first step (see Figure 1 (c)). In this second step, one needs to be careful in order to ensure that the process terminates at all and that it takes only polynomial time. For this, we choose an appropriate order for processing the fuse-nodes. After these two steps, we replace every sequence consisting of a union-node and following fuse-nodes with a glue-node to obtain a glue-expression.

In the second phase, we make our glue-expression reduced as follows (see Definition 8). First, given two join-nodes creating the same edge, we can show that at least of them can be safely removed. Second, if a glue-vertex of two glued graphs has no incident edge in one of them, then we can remove this vertex from that graph without changing the result of the gluing. We refer to the full version for details. Altogether, we prove the following:

► **Theorem 9.** *Let  $\phi$  be a fuse- $k$ -expression of a graph  $H$  on  $n$  vertices and  $m$  edges. Then in time polynomial in  $|\phi|$  and  $k$  we can compute a reduced glue- $k$ -expression  $\zeta$  of  $H$  such that the parse tree of  $\zeta$  contains  $\mathcal{O}(k^2(m+n))$  nodes.*

Let us remark, that unlike clique-expressions (whose leaves are in bijection with the vertices of the arising graph), the number of leaves in a fuse-expression can be unbounded in general. This is due to fuse-nodes reducing the number of vertices in the constructed graph. So Theorem 9 in particular shows that a polynomial number of introduce-nodes suffices.

## 5 Algorithms Parameterized by Fusion-Width

In this section we show how to employ reduced glue-expressions to obtain algorithms parameterized by fusion-width (given a fuse-expression of corresponding width). In the previous section, we showed that every fuse- $k$ -expression can be transformed into a reduced glue- $k$ -expression of small size in polynomial time. So for the remainder of this section we assume that a glue- $k$ -expression  $\phi$  of an input graph  $G$  is given. Recall that in particular, two graphs glued at any glue-node of  $\phi$  are edge-disjoint.

All algorithms in this section have running time  $f(\text{fw})n^{\mathcal{O}(\text{fw})}$ . For each of the problems considered here, in the literature there is a lower bound stating that under ETH, the problem cannot be solved in time  $f(\text{cw})n^{\mathcal{O}(\text{cw})}$  even if a clique-expression of corresponding width is provided [17, 18]. Since fusion-width is at most as large as clique-width, these lower bounds hold for fusion-width as well implying the tightness of our results. Fürer observed that there exist graphs whose clique-width is exponential in their fusion-width [19]. Therefore, in addition to solving these problems for a larger class of graphs, we obtain an exponential improvement in the running time for some families of graphs. The only difference between glue- and clique-expressions is the possibility of using glue-nodes so it will suffice to extend existing dynamic-programming algorithms from the literature to glue-nodes.

## 5.1 Max Cut

In this problem, given a graph  $G = (V, E)$  we are asked about the maximum cardinality of  $E_G(V_1, V_2)$  over all partitions  $(V_1, V_2)$  of  $V$ . Fomin et al. have developed an  $n^{\mathcal{O}(\text{cw})}$  algorithm [17], which we now extend to reduced glue-expressions by showing how to deal with glue-nodes. Before this, a small remark: the correctness of their algorithm for a join-node  $t$  requires that none of edges created by  $t$  is already present in the graph. A reduced glue-expression satisfies this property so the procedures for all node types other than glue-nodes can indeed be adopted.

Their dynamic-programming tables are defined as follows. For a graph  $H$ , the table  $T_H$  contains all vectors  $h = (s_1, \dots, s_k, r)$  with  $0 \leq s_i \leq |U_i^H|$  for every  $i \in [k]$  and  $0 \leq r \leq |E(H)|$  for which there exists a partition  $(V_1, V_2)$  of  $V(H)$  such that  $|V_1 \cap U_i^H| = s_i$  for every  $i \in [k]$  and there are at least  $r$  edges between  $V_1$  and  $V_2$  in  $H$ . We say that the partition  $(V_1, V_2)$  *witnesses* the vector  $h$ . Then the output of the algorithm is the largest integer  $r$  such that  $T_G$  contains an entry  $(s_1, \dots, s_k, r)$  for some  $s_1, \dots, s_k \in \mathbb{N}_0$ . Processing a fuse-operation  $\theta_i$  applied to some subgraph  $H$  seems to be problematic in this setting for the following reason. Some vertices of label  $i$  might have common neighbors so after the application of the fuse-operator, multiple edges fall together. Given the table  $T_H$  only we cannot deduce how many of those edges were running across the partition and it is unclear how to update the table correctly. To avoid such issues, we replace fuse-nodes with glue-nodes.

Now we provide a way to compute the table  $T_H$  if  $H = H^1 \sqcup H^2$  for two glueable edge-disjoint  $k$ -labeled graphs  $H^1$  and  $H^2$  if the tables  $T_{H^1}$  and  $T_{H^2}$  are provided. Let  $\{v_1, \dots, v_q\} = V(H^1) \cap V(H^2)$  for some  $q \in \mathbb{N}_0$  and let  $i_1, \dots, i_q$  be the labels of  $v_1, \dots, v_q$  in  $H^1$ , respectively. Glueability implies that for every  $j \in [q]$ , it holds that  $|U_{i_j}^{H^1}| = |U_{i_j}^{H^2}| = 1$ . Hence, for every entry  $(s_1, \dots, s_k, r)$  of  $T_{H^1}$  and every  $j \in [q]$ , it also holds that  $s_{i_j} \in \{0, 1\}$  with  $s_{i_j} = 1$  if and only if  $v_j$  is put into  $V_1$  in the partition witnessing this entry. The same holds for the entries in  $T_{H^2}$ . This gives the following way to compute the table  $T_H$ . We initialize this table to be empty. Then we iterate through all pairs of vectors  $h^1 = (s_1^1, \dots, s_k^1, r^1)$  from  $T_{H^1}$  and  $h^2 = (s_1^2, \dots, s_k^2, r^2)$  from  $T_{H^2}$ . If there is an index  $j \in [q]$  such that  $s_{i_j}^1 \neq s_{i_j}^2$ , then we skip this pair. Otherwise, for every  $0 \leq r \leq r^1 + r^2$ , we add to  $T_H$  the vector  $h = (s_1, \dots, s_k, r)$  where for all  $i \in [k]$

$$s_i = \begin{cases} s_i^1 + s_i^2 & i \notin \{i_1, \dots, i_q\} \\ s_i^1 \cdot s_i^2 & i \in \{i_1, \dots, i_q\} \end{cases}.$$

Note that for  $i \in \{i_1, \dots, i_q\}$ , the above definition simply states that we have  $s_i = 1$  iff both  $s_i^1$  and  $s_i^2$  are equal to 1, and  $s_i = 0$  iff both  $s_i^1$  and  $s_i^2$  are equal to 0. It is not difficult to verify the correctness of this procedure. If there are no glue-vertices, then our approach coincides with the one for union-nodes by Fomin et al. If there is a glue-vertex, say  $v$ , then we consider partitions  $(V_1^1, V_2^1)$  and  $(V_1^2, V_2^2)$  of  $H^1$  and  $H^2$ , respectively, putting  $v$  on the same side. Then a partition of  $H$  naturally arises as a union  $(V_1^1 \cup V_1^2, V_1^1 \cup V_2^2)$ . Since the graphs are edge-disjoint, every edge crossing this partition crosses exactly one of the partitions  $(V_1^1, V_2^1)$  and  $(V_1^2, V_2^2)$  implying that the choice of  $r$  is correct. We refer to the full version for a formal proof.

Recall that every graph constructed from any sub-expression of  $\phi$  is a subgraph of  $G$  so the tables for graphs  $H^1$  and  $H^2$  contain  $n^{\mathcal{O}(k)}$  entries. Thus, the procedure for glue-nodes runs in time  $n^{\mathcal{O}(k)}$ . By Theorem 9 we may assume that  $\phi$  contains a polynomial number of nodes. Altogether, we obtain an algorithm solving MAX CUT in time  $n^{\mathcal{O}(\text{fw})}$ . Fomin et al. have also proven that under ETH, it cannot be solved in time  $f(\text{cw})n^{\mathcal{O}(\text{cw})}$  for any computable function  $f$  (see [17] Theorem 4.1) so our result is tight.

## 5.2 Edge Dominating Set

In this problem, given a graph  $G = (V, E)$  we are asked about the cardinality of a minimum set  $X \subseteq E$  such that every edge in  $E$  either belongs to  $X$  itself or it has an incident edge in  $X$ . Fomin et al. have developed an  $n^{\mathcal{O}(\text{cw})}$  algorithm solving this problem [17], which we now extend to reduced glue-expressions. As for MAX CUT, the algorithm requires that for any join-node, the edges created by this node are not yet present in the graph. A reduced glue-expression satisfies this property so their procedures for introduce-, join-, and relabel-nodes can be adopted.

For a  $k$ -labeled graph  $H$ , the table  $T_H$  contains all vectors  $(s_1, \dots, s_k, r_1, \dots, r_k, \ell)$  of non-negative integers such that there exists a set  $S \subseteq E(H)$  and a set  $R \subseteq V(H) \setminus V(S)$  with the following properties:

- $|S| \leq \ell \leq |E(H)|$ ;
- for every  $i \in [k]$ , exactly  $s_i$  vertices of  $U_i^H$  are incident with edges in  $S$ ;
- for every  $i \in [k]$ , we have  $|R \cap U_i^H| = r_i$ ;
- every edge of  $H$  undominated by  $S$  has an end-vertex in  $R$ .

We say that the pair  $(S, R)$  witnesses the vector  $(s_1, \dots, s_k, r_1, \dots, r_k, \ell)$  in  $H$ . The last property reflects that it is possible to attach a *pendant* edge to every vertex in  $R$  so that the set  $S$  together with these pendant edges dominates all edges of  $H$ . The size of the minimum edge dominating set of  $G$  is then the smallest integer  $\ell$  such that the table  $T_G$  contains an entry  $(s_1, \dots, s_k, 0, \dots, 0, \ell)$  for some  $s_1, \dots, s_k \in \mathbb{N}_0$ .

To complete the algorithm for the fusion-width parameterization, we provide a way to compute the table  $T_H$  if  $H = H^1 \sqcup H^2$  for two glueable edge-disjoint  $k$ -labeled graphs  $H^1$  and  $H^2$  if the tables  $T_{H^1}$  and  $T_{H^2}$  are provided. Let  $\{v_1, \dots, v_q\} = V(H^1) \cap V(H^2)$  for some  $q \in \mathbb{N}_0$  and let  $i_1, \dots, i_q$  be the labels of  $v_1, \dots, v_q$  in  $H^1$ , respectively. Then for every  $j \in [q]$ , it holds that  $|U_{i_j}^{H^1}| = |U_{i_j}^{H^2}| = 1$ . Hence, for every entry  $(s_1, \dots, s_k, r_1, \dots, r_k, \ell)$  of  $T_{H^1}$  and every  $j \in [q]$ , it holds that  $s_{i_j} + r_{i_j} \leq 1$ . The same holds for the entries in  $T_{H^2}$ . This motivates the following way to compute the table  $T_H$ . We initialize this table to be empty. Then we iterate through all pairs of vectors  $h^1 = (s_1^1, \dots, s_k^1, r_1^1, \dots, r_k^1, \ell^1)$  from  $T_{H^1}$  and  $h^2 = (s_1^2, \dots, s_k^2, r_1^2, \dots, r_k^2, \ell^2)$  from  $T_{H^2}$  and for every  $\ell^1 + \ell^2 \leq \ell \leq |E(H)|$ , we add to  $T_H$  the vector  $h = (s_1, \dots, s_k, r_1, \dots, r_k, \ell)$  defined as follows. For every  $i \in [k] \setminus \{i_1, \dots, i_q\}$ , it holds that  $s_i = s_i^1 + s_i^2$  and  $r_i = r_i^1 + r_i^2$ . And for every  $i \in \{i_1, \dots, i_q\}$ , it holds that  $s_i = s_i^1 \vee s_i^2$  and  $r_i = \neg s_i^1 \wedge \neg s_i^2 \wedge (r_i^1 \vee r_i^2)$ .

To argue the correctness, we sketch only one direction here. The other is similar and for all details refer to the full version. We now show that if  $h_1$  and  $h_2$  belong to  $T_{H^1}$  and  $T_{H^2}$ , respectively, then the vector  $h$  indeed belongs to  $T_H$ . So let  $(S^1, R^1)$  witness  $h^1$  in  $H^1$  and let  $(S^2, R^2)$  witness  $h^2$  in  $H^2$ . Then we set  $S = S^1 \cup S^2$  and construct  $R$  from  $R^1 \cup R^2$  by removing all vertices incident with  $S$ . Recall that every vertex in  $R^1$  has no incident edge in  $S^1$ . So a vertex  $v \in R^1 \setminus R$  must have an incident edge in  $S^2$  by construction and therefore, the vertex  $v$  must be a glue-vertex. The analogous is true for  $R^2 \setminus R$ . With this, one can verify that  $R$  complies with  $r_1, \dots, r_k$ . Also it is straight-forward to verify that this is true for  $S$  and  $s_1, \dots, s_k$ . The bound  $\ell^1 + \ell^2 \leq \ell$  implies that the size of  $S$  is at most  $\ell$  (when proving the other direction, we use that  $H^1$  and  $H^2$  are edge-disjoint). So it remains to show that every edge of  $H$  undominated by  $S$  has an end-point in  $R$ . Recall that  $E(H) = E(H^1) \cup E(H^2)$ . Let  $e$  be an edge of  $E(H^1)$  undominated by  $S = S^1 \cup S^2$ . Since it is not dominated by  $S^1$ , it has an end-point, say  $v$ , in  $R^1$ . By construction of  $R$ , either  $v$  still belongs to  $R$  or it has an incident edge in  $S^2$ . We have assumed that  $e$  is not dominated by  $S^1 \cup S^2$  so  $v$  belongs to  $R$  as desired. A symmetric argument applies to edges of  $H^2$ . This concludes the proof that  $h$  is an entry of  $T_H$ .

As in the previous subsection, for any subgraph  $H$  of  $G$  constructed in some sub-expression of  $\phi$ , the table  $T_H$  contains  $n^{\mathcal{O}(k)}$  entries and we obtain an algorithm solving EDGE DOMINATING SET in time  $n^{\mathcal{O}(fw)}$ . Fomin et al. have also proven that under ETH, it cannot be solved in time  $f(cw)n^{\mathcal{O}(cw)}$  for any computable function  $f$  (see [17] Theorem 5.1) so our result is tight.

### 5.3 Hamiltonian Cycle

In this problem, given a graph  $G = (V, E)$  we are asked about the existence of a cycle visiting each vertex exactly once. Our algorithm relies on the algorithm by Bergougnoux et al. [1] running in time  $f(cw)n^{\mathcal{O}(cw)}$ . A partial solution for this problem is usually a path packing, that is, a set of paths containing every vertex of the graph (constructed by the current sub-expression) exactly once. The earlier  $f(cw)n^{\mathcal{O}(cw^2)}$  algorithm by Espelage et al. stores for every pair of labels  $i$  and  $j$ , the number of paths in the path packing between a vertex with label  $i$  and a vertex with label  $j$  [14]. This naturally defines a graph on  $k$  vertices in which there is an edge for every path in the path packing. Bergougnoux et al. [1] show that instead of keeping track of all edges, it suffices to remember the degree sequence and the set of connected components of this graph. To obtain an algorithm relying on this idea they employ the technique of so-called representative sets: they define what does it mean for a set of partial solutions to be representative and then show that their procedures for nodes of a clique-expression maintain representativity.

To extend this algorithm to the parameterization by fusion-width, we describe how to handle glue-nodes. Let  $H_1$  and  $H_2$  be two edge-disjoint glueable graphs and let  $\mathcal{P}_1$  and  $\mathcal{P}_2$  be path packings of  $H_1$  and  $H_2$ , respectively. Then a natural combination of these partial solutions is the gluing  $\mathcal{P} := \mathcal{P}_1 \sqcup \mathcal{P}_2$  (a subgraph of  $H_1 \sqcup H_2$ ). Unlike a union-node (as handled in [1]), the subgraph  $\mathcal{P}$  is not necessarily a path packing: first, glue-vertices might have degree larger than 2 in  $\mathcal{P}$  and second, cycles might occur (e.g., if two paths with the same end-vertices are glued). We can show that if we iterate over all  $\mathcal{P}_1$  and  $\mathcal{P}_2$  and filter out combinations  $\mathcal{P}_1 \sqcup \mathcal{P}_2$  that are not path packings, then we obtain exactly the set of all partial solutions of  $H_1 \sqcup H_2$ . After that, we show that this approach maintains representativity. This part is very technical and we refer to the full version for all details. Let us remark that although we follow the idea by Bergougnoux et al. [1], our proof of correctness gets more involved than the one for union-nodes from their work: when gluing two graphs, the partial solutions are combined in a less trivial way than when forming a disjoint union of two graphs. The tightness is implied by [18].

## 6 Algorithms Parameterized by Multi-Clique-Width

In this section, we consider algorithms for problems parameterized by multi-clique-width. For all of these problems, SETH-tight (and for CHROMATIC NUMBER even an ETH-tight) algorithms for clique-width are known, we refer to [18, 25, 27, 21] for the corresponding lower bounds. We show that algorithms with the same running time exist relative to multi-clique-width. The clique-width lower bounds then transfer and imply the tightness of our results. As for fusion-width, Fürer observed that there exist graphs whose clique-width is exponential in their multi-clique-width [20]. So we obtain exponentially faster algorithms for some graph classes.

For our results, we rely on existing algorithms for the parameterization by clique-width and show that these (almost) do not use the fact that every vertex holds exactly one label: Some of the algorithms use clique-expressions with certain properties (e.g., so-called

*irredundancy*) though, so we need to either show that such a property holds for multi-clique-width expressions or provide an alternative way to keep the algorithm correct. Now we will sketch for each of the problems what changes need to be carried out and refer to the full version of the paper for all details. Using simple transformations we may assume that every introduce-node has form  $1\langle i \rangle$  and every relabel-node has form  $\rho_{i \rightarrow \emptyset}$  or  $\rho_{i \rightarrow \{i,j\}}$  for some  $i \neq j \in [k]$ . Also we may assume that a multi- $k$ -expression contains at most  $\mathcal{O}(k^2n)$  nodes.

For DOMINATING SET, the algorithm by Bodlaender et al. runs in time  $\mathcal{O}^*(4^{cw})$  [4] and never uses the fact that every vertex holds exactly one label. So using a straight-forward procedure to handle new relabel-nodes (of form  $\rho_{i \rightarrow \emptyset}$  and  $\rho_{i \rightarrow \{i,j\}}$ ) we obtain a  $\mathcal{O}^*(4^{mcw})$  algorithm for this problem.

The situation is similar for the CHROMATIC NUMBER algorithm by Kobler and Rotics [26]. The only minor thing one needs to handle is that the algorithm assumes that every color used by a graph coloring appears on some label: in a multi-expression, it might occur that all labels are removed from a vertex. To avoid this issue, we increase the number of labels in the expression by 1 and ensure that every vertex holds the new label at all times. Also we provide a procedure for the new relabel-nodes. Apart from that, the algorithm remains the same.

In his work, Fürer presents an algorithm for  $q$ -COLORING parameterized by multi-clique-width but it is not tight yet. For the  $q$ -COLORING problem, a naive  $\mathcal{O}^*((2^q)^{cw})$  algorithm tracks for every label the set of colors used on this label. Lampis improves this running time to  $\mathcal{O}^*((2^q - 2)^{cw})$  by observing that the empty set of colors can only be used by an empty label, while all colors can only occur if the label does not participate in any join later (such a label is called *dead*): otherwise, a monochromatic edge would occur [27]. Hegerfeld and Kratsch employ the same idea to obtain an  $\mathcal{O}^*(6^{cw})$  algorithm for CONNECTED VERTEX COVER [21]. To define *dead* labels, they rely on the existence of so-called *irredundant* clique-expression whose existence is unknown for multi-clique-width. We show that one can still make these two algorithms work for multi-clique-width by using a slightly different definition of *dead* and their counterpart, namely *active*, labels. Finally, for CONNECTED DOMINATING SET, to extend the  $\mathcal{O}^*(5^{cw})$  algorithm by Hegerfeld and Kratsch [21], there slightly more work is needed to adapt their inclusion-exclusion technique to a multi-label setting.

## 7 Conclusion

In this work, we studied two generalizations of clique-width, namely fusion-width and multi-clique-width, both introduced by Fürer [19, 20]. First, we showed that the fusion-width of a graph is an upper bound for its multi-clique-width. For the other direction, the best upper bound we are aware of is  $fw \leq 2^{mcw}$  and we leave open whether this is tight. By extending existing algorithms for clique-width, we have obtained tight algorithms parameterized by multi-clique-width for DOMINATING SET, CHROMATIC NUMBER,  $q$ -COLORING, CONNECTED VERTEX COVER, and CONNECTED DOMINATING SET. The running times are the same as for (S)ETH-optimal algorithms parameterized by clique-width.

For HAMILTONIAN CYCLE, MAXCUT, and EDGE DOMINATING SET, we were not able to achieve analogous results and these complexities remain open. Instead, we have introduced glue-expressions equivalent to fuse-expressions and then we employed them for these three problems to obtain tight algorithms parameterized by fusion-width with the same running times as ETH-optimal algorithms for clique-width.

Finally, in all algorithms we assume that a multi- $k$ -expression / fuse- $k$ -expression is provided. However, the complexity of computing these parameters is unknown. To the best of our knowledge, the best approximation would proceed via clique-width, have FPT running time, and a double-exponential approximation ratio.

## Abstract

For three decades *binary decision diagrams*, a data structure efficiently representing Boolean functions, have been widely used in many distinct contexts like model verification, machine learning, cryptography and also resolution of combinatorial problems. The most famous variant, called reduced ordered binary decision diagram (ROBDD for short), can be viewed as the result of a compaction procedure on the full decision tree. A useful property is that once an order over the Boolean variables is fixed, each Boolean function is represented by exactly one ROBDD. In this paper we aim at computing the *exact distribution of the Boolean functions in  $k$  variables according to the ROBDD size*, where the ROBDD size is equal to the number of decision nodes of the underlying directed acyclic graph (DAG) structure. Recall the number of Boolean functions with  $k$  variables is equal to  $2^{2^k}$ , which is of double exponential growth with respect to the number of variables. The maximal size of a ROBDD with  $k$  variables is  $M_k \approx 2^k/k$ . Apart from the natural combinatorial explosion observed, another difficulty for computing the distribution according to size is to take into account dependencies within the DAG structure of ROBDDs. In this paper, we develop the first polynomial algorithm to derive the distribution of Boolean functions over  $k$  variables with respect to ROBDD size denoted by  $n$ . The algorithm computes the (enumerative) generating function of ROBDDs with  $k$  variables up to size  $n$ . It performs  $O(k n^4)$  arithmetical operations on integers and necessitates storing  $O((k+n)n^2)$  integers with bit length  $O(n \log n)$ . Our new approach relies on a decomposition of ROBDDs layer by layer and on an inclusion-exclusion argument.

## 1 Introduction

Three decades ago a central data structure in computer science, designed to represent Boolean functions, emerged under the name of Binary Decision Diagrams (or BDDs) [1]. Their algorithmic paradigm gives great advantages: it is based on a *divide-and-conquer* approach combined with a compaction process. Their benefits compared to other Boolean representations are so obvious that several dozens of BDD variants have been developed

in recent years. In his monograph [16], Wegener presents several ones like ROBDDs [2], OKFBDDs [5], QOBDDs [15], ZBDDs [10], and others. While most of these data structures are used in the context of verification [16], they also appear, for example, in the context of cryptography [9] or knowledge compilation [4]. Also, the size of the structure, depending on the compaction of a decision tree, allows improving classification in the context of machine learning [11]. Finally, some specific BDDs are relevant to strategies for the resolution of combinatorial problems, cf. [8, vol. 4], like the classical satisfiability count problem.

The classical way to represent the different diagrams consists in their embedding as directed acyclic graphs (or DAGs). In the following we are interested in the original form of decision diagrams that are ROBDDs, for *Reduced Ordered Binary Decision Diagrams*. One of their fundamental properties relies on the single, thus canonical, representative property for each Boolean function (with a given order over the Boolean variables). In his book [8] Knuth recalls and proves several combinatorial results for ROBDDs. He is, for example, interested in the profile of a typical ROBDD, or in the way to combine two structures to represent a more complex Boolean function. However, thirty years after the takeoff of ROBDDs, the study of the distribution of Boolean functions with respect to the size, defined as the number of decision nodes (see Figure 2), of the DAG structure is not totally understood. The main problem is that no recursive characterization describing the structure of ROBDDs is known, as opposed, for instance, to the recursive decomposition of binary trees which is the core approach in their combinatorial studies (profile, width, depth).

**Related work.** An important step in the comprehension of the distribution of the Boolean functions according to their ROBDD size has been achieved by Wegener [15] and improved by Gröpl *et al.* [7]. These authors proved that almost all functions have the same ROBDD size up to a factor of  $1 + o(1)$  when the number of variables  $k$  tends to infinity, exhibiting the Shannon effect (strong or weak depending on the value of  $k$ ). The strong (respectively weak) Shannon effect states that almost all functions have the same ROBDD size as the largest ROBDDs up to a factor of  $1 + f(k)$  with  $f(k) = o(1)$  (resp.  $f(k) = \Omega(1)$ ) as  $k$  tends to infinity (see also [14]). The reader may find an illustration of this phenomenon in Figure 1 with the plot of the exact distribution for  $k = 13$  variables. A consequence of these first analyses is that picking *uniformly at random* a Boolean function whose ROBDD is small is not an easy task, although in practice ROBDDs are often not of exponential size (with respect to  $k$ ).

In [12], the authors study, experimentally, numerically, and theoretically, the size of ROBDDs when the number  $k$  of variables is increasing. However, their main approach relies on an exhaustive enumeration of the decision trees of all Boolean functions, that are in a second step compressed into ROBDDs. The doubly exponential growth of Boolean functions over  $k$  variables, equal to  $2^{2^k}$ , allows only to compute the first values for  $k = 1, \dots, 4$ . Then the authors extrapolate the distributions by sampling decision trees (uniformly at random).

Later in the paper [3] we obtain similar combinatorial results. Using a new approach based on a partial recursive decomposition, we partition the ROBDDs according to their profile (which describes the number of nodes per level in the DAG). Another key feature of [3] is that we can restrict ourselves to a maximal size  $n$  for ROBDDs, as opposed to the exhaustive-oriented approach of [12]. Although more efficient, still algorithms with this approach are bound to be at least of complexity  $\Omega(n k^{3/2 \cdot k^2 / \log k})$ , while using a huge amount of extra memory. However, after a lengthy computation we obtain the exact distributions of the size of ROBDDs up to  $k = 9$ , thus partitioning the set of  $2^{512}$  Boolean functions into ROBDDs of sizes ranging from 0 to 141.

**Main results.** In this paper, we describe an algorithm that calculates the exact distribution for ROBDDs up to size  $n$  in time complexity  $O(k n^4)$  using  $O((n+k)n^2)$  extra storage memory for integers. To the best of our knowledge, this is the first polynomial complexity algorithm computing the distribution of the ROBDD size for Boolean functions. Our combinatorial approach is based on an iteration process instead of a recursive approach.

We improve drastically on previous work and all the extrapolated results presented in [12] for Boolean functions up to 13 variables are now fully and exactly described. Using a personal computer, in a couple of minutes we obtain an exhaustive counting of the ROBDDs representing functions over 11 variables. With a computer with several hundreds gigabytes of RAM we compute the distribution over 13 variables in about a day. Indeed, we partition the  $2^{8192}$  Boolean functions according to their ROBDDs size (which ranges from 0 to 1277).

In Figure 1 the exact distribution is depicted in two ways of presentation: a red point  $(x, y)$  states that  $2^y$  functions have a ROBDD size  $x$ , in logarithmic scale; the blue curve is the probability distribution.

■ **Figure 1** The ROBDD size distribution of Boolean functions in 13 variables. The exact distribution is depicted in two ways of presentation: the red curve is the logarithmic scale of the distribution; the blue curve is the probability distribution.

**Organization of the paper.** In Section 2 we present the formal notions and objects necessary for the description of our counting approach. Section 3 presents the iterative process for computing the number of ROBDDs having a given profile (the profile describes the number of decision nodes labelled with each variable). Section 3 also states the main result of this paper which is a formula for computing the number of ROBDDs involving linear maps over a polynomial ring. Finally, Section 4 presents the algorithmic context for computing the complete distribution (under the form of the enumerative generating function [6] of ROBDDs).

## 2 Preliminaries

A Boolean function in  $k$  variables is a function from the set  $\{0, 1\}^k$  into the set  $\{0, 1\}$ . The set of functions is denoted by  $\mathcal{B}_k$  and its cardinality is  $2^{2^k}$ . Furthermore, for the rest of this paper, we choose an ordering of the sequence of variables that corresponds to  $x_1, x_2, \dots, x_k$ . Any other ordering could be chosen, but one must be fixed.

### 2.1 Boolean functions representation

Figure 2 shows a decision tree representing a 4-variable Boolean function and its associated ROBDD. In both structures, traversing a path from the root to a leaf allows to evaluate the function for a given assignment. Being in a node labelled by  $x_i$  and going to its low child (using the dotted edge) corresponds with evaluating  $x_i$  to 0; going to its high child (using the solid edge) corresponds with evaluating  $x_i$  to 1.

■ **Figure 2 (left)** A decision tree and **(right)** its associated ROBDD.

► **Definition 1 (DAG representation).** Let  $f \in \mathcal{B}_k$  be a Boolean function in variables  $x_1, \dots, x_k$ . The function  $f$  can be represented as a rooted directed acyclic graph (DAG for short) composed of internal decision nodes, labelled by variables and two terminal nodes labelled by  $\{\perp, \top\}$  representing respectively the constants 0 and 1. Each decision node labelled by  $x_i$  has two children, the low child (resp. high child) such that traversing the edge to the low child (resp. high child) corresponds to assign  $x_i$  to 0 (resp. to 1). The size of a DAG is its number of decision nodes.

► **Definition 2 (OBDD).** Let  $f \in \mathcal{B}_k$  and pick one of its DAG representation. The DAG is called an Ordered Binary Decision Diagram for  $f$  (OBDD for short) when all paths from the root to a terminal node traverse decision nodes with index in increasing order.

By taking an OBDD for a function with a pointed decision node  $\nu$  labelled by  $x_i$ , and extracting the sub-DAG rooted in  $\nu$  by taking all its descendants, we obtain an OBDD representing a Boolean function in the variables  $x_i, x_{i+1}, \dots, x_k$ .

► **Definition 3 (ROBDD).** Let  $f \in \mathcal{B}_k$  and let  $B$  be one of its OBDD. If all sub-DAGs of  $B$  are representing distinct Boolean functions, then  $B$  is called Reduced Ordered Binary Decision Diagram (ROBDD).

Figure 3 shows the forbidden configurations in ROBDD and the operations used to compress the structure.

■ **Figure 3** The two forbidden configurations in ROBDDs and the resulting operations when compressing: **(left)**  $\nu$  and  $\nu'$  are merged; **(right)**  $\nu$  is deleted (from [7]).

► **Fact.** *Let  $f \in \mathcal{B}_k$ , there exists a single ROBDD representing  $f$ .*

The data structure of ROBDDs is especially famous due to this property of canonicity<sup>1</sup>. The reader may read Knuth [8] for the proof of uniqueness and several other properties satisfied by ROBDDs.

For the rest of the paper we are only dealing with ROBDDs. Furthermore, we take the point of view of layered ROBDD by studying and representing ROBDDs layer by layer: each layer contains all decision nodes labelled by the same variable. This layer-by-layer decomposition is natural since the variables are ordered. Thus, a ROBDD for a function in  $k$  variables is composed of  $k$  layers (plus a layer for the two terminal nodes). Note that a layer could be empty (which means the Boolean function does not depend on the particular variable associated to this layer).

► **Definition 4** (ROBDD's profile). *Let  $f \in \mathcal{B}_k$  and let  $B$  be its ROBDD. Using the layer-by-layer point of view, we define the profile  $B$  to be the non-negative integer sequence  $[p_1, p_2, \dots, p_k]$  such that  $p_i$  is the number of nodes labelled by  $x_i$  in  $B$ , i.e. the size of the layer corresponding to  $x_i$ , for all  $i \in \{1, \dots, k\}$ .*

## 2.2 Combinatorial description

In our previous paper [3] we proposed a kind of recursive decomposition of a ROBDD based on the low and high children of the root. Here we propose a new and simpler point of view, based on a layer-by-layer description, which is much more efficient for the counting problem (also for the generating problem). We need to introduce a generalization of a ROBDD, called multientry ROBDDs, which corresponds exactly to the structure obtained by removing some upper layers in a standard ROBDD (see Figure 4 for an example).

Informally a multientry ROBDD is a structure obtained by cutting off a certain number of the top layers of a ROBDD. The resulting structure is still a DAG, but with several sources. We also keep track of where the half-edges from the top layers were pointing. In Figure 4 a ROBDD and multientry ROBDD obtained by removing the 3 top layers are depicted.

► **Definition 5** (Multientry ROBDD). *A multientry ROBDD  $M$  with at most  $k \geq 0$  variables and size  $n \geq 0$  is a couple  $(M, \mathfrak{E})$ . The structure  $M$  is a layered DAG structure with  $n$  decision nodes  $\mathcal{Q}$  distributed on  $k$  layers and two constant nodes  $\{\top, \perp\}$  such that any two subgraphs are non-identical (as in ROBDDs). The multiset  $\mathfrak{E}$  has its elements in  $\mathcal{Q} \cup \{\top, \perp\}$  and is such that any source node in  $M$  (i.e., having in-degree 0), must appear at least once. The nodes in  $\mathfrak{E}$  are called distinguished (and correspond with destination nodes of red half-edges in Figure 4).*

As a special case, a ROBDD is a multientry ROBDD having one source (the root) and a multiset  $\mathfrak{E}$  reduced to the root (with multiplicity 1).

In the multientry ROBDD in Figure 4, by numbering the nodes from top to bottom and from left to right, i.e. the leftmost  $x_4$  is number 1, the second  $x_4$  is 2, the rightmost  $x_4$  is 3, the rightmost  $x_5$  is 4,  $\dots$ ,  $x_6$  is 7 and  $\perp$  and  $\top$  are respectively 8 and 9, we obtain the multiset  $\mathfrak{E} = \{1, 2, 2, 3, 4, 4, 5\}$ . We note that our definition of multientry ROBDD is similar (but not exactly identical) to the one of *shared*-BDDs presented by Knuth [8] to represent several Boolean functions in the same decision diagram.

Furthermore, remark that the same multientry ROBDD can be exhibited by cutting off top layers (not even the same number) of different ROBDDs.

<sup>1</sup> Uniqueness of the ROBDD for  $f$  is ensured when a variable ordering is fixed.

■ **Figure 4** A ROBDD of size 13 (not counting the constant nodes  $\{\perp$  and  $\top\}$ ), with 6 variables and profile  $\mathbf{p} = [1, 2, 3, 3, 3, 1]$ . **(left)** A DAG representation of the ROBDD; **(right)** Cutting off top three layers, we obtain the multientry ROBDD keeping track with red half edges of nodes which were disconnected.

### 3 Full iterative counting formula

In the following we describe an approach to counting the number of ROBDDs with a given profile  $\mathbf{p}$ . We use a powerful algebraic representation to encapsulate a kind of inclusion-exclusion principle. This motivates the definition of a linear application on polynomials using substitutions. The linearity property of the applications is crucial for achieving our algorithm polynomial complexity. We consider the polynomial ring  $\mathbb{Z}[X]$  and linear endomorphisms over  $\mathbb{Z}[X]$  (i.e., linear maps between  $\mathbb{Z}[X]$  and  $\mathbb{Z}[X]$ ). Thus, for a linear map  $g : \mathbb{Z}[X] \rightarrow \mathbb{Z}[X]$  and two polynomials  $P$  and  $Q$  in  $\mathbb{Z}[X]$ ,  $g[P + Q] = g[P] + g[Q]$ , and for any scalar  $\lambda \in \mathbb{Z}$  and polynomial  $P \in \mathbb{Z}[X]$  we have  $g[\lambda P] = \lambda g[P]$ .

In the following theorem, we state the main result of the paper which gives access to the number of multientry ROBDDs for a given profile.

► **Theorem 6** (Multientry ROBDDs counting formula). *For the family of linear maps  $(\phi_r)_{r \geq 0}$ , each mapping  $\phi_r : \mathbb{Z}[X] \rightarrow \mathbb{Z}[X]$  is defined with respect to the canonical basis  $(X^m)_{m \geq 0}$  by*

$$\phi_r[X^m] = \left( \prod_{i=0}^{r-1} (X^2 - X - i) \right) \cdot \left( \sum_{j=0}^{m-r} \binom{m}{j} \left\{ \begin{matrix} m-j \\ r \end{matrix} \right\} X^j \right). \tag{1}$$

Let  $M(\mathbf{p}, m)$  be the number of multientry ROBDDs with profile  $\mathbf{p} = [p_1, \dots, p_k]$  and  $m$  incoming half edges. We have, for  $k \geq 0$ ,

$$M(\mathbf{p}, m) = (\phi_{\mathbf{p}}[X^m])_{X=2}, \tag{2}$$

where

- $\phi_{\mathbf{p}}$  is the composition product  $\phi_{p_k} \circ \phi_{p_{k-1}} \circ \dots \circ \phi_{p_1}$ ;
- for a polynomial  $P \in \mathbb{Z}[X]$ ,  $(P)_{X=2}$  is the evaluation of  $P$  at  $X = 2$ .

In the theorem,  $\binom{m}{j}$  stands for the binomial coefficient and  $\left\{ \begin{matrix} n \\ k \end{matrix} \right\}$  is the Stirling number of the second kind counting the number ways to partition a set of  $n$  objects into  $k$  non-empty subsets.

► **Remark 7.** This is actually a stronger result than what we need for counting ROBDDs, since the number of ROBDDs corresponds to the special case where  $\mathbf{p} = [p_1 = 1, p_2, \dots, p_k]$  and  $m = 1$  (meaning there is one source node in the top layer). However, the fact that we are able to compute  $\phi_{\mathbf{p}}$  on the basis  $(X^m)_{m \geq 0}$  is key to our approach.

The detailed proof of Theorem 6 is deferred to after an example of such a computation.

► **Example.** Let us consider a profile  $\mathbf{p} = [1, 2, 4, 2]$  for 4 variables  $x_1, x_2, x_3, x_4$  and choosing  $m = 1$  in (2). Then, for  $1 \leq i \leq 4$ , we compute iteratively  $\phi_{p_i} \circ \dots \circ \phi_{p_1}(X)$ :

$$\begin{aligned} X &\stackrel{\phi_1}{\mapsto} X^2 - X \\ &\stackrel{\phi_2}{\mapsto} X^4 - 2X^3 + X \\ &\stackrel{\phi_4}{\mapsto} X^8 - 4X^7 + 14X^5 - 6X^4 - 16X^3 + 5X^2 + 6X \\ &\stackrel{\phi_2}{\mapsto} 28X^{10} + 28X^9 - 98X^8 - 112X^7 + 76X^6 + 92X^5 - 12X^4 - 8X^3 + 6X^2. \end{aligned}$$

Evaluating the last polynomial at  $X = 2$ , we get that there are 11 160 ROBDDs with profile  $[1, 2, 4, 2]$ . The power of our approach is that we could have stopped at any iteration, and still get the number of ROBDDs for the considered truncated profile. On the particular example this yields

$\mathbf{p}$	$\phi_{\mathbf{p}}$	$(\phi_{\mathbf{p}})_{X=2}$
$[\ ]$	$X$	2
$[1]$	$X^2 - X$	2
$[1, 2]$	$X^4 - 2X^3 + X$	2
$[1, 2, 4]$	$X^8 - 4X^7 + 14X^5 - 6X^4 - 16X^3 + 5X^2 + 6X$	0
$[1, 2, 4, 2]$	$28X^{10} + 28X^9 - 98X^8 - 112X^7 + 76X^6 + 92X^5 - 12X^4 - 8X^3 + 6X^2$	11 160

The number 0 when considering  $[1, 2, 4]$  may seem counterintuitive at first, but indeed a ROBDD can only have up to 2 nodes on its last layer, otherwise one node has to be a duplicate of another.

**Proof of Theorem 6.** (Multientry ROBDDs counting formula). The proof is obtained by induction on the number  $k \geq 0$  of layers with decision nodes.

**Base case.** When  $k = 0$  and  $n \geq 0$ . The number of multientry ROBDDs is  $M([\ ], m) = 2^m$ , i.e.,  $X^m$  evaluated at  $X = 2$ , as we must map the  $m$  half edges to either one of the two constants. Note that if  $m = 0$  then  $M([\ ], m) = 1$  corresponding to the void function (which is a special case).

**Induction step.** Now suppose Theorem 6 is true for  $k \geq 0$ .

Let us consider a profile of length  $k + 1$  as  $[r] \cdot \mathbf{p}$  with  $r \geq 0$  and  $\mathbf{p}$  a profile of length  $k$ .

- If  $r = 0$ , a simple computation shows that  $\phi_0$  is the identity. Hence, the empty layer can in fact be omitted since

$$\phi_{\mathbf{p}} \circ \phi_0 [X^m] = \phi_{\mathbf{p}} [X^m], \quad \text{so that } M([0] \cdot \mathbf{p}, m) = M(\mathbf{p}, m). \tag{3}$$

- From now on let us suppose  $0 < r \leq m$ . The set of  $m$  half edges pointing at the first layer can be decomposed in two subsets for  $j \in \{0, \dots, m - r\}$ :  $j$  entries will go to layers below the first one, and  $m - j$  entries will be mapped to the  $r$  nodes of the first layer. A Stirling number of the second kind  $\left\{ \begin{smallmatrix} n \\ k \end{smallmatrix} \right\}$  counts the number of ways to partition a set of  $n$  objects into  $k$  non-empty subsets. So there are  $\binom{m}{j} \cdot \left\{ \begin{smallmatrix} m-j \\ r \end{smallmatrix} \right\}$  such partitions. We write

$$M([r] \cdot \mathbf{p}, m) = \sum_{j=0}^{m-r} \binom{m}{j} \left\{ \begin{smallmatrix} m-j \\ r \end{smallmatrix} \right\} f_{\mathbf{p}}^{(r)}(j), \tag{4}$$

## 36:8 An Iterative Approach for Counting ROBDDs

where  $f_{\mathbf{p}}^{(r)}(j)$  denotes the number of multientry ROBDDs with  $j$  free half edges and  $r$  pairs of half edges (the ones resulting from the  $r$  nodes of the first layer). These  $2r$  half edges must thus obey the following constraints:

- in each pair, the two half edges must be distinct, i.e., point to different nodes;
- all  $r$  pairs of half edges must be distinct with one another (as pairs).

Our goal now is to get rid of the constraints coming from these  $r$  nodes and express all quantities in terms of free half edges.

The following equation translates the previous constraints on the pair of adjacent half edges coming from the first of the  $r$  nodes

$$f_{\mathbf{p}}^{(r)}(j) = f_{\mathbf{p}}^{(r-1)}(j+2) - f_{\mathbf{p}}^{(r-1)}(j+1) - (r-1)f_{\mathbf{p}}^{(r-1)}(j). \quad (5)$$

Indeed, the first term  $f_{\mathbf{p}}^{(r-1)}(j+2)$  corresponds in adding 2 free half edges, and results in overcounting. Then following an inclusion-exclusion principle, firstly we subtract  $f_{\mathbf{p}}^{(r-1)}(j+1)$  which would count the number of configurations if the two half edges in this pair were merged. Finally, we subtract  $(r-1)f_{\mathbf{p}}^{(r-1)}(j)$  in (5). This last quantity counts the number of configurations if the pair of half edges was merged with one of the  $r-1$  remaining ones (hence  $r-1$  choices). Note that no additional free half edge is added because of this merge. This yields (5).

Solving the simple recurrence (5) with respect to  $r$  yields

$$f_{\mathbf{p}}^{(r)}(j) = \sum_{i=0}^{2r} a_i f_{\mathbf{p}}^{(0)}(i+j), \quad (6)$$

where coefficients  $(a_i)$  are obtained by identifying  $P(X) = \prod_{i=0}^{r-1}(X^2 - X - i) = \sum_{i=0}^{2r} a_i X^i$ . At this point, we remark the equality true for  $m \geq 0$

$$M(\mathbf{p}, m) = f_{\mathbf{p}}^{(0)}(m), \quad (7)$$

which reflects the fact that in  $M(\mathbf{p}, m)$ , all  $m$  half edges are unconstrained. Then (4) rewrites

$$M([r] \cdot \mathbf{p}, m) = \sum_{j=0}^{m-r} \binom{m}{j} \left\{ \begin{matrix} m-j \\ r \end{matrix} \right\} \sum_{i=0}^{2r} a_i M(\mathbf{p}, i+j) = \sum_{i=0}^{m+r} c_i M(\mathbf{p}, i),$$

with coefficients  $c_i$  obtained by identifying  $\sum_{i=0}^{m+r} c_i X^i = \phi_r(X^m)$  from (1).

By induction hypothesis on the length  $k$  of  $\mathbf{p}$  we have for  $0 \leq i \leq m+r$

$$M(\mathbf{p}, i) = (\phi_{\mathbf{p}} [X^i])_{X=2}. \quad (8)$$

By linearity

$$\sum_{i=0}^{m+r} c_i \phi_{\mathbf{p}} [X^i] = \phi_{\mathbf{p}} \left[ \sum_{i=0}^{m+r} c_i X^i \right] = \phi_{\mathbf{p}} [\phi_r [X^m]] = \phi_{\mathbf{p}} \circ \phi_r [X^m],$$

and finally

$$M([r] \cdot \mathbf{p}, m) = \sum_{i=0}^{m+r} c_i M(\mathbf{p}, i) = \sum_{i=0}^{m+r} c_i (\phi_{\mathbf{p}} [X^i])_{X=2} = (\phi_{\mathbf{p}} \circ \phi_r [X^m])_{X=2}$$

This ends the proof. ◀

## 4 Counting algorithms

In this section, we present an algorithm for counting ROBDDs of size  $n$ .

*The time and space complexities are measured respectively in terms of arithmetical operations on  $\mathbb{Z}$  and memory space used to store integers in  $\mathbb{Z}$ . When considering ROBDDs of size upper bounded by  $n$ , all integers in  $\mathbb{Z}$  involved can be checked to be of bit length  $O(n \log n) = O(\log n!)$ .*

The reader can find an implementation of the following algorithms at <https://github.com/agenitrini/BDDgen>.

### 4.1 Linear maps: precomputation step

A first step is to pre-compute a representation of linear maps  $(\phi_r)_{r \geq 0}$ . For a ROBDD of size  $n$  we know that the maximal number of half edges is  $n + 1$ , and the maximal number of nodes on a layer is also loosely upper bound by  $n$ . Hence, it is sufficient to compute  $\phi_r[X^m]$  in  $\mathbb{Z}[X]$  for  $0 \leq r \leq n$  and  $0 \leq m \leq n + 1$ . In the form of (1),  $\phi_r[X^m]$  is equal to  $P_r(X)Q_{r,m}(X)$  with

$$P_r(X) = \prod_{i=0}^{r-1} (X^2 - X - i), \quad \text{and} \quad Q_{r,m}(X) = \sum_{j=0}^{m-r} \binom{m}{j} \left\{ \begin{matrix} m-j \\ r \end{matrix} \right\} X^j.$$

So the first step is to compute coefficients of  $P_r(X)$  and  $Q_{r,m}(X)$ . Concerning binomial coefficient and Stirling numbers of the second kind, both tables can be computed by a naive algorithm (for binomials, it is the famous Pascal's triangle) in space  $O(n^2)$  with  $O(n^2)$  arithmetic operations on integers.

Once these coefficients are available, we compute the products  $\phi_r[X^m] = P_r(X)Q_{r,m}(X)$ . Computing  $P_r$  from  $P_{r-1}$  necessitates  $O(n)$  arithmetical operations on integers, yielding a total  $O(n^2)$  number of arithmetical operations for the whole family  $(P_r)_{r \leq n}$ . Each polynomial  $(Q_{r,m})$  necessitates  $O(n)$  arithmetical operations per polynomial (supposing binomial coefficients and Stirling number of the second kind are precomputed). Finally,  $\phi_r[X^m]$  is computed with  $O(n^2)$  arithmetical operations (by a naive product of two polynomials). There are  $O(n^2)$  such polynomials to compute. Hence, we get a total  $O(n^4)$  of arithmetic operations using  $O(n^3)$  storage memory space for coefficients. We thus get the next lemma.

► **Lemma 8** (Precomputing step: linear maps). *The precomputation step for the representation of linear maps by computing  $\phi_r[X^m]$  for  $0 \leq r \leq n$  and  $0 \leq m \leq n + 1$  necessitates  $O(n^4)$  arithmetical operations on integers and uses memory space for  $O(n^3)$  coefficients in  $\mathbb{Z}$ .*

### 4.2 Basic counting

The basic block in our approach is to be able to compute  $\phi_r[P]$  for  $r \geq 0$ . This is done by Algorithm 1 which is a direct translation of Theorem 6 using the linearity of the linear maps  $(\phi_r)_r$ .

► **Proposition 9** (Complexity of basic step). *Let  $P$  be a polynomial of degree  $d$ . Algorithm 1 computes  $\phi_r[P]$  and performs  $O(rd + d^2)$  arithmetical operations over  $\mathbb{Z}$  to compute  $\phi_r[P]$ , using  $O(d^2)$  memory space<sup>2</sup>.*

<sup>2</sup> Recall in Proposition 9 we do not take into account the precomputation step of the family  $(\phi_r[X^m])_r$ .

**Algorithm 1** Computing  $\phi_r[P]$ .

---

**Input:** an integer  $r \geq 0$ , a polynomial  $P(X) = \sum_{m=0}^d p_m X^m \in \mathbb{Z}[X]$   
**Output:**  $\phi_r[P] \in \mathbb{Z}[X]$   
 $Q \leftarrow 0$   
**for**  $m$  **from**  $r$  **to**  $d$  **do**  
    $Q \leftarrow Q + p_m \phi_r[X^m]$   
**return**  $Q$

---

**Algorithm 2** Computing  $(\phi_{\mathbf{p}}[X])_{X=2}$ .

---

**Input:** a profile  $\mathbf{p} = [p_1, \dots, p_k]$   
**Output:** the number of ROBDDs with profile  $\mathbf{p}$   
 $P \leftarrow X$   
**for**  $i$  **from** 1 **to**  $k$  **do**  
    $P \leftarrow \phi_{p_i}[P]$   
**return**  $P(2)$

---

**Proof.** Each polynomial  $\phi_r[X^m]$  is of degree  $r + m = O(r + d)$ . Thus, the number of operations needed on coefficients is  $O(rd + d^2)$  if  $r > 0$  (or  $O(1)$  if  $r = 0$  since  $\phi_0$  is the identity). ◀

By Remark 7 and applying Theorem 6, it is straightforward to compute the number of ROBDDs with profile  $\mathbf{p} = [p_1, \dots, p_k]$  (using  $m = 1$ ). The pseudocode is given in Algorithm 2. We have the following proposition.

► **Proposition 10.** *Algorithm 2 computes the number of ROBDDs of size  $n$  with  $k$  variables and given profile  $\mathbf{p}$ . It performs  $O(k n^2)$  arithmetical operations over  $\mathbb{Z}$  and uses  $O(n)$  extra memory space to store integers.*

**Proof.** The number of ROBDDs is  $(\phi_{\mathbf{p}}[X])_{X=2}$ . The polynomial  $\phi_{\mathbf{p}}[X]$  is computed by iterating  $k$  times a linear map of type  $\phi_r$  starting from an initial polynomial  $X$ . By Proposition 9, the algorithm performs  $O(n^2)$  operations for each iteration since polynomials have  $O(n)$  coefficients. The total computation thus performs  $O(k n^2)$  arithmetical operations over  $\mathbb{Z}$  and use  $O(n)$  memory space to store coefficients. Evaluating  $(\phi_{\mathbf{p}}[X^m])_{X=2}$  at  $X = 2$  can be done in time complexity  $O(n)$  (by Horner's method for instance). ◀

### 4.3 Generating function for ROBDD size

The main goal of this section is compute the distribution of Boolean functions in  $k$  variables according to the ROBDD size. For  $f \in \mathcal{B}_k$  a Boolean function, we let  $\lambda(f)$  be the size of its ROBDD, i.e., its number of decision nodes. A convenient way to represent the distribution of the size  $\lambda$  on  $\mathcal{B}_k$  consists in computing the generating function [6]

$$F_k(u) = \sum_{f \in \mathcal{B}_k} u^{\lambda(f)} = \sum_{i \geq 0} f_i u^i,$$

where  $u$  is a formal variable marking the size. Then for  $i \geq 0$ , the coefficient  $f_i = [u^i]F_k(u)$  is the number of ROBDDs of size  $i$  with  $k$  variables, i.e. the notation  $[u^i]F_k(u)$  corresponds to the coefficient-extraction of the monomial  $u^i$ . We also introduce the truncation  $F_k^{\leq n}(u) = \sum_{0 \leq i \leq n} f_i u^i$  as the generating functions of ROBDDs of size less than or equal to  $n$ .

We first extend the formalism introduced in Section 3 and define a linear map  $\varphi : \mathbb{Z}[u, X] \rightarrow \mathbb{Z}[u, X]$ .

► **Definition 11.** *The linear map  $\varphi : \mathbb{Z}[u, X] \rightarrow \mathbb{Z}[u, X]$  is defined via its action on the basis  $(u^r X^m)_{r, m \geq 0}$  as*

$$\varphi : u^r X^m \mapsto \varphi[u^r X^m] = \sum_{i=0}^{m+1} u^{r+i} \phi_i[X^m]. \quad (9)$$

With this notation we have the following proposition.

► **Proposition 12** (Generating function for ROBDD size). *The generating function enumerating Boolean functions by considering the ROBDD size is given by*

$$F_k(u) = (\varphi^k[X])_{X=2}, \quad \text{where } \varphi^k \text{ denotes the composition product } \underbrace{\varphi \circ \dots \circ \varphi}_{k \text{ times}}$$

**Proof.** Each application of  $\varphi$  corresponds with adding a layer. The formal variable  $u$  marks the number of decision nodes added on the current layer. ◀

We remark that in practice we can truncate polynomials, keeping only the terms useful along the computation. The key point here is that if we consider ROBDDs with size bounded by  $n$ , we should make all computation modulo  $u^{n+1}$ . Indeed, the formal variable  $u$  marks the number of nodes (which is bounded by  $n$ ). Sections A.1 and A.2 in the appendix illustrate this point.

Algorithm 3 computes the bivariate polynomial  $\varphi[X^m]$  for  $m \geq 0$ . Algorithm 4, computes recursively the iterated (univariate) version  $(\varphi^\ell[X^m])_{X=2}$  (that is the evaluation at  $X = 2$ ).

■ **Algorithm 3** Computing  $\varphi[X^m]$ .

     $M \leftarrow (\varphi^{\ell-1}[X^j])_{X=2}$  ▷ Call Alg. 4  
     $N \leftarrow [X^j] R(u, X)$  ▷  $N \in \mathbb{Z}[u]$   
     $Q \leftarrow Q + M \cdot N$   
**return**  $Q$

---

► **Lemma 13.** *Algorithm 3 computes  $\varphi[X^m] \in \mathbb{Z}[X, u]$ , which has  $O(n^2)$  integer coefficients. It performs  $O(n^2)$  arithmetical operations over  $\mathbb{Z}$ .*

*Algorithm 4 computes  $(\varphi^\ell[X^m])_{X=2} \in \mathbb{Z}[u]$ , which has  $O(n)$  coefficients. If we omit recursive calls, it performs  $O(n^3)$  arithmetical operations over  $\mathbb{Z}$ , using memoization techniques with  $O((n+k)n^2)$  extra memory storage.*

**Proof.** For Algorithm 3, we perform  $m = O(n)$  additions of polynomials in  $\mathbb{Z}[X, u]$  with  $O(n)$  terms, yielding  $O(n^2)$  arithmetical operations over  $\mathbb{Z}$ . The result is a bivariate polynomial of bounded degree ( $n$  for the variable  $u$ ,  $2n$  for the variable  $X$ ) yielding  $O(n^2)$  coefficients. We suppose Algorithm 3 has access to polynomials  $\phi_r[X^m] \in \mathbb{Z}[X]$  from a precomputation step.

For Algorithm 4, two ingredients are essential. Firstly we have to truncate polynomials modulo  $u^{n+1}$  so that operations on univariate polynomials have complexity  $O(n)$  for addition and  $O(n^2)$  for multiplication (using the naive multiplication on polynomials). Secondly we also use memoization techniques (meaning we compute in lazy manner intermediate results only once and keep it for further reference, at the expense of memory storage). That means that we consider that at the time we compute  $(\varphi^\ell[X^m])_{X=2}$ , the polynomials  $(\varphi^{\ell-1}[X^j])_{X=2}$  are available (i.e., their complexity is taken into account independently). By an amortizing argument, the complexity of computing the complete family of polynomials  $(\varphi^\ell[X^m])_{X=2}$

## 36:12 An Iterative Approach for Counting ROBDDs

$(0 \leq \ell \leq k$  and  $0 \leq m \leq n + 1)$  is still  $O(n^3)$  arithmetical coefficients per polynomial. We need to store  $O(kn^2)$  integer coefficients for memoization of all intermediate polynomials. We also suppose Algorithm 4 has access to bivariate polynomials  $(\varphi[X^m] \in \mathbb{Z}[u, X])_{0 \leq m \leq n+1}$  from a precomputation step which requires  $O(n^3)$  memory space for integer coefficients. A subtle point is to understand that we can truncate polynomials at each step in Algorithm 4 and still get the correct result: this can be proved by recurrence on  $\ell$  (see also Section A.2 of the appendix for an example). ◀

Algorithm 4 also computes the generating function of ROBDDs for size up to  $n$  since posing  $\ell = k$  and  $m = 1$  we have

$$F_k^{\leq n}(u) = (\varphi^\ell[X])_{X=2} \pmod{u^{n+1}}.$$

► **Theorem 14** (Algorithm for computing the exact distribution). *We compute the generating function  $F_k^{\leq n}(u)$  of Boolean functions in  $\mathcal{B}_k$  for ROBDDs of size less than or equal to  $n$  using  $O(k n^4)$  arithmetical operations in  $\mathbb{Z}$  and  $O((k+n)n^2)$  for memory space storing integers.*

**Proof.** From Lemmas 13 and 8, the overall complexity is dominated by the computation of the family  $(\phi_r[X^m])_{r,m}$  and the calls to Algorithm 4. By Lemma 13, each polynomial  $(\varphi^\ell[X^j])_{X=2}$  is computed with  $O(n^3)$  arithmetic operations on integer coefficients and there are  $O(k n)$  such polynomials. Hence, the total number operations over  $\mathbb{Z}$  is  $O(k n^4)$ . Furthermore, we store  $O(k n^2)$  coefficients in  $\mathbb{Z}$  for memoization. We also store  $O(n^3)$  coefficients for the family  $(\phi_r[X^m])_{m,r} \in \mathbb{Z}[X]$ . This yields the claimed complexity. ◀

To evaluate the complete size distribution we need to consider the size of largest ROBDDs with  $k$  variables.

► **Theorem 15** (Maximal size of ROBDDs). *Let  $k \geq 1$  be an integer, the maximal number of nodes in a ROBDD with at most  $k$  variables is*

$$M_k = 2^{k-\theta} - 3 + 2^{2^\theta}, \quad \text{with } \theta = \lfloor \log_2(k - \lfloor \log_2(k) \rfloor) \rfloor.$$

*The generating function  $F_k(u)$  of Boolean functions in  $\mathcal{B}_k$  according to the ROBDD size can be computed with  $O(2^{4k}/k^3)$  arithmetical operations in  $\mathbb{Z}$  and uses  $O(2^{2k}/k)$  space.*

**Proof.** Note that this formula is equivalent to the one given without proof by Pontus von Brömssen [13]. The existence of  $\theta$  is proved in [12] and from there we can derive the explicit expression of  $\theta$  (details omitted here). Then substituting  $n = M_k$  in Theorem 14, and noting that  $M_k \approx 2^k/k$  yields the computational complexity result. ◀

Note this is the polynomial with respect to the maximal size of a ROBDD for  $k$  variables, hence a huge improvement compared to exponential brute force algorithms enumerating all  $2^{2^k}$  Boolean functions and computing their ROBDD size obtained after a compaction process. With a careful implementation, we can achieve the computation of  $F_k(u)$  for  $k$  up to 11 variables on a personal computer, and, on a high-performance computer with 512 GB RAM memory, for  $k = 12$  in less than 1 hour 30 minutes, and even for  $k = 13$  in less than 30 hours using the PyPy implementation of Python.

## 5 Conclusion

As an application of the counting approach of this paper we are able sample at random ROBDDs. More precisely, we can efficiently and uniformly pick ROBDDs either according to a given size, or even a given profile or a given spine. This is a great improvement when comparing to the classical uniform random generation over the set of Boolean functions, like in [12], that is drastically biased to the largest ROBDDs due to the Shannon effect. For instance with 12 variables, the probability of drawing uniformly a Boolean function giving a ROBDD of (quadratic in  $k$ ) size  $144 = 12^2$  is approximately  $1.212 \cdot 10^{-957}$ .

In practice, several classical functions have ROBDDs of small size. For example the symmetrical functions in  $k$  variables are associated with ROBDDs of quadratic size in  $k$  (see [8]). Hence, the approach described in this paper leads the way to provide (polynomial) uniform random generator for ROBDDs of small size (i.e., of size less than exponential).

An interesting future work consists in enumerating the BDD structures where our counting and sampling methods can be applied such as (non-reduced) OBDD, or ZDD which generally used to represent sets.

Finally, another research direction consists in noting that the generating function of ROBDDs with both size and number of variables can be specified thanks to an iterative process as in Theorem 12. It would be interesting to see if the machinery of analytic combinatorics [6] is amenable to this kind of specification.

## A Appendix

### A.1 Iterating $\varphi$ (an example)

In this section, we illustrate how  $\varphi$  can be iterated to count the distribution of ROBDDs up to 4 variables. Let us consider the set of Boolean function  $\mathcal{B}_k$  for  $k \in \{1, 2, 3\}$  and pose  $H_k(u, X) = \varphi^k[X]$ .

- $H_1(u, X) = \varphi[X] = (\phi_0(X) + u\phi_1(X)) = (X^2 - X)u + X^2$ . We can verify that substituting  $X = 2$  we get  $F_1(u) = H_1(u, 2) = 2u + 2$ . Indeed,  $\mathcal{B}_1 = \{\perp, x_1, \overline{x_1}, \top\}$ , with respective truth tables  $\{00, 01, 10, 11\}$  leading to 2 ROBDDs of size 1 and 2 ROBDDs of size 0, i.e., with no decision node.
- Adding a second layer, we get  $H_2(u, X) = \varphi(H_1(u, X)) = \varphi^2[X]$ , yielding

$$H_2(u, X) = (X^4 - 2X^3 + X)u^3 + 2(X^3 - X^2)u^2 + 2(X^2 - X)u + X.$$

We get  $F_2(u) = 2u^3 + 8u^2 + 4u + 2$ , hence there are 2, 8, 4, 2 ROBDDs of respective sizes 3, 2, 1 and 0 for 16 Boolean functions on 2 variables.

- Iterating with a third layer, we get  $H_3(u, X) = \varphi(H_2(u, X)) = \varphi^3[X]$  which has 34 terms and gives

$$F_3(u) = 74u^5 + 88u^4 + 62u^3 + 24u^2 + 6u + 2.$$

Hence, there are respectively 74, 88, 62, 24, 6 and 2 ROBDDs of size 5, 4, 3, 2, 1 and 0.

- Adding a fourth layer yields for  $H_4(u, X) = \varphi^4[X]$  a polynomial with 134 terms and

$$F_4(u) = 11160u^9 + 23280u^8 + 17666u^7 + 8928u^6 + 3248u^5 + 960u^4 + 236u^3 + 48u^2 + 8u + 2.$$

There are 11160 ROBDDs with 4 variables of size 9, 23280 ROBDDs of size 8, etc.

Of course, we can check that  $F_k(1) = 2^{2^k}$ , which is the number of Boolean functions on  $k$  variables.

### A.2 Truncating polynomials (an example)

In this subsection, we illustrate on an example the computational effect of truncating polynomials.

Let us consider that the generating function  $F_3^{\leq 3}(u)$  of ROBDD with  $k = 3$  variables and with less or equal to  $n = 3$  decision nodes. The maximal size of a ROBDD for  $k = 3$  variables is  $M_3 = 7$  (7 decision nodes). Then  $\varphi^3[X]$  is a polynomial with 34 terms. We can write (terms who would disappear modulo  $u^{n+1} = u^4$  are grayed)

$$\begin{aligned}
\varphi^3[X] &= (X^8 - 4X^7 + 14X^5 - 6X^4 - 16X^3 + 5X^2 + 6X)u^7 \\
&\quad + 4(X^7 - 2X^6 - 3X^5 + 5X^4 + 4X^3 - 3X^2 - 2X)u^6 \\
&\quad + (8X^6 - 12X^5 - 11X^4 + 14X^3 + 4X^2 - 3X)u^5 \\
&\quad + 2(5X^5 - 6X^4 - 5X^3 + 4X^2 + 2X)u^4 \\
&\quad + (9X^4 - 10X^3 - 2X^2 + 3X)u^3 \\
&\quad + 6(X^3 - X^2)u^2 \\
&\quad + 3(X^2 - X)u \\
&\quad + X
\end{aligned}$$

Truncating modulo  $u^4$  and substituting  $X = 2$  yields the polynomial

$$F_3^{\leq 4}(u) = 62u^3 + 24u^2 + 6u + 2.$$

The problem of computing all the terms before truncating the result is that there are  $O(\frac{2^{2k}}{k^2})$  terms (since  $M_k \approx 2^k/k$ ), hence a combinatorial explosion.

In contrast, Algorithm 4 works in a recursive manner and truncate polynomials along the way so that we have a polynomial number of terms. In the following, we describe with some details how to compute  $(\varphi^3(X))_{X=2}$ .

First, Algorithm 4 decomposes  $(\varphi^3(X))_{X=2}$  as  $(\varphi^2 \circ \varphi[X])_{X=2}$ . In general,  $\varphi[X^m]$  is a polynomial of respective degree  $m$  and  $2m$  in variables  $u$  and  $X$  and has  $O(m^2)$  integer coefficients. We compute (collecting terms with respect to variable  $X$ )

$$\varphi[X] = (X^2 - X)u + X = X^2u + X(1 - u). \quad (10)$$

Denoting  $B_m^{(2)}(u) = (\varphi^2[X^m])_{X=2}$ , our algorithm computes recursively for the basis  $(1, X, X^2)$  (removed monomials modulo  $u^4$  are grayed)

$$\begin{aligned}
B_0^{(2)}(u) &= 1 \\
B_1^{(2)}(u) &= 2u^3 + 8u^2 + 4u + 2 \\
B_2^{(2)}(u) &= 74u^4 + 90u^3 + 68u^2 + 20u + 4
\end{aligned}$$

Then since  $\varphi$  is linear, we compute (still modulo  $u^4$ ) using Equation (10)

$$\begin{aligned}
(\varphi^3(X))_{X=2} &= B_2(u)u + B_1(u)(1 - u) \\
&= u(90u^3 + 68u^2 + 20u + 4) + (1 - u)(2u^3 + 8u^2 + 4u + 2) \\
&= 88u^4 + 62u^3 + 24u^2 + 6u + 2.
\end{aligned}$$

In summary, computing modulo  $u^{n+1}$  along the process allows us to control the degree  $O(n)$  of polynomials involved, which in turn ensures that the computation stays of polynomial complexity (with respect to arithmetical operations on integers).

Observing such curves for  $k$  from 1 to 13, we notice the exponential growth of the largest ROBDDs when the number  $k$  of variables increases. Indeed, in Theorem 15 we define  $M_k$  to be the size of the largest ROBDDs with  $k$  variables. The sequence starts as  $(M_k)_{k=1, \dots, 13} = (1, 3, 5, 9, 17, 29, 45, 77, 141, 269, 509, 765, 1277)$ .

## Abstract

Continuity is a key principle of intuitionistic logic that is generally accepted by constructivists but is inconsistent with classical logic. Most commonly, continuity states that a function from the Baire space to numbers, only needs approximations of the points in the Baire space to compute. More recently, another formulation of the continuity principle was put forward. It states that for any function  $F$  from the Baire space to numbers, there exists a (dialogue) tree that contains the values of  $F$  at its leaves and such that the modulus of  $F$  at each point of the Baire space is given by the length of the corresponding branch in the tree. In this paper we provide the first internalization of this “inductive” continuity principle within a computational setting. Concretely, we present a class of intuitionistic theories that validate this formulation of continuity thanks to computations that construct such dialogue trees internally to the theories using effectful computations. We further demonstrate that this inductive continuity principle implies other forms of continuity principles.

## 1 Introduction

The continuity principle is a cornerstone in intuitionistic theories which is generally accepted by constructivists but contradicts classical mathematics. In essence, the principle states that functions on the Baire space (i.e.,  $\mathfrak{B} \equiv \text{Nat} \rightarrow \text{Nat}$ ) only need finite inputs, i.e., initial segments of points of the Baire space, to produce outputs. Different variants of the continuity principle have been developed to capture different levels of strictness in the notion of continuity and different computational aspects. Perhaps the most common continuity principle is the continuity principle for numbers, sometimes referred to as the weak continuity principle (WCP) [24, 15, 4, 7, 36]. WCP states that given a function  $F \in \mathfrak{B} \rightarrow \text{Nat}$  and an point  $\alpha$  of the Baire space  $\mathfrak{B}$ ,  $F(\alpha)$  can only depend on an initial segment of  $\alpha$ , and the

## 37:2 Inductive Continuity via Brouwer Trees

length of the smallest such segment is the modulus of continuity of  $F$  at  $\alpha$ . This is standardly formalized as follows, where  $\mathfrak{B}_n \equiv \{x : \text{Nat} \mid x < n\} \rightarrow \text{Nat}$  is the set of finite sequences of length  $n$ :

$$\text{WCP} \equiv \prod F : \mathfrak{B} \rightarrow \text{Nat} . \prod \alpha : \mathfrak{B} . \|\Sigma n : \text{Nat} . \prod \beta : \mathfrak{B} . (\alpha = \beta \in \mathfrak{B}_n) \rightarrow (F(\alpha) = F(\beta) \in \text{Nat})\|$$

However, as shown, e.g., by Kreisel [25, p.154], Troelstra [38, Thm.IIA], and Escardó and Xu [18, 40], continuity is not an extensional property in the sense that two (extensionally) equal functions might have different moduli of continuity. Therefore, to computationally realize continuity, the existence of a modulus of continuity has to be truncated as explained, e.g., in [18, 40, 32, 33], which is what the  $\|\_ \|\_$  operator achieves in  $\text{WCP}$ 's definition above.

Brouwer used  $\text{WCP}$ , along with a consequence of Bar Induction called the Fan Theorem, to derive the following uniform continuity principle ( $\text{UCP}$ ) [7, p.113], which he then used to prove that all real-valued function on the unit interval are uniformly continuous [24, 15, 4, 7, 36], where  $\mathfrak{C} \equiv \text{Nat} \rightarrow \text{Bool}$  is the Cantor space and  $\mathfrak{C}_n \equiv \{x : \text{Nat} \mid x < n\} \rightarrow \text{Bool}$ :

$$\text{UCP} \equiv \prod F : \mathfrak{C} \rightarrow \text{Nat} . \Sigma n : \text{Nat} . \prod \alpha, \beta : \mathfrak{C} . (\alpha = \beta \in \mathfrak{C}_n) \rightarrow (F(\alpha) = F(\beta) \in \text{Nat})$$

Note that  $\text{UCP}$  does not need to be truncated as shown for example in [18].

Another version of the continuity principle, which originates from the completeness of Brouwer's bar thesis and implies both  $\text{WCP}$  and  $\text{UCP}$ , has been recently studied [20, 22, 21, 19]. This principle, referred to here as the Inductive Continuity Principle ( $\text{ICP}$ ), relies on a notion of dialogue trees related to Brouwer trees [36] and reminiscent of Kleene trees [23]. This tree-based technique of capturing continuity information, pioneered in [20, 22, 21, 19], and reused for example in [9, 35, 3], consists in computing a tree that, given a function  $F$  from a subset of  $\mathfrak{B}$  to numbers, contains the values of  $F$  at its leaves, and such that the amount of information needed to compute these values, i.e., the modulus of continuity of  $F$  at each point, is given by its branches. This can be formalized as follows where  $\mathfrak{B}_{\text{SNat}} \equiv \text{Nat} \rightarrow \text{SNat}$  for  $\text{SNat}$  a subtype of  $\text{Nat}$  ( $\text{Bt}$  and  $\text{follow}(d, \alpha)$  are made formal in Sec. 3.2).<sup>1</sup>

$$\text{ICP} \equiv \prod F : \mathfrak{B}_{\text{SNat}} \rightarrow \text{Nat} . \|\Sigma d : \text{Bt} . \prod \alpha : \mathfrak{B}_{\text{SNat}} . \text{follow}(d, \alpha) = F(\alpha) \in \text{Nat}\|$$

A number of theories have been shown to satisfy Brouwer's continuity principle, or uniform variants, such as  $\text{N-HA}^\omega$  by Troelstra [37, p.158],  $\text{MLTT}$  by Coquand and Jaber [12, 13],  $\text{System T}$  by Escardó [19],  $\text{MLTT}$  by Xu [40],  $\text{CTT}$  by Rahli and Bickford [32],  $\text{BTT}$  by Baillon, Mahboubi and Pedrot [3], among others (see Sec. 6 for details). These proofs often rely on a semantic forcing-based approach [12, 13], where the forcing conditions capture the amount of information needed when applying a function to a sequence in the Baire space, or through suitable models that internalize ( $\text{C-Spaces}$  in [41]) or exhibit continuous behavior (e.g., dialogue trees in [19, 3]).

Not only can functions on the Baire space be proved to be continuous, but using effectful computations one can in fact *compute* their modulus of continuity [28]. The  $\text{TT}_{\mathfrak{C}}^\square$  family of effectful extensional type theories, recalled in Sec. 2, was shown to be consistent with a version of  $\text{WCP}$  using a family of realizability models that allow validating this principle using effectful computations, and in particular using reference cells [11]. Building on this result, in this paper we identify a family of effectful type theories that are consistent with a variant of  $\text{ICP}$ , and prove this consistency result using effectful computations, namely references.

<sup>1</sup> We use here Brouwer trees, which are equivalent to dialogue trees for functions on the Baire space [17].

■ **Figure 1** Core syntax (above) and small-step operational semantics (below).

Importantly, in addition to validating the continuity of  $\text{TT}_{\mathcal{C}}^{\square}$  functions using dialogue trees, our work provides the first internalization of the principle into a computational system in the sense that we extend  $\text{TT}_{\mathcal{C}}^{\square}$  with a variant of ICP in Sec. 3, and exhibit in Sec. 5 an effectful  $\text{TT}_{\mathcal{C}}^{\square}$  program that realizes this axiom. The most challenging aspect of internalizing this dialogue-based technique is in proving termination of the computation of such trees. We further show in Sec. 4 that ICP encompasses both weak and uniform continuity. It is however still unknown whether ICP is in fact strictly stronger than the other principles.

## 2 Background

This section reviews  $\text{TT}_{\mathcal{C}}^{\square}$  [10] – a family of extensional type theories parameterized by a choice operator  $\mathcal{C}$  and a metatheoretical modality  $\square$ , which allows typing the choice operators.

### 2.1 Metatheory

Our metatheory is Agda’s type theory [2]. The results presented in this paper have been formalized in Agda: <https://github.com/vrahli/opentt/>. We use  $\forall, \exists, \wedge, \vee, \rightarrow, \neg$  in place of Agda’s logical connectives in this paper, and use  $\top$  for True and  $\perp$  for False. Agda provides a hierarchy of types annotated with universe labels which we omit for simplicity. Following Agda’s terminology, we refer to an Agda type as a *set*, and reserve the term *type* for  $\text{TT}_{\mathcal{C}}^{\square}$ ’s types. We use  $\mathbb{P}$  as the type of sets that denote propositions;  $\mathbb{N}$  for the set of natural numbers; and  $\mathbb{B}$  for the set of Booleans true and false. We use induction-recursion to define the forcing interpretation in Sec. 2.3, where we use function extensionality to interpret universes. We also use classical reasoning twice in the proof presented in Sec. 5.

### 2.2 $\text{TT}_{\mathcal{C}}^{\square}$ ’s Syntax and Operational Semantics

Fig. 1 recalls  $\text{TT}_{\mathcal{C}}^{\square}$ ’s syntax and operational semantics, where the blue boxes highlight the effectful components, and where  $x$  belongs to a set of variables  $\text{Var}$ . For simplicity, numbers are considered to be primitive and the constant  $\star$  is used in place of a term when the particular term used is irrelevant. We use all letters as metavariables for terms and denote

by  $t[x \setminus u]$  the capture-avoiding substitution of all the free occurrences of  $x$  in  $t$  by  $u$ . We write **if**  $t_1$  **then**  $t_2$  **else**  $t_3$  for **case**  $t_1$  of **inl**( $x$ )  $\Rightarrow t_2$  | **inr**( $x$ )  $\Rightarrow t_3$ , where  $x$  does not occur in  $t_2$  or  $t_3$ , and  $t_1; t_2$  for **let**  $x = t_1$  **in**  $t_2$  where  $x$  does not occur free in  $t_2$ .

Types are syntactic forms that are given semantics in Sec. 2.3 via a forcing interpretation. The type system contains standard types such as dependent products of the form  $\prod x:t_1.t_2$  and dependent sums of the form  $\sum x:t_1.t_2$ . We write  $t_1 \rightarrow t_2$  for the non-dependent  $\prod$  type; **Unit** for  $\underline{0}=\underline{0} \in \text{Nat}$ ; **Void** for  $\underline{0}=\underline{1} \in \text{Nat}$ ;  $\neg T$  for  $(T \rightarrow \text{Void})$ ; and **Bool** for  $\text{Unit} + \text{Unit}$ .

To capture the time progression notion which underlines choice operators,  $\text{TT}_{\mathcal{C}}^{\square}$  is parameterized by a Kripke frame [26, 27], consisting of a set of *worlds*  $\mathcal{W}$  equipped with a reflexive and transitive binary relation  $\sqsubseteq$ . Let  $w$  range over  $\mathcal{W}$ . We sometimes write  $w' \sqsupseteq w$  for  $w \sqsubseteq w'$ . Let  $\mathcal{P}_w$  be the collection of predicates on world extensions, i.e., functions in  $\forall w' \sqsupseteq w. \mathbb{P}$ . Due to  $\sqsubseteq$ 's transitivity, if  $P \in \mathcal{P}_w$  then for every  $w' \sqsupseteq w$  it naturally extends to a predicate in  $\mathcal{P}_{w'}$ . Let  $\forall_w^{\sqsubseteq}(P)$  stand for the fact that  $P \in \mathcal{P}_w$  is true for all extensions of  $w$ , i.e.,  $P$  holds for all  $w' \sqsupseteq w$ . We sometime write  $\forall_w^{\sqsubseteq}(w'.P)$  instead of  $\forall_w^{\sqsubseteq}(\lambda w'.P)$ .

Fig. 1's lower part presents  $\text{TT}_{\mathcal{C}}^{\square}$ 's small-step call-by-name operational semantics, where  $t_1 \xrightarrow{w_1 \mapsto w_2} t_2$  expresses that  $t_1$  reduces to  $t_2$  in one step of computation from the world  $w_1$  and potentially updating it so that the resulting world is  $w_2$ . We omit the congruence rules such as: if  $t_1 \xrightarrow{w_1 \mapsto w_2} t_2$  then  $t_1(u) \xrightarrow{w_1 \mapsto w_2} t_2(u)$ . We denote by  $\mapsto^*$  the reflexive transitive closure of  $\mapsto$ , i.e.,  $a \xrightarrow{w_1 \mapsto w_2}^* b$  states that  $a$  computes to  $b$  in 0 or more steps. We write  $a \mapsto_w^* b$  for  $\exists(w' : \mathcal{W}). a \xrightarrow{w \mapsto w'}^* b$ , and  $a \Rightarrow_w b$  for  $\forall_w^{\sqsubseteq}(w'. a \mapsto_{w'}^* b)$ .

$\text{TT}_{\mathcal{C}}^{\square}$  includes effectful notions that rely on worlds to record choices and provides operators to access and update choices. In this paper, for conciseness of presentation, we focus on one instance of choice operators as mutable references to natural numbers. Reference cells, which allow a program to indirectly access a particular object, are choice operators since they can point to different objects over their lifetime. See [10] for the general notion of choice operators. To define references to numbers<sup>2</sup>, we let the set of choices  $\mathcal{C} \subseteq \text{Term}$  to be  $\mathbb{N}$ . A choice stored in a reference cell is referred to through the reference's name. To this end,  $\text{TT}_{\mathcal{C}}^{\square}$ 's computation system is parameterized by a set  $\mathcal{N}$  of choice names, ranged over by  $\delta$ , equipped with a decidable equality, and an operator that given a list of names, returns a name not in the list ( $\mathcal{N} \equiv \mathbb{N}$  for simplicity). This can be given by nominal sets [30]. We take worlds to be lists of cells, where a cell is a pair of a choice name and a choice, and  $\sqsubseteq$  is the reflexive transitive closure of two operations that allow creating and updating reference cells.

As shown in Fig. 1, a choice name  $\delta$  can be used in a computation to access choices from a world using  $! \delta \xrightarrow{w \mapsto w} \text{read}(w, \delta)$ , where the partial function  $\text{read} \in \mathcal{W} \rightarrow \mathcal{N} \rightarrow \mathcal{C}$  accesses the content of the  $\delta$ -cell in  $w$  if that cell exists.<sup>3</sup> Choices can be made using  $(\delta := t) \xrightarrow{w \mapsto \text{write}(w, \delta, t)} \star$ , where  $\text{write}(w, \delta, t)$  updates the reference  $\delta$  with the choice  $t$  if  $\delta$  occurs in  $w$ , and otherwise returns  $w$ , and therefore  $w \sqsubseteq \text{write}(w, \delta, t)$ . The computation returns  $\star$ , which is reminiscent of reference updates in OCaml for example, which are of type **unit**. Finally, new choice names can be generated using  $\nu x.t \xrightarrow{w \mapsto \text{start}\nu\mathcal{C}(w)} t[x \setminus \nu\mathcal{C}(w)]$ , where  $\nu\mathcal{C}(w)$  returns a “fresh” name not occurring in the list  $w$ , which  $x$  gets replaced with in the expression above, and  $\text{start}\nu\mathcal{C}(w)$  returns the list  $w$  extended with the pair  $\langle \nu\mathcal{C}(w), 0 \rangle$ , where 0 is the default value with which reference cells are filled, and therefore  $\forall(w : \mathcal{W}). w \sqsubseteq \text{start}\nu\mathcal{C}(w)$ .<sup>4</sup>

<sup>2</sup> Only relevant components of the choice operator are discussed. See `worldInstanceRef.lagda` for details.

<sup>3</sup> In general, `read`,  `$\nu\mathcal{C}$` , `start $\nu\mathcal{C}$` , and `write` are all parameters of  $\text{TT}_{\mathcal{C}}^{\square}$ , as described in [10]. Here they too are instantiated with references to numbers.

<sup>4</sup>  $\text{TT}_{\mathcal{C}}^{\square}$  also contains a quotienting type operator  $\zeta$  used to assign types to computations that can compute to different values in different worlds, such as choices `! $\delta$`  [11]. For readability, we elide it here.

- Numbers:**  $w \vDash \text{Nat} \equiv \text{Nat} \iff \text{True}$   
 $w \vDash t \equiv t' \in \text{Nat} \iff \Box_w(w'.\exists(n : \mathbb{N}).t \mapsto_{w'} n \wedge t' \mapsto_{w'} n)$
- Products:**  $w \vDash \prod x:A_1.B_1 \equiv \prod x:A_2.B_2 \iff \text{Fam}_w(A_1, A_2, \lambda x.B_1, \lambda x.B_2)$   
 $w \vDash f \equiv g \in \prod x:A.B \iff \Box_w(w'.\forall(a_1, a_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A \rightarrow w' \vDash f a_1 \equiv g a_2 \in B[x \setminus a_1])$
- Sums:**  $w \vDash \sum x:A_1.B_1 \equiv \sum x:A_2.B_2 \iff \text{Fam}_w(A_1, A_2, \lambda x.B_1, \lambda x.B_2)$   
 $w \vDash p_1 \equiv p_2 \in \sum x:A.B \iff \Box_w(w'.\exists(a_1, a_2, b_1, b_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A \wedge w' \vDash b_1 \equiv b_2 \in B[x \setminus a_1] \wedge p_1 \mapsto_{w'} \langle a_1, b_1 \rangle \wedge p_2 \mapsto_{w'} \langle a_2, b_2 \rangle)$
- Sets:**  $w \vDash \{x : A_1 \mid B_1\} \equiv \{x : A_2 \mid B_2\} \iff \text{Fam}_w(A_1, A_2, \lambda x.B_1, \lambda x.B_2)$   
 $w \vDash a_1 \equiv a_2 \in \{x : A \mid B\} \iff \Box_w(w'.\exists(b_1, b_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A \wedge w' \vDash b_1 \equiv b_2 \in B[x \setminus a_1])$
- Disjoint unions:**  $w \vDash A_1 + B_1 \equiv A_2 + B_2 \iff w \vDash A_1 \equiv A_2 \wedge w \vDash B_1 \equiv B_2$   
 $w \vDash a_1 \equiv a_2 \in A + B \iff \Box_w(w'.\exists(u, v : \text{Term}).(a_1 \mapsto_{w'} \text{inl}(u) \wedge a_2 \mapsto_{w'} \text{inl}(v) \wedge w' \vDash u \equiv v \in A) \vee (a_1 \mapsto_{w'} \text{inr}(u) \wedge a_2 \mapsto_{w'} \text{inr}(v) \wedge w' \vDash u \equiv v \in B))$
- Equalities:**  $w \vDash (a_1 = b_1 \in A) \equiv (a_2 = b_2 \in B) \iff w \vDash A \equiv B \wedge w \vDash a_1 \equiv a_2 \in A \wedge w \vDash b_1 \equiv b_2 \in B$   
 $w \vDash a_1 \equiv a_2 \in (a = b \in A) \iff \Box_w(w'.w' \vDash a \equiv b \in A)$
- Subsingletons:**  $w \vDash \|A\| \equiv \|B\| \iff w \vDash A \equiv B$   
 $w \vDash a \equiv b \in \|A\| \iff \Box_w(w'.w' \vDash a \equiv a \in A \wedge w' \vDash b \equiv b \in A)$
- Purity:**  $w \vDash \text{pure} \equiv \text{pure} \iff \top$   
 $w \vDash a_1 \equiv a_2 \in \text{pure} \iff \text{namefree}(a_1) \wedge \text{namefree}(a_2)$
- Binary intersections:**  $w \vDash A_1 \cap B_1 \equiv A_2 \cap B_2 \iff w \vDash A_1 \equiv A_2 \wedge w \vDash B_1 \equiv B_2$   
 $w \vDash a_1 \equiv a_2 \in A \cap B \iff \Box_w(w'.w' \vDash a_1 \equiv a_2 \in A \wedge w' \vDash a_1 \equiv a_2 \in B)$
- Modality closure:**  $w \vDash T_1 \equiv T_2 \iff \Box_w(w'.\exists(T'_1, T'_2 : \text{Term}).T_1 \mapsto_{w'} T'_1 \wedge T_2 \mapsto_{w'} T'_2 \wedge w' \vDash T'_1 \equiv T'_2)$   
 $w \vDash t_1 \equiv t_2 \in T \iff \Box_w(w'.\exists(T' : \text{Term}).T \mapsto_{w'} T' \wedge w' \vDash t_1 \equiv t_2 \in T')$

■ **Figure 2** Forcing Interpretation.

### 2.3 Forcing Interpretation

$\text{TT}_C^\square$ 's semantics is similar to the one presented in [10], which we recall and extend in Fig. 2. Types are interpreted via a forcing interpretation defined using induction-recursion [16] as follows, where the forcing conditions are worlds: (1) the inductive relation  $w \vDash T_1 \equiv T_2$  expresses type equality in the world  $w$ ; (2) the recursive function  $w \vDash t_1 \equiv t_2 \in T$  expresses equality in a type. We also define  $a \mapsto_{!w} b$  as  $\forall_w^\square(w'.a \mapsto_{w'}^* b)$ , capturing the fact that the computation can read using  $!\delta$  but not write, and therefore does not change the initial world (this is used in Thm. 1). Fig. 2 defines in particular the semantics of `pure`, which is inhabited by name-free terms, where `namefree`( $t$ ) is defined recursively over  $t$  and returns false iff  $t$  contains a choice name  $\delta$  or a fresh operator of the form  $\nu x.t$ . We also write  $\text{Fam}_w(A_1, A_2, B_1, B_2)$  for  $w \vDash A_1 \equiv A_2 \wedge \forall_w^\square(w'.\forall(a_1, a_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A_1 \rightarrow w' \vDash B_1(a_1) \equiv B_2(a_2))$ . This forcing interpretation is parameterized by a family of abstract modalities  $\Box$ , which we sometimes refer to simply as a modality, which is a function that takes a world  $w$  to its modality  $\Box_w \in \mathcal{P}_w \rightarrow \mathbb{P}$ . We often write  $\Box_w(w'.P)$  for  $\Box_w \lambda w'.P$ . To guarantee that this interpretation yields a type system in the sense of Thm. 1, we require that the modalities satisfy certain properties detailed in [10] and reminiscent of standard modal axiom schemata [14].

► **Theorem 1** ([10]).  $\text{TT}_C^\square$  is a standard type system in the sense that its forcing interpretation induced by  $\Box$  satisfies the following properties (free variables are universally quantified):

<i>transitivity:</i>	$w \vDash T_1 \equiv T_2 \rightarrow w \vDash T_2 \equiv T_3 \rightarrow w \vDash T_1 \equiv T_3$	$w \vDash t_1 \equiv t_2 \in T \rightarrow w \vDash t_2 \equiv t_3 \in T \rightarrow w \vDash t_1 \equiv t_3 \in T$
<i>symmetry:</i>	$w \vDash T_1 \equiv T_2 \rightarrow w \vDash T_2 \equiv T_1$	$w \vDash t_1 \equiv t_2 \in T \rightarrow w \vDash t_2 \equiv t_1 \in T$
<i>computation:</i>	$w \vDash T \equiv T' \rightarrow T \mapsto_{!w} T' \rightarrow w \vDash T \equiv T'$	$w \vDash t \equiv t' \in T \rightarrow t \mapsto_{!w} t' \rightarrow w \vDash t \equiv t' \in T$
<i>monotonicity:</i>	$w \vDash T_1 \equiv T_2 \rightarrow w \sqsubseteq w' \rightarrow w' \vDash T_1 \equiv T_2$	$w \vDash t_1 \equiv t_2 \in T \rightarrow w \sqsubseteq w' \rightarrow w' \vDash t_1 \equiv t_2 \in T$
<i>locality:</i>	$\Box_w(w'.w' \vDash T_1 \equiv T_2) \rightarrow w \vDash T_1 \equiv T_2$	$\Box_w(w'.w' \vDash t_1 \equiv t_2 \in T) \rightarrow w \vDash t_1 \equiv t_2 \in T$
<i>consistency:</i>	$\neg w \vDash t \equiv t \in \text{Void}$	

Note that due to effects, types are not closed under all computations. For example, when  $T \equiv \text{Nat}$ ,  $t' \Vdash_w \underline{n}$  does not necessarily follow from  $t \Vdash_w t'$  and  $t \Vdash_w \underline{n}$ . An example is  $t \equiv (\delta := \underline{1}; \text{if } !\delta < \underline{1} \text{ then } \underline{0} \text{ else } \underline{1})$ , which reduces to  $t' \equiv (\text{if } !\delta < \underline{1} \text{ then } \underline{0} \text{ else } \underline{1})$  and also to  $\underline{1}$  in all worlds, but  $t'$  does not reduce to  $\underline{1}$  in all worlds, because  $\delta$  could be initialized differently in different worlds. However, the following holds by transitivity of  $\Vdash_w$ :  $t' \Vdash_w t \rightarrow w \Vdash t \equiv t \in \text{Nat} \rightarrow w \Vdash t \equiv t' \in \text{Nat}$ . Similarly, the following also holds by transitivity of  $\Vdash_w$ :  $w \Vdash T \equiv T \rightarrow T' \Vdash_w T \rightarrow w \Vdash T \equiv T'$ . Finally, note that, as indicated in Thm. 1, this semantics is closed under  $\beta$ -reduction, as  $\beta$ -reduction does not modify the current world.

## 2.4 $\text{TT}_{\mathcal{C}}^{\square}$ 's Inference Rules

$\text{TT}_{\mathcal{C}}^{\square}$ 's inference rules are standard and they reflect the semantics of the types, which is given meaning through a forcing interpretation presented in Sec. 2.3. Concetely, sequents in  $\text{TT}_{\mathcal{C}}^{\square}$  are of the form  $h_1, \dots, h_n \vdash t : T$ . Such a sequent denotes that, assuming  $h_1, \dots, h_n$ ,  $T$  is a type inhabited by  $t$ . An hypothesis  $h$  is of the form  $x:A$ , where the variable  $x$  stands for the name of the hypothesis and  $A$  its type. We write  $a \in A$  for  $a = a \in A$ . To illustrate the naturality of the typing rules and their correspondence to the forcing interpretation, we provide examples of  $\text{TT}_{\mathcal{C}}^{\square}$ 's inference rules for  $\Pi$  types. The following rules are the standard  $\Pi$ -elimination,  $\Pi$ -introduction, type equality for  $\Pi$  types, and  $\lambda$ -introduction rules, respectively.

$$\frac{H, f: \Pi x:A. B, J \vdash a \in A \quad H, f: \Pi x:A. B, J, z: f(a) \in B[x \setminus a] \vdash e : C}{H, f: \Pi x:A. B, J \vdash e[z \setminus *] : C} \quad \frac{H, z:A \vdash b : B[x \setminus z] \quad H \vdash A \in \mathbb{U}_i}{H \vdash \lambda z. b : \Pi x:A. B}$$

$$\frac{H \vdash A_1 = A_2 \in \mathbb{U}_i \quad H, y:A_1 \vdash B_1[x_1 \setminus y] = B_2[x_2 \setminus y] \in \mathbb{U}_i}{H \vdash \Pi x_1:A_1. B_1 = \Pi x_2:A_2. B_2 \in \mathbb{U}_i} \quad \frac{H, z:A \vdash t_1[x_1 \setminus z] = t_2[x_2 \setminus z] \in B[x \setminus z] \quad H \vdash A \in \mathbb{U}_i}{H \vdash \lambda x_1. t_1 = \lambda x_2. t_2 \in \Pi x:A. B}$$

The following rules are the standard function extensionality and  $\beta$ -reduction rules, resp.:

$$\frac{H, z:A \vdash f_1(z) = f_2(z) \in B[x \setminus z] \quad H \vdash A \in \mathbb{U}_i}{H \vdash f_1 = f_2 \in \Pi x:A. B} \quad \frac{H \vdash t[x \setminus s] = u \in T}{H \vdash (\lambda x. t) s = u \in T}$$

## 3 Inductive Continuity via Brouwer Trees

This section states a dialogue tree-based continuity principle, referred to as the inductive continuity principle, since it relies on trees to capture functions. As we show in Sec. 4, it implies both Brouwer's continuity principle for numbers and his uniform continuity principle on the Cantor space. Furthermore, it is still unknown whether the inductive continuity principle is strictly stronger than Brouwer's continuity principle for numbers. Sec. 5 internally validates this inductive principle. In particular, Thm. 4 shows that, given a pure function  $F \in \mathfrak{B} \rightarrow \text{Nat}$ ,  $\text{TT}_{\mathcal{C}}^{\square}$  provides a computation, introduced in Sec. 5.1, that builds a dialogue tree capturing  $F$ 's continuity.

As mentioned above, we rely here on Brouwer trees, which are a simple form of dialogue trees. Let us provide an example of how dialogue and Brouwer trees work. Consider the function  $F \equiv \lambda \alpha. \alpha(2) \in \mathfrak{B} \rightarrow \text{Nat}$ . Fig. 3 (left) shows its dialogue tree, where the internal (root) node is labeled with the value  $\alpha$  is applied to, and the leaves contain the values of  $F$  for all possible inputs. For example if  $F$  is applied to  $\alpha \equiv \lambda x. x$ , then starting from the root, we apply  $\alpha$  to the node's value, i.e.,  $\underline{2}$ , which gives us  $\underline{2}$ , and we therefore follow the 2nd path, which leads to the leaf labeled 2, the value of  $F(\alpha)$ . If  $\alpha \equiv \lambda x. \underline{0}$ , then  $\alpha(2)$  is now  $\underline{0}$ , and following the 0th path leads to the leaf labeled 0, which is the value of  $F(\alpha)$ . Fig. 3 (right) shows  $F$ 's Brouwer tree, where as opposed to dialogue trees, internal nodes are not labeled, and as for dialogue trees, the leaves contain the values of  $F$  for all inputs. For

■ **Figure 3** Examples of dialogue (left) and Brouwer (right) trees for  $\lambda\alpha.\alpha(2)$ .

example if  $F$  is applied to  $\alpha \equiv \lambda x.x$ , because  $\alpha(0)$  is  $\underline{0}$ , we first follow the 0th branch; then because  $\alpha(1)$  is  $\underline{1}$ , we follow the 1st branch, and finally because  $\alpha(2)$  is  $\underline{2}$ , we follow the 2nd branch, leading to a leaf labeled 2 (following the green path in Fig. 3). If  $\alpha \equiv \lambda x.\underline{0}$ , then we instead always follow the 0th branch, leading to a leaf labeled with 0.

In the dialogue tree, the modulus of continuity of  $F$  at some point  $\alpha$  is given by the maximum value of the internal nodes followed using  $\alpha$ , while in the Brouwer tree, the modulus is the length of the branch followed using  $\alpha$ . Note that, in general, the values of the internal nodes of a dialogue tree of a function  $F \in \mathfrak{B} \rightarrow \text{Nat}$  are used to “ask questions” to an argument  $\alpha \in \mathfrak{B}$  to decide what branch to take in the tree (by applying  $\alpha$  to those values), while in a Brouwer tree, “dialogues” happen by asking all the values of an initial segment of  $\alpha$ .

### 3.1 Extending $\text{TT}_{\mathcal{C}}^{\square}$ with (Co-)W Types and Infinite Sequences

In order to state the inductive continuity principle, we make use of the notion of a Brouwer tree, which we define in  $\text{TT}_{\mathcal{C}}^{\square}$  using W types [1, Sec.5.2], which is a standard way of representing inductive types. Additionally, we use co-W types (also called M types) [1, Sec.5.2], the dual notion to that of a W type, to prove the validity of the principle. Thus, we add W and M types to  $\text{TT}_{\mathcal{C}}^{\square}$ , using  $\text{sup}$  as a W type and M type constructor and  $\text{wrec}$  as a W type recursor.

$$\begin{aligned}
 vt \in \text{Type} & ::= \dots \mid W(t_1, t_2) \mid M(t_1, t_2) \\
 t \in \text{Term} & ::= \dots \mid \text{sup}(t_1, t_2) \mid \text{wrec}(t_1, t_2) \\
 v \in \text{Value} & ::= \dots \mid \lceil \mathbf{s} \rceil, \text{ where } \mathbf{s} \text{ is a metatheoretical function in } \mathbb{N} \rightarrow \mathbb{N}
 \end{aligned}$$

where  $\text{wrec}(t_1, t_2)$  and  $\lceil \mathbf{s} \rceil$  compute as follows:

$$\text{wrec}(\text{sup}(a, f), g) \quad w \mapsto_w \quad g \ a \ f \ (\lambda b. \text{wrec}(f(b), g)) \qquad \lceil \mathbf{s} \rceil \ \underline{n} \quad w \mapsto_w \quad \underline{\mathbf{s}(n)}$$

In addition, the application operator is modified so that it evaluates its argument whenever the function is of the form  $\lceil \mathbf{s} \rceil$ , i.e.,  $\lceil \mathbf{s} \rceil \ a$  reduces to  $\lceil \mathbf{s} \rceil \ b$  when  $a$  reduces to  $b$ . Hence, for any metatheoretical function  $\mathbf{s}$  in  $\mathbb{N} \rightarrow \mathbb{N}$ ,  $\lceil \mathbf{s} \rceil$  inhabits  $\mathfrak{B}$ . These sequences are used in Sec. 5.5 to prove that the computation of Brouwer trees provided in Sec. 5.1 terminates. They are similar to the sequences of the form  $\lambda x.M_x$  in [5], where the infinite sequence of terms  $M_1, M_2, \dots$  does not have a computational purpose, but is used to prove termination in their proof that some bar recursion operator realizes the negative translation of the axiom of choice. Similar sequences have been used in [31] to validate versions of the axiom of choice, and in [34] to validate variants of Brouwer’s Bar Induction principle [24].

W and M types are interpreted in a standard way:

**W types:**  $w \vDash W(A_1, B_1) \equiv W(A_2, B_2) \iff \text{Fam}_w(A_1, A_2, B_1, B_2)$   
 $w \vDash s_1 \equiv s_2 \in W(A, B) \iff \Box_w(w'.\mu(R.\exists(a_1, a_2, f_1, f_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A \wedge$   
 $(\forall(b_1, b_2 : \text{Term}).w' \vDash b_1 \equiv b_2 \in B(a_1) \rightarrow R f_1(b_1) f_2(b_2)) \wedge s_1 \vDash_{w'} \text{sup}(a_1, f_1) \wedge s_2 \vDash_{w'}$   
 $\text{sup}(a_2, f_2)) s_1 s_2)$

**M types:**  $w \vDash M(A_1, B_1) \equiv M(A_2, B_2) \iff \text{Fam}_w(A_1, A_2, B_1, B_2)$   
 $w \vDash s_1 \equiv s_2 \in M(A, B) \iff \Box_w(w'.\nu(R.\exists(a_1, a_2, f_1, f_2 : \text{Term}).w' \vDash a_1 \equiv a_2 \in A \wedge$   
 $(\forall(b_1, b_2 : \text{Term}).w' \vDash b_1 \equiv b_2 \in B(a_1) \rightarrow R f_1(b_1) f_2(b_2)) \wedge s_1 \vDash_{w'} \text{sup}(a_1, f_1) \wedge s_2 \vDash_{w'}$   
 $\text{sup}(a_2, f_2)) s_1 s_2)$

Therefore,  $W(A, B)$  and  $M(A, B)$  are types in  $\mathbb{U}_i$  whenever  $A \in \mathbb{U}_i$  and  $B \in A \rightarrow \mathbb{U}_i$ . Given  $a \in A$  and  $f \in B[a] \rightarrow W(A, B)$ ,  $\text{sup}(a, f) \in W(A, B)$  is a W type constructor, and if  $f \in B[a] \rightarrow M(A, B)$  then  $\text{sup}(a, f) \in M(A, B)$  is an M type constructor. Given  $t \in W(A, B)$  and  $g \in \Pi a:A.(B(a) \rightarrow W(A, B)) \rightarrow (B(a) \rightarrow C) \rightarrow C$ ,  $\text{wrec}(t, g) \in C$  is a W type recursor.

► **Example 2.** Given  $A \in \mathbb{U}_i$  and  $B \in A \rightarrow \mathbb{U}_i$ ,  $W(A, B)$  denotes the type of inductive definitions with inhabitants of  $A$  representing the constructors (as well as their non-inductive parameters), and  $B(a)$  representing the indices of inductive parameters at a given constructor  $a$ . For example, the natural numbers have two constructors: `zero` and `succ`, the latter having one inductive parameter. Therefore, natural numbers are encoded as:

$$W(\text{Bool}, \lambda x.\text{case } x \text{ of } \text{inl}(\_) \Rightarrow \text{Void} \mid \text{inr}(\_) \Rightarrow \text{Unit}),$$

where `Void` captures the lack of inductive parameters for `zero` and `Unit` captures `succ`'s single inductive parameter. The constructors `zero` and `succ` are then be encoded as:

$$\text{zero} \equiv \text{sup}(\text{inl}(\star), \lambda x.\star) \quad \text{and} \quad \text{succ} \equiv \lambda n.\text{sup}(\text{inr}(\star), \lambda x.n)$$

### 3.2 Brouwer Tree-Based Inductive Continuity Principle

We can now state the inductive continuity principle that captures the moduli of continuity of functions in  $\mathfrak{B}_{\text{SNat}} \rightarrow \text{Nat}$  using Brouwer trees, where  $\mathfrak{B}_{\text{SNat}} \equiv \text{Nat} \rightarrow \text{SNat}$  for  $\text{SNat}$  a subtype of  $\text{Nat}$  (this principle is therefore a family of principles for all such  $\text{SNats}$ ). This continuity result, as well as the ones recalled in Sec. 4, are stated for pure functions only using the following quantification:  $\Pi_p a:A.B \equiv \Pi a:(A \cap \text{pure}).B$ , which quantifies over pure members of  $A$ . We also write  $A_p$  for  $A \cap \text{pure}$  and  $A +_p B$  for  $(A+B) \cap \text{pure}$ . It remains to be determined whether some effectful computations can be proved to be continuous.

We first define Brouwer trees (a class of dialogue trees where internal nodes are not labeled) using W types as follows.

► **Definition 3** (Brouwer Trees). *A Brouwer tree is a member of  $\text{Bt} \equiv W(\text{BtA}, \text{BtB})$ , where  $\text{BtA} \equiv \text{Nat} +_p \text{Unit}$  and  $\text{BtB} \equiv \lambda a.\text{if } a \text{ then } \text{Void} \text{ else } \text{SNat}_p$ . Such trees have two constructors:  $\eta(i) \equiv \text{sup}(\text{inl}(i), \lambda x.\star)$ , which builds a leaf node with value  $i \in \text{Nat}$ ; and  $F(f) \equiv \text{sup}(\text{inr}(\star), f)$ , which builds an internal node from a function  $f \in \text{SNat}_p \rightarrow \text{Bt}$ .*

Using this definition, the Brouwer tree depicted in Fig. 3 is  $F(\lambda i.F(\lambda j.F(\lambda k.\eta(k))))$ .

► **Theorem 4** (Inductive Continuity Principle). *The following continuity principle, referred to as  $\text{ICP}_p$ , is valid in  $\text{TT}_C^{\square 5}$  (see `contDiagVal` in `barContP10.lagda` for details):*

$$\Pi_p F:\mathfrak{B}_{\text{SNat}} \rightarrow \text{Nat}.\|\Sigma d:\text{Bt}.\Pi_p \alpha:\mathfrak{B}_{\text{SNat}}.\text{follow}(d, \alpha) = F(\alpha) \in \text{Nat}\| \quad (\text{ICP}_p)$$

where  $\text{follow}(d, \alpha)$  extracts the value of the leaf encountered when following  $\alpha$  in  $d$  as follows:

$$\text{follow}(d, \alpha) \equiv \text{wrec}(d, \lambda a.\lambda f.\lambda r.\lambda k.\text{case } a \text{ of } \text{inl}(i) \Rightarrow i \mid \text{inr}(\_) \Rightarrow r (\alpha k) (k + \underline{1}) \underline{0}) \underline{0}$$

<sup>5</sup> “Valid in  $\text{TT}_C^{\square}$ ” here means that the principle is realizable in  $\text{TT}_C^{\square}$ , thus it is consistent with the theory.

At a high-level, the proof goes as follows (the full proof is carried out in Sec. 5).

- Step 1:** Given a function in  $\mathfrak{B}_{\text{SNat}} \rightarrow \text{Nat}$ , we first build by coinduction a possibly infinite co-Brouwer tree as an M type. This co-Brouwer tree contains the result of  $F$  applied to the finite sequence  $s$  at the leaf ending the path following  $s$  whenever  $s$  contains enough information to compute the result of  $F$ .
- Step 2:** Classically, this co-Brouwer tree is either finite or contains an infinite branch.
- Step 3:** If the co-Brouwer tree is finite, it is a Brouwer tree.
- Step 4:** If the co-Brouwer tree contains an infinite branch, then the branch gives rise to an infinite sequence  $\alpha$ , and since  $F$  is continuous, the path must be finite. As discussed in Sec. 5.5, this step relies on a continuity argument similar to the one used to validate the weak continuity principle  $\text{WCP}_p$  recalled in Sec. 4.1.
- Step 5:** Finally, the obtained Brouwer tree is shown to contain the values of  $F$  at its leaves.

## 4 Relation with Other Continuity Principles

This section demonstrates that inductive continuity implies both Brouwer’s continuity principle for numbers (referred to as weak continuity here) and uniform continuity.

### 4.1 Weak Continuity

$\text{TT}_C^\square$  was shown to satisfy the following version of Brouwer’s continuity principle for numbers, also called the weak continuity principle, which therefore can be added as an axiom [11].

$$\prod_p F : \mathfrak{B} \rightarrow \text{Nat} . \prod_p \alpha : \mathfrak{B} . \|\Sigma n : \text{Nat} . \prod_p \beta : \mathfrak{B} . (\alpha = \beta \in \mathfrak{B}_n) \rightarrow (F(\alpha) = F(\beta) \in \text{Nat})\| \quad (\text{WCP}_p)$$

$\text{WCP}_p$  is realized in every world by the term  $\lambda F . \lambda \alpha . \langle \text{mod}(F, \alpha), \lambda \beta . \lambda e . \star \rangle$ , where  $\text{mod}(F, \alpha)$  computes the modulus of continuity of the function  $F \in \mathfrak{B} \rightarrow \text{Nat}$  at  $\alpha \in \mathfrak{B}$ . Roughly speaking,  $\text{mod}(F, \alpha)$  generates a reference cell  $\delta$  initialized with 0, applies  $F$  to a modified version of  $\alpha$  (namely  $\text{upd}(\delta, \alpha)$ ) that keeps track using  $\delta$  of the highest number  $\alpha$  gets applied to, and then returns the value held by  $\delta$  (plus one). Formally:

$$\begin{aligned} \text{mod}(F, \alpha) &\equiv \nu x . (x := \underline{0}; F(\text{upd}(x, \alpha)); !x + \underline{1}) \\ \text{upd}(\delta, \alpha) &\equiv \lambda x . (\text{let } y = x \text{ in } ((\text{if } !\delta < y \text{ then } \delta := y \text{ else } \star); \alpha(y))) \end{aligned}$$

Note that the truncation in  $\text{WCP}_p$  is necessary. It has been shown that a non-truncated version of  $\text{WCP}$  is inconsistent with MLTT [18, 40], and the same applies to  $\text{WCP}_p$  and  $\text{TT}_C^\square$ . The main reason for this is the semantics of dependent functions given by  $\text{TT}_C^\square$ ’s realizability model (see Fig. 2). Under this semantics,  $f \in \prod x : A . B$  if  $f$  maps equal terms  $a_1 = a_2 \in A$  to equal terms  $f(a_1) = f(a_2) \in B[x \setminus a_1]$ . As continuity is a non-extensional property [25], extensionally equal functions in  $\mathfrak{B}$  might have different moduli of continuity, so  $\text{WCP}_p$ ’s realizer cannot inhabit a non-truncated version of  $\text{WCP}_p$ . However, when  $B$  is of the form  $\|C\|$ , it suffices that  $f(a_1)$  and  $f(a_2)$  are both members of  $C[x \setminus a_1]$ , allowing  $\text{WCP}_p$ ’s validation.

► **Theorem 5.**  $\text{WCP}_p$  is derivable from  $\text{ICP}_p$  in  $\text{TT}_C^\square$  when  $\text{SNat} \equiv \text{Nat}$ .

**Proof outline.** Let  $F \in \mathfrak{B} \rightarrow \text{Nat}$  a pure function and let  $\alpha \in \mathfrak{B}$ . It follows from  $\text{ICP}_p$  that:  $\|\Sigma d : \text{Bt} . \prod_p \alpha : \mathfrak{B} . \text{follow}(d, \alpha) = F(\alpha) \in \text{Nat}\|$ . Because both principles are truncated, we can assume the existence of a tree  $d \in \text{Bt}$  such that:  $\prod_p \alpha : \mathfrak{B} . \text{follow}(d, \alpha) = F(\alpha) \in \text{Nat}$ . Because  $d$  encodes the modulus of continuity of each sequence  $\alpha \in \mathfrak{B}$ , as the length of the branch in  $d$  that “follows”  $\alpha$ , we instantiate the conclusion with:  $n \equiv \text{lenBranch}(d, \alpha) \in \text{Nat}$ , where:

$$\text{lenBranch}(d, \alpha) \equiv \text{wrec}(d, \lambda a . \lambda f . \lambda r . \lambda k . \text{case } a \text{ of } \text{inl}(i) \Rightarrow k \mid \text{inr}(\_) \Rightarrow r(\alpha k)(k + \underline{1}) \underline{0}$$

## 37:10 Inductive Continuity via Brouwer Trees

It now remains to prove that  $F(\alpha)=F(\beta)\in\mathbf{Nat}$ , for any pure function  $\beta \in \mathfrak{B}$  such that  $\alpha=\beta\in\mathfrak{B}_n$ . From  $\mathbf{ICP}_p$ , we know that  $\mathbf{follow}(d, \alpha)=F(\alpha)\in\mathbf{Nat}$  and  $\mathbf{follow}(d, \beta)=F(\beta)\in\mathbf{Nat}$ . Therefore, it is enough to prove  $\mathbf{follow}(d, \alpha)=\mathbf{follow}(d, \beta)\in\mathbf{Nat}$ , which follows from the following fact:  $\prod\alpha, \beta:\mathfrak{B}.\alpha=\beta\in\mathfrak{B}_{\mathbf{lenBranch}(d, \alpha)} \rightarrow \mathbf{follow}(d, \alpha)=\mathbf{follow}(d, \beta)\in\mathbf{Nat}$ . ◀

### 4.2 Uniform Continuity

The uniform continuity principle states that all functions on the Cantor space ( $\mathfrak{C} \equiv \mathbf{Nat} \rightarrow \mathbf{Bool}$ ) are uniformly continuous, meaning that all points  $\alpha \in \mathfrak{C}$  have the same modulus of continuity. We consider here the following version:

$$\prod_p F:\mathfrak{C} \rightarrow \mathbf{Nat}.\|\sum n:\mathbf{Nat}.\prod_p \alpha, \beta:\mathfrak{C}.\alpha=\beta\in\mathfrak{C}_n \rightarrow (F(\alpha)=F(\beta)\in\mathbf{Nat})\| \quad (\mathbf{UCP}_p)$$

Brouwer proved that all real-valued functions on the unit interval are uniformly continuous [8, Thm.3] using  $\mathbf{WCP}$  and the Fan Theorem [36, 15], which he derived from Bar Induction. While it was shown that in the case of uniform continuity the truncation can be removed [18, 40], we leave formalizing this in  $\mathbf{TT}_{\mathfrak{C}}^{\square}$  for future work.

► **Theorem 6.**  $\mathbf{UCP}_p$  is derivable from  $\mathbf{ICP}_p$  in  $\mathbf{TT}_{\mathfrak{C}}^{\square}$  when  $\mathbf{SNat} \equiv \{x : \mathbf{Nat} \mid x < 2\}$  or equivalently  $\mathbf{SNat} \equiv \mathbf{Bool}$  (and therefore  $\mathfrak{B}_{\mathbf{SNat}}$  is  $\mathfrak{C}$ ).

**Proof outline.** Let  $F \in \mathfrak{C} \rightarrow \mathbf{Nat}$  be a pure function. Because both principles are truncated, we can assume the existence of a tree  $d \in \mathbf{Bt}$  such that:  $\prod_p \alpha:\mathfrak{C}.\mathbf{follow}(d, \alpha)=F(\alpha)\in\mathbf{Nat}$ . As  $d$  is finitely branching and encodes the modulus of continuity of each  $\alpha \in \mathfrak{C}$  as the length of the branch in  $d$  that “follows”  $\alpha$ , we compute the uniform modulus of continuity of  $F$  as  $d$ ’s depth as follows, where  $\mathbf{max}(i, j)$  returns the maximum among the numbers  $i$  and  $j$ :

$$\mathbf{depth}(d) \equiv \mathbf{wrec}(d, \lambda a.\lambda f.\lambda r.\mathbf{case} \ a \ \mathbf{of} \ \mathbf{inl}(i) \Rightarrow \underline{1} \mid \mathbf{inr}(\_) \Rightarrow \mathbf{max}(r(0), r(1)) + 1)$$

We then instantiate our conclusion with  $n \equiv \mathbf{depth}(d) \in \mathbf{Nat}$ , and have to prove that  $F(\alpha)=F(\beta)\in\mathbf{Nat}$ , for all pure functions  $\alpha, \beta \in \mathfrak{C}$  such that  $\alpha=\beta\in\mathfrak{C}_n$ . From  $\mathbf{ICP}_p$ , we know that  $\mathbf{follow}(d, \alpha)=F(\alpha)\in\mathbf{Nat}$  and  $\mathbf{follow}(d, \beta)=F(\beta)\in\mathbf{Nat}$ . Therefore, it is enough to prove  $\mathbf{follow}(d, \alpha)=\mathbf{follow}(d, \beta)\in\mathbf{Nat}$ , which follows from the following fact, which can be proved by induction on  $d$ :  $\prod\alpha, \beta:\mathfrak{C}.\alpha=\beta\in\mathfrak{C}_{\mathbf{depth}(d)} \rightarrow \mathbf{follow}(d, \alpha)=\mathbf{follow}(d, \beta)\in\mathbf{Nat}$ . ◀

## 5 Validity of the Inductive Continuity Principle

This section sketches the proof of Thm. 4, which has been formalized in Agda. For simplicity we focus here on functions in  $\mathfrak{B} \rightarrow \mathbf{Nat}$ , but as mentioned in Sec. 3, the principle holds for all functions in  $\mathfrak{B}_{\mathbf{SNat}} \rightarrow \mathbf{Nat}$  where  $\mathbf{SNat}$  is a subtype of  $\mathbf{Nat}$ .

To validate  $\mathbf{ICP}_p$  we assume that  $\mathbf{TT}_{\mathfrak{C}}^{\square}$ ’s  $\square$  modality is a Kripke-like modality, i.e.,  $\forall(w : \mathcal{W}).\square_w f \rightarrow \forall_w^{\square}(f)$ . This is used to derive a co-Brouwer tree from an  $F \in \mathfrak{B} \rightarrow \mathbf{Nat}$ . In short, when building a co-Brouwer tree in **Step 1** by extending a node with branches for all  $n \in \mathbf{Nat}$ , if  $n$  does not compute to a number in the current world  $w$  (which a Kripke modality enforces), it is unclear how this can result in a co-tree in  $w$ . It was proved in [10] that  $\mathbf{TT}_{\mathfrak{C}}^{\square}$  is inconsistent with classical logic when  $\square$  is a Kripke modality and  $\mathfrak{C}$  is instantiated using references, which is expected because continuity contradicts classical logic [36, 39].

## 5.1 Computing Brouwer Trees

To show that  $\text{ICP}_p$  is valid, we must exhibit a  $\text{TT}_C^\square$  computation that can compute a Brouwer tree from a pure function in  $\mathfrak{B} \rightarrow \text{Nat}$ . This computation is similar to the one provided in [35, Sec.1.3], and proceeds as follows: given  $F \in \mathfrak{B} \rightarrow \text{Nat}$ ,  $\text{loop}(F) \underline{0} \alpha_0$  builds a tree in  $\text{Bt}$  satisfying the condition in Thm. 4, where  $\alpha_0 \equiv \lambda\_.\underline{0}$ , and  $\text{loop}$  is defined as follows:

$$\begin{aligned} \text{loop}(F) &\equiv \text{fix}(\lambda R. \lambda k. \lambda \alpha. \nu x. (x := \underline{0}); \text{let } i = F(\text{upd}(x, \alpha)) \text{ in cases}(x, R, k, \alpha, i)) \\ \text{cases}(\delta, R, k, \alpha, i) &\equiv \text{if } !\delta < k \text{ then } \eta(i) \text{ else } F(\lambda x. R (k + \underline{1}) \text{ append}(k, \alpha, x)) \end{aligned}$$

The goal of this computation is to recursively build a Brouwer tree from the root, by applying  $F$  to a finite sequence (essentially, the pair  $\langle k, \alpha \rangle$ ), which corresponds to a path in the tree, and which is extended as long as it does not contain enough information for  $F$  to compute a value, i.e., as long as  $F$  makes use of more than  $k$  values from  $\alpha$ .

Note that a finite sequence, or a list, of elements of type  $A$  is encoded here as a pair of its length  $k$  and a function in  $\text{Nat} \rightarrow A$  where only its initial segment of length  $k$  is relevant. Given a list  $l$  given by the pair  $k$  and  $f$ , the operator  $\text{append}(k, f, a) \equiv \lambda x. \text{if } x = k \text{ then } a \text{ else } f(x)$  returns a list of length  $k + 1$  that appends  $a$  to  $l$ . Lists are defined like this instead of using a  $W$  type because  $\text{loop}(F)$  applies  $F$  to a function with initial segment the list given as argument. Therefore, instead of using an additional operator to turn an element of such a  $W$  type into a function, with this encoding lists directly provide such functions.

The computation in [35] uses exceptions to test whether  $F$  requires more values than the ones provided in the current finite sequence, while we use here references as in [11]. Exceptions are well-suited to test whether the modulus of continuity is reached, but not to directly compute moduli of continuity. For example, the computation in [32] relies on exceptions and a loop, while the computation in [11] makes use of references and does not require an additional loop because a reference cell can be used to store the moduli of continuity. Instead of using a reference to a Boolean, which would be similar to using an exception, we use here a reference  $\delta$  that points to a number, and apply  $F$  to  $\text{upd}(\delta, \alpha)$ , as in  $\text{WCP}_p$ 's realizer, as it allows us to reuse some of the results used in [11] to validate  $\text{WCP}_p$ .

## 5.2 Step 1: Building a co-W

First, we prove that from a function  $F \in \mathfrak{B} \rightarrow \text{Nat}$ , we get  $\text{loop}(F) \underline{0} \alpha_0 \in \text{CoDiag}$ , where  $\text{CoDiag} \equiv M(\text{Nat} +_p \text{Unit}, \lambda a. \text{if } a \text{ then } \text{Void} \text{ else } \text{Nat}_p)$ . We prove this by coinduction, and by inspecting the computation of  $\text{loop}(F)$  (see `coSem` in `barContP2.lagda`). Given  $k \in \text{Nat}_p$  and  $\alpha \in \mathfrak{B}$ ,  $(\text{loop}(F) k \alpha)$  first evaluates  $F(\text{upd}(\delta, \alpha))$  to  $i$  for some “fresh”  $\delta$ , and then returns  $\eta(i)$  if  $!\delta < k$ , and otherwise returns  $F(\lambda x. \text{loop}(F) (k + \underline{1}) \text{ append}(k, \alpha, x))$ . We now prove  $\text{loop}(F) k \alpha \in \text{CoDiag}$  by cases. If  $!\delta < k$  then it remains to prove that  $\eta(i) \in \text{CoDiag}$ , which is straightforward because  $F(\text{upd}(\delta, \alpha)) \in \text{Nat}$ , and therefore  $i$  too. If  $!\delta \not< k$  then it remains to prove  $F(\lambda x. \text{loop}(F) (k + \underline{1}) \text{ append}(k, \alpha, x)) \in \text{CoDiag}$ , which follows from the fact that  $\lambda x. \text{loop}(F) (k + \underline{1}) \text{ append}(k, \alpha, x) \in \text{Nat}_p \rightarrow \text{CoDiag}$ , which follows by coinduction.

## 5.3 Step 2: Case analysis

Using classical logic we analyze two cases: given  $t \in M(A, B)$ , either  $t$ 's branches are all finite or there exists an infinite branch, where the type of branches w.r.t. the world  $w$ , type  $A$ , and family  $B$  is defined as follows, a right injection capturing the termination of a branch:

$$\text{Branch} \equiv \forall (n : \mathbb{N}). (\exists (a, b : \text{Term}). w \vDash a \equiv a \in A \wedge w \vDash b \equiv b \in B(a)) \vee \top$$

## 37:12 Inductive Continuity via Brouwer Trees

Note that a branch can either be finite if it returns an element of the right disjunct (i.e.,  $\top$ ) for some  $n \in \mathbb{N}$ , or infinite if it always returns an element of the left disjunct for all  $n \in \mathbb{N}$ . Branches are defined w.r.t. a term  $t$  in  $W(A, B)$  or in  $M(A, B)$ , and we say that *a branch  $p \in \text{Branch}$  is a branch of a term  $t$*  if:  $\forall (n : \mathbb{N}). p \in_n t$ , where  $p \in_n t$  is defined recursively as follows (for  $\text{shift}(p) \equiv \lambda k. p(k + 1)$ ):

$$p \in_0 t \equiv \top \quad p \in_{n+1} t \equiv \begin{cases} \exists (f : \text{Term}). t \Rightarrow_w \text{sup}(a, f) \wedge \text{shift}(p) \in_n f b, \\ \quad \text{when } p(0) \text{ is a left injection of } (a, b, \_, \_) \\ \top, \text{ otherwise} \end{cases}$$

The tree  $t \in M(A, B)$  is  $\text{loop}(F) \sqcup \alpha_0$ . In case  $t$ 's branches are all finite, we show that  $t \in W(A, B)$  (Sec. 5.4). In case  $t$  has an infinite branch, we derive a contradiction using an argument similar to one used to validate weak continuity in [11] (Sec. 5.5).

### 5.4 Step 3: Building a W type

In case  $t$ 's branches are all finite, we prove that if  $t \in M(A, B)$  then  $t \in W(A, B)$ . Again, we use classical logic: assuming  $t \notin W(A, B)$  and deriving a contradiction. Given that  $t \in M(A, B)$  and  $t \notin W(A, B)$ , we extract, by coinduction, an infinite co-branch  $u$  from  $t$ , where the type of co-branches  $u$  w.r.t. the world  $w$ , type  $A$ , and family  $B$ , is coinductively defined as follows (see `m2mb` in `barContP.lagda`):

$$\nu(R. \exists (a, f, b : \text{Term}). u \Rightarrow_w \text{sup}(a, f) \wedge w \vDash b \equiv b \in B(a) \wedge R f(b))$$

In particular, such a co-branch provides a sequence of  $B$ s. From this co-branch  $u$ , we build an infinite branch  $p \in \text{Branch}$  (see `mb2path` in `barContP.lagda`), which is a function from  $n \in \mathbb{N}$  to (left injections of)  $B$ s along with their corresponding  $A$ s, derived by induction on  $n$ . From the assumption that  $t$ 's branches are all finite we obtain that  $p$  must also be finite, from which we derive a contradiction (see `m2w` in `barContP.lagda`).

### 5.5 Step 4: Termination

In case  $t$ , which is here  $\text{loop}(F) \sqcup \alpha_0$ , contains an infinite branch  $p$ , we derive a contradiction from  $F$ 's continuity. Because  $p$  is infinite, i.e., only returns left injections, we obtain a metatheoretical function of the following type, which follows the branch  $p$  of  $\text{loop}(F) \sqcup \alpha_0$ :

$$\mathbb{N} \rightarrow \exists (a, b : \text{Term}). w \vDash a \equiv a \in \text{Bt}A \wedge w \vDash b \equiv b \in \text{Bt}B(a)$$

Therefore, for each  $n \in \mathbb{N}$ , there are two cases: either ( $w \vDash a \equiv a \in \text{Nat}$  and  $w \vDash b \equiv b \in \text{Void}$ ) or ( $w \vDash a \equiv a \in \text{Unit}$  and  $w \vDash b \equiv b \in \text{Nat}_p$ ). Since  $\text{Void}$  is not inhabited, it must be that  $w \vDash a \equiv a \in \text{Unit}$  and  $w \vDash b \equiv b \in \text{Nat}_p$ . Hence, from this function, we obtain a metatheoretical function of the following type, which follows the branch  $p$  of  $\text{loop}(F) \sqcup \alpha_0$ :

$$\mathbb{N} \rightarrow \exists (b : \text{Term}). w \vDash b \equiv b \in \text{Nat}_p$$

From this function, since  $\square$  is a Kripke-like modality, we obtain a metatheoretical function  $\mathbf{s} \in \mathbb{N} \rightarrow \mathbb{N}$ , which given  $n \in \mathbb{N}$  returns the path taken in the  $n^{\text{th}}$   $F$  along the branch  $p$  following the computation  $\text{loop}(F) \sqcup \alpha_0$ . As explained in Sec. 3.1,  $\text{TT}_{\mathcal{C}}^{\square}$ 's calculus includes all metatheoretical functions from  $\mathbb{N}$  to  $\mathbb{N}$ , which inhabit  $\mathfrak{B}$ . These sequences do not have any computational purpose here, and are only used to prove termination. We have  $\lceil \mathbf{s} \rceil \in \mathfrak{B}$ , so by continuity of  $F$  we know that there is a  $k \in \mathbb{N}$  such that the  $k^{\text{th}}$  iteration of  $\text{loop}(F) \sqcup \alpha_0$  runs  $F(\text{upd}(\delta, \lceil \mathbf{s} \rceil))$  for some “fresh”  $\delta$  such that  $\delta$ 's value stays under  $k$  during the computation

of  $F(\text{upd}(\delta, [\mathbf{s}]))$ . This result makes use of `steps-sat-isHighestN` in `continuity3.lagda`, which was used to prove `WCPp` in [11], and in particular to prove that  $F(\text{upd}(\delta, [\mathbf{s}]))$  keeps track in  $\delta$  of the highest number that  $\mathbf{s}$  is applied to in the computation it performs. The modulus of continuity  $k$  of  $F$  at  $\text{upd}(\delta, [\mathbf{s}])$  is then the value stored by  $\delta$  at the end of this computation.

Therefore, because the  $k^{\text{th}}$  iteration of `loop(F) 0 α0` runs  $F(\text{upd}(\delta, [\mathbf{s}]))$  such that  $\delta$ 's value stays under  $k$ , it returns  $\eta(i)$  for some  $i$ , which contradicts the assumption that the branch is infinite, i.e., contains only  $F$ 's (see `noInfPath` in `barContP6.lagda` for details).

Note that the  $k^{\text{th}}$  iteration of `loop(F) 0 α0` does not quite run  $F(\text{upd}(\delta, [\mathbf{s}]))$ , but instead  $F(\text{upd}(\delta, \alpha))$ , where as indicated in Sec. 5.1,  $\alpha$  is built starting from  $\alpha_0$  using the `append` function, and therefore is equal to  $[\mathbf{s}]$  up to  $k$ . We can interchangeably use  $F(\text{upd}(\delta, [\mathbf{s}]))$  or  $F(\text{upd}(\delta, \alpha))$  thanks to Lem. 8 below (see `updSeq-steps-NUM` in `barContP6.lagda`).

► **Definition 7.** *The simulation relation  $t_1 \approx_{\delta, \mathbf{s}, n} t_2$  holds iff*

$$\begin{aligned} & (t_1 = \text{upd}(\delta, \mathbf{s}) \wedge t_2 = \text{upd}(\delta, s2l(\mathbf{s}, n))) \vee (t_1 = \text{upd}(\delta, s2l(\mathbf{s}, n)) \wedge t_2 = \text{upd}(\delta, \mathbf{s})) \\ \vee & (t_1 = x \wedge t_2 = x) \vee (t_1 = \underline{n} \wedge t_2 = \underline{n}) \vee (t_1 = \lambda x.a \wedge t_2 = \lambda x.b \wedge a \approx_{\delta, \mathbf{s}, n} b) \\ \vee & (t_1 = (a_1 \ b_1) \wedge t_2 = (a_2 \ b_2) \wedge a_1 \approx_{\delta, \mathbf{s}, n} b_1 \wedge a_2 \approx_{\delta, \mathbf{s}, n} b_2) \vee \dots \end{aligned}$$

where  $s2l(\mathbf{s}, 0) \equiv \alpha_0$  and  $s2l(\mathbf{s}, n+1) \equiv \text{append}(n, s2l(\mathbf{s}, n), \mathbf{s}(n+1))$ .

Most cases are omitted in this definition as they are similar to the ones presented above. Crucially terms of the form  $\delta$  or  $\nu x.t$  are not related, and those are the only expressions not related, thereby ruling out names except when occurring inside `upd` through the first clause.

► **Lemma 8.** *If  $a \approx_{\delta, \mathbf{s}, n} b$  and  $a \xrightarrow{w_1}^* \underline{k}$  such that  $n$  is higher than any value held by  $\delta$  throughout this computation, then  $b \xrightarrow{w_1}^* \underline{k}$ .*

## 5.6 Step 5: The Continuity Property

It now remains to prove that given  $F \in \mathfrak{B} \rightarrow \text{Nat}$ , the tree  $d \equiv (\text{loop}(F) \ 0 \ \alpha_0) \in \mathbf{Bt}$  satisfies the property  $\prod_p \alpha : \mathfrak{B}. \text{follow}(d, \alpha) = F(\alpha) \in \text{Nat}$  (see `semCond` in `barContP9.lagda`). For this we need to prove that `follow(d, α)` computes to the same number that  $F(\alpha)$  computes to, and this for any pure sequence  $\alpha \in \mathfrak{B}$  and tree  $d \equiv \text{loop}(F) \ \underline{k} \ \alpha_k$ , where  $\alpha_k$  agrees with  $\alpha$  up to  $k$  (see `follow-NUM` in `barContP9.lagda`). We prove this by induction on  $d$ . Either  $d$  is an  $\eta(i)$ , which we discuss below, or a  $F(f)$ , in which case we conclude by induction. In case  $d$  is  $\eta(i)$ , we must prove that  $F(\alpha)$  computes to  $i$ . In that case,  $d$  runs  $F(\text{upd}(\delta, \alpha_k))$  for some “fresh”  $\delta$ , which computes to  $i$  for some  $\alpha_k$  that agrees with  $\alpha$  up to  $k$ . Here  $\alpha_k$  is  $s2l(\mathbf{s}, k)$ , for some  $\mathbf{s}$  equal to  $\alpha$  in  $\mathfrak{B}$ . We use again here a metatheoretical sequence  $\mathbf{s}$ , which does not have any computational purpose. We can then prove that  $F(\alpha)$  and  $F(\mathbf{s})$  compute to the same number, and appealing to Lem. 8, we prove that  $F(\mathbf{s})$  and  $F(\text{upd}(\delta, \alpha_k))$  compute to the same number, and therefore that  $F(\alpha)$  computes to  $i$ , which concludes our proof.

## 6 Conclusion and Related Works

The paper presents the first internalization of the inductive dialogue-based continuity principle in a dependent type theory, namely  $\text{TT}_{\mathcal{C}}^{\square}$ , which has been formalized in Agda. For this, we construct Brouwer trees via effectful computations that use references. Proving the inductive continuity principle internally entails new challenges, such as the termination proof which requires maintaining a strict connection between a meta-theoretical generic element and an internal computation. More generally, the class of effectful intuitionistic theories  $\text{TT}_{\mathcal{C}}^{\square}$ ,

which now internalizes several continuity principles, provides a computational framework for further studying the relationship between these principles. WCP and ICP have been shown to coincide in the presence of Bar Induction (under certain restrictions), or assuming classical reasoning [6, 22, 9]. Bar Induction was shown to be consistent with a subsystem of  $\text{TT}_{\mathcal{C}}^{\square}$  [34]. Thus, it seems that  $\text{TT}_{\mathcal{C}}^{\square}$  provides an ideal framework in which one can formally verify this implication internally, as well as produce a corresponding computation. An immediate related question we leave for further study is then to establish the relation between the two principles in a general setting, without assuming Bar Induction or resorting to classical reasoning.

The technique of using dialogue trees to compute moduli of continuity originated in [20, 22, 21, 19], while the idea of recording the interaction of a function with an oracle to compute continuity goes back to Longley [28], where exceptions and references were used as a probing mechanism to compute moduli of continuity. In [19], Escardó defined a model of System T where  $\mathbb{N}$  is interpreted as the type of dialogue trees and function types as functions between the interpretations of the source and target types. This model contains a *generic element* of type  $\mathbb{N} \rightarrow \mathbb{N}$ , a function from dialogue trees to dialogue trees, that records queries to it in the structure of the resulting dialogue tree. Then, a dialogue tree is built using this generic element, from which the modulus of continuity can be calculated. Sterling [35] extended the effectful forcing technique to prove that System T validates the realizable bar thesis, which is equivalent to the inductive continuity principle considered here. System T was given a call-by-name interpretation, where types are interpreted as algebras over a dialogue tree monad. Although the carrier sets of this interpretation agree with those of Escardó, the actions of the algebras allow for a compositional interpretation of the recursor on numbers.

In [3], the authors prove that all BTT [29] functions are continuous by generalizing the method of [19]. However, their method does not allow *internalizing* the continuity principle, which is the goal of the present work. As they work in the metatheory, they can induct on the syntax of the  $F \in \mathfrak{B} \rightarrow \text{Nat}$  when constructing the dialogue trees, allowing for a constructive proof of continuity. In this work, we construct a program computing such trees in the theory itself, where recursion on syntax of terms is not available. As a result we resort to classical logic to prove finiteness of the computed trees and termination of this program. It remains to be seen if this can also be done internally, without resorting to classical logic.

Richard Mayr

School of Informatics, University of Edinburgh, UK

---

## Abstract

---

We consider simple stochastic games  $\mathcal{G}$  with energy-parity objectives, a combination of quantitative rewards with a qualitative parity condition. The Maximizer tries to avoid running out of energy while simultaneously satisfying a parity condition.

We present an algorithm to approximate the value of a given configuration in 2-NEXPTIME. Moreover,  $\varepsilon$ -optimal strategies for either player require at most  $\mathcal{O}(2\text{-EXP}(|\mathcal{G}|) \cdot \log(\frac{1}{\varepsilon}))$  memory modes.

## 1 Introduction

**Background.** *Simple stochastic games* (SSGs) are 2-player turn-based perfect information stochastic games played on finite graphs. They are also called *competitive Markov decision processes* [20], or  *$2\frac{1}{2}$ -player games* [13, 12]. Introduced by Shapley [36] in 1953, they have since played a central role in the solution of many problems, e.g., synthesis of reactive systems [35, 34] and formal specification and verification [17, 18, 1]. Every state either belongs to one of the players (Maximizer or Minimizer) or is a random state. In each round of the game the player who owns the current state gets to choose the successor state along the game graph. For random states the successor is chosen according to a predefined distribution. Given a start state and strategies of Maximizer and Minimizer, this yields a distribution over induced infinite plays. We consider objectives  $\mathbf{0}$  that are measurable subsets of the set of possible plays, and the players try to maximize (resp. minimize) the probability of  $\mathbf{0}$ .

Many different objectives for SSGs have been studied in the literature. Here we focus on parity, mean-payoff and energy objectives. We assign numeric rewards to transitions and priorities (aka colors), encoded by bounded non-negative numbers, to states. A play satisfies the (min-even) *parity objective* iff the minimal priority that appears infinitely often in a play is even. It subsumes all  $\omega$ -regular objectives, and in particular safety, liveness, fairness, etc. On finite SSGs, the parity objective can be seen as a special case of the *mean-payoff objective* which requires the limit average reward per transition along a play to be positive (or non-negative). Mean-payoff objectives in SSGs go back to a 1957 paper by Gillette [21] and have been widely studied, due to their relevance for efficient control. The *energy objective* [6] requires that the accumulated reward at any time in a play stays above some finite threshold. The intuition is that a controlled system has some finite initial energy level that must never become depleted. Since the accumulated reward is not bounded a-priori, this essentially turns a finite-state game into an infinite-state one.

**Energy-parity.** We consider SSGs with *energy-parity* objectives, where plays need to satisfy both an energy and a parity objective. The parity objective specifies functional correctness, while the energy condition can encode efficiency or risk considerations, e.g., the system should not run out of energy since manually recharging would be costly or risky.

**Previous work.** Much work on combined objectives for stochastic systems is restricted to Markov decision processes (MDPs) [8, 9, 4, 28].

For (stochastic) games, the computational complexity of single objectives is often in  $\text{NP} \cap \text{coNP}$ , e.g., for parity or mean-payoff objectives [25]. Multi-objective games can be harder, e.g., satisfying *two different* parity objectives leads to  $\text{coNP}$  completeness [11].

Stochastic mean-payoff parity games can be solved in  $\text{NP} \cap \text{coNP}$  [10]. However, this does not imply a solution for stochastic energy-parity games, since, unlike in the non-stochastic case [7], there is no known reduction from energy-parity to mean-payoff parity in stochastic games. The reduction in [7] relies on the fact that Maximizer has a winning *finite-memory* strategy for energy-parity, which does not generally hold for stochastic games, or even MDPs [28]. For the same reason, the direct reduction from stochastic energy-parity to ordinary energy games proposed in [8, 9] does not work for general energy-parity but only for energy-Büchi; cf. [28].

Non-stochastic energy-parity games can be solved in  $\text{NP} \cap \text{coNP}$  (and even in pseudo-quasi-polynomial time [16]) and Maximizer strategies require only finite (but exponential) memory [7].

Stochastic energy-parity games have been studied in [29], where it was shown that the almost-sure problem is decidable and in  $\text{NP} \cap \text{coNP}$ . That is, given an initial configuration (control-state plus current energy level), does Maximizer have a strategy to ensure that energy-parity is satisfied with probability 1 against any Minimizer strategy? Unlike in many single-objective games, such an almost-surely winning Maximizer strategy (if it exists) requires infinite memory in general. This holds even in MDPs and for energy-coBüchi objectives [28].

However, [29] did not address quantitative questions about energy-parity objectives, such as computing/approximating the value of a given configuration, or the decidability of exact questions like “Is the value of this configuration  $\geq k$ ?” for some constant  $k$  (e.g.,  $k = 1/2$ ).

The decidability of the latter type of exact question about the energy-parity value is open, but there are strong indications that it is very hard. In fact, even simpler subproblems are already at least as hard as the *positivity problem for linear recurrence sequences*, which in turn is at least as hard as the *Skolem problem* [19]. (The decidability of these problems has been open for decades; see [30] for an overview.) Given an SSG with an energy-parity objective, suppose we remove the parity condition (assume it is always true) and also suppose that Maximizer is passive (does not get to make any decisions). Then we obtain an MDP where the only active player (the Minimizer in the SSG) has a *termination objective*, i.e., to reach a configuration where the energy level is  $\leq 0$ . Exact questions about the value of the termination objective in MDPs are already at least as hard as the positivity problem [31, Section 5.2.3] (see also [32, 33]). Thus exact questions about the energy-parity value in SSGs are also at least as hard as the positivity problem.

**Our contributions.** Since exact questions about the energy-parity value in SSGs are positivity-hard, we consider the problem of computing approximations of the value. We present an algorithm that, given an SSG  $\mathcal{G}$  and error  $\varepsilon$ , computes  $\varepsilon$ -close approximations of the energy-parity value of any given configuration in 2-NEXPTIME. Moreover, we show that

$\varepsilon$ -optimal Maximizer (resp. Minimizer) strategies can be chosen as deterministic and using only finite memory with  $\mathcal{O}(2\text{-EXP}(|\mathcal{G}|) \cdot \log(\frac{1}{\varepsilon}))$  memory modes. One can understand the idea as a constructive upper bound on the accuracy with which the players need to remember the current energy level in the game. (This is in contrast to the result in [28] that almost-surely winning Maximizer strategies require infinite memory in general.) Once the upper bound on Maximizer's memory for  $\varepsilon$ -optimal strategies is established, one might attempt a reduction from energy-parity to mean-payoff parity, along similar lines as for non-stochastic games in [7]. However, instead we use a more direct reduction from energy-parity to parity in a derived SSG for our approximation algorithm.

## 2 Preliminaries

A *probability distribution* over a countable set  $S$  is a function  $f: S \rightarrow [0, 1]$  with  $\sum_{s \in S} f(s) = 1$ .  $\text{supp}(f) \stackrel{\text{def}}{=} \{s \mid f(s) > 0\}$  denotes the support of  $f$  and  $\mathcal{D}(S)$  is the set of all probability distributions over  $S$ . Given an alphabet  $\Sigma$ , let  $\Sigma^\omega$  and  $\Sigma^*$  ( $\Sigma^+$ ) denote the set of infinite and finite (non-empty) sequences over  $\Sigma$ , respectively. Elements of  $\Sigma^\omega$  or  $\Sigma^*$  are called words.

**Games, MDPs and Markov chains.** A *Simple Stochastic Game* (SSG) is a finite-state 2-player turn-based perfect-information stochastic game  $\mathcal{G} = (S, (S_\square, S_\diamond, S_\circ), E, P)$  where the finite set of states  $S$  is partitioned into the states  $S_\square$  of the player  $\square$  (*Maximizer*), states  $S_\diamond$  of player  $\diamond$  (*Minimizer*), and chance vertices (aka random states)  $S_\circ$ . Let  $E \subseteq S \times S$  be the transition relation. We write  $s \rightarrow s'$  if  $(s, s') \in E$  and assume that  $\text{Succ}(s) \stackrel{\text{def}}{=} \{s' \mid sEs'\} \neq \emptyset$  for every state  $s$ . The *probability function*  $P$  assigns each random state  $s \in S_\circ$  a distribution over its successor states, i.e.,  $P(s) \in \mathcal{D}(\text{Succ}(s))$ . For ease of presentation, we extend the domain of  $P$  to  $S^*S_\circ$  by  $P(\rho s) \stackrel{\text{def}}{=} P(s)$  for all  $\rho s \in S^*S_\circ$ . An *MDP* is a game where one of the two players does not control any states. An MDP is *maximizing* (resp. *minimizing*) iff  $S_\diamond = \emptyset$  (resp.  $S_\square = \emptyset$ ). A *Markov chain* is a game with only random states, i.e.,  $S_\square = S_\diamond = \emptyset$ .

**Strategies.** A *play* is an infinite sequence  $s_0s_1 \dots \in S^\omega$  such that  $s_i \rightarrow s_{i+1}$  for all  $i \geq 0$ . A *path* is a finite prefix of a play. Let  $\text{Plays}(\mathcal{G}) \stackrel{\text{def}}{=} \{\rho = (q_i)_{i \in \mathbb{N}} \mid q_i \rightarrow q_{i+1}\}$  denote the set of all possible plays. A strategy of the player  $\square$  ( $\diamond$ ) is a function  $\sigma: S^*S_\square \rightarrow \mathcal{D}(S)$  ( $\pi: S^*S_\diamond \rightarrow \mathcal{D}(S)$ ) that assigns to every path  $ws \in S^*S_\square$  ( $\in S^*S_\diamond$ ) a probability distribution over the successors of  $s$ . If these distributions are always Dirac then the strategy is called *deterministic* (aka pure), otherwise it is called *randomized* (aka mixed). The set of all strategies of player  $\square$  and  $\diamond$  in  $\mathcal{G}$  is denoted by  $\Sigma_{\mathcal{G}}$  and  $\Pi_{\mathcal{G}}$ , respectively. A play/path  $s_0s_1 \dots$  is compatible with a pair of strategies  $(\sigma, \pi)$  if  $s_{i+1} \in \text{supp}(\sigma(s_0 \dots s_i))$  whenever  $s_i \in S_\square$  and  $s_{i+1} \in \text{supp}(\pi(s_0 \dots s_i))$  whenever  $s_i \in S_\diamond$ .

Finite-memory deterministic (FD) strategies are a subclass of strategies described by deterministic transducers  $T = (M, m_0, \text{upd}, \text{nxt})$  where  $M$  is a finite set of memory modes with initial mode  $m_0$ ,  $\text{upd}: M \times E \mapsto M$  updates the memory mode upon observing a transition and  $\text{nxt}: M \times S_\circ \mapsto S$  chooses the successor state based on the current memory mode and state. FD strategies without memory ( $|M| = 1$ ) are called memoryless deterministic (MD). For deterministic strategies, there is no difference between public memory (observable by the other player) and private memory.

**Measure.** A game  $\mathcal{G}$  with initial state  $s_0$  and strategies  $(\sigma, \pi)$  yields a probability space  $(s_0S^\omega, \mathcal{F}_{s_0}, \mathcal{P}_{\sigma, \pi, s_0}^{\mathcal{G}})$  where  $\mathcal{F}_{s_0}$  is the  $\sigma$ -algebra generated by the cylinder sets  $s_0s_1 \dots s_nS^\omega$  for  $n \geq 0$ . The probability measure  $\mathcal{P}_{\sigma, \pi, s_0}^{\mathcal{G}}$  is first defined on the cylinder sets. For

$\rho = s_0 \dots s_n$ , let  $\mathcal{P}_{\sigma, \pi, s_0}^{\mathcal{G}}(\rho) \stackrel{\text{def}}{=} 0$  if  $\rho$  is not compatible with  $\sigma, \pi$  and otherwise  $\mathcal{P}_{\sigma, \pi, s_0}^{\mathcal{G}}(\rho S^\omega) \stackrel{\text{def}}{=} \prod_{i=0}^{n-1} \tau(s_0 \dots s_i)(s_{i+1})$  where  $\tau$  is  $\sigma$  or  $\pi$  or  $P$  depending on whether  $s_i \in S_\square$  or  $S_\diamond$  or  $S_\circ$ , respectively. By Carathéodory's extension theorem [2], this defines a unique probability measure on the  $\sigma$ -algebra.

**Objectives and Payoff functions.** General objectives are defined by real-valued measurable functions. However, we only consider indicator functions of measurable sets. Hence our objectives can be described by measurable subsets  $\mathbf{0} \subseteq S^\omega$  of plays. The payoff, under strategies  $(\sigma, \pi)$ , is the probability that plays belong to  $\mathbf{0}$ .

We use the syntax and semantics of the LTL operators [14] **F** (eventually), **G** (always) and **X** (next) to specify some conditions on plays.

*Reachability & Safety.* A reachability objective is defined by a set of target states  $T \subseteq S$ . A play  $\rho = s_0 s_1 \dots$  belongs to **FT** iff  $\exists i \in \mathbb{N} s_i \in T$ . Similarly,  $\rho$  belongs to  $\mathbf{F}^{\leq n} T$  (resp.  $\mathbf{F}^{\geq n} T$ ) iff  $\exists i \leq n$  (resp.  $i \geq n$ ) such that  $s_i \in T$ . Dually, the safety objective **GT** consists of all plays which never leave  $T$ . We have  $\mathbf{GT} = \neg \mathbf{F}\neg T$ .

*Parity.* A parity objective is defined via bounded function  $Col : S \rightarrow \mathbb{N}$  that assigns non-negative priorities (aka colors) to states. Given an infinite play  $\rho = s_0 s_1 \dots$ , let  $\text{Inf}(\rho)$  denote the set of numbers that occur infinitely often in the sequence  $Col(s_0) Col(s_1) \dots$ . A play  $\rho$  satisfies *even parity* w.r.t.  $Col$  iff the minimum of  $\text{Inf}(\rho)$  is even. Otherwise,  $\rho$  satisfies *odd parity*. The objective even parity is denoted by **EPAR**( $Col$ ) and odd parity is denoted by **OPAR**( $Col$ ). Most of the time, we implicitly assume that the coloring function is known and just write **EPAR** and **OPAR**. Observe that, given any coloring  $Col$ , we have  $\overline{\mathbf{EPAR}} = \mathbf{OPAR}$  and  $\mathbf{OPAR}(Col) = \mathbf{EPAR}(Col + 1)$  where  $Col + 1$  is the function which adds 1 to the color of every state. This justifies to consider only one of the even/odd parity objectives, but, for the sake of clarity, we distinguish these objectives wherever necessary.

*Energy/Reward/Counter based objectives.* Let  $r : E \rightarrow \{-R, \dots, 0, \dots, R\}$  be a bounded function that assigns weights to transitions. Depending on context, the sum of these weights in a path can be viewed as energy, cost/reward or a counter. If  $s \xrightarrow{c} s'$  and  $r((s, s')) = c$ , we write  $s \xrightarrow{c} s'$ . Let  $\rho = s_0 \xrightarrow{c_0} s_1 \xrightarrow{c_1} \dots$  be a play. We say that  $\rho$  satisfies

1. the *k-energy* objective **EN**( $k$ ) iff  $\left(k + \sum_{i=0}^{n-1} c_i\right) > 0$  for all  $n \geq 0$ .
2. the *l-storage condition* if  $l + \sum_{i=m}^{n-1} c_i \geq 0$  holds for every infix  $s_m \xrightarrow{c_m} s_{m+1} \dots s_n$  of the play. Let **ST**( $k, l$ ) denote the set of plays that satisfy both the *k-energy* and the *l-storage condition*. Let  $\mathbf{ST}(k) \stackrel{\text{def}}{=} \bigcup_l \mathbf{ST}(k, l)$ . Clearly,  $\mathbf{ST}(k) \subseteq \mathbf{EN}(k)$ .
3. *k-Termination* **Term**( $k$ ) iff there exists  $n \geq 0$  such that  $\left(k + \sum_{i=0}^{n-1} c_i\right) \leq 0$ .
4. *Limit* objective **LimInf**( $\triangleright z$ ) iff  $\left(\liminf_{n \rightarrow \infty} \sum_{i=0}^{n-1} c_i\right) \triangleright z$  for  $\triangleright \in \{<, \leq, =, \geq, >\}$  and  $z \in \mathbb{R} \cup \{\infty, -\infty\}$  and similarly for **LimSup**( $\triangleright z$ ).
5. *Mean payoff* **MP**( $\triangleright c$ ) for some constant  $c \in \mathbb{R}$  iff  $\left(\liminf_{n \rightarrow \infty} \frac{1}{n} \sum_{i=0}^{n-1} c_i\right) \triangleright c$ .

Observe that the objectives *k-energy* and *k-termination* are mutually exclusive and cover all of the plays. A different way to consider these objectives is to encode the energy level (the sum of the transition weights so far) into the state space and then consider the obtained infinite-state game with safety/reachability objective, respectively.

An objective  $\mathbf{0}$  is called *shift-invariant* iff for all finite paths  $\rho$  and plays  $\rho' \in S^\omega$ , we have  $\rho\rho' \in \mathbf{0} \iff \rho' \in \mathbf{0}$ . Parity and mean payoff objectives are shift-invariant, but energy and termination objectives are not. Objective  $\mathbf{0}$  is called *submixing* iff for all sequences of finite non-empty words  $u_0, v_0, u_1, v_1 \dots$  we have  $u_0 v_0 u_1 v_1 \dots \in \mathbf{0} \implies ((u_0 u_1 \dots \in \mathbf{0}) \vee (v_0 v_1 \dots \in \mathbf{0}))$ .

**Determinacy.** Given an objective  $\mathbf{0}$  and a game  $\mathcal{G}$ , state  $s$  has value (w.r.t to  $\mathbf{0}$ ) iff

$$\sup_{\sigma \in \Sigma_{\mathcal{G}}} \inf_{\pi \in \Pi_{\mathcal{G}}} \mathcal{P}_{\sigma, \pi, s}^{\mathcal{G}}(\mathbf{0}) = \inf_{\pi \in \Pi_{\mathcal{G}}} \sup_{\sigma \in \Sigma_{\mathcal{G}}} \mathcal{P}_{\sigma, \pi, s}^{\mathcal{G}}(\mathbf{0}).$$

If  $s$  has value then  $\text{val}_{\mathbf{0}}^{\mathcal{G}}(s)$  denotes the value of  $s$  defined by the above equality. A game with an objective is called *weakly determined* if every state has value. Stochastic games with Borel objectives are weakly determined [26, 27]. Our objectives above are Borel, hence any boolean combination of them is also weakly determined. For  $\varepsilon > 0$  and state  $s$ , a strategy

1.  $\sigma \in \Sigma_{\mathcal{G}}$  is  $\varepsilon$ -optimal (maximizing) iff  $\mathcal{P}_{\sigma, \pi, s}^{\mathcal{G}}(\mathbf{0}) \geq \text{val}_{\mathbf{0}}^{\mathcal{G}}(s) - \varepsilon$  for all  $\pi \in \Pi_{\mathcal{G}}$ .
2.  $\pi \in \Pi_{\mathcal{G}}$  is  $\varepsilon$ -optimal (minimizing) iff  $\mathcal{P}_{\sigma, \pi, s}^{\mathcal{G}}(\mathbf{0}) \leq \text{val}_{\mathbf{0}}^{\mathcal{G}}(s) + \varepsilon$  for all  $\sigma \in \Sigma_{\mathcal{G}}$ .

A 0-optimal strategy is called *optimal*. An MD strategy is called *uniformly  $\varepsilon$ -optimal* (resp. uniformly optimal) if it is so from every start state. An optimal strategy for player  $\square$  from state  $s$  is *almost surely winning* if  $\text{val}_{\mathbf{0}}^{\mathcal{G}}(s) = 1$ . By AS ( $\mathbf{0}$ ) we denote the set of states that have an almost surely winning strategy for objective  $\mathbf{0}$ . For ease of presentation, we drop subscripts and superscripts wherever possible if they are clear from the context.

**Energy-parity.** We are concerned with approximating the value for the combined energy-parity objective  $\text{EN}(k) \cap \text{EPAR}$  and building  $\varepsilon$ -optimal strategies.

In our constructions we use some auxiliary objectives. Following [29], these are defined as  $\text{Gain} \stackrel{\text{def}}{=} \text{LimInf}(\triangleright -\infty) \cap \text{EPAR}$  and  $\text{Loss} \stackrel{\text{def}}{=} \overline{\text{Gain}} = \text{LimInf}(=\infty) \cup \text{OPAR}$ .

► **Remark 1.** For finite-state SSGs and the following objectives there exist optimal MD strategies for both players. Moreover, if the SSG is just a maximizing MDP then the set of states that are almost surely winning for Maximizer can be computed in polynomial time.

1. FT [15]
2.  $\text{LimInf}(\triangleright -\infty)$ ,  $\text{LimInf}(\triangleright \infty)$ ,  $\text{LimSup}(\triangleright -\infty)$ ,  $\text{LimSup}(\triangleright \infty)$ ,  $\text{MP}(\triangleright 0)$  [5, Prop. 1]
3. EPAR [37]

### 3 The Main Result

The following theorem states our main result.

► **Theorem 2.** Let  $\mathcal{G} = (S, (S_{\square}, S_{\diamond}, S_{\circ}), E, P)$  be an SSG with transition rewards in unary assigned by function  $r$  and colors assigned to states by function  $\text{Col}$ . For every state  $s \in S$ , initial energy level  $i \geq 0$  and error margin  $\varepsilon > 0$ , one can compute

1. a rational number  $v'$  such that  $0 \leq v' - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon$  in 2-NEXPTIME.<sup>1</sup>
2.  $\varepsilon$ -optimal FD strategies  $\sigma_{\varepsilon}$  and  $\pi_{\varepsilon}$  for Maximizer and Minimizer, resp., in 2-NEXPTIME.

These strategies use  $\mathcal{O}(2\text{-EXP}(|\mathcal{G}|) \cdot \log(\frac{1}{\varepsilon}))$  memory modes.

For rewards in binary, the bounds above increase by one exponential.

We outline the main steps of the proof; details in the following sections. We begin with the observation that  $\text{EN}(i) \subseteq \text{EN}(j)$  for  $i \leq j$ , and thus for all states  $s$  we have  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \text{val}_{\text{EN}(j) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq 1$ . So  $\lim_{n \rightarrow \infty} \text{val}_{\text{EN}(n) \cap \text{EPAR}}^{\mathcal{G}}(s)$  exists. We define

$$\text{Lval}^{\mathcal{G}}(s) \stackrel{\text{def}}{=} \lim_{n \rightarrow \infty} \text{val}_{\text{EN}(n) \cap \text{EPAR}}^{\mathcal{G}}(s). \quad (1)$$

<sup>1</sup> We write “computing a number  $v'$  in 2-NEXPTIME” as a shorthand for the property that questions like  $v' \leq c$  for constants  $c$  are decidable in 2-NEXPTIME.

We will see that  $\text{Lval}^{\mathcal{G}}(s)$  and  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  are in fact equal (a consequence of Lemma 9) and  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  can be computed in nondeterministic polynomial time (Theorem 5). Intuitively, for high energy levels, the precise energy level does not matter much for the value.

The main steps of the approximation algorithm are as follows.

1. Compute FD strategies  $\sigma^*(s)$  that are optimal maximizing for the objective **Gain** starting from state  $s$  in  $\mathcal{G}$ . Compute an MD strategy  $\pi^*$  that is uniformly optimal minimizing for the objective **Gain**. Compute the value  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  for every  $s \in S$ . See Section 4.
2. Compute a natural number  $N$  such that for all  $s \in S$  and all  $i \geq N$  we have

$$0 \leq \text{val}_{\text{Gain}}^{\mathcal{G}}(s) - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon.$$

$N$  will be doubly exponential. See Section 5.

3. Consider the finite-state parity game  $\mathcal{G}'$  derived from  $\mathcal{G}$  by encoding the energy level up-to  $N$  into the states, i.e., the states of  $\mathcal{G}'$  are of the form  $(s, k)$  for  $s \in S$  and  $0 \leq k \leq N$ , and colors are inherited from  $s$ . Moreover, we add gadgets that ensure that states  $(s, N)$  at the upper end win with probability  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  and states  $(s, 0)$  at the lower end lose. By the previous item,  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  is  $\varepsilon$ -close to  $\text{val}_{\text{EN}(N) \cap \text{EPAR}}^{\mathcal{G}}(s)$ . Thus, for  $k < N$  we can  $\varepsilon$ -approximate the value  $v = \text{val}_{\text{EN}(k) \cap \text{EPAR}}^{\mathcal{G}}(s)$  by  $v' \stackrel{\text{def}}{=} \text{val}_{\text{EPAR}}^{\mathcal{G}'}((s, k))$ . If  $k \geq N$  we can  $\varepsilon$ -approximate  $v$  by  $v' \stackrel{\text{def}}{=} \text{val}_{\text{Gain}}^{\mathcal{G}}(s)$ .

Moreover, we obtain  $\varepsilon$ -optimal FD strategies  $\sigma_\varepsilon$  for Maximizer (resp.  $\pi_\varepsilon$  for Minimizer) for  $\text{EN}(k) \cap \text{EPAR}$  in  $\mathcal{G}$ . Let  $\hat{\sigma}$  (resp.  $\hat{\pi}$ ) be optimal MD strategies for Maximizer (resp. Minimizer) for the objective **EPAR** in  $\mathcal{G}'$ . Then  $\sigma_\varepsilon$  plays as follows. While the current energy level  $j$  ( $k$  plus the sum of the rewards so far) stays  $< N$ , then, at any state  $s'$ , play like  $\hat{\sigma}$  at state  $(s', j)$  in  $\mathcal{G}'$ . Once the energy level reaches a value  $\geq N$  at some state  $s'$  for the first time, then play like  $\sigma^*(s')$  forever. Similarly,  $\pi_\varepsilon$  plays as follows. While the current energy level  $j$  ( $k$  plus the sum of the rewards so far) stays  $< N$ , then, at any state  $s'$ , play like  $\hat{\pi}$  at state  $(s', j)$  in  $\mathcal{G}'$ . Once the energy level reaches a value  $\geq N$  (at any state) for the first time, then play like  $\pi^*$  forever. See Section 6.

As a technical tool, we sometimes consider the dual of a game  $\mathcal{G}$  (resp. the dual maximizing MDP of some minimizing MDP). Consider  $\mathcal{G}^d \stackrel{\text{def}}{=} (S', (S'_\square, S'_\diamond, S'_\circ), E', P')$  with the complement objective  $\overline{\text{EN}(k) \cap \text{EPAR}} = \text{Term}(k) \cup \text{OPAR}$ , where  $\mathcal{G}^d$  is simply the game with the roles of Maximizer and Minimizer reversed, i.e.,

$$S' = S \quad S'_\square = S_\diamond \quad S'_\diamond = S_\square \quad S'_\circ = S_\circ \quad E' = E \quad P' = P$$

Hence  $\Sigma_{\mathcal{G}^d} = \Pi_{\mathcal{G}}$  and  $\Pi_{\mathcal{G}^d} = \Sigma_{\mathcal{G}}$ . It is easy to see that for any objective  $\mathbb{O}$  and start state  $s$

1.  $\text{val}_{\mathbb{O}}^{\mathcal{G}}(s) + \text{val}_{\overline{\mathbb{O}}}^{\mathcal{G}^d}(s) = 1$ .
2.  $\sigma$  is  $\varepsilon$ -optimal maximizing for  $\mathbb{O}$  in  $\mathcal{G}$  iff it is  $\varepsilon$ -optimal minimizing for  $\overline{\mathbb{O}}$  in  $\mathcal{G}^d$ .
3.  $\pi$  is  $\varepsilon$ -optimal minimizing for  $\mathbb{O}$  in  $\mathcal{G}$  iff it is  $\varepsilon$ -optimal maximizing for  $\overline{\mathbb{O}}$  in  $\mathcal{G}^d$ .

So approximating the value of  $\text{EN}(k) \cap \text{EPAR}$  in  $\mathcal{G}$  can be reduced in linear time to approximating the value of  $\text{Term}(k) \cup \text{OPAR}$  in  $\mathcal{G}^d$ .

#### 4 Computing $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$

Given an SSG  $\mathcal{G} = (S, (S_\square, S_\diamond, S_\circ), E, P)$  and a start state  $s$ , we will show how to compute  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  and the optimal strategies for both players.

We start with the case of maximizing MDPs. The following lemma summarizes some previous results ([29, Lemmas 30,16], [28, Lemma 26], [24, Proposition 4]).

► **Lemma 3.** *Let  $\mathcal{M}$  be a maximizing MDP.*

1.  $\text{Lval}^{\mathcal{M}}(s) = \text{val}_{\text{Gain}}^{\mathcal{M}}(s)$  for all states  $s \in S$ .
2. *Optimal strategies for Gain in  $\mathcal{M}$  exist and can be chosen FD, with  $\mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}))$  memory modes, and exponential memory is also necessary.*
3. *For any state  $s \in S$ ,  $\text{Lval}^{\mathcal{M}}(s)$  is rational and can be computed in  $\mathcal{O}(|\mathcal{M}|^8)$  deterministic polynomial time if rewards are in unary, and in NP and coNP if rewards are in binary.*

**Proof.** Item 1 holds by [29, Lemma 30].

Towards Item 2, we follow the proof of [29, Lemma 16]. Since  $\text{Gain} = \text{LimInf}( > -\infty ) \cap \text{EPAR}$  is shift-invariant, there exist optimal strategies by [22]. By [28, Theorem 18] and Item 1, an optimal strategy for  $\text{Gain}$  can be constructed as follows. Let  $A \stackrel{\text{def}}{=} \bigcup_{k \in \mathbb{N}} \text{AS}(\text{ST}(k) \cap \text{EPAR})$  and  $B \stackrel{\text{def}}{=} \text{AS}(\text{LimInf}(= \infty) \cap \text{EPAR})$  be the subsets of states from which there exist almost surely winning strategies for the objectives  $\text{ST}(k) \cap \text{EPAR}$  and  $\text{LimInf}(= \infty) \cap \text{EPAR}$ , respectively. By [28, Theorem 8], we can restrict the values  $k$  in the definition of  $A$  by some  $k' = \mathcal{O}(|S| \cdot R)$ , i.e.,  $A = \bigcup_{k \leq k'} \text{AS}(\text{ST}(k) \cap \text{EPAR})$ . An optimal strategy  $\sigma$  for  $\text{Gain}$  works in two phases. First it plays an optimal strategy  $\sigma_R$  towards reaching the set  $A \cup B$ , where  $\sigma_R$  can be chosen MD by Remark 1. Then, upon reaching  $A$  (resp.  $B$ ), it plays an almost surely winning strategy  $\sigma_A$  for the objective  $\text{ST}(k) \cap \text{EPAR}$  (resp.  $\sigma_B$  for the objective  $\text{LimInf}(= \infty) \cap \text{EPAR}$ ). By [28, Theorem 8], the strategy  $\sigma_A$  requires  $\mathcal{O}(k \cdot |S|)$  memory modes for a given  $k$  and thus at most  $\mathcal{O}(|S|^2 \cdot R)$ , since we can assume that  $k \leq k'$ . Towards the strategy  $\sigma_B$ , we first observe that in finite MDPs a strategy is almost-surely winning for  $\text{LimInf}(= \infty) \cap \text{EPAR}$  iff it is almost-surely winning for  $\text{MP}( > 0 ) \cap \text{EPAR}$ . By [24, Proposition 4], there exist optimal deterministic strategies for  $\text{MP}( > 0 ) \cap \text{EPAR}$  that use exponential memory, i.e.,  $\mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}))$  memory modes. The memory required for  $\sigma_B$  exceeds that of  $\sigma_R$  and  $\sigma_A$  (even when  $R$  is given in binary), and the one extra memory mode to record the switch from  $\sigma_R$  to  $\sigma_A$  (resp.  $\sigma_B$ ) is negligible in comparison. Thus we can conclude that  $\sigma$  uses  $\mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}))$  memory modes. [24, Fig. 1 and Prop. 4] shows that exponential memory is necessary.

Towards Item 3, let  $d \stackrel{\text{def}}{=} |\text{Col}(S)|$  be the number of priorities in the parity condition. By [28, Lemma 26], for each  $s \in S$ ,  $\text{Lval}^{\mathcal{M}}(s)$  is rational and can be computed in deterministic time  $\tilde{\mathcal{O}}(|E| \cdot d \cdot |S|^4 \cdot R + d \cdot |S|^{3.5} \cdot (|P| + |r|)^2)$  (and still in NP and coNP if  $R$  is given in binary). So  $\text{Lval}^{\mathcal{M}}(s)$  can be computed in  $\mathcal{O}(|\mathcal{M}|^8)$  deterministic polynomial time if weights are given in unary, and in NP and coNP if weights are given in binary. ◀

In order to extend Lemma 3 from MDPs to games, we need the notion of derived MDPs, obtained by fixing the choices of one player according to some FD strategy. Given an SSG  $\mathcal{G} = (S, (S_{\square}, S_{\diamond}, S_{\circ}), E, P)$  and a finite memory deterministic (FD) strategy  $\pi$  for Minimizer (resp.  $\sigma$  for Maximizer) from a state  $s$ , described by  $(M, m_0, \text{upd}, \text{nxt})$ , let  $\mathcal{G}_{\pi}$  (resp.  $\mathcal{G}^{\sigma}$ ) be the maximizing (resp. minimizing) MDP with state space  $M \times S$  obtained by fixing Minimizer's (resp. Maximizer's) choices according to  $\pi$  (resp.  $\sigma$ ).

► **Lemma 4.** *For every SSG  $\mathcal{G}$ , objective  $\mathbb{0}$  and Minimizer (resp. Maximizer) FD strategy  $\pi = (M, m_0, \text{upd}, \text{nxt})$  (resp.  $\sigma$ ), from state  $s$  we get  $\text{val}_{\mathbb{0}}^{\mathcal{G}^{\sigma}}((m_0, s)) \leq \text{val}_{\mathbb{0}}^{\mathcal{G}}(s) \leq \text{val}_{\mathbb{0}}^{\mathcal{G}_{\pi}}((m_0, s))$  and equality holds if  $\pi$  (resp.  $\sigma$ ) is optimal from state  $s$ .*

► **Theorem 5.** *Consider an SSG  $\mathcal{G} = (S, (S_{\square}, S_{\diamond}, S_{\circ}), E, P)$  with the Gain objective.*

1. *Optimal Minimizer strategies exist and can be chosen uniform MD.*
2.  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  is rational and questions about it, i.e.,  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s) \leq c$  for constants  $c$ , are decidable in NP.
3. *Optimal Maximizer strategies exist and can be chosen FD, with  $\mathcal{O}(\exp(|\mathcal{G}|^{\mathcal{O}(1)}))$  memory modes. Moreover, exponential memory is also necessary.*

**Proof.** Towards Item 1, observe that since both the objectives  $\text{LimInf}(= -\infty)$  and  $\text{OPAR}$  are shift-invariant and submixing, so is their union, i.e.,  $\overline{\text{Gain}}$  is shift-invariant and submixing. Hence, by [23, Theorem 1.1], an optimal MD strategy  $\pi_s^*$  for Minimizer exists from any state  $s \in S$ . Since  $S$  is finite and  $\text{Gain}$  is shift-invariant, we can also obtain a uniformly optimal MD strategy  $\pi^*$ , i.e.,  $\pi^*$  is optimal from every state.

Towards Item 2, consider the maximizing MDP  $\mathcal{G}_{\pi^*}$  obtained from  $\mathcal{G}$  by fixing  $\pi^*$ . Since  $\pi^*$  is MD, the states of  $\mathcal{G}_{\pi^*}$  are the same as the states as  $\mathcal{G}$ . Since  $\pi^*$  is optimal for Minimizer from every state  $s$ , we obtain that  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s) = \text{val}_{\text{Gain}}^{\mathcal{G}_{\pi^*}}(s)$  for every state  $s$  by Lemma 4. By Lemma 3, the latter is rational and can be computed in polynomial time for weights in unary (resp. in NP and coNP for weights in binary). Thus, by guessing  $\pi^*$ , we can decide questions  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s) \leq c$  in NP.

Towards Item 3, we again use the property that  $\overline{\text{Gain}}$  is shift-invariant and submixing (see above). By [29, Theorem 6, Def. 24], optimal FD Maximizer strategies for  $\text{Gain}$  in an SSG require only  $|S_{\diamond}| \cdot \lceil \log(|E|) \rceil$  many extra bits of memory above the memory required for optimal Maximizer strategies in any derived MDP  $\mathcal{M}$  where Minimizer's choices are fixed. Hence, by Lemma 3, one can obtain optimal FD Maximizer strategies in  $\mathcal{G}$  that use at most  $2^{|S_{\diamond}| \cdot \lceil \log(|E|) \rceil} \cdot \mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)})) = \mathcal{O}(\exp(|\mathcal{G}|^{\mathcal{O}(1)}))$  memory modes. The corresponding exponential lower bound on the memory holds already for MDPs by Lemma 3.  $\blacktriangleleft$

## 5 Computing the Upper Bound $N$

We show how to compute the upper bound  $N$ , up-to which Maximizer needs to remember the energy level, for any given error margin  $\varepsilon > 0$ . Similarly as in Section 4, we first solve the problem for maximizing MDPs and then extend the solution to SSGs.

### 5.1 Computing $N$ for maximizing MDPs

Given a maximizing MDP  $\mathcal{M} = (S, S_{\square}, S_{\circ}, E, P)$  and  $\varepsilon > 0$ , we will compute an  $N \in \mathbb{N}$  such that for all  $s \in S$  and all  $j \geq N$

$$0 \leq \text{val}_{\text{Term}(j) \cup \text{OPAR}}^{\mathcal{M}}(s) - \text{val}_{\text{Loss}}^{\mathcal{M}}(s) \leq \varepsilon.$$

Recall that  $\text{Loss} = \text{LimInf}(= -\infty) \cup \text{OPAR}$ . We now define the sets of states  $W_0 \stackrel{\text{def}}{=} \text{AS}(\text{Loss})$ ,  $W_1 \stackrel{\text{def}}{=} \text{AS}(\text{LimInf}(= -\infty))$  and  $W_2 \stackrel{\text{def}}{=} \text{AS}(\text{OPAR})$ . By Remark 1, there exist optimal MD strategies for  $\text{LimInf}(= -\infty)$  and  $\text{OPAR}$ . Since  $\text{Loss}$  is shift-invariant and submixing, there exists an optimal MD strategy for it by [23, Theorem 1.1].

► **Lemma 6.** *For every state  $s$  in the MDP  $\mathcal{M}$  we have*

1.  $W_1 \cup W_2 \subseteq W_0$
2.  $\text{val}_{\text{FW}_0}(s) \leq \text{val}_{\text{Loss}}(s)$
3.  $\text{val}_{\text{OPAR} \cap \overline{\text{FW}_2}}(s) = 0$
4. *for every initial energy level  $j \geq 0$*

$$\text{val}_{(\text{Term}(j) \cup \text{OPAR}) \cap \text{FW}_0}(s) = \text{val}_{\text{FW}_0}(s) \tag{2}$$

$$\text{val}_{\text{Loss}}(s) \leq \text{val}_{\text{Term}(j) \cup \text{OPAR}}(s) \leq \text{val}_{\text{Loss}}(s) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{\text{FW}_1}) \tag{3}$$

**Proof.**

1. This follows directly from the definitions of  $W_0, W_1, W_2$ .
2. Let  $\sigma'$  be an optimal MD strategy for  $\text{FW}_0$  from  $s$  and  $\sigma''$  be an almost surely winning MD strategy for  $\text{Loss}$  from any state in  $W_0$ . Let  $\sigma$  be the strategy that plays  $\sigma'$  until reaching  $W_0$  and then switches to  $\sigma''$ . We have  $\text{val}_{\text{Loss}}(s) \geq \mathcal{P}_{\sigma, s}(\text{Loss}) \geq \mathcal{P}_{\sigma', s}(\text{FW}_0) = \text{val}_{\text{FW}_0}(s)$ .

3. For  $s \in W_2$  the statement is obvious. So let  $s \notin W_2$  and consider the modified MDP  $\mathcal{M}' = (S', S'_\square, S'_\circ, E', P')$  where all states in  $W_2$  are collapsed into a losing sink. I.e.,  $S' \stackrel{\text{def}}{=} (S \setminus W_2) \uplus \{\text{trap}\}$ , with  $\text{trap}$  a new random sink state having color 0 (thus losing for objective  $\text{OPAR}$ ),  $E'$  contains all of  $(E \cap \{(S \setminus W_2) \times (S \setminus W_2)\} \cup (\text{trap}, \text{trap}))$  and all transitions to  $W_2$  are redirected to  $\text{trap}$  and  $P'$  is derived accordingly from  $P$ . Then  $\text{val}_{\text{OPAR}}^{\mathcal{M}'}(\hat{s}) = \text{val}_{\text{OPAR} \cap \overline{FW_2}}^{\mathcal{M}}(\hat{s})$  for all states  $\hat{s} \in S \setminus W_2$ . Towards a contradiction, assume that  $\text{val}_{\text{OPAR} \cap \overline{FW_2}}^{\mathcal{M}}(s) > 0$ . Hence  $\text{val}_{\text{OPAR}}^{\mathcal{M}'}(s) > 0$ . Then, by [22, Theorem 3.2], there exists a state  $s' \in S'$  such that  $\text{val}_{\text{OPAR}}^{\mathcal{M}'}(s') = 1$ , and it is easy to see that  $s' \neq \text{trap}$  and thus  $s' \in S \setminus W_2$ . But this implies that  $\text{val}_{\text{OPAR}}^{\mathcal{M}}(s') = 1$  and thus  $s' \in W_2$ , a contradiction.
4. Let  $0 \stackrel{\text{def}}{=} \text{Term}(j) \cup \text{OPAR}$ . For Equation (2), the first inequality  $\text{val}_{0 \cap FW_0}(s) \leq \text{val}_{FW_0}(s)$  is trivial, since  $0 \cap FW_0 \subseteq FW_0$ . To show the reverse inequality, consider the strategy  $\sigma$  that first plays like an optimal MD strategy  $\sigma'$  for the objective  $FW_0$  and after reaching  $W_0$  switches to an almost surely winning MD strategy  $\sigma''$  for the objective  $\text{Loss}$ . Then  $\text{val}_{0 \cap FW_0}(s) \geq \mathcal{P}_{\sigma, s}(0 \cap FW_0) \geq \mathcal{P}_{\sigma, s}(\text{Loss} \cap FW_0) = \mathcal{P}_{\sigma', s}(FW_0) = \text{val}_{FW_0}(s)$ , where the second inequality is due to  $\text{LimInf}(= -\infty) \subseteq \text{Term}(j)$ .
- For Equation (3), the first inequality is again due to the fact that  $\text{LimInf}(= -\infty) \subseteq \text{Term}(j)$  for all  $j \geq 0$ . Towards the second inequality of Equation (3) we have

$$\begin{aligned}
& \text{val}_0(s) \\
&= \sup_{\sigma} \mathcal{P}_{\sigma, s}(0) \\
&= \sup_{\sigma} (\mathcal{P}_{\sigma, s}(0 \cap FW_0) + \mathcal{P}_{\sigma, s}(0 \cap \overline{FW_0})) && \text{(Law of total probability)} \\
&\leq \sup_{\sigma} \mathcal{P}_{\sigma, s}(0 \cap FW_0) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(0 \cap \overline{FW_0}) && (\sup(f+g) \leq \sup f + \sup g) \\
&= \sup_{\sigma} \mathcal{P}_{\sigma, s}(FW_0) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(0 \cap \overline{FW_0}) && \text{(Equation (2))} \\
&\leq \text{val}_{\text{Loss}}(s) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(0 \cap \overline{FW_0}) && \text{(Item 2)}
\end{aligned}$$

We can upper-bound the second summand above as follows.

$$\begin{aligned}
& \sup_{\sigma} \mathcal{P}_{\sigma, s}(0 \cap \overline{FW_0}) \\
&= \sup_{\sigma} \mathcal{P}_{\sigma, s}((\text{Term}(j) \cup \text{OPAR}) \cap \overline{FW_0}) \\
&\leq \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{FW_0}) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{OPAR} \cap \overline{FW_0}) && \text{(Union bound)} \\
&\leq \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{FW_1}) + \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{OPAR} \cap \overline{FW_2}) && \text{(Item 1)} \\
&= \sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{FW_1}) && \text{(Item 3)} \quad \blacktriangleleft
\end{aligned}$$

We show that the term  $\sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{FW_1})$  in Equation (3) can be made arbitrarily small for large  $j$ . To this end, we use [3, Lemma 3.9] (adapted to our notation).

► **Lemma 7** ([3, Lemma 3.9 and Claim 6]). *Let  $\mathcal{M} = (S, S_\square, S_\circ, E, P)$  be a maximizing finite MDP with rewards in unary and  $W_1 \stackrel{\text{def}}{=} \text{AS}(\text{LimInf}(= -\infty))$ . One can compute, in polynomial time, a rational constant  $c < 1$ , and an integer  $h \geq 0$  such that for all  $j \geq h$  and  $s \in S$*

$$\sup_{\sigma} \mathcal{P}_{\sigma, s}(\text{Term}(j) \cap \overline{FW_1}) \leq \frac{c^j}{1-c}.$$

Moreover,  $1/(1-c) \in \mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}))$  and  $h \in \mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}))$ .

► **Lemma 8.** Consider a maximizing MDP  $\mathcal{M} = (S, S_{\square}, S_{\circ}, E, P)$ ,  $\varepsilon > 0$  and the constants  $c, h$  from Lemma 7. For rewards in unary and  $i \geq N$  we have  $\text{val}_{\text{Term}(i) \cup \text{OPAR}}^{\mathcal{M}}(s) - \text{val}_{\text{Loss}}^{\mathcal{M}}(s) \leq \varepsilon$  where  $N \stackrel{\text{def}}{=} \max(h, \lceil \log_c(\varepsilon \cdot (1 - c)) \rceil) \in \mathcal{O}(\exp(|\mathcal{M}|^{\mathcal{O}(1)}) \cdot \log(1/\varepsilon))$ .

For rewards in binary we have  $N \in \mathcal{O}(\exp(\exp(|\mathcal{M}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$ , i.e., the size of  $N$  increases by one exponential.

**Proof sketch.** For rewards in unary, the result follows from Lemma 6 (Equation (3)) and Lemma 7. For rewards in binary, the constants increase by one exponential via encoding binary rewards into unary rewards in a modified MDP. ◀

## 5.2 Computing $N$ for SSGs

In order to compute the bound  $N$  for an SSG  $\mathcal{G}$ , we first consider bounds  $N(s)$  for individual states  $s$  and then take their maximum. Given a state  $s$ , we can use Theorem 5 (Item 3) to obtain an optimal FD strategy (with  $\mathcal{O}(\exp(|\mathcal{G}|^{\mathcal{O}(1)}))$  memory modes)  $\sigma^*(s) = (M, m_0, \text{upd}, \text{nxt})$  for Maximizer from state  $s$  w.r.t. the **Gain** objective. Theorem 5 (Item 1) yields a uniform MD strategy  $\pi^*$  that is optimal for Minimizer from all states  $s$  w.r.t. the **Gain** objective.

► **Lemma 9.** Given an SSG  $\mathcal{G} = (S, (S_{\square}, S_{\circ}, S_{\circ}), E, P)$  and  $\varepsilon > 0$ , we can compute a number  $N \in \mathbb{N}$  such that for all  $i \geq N$  and states  $s \in S$  we have

$$\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) - \varepsilon \leq \text{val}_{\text{Gain}}^{\mathcal{G}}(s) - \varepsilon \leq \inf_{\pi} \mathcal{P}_{\sigma^*(s), \pi, s}^{\mathcal{G}}(\text{EN}(i) \cap \text{EPAR}) \leq \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \quad (4)$$

i.e.,  $\sigma^*(s)$  is  $\varepsilon$ -optimal for Maximizer for  $\text{EN}(i) \cap \text{EPAR}$  for all  $i \geq N$ . In particular,  $0 \leq \text{val}_{\text{Gain}}^{\mathcal{G}}(s) - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon$ .

Moreover,  $\pi^*$  is  $\varepsilon$ -optimal for Minimizer from any state  $s$  for  $i \geq N$ .

$$\sup_{\sigma} \mathcal{P}_{\sigma, \pi^*, s}^{\mathcal{G}}(\text{EN}(i) \cap \text{EPAR}) \leq \sup_{\sigma} \mathcal{P}_{\sigma, \pi^*, s}^{\mathcal{G}}(\text{Gain}) = \text{val}_{\text{Gain}}^{\mathcal{G}}(s) \leq \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) + \varepsilon \quad (5)$$

For rewards in unary,  $N$  is doubly exponential, i.e.,  $N \in \mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  and it can be computed in exponential time. For rewards in binary, the size of  $N$  and its computation time increase by one exponential, respectively.

**Proof.** Assume that rewards are in unary. The first inequality of (4) holds because  $\text{EN}(i) \cap \text{EPAR} \subseteq \text{Gain}$  for any  $i$ . The third inequality of (4) follows from the definition of the value. Towards the second inequality of (4), we consider the minimizing MDP  $\mathcal{M}(s) \stackrel{\text{def}}{=} \mathcal{G}^{\sigma^*(s)}$  obtained by fixing the Maximizer strategy  $\sigma^*(s)$ . Since  $\sigma^*(s)$  is optimal for Maximizer from state  $s$  wrt. the objective **Gain**, Lemma 4 yields that

$$\text{val}_{\text{Gain}}^{\mathcal{G}}(s) = \text{val}_{\text{Gain}}^{\mathcal{M}(s)}((m_0, s)). \quad (6)$$

Since  $\sigma^*(s)$  has  $\mathcal{O}(\exp(|\mathcal{G}|^{\mathcal{O}(1)}))$  memory modes, the size of  $\mathcal{M}(s)$  is exponential in  $|\mathcal{G}|$  and  $\mathcal{M}(s)$  can be computed in exponential time.

Now we consider the dual maximizing MDP  $\mathcal{M}(s)^d$  and the objectives  $\text{Term}(i) \cup \text{OPAR}$  and **Loss**. (Note that  $\mathcal{M}(s)^d$  has the same size as  $\mathcal{M}(s)$ .) From Lemma 8, we obtain a bound  $N(s) \in \mathbb{N}$  such that for all  $i \geq N(s)$

$$0 \leq \text{val}_{\text{Term}(i) \cup \text{OPAR}}^{\mathcal{M}(s)^d}((m_0, s)) - \text{val}_{\text{Loss}}^{\mathcal{M}(s)^d}((m_0, s)) \leq \varepsilon. \quad (7)$$

By Lemma 8 and Lemma 7,  $N(s)$  is exponential in  $|\mathcal{M}(s)^d|$  and thus doubly exponential in  $|\mathcal{G}|$ , i.e.,  $N(s) \in \mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$ . Moreover,  $N(s)$  can be computed in time polynomial in  $|\mathcal{M}(s)^d|$  and thus in time exponential in  $|\mathcal{G}|$ . By duality, we can rewrite Equation (7) for  $\mathcal{M}(s)$  as follows. For all  $i \geq N(s)$

$$0 \leq \text{val}_{\text{Gain}}^{\mathcal{M}(s)}((m_0, s)) - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{M}(s)}((m_0, s)) \leq \varepsilon. \quad (8)$$

In order to get a uniform upper bound that holds for all states, let  $N \stackrel{\text{def}}{=} \max_{s \in S} N(s)$ . Since  $|S|$  is linear, we still have  $N \in \mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  and it can be computed in exponential time in  $|\mathcal{G}|$ . Finally, we can show the second inequality of (4).

$$\begin{aligned} & \inf_{\pi} \mathcal{P}_{\sigma^*(s), \pi, s}^{\mathcal{G}}(\text{EN}(i) \cap \text{EPAR}) \\ &= \inf_{\pi} \mathcal{P}_{\pi, (m_0, s)}^{\mathcal{M}(s)}(\text{EN}(i) \cap \text{EPAR}) \\ &= \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{M}(s)}((m_0, s)) \\ &\geq \text{val}_{\text{Gain}}^{\mathcal{M}(s)}((m_0, s)) - \varepsilon && \text{by } i \geq N \geq N(s) \text{ and Equation (8)} \\ &= \text{val}_{\text{Gain}}^{\mathcal{G}}(s) - \varepsilon && \text{by (6)} \end{aligned}$$

The first inequality of (5) holds because  $\text{EN}(i) \cap \text{EPAR} \subseteq \text{Gain}$  for any  $i$ . The equality in (5) holds by the optimality of  $\pi^*$ . The second inequality of (5) follows from the previously stated consequence of (4).

For rewards in binary, the sizes of the numbers  $N(s)$  (and hence  $N$ ) and the time to compute it increase by one exponential by Lemma 8.  $\blacktriangleleft$

## 6 Unfolding the Game to Energy Level $N$

Given an SSG  $\mathcal{G} = (S, (S_{\square}, S_{\diamond}, S_{\circ}), E, P)$  and error tolerance  $\varepsilon > 0$ , for each state  $s \in S$  and energy level  $i \geq 0$ , we want to compute a rational number  $v'$  which satisfies  $0 \leq v' - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon$ , and  $\varepsilon$ -optimal FD strategies  $\sigma_{\varepsilon}$  and  $\pi_{\varepsilon}$  for Maximizer and Minimizer, resp. We achieve this by constructing a finite-state parity game  $\mathcal{G}'$  that closely approximates the original game  $\mathcal{G}$ , as described in Section 3(Item 3).

For clarity, we explain the construction in two steps. In the first step, we consider a finite-state parity game  $\mathcal{G}[N]$ . (Unlike  $\mathcal{G}'$ , the game  $\mathcal{G}[N]$  is not actually constructed. It just serves as a part of the correctness proof.)  $\mathcal{G}[N]$  encodes the energy level up-to  $N + R$  (where  $R$  is the maximal transition reward) into the states, i.e., it has states of the form  $(s, k)$  with  $k \leq N + R$ . It imitates the original game  $\mathcal{G}$  till energy level  $N + R$ , but at any state  $(s, i)$  with energy level  $i \geq N$  it jumps to a winning state with probability  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$  and to a losing state with probability  $1 - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$ . (We need the margin up-to  $N + R$ , because transitions can have rewards  $> 1$ , so the level  $N$  might not be hit exactly.) Similarly, at states  $(s, 0)$  with energy level 0, we jump to a losing state. The coloring function in the new game  $\mathcal{G}[N]$  derives its colors from the colors in the original game  $\mathcal{G}$ , i.e., all states  $(s, i)$  have the same color as  $s$  in  $\mathcal{G}$ .

By construction of  $\mathcal{G}[N]$ , for  $i \leq N$ , the EPAR value of  $(s, i)$  in  $\mathcal{G}[N]$  coincides with  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$ .

In the second step, since we do not know the exact values  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$  for  $N + R \geq i > N$ , we approximate these by the slightly larger  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$ . I.e., we modify  $\mathcal{G}[N]$  by replacing the probability values  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$  for the jumps to the winning state by  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$ . Let  $\mathcal{G}'$  be the resulting finite-state parity game. It follows from Lemma 9 that  $0 \leq \text{val}_{\text{Gain}}^{\mathcal{G}}(s) - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon$  for  $i \geq N$  and  $\text{Lval}_{\text{EN} \cap \text{EPAR}}^{\mathcal{G}}(s) = \text{val}_{\text{Gain}}^{\mathcal{G}}(s)$ . Thus  $\mathcal{G}'$   $\varepsilon$ -over-approximates  $\mathcal{G}[N]$  and  $\mathcal{G}$ , and we obtain the following lemma.

► **Lemma 10.** For all states  $s$  and all  $0 \leq i \leq N$

$$\begin{aligned} \text{val}_{\text{EPAR}}^{\mathcal{G}[N]}((s, i)) &= \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s), \text{ and} \\ 0 \leq \text{val}_{\text{EPAR}}^{\mathcal{G}'}((s, i)) - \text{val}_{\text{EPAR}}^{\mathcal{G}[N]}((s, i)) &\leq \varepsilon. \end{aligned}$$

Now we are ready to prove the main theorem.

► **Theorem 2.** Let  $\mathcal{G} = (S, (S_{\square}, S_{\diamond}, S_{\circ}), E, P)$  be an SSG with transition rewards in unary assigned by function  $r$  and colors assigned to states by function  $\text{Col}$ . For every state  $s \in S$ , initial energy level  $i \geq 0$  and error margin  $\varepsilon > 0$ , one can compute

1. a rational number  $v'$  such that  $0 \leq v' - \text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s) \leq \varepsilon$  in 2-NEXPTIME.<sup>2</sup>
2.  $\varepsilon$ -optimal FD strategies  $\sigma_{\varepsilon}$  and  $\pi_{\varepsilon}$  for Maximizer and Minimizer, resp., in 2-NEXPTIME. These strategies use  $\mathcal{O}(2\text{-EXP}(|\mathcal{G}|) \cdot \log(\frac{1}{\varepsilon}))$  memory modes.

For rewards in binary, the bounds above increase by one exponential.

**Proof.** For  $i > N$  we output  $v' = \text{val}_{\text{Gain}}^{\mathcal{G}}(s)$ , which satisfies the condition by Lemma 9. For  $i \leq N$  we output  $v' = \text{val}_{\text{EPAR}}^{\mathcal{G}'}((s, i))$ , which satisfies the condition by Lemma 10. By Theorem 5, the values  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  are rational for all states  $s$ . Therefore all probability values in  $\mathcal{G}'$  are rational and thus the EPAR values of all states in  $\mathcal{G}'$  are rational. Hence our numbers  $v'$  are always rational.

By Theorem 5, the values  $\text{val}_{\text{Gain}}^{\mathcal{G}}(s)$  for all states  $s \in S$  can be computed in exponential time. By Lemma 9,  $N \in \mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  is doubly exponential. Therefore, we can construct  $\mathcal{G}'$  in  $\mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  time and space. Questions about the parity values of states in  $\mathcal{G}'$  can be decided in nondeterministic time polynomial in  $|\mathcal{G}'|$ . Thus the numbers  $v'$  are computed in 2-NEXPTIME.

Towards Item 2, we construct  $\varepsilon$ -optimal FD strategies  $\sigma_{\varepsilon}$  for Maximizer (resp.  $\pi_{\varepsilon}$  for Minimizer) for  $\text{EN}(i) \cap \text{EPAR}$  in  $\mathcal{G}$ . Let  $\hat{\sigma}$  (resp.  $\hat{\pi}$ ) be optimal MD strategies for Maximizer (resp. Minimizer) for the objective EPAR in  $\mathcal{G}'$ , which exist by Remark 1. Since these strategies are MD, they can be guessed in nondeterministic time polynomial in the size  $|\mathcal{G}'|$ , and thus in  $\mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  nondeterministic time.

Then  $\sigma_{\varepsilon}$  plays as follows. While the current energy level  $j$  ( $i$  plus the sum of the rewards so far) stays  $< N$ , then, at any state  $s'$ , play like  $\hat{\sigma}$  at state  $(s', j)$  in  $\mathcal{G}'$ . Once the energy level reaches a value  $\geq N$  at some state  $s'$  for the first time, then play like  $\sigma^*(s')$  forever. (Recall that  $\sigma^*(s')$  is the optimal FD Maximizer strategy for Gain from state  $s'$  from Section 5.2.)  $\sigma_{\varepsilon}$  is  $\varepsilon$ -optimal by Lemma 10 and Lemma 9. It needs to remember the energy level up-to  $N$  while simulating  $\hat{\sigma}$ . Moreover,  $\sigma^*(s')$  needs  $\mathcal{O}(\exp(|\mathcal{G}|^{\mathcal{O}(1)}))$  memory modes by Theorem 5. Finally, it needs to remember the switch from  $\hat{\sigma}$  to  $\sigma^*(s')$ . Since  $N \in \mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  dominates the rest,  $\sigma_{\varepsilon}$  uses  $\mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  memory modes.

Similarly,  $\pi_{\varepsilon}$  plays as follows. While the current energy level  $j$  stays  $< N$ , at any state  $s'$ , play like  $\hat{\pi}$  at state  $(s', j)$  in  $\mathcal{G}'$ . Once the energy level reaches a value  $\geq N$  (at any state) for the first time, then play like  $\pi^*$  forever (where  $\pi^*$  is the uniform optimal MD Minimizer strategy for Gain from Section 5.2.)  $\pi_{\varepsilon}$  is  $\varepsilon$ -optimal by Lemma 10 and Lemma 9. While  $\pi^*$  is MD and does not use any memory,  $\pi_{\varepsilon}$  still needs to remember the energy level up-to  $N$  while simulating  $\hat{\pi}$ , and thus it uses  $\mathcal{O}(\exp(\exp(|\mathcal{G}|^{\mathcal{O}(1)})) \cdot \log(1/\varepsilon))$  memory modes.

For rewards in binary, all bounds increase by one exponential via an encoding of  $\mathcal{G}$  into an exponentially larger but equivalent game with rewards in unary. ◀

<sup>2</sup> We write “computing a number  $v'$  in 2-NEXPTIME” as a shorthand for the property that questions like  $v' \leq c$  for constants  $c$  are decidable in 2-NEXPTIME.

No nontrivial lower bounds are known on the computational complexity of approximating  $\text{val}_{\text{EN}(i) \cap \text{EPAR}}^{\mathcal{G}}(s)$ . However, even without the parity part, the problem appears to be hard. The best known algorithm for approximating the value of the energy objective (resp. the dual termination objective) runs in NEXPTIME for SSGs with rewards in unary [3].

As for lower bounds on the strategy complexity,  $\varepsilon$ -optimal Maximizer strategies need at least an exponential number of memory modes (for any  $0 < \varepsilon < 1$ ) even in maximizing MDPs. This can easily be shown by extending the example in Lemma 3 (Item 2) and [24, Fig. 1 and Prop. 4] that shows the lower bound for the Gain objective. First loop in a state with an unfavorable color to accumulate a sufficiently large reward (depending on  $\varepsilon$ ) and then switch to the MDP in [24, Fig. 1 and Prop. 4] to play for Gain (since  $\text{EN}(i) \cap \text{EPAR}$  will be very close to Gain then). Even the latter part requires exponentially many memory modes.

## 7 Conclusion & Extensions

We gave a procedure to compute  $\varepsilon$ -approximations of the value of combined energy-parity objectives in SSGs. The decidability of questions about the exact values is open, but the problem is at least as hard as the positivity problem for linear recurrence sequences [31, Section 5.2.3]. Unlike almost surely winning Maximizer strategies which require infinite memory in general [28, 29],  $\varepsilon$ -optimal strategies for either player require only finite memory with at most doubly exponentially many memory modes.

An interesting topic for further study is whether these results can be extended to other combined objectives where the parity part is replaced by something else, i.e., energy-X for some objective X (e.g., some other color-based condition like Rabin/Streett, or a quantitative objective about multi-dimensional transition rewards). While our proofs are not completely specific to parity, they do use many strong properties that parity satisfies.

- Shift-invariance of EPAR is used in several places, e.g. in Lemma 6 (and thus its consequences) and for the correctness of the constructions in Section 6.
- We use the fact that EPAR goes well together with  $\text{LimInf}(> -\infty)$ , i.e., the objective  $\text{Gain} = \text{LimInf}(> -\infty) \cap \text{EPAR}$  allows optimal FD strategies for Maximizer in MDPs; cf. Lemma 3.
- The submixing property of  $\text{OPAR} = \overline{\text{EPAR}}$  is used in Theorem 5 to lift Lemma 3 from MDPs to SSGs.

## Abstract

Planar Embedding is a drawing of a graph on the plane such that the edges do not intersect each other except at the vertices. We know that testing the planarity of a graph and computing its embedding (if it exists), can efficiently be computed, both sequentially [24] and in parallel [33], when the entire graph is presented as input.

In the dynamic setting, the input graph changes one edge at a time through insertion and deletions and planarity testing/embedding has to be updated after every change. By storing auxiliary information we can improve the complexity of dynamic planarity testing/embedding over the obvious recomputation from scratch. In the sequential dynamic setting, there has been a series of works [17, 25, 20, 22], culminating in the breakthrough result of  $\text{polylog}(n)$  sequential time (amortized) planarity testing algorithm of Holm and Rotenberg [21].

In this paper we study planar embedding through the lens of DynFO, a parallel dynamic complexity class introduced by Patnaik et al [31] (also [16]). We show that it is possible to dynamically maintain whether an edge can be inserted to a planar graph without causing non-planarity in DynFO. We extend this to show how to maintain an embedding of a planar graph under both edge insertions and deletions, while rejecting edge insertions that violate planarity.

Our main idea is to maintain embeddings of only the triconnected components and a special two-colouring of separating pairs that enables us to side-step cascading flips when embedding of a biconnected planar graph changes, a major issue for sequential dynamic algorithms [22, 21].

## 1 Introduction

Planar graphs are graphs for which there exists an embedding of vertices on the plane such that the edges can be drawn without intersecting with each other, except at their endpoints. The notion of planar graphs is fundamental to graph theory as underlined by the Kuratowski theorem [26]. The planarity testing problem is to determine if the encoded graph is planar and the planar embedding problem is to construct such an embedding. These are equally fundamental questions to computer science and their importance has been recognized from the early 1970s in the linear time algorithm by Hopcroft and Tarjan [24]. Since then there have

been a plethora of algorithmic solutions presented for the planarity testing and embedding problems such as [28, 4, 18] that culminated in an alternative linear-time algorithm [18], a work efficient parallel algorithm running in  $O(\log n)$  time [33], a deterministic logspace algorithm [1, 13], and many more.

All of the above algorithms are static i.e., the input is presented at once and we need to answer the planarity testing query and produce an embedding only once. However, in many real-life scenarios, the input is itself dynamic and evolves by insertion and deletion of edges. The same query can be asked at any instance and even the embedding may be required. Rather than recomputing the result from scratch after every update to the input in many scenarios, it is advantageous to preserve some auxiliary data such that each testing or embedding query can be answered much faster than recomputation from scratch. The notion of “fast” can be quantified via the sequential time required to handle the updates and queries which can be achieved in polylogarithmic time as in the recent breakthrough works of [22, 21]. These in turn built upon the previous work that dealt with only a partially dynamic model of computation – insertion only [32, 3, 34] or, deletion only [25] or the fully dynamic model (that supports both insertions and deletions) but with polynomial time updates [17].

Our metric for evaluating updates is somewhat different and determined according to the Dynamic Complexity framework of Immerman and Patnaik [31], and is closely related to the setting of Dong, Su, and Topor [16]. In it, a dynamic problem is characterised by the smallest complexity class in which it is possible to place the updates to the auxiliary database and still be able to answer the queries (notice that if the number of possible queries is polynomial we can just maintain the answers of all queries in the auxiliary database).

Notable amongst these has been the first-order logic formulas or equivalently, the descriptive complexity class FO. Thus we obtain the class DynFO of dynamic problems for which the updates to the auxiliary data structure are in FO given the input structure and stored auxiliary data structures. The motivation to use first-order logic as the update method has connections to other areas as well e.g., it implies that such queries are highly parallelisable, i.e., can be updated by polynomial-size circuits in constant-time due to the correspondence between FO and uniform  $AC^0$  circuits [2]. From the perspective of database theory, such a program can be translated into equivalent SQL queries.

A particular recent success story of dynamic complexity has been that directed graph reachability (which is provably not in FO) can be maintained in DynFO [8] resolving a conjecture from Immerman and Patnaik [31], open since the inception of the field. Since then, progress has been made in terms of the size of batch updates (i.e., multiple simultaneous insertions and deletions) that can be handled for reachability, distance, and maximum matching [12, 30]. Later, improved bounds have been achieved for these problems in various special graph classes, including in planar graphs [9, 5]. Problems in planar graphs have been studied in the area of dynamic complexity starting much earlier e.g., before the reachability conjecture was resolved, it was shown in [6] that reachability in embedded planar graphs is in DynFO. Also, in [29] it was shown that 3-connected planar graph isomorphism too is in DynFO with some precomputation. However, despite these works the dynamic complexity of the planarity testing problem itself is not yet resolved, let alone maintaining a planar embedding efficiently.

**Our contribution.** In this paper, we build on past work in dynamic complexity to show that a planar embedding can be maintained efficiently, where we test for planarity at every step. Here, by planar embedding we mean a cyclic order on the neighbours of every vertex in some drawing of the graph on the plane (also known as combinatorial embedding [15]).

► **Theorem 1.** *Given a dynamic graph undergoing insertion and deletion of edges we can maintain a planar embedding of the graph in DynFO (while never allowing insertion of edges that cause the graph to become non-planar).*

**Organization.** We start with preliminaries concerning graph theory and dynamic complexity in Section 2. We present a technical overview of our work in Section 3. In Section 4 we develop the graph theoretic machinery we need for our algorithm. Next, we describe the dynamic planar embedding algorithm in Section 5. For the implementation details please refer to the full version of this paper [7].

## 2 Preliminaries

We start with some notations followed by graph theoretic preliminaries related to connectivity and planarity – see [14, Chapters 3, 4] for a thorough introduction. Then we reproduce some essentials of Dynamic Complexity from [9, 12].

Given a graph  $G = (V, E)$ , we write  $V(G)$  and  $E(G)$  to denote the sets of vertices and edges of  $G$ , respectively. For a set of edges  $S \subseteq E(G)$  we denote by  $G - S$ , the graph with the edges in  $S$  deleted. Similarly for  $S \subseteq V(G) \times V(G)$  we denote by  $G + S$  the graph to which new edges in  $S$  have been added. For a set of vertices  $T \subseteq V(G)$ , by  $G - T$  we refer to the induced graph  $G[V(G) \setminus T]$ . An undirected path between  $u$  and  $v$  is denoted by  $u \rightsquigarrow v$ .

**Biconnected and Triconnected Decomposition.** We assume familiarity with common connectivity related terminology including 2-vertex connectivity, 3-vertex connectivity and the related separating sets viz. cut vertices, separating pairs and the notion of virtual edges in the triconnected decomposition [23]. Please see the definitions of these terms in the full version [7, Section 2.1]. The following are two data structures that help in representing tree decompositions associated with biconnectivity and 3-connectivity respectively.

1. **BC-tree** or block-cut tree of a connected component of the graph, say  $H$ , denoted by  $T_2(H)$ . The nodes of the tree are the biconnected components (block nodes) and the cut vertices (cut nodes) of  $H$  and the edges are only between cut and block nodes. Block nodes are denoted by  $B$  and the cut nodes are denoted by  $C$ .
2. **SPQR-tree** or the triconnected decomposition tree of a biconnected component of the graph say  $B$ , is denoted by  $T_3(B)$ . The nodes in the SPQR-tree are of one of four types:  $S$  denotes a cycle component (serial node),  $P$  denotes a 3-connected separating pair (parallel node),  $Q$  denotes that there is just a single edge in  $B$ , and  $R$  denotes the 3-connected components or the so-called rigid nodes. There is an edge between an R-node, say  $R_i$  and a P-node, say  $P_j$  if  $V(P_j) \subset V(R_i)$ , and similarly, edges between S and P-nodes are defined.

We will conflate a node in one of the two trees with the corresponding subgraph. For example, an R-node interchangeably refers to the tree node as well the associated rigid subgraph.

**Planar Embedding.** A planar embedding of a graph  $G = (V, E)$  is a mapping of vertices and edges in the plane  $\mathbb{R}^2$  such that the vertices are mapped to distinct points in the plane and every edge is mapped to an arc between the points corresponding to the two vertices incident on it such that no two arcs have any point in common except at their endpoints. This embedding is called a *topological embedding*. Corresponding to a given topological embedding, the faces of the graph are the open regions in  $\mathbb{R}^2 \setminus G$  (plane with points corresponding to the vertices and edges removed), call the set of faces as  $F$ . For a face  $f \in F$ , the set of all the

vertices that lie on the boundary of  $f$ , is denoted by  $V(f)$ . The unbounded face is called the outer face. An embedding on the surface of a sphere is similarly defined. On the sphere, every face is bounded. Two topological embeddings are equivalent if, for every vertex, the cyclic order of its neighbours around the vertex is the same in both embeddings. So, the cyclic order (or rotation scheme) around each vertex defines an equivalence on the topological embeddings. The vertex rotation scheme around each vertex encodes the embedding equivalence class (combinatorial embedding). We now recall two important results. The first one is due to Whitney [35] that says that a 3-connected planar graph has unique planar embedding on the sphere (up to reflection). The second one is due to Mac Lane [27] that shows a biconnected graph is planar iff its triconnected components are planar.

## 2.1 Dynamic Complexity

The goal of a dynamic program is to answer a given query on an *input structure* subject to changes that insert or delete tuples. The program may use an auxiliary data structure represented by an *auxiliary structure* over the same domain. Initially, both input and auxiliary structure are empty; and the domain is fixed during each run of the program.

For a (relational) structure  $\mathcal{I}$  over domain  $D$  and schema  $\sigma$ , a change  $\Delta\mathcal{I}$  consists of sets  $R^+$  and  $R^-$  of tuples for each relation symbol  $R \in \sigma$ . The result  $\mathcal{I} + \Delta\mathcal{I}$  of an application of the change  $\Delta\mathcal{I}$  to  $\mathcal{I}$  is the input structure where  $R^{\mathcal{I}}$  is changed to  $(R^{\mathcal{I}} \cup R^+) \setminus R^-$ . The *size* of  $\Delta\mathcal{I}$  is the total number of tuples in relations  $R^+$  and  $R^-$  and the set of *affected elements* is the (active) domain of tuples in  $\Delta\mathcal{I}$ .

**Dynamic Programs and Maintenance of Queries.** A dynamic program consists of a set of update rules that specify how auxiliary relations are updated after changing the input structure. An *update rule* for updating an  $\ell$ -ary auxiliary relation  $T$  after a change is a first-order formula  $\varphi$  over schema  $\tau \cup \tau_{\text{aux}}$  with  $\ell$  free variables, where  $\tau_{\text{aux}}$  is the schema of the auxiliary structure. After a change  $\Delta\mathcal{I}$ , the new version of  $T$  is  $T := \{\bar{a} \mid (\mathcal{I} + \Delta\mathcal{I}, \mathcal{A}) \models \varphi(\bar{a})\}$  where  $\mathcal{I}$  is the old input structure and  $\mathcal{A}$  is the current auxiliary structure. Note that a dynamic program can choose to have access to the old input structure by storing it in its auxiliary relations.

For a state  $\mathcal{S} = (\mathcal{I}, \mathcal{A})$  of the dynamic program  $\mathcal{P}$  with input structure  $\mathcal{I}$  and auxiliary structure  $\mathcal{A}$ , we denote by  $\mathcal{P}_\alpha(\mathcal{S})$ , the state of the program after applying a change sequence  $\alpha$  and updating the auxiliary relations accordingly. The dynamic program *maintains* a  $q$ -ary query  $Q$  under changes that affect  $k$  elements (under changes of size  $k$ , respectively) if it has a  $q$ -ary auxiliary relation  $Ans$  that at each point stores the result of  $Q$  applied to the current input structure. More precisely, for each non-empty sequence  $\alpha$  of changes that affect  $k$  elements (changes of size  $k$ , respectively), the relation  $Ans$  in  $\mathcal{P}_\alpha(\mathcal{S}_\emptyset)$  and  $Q(\alpha(\mathcal{I}_\emptyset))$  coincide, where  $\mathcal{I}_\emptyset$  is an empty input structure,  $\mathcal{S}_\emptyset$  is the auxiliary structure with empty auxiliary relations over the domain of  $\mathcal{I}_\emptyset$ , and  $\alpha(\mathcal{I}_\emptyset)$  is the input structure after applying  $\alpha$ . If a dynamic program maintains a query, we say that the query is in DynFO.

## 3 Technical Overview

It is well known from Whitney's theorem [35] that 3-connected planar graphs are rigid i.e., they (essentially) have a unique embedding. Thus, for example, under the promise that the graph remains 3-connected and planar it is easy to maintain an embedding in DynFO (see for example [29]). An edge insertion occurs within a face and there are only local changes to the embedding – restricted to a face. Deletions are exactly the reverse.

On the other extreme are trees, which are minimally connected. These are easy to maintain as well because any vertex rotation scheme is realisable. However, biconnected components are not rigid and yet not every rotation scheme for a vertex is valid (see Figure 3a for an illustration). The real challenge is in maintaining embeddings of biconnected components.

This has been dealt with in literature by decomposing biconnected graphs into 3-connected components (which are rigid components in the context of planar graphs). The 3-connected components are organized into trees<sup>1</sup> popularly called SPQR-trees [3]. The approach is to use the rigidity of the 3-connected planar components and the flexibility of trees to maintain a planar embedding of biconnected graphs. In order to maintain a planar embedding of connected graphs we need a further tree decomposition into biconnected components that yields the so-called block-cut trees or BC-trees ([14, Lemma 3.1.4], [19]). Notice that the tree decomposition into SPQR-trees and BC-trees is Logspace hard [10] and hence not in FO. Thus, in the parallel dynamic setting, we emulate previous sequential dynamic algorithms in *maintaining* (rather than computing from scratch) SPQR-trees and BC-trees in our algorithm.

**Issues with biconnected embedding.** The basic problem with maintaining biconnected planar components is their lack of rigidity (with reaching complete flexibility). Thus insertion of an edge into a biconnected component might necessitate changing the embedding through operations called *flips* and *slides* in literature [22, 21] (see [7, Figure 4]). We might need lots of flips and slides for a single edge insertion – causing an exponentially large search space. We now proceed to describe these changes in more detail.

In the simplest form consider a biconnected graph and a separating pair contained within, separating the component into two 3-connected components. We can reflect one of the 3-connected components, that is, the vertex rotation for each vertex in the 3-connected component is reversed. More intuitively, mirror a piece across one of its separating pairs. In more complicated cases there may be cascading flips i.e., reflections across multiple separating pairs in the biconnected component. We also need to deal with *slides*, that is changes in ordering of the biconnected components at a separating pair. A single edge insertion might need multiple flips and slides.

This induces the definition of flip-distance i.e., the minimum number of flips and slides to change one embedding of the graph to another. Intuitively, the flip-distance lower bounds the sequential time needed to transition from one embedding to another.

Thus a crucial part of previous algorithms [22] deals with maintaining an embedding of small flip distance with every possible embedding that can arise after a single change. In [21] this algorithm is converted to a fully dynamic algorithm that handles updates in  $O(\log^3 n)$  time using a sophisticated amortization over the number of flips required to transition to an appropriate embedding dominates the running time of their algorithm. Notice that [22] handles changes in  $O(\log^3 n)$  worst case time but only in the incremental setting.

**Our approach for dynamic planarity testing.** We now switch to motivating our approach in the parallel dynamic setting that is fully dynamic and does not use amortization. There are fundamentally two issues to be resolved while inserting an edge – one is whether the resulting graph is planar. The other is, how to update the embedding, possibly by performing multiple flips, when the graph remains planar. Let us first focus on biconnected graphs and the corresponding tree decomposition SPQR-tree introduced in Section 2.

---

<sup>1</sup> The tree decomposition of a biconnected graph into 3-connected pieces is a usual tree decomposition ([14, Chapter 12.3]).

To check for planarity on insertion of an edge, we introduce the notion of  $P_i, P_j$ -coherent paths. A path between two P-nodes  $P_i, P_j$  in an SPQR-tree is said to be coherent if for every R-node  $R_k$  on the path, all the (at most four) vertices of the two adjacent P-nodes are all on one face of  $R_k$  (see Lemma 4). This yields a combinatorial characterisation of coherent paths, given an embedding of each rigid component. The embedding of a rigid component is dealt with separately, later on. The significance of coherent paths stems from a crucial lemma (Lemma 4). This shows that an edge  $(a, b)$  is insertable in the graph preserving planarity if and only if the “projection” of any simple  $a, b$  path in the graph<sup>2</sup> onto the corresponding SPQR-tree roughly corresponds to a coherent path. This yields a criterion for testing planarity after an edge insertion which can be implemented in FO.

**Insertions in biconnected components.** Having filtered out non-planarity causing edges we turn to the question of how to construct the new planar embedding of the biconnected components after an edge insertion. The answer will lead us to investigate how to embed a rigid component when it is synthesized from a biconnected component.

It is in this context that we introduce the notion of two-colouring of separating pairs. This is a partial sketch of the new 3-connected component formed after an edge insertion. More concretely, the separating pairs along the path in the SPQR-tree are no longer separating pairs after the edge insertion and the common face (as ensured by the crucial lemma alluded to above) on which all the endpoints of the previous separating pairs lie splits into two faces. Since the embedding of a 3-connected planar graph is unique, after the edge insertion the two new faces formed are also unique, i.e., do not depend on the embedding. Thus the endpoints of each previous separating pair can be two coloured depending on which of the two faces a separating pair belongs to. We prove in the two-colouring lemma (Lemma 5) that no separating pair has both vertices coloured with the same colour.

Notice that when an edge is inserted such that its endpoints lie on a coherent path, all the rigid components on the path coalesce into one large rigid component (see Figure 3c). Two-colouring allows us to deal with flips by telling us the correct orientation of the coalescing rigid components on edge insertion. This, in turn, allows us to obtain the face-vertex rotation scheme of the modified component. In addition, it helps us to maintain the vertex rotation scheme in some corner cases (when two or more separating pairs share a vertex).

**Face-vertex rotation scheme.** The sceptical reader might question the necessity of maintaining the face-vertex rotation scheme for a 3-connected component. This is necessary for two reasons – first, to apply the planarity test we need to determine the existence of a common face containing a 4-tuple (or 3-tuple) of vertices. The presence of a face-vertex rotation scheme directly shows that this part is in FO. Second and more crucially, we need it to check if a particular triconnected component needs to be reflected after cascaded flips. Maintaining the vertex rotation scheme for biconnected components is now simple – we just need to collate the vertex rotation schemes for individual rigid components into one for the entire graph.

**Handling deletions.** On deleting edges while it’s not necessary to perform additional flips, the rest of the updates is roughly the reverse of insertion. On deleting an edge from a rigid component, we infer two-colourings from the embedding of erstwhile rigid components

---

<sup>2</sup> which satisfies a minimality condition – it does not pass through both vertices of a separating pair

that decompose into pieces. Further, we have to update the coherent paths since possibly more edges are insertable preserving planarity. Notice that when an edge is deleted from a biconnected component this might lead to many simultaneous virtual edge deletions that might in turn cause triconnected components to decompose. Many ( $O(n)$ ) invocations of the above triconnected edge deletion will be needed, but they can be handled in constant parallel time because they independent of each other as far as the updates required are concerned (see Figure 2).

**Extension to the entire embedding.** BC-trees for connected components have blocks and cut vertices as their nodes. We can maintain an embedding for the graph corresponding to a block or B-node as above. Since a non-cut vertex belongs to precisely one block, we can inherit the rotation scheme for such vertices from that of the blocks. For cut vertices, we need to splice together the vertex rotation scheme from each block that the cut vertex is incident on as long as the order respects the ordering provided by individual blocks.

**Low level details of the information maintained.** We maintain BC-tree for each connected component and SPQR-trees for each biconnected component thereof. In each of these trees we maintain betweenness information, i.e., for any three nodes  $X_1, X_2$  and  $X_3$  whether  $X_2$  occurs on the tree path between  $X_1$  and  $X_3$ . We also maintain a two-colouring of separating pairs for each  $P_i, P_j$ -coherent path in every SPQR-tree. For each rigid component  $R_i$  and each cycle component  $S_j$  we maintain their extended planar embedding. Specifically, we maintain the vertex rotation scheme in the following form. For every vertex  $v$ , we maintain triplet(s)  $(v_i, v_j, v_k)$  of neighbours of  $v$  that occur in the clockwise order though not necessarily consecutively. This enables us to insert and delete an arbitrarily large number of neighbours in FO making it crucial for the planar embedding procedure. This would not be possible if we were to handle individual insertions and deletions separately. See [7, Figure 6] for an example. We use a similar representation for the face-vertex rotation scheme.

For biconnected components, we maintain only a planar embedding (not the extended version) since the face-vertex rotation scheme is not necessary.

**Comparison with existing literature.** The main idea behind recent algorithms for planar embedding in the sequential dynamic setting has been optimizing the number of flips necessitated by the insertion of an edge. This uses either a purely incremental algorithm or alternatively, a fully dynamic but amortized algorithm. Since our model of computation is fully dynamic and does not allow for amortization, each change must be handled (i.e., finding out the correct cascading flips) in worst case  $O(1)$ -time on CRCW-PRAM. We note that filtering out edges that violate planarity in dynamic sequential  $t(n)$  time (a *test-and-reject* model) implies an amortized planarity testing algorithm with  $O(t(n))$  time (i.e., a *promise-free* model). In contrast, although we have a test-and-reject model we are unable to relax the model to promise-free because of lack of amortization.

There are weaker promise models such as the one adopted in [11] where for maintaining a bounded tree-width decomposition it is assumed that the graph has tree-width at most  $k$  without validating the promise at every step. In contrast our algorithm can verify the promise that no non-planarity-causing edge is added.

In terms of query model support, most previous algorithms [22, 21, 25] only maintain the vertex rotation scheme in terms of clockwise next neighbour, in fact, [22, 21] need  $O(\log n)$  time to figure out the next neighbour. In contrast, we maintain more information in terms of arbitrary triplets of neighbours in (not necessarily consecutive) clockwise order. This allows

us to sidestep following arbitrarily many pointers, which is not in FO. Finally, in terms of parallel time our algorithm (since it uses  $O(1)$  time per query/update on CRCW-PRAMs) is optimal in our chosen model. In contrast, the algorithm of [21] comes close but fails to achieve the lower bound (of  $\Omega(\log n)$ ) in the sequential model of dynamic algorithms.

#### 4 Graph Theoretic Machinery

In this section, we present some graph theoretic results which will be crucial for our maintenance algorithm. We begin with a simple observation and go on to present some criteria for the planarity of the graph on edge insertion based on the type of the inserted edge.

► **Observation 2.** *For a 3-connected planar graph  $G$ , two planar embeddings  $\mathcal{E}_1$  and  $\mathcal{E}_2$  in the plane have the same vertex rotation scheme if between the two embeddings only the clockwise order of vertices on the boundary of the outer faces of the two embeddings are reverse if each other and all the clockwise order of vertices on the boundary of internal faces is same.*

Notice that due to the above fact, given a planar embedding with its outer face  $F_0$  and an internal face  $F_1$  specified, we can modify it to make  $F_1$  the outer face while keeping the vertex rotation scheme unchanged by just reversing the orientation of the faces  $F_0$  and  $F_1$ .

Next, we present some criteria to determine if an edge to be inserted in a planar graph causes it to become non-planar.

► **Lemma 3.** *For any 3-connected planar graph  $G$ ,  $G + \{a, b\}$  is planar if and only if  $a$  and  $b$  lie on the boundary of a common face.*

Next, let us consider the case where the vertices  $a$  and  $b$  are in the same block, say  $B_i$ , of a connected component of the graph. Let  $R_a, R_b \in V(T_3(B_i))$  be two R-nodes in the SPQR-tree of  $B_i$  such that  $a \in V(R_a)$  and  $b \in V(R_b)$ . Consider the path between  $R_a$  and  $R_b$  nodes in  $T_3(B_i)$ ,  $R_a, P_1, R_1, P_2, \dots, R_k, P_{k+1}, R_b$ , where  $R_i$  and  $P_i$  are R-nodes and S-nodes in  $T_3(B_i)$  respectively, that appear on the path between  $R_a, R_b$  (see Figure 3). We have the following lemma (see the full version [7, Section 8] for the proof).

► **Lemma 4.**  *$G + \{a, b\}$  is planar if and only if*

- (a) *all vertices in  $\{a\} \cup V(P_1)$  lie on a common face boundary in the embedding of  $R_a$*
- (b) *all vertices in  $V(P_{k+1}) \cup \{b\}$  lie on a common face boundary in the embedding of  $R_b$ , and*
- (c) *for each  $i \in [k]$  all vertices in  $V(P_i) \cup V(P_{i+1})$  lie on a common face in the embedding of  $R_i$ . Equivalently  $R_a \leftrightarrow R_b$  tree path is a coherent path.*

Consider the case in which  $[2 \xrightarrow{\pm} 3]$  edge  $\{a, b\}$  can be inserted into  $G$  preserving planarity. Notice that the 3-connected components  $R_a, R_1, \dots, R_k, R_b$  coalesce into one 3-connected component after the insertion of the edge. Let this coalesced 3-connected component be  $R_{ab}$ . Obviously,  $\{a, b\}$  would be at the boundary of exactly two faces of  $R_{ab}$ , say  $F_0, F_1$ . We claim that the separating pair vertices in  $\bigcup_{i \in [k+1]} V(P_i)$  all lie either on the boundary of  $F_0$  or  $F_1$ . See Figure 1. We provide the proof of the following lemma in the full version of this paper [7, Section 8].

► **Lemma 5.** *The faces  $F_0$  and  $F_1$  define a partition into two parts on the set of vertices in the separating pairs  $\bigcup_{i \in [k+1]} V(P_i)$  such that, for all  $i \in [k+1]$  the two vertices in  $V(P_i)$  belong to different blocks of the partition.*

Finally, if the vertices  $a$  and  $b$  are in the same connected component but not in the same biconnected component then we use the following lemma to test for edge insertion validity. Let the vertices  $a, b$  lie in a connected component  $C_i$ . Let  $B_a, B_b \in N(T_2(C_i))$  be two block

■ **Figure 1** Two-colouring of P-node vertices.

nodes in the BC-Tree of the connected component  $C_i$  such that  $a \in V(B_a)$  and  $b \in V(B_b)$ . Consider the following path between  $B_a$  and  $B_b$  in  $T_2(C_i)$ ,  $B_a, c_1, B_1, c_2, \dots, c_k, B_k, c_{k+1}, B_b$  where  $B_i$  and  $c_i$  are block and cut nodes respectively, in  $T_2(C_i)$  that appear on the path between  $B_a$  and  $B_b$  (see Figure 2). We abuse the names of cut nodes to also denote the cut vertex's name. Insertion of such an edge, i.e.  $[1 \xrightarrow{+} 2]$  leads to the blocks  $B_a, B_1, \dots, B_k, B_b$  coalescing into one block, call it  $B_{ab}$ . In the triconnected decomposition of  $B_{ab}$  a new cycle component is introduced that consists of the edge  $\{a, b\}$  and virtual edges between the consecutive cut vertices  $c_i, c_{i+1}$ ,  $i \in [k]$ . See Figure 2d. We provide the proof of the following lemma in the full version of this paper [7, Section 8].
