► **Lemma 6.**  $G + \{a, b\}$  is planar if and only if (a)  $G[V(B_a)] + \{a, c_1\}$  is planar, (b)  $G[V(B_b)] + \{c_{k+1}, b\}$  is planar, and (c) for each  $i \in [k]$ ,  $G[V(B_i)] + \{c_i, c_{i+1}\}$  is planar.

## 5 Dynamic Planar Embedding

Our idea is to maintain planar embeddings of all triconnected components (S and R-nodes) of the graph and use those to find the embedding of the entire graph. Insertions and deletions of edges change the triconnected components of the graph, i.e., a triconnected component might decompose into multiple triconnected components or multiple triconnected components may coalesce together to form a single one. The same is true of biconnected components, i.e., a biconnected component might decompose into multiple biconnected components or multiple triconnected components may coalesce together to form a single biconnected component.

We discuss here how we update the embeddings of the triconnected components under insertions and deletions, assuming that we have the SPQR-tree and BC-tree relations available at every step (which we show how to maintain in the full version of this paper [7, Section 6]).

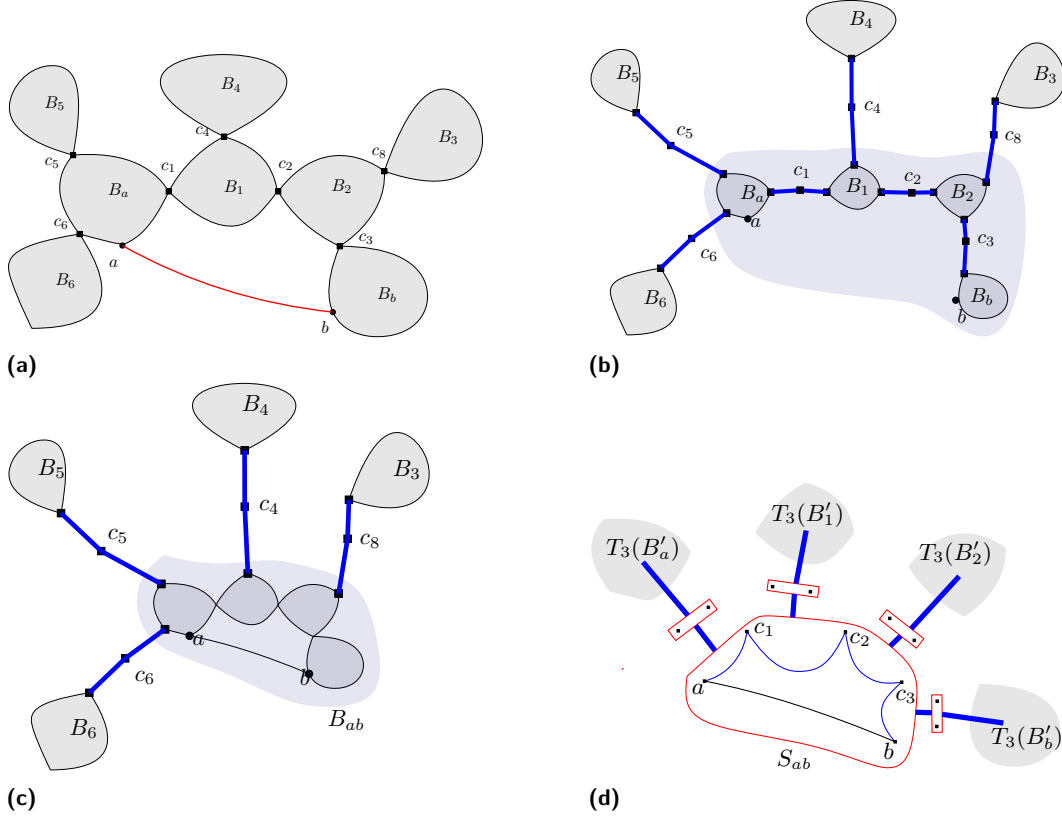

Some of the edge insertions/deletions are easier to describe, for example if the edge is being inserted in a rigid component then only the embedding of that rigid component has to change to reflect the presence of the new edge and introduction of two new faces. Thus, we first establish some notation to differentiate between classes of edges for ease of exposition.

► **Definition 7.** A graph is actually  $i$ -connected if it is  $i$ -connected but is not  $i+1$ -connected for  $i \in \{0, 1, 2\}$ . For  $i = 3$ , a graph is actually  $i$ -connected if the graph is 3-connected.

► **Definition 8.** The type of an edge is  $[i \xrightarrow{\sigma} j]$  where  $i, j \in \{0, 1, 2, 3\}$  and  $\sigma \in \{+, -\}$  such that

- $\sigma = +$  if the edge is being inserted into  $G$ .  $\sigma = -$  if the edge is being deleted.
- both the endpoints are in a common actually  $i$ -connected component before the change and in a common actually  $j$ -connected component after the change.

In the next two subsections we outline the updates in the triconnected planar embedding relations as well as the two-colouring relations which are described in complete detail in the full version of this paper [7, Section 10 and 11].

**Figure 2**  $[1 \xrightarrow{+} 2]$  edge  $\{a, b\}$  insertion. (2a) To-be-inserted edge is highlighted in red. (2b) The path between block nodes  $B_a$  and  $B_b$  is highlighted in the BC-tree. (2c) The BC-tree of the connected component  $CC_i$ .  $B_a \rightsquigarrow B_b$  path has shrunk to a single node  $B_{ab}$  in the BC-tree. (2d) The SPQR-tree of the block  $B_{ab}$  contains a cycle component  $S_{ab}$  made of the inserted edge and the new virtual edges that are introduced after its insertion.

### 5.1 Edge insertion

Find the type  $[i \xrightarrow{+} j]$  of the inserted edge  $\{a, b\}$  (where  $i, j \in \{0, 1, 2, 3\}$ ). This can be done using [7, Lemma 10 and 11]. Depending on the type we branch to one of the following options:

- (a)  $[0 \xrightarrow{+} 1]$  This case affects only the BC-tree and SPQR-tree relations. Embedding and colouring relations remain unaffected.
- (b)  $[1 \xrightarrow{+} 2]$ : In this case, both the endpoints  $a, b$  are in the same connected component  $C$  but not in the same biconnected component  $B_a, B_b$  (see Figure 2a). On this insertion, the BC-tree of the connected component changes. All the biconnected components on the  $B_a \rightsquigarrow B_b$  path in the BC-tree of  $C$  coalesce into one biconnected component  $B_{ab}$  (see Figure 2c). In the BC-tree of the connected component, for each pair of consecutive cut-vertices on the  $B_a \rightsquigarrow B_b$  path, a virtual edge is inserted in the biconnected component shared by the cut-vertex pair. This edge is a  $[2 \xrightarrow{+} 3]$  or  $[3 \xrightarrow{+} 3]$  edge and is handled

below. Since the biconnected components involved are distinct, all these edges can be simultaneously inserted. In addition, a cycle component is introduced for which the face-vertex rotation scheme is computed via the betweenness relation in the BC-tree (see Figure 2d). The two-colouring relation is updated by extending the colouring of old biconnected components across the new cycle component (in Figure 2d, a coherent path from a P-node in  $T_3(B'_a)$  to a P-node in  $T_3(B'_b)$  will have to go via an S-node  $S_{ab}$ ).

- (c)  $[2 \xrightarrow{+} 3]$ : Both  $a, b$  are in the same biconnected component, say  $B_i$ , but not in the same rigid component. Let  $a \in V(R_a)$  and  $b \in R_b$ , where  $R_a$  and  $R_b$  are two R-nodes in the SPQR-tree of  $B_i$ . The SPQR-tree of the biconnected component changes after the insertion as follows. All the rigid components on the  $R_a \rightsquigarrow R_b$  SPQR-tree path coalesce into one rigid component (see Figures 3a, 3b). The embedding of the coalesced rigid component is obtained by combining the embeddings of the old triconnected components that are on the  $R_a \rightsquigarrow R_b$  path, with their correct orientation computed from the two-colouring of the separating pairs for the corresponding coherent path. To update the two-colouring of the separating pair vertices, first we discard those old coherent paths and their two-colouring, that are no longer coherent as result of the insertion of  $\{a, b\}$ . While for the subpaths of the old coherent paths that remain coherent we obtain their two-colouring from that of the old path by ignoring colourings of old P-nodes on the  $R_a \rightsquigarrow R_b$  path.
- (d)  $[3 \xrightarrow{+} 3]$ : In this case, both the vertices are in the same 3-connected component. Due to this insertion, connectivity relations do not change. We identify the unique common face in the embedding of the 3-connected component that the two vertices lie on. We split the face into two new faces with the new edge being their common edge, i.e, the face vertex rotation scheme of the old face is split across the new edge. In the vertex rotation scheme of the two vertices, we insert the new edge in an appropriate order.

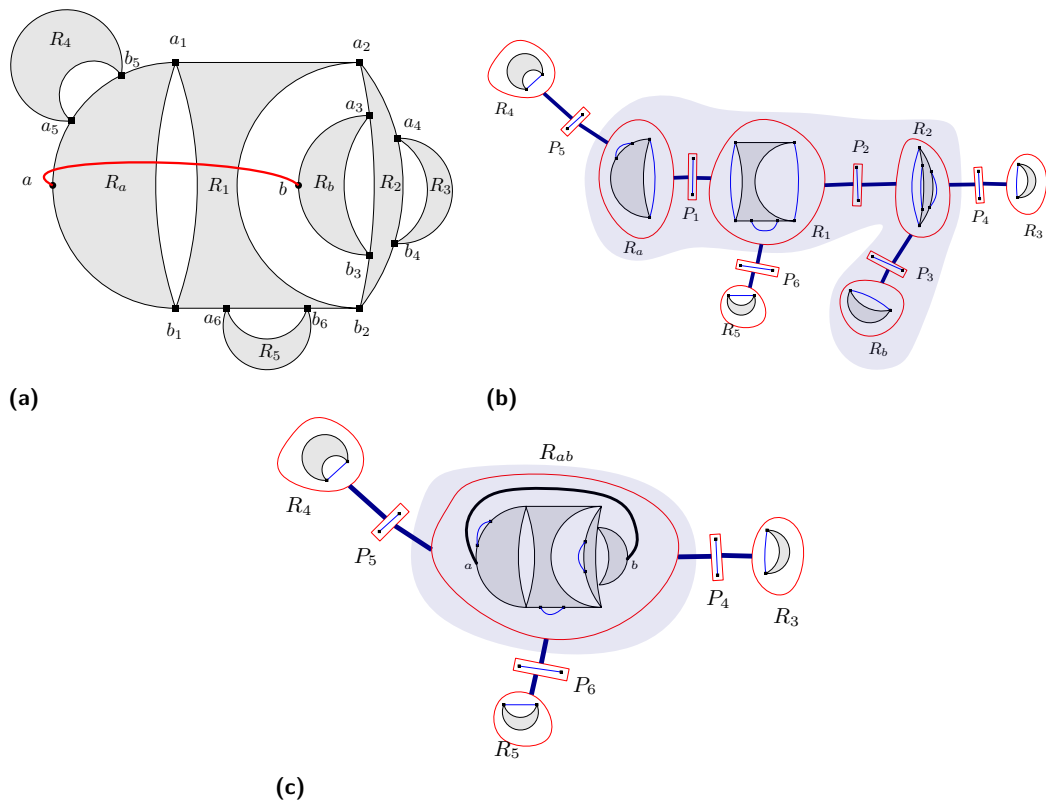

## 5.2 Edge deletion

Find the type of the edge  $\{a, b\}$  that is being deleted. Depending on the type we branch to one of the following options:

- (a)  $[1 \xrightarrow{-} 0]$ : This case occurs when both  $a, b$  are in the same connected component but not in the same biconnected component. The edge is a cut edge and only BC-tree and SPQR-tree relations are affected.
- (b)  $[2 \xrightarrow{-} 1]$ : In this case, both vertices are in the same biconnected component but not in the same 3-connected component before the change. This is the inverse of the insertion operation of an edge of the type  $[1 \xrightarrow{+} 2]$ . The biconnectivity of the old biconnected component changes and it unfurls into a path consisting of multiple biconnected components that are connected via new cut vertices (in Figure 2c if the edge  $\{a, b\}$  is deleted, the block  $B_{ab}$  will unfurl into the highlighted path in Figure 2b). Old virtual edges that are still present in the new biconnected components are deleted. These virtual edge deletions are of type  $[3 \xrightarrow{-} 3]$  or  $[3 \xrightarrow{-} 2]$  which we describe how to handle in the following cases.
- (c)  $[3 \xrightarrow{-} 2]$ : In this case  $a, b$  are in the same rigid component  $R_{ab}$  (see Figure 3c) before the change. But after the deletion of  $\{a, b\}$ ,  $R_{ab}$  decomposes into smaller triconnected components that are unfurled into a path in the SPQR-tree (see Figure 3b). We compute an embedding of the triconnected fragments of  $R_{ab}$  using the embedding of  $R_{ab}$ . From the updated embedding of  $R_{ab}$ , we compute the two-colouring of the separating pair vertices pertaining to the unfurled path on an SPQR-tree. We compose the obtained colouring with the rest of  $B_{ab}$ . The two-colouring of the elongated coherent paths is made consistent by flipping the colouring of the P-nodes of one subpath, if necessary.

(d)  $[3 \bar{\rightarrow} 3]$ : In this case both  $a, b$  are in the same 3-connected component before and after the deletion of  $\{a, b\}$ . Connectivity relations (connectedness, bi/tri-connectivity) remain unchanged. The two faces in the embedding of the 3-connected component that are adjacent to each other via the to-be-deleted edge are merged together to form a new face. From the vertex rotation schemes of the two vertices, the edge is omitted. Pairs of coherent paths that merge due to the merging of two faces have to be consistently two-coloured.

Notice that we do not describe changes of types  $[0 \bar{\rightarrow} 2]$ ,  $[0 \bar{\rightarrow} 3]$ ,  $[1 \bar{\rightarrow} 3]$ ,  $[3 \bar{\rightarrow} 0]$ ,  $[3 \bar{\rightarrow} 1]$ ,  $[2 \bar{\rightarrow} 0]$ , since edge insertion or deletion only changes the number of disjoint paths between any two vertices at most by one and thus these type of edge change are not possible. Also, we omit the changes of type  $[2 \bar{\rightarrow} 2]$  and  $[2 \bar{\rightarrow} 2]$  (related to S-nodes) as they are corner cases that we discuss in the full version of this paper [7, Section 11.4].

■ **Figure 3** A  $[2 \bar{\rightarrow} 3]$  edge  $\{a, b\}$  insertion. (3a) To-be-inserted edge is highlighted in red. (3b) The SPQR-tree of block  $B_i$  before insertion. The path between R-nodes  $R_a$  and  $R_b$  is highlighted. (3c) SPQR-tree of  $B_i$  after insertion. The  $R_a \rightsquigarrow R_b$  path has shrunk to a single node  $R_{ab}$ .

### 5.3 Embedding the biconnected components

For each biconnected component, we maintain an embedding in the form of the vertex rotation scheme for its vertices. Note that we do not need to maintain the face-vertex rotation scheme for the biconnected components. The relevant updates for maintaining the biconnected components embedding are edge changes of type  $[1 \bar{\rightarrow} 2]$ ,  $[2 \bar{\rightarrow} 3]$ ,  $[3 \bar{\rightarrow} 3]$ ,  $[3 \bar{\rightarrow} 2]$ , and  $[2 \bar{\rightarrow} 1]$ . For a  $[2 \bar{\rightarrow} 3]$  change, the part of the block that becomes triconnected, after the insertion of the edge, we patch together its vertex rotation scheme with unchanged fragments

of the existing vertex rotation scheme in the affected block. For example, in Figure 3, after the insertion of edge  $\{a, b\}$ , R-nodes  $R_a, R_1, R_2$  and  $R_b$  coalesce together to form  $R_{ab}$  (part of the block that has become triconnected). The embedding of the unchanged fragments of the block, viz.,  $R_3, R_4$  and  $R_5$  is patched together at the appropriate P-nodes with the updated embedding of  $R_{ab}$  to update the embedding of the entire block. In a  $[1 \xrightarrow{+} 2]$  change, multiple biconnected components coalesce together. First, we update the vertex rotation scheme of each block by inserting a required virtual edge and then patch together the vertex rotation schemes at the old cut vertices. For a  $[3 \xrightarrow{-} 2]$  change, we splice in new virtual edges, that arise as a result of the change, in appropriate places in the vertex rotation scheme of the affected block. Details of the updates required in all types of edge changes are described in the full version of this paper [7, Section 12.1].

## 5.4 Embedding the entire graph

Assuming that we have planar embedding (in terms of the vertex rotation scheme) of each biconnected component of the graph we can compute a planar embedding of the whole graph as follows. For the vertices that are not cut vertices, their vertex rotation scheme is the same as their vertex rotation scheme in the embedding of their respective blocks that they belong to. For a cut vertex  $v$ , we join together its vertex rotation schemes from each block  $v$  belongs to. We only need to take care that in the combined vertex rotation scheme of  $v$ , its neighbours in each block appear together and are not interspersed.

We now complete the proof of the main theorem. We provide the complete details in the full version of this paper [7, Section 10, 11 and 12].

► **Lemma 9.** *The extended planar embeddings of all cycle, rigid components and a planar embedding for each biconnected component of the graph can be updated in DynFO under edge changes of type:  $[1 \xrightarrow{+} 2], [2 \xrightarrow{+} 3], [3 \xrightarrow{+} 3], [2 \xrightarrow{+} 2], [2 \xrightarrow{-} 2], [2 \xrightarrow{-} 1], [3 \xrightarrow{-} 2], [3 \xrightarrow{-} 3]$ .*

The above lemma combined with the implementation details provided in the full version [7, Section 12] allows us to prove the main theorem:

► **Theorem 1.** *Given a dynamic graph undergoing insertion and deletion of edges we can maintain a planar embedding of the graph in DynFO (while never allowing insertion of edges that cause the graph to become non-planar).*

**Proof.** If an edge insertion is within a 3-connected component the criterion in Lemma 3 tells us when the resulting component becomes non-planar. Analogously, Lemma 4 informs us when a 2-connected component is non-planar on an edge insertion within it (but across different 3-connected components). Similarly Lemma 6 allows us to determine if an edge added within a connected component but between two different 2-connected components causes non-planarity. An invocation of Lemma 9 shows how to update the planar embedding for biconnected graphs. Moving on to connected graphs, vertex rotation schemes of the cut-vertices is obtained by combining their vertex rotation schemes in each block in any non-interspersed order, using FO primitive *merge vertex rotation schemes* (see [7, Section 9]). Remaining vertices inherit their vertex rotation scheme from the unique block they belong to. This completes the proof. ◀

## 6 Conclusion

We show that planarity testing and embedding is in DynFO where we are able to ensure that an edge is inserted if and only if it does not cause the graph to become non-planar. This is potentially an important step in the direction of solving problems like distance and matching

where only an upper bound of  $\text{DynFO}[\oplus]$  (where  $\text{FO}[\oplus]$  is FO with parity quantifiers) was known in planar graphs. This is because we might be able to improve the known bound making use of planar duality which presupposes a planar embedding. It might also make problems like max flow, graph isomorphism, and counting perfect matchings which are all statically parallelisable when restricted to planar graphs, accessible to a DynFO bound.

# Universality and Forall-Exactness of Cost Register Automata with Few Registers

Laure Daviaud

---

## Abstract

The universality problem asks whether a given finite state automaton accepts all the input words. For quantitative models of automata, where input words are mapped to real values, this is naturally extended to ask whether all the words are mapped to values above (or below) a given threshold. This is known to be undecidable for commonly studied examples such as weighted automata over the positive rational (plus-times) or the integer tropical (min-plus) semirings, or equivalently cost register automata (CRAs) over these semirings. In this paper, we prove that when restricted to CRAs with only three registers, the universality problem is still undecidable, even with additional restrictions for the CRAs to be copyless linear with resets.

In contrast, we show that, assuming the unary encoding of updates, the  $\forall$ -exact problem (does the CRA output zero on all the words?) for integer min-plus linear CRAs can be decided in polynomial time if the number of registers is constant. Without the restriction on the number of registers this problem is known to be PSPACE-complete.

## 1 Introduction

Cost register automata (CRAs), introduced by Alur et al. [3], are an extension of finite state automata. Instead of just accepting or rejecting words, they assign each word a value, usually from some semiring. This allows to reason about quantitative properties of systems, such as costs, probabilities, or durations. A CRA is a deterministic finite automaton equipped with a finite set of write-only registers which store values from a semiring, and which are combined using the operations of this semiring. The transitions that a CRA takes thus depend only on the input word, and not on the values of the registers, which makes them different to automata with counters (such as Minsky machines), and allows more of their properties to be decidable.

CRAs are tightly related to weighted automata (WAs), a classical computational model which maps words to values from a fixed semiring. In general, WAs are less expressive than CRAs [3]. However, WAs are equally expressive to linear CRAs, which are CRAs where the updates of the registers are restricted to linear transformations. Hence linear CRAs can be seen as a deterministic model for WAs. Transforming a linear CRA into an equivalent WA and vice versa can be done in polynomial time.

WAs extend automata to a quantitative setting and have been extensively studied since their introduction by Schützenberger in [21], see also surveys [11, 12]. Two widely studied models are WAs over the tropical (or min-plus) semiring and probabilistic WAs, a restricted case of WAs over the semiring of rational numbers with usual addition and multiplication (plus-times semiring). They find their applications in such areas as language and speech processing [19], verification [6], image processing [7], and analysis of on-line algorithms [4] and probabilistic systems [23].

Most applications are algorithmic in their nature, that is, require checking some property of the automaton which models a given system. Often these are classical automata-theoretic properties such as universality, emptiness, boundedness, equivalence, etc., generalised to the quantitative setting. For example, the universality problem for non-deterministic finite state automata asks whether all the input words are accepted. It is PSPACE-complete and is solvable in polynomial time for deterministic finite automata [22]. A natural way to generalise this problem to the quantitative setting is to ask whether all the input words are mapped to a value above (or below, depending on the semiring) a certain threshold. For the min-plus semiring  $(\mathbb{Z} \cup \{+\infty\}, \min, +)$  (are all the values strictly below 0?), and the plus-times semiring  $(\mathbb{Q}, +, \times)$  (are all the values strictly above 1?) this problem is undecidable, see [16, 1] and [20] respectively.

It is thus important to try to find subclasses where this problem becomes decidable. A WA is called linearly ambiguous (respectively, finitely ambiguous) if there is a constant  $C$  such that for every word  $w$  the number of accepting runs labelled by  $w$  is bounded by  $C|w|$  (respectively, by  $C$ ). In both cases (min-plus and plus-times), undecidability is retained even for linearly ambiguous WAs, see [16, 1] and [9] respectively. For finitely ambiguous min-plus WAs universality becomes decidable [24, 13].

Some syntactic restrictions on CRAs allow to introduce subclasses whose expressiveness is incomparable to known classes of WAs. One natural restriction is to bound the number of registers: there exist CRAs with only two registers that compute functions which cannot be computed by a finitely ambiguous WA (Example 2 provides one such CRA). This means that if universality is decidable for CRAs with only two registers, that would allow to decide it for more WAs than it was possible before. We show that for three registers this is not the case, even when restricted further to copyless linear CRAs with resets (see next section for a formal definition), leaving the two-register case as the only remaining option. Undecidability for five registers in the min-plus case follows from a construction in [2], which we use as a starting idea in Subsection 3.1. We note that no characterisation of CRAs with bounded number of registers (or any of its subclasses) in terms of WAs is known, so our results do not follow from any results about WAs.

Informally, a CRA is called copyless if the value of each its registers can only be used once for each transition. In [3], Alur et al. conjectured that universality is decidable for the class of copyless CRAs over the min-plus semiring. In [2], Almagor et al. disproved this conjecture and showed that universality is still undecidable for them. It is natural to ask the same question for the plus-times semiring, but no such results have been known so far. In this paper we show that this conjecture is not true for the plus-times case as well.

CRAs with a bounded number of registers were also studied in the context of register complexity. The register complexity of a function is the minimum number of registers of a CRA that computes it. The problem of computing the register complexity is known to be decidable for unambiguous WA [10], but is open and highly challenging in general. This problem can be seen as a generalisation of the classical determinisation problem, asking if for a given WA there exists an equivalent deterministic one, which amounts to ask whether there exists an equivalent linear CRA with one register [15, 14, 8].

**Our contributions.** In this paper we prove that for CRAs which are linear with resets, copyless and have only 3 registers universality is still undecidable, both for the min-plus and the plus-times semirings. Our approach gives in fact a more general result, encompassing both semirings at the same time, and proves undecidability of universality under some specific conditions on the semiring. This is an additional advantage of our technique, since usually the proofs for the two mentioned semirings are very different.

Another natural decision problem we consider is the  $\forall$ -exact problem, which asks for a given CRA or WA if it outputs zero on all the words. It is known to be PSPACE-complete for WAs (and hence for linear CRAs) over the min-plus semiring [1]. It was also investigated for polynomial automata, which can be seen as a generalisation of WAs over a field [5]. We prove that for this problem bounding the number of registers does help: namely, the  $\forall$ -exact problem is solvable in polynomial time for a linear CRA over the min-plus semiring when the number of its registers is a constant, and the updates of registers are given in the unary encoding.

**Organisation of the paper.** In Section 2, we introduce the model under consideration, namely copyless linear cost-register automata with resets, and the decision problems we study, the universality and the  $\forall$ -exact problems. In Sections 3 and 4, we give the proof of undecidability for the universality problem. To make the content more understandable, we do it in two steps: first we explain the main ideas on a specific sub-problem and on a particular semiring in Section 3, and then extend these ideas to give the general proof in Section 4.

## 2 Cost register automata and decision problems

### 2.1 Cost register automata

Cost register automata (CRAs) are defined in a general way as deterministic finite automata equipped with so-called registers that can store values (numbers, words...) and be combined with operations (addition, multiplication, minimum, discounted sum, concatenation...). In this paper, we consider a quite restrictive class of CRAs. The undecidability results we obtain for this specific class are then applicable to larger classes and CRAs in general.

► **Definition 1.** A *linear cost register automaton with resets* with  $k$  registers over a semiring  $(\mathbb{K}, \oplus, \otimes)$  is a deterministic finite automaton  $(Q, \Sigma, \delta, s)$  equipped with registers  $r_1, \dots, r_k$  taking values in  $\mathbb{K}$ , where  $Q$  is a finite set of states and  $s$  the unique initial state,  $\Sigma$  the alphabet and  $\delta$  the transition function. The initial values of the registers are specified by a vector  $\lambda \in \mathbb{K}^k$  and the output function at a state  $q$  is specified as (a linear transformation)  $\oplus_{j=1}^k (m_j^{(q)} \otimes r_j)$  or (a constant)  $m^{(q)}$ , where  $m_1^{(q)}, \dots, m_k^{(q)}, m^{(q)}$  are elements of  $\mathbb{K}$ . Finally, each transition of  $\delta$  is equipped with  $k$  transformations, one for every register, each of one of the two forms:

$$r_i \leftarrow \bigoplus_{j=1}^k m_{i,j} \otimes r_j \text{ (a linear transformation),}$$

$$r_i \leftarrow m_{i,k+1} \text{ (a reset to a constant)}$$

with  $m_{i,j} \in \mathbb{K}$  for all  $1 \leq i \leq k$ ,  $1 \leq j \leq k+1$ .

The semantics of a CRA is defined by means of valuations of the registers. A valuation  $\sigma$  of the registers is a function  $\{r_1, \dots, r_k\} \rightarrow \mathbb{K}$ . A run on a word  $a_1 a_2 \dots a_n$ , where  $a_i \in \Sigma$  for all  $i$ , is a sequence:  $\rho = (q_1, \sigma_1) \xrightarrow{a_1} (q_2, \sigma_2) \xrightarrow{a_2} \dots \xrightarrow{a_n} (q_{n+1}, \sigma_{n+1})$  where  $q_1 \xrightarrow{a_1} q_2 \xrightarrow{a_2}$

■ **Figure 1** An example of CRA on the semiring  $(\mathbb{Z} \cup \{+\infty\}, \min, +)$ .

$\dots \xrightarrow{a_n} q_{n+1}$  is a run in the underlying deterministic finite automaton, and the valuations of the registers  $\sigma_1, \dots, \sigma_{n+1}$  are updated according to the transitions: for all  $1 \leq \ell \leq n$ ,  $\sigma_{\ell+1}(r_i) = \bigoplus_{j=1}^k m_{i,j} \otimes \sigma_\ell(r_j)$  if the transition update is given by a linear transformation and  $\sigma_{\ell+1}(r_i) = m_{i,k+1}$  if it is given by a reset to a constant.

The run is accepting if additionally  $q_1 = s$  and  $\sigma_1(r_i) = \lambda_i$  for all  $i$ , and the output on  $a_1 a_2 \dots a_n$  is given by the output function at state  $q_{n+1}$ , i.e.  $\bigoplus_{j=1}^k m_j^{(q_{n+1})} \otimes \sigma_{n+1}(r_j)$  if this is given by a linear transformation and  $m^{(q_{n+1})}$  if this is given by a constant. Finally, a CRA is called **copyless** if for each transition, every register appears at most once on the right hand-side of the updates: for all  $j$ ,  $m_{i,j}$  is the zero of  $\mathbb{K}$ , except for at most one  $i$ .

All CRAs considered in this paper are from this restrictive class of copyless linear CRAs with resets, so unless specified otherwise by CRAs we mean CRAs from this class. Given a CRA  $\mathcal{A}$ , we will use  $\mathcal{A}$  to denote both the CRA itself and the function  $\Sigma^* \rightarrow \mathbb{K}$  it computes.

► **Example 2.** In Figure 1, we give an example of a CRA over the semiring  $(\mathbb{Z} \cup \{+\infty\}, \min, +)$  and alphabet  $\{a, \#\}$ . It has two states  $p$  (which is initial) and  $q$ , and two registers  $x$  and  $y$ . The output function at state  $p$  (words ending with  $a$  and the empty word) is  $\min\{x, y\}$  and at state  $q$  (words ending with  $\#$ ) is 0. Both registers are initialised with value 0.

If the input word ends with  $\#$  or is empty, this CRA outputs 0. If it ends with  $a$ , the CRA outputs the length of the shortest maximal blocks of consecutive  $a$ 's. Register  $x$  stores the number of  $a$ 's read in the current block, and  $y$  stores the minimum length of the blocks read so far. This CRA is copyless linear with resets.

For any semiring, copyless linear CRAs with resets are at most as expressive as linearly ambiguous WAs, strictly less expressive than polynomially ambiguous WAs, and are incomparable to unambiguous WAs [8]. For the min-plus semiring specifically, they are strictly less expressive than linearly ambiguous WAs [2], incomparable to unambiguous WAs [2] and, at the same time, there exists a copyless CRA (but not linear with resets) with 3 registers which is not equivalent to any polynomially ambiguous WA [17].

## 2.2 Decision problems

We are mainly interested in two classes of CRAs: CRAs over  $(\mathbb{Z} \cup \{+\infty\}, \min, +)$ , called min-plus CRAs, and over  $(\mathbb{Q}, +, \times)$ , called plus-times CRAs in this paper. Our main result is that the universality problem for these two classes, where the number of registers is restricted to 3, is undecidable. We define this problem as follows:

UNIVERSALITY PROBLEM FOR 3-REGISTER CRAs  
 INPUT: A min-plus (respectively, plus-times) CRA  $\mathcal{A}$  with 3 registers.  
 OUTPUT: Yes if and only if for all words  $w$ , we have  $\mathcal{A}(w) < 0$  (respectively,  $\mathcal{A}(w) > 1$ ).

► **Theorem 3.** *The universality problem for 3-register CRAs is undecidable both for min-plus CRAs and for plus-times CRAs.*

To prove this result we give a reduction from the halting problem for Minsky machines with 2 counters, which is known to be undecidable. This leads us to prove a slightly more general result, encompassing both the min-plus and plus-times cases at the same time.

To simulate the behaviour of a Minsky machine with a CRA, we encode the run of the Minsky machine into a specific word and use the CRA to check that a given word corresponds to a correct encoding of the halting run. This boils down to checking some regular properties and verifying that the counters are updated accordingly to the transitions. To explain our approach of this later part, we start by looking at a simpler problem in Section 3: checking that  $n_1 = n_2 = \dots = n_p$  for a word of the shape  $a^{n_1}\#a^{n_2}\#\dots\#a^{n_{p-1}}\#a^{n_p}$ . We explain how to do this with only 3 registers in the min-plus case. In Section 4, we give the full proof of Theorem 3 in a more general setting, allowing us to apply it to both min-plus and plus-times.

On the other hand, we also give a more positive result in the min-plus case: the  $\forall$ -exact problem, as defined below, is known to be PSPACE-complete for linear CRAs with a non-restricted number of registers [1, Theorem 6.13]. We show that it becomes solvable in polynomial time when the number of registers is fixed (and is not a part of the input). For a fixed number of registers, we assume that the size of a CRA is given by its number of states plus the largest absolute value of an integer appearing in an update of a transition or in the output function at a state. Hence, we assume the unary encoding of the numbers in the input. Without the restriction on the number of registers the  $\forall$ -exact problem remains PSPACE-complete in this case [1]. Note that for this results, and for this result only, we consider the class of linear CRAs instead of the class of copyless linear CRAs with resets.

THE  $\forall$ -EXACT PROBLEM FOR  $k$ -REGISTER MIN-PLUS LINEAR CRAS  
 INPUT: A min-plus linear CRA  $\mathcal{A}$  with  $k$  registers.  
 OUTPUT: Yes if and only if for all words  $w$ , we have  $\mathcal{A}(w) = 0$ .

► **Theorem 4.** *For a fixed  $k$ , the  $\forall$ -exact problem is decidable in polynomial time for  $k$ -register min-plus linear CRAs, assuming that the numbers in the transformations are given in the unary encoding.*

This result comes from a variation of a pumping argument, showing that for all words to have value 0, the (useful) values of the registers have to be bounded (below and above) by a constant that is polynomial in the size of the CRA. One can then just keep track of these values. The full proof of this result can be found in the full version of the paper.

**Variants.** The proofs given in this paper can be easily adapted to obtain the undecidability of other variants of the universality problem: for plus-times, whether  $\mathcal{A}(w) > c$  or  $\mathcal{A}(w) < c$ , and for min-plus, whether  $\mathcal{A}(w) < c$  for any constant  $c$ , and the polynomial-time complexity of variants of the  $\forall$ -exact problem: for min-plus, whether  $\mathcal{A}(w) = c$  for any given constant  $c$ . Note that in some cases (for min-plus), a direct translation between these problems is possible and preserves the number of registers. In others (plus-times), the natural translation between these problems would increase the number of registers by 1, but an adaptation of the proofs given in this paper would maintain this number to 3.

### 3 Recognising equal-length blocks

To explain our approach, we first look at a simpler problem: given a word

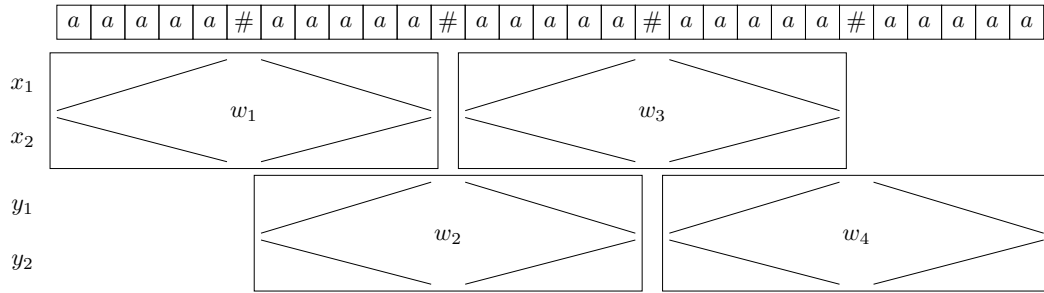

$$w = a^{n_1} \# a^{n_2} \# \dots \# a^{n_{p-1}} \# a^{n_p},$$

check with a min-plus CRA if all  $n_i$  are equal. We assume that the CRA knows that it is going to read the last block of  $a$ 's. For example, that can be done by duplicating the last  $\#$  symbol in the word, but we omit this technical detail for now. More precisely:

► **Proposition 5.** *There exist a min-plus CRA  $\mathcal{A}$  over the alphabet  $\{a, \#\}$  with 3 registers such that  $\mathcal{A}(w) \leq 0$  for all words  $w$ , and  $\mathcal{A}(w) = 0$  if and only if  $w = (a^n \#)^m \# a^n$  for some integers  $n, m$ .*

We describe the solution to this problem in an incremental way, starting from a CRA with 5 registers and then using more and more complex ideas to get to 4 and then finally to only 3 registers. We call a maximal subword of consecutive  $a$ 's a *block*. For  $1 \leq i \leq p - 1$ , define  $w_i = a^{n_i} \# a^{n_{i+1}}$ .

#### 3.1 Five registers

■ **Figure 2** The computations of two pairs of registers processing  $w_i$ ,  $1 \leq i \leq 4$ . An increasing line means that the register is incremented by 1 for each letter and a decreasing line that the register is decremented by 1 for each letter.

The case of five registers is easy and uses the idea described in [2]. To test if for a word  $w_i = a^{n_i} \# a^{n_{i+1}}$  we have  $n_i = n_{i+1}$ , we use two registers, call them  $x_1$  and  $x_2$ , initialised to zero. While reading the first of two blocks,  $x_1$  is incremented by one, and  $x_2$  is decremented by one. While reading the second block, they do the opposite. Thus, after reading  $w_i$ , the value of  $x_1$  is  $n_i - n_{i+1}$ , and the value of  $x_2$  is  $-n_i + n_{i+1}$ . Observe that  $n_i = n_{i+1}$  if and only if  $\min\{n_i - n_{i+1}, -n_i + n_{i+1}\} = 0$ . Moreover,  $\min\{n_i - n_{i+1}, -n_i + n_{i+1}\}$  is always non-positive. We introduce a new special register  $z$ . After reading  $w_i$ , we set  $z \leftarrow \min\{z, x_1, x_2\}$  and reset  $x_1$  and  $x_2$  to zero. Hence the value of  $z$  is then the minimum of its previous value and  $\min\{n_i - n_{i+1}, -n_i + n_{i+1}\}$ .

After doing that, we have already read the second block of  $w_i$ , so we cannot do the same for  $w_{i+1}$  using the same registers. However, we can cover all words  $w_i$  by using two pairs of registers: one pair  $x_1, x_2$  for  $w_i$  with  $i$  odd, and another pair  $y_1, y_2$  for  $i$  even, because each pair is reset to zero at the end of reading  $w_{i+1}$ , and hence can be used for processing  $w_{i+2}$ . Register  $z$  is shared between these two pairs. Figure 2 illustrates the computations performed by the pairs  $x_1, x_2$  and  $y_1, y_2$ .

The register  $z$  is initialised with zero at the beginning, and changes its value as described above. The output of the CRA is then defined as  $\min\{z, x_1, x_2\}$  if  $i$  is odd, and  $\min\{z, y_1, y_2\}$  if  $i$  is even. This value is the minimum of the values  $\{n_i - n_{i+1}, -n_i + n_{i+1} \mid 1 \leq i \leq p - 1\}$ . It is equal to zero if and only if all  $n_i$  are equal, for  $1 \leq i \leq p$ , otherwise it is strictly negative.

### 3.2 Four registers

The case of four registers is handled similarly, but now we want to get rid of the register  $z$ , and accumulate the non-positive value  $\min\{n_i - n_{i+1}, -n_i + n_{i+1}\}$  in one of the registers that we use for its computation.

Once again, we use two pairs  $x_1, x_2$  and  $y_1, y_2$  of registers to separately process  $w_i$  for odd and even values of  $i$ , and before reading the input we initialise them all with zeros. Assume that  $i$  is odd, and hence we use  $x_1, x_2$  to process the word  $w_i = a^{n_i} \# a^{n_{i+1}}$ . When processing  $w_i$ , the registers  $x_1$  and  $x_2$  perform the same computations as in the case of five registers, thus computing  $n_i - n_{i+1}$  and  $-n_i + n_{i+1}$  respectively. However, after that, instead of sending these values to  $z$  and resetting both registers to zero, we reset to zero only  $x_1$ , and set  $x_2 \leftarrow \min\{x_1, x_2\}$ . Let  $m_i$  be the value of  $x_2$  after processing  $w_i$  if  $i \geq 1$ , and zero otherwise. We can show by induction that  $m_i$  is always non-positive and 0 if and only if  $n_j = n_{j+1}$  for all odd  $j < i$ . Indeed, after processing  $w_i$  the value of  $x_2$  is  $\min\{n_i - n_{i+1}, -n_i + n_{i+1} + m_{i-2}\}$ . By the induction hypothesis, it is always non-positive, and is 0 if and only if  $n_i - n_{i+1} = -n_i + n_{i+1} = 0$  and  $m_{i-2} = 0$ , which concludes the argument. For even  $i$ , we do similarly for  $y_1, y_2$ .

After reading  $w$ , the CRA then outputs the value  $\min\{x_1, x_2, y_1, y_2\}$ . As explained above, this value is zero if and only if for all  $i$  we have  $n_i = n_{i+1}$ , which means that all blocks have the same length. Otherwise this value is strictly negative.

### 3.3 Three registers

**Idea.** For the case of three registers we use the idea described for four registers, but now we only leave the first register of each pair (call these registers  $x$  and  $y$ ), and use the third register (call it  $z$ ) to act simultaneously as the second register from both pairs. Since in the case of four registers the computations performed by two pairs overlap, this will require some adjustments for the behaviour of  $x$  and  $y$  to deal with the overlapping parts.

We use register  $x$  to process  $w_i = a^{n_i} \# a^{n_{i+1}}$  for odd values of  $i$ , and  $y$  for even values of  $i$ . Assume for example that  $i$  is odd. The idea remains the same: we want  $x$  to compute  $n_i - n_{i+1}$ , and  $z$  to compute  $-n_i + n_{i+1}$ . However, if we want  $z$  to perform such computations for all  $w_i$ , then  $z$  is also involved first in processing  $w_{i-1}$  and then in processing  $w_{i+1}$ . The solution is to consider this unwanted change for  $z$  and to make the same change to  $x$ , which then allows to meaningfully compare the values of  $x$  and  $z$  despite the overlaps. Refer to Figure 3 for the symbolic depiction of these computations. The dashed lines illustrate the additional decrements made by  $x$  and  $y$  to adjust for overlap with  $y$  and  $x$  respectively. After processing each  $w_i$ , we set  $z \leftarrow \min\{z, x\}$  if  $i$  is odd, and  $z \leftarrow \min\{z, y\}$  if  $i$  is even.

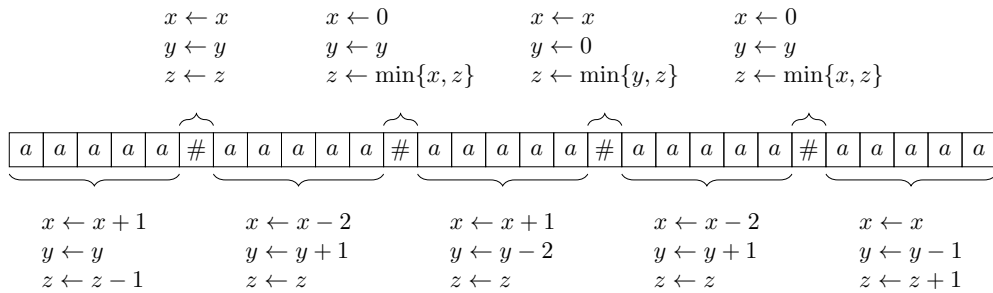

The output of the CRA after reading  $w$  is  $\min\{z, x\}$  if  $i$  is odd, and  $\min\{z, y\}$  if  $i$  is even. Below we show how to construct the CRA implementing this idea.

**Implementation.** As mentioned above, we separate the cases of odd and even  $i$ , and process each  $w_i$  with only one register. At the beginning all registers are initialised with zeros. When processing  $w_i$ ,  $1 \leq i \leq p - 2$ , we compute the value  $n_i - 2n_{i+1}$  by incrementing the corresponding register by one when reading each letter of  $a^{n_i}$ , and decrementing it by two when reading each letter of  $a^{n_{i+1}}$ . After processing  $w_i$ , we set  $z \leftarrow \min\{z, x\}$  if  $i$  is odd, and  $z \leftarrow \min\{z, y\}$  if  $i$  is even. We reset to zero the corresponding used register  $x$  or  $y$ . When processing  $w_{p-1}$  by  $x$  or  $y$ , we compute the value  $n_{p-1} - n_p$  instead.

■ **Figure 3** The computations of the registers processing  $w_i$ ,  $1 \leq i \leq 4$ . An increasing line means that the register is incremented by 1 for each letter and a decreasing line – whether plain or dash – that the register is decremented by 1 for each letter. When both a plain and a dashed line are present it means that the increment/decrement is by 2. The two last lines are for register  $z$ , and hence  $z$  is only incremented/decremented in the first and last block – the increasing and decreasing lines cancel each other but we show them to explain the idea used for the general construction. Note that additionally after reading each block the value of the register  $z$  is changed (not shown in the picture). The dotted sides of the boxes represent that the corresponding boxes from Figure 2 were cut in halves and reassigned to different registers.

The description of the computation is almost done. While reading  $a^{n_1}$ , we decrement  $z$  by one for each letter  $a$ , and while reading  $a^{n_p}$  we increment it by one for each reading of  $a$  (we use here the fact that we know in advance when we are going to read the last block). The output of the CRA is defined as the minimum of the values of the register processing  $w_{p-1}$  (which has the value  $n_{p-1} - n_p$  at the end) and  $z$ . Figure 4 illustrates the computations of thus constructed CRA.

■ **Figure 4** The output value is  $\min\{y, z\}$ .

► **Lemma 6.** *The output of thus constructed CRA is zero if and only if all blocks of  $w$  have the same length, otherwise it is strictly negative.*

**Proof.** After processing  $w_1$ , register  $x$  has value  $n_1 - 2n_2$ , and register  $z$  has value  $-n_1$ . Then  $x$  is reset to 0, and its value is passed to  $z$ , hence the value of  $z$  is  $\min\{-n_1, n_1 - 2n_2\} = -n_2 + \min\{-n_1 + n_2, n_1 - n_2\} = -n_2 + C_1$ , where we define  $C_1 = \min\{n_1 - n_2, -n_1 + n_2\}$ .

For  $2 \leq i \leq p-2$ , define  $C_i = \min\{n_i - n_{i+1}, -n_i + n_{i+1} + C_{i-1}\}$ . Then inductively after reading  $a^{n_{i+1}}$  for  $2 \leq i \leq p-2$  the corresponding register finishes processing  $w_i$  and passes its value to  $z$ , which then has value

$$\min\{n_i - 2n_{i+1}, -n_i + C_{i-1}\} = -n_{i+1} + \min\{n_i - n_{i+1}, -n_i + n_{i+1} + C_{i-1}\} = -n_{i+1} + C_i.$$

Moreover, after reading  $a^{n_p}$  the output of the CRA is  $\min\{n_{p-1} - n_p, -n_{p-1} + n_p + C_{p-2}\}$ , which we accordingly denote by  $C_{p-1}$ . Note that even though the shape of the formula for  $C_{p-1}$  is the same as for  $C_i$  with  $i \leq p-2$ , the way this value is computed by the CRA is different, since while reading  $a^{n_p}$  both  $z$  and the register processing  $w_{p-1}$  behave differently than before.

To show that the constructed CRA satisfies the requirements, we inductively analyse the values  $C_1, \dots, C_{p-1}$ . As noted above,  $C_1 = 0$  if and only if  $n_1 = n_2$ , otherwise  $C_1 < 0$ . Moreover,  $C_i = 0$  if and only if  $n_i = n_{i+1}$  and  $C_{i-1} = 0$ , otherwise  $C_i < 0$ . Hence the output  $C_{p-1} = 0$  if and only if all blocks have the same length, and  $C_{p-1} < 0$  otherwise.  $\blacktriangleleft$

With a similar proof, we can show that the same result applies to plus-times CRA (see end of Section 4 for a general scheme).

## 4 Simulating a Minsky machine with a CRA with 3 registers

In this section, we show how to, given a Minsky machine  $\mathcal{M}$  with two counters, construct a CRA  $\mathcal{A}$  with three registers which simulates  $\mathcal{M}$ . For min-plus, this will mean that  $\mathcal{A}$  outputs 0 on the (unique) word encoding the halting run of  $\mathcal{M}$  if it exists, and outputs a strictly negative value for all other words. For plus-times,  $\mathcal{A}$  outputs 1 on the (unique) word encoding the halting run of  $\mathcal{M}$  if it exists, and outputs a value strictly greater than 1 for all other words. This will prove Theorem 3 as the halting problem for Minsky machine with two counters is undecidable. We will in fact prove a more general result, extending both the min-plus and the plus-times cases. This result is given in Theorem 8.

### 4.1 Minsky machines

Let  $P = \cup_{1 \leq i \leq 2} \{\text{inc}_i, \text{dec}_i, \text{test}_i\}$  be a set of operations (increments, decrements and tests for zero of the  $i$ th counter) on two counters. A Minsky machine  $\mathcal{M}$  with 2 counters is a deterministic finite automaton over the alphabet  $P$ , such that there is a designated *initial* state, and the transitions satisfy the following restrictions: for each state  $q$ , exactly one of the following holds

- $q$  has exactly one outgoing transition, which is then labelled by  $\text{inc}_i$  for some  $i \in \{1, 2\}$ ,
- $q$  has exactly two outgoing transitions, which are then labelled respectively by  $\text{dec}_i, \text{test}_i$  for the same  $i \in \{1, 2\}$ ,
- $q$  has no outgoing transition, in which case it is a unique state called the *halting state*.

Let  $\mathcal{M}$  be a Minsky machine with 2 counters. Consider an alternating sequence

$$\rho = (q_1, \mathbf{v}_1) \xrightarrow{t_1} (q_2, \mathbf{v}_2) \xrightarrow{t_2} \dots \xrightarrow{t_{p-1}} (q_p, \mathbf{v}_p)$$

of pairs  $(q_i, \mathbf{v}_i)$ , where each  $q_i$  is a state and each  $\mathbf{v}_i$  is a pair of non-negative integers, and of operations  $t_i \in P$ . The pairs  $\mathbf{v}_i$  represent the values of the two counters, and we denote by  $\mathbf{v}_i[j]$  its  $j$ th component. Such sequence  $\rho$  is called a *halting run* of  $\mathcal{M}$  if  $q_1 \xrightarrow{t_1} q_2 \xrightarrow{t_2} \dots \xrightarrow{t_{p-1}} q_p$  is a run in the underlying DFA of  $\mathcal{M}$ ,  $q_1$  is the initial state,  $q_p$  is the halting state,  $\mathbf{v}_1 = (0, 0)$ , and for each  $i$ ,  $1 \leq i \leq p-1$ , we have the following (where  $\mathbf{e}_1 = (1, 0)$  and  $\mathbf{e}_2 = (0, 1)$ ):

- if  $t_i = \text{inc}_j$ , then  $\mathbf{v}_{i+1} = \mathbf{v}_i + \mathbf{e}_j$ ;
- if  $t_i = \text{test}_j$ , then  $\mathbf{v}_i[j] = 0$  and  $\mathbf{v}_{i+1} = \mathbf{v}_i$ ;
- if  $t_i = \text{dec}_j$ , then  $\mathbf{v}_i[j]$  is positive and  $\mathbf{v}_{i+1} = \mathbf{v}_i - \mathbf{e}_j$ .

► **Theorem 7** ([18], Theorem 14.1-1). *The problem whether a given Minsky machine with two counters has a halting run is undecidable.*

## 4.2 Encoding a run of a Minsky machine

To construct a CRA simulating a given Minsky machine with two counters, we first specify how to represent a run of a Minsky machine by a finite word. For now on, fix a Minsky machine  $\mathcal{M}$ .

**Encoding the values of two counters as one number.** If  $\mathbf{v}$  is a vector of two components which are non-negative integer numbers, define  $\nu(\mathbf{v}) = 2^{\nu[1]} \times 3^{\nu[2]}$ . We use  $\nu(\mathbf{v})$  to encode the values of two counters of  $\mathcal{M}$  in a given moment of time. Note that since 2 and 3 are coprime, there is at most one vector  $\nu^{-1}(x)$  for a natural number  $x$ , so this encoding is injective.

**Encoding the runs.** Given a halting run  $\rho = (q_1, \mathbf{v}_1) \xrightarrow{t_1} \dots \xrightarrow{t_{p-1}} (q_p, \mathbf{v}_p)$  of  $\mathcal{M}$ , we construct the word  $W(\rho)$  over the alphabet  $\Sigma = P \cup \{a, \#\}$ , where

$$W(\rho) = t_1 a^{\nu(\mathbf{v}_1)} t_2 a^{\nu(\mathbf{v}_2)} t_3 \dots t_{p-1} a^{\nu(\mathbf{v}_{p-1})} \# a^{\nu(\mathbf{v}_p)}$$

We say that the word  $W(\rho)$  *encodes* the halting run  $\rho$ . Note that each letter  $t_i$  appears before the blocks encoding the values of  $\mathbf{v}_i$  (the argument of  $t_i$ ) and  $\mathbf{v}_{i+1}$  (the result of  $t_i$ ), so that the CRA knows which operation to expect before starting to check that this operation was applied correctly. Note also that the new symbol  $\#$  announces the last block of  $a$ 's. We call the word  $w$  over  $\Sigma$  encoding the halting run of  $\mathcal{M}$  the *run word*.

**Regular tests for run words.** To test if a given word  $w$  over  $\Sigma$  is a run word, we first check if this word has shape

$$t_1 a^{n_1} t_2 a^{n_2} t_3 \dots t_{p-1} a^{n_{p-1}} \# a^{n_p}$$

for some positive integers  $p, n_1, \dots, n_p$ , and for some  $t_1, t_2, \dots, t_{p-1}$  in  $P$ . We then check that there exist states  $q_1, q_2, \dots, q_p$  of  $\mathcal{M}$  such that for each  $1 \leq i \leq p-1$  there is a transition  $q_i \xrightarrow{t_i} q_{i+1}$  in  $\mathcal{M}$ , and also that  $q_1$  is the initial and  $q_p$  is the halting state of  $\mathcal{M}$ .

Next, we check that if  $t_i = \text{test}_\ell$  for  $\ell \in \{1, 2\}$ , we have that the  $\ell$ th component of  $\nu^{-1}(a^{n_i})$  is 0. To do so, we simply check that  $n_i$ , the length of  $a^{n_i}$ , is not divisible by 2 (respectively, 3) if  $\ell = 1$  (respectively,  $\ell = 2$ ). Finally, to test that the values of the counters in the beginning are 0, we simply check that  $n_1 = 1$ .

It is easy to see all these checks are regular, hence they can be performed by the underlying deterministic finite automaton of a CRA, that is, without using any registers. We call a word satisfying these regular properties a *pre-run word*.

What remains to check is that the values of the counters (encoded by  $\nu$ ) change according to the corresponding operations of  $\mathcal{M}$ . This check is the main challenge if we want to perform it by a CRA with a small number of registers. The next section describes how to deal with it.

### 4.3 Handling operations

Let  $\mathcal{M}$  be a Minsky machine, and  $w$  be a pre-run word. We now describe how to construct a CRA  $\mathcal{A}$  with three registers which checks that  $w$  is a run word. The idea of this construction is similar to the idea described in Section 3. The main difference is that now instead of testing that all blocks of  $a$ 's have the same length, we need to test that these lengths are changed according to the corresponding operations.

We give a general construction, that we will be able to apply later on to min-plus and plus-times CRAs and prove the following result, where all the notions will be introduced in due course:

► **Theorem 8.** *Let  $\mathcal{M}$  be a Minsky machine and let  $(\mathbb{K}, \oplus, \otimes, \leq)$  be an ordered semiring with a multiplicative group, such that:*

- *there exists a linear transformation which is a 1-peak (where  $\mathbf{1}$  is the identity element of  $\otimes$ ), and*
- *there exists an element with no finite order.*

*Then one can construct a CRA  $\mathcal{A}$  over  $(\mathbb{K}, \oplus, \otimes)$  such that:*

- *$\mathcal{A}(w) \leq \mathbf{1}$  for all words  $w$ , and*
- *$\mathcal{A}(w) = \mathbf{1}$  if and only if  $w$  encodes the halting run of  $\mathcal{M}$ .*

We consider a semiring  $(\mathbb{K}, \oplus, \otimes)$ . It is said to have a multiplicative group if  $(\mathbb{K} - \{\mathbf{0}\}, \otimes)$  is a group, where  $\mathbf{0}$  is the identity element of  $\oplus$ . We denote by  $\mathbf{1}$  the identity element of this group. We also denote, for an element  $d$  of the group and some positive integer  $\ell$ , by  $d^\ell$  the product of  $d$  by itself  $\ell$  times, and by  $d^{-\ell}$  its inverse. By convention  $d^0 = \mathbf{1}$ . We also fix a linear transformation  $\varphi : \mathbb{K}^2 \rightarrow \mathbb{K}$ , i.e.  $\varphi(x, y) = (c \otimes x) \oplus (d \otimes y)$  for some  $c, d$  in  $\mathbb{K}$ , and we fix an element  $\alpha$  of  $\mathbb{K}$ .

We will now construct a CRA over the semiring  $(\mathbb{K}, \oplus, \otimes)$  using  $\alpha$  and  $\varphi$ .

Let  $w = t_1 a^{n_1} t_2 a^{n_2} t_3 \dots t_{p-1} a^{n_{p-1}} \# a^{n_p}$  be a pre-run input word. For convenience of the presentation, we denote  $t_p = \#$ . As before, we call a maximal continuous subword of  $w$  consisting of  $a$ 's a *block*. Denote  $w_i = t_i a^{n_i} t_{i+1} a^{n_{i+1}}$ . Call  $x, y, z$  the three registers of  $\mathcal{A}$ . We process  $w_i$  with  $x$  for odd values of  $i$ , and with  $y$  for even values of  $i$ , and send the results to  $z$ .

First we describe what  $\mathcal{A}$  does when reading  $a^{n_i}$  for  $1 < i < p$ . The word  $a^{n_i}$  is the second block in  $w_{i-1}$  and the first block in  $w_i$ . Assume without loss of generality that  $i$  is odd (otherwise switch  $x$  and  $y$  in the further description). Then  $w_i$  is processed by  $x$ , and  $w_{i-1}$  is processed by  $y$ . The computations performed by  $x$  depend only on  $t_i$ : for each occurrence of  $a$ , we set

- $x \leftarrow x \otimes \alpha$  if  $t_i \in \{\text{test}_\ell, \text{dec}_\ell\}$  for  $\ell \in \{1, 2\}$ ,
- $x \leftarrow x \otimes \alpha^2$  if  $t_i = \text{inc}_1$ ,
- $x \leftarrow x \otimes \alpha^3$  if  $t_i = \text{inc}_2$ .

The computations performed by  $y$  depend on both  $t_{i-1}$  and  $t_i$ . Let  $c$  be the value (1, 2 or 3) used above in the transformation  $x \leftarrow x \otimes \alpha^c$  depending on  $t_i$ . Then for each occurrence of  $a$  we set:

- $y \leftarrow y \otimes \alpha^{-1} \otimes \alpha^{-c}$  if  $t_{i-1} \in \{\text{test}_\ell, \text{inc}_\ell\}$  for  $\ell \in \{1, 2\}$ ,
- $y \leftarrow y \otimes \alpha^{-2} \otimes \alpha^{-c}$  if  $t_{i-1} = \text{dec}_1$ ,
- $y \leftarrow y \otimes \alpha^{-3} \otimes \alpha^{-c}$  if  $t_{i-1} = \text{dec}_2$ .

Furthermore, if, for each letter of  $a^{n_i}$ , register  $x$  is multiplied by  $\alpha^c$  and  $y$  is multiplied by  $\alpha^{-d} \otimes \alpha^{-c}$ , then we set  $z \leftarrow z \otimes \alpha^{-c} \otimes \alpha^d$  for each letter of  $a^{n_i}$ . After reading  $t_{i+2}$ , the next letter after  $a^{n_i}$ , we set  $z \leftarrow \varphi(y, z)$ , and reset  $y$  to  $\mathbf{1}$ .

## 40:12 Universality and Forall-Exactness of Cost Register Automata with Few Registers

It remains to describe the transformations of the registers for  $a^{n_1}$  and  $a^{n_p}$ . For each letter of  $a^{n_1}$ ,  $x$  performs the same update as described above, and  $z$  is updated by the inverse of that value. Assume without loss of generality that  $p - 1$  is even (otherwise use  $x$  instead of  $y$  in the further description). Then  $w_{p-1}$  is processed by  $y$ . For each letter in  $a^{n_p}$  we set

- $y \leftarrow y \otimes \alpha^{-1}$ ,  $z \leftarrow z \otimes \alpha$  if  $t_{p-1} \in \{\text{test}_\ell, \text{inc}_\ell\}$  for  $\ell \in \{1, 2\}$ ,
- $y \leftarrow y \otimes \alpha^{-2}$ ,  $z \leftarrow z \otimes \alpha^2$  if  $t_{p-1} = \text{dec}_1$ ,
- $y \leftarrow y \otimes \alpha^{-3}$ ,  $z \leftarrow z \otimes \alpha^3$  if  $t_{p-1} = \text{dec}_2$ .

Finally, we set the output of  $\mathcal{A}$  to be  $\varphi(y, z)$ . Note that in this construction, the CRA is linear with resets and copyless.

► **Example 9.** Consider the following halting run:

$$\rho = (q_1, (0, 0)) \xrightarrow{\text{inc}_2} (q_1, (0, 1)) \xrightarrow{\text{inc}_1} (q_1, (1, 1)) \xrightarrow{\text{dec}_1} (q_1, (0, 1)) \xrightarrow{\text{test}_1} (q_1, (0, 1))$$

We abbreviate by  $t_1, t_2, t_3, t_4$  the operations along this run and by  $t_5$  the  $\#$  symbol indicating that we are going to read the last block. Note again that in  $w$  the operation is written before its argument, hence for example  $t_1 = \text{inc}_2$  is applied to the first block, and its result is the second block. The computations of  $\mathcal{A}$  for the word encoding  $\rho$  are shown in Figure 5. The CRA outputs  $\varphi(y, z)$  in this example.

$x \leftarrow x$	$x \leftarrow \mathbf{1}$	$x \leftarrow x$	$x \leftarrow \mathbf{1}$
$y \leftarrow y$	$y \leftarrow y$	$y \leftarrow \mathbf{1}$	$y \leftarrow y$
$z \leftarrow z$	$z \leftarrow \varphi(x, z)$	$z \leftarrow \varphi(y, z)$	$z \leftarrow \varphi(x, z)$

$t_1$	$a$	$t_2$	$a$	$a$	$a$	$t_3$	$a$	$a$	$a$	$a$	$a$	$t_4$	$a$	$a$	$a$	$t_5$	$a$	$a$	$a$
-------	-----	-------	-----	-----	-----	-------	-----	-----	-----	-----	-----	-------	-----	-----	-----	-------	-----	-----	-----

$x \leftarrow x \otimes \alpha^3$	$x \leftarrow x \otimes \alpha^{-3}$	$x \leftarrow x \otimes \alpha$	$x \leftarrow x \otimes \alpha^{-3}$	$x \leftarrow x$
$y \leftarrow y$	$y \leftarrow y \otimes \alpha^2$	$y \leftarrow y \otimes \alpha^{-2}$	$y \leftarrow y \otimes \alpha$	$y \leftarrow y \otimes \alpha^{-1}$
$z \leftarrow z \otimes \alpha^{-3}$	$z \leftarrow z \otimes \alpha^{-1}$	$z \leftarrow z$	$z \leftarrow z \otimes \alpha$	$z \leftarrow z \otimes \alpha$

■ **Figure 5** The computations of  $\mathcal{A}$  on the word encoding the halting run  $\rho$ .

Suppose now that  $\mathbb{K}$  is equipped with a linear order  $\leq$ , and denote by  $<$  the associated strict order (we call such  $\mathbb{K}$  an *ordered semiring*). We say that  $\alpha$  has no finite order if  $\alpha^\ell = \mathbf{1}$  implies  $\ell = 0$  and that  $\varphi$  is a *1-peak* if, for all  $d, e$  in  $\mathbb{K}$  such that  $d \otimes e \leq \mathbf{1}$ , we have  $\varphi(d, e) = \mathbf{1}$  if and only if  $d = e = \mathbf{1}$ , and otherwise  $\varphi(d, e) < \mathbf{1}$ .

► **Lemma 10.** *Suppose that  $\varphi$  is a 1-peak and that  $\alpha$  has no finite order. Then, for a pre-run word  $w$ , we have  $\mathcal{A}(w) = \mathbf{1}$  if and only if  $w$  is a run word, otherwise  $\mathcal{A}(w) < \mathbf{1}$ .*

**Proof.** We adapt the proof of Lemma 6. Define  $C_0 = \mathbf{1}$  and for  $1 \leq i \leq p - 1$  define

$$C_i = \begin{cases} \{\varphi(\alpha^{n_i - n_{i+1}}, \alpha^{-n_i + n_{i+1}} \otimes C_{i-1})\} & \text{if } t_i = \text{test}_\ell \text{ for } \ell = 1, 2 \\ \{\varphi(\alpha^{2n_i - n_{i+1}}, \alpha^{-2n_i + n_{i+1}} \otimes C_{i-1})\} & \text{if } t_i = \text{inc}_1 \\ \{\varphi(\alpha^{3n_i - n_{i+1}}, \alpha^{-3n_i + n_{i+1}} \otimes C_{i-1})\} & \text{if } t_i = \text{inc}_2 \\ \{\varphi(\alpha^{n_i - 2n_{i+1}}, \alpha^{-n_i + 2n_{i+1}} \otimes C_{i-1})\} & \text{if } t_i = \text{dec}_1 \\ \{\varphi(\alpha^{n_i - 3n_{i+1}}, \alpha^{-n_i + 3n_{i+1}} \otimes C_{i-1})\} & \text{if } t_i = \text{dec}_2 \end{cases}$$

Observe that by construction after a register ( $x$  or  $y$ ) processes  $w_i$ ,  $1 \leq i \leq p-2$ , and passes its value to  $z$ , the value of  $z$  is

$$\begin{cases} \alpha^{-n_{i+1}} \otimes C_i & \text{if } t_{i+1} = \text{test}_\ell \text{ or } t_{i+1} = \text{inc}_\ell \text{ for } \ell \in \{1, 2\} \\ \alpha^{-2n_{i+1}} \otimes C_i & \text{if } t_{i+1} = \text{dec}_1 \\ \alpha^{-3n_{i+1}} \otimes C_i & \text{if } t_{i+1} = \text{dec}_2 \end{cases}$$

Moreover, the output of  $\mathcal{A}$  equals  $C_{p-1}$ .

Observe that using the definition of  $C_i$  and by induction, one can prove that  $C_i = \mathbf{1}$  if and only if  $t_i$  is performed correctly (that is, the result of  $t_i$  on the pair  $v^{-1}(a^{n_i})$  is  $v^{-1}(a^{n_{i+1}})$ ) and  $C_{i-1} = \mathbf{1}$ , otherwise  $C_i < \mathbf{1}$ , since  $\varphi$  is  $\mathbf{1}$ -peak and  $\alpha$  has no finite order. Hence the output  $C_{p-1}$  equals  $\mathbf{1}$  if and only if the input is a run word, otherwise it is  $< \mathbf{1}$ . ◀

By combining this proposition with the checks for pre-run words described in Section 4.2, we get a CRA which outputs  $\mathbf{1}$  if and only if the input encodes a halting run of  $\mathcal{M}$ . Indeed, if a word is not a pre-run word (which is checked by the underlying DFA of the CRA), the run labelled by it will end in a state which outputs a constant value  $f < \mathbf{1}$ . All runs ending in other states are thus labelled by pre-run words, and for each such word the computations described in this section output the desired value depending on whether this word encodes a halting run or not. This means that all runs in the CRA are considered, concluding the proof of Theorem 8.

**Min-plus and plus-times cases.** To finish the proof of Theorem 3, it is enough to instantiate  $(\mathbb{K}, \oplus, \otimes, \leq)$ ,  $\alpha$  and  $\varphi$  to suitable elements. For min-plus, we take  $(\mathbb{K}, \oplus, \otimes, \leq) = (\mathbb{Z} \cup \{+\infty\}, \min, +, \leq)$ ,  $\alpha = 1$  and  $\varphi = \min$ . For plus-times, we take  $(\mathbb{K}, \oplus, \otimes, \leq) = (\mathbb{Q}_+, +, \times, \geq)$ ,  $\alpha = 2$  and  $\varphi(c, d) = 2^{-1}(c + d)$ , where  $\mathbb{Q}_+$  is the set of positive rational numbers. It is easy to check that in both cases,  $\varphi$  is  $\mathbf{1}$ -peak and  $\alpha$  has no finite order.

## 5 Conclusions

In this paper, we prove the undecidability of the universality problem for models of CRAs where the number of registers is limited to 3. Our main result holds for min-plus and plus-times CRAs, but we give a slightly more general construction and it would be interesting to see if our techniques can be applied to other cases, and in particular to see its link to infinitary groups that have already been studied in conjunction to the register complexity [10].

The main open question that remains is whether this is still true when considering CRAs with only 2 registers. Our proof cannot be adapted easily to the 2-register case. One approach is to understand whether with only 2 registers, one can recognise the language with equal length blocks as defined in Section 3. Even this is difficult.

Finally, we proved that the  $\forall$ -exact problem is solvable in polynomial time when the number of registers of a min-plus linear CRA is fixed. The same question can be asked for the boundedness problem over the  $(\mathbb{N} \cup \{+\infty\}, \min, +)$  semiring, which is known to be PSPACE-complete for WAs (and hence linear CRAs) [1].

# Relaxed Core Stability for Hedonic Games with Size-Dependent Utilities

Tom Demeulemeester    
KU Leuven, Belgium

Jannik Peters    
TU Berlin, Germany

---

## Abstract

We study relationships between different relaxed notions of core stability in hedonic games. In particular, we study (i)  $q$ -size core stable outcomes in which no deviating coalition of size at most  $q$  exists and (ii)  $k$ -improvement core stable outcomes in which no coalition can improve by a factor of more than  $k$ . For a large class of hedonic games, including fractional and additively separable hedonic games, we derive upper bounds on the maximum factor by which a coalition of a certain size can improve in a  $q$ -size core stable outcome. We further provide asymptotically tight lower bounds for a large class of hedonic games. Finally, our bounds allow us to confirm two conjectures by Fanelli et al. [20][IJCAI'21] for symmetric fractional hedonic games (S-FHGs): (i) every  $q$ -size core stable outcome in an S-FHG is also  $\frac{q}{q-1}$ -improvement core stable and (ii) the price of anarchy of  $q$ -size stability in S-FHGs is precisely  $\frac{2q}{q-1}$ .

## 1 Introduction

Coalition formation is one of the core topics of multiagent systems and algorithmic game theory. Hedonic games ([19]) constitute the most popular subcase of coalition formation. In a hedonic game, the goal is to divide a set of agents into disjoint coalitions, respecting the preferences of the agents. Over the years, multiple different ways of representing the agents’ preferences and multiple different solution concepts emerged. Among the strongest solution concepts is core stability ([9]): a coalition structure is core stable, if no subset of agents could together form a new coalition in which they are all better off than in the original coalition structure. While being a seemingly natural concept, it has been shown that even for very simple preference structures, core stable outcomes may not exist ([2, 3]). Further, in these structures, it is also often computationally intractable to decide whether a core stable

outcome exists.<sup>1</sup> These results led Fanelli et al. [20] to introduce two natural weakenings of core stability: (i)  $q$ -size (core) stability, which requires that no blocking coalitions of size at most  $q$  exist, (ii)  $k$ -improvement (core) stability, which requires that no blocking coalition exists in which every agent improves by a factor of more than  $k$ . For the example of fractional hedonic games ([2]), [20] showed that a 2-size stable outcome and a 2-improvement stable outcome always exist. Further, they also studied the relationship between these two notions and were able to show that a 2-size stable outcome is indeed also always 2-improvement stable.

In this paper, we contribute to this literature in two ways. First, we propose a new class of hedonic games, called  $\alpha$ -hedonic games, in which the utility an agent receives from being in a coalition of size  $m$  is equal to the sum of the cardinal utilities it ascribes to the other agents in that coalition, multiplied by a factor  $\alpha_m$  which depends on the size of that coalition. Several well-studied classes of hedonic games, such as fractional hedonic games [2], modified fractional hedonic games [27], and additively separable hedonic games [9] are a special case of  $\alpha$ -hedonic games.

Second, we further study the two weakenings of core stability that were introduced by Fanelli et al. [20]. Our main result quantifies, for any  $\alpha$ -hedonic game and for any  $q$ -size stable outcome, the maximum factor with which the agents can improve their utility by forming a blocking coalition of size  $m \geq q + 1$ . As a corollary, this allows us to prove two conjectures by Fanelli et al. [20]: (i) every  $q$ -size stable outcome is  $\frac{q}{q-1}$ -improvement stable for fractional hedonic games and (ii) the  $q$ -size core price of anarchy (i.e., the worst-case approximation to the social welfare of any  $q$ -size core stable outcome) is exactly  $\frac{2q}{q-1}$  for fractional hedonic games.

## Related Work

Since its inception hedonic games have been a widely studied topic in algorithmic game theory, with several works studying axiomatic or computational properties of hedonic games. For an overview on earlier developments, we refer the reader to the book chapter by Aziz and Savani [1]. In recent years, several new models and optimality notions for hedonic games were introduced and analyzed. Among the most popular of these notions are the aforementioned fractional hedonic games, introduced by Aziz et al. [2] and studied in various forms by, e.g., Bilò et al. [5], Aziz et al. [4], or Carosi et al. [15]. Fractional hedonic games are also related to the model of hedonic diversity games [13, 8, 21] in which agents possess types and derive utility based on the fraction of agents of their own type in their coalition.

The paper closest to ours is the work by Fanelli et al. [20], who introduced the aforementioned notions of  $q$ -size and  $k$ -improvement core stability for fractional hedonic games. Alternative simplifications of core stability were introduced by Carosi et al. [15], who studied a local variant of core stability for simple fractional hedonic games, i.e., hedonic games in which all utility values are either 0 or 1. In their local variant of core stability, the agents deviating are required to form a clique. For this weakened notion, they show that core stable outcomes always exist and can be computed via improving response dynamics.

Finally, some very recent works on hedonic games include [7, 12, 11] who study various aspects of dynamics, i.e., decentralized processes in which agents perform beneficial changes until a stable outcome is reached, the study of coalition formation with (almost) fixed

---

<sup>1</sup> For some preference structures, it can even be hard to find a coalition structure in the core, even if it is guaranteed to exist, see Bullinger and Kober [14].

coalition sizes [18, 6, 25, 24], or studies of the complexity of various hedonic games variants [17, 16, 22, 10]. Another interesting direction are the models of altruistic [23] and loyal [14] hedonic games, in which the utilities of agents do not only depend on their own utility, but also on the utility of their friends/agents they are loyal to.

## 2 Preliminaries

For any  $n \in \mathbb{N}^+$  and  $\alpha: [n] \rightarrow \mathbb{R}^+$  an  $\alpha$ -hedonic game ( $\alpha$ HG) consists of a set of agents  $A = \{a_1, \dots, a_n\}$  with a utility function  $u: A \times A \rightarrow \mathbb{R}$ . We restrict ourselves to symmetric  $\alpha$ -hedonic games (S- $\alpha$ HGs) in this paper, and require that  $u(i, j) = u(j, i)$  for all  $i, j \in A$ . A coalition is a subset of  $A$  and a coalition structure is a partition of  $A$  into coalitions. The utility of an agent  $i$  in a coalition  $C$  is  $u_i(C) := \sum_{j \in C} \alpha(|C|) \cdot u(i, j)$ . We assume that  $u(i, i) = 0$ . For a coalition structure  $\mathcal{C}$  the utility  $u_i(\mathcal{C})$  of the coalition structure for agent  $i$  is the utility of the coalition agent  $i$  belongs to. To simplify notation, for agents  $a_i$  and  $a_j$  and  $C \subseteq A$  we also write  $u_i(a_j) := u(a_i, a_j)$  and  $u_i(C) := u_{a_i}(C)$ .

The class of  $\alpha$ -hedonic games generalizes multiple previously studied hedonic game classes, e.g.,

- Symmetric additively separable hedonic games (S-ASHGs) with  $\alpha(m) = 1$  for any  $m \in \mathbb{N}$ .
- Symmetric fractional hedonic games (S-FHG) with  $\alpha(m) = \frac{1}{m}$  for any  $m \in \mathbb{N}$ .
- Symmetric modified fractional hedonic games (S-MFHGs) with  $\alpha(m) = \frac{1}{m-1}$  for any  $m \in \mathbb{N}^+$  and  $\alpha(1) = 0$ .

A given coalition structure  $\mathcal{C}$  is

- core stable if for any coalition  $C$  it holds that  $u_i(C) \leq u_i(\mathcal{C})$  for at least one  $i \in C$ ;
- $q$ -size core stable if for any coalition  $C$  with  $|C| \leq q$  it holds that  $u_i(C) \leq u_i(\mathcal{C})$  for at least one  $i \in C$ ;
- $k$ -improvement core stable if for any coalition  $C$  it holds that  $u_i(C) \leq k u_i(\mathcal{C})$  for at least one  $i \in C$ ;
- $(q, k)$ -core stable if for any coalition  $C$  with  $|C| = q$  it holds that  $u_i(C) \leq k u_i(\mathcal{C})$  for at least one  $i \in C$ .

If there is a coalition witnessing a violation to one of these criteria, for instance a coalition  $C$  with  $u_i(C) > u_i(\mathcal{C})$  for all  $i \in C$ , we say that  $C$  is a blocking coalition. In further parts of the paper, we shorten  $\alpha(m)$  to  $\alpha_m$  to increase readability. Moreover, denote by  $\mathbb{1}: \mathbb{N} \rightarrow \{0, 1\}$  the indicator function such that for any  $i \in \mathbb{N}$

$$\mathbb{1}(i) = \begin{cases} 0 & \text{if } i = 0, \\ 1 & \text{else.} \end{cases}$$

Lastly, every S- $\alpha$ HG can be represented by a graph  $G(A, E, w)$ , where  $A$  represents the set of agents, and  $E$  contains an undirected edge  $\{i, j\}$  between agents  $i$  and  $j$  with weight  $w_{ij} = u(i, j) = u(j, i)$  if  $u(i, j) > 0$ . Alternatively, given a coalition  $C \subseteq A$ , we denote the subgraph of  $G(A, E, w)$  that is induced by only considering the agents in  $C$  by  $G(C)$ .

Before turning to our result, we present two simple examples, with the second example motivating why we exclusively focus on symmetric instances.

► **Example 1.** First, consider the hedonic game induced by the graph on the left of Figure 1, with utilities as indicated by the edges and omitted edges indicating a utility of 0. Here, consider the coalition structure  $\{\{a_1, a_2\}, \{a_3, a_4\}\}$ . In an S-ASHG, the utility of every agent would be 3, and the coalition structure would be 2-size core stable, but not 3-size core stable, since, for instance,  $\{a_1, a_2, a_3\}$  would block. Further, the coalition structure is  $(3, \frac{5}{3})$ - and

■ **Figure 1** Example of a symmetric hedonic game on the left and of a blocking coalition for an asymmetric game on the right, for which the improvement ratio is unbounded.

(4, 2)-core stable and thus also 2-improvement core stable. In an S-FHG, on the other hand, the utility of every agent would be  $\frac{3}{2}$  and the coalition  $\{a_1, a_2, a_3\}$  would still block. The coalition consisting of all agents, however, would no longer be blocking, since the utility of agent  $a_2$  would be  $\frac{6}{4} = \frac{3}{2}$ , which was their utility in the original coalition structure. Finally, in an S-MFHG, the utility of every agent would be 3 and the coalition structure would be core stable. Even the coalition  $\{a_1, a_2, a_3\}$  would no longer block, since the utility of agent  $a_1$  would be  $\frac{5}{2} < 3$ .

Secondly, to motivate the choice of symmetric hedonic games, consider the (asymmetric) hedonic game depicted on the right of Figure 1 with all three agents originally being in a coalition structure  $\mathcal{C}$  in which they experience utility 1. This coalition structure would be 2-size core stable. However, there is no upper bound on the improvement ratio for the coalition consisting of all three agents, as  $M$  goes to infinity. We note that this behaviour can be observed independently of the considered  $\alpha$  function.

## 2.1 Our results

Fanelli et al. [20] conjectured that for fractional hedonic games, every  $q$ -size core stable coalition structure is also  $\frac{q}{q-1}$ -improvement core stable. We refine this conjecture and show that every  $q$ -size core stable coalition structure is

$$\left( m, 1 + \frac{\lfloor \frac{1}{q-1}(m-2) \rfloor}{m} \right) \text{-core stable} \quad (1)$$

for any  $m \geq q + 1$ . As  $1 + \frac{\lfloor \frac{1}{q-1}(m-2) \rfloor}{m} \leq \frac{q}{q-1}$  for any  $m$  this implies the conjecture of Fanelli et al. [20]. Further, this result together with the results of Fanelli et al. [20] also allows us to confirm their second conjecture that the *price of anarchy* of  $q$ -size stability is exactly  $\frac{2q}{q-1}$ .

To gain a better intuition of this quite unhandy term, we refer the reader to Table 1 and Figure 2.

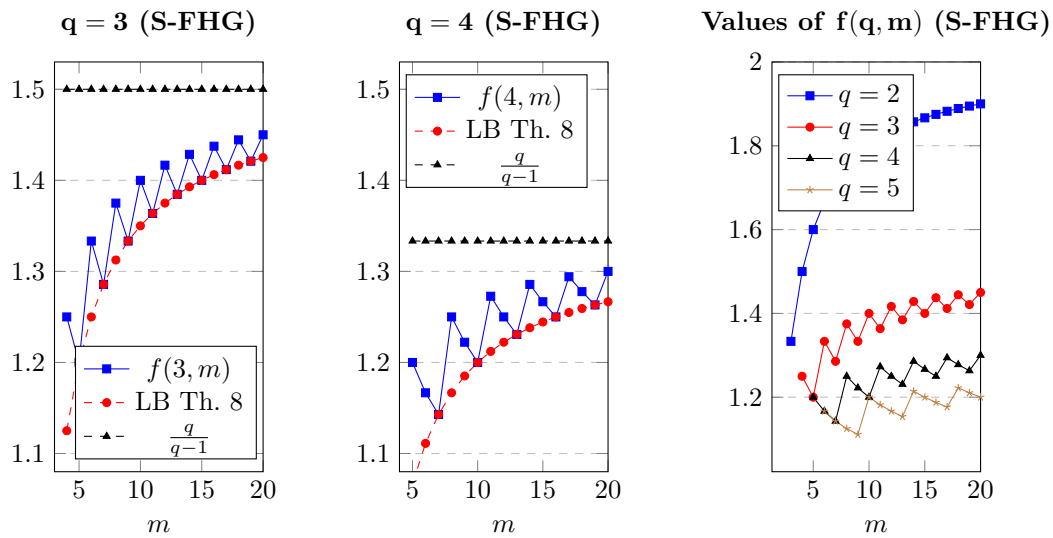

In fact, our proof does not only apply to S-FHGs, but to all symmetric  $\alpha$ -hedonic games. The more general result that we are able to show is that every  $q$ -size core stable outcome in an S- $\alpha$ HG is  $(m, f(q, m))$ -core stable with

$$f(q, m) = \max \left( 1, \left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{\alpha_m}{\alpha_q} + \frac{\mathbb{1}((m-1) \bmod (q-1)) \alpha_m}{\alpha((m-1) \bmod (q-1) + 1)} \right).$$

As we discuss in Section 3, this bound is equivalent to Equation (1) for S-FHGs. For S-ASHGs this implies a bound of  $f(q, m) = 1 + \left\lfloor \frac{m-2}{q-1} \right\rfloor$ .

■ **Table 1** For the given combinations of  $q$  and  $m$ , the table contains the value  $f(q, m)$  derived from Equation (1), such that a  $q$ -size core stable is  $(m, f(q, m))$ -stable in S-FHG.

$q \backslash m$	3	4	5	6	7	8	9	...	$\frac{q}{q-1}$
2	$\frac{4}{3}$	$\frac{6}{4}$	$\frac{8}{5}$	$\frac{10}{6}$	$\frac{12}{7}$	$\frac{14}{8}$	$\frac{16}{9}$		2
3	\	$\frac{5}{4}$	$\frac{6}{5}$	$\frac{8}{6}$	$\frac{9}{7}$	$\frac{11}{8}$	$\frac{12}{9}$	...	$\frac{3}{2}$
4	\	\	$\frac{6}{5}$	$\frac{7}{6}$	$\frac{8}{7}$	$\frac{10}{8}$	$\frac{11}{9}$		$\frac{4}{3}$

■ **Figure 2** Plotted values of  $f(q, m)$  for S-FHG such that every  $q$ -size core stable coalition structure is  $(m, f(q, m))$ -core stable. In the two leftmost figures, LB indicates the lower bound obtained in Theorem 8, while the black line indicates  $\frac{q}{q-1}$ , the limit of the upper bound.

Further, in Section 4 we derive lower bounds on these values as well, and show tightness for various combinations of  $(q, m)$ , and for various types of hedonic games. A summary of our results can be found in Table 3.

### 3 Main result

We begin with our main result, which quantifies the relationship between the two considered relaxed notions of core stability in symmetric  $\alpha$ -hedonic games. As the general proof for symmetric  $\alpha$ -hedonic games is quite notationally heavy, we defer the full proof to the supplementary material and only give the proof for symmetric fractional hedonic games here.

► **Theorem 2.** Any  $q$ -size core stable coalition structure  $\mathcal{C}$  in an  $S$ - $\alpha$ HG is  $(m, f(q, m))$ -core stable, for any integers  $m, q$  with  $m \geq q + 1$ , and  $f(q, m) =$

$$\max \left( 1, \left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{\alpha_m}{\alpha_q} + \frac{\mathbb{1}((m-1) \bmod (q-1)) \alpha_m}{\alpha((m-1) \bmod (q-1) + 1)} \right).$$

For fractional hedonic games, this reduces to:

► **Corollary 3.** For  $S$ -FHGs, every  $q$ -size core stable coalition structure  $\mathcal{C}$  is  $\left(m, 1 + \lfloor \frac{1}{q-1}(m-2) \rfloor\right)$ -core stable for any  $m \geq q + 1$ .

**Proof.** Consider a  $q$ -size core stable coalition structure  $\mathcal{C}$  and a coalition  $C$  of size  $m \geq q + 1$ . For a given coalition  $C' \subseteq C$  we let  $w(C') = \sum_{a_i \in C'} \left(u_i(C') - 2\frac{q}{q-1}u_i(\mathcal{C})\right)$  denote the *modified social welfare* of coalition  $C'$ . Let  $\mathcal{C}_{q-1}$  be the set of coalitions of size  $q - 1$  and consider the weighted hypergraph  $(C, \mathcal{C}_{q-1}, w)$ . Let  $M = \{C_1, \dots, C_{\lfloor \frac{m-1}{q-1} \rfloor}\}$  be any maximum weight, with regard to  $w$ , hypergraph matching, i.e., selection of non-overlapping sets from  $\mathcal{C}_{q-1}$ , of size  $\lfloor \frac{m-1}{q-1} \rfloor$  in this hypergraph. We note that a maximum weight hypergraph matching not of size  $\lfloor \frac{m-1}{q-1} \rfloor$  might have a larger weight, due to  $w$  being potentially negative. Let  $C_0$  be the set of unmatched agents by this hypergraph matching. The goal of our proof is now to show that there must be an unmatched agent who can only improve by a factor of at most  $1 + \lfloor \frac{1}{q-1}(m-2) \rfloor$ . The set  $C_0$  contains exactly  $(m - 1) \bmod (q - 1) + 1$  agents that are unmatched by  $M$ . Let  $a_0 \in C_0$ . For any  $i \in [\lfloor \frac{m-1}{q-1} \rfloor]$  we know that the coalition  $\{a_0\} \cup C_i$  is not  $q$ -size blocking. Thus, either one of the following two conditions has to hold:

- (i)  $\sum_{a_j \in C_i} u_0(a_j) \leq qu_0(\mathcal{C})$ ,
- (ii)  $\sum_{a_j \in C_i} u_0(a_j) > qu_0(\mathcal{C})$  and there is an  $a_\ell \in C_i$  with  $\sum_{a_j \in C_i \cup \{a_0\}} u_\ell(a_j) \leq qu_\ell(\mathcal{C})$

If we assume the latter scenario, we first notice that

$$\begin{aligned}
 \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} - 2\frac{q}{q-1}u_\ell(\mathcal{C}) &\leq \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} - 2 \sum_{a_j \in C_i \cup \{a_0\}} \frac{u_\ell(a_j)}{q-1} \\
 &= 2 \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} - 2 \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} - 2\frac{u_0(a_\ell)}{q-1} - \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} \\
 &= -2\frac{u_0(a_\ell)}{q-1} - \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} = 2 \sum_{a_j \in C_i \setminus \{a_\ell\}} \frac{u_0(a_j)}{q-1} - 2 \sum_{a_j \in C_i} \frac{u_0(a_j)}{q-1} - \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} \\
 &< 2 \sum_{a_j \in C_i \setminus \{a_\ell\}} \frac{u_0(a_j)}{q-1} - 2\frac{q}{q-1}u_0(\mathcal{C}) - \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} \\
 &= 2 \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(\frac{u_0(a_j)}{q-1}\right) - 2\frac{q}{q-1}u_0(\mathcal{C}) - \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(\frac{u_j(a_\ell)}{q-1}\right).
 \end{aligned}$$

For the first inequality, we used the second part of the assumption, while in the second-to-last line we used the first part of the assumption. Further, in the last equality, we used the symmetry of the utilities and the fact that  $u_\ell(a_\ell) = 0$ . Using this inequality, we can now obtain

$$\begin{aligned}
 &w((C_i \cup \{a_0\}) \setminus \{a_\ell\}) \\
 &= \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(u_j(C_i \cup \{a_0\} \setminus \{a_\ell\}) - 2\frac{q}{q-1}u_j(\mathcal{C})\right) \\
 &\quad + \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(\frac{u_0(a_j)}{q-1}\right) - 2\frac{q}{q-1}u_0(\mathcal{C}) \\
 &= \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(u_j(C_i) + \frac{u_j(a_0)}{q-1} - \frac{u_j(a_\ell)}{q-1} - 2\frac{q}{q-1}u_j(\mathcal{C})\right) \\
 &\quad + \sum_{a_j \in C_i \setminus \{a_\ell\}} \left(\frac{u_0(a_j)}{q-1}\right) - 2\frac{q}{q-1}u_0(\mathcal{C})
 \end{aligned}$$

$$\begin{aligned}
&= \sum_{a_j \in C_i \setminus \{a_\ell\}} \left( u_j(C_i) - 2 \frac{q}{q-1} u_j(\mathcal{C}) \right) \\
&\quad + 2 \sum_{a_j \in C_i \setminus \{a_\ell\}} \left( \frac{u_0(a_j)}{q-1} \right) - 2 \frac{q}{q-1} u_0(\mathcal{C}) - \sum_{a_j \in C_i \setminus \{a_\ell\}} \left( \frac{u_j(a_\ell)}{q-1} \right) \\
&> \sum_{a_j \in C_i \setminus \{a_\ell\}} \left( u_j(C_i) - 2 \frac{q}{q-1} u_j(\mathcal{C}) \right) + \sum_{a_j \in C_i} \frac{u_\ell(a_j)}{q-1} - 2 \frac{q}{q-1} u_\ell(\mathcal{C}) = w(C_i).
\end{aligned}$$

Hence, we get that  $w(C_i \cup \{a_0\} \setminus \{a_\ell\}) > w(C_i)$  and thus the hypergraph matching was not of maximum weight. Therefore,  $\sum_{a_j \in C_i} u_0(a_j) \leq q u_0(\mathcal{C})$  has to hold for every  $C_i$  and every  $a_0 \in C_0$ .

Next, if  $|C_0| = 1$  we know that  $(m-1)$  must be divisible by  $(q-1)$  and thus we can reformulate our bound as

$$1 + \frac{\lfloor \frac{1}{q-1}(m-2) \rfloor}{m} = 1 + \frac{\frac{1}{q-1}(m-q)}{m} = \frac{q(m-1)}{m(q-1)}.$$

Hence, by applying the previously calculated bound and by using the observation that  $|M| = \frac{m-1}{q-1}$  in the case, we obtain

$$\sum_{a_j \in \mathcal{C}} \frac{u_0(a_j)}{m} \leq \sum_{C_i \in M} \frac{q}{m} u_0(\mathcal{C}) = u_0(\mathcal{C}) \frac{q(m-1)}{m(q-1)},$$

which implies the result in case  $|C_0| = 1$ .

If  $|C_0| > 1$ , there has to be at least one agent  $a_0$  in  $C_0$  with  $\sum_{a_i \in C_0} u_0(a_i) \leq |C_0| u_0(\mathcal{C}) = ((m-1) \bmod (q-1) + 1) u_0(\mathcal{C})$ , since the set  $C_0$  of unmatched agents is non-blocking. Hence, we obtain that

$$\begin{aligned}
\sum_{a_j \in \mathcal{C}} \frac{u_0(a_j)}{m} &= \sum_{C_i \in M} \sum_{a_j \in C_i} \frac{u_0(a_j)}{m} + \sum_{a_i \in C_0} \frac{u_0(a_i)}{m} \\
&\leq \sum_{C_i \in M} \frac{q}{m} u_0(\mathcal{C}) + \frac{(m-1) \bmod (q-1) + 1}{m} u_0(\mathcal{C}) \\
&= \left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{q}{m} u_0(\mathcal{C}) + \frac{(m-1) \bmod (q-1) + 1}{m} u_0(\mathcal{C}) \\
&= \frac{u_0(\mathcal{C})}{m} \left( \left\lfloor \frac{m-1}{q-1} \right\rfloor q + (m-1) \bmod (q-1) + 1 \right) \\
&= \frac{u_0(\mathcal{C})}{m} \left( \frac{(m-1) - (m-1) \bmod (q-1)}{q-1} (q-1) \right. \\
&\quad \left. + \frac{(m-1) - (m-1) \bmod (q-1)}{q-1} + (m-1) \bmod (q-1) + 1 \right) \\
&= \frac{u_0(\mathcal{C})}{m} \left( m + \frac{(m-1) - (m-1) \bmod (q-1)}{q-1} \right) = \frac{u_0(\mathcal{C})}{m} \left( m + \left\lfloor \frac{m-2}{q-1} \right\rfloor \right).
\end{aligned}$$

The last step holds since  $(m-1) \bmod (q-1) > 0$ . Thus, every  $q$ -size core stable coalition structure  $\mathcal{C}$  is

$$\left( m, 1 + \frac{\lfloor \frac{1}{q-1}(m-2) \rfloor}{m} \right) \text{-core stable.}$$

Finally, to see that this is equivalent to the bound in Theorem 2 we see that if  $(m - 1) \bmod (q - 1) = 0$  it holds that

$$\left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{\alpha_m}{\alpha_q} + \frac{\mathbb{1}((m-1) \bmod (q-1)) \alpha_m}{\alpha((m-1) \bmod (q-1) + 1)} = \frac{m-1}{q-1} \frac{q}{m} = 1 + \frac{\left\lfloor \frac{1}{q-1}(m-2) \right\rfloor}{m}$$

and if  $(m - 1) \bmod (q - 1) \neq 0$

$$\begin{aligned} \left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{\alpha_m}{\alpha_q} + \frac{\mathbb{1}((m-1) \bmod (q-1)) \alpha_m}{\alpha((m-1) \bmod (q-1) + 1)} &= \left\lfloor \frac{m-1}{q-1} \right\rfloor \frac{q}{m} + \frac{(m-1) \bmod (q-1) + 1}{m} \\ &= 1 + \frac{\left\lfloor \frac{1}{q-1}(m-2) \right\rfloor}{m}. \end{aligned} \quad \blacktriangleleft$$

As a corollary we obtain an answer to the conjecture of [20], by confirming that every  $q$ -size core stable outcome is also  $\frac{q}{q-1}$ -improvement stable.

► **Corollary 4.** *For S-FHG, every  $q$ -size core stable coalition structure  $\mathcal{C}$  is  $\frac{q}{q-1}$ -improvement stable.*

**Proof.** This result follows from the observation that

$$1 + \frac{\left\lfloor \frac{1}{q-1}(m-2) \right\rfloor}{m} \leq 1 + \frac{\frac{1}{q-1}(m-2)}{m} \leq 1 + \frac{1}{q-1} = \frac{q}{q-1}$$

holds for all  $m$ . Thus, there is no coalition of size  $m > q$  in which every agent improves by a factor of more than  $\frac{q}{q-1}$ .  $\blacktriangleleft$

If we restrict ourselves to the case of *simple fractional hedonic games (SS-FHG)*, i.e., S-FHG with binary utilities, we can show that this bound is not tight. This proof further provides a strengthening of Theorem 2 by [20].

► **Theorem 5.** *For every simple symmetric fractional hedonic game, any 3-size core stable coalition structure  $\mathcal{C}$  is*

$$\left( m, \frac{3}{2} \frac{(m-1)}{m} \right)\text{-core stable,}$$

for any integer  $m \geq 4$ .

**Proof.** We only prove the result for even values of  $m$ , as the result for odd  $m$  follows from the general result of Corollary 3. Consider a 3-size core stable coalition structure  $\mathcal{C}$  and a blocking coalition  $C$  of size  $m \geq 4$ . Further, we assume that every agent in  $C$  improves by more than a factor of  $k$ . Because all agents experience a strict improvement by forming  $C$ , each agent should be adjacent to at least one edge in the related graph  $G(C)$ . Since 3-size core stability implies 2-size core stability, there should be at least one agent  $a_i \in C$  for whom  $u_i(\mathcal{C}) \geq \frac{1}{2}$ . Since  $a_i$  improves by more than a factor of  $k$  it holds that

$$\sum_{a_\ell \in C \setminus \{a_i\}} u(i, \ell) > k \cdot m \cdot u_i(\mathcal{C}) \geq \frac{m}{2}, \quad (2)$$

which implies that  $a_i$  should be adjacent to at least  $\frac{m}{2} + 1$  edges in  $G(C)$ . Denote the set of agents that are connected to  $a_i$  through these edges by  $C' \subset C$ . For any triplet of agents  $\{a_i, a_j, a_k\}$  with  $\{a_j, a_k\} \subset C'$ , the 3-size core stability of  $\mathcal{C}$  implies that either  $u_i(\mathcal{C}) \geq \frac{2}{3}$ ,  $u_j(\mathcal{C}) \geq \frac{1}{2}$ , or  $u_k(\mathcal{C}) \geq \frac{1}{2}$  must hold. If  $u_i(\mathcal{C}) \geq \frac{2}{3}$  holds, then because  $a_i$  improves in  $C$  by a factor of more than  $k$  we get that

$$\frac{2}{3}k \leq k \cdot u_i(\mathcal{C}) < \frac{1}{m} \sum_{a_\ell \in C' \setminus \{a_i\}} u(i, \ell) \leq \frac{m-1}{m}. \quad (3)$$

Thus, we get that  $k < \frac{3}{2} \frac{m-1}{m}$  in this case. Alternatively, assume without loss of generality that  $u_j(\mathcal{C}) \geq \frac{1}{2}$ . Following the logic from Equation (2),  $a_j$  should be adjacent to at least  $\frac{m}{2} + 1$  edges in  $G(\mathcal{C})$ . This implies that there exists an agent  $a_\ell \in C'$  such that the agents  $\{a_i, a_j, a_\ell\}$  form a triangle, and hence at least one of these three agents should experience a utility of at least  $\frac{2}{3}$  in  $\mathcal{C}$ . Thus, Equation (3) holds for this agent and the result follows. ◀

Finally, as a second corollary of Theorem 2, we also obtain a bound for s-ASHGs.

► **Corollary 6.** *For S-ASHGs, every  $q$ -size core stable coalition structure  $\mathcal{C}$  is  $(m, 1 + \lfloor \frac{m-2}{q-1} \rfloor)$ -core stable for any  $m > q$ .*

## 4 Lower Bounds

Next, we focus on proving lower bounds for our setting. We first show a lower bound for the following subclass of S- $\alpha$ HGs, which includes S-FHGs, S-MFHGs, and S-ASHGs.

► **Definition 7.** *A function  $\alpha: [n] \rightarrow \mathbb{R}$  is hospitable if  $\frac{\alpha_q}{\alpha_{q-1}} \geq \frac{q-2}{q-1}$  for all integers  $q \geq 2$ . Accordingly, an S- $\alpha$ HG is hospitable if  $\alpha$  is hospitable.*

The intuition behind hospitable S- $\alpha$ HGs is that the utility of an agent in a coalition of size  $q-1$  will never decrease with more than a factor  $\frac{q-2}{q-1}$  when an additional agent is added to that coalition. This class includes ASHG, FHG, and MFHG. First, we can show that the bound derived in Theorem 2 is tight for hospitable S- $\alpha$ HGs when  $(m-1) \bmod (q-1) = 0$ .

► **Theorem 8.** *For any hospitable  $\alpha$ , there exists an instance of an S- $\alpha$ HG that contains a  $q$ -size core stable coalition structure  $\mathcal{C}$  which is not  $(m, \delta)$ -core stable for any  $\delta < \frac{\alpha_m(m-1)}{\alpha_q(q-1)}$ , with  $q, m \in \mathbb{N}$  and  $m \geq q+1$ .*

**Proof.** We construct an instance of an S- $\alpha$ HG that is  $q$ -size core stable, but which allows for a blocking coalition of size  $m \geq q+1$  in which all agents improve with at least a factor  $(\frac{\alpha_m(m-1)}{\alpha_q(q-1)})$ . Given a coalition structure  $\mathcal{C}$  in which  $u_i(\mathcal{C}) = 1$  for all agents  $i$ , and a blocking coalition  $C$  of size  $m$ , let  $u(i, j) = \frac{1}{\alpha_q(q-1)}$  for all agent pairs  $\{i, j\} \subset C$ . The resulting S- $\alpha$ HG is  $q$ -size core stable, since for any coalition  $C'$  of size at most  $q$  the utility of agent  $i$  in  $C'$  is at most

$\frac{(|C'|-1)\alpha_{|C'|}}{\alpha_q(q-1)} \leq \frac{\alpha_q(q-1)}{\alpha_q(q-1)} = 1$ , where the inequality is implied by recursively applying the definition of a hospitable S- $\alpha$ HG. As  $u_i(\mathcal{C}) = 1$  and since the utility of agent  $i$  in  $C$  is  $\frac{\alpha_m(m-1)}{\alpha_q(q-1)}$  for all agents  $i \in C$ , this implies that the coalition structure  $\mathcal{C}$  is not  $(m, \delta)$ -core stable for any  $\delta < \frac{\alpha_m(m-1)}{\alpha_q(q-1)}$ . ◀

Since if  $(m-1) \bmod (q-1) = 0$  it holds that  $\lfloor \frac{m-1}{q-1} \rfloor = \frac{m-1}{q-1}$  and  $\mathbf{1}((m-1) \bmod (q-1)) \alpha_m = 0$ , this implies that the bound obtained in Corollary 3 is tight for  $(m-1) \bmod (q-1) = 0$  and thus also for  $q = 2$ . Figure 2 illustrates the tightness of this lower bound for S-FHGs. Further, we show tightness of the bound in Theorem 2 for hospitable S- $\alpha$ HGs when  $q = 3$ .

► **Theorem 9.** *For any hospitable  $\alpha$ , there exists an instance of an S- $\alpha$ HG that contains a 3-size core stable coalition structure  $\mathcal{C}$  which is not  $(m, \delta)$ -core stable for any  $\delta < f(3, m)$ , with  $q, m \in \mathbb{N}$  and  $m \geq 4$ .*

## 41:10 Relaxed Core Stability for Hedonic Games with Size-Dependent Utilities

**Proof.** Note that when  $f(3, m) = 1$ , the result follows directly. Moreover, when  $m$  is odd, so  $(m-1) \bmod 2 = 0$ , the result follows from Theorem 8. When  $m$  is even and when  $f(3, m) > 1$ , we first observe that

$$f(3, m) = \left\lfloor \frac{m-1}{2} \right\rfloor \frac{\alpha_m}{\alpha_3} + \frac{\mathbb{1}((m-1) \bmod 2) \alpha_m}{\alpha((m-1) \bmod 2 + 1)} = \frac{m-2}{2} \frac{\alpha_m}{\alpha_3} + \frac{\alpha_m}{\alpha_2}.$$

Now we assume that we are given  $m$  agents  $c_1, \dots, c_m$  with  $u_i(\mathcal{C}) = 1$  for each  $c_i$ . We partition the agents into two sets  $C_1, C_2$  with  $C_1 = \{c_1, \dots, c_{\frac{m}{2}}\}$  and  $C_2 = \{c_{\frac{m}{2}+1}, \dots, c_m\}$ . If two agents  $c_i$  and  $c_j$  are in the same set, we define  $u(i, j) = \frac{1}{\alpha_3} - \frac{1}{\alpha_2}$ . Otherwise, we set  $u(i, j) = \frac{1}{\alpha_2}$ .

For any two agents  $\{c_i, c_j\}$  it thus holds that  $u_i(\{c_i, c_j\}) \leq \alpha_2 \max(\frac{1}{\alpha_3} - \frac{1}{\alpha_2}, \frac{1}{\alpha_2}) = \max(\frac{\alpha_2}{\alpha_3} - 1, 1) \leq 1$  and, therefore, these two agents do not form a blocking coalition. Further, for any three agents  $\{c_i, c_j, c_k\}$  we have two cases: (i) either all three agents come from the same set, then we get that  $u_i(\{c_i, c_j, c_k\}) = \frac{2\alpha_3}{\alpha_3} - \frac{2\alpha_3}{\alpha_2} = 2 - \frac{2\alpha_3}{\alpha_2} \leq 2 - \frac{\alpha_3}{\alpha_3} = 1$ ; (ii) one agent (without loss of generality  $c_k$ ) has to be from a different partition than the other two; then it holds that  $u_i(\{c_i, c_j, c_k\}) = \frac{\alpha_3}{\alpha_3} - \frac{\alpha_3}{\alpha_2} + \frac{\alpha_3}{\alpha_2} = 1$ . Hence, this coalition is 3-stable.

Finally, we get that

$$u_i(\{c_1, \dots, c_m\}) = \alpha_m \left( \frac{m-2}{2} \left( \frac{1}{\alpha_3} - \frac{1}{\alpha_2} \right) + \frac{m}{2} \frac{1}{\alpha_2} \right) = \frac{m-2}{2} \frac{\alpha_m}{\alpha_3} + \frac{\alpha_m}{\alpha_2} = f(3, m). \blacktriangleleft$$

Lastly, we provide additional tightness results of the bound in Theorem 2 for S-FHG and S-ASHG. We defer the proofs of Theorems 11 and 12 to the supplementary material.

► **Theorem 10.** *There exists a  $q$ -size core stable coalition structure  $\mathcal{C}$  in an S-FHG which is not  $(q+1, \delta)$ -core stable for any  $\delta < \frac{q+2}{q+1}$ .*

**Proof.** Assume we are given  $q+1$  agents  $a_1, \dots, a_{q+1}$  with  $u_i(\mathcal{C}) = 1$ . Let the edge weights be such that the edges with weight two form a cycle and all other edges have weight one, i.e., let  $u(i, j) = 2$  for all  $(i, j) \in \mathcal{C}$  for which  $j = i+1$ , let  $u(n, 1) = 2$ , and let  $u(k, l) = 1$  for all other edges. Note that in each subset  $C \subset \mathcal{C}$  with  $|C| < q+1$  there is at least one agent who is adjacent to at most one edge of weight two to the other agents in  $C$ , because the edges with weight two form a cycle over all  $q+1$  agents. Hence, for each subset  $C \subset \mathcal{C}$  with  $|C| < q+1$  there is at least one agent with a utility of at most  $\frac{2+|C|-2}{|C|} = 1$ , which implies that  $\mathcal{C}$  is  $q$ -size core stable. Furthermore, the coalition of all  $q+1$  agents offers a utility of  $\frac{2 \cdot 2 + q - 2}{q+1} = \frac{q+2}{q+1}$ . As a result,  $\mathcal{C}$  is not  $(q+1, \frac{q+2}{q+1} - \varepsilon)$ -core stable for any  $\varepsilon > 0$ . ◀

► **Theorem 11.** *There exists a  $4$ -size core stable coalition structure  $\mathcal{C}$  in an S-FHG which is not  $(m, \delta)$ -core stable, for any  $\delta < 1 + \frac{\lfloor \frac{1}{3}(m-2) \rfloor}{m}$ , and for any integer  $m \geq 5$ .*

► **Theorem 12.** *There exists a  $4$ -size core stable coalition structure  $\mathcal{C}$  in an S-ASHG which is not  $(m, \delta)$ -core stable, for any  $\delta < 1 + \lfloor \frac{m-2}{3} \rfloor$ , and for any integer  $m \geq 5$ .*

While we were not able to show the tightness of Theorem 2 for other values of  $\alpha$ ,  $q$ , and  $m$  than the ones described in this section, we found some examples to show the tightness of the result for additional values of  $(q, m)$  that are not covered by Theorems 8-12 through the use of the integer linear programming approach described in the supplementary material, as shown in Table 2. A summary of our results can be found in Table 3.

■ **Table 2** Additional values of  $(q, m)$  for which we found instances proving the tightness of the bound in Theorem 2 by using the integer linear programming approach described in the supplementary material.

<b>S-FHG</b>	$(5, m \leq 8), (6, m \leq 10), (7, m \leq 10),$ $(8, m \leq 11)$
<b>S-ASHG</b>	$(5, m \leq 8), (6, m \leq 10), (7, m \leq 12),$ $(8, m \leq 13), (9, m \leq 13), (10, m \leq 13),$ $(11, m \leq 13), (12, 13)$

■ **Table 3** Summary and tightness results for the values of  $f(q, m)$  such that every  $q$ -size core stable coalition structure is  $(q, f(q, m))$ -stable, with  $m \geq q + 1$ , for various types of hedonic games. A ✓ indicates that we were able to show tightness of  $\mathbf{f}(\mathbf{q}, \mathbf{m})$  for this type of hedonic game, while a ✗ indicates that this tightness is still open.

## 5 Efficiency

In this section, we study the price of anarchy for core-relaxations of symmetric  $\alpha$ -hedonic games. Using the same notation as Fanelli et al. [20], we denote the *social welfare* of a coalition structure  $\mathcal{C}$  by  $SW(\mathcal{C}) = \sum_{i \in A} u_i(\mathcal{C})$ , which is simply the sum of the agents' utilities. Moreover, let  $\mathcal{G} = (\alpha, A, u)$  represent an instance of an S- $\alpha$ HG. Given an S- $\alpha$ HG  $\mathcal{G}$ , let  $q$ -SIZE CORE( $\mathcal{G}$ ) be the set of  $q$ -size core stable coalition structures, and let  $k$ -IMPR CORE( $\mathcal{G}$ ) be the set of  $k$ -improvement core stable coalition structures. We define the  *$q$ -size core price of anarchy* of an S- $\alpha$ HG  $\mathcal{G}$  as the ratio between the social welfare of the coalition structure  $\mathcal{C}^*(\mathcal{G})$  that maximizes social welfare, and that of the  $q$ -size core stable coalition structure with the worst social welfare, i.e.,  $q$ -SIZE CPOA( $\mathcal{G}$ ) =  $\max_{\mathcal{C} \in q\text{-SIZE CORE}(\mathcal{G})} \frac{SW(\mathcal{C}^*(\mathcal{G}))}{SW(\mathcal{C})}$ . Similarly, we define the  *$k$ -improvement core price of anarchy* as  $k$ -IMPR CPOA( $\mathcal{G}$ ) =  $\max_{\mathcal{C} \in k\text{-IMPR CORE}(\mathcal{G})} \frac{SW(\mathcal{C}^*(\mathcal{G}))}{SW(\mathcal{C})}$ .

Using Corollary 3, we can extend the results by Fanelli et al. [20] about the  $q$ -size core price of anarchy for S-FHGs.

► **Corollary 13.** *For any S-FHG  $\mathcal{G}$ , it holds that  $q$ -SIZE CPOA( $\mathcal{G}$ )  $\leq \frac{2q}{q-1}$ , for any integer  $q \geq 2$ , and this bound is tight.*

**Proof.** By Corollary 4, we know that the social welfare of the worst  $q$ -size core stable coalition structure is at least the social welfare of the worst  $\frac{q}{q-1}$ -improvement core stable coalition structure. Moreover, by Theorem 8 by [20], we know that the  $k$ -improvement CPOA of an S-FHG is upper bounded by  $2k$ , for any  $k \geq 1$ . The tightness of the bound follows from Theorem 9 by [20]. ◀

Next, we show upper bounds on the  $q$ -SIZE CPOA( $\mathcal{G}$ ) and the  $k$ -IMPR CPOA( $\mathcal{G}$ ) for the following subclass of S- $\alpha$ HGs.

► **Definition 14.** A function  $\alpha: [n] \rightarrow \mathbb{R}$  is decreasing if  $\alpha_q \geq \alpha_{q+1}$  for all integers  $q \geq 1$ . Accordingly, an S- $\alpha$ HG is decreasing if  $\alpha$  is decreasing.

The class of decreasing S- $\alpha$ HGs is distinct from the class of hospitable S- $\alpha$ HGs defined in Definition 7, but it also contains S-FHGs, S-ASHGs, and S-MFHGs. When restricting our focus to the subclass of decreasing S- $\alpha$ HGs, we can generalize Theorem 8 by [20] to obtain the same upper bound on the  $k$ -improvement core price of anarchy.

► **Theorem 15.** For any decreasing S- $\alpha$ HG  $\mathcal{G}$  and for every  $k \geq 1$ ,  $k$ -IMPR  $\text{CPOA}(\mathcal{G}) \leq 2k$ .

**Proof.** The proof is identical to the proof of Theorem 8 by [20]. Using their notation, with the adapted definition that  $\mu_i^>(C) = \alpha(|C|) \cdot \delta_C^>(i)$ , the only required alteration to their proof is that equation (2) in their proof should be replaced by:

$$\mu_{i_t}(C_t^*) = \alpha(|C_t^*|) \cdot \delta_{C_t^*}^>(i_t) \geq \alpha(|C^*|) \cdot \delta_{C^*}^>(i_t) = \mu_{i_t}^>(C^*),$$

which holds, by definition, because we are only considering decreasing S- $\alpha$ HGs. ◀

Lastly, we can use a similar reasoning as in the proof of Corollary 13 and use the bounds from Theorems 3 and 15 to obtain a general upper bound on the  $q$ -size core price of anarchy for decreasing S- $\alpha$ HGs.

► **Theorem 16.** For any decreasing S- $\alpha$ HG  $\mathcal{G}$ ,  $q$ -SIZE  $\text{CPOA}(\mathcal{G}) \leq 2 \cdot \max_{m \geq q+1} f(m, q)$ .

Note that this result implies a core price of anarchy of 2 for S-MFHGs, where the core price of anarchy of an S- $\alpha$ HG  $\mathcal{G}$  is simply defined as  $\max_q q$ -SIZE  $\text{CPOA}(\mathcal{G})$ . As such, we answered an open question by [26], who found a lower bound on the core price of stability of 2 and an upper bound for the core price of anarchy of 4 in S-MFHGs.

► **Corollary 17.** For any S-MFHG, the core price of anarchy is upper bounded by 2.

## 6 Conclusion and Outlook

In our paper, we studied hedonic games and the relationship between different relaxed notions of core stability. Most importantly, for a large class of hedonic games, we obtained a general upper bound  $f(q, m)$  such that every  $q$ -size core stable outcome is  $(m, f(q, m))$ -core stable. That is, a coalition of size  $m$  can deviate at most by a factor of  $f(q, m)$ . Our bound also allows us to answer a conjecture by [20] that every  $q$ -size core stable outcome in symmetric fractional hedonic games is  $\frac{q}{q-1}$ -improvement core stable. Finally, we also obtain some lower bounds. However, even for fractional and additively separable hedonic games, our bounds are not tight yet. For both, we were only able to show the tightness up to  $q = 4$ . The smallest case which is unknown (both for fractional and additively separable hedonic games) is the tightness for  $q = 5$  and  $m = 10$ , see Table 2 and Theorem 8. For both kinds of hedonic games, our integer linear programming approach was not able to construct a counterexample, nor show that no counterexample exists. Thus, improving our lower bounds seems like a challenging and interesting venue for future work. Further, it would be interesting to see if the generalization of  $\alpha$ -hedonic games, could see application in other areas of hedonic games as well. For instance, it might be interesting to classify for which  $\alpha$ -hedonic games certain dynamics converge (see for instance Boehmer et al. [7].)

## Abstract

The HUNTERS AND RABBIT game is played on a graph  $G$  where the Hunter player shoots at  $k$  vertices in every round while the Rabbit player occupies an unknown vertex and, if it is not shot, must move to a neighbouring vertex after each round. The Rabbit player wins if it can ensure that its position is never shot. The Hunter player wins otherwise. The hunter number  $h(G)$  of a graph  $G$  is the minimum integer  $k$  such that the Hunter player has a winning strategy (i.e., allowing him to win whatever be the strategy of the Rabbit player). This game has been studied in several graph classes, in particular in bipartite graphs (grids, trees, hypercubes...), but the computational complexity of computing  $h(G)$  remains open in general graphs and even in more restricted graph classes such as trees. To progress further in this study, we propose a notion of monotonicity (a well-studied and useful property in classical pursuit-evasion games such as Graph Searching games) for the HUNTERS AND RABBIT game imposing that, roughly, a vertex that has already been shot “must not host the rabbit anymore”. This allows us to obtain new results in various graph classes.

More precisely, let the monotone hunter number  $mh(G)$  of a graph  $G$  be the minimum integer  $k$  such that the Hunter player has a monotone winning strategy. We show that  $pw(G) \leq mh(G) \leq pw(G) + 1$  for any graph  $G$  with pathwidth  $pw(G)$ , which implies that computing  $mh(G)$ , or even approximating  $mh(G)$  up to an additive constant, is NP-hard. Then, we show that  $mh(G)$  can be computed in polynomial time in split graphs, interval graphs, cographs and trees. These results go through structural characterisations which allow us to relate the monotone hunter number with the pathwidth in some of these graph classes. In all cases, this allows us to specify the hunter number or to show that there may be an arbitrary gap between  $h$  and  $mh$ , i.e., that monotonicity does not help. In particular, we show that, for every  $k \geq 3$ , there exists a tree  $T$  with  $h(T) = 2$  and  $mh(T) = k$ . We conclude by proving that computing  $h$  (resp.,  $mh$ ) is FPT parameterised by the minimum size of a vertex cover.

## 1 Introduction

The HUNTERS AND RABBIT game is played on a graph  $G$  and with a positive integer  $k$  (the number of hunters), where the Hunter player shoots at  $k$  vertices in every round while the Rabbit player occupies an unknown vertex and, if it is not shot, must move to a neighbouring vertex after each round. The Rabbit player wins if he can ensure that its position is never shot. The Hunter player wins otherwise. The HUNTERS AND RABBIT game was first introduced in [7], in the case  $k = 1$ , where it was shown that the Hunter player wins in a tree  $T$  if and only if  $T$  does not contain as subgraph any tree obtained from a star with 3 leaves by subdividing each edges twice. This result was also observed in [19], where the authors also consider the minimum number of rounds needed for the Hunter player to win. The version where  $k > 1$  was first considered in [1]. Observe that, if  $k = |V(G)| - 1$ , the Hunter player can win in any graph  $G$  (in two rounds) by shooting twice a subset of  $k$  vertices of  $G$ . Hence, let the *hunter number* of  $G$ , denoted by  $h(G)$ , be the minimum integer  $k$  such that  $k$  hunters can win in  $G$  whatever be the rabbit strategy.

In [1], it is shown that the hunter number is closed under taking subgraphs. Moreover, this result trivially extends to the case when the starting positions of the rabbit are restricted. The exact value of  $h(G)$  has been determined for several specific families of graphs  $G$ . For any  $n \geq 2$ ,  $h(P_n) = 1$  where  $P_n$  is the path with  $n$  vertices [7] (because the rabbit is forced to move at every round,  $h(P_1) = 0$ ). For any  $n \geq 3$ ,  $h(C_n) = 2$  and  $h(K_n) = n - 1$ , where  $C_n$  and  $K_n$  are the cycle and complete graph on  $n$  vertices respectively [1]. Moreover,  $h(G_{n \times m}) = \lfloor \frac{\min\{n,m\}}{2} \rfloor + 1$  [1] and  $h(Q^n) = 1 + \sum_{i=0}^{n-2} \binom{i}{\lfloor i/2 \rfloor}$  [5], where  $G_{n \times m}$  is the  $n \times m$  grid and  $Q^n$  is the hypercube with dimension  $n$ . The case of bipartite graphs has been particularly studied because it was proved in [1] that we may constrain the rabbit to start in a fixed part of the bipartition, without decreasing the hunter number. By taking advantage of the bipartiteness of trees, it was proved that, for any tree  $T$ ,  $h(T) \leq \lceil \frac{1}{2} \log_2(|V(T)|) \rceil$  [17]. Surprisingly, the computational complexity of the problem that takes a graph  $G$  and an integer  $k$  as inputs and aims at deciding whether  $h(G) \leq k$  is still open, even if  $G$  is restricted to be a tree.

In this paper, we progress further in this research direction by exhibiting new classes of graphs  $G$  where  $h(G)$  can be determined in polynomial time.

**Graph Searching games.** The HUNTERS AND RABBIT game takes place in the larger class of Graph Searching games initially introduced in [6, 26]. In these pursuit-evasion games, one player plays with a team of searchers (or hunters, etc.) that must track a fugitive (or robber, rabbit, etc.) moving in a graph. Multiple games fall under this framework, each one specifying its own rules on, for example, the available moves of the searchers, the speed of the fugitive, whether the fugitive is visible or not, etc. Several variations of Graph Searching games have been studied in the literature due to their numerous applications in artificial intelligence [21], robot motion planning [9], constraint satisfaction problems and database theory [16], and distributed computing [25]. The study of such games also leads to significant implications in graph theory and algorithms. Indeed, many variants of these games provide algorithmic interpretations of width measures of graphs like treewidth [27], pathwidth [26], tree-depth [15], hypertree-width [2], cycle-rank [15], and directed tree-width [22]. Central to the connection between Graph Searching games and such structural parameters is the notion of *monotonicity* [3, 27, 24, 20]. In short, a searchers' strategy is *monotone* if it ensures that the fugitive can never "recontaminate" a vertex, i.e., it can never access a vertex that has already been "visited" by a searcher. The main question is then, given a game,

whether “recontamination does not help in this game” [23], i.e., whether there always exists, in this game, an optimal (in terms of number of searchers) monotone winning strategy for the searchers. In particular, the monotonicity played a central role in the proof that the minimum number of searchers to capture an invisible (resp., visible) fugitive in the node-searching game played in a graph  $G$  equals its pathwidth plus one [3] (resp., treewidth plus one [27]).

Unsurprisingly, the HUNTERS AND RABBIT game also has a close relationship with the pathwidth of graphs. Precisely, the hunter number of any graph is at most its pathwidth plus one [1]. In this paper, we investigate further this relationship and, for this purpose, we define, and study, a notion of monotonicity adapted to the HUNTERS AND RABBIT game.

**Our contribution.** In Section 2, we give the main notations used throughout this paper. In Section 3, we introduce the notion of monotonicity for the HUNTERS AND RABBIT game which is not straightforward; let  $mh(G)$  denote the *monotone hunter number* of  $G$ . Then, we prove that  $mh(G) \in \{pw(G), pw(G) + 1\}$  in any graph  $G$ . Along with implying that it is NP-complete to compute  $mh(G)$  for a graph  $G$ , this result also implies that it is NP-hard to approximate  $mh(G)$  up to an additive error of  $|V(G)|^\varepsilon$ , for  $0 < \varepsilon < 1$ . On the positive side, in Section 4, we give polynomial time algorithms to determine  $h(G)$  and/or  $mh(G)$  in cographs, split and interval graphs. In Section 5, we adapt the Parsons’ Lemma [26] to the case of the monotone HUNTERS AND RABBIT game which leads to a polynomial time algorithm that computes  $mh(T)$  for any tree  $T$ . Then, we investigate the monotonicity property in the case of the “bipartite” variant of the HUNTERS AND RABBIT game (see [1, 17]) in trees. In particular, we show that, for any  $k \in \mathbb{N}$ , there exist trees  $T$  such that  $h(T) = 2$  and  $mh(T) \geq k$ . That is, “recontamination helps a lot” in the HUNTERS AND RABBIT game. Finally, in Section 6, we show as a general positive result that the problem of deciding if  $h(G) \leq k$  or  $mh(G) \leq k$ , for some given integer  $k$ , is in FPT when parameterized by the vertex cover number of  $G$ . This is done through kernelization. We close our study by providing directions for further research in Section 7.

## 2 Preliminaries

Unless mentioned otherwise, in this paper we will always deal with graphs  $G = (V, E)$  that are non empty, finite, undirected, connected and simple. For any two adjacent vertices  $x, y \in V$ , let  $xy \in E$  denote the edge between  $x$  and  $y$ . Given a set  $S \subseteq V$ , let  $G[S]$  denote the subgraph of  $G$  induced by (the vertices in)  $S$  and let  $G \setminus S$  denote the subgraph  $G[V \setminus S]$ . For any  $v \in V$  and  $X \subseteq V$ , let  $N_X(v) = \{u \in X \mid uv \in E\}$  be the *open neighbourhood* of  $v$  in  $X$  and let the *closed neighbourhood* of  $v$  in  $X$  be  $N_X[v] = (N_X(v) \cup \{v\}) \cap X$ . If  $X = V$ , we simply write  $N(v)$  and  $N[v]$  respectively. For any  $S \subseteq V$ , let  $N(S) = \bigcup_{v \in S} N(v) \setminus S$  and  $N[S] = N(S) \cup S$ . The degree  $d(v) = |N(v)|$  is the number of neighbours of  $v$  and let  $\delta(G) = \min_{v \in V} d(v)$ . An *independent set* of a graph  $G = (V, E)$  is a subset  $I$  of  $V$  such that, for every  $u, v \in I$ ,  $uv \notin E$ . A graph is *bipartite* if its vertex-set can be partitioned into two independent sets.

**Hunters and Rabbit game.** The HUNTERS AND RABBIT game is played between two players, Hunter and Rabbit, on a graph. Let  $k \in \mathbb{N}^*$ . The Hunter player controls  $k$  hunters and the Rabbit player controls a single rabbit. First, the Rabbit player places the rabbit at a vertex  $r_0 \in V$ . The rabbit is *invisible*, i.e., the position of the rabbit is not known to the hunters. Then, the game proceeds in *rounds*. In each round  $i \geq 1$ , first, the Hunter player selects a non empty subset  $S_i \subseteq V$  of at most  $k$  vertices of  $G$  (we say that the vertices in  $S_i$

are *shot* at round  $i$ ). If the current position  $r_{i-1}$  of the rabbit is shot, i.e., if  $r_{i-1} \in S_i$  (we say that the rabbit is shot), then the Hunter player wins, and the game stops. Otherwise, the rabbit must move from its current position  $r_{i-1}$  to a vertex  $r_i \in N(r_{i-1})$ , and the next round starts. The Rabbit player wins if the rabbit avoids being shot forever.

A *hunter strategy* in  $G = (V, E)$  is a finite sequence  $\mathcal{S} = (S_1, \dots, S_\ell)$  of non empty subsets of vertices of  $G$ . Let  $h(\mathcal{S}) := \max_{1 \leq i \leq \ell} |S_i|$  and let us say that  $\mathcal{S}$  *uses*  $h(\mathcal{S})$  hunters. A *rabbit trajectory* in  $G$  starting from  $W \subseteq V$  ( $W$  will always be assumed non empty) is any walk  $(r_0, \dots, r_\ell)$  such that  $r_0 \in W$  and  $r_i \in N(r_{i-1})$  for every  $1 \leq i \leq \ell$ . A hunter strategy is *winning with respect to*  $W$  if, for every rabbit trajectory  $(r_0, \dots, r_\ell)$  starting from  $W$ , there exists  $0 \leq j < \ell$  such that  $r_j \in S_{j+1}$ , i.e, the rabbit is eventually shot whatever be its trajectory starting from  $W$ . Given a hunter strategy  $\mathcal{S} = (S_1, \dots, S_\ell)$ , a rabbit trajectory  $(r_0, \dots, r_\ell)$  starting from  $W$  is *winning against*  $\mathcal{S}$  if  $r_i \notin S_{i+1}$  for every  $0 \leq i < \ell$ . A *winning hunter strategy* is any winning hunter strategy with respect to  $V$  and a *rabbit trajectory* is any rabbit trajectory starting from  $V$ .

The *hunter number of*  $G = (V, E)$  *with respect to*  $W \subseteq V$ , denoted by  $h_W(G)$ , is the minimum integer  $k$  such that there exists a winning hunter strategy with respect to  $W$  and using  $k$  hunters. Let  $h(G) = h_V(G)$  be the *hunter number* of  $G$ . The Rabbit player has a *strategy*  $\mathcal{R}$  *starting from*  $W \subseteq V$  *against*  $k \geq 1$  *hunters* if, for every hunter strategy  $\mathcal{S}$  using  $k$  hunters, there exists a rabbit trajectory  $\mathcal{R}(\mathcal{S})$  that is winning against  $\mathcal{S}$ . If such a strategy  $\mathcal{R}$  exists, then  $h_W(G) > k$ .

For any hunter strategy  $\mathcal{S} = (S_1, \dots, S_\ell)$ , it will be convenient to identify the potential positions of a rabbit (starting in  $W \subseteq V$ ) after each round. Precisely, let  $\mathcal{Z}^W(\mathcal{S}) = (Z_0^W(\mathcal{S}), \dots, Z_\ell^W(\mathcal{S}))$  be defined as follows. Let  $Z_0^W(\mathcal{S}) = W$  and, for every  $0 < i \leq \ell$ , let  $Z_i^W(\mathcal{S})$  be the set of vertices  $v$  such that there exists a rabbit trajectory  $(r_0, r_1, \dots, r_i = v)$  such that  $r_0 \in W$  and, for every  $0 \leq j < i$ ,  $r_j \notin S_{j+1}$ . Formally, for any  $1 \leq i \leq \ell$ , let  $Z_i^W(\mathcal{S}) = \{x \in V(G) \mid \exists y \in (Z_{i-1}^W(\mathcal{S}) \setminus S_i) \wedge (xy \in E(G))\}$ . Intuitively,  $Z_i^W(\mathcal{S})$  is the set of vertices that the rabbit (starting from some vertex in  $W$ ) can have reached at the end of the  $i^{\text{th}}$  round without having been shot. We will refer to the vertices in  $Z_i^W(\mathcal{S})$  as the *contaminated* vertices after round  $i$ . Note that, if  $\mathcal{S}$  is winning, then  $Z_\ell^W(\mathcal{S}) = \emptyset$ . In what follows, we write  $Z_i$  (resp.,  $Z_i(\mathcal{S})$ ) instead of  $Z_i^W(\mathcal{S})$  when  $\mathcal{S}$  and  $W$  (resp., when  $W$ ) are clear from the context.

To reduce the search space for the possible hunter strategies, we establish that we can have winning hunter strategies that shoot only on a subset of contaminated vertices in each round, without increasing the number of hunters required. More precisely, a hunter strategy  $\mathcal{S} = (S_1, \dots, S_\ell)$  is said to be *parsimonious* if, for every  $1 \leq i \leq \ell$ ,  $S_i \subseteq Z_{i-1}(\mathcal{S})$ .

### 3 Monotonicity

In classical graph pursuit-evasion games, an important notion is that of *monotonicity*. On a high level, a strategy is *monotone* if the area reachable by the fugitive never increases. In the particular case of Graph Searching games, a strategy is monotone if, once a searcher is removed from some vertex, it is never necessary to occupy this vertex during a subsequent round. Monotone strategies have been widely studied [3, 29, 24] because it is generally easier to design them and because they have length polynomial in the size of the graph and so, corresponding decision problems can be proven to be in NP.

It is clear that such a definition is not suitable to the HUNTERS AND RABBIT game. Indeed, consider the graph that consists of a single edge  $uv$ : the hunter must shoot at some vertex, say  $u$ , and, if the rabbit was at  $v$ , it will move to  $u$ , i.e., the vertex  $u$  is “recontaminated”.

■ **Figure 1** Example of a bipartite graph (where  $V_r = \{a, c, e, g\}$  corresponds to the red part of the bipartition, illustrated by the red vertices in the figures) and of a parsimonious winning strategy with respect to  $V_r$ , such that no vertex in  $\{a, e, g\}$  is ever shot. Each subfigure depicts the situation at the end of the corresponding round. The cross indicates the shot of the hunter, and all the possible positions of the rabbit are shown by a rabbit next to the corresponding vertex.

Therefore, we propose to define monotonicity in the HUNTERS AND RABBIT game as follows (see the formal definition below): once a vertex has been “cleared”, if the rabbit can access it in a subsequent round, then the vertex must be shot immediately.

In classical Graph Searching games, a vertex being cleared at some round means that the searcher’s strategy ensures that the fugitive cannot occupy this vertex at this round. A recontaminated vertex can be intuitively defined as a vertex that can be reached by the fugitive while having been cleared in a previous round. This intuitive definition does not make any sense in the HUNTERS AND RABBIT game. For example, it is shown in [1] that, in bipartite graphs,  $h(G) = h_{V_r}(G) = h_{V_w}(G)$ , where  $(V_r, V_w)$  denotes the bipartition of  $V$ . In other words, it is sufficient to consider winning hunter strategies with respect to one of the independent sets of the bipartition; we call this the *red variant* of the game. In this case, every vertex of  $V_r$  is cleared at every odd round (since the rabbit can only occupy vertices of  $V_w$  at odd rounds) and so looking for a strategy without recontamination would be meaningless.

A related difficulty comes from the fact that, contrary to classical Graph Searching games, a vertex may be “cleared” without having been shot during the game. As a concrete example, consider a star with three leaves whose edges have been subdivided once each. Then, assuming that the leaves and the centre are red, in the red variant, it is possible for one hunter to win without shooting any of the leaves. Indeed, consider the strategy illustrated in Figure 1.

To overcome these difficulties, we propose to define the clearing of a vertex at some round by the fact that the actions of the hunters ensure that this vertex cannot be occupied by the rabbit at this round. Precisely, two actions of the hunters may clear a vertex: either a

hunter shoots a vertex  $v$  at round  $i$  and does not shoot the rabbit (meaning that  $v \neq r_{i-1}$ ), or the hunters shoot on every contaminated vertex in the neighbourhood of  $v$ . In this case, either  $v$  was occupied and the rabbit has to leave  $v$ , or  $v$  was not occupied and cannot be occupied after the move of the rabbit. In both cases,  $v \notin Z_i$ . This discussion motivates the following definition for the monotonicity of hunter strategies.

► **Definition 1** (Monotone strategy). *Let  $G$  be a graph and  $\mathcal{S}$  be a winning hunter strategy with respect to  $W \subseteq V(G)$ . We say that a vertex  $v$  is cleared at round  $i$  if either  $v \in S_i$  or,  $N(v) \cap Z_{i-1} \neq \emptyset$  and  $N(v) \cap Z_{i-1} \subseteq S_i$ . A strategy  $\mathcal{S} = (S_1, \dots, S_\ell)$  is monotone if, for every vertex  $v \in V$ , if there exists an  $i$  such that  $v$  is cleared at round  $i$ , then for every  $j > i$  such that  $v \in Z_j$ , the strategy ensures that  $v \in S_{j+1}$ . A vertex  $v$  is recontaminated at round  $j$  if there exists  $i \leq j$  such that  $v$  is cleared at round  $i$  and  $v \in Z_j \setminus S_{j+1}$ .*

The *monotone hunter number* of a graph  $G$  with respect to  $W \subseteq V(G)$ , denoted by  $mh_W(G)$ , is the minimum number  $k$  such that  $k$  hunters have a monotone winning hunter strategy in  $G$  with respect to  $W$ . Let us denote the *monotone hunter number*  $mh_V(G)$  of  $G$  by  $mh(G)$ . Note that, by definition,  $h_W(G) \leq mh_W(G) \leq mh(G)$ .

We can prove that monotone strategies have many interesting properties that are used in most of the proofs of our results. The proofs of these properties, which are omitted due to lack of space, are not trivial. The most intuitive one, is that, when the hunters follow a monotone strategy  $\mathcal{S}$ , the set of possible positions of the rabbit cannot increase. That is,  $Z_\ell(\mathcal{S}) \subseteq \dots \subseteq Z_1(\mathcal{S})$ . Moreover,  $mh(G)$  is closed under taking subgraphs. A crucial property is that there exists an optimal (using  $mh(G)$  hunter) parsimonious monotone strategy in any graph  $G$ . Finally, in any monotone strategy, once a vertex is shot, it has to be continuously shot until the rabbit can no longer reach it. In particular, this last property is used in the proof of upcoming Theorem 2 and it implies that the problem of computing  $mh$  is in NP.

### 3.1 Monotone hunter number and pathwidth

Here, we relate the monotone hunter number of a graph to its pathwidth. Our result might be surprising since the pathwidth of a graph  $G$  is equivalent to the number of searchers required to (monotonously) capture an arbitrary fast invisible fugitive [3] while, in our case, the invisible rabbit seems much weaker than the fugitive: the rabbit is “slow” (it moves only to neighbours) and constrained to move at every round. In this view, one might guess that the monotone hunter number of a graph could be arbitrary smaller than its pathwidth. On the contrary, we show that these parameters differ by at most one.

A *path-decomposition* of a graph  $G = (V, E)$  is a sequence  $P = (X_1, \dots, X_p)$  of subsets of vertices, called *bags*, such that (1)  $\bigcup_{i \leq p} X_i = V$ ; (2) for every  $uv \in E$ , there exists  $i \leq p$  with  $\{u, v\} \subseteq X_i$ ; and (3): for every  $1 \leq i < j \leq p$ ,  $X_i \cap X_j \subseteq X_{i-1} \cup X_{j+1}$ . The *width*  $w(P)$  of  $P$  is the size of a largest bag of  $P$  minus one, i.e.,  $w(P) = \max_{i \leq p} |X_i| - 1$ . The *pathwidth*  $pw(G)$  of  $G$  is the minimum width of its path-decompositions. A path-decomposition of  $G$  of width  $pw(G)$  is said to be *optimal*.

► **Theorem 2.** *For any graph  $G = (V, E)$ ,  $pw(G) \leq mh(G) \leq pw(G) + 1$ .*

**Sketch of proof.** Let  $P = (X_1, \dots, X_\ell)$  be a path-decomposition of  $G$  with width  $k$ . Then,  $P$  is a monotone hunter strategy in  $G$  using  $k + 1$  hunters.

To show the other inequality, let  $\mathcal{S} = (S_1, \dots, S_\ell)$  be a parsimonious winning monotone hunter strategy in  $G$  using at most  $k \geq mh(G)$  hunters. Observe that  $\mathcal{S}$  is almost a path-decomposition due to the fact that it is parsimonious and monotone. Indeed, any vertex  $v$  that is shot by  $\mathcal{S}$ , will be shot during some consecutive rounds (will belong to consecutive

bags of the decomposition). It remains to take care of unshot vertices. Such vertices are cleared by shooting at all of their neighbours during a round of  $\mathcal{S}$ . So, starting from  $\mathcal{S}$ , we build a path-decomposition  $\mathcal{P}$  of  $G$  as follows: we start with a bag  $B_i$  corresponding to  $S_i$ , for each  $i$ . Then, for each vertex  $u$  that has never been shot, all the neighbours of which are shot during the round  $i + 1$  for the first time, we create an intermediate bag, between  $B_i$  and  $B_{i+1}$ , containing all the vertices of  $B_i$  and the vertex  $u$ . ◀

Theorem 2 has important consequences, following from the inapproximability of the pathwidth of a graph [4]. Moreover, using a result in [17], this implies that recontamination may help in the HUNTERS AND RABBIT game.

► **Corollary 3.** *Given an  $n$ -node graph  $G$  and  $k \in \mathbb{N}$ , it is NP-complete to decide whether  $mh(G) \leq k$ . Moreover, it is NP-hard to approximate  $mh(G)$  up to an additive error of  $n^\varepsilon$ , for  $0 < \varepsilon < 1$ .*

► **Corollary 4.** *There exists  $\varepsilon > 0$  such that, for any  $k \in \mathbb{N}$ , there exists a tree  $T$  with  $h(T) \geq k$  and  $mh(T) \geq (1 + \varepsilon)h(T)$ .*

## 4 (Monotone) hunter number of some graph classes

In this section, we characterise the (monotone) hunter number of several graph classes such as cographs, split and interval graphs. In all these cases, our results lead to a polynomial time algorithm to compute the monotone hunter number.

### 4.1 Split and interval graphs

A graph  $G = (V, E)$  is a *split graph* if  $V = C \cup I$  can be partitioned into two sets  $C$  and  $I$ , inducing an inclusion-maximal clique and an independent set, respectively. Given a split graph  $G$ , a partition  $(C, I)$  of  $V(G)$  can be computed in linear time [18]. The following theorem fully characterises the hunter number of split graphs. It also allows us to show that the hunter number and the pathwidth of split graphs coincide.

► **Theorem 5.** *Let  $G = (C \cup I, E)$  be a split graph. Then,  $h(G) = |C|$  if and only if for every two distinct vertices  $x, y \in C$ , there exists a vertex  $z \in N_I(x) \cap N_I(y)$ . Otherwise,  $h(G) = |C| - 1$ .*

**Sketch of proof.** If every two vertices of  $C$  have a common neighbour in  $I$ , there exists a rabbit strategy against  $|C| - 1$  hunters. The idea is to take advantage of the fact that not all the vertices of  $C$  can be shot during a same round. Thus, the rabbit will remain as much as possible on  $C$ , and if it is unable to do so, it will go to  $I$  and then return to  $C$ , which is possible due to the hypothesis. For the reverse direction, let  $x$  and  $y$  be two vertices of  $C$  without common neighbour in  $I$ . The strategy  $\mathcal{S} = (S_1, S_2, S_3, S_4, S_5)$ , where  $S_1 = S_2 = S_5 = C \setminus \{y\}$  and  $S_3 = S_4 = C \setminus \{x\}$ , is a winning hunter strategy using  $|C| - 1$  hunters. ◀

Recall that a vertex in a graph  $G$  is *simplicial* if its neighbourhood induces a clique. Recall also that an *interval graph* is the intersection graph of a set of intervals in the real line. Let  $\omega(G)$  denote the maximum size of a clique of  $G$ .

► **Theorem 6.** *Let  $G$  be a interval (resp. split) graph. Then,  $h(G) = mh(G) = \omega(G) - 1$  (resp.  $mh(G) = \omega(G) - 1$ ) if every maximum clique has a simplicial vertex. Otherwise,  $mh(G) = \omega(G)$ .*

**Sketch of proof.** For the first direction, in case  $G = (C \cup I, E)$  is a split graph with  $v$  being a simplicial vertex of  $C$ ,  $S = (C \setminus v, C \setminus v)$  is a monotone winning hunter strategy using  $|C| - 1$  hunters. In case  $G$  is an interval graph, recall that  $pw(G) = \omega(G) - 1$  and  $G$  admits an optimal path-decomposition where each bag induces a complete graph. We adapt such an optimal path-decomposition, to a hunter strategy using  $\omega(G) - 1$  hunters, by removing a simplicial vertex from each bag containing a maximum clique and shooting twice at each of these bags.

For the reverse direction, let  $C$  be any maximum clique of  $G$  without simplicial vertex. Assume that there exists a monotone hunter strategy  $\mathcal{S}$  using  $|C| - 1$  hunters. Then there exists at least one round such that  $C$  hunters shoot on vertices of  $C$  (otherwise the rabbit can survive by staying on  $C$ ). Consider the first such round and let  $u$  be the vertex of  $C$  that is not shot. Using the fact that  $C$  has no simplicial vertex, we prove that there exists  $w \in N(u) \setminus C$  such that both  $u$  and  $w$  have never been shot until this round. Thus, the rabbit can oscillate between  $u$  and  $w$  either until the end, or until the first round where at least one of  $u$  or  $w$  is shot, where it recontaminates a vertex of  $C$ . This is a contradiction. ◀

From the above, we can show that there exist split and interval graphs  $G$  for which  $mh(G) \neq h(G)$ , i.e., recontamination helps in these graph families. Note also that, even knowing that  $\omega(G) - 1 \leq h(G) \leq \omega(G)$  for interval graphs, computing  $h(G)$  when some maximum clique has no simplicial vertex is challenging.

## 4.2 Cographs

The class of *cographs* can be defined recursively as follows [10]. One vertex is a cograph. Given two cographs  $A$  and  $B$ , their disjoint union  $A \cup B$  is a cograph, and their join  $A \bowtie B$  (where all edges between  $A$  and  $B$  are added) is a cograph. A decomposition of a cograph (i.e., a building sequence of unions and joins performed from single vertices) can be computed in linear time [10].

► **Theorem 7.**  *$mh(G)$  can be computed in linear time in the class of cographs.*

**Sketch of proof.** It suffices to calculate  $mh(G)$  in the case where  $G = A \bowtie B$ . It is easy to see that  $mh(A \bowtie B) \leq m = \min(mh(A) + |V(B)|, |V(A)| + mh(B))$ . Assume that there exists a winning monotone hunter strategy  $\mathcal{S} = (S_1, \dots, S_\ell)$  using at most  $m - 1$  hunters. Let  $v$  be the first vertex that is no longer available for the rabbit and assume, w.l.o.g., that  $v \in V(A)$ . Then, all the vertices in  $N_B(v) = V(B)$  were shot. Thus,  $V(B)$  must be shot during every subsequent round. This means that  $\mathcal{S}$  can clear  $A$  using  $m - |V(B)| - 1 < mh(A)$  hunters, a contradiction. ◀

Once again, the case of the hunter number seems more challenging. In particular, the following lemma shows that recontamination may help in cographs.

► **Lemma 8.** *For every  $k \geq 1$ , there exists a cograph  $G$  such that  $h(G) \geq k$  and  $mh(G) \geq \frac{3}{2}h(G) - 1$ .*

**Sketch of proof.** Let  $A$  and  $B$  be two (isomorphic) cographs consisting of the disjoint union of a complete graph with  $a \geq 3$  vertices and  $a$  independent vertices. The graph  $G = A \bowtie B$  verifies that  $mh(G) = 3a - 1$  and  $h(G) = 2a$ . ◀

## 5 (Monotone) hunter number of trees

This section is devoted to showing that  $mh$  can be computed in polynomial-time in the class of trees. Then, we show that recontamination helps a lot in trees.

### 5.1 Monotone hunter number in trees

Let  $T$  be a tree and  $v \in V(T)$ . A *branch* at  $v$  is any connected component of  $T - v$ . A *star* is any tree with at least two vertices and at most one vertex with degree at least three. Roughly, Parsons' Lemma [26] states that, for any tree  $T$  and  $k \in \mathbb{N}$ ,  $pw(T) \geq k + 1$  if and only if there exists a vertex  $v$  such that at least three branches at  $v$  have pathwidth at least  $k$ . Here, we adapt this lemma in the case of the monotone hunter number of trees.

► **Lemma 9** (Parsons' like lemma). *Let  $T = (V, E)$  be any tree.*

- $mh(T) = 0$  if and only if  $|V| = 1$ ;
- $mh(T) = 1$  if and only if  $T$  is a star;
- $mh(T) = 2$  if and only if  $T$  is not a star and contains a path  $P$  such that  $T \setminus P$  is a forest of stars and isolated vertices;
- For every  $k \geq 3$ ,  $mh(T) \geq k$  if and only if there exists a vertex  $v \in V$  such that at least three branches at  $v$  have monotone hunter number at least  $k - 1$ .

Taking advantage of Lemma 9, we design a dynamic programming algorithm to compute  $mh(T)$  of a given tree  $T$ . Our algorithm is heavily inspired by the polynomial time algorithm computing the pathwidth of  $T$  [13].

► **Theorem 10.** *For a tree  $T$ ,  $mh(T)$  can be computed in polynomial time.*

### 5.2 Monotone hunter number in the red variant in trees

So far, we have investigated the monotone HUNTERS AND RABBIT, since monotone strategies are often easier to deal with. Previous works on the HUNTERS AND RABBIT game in bipartite graphs  $G = (V_r \cup V_w, E)$  have shown that studying the *red variant* of the HUNTERS AND RABBIT game, i.e., when the rabbit is constrained to start in a vertex in  $V_r$ , could be very fruitful. For instance,  $h(G) = h_{V_r}(G)$  holds for every bipartite graph  $G = (V_r \cup V_w, E)$ , which helped to get many results on the HUNTERS AND RABBIT game [1, 5, 17]. Therefore, it is interesting to consider the monotonicity constraint when restricted to the red variant of the HUNTERS AND RABBIT game. We now focus on investigating the difference between  $h_{V_r}(T)$  and  $mh_{V_r}(T)$ , for any tree  $T$ . Thankfully, all the useful properties we observed for the monotone version can be adapted for the monotone red variant as well.

By Corollary 4, there exists  $\varepsilon > 0$  such that, for any  $k \in \mathbb{N}$ , there exists a tree  $T$  with  $h(T) \geq k$  and  $mh(T) \geq (1 + \varepsilon)h(T)$ . In the following theorem we improve this, by showing that there exists an infinite family of trees  $T$  such that the difference between  $mh(T)$  and  $h(T)$  is arbitrarily large. This follows from the next theorem since  $h_{V_r}(T) = h(T)$  and  $mh(T) \geq mh_{V_r}(T)$  for any tree  $T$ . Its proof follows from Lemmas 12 and 13, presented below.

► **Theorem 11.** *For every  $i \geq 3$ , there exists a tree  $T$  such that  $mh_{V_r}(T) \geq i$  and  $h_{V_r}(T) = 2$ .*

■ **Figure 2** The graph  $T_{i,6}$ . The labels on the edges are used to represent their respective lengths. In particular, for every  $2 \leq j \leq 6$ , we have that  $p_i^j > \sum_{1 \leq k \leq j-1} p_i^k + l_{i-1}$ , where  $p_i^1 = 2$  and  $l_{i-1}$  is equal to the number of turns needed to clear any copy of the  $T_{i-1,6}$  graph.

**The construction of the tree  $T_{i,q}$ .** Let  $S_{k,q}$  be the rooted tree obtained from  $q \geq 6$  paths of length  $k \geq 3$  (with  $k$  edges) by identifying an endpoint of each path into a common vertex called the *root* of  $S_{k,q}$  and denoted by  $c$ . From now on, let  $(V_r, V_w)$  be the bipartition of  $V(S_{k,q})$  and assume that  $c \in V_r$ . Let  $\mathcal{S}_1$  be a winning hunter strategy such that  $mh_{V_r}(S_{3,q}) = 2$  [7], and let  $l_1$  be the smallest even integer greater or equal to the length of  $\mathcal{S}_1$ .

For every  $i \geq 2$  and  $q \geq 6$ , let  $T_{i,q}$  be the tree recursively built as follows (see Figure 2). First,  $T_{1,q} = S_{3,q}$ . Then, for  $i > 1$ , we assume that  $T_{i-1,q}$  has been defined recursively and that there exists a winning hunter strategy, of length  $l_{i-1}$ , using 2 hunters in the red variant in  $T_{i-1,q}$ .  $T_{i,q}$  is obtained from  $q$  vertex disjoint copies  $T_i^1, \dots, T_i^q$  of  $T_{i-1,q}$  and from a vertex  $c_i$ , the root of  $T_{i,q}$ . Then, for every  $1 \leq j \leq q$ , add a path  $P_i^j$  of length  $p_i^j$  between the root  $c_i^j$  of  $T_i^j$  and  $c_i$  (that is,  $c_i$  and  $c_i^j$  are at distance  $p_i^j$  in  $T_{i,q}$ ). The lengths  $p_i^j$  are defined recursively as follows. Let  $p_i^1 = 2$  and, for every  $1 < j \leq q$ , let  $p_i^j$  be the minimum even integer greater or equal to  $l_{i-1} + \sum_{1 \leq k < j} p_i^k$ . Finally, let us assume that  $c_i \in V_r$  and note that, since  $p_i^j$  is even, this implies that  $c_i, c_i^1, \dots, c_i^q$  all belong to  $V_r$ .

► **Lemma 12.** For any  $i \in \mathbb{N}^*$  and  $q \geq 6$ ,  $h_{V_r}(T_{i,q}) = 2$ .

**Sketch of proof.** It suffices to give a winning hunter strategy using 2 hunters. The strategy  $\mathcal{S}^i$  is defined recursively, and consists of  $q$  phases. During the  $j^{\text{th}}$  phase, for  $1 \leq j \leq q$ , one hunter shoots at  $c_i$ , while the other “pushes” the rabbit toward the subtrees  $T_i^q$ , then  $T_i^{q-1}$ , and so on, until  $T_i^j$ . Then, the two hunters clear the subtree  $T_i^j$ , following the strategy  $\mathcal{S}^{i-1}$  (without the rabbit being able to leave  $T_i^j$  if it was there). The lengths of the paths linking the roots of the subtrees to  $c_i$  guarantee that the rabbit cannot reach  $c_i$  before  $T_i^j$  has been cleared. ◀

As a consequence, the hunter number is not closed under taking a minor.

► **Lemma 13.** For  $i \geq 3$  and  $q \geq 2i$ ,  $mh_{V_r}(T_{2i,q}) \geq i$ .

■ **Figure 3** A representation of the tree  $T_{2i,d}$ . Wiggly edges represent paths whose internal vertices have degree 2.

**Sketch of proof.** Let  $\gamma_{2i}$  denote the root of  $T_{2i,q}$  (see Figure 3) and assume that  $mh_{V_r}(T_{2i,q}) \leq i - 1$ . Let  $B_1^{2i}, \dots, B_q^{2i}$  denote the branches of  $\gamma_{2i}$ . The main ingredient of our proof is that  $q$  is large enough so that when, say during round  $j_{2i}$ , the first branch of  $\gamma_{2i}$ , say  $B_1^{2i}$ , is definitively cleared according to any monotone hunter strategy (i.e. the hunters will never shoot a vertex in  $B_1^{2i}$  for the remaining of the game), then there are at least two other branches of  $\gamma_{2i}$ , say  $B_2^{2i}$  and  $B_3^{2i}$ , whose vertices have never been shot. Note that  $\gamma_{2i}$  must be shot during the round  $j_{2i}$  or  $j_{2i} + 1$ . Then, the same arguments can be stated recursively on the tree  $T_{2i-1,q}$ , contained in the first branch among  $B_2^{2i}$  and  $B_3^{2i}$  that will be definitively cleared. In addition, we prove that  $j_{2i} < \dots < j_1$  and every  $\gamma_q$  (or some vertex of  $B_2^q$  or  $B_3^q$ ), for  $1 \leq q \leq 2i$ , must be shot during the round  $j_1$  or  $j_1 + 1$ . Thus, we obtain that at least  $i$  vertices are shot during the round  $j_1$  or  $j_1 + 1$ , a contradiction. ◀

## 6 Kernelization by vertex cover

Two instances  $I$  and  $I'$  are *equivalent* when  $I$  is a Yes-instance if and only if  $I'$  is a Yes-instance. A *kernelization algorithm* of a parameterized problem  $\Pi$  is a polynomial time algorithm that maps each instance  $(I, k)$  of  $\Pi$  to an equivalent instance  $(I', k')$  of  $\Pi$  such that the size of  $(I', k')$  is bounded by  $g(k)$  for some computable function  $g(\cdot)$ . Here,  $(I', k')$  is said to be a *kernel*. It is well-known that a parameterized problem  $\Pi$  is FPT if and only if it admits a kernel. We refer to the book [11] for details on parameterized complexity. We remark that similar techniques were used to obtain kernelization algorithms for several variants of COPS AND ROBBER game parameterized by  $vc(G)$  [14].

Recall that a set  $U$  is a *vertex cover* of a graph  $G = (V, E)$  if  $G[V \setminus U]$  is an independent set. For the rest of this section, let  $U$  be a vertex cover of size  $t$  and  $I$  be the independent set  $G[V \setminus U]$ . If no such vertex cover is given, we can compute a vertex cover using a 2-approximation algorithm [28].

► **Theorem 14.** *Let  $G$  be a graph having a vertex cover  $U$  of size  $t$ , and let  $k \in \mathbb{N}$ . Deciding whether  $h(G) \leq k$  (resp.,  $mh(G) \leq k$ ) is FPT parameterized by  $t$ . More specifically, these problems admit a kernel with at most  $4^t(t+1) + 2t$  vertices.*

**Sketch of proof.** First, observe that  $mh(G) \leq t$  since the hunters have a monotone winning strategy by shooting the vertices of  $U$  twice. Second, we argue that the standard rule of removing twins from  $I$  leads to an exponential kernel for these questions. More specifically, we have the following reduction rule along with the rule that if  $k \leq t$ , return a Yes-instance: If there is some  $I' \subset I$  such that  $|I'| > k+1$  and for any two vertices  $x, y \in I'$ ,  $N(x) = N(y)$ , then delete an arbitrary vertex, say  $v$ , from  $I'$  to get  $G'$  and let  $k' = k$ . It is not difficult to see that this will give us a kernel with at most  $2^t(t+1) + t$  vertices.

Next, we give an intuition regarding the safeness of our reduction rule. It is easy to see that if  $(G, k)$  is a Yes-instance, then  $(G', k)$  is also a Yes-instance as both  $h(G)$  and  $mh(G)$  are closed under taking subgraphs. For the reverse direction, and towards a contradiction, we will assume that  $(G, k)$  is a no-instance but  $(G', k)$  is a yes-instance. Since  $(G', k)$  is a yes instance, there exists a winning hunter strategy  $\mathcal{S}'$  using at most  $k$  hunters in  $G'$ . Since  $(G, k)$  is a no-instance, there exists a rabbit strategy  $R$  winning against  $\mathcal{S}'$  in  $G$ . From  $R$ , we can design  $R'$ , an equivalent rabbit strategy winning against  $\mathcal{S}'$  in  $G'$ , contradicting that  $(G', k)$  was a yes-instance. ◀

## 7    **Some Future Directions**

In this paper, we studied the HUNTERS AND RABBIT game by defining the notion of monotonicity for this game. Using this notion of monotonicity, we characterised the monotone hunter number for various classes of graphs. Moreover, we established that, unlike several Graph Searching games, the monotonicity helps in this game, i.e.,  $h(G)$  can be arbitrary smaller than  $mh(G)$ .

There are still several challenging open questions in this area. The most important among them is the computational complexity of HUNTERS AND RABBIT. Although our results establish that computing  $mh(G)$  is NP-hard, the computational complexity of computing/deciding  $h(G)$  remains open, even if  $G$  is restricted to be a tree.

We also established that both HUNTERS AND RABBIT, as well as its monotone variant, are FPT parameterised by  $vc(G)$  by designing exponential kernels. It is not difficult to see that both of these variants admit AND Composition parameterised by the solution size (by taking the disjoint union of the instances). Thus, since computing  $mh(G)$  is NP-hard and  $pw(G) \leq mh(G) \leq pw(G) + 1$ , it is unlikely for MONOTONE HUNTERS AND RABBIT parameterized by  $k + pw(G)$  to admit a polynomial compression. Note that the same cannot be argued about HUNTERS AND RABBIT since it is not yet proved to be NP-hard. Moreover, since  $mh(G)$  is closely related to  $pw(G)$  and pathwidth admits a polynomial kernel with respect to  $vc(G)$  [8], it might be interesting to see if deciding  $mh(G) \leq k$  (resp.,  $h(G) \leq k$ ) also admits a polynomial kernel when parameterised by  $vc(G)$ . Moreover, another interesting research direction is to study the parameterised complexity of both these games by considering parameters such as solution size, treewidth, and pathwidth.

Finally, we propose some open questions concerning the computation of  $h(G)$  for various graph classes including trees, cographs, and interval graphs. Specifically, it will be interesting to design a polynomial time algorithm to compute  $h(T)$  for a tree  $T$ , a challenge that was already proposed in [1]. The natural way that one could tackle this question is through the notion of monotonicity, which we defined and studied in this paper. Unfortunately, Theorem 11 implies that such an approach will not work. This means that a positive answer to this question (if any) would require the introduction of new tools and techniques. Moreover, it would be interesting to know the monotone hunter number of grids.

## Abstract

We extend the theory of formal languages in monoidal categories to the multi-sorted, symmetric case, and show how this theory permits a graphical treatment of topics in concurrency. In particular, we show that Mazurkiewicz trace languages are precisely *symmetric monoidal languages* over *monoidal distributed alphabets*. We introduce *symmetric monoidal automata*, which define the class of regular symmetric monoidal languages. Furthermore, we prove that Zielonka’s asynchronous automata coincide with symmetric monoidal automata over monoidal distributed alphabets. Finally, we apply the string diagrams for symmetric premonoidal categories to derive serializations of traces.

## 1 Introduction

*Monoidal languages* [12] generalize formal languages of words to formal languages of *string diagrams*. String diagrams [16, 29] are a graphical representation of morphisms in *monoidal categories*. Monoidal categories can be considered *2-dimensional monoids* [6]: just as monoids are categories with one object, whose morphisms are elements of the monoid, (strict) monoidal categories can be defined as 2-categories with one object. Accordingly, *monoidal languages* are subsets of morphisms in free monoidal categories, just as word languages are subsets of free monoids. *Regular* monoidal languages are those specifiable by finitary grammars or automata. Our paper [12] introduced these devices and examined properties of languages in single-sorted, planar monoidal categories. These include regular languages of words and trees, but also languages of *planar* string diagrams that are neither linear nor tree-like.

In this paper, motivated by concurrency theory, we extend this theory to *coloured props*: multi-sorted monoidal categories with symmetries (Section 2). The resulting theory of *symmetric* monoidal languages (Section 3) captures languages of diagrams having multiple colours of string and in which strings may cross, permitting non-planar diagrams. In terms of concurrency, colours represent different *runtimes*, or *threads of execution*.

Indeed, in Section 4 we show that Mazurkiewicz trace languages [21] are exactly symmetric monoidal languages over alphabets of a particular shape called *monoidal distributed alphabets*. In Section 5 we introduce automata for symmetric monoidal languages, defining the class of *regular* symmetric monoidal languages. Then, in Section 6 we show that these are exactly the asynchronous automata of Zielonka [32] when instantiated over monoidal distributed alphabets. Finally, in Section 7 we use the algebra of symmetric *premonoidal* categories to show how serialization of traces can be treated string-diagrammatically.

**Related work**

Our previous work [12] introduced monoidal languages in the planar, single-sorted case; that is, languages of morphisms in free *props*. Similar languages of graphs were studied by Bossut [5], but their underlying algebra was not made explicit. Here, we again leverage the algebraic perspective, extending our theory to symmetric multi-sorted monoidal categories (props).

In the introduction to Joyal & Street’s foundational work on string diagrams for monoidal categories [16], it is suggested that string diagrams have a connection to the *heaps* of Viennot [30]. Heaps are known to be equivalent to Mazurkiewicz trace monoids (also known as partially commutative monoids) [17], but a precise formulation of the suggested relation with string diagrams has not appeared in the literature until now.

The notion of dependence graph [13] has also been used to give a topological presentation of Mazurkiewicz traces. Our use of the algebra of monoidal categories, rather than graphs, has various advantages. For example, we can apply our language theory for monoidal categories to traces, and we see notions such as asynchronous automata arise naturally from this. It also suggests generalizations of trace languages, in particular going beyond the case of atomic actions (Remark 23). Finally, it brings our work into proximity with the semantics of Petri nets and other formalisms for concurrency based on monoidal categories [2, 24].

**2 Monoidal Graphs, Props and their String Diagrams**

In this section we recall the basic definitions used in the following, including the specific flavour of monoidal categories known as *props* [20], along with their string diagrams [16, 29]. Just as a category can be presented by a directed graph, (strict) monoidal categories can be presented by *monoidal graphs*, a kind of multi-input, multi-output directed graph.

► **Definition 1.** A monoidal graph  $\mathcal{G}$  is a set  $B_{\mathcal{G}}$  of boxes, a set  $S_{\mathcal{G}}$  of sorts, and functions  $s, t : B_{\mathcal{G}} \rightrightarrows S_{\mathcal{G}}^*$  to the free monoid over  $S_{\mathcal{G}}$ , giving source and target boundaries of each box.

The alphabets of monoidal languages will be finite monoidal graphs: those in which  $B_{\mathcal{G}}$  and  $S_{\mathcal{G}}$  are both finite sets. In fact, since we are interested in finite state machines over finite alphabets, we will work exclusively with finite monoidal graphs. Diagrammatically, a (finite) monoidal graph can be pictured as a collection of boxes, labelled by elements of  $B_{\mathcal{G}}$  with strings entering on the left and exiting on the right, labelled by sorts given by the source and target functions. For example, the following depicts the monoidal graph  $\mathcal{G}$  with  $B_{\mathcal{G}} = \{\gamma, \gamma'\}$ ,  $S_{\mathcal{G}} = \{A, B\}$ ,  $s(\gamma) = AB$ ,  $t(\gamma) = ABA$ ,  $s(\gamma') = A$ ,  $t(\gamma') = BB$ :

Sorts of a monoidal graph are sometimes called *colours*, since we could equally use different colours of string to represent different sorts, and we shall do so in places below. For a box  $\gamma \in B_{\mathcal{G}}$  we call  $s(\gamma)$  and  $t(\gamma)$  the *arity* and *coarity* of  $\gamma$ , respectively, and write  $\gamma : s(\gamma) \rightarrow t(\gamma)$ . We will also call  $\gamma$  considered together with its arity and coarity a *generator*.

Monoidal graphs are generating data for monoidal categories. Recall that a *strict monoidal category* is a category  $\mathcal{C}$ , equipped with a functor  $\otimes : \mathcal{C} \times \mathcal{C} \rightarrow \mathcal{C}$  (the *monoidal product*) and a unit object  $I \in \mathcal{C}$ , such that  $\otimes$  is associative and unital. A strict monoidal category is *symmetric* if there is a natural family of *symmetry morphisms*  $\sigma_{A,B} : A \otimes B \rightarrow B \otimes A$ , for each pair of sorts, satisfying  $\sigma_{B,A} \circ \sigma_{A,B} = 1_{A \otimes B}$ . The monoidal product turns the sets of objects and morphisms in  $\mathcal{C}$  into monoids. A *prop* is a symmetric strict monoidal category

whose monoid of objects is a free monoid.<sup>1</sup> While the above data can be intimidating to the non-expert, the free prop  $\mathcal{F}_\times \mathcal{G}$  on a monoidal graph  $\mathcal{G}$  can be described in an intuitive and straightforward way: its arrows are the *string diagrams* generated by  $\mathcal{G}$ .

► **Definition 2.** *The free prop  $\mathcal{F}_\times \mathcal{G}$  on a monoidal graph  $\mathcal{G}$  has monoid of objects  $S_\mathcal{G}^*$  and morphisms string diagrams inductively defined as follows: Left to right: the empty diagram*

is a diagram; for every sort, the string on that sort is a diagram; for every pair of sorts, the symmetric braiding is a diagram; the diagram for every generator  $\alpha$  is a diagram; for any two diagrams their vertical juxtaposition is a diagram; and for any two diagrams with matching right and left boundaries, the diagram obtained by joining the matching wires is a diagram (their composition). The monoidal product is given on objects by concatenation, on diagrams by juxtaposition, and the unit is the empty word.

The idea is simple: we treat generators like circuit components, and we have a supply of wires (identity morphisms). We also have the ability to cross wires, without tangling them; we do not distinguish over-crossings from under-crossings. A string diagram is then just any (open) circuit that we can build. This notation is sound and complete: an equation between morphisms of strict monoidal categories follows from their axioms if and only if it holds between string diagrams up to planar isotopy [16]. Working with string diagrams rather than the usual term syntax for morphisms is more intuitive, and leads to shorter proofs as the structural equations hold automatically: for example, interchange of morphisms (Figure 1, left), unbraiding of symmetries (centre), and sliding of morphisms past symmetries (right).

■ **Figure 1** These pairs of string diagrams are equal, reflecting the functoriality of  $\otimes$  (interchange), inverses of symmetries, and naturality of symmetries, respectively.

► **Definition 3.** *A morphism of monoidal graphs  $\varphi : \mathcal{H} \rightarrow \mathcal{G}$  is given by functions  $B_\varphi : B_\mathcal{H} \rightarrow B_\mathcal{G}$  and  $S_\varphi : S_\mathcal{H} \rightarrow S_\mathcal{G}$  compatible with source and target functions:  $S_\varphi^* \circ s = s \circ B_\varphi$  and  $S_\varphi^* \circ t = t \circ B_\varphi$ , where  $S_\varphi^*$  is the unique monoid homomorphism determined by  $S_\varphi$ .*

Morphisms of monoidal graphs freely generate morphisms of props: strict monoidal functors preserving sorts. Every prop has an underlying monoidal graph whose boxes are all the morphisms of the prop. This extends to an adjunction  $\mathcal{F}_\times \dashv \mathcal{U}$  between the categories of monoidal graphs and props, where  $\mathcal{U}$  takes the underlying monoidal graph of a prop [16].

Monoidal categories have been applied to the study of both computing and physical processes [8, 9, 18, 25]. In these contexts, the monoidal product represents parallel composition of processes, and interchange reflects the *independence* of processes running in parallel. This is the main feature of monoidal categories that we will leverage in our representation of *traces* (Section 4). The use of multi-sorted props will allow fine-grained control of interchange.

<sup>1</sup> Some literature takes prop to mean that the monoid of objects is generated by a single object (and so isomorphic to  $\mathbb{N}$ ), using the term *coloured prop* for the general case above.

### 3 Symmetric Monoidal Languages

Our paper [12] treated the case of languages, grammars and automata over single-sorted *pros* (strict monoidal categories *without* symmetries), corresponding to languages of *planar* string diagrams with one string colour. In this section we introduce the *multi-sorted* (or “coloured”) *symmetric monoidal languages*, which will be needed in the following to extend monoidal language theory to trace theory. In Section 5 we introduce the corresponding automata.

Just as a classical formal language is a subset of a free monoid, a symmetric monoidal language is a subset of morphisms in a free prop:

► **Definition 4.** *Let  $\Gamma$  be a finite monoidal graph. A symmetric monoidal language over  $\Gamma$  is a set of morphisms in the free prop  $\mathcal{F}_\times \Gamma$  over  $\Gamma$ .*

A morphism of finite directed graphs  $G \rightarrow \Sigma$ , where  $\Sigma$  is a graph with one vertex, amounts to a labelling of the edges of  $G$  by edges of  $\Sigma$ . This is the starting point of Walters’ definition of regular grammar [31], which inspires the following definition:

► **Definition 5.** *A regular monoidal grammar is a morphism of finite monoidal graphs.*

For a regular monoidal grammar  $M \xrightarrow{\varphi} \Gamma$ , the monoidal graph  $\Gamma$  is the *alphabet*, and the generators of  $M$ , with their labelling by  $\varphi$ , correspond to production rules: see Example 7.

In the classical setting of word languages, a morphism of finite directed *graphs*  $G \rightarrow \Sigma$  determines a *regular language* over  $\Sigma$  once we specify initial and final state vertices in  $G$ . In a regular monoidal grammar  $M \rightarrow \Gamma$ , the “vertices” of  $M$  are words over  $S_M$ , leading to various natural choices of boundary condition (Remark 8). In this paper, we will take initial and final words over  $S_M^*$ . Specifying these words defines the symmetric monoidal language of the grammar (Definition 9), and we define the languages arising in this way to be the regular symmetric monoidal languages.

We illustrate these definitions with some pedagogical toy examples. In the remaining sections of this paper, we turn to our extended application in concurrency, and we shall see that Mazurkiewicz trace languages are a natural example of symmetric monoidal languages.

► **Example 6.** Let  $\varphi : M \rightarrow \Gamma$  be the regular monoidal grammar where  $M$  and  $\Gamma$  have a single sort ( $\bullet$ ) and no boxes, with  $S_\varphi(\bullet) = \bullet$ , and initial and final states  $n \in S_M^* \cong \mathbb{N}$ . Then the symmetric monoidal language of this grammar is the set of *permutations* of  $n$  wires: morphisms consisting only of symmetries and identities.

Props have been used to give syntax and semantics for various kinds of *signal flow graph* and *circuit diagrams* [1, 3, 4]. Intuitively, props are well suited for this purpose since wires may freely cross in a circuit.

► **Example 7.** We give a regular monoidal grammar for the syntax of (open) circuits with  $n \geq 0$  capacitors in series with a single voltage source (Figure 2). The alphabet  $\Gamma$  has a single sort, and boxes four circuit components (Figure 2, left). The monoidal graph  $M$  has four sorts  $\{S, A, B, C\}$  and four boxes  $s : S \rightarrow AB, c : A \rightarrow A, v : B \rightarrow C, s' : AC \rightarrow S$ .  $S_\varphi$  maps the four sorts to the single sort of  $\Gamma$ , and  $B_\varphi$  maps each box to a circuit component. We can draw the grammar  $\varphi : M \rightarrow \Gamma$  in a single diagram by drawing the graph for  $M$  but replacing each box  $b$  with its image under the grammar morphism  $B_\varphi(b)$  (Figure 2, centre). The initial and final languages are the single state  $\{S\}$ . Intuitively, the symmetric monoidal language determined by the grammar is all of the string diagrams  $S \rightarrow S$  that can be built using the “sorted” boxes of  $\Gamma$ , then forgetting the sorts.

■ **Figure 2** (Left) The alphabet  $\Gamma$ , giving syntax for circuits. (Centre) A regular monoidal grammar over  $\Gamma$ . (Right) An element of the regular symmetric monoidal language determined by this grammar.

► **Remark 8.** As mentioned above, there are various possible choices for the “initial and final states” of a monoidal grammar. In our previous paper [12], we took the empty word, giving languages of scalar string diagrams (i.e. no “dangling wires”): this neatly generalizes tree grammars. More generally, one can take initial and final *regular languages* of states over  $S_M$ , as considered by Bossut [5].

The free prop construction can be used to concisely describe the symmetric monoidal language of a regular monoidal grammar, defining the class of *regular symmetric monoidal languages*:

► **Definition 9.** Let  $(\varphi : M \rightarrow \Gamma, I, F)$  be a regular monoidal grammar equipped with regular languages  $I, F \subseteq S_M^*$ . This determines a symmetric monoidal language by taking the image of the set of morphisms  $\bigcup_{i \in I, f \in F} \mathcal{F}_\times M(i, f)$  under  $\mathcal{F}_\times \varphi$ , giving a set of morphisms in  $\mathcal{F}_\times \Gamma$ . The languages arising in this way are defined to be the regular symmetric monoidal languages.

In this paper, we will only need the case where  $I, F$  consist of single words. The slogan for the general case is that 2-dimensional regular languages have 1-dimensional regular boundaries. In Section 5, we will see that regular symmetric monoidal languages may equivalently be specified by *non-deterministic monoidal automata*.

► **Remark 10.** A regular monoidal grammar determines not only a regular symmetric monoidal language, but also a language in any algebraic structure generated by monoidal graphs, including planar monoidal categories (treated in [12]), and premonoidal categories (which we will use in Section 7). This is analogous to the way in which a finite labelled directed graph may generate both a subset of a free monoid, but also a subset of a free group, by freely adding inverses to the graph. Moreover, many properties of planar regular monoidal languages such as their closure properties proved in [12] only use grammars, and hence the same proofs work for languages in these other algebras.

## 4 Mazurkiewicz Trace Languages as Symmetric Monoidal Languages

The theory of Mazurkiewicz traces [10, 21, 23] provides a simple but powerful model of concurrent systems. Traces are a generalization of *words* in which specified pairs of letters can commute. If we think of letters as corresponding to atomic *actions*, then commuting letters reflect the *independence* of those particular actions and so their possible concurrent execution:  $ab$  is observationally indistinguishable from  $ba$  if  $a$  and  $b$  are independent.

In this section, we show that trace languages are symmetric monoidal languages over monoidal graphs of a particular form that we call *monoidal distributed alphabets*. In Section 5 we introduce *symmetric monoidal automata*, which operationally characterize the regular symmetric monoidal languages. In Section 6 we turn to *asynchronous automata* [32], a well-known model accepting exactly the *recognizable* trace languages, and show that these automata are precisely symmetric monoidal automata over monoidal distributed alphabets.

## 4.1 Independence and distribution

We recall some definitions from Mazurkiewicz trace theory, before recasting them in terms of monoidal languages. Fix a finite set  $\Sigma$ , an alphabet thought of as a set of atomic actions.

► **Definition 11.** An independence relation on  $\Sigma$  is a symmetric, irreflexive relation  $I$ . The induced dependence relation,  $D_I$  is the complement of  $I$ .

► **Definition 12.** For  $I$  an independence relation, let  $\equiv_I$  be the least congruence on  $\Sigma^*$  such that  $\forall a, b: (a, b) \in I \implies ab \equiv_I ba$ . The quotient monoid  $\mathcal{T}(\Sigma, I) := \Sigma^*/\equiv_I$  is the trace monoid.

► **Definition 13.** A (Mazurkiewicz) trace language over  $(\Sigma, I)$  is a subset of the trace monoid  $\mathcal{T}(\Sigma, I)$ .

An element of  $\mathcal{T}(\Sigma, I)$  or *trace over*  $(\Sigma, I)$  is thus an equivalence class of words up to commutation of independent letters. A trace language may be thought of as the set of possible observations of a concurrent system's behaviour, in which independent letters stand for actions which may occur concurrently. Independence relations correspond to *distributions*:

► **Definition 14** ([23]). A distribution of an alphabet  $\Sigma$  is a finite tuple of non-empty alphabets  $(\Sigma_1, \dots, \Sigma_k)$  such that  $\bigcup_{i=1}^k \Sigma_i = \Sigma$ .

► **Proposition 15** ([23]). A distribution of  $\Sigma$  corresponds to a function  $\text{loc} : \Sigma \rightarrow \mathcal{P}^+(\{1, \dots, k\}) : \sigma \mapsto \{i \mid \sigma \in \Sigma_i\}$ .

Such a function gives the set of “locations” of each action  $\sigma \in \Sigma$ . In terms of concurrency, we can consider this to be a set of memory locations, threads of execution, or runtimes in which  $\sigma$  participates. In particular, every action has a non-empty set of locations.

A well-known construction [23] allows us to move between independence relations and distributions: locations correspond to maximal cliques in the graph of the dependency relation. We recall this construction in the proof of Proposition 16, which refines this correspondence.

Let  $\text{Ind}_\Sigma$  be the poset of independence relations on  $\Sigma$ , with order the inclusion of relations. Similarly, define a preorder  $\text{Dist}_\Sigma$  on distributions by  $(\Sigma_1, \dots, \Sigma_p) \leq (\Sigma'_1, \dots, \Sigma'_q)$  iff for each pair of distinct elements  $a, b \in \Sigma$ , if there exists  $1 \leq j \leq q$  such that  $\Sigma'_j$  contains both  $a$  and  $b$ , then there exists an  $\Sigma_i$  containing both  $a$  and  $b$ . Finally, quotient this preorder by taking distributions to be equal up to permutation.

► **Proposition 16.** There is a Galois insertion  $\text{Ind}_\Sigma \leftrightarrow \text{Dist}_\Sigma$ .

**Proof.** We construct an injective monotone function  $i : \text{Ind}_\Sigma \rightarrow \text{Dist}_\Sigma$ . Let an independence relation  $I$  over  $\Sigma$  be given, with induced dependence relation  $D_I$ . Construct the undirected *dependency graph*: vertices are elements of  $\Sigma$  and there is an edge  $(a, b)$  for every  $(a, b) \in D_I$ . Choose an ordering of maximal cliques of  $D_I$ , and define a distributed alphabet by taking  $\Sigma_i$  to be the elements of  $\Sigma$  in the maximal clique  $i$ . Different orderings give the same distribution up to permutation, and so the same element of  $\text{Dist}_\Sigma$ . This is injective since distinct independence relations induce distinct dependency graphs. It is monotone since if  $I \subseteq I'$  then the dependency graph  $D_I$  is at least as connected as  $D_{I'}$ , so if  $a, b$  both belong to a maximal clique of  $D_{I'}$  then they will both belong to a maximal clique of  $D_I$ .

We construct a monotone function  $r : \text{Dist}_\Sigma \rightarrow \text{Ind}_\Sigma$ . Let  $(\Sigma_1, \dots, \Sigma_k)$  be a distribution. Define a relation  $I$  by  $(a, b) \in I \iff \text{loc}(a) \cap \text{loc}(b) = \emptyset$ . This is irreflexive and symmetric, and so an independence relation.  $r$  is also clearly well-defined and monotone. Finally it is easy to check that  $r \circ i : \text{Ind}_\Sigma \rightarrow \text{Ind}_\Sigma$  is the identity. ◀

Put otherwise, though the same independence relation may be induced by many different distributions, independence relations correspond bijectively with the distributions in the image of  $i \circ r$ , that is, the distributions obtained via the maximal clique construction.

### 4.2 Symmetric monoidal languages over monoidal distributed alphabets

We now turn to the interpretation of these notions in terms of symmetric monoidal languages. A distribution can be seen as a monoidal graph in which sorts are the locations (runtimes).

► **Definition 17.** *A monoidal distributed alphabet is a finite monoidal graph  $\Gamma$  with the following properties:*

- $\Gamma$  has set of sorts a finite ordinal  $S_\Gamma = \{1 < 2 < \dots < k\}$  for  $k \geq 1$ ,
- sorts  $i \in S_\Gamma$  appear in order in the sources and targets of each generator  $\gamma \in B_\Gamma$ ,
- each sort  $i \in S_\Gamma$  appears at most once in each source and target,
- for each generator  $\gamma \in B_\Gamma$ , the sources and targets are non-empty and equal:  $s(\gamma) = t(\gamma)$ .

In brief, every generator in the alphabet is equipped with some set of runtimes, which serve as its source and target, and the runtimes are conserved. Figure 3 gives an example.

■ **Figure 3** An example of a monoidal distributed alphabet. For example,  $\delta$  and  $\beta$  are independent but  $\gamma$  and  $\alpha$  are not. We use colours for clarity, here blue = 1 < red = 2 < green = 3.

This gives us a way of representing distributions as monoidal graphs and vice-versa, if the graph is a monoidal distributed alphabet. Following Proposition 15, we will use  $\text{loc}(\boxed{\gamma})$  to mean the arity (= coarity) of a generator  $\boxed{\gamma}$ . Since we choose a finite ordinal for the sorts, we have that:

► **Proposition 18.** *Distributed alphabets are in bijection with monoidal distributed alphabets.*

Since the *ordering* of the runtimes is ultimately not relevant to the structure of a trace, we should allow them to freely cross each other in our string diagrams: this is precisely what is enabled by taking the *symmetric* monoidal languages over these alphabets. We also need each runtime to appear once in each element of these languages, so we take the boundaries to be  $1 \otimes \dots \otimes n$ , which we will write as  $\frac{1}{n}$ .

► **Definition 19.** *A monoidal trace language is a symmetric monoidal language of the form  $L \subseteq \mathcal{F}_\times \Gamma \left( \frac{1}{n}, \frac{1}{n} \right)$  where  $\Gamma$  is a monoidal distributed alphabet.*

Figure 4 gives an example of an element in a monoidal trace language over the monoidal distributed alphabet in Figure 3. We call such morphisms *monoidal traces*, and indeed we shall see below that they are exactly Mazurkiewicz traces. The corresponding string diagram gives an intuitive representation of traces as topological objects.

We now show that monoidal trace languages correspond precisely to Mazurkiewicz trace languages (Theorem 22), by establishing an isomorphism of monoids between trace monoids and monoids of string diagrams generated by monoidal distributed alphabets. Fix a monoidal distributed alphabet  $\Gamma$ . Recall that endomorphism hom-sets in a category are monoids under composition, and that the hom-set  $\mathcal{F}_\times \Gamma \left( \frac{1}{n}, \frac{1}{n} \right)$  has elements string diagrams  $\frac{1}{n} \rightarrow \frac{1}{n}$  over  $\Gamma$ .

■ **Figure 4** An example of a monoidal trace.  $\beta$  is independent of  $\alpha$  and  $\gamma$ , but not  $\delta$  or  $\epsilon$ . Thus  $\alpha\gamma\beta\delta\epsilon$  and  $\beta\alpha\gamma\delta\epsilon$  are two possible serializations of this trace, corresponding to sliding  $\beta$  past  $\alpha$  and  $\gamma$  in the string diagram. We use colours for sorts, blue = 1 < red = 2 < green = 3.

- **Lemma 20.** *The hom-set  $\mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$  admits the following presentation as a monoid:*
- *Generators:* For each  $\boxed{\gamma} \in \Gamma$ , the string diagram  $N(\gamma) : 1 \otimes \dots \otimes n \rightarrow 1 \otimes \dots \otimes n$  built from symmetries, followed by  $\boxed{\gamma}$  tensored with identities, followed by the inverse symmetry. See Figure 5 for an example.
  - *Equations:*  $N(\alpha) \circledast N(\beta) = N(\beta) \circledast N(\alpha) \iff \text{loc}(\boxed{\alpha}) \cap \text{loc}(\boxed{\beta}) = \emptyset$ , where  $\circledast$  denotes composition of string diagrams in diagrammatic (left-to-right) order.

**Proof.** We construct an isomorphism between the monoids. Let  $s \in \mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$  be a string diagram. We can use interchange (Figure 1) to impose a linear order of generators from left to right in the diagram, e.g.  $\boxed{\gamma_1}, \dots, \boxed{\gamma_n}$ . This is called putting  $s$  in *general position*, by perturbing generators at the same horizontal position [16]. We then split the string diagram into a sequence of slices, each containing one generator. For a slice with right (or left) boundary  $\begin{smallmatrix} k_1 \\ \vdots \\ k_n \end{smallmatrix}$ , we can use the permutation  $\begin{smallmatrix} k_1 \\ \vdots \\ k_n \end{smallmatrix} \rightarrow \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}$  followed by its inverse (or vice-versa) to finally obtain  $s$  as a sequence  $N(\gamma_1) \circledast \dots \circledast N(\gamma_n)$ . Any other possible sequence of generators is obtainable by repeatedly interchanging generators: this is possible if and only if their locations are disjoint. Consequently, this defines a function from  $\mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$  to the monoid presented above. Given that, as argued above, the slicing construction is unique up to interchanging independent generators, this defines a homomorphism. Conversely, given a generator  $N(\gamma)$  in the presentation, we map this to the same string diagram in  $\mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$ . Again, it follows from interchange that this extends to a homomorphism, inverse to that above. ◀

■ **Figure 5** An example of a generator  $N(\gamma)$  as in Lemma 20.

We now show that trace monoids are isomorphic to the endomorphism monoids  $\mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$ .

- **Lemma 21.** *Let  $I$  be an independence relation on an alphabet  $\Sigma$ , and  $\Gamma$  the monoidal distributed alphabet induced by the corresponding distribution (Proposition 18). Then there is an isomorphism of monoids  $\mathcal{T}(\Sigma, I) \cong \mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$ .*

**Proof.** We use the presentation of the endomorphism monoid given in Lemma 20. Define a homomorphism  $\alpha : \mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right) \rightarrow \mathcal{T}(\Sigma, I)$  by mapping generators  $N(\gamma) \mapsto [\gamma]$ . Let  $N(\gamma) \circledast N(\gamma') = N(\gamma') \circledast N(\gamma)$ , then it follows  $[\gamma\gamma'] = [\gamma'\gamma]$  in  $\mathcal{T}(\Sigma, I)$ , since the former holds

iff  $\text{loc}(\gamma) \cap \text{loc}(\gamma') = \emptyset$ , and so this extends to a homomorphism. Define a homomorphism  $\beta : \mathcal{T}(\Sigma, I) \rightarrow \mathcal{F}_\times \Gamma \left( \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix} \right)$  by mapping generators  $[\gamma] \mapsto N(\gamma)$ .  $[\gamma\gamma'] = [\gamma'\gamma]$  holds iff  $\text{loc}(\gamma) \cap \text{loc}(\gamma') = \emptyset$ , iff  $\text{loc}(\boxed{\gamma}) \cap \text{loc}(\boxed{\gamma'}) = \emptyset$ , iff  $N(\gamma) \circ N(\gamma') = N(\gamma') \circ N(\gamma)$ . Finally it is clear that  $\alpha$  and  $\beta$  are inverses, and so witness an isomorphism of monoids. ◀

The following theorem is now immediate: given a monoidal trace language  $L \subseteq \mathcal{F}_\times \Gamma \left( \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix} \right)$  we obtain a trace language  $L' \subseteq \mathcal{T}(\Sigma, I)$  using the isomorphism, and vice-versa:

► **Theorem 22.** *Monoidal trace languages are exactly Mazurkiewicz trace languages.*

Lemma 21 also shows that composition of traces corresponds simply to concatenation of the corresponding monoidal traces. Diagrams like Figure 4 are commonplace in the trace literature [11, 32]. Theorem 22 gives a formal basis for these diagrams as elements of symmetric monoidal languages.

► **Remark 23.** The idea of monoidal categories with a runtime is made precise by string diagrams for the *effectful categories* of Román [28]. Free props over monoidal distributed alphabets, considered as monoidal categories with *multiple runtimes* suggest a further generalization of effectful categories, sketched as a setting for concurrency by Jeffrey [14, Section 9.4]. We return to this in Section 7, where effectful (premonoidal) categories will be used to equip a trace language with a new runtime that enforces a strict ordering of events.

## 5 Symmetric Monoidal Automata

*Monoidal automata* give an alternative specification of the class of regular monoidal languages: they are analogues of finite-state automata in which transitions have multiple inputs and multiple outputs. Our paper [12] introduced monoidal automata for single-sorted, planar monoidal languages. However, the same data specifies an acceptor for single-sorted symmetric monoidal languages, if we inductively extend to *props*, rather than planar monoidal categories.

In this section we introduce monoidal automata over *multi-sorted* monoidal graphs and show how these recognize (multi-sorted) symmetric monoidal languages. In Section 6, we will see that the asynchronous automata of Zielonka [32] are a natural class of symmetric monoidal automata: those over monoidal distributed alphabets.

► **Definition 24.** *A non-deterministic monoidal semi-automaton is:*

- an input alphabet, given by a finite monoidal graph  $\Gamma$ ,
- an family of non-empty, finite state sets  $\{Q_c\}_{c \in S_\Gamma}$  indexed by the sorts of  $\Gamma$ ,
- for each  $\gamma : c_1 \dots c_n \rightarrow c'_1 \dots c'_m$  in  $\Gamma$ , a transition function  $\Delta_\gamma : \prod_{i=1}^n Q_{c_i} \rightarrow \mathcal{P}(\prod_{j=1}^m Q_{c'_j})$ .

As noted in Section 3, there are several candidates for a notion of initial/final state. In the following, we take initial and final words  $i, f$  over  $\prod Q_c$ . A monoidal semi-automaton equipped with initial and final words turns it into a (non-deterministic) *monoidal automaton*.

For classical NFAs, the assignment  $a \mapsto \Delta_a$  extends uniquely to a functor  $\Sigma^* \rightarrow \text{Rel}$ , the inductive extension of the transition structure from letters to words. We can similarly extend monoidal automata to string diagrams. First, we define the codomain prop,  $\text{Rel}_{\Gamma, Q}$ :

► **Definition 25.** *For a family of sets  $\{Q_c\}_{c \in S_\Gamma}$  indexed by the sorts of  $\Gamma$  then  $\text{Rel}_{\Gamma, Q}$  is the prop with:*

- set of objects  $S_\Gamma^*$ ,
- morphisms  $c_1 \dots c_n \rightarrow c'_1 \dots c'_m$  functions  $\prod_{i=1}^n Q_{c_i} \rightarrow \mathcal{P}(\prod_{j=1}^m Q_{c_j})$ ,

- composition is the usual composition of relations, i.e.  $f \circ g := \mu \circ \mathcal{P}(g) \circ f$ , where  $\mu$  is the canonical map from sets of subsets to subsets,
- $\otimes$  is given on objects by concatenation,
- and on morphisms  $f : \otimes_i c_i \rightarrow \otimes_j c'_j$  and  $g : \otimes_k d_k \rightarrow \otimes_l d'_l$  by  $f \otimes g := \nabla \circ (f \times g)$ , where  $\nabla$  sends pairs of subsets to their cartesian product,
- symmetries  $\sigma : c_1 c_2 \rightarrow c_2 c_1$  are functions  $Q_{c_1} \times Q_{c_2} \rightarrow \mathcal{P}(Q_{c_2} \times Q_{c_1}) : (q, q') \mapsto \{(q', q)\}$ .

Note that a non-deterministic monoidal semi-automaton amounts to a morphism of monoidal graphs  $\Gamma \rightarrow \mathcal{U} \text{Rel}_{\Gamma, Q}$ . The adjunction  $\mathcal{F}_X \dashv \mathcal{U}$  implies that there is a unique extension to a strict monoidal functor  $\mathcal{F}_X \Gamma \rightarrow \text{Rel}_{\Gamma, Q}$ , which we call a non-deterministic symmetric monoidal semi-automaton. This functor maps a string diagram to a relation. When this relation relates the initial word to the final word, the string diagram is *accepted*:

► **Definition 26.** Let  $\Delta : \mathcal{F}_X \Gamma \rightarrow \text{Rel}_{\Gamma, Q}$  be a non-deterministic monoidal automaton with initial and final states  $i, f \in S_\Gamma^*$ . Then the symmetric monoidal language accepted by  $\Delta$  is the set of morphisms  $\mathcal{L}(\Delta) := \{\alpha \in \mathcal{F}_X \Gamma \mid f \in \Delta(\alpha)(i)\}$ .

Intuitively, a run of a symmetric monoidal automaton starts with a *word* of states, whose subwords are modified by transitions corresponding to generators. Identity wires do not modify the states, and symmetries permute adjacent states.

► **Observation 27.** There is an evident correspondence between non-deterministic monoidal automata and regular monoidal grammars. The graphical representation of a grammar (such as Figure 2) makes this most clear: it can also be thought of as the “transition graph” of a non-deterministic monoidal automaton.

► **Remark 28.** We can further abstract our definition of monoidal automaton by noting that  $\text{Rel}_{\Gamma, Q}$  is a sub-prop of the Kleisli category of the powerset monad  $\mathcal{P}$ , and that this monad could be replaced by another commutative monad [27, Corollary 4.3]. For example, replacing  $\mathcal{P}$  with the maybe monad, we obtain deterministic monoidal automata.

## 6 Asynchronous Automata as Symmetric Monoidal Automata

Asynchronous automata were introduced by Zielonka [32] as a true-concurrent operational model of recognizable trace languages, a well-behaved subclass of trace languages analogous to regular languages. In this section we show they are precisely symmetric monoidal automata over monoidal distributed alphabets, which leads to the following theorem:

► **Theorem 29.** *Recognizable trace languages are exactly regular symmetric monoidal languages over monoidal distributed alphabets.*

We recall the definition of asynchronous automata, before turning to monoidal automata.

► **Definition 30 (Asynchronous automaton [32]).** Let  $(\Sigma_1, \dots, \Sigma_k)$  be a distribution of an alphabet  $\Sigma$ . For each  $1 \leq i \leq k$ , let  $Q_i$  be a non-empty finite set of states, and for each  $\sigma \in \Sigma$  take a transition relation  $\Delta_\sigma : \prod_{i \in \text{loc}(\sigma)} Q_i \rightarrow \mathcal{P}(\prod_{i \in \text{loc}(\sigma)} Q_i)$ . This defines a global transition relation on the set  $Q := \prod_{i=1}^k Q_i$  as follows:

$(q_1, \dots, q_k) \xrightarrow{\sigma} (q'_1, \dots, q'_k) \iff q_i = q'_i \text{ for } i \notin \text{loc}(\sigma) \text{ and } (q'_{i_1}, \dots, q'_{i_j}) \in \Delta_\sigma(q_{i_1}, \dots, q_{i_j})$   
where  $\{i_1, \dots, i_j\} \in \text{loc}(\sigma)$ . Finally let  $\vec{i} \in Q, F \subseteq Q$  be initial and final words of states.

The global transition relation for  $\sigma$  leaves unchanged those states at locations in the complement of  $\text{loc}(\sigma)$ , and otherwise acts according to the local transition  $\Delta_\sigma$ . An asynchronous automaton has a language over  $\Sigma$  given by the extension of the transition relation

to words. Moreover, asynchronous automata have a language of Mazurkiewicz traces over the distribution of  $\Sigma$ : a trace in  $\mathcal{T}(\Sigma, I)$  is accepted when all of its serializations are accepted, which happens when one of its serializations is accepted [32, p. 109]. *Recognizable trace languages* are defined algebraically as those whose syntactic congruence is of finite index [32]. Zielonka’s theorem says that they also have an operational characterization:

► **Theorem 31** (Zielonka [32]). *Asynchronous automata accept precisely the recognizable trace languages.*

Definition 30 closely resembles that of symmetric monoidal automata. Indeed, asynchronous automata are precisely symmetric monoidal automata over monoidal distributed alphabets:

► **Proposition 32.** *For an asynchronous automaton  $\mathcal{A}$ , there is a symmetric monoidal automaton over a monoidal distributed alphabet with the same trace language, and vice-versa.*

**Proof.** An asynchronous automaton with multiple final state words can be normalized to a single final state word in the usual way by introducing a new final state word and modifying transitions appropriately. Then a symmetric monoidal automaton can be constructed by taking the monoidal distributed alphabet associated to the distribution of  $\Sigma$  (Proposition 18), the same transition relations, initial and final state words. We show that the languages coincide. Let  $w \in \mathcal{L}(\mathcal{A})$ , and consider the corresponding trace  $[w]$ . Using Lemma 21, we can produce the corresponding monoidal trace. By construction, this is accepted by the symmetric monoidal automaton defined above. The converse is analogous. ◀

As a corollary, we can invoke Theorem 31 to obtain Theorem 29. In contrast to asynchronous automata, the constructed symmetric monoidal automaton directly accepts traces qua string diagrams, rather than a language of words corresponding to a trace language.

► **Observation 33.** *Jesi, Pighizzini, and Sabadini [15] introduced probabilistic asynchronous automata. Initial and final states, and transition relations are replaced by initial and final distributions, and stochastic transitions. These are precisely what are obtained if the powerset monad in our definition of non-deterministic monoidal automaton (Remark 28) is replaced with the distribution monad [26], whose Kleisli category has morphisms stochastic matrices.*

## 7 Serialization via Premonoidal Categories

Trace theorists often consider trace languages to be word languages with the property of *trace-closure* with respect to an independence relation [19]: if  $u \in L$  and  $u \equiv_I v$  then  $v \in L$ . These languages arise as preimages of trace languages along the quotient map  $q_{\Sigma, I} : \Sigma^* \rightarrow \mathcal{T}(\Sigma, I)$ . For  $L \subseteq \mathcal{T}(\Sigma, I)$  a trace language,  $q_{\Sigma, I}^{-1}(L) \subseteq \Sigma^*$  is its *flattening* or *serialization*.

In this section we show that the serialization of monoidal trace languages can be carried out using the algebra and string diagrams of symmetric premonoidal categories. Premonoidal categories are like monoidal categories, except interchange (Figure 1) does not hold in general. The free (symmetric) premonoidal category on a monoidal graph was described using string diagrams by Román [28]. The idea is simple: the string diagrams are the same as for props, but an extra string (the “runtime”) threads through each generator, preventing interchange. Figure 6 shows two premonoidal morphisms  $\bullet \otimes \bullet \rightarrow \bullet \otimes \bullet$  that are not equal:

In Appendix A, we explain in more detail the construction of the free symmetric premonoidal category  $\mathcal{F}_p\Gamma$  on a monoidal graph  $\Gamma$  using string diagrams. In particular, the runtime string appears only once in each string diagram, reflecting that premonoidal categories do not have a tensor product on morphisms. The endomorphism monoid  $\mathcal{F}_p\Gamma\left(\begin{smallmatrix} 1 & 1 \\ \vdots & \vdots \\ n & n \end{smallmatrix}\right)$  is now the free monoid over the boxes of  $\Gamma$ , since the runtime prevents interchange:

■ **Figure 6** In the free premonoidal category over a monoidal graph, generators are augmented by a string on a new object called the *runtime* (dashed red). This prevents interchange (cf. Figure 1).

► **Proposition 34.** *Let  $\Gamma$  be a monoidal distributed alphabet. Then  $\mathcal{F}_p\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right) \cong B_\Gamma^*$ , where  $B_\Gamma$  is the set of boxes of  $\Gamma$ .*

**Proof (Sketch).** By augmenting the generators of  $\Gamma$  with a new runtime, we create a monoidal distributed alphabet in which every generator depends on every other, that is, the independence relation is empty. Thus the corresponding trace monoid is simply  $B_\Gamma^*$ . From here, we can follow the idea of Lemma 21. ◀

We can define a morphism of monoids  $q_\Gamma : \mathcal{F}_p\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right) \rightarrow \mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$  by presenting  $\mathcal{F}_p\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right)$  as in Lemma 20, and defining  $q_\Gamma$  on generators by erasing the runtime string. Theorem 35 then follows immediately from the definitions along with Lemma 21 and Proposition 34:

► **Theorem 35.** *For every alphabet  $B_\Gamma$ , the following square of monoid homomorphisms commutes, where  $q$  is the quotient monoid homomorphism.*

$$\begin{array}{ccc} B_\Gamma^* & \xrightarrow{q} & \tau(B_\Gamma, I) \\ \cong \downarrow & & \downarrow \cong \\ \mathcal{F}_p\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right) & \xrightarrow{q_\Gamma} & \mathcal{F}_\times\Gamma\left(\begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}, \begin{smallmatrix} 1 \\ \vdots \\ n \end{smallmatrix}\right) \end{array}$$

As a result, the preimage of a monoidal trace language under the morphism  $q_\Gamma$  corresponds to the serialization of that language.

## 8 Conclusion

There are several directions in which our theory could be developed. A semi-independence relation drops symmetry from an independence relation: it is simply an irreflexive relation. This gives rise to the theory of semicommutations [7], in which *directed* commutations may occur e.g.  $ab \rightarrow ba$ , but not vice-versa. This allows for a more fine-grained specification of concurrency. In terms of monoidal languages, it suggests consideration of monoidal distributed alphabets in which the sources and targets of generators may differ.

As noted in Remark 23, our treatment of trace languages suggests a generalization of the notion of *effectful category* [28] (which include premonoidal categories), in which there are *multiple runtimes*. This would enable a semantics for concurrent systems in which we can consider not only *atomic* actions, but also actions with input and output types. We plan to pursue this axiomatically in future work.

Mazurkiewicz originally introduced traces to give semantics to Petri nets, and showed that this semantics is compositional with respect to *synchronization* of traces [21]. Petri nets have been given semantics in monoidal categories [2, 22], and so the precise relationship of our monoidal formulation of traces to Petri nets remains to be worked out. In particular, this would involve understanding trace synchronization in terms of monoidal categories.

Finally, proofs of Zielonka’s theorem (Theorem 31, see [32] for details) remain highly technical, despite several simplifications since Zielonka’s version. Investigation of whether the algebra of monoidal categories might yield further simplifications is an intriguing direction.

## A Symmetric Strict Premonoidal Categories and Functors

We recall the definitions of (symmetric) strict premonoidal categories and their functors. For more details, see the papers [27, 28].

► **Definition 36.** *A strict premonoidal category is a category  $\mathcal{C}$  equipped with:*

- *for each pair of objects  $A, B \in \mathcal{C}$  an object  $A \otimes B$ ,*
- *for each object  $A \in \mathcal{C}$  a functor  $A \triangleleft -$  whose action on objects sends  $B$  to  $A \otimes B$ ,*
- *for each object  $A \in \mathcal{C}$  a functor  $- \triangleright A$  whose action on objects sends  $B$  to  $B \otimes A$ , and*
- *a unit object  $I$ ,*

*such that,*

- *for each  $A \in \mathcal{C}$ , strict unitality  $I \otimes A = A = A \otimes I$  holds, and*
- *for each triple  $A, B, C \in \mathcal{C}$ , strict associativity  $A \otimes (B \otimes C) = (A \otimes B) \otimes C$  holds.*

The families of functors  $A \triangleleft -$ ,  $- \triangleright A$  are called the *whiskerings* with  $A$ : in a premonoidal category we do not have a tensor product of morphisms in general, but we can put an identity on either side of a morphism. A morphism  $f : A \rightarrow B \in \mathcal{C}$  is *central* if for every morphism  $g : C \rightarrow D$ ,  $(B \triangleleft g) \circ (f \triangleright C) = (f \triangleright C) \circ (A \triangleleft g)$ , in other words,  $f$  is central if it interchanges with every other morphism  $g$ .

► **Definition 37.** A strict premonoidal category is symmetric if it is further equipped with a natural isomorphism whose components  $c_{A,B} : A \otimes B \rightarrow B \otimes A$  are central and such that  $c_{B,A} \circ c_{A,B} = 1_{A \otimes B}$ .

► **Definition 38.** A strict premonoidal functor  $F : \mathcal{C} \rightarrow \mathcal{D}$  is a functor sending central morphisms to central morphisms and such that  $F(I_{\mathcal{C}}) = I_{\mathcal{D}}$ ,  $F(X \otimes Y) = F(X) \otimes F(Y)$ .

### A.1 String Diagrams for Premonoidal Categories

We recall the construction of the free symmetric strict premonoidal category over a monoidal graph. This is a special case of the construction of free *effectful categories* in [28, Section 2.3].

We first define the *runtime monoidal graph* over a monoidal graph, which augments the generators with a new wire:

► **Definition 39.** Let  $\mathcal{G}$  be a monoidal graph. Let  $R$  be a sort disjoint from  $S_{\mathcal{G}}$ . The runtime monoidal graph  $\mathcal{G}_R$  has sorts  $S_{\mathcal{G}} + \{R\}$  and for each generator  $\gamma : S_1 \dots S_n \rightarrow S'_1 \dots S'_m$  in  $\mathcal{G}$  a generator  $\gamma : RS_1 \dots S_n \rightarrow RS'_1 \dots S'_m$ .

Graphically we can depict  $\mathcal{G}_R$  as in Figure 7 (right):

■ **Figure 7** Left: A monoidal graph  $\mathcal{G}$ . Right: the associated runtime monoidal graph  $\mathcal{G}_R$ , where the new sort  $R$  is drawn as a dashed string.

► **Definition 40.** The symmetric runtime monoidal category is the free prop  $\mathcal{F}_\times \mathcal{G}_R$  on  $\mathcal{G}_R$ .

► **Theorem 41.** The free symmetric strict premonoidal category  $\mathcal{F}_p \mathcal{G}$  on a monoidal graph  $\mathcal{G}$  has set of objects  $S_{\mathcal{G}}$  and a morphism  $S_1 \otimes \dots \otimes S_n \rightarrow S'_1 \otimes \dots \otimes S'_m$  is a morphism  $R \otimes S_1 \otimes \dots \otimes S_n \rightarrow R \otimes S'_1 \otimes \dots \otimes S'_m$  in the symmetric runtime monoidal category.

**Proof.** The proof follows [28, Theorem 2.14], in the case where  $\mathcal{V}$  is empty, and taking instead the free symmetric strict monoidal category. ◀

In particular note that we no longer have a tensor product of morphisms in  $\mathcal{F}_p \mathcal{G}$ , since the runtime must appear only once in each domain and codomain, but we do have whiskerings for each object.

Consequently the string diagrams for morphisms  $A \rightarrow B$  in  $\mathcal{F}_p \mathcal{G}$  are just morphisms  $R \otimes A \rightarrow R \otimes B$  in the symmetric runtime monoidal category [28, Corollary 2.15].

# Upward Translation of Optimal and P-Optimal Proof Systems in the Boolean Hierarchy over NP

## Abstract

We study the existence of optimal and p-optimal proof systems for classes in the Boolean hierarchy over NP. Our main results concern DP, i.e., the second level of this hierarchy:

- If all sets in DP have p-optimal proof systems, then all sets in coDP have p-optimal proof systems.
- The analogous implication for optimal proof systems fails relative to an oracle.

As a consequence, we clarify such implications for all classes  $\mathcal{C}$  and  $\mathcal{D}$  in the Boolean hierarchy over NP: either we can prove the implication or show that it fails relative to an oracle.

Furthermore, we show that the sets SAT and TAUT have p-optimal proof systems, if and only if all sets in the Boolean hierarchy over NP have p-optimal proof systems which is a new characterization of a conjecture studied by Pudlák.

## 1 Introduction

This paper contributes to the study of proof systems initiated by Cook and Reckhow [11]. A proof system for a set  $L$  is a polynomial-time computable function  $f$  whose range is  $L$ . Cook and Reckhow motivate the study of proof systems with the  $\text{NP} = \text{coNP}$  question: they consider propositional proof systems (pps), i.e., proof systems for the set of propositional tautologies (TAUT). They show that there exists a pps with polynomially bounded proofs if and only if  $\text{NP} = \text{coNP}$ . This approach to the  $\text{NP} = \text{coNP}$  question is called the Cook-Reckhow program [9]. To obtain  $\text{NP} \neq \text{coNP}$  one can either show that optimal pps (i.e., pps with at most polynomially longer proofs than any other pps) do not exist or show that a specific pps is optimal and has a non-polynomial lower bound on the length of proofs. This connection led to the investigation of upper and lower bounds for different pps [20] as well as the existence of optimal and p-optimal<sup>1</sup> proof systems for general sets.

---

<sup>1</sup> A stronger notion of optimal. We write (p-)optimal when the statement holds using optimal as well as p-optimal.

The latter question was explicitly posed by Krajíček and Pudlák [21] in the context of finite consistency. They revealed the following connection between both concepts: optimal pps exist if and only if there is a finitely axiomatized theory  $S$  that proves for every finitely axiomatized theory  $T$  the statement “ $T$  has no proof of contradiction of length  $n$ ” by a proof of polynomial length in  $n$ . If optimal pps exist, then a weak version of Hilbert’s program is possible, i.e., proving the “consistency up to some feasible length of proofs” of all mathematical theories [24]. We refer to Krajíček [19] and Pudlák [26] for details on the relationship between proof systems and bounded arithmetic. More recently, Pudlák [25] draws new connections of (p-)optimal proof systems and statements about incompleteness in the finite domain.

Furthermore, proof systems have shown to be tightly connected to promise classes, especially pps to the class of disjoint NP-pairs, called DisjNP. Initiated by Razborov [27], who showed that the existence of p-optimal pps implies the existence of complete sets in DisjNP, many further connections were investigated. More generally, Köbler, Messner and Torán [18] show that the existence of p-optimal proof systems for sets of the polynomial-time hierarchy imply complete sets for promise classes like UP,  $\text{NP} \cap \text{coNP}$ , and BPP. Beyersdorff, Köbler, and Messner [7] and Pudlák [25] connect proof systems to function classes by showing that p-optimal proof systems for SAT imply complete sets for TFNP. Questions regarding non-deterministic function classes can be characterized by questions about proof systems [7]. Beyersdorff [3, 4, 5, 6], Beyersdorff and Sadowski [8] and Glaßer, Selman, and Zhang [13, 14] show further connections between pps and disjoint NP-pairs.

The above connections to important questions of complexity theory, bounded arithmetic, and promise classes motivate the investigation of the question “which sets do have optimal proof systems” posed by Messner [22]. Krajíček and Pudlák [21] were the first to study sufficient conditions for pps by proving that  $\text{NE} = \text{coNE}$  implies the existence of optimal pps and  $\text{E} = \text{NE}$  implies the existence of p-optimal pps. Köbler, Messner, and Torán [18] improve this result to  $\text{NEE} = \text{coNEE}$  for optimal pps and  $\text{EE} = \text{NEE}$  for p-optimal pps. Sadowski [28] shows different characterizations for the existence of optimal pps, e.g., the uniform enumerability of the class of all easy subsets of TAUT. In certain settings one can prove the existence of optimal proof systems for different classes: e.g., by allowing one bit of advice [10], considering randomized proof systems [16, 15], or using a weak notion of simulation [29].

Messner [22] shows that all nonempty<sup>2</sup> sets in P but not all sets in E have p-optimal proof systems. Similarly, all sets in NP but not all sets in coNE have optimal proof systems. Therefore, when going from smaller to larger complexity classes, there has to be a tipping point such that all sets contained in classes below this point have (p-)optimal proof systems, but some set contained in all classes above this point has no (p-)optimal proof systems. Unfortunately, oracle constructions tell us that for many classes between P and E (resp., NP and coNE) the following holds: with relativizable proofs one can neither prove nor refute that p-optimal (resp., optimal) proof systems exist (e.g. coNP [1, 21] and PSPACE [1, 12]). Thus, with the currently available means it is not possible to precisely locate this tipping point, but we can rule out certain regions for its location. For this, we investigate how the existence of (p-)optimal proof system for all sets of the class  $\mathcal{C}$  “translate upwards” to all sets of a class  $\mathcal{D}$  with  $\mathcal{C} \subseteq \mathcal{D}$ . This rules out tipping points between  $\mathcal{C}$  and  $\mathcal{D}$ .

---

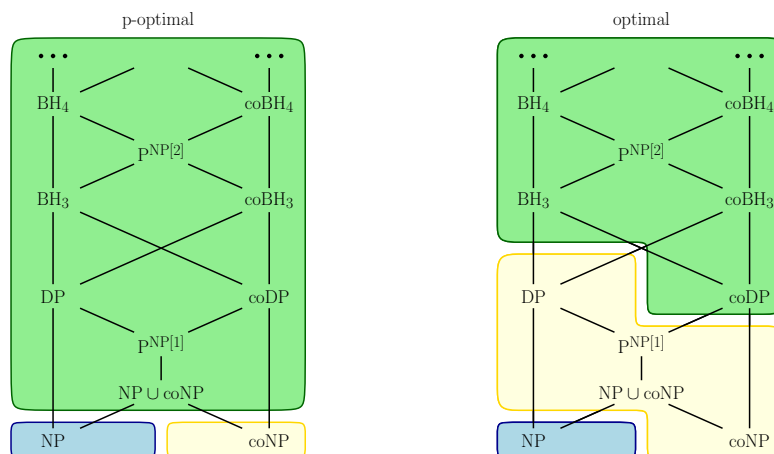

<sup>2</sup> By our definition, FP-functions are total, thus the empty set has no proof system. For the rest of this paper, we omit the word “nonempty” when referring to proof systems for all sets of a class, since this is only a technicality.

**Our Contribution.** Motivated by Messner’s general question, we study the existence of (p-)optimal proof systems for classes inside the Boolean hierarchy over NP. We use the expression “the class  $\mathcal{C}$  has (p-)optimal proof systems” for “all sets of a class  $\mathcal{C}$  have (p-)optimal proof systems”. We say that two classes  $\mathcal{C}$  and  $\mathcal{D}$  are equivalent with respect to (p-)optimal proof systems if  $\mathcal{C}$  has (p-)optimal proof systems if and only if  $\mathcal{D}$  has (p-)optimal proof systems.

For the classes of the Boolean hierarchy over NP, denoted by BH, we identify three equivalence classes for p-optimal proof systems and three other classes for optimal proof systems. We also show that the classes of the bounded query hierarchy over NP are all equivalent for p-optimal proof systems and we identify two equivalence classes for optimal proof systems. Moreover, we show that relativizable techniques cannot prove all identified equivalence classes to coincide. These results follow from our main theorems:

- (i) If DP has p-optimal proof systems, then coDP has p-optimal proof systems.
- (ii) There exists an oracle relative to which coNP has p-optimal proof systems and coDP does not have optimal proof systems.

Using the result by Köbler, Messner, and Torán that (p-)optimality is closed under intersection [18] and two oracles by Khaniki [17], we obtain the equivalence classes visualized in Figure 1, which cannot be proved to coincide with relativizable proofs.

■ **Figure 1** Equivalence classes for p-optimal proof systems (left) and optimal proof systems (right) in the Boolean hierarchy over NP and the bounded query hierarchy over NP.

This clarifies all questions regarding relativizably provable translations of (p-)optimal proof systems for classes in the Boolean hierarchy over NP and the bounded query hierarchy over NP. We cannot expect to prove any further translations with the currently available means, because for every such translation there is an oracle against it. So we are dealing with an interesting situation: while p-optimal proof systems for DP *relativizably imply* p-optimal proof systems for coDP, this does not hold for optimal proof systems. Similarly, all classes of the bounded query hierarchy over NP are equivalent with respect to p-optimal proof systems, but  $P^{NP[1]}$  and  $P^{NP[2]}$  cannot be shown to be equivalent with respect to optimal proof systems by a relativizable proof. The result drastically limits the potential locations of a tipping point in the BH and the bounded query hierarchy over NP. They can only occur between two classes belonging to two different equivalence classes.

Furthermore, our results provide a new perspective on an hypothesis related to feasible versions of Gödel’s incompleteness theorem: Pudlák [25] studies several conjectures about incompleteness in the finite domain by investigating the (un)provability of sentences of some

specific form in weak theories. These conjectures can also be expressed as the non-existence of complete sets in promise classes or non-existence of (p-)optimal proof systems for sets. Pudlák considers the conjecture  $\text{CON} \vee \text{SAT}$  stating that  $\text{TAUT}$  does not have p-optimal proof systems or  $\text{SAT}$  does not have p-optimal proof systems. Khaniki [17] proves this conjecture to be equivalent to  $\text{RFN}_1$ , which is another conjecture considered by Pudlák. Our results show that both conjectures are equivalent to the statement that  $\text{BH}$  does not have p-optimal proof systems.

## 2 Preliminaries

Let  $\Sigma = \{0, 1\}$  be the default alphabet and  $\Sigma^*$  be the set of finite words over  $\Sigma$ . We call subsets of  $\Sigma^*$  languages and sets of languages classes. We denote the length of a word  $w \in \Sigma^*$  by  $|w|$ . The  $i$ -th letter of a word  $w$  for  $0 \leq i < |w|$  is denoted as  $w(i)$ , i.e.,  $w = w(0)w(1) \cdots w(|w| - 1)$ .

The set of all (positive) natural numbers is denoted as  $\mathbb{N}$  ( $\mathbb{N}^+$ ). We write the empty set as  $\emptyset$ . We identify  $\Sigma^*$  with  $\mathbb{N}$  through the polynomial time computable and invertible bijection  $\Sigma^* \rightarrow \mathbb{N}; w \mapsto \sum_{i < |w|} (1 + w(i))2^i$ . This is a variant of the dyadic representation. Thus, we can treat words from  $\Sigma^*$  as numbers from  $\mathbb{N}$  and vice versa, which allows us to use notations, relations and operations of words for numbers and vice versa (e.g. we can define the length of a number by this). We resolve the ambiguity of  $0^i$  and  $1^i$  by always interpreting them as words from  $\Sigma^*$ . The cardinality of a set  $A$  is denoted as  $|A|_c$ . For  $\circ \in \{<, \leq, =, \geq, >\}$ , a set  $A \subseteq \Sigma^*$  and a number  $n \in \mathbb{N}$  we define  $A^{\circ n} = \{w \in A \mid |w| \circ n\}$ . For a clearer notation we use  $\Sigma^{\circ n}$  as  $\Sigma^{*\circ n}$  and  $\Sigma^n$  for  $\Sigma^{=n}$ . The operators  $\cup$ ,  $\cap$ , and  $\setminus$  denote the union, intersection and set-difference. We denote the complement of a set  $A$  relative to  $\Sigma^*$  as  $\bar{A} = \Sigma^* \setminus A$ .

The image of a function  $f$  is denoted as  $\text{img}(f)$ . Let  $\langle \cdot \rangle: \bigcup_{i \geq 0} \mathbb{N}^i \rightarrow \mathbb{N}$  be an injective polynomial time computable and invertible pairing function such that  $|\langle u_1, \dots, u_n \rangle| = 2(|u_1| + \dots + |u_n| + n)$ . The logarithm to the base 2 is denoted as  $\log$ . Furthermore, we define polynomial functions  $p_i: \mathbb{N} \rightarrow \mathbb{N}$  for  $i \in \mathbb{N}^+$  by  $p_i(x) = x^i + i$ .

We use the default model of a Turing machine in the deterministic as well as in the non-deterministic variation, abbreviated by DTM and NTM respectively. The language decided by a Turing machine  $M$  is denoted as  $L(M)$ . For a number  $s \in \mathbb{N}$  the language of words that are accepted by a Turing machine  $M$  in  $s$  computation steps is denoted as  $L^s(M)$ . We use Turing transducer to compute functions. For a Turing transducer  $F$  we write  $F(x) = y$  when on input  $x$  the transducer outputs  $y$ . A Turing transducer  $F$  computes a total function and we sometimes refer to the function computed by  $F$  as “the function  $F$ ”. Let  $\{F_i\}_{i \in \mathbb{N}}$  and  $\{G_i\}_{i \in \mathbb{N}}$  be standard enumerations of polynomial time Turing transducers. Let  $\{N_i\}_{i \in \mathbb{N}}$  be a standard enumeration of non-deterministic polynomial time Turing machines with the special property that  $N_0$  is the machine that always rejects and  $N_1$  is the machine that always accepts, that is  $L(N_0) = \emptyset$  and  $L(N_1) = \mathbb{N}$ . The runtime of  $F_i$ ,  $G_i$  and  $N_i$  is bounded by  $p_i$ .

► **Proposition 1.** *There is a Turing machine  $M$  and a Turing transducer  $F$  such that for all  $i, s, x \in \mathbb{N}$  the following properties hold:*

- $\langle i, x, 0^s \rangle \in L(M) \Leftrightarrow x \in L^s(N_i)$
- $F(\langle i, x, 0^s \rangle) = \begin{cases} \langle 1, F_i(x) \rangle & \text{if } F_i(x) \text{ stops within } s \text{ steps} \\ \langle 0, 0 \rangle & \text{else} \end{cases}$
- Both machines run in time  $O(|i|s \log s)$ .

FP, P, and NP denote standard complexity classes [23]. For a class  $\mathcal{C}$  define  $\text{co}\mathcal{C} = \{A \subseteq \Sigma^* \mid \overline{A} \in \mathcal{C}\}$ . We define the Boolean hierarchy over NP inductively. Let  $\mathcal{C}$  and  $\mathcal{D}$  be arbitrary complexity classes. First, we define boolean operators on classes:

$$\begin{aligned}\mathcal{C} \wedge \mathcal{D} &= \{A \cap B \mid A \in \mathcal{C} \wedge B \in \mathcal{D}\} \\ \mathcal{C} \vee \mathcal{D} &= \{A \cup B \mid A \in \mathcal{C} \vee B \in \mathcal{D}\}\end{aligned}$$

Then  $\text{BH}_1 = \text{NP}$ ,  $\text{BH}_{2k} = \text{coNP} \wedge \text{BH}_{2k-1}$ ,  $\text{BH}_{2k+1} = \text{NP} \vee \text{BH}_{2k}$ , and  $\text{BH} = \bigcup_{k \geq 1} \text{BH}_k$  where  $\text{BH}_2$  is called DP and BH is called Boolean hierarchy over NP. We want to emphasize that  $\text{DP} = \text{NP} \wedge \text{coNP}$  and  $\text{coDP} = \text{NP} \vee \text{coNP}$ . Wagner [30] showed that  $\text{BH}_k \subseteq \text{BH}_{k+1}$  and  $\text{BH}_k \subseteq \text{coBH}_{k+1}$ . The classes  $\text{P}^{\text{NP}[k]}$  for  $k \in \mathbb{N}^+$  contain all sets that can be accepted by a polynomial time Turing machine that queries at most  $k$  elements from an NP-set. The resulting hierarchy  $\text{P}^{\text{NP}[1]}, \text{P}^{\text{NP}[2]}, \dots$  is called bounded query hierarchy over NP. Beigel [2] shows that  $\text{BH}_{2^k-1} \cup \text{coBH}_{2^k-1} \subseteq \text{P}^{\text{NP}[k]} \subseteq \text{BH}_{2^k} \cap \text{coBH}_{2^k}$ .

We use the common polynomial time many-one reducibility for sets  $A, B \subseteq \Sigma^*$ , i.e.,  $A \leq_m^p B$  if there exists an  $f \in \text{FP}$  such that  $x \in A \Leftrightarrow f(x) \in B$ . For a class  $\mathcal{C}$  and some problem  $A$ , we say that  $A$  is hard for  $\mathcal{C}$  if for all  $B \in \mathcal{C}$  it holds  $B \leq_m^p A$ . The set  $A$  is called complete for  $\mathcal{C}$  if  $A \in \mathcal{C}$  and  $A$  is hard for  $\mathcal{C}$ . We define the following complete problems for NP and DP.

$$\begin{aligned}\mathcal{C} &= \{\langle 0^i, x, 0^p \rangle \mid i \in \mathbb{N}, x \in \Sigma^* \text{ and } x \in L^p(N_i)\} \\ \mathcal{D} &= \{\langle 0^i, 0^j, x, 0^p \rangle \mid i, j \in \mathbb{N}, x \in \Sigma^* \text{ and } x \in L^p(N_i) \cap \overline{L^p(N_j)}\} \\ \mathcal{D}' &= \mathcal{D} \cup \{w \mid \nexists i, j \in \mathbb{N}, x \in \Sigma^* : \langle 0^i, 0^j, x, 0^p \rangle = w\}\end{aligned}$$

It is easy to see that  $\mathcal{C}$  is NP-complete and  $\mathcal{D}$  and  $\mathcal{D}'$  are DP-complete. Furthermore, their complements are complete for coNP and coDP respectively. The purpose of  $\mathcal{D}'$  is that  $\overline{\mathcal{D}'}$  consists only of words of the form  $\langle 0^i, 0^j, x, 0^p \rangle$ , which simplifies some arguments in section 3. Let  $N_{\mathcal{C}}$  denote the polynomial time machine with  $L(N_{\mathcal{C}}) = \mathcal{C}$ .

We use proof systems for sets defined by Cook and Reckhow [11]. They define a function  $f \in \text{FP}$  to be a proof system for  $\text{img}(f)$ . Furthermore:

- A proof system  $g$  is (p-)simulated by a proof system  $f$ , denoted by  $g \leq f$  (resp.,  $g \leq^p f$ ), if there exists a total function  $\pi$  (resp.,  $\pi \in \text{FP}$ ) and a polynomial  $p$  such that  $|\pi(x)| \leq p(|x|)$  and  $f(\pi(x)) = g(x)$  for all  $x \in \Sigma^*$ . In this context the function  $\pi$  is called simulation function. Note that  $g \leq^p f$  implies  $g \leq f$ .
- A proof system  $f$  is (p-)optimal for  $\text{img}(f)$ , if  $g \leq f$  (resp.,  $g \leq^p f$ ) for all  $g \in \text{FP}$  with  $\text{img}(g) = \text{img}(f)$ .
- A complexity class  $\mathcal{C}$  has (p-)optimal proof systems, if every  $A \in \mathcal{C}$  with  $A \neq \emptyset$  has a (p-)optimal proof system.
- We say that (p-)optimal proof systems translate from a class  $\mathcal{C}$  to  $\mathcal{D}$  if the existence of (p-)optimal proof systems for  $\mathcal{C}$  implies their existence for  $\mathcal{D}$ .

By the following result of Köbler, Messner and Torán [18], we can prove or refute the existence of (p-)optimal proof systems for a class  $\mathcal{C}$  by proving or refuting the existence of such proof systems for a complete set of  $\mathcal{C}$ .

► **Proposition 2** ([18]). *If  $A \subseteq \Sigma^*$  has a (p-)optimal proof system and  $\emptyset \neq B \leq_m^p A$ , then  $B$  has a (p-)optimal proof system.*

► **Corollary 3.** *If  $A \subseteq \Sigma^*$  is a hard set for some class  $\mathcal{C}$  and  $A$  has a (p-)optimal proof system, then  $\mathcal{C}$  has (p-)optimal proof systems.*

Furthermore, it was shown by Köbler, Messner, and Torán [18] that the class of sets having (p-)optimal proof systems is closed under intersection. This result can easily be extended to the operator  $\wedge$  for complexity classes.

► **Proposition 4** ([18]). *If  $A, B \subseteq \Sigma^*$ ,  $A \cap B \neq \emptyset$  and both sets have a (p-)optimal proof system, then  $A \cap B$  has a (p-)optimal proof system.*

► **Corollary 5.** *If two classes  $\mathcal{C}$  and  $\mathcal{D}$  have (p-)optimal proof systems, then  $\mathcal{C} \wedge \mathcal{D}$  has (p-)optimal proof systems.*

Finally, every (p-)optimal proof system can be transformed into a (p-)optimal proof system that runs in linear time by polynomially padding the proofs.

► **Proposition 6.** *If  $f$  is a (p-)optimal proof system for  $A \subseteq \Sigma$ , then there is a (p-)optimal proof system  $g$  for  $A$  that runs in linear time.*

### 3 Translation of P-Optimal Proof Systems from DP to coDP

In this chapter we show that p-optimal proof systems for DP imply p-optimal proof systems for coDP. This proof is based on machine simulation which is a relativizable proof technique. Thus, the following theorem also holds in the presence of an arbitrary oracle  $O$ .

► **Theorem 7.** *If there exists a p-optimal proof system for  $D$ , then there exists a p-optimal proof system for  $\overline{D}$ .*

We start by sketching the key idea used in the proof. Our approach needs some technique to verify that a given instance is in  $\overline{D}$ . There is no known way to decide  $\overline{D}$  in polynomial time, but we can use the p-optimal proof system for  $D$  for this verification. We define a function  $f' : \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$  such that there is a polynomial-time-computable encoding  $c : \mathbb{N} \rightarrow \mathbb{N}$  with  $f'(a, c(x)) \in D$  if and only if  $F_a(x) \in \overline{D}$  for all  $a \in \mathbb{N}$  and  $x \in \mathbb{N}$ . Furthermore,  $f'(a, x)$  can be computed in time  $|x|^{O(a)}$ . We derive a class of functions  $\{f'_a\}_{a \in \mathbb{N}}$  from  $f'$  by fixing the first input to  $a$ . Note that  $f'_a$  runs in polynomial time for a fixed  $a \in \mathbb{N}$  and that  $f'_a$  is a proof system for  $D$  if and only if  $F_a$  is a proof system for  $\overline{D}$ . Now, we define a machine that uses an additional input to verify  $F_a(x) \in \overline{D}$ . The inputs of the machine are  $a, x, b$  and it accepts if and only if  $f(F_b(x)) = f'_a(x)$  for a p-optimal proof system  $f$  of  $D$ . So, if  $F_a$  is a proof system for  $\overline{D}$ , we know  $f'_a$  is a proof system for  $D$ . Thus, by the fact that  $f$  is p-optimal, there is a  $b \in \mathbb{N}$  such that  $f(F_b(x)) = f'_a(x)$  for all  $x \in \mathbb{N}$ . Thus, when knowing the value  $b$ , the machine can verify  $F_a(x) \in \overline{D}$  for all  $x \in \mathbb{N}$  for a proof system  $F_a(x)$  for  $\overline{D}$  by accepting  $f(F_b(c(x))) = f'_a(c(x))$ . On the other hand if  $F_a(x) \notin \overline{D}$  there is no  $b$  such that  $f(F_b(c(x))) = f'_a(c(x))$  because  $f'_a(c(x)) \notin D = \text{img}(f)$ .

**Proof.** We start by defining an NTM  $A$  that checks for given  $a, y'$  whether  $F_a(y') = \langle i, j, x', 0^p \rangle \in \overline{D}$ . Since a deterministic polynomial-time computation cannot check every possible path of a coNP machine  $N_j$ ,  $A$  gets a path  $y$  of  $N_j$  as an additional input and has the property that it accepts for all possible paths  $y$  if and only if  $F_a(y') \in \overline{D}$ . Arguing over all  $y'$  this means if  $F_a$  is a proof system for  $\overline{D}$ , then for all  $y'$  and all corresponding paths  $y$  the machine  $A$  accepts on input  $a, y', y$ .

Let  $f$  be a p-optimal proof system for  $D$ . Without loss of generality we assume  $f(x)$  can be computed in  $O(|x|)$  time by Proposition 6. We define  $A$  on input  $x$  as follows.

- (i) Check whether  $x = \langle a, y, y' \rangle$  for some  $a \in \mathbb{N}$  and  $y, y' \in \Sigma^*$ , otherwise reject.
- (ii) Check whether  $F_a(y') = \langle i, j, x', 0^p \rangle$  with  $i, j, p \in \mathbb{N}$  and  $x' \in \Sigma^*$  and whether  $y \in \Sigma^p$ , otherwise reject.

- (iii) Accept if  $N_i(x')$  does not accept on path  $y$  within  $p$  steps.
- (iv) Simulate the first  $p$  steps of  $N_j(x')$ .
- (v) Accept if the simulation of  $N_j(x')$  accepted within the first  $p$  steps, otherwise reject.

► **Observation 8.**  $A(x)$  runs in time  $O(|x|^{3a})$  for  $x = \langle a, y, y' \rangle$ .

**Proof.** Checking whether  $x$  has the required format is possible in linear time. By Proposition 1,  $F_a(y')$  can be computed in time

$$\begin{aligned} O(|a| \cdot (|y'|^a + a) \log(|y'|^a + a)) &\subseteq O(|a| \cdot (|y'|^a + a)^2) \subseteq O((|x|^a + a)^3) \\ &\subseteq O(|x|^{3a} + a^3) \subseteq O(|x|^{3a}). \end{aligned}$$

The first  $p$  steps of the path  $y$  of  $N_i(x')$  can be simulated in time

$$O(|i| \cdot p \log p) \subseteq O(|F_a(y')| \cdot |F_a(y')|^2) \subseteq O(|x|^{3a})$$

for all  $a \in \mathbb{N}$ . The computation  $N_j(x')$  can be simulated in  $O(|j| \cdot p \log p) \subseteq O(|x|^{3a})$  time for all  $a \in \mathbb{N}$ . ◀

► **Claim 9.** Let  $F_a(y') = \langle i, j, x', 0^p \rangle$ . Then  $F_a(y') \in \overline{D'} \Leftrightarrow \forall y \in \Sigma^p : \langle a, y, y' \rangle \in L(A)$ .

**Proof.** First we show " $\Rightarrow$ ". We consider two cases:

- Suppose  $x' \in L^p(N_i)$ . By  $\langle i, j, x', 0^p \rangle \in \overline{D'}$ , it holds  $x' \in L^p(N_j)$ . The machine  $A$  on input  $\langle a, y, y' \rangle$  with  $F_a(y') = \langle i, j, x', 0^p \rangle \in \overline{D'}$  and  $y \in \Sigma^p$  rejects only, if the non-deterministic check in step (iv) fails. But this is impossible since  $x' \in L^p(N_j)$ .
- Suppose  $x' \notin L^p(N_i)$ . In this case  $N_i(x')$  does not accept within  $p$  steps for all paths  $y \in \Sigma^p$ . Thus, the machine accepts in step (iii).

Now, we show " $\Leftarrow$ ". Again, we distinguish two cases:

- Suppose  $A(\langle a, y, y' \rangle)$  accepts in step (iii) for all  $y \in \Sigma^p$ . This implies that  $x' \notin L^p(N_i)$ . Thus,  $\langle i, j, x', 0^p \rangle \in \overline{D'}$ .
- If  $A$  accepts but not in step (iii), we conclude it accepts in step (v). Hence, it holds  $x' \in L^p(N_j)$  and  $\langle i, j, x', 0^p \rangle \in \overline{D'}$ . ◀

We want to define functions  $f_a$  in such a way that  $f_a$  is a proof system for  $D$  if  $F_a$  is a proof system for  $\overline{D'}$ . For this, we can exploit the relationship of  $A$  to proof systems of  $\overline{D'}$  shown in Claim 9. Specifically,  $f_a$  trusts that  $A(\langle a, y, y' \rangle)$  accepts for specific  $y$  and  $y'$  (note that the accepting behavior of  $A$  has influence on  $D$ ), which is equivalent to  $F_a$  being a proof system for  $\overline{D'}$ .

Choose  $a_1 \in \mathbb{N}$  such that  $N_{a_1} = A$ . Let  $k_A \in \mathbb{N}^+$  be a constant such that  $A(x)$  runs in time  $k_A|x|^{3a} + k_A$ . Recall that  $N_0$  always rejects. We define a function  $f^* : \mathbb{N} \rightarrow \mathbb{N}$ :

$$f^*(x) = \begin{cases} \langle a_1, 0, \langle a, y, y' \rangle, 0^{k_A|x|^{3a}+k_A} \rangle & \text{if } x = \langle a, y, y' \rangle 0 \wedge F_a(y') = \langle i, j, x', 0^p \rangle \\ & \wedge y \in \Sigma^p \\ f(x') & \text{if } x = x' 1 \\ f(0) & \text{else} \end{cases}$$

► **Observation 10.**  $f^*(x)$  runs in  $O(|x|^{3a})$  time for  $x = \langle a, y, y' \rangle 0$ .

**Proof.** The case distinction for the first case is possible in  $O(|x|^{3a})$  time because computing  $F_a(y')$  is possible in that time. The output of the first case with exception of the unary runtime parameter  $0^{k_A \cdot (|x|^{3a}) + k_A}$  is possible in linear time. The unary runtime parameter can be computed in  $O(|x|^{3a})$  time. The output of the other cases is possible in linear time. ◀

We define a function  $f_a$  that is obtained from  $f^*$  by fixing an index  $a \in \mathbb{N}$  of a polynomial-time function  $F_a$ .

$$f_a(x) = \begin{cases} f^*(\langle a, y, y' \rangle 0) & \text{if } x = \langle a, y, y' \rangle 0 \\ f(x') & \text{if } x = x' 1 \\ f(0) & \text{else} \end{cases}$$

► **Observation 11.** For  $a \in \mathbb{N}$  and  $y, y' \in \Sigma^*$  it holds that  $f_a(\langle a, y, y' \rangle 0) = f^*(\langle a, y, y' \rangle 0)$ .

► **Observation 12.** For a fixed  $a \in \mathbb{N}$  the function  $f_a(x)$  can be computed in polynomial time.

**Proof.** This follows from Observation 10 and the linear runtime of  $f$ . ◀

▷ **Claim 13.** Let  $a \in \mathbb{N}$  and  $y' \in \Sigma^*$  such that  $F_a(y') = \langle i, j, x', 0^p \rangle \notin \overline{D'}$ . Then there is a  $y \in \Sigma^p$ , such that  $f_a(\langle a, y, y' \rangle 0) \notin D$ .

**Proof.** By Claim 9 we conclude the existence of a  $y \in \Sigma^p$  such that  $A(\langle a, y, y' \rangle)$  rejects. This implies  $f_a(\langle a, y, y' \rangle 0) = \langle a_1, 0, \langle a, y, y' \rangle, 0^{k_A|x|^{3a}+k_A} \rangle \notin D$ . ◀

▷ **Claim 14.** Let  $a \in \mathbb{N}$ . Then  $\text{img}(F_a) \subseteq \overline{D'} \Leftrightarrow \text{img}(f_a) = D$ .

**Proof.** First we show " $\Rightarrow$ ".  $D \subseteq \text{img}(f_a)$  holds because  $\text{img}(f) \subseteq \text{img}(f_a)$  and  $f$  is a proof system for  $D$ . Let  $x \in \Sigma^*$ . In the bottom two cases of  $f_a$  and  $f^*$  it is easy to see  $f_a(x) \in D$  and  $f^*(x) \in D$ . So we can assume  $x = \langle a, y, y' \rangle 0$  with  $F_a(y') = \langle i, j, x', 0^p \rangle$  and  $y \in \Sigma^p$ . Since  $\text{img}(F_a) \subseteq \overline{D'}$ , it holds  $\langle i, j, x', 0^p \rangle \in \overline{D'}$ . By Claim 9 we obtain that  $\langle a, y, y' \rangle \in L(A)$  for all  $y \in \Sigma^p$ . Thus,  $f_a(x) = f^*(\langle a, y, y' \rangle 0) = \langle a_1, 0, \langle a, y, y' \rangle, 0^{k_A|x|^{3a}+k_A} \rangle \in D$  since for all  $y \in \Sigma^p$ ,  $N_{a_1}(\langle a, y, y' \rangle)$  accepts,  $N_0(\langle a, y, y' \rangle)$  rejects and  $|\langle a, y, y' \rangle| \leq |x|$ .

" $\Leftarrow$ " follows directly as the contraposition of Claim 13. ◀

We want to define another NTM  $B$  that checks for given  $a, y'$  whether  $F_a(y') \in \overline{D'}$ . To achieve this we use Claims 13 and 14.  $B$  checks for all  $y \in \Sigma^p$  whether  $f(F_b(\langle a, y, y' \rangle 0)) = f_a(\langle a, y, y' \rangle 0)$  on input  $a, b, y'$ . So if  $F_a$  is a proof system for  $\overline{D'}$ , then there is a  $b$  such that  $B(a, b, y')$  rejects for all  $y'$ . Furthermore, if  $F_a(y') \notin \overline{D'}$ , then  $B(a, b, y')$  accepts for all  $b$ .  $B(x)$  operates as follows.

- (i) Check whether  $x = \langle a, b, y' \rangle$  for some  $a, b \in \mathbb{N}$  and  $y' \in \Sigma^*$ , otherwise reject.
- (ii) Check whether  $F_a(y') = \langle i, j, x', 0^p \rangle$  for some  $i, j, p \in \mathbb{N}$  and  $x' \in \Sigma^*$ , otherwise reject.
- (iii) Branch non-deterministically every  $y \in \Sigma^p$ .
- (iv) Accept if  $f(F_b(\langle a, y, y' \rangle 0)) \neq f_a(\langle a, y, y' \rangle 0)$ .
- (v) Reject.

► **Observation 15.**  $B(x)$  runs in time  $O(|x|^{9a^2b})$  for  $x = \langle a, b, y' \rangle$ .

**Proof.** Checking whether the input is formatted correctly is possible in linear time.  $F_a(y')$  can be computed in  $O(|a| \cdot (|y'|^a + a) \log(|y'|^a + a)) \subseteq O(|x|^{3a})$  time. We also observe that  $|F_a(y')| \leq |y'|^a + a$ . In line (iv) it holds that  $|F_a(y')| \geq 2p \geq 2|y|$  and in line 1 it holds that  $2|a| + 2|y'| + 8 \leq |x|$ , and therefore,

$$|\langle a, y, y' \rangle 0| = 2(|a| + |y| + |y'| + 3) + 1 \leq |F_a(y')| + |x| \leq |x|^a + a + |x| \leq |x|^{a+1} + a.$$

Thus, by Observation 10, computing  $f_a(\langle a, y, y' \rangle 0)$  is possible in time

$$O((|x|^{a+1} + a)^{3a}) \subseteq O(|x|^{a^2+3a}) \subseteq O(|x|^{3a^2+6a}) \subseteq O(|x|^{9a^2}).$$

The value  $F_b(\langle a, y, y' \rangle 0)$  can be computed in time

$$\begin{aligned} O(|b| \cdot ((|x|^{a+1} + a)^b + b) \log((|x|^{a+1} + a)^b + b)) &\subseteq O(|b| \cdot (|x|^{a+2})^b + b) \\ &\quad \cdot \log((|x|^{a+2})^b + b) \\ &\subseteq O(|b| \cdot (|x|^{ab+2b} + b) \log(|x|^{ab+2b} + b)) \\ &\subseteq O(|b| \cdot (|x|^{ab+2b+1}) \log(|x|^{ab+2b+1})) \\ &\subseteq O(|b| \cdot |x|^{2ab+4b+1}) \subseteq O(|x|^{2ab+4b+2}). \end{aligned}$$

In particular  $|F_b(\langle a, y, y' \rangle 0)| \in O(|x|^{2ab+4b+2})$  and hence the computation of  $f(F_b(\langle a, y, y' \rangle 0))$  is possible in time  $O(|x|^{2ab+4b+2})$ . We simplify the sum of these runtimes.

$$O(|x|^{3a} + |x|^{9a^2} + |x|^{2ab+4b+2}) \subseteq O(|x|^{9a^2b}) \quad \blacktriangleleft$$

▷ **Claim 16.** Let  $a \in \mathbb{N}$  and  $y' \in \Sigma^*$ , such that  $F_a(y') = \langle i, j, x', 0^p \rangle \notin \overline{D'}$ . Then for all  $b \in \mathbb{N}$  it holds that  $\langle a, b, y' \rangle \in L(B)$ .

*Proof.* By Claim 13 there is a  $y \in \Sigma^p$  such that  $f_a(\langle a, y, y' \rangle 0) \notin D = \text{img}(f)$ . Thus,  $B$  accepts in step (iv), because  $\text{img}(f) = D$ .  $\blacktriangleleft$

▷ **Claim 17.** Let  $a \in \mathbb{N}$ , such that  $\text{img}(F_a) \subseteq \overline{D'}$ . Then, there is some  $b \in \mathbb{N}$ , such that for all  $y' \in \Sigma^*$  it holds that  $\langle a, b, y' \rangle \notin L(B)$ .

*Proof.* By Claim 14 and Observation 12, we know that  $f_a$  is a proof system for  $D$ . Since  $f$  is a p-optimal proof system for  $D$ , there exists some  $b \in \mathbb{N}$ , such that for all  $\hat{x} \in \Sigma^*$  it holds that  $f_a(\hat{x}) = f(F_b(\hat{x}))$ . Thus, the computation  $B(\langle a, b, y' \rangle)$  cannot accept in step (iv) independent of  $y'$ . Hence, the machine rejects.  $\blacktriangleleft$

Now, we define a function  $g_{a,b}$  for every pair of possible proof system  $F_a$  and possible simulation function  $F_b$ . Similarly to  $f_a$ , the function  $g_{a,b}$  trusts that  $B(\langle a, b, y' \rangle)$  accepts for all  $y'$  (note that the accepting behavior of  $B$  has influence on  $D$ ). If  $F_a$  is a proof system for  $\overline{D'}$ , then there is a  $b \in \mathbb{N}$  such that  $g_{a,b}$  is a proof system for  $D$  because the machine  $B$  accepts on input  $a, b, y'$  for all  $y' \in \Sigma^*$ . For  $F_a(y') \notin \overline{D'}$ , we know there is no  $b \in \mathbb{N}$  such that  $B$  accepts on input  $a, b, y'$ . Hence, the corresponding output of  $g_{a,b}$  is not in  $D$ .

Let  $b_1$  be the index of the NTM  $B$ , that is  $N_{b_1} = B$ . Furthermore, let  $k_B \in \mathbb{N}^+$  be a constant such that  $B(x)$  runs in time  $k_B|x|^{9a^2b} + k_B$  for all  $x \in \Sigma^*$ . Recall that  $N_1$  always accepts. We define a function  $g : \mathbb{N} \rightarrow \mathbb{N}$  whose input consists of two indices  $a, b \in \mathbb{N}$  of polynomial-time functions  $F_a, F_b$  and a proof  $y' \in \Sigma^*$ .

$$g(x) = \begin{cases} \langle 1, b_1, \langle a, b, y' \rangle, 0^{k_B|x|^{9a^2b} + k_B} \rangle & \text{if } x = \langle a, b, y' \rangle 0 \\ f(x') & \text{if } x = x' 1 \\ f(0) & \text{else} \end{cases}$$

► **Observation 18.**  $g(x)$  runs in  $O(|x|^{9a^2b})$  time for  $x = \langle a, b, y' \rangle 0$ .

**Proof.** Checking whether the input is formatted correctly is possible in linear time. Furthermore, the output with exception of the last entry of the list can be computed in linear time. The string  $0^{k_B|x|^{9a^2b} + k_B}$  can be computed in  $O(|x|^{9a^2b})$  time.  $\blacktriangleleft$

## 44:10 Upward Translation of (P-)Optimal Proof Systems in the Boolean Hierarchy over NP

We define a function  $g_{a,b} : \mathbb{N} \rightarrow \mathbb{N}$  that is obtained from  $g$  by fixing two indices  $a, b \in \mathbb{N}$  of polynomial-time functions  $F_a, F_b$ .

$$g_{a,b}(x) = \begin{cases} g(\langle a, b, y' \rangle 0) & \text{if } x = \langle a, b, y' \rangle 0 \\ f(x') & \text{if } x = x' 1 \\ f(0) & \text{else} \end{cases}$$

► **Observation 19.** For  $x = \langle a, b, y' \rangle 0$  it holds that  $g(x) = g_{a,b}(x)$ .

► **Observation 20.** For fixed  $a, b \in \mathbb{N}$  the function  $g_{a,b}(x)$  can be computed in polynomial time.

**Proof.** This follows directly from Observation 18 and the linear runtime of  $f$ . ◀

▷ **Claim 21.** Let  $a \in \mathbb{N}$  and  $y' \in \Sigma^*$  such that  $F_a(y') = \langle i, j, x', 0^p \rangle \notin \overline{D'}$ . Then for all  $b \in \mathbb{N}$  it holds that  $g_{a,b}(\langle a, b, y' \rangle 0) \notin D$ .

**Proof.** By Claim 16 we know that for all  $b \in \mathbb{N}$  the computation  $B(\langle a, b, y' \rangle)$  accepts. This implies  $g_{a,b}(\langle a, b, y' \rangle 0) = \langle 1, b_1, \langle a, b, y' \rangle, 0^{k_B |x|^{9a^2b} + k_B} \rangle \notin D$ . ◀

▷ **Claim 22.** Let  $a \in \mathbb{N}$  such that  $\text{img}(F_a) \subseteq \overline{D'}$ . Then there is some  $b \in \mathbb{N}$  with  $\text{img}(g_{a,b}) = D$ .

**Proof.** Choose  $b \in \mathbb{N}$  according to Claim 17. Then  $D = \text{img}(f) \subseteq \text{img}(g_{a,b})$  because  $f$  is a proof system for  $D$ . Let  $x \in \Sigma^*$ . In the bottom two cases of  $g_{a,b}$  and  $g$  we have  $g_{a,b}(x) \in D$  and  $g(x) \in D$ . So we can assume  $x = \langle a, b, y' \rangle 0$  and  $g_{a,b}(x) = \langle 1, b_1, \langle a, b, y' \rangle, 0^{k_B |x|^{9a^2b} + k_B} \rangle$ . By the choice of  $b$ , it holds  $\langle a, b, y' \rangle \notin L(B)$ . By Observation 15 and the choice of  $k_B$ ,  $B(\langle a, b, y' \rangle)$  runs in time  $k_B |\langle a, b, y' \rangle|^{9a^2b} + k_B \leq k_B |x|^{9a^2b} + k_B$ . Therefore,  $\langle 1, b_1, \langle a, b, y' \rangle, 0^{k_B |x|^{9a^2b} + k_B} \rangle \in D$  and hence  $g_{a,b}(x) \in D$ . This shows  $\text{img}(g_{a,b}) \subseteq D$ . ◀

Finally, we define the p-optimal proof system  $h$  for  $\overline{D'}$ . The key difficulty is that  $h$  wants to output  $F_a(y')$  for all  $a$  and  $y'$  using a short proof only when  $F_a$  is a proof system for  $\overline{D'}$ . To do this  $h$  must be able to check this property efficiently. We can do this as follows: if  $f(F_c(\langle a, b, y' \rangle)) = g_{a,b}(\langle a, b, y' \rangle)$ , then we output  $F_a(y')$  and otherwise some arbitrary word from  $\overline{D'}$ . If  $F_a(y') \notin \overline{D'}$ , we know that there is no  $b \in \mathbb{N}$  such that the corresponding output of  $g_{a,b}$  is in  $D$  and the check correctly fails and  $F_a(y')$  is not outputted. By contraposition we observe that we output  $F_a(y')$  only if it is in  $\overline{D'}$ . Hence,  $h$  is a proof system for  $\overline{D'}$ . Lastly, we show that  $h$  p-simulates all proof systems for  $\overline{D'}$ . Let  $F_a$  be an arbitrary proof system for  $\overline{D'}$ . Then there is a  $b \in \mathbb{N}$  such that  $g_{a,b}$  is a proof system for  $D$ . Let  $c \in \mathbb{N}$  be such that  $f$  p-simulates  $g_{a,b}$  with the function  $F_c$ . So, for all  $y' \in \mathbb{N}$  the function  $h$  outputs  $F_a(y')$  for the input to  $h$  corresponding to  $a, b, c, y'$ . Also this input is short in  $a, b, c, y'$  and can be computed in polynomial time in these parameters.

Let  $h' : \mathbb{N} \rightarrow \mathbb{N}$  be a linear time proof system for  $\overline{D'}$ . We define a function  $h : \mathbb{N} \rightarrow \mathbb{N}$ .

$$h(x) = \begin{cases} \langle i, j, x', 0^p \rangle & \text{if } x = \langle a, b, c, \langle a, b, y' \rangle 0, 0^{k_B \cdot |\langle a, b, y' \rangle|^{9a^2b} + k_B}, 0^{|c| \cdot (|\langle a, b, y' \rangle|^{c+c^2})} 0 \rangle \wedge \\ & f(F_c(\langle a, b, y' \rangle 0)) = g_{a,b}(\langle a, b, y' \rangle 0) \wedge \\ & F_a(y') = \langle i, j, x', 0^p \rangle \\ h'(x') & \text{if } x = x' 1 \\ h'(0) & \text{else} \end{cases}$$

► **Observation 23.**  $h(x)$  runs in time  $O(|x|)$ .

**Proof.** The bottom two cases are trivial. For the first case we observe that checking, whether the input is formatted correctly, can be done in linear time. The part  $0^{k_B \cdot \langle a, b, y' \rangle 0^{9a^2b + k_B}}$  can be checked in linear time by iterated multiplication. The computation  $F_a(y')$  can be simulated in  $O(|a| \cdot (|y'|^a + a) \log(|y'|^a + a)) \subseteq O((|y'|^a + a)^3) \subseteq O(|y'|^{3a}) \subseteq O(|x|)$  time. The computation  $f(F_c(\langle a, b, y' \rangle 0))$  can be simulated in  $O(|c| \cdot (|\langle a, b, y' \rangle 0|^c + c) \log(|\langle a, b, y' \rangle 0|^c + c)) \subseteq O(|x|)$  time and  $g_{a,b}(\langle a, b, y' \rangle 0)$  can be simulated in  $O(|\langle a, b, y' \rangle 0|^{9a^2b}) \subseteq O(|x|)$  time by Observation 18. The output  $\langle i, j, x', 0^p \rangle$  can be computed in  $O(|x|)$  time because all of its elements have been computed in the steps analyzed above. ◀

▷ **Claim 24.**  $h$  is a proof system for  $\overline{D'}$ .

**Proof.** We have  $h \in \text{FP}$  by Observation 23.  $\overline{D'} \subseteq \text{img}(h)$ , since  $\text{img}(h') \subseteq \text{img}(h)$  and  $h'$  is a proof system for  $\overline{D'}$ . We show  $\text{img}(h) \subseteq \overline{D'}$  by contradiction. Assume that there exists  $x \in \Sigma^*$  such that  $h(x) \notin \overline{D'}$ . The last two cases in the definition of  $h$  give values obviously in  $\overline{D'}$ . Thus, we only look at the first case. In particular  $F_a(y') = \langle i, j, x', 0^p \rangle$  and  $g_{a,b}(\langle a, b, y' \rangle 0) = f(F_c(\langle a, b, y' \rangle 0))$ . The second implies directly  $g_{a,b}(\langle a, b, y' \rangle 0) \in \text{img}(f) = \overline{D'}$ . Since  $h(x) = F_a(y')$  in this case, by assumption  $F_a(y') \notin \overline{D'}$ . By Claim 21 we conclude the contradiction  $g_{a,b}(\langle a, b, y' \rangle 0) \notin \overline{D'}$ . ◀

▷ **Claim 25.** Let  $a \in \mathbb{N}$  with  $\text{img}(F_a) \subseteq \overline{D'}$ . Then there exist  $b, c \in \mathbb{N}$ , such that

$$\forall y' \in \Sigma^* : F_a(y') = \langle i, j, x', 0^p \rangle = h(\langle a, b, c, \langle a, b, y' \rangle 0, 0^{k_B \cdot |y'|^{9a^2b + k_B}}, 0^{|c| \cdot (|\langle a, b, y' \rangle 0|^c + c)^2} \rangle 0)$$

**Proof.** Claim 22 shows that there is some  $b \in \mathbb{N}$  such that  $\text{img}(g_{a,b}) = D$ . By Observation 20 this  $g_{a,b}$  is a proof system for  $D$ . Since  $f$  is  $p$ -optimal, there exists  $c \in \mathbb{N}$  such that  $f(F_c(x)) = g_{a,b}(x)$  for all  $x \in \Sigma^*$ . Let  $y' \in \Sigma^*$ . From  $\text{img}(F_a) \subseteq \overline{D'}$  it follows  $F_a(y') = \langle i, j, x', 0^p \rangle$  for suitable  $i, j, x', p$ . Hence, in Claim 25 we are always in the first case of  $h$ . It follows

$$h(\langle a, b, c, \langle a, b, y' \rangle 0, 0^{k_B \cdot |y'|^{9a^2b + k_B}}, 0^{|c| \cdot (|\langle a, b, y' \rangle 0|^c + c)^2} \rangle 0) = \langle i, j, x', 0^p \rangle.$$

This shows Claim 25. ◀

Let  $a \in \mathbb{N}$  be arbitrary such that  $F_a$  is a proof system for  $\overline{D'}$ . Choose  $b, c$  according to Claim 25. Then the following  $z : \mathbb{N} \rightarrow \mathbb{N}$  shows  $F_a \leq^p h$ .

$$z(y') = \langle a, b, c, \langle a, b, y' \rangle 0, 0^{k_B \cdot |y'|^{9a^2b + k_B}}, 0^{|c| \cdot (|\langle a, b, y' \rangle 0|^c + c)^2} \rangle 0$$

By Claim 25 it holds  $F_a(y') = h(z(y'))$ . The function  $z$  can be computed in polynomial time, because  $a, b, c \in \mathbb{N}$  and  $k_B \in \mathbb{N}^+$  are constant values for a fixed  $F_a$ . This proves that  $h$  is a  $p$ -optimal proof system for  $\overline{D'}$ . ◀

► **Corollary 26.** *If DP has  $p$ -optimal proof systems, coDP has  $p$ -optimal proof systems.*

**Proof.** Since  $D \in \text{DP}$ , we obtain that there is a  $p$ -optimal proof system for  $D$ . Theorem 7 shows that it follows that there is a  $p$ -optimal proof system for  $\overline{D'}$ . The language  $\overline{D'}$  is  $\leq_m^p$ -hard for coDP. By Corollary 3, there are  $p$ -optimal proof systems for coDP. ◀

## 4 Oracle Construction

Corollary 26 naturally leads to the question of whether optimal proof systems for DP translate to optimal proof systems for coDP. We show that a proof for this translation cannot be relativizable, i.e., we cannot expect to show this translation with the currently available means. This result is a consequence of the following theorem:

► **Theorem 27.** *There exists an oracle  $O$  with the following properties:*

1.  $\overline{C^O}$  has  $p$ -optimal proof systems (implying  $p$ -optimal proof systems for  $\text{coNP}$ ).
2.  $\overline{D^O}$  has no optimal proof systems (ruling out optimal proof systems for  $\text{coDP}$ ).

**Sketch of the construction.** Work towards 1 (coding): For all  $a \in \mathbb{N}$ , the construction tries to achieve that  $\text{img}(F_a^O) \neq \overline{C^O}$  and thus,  $F_a^O$  is no proof system for  $\overline{C^O}$ . If this is not possible, we start to *encode* the mappings of  $F_a$  (i.e., on which input it gives which output) into the oracle. For the coding, we define code words of the form  $c(a, x, y) := \langle 0^a, 0^{4(|x|^a + a + |y|)}, x, y \rangle$  for  $a \in \mathbb{N}$ ,  $x, y \in \Sigma^*$ . The purpose of a code word  $c(a, x, y)$  is to encode the computation  $F_a(x) = y$ . Thus, the final oracle  $O$  will contain the encoded mappings of all proof systems for  $\overline{C^O}$ . The crucial point is that such a code word lets us recognize that  $F_a$  is a proof system for  $\overline{C^O}$  and  $y \in \overline{C^O}$ . This allows us to define a  $p$ -optimal proof system  $h$  which is able to simulate every proof system for  $\overline{C^O}$  using oracle queries.

Work towards 2 (diagonalization): For all  $b \in \mathbb{N}$ , the construction tries to achieve that  $\text{img}(G_b^O) \neq \overline{D^O}$  and thus,  $G_b^O$  is no proof system for  $\overline{D^O}$ . If this is not possible, we define some proof system  $z_b^O$  for  $\overline{D^O}$  and show that  $z_b^O$  cannot be simulated by  $G_b^O$ . The latter is achieved by diagonalizing against every simulation function  $\pi$ , i.e., we make sure that  $G_b^O$  does not simulate  $z_b^O$  via  $\pi$ .

We call the functions  $z_b^O$  witness proof systems. The intuition behind their definition and behind the whole diagonalization is as follows: independent of the oracle each function  $z_b^O$  has short proofs for all elements of some polynomial-time-decidable set. But our construction offers the freedom to choose whether or not this set is a subset of  $\overline{D^O}$ . The latter depends on the following language

$$\begin{aligned} A^O &= \{x \in \Sigma^* \mid |O^{|x|}|_c \geq 2\} \cup \{x \in \Sigma^* \mid |O^{|x|}|_c = 0\} \\ &= \{x \in \Sigma^* \mid |O^{|x|}|_c \neq 1\}, \end{aligned}$$

which lies inside  $\text{coDP}^O$  and thus has influence on  $\overline{D^O}$ . Let  $y$  be a word whose membership to  $\overline{D^O}$  is influenced by the question of whether  $0^n \in A^O$ . Observe that  $0^n \in A^O$  if and only if  $|O|_c^n \neq 1$ . Thus, we can control the membership of  $y$  to  $\overline{D^O}$  by adding none, one or more words of length  $n$  to  $O$ . There are  $2^n$  such words. Let  $G_b^O$  be some proof system for  $\overline{D^O}$ . During the construction of  $O$ , we initially have no word of length  $n$  inside  $O$  and thus  $y \in \overline{D^O}$  and  $G_b^O$  must have a proof for  $y$ . Case 1: All  $G_b^O$ -proofs for  $y$  are long. When  $G_b^O$  is given such a proof it can determine by exhaustive search the number of words of length  $n$  in  $O$ . However,  $G_b^O$  does not simulate  $z_b^O$ , because  $z_b^O$  has short proofs for  $y$ , but  $G_b^O$  has not. Case 2:  $G_b^O$  has a short proof  $x$  for  $y$ . In this case,  $G_b^O(x)$  cannot query all  $2^n$  words and hence cannot determine whether  $y \in \overline{D^O}$ . We can exploit this to create a situation where  $G_b^O(x)$  outputs an element outside  $\overline{D^O}$  and hence is no proof system for this set. So  $G_b^O$  can either simulate  $z_b^O$  or be a proof system for  $\overline{D^O}$ , but not both at once.

The main challenge of the oracle construction is to combine the work for 1 and 2, because the code words interact with the diagonalization. Indeed, in the example above  $G_b^O$  cannot query all  $2^n$  words when having a short proof  $x$  for  $y$ , but there are many code words that can be queried by  $G_b^O(x)$  whose memberships together can depend on all  $2^n$  words of length  $n$ . We capture these dependencies in a graph data structure, where nodes are words from  $\Sigma^*$  and edges are oracle queries of underlying FP-computations of code words, i.e., for a code word  $c(a, x, y)$  the computation  $F_a^O(x)$ . This helps to identify words of length  $n$  that are independent of the computation  $G_b^O(x)$  and all queried code words.

## 5 Conclusion

We summarize all results to obtain the equivalence classes from Figure 1. First observe that (p-)optimal proof systems always translate from a class  $\mathcal{C}$  to  $\mathcal{D}$  when  $\mathcal{C} \subseteq \mathcal{D}$  (respective solid arrows are omitted in Figure 2). We start with the equivalence classes for p-optimal proof systems (see Figure 2, left, solid arrows). P-optimal proof systems translate as follows:

- from  $\text{NP} \cup \text{coNP}$  to  $\text{DP}$  by  $\text{NP} \cup \text{coNP} \supseteq \text{NP}$ ,  $\text{NP} \cup \text{coNP} \supseteq \text{coNP}$ ,  $\text{NP} \wedge \text{coNP} = \text{DP}$ , and Corollary 5 following from Köbler, Messner, and Torán [18].
- from  $\text{DP}$  to  $\text{coDP}$  by Corollary 26.
- from  $\text{coBH}_k$  to  $\text{coBH}_{k+1}$  for  $k \geq 2$  by Corollary 5 following from Köbler, Messner, and Torán [18] and the following inclusions:

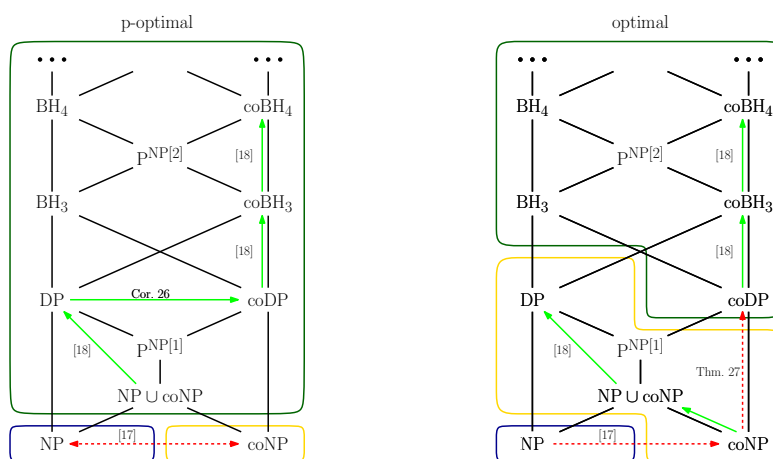

$$\begin{aligned} \text{coBH}_k \wedge \text{coBH}_k &\supseteq \text{coDP} \wedge \text{coBH}_k = (\text{NP} \vee \text{coNP}) \wedge \text{coBH}_k \\ &\supseteq \begin{cases} \text{coNP} \wedge \text{coBH}_k = \text{coBH}_{k+1} & \text{if } k \text{ is even} \\ \text{NP} \vee \text{coBH}_k = \text{coBH}_{k+1} & \text{else} \end{cases} \end{aligned}$$

Next, we derive the equivalence classes for optimal proof systems (see Figure 2, right, solid arrows). Optimal proof systems translate as follows:

- from  $\text{coNP}$  to  $\text{NP} \cup \text{coNP}$  by the fact that  $\text{NP}$  has optimal proof systems.
- from  $\text{NP} \cup \text{coNP}$  to  $\text{DP}$  by Corollary 5 following from Köbler, Messner, and Torán [18].
- from  $\text{coBH}_k$  to  $\text{coBH}_{k+1}$  for  $k \geq 2$  by the same argument used for p-optimal proof systems.

The resulting equivalence classes for (p-)optimal proof systems are different (see Figure 2, left and right, dashed arrows) relative to oracles  $A, B, O$  with the following properties:

- $\text{NP}^A$  has p-optimal proof systems and  $\text{coNP}^A$  has no optimal proof systems [17].
- $\text{coNP}^B$  has p-optimal proof systems and  $\text{NP}^B$  has no p-optimal proof systems [17].
- $\text{coNP}^O$  has p-optimal proof systems and  $\text{coDP}^O$  has no optimal proof systems (Thm. 27).

■ **Figure 2** Equivalence classes for p-optimal proof systems (left) and optimal proof systems (right) in the Boolean hierarchy over  $\text{NP}$  and the bounded query hierarchy over  $\text{NP}$ . Green solid arrows from  $A$  to  $B$  mean that (p-)optimal proof systems for  $A$  imply (p-)optimal proof systems for  $B$ . Red dashed arrows from  $A$  to  $B$  mean that there exists an oracle  $Q$  relative to which  $A^Q$  has (p-)optimal proof systems and  $B^Q$  has no (p-)optimal proof systems. Note that green solid arrows pointing downwards are omitted, since those are trivial and only the minimum number of required red dashed arrows to separate all equivalence classes are drawn.

Oracle  $A$  rules out translations from NP to any other class in Figure 2 for optimal and p-optimal proof systems. Oracle  $B$  rules out translations from coNP to NP and thus also to  $\text{NP} \cup \text{coNP}$  for p-optimal proof systems. Oracle  $O$  rules out translations from coNP to coDP for optimal proof systems.

We obtain the following connection to a conjecture studied by Pudlák [25].

► **Corollary 28.** *The following statements are equivalent:*

- BH has no p-optimal proof system.
- TAUT has no p-optimal proof systems or SAT has no p-optimal proof systems (i.e.,  $\text{CON} \vee \text{SAT}$  in Pudlák's notation).

**Proof.** Figure 2 shows that  $\text{NP} \cup \text{coNP}$  and BH are equivalent with respect to p-optimal proof systems. Hence, BH has no p-optimal proof systems if and only if  $\text{NP} \cup \text{coNP}$  has no p-optimal proof systems. The latter holds if and only if TAUT has no p-optimal proof systems or SAT has no p-optimal proof systems. ◀

## Abstract

---

Given a (connected) undirected graph  $G$ , a set  $X \subseteq V(G)$  and integers  $k$  and  $p$ , the STEINER SUBGRAPH EXTENSION problem asks whether there exists a set  $S \supseteq X$  of at most  $k$  vertices such that  $G[S]$  is a  $p$ -edge-connected subgraph. This problem is a natural generalization of the well-studied STEINER TREE problem (set  $p = 1$  and  $X$  to be the terminals). In this paper, we initiate the study of STEINER SUBGRAPH EXTENSION from the perspective of parameterized complexity and give a fixed-parameter algorithm (i.e., FPT algorithm) parameterized by  $k$  and  $p$  on graphs of bounded degeneracy (removing the assumption of bounded degeneracy results in W-hardness).

Besides being an independent advance on the parameterized complexity of network design problems, our result has natural applications. In particular, we use our result to obtain new single-exponential FPT algorithms for several vertex-deletion problems studied in the literature, where the goal is to delete a smallest set of vertices such that: (i) the resulting graph belongs to a specified hereditary graph class, and (ii) the deleted set of vertices induces a  $p$ -edge-connected subgraph of the input graph.

## 1 Introduction

Given a simple undirected graph  $G = (V, E)$  and a set  $T \subseteq V(G)$ , called *terminals*, the STEINER TREE problem asks if there are at most  $k$  edges  $F \subseteq E(G)$  such that there is a path between every pair of vertices of  $T$  in  $G' = (V, F)$ . STEINER TREE is one of the fundamental problems in network design and is a well-studied problem in parameterized complexity ([14, 9, 7, 3, 21]). We refer to Section 2 for definitions related to parameterized complexity and graph theory. In this paper, we study the STEINER SUBGRAPH EXTENSION problem, which is formally defined below.

STEINER SUBGRAPH EXTENSION

**Input:** A simple undirected graph  $G = (V, E)$ ,  $X \subseteq V(G)$  and integers  $k, p \in \mathbb{N}$ .

**Parameter:**  $k + p$

**Goal:** Is there  $S \supseteq X$  of size at most  $k$  such that  $G[S]$  is  $p$ -edge-connected?

---

<sup>1</sup> Corresponding author

Observe that this is a natural generalization of STEINER TREE problem. To the best of our knowledge, the parameterized complexity status of STEINER SUBGRAPH EXTENSION is unexplored even for arbitrary fixed constant  $p$ . When  $p = 2$ , STEINER SUBGRAPH EXTENSION is closely related to a special variant of EDGE-CONNECTED SURVIVABLE NETWORK DESIGN (defined by Feldman et al. [15]) problem. The goal of EDGE-CONNECTED SURVIVABLE NETWORK DESIGN is to find a collection of “at most  $k$  edges” so that there are two edge-disjoint paths between every pair of vertices in the terminal set. Abhinav et al. [1] studied the above problem when  $p = n - k$ , with  $k$  as the parameter. Moreover, they aim to find an  $(n - k)$ -edge-connected steiner subgraph with exactly  $\ell$  vertices. In our problem, observe that  $p \leq k - 1$  as any graph with  $k$  vertices can be  $(k - 1)$ -edge-connected and not  $p$ -edge-connected for  $p \geq k$ . If we set  $p = k - 1$ , then our problem becomes precisely the CLIQUE problem, where we want to decide if a graph has a clique with exactly  $k$  vertices, a W[1]-hard problem. Hence, one must place further restrictions on the input when aiming for fixed-parameter tractability. In this paper, we consider the STEINER SUBGRAPH EXTENSION problem when  $\eta$  is the degeneracy of the input graph  $G$  and  $\eta$  is a fixed-constant. Note that many well-known sparse graph classes are subclasses of graphs of bounded degeneracy. For instance, planar graphs are 5-degenerate, graphs with treewidth (or treedepth or pathwidth) at most  $\eta$  are  $(\eta + 1)$ -degenerate.

**Our Contributions.** The input to our problem STEINER SUBGRAPH EXTENSION is a simple undirected graph with  $n$  vertices and  $\eta$  is a fixed constant. Recall that the parameter is  $k + p$ . The first part of our paper proves that STEINER SUBGRAPH EXTENSION is FPT when the input graph has constant degeneracy. In particular, we give an FPT algorithm with running time  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ -time for STEINER SUBGRAPH EXTENSION when the input graph  $G$  is  $\eta$ -degenerate. The formal statement of the theorem is given below.

► **Theorem 1.** STEINER SUBGRAPH EXTENSION can be solved in time  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ , where  $\eta$  is the degeneracy of the input graph.

In particular, on graphs of constant degeneracy and for constant  $p$ , the above result gives a  $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ -time algorithm, which is useful in several applications as we show in this paper.

The above result crucially relies on the use of the *out-partition* matroid, its linear representability in deterministic polynomial-time, and a dynamic programming subroutine using the notion of representative sets. We would like to highlight that Einarson et al. [13] have studied the same problem when  $X$  is a vertex cover. Our dynamic programming algorithm over representative sets has some similarities with the algorithm of Einarson et al. [13] but  $X$  is not necessarily a vertex cover of  $G$  for STEINER SUBGRAPH EXTENSION. Despite the fact that  $G$  is a bounded degenerate graph, designing an algorithm for STEINER SUBGRAPH EXTENSION needs careful adjustment to the subproblem definitions and some additional conditions have to be incorporated while constructing the collection of sets in the DP formulation. Furthermore, our algorithm in Theorem 1 does not depend on  $\eta$  in the exponent of  $n$ .

The second part of our paper describes some applications of our main result (Theorem 1) to some natural problems in graph theory with connectivity constraints. Einarson et al. [13] have initiated the study of  $p$ -EDGE-CONNECTED VERTEX COVER with stronger connectivity constraints. Being motivated by their results, we illustrate how Theorem 1 lays us a foundation to *design efficient deterministic parameterized singly exponential-time algorithms* for BOUNDED DEGREE DELETION SET,  $\eta$ -TREEDPTH DELETION SET, PATHWIDTH-ONE DELETION SET and  $\eta$ -PATH VERTEX COVER with  $p$ -edge-connectivity constraints. Each of

these problems are well-studied without the connectivity constraints (see [18, 5, 6] for more details). We state the problem definitions below. Given an undirected graph  $G = (V, E)$ , the following questions are asked by these problems.

- $p$ -EDGE-CONNECTED  $\eta$ -DEGREE DELETION SET ( $p$ -EDGE-CON-BDDS) asks if there is  $S \subseteq V(G)$  such that  $G - S$  is a graph of maximum degree at most  $\eta$  and  $G[S]$  is  $p$ -edge-connected.
- $p$ -EDGE-CONNECTED  $\eta$ -TREEDEPTH DELETION SET ( $p$ -EDGE-CON- $\eta$ -TDDS) asks if there is  $S \subseteq V(G)$  such that  $G - S$  has treedepth at most  $\eta$  and  $G[S]$  is  $p$ -edge-connected.
- $p$ -EDGE CONNECTED PATHWIDTH-1 VERTEX DELETION ( $p$ -EDGE-CON-PW1DS) asks if there is  $S \subseteq V(G)$  such that  $G - S$  has pathwidth at most 1 and  $G[S]$  is  $p$ -edge-connected.
- $p$ -EDGE-CONNECTED  $\eta$ -PATH VERTEX COVER ( $p$ -EDGE-CON- $\eta$ -PVC) asks if there is  $S \subseteq V(G)$  such that  $G - S$  has no  $P_\eta$  as subgraph and  $G[S]$  is  $p$ -edge-connected.

Applications to each of the above mentioned problems crucially rely on a property. The property is that all minimal vertex-deletion sets that must be part of any optimal solution can be enumerated in  $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ -time for some fixed constant  $\eta$ . Since a graph of maximum degree  $\eta$  is also an  $\eta$ -degenerate graph, we have the following result as a direct application of our main result.

► **Corollary 2.**  $p$ -EDGE-CON-BDDS admits a  $2^{\mathcal{O}(pk+k\eta)}n^{\mathcal{O}(1)}$ -time algorithm.

Our second application is  $p$ -EDGE-CON-PW1DS problem. The graphs of pathwidth at most one are also 2-degenerate. But it is not straightforward to enumerate all the minimal pathwidth one vertex deletion sets. So we use some additional characterizations of graphs of pathwidth one and exploit some problem specific structures to prove our next result.

► **Theorem 3.**  $p$ -EDGE-CON-PW1DS admits an algorithm that runs in  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time.

Note that the algorithm for the above result does not directly invoke the subroutine from Theorem 1. Instead, it uses some dynamic programming ideas that are closely similar to that of Theorem 1 proof but also makes careful local adjustments to take care of some additional constraints. Finally, our last two applications are  $p$ -EDGE-CONNECTED  $\eta$ -TREEDEPTH DELETION SET and  $p$ -EDGE-CON- $\eta$ -PVC problems and we have the following two results.

► **Theorem 4.**  $p$ -EDGE-CON- $\eta$ -TDDS admits an algorithm that runs in  $2^{2^{2^\eta} + \mathcal{O}((p+\eta)k)}n^{2^{2^\eta}}$ -time.

► **Theorem 5.**  $p$ -EDGE-CON- $\eta$ -PVC admits an algorithm that runs in  $2^{\mathcal{O}((p+\eta)k)}n^{\mathcal{O}(1)}$ -time.

**Organization of our paper.** We organize the paper as follows. Initially in Section 2, we introduce the basic notations related to graph theory, parameterized complexity and matroids. Then, in Section 3, we prove our main result, i.e. Theorem 1. Then, in Section 4, we illustrate the applications of our main result to design singly exponential-time algorithms for  $p$ -EDGE-CON-BDDS,  $p$ -EDGE-CON-PW1DS,  $p$ -EDGE-CON- $\eta$ -TDDS and  $p$ -EDGE-CON- $\eta$ -PVC.

**Related Work.** Heggernes et al. [19] studied the parameterized complexity of  $p$ -CONNECTED STEINER SUBGRAPH that is the vertex-connectivity counterpart of our problem. The authors in their paper have proved that when parameterized by  $k$ , the above mentioned problem is FPT for  $p = 2$  and W[1]-hard when  $p = 3$ . Nutov [23] has studied a variant of  $p$ -CONNECTED STEINER SUBGRAPH problem in which they have studied VERTEX CONNECTIVITY AUGMENTATION problem. Given an undirected graph  $G$ , a  $p$ -connected subgraph  $G[S]$ , the

VERTEX CONNECTIVITY AUGMENTATION problem asks if at most  $k$  additional edges can be added to  $G[S]$  to make the subgraph  $(p+1)$ -connected. In particular, Nutov [23] provided a parameterized algorithm for the above mentioned problem. Feldman et al. [15] have studied parameterized complexity of VERTEX/EDGE-CONNECTED SURVIVABLE NETWORK DESIGN PROBLEM where given fixed constant  $p$ , they want to compute a subgraph that has minimum number of edges and provides  $p$ -vertex/edge-connectivity between every pair of vertices in the terminals.

## 2 Preliminaries

**Sets, numbers and graph theory.** We use  $\mathbb{N}$  to denote the set of all natural numbers. For  $r \in \mathbb{N}$ , we use  $[r]$  to denote the set  $\{1, \dots, r\}$ . Given a set  $S$  and an integer  $k$ , we use  $\binom{S}{\leq k}$  and  $\binom{S}{k}$  to denote the collection of all subsets of  $S$  of size at most  $k$  and of size exactly  $k$  respectively. We use standard graph theoretic notations from Diestel's book [10] for all notations of undirected and directed graphs. For undirected graphs, we use  $uv \in E(G)$  to denote that there is an edge between  $u$  and  $v$ . On the other hand for directed graphs, we are more explicit. We use  $(u, v)$  to represent that the edge is directed from  $u$  to  $v$ . For the directed graphs, the directed edges are also called arcs. We use the term arc and edge interchangeably. In an undirected graph  $G$ , we use  $\deg_G(v)$  to denote the degree of  $v$  in  $G$ . When the graph is clear from the context, we drop this subscript and simply use  $\deg(v)$ . An undirected graph  $G$  is called a *degree- $\eta$ -graph* if every vertex of  $G$  has degree at most  $\eta$ . We use  $\Delta(G)$  to denote the  $\max\{\deg_G(v) : v \in V(G)\}$ , i.e. the maximum degree of any vertex in  $G$ . It is clear from the definition that if a graph  $G$  is a degree- $\eta$ -graph then  $\Delta(G) \leq \eta$ . When we consider directed graphs, we have *in-degree* and *out-degree* for all the vertices. For a vertex  $v$ , the *in-degree* of  $v$  is the number of arcs of the form  $(v, u) \in A$  and the *out-degree* of  $v$  is the number of arcs of the form  $(u, v) \in A$ . A connected undirected graph  $G = (V, E)$  is said to be  *$p$ -edge-connected* if at least two vertices and  $G - Y$  remains connected after deleting at most  $p - 1$  edges. Due to the Menger's Theorem, a connected graph is said to be  *$p$ -edge-connected* if and only if there are  $p$  edge-disjoint paths between every pair of vertices. Given an undirected graph, a set  $S \subseteq V(G)$  is said to be a  *$p$ -segment* of  $G$  if for every  $u, v \in S$ , there are  $p$  edge-disjoint paths from  $u$  to  $v$  in  $G$ . An undirected graph is said to be an  *$\eta$ -degenerate graph* if every subgraph has a vertex of degree at most  $\eta$ . Given an undirected  $\eta$ -degenerate graph  $G = (V, E)$ , a sequence of vertices  $\rho_G = (v_1, \dots, v_n)$  is said to be an  *$\eta$ -degeneracy sequence* if for every  $2 \leq i \leq n$ ,  $v_i$  has at most  $\eta$  neighbors from the vertices  $\{v_1, \dots, v_{i-1}\}$ . For an  $\ell \in \mathbb{N}$ , we use  $P_\ell$  to denote a path containing  $\ell$  vertices and  $C_\ell$  to denote a cycle containing  $\ell$  vertices. A graph is said to be a *degree- $\eta$ -graph* if every vertex has degree at most  $\eta$ . It follows from the definition that every degree- $\eta$ -graph is an  $\eta$ -degenerate graph, but the converse does not hold true. An undirected graph is said to be a *caterpillar graph* if every connected component is an induced path with hairs attached to each of its pendant vertices. Given a directed graph  $D = (V, A)$ , we define an *outbranching* of  $D$  rooted at  $v \in V(D)$  is a subset  $A' \subseteq A$  such that  $v$  has in-degree 0 and every other vertex has in-degree exactly one in  $D' = (V, A')$ .

We define the following two graph parameters treedepth and pathwidth that we use in our paper.

► **Definition 6 (Treedepth).** Given an undirected graph  $G = (V, E)$ ,  $\text{td}(G)$ , i.e. the treedepth of  $G$  is defined as follows. If  $|V(G)| = 1$ , then  $\text{td}(G) = 1$ . If  $G$  is connected, then  $\text{td}(G) = 1 + \min_{u \in V(G)} \text{td}(G - \{u\})$ . Finally, if  $G_1, \dots, G_r$  are the connected components of  $G$ , then  $\text{td}(G) = \max_{i=1}^r \text{td}(G_i)$ .

Informally, a *treedepth decomposition* of an undirected graph  $G$  can be considered as a rooted forest  $Y$  with vertex set  $V$  such that for each  $uv \in E(G)$ , either  $u$  is an ancestor of  $v$  or  $v$  is an ancestor of  $u$  in  $Y$ . The context of treedepth is also sometimes referred to as *elimination tree* of  $G$ . It follows from the (recursive) definition above that treedepth of a graph is referred to as the minimum depth of a treedepth decomposition of  $G$ , where depth is defined as the maximum number of vertices in a root to leaf path.

► **Definition 7 (Path Decomposition).** A path decomposition of an undirected graph  $G = (V, E)$  is a sequence  $(X_1, \dots, X_r)$  of bags  $X_i \subseteq V(G)$  such that **(i)** every vertex belongs to at least one bag, **(ii)** for every edge  $uv \in E(G)$ , there is  $X_i$  such that  $u, v \in X_i$ , and **(iii)** for every vertex  $v$ , the bags containing  $v$  forms a contiguous subsequence, i.e.  $(X_i, X_{i+1}, \dots, X_j)$ . The width of a decomposition is  $\max_{i \in [r]} |X_i| - 1$ .

The *pathwidth* of a graph is defined as the smallest number  $\eta$  such that there exists a path decomposition of width  $\eta$ . Informally, pathwidth is a measure how much a graph is close to a path (or a linear forest). We use  $\text{pw}(G)$  to denote the pathwidth of  $G$ .

Given a class of graphs  $\mathcal{G}$ , we say that  $\mathcal{G}$  is *polynomial-time recognizable*, if given a graph  $G$ , there is a polynomial-time algorithm that can correctly check if  $G \in \mathcal{G}$ . A graph class is said to be *hereditary* if it is closed under induced subgraphs.

**Parameterized Complexity and W-hardness.** A parameterized problem  $L$  is a subset of  $\Sigma^* \times \mathbb{N}$  for some finite alphabet  $\Sigma$ . An instance of a parameterized problem is a pair  $(x, k)$  where  $x \in \Sigma^*$  is the *input* and  $k$  is the *parameter*. A parameterized problem  $L \subseteq \Sigma^* \times \mathbb{N}$  is said to be *fixed-parameter tractable* if there exists an algorithm  $\mathcal{A}$  that given  $(x, k) \in \Sigma^* \times \mathbb{N}$ , the algorithm  $\mathcal{A}$  runs in  $f(k)|x|^c$ -time for some constant  $c$  independent of  $n$  and  $k$  and correctly decides  $L$ . The algorithm  $\mathcal{A}$  that runs in  $f(k)|x|^{\mathcal{O}(1)}$ -time is called a *fixed-parameter algorithm* (or FPT algorithm). A fixed-parameter algorithm is said to be a *singly exponential FPT algorithm* if it runs in  $c^k|x|^{\mathcal{O}(1)}$ -time for some fixed constant  $c$  independent of  $|x|$  and  $k$ . There is a hardness theory in parameterized complexity that is associated with the notion of *parameterized reduction* and the hierarchy of parameterized complexity classes. Broadly, the *W-hierarchy* (of parameterized complexity classes) is denoted by  $\text{FPT} \subseteq \text{W}[1] \subseteq \text{W}[2] \subseteq \dots \subseteq \text{XP}$ . Given two distinct parameterized problems  $L_1$  and  $L_2$ , there is a *parameterized reduction* from  $L_1$  to  $L_2$  if given an instance  $(x, k)$  of  $L_1$ , an algorithm  $\mathcal{A}$  runs in  $g(k)|x|^{\mathcal{O}(1)}$ -time and outputs an equivalent instance  $(x', k')$  of  $L_2$  such that  $k' = f(k)$  for some function depending only on  $k$ . For more details on parameterized complexity and its associated hardness theory, we refer to the books [8, 22, 11].

**Matroids and Representative Families.** We use the following definitions and results related to matroid theory to design our algorithms.

► **Definition 8.** Given a universe  $U$  and a subfamily  $\mathcal{I} \subseteq 2^U$ , a set system  $\mathcal{M} = (U, \mathcal{I})$  is said to be a matroid if **(i)**  $\emptyset \in \mathcal{I}$ , **(ii)** if  $A \in \mathcal{I}$ , then for all  $A' \subseteq A$ ,  $A' \in \mathcal{I}$  (*hereditary property*), and **(iii)** if there exists  $A, B \in \mathcal{I}$  such that  $|B| > |A|$ , then there is  $x \in B \setminus A$  such that  $A \cup \{x\} \in \mathcal{I}$  (*exchange property*). The set  $U$  is called ground set of  $\mathcal{M}$  and a set  $A \in \mathcal{I}$  is called an independent set of matroid  $\mathcal{M}$ .

It follows from the definition that all maximal independent sets are of the same size. A maximal independent set is called a *basis*. Let  $U$  be a universe with  $n$  elements and  $\mathcal{I} = \binom{U}{\leq r}$ . The set system  $(U, \mathcal{I})$  is called a *uniform matroid*. Let  $G = (V, E)$  be an undirected graph and  $\mathcal{I} = \{F \subseteq E(G) \mid G' = (V, F) \text{ is a forest}\}$ . The set system  $(E(G), \mathcal{I})$  is called a *graphic matroid*. Let  $U$  be partitioned as  $U_1 \uplus \dots \uplus U_r$  and  $\mathcal{I} = \{A \subseteq U : |A \cap U_i| \leq 1 \text{ for all } i \in [r]\}$ .

We say that  $(U, \mathcal{I})$  is a *partition matroid*. A matroid  $M$  is said to be *representable over a field*  $\mathbb{F}$  if there is a matrix  $A$  over  $\mathbb{F}$  and a bijection  $f : U \rightarrow \text{Col}(A)$  where  $\text{Col}(A)$  is the set of columns of  $A$  such that  $B \subseteq U$  is an independent set of  $U$  if and only if the set of columns  $\{f(b) \mid b \in B\}$  are linearly independent. A matroid representable over a field  $\mathbb{F}$  is called a *linear matroid*.

Given two matroids  $M_1 = (U_1, \mathcal{I}_1)$  and  $M_2 = (U_2, \mathcal{I}_2)$ , the *direct sum*  $M = M_1 \oplus M_2$  is the matroid  $(U_1 \uplus U_2, \mathcal{I})$  such that  $I \in \mathcal{I}$  if and only if  $I \cap U_1 \in \mathcal{I}_1$  and  $I \cap U_2 \in \mathcal{I}_2$ . If  $M_1$  and  $M_2$  are represented by matrices  $A_1$  and  $A_2$  respectively then  $M = M_1 \oplus M_2$  also admits a matrix representation.

Given a matroid  $M$ , a *truncation* of  $M$  to rank  $r$  is the matroid  $M' = (U, \mathcal{I}')$  where a set  $A \subseteq U$  is independent in  $M'$  if and only if  $A \in \mathcal{I}$  and  $|A| \leq r$ . Given a matroid  $M$  with its representation (in matrix-form), the truncation of  $M$  can be computed in polynomial-time. Let  $M = (U, \mathcal{I})$  be a matroid and  $X, Y \subseteq U$ . We say that  $X$  *extends*  $Y$  in  $M$  if  $X \cap Y = \emptyset$  and  $X \cup Y \in \mathcal{I}$ . Moreover, let  $\mathcal{S} \subseteq 2^U$  be a family. A subfamily  $\hat{\mathcal{S}} \subseteq \mathcal{S}$  is a *q-representative* of  $\mathcal{S}$  if the following holds: for every set  $Y \subseteq U$  with  $|Y| \leq q$ , there is a set  $X \in \hat{\mathcal{S}}$  such that  $X$  extends  $Y$  if and only if there is a set  $\hat{X} \in \hat{\mathcal{S}}$  such that  $\hat{X}$  extends  $Y$ . We use  $\hat{\mathcal{S}} \subseteq_{\text{rep}}^q \mathcal{S}$  to denote that  $\hat{\mathcal{S}}$  is a *q-representative family* of  $\mathcal{S}$ . The following result holds true due to Fomin et al. [17, 20].

► **Proposition 9.** *Let  $M = (U, \mathcal{I})$  be a linear matroid of rank  $n$  and  $p, q \leq n$  over a field  $\mathbb{F}$  and let  $\mathcal{S} = \{S_1, \dots, S_t\} \subseteq \mathcal{I}$  each having cardinality  $p$ . Then, there exists an algorithm that computes a *q-representative subfamily*  $\hat{\mathcal{S}} \subseteq_{\text{rep}}^q \mathcal{S}$  consisting of at most  $\binom{p+q}{q}$  sets using  $\mathcal{O}\left(\binom{p+q}{p}^2 tp^3 n^2 + t \binom{p+q}{q}^\omega np\right) + (n + |U|)^{\mathcal{O}(1)}$  field operations over  $\mathbb{F}$ . Here  $\omega < 2.37$  is the matrix multiplication exponent.*

Let  $G = (V, E)$  be an undirected graph and  $D_G = (V, A_E)$  is defined as follows. For every  $uv \in E(G)$ , we add  $(u, v)$  and  $(v, u)$  into  $A_E$  and fix  $v_r \in V$ . Since the definition of  $D_G$  is based on  $G = (V, E)$ , we call the pair  $(D_G, v_r)$  an *equivalent digraph of  $G$  with root  $v_r$* . Then, an *out-partition matroid with root  $v_r$*  for  $D_G$  is the partition matroid with ground set  $A_E$  where arcs are partitioned according to their heads and arcs  $(u, v_r)$  are dependent. Equivalently, what it means is that a set of arcs  $F \subseteq A_E$  is an *independent* in the out-partition matroid with root  $v_r$  if and only if  $v_r$  has in-degree 0 in  $F$  and every other vertex has in-degree at most 1 in  $F$ . The graphic matroid in the ground set  $A_E$  is the graphic matroid for  $G$  where every arc is represented by its underlying undirected edge and the antiparallel arcs  $(u, v), (v, u)$  represent distinct copies of  $uv$ . Then,  $\{(u, v), (v, u)\}$  becomes a dependent set. The following two propositions are proved by Agrawal et al. [2] and Einarson et al. [13] respectively.

► **Proposition 10** (Agrawal et al. [2]). *Let  $G = (V, E)$  be an undirected graph,  $v_r \in V$  and  $D_G = (V, A_E)$  as defined above. Then,  $G$  is  $p$ -edge-connected if and only if  $D_G$  has pairwise arc-disjoint out-branchings rooted at  $v_r$ .*

► **Proposition 11** (Einarson et al. [13]). *Let  $G = (V, E)$  be an undirected graph,  $v_r \in V$  and  $D_G = (V, A_E)$  as defined above. Then,  $F$  is the arc set of an out-branching rooted at  $v_r$  if and only if  $|F| = |V(G)| - 1$  and  $F$  is independent both in the out-partition matroid for  $D_G$  with root  $v_r$  and the graphic matroid for  $G$  with ground set  $A_E$ .*

Let  $G$  be an undirected graph,  $X \subseteq V(G)$  and  $p$  be an integer. It is not immediate whether in polynomial-time we can check whether there exists a *feasible* solution, that is, a set  $S \supseteq X$  such that  $G[S]$  is  $p$ -edge-connected. The following lemma illustrates that the above can be achieved in polynomial-time. In fact, in this case the input graph does not have to be a bounded degenerate graph.

► **Lemma 12** ( $\star$ ).<sup>2</sup> Let  $G = (V, E)$  be a connected undirected graph and  $X \subseteq V(G)$ . Then, we can check in polynomial-time if there exists a set  $S \supseteq X$  such that  $G[S]$  is a  $p$ -edge-connected subgraph.

We refer to Oxley [24] for more details on matroid theory and a survey by Panolan and Saurabh [25] for more information on use of matroids in FPT algorithms.

### 3 Algorithm for STEINER SUBGRAPH EXTENSION

This section is devoted to the proof of the main contribution of our paper. We first provide a singly exponential algorithm for STEINER SUBGRAPH EXTENSION (we restate below) when the input graph has bounded degeneracy. We assume that a fixed constant  $\eta$  is the degeneracy of  $G$ . We restate the problem definition.

STEINER SUBGRAPH EXTENSION

**Input:** An undirected graph  $G = (V, E)$ ,  $X \subseteq V(G)$  and integers  $k, p \in \mathbb{N}$ .

**Parameter:**  $k + p$

**Goal:** Is there  $S \supseteq X$  of size at most  $k$  such that  $G[S]$  is  $p$ -edge-connected?

Let  $(G, X, k)$  be given as an input instance and  $\sigma$  be a degeneracy sequence for the vertices of  $G - X$  witnessing that  $G - X$  is also an  $\eta$ -degenerate graph. Note that one can compute a degeneracy sequence easily in polynomial time by iteratively picking the minimum degree vertex, hence, we assume an ordering  $\sigma = (u_1, \dots, u_n)$  of the vertices of  $G - X$  is given along with the input. Due to Lemma 12, we can check if there exists a feasible solution  $S \supseteq X$  (not necessarily of size at most  $k$ ) such that  $G[S]$  is  $p$ -edge-connected subgraph. So, we can assume without loss of generality that a feasible solution actually exists. We first state a proposition that we use later in the proof of our result.

► **Proposition 13** ([13]). Let  $G = (V, E)$  be an undirected graph,  $v_r \in V$ , and  $D_G = (V, A_E)$  such that  $(D_G, v_r)$  is an equivalent digraph with root  $v_r$ . We also assume that  $M$  is a direct sum  $M_1 \oplus \dots \oplus M_{2p+1}$  as follows. The matroids  $M_1, M_3, \dots, M_{2p-1}$  are the copies of graphic matroid of  $G$  on ground set  $E$ , the matroids  $M_2, M_4, \dots, M_{2p}$  are the copies of out-partition matroids with ground set  $A_E$  with root  $v_r$ , and the matroid  $M_{2p+1}$  is a uniform matroid over  $A_E$  with rank  $p(k-1)$ . Furthermore, suppose that  $F \subseteq A_E$ , then the followings two are equivalent.

- (i)  $F$  is the set of  $p$  pairwise arc-disjoint out-branchings rooted at  $v_r$  in  $D_G[S]$  for some  $S \in \binom{V(G)}{k}$  and  $v_r \in S$ .
- (ii)  $|V(F)| = k$ ,  $|F| = p(k-1)$ ,  $v_r \in V(F)$ , and there is an independent set  $I$  in  $M$  such that every arc  $a \in F$  occurs in  $I$  precisely in its copies in matroids  $M_{2i-1}, M_{2i}$  and  $M_{2p+1}$  for some  $i \in \{1, \dots, p\}$ .

In addition, a linear representation of  $M$  and the truncation of  $M$  to  $\hat{M}$  of rank  $3p(k-1)$  can be computed in deterministic polynomial-time.

Our algorithm for STEINER SUBGRAPH EXTENSION works as follows. There are two cases. If  $X = \emptyset$ , then we choose an arbitrary vertex  $u \in V(G)$  and set  $X = \{u\}$ . There are  $n = |V(G)|$  possible choices of  $X$ . For each such choice we assign  $v_r = u \in X$ . Otherwise, it is already the case that  $X \neq \emptyset$ . Therefore, we can assume without loss of generality that  $X \neq \emptyset$ .

<sup>2</sup> Due to lack of space, the lemmas marked  $\star$  and the other omitted proofs can be found in the full version.

On the other hand, if  $X \neq \emptyset$  and  $G[X]$  is  $p$ -edge-connected, then we can trivially output yes-instance since  $|X| \leq k$ . So, we are in the situation that  $G[X]$  is not  $p$ -edge-connected and  $|X| < k$ . In the algorithm, we use the above characterization and representative sets framework to check if  $X$  can be extended to a  $p$ -edge-connected subgraph  $G[S]$  with at most  $k$  vertices. We fix an arbitrary vertex  $v_r \in X$ . Due to Proposition 13, there is an independent set  $I$  such that **(i)**  $X \subset V(I)$  and  $|V(I)| = k$ , **(ii)**  $|I| = 3p(k-1)$ , and **(iii)** every arc that is in  $I$  is represented precisely in three matroids  $M_{2i-1}, M_{2i}$  and  $M_{2p+1}$  for some  $i \in [p]$ .

We will build the set  $I$  via dynamic programming procedure. Since  $X$  is already included in  $V(I)$  it allows us to replace the first condition with  $|V(I) \setminus X| = k - |X|$ . The purpose of this dynamic programming is to construct a table that keeps track of  $|V(I) \setminus X|$  and  $|I|$ . Let  $\{v_1, \dots, v_{n'}\}$  be a degeneracy sequence of the vertices of  $G - X$  and  $\mathcal{X} = \{A_i \mid A_i = N(v_i) \cap \{v_1, \dots, v_{i-1}\} \setminus X\}$ . Each entry of the dynamic programming table  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  will contain a collection of independent sets of  $M$  that is a  $(3p(k-1) - q)$ -representative family of all the independent sets  $I$  of  $M$  such that  $|V(I) \setminus X| = i$ ,  $|I| = q$ ,  $Y = A_j \cap V(I)$ , the largest index of  $V(G) - X$  that occurs in  $V(I)$  is  $j$  and  $Z = A_\ell \cap V(I)$  for some  $\ell > j$ . Informally, it means that every independent set  $I$  has size  $q$  in  $M$ ,  $V(I)$  intersects  $A_j$  exactly in  $Y$ , and  $V(I)$  spans  $i$  vertices from  $G - X$ ,  $v_j \in V(I)$ , and  $V(I)$  has no vertex from  $\{v_{j+1}, \dots, v_{n'}\}$ . Furthermore, for every  $1 \leq j < n'$ ,  $V(I)$  intersects  $A_\ell$  exactly in  $Z$  for some  $\ell > j$ . Observe that for  $j = n'$ , there is no index  $\ell > j$ . Then we denote  $\ell = n' + 1$  and  $Z = \emptyset$  to keep the DP-states well-defined. We prove the following lemma that illustrates how a dynamic programming algorithm can construct all the entries of a table  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  for  $i \leq k - |X|, j \leq n', q \leq 3p(k-1), Y \subseteq A_j, Z \subseteq A_\ell$  and  $\ell > j$ . Indeed, if  $j = n'$ , then  $\ell = n' + 1$  and  $Z = \emptyset$ . Observe that there are at most  $2^n n$  possible choices of  $Y$  and  $2^n n$  possible choices for  $(Z, \ell)$  in the DP table  $\mathcal{T}$ . The following lemma illustrates how we compute the DP-table entries.

► **Lemma 14.** *Given matroid  $M$  of rank  $r = 3p(k-1)$  as described above, the entries of the table  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  for  $i \leq k - |X|, j \leq n', j < \ell, q \leq 3p(k-1), Y \subseteq A_j$  and  $Z \subseteq A_\ell$  can be computed in  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ -time.*

**Proof.** We describe a procedure  $\text{Construct}(\mathcal{T}[(i, j, q, Y), (Z, \ell)])$  for  $i \leq k - |X|, j \leq n'$  and  $q \leq 3p(k-1)$  as follows. Observe that every arc of  $I$  occurs in three copies, one in  $M_{2i-1}$ , one in  $M_{2i}$  and the other in  $M_{2p+1}$ . Given an arc  $a \in A_E$ , we use  $F_{a,i}$  to denote the set that contains the copies of  $a$  in  $M_{2i-1}, M_{2i}$  and  $M_{2p+1}$ . In the first part, we describe constructing the table entries  $\mathcal{T}[(0, 0, q, Y), (Z, \ell)]$  as follows.

- **(i)** For all  $1 \leq \ell \leq n'$ , we initialize  $\mathcal{T}[(0, 0, 0, \emptyset), (\emptyset, \ell)] = \{\emptyset\}$ .
- **(ii)** Consider the set of all the arcs in  $D_G[X]$ . We construct  $\mathcal{T}[(0, 0, q+3, \emptyset), (\emptyset, \ell)]$  from  $\mathcal{T}[(0, 0, q, \emptyset), (\emptyset, \ell)]$  as follows. For every  $I \in \mathcal{T}[(0, 0, q, \emptyset), (\emptyset, \ell)]$ , for every arc  $a \in D_G[X]$ , ( $1 \leq j \leq m$ ), and  $i \in \{1, \dots, p\}$ , we add  $I \cup F_{a,i}$  such that  $F_{a,i}$  extends  $I$ .
- **(iii)** Finally, we invoke Proposition 9 to reduce  $\mathcal{T}[(0, 0, q+3, \emptyset), (\emptyset, \ell)]$  into a  $(3p(k-1) - q - 3)$ -representative family of size  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ .

When we consider the table entries  $\mathcal{T}[(i, j, q+3, Y), (Z, \ell)]$  such that  $j = 0$ , observe that  $Y = Z = \emptyset$ . The reason is that for any  $I \in \mathcal{T}[(i, j, q+3, Y), (Z, \ell)]$  with the assumption of  $j = 0$  implies that  $i = 0$  and no vertex from  $G - X$  is part of  $V(I)$ . Since  $Y, Z \subseteq V(G) \setminus X$ , it must be that  $Y = Z = \emptyset$ . So, we consider only those entries in this first phase.

We analyze the running-time of the above process. Given  $\mathcal{T}[(0, 0, q, \emptyset), (\emptyset, \ell)]$ , computing  $\mathcal{T}[(0, 0, q+3, \emptyset), (\emptyset, \ell)]$  requires polynomial in the size of  $|\mathcal{T}[(0, 0, q, \emptyset), (\emptyset, \ell)]|$ . Then, computing a  $(3p(k-1) - q - 3)$ -representative family requires  $2^{\mathcal{O}(pk)}$ -time.

The process of computing table entries for  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  for  $Y \subseteq A_j$  and  $Z \subseteq A_\ell$  for  $\ell > j$  is more complex and needs more careful approach. We consider a lexicographic ordering of the indices  $((i, j, q, Y), (Z, \ell))$  and consider one by one as follows. For every

$i \geq 1$ , we compute the collection of independent sets in  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  using the collection of independent sets of  $\mathcal{T}[(i', j', q', Y'), (Z', \ell')]$  for  $j' < j$ ,  $j' < \ell'$ ,  $i = i' + 1$ , and  $q' < q$  as follows. We want to include  $v_j$  into  $V(I)$  such that  $|V(I) \setminus X| = i$ . We look at all the previous subproblems in the lexicographic ordering one by one. Suppose that  $I' \in \mathcal{T}[(i', j', q', Y'), (Z', \ell')]$ . By definition, it holds true that  $Y' = V(I') \cap A_{j'}$  and  $Z' = A_{\ell'} \cap V(I')$ . We say that  $I'$  is *extendable* to a set  $I \in \mathcal{T}[(i, j, q, Y), (Z, \ell)]$  if  $i = i' + 1$ ,  $Z' = Y$ , and  $\ell' = j$ . Observe that by definition  $V(I)$  and  $V(I')$  both intersect  $A_j$  exactly in  $Y$ , i.e.  $V(I) \cap A_j = Y$  and  $V(I') \cap A_j = Y$ . Moreover,  $j$  is the next larger index vertex included in  $V(I)$  after  $v_{j'}$ .

We construct the table entries of  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  using the table entries of  $\mathcal{T}[(i', j', q', Y'), (Z', \ell')]$  as follows.

Let  $d$  be the number of arcs that are incident to  $v_j$  such that either the other endpoints have lower indices or the other endpoint is in  $X$ . Formally, we consider the arcs that are either of the form  $(v_{j'}, v_j), (v_j, v_{j'}) \in A_E$  such that  $j' < j$  or of the form  $(u, v_j), (v_j, u)$  for some  $u \in X$ . Since  $G$  is an  $\eta$ -degenerate graph, observe that  $d \leq 2\eta + 2|X| \leq 2(k + \eta)$ . We create a set  $F$  of arcs as follows. For every arc  $a$  incident to  $v_j$ , we consider the sets  $F_{a,h}$  for every  $h \in [p]$ . We either add  $F_{a,h}$  into  $F$  for some  $h \in [p]$ , or do not add  $F_{a,h}$  into  $F$ . This ensures that there are  $(p+1)^d \leq (p+1)^{2\eta+2k}$  possible collections of arc-sets. For every nonempty such arc-set  $F$  and for every  $I' \in \mathcal{T}[(i', j', q', Y'), (Z', \ell)]$  satisfying  $Y = Z'$ ,  $i = i' + 1$  and  $\ell' = j$  (in other words  $I'$  that is extendable to a set in  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$ ), we add  $I' \cup F$  into  $\mathcal{T}[(i, j, q + |F|, Y), (Z, \ell)]$  when  $F$  extends  $I'$  and  $q = q' + |F|$ . Finally, invoke Proposition 9 to reduce  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  into its  $(3p(k-1) - q)$ -representative family containing at most  $2^{3p(k-1)}$  sets.

Observe that for every set  $I' \in \mathcal{T}[(i', j', q', Y'), (Z', \ell')]$ , there are at most  $(p+1)^{2\eta}$  sets  $I = I' \cup F$  that are added to the slot  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$ . Hence we have that

$$|\mathcal{T}[(i, j, q, Y), (Z, \ell)]| \leq (p+1)^{2|X|+2\eta} 2^{3pk} (p+k+\eta)^{\mathcal{O}(1)}$$

Since the number of indices is  $4^\eta n^2$ , the above implies that computing all the table entries can be performed in  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ -time. This completes the proof of the lemma.  $\blacktriangleleft$

Our next lemma ensures that the vertices of any independent set of size  $3p(k-1)$  computed by the above lemma induces a  $p$ -edge-connected subgraph.

**► Lemma 15.** *There is a set  $I \in \mathcal{T}[(k - |X|, j, 3p(k-1), Y), (Z, \ell)]$  for some  $Y \subseteq A_j$  and  $Z \subseteq A_\ell$  if and only if there exists  $S \supset X$  such that  $G[S]$  is a  $p$ -edge-connected subgraph of  $G$  with  $k$  vertices.*

**Proof (Sketch).**<sup>3</sup> First part of the proof is forward direction ( $\Rightarrow$ ). Let  $I \in \mathcal{T}[(k - |X|, j, 3p(k-1), Y), (Z, \ell)]$  be an independent set for some  $j \in [n']$ ,  $Y = A_j \cap V(I)$  and  $Z = V(I) \cap A_\ell$ . Let  $S = V(I)$  and it follows that  $|S \setminus X| = k - |X|$ . Note that  $|I| = 3p(k-1)$ . Due to Proposition 13, every arc of  $D_G$  occurs precisely in three copies. Recall that  $I$  was constructed by adding arcs  $F_{a,i}$  for some  $i \in [p]$  when the arc  $a$  incident to  $v \in V(G) \setminus X$  was added. But,  $F_{a,i}$  contains a copy of arc  $a$  in  $M_{2p+1}$ . Therefore, the construction of  $I$  ensures that no two distinct sets  $F_{a,i}$  and  $F_{a,i'}$  both are added. Hence  $D_G[V(I)]$  has  $p$  pairwise arc-disjoint out-branchings rooted at  $v_r$  and it follows from Proposition 10 that  $G[S]$  is  $p$ -edge-connected.

The other part of the proof is the backward direction ( $\Leftarrow$ ). Let  $G[S]$  be  $p$ -edge-connected with  $|S| = k$ , such that  $X \subseteq S$  and  $v_j$  is the vertex with highest index from  $\{v_1, \dots, v_n\} = V(G) \setminus X$ . It follows from Proposition 10 that there are  $p$  pairwise arc-disjoint out-branchings

<sup>3</sup> A complete detailed proof can be found in the full version.

## 45:10 Finding a Highly Connected Steiner Subgraph and its Applications

in  $D_G[S]$  rooted at  $v_r$ . Then, by Proposition 13, there is an independent set  $I$  such that  $V(I) = S$  containing the the set of arcs  $F \subseteq A_E$  such that  $|F| = p(k-1)$  and  $|I| = 3p(k-1)$ . We complete our proof by justifying that  $I$  is a candidate independent set of  $M$  for the slot  $\mathcal{T}[(k-|X|, j, 3p(k-1), Y), (Z, \ell)]$  for some  $Z = V(I) \cap A_\ell$  and  $\ell > j$ . If we prove that there is  $Y \subseteq N(v_j) \cap \{v_1, \dots, v_{j-1}\}$  such that  $\mathcal{T}[(k-|X|, j, 3p(k-1), Y), (Z, \ell)] \neq \emptyset$ , then we are done. We can give a proof of this claim by induction on  $i, j, q$  that  $\mathcal{T}[(k-|X|, j, 3p(k-1), Y), (Z, \ell)] \neq \emptyset$ . ◀

Using Lemma 14 and Lemma 15, we are ready to prove our theorem statement of our main result, i.e. Theorem 1 (we restate below).

► **Theorem 1.** STEINER SUBGRAPH EXTENSION can be solved in time  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ , where  $\eta$  is the degeneracy of the input graph.

**Proof.** We assume without loss of generality that  $X \neq \emptyset$  and  $G[X]$  is not  $p$ -edge-connected. Also, we use  $(G, X, k, p)$  to denote the input instance. Let  $\{v_1, \dots, v_{n'}\}$  be a degeneracy sequence of the vertices of  $G - X$  and consider an arbitrary vertex  $v_r \in X$ . The first step is to invoke Proposition 13 and construct a matroid  $M$ . We can also assume without loss of generality that  $(G, X, k-1, p)$  is a no-instance. Our next step is to invoke Lemma 14 and compute the table entries  $\mathcal{T}[(i, j, q, Y), (Z, \ell)]$  for all  $i \in \{1, \dots, k-|X|\}$ ,  $j \in [n']$ ,  $q \leq 3p(k-1)$ ,  $Y \subseteq A_j$ ,  $Z \subseteq A_\ell$  and  $\ell > j$ . It follows from Lemma 14 that all the table entries can be computed in  $2^{\mathcal{O}(pk+\eta)} n^{\mathcal{O}(1)}$ -time. Moreover, it follows from the Lemma 15 that for any  $I \in \mathcal{T}[(k-|X|, j, 3p(k-1), Y), (Z, \ell)]$ , it holds that  $G[V(I)]$  is a  $p$ -edge-connected subgraph. This completes the correctness proof of our algorithm. We finally output  $S = V(I)$  as the solution to the input instance. ◀

### 4 Applications of STEINER SUBGRAPH EXTENSION to some Graph Theoretic Problems

In this section, we describe some applications of our main result (Theorem 1) in parameterized algorithms. But before that, we prove the following lemma (proof is similar to the proof of Lemma 12).

► **Lemma 16** ( $\star$ ). *Let  $G$  be an input graph,  $p$  be a fixed constant, and  $\mathcal{G}$  be a polynomial-time recognizable hereditary graph class. Then, there exists a polynomial-time algorithm that can check if there is a set  $S \subseteq V(G)$  such that  $G - S \in \mathcal{G}$  and  $G[S]$  is  $p$ -edge-connected.*

The above lemma implies that for any polynomial-time recognizable (hereditary) graph class  $\mathcal{G}$ , we can test in polynomial-time if a feasible  $p$ -edge-connected vertex subset exists whose deletion results in a graph of class  $\mathcal{G}$ . Note that the class of all pathwidth-one graphs is a polynomial-time recognizable graph class. Moreover, for every fixed constant  $\eta$ , the class of all degree- $\eta$ -graphs, or the class of all  $\eta$ -treedepth graphs, or the class of all graphs with no  $P_\eta$  as subgraphs are all polynomial-time recognizable graph classes. So, we can test the existence of feasible solutions for all our problems in polynomial-time.

**Singly Exponential Algorithm for  $p$ -EDGE-CONNECTED- $\eta$ -DEGREE DELETION SET.** Now, we explain how Theorem 1 implies a singly exponential algorithm for  $p$ -EDGE-CONNECTED  $\eta$ -DEGREE DELETION SET problem. We formally state the problem below.

■ **Figure 1** An illustration of  $T_2$  and a cycle with hairs attached.

$p$ -EDGE-CONNECTED  $\eta$ -DEGREE DELETION SET ( $p$ -EDGE-CON-BDDS)

**Input:** An undirected graph  $G = (V, E)$  and an integer  $k$ .

**Parameter:**  $k$

**Goal:** Is there  $S \subseteq V(G)$  such that  $\Delta(G - S) \leq \eta$  and  $G[S]$  is  $p$ -edge-connected?

The following is the first application of our main result (Theorem 1). As we have a guarantee from Lemma 16 that we can test if an input graph has a feasible solution to our problems, we assume without loss of generality that the input graph actually has a feasible solution. We use this assumption for all our subsequent problems.

► **Corollary 2.**  $p$ -EDGE-CON-BDDS admits a  $2^{\mathcal{O}(pk+k\eta)}n^{\mathcal{O}(1)}$ -time algorithm.

The first part of the algorithm<sup>4</sup> for the above result uses enumeration of all minimal vertex subsets the removal of which results in a graph of maximum degree at most  $\eta$  and then it invokes Theorem 1.

**Singly Exponential Algorithm for  $p$ -EDGE-CON-PW1DS.** Now, we describe a singly exponential time algorithm for  $p$ -EDGE CONNECTED PATHWIDTH-1 VERTEX DELETION problem using Theorem 1. We formally define the problem as follows.

$p$ -EDGE-CON-PW1DS

**Input:** An undirected graph  $G = (V, E)$  and an integer  $k$ .

**Parameter:**  $k$

**Goal:** Is there  $S \subseteq V(G)$  such that  $G[S]$  is  $p$ -edge-connected and  $\text{pw}(G - S) \leq 1$ ?

We use the following characterization that are related to pathwidth one graphs.

► **Proposition 17** ([16, 4]). A graph  $G$  has pathwidth at most one if and only if it does not contain a cycle or  $T_2$  as a subgraph.

► **Proposition 18** ([26]). If  $G$  is a graph that does not contain any  $T_2, C_3, C_4$  as subgraphs, then each connected component of  $G$  is either a tree, or a cycle with zero or more pendant vertices (“hairs”) attached to it. (See Figure 1 for an illustration)

Observe that the graphs of pathwidth one do not have  $T_2, C_3, C_4$  as subgraphs. We prove the following lemma now.

► **Lemma 19** (\*). Let  $G$  be an undirected graph that does not have any  $T_2, C_3, C_4$  as subgraphs. Then, a 2-degeneracy sequence of  $G$  can be constructed in polynomial-time. Moreover, for every connected component  $D$  of  $G$ , a partition  $D = C \uplus P$  can be computed in polynomial-time such that  $C$  is an induced path (or cycle) and  $P$  is the set of pendant vertices attached to  $C$ .

<sup>4</sup> We refer to the full version for the proof

## 45:12 Finding a Highly Connected Steiner Subgraph and its Applications

It follows from Proposition 17 and Proposition 18 that any pathwidth one vertex deletion set must intersect all the subgraphs  $T_2, C_3, C_4$  of a graph. But, once we have a set  $X$  such that  $G - X$  has no  $T_2, C_3, C_4$  as subgraphs, then there are some connected components of  $G - X$  that can have cycles. In particular, due to Proposition 18, it holds that if a connected component of  $G - X$  has a cycle, then it must be a cycle with some (possibly empty set of) pendant hairs attached to it. Then, we would need to find  $S \supseteq X$  such that  $G[S]$  is  $p$ -edge-connected and  $S$  contains at least one vertex from each of these cycles. This requires us to design an algorithm that uses the ideas similar to Lemma 14 and Lemma 15 but also has to satisfy an additional condition. We state the following lemma and give a proof for completeness.

► **Lemma 20** ( $\star$ ). *Let  $G = (V, E)$  be an undirected graph and  $X \subseteq V(G)$  such that  $G - X$  has no  $T_2, C_3, C_4$  as subgraphs. Then, there exists an algorithm that runs in  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time and computes  $S \supseteq X$  of size at most  $k$  such that  $G - S$  has pathwidth at most one and  $G[S]$  is a  $p$ -edge-connected subgraph.*

Using the above lemma, we provide an  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time algorithm for  $p$ -EDGE CONNECTED PATHWIDTH-1 VERTEX DELETION problem as follows.

► **Theorem 3.**  *$p$ -EDGE-CON-PW1DS admits an algorithm that runs in  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time.*

**Proof.** Let  $(G, k)$  be an instance of  $p$ -EDGE CONNECTED PATHWIDTH-1 VERTEX DELETION problem. First we enumerate all minimal vertex subsets  $X$  of size at most  $k$  such that  $G - X$  has no  $T_2, C_3, C_4$  as subgraphs. Since  $T_2$  has 7 vertices,  $C_3$  has 3 vertices and  $C_4$  has 4 vertices, it takes  $\mathcal{O}^*(7^k)$ -time to enumerate all such subsets the deletion of which results in a graph that has no  $C_3, C_4, T_2$  as subgraphs. Let  $X$  be one such set such that  $G - X$  has no  $C_3, C_4, T_2$  as subgraphs. Due to Propositions 17 and 18, if  $D$  is a connected component of  $G - X$ , then either  $D$  is a caterpillar, or a cycle with hairs attached to it. It follows from Lemma 19 that there is a polynomial-time algorithm that gives a 2-degeneracy sequence  $\rho$  of the vertices of  $G - X$ . Moreover, if  $D$  is a connected component of  $G - X$ , then  $\rho$  provides a partition of  $D = C \uplus P$  such that  $C$  is a cycle and  $P$  is the set of hairs attached to  $C$ . In particular, the vertices of  $C$  are put first, followed by the vertices of  $P$  in  $\rho$ . Furthermore, putting the vertices of  $C$  first followed by the vertices of  $P$  gives a 2-degeneracy ordering of  $D$ . For each such subset  $X$ , we invoke Lemma 20 to give an algorithm that runs in  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time and outputs  $S$  such that  $X \subseteq S$  and  $G - S$  has pathwidth at most one. The correctness of this algorithm also follows from the proof of Lemma 20. This completes the proof of this theorem. ◀

### Singly Exponential Time Algorithms for $p$ -EDGE-CON- $\eta$ -TDDS and $p$ -EDGE-CON- $\eta$ -PVC.

Finally, we describe how we can get  $2^{\mathcal{O}(pk)}n^{\mathcal{O}(1)}$ -time algorithm for  $p$ -EDGE-CONNECTED  $\eta$ -TREEDEPTH DELETION SET and  $p$ -EDGE-CONNECTED  $\eta$ -PATH VERTEX COVER problems. Note that both  $p$  and  $\eta$  are fixed constants. We restate the problem definitions below.

$p$ -EDGE-CONNECTED  $\eta$ -TREEDEPTH DELETION SET ( $p$ -EDGE-CON- $\eta$ -TDDS)

**Input:** An undirected graph  $G = (V, E)$  and an integer  $k$ .

**Parameter:**  $k$

**Goal:** Is there  $S \subseteq V(G)$  such that  $G[S]$  is  $p$ -edge-connected and  $\text{td}(G - S) \leq \eta$ .

$p$ -EDGE-CONNECTED  $\eta$ -PATH VERTEX COVER

**Input:** An undirected graph  $G = (V, E)$  and an integer  $k$ .

**Parameter:**  $k$

**Goal:** Is there an  $S \subseteq V(G)$  with at most  $k$  vertices such that  $G - S$  has no  $P_\eta$  as subgraphs and  $G[S]$  is  $p$ -edge-connected?

It is clear from the problem definition that a set  $S$  is called an  $\eta$ -path vertex cover of  $G$  if  $G - S$  has no  $P_\eta$  as subgraph. The following proposition holds true for graphs of treedepth at most  $\eta$ .

► **Proposition 21** ([12]). *If a graph  $G$  has treedepth at least  $\eta + 1$ , then it has a connected subgraph  $H$  such that  $\text{td}(H) > \eta$  and  $|V(H)| \leq 2^{2^\eta}$ .*

The above proposition implies that  $\eta$ -TREEDPTH DELETION SET problem can be characterized as  $\mathcal{H}$ -HITTING SET problem where  $\mathcal{H}$  contains only subgraphs of bounded size. It follows from the definition that  $p$ -EDGE-CON- $\eta$ -PVC can be formulated in  $p$ -EDGE-CONNECTED  $\mathcal{H}$ -HITTING SET problem. It means that every minimal  $p$ -edge-connected  $\eta$ -treedepth deletion set contains a minimal  $\eta$ -treedepth deletion set and every minimal every minimal  $p$ -edge connected  $\eta$ -path vertex cover contains a minimal  $\eta$ -path vertex cover. We prove the following lemma that explains how we can construct a collection of all the minimal such solutions of size at most  $k$ .

► **Lemma 22** ( $\star$ ). *Given a (connected) undirected graph  $G = (V, E)$  and an integer  $k$ , the collection of all minimal  $\eta$ -treedepth deletion sets and the collection of all minimal  $\eta$ -path vertex covers can be obtained in  $2^{2^\eta k} n^{\mathcal{O}(1)}$ -time and  $\eta^k n^{\mathcal{O}(1)}$ -time respectively.*

The above lemma implies the next two results<sup>5</sup> as other applications of our main result.

► **Theorem 4.**  $p$ -EDGE-CON- $\eta$ -TDDS admits an algorithm that runs in  $2^{2^{2^\eta} + \mathcal{O}((p+\eta)k)} n^{2^{2^\eta}}$ -time.

Observe that a graph with no  $P_\eta$  as subgraph has treedepth at most  $\eta + 1$ . It means that such a graph also has bounded degeneracy. So, we have the following theorem.

► **Theorem 5.**  $p$ -EDGE-CON- $\eta$ -PVC admits an algorithm that runs in  $2^{\mathcal{O}((p+\eta)k)} n^{\mathcal{O}(1)}$ -time.

## 5 Conclusions and Future Work

There are several possible directions of future work. Our main result proves that STEINER SUBGRAPH EXTENSION is FPT when the removal of terminals results in a bounded degenerate graph. It is unclear if STEINER SUBGRAPH EXTENSION is FPT even when  $G - X$  is an arbitrary graph class and  $p$  is a fixed constant. Proving such a (positive or negative) result STEINER SUBGRAPH EXTENSION remains an interesting future work. If  $p = 2$ , then finding  $p$ -vertex/edge-connected steiner subgraph admits  $k^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ -time algorithm [19, 15]. It remains open if a 2-vertex-connected steiner subgraph can be obtained in  $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ -time even when the set of terminals is a vertex cover of the input graph. On the perspective of applications of Theorem 1, we have been successful in designing singly exponential-time FPT algorithms for  $p$ -EDGE-CON-BDDS,  $p$ -EDGE-CON- $\eta$ -TDDS,  $p$ -EDGE-CON-PW1DS and  $p$ -EDGE-CON- $\eta$ -PVC. But, our results do not capture several other graph classes. For instance,

<sup>5</sup> The proofs of the next two theorems can be found in the full version.

the above algorithm crucially relies that all minimal vertex deletion sets without connectivity requirements can be enumerated in  $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$ -time and that a bounded degeneracy sequence can be computed in polynomial-time. Therefore, obtaining an FPT algorithm with singly exponential running time for each of FEEDBACK VERTEX SET, CLUSTER VERTEX DELETION, COGRAPH VERTEX DELETION with  $p$ -edge-connectivity constraints (even with  $p = 2$ ) also remain interesting open problems.

---

## Abstract

We study the  $\alpha$ -FIXED CARDINALITY GRAPH PARTITIONING ( $\alpha$ -FCGP) problem, the generic local graph partitioning problem introduced by Bonnet et al. [Algorithmica 2015]. In this problem, we are given a graph  $G$ , two numbers  $k, p$  and  $0 \leq \alpha \leq 1$ , the question is whether there is a set  $S \subseteq V$  of size  $k$  with a specified coverage function  $\text{cov}_\alpha(S)$  at least  $p$  (or at most  $p$  for the minimization version). The coverage function  $\text{cov}_\alpha(\cdot)$  counts edges with exactly one endpoint in  $S$  with weight  $\alpha$  and edges with both endpoints in  $S$  with weight  $1 - \alpha$ .  $\alpha$ -FCGP generalizes a number of fundamental graph problems such as DENSEST  $k$ -SUBGRAPH, MAX  $k$ -VERTEX COVER, and MAX  $(k, n - k)$ -CUT.

A natural question in the study of  $\alpha$ -FCGP is whether the algorithmic results known for its special cases, like MAX  $k$ -VERTEX COVER, could be extended to more general settings. One of the simple but powerful methods for obtaining parameterized approximation [Manurangsi, SOSA 2019] and subexponential algorithms [Fomin et al. IPL 2011] for MAX  $k$ -VERTEX COVER is based on the greedy vertex degree orderings. The main insight of our work is that the idea of greedy vertex degree ordering could be used to design fixed-parameter approximation schemes (FPT-AS) for  $\alpha > 0$  and the subexponential-time algorithms for the problem on apex-minor free graphs for maximization with  $\alpha > 1/3$  and minimization with  $\alpha < 1/3$ .

## 1 Introduction

In this work, we study a broad class of problems called  $\alpha$ -FIXED CARDINALITY GRAPH PARTITIONING ( $\alpha$ -FCGP), originally introduced by Bonnet et al. [2]<sup>1</sup>. The input is a graph  $G = (V, E)$ , two non-negative integers  $k, p$ , and a real number  $0 \leq \alpha \leq 1$ . The question is whether there is a set  $S \subseteq V$  of size exactly  $k$  with  $\text{cov}_\alpha(S) \geq p$  ( $\text{cov}_\alpha(S) \leq p$  for the minimization variant), where

---

<sup>1</sup> Bonnet et al. [2] called the problem “local graph partitioning problem”, however we adopt the nomenclature from Koana et al. [19].

$$\text{cov}_\alpha(S) := (1 - \alpha) \cdot m(S) + \alpha \cdot m(S, V \setminus S).$$

Here,  $m(S)$  is the number of edges with both endpoints in  $S$ , and  $m(S, V \setminus S)$  is the number of edges with one endpoint in  $S$  and other in  $V \setminus S$ . We will call the maximization and minimization problems MAX  $\alpha$ -FCGP and MIN  $\alpha$ -FCGP, respectively. This problem generalizes many problems, namely, DENSEST  $k$ -SUBGRAPH (for  $\alpha = 0$ ), MAX  $k$ -VERTEX COVER<sup>2</sup> (for  $\alpha = 1/2$ ), MAX  $(k, n - k)$ -CUT (for  $\alpha = 1$ ), and their minimization counterparts.

Although there are plethora of publications that study these special cases, the general  $\alpha$ -FCGP has not received much attention, except for the work of Bonnet et al. [2], Koana et al. [19], and Schachnai and Zehavi [23]. In this paper, we aim to demonstrate the wider potential of the existing algorithms designed for specific cases, such as MAX  $k$ -VERTEX COVER, by presenting an algorithm that can handle the more general problem of  $\alpha$ -FCGP. Algorithms for these specific cases often rely on greedy vertex degree orderings. For instance, Manurangsi [20], showing that a  $(1 - \varepsilon)$ -approximate solution can be found in the set of  $\mathcal{O}(k/\varepsilon)$  vertices with the largest degrees, gave a  $(1 - \varepsilon)$ -approximation algorithm for MAX  $k$ -VERTEX COVER that runs in time  $(1/\varepsilon)^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ . Fomin et al. [14] gave a  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ -time algorithm for MAX  $k$ -VERTEX COVER on apex-minor graphs via bidimensionality arguments, by showing that an optimal solution  $S$  is adjacent to every vertex of degree at least  $d + 1$ , where  $d$  is the minimum degree over vertices in  $S$ . In this work, we will give approximation algorithms as well as subexponential-time algorithms for apex-minor free graphs exploiting the greedy vertex ordering.

For approximation algorithms, we will show that both MAX  $\alpha$ -FCGP and MIN  $\alpha$ -FCGP admit *FPT Approximation Schemes* (FPT-AS) for  $\alpha > 0$ , i.e., there is an algorithm running in time  $f(k, \alpha, \varepsilon) \cdot n^{\mathcal{O}(1)}$  that finds a set  $S$  of size  $k$  with  $\text{cov}_\alpha(S) \geq (1 - \varepsilon) \cdot \text{OPT}$  (or  $\text{cov}_\alpha(S) \leq (1 + \varepsilon) \cdot \text{OPT}$  for the minimization variant), where  $\text{OPT}$  denotes the optimal value of  $p$ . Previously, the special cases were known to admit FPT approximation schemes; see [22, 16, 17, 20] for  $\alpha = 1/2$  and [2] for  $\alpha = 1$ . In particular, the state-of-the-art running time for  $\alpha = 1/2$  is the aforementioned algorithm of Manurangsi that runs in time  $(1/\varepsilon)^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$  for maximization (also for the minimization variant). For  $\alpha = 0$ , the situation is more negative; MAX  $\alpha$ -FCGP (namely, DENSEST  $k$ -SUBGRAPH) does not admit any  $o(k)$ -approximation algorithm with running time  $f(k) \cdot n^{\mathcal{O}(1)}$  under the Strongish Planted Clique Hypothesis [21]. MIN  $\alpha$ -FCGP is also hard to approximate when  $\alpha = 0$  since it encompasses INDEPENDENT SET as a special case for  $p = 0$ .

Next, we discuss the regime of subexponential-time algorithms. Amini et al. [1] showed that MAX  $k$ -VERTEX COVER is FPT on graphs of bounded degeneracy, including planar graphs, giving a  $k^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ -time algorithm. They left it open whether it can be solved in time  $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ . This was answered in the affirmative by Fomin et al. [14], who showed that MAX  $k$ -VERTEX COVER on apex-minor free graphs can be solved in time  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$  time. Generalizing this result, we give a  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ -time algorithm for MAX  $\alpha$ -FCGP with  $\alpha > 1/3$  and MIN  $\alpha$ -FCGP with  $\alpha < 1/3$ . The complexity landscape of MAX  $\alpha$ -FCGP with  $\alpha < 1/3$  (and MIN  $\alpha$ -FCGP with  $\alpha > 1/3$ ) is not well understood. It is a long-standing open question whether DENSEST  $k$ -SUBGRAPH on planar graphs is NP-hard [4]. Note that the special case CLIQUE is trivially polynomial-time solvable on planar graphs because a clique on 5 vertices does not admit a planar embedding.

---

<sup>2</sup> This problem is also referred to as PARTIAL VERTEX COVER.

### Further related work

As mentioned, special cases of  $\alpha$ -FCGP when  $\alpha \in \{0, 1/2, 1\}$  have been extensively studied. For instance, the W[1]-hardness for the parameter  $k$  has been long known for these special cases [3, 11, 15]. Both MAX  $\alpha$ -FCGP and MIN  $\alpha$ -FCGP are actually W[1]-hard for every  $\alpha \in [0, 1]$  with the exception  $\alpha \neq 1/3$ , as can be seen from a parameterized reduction from CLIQUE and INDEPENDENT SET on regular graphs. Note that  $\alpha$ -FIXED CARDINALITY GRAPH PARTITIONING becomes trivial when  $\alpha = 1/3$  because  $\text{cov}_\alpha(S) = \frac{1}{3} \cdot \sum_{v \in S} d(v)$  for any  $S \subseteq V$  where  $d(v)$  is the degree of  $v$ .

Bonnet et al. [2] gave a  $(\Delta k)^{2k} \cdot n^{\mathcal{O}(1)}$ -time algorithm for  $\alpha$ -FCGP where  $\Delta$  is the maximum degree. They also gave an algorithm with running time  $\Delta^k \cdot n^{\mathcal{O}(1)}$  for MAX  $\alpha$ -FCGP with  $\alpha > 1/3$  and MIN  $\alpha$ -FCGP with  $\alpha < 1/3$ . This result was strengthened by Schachnai and Zehavi [23]; they gave a  $4^{k+o(k)} \Delta^k \cdot n^{\mathcal{O}(1)}$ -time algorithm for any value of  $\alpha$ . Koana et al. [19] showed that MAX  $\alpha$ -FCGP admits polynomial kernels on sparse families of graphs when  $\alpha > 1/3$ . For instance, MAX  $\alpha$ -FCGP admits a  $k^{\mathcal{O}(d)}$ -sized kernel where  $d$  is the degeneracy of the input graph. They also showed analogous results for MIN  $\alpha$ -FCGP with  $\alpha < 1/3$ .

### Preliminaries

For an integer  $n$ , let  $[n]$  denote the set  $\{1, \dots, n\}$ .

We use the standard graph-theoretic notation and refer to the textbook of Diestel [10] for undefined notions. In this work, we assume that all graphs are simple and undirected. For a graph  $G$  and a vertex set  $S$ , let  $G[S]$  be the subgraph of  $G$  induced by  $S$ . For a vertex  $v$  in  $G$ , let  $d(v)$  be its *degree*, i.e., the number of its neighbors. For vertex sets  $X, Y$ , let  $m(X) := |\{uv \in E \mid u, v \in X\}|$  and  $m(X, Y) := |\{uv \in E \mid u \in X, v \in Y\}|$ . In this work, an optimal solution for MAX  $\alpha$ -FCGP (and MIN  $\alpha$ -FCGP) is a vertex set  $S$  of size  $k$  such that  $\text{cov}_\alpha(S) \geq \text{cov}_\alpha(S')$  (resp.,  $\text{cov}_\alpha(S) \leq \text{cov}_\alpha(S')$ ) for every vertex set of size  $k$ . A graph  $H$  is a *minor* of  $G$  if a graph isomorphic to  $H$  can be obtained from  $G$  by vertex and edge removals and edge contractions. Given a graph  $H$ , a family of graph  $\mathcal{H}$  is said to be  *$H$ -minor free* if there is no  $G \in \mathcal{H}$  having  $H$  as a minor. A graph  $H$  is an *apex graph* if  $H$  can be made planar by the removal of a single vertex.

We refer to the textbook of Cygan et al. [5] for an introduction to Parameterized Complexity and we refer to the paper of Marx [22] for an introduction to the area of parameterized approximation.

## 2 FPT Approximation Algorithms

In this section, we design an FPT Approximation Scheme for MAX  $\alpha$ -FCGP as well as MIN  $\alpha$ -FCGP parameterized by  $k$  and  $\alpha$ , assuming  $\alpha > 0$ . More specifically, we prove the following theorem.

► **Theorem 1.** *For any  $0 < \alpha \leq 1$  and  $0 < \epsilon \leq 1$ , MAX  $\alpha$ -FCGP and MIN  $\alpha$ -FCGP each admits an FPT-AS parameterized by  $k$ ,  $\epsilon$  and  $\alpha$ . More specifically, given a graph  $G = (V, E)$  and an integer  $k$ , there exists an algorithm that runs in time  $f(k, \alpha, \epsilon) \cdot n^{\mathcal{O}(1)}$ , and finds a set  $S \subseteq V$  such that  $\text{cov}_\alpha(S) \geq (1 - \epsilon) \cdot \text{cov}_\alpha(O)$  for MAX  $\alpha$ -FCGP and  $\text{cov}_\alpha(S) \leq (1 + \epsilon) \cdot \text{cov}_\alpha(O)$  for MIN  $\alpha$ -FCGP, where  $O \subseteq V$  is an optimal solution.*

For the case that  $\text{OPT} := \text{cov}_\alpha(O)$  is large, the following greedy argument will be helpful.

► **Lemma 2.** For MAX  $\alpha$ -FCGP, let  $S$  be the set of  $k$  vertices with the largest degrees. Then,  $\text{cov}_\alpha(S) \geq \text{OPT} - 2k^2$ . For MIN  $\alpha$ -FCGP, let  $S$  be the set of  $k$  vertices with the smallest degrees. Then,  $\text{cov}_\alpha(S) \leq \text{OPT} + 2k^2$ .

**Proof.** Without loss of generality, we assume that  $O \neq S$ . Let  $S \setminus O = \{y_1, y_2, \dots, y_t\}$ , and  $O \setminus S = \{w_1, w_2, \dots, w_t\}$ , where  $1 \leq t \leq k$ . Here, we index the vertices so that  $d(y_i) \geq d(y_j)$  and  $d(w_i) \geq d(w_j)$  (for MIN  $\alpha$ -FCGP,  $d(y_i) \leq d(y_j)$  and  $d(w_i) \leq d(w_j)$ ) for  $i < j$ . Note that due to the choice of  $S$ , it holds that  $d(y_i) \geq d(w_i)$  ( $d(y_i) \leq d(w_i)$  for MIN  $\alpha$ -FCGP) for each  $1 \leq i \leq t$ .

Now we define a sequence of solutions  $O_0, O_1, \dots, O_t$ , where  $O_0 = O$ , and for each  $1 \leq i \leq t$ ,  $O_i := (O_{i-1} \setminus \{w_i\}) \cup \{y_i\}$ . Note that  $O_t = S$ . We claim that for each  $1 \leq i \leq t$ ,  $\text{cov}_\alpha(O_i) \geq \text{cov}_\alpha(O_{i-1}) - 2k$  for MAX  $\alpha$ -FCGP and  $\text{cov}_\alpha(O_i) \leq \text{cov}_\alpha(O_{i-1}) + 2k$  for MIN  $\alpha$ -FCGP. To this end, we note that  $O_i$  is obtained from  $O_{i-1}$  by removing  $w_i$  and adding  $y_i$ . Thus,  $\text{cov}_\alpha(O_i) = \text{cov}_\alpha(O_{i-1}) - (\alpha m_1 + ((1 - \alpha) - \alpha) \cdot m_2) + \alpha m_3 + ((1 - \alpha) - \alpha) \cdot m_4$ , where

$$\begin{aligned} m_1 &:= m(\{w_i\}, V \setminus O_{i-1}), & m_2 &:= m(\{w_i\}, O_{i-1} \setminus \{w_i\}), \\ m_3 &:= m(\{y_i\}, V \setminus O_i), & m_4 &:= m(\{y_i\}, O_i \setminus \{w_i\}). \end{aligned}$$

Observe that  $d(w_i) - k \leq m_1 \leq d(w_i)$ ,  $d(y_i) - k \leq m_3 \leq d(y_i)$ , and  $0 \leq m_2, m_4 \leq k$ . We consider MAX  $\alpha$ -FCGP first. We have that

$$\begin{aligned} \text{cov}_\alpha(O_i) &= \text{cov}_\alpha(O_{i-1}) + \alpha(m_3 - m_1) + (1 - 2\alpha)(m_4 - m_2) \\ &\geq \text{cov}_\alpha(O_{i-1}) + \alpha(m_3 - m_1) - |(1 - 2\alpha)(m_4 - m_2)|. \end{aligned}$$

Since  $m_3 - m_1 \geq d(y_i) - d(w_i) - k \geq -k$  and  $|(1 - 2\alpha)(m_4 - m_2)| \leq k$ , we obtain  $\text{cov}_\alpha(O_i) \geq \text{cov}_\alpha(O_{i-1}) - 2k$ , regardless of the value of  $\alpha$ . We consider MIN  $\alpha$ -FCGP next. It holds that

$$\begin{aligned} \text{cov}_\alpha(O_i) &= \text{cov}_\alpha(O_{i-1}) + \alpha(m_3 - m_1) + (1 - 2\alpha)(m_4 - m_2) \\ &\leq \text{cov}_\alpha(O_{i-1}) + \alpha(m_3 - m_1) + |(1 - 2\alpha)(m_4 - m_2)|. \end{aligned}$$

Since  $m_3 - m_1 \leq d(y_i) - d(w_i) + k \leq k$  and  $|(1 - 2\alpha)(m_4 - m_2)| \leq k$ , we obtain  $\text{cov}_\alpha(O_i) \leq \text{cov}_\alpha(O_{i-1}) + 2k$ , regardless of the value of  $\alpha$ .

Therefore,  $\text{cov}_\alpha(O_t) \geq \text{cov}_\alpha(O_0) - 2kt \geq \text{OPT} - 2k^2$  for MAX  $\alpha$ -FCGP and  $\text{cov}_\alpha(O_t) \leq \text{cov}_\alpha(O_0) + 2kt \leq \text{OPT} + 2k^2$  for MIN  $\alpha$ -FCGP. ◀

Lemma 2 allows us to find an approximate solution when OPT is sufficiently large. The case that OPT is small remains. We use different approaches for MAX  $\alpha$ -FCGP and MIN  $\alpha$ -FCGP.

### Algorithm for MAX $\alpha$ -FCGP

Let  $v_1$  be a vertex with the largest degree. Our algorithm considers two cases depending on whether  $d(v_1) > \Delta := \frac{2k^2}{\epsilon\alpha} + k$ . If  $d(v_1) > \Delta$ , we can argue that the set  $S$  from Lemma 2 a  $(1 - \epsilon)$ -approximate solution. To that end, we make the following observation.

► **Observation 3.** If  $d(v_1) > \Delta$ , then  $2k^2 \leq \epsilon \cdot \text{cov}_\alpha(S)$ .

**Proof.** Note that  $m(S, V \setminus S) = \sum_{u \in S} m(\{u\}, V \setminus S) \geq m(\{v_1\}, V \setminus S) \geq d(v_1) - k$ , where the inequality follows from the fact that at most  $k$  edges incident to  $v_1$  can have the other endpoint in  $S$ . This implies that

$$\text{cov}_\alpha(S) \geq \alpha \cdot m(S, V \setminus S) \geq \alpha \cdot (d(v_1) - k) \geq \frac{2k^2}{\epsilon}.$$

Where we use the assumptions that  $0 < \alpha \leq 1$  and  $d(v_1) \geq \Delta$ . ◀

Thus, for  $d(v_1) > \Delta$ , we have  $\text{OPT} \leq \text{cov}_\alpha(S) + 2k^2 \leq (1 + \varepsilon) \cdot \text{cov}_\alpha(S)$ , and thus  $\text{cov}_\alpha(S) \geq (1 - \varepsilon) \cdot \text{OPT}$ .

So assume that  $d(v_1) < \Delta$ . In this case, the maximum degree of the graph is bounded by  $\Delta$ . Let  $O \subseteq V$  be an optimal solution. Then the total number of edges contributing to  $\text{cov}_\alpha(O)$  is bounded by  $k\Delta = \mathcal{O}(k^3/\alpha\epsilon)$ . Let  $Q$  be the set of vertices in  $V \setminus O$  that have a neighbor in  $O$ , and note that  $|Q| = \mathcal{O}(k^3/\alpha\epsilon)$ . Let  $z = |O| + |Q|$ , and note that  $z = \mathcal{O}(k^3/\alpha\epsilon)$ .

We first guess the structure of the subgraph  $G' = (O \cup Q, E')$ , where  $E'$  consists of all edges with at least one endpoint in  $O$ . For each guess for  $G'$ , we check whether there exists a subgraph in  $G$  that is isomorphic to  $G'$ . Over all guesses where we find an isomorphic subgraph, we return the solution maximizing the  $\text{cov}_\alpha(\cdot)$  value. Note that the number of guesses is bounded by  $2^{z^2} = g(k, \alpha, \epsilon)$ . Since the maximum degree of  $G$  is bounded by  $\Delta$ , and the number of vertices in the subgraph corresponding to each guess is  $z$ , we can solve each instance of SUBGRAPH ISOMORPHISM in time  $2^{\mathcal{O}(z\Delta)} z! \cdot n^{\mathcal{O}(1)} = g'(k, \alpha, \epsilon) \cdot n^{\mathcal{O}(1)}$  using random separation, e.g., Theorem 5.7 in [5]. Thus, overall, the running time of the algorithm is bounded by some  $f(k, \alpha, \epsilon) \cdot n^{\mathcal{O}(1)}$ . Combining both cases, we conclude the proof of Theorem 1.

### Algorithm for MIN $\alpha$ -FCGP

For MIN  $\alpha$ -FCGP, our algorithm considers two cases depending on the value of OPT. If  $\text{OPT} \geq \frac{2k^2}{\epsilon}$ , then our algorithm returns the set  $S$  from Lemma 2. Note that  $\text{cov}_\alpha(S) \leq \text{OPT} + 2k^2 \leq (1 + \varepsilon) \cdot \text{OPT}$ .

Now suppose that  $\text{OPT} < \frac{2k^2}{\epsilon}$ . In this case, we know that  $O$  cannot contain a vertex of degree larger than  $\Delta = \frac{2k^2}{\alpha\epsilon} + k$ , for otherwise,  $\text{cov}_\alpha(O) > \alpha(\Delta - k) \geq \text{OPT}$ , which is a contradiction.

In this case, we can guess the structure of  $G' = (O \cup N(O), E')$ , where  $E'$  consists of all edges with at least one endpoint in  $E'$ . Then, we can find a subgraph isomorphic to  $G'$  using an FPT algorithm (we can delete the edges between all vertices whose degree is larger than  $\Delta$ ). This takes FPT time.

Since the value of OPT is unknown to us, we cannot directly conclude which case is applicable. So we find a solution for each case and return a better one.

## 3 Subexponential FPT Algorithm for MAX $\alpha$ -FCGP on Apex-Minor Free Graphs

Fomin et al. [14] showed that PARTIAL VERTEX COVER on apex-minor free graphs can be solved in time  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ . In this section, we will prove its generalization to MAX  $\alpha$ -FCGP as well as MIN  $\alpha$ -FCGP:

- **Theorem 4.** *For an apex graph  $H$ , let  $\mathcal{H}$  be a family of  $H$ -minor free graphs.*
- *For any  $\alpha \geq 1/3$ , MAX  $\alpha$ -FCGP for  $\mathcal{H}$  can be solved in  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$  time.*
  - *For any  $\alpha \leq 1/3$ , MIN  $\alpha$ -FCGP for  $\mathcal{H}$  can be solved in  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$  time.*

We will give a proof for the maximization variant. The minimization variant follows analogously. Let  $\sigma = v_1, v_2, \dots, v_n$  be an ordering of vertices of  $V$  in the non-increasing order of degrees, with ties broken arbitrarily. That is,  $d(v_1) \geq d(v_2) \geq \dots \geq d(v_{n-1}) \geq d(v_n)$ . We will denote the graph by  $G = (V_\sigma, E)$  to emphasize the fact that the vertex set is ordered w.r.t.  $\sigma$ . We also let  $V_\sigma^j = \{v_1, \dots, v_j\}$ . We first prove the following lemma.

► **Lemma 5.** *Let  $G = (V_\sigma, E)$  be a yes-instance for MAX  $\alpha$ -FCGP, where  $1/3 \leq \alpha \leq 1$ . Let  $C = \{u_{i_1}, u_{i_2}, \dots, u_{i_k}\}$  be the lexicographically smallest solution for MAX  $\alpha$ -FCGP and  $u_{i_k} = v_j$  for some  $j$ . Then  $C$  is a dominating set of size  $k$  for  $G[V_\sigma^j]$ .*

**Proof.** Suppose for the contradiction that  $C$  is not a dominating set for  $G[V_\sigma^j]$ . Then, there exists a vertex  $v_i$  with  $1 \leq i < j$  such that  $N[v_i] \cap C = \emptyset$ . Set  $C' = (C \setminus \{v_j\}) \cup \{v_i\}$ . Note that  $d(v_i) \geq d(v_j)$ . Define the following:

$$\begin{aligned} m_1 &= m(\{v_j\}, V \setminus C), \\ m_2 &= m(\{v_j\}, C \setminus \{v_j\}), \\ m_3 &= m(\{v_i\}, (V \setminus C) \cup \{v_j\}) = d(v_i), \\ m_4 &= m(\{v_i\}, C \setminus \{v_j\}) = 0. \end{aligned}$$

We will show that  $C'$  is another solution for the MAX  $\alpha$ -FCGP instance. Since  $C' \setminus \{v_i\} = C \setminus \{v_j\}$ , it suffices to show that

$$\text{cov}_\alpha(C') - \text{cov}_\alpha(C) = (\text{cov}_\alpha(C') - \text{cov}_\alpha(C' \setminus \{v_i\})) - (\text{cov}_\alpha(C) - \text{cov}_\alpha(C \setminus \{v_j\}))$$

is nonnegative. By definition,

$$\begin{aligned} \text{cov}_\alpha(C') - \text{cov}_\alpha(C' \setminus \{v_i\}) &= \alpha \cdot m_3 + ((1 - \alpha) - \alpha) \cdot m_4 = \alpha \cdot d(v_i) \text{ and} \\ \text{cov}_\alpha(C) - \text{cov}_\alpha(C \setminus \{v_j\}) &= \alpha \cdot m_1 + ((1 - \alpha) - \alpha) \cdot m_2 \leq \alpha \cdot (m_1 + m_2) = \alpha \cdot d(v_j), \end{aligned} \tag{1}$$

where the inequality is due to the assumption that  $\alpha \geq 1/3$ . Therefore,

$$\text{cov}_\alpha(C') - \text{cov}_\alpha(C) = \alpha \cdot (d(v_i) - d(v_j)) \geq 0,$$

which is a contradiction to the assumption that  $C$  is the lexicographically smallest solution for MAX  $\alpha$ -FCGP. ◀

In view of Lemma 5, we can use the following approach to search for the lexicographically smallest solution  $C$ . First, we guess the last vertex  $v_j$  of  $C$  in the ordering  $\sigma$ , i.e., we search for a solution  $C$  such that  $v_j \in C$  and  $C \subseteq V_\sigma^j$ . If  $G[V_\sigma^j]$  has no dominating set of size at most, say  $2k$ , then we reject. This can be done in polynomial time, since DOMINATING SET admits a PTAS on apex-minor free graphs [7]. We thus may assume that there is a dominating set of size  $2k$  in  $G[V_\sigma^j]$ . It is known that an apex-minor free graph with a dominating set of size  $\kappa$  has treewidth  $\mathcal{O}(\sqrt{\kappa})$ , where  $\mathcal{O}$  hides a factor depending on the apex graph whose minors are excluded [6, 9, 12]. We can use a constant-factor approximation algorithm of Demaine [8] to find a tree decomposition  $\mathcal{T}$  of width  $w \in \mathcal{O}(\sqrt{k})$ . Finally, we solve the problem via dynamic programming over the tree decomposition. Bonnet et al. [2] gave a  $\mathcal{O}^*(2^w)$ -time algorithm that solves MAX  $\alpha$ -FCGP with a tree decomposition of width  $w$  given. We need to solve a slightly more general problem because  $\mathcal{T}$  is the tree decomposition is over  $V_\sigma^j$ . To remove  $V \setminus V_\sigma^j$ , we introduce a weight  $\omega: V_\sigma^j \rightarrow \mathbb{N}$  defined by  $\omega(v) = |N(v) \cap (V \setminus V_\sigma^j)|$ . The objective is then to maximize  $\text{cov}_\alpha(C) + \alpha \sum_{v \in C} \omega(v)$ . The dynamic programming algorithm of Bonnet et al. can be adapted to solve this weighted variant in the same running time. Thus, we obtain a  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ -time algorithm for MAX  $\alpha$ -FCGP.

For MIN  $\alpha$ -FCGP, we can show the following lemma whose proof is omitted because it is almost analogous to the previous one. The only change is that,  $V_\sigma$  refers to the vertices in the non-decreasing order of degrees. Also, we consider the regime where  $0 \leq \alpha \leq 1/3$ , which implies  $\alpha \leq 1 - 2\alpha$ , which would give the reverse inequality in (1).

► **Lemma 6.** *Let  $G = (V_\sigma, E)$  be a yes-instance for MAX  $\alpha$ -FCGP, where  $0 \leq \alpha \leq 1/3$ . Let  $C = \{u_{i_1}, u_{i_2}, \dots, u_{i_k}\}$  be the lexicographically smallest solution for MAX  $\alpha$ -FCGP and  $u_{i_k} = v_j$  for some  $j$ . Then  $C$  is a dominating set of size  $k$  for  $G[V_\sigma^j]$ .*

With this lemma at hand, an analogous algorithm solves MIN  $\alpha$ -FCGP in  $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$  time, thereby proving Theorem 4.

## 4 Conclusion

In this paper, we demonstrated that the algorithms exploiting the “degree-sequence” that have been successful for designing algorithms for MAX  $k$ -VERTEX COVER naturally generalize to MAX/MIN  $\alpha$ -FCGP. Specifically, we designed FPT approximations for MAX/MIN  $\alpha$ -FCGP parameterized by  $k, \alpha$ , and  $\epsilon$ , for any  $\alpha \in (0, 1]$ . For MAX  $\alpha$ -FCGP, this result is tight since, when  $\alpha = 0$ , the problem is equivalent to DENSEST  $k$ -SUBGRAPH, which is hard to approximate in FPT time [21]. We also designed subexponential FPT algorithms for MAX  $\alpha$ -FCGP (resp. MIN  $\alpha$ -FCGP) for the range  $\alpha \geq 1/3$  (resp.  $\alpha \leq 1/3$ ) on any apex-minor closed family of graphs. It is a natural open question whether one can obtain subexponential FPT algorithms for MAX/MIN  $\alpha$ -FCGP for the entire range  $\alpha \in [0, 1]$ . A notable special case is that of DENSEST  $k$ -SUBGRAPH on planar graphs. In this case, the problem is not even known to be NP-hard, if the subgraph is allowed to be disconnected. For the DENSEST CONNECTED  $k$ -SUBGRAPH problem, it was shown by Keil and Brecht [18] that the problem is NP-complete on planar graphs. From the other side, it can be shown that DENSEST CONNECTED  $k$ -SUBGRAPH admits a subexponential in  $k$  randomized algorithm on apex-minor free graphs using the general results of Fomin et al. [13]. Thus, dealing with disconnected dense subgraphs is difficult for both algorithms and lower bounds.

## Abstract

Graph connectivity is a fundamental combinatorial optimization problem that arises in many practical applications, where usually a spanning subgraph of a network is used for its operation. However, in the real world, links may fail unexpectedly deeming the networks non-operational, while checking whether a link is damaged is costly and possibly erroneous. After an event that has damaged an arbitrary subset of the edges, the network operator must find a spanning tree of the network using non-damaged edges by making as few checks as possible.

Motivated by such questions, we study the problem of finding a spanning tree in a network, when we only have access to noisy queries of the form “Does edge  $e$  exist?”. We design efficient algorithms, even when edges fail adversarially, for all possible error regimes; 2-sided error (where any answer might be erroneous), false positives (where “no” answers are always correct) and false negatives (where “yes” answers are always correct). In the first two regimes we provide efficient algorithms and give matching lower bounds for general graphs. In the False Negative case we design efficient algorithms for large interesting families of graphs (e.g. bounded treewidth, sparse). Using the previous results, we provide tight algorithms for the practically useful family of planar graphs in all error regimes.

## 1 Introduction

From road and railway networks to electric circuits and computer networks, maintaining an operational spanning subgraph of a network is crucial in many real-life applications. This problem can be viewed as a traditional combinatorial optimization problem, graph connectivity. However, in real-life applications, edges sometimes fail; a natural destruction on the road or a malfunction in the connector cable can render a link in the network non

operational. Worse still, detecting faulty connections is not always that simple; our tools may be unreliable, resulting in untrustworthy indications. Can we efficiently find an operational spanning tree, when we cannot obtain reliable signals on the operation of edges?

**In this work we study the problem of finding a spanning tree using noisy queries on the existence of edges.** Specifically, given a moldgraph  $G$ , where some subgraph  $H$  of  $G$  is realized, we have access to an oracle that answers questions of the form “Does edge  $e$  exist in  $H$ ?”. The answers the oracle gives are *inconsistent*: for a specific edge  $e$ , the answer might differ every time. Queries to the oracle are costly, therefore our goal is to find a spanning tree asking as few queries as possible. We design efficient algorithms that achieve this goal, in all 3 different error regimes; 2-sided (where any answer might be erroneous), 1-sided false positives (where “no” answers are always correct) and 1-sided false negatives (where “yes” answers are always correct).

## 1.1 Our Contribution

As a warm-up, we begin by solving the simpler problem of learning whether the tree is connected (Theorem 7). Following that, we proceed to our main problem, which is finding a realized spanning tree in three different error regimes. In the 2-sided error case, we give an algorithm performing  $O(m \log m)$  queries and show that no algorithm can perform better, even on special cases like sparse graphs. In the 1-sided False Negative error regime, we design an algorithm that is optimal on planar graphs and yields efficient guarantees for other special families like graphs with treewidth  $k$  or degeneracy  $k$  ( $O(km)$  queries) and graphs with Hadwiger number  $k$  ( $O(k\sqrt{\log km})$  queries). The same algorithm can be used for general graphs, and outside the aforementioned families, its performance gracefully degrades to that of the naive strategy (that is  $O(m \log n)$  queries). It is noteworthy that this is the only algorithm that breaks the  $O(m \log m)$  barrier and it achieves it by employing an adaptive strategy.

In the False-Positive error case, our algorithm obtains tight guarantees for general graphs (Theorem 19), while in the special case where the realized graph is acyclic and the moldgraph is planar, the query complexity becomes linear. Both in the False-Negative and the False-Positive case, our algorithms *do not need to know* whether the graph has any special properties (sparsity, acyclic realized subgraph etc), they can simply run a unified algorithm that achieves the best guarantee according to each case.

Our results, imply tight algorithms for planar graphs, which is a family of graphs that is frequently encountered in road/railway networks, electrical circuits, image processing/computer vision [15, 14].

## 1.2 Related Work

Variations of this problem have been studied in literature, however they differ from our setting. A crucial assumption in all of the previous works, is that each edge has an independent probability of existence, which however, does not always bear out in practice. For example, a power outage may deem several local network links non-operational. In our work, we allow the existence of different edges to be arbitrarily correlated.

Feige et al. in [4] first studied the evaluation of boolean decision trees where the nodes are noisy and the goal is to find the correct leaf within a tolerance parameter  $Q$ . In [6, 5] the authors study finding spanning trees in Erdos-Renyi graphs, a special class of random graphs where each edge exists independently with some probability. In their setting each edge has a *query cost*, and the goal is to find a spanning tree using the least number of queries. However,

contrary to their setting, we handle both adversarially selected realized graphs and noisy answers to existence queries. More recently, Lyu et al. in [11] also studied the problem of finding a MST when the edges can fail with some probability. The work of Hoffmann et al. [7] and Erlebach and Hoffmann [3] considers verifying spanning trees where each edge has a weight inside an uncertainty region and the algorithm can ask the edge to reveal it. The goal is to find a small weight spanning tree without asking all the edges for their weight. None of these settings account for *inconsistent* queries, like in our setting.

In Bhaskara et al. [1] they studied the problem of finding a shortest path in a graph where there are ML-generated hints on the edge lengths, and also costly access to a zero-error oracle. The goal is to find a good enough shortest path, without asking the oracle too many times.

On a different problem in Mazumdar and Saha [12], the authors study clustering in a similar setting to ours where they have access to queries of the form “is  $u$  and  $v$  in the same cluster?”. However in their model, the oracle gives *consistent* answers on each query.

## 2 Preliminaries

In GRAPH CONNECTIVITY WITH NOISY QUERIES we are given a graph  $G = (V, E)$ , with edge set  $E$  and node set  $V$  called the *moldgraph*, then an adversary selects a *connected* subgraph  $G'$  of  $G$  to be realized. The goal of the algorithm is to find a spanning tree in the subgraph  $G'$  spending as little time as possible gathering information. The algorithm does not directly observe the subgraph that is realized, but only has access to an oracle that answers questions of the form “Is edge  $e \in E$  realized?”. Each call to this oracle costs 1, therefore our goal is to find a realized spanning tree, with constant probability using the minimum number of queries to the oracle.

This oracle, however, is noisy and inconsistent; it might not give the correct answer and when asked multiple times on the same edge, it may give different answers. More formally, the oracle is a function  $\mathcal{O} : E \rightarrow \{\text{Yes}, \text{No}\}$ , that given an edge  $e \in E$  answers either *Yes* or *No*, indicating whether the edge is realized or not. We study all the possible error types for the oracle, outlined below.

**2-sided error.** the oracle’s answer is wrong (ie. with “No” for realized edges and “Yes” for non-realized) with *constant* error probability  $p < 1/2$ .

**1-sided error, False Negative (FN).** if the edge is not realized then the response is always “No”. If it is realized then the response is “No” with *constant* error probability  $p < 1/2$ , and “Yes” with probability  $(1 - p)$ . Thus, when the oracle responds “Yes” then it is certain that this edge is realized, but when it responds “No” then the edge may or may not be realized, hence the False Negative responses.

**1-sided error, False Positive (FP).** if the edge is realized then the response is always “Yes”. If it is not realized then the response is “Yes” with *constant* error probability  $p < 1/2$ , and “No” with probability  $(1 - p)$ . Thus, when the oracle responds “No” then it is certain that this edge is not realized, but when it responds “Yes” then the edge may or may not be realized, hence the False Positive responses.

## 2.1 Graphs notation

We present some useful definitions for concepts we use throughout the paper. We begin by our definition of sparsity. Another possible name for the  $\rho$  parameter in the literature is “average degree” of the graph.

► **Definition 1** ( $\rho$ -sparse Graphs). *A graph  $G$  with  $m$  edges and  $n$  vertices is called  $\rho$ -sparse if  $m \leq \rho n$ .*

It is noteworthy that our definition of  $\rho$ -sparsity for graphs is weaker than the usual definitions of graph sparsity, in the sense that it can be easily satisfied without requiring local sparsity properties. This means that constructing efficient algorithms for this property, directly translates to efficient algorithms for other usual sparsity parameters. For example, using our definition,  $k$ -degenerate graphs are  $k$ -sparse [9],  $k$ -treewidth graphs are also  $k$ -sparse [13], and graphs with Hadwiger number  $k$  are  $O(k\sqrt{\log k})$ -sparse [8, 2].

► **Definition 2** (Edge Contraction). *The edge contraction operation on an edge  $e = \{u, v\}$  of a graph  $G$  results in a new graph  $G'$  wherein  $u$  and  $v$  are replaced by a new vertex  $uv$  which is connected to all vertices of  $G$  that were incident to either  $u$  or  $v$ .*

► **Definition 3** (Graph minor [10]). *A graph  $H$  is called a minor of a graph  $G$ , if  $H$  can occur after applying a series of edge deletions, vertex deletions, and edge contractions.*

► **Definition 4** (Minor-closed Graph Family). *A set  $\mathcal{F}$  of graphs is called a minor-closed graph family if for any  $G \in \mathcal{F}$  all minors of  $G$  also belong to  $\mathcal{F}$ .*

The algorithms that we present for FN and FP queries produce and handle multigraphs during intermediate steps. Here, we present and define some of the main concepts we are using from multigraphs.

An edge  $e = \{u, v\}$  in a multigraph is a link connecting  $u$  and  $v$ . There might be other parallel edges between  $u$  and  $v$ , and each one is distinct. Sometimes we will need to work with the set of all parallel edges between  $u$  and  $v$ . We call this set a *super-edge* between  $u$  and  $v$ . For simplicity, we consider simple edges to be super-edges with size 1.

► **Definition 5** (Neighborhood). *For a vertex  $v \in V$ , we denote by  $N(v)$  its neighborhood, which is the set of all super-edges with  $v$  as one of the endpoints.*

► **Definition 6** (Degree). *For a node  $v \in V$ , degree  $\deg(v)$  of  $v$  is the size of  $N(v)$ .*

Finally, we note that whenever an algorithm performs an edge-contraction operation on edge  $e$  of a multigraph, then we delete all the other parallel edges to  $e$  as well, leaving no self-loops in the graph. Moreover, if any parallel super-edges result after the contraction, they are replaced by a larger super-edge, their union.

## 3 Verifying Connectivity

As a warm-up, before attempting to find a realized spanning tree of the graph, we begin by presenting an algorithm for verifying the connectivity of a tree. Specifically, given a tree, which could be the operating spanning tree of a network, we want to verify whether it is connected or not, that is whether all of its edges are realized.

Naively verifying this property (ie. performing a fixed number of queries on every edge) needs  $O(n \log n)$  queries to yield a constant probability guarantee. However, we show that it is possible to verify the connectivity of the tree using only  $O(n)$  queries, which is asymptotically the same as if our oracle had no noise.

■ **Algorithm 1** *Verify(T)*: A verification protocol for tree connectivity with 2-sided error.

**Input:** Tree  $\mathcal{T}$  of  $n$  edges, **Parameters:**  $\varepsilon, \delta, p$

**Output:** True iff  $T$  is connected

---

```

1: threshold  $\leftarrow \lceil \log_{\frac{1-p}{p}} \left( \frac{1}{\delta} \right) \rceil$ 
2: budget  $\leftarrow \lceil \frac{1}{\varepsilon} \cdot \frac{1}{1-2p} \rceil \cdot \textit{threshold} \cdot n$ 
3: for  $e \in E(T)$  do
4:   counter  $\leftarrow 0$ 
5:   while (counter < threshold) & (budget > 0) do
6:     q  $\leftarrow$  Query edge  $e$ 
7:     budget  $\leftarrow$  budget  $-1$ 
8:     if q is “Yes” then
9:       counter  $\leftarrow$  counter  $+1$ 
10:    else
11:      counter  $\leftarrow$  counter  $-1$ 
12:    end if
13:  end while
14:  if budget = 0 then
15:    return False
16:  end if
17: end for
18: return True

```

---

Our algorithm (Algorithm 1) has a predetermined budget of queries that depends on the requested guarantees. It fixes an ordering of the edges, and for each edge it performs queries until it receives  $c$  more positive answers than negative ones (where  $c$  is also fixed and depends on the requested guarantees). For realized edges, since  $p < 1/2$ , the expected number of queries until they reach  $c$  is polynomial in  $c$ . On the other hand, the probability to never yield  $c$  more positive answers than negative ones, within the budget, is exponentially small in  $c$ . Using a global budget instead of a fixed per-edge number of queries, allows us to dynamically allocate it based on need. We save up queries from realized edges that reach the threshold quickly and spend it on other edges that are slow to reach the threshold. On the other hand, the probability that a non-realized edge reaches  $c$  is exponentially small in  $c$ . As a result, if a non-realized edge exists in the tree, the algorithm will consume all of its budget on this edge before reaching the threshold. Using this approach, Algorithm 1 achieves the following guarantees.

► **Theorem 7.** *Algorithm 1 correctly classifies connected trees with probability  $1 - \varepsilon$  and disconnected trees with probability  $1 - \delta$ , while performing at most  $O\left(\frac{1}{\varepsilon} n \log \frac{1}{\delta}\right)$  queries.*

The proof is deferred to the full version. As a Corollary of Theorem 7, we get that, for constant probability guarantees, Algorithm 1 requires  $O(n)$  queries.

► **Corollary 8.** *Algorithm 1 correctly classifies connected trees with probability .99 and disconnected trees with probability .99, using  $O(n)$  queries.*

## 4 Two-sided error oracle

Moving on to our main result, we show how to find a realized spanning tree in the 2-sided error oracle. Recall that in this case, the oracle may give false responses either when the edge is realized or when it is non-realized. The main result for this regime is the following theorem.

► **Theorem 9.** *In the 2-sided error regime, there exists an algorithm that finds a realized spanning tree with high probability, using  $O(m \log m)$  queries in a moldgraph of  $m$  edges. Moreover, no algorithm can do better than  $\Omega(m \log m)$ .*

To show this theorem, we separately show the upper and lower bounds in Lemmas 10 and 12. Combining them we immediately get the theorem.

### 4.1 Upper Bound

In order to show the upper bound (Lemma 10), we describe an algorithm that achieves this query complexity and prove its correctness in Lemma 11

► **Lemma 10.** *In the 2-sided error regime, there exists an algorithm that finds a realized spanning tree with high probability, using  $O(m \log m)$  queries in a moldgraph of  $m$  edges.*

Our algorithm, described below, uses the same idea as the naive algorithm for the connectivity verification problem.

#### Naive algorithm

The algorithm is as follows. First, query each edge of the moldgraph  $O(\log m)$  times. Second, by treating all edges with more “Yes” than “No” responses as realized, compute a spanning tree on the discovered realized subgraph. If the graph is disconnected, output any spanning tree of the moldgraph.

The algorithm performs  $O(m \log m)$  queries in total. The following lemma shows the correctness of the algorithm, and its proof is deferred to the full version.

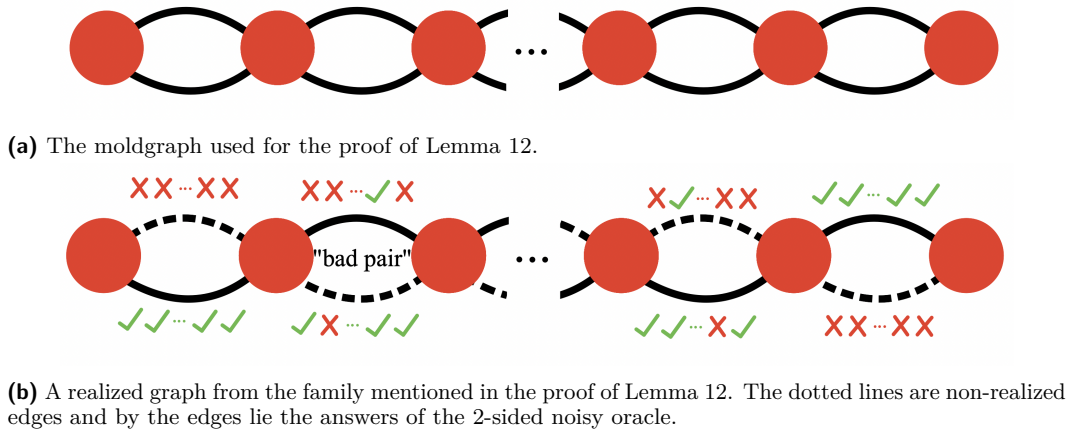

► **Lemma 11.** *The Naive algorithm finds a realized spanning tree with high probability.*

### 4.2 Lower Bound

Switching gears towards the lower bound, we give an instance showing that we cannot hope for anything better than the  $O(m \log m)$  upper bound shown in the previous section. As we expected, this is a strictly harder problem than verifying the connectivity of a tree, since in this case we have to identify a realized edge in each independent cut of the moldgraph.

► **Lemma 12.** *In the 2-sided error regime, there exists a graph where any algorithm requires  $\Omega(m \log m)$  queries to discover a spanning tree with constant failure probability.*

**Proof of Lemma 12.** We consider the graph in Figure 1 which has  $n + 1$  vertices and  $2n$  edges. Between any two consecutive vertices there exist 2 parallel edges, one of which is realized and the other is not. Note that this moldgraph is a multigraph for simplicity of presentation. But the arguments hold analogously for a 2-by- $n$  grid moldgraph, if we additionally give our algorithms the extra information that all vertical edges are realized. This only makes an algorithm more powerful as, in the worst-case, it can choose to ignore this information and execute independently. Then, we show that even with this extra knowledge, no algorithm can achieve a better query complexity than the desired bound.

■ **Figure 1**

Any algorithm on this graph will have to treat each edge-pair independently of the others, because uncovering a realized edge in one pair does not give any information on the solution to other pairs. Moreover, the optimal strategy for any algorithm is to query both edges in a pair an equal number of times and then pick the one with the majority of positive responses. Otherwise, picking the one with the least positive responses gives us smaller probability of success.

Let us suppose that the algorithm performs  $k$  queries on a specific edge-pair. If more than  $k/2$  of them give false responses then the wrong edge will be picked as realized. Consequently, the algorithm will have to perform more than  $k$  queries on this edge-pair to discover the correct edge. We set  $k = \Theta(\log(n/\log n)) = \Theta(\log n)$  and call such a faulty edge-pair a “bad” pair. Then, by the fact that false queries follow a binomial distribution, we get  $\Pr[\text{bad}] > p^{k/2} > \log n/n$ . Thus the probability that *at least* one such “bad pair” exists is

$$\Pr[\text{bad exists}] = 1 - \Pr[\text{all good}] \geq 1 - \left(1 - \frac{\log n}{n}\right)^n \geq 1 - \frac{1}{n}.$$

Assuming that there exists such a “bad pair” then the algorithm will have to perform  $\Omega(\log n)$  queries on it. However, there is no way to know from the beginning which pair it will be. This means that any algorithm in this case will have to pick an  $\alpha$ -fraction of edge-pairs on which to perform these many queries, for some (not necessarily constant)  $\alpha$ . Define  $Q_b$  to be the event that the algorithm performs  $\Omega(\log n)$  queries on the “bad pair”. Then,  $\Pr[Q_b] = \alpha$  and the probability of failure for the algorithm when a bad pair exists is

$$\Pr[\text{fail}|\text{bad exists}] = \alpha \Pr[\text{fail}|Q_b] + (1 - \alpha) \geq (1 - \alpha)$$

Thus, the total probability of failure to discover a spanning tree will be

$$\Pr[\text{fail}] \geq \Pr[\text{fail}|\text{bad exists}] \Pr[\text{bad exists}] \geq (1 - \alpha) \left(1 - \frac{1}{n}\right)$$

If we want the failure probability to be constant then it must hold that  $\alpha = 1 - o(1)$ . Consequently, we perform  $\Omega(\log n)$  queries on  $\alpha n = \Theta(n)$  edges, giving us an  $\Omega(n \log n)$  lower bound for this graph instance. The desired lower bound comes from the fact that any algorithm performing better than  $\Omega(m \log m)$  queries would perform better than  $\Omega(n \log n)$  in this instance, as it has  $m = O(n)$ . ◀

## 5 One-sided error oracle: False Negatives

Moving on to the one-sided error regime, we first consider the case of False Negative errors in the oracle. Our main contribution is an algorithm for the case of sparse and minor-closed graph families. We also show how we can obtain an algorithm for general graphs, that still performs well on  $\rho$ -sparse graphs, even when this property is unknown to us.

Finally, we show how to combine these results to obtain an algorithm for planar graphs that uses  $O(m)$  queries to find a spanning tree, while no algorithm can do better (Corollary 17). This also implies better guarantees for other special families of graphs, as shown in Corollary 18.

► **Theorem 13.** *In the 1-sided False Negative regime, given a moldgraph of  $m$  edges and  $n$  nodes, there exists an algorithm that finds a realized spanning tree using  $O(m \log n)$  queries in expectation. If the moldgraph belongs to a  $\rho$ -sparse and minor-closed family, the algorithm uses  $O(\rho m)$  queries in expectation.*

**Proof of Theorem 13.** To create such an algorithm, we can run in parallel both the Naive Algorithm presented in the next subsection (Lemma 14) and Algorithm 3 for sparse minor-closed graph families. In particular, it suffices to let the two algorithms perform their queries alternately and independently of each other.

If the moldgraph belongs in a  $\rho$ -sparse and minor-closed family, then by Lemma 15, Algorithm 3 will perform  $O(\rho m)$  queries in expectation before finding a spanning tree. For each one of these queries, we have just performed one extra query for the naive algorithm. Thus, eventually the combined algorithm will find the spanning tree in the same query complexity.

Otherwise, in general graphs, by using Lemma 14 for the Naive Algorithm and a similar argument as before, we get  $O(m \log n)$  queries in expectation. ◀

### 5.1 Warm-up: naive algorithm

We start by describing the naive algorithm used for general graphs, that obtains the  $O(m \log n)$  guarantee. The algorithm proceeds in rounds, where in each round it performs one query on all  $m$  edges of the moldgraph. It repeats this process until  $n - 1$  realized edges forming a spanning tree are discovered. Note that in the case of FN queries we can be completely certain when a realized edge is discovered. The proof is deferred to the full version.

► **Lemma 14.** *The Naive Algorithm finds a spanning tree while performing  $O(m \log n)$  queries on expectation.*

### 5.2 An Algorithm for $\rho$ -sparse graphs

We present the algorithm used to obtain better guarantees for the family of  $\rho$ -sparse and minor closed graphs. The algorithm is presented in Algorithm 3 and the guarantees in Lemma 15.

► **Lemma 15.** *Given a moldgraph of  $m$  edges, belonging to a  $\rho$ -sparse and minor-closed family of graphs, Algorithm 3 performs  $O(\rho m)$  queries in expectation and uncovers a realized spanning tree with probability 1.*

The basic primitive that our algorithm uses is a **DISCOVER** subroutine that cleverly orders queries in a way that it allows it to explore multiple edge sets in parallel. The subroutine is presented in more detail in Algorithm 2 and the Lemma that follows.

■ **Algorithm 2** DISCOVER( $\mathcal{S}$ ): Discovers an edge in a collection  $\mathcal{S}$  of edge sets.

**Input:** Set  $\mathcal{S} = \{E_1, E_2, \dots, E_k\}$

**Output:** Realized edge  $e$

---

```

1: while no edge is found do
2:   for  $i = 1$  to  $k$  do
3:     Let  $e$  be the next edge in the cyclic order of  $E_i$ 
4:      $q \leftarrow$  Query edge  $e$ 
5:     if  $q$  is “Yes” then
6:       return  $e$ 
7:     end if
8:   end for
9: end while

```

---

■ **Algorithm 3** SolveSparseFN( $G$ ): Solves the problem in sparse moldgraphs using an 1-sided error oracle with False Negatives.

**Input:** Graph  $G$

**Output:** A realized spanning tree

---

```

1: if  $G$  is a single node then
2:   return  $\emptyset$ 
3: end if
4:  $u = \operatorname{argmin}\{\deg(v)\}$ 
5:  $e = \text{DISCOVER}(N(u))$  // Let  $G'$  be the resulting graph after contracting edge  $e$ .
6: return SolveSparseFN( $G'$ )  $\cup \{e\}$ 

```

---

► **Lemma 16.** *Let  $\mathcal{S}$  be a collection of  $k$  sets of edges. Assume as well that there exists at least one set in  $\mathcal{S}$  containing some realized edge, then Algorithm 2 finds and returns such an edge using at most  $2k|E_f|$  queries in expectation, where  $E_f$  is the set containing the found edge.*

The proof is deferred to the full version. We are now ready to prove the main result of the section, Lemma 15.

**Proof of Lemma 15.** We use induction on the number  $n$  of vertices of  $G$  to prove that Algorithm 3 performs at most  $4\rho m$  queries in expectation. Throughout this proof we denote by  $m$  the total number of simple edges of the graph, and by  $m_s$  the number of super-edges.

The base case of induction for  $n = 1$  holds trivially, as the algorithm needs no queries. Now assume that it holds for all graphs of at most  $n - 1$  vertices. We will prove that it also holds for graphs of  $n$  vertices.

By using the sparsity property that  $m_s \leq \rho n$ , we can see that there always exists at least one vertex  $u$  with degree  $\deg(u) \leq 2\rho$ . Otherwise, the number of super-edges would be

$$m_s = \frac{1}{2} \sum_{v \in V} \deg(v) > \rho n$$

which leads to the graph not being  $\rho$ -sparse, a contradiction.

The algorithm uses Algorithm 2 as a basic subroutine, passing as input the neighborhood  $N(u)$  of the least-degree vertex  $u$ . This is allowed because  $N(u)$  is a cut of the moldgraph and thus satisfies the assumption of Lemma 16 that at least one edge-set contains a realized edge.

The DISCOVER subroutine will find a realized edge inside a super-edge  $E_f$ , spending in expectation at most  $2 \cdot \deg(u)|E_f| \leq 4\rho|E_f|$  queries.

After contracting the super-edge  $E_f$  that contains the realized edge found by the subroutine, the algorithm will continue on the contracted graph  $G'$  that has  $n - 1$  vertices. It is important to note here that the graph  $G'$  will still be  $\rho$ -sparse, because of our assumption that graphs belong in a minor-closed family. By the induction hypothesis, the algorithm will find a realized spanning tree of  $G'$ , by performing at most  $4\rho(m - |E_f|)$  queries in expectation. Therefore, the total number of queries performed will be at most

$$4\rho|E_f| + 4\rho(m - |E_f|) = 4\rho m$$

in expectation, and thus gives us the desired  $O(\rho m)$  upper bound.  $\blacktriangleleft$

► **Corollary 17.** *If the moldgraph is planar, then Algorithm 3 performs  $O(m)$  queries in expectation and succeeds in finding a realized spanning tree with probability 1. Moreover, this is tight and no better algorithm exists for this case.*

**Proof of Corollary 17.** The upper bound follows directly by Lemma 15 and the fact that planar graphs are a minor-closed and 3-sparse family, as  $m \leq 3n - 6$ .

To argue that the algorithm is tight, we remind that in all cases the realized spanning subgraph is chosen arbitrarily, and even in an adversarial way. This means that any algorithm aiming to find a realized spanning tree has to perform at least  $n - 1$  queries, for the  $n - 1$  realized edges of the spanning tree that it discovers. As planar graphs have  $m = \Theta(n)$  the desired lower bound follows.  $\blacktriangleleft$

Apart from planar graphs, as we hinted when defining  $\rho$ -sparsity, an efficient algorithm for  $\rho$ -sparse graphs immediately gives us efficient algorithms for minor-closed families of graphs that are sparse with respect to other widely-used parameters. Based on [13, 8], we can see that the parameters of treewidth and Hadwiger Number define minor-closed graph families. Moreover,  $k$ -treewidth graphs have sparsity  $k$ , while graphs with Hadwiger number  $k$  are  $O(k\sqrt{\log k})$ -sparse. Hence, applying Lemma 15 we get the following Corollary.

► **Corollary 18.** *Algorithm 3 performs  $O(km)$  queries for graphs with treewidth  $k$  and  $O(k\sqrt{\log km})$  queries for graphs with Hadwiger number  $k$ .*

## 6 One-sided error oracle: False Positives

In the 1-sided, False-Positive error case, we initially present an  $O(m \log m)$  algorithm for general graphs, while dropping the complexity to linear when the realized graph is a tree. Each of these guarantees are tight for their respective case. We also show how using one algorithm, we can capture both cases, without actually knowing the structure of the realized graph, and obtain the tight guarantees for each case. Our formal guarantees are formally stated in Theorem 19.

► **Theorem 19.** *In the 1-sided error FP regime, there exists an algorithm that performs  $O(m \log m)$  queries in the general case and finds a realized spanning tree with high probability. Moreover, if the realized subgraph is a tree, the algorithm performs  $O(m)$  queries in expectation and succeeds to find the spanning tree with high probability. These complexities are tight for their respective cases.*

**Proof of Theorem 19.** Similarly to the case of False Negative oracle errors (Lemma 13) we can combine the Naive Algorithm with Algorithm 4, letting them perform queries alternately. When any of the two algorithms halts, the process ends.

Consider the case of general graphs. By Lemma 20 the naive algorithm succeeds in finding a realized spanning tree with high probability by performing  $O(m \log m)$  queries. Thus, the combined algorithm also succeeds with at most  $O(m \log m)$  queries.

Now, we look at the special case where the moldgraph is planar and the realized subgraph is a tree. By Lemma 23, Algorithm 4 performs at most  $O(m)$  queries in expectation. Let  $X$  be the random variable denoting the number of queries performed by Algorithm 4, and let  $E = \{X > m \log_2(m^2)\}$  be the event that  $X$  is more than the queries of the naive algorithm. Using Markov's inequality we get

$$\Pr[E] \leq \frac{\mathbb{E}[X]}{m \log_2(m^2)} \leq O\left(\frac{1}{\log m}\right)$$

Thus, the number  $Q$  of queries performed before the combined algorithm terminates for this case is

$$\mathbb{E}[Q] = \mathbb{E}[Q|\neg E] \Pr[\neg E] + \mathbb{E}[Q|E] \Pr[E] \leq \mathbb{E}[X] + (m \log_2(m^2))O\left(\frac{1}{\log m}\right) \leq O(m)$$

When the algorithm has terminated, there still exists some probability of failure, in the case that both event  $E$  happens and the naive algorithm fails to find a realized spanning tree. By using the failure probability from Lemma 20 and the previously calculated probability of event  $E$  happening, we get

$$\Pr[E \wedge \text{naive algo fails}] = O\left(\frac{1}{m \log m}\right)$$

Thus, the combined algorithm succeeds in this case with high probability as well, and the proof is concluded.  $\blacktriangleleft$

## 6.1 Upper & Lower Bounds

We start by showing, similar to the previous section, how to obtain the upper bound in the case of general graphs. The proof is deferred to the full version.

► **Lemma 20.** *In the 1-sided error FP regime, there exists an algorithm that performs  $O(m \log m)$  queries in the general case and finds a realized spanning tree with high probability.*

Furthermore, we show the lower bound for the general case graphs, stated formally below. Observe that from the construction of this lower bound, no algorithm can do better in planar or sparse graphs. The proof is deferred to the full version.

► **Lemma 21.** *In the regime of 1-sided FP errors, there exists a realized graph with cycles, for which any algorithm requires  $\Omega(m \log m)$  queries to discover a spanning tree with constant failure probability.*

## 6.2 Special Case: Acyclic Realized Graphs

In this section we focus on the special case where the realized subgraph is a tree. This property implies that for each cycle in the moldgraph, at least one edge of the cycle must be non-realized. Since our oracle only commits False Positive errors, the negative answers

## 47:12 Graph Connectivity with Noisy Queries

■ **Algorithm 4**  $\text{SolvePlanarFP}(G)$ : Discovers a realized spanning tree in planar moldgraphs using an 1-sided error oracle with False Positives.

---

**Input:** Planar Graph  $G(V, E)$

**Output:** A realized spanning tree

```
1: // Construct the dual graph of G
2:  $G' \leftarrow \text{dual}(G)$ 
3: // Inverse all the oracle answers and use SolveSparseFN
4: return  $E(G) \setminus \text{SolveSparseFN}(G')$ 
```

---

are definitive, meaning that we can completely remove the edges which have yielded such answers. We design an algorithm (Algorithm 4) that utilizes this fact and progressively removes non-realized edges until it is left with a tree which will also be the realized subgraph. This result is stated formally in the theorem below.

► **Theorem 22.** *In the regime of 1-sided FP errors, if the moldgraph  $G$  is a planar graph and the realized subgraph is a tree, Algorithm 4 recovers the realized spanning tree with probability 1 while performing at most  $O(m)$  queries in expectation.*

Our main observation is that the FP setting is very similar, and in fact can be reduced to, the FN setting. In the FN setting, we know that at least one realized edge lies in every cut of the moldgraph and we repeatedly query the edges of a cut in order to unveil the realized edge. In a similar manner, in the FP setting, we can repeatedly query the edges of the cycle in order to discover the non-realized edge in every cycle. Hence, the question that arises is: how can one decide a sequence of cycles to query such that the expected number of queries is minimized? Algorithm 4 does so by utilizing the planarity of the moldgraph to consistently find small cycles to query.

### Description of Algorithm 4

Our algorithm reduces the FP setting of this special case to solving an FN instance on the *dual graph* of the moldgraph. The dual of a planar graph has one node for each face of the planar graph, as illustrated in a Figure found in the full version. Two face nodes are connected by an edge in the dual graph if and only if they share an edge in the planar graph. With this transformation we can now focus on cuts of the dual graph which directly correspond to cycles of the moldgraph. Notice that removing an edge in the moldgraph (after identifying it as non-realized) is the same as contracting it in the dual graph. As a result, removing all the non-realized edges until we are left with a tree in the moldgraph is exactly equivalent to contracting the same edges in the dual until we are left with one node (Lemma 23). For this reason, Algorithm 4 constructs the dual graph of the moldgraph and calls Algorithm 3 to retrieve a non-realized spanning tree of the dual graph. Note that we reverse all the oracle's answers before we hand them out to Algorithm 3, since by design it contracts the edges for which we get positive answers but in the FP setting we want to contract the edges of the dual graph whose corresponding edges yielded negative answers.

We will now prove the correctness of Algorithm 4 and bound its query complexity.

► **Lemma 23.** *Let  $G$  be a planar moldgraph,  $T$  be the realized tree of  $G$  and  $G'$  be a dual graph of  $G$ . The induced subgraph of  $G'$  containing all the edges corresponding to non-realized edges of  $G$ , is a spanning tree of  $G'$ .*

The proof of Lemma 23 is deferred to the full version.

**Proof of Theorem 22.** Algorithm 4 constructs the dual graph of  $G$  and uses Algorithm 3 to find a spanning tree of  $G'$  consisting of non-realized edges. From Lemma 23 we know that by removing these edges, we are left with the realized tree  $T$  of  $G$ . All the queries performed during this process are made through Algorithm 3. Therefore, from Lemma 15, the total number of queries conducted is  $O(m)$ . ◀

## Abstract

Positive data languages are languages over an infinite alphabet closed under possibly non-injective renamings of data values. Informally, they model properties of data words expressible by assertions about equality, but not inequality, of data values occurring in the word. We investigate the class of positive data languages recognizable by nondeterministic orbit-finite nominal automata, an abstract form of register automata introduced by Bojańczyk, Klin, and Lasota. As our main contribution we provide a number of equivalent characterizations of that class in terms of positive register automata, monadic second-order logic with positive equality tests, and finitely presentable nondeterministic automata in the categories of nominal renaming sets and of presheaves over finite sets.

## 1 Introduction

Automata over infinite alphabets provide a simple computational model for reasoning about structures involving *data* such as nonces [21], URLs [3], or values in XML documents [25]. Consider, for instance, the (infinite) set  $\mathbb{A}$  of admissible user IDs for a server. The sequence of all user logins within a given time period then forms a finite word  $a_1 \cdots a_n \in \mathbb{A}^*$  over the infinite alphabet  $\mathbb{A}$ , and behaviour patterns may be modelled as data languages over  $\mathbb{A}$ , e.g.

$$\begin{aligned} L_0 &= \{ a_1 \cdots a_n \in \mathbb{A}^* \mid a_i \neq a_n \text{ for all } i < n \} && \text{ (“last user has not logged in before”)}, \\ L_1 &= \{ a_1 \cdots a_n \in \mathbb{A}^* \mid a_i = a_j \text{ for some } i \neq j \} && \text{ (“some user has logged in twice”)}. \end{aligned}$$

Both  $L_0$  and  $L_1$  involve assertions about equality, or inequality, of data values (here, user IDs). However, asserting *inequality* is sometimes considered problematic and thus undesired. For example, since users may have multiple IDs, a logfile  $a_1 \cdots a_n \in L_0$  does not actually guarantee that the last user has not logged in before. In contrast, if  $a_1 \cdots a_n \in L_1$ , then it is guaranteed that some user has indeed logged in twice. The structural difference between the

■ **Figure 1** Equivalent characterizations of positive NOFA-recognizable languages.

two languages is that  $L_1$  is closed under arbitrary renamings  $\rho: \mathbb{A} \rightarrow \mathbb{A}$  (i.e.  $a_1 \cdots a_n \in L_1$  implies  $\rho(a_1) \cdots \rho(a_n) \in L_1$ ), taking into account possible identification of data values, while  $L_0$  is only closed under injective (equivalently bijective) renamings. We refer to languages with the former, stronger closure property as *positive data languages*. Intuitively, such languages model properties of data words expressible by positive statements about equality of data values. It is one of the goals of our paper to turn this into a theorem.

For that purpose, we build on the abstract account of data languages and their automata based on the theory of nominal sets [13, 27], initiated by the work of Bojańczyk, Klin, and Lasota [6]. Specifically, we investigate *nondeterministic orbit-finite nominal automata (NOFA)*, the nominal version of classical nondeterministic finite automata. We approach the class of *positive* NOFA-recognizable data languages from several different perspectives, ranging from concrete to more abstract and conceptual, and establish the equivalent characterizations summarized in Figure 1. In more detail, our main contributions are as follows.

**Register automata.** NOFAs are known to be expressively equivalent to register automata [17, 19], i.e. finite automata that can memorize data values using a fixed number of registers and test the input for (in)equality with previously stored values. Restricting transitions to positive equality tests leads to *positive register automata*, which correspond to *finite-state unification-based automata (FSUBA)* [18, 32] and are shown to capture precisely positive NOFA-recognizable languages (Theorem 3.2 and Remark 3.3). On the way, we isolate a remarkable property of this language class: while NOFAs generally require the ability to guess data values during the computation to reach their full expressive strength, guessing and non-guessing NOFA are equivalent for positive data languages (Theorem 2.17).

**Monadic second-order logic.** As illustrated above, positive data languages model (only) positive assertions about the equality of data values. To substantiate this intuition, we employ monadic second-order logic ( $\text{MSO}^\sim$ ) over data words [4, 9, 25], an extension of classical MSO with equality tests for data values, and consider its restriction  $\text{MSO}^{\sim,+}$  to positive equality tests. While this logic is more expressive than NOFA, we show that within the class of NOFA-recognizable languages it models exactly the positive languages (Theorem 4.4).

**Categorical perspective.** The classical notion of nondeterministic finite automata can be categorified by replacing the finite set of states with a finitely presentable object of a category  $\mathcal{C}$ . For example, NOFAs are precisely nondeterministic  $\mathcal{C}$ -automata for  $\mathcal{C} =$  nominal sets. Apart from the latter category, several other toposes have been proposed as abstract foundations for reasoning about names (data values), most prominently the category of *nominal renaming sets* [12], the category  $\mathbf{Set}^\mathbb{I}$  of presheaves over finite sets and injective maps [31], and the category  $\mathbf{Set}^\mathbb{F}$  of presheaves over finite sets and all maps (equivalently, finitary set functors) [10]. It is thus natural to study nondeterministic automata in the latter three categories, viz. *nondeterministic orbit-finite renaming automata (NOFRA)*,

*nondeterministic super-finitary*  $\mathbf{Set}^{\mathbb{I}}$ -automata and *nondeterministic super-finitary*  $\mathbf{Set}^{\mathbb{F}}$ -automata. Our final contribution is a classification of their expressive power: we show that  $\mathbf{Set}^{\mathbb{I}}$ -automata are equivalent to NOFAs, while both NOFRAs and  $\mathbf{Set}^{\mathbb{F}}$ -automata capture positive NOFA-recognizable languages (Theorems 2.9 and 7.7). Hence, both nominal and presheaf-based automata are able to recognize positive and all NOFA-recognizable languages, respectively.

## 2 Nominal Automata and Positive Data Languages

For the remainder of the article, we fix a countably infinite set  $\mathbb{A}$  of *data values*, a.k.a. *names* or *atoms*. The goal is to study positive data languages, that is, languages of finite words over  $\mathbb{A}$  closed under arbitrary renamings. This is achieved via the framework of nominal (renaming) sets [12, 13, 27].

### 2.1 Nominal Sets and Nominal Renaming Sets

A *renaming* is a finite map  $\rho: \mathbb{A} \rightarrow \mathbb{A}$ , that is,  $\rho(a) = a$  for all but finitely many  $a \in \mathbb{A}$ . We let  $\text{Fin}(\mathbb{A})$  denote the monoid of renamings, with multiplication given by composition, and  $\text{Perm}(\mathbb{A})$  its subgroup given by *finite permutations*, i.e. bijective renamings. For  $M \in \{\text{Perm}(\mathbb{A}), \text{Fin}(\mathbb{A})\}$  an *M-set* is a set  $X$  equipped with a monoid action  $M \times X \rightarrow X$ , denoted  $(\rho, x) \mapsto \rho \cdot x$ . A subset  $S \subseteq \mathbb{A}$  is a *support* of  $x \in X$  if for every  $\rho, \sigma \in M$  such that  $\rho|_S = \sigma|_S$  one has  $\rho \cdot x = \sigma \cdot x$ . Informally, consider  $X$  as a set of syntactic objects (e.g. words, trees,  $\lambda$ -terms) whose description may involve free names from  $S$ . A *nominal M-set* is an *M-set* where every element  $x$  has a finite support. This implies that  $x$  has a least finite support  $\text{supp } x \subseteq \mathbb{A}$ . A name  $a \in \mathbb{A}$  is *fresh* for  $x$ , denoted  $a \# x$ , if  $a \notin \text{supp } x$ .

Nominal  $\text{Perm}(\mathbb{A})$ -sets are called *nominal sets*, and nominal  $\text{Fin}(\mathbb{A})$ -sets are called *nominal renaming sets*. A nominal renaming set  $X$  can be regarded as a nominal set by restricting its  $\text{Fin}(\mathbb{A})$ -action to a  $\text{Perm}(\mathbb{A})$ -action. The least supports of an element  $x \in X$  w.r.t. both actions coincide [11, Thm. 4.8], so the notation  $\text{supp } x$  is unambiguous.

A subset  $X$  of a nominal *M-set*  $Y$  is *M-equivariant* if  $\rho \cdot x \in X$  for all  $x \in X$  and  $\rho \in M$ . More generally, a map  $f: X \rightarrow Y$  between nominal *M-sets* is *M-equivariant* if  $f(\rho \cdot x) = \rho \cdot f(x)$  for all  $x \in X$  and  $\rho \in M$ . This implies  $\text{supp } f(x) \subseteq \text{supp } x$  for all  $x \in X$ .

We write  $X \times Y$  for the cartesian product of nominal *M-sets* with componentwise action, and  $\coprod_{i \in I} X_i$  for the coproduct (disjoint union) with action inherited from the summands.

Given a nominal set  $X$ , the *orbit* of an element  $x \in X$  is the set  $\{\pi \cdot x : \pi \in \text{Perm}(\mathbb{A})\}$ . The orbits form a partition of  $X$ . A nominal set is *orbit-finite* if it has only finitely many orbits. A nominal renaming set is *orbit-finite* if it is orbit-finite as a nominal set.

► **Example 2.1.** The set  $\mathbb{A}$  with the  $\text{Fin}(\mathbb{A})$ -action  $\rho \cdot a = \rho(a)$  is a nominal renaming set, as is the set  $\mathbb{A}^*$  of finite words over  $\mathbb{A}$  with  $\rho \cdot w = \rho^*(w) = \rho(a_1) \cdots \rho(a_n)$  for  $w = a_1 \cdots a_n$ . The least support of  $a_1 \cdots a_n \in \mathbb{A}^*$  is the set  $\{a_1, \dots, a_n\}$ . The set  $\mathbb{A}^*$  has infinitely many orbits; its equivariant subsets  $\mathbb{A}^n$  (words of a fixed length  $n$ ) are orbit-finite. For instance,  $\mathbb{A}^2$  has the two orbits  $\{aa : a \in \mathbb{A}\}$  and  $\{ab : a \neq b \in \mathbb{A}\}$ . An example of a nominal set that is not a renaming set is  $\mathbb{A}^{\#n} = \{a_1 \dots a_n : a_i \neq a_j \text{ for } i \neq j\}$  with pointwise  $\text{Perm}(\mathbb{A})$ -action.

A nominal set  $X$  is *strong* if, for every  $x \in X$  and  $\pi \in \text{Perm}(\mathbb{A})$ , one has  $\pi \cdot x = x$  if and only if  $\pi$  fixes every element of  $\text{supp}(x)$ . (The “if” statement holds in every nominal set.) For instance, the nominal sets  $\mathbb{A}^{\#n}$ ,  $\mathbb{A}^n$  and  $\mathbb{A}^*$  are strong. Up to isomorphism, (orbit-finite) strong nominal sets are precisely (finite) coproducts  $\coprod_{i \in I} \mathbb{A}^{\#n_i}$  where  $n_i \in \mathbb{N}$ . For every orbit-finite nominal set  $X$ , there exists a surjective  $\text{Perm}(\mathbb{A})$ -equivariant map  $e: Y \rightarrow X$  for

some orbit-finite strong nominal set  $Y$  (see e.g. [23, Cor. B.27]). In fact, if  $o$  is the number of orbits of  $X$ , one may take  $Y = J \times \mathbb{A}^{\#n}$  where  $J = \{1, \dots, o\}$  and  $n = \max_{x \in X} |\text{supp } x|$ . We refer the reader to [14, Sec. 4.1] and [6, Thm. 10.9] for more details on representing orbit-finite nominal sets.

## 2.2 Nominal Automata and Nominal Renaming Automata

The object of interest in this paper is data languages  $L \subseteq \mathbb{A}^*$  closed under renamings:

► **Definition 2.2.**

1. A data language  $L \subseteq \mathbb{A}^*$  is *positive* if it is  $\text{Fin}(\mathbb{A})$ -equivariant.
2. The *positive closure* of  $L \subseteq \mathbb{A}^*$  is given by  $\bar{L} = \{\rho^*(w) : w \in L, \rho \in \text{Fin}(\mathbb{A})\}$ .

A natural automata model for data languages is given by nondeterministic orbit-finite automata [6] over nominal sets and their restriction to nominal renaming sets:

► **Definition 2.3.** Let  $M \in \{\text{Perm}(\mathbb{A}), \text{Fin}(\mathbb{A})\}$ .

1. A *nondeterministic orbit-finite  $M$ -automaton*  $A = (Q, \delta, I, F)$  consists of an orbit-finite nominal  $M$ -set  $Q$  of states, an  $M$ -equivariant transition relation  $\delta \subseteq Q \times \mathbb{A} \times Q$ , and  $M$ -equivariant subsets  $I, F \subseteq Q$  of initial and final states. Nominal orbit-finite  $M$ -automata are called *nondeterministic orbit-finite automata (NOFA)* for  $M = \text{Perm}(\mathbb{A})$  and *nondeterministic orbit-finite renaming automata (NOFRA)* for  $M = \text{Fin}(\mathbb{A})$ .
2. Given a nominal orbit-finite  $M$ -automaton  $A$ , we write  $q \xrightarrow{a} q'$  if  $q' \in \delta(q, a)$ . A *run* of  $A$  on input  $w = a_1 \cdots a_n \in \mathbb{A}^*$  is a sequence  $(q_0, a_1, q_1, a_2, \dots, a_n, q_n)$  such that  $q_0 \in I$  and  $q_r \xrightarrow{a_{r+1}} q_{r+1}$  for  $0 \leq r < n$ . The run is *accepting* if  $q_n \in F$ . The automaton  $A$  *accepts* the word  $w$  if  $A$  admits an accepting run on input  $w$ . The *accepted language*  $L(A) \subseteq \mathbb{A}^*$  is the set of all accepted words. A data language is *NOF(R)A-recognizable* if some NOF(R)A accepts it.

For example, the languages  $L_0$  and  $L_1$  from the Introduction are NOFA-recognizable.

► **Remark 2.4.**

1. The restriction to the input alphabet  $\mathbb{A}$  is for simplicity: all our results extend to alphabets  $\Sigma = \Sigma_0 \times \mathbb{A}$  for a finite set  $\Sigma_0$ , i.e. finite coproducts of copies of  $\mathbb{A}$ .
2. Another use of nominal renaming sets in automata theory appears in the work by Moerman and Rot [24] on deterministic nominal automata with outputs. The restrictions of their model make it unsuitable for language recognition [24, Rem. 4.1] but allow for a succinct representation of computed maps via *separating automata*.

To relate the expressive power of NOFA and NOFRA, we start with a simple observation:

► **Proposition 2.5.** *Every NOFRA accepts a positive language.*

The converse (Theorem 2.9) needs an automata-theoretic construction of the closure of a language. To this end, we first turn the states of a NOFA into a sort of normal form.

► **Remark 2.6** (cf. [6]). Every NOFA  $A = (Q, \delta, I, F)$  is equivalent to one whose nominal set of states is of the form  $J \times \mathbb{A}^{\#m}$  for some finite set  $J$  and  $m \in \mathbb{N}$ . Indeed, choose a nominal set  $Q' = J \times \mathbb{A}^{\#m}$  and an equivariant surjection  $e: Q' \twoheadrightarrow Q$  (see Section 2.1), and consider the NOFA  $A' = (Q', \delta', I', F')$  whose structure is given by the preimages

$$\delta' = (e \times \text{id}_{\mathbb{A}} \times e)^{-1}[\delta], \quad I' = e^{-1}[I], \quad F' = e^{-1}[F].$$

It is not difficult to verify that  $L(A') = L(A)$ ; see also Proposition 6.9. Note that in a NOFA with states  $J \times \mathbb{A}^{\#m}$ , the equivariant sets of initial and final states are of the form  $I = J_I \times \mathbb{A}^{\#m}$  and  $F = J_F \times \mathbb{A}^{\#m}$  for some  $J_I, J_F \subseteq J$ .

► **Construction 2.7** (Positive Closure of a NOFA). Let  $A = (Q, \delta, I, F)$  be a NOFA with states  $Q = J \times \mathbb{A}^{\#m}$  (cf. Remark 2.6). The NOFRA  $\bar{A} = (\bar{Q}, \bar{\delta}, \bar{I}, \bar{F})$  is given by the states  $\bar{Q} = J \times \mathbb{A}^m$ , initial states  $\bar{I} = J_I \times \mathbb{A}^m$ , final states  $\bar{F} = J_F \times \mathbb{A}^m$ , and transitions

$$\bar{\delta} = \{ (j, \rho^* p) \xrightarrow{\rho a} (j', \rho^* p') : (j, p) \xrightarrow{a} (j', p') \text{ in } A \text{ and } \rho \in \text{Fin}(\mathbb{A}) \}.$$

► **Proposition 2.8.** *The NOFRA  $\bar{A}$  accepts the positive closure of the language of  $A$ .*

The proof of  $L(\bar{A}) \subseteq \overline{L(A)}$  is slightly subtle since the transitions of a run in  $\bar{A}$  may be induced by different  $\rho$ 's; some bookkeeping and sensible choice of fresh names ensures compatibility.

Now we come to our first characterization of positive NOFA-recognizable languages:

► **Theorem 2.9.** *A language is positive and NOFA-recognizable iff it is NOFRA-recognizable.*

Indeed, the “if” direction holds due to Proposition 2.5 and because every NOFRA is a NOFA. The “only if” direction follows from Proposition 2.8, using that  $\bar{L} = L$  for positive  $L$ .

► **Remark 2.10.** A NOF(R)A is *deterministic*, and hence called a *DOF(R)A*, if it admits a single initial state and its transition relation is a function  $\delta: Q \times \mathbb{A} \rightarrow Q$ . In contrast to classical finite automata, DOFAs are less expressive than NOFAs [6]. We leave it as an open problem whether Theorem 2.9 restricts to DOF(R)As. In this regard, observe that Construction 2.7 produces a *nondeterministic* automaton  $\bar{A}$  even if the given automaton  $A$  is deterministic. Computing the positive closure of a DOFA-recognizable language necessarily requires the introduction of nondeterminism, as illustrated by the following example due to Bartek Klin (personal communication). Consider the language  $L$  consisting of all words whose last letter appears immediately before the last occurrence of a repeated letter; that is, words of the form  $vabw$  where (i)  $v, w \in \mathbb{A}^*$  and  $a, b \in \mathbb{A}$ , (ii) any two consecutive letters in  $w$  are distinct, (iii) the first letter of  $w$  is distinct from  $b$  and (iv) the last letter of  $w$  is distinct from  $a$ . This language is recognizable by a DOFA, in fact by an orbit-finite nominal monoid [4]. Its positive closure  $\bar{L}$  consists of all words whose last letter appears immediately before *some* occurrence of a repeated letter, which is not DOFA-recognizable.

### 2.3 Abstract Transitions and Runs

Sections 3 and 4 will relate positive NOFA-recognizable languages to register automata and monadic second-order logic. This relies on a presentation of transitions of  $\bar{A}$  in terms of abstract transitions, given by equations involving register entries and input values.

► **Definition 2.11.** Let  $A = (Q, \delta, I, F)$  and  $\bar{A} = (\bar{Q}, \bar{\delta}, \bar{I}, \bar{F})$  be as in Construction 2.7.

1. An *equation* is an expression of the form  $k = \bullet$ ,  $\bullet = k$  or  $k = \bar{k}$ , where  $k, \bar{k} \in \{1, \dots, m\}$ .
2. An *abstract transition* is a triple  $(j, E, j')$  where  $j, j' \in J$  and  $E$  is a set of equations.
3. Every triple  $((j, p), a, (j', p')) \in Q \times \mathbb{A} \times Q$  induces an abstract transition  $(j, E, j')$  defined as follows for  $k, \bar{k} \in \{1, \dots, m\}$  (we write  $(-)_i$  for the  $i$ -th letter of a word):

$$k = \bullet \in E \iff p_k = a, \quad \bullet = k \in E \iff a = p'_k, \quad k = \bar{k} \in E \iff p_k = p'_{\bar{k}}.$$

We let  $\text{abs}(\delta)$  denote the set of abstract transitions induced by transitions in  $\delta$ , and we write  $j \xrightarrow{E} j'$  for  $(j, E, j') \in \text{abs}(\delta)$ .

4. A triple  $((j, q), b, (j', q')) \in \bar{Q} \times \mathbb{A} \times \bar{Q}$  is *consistent* with the abstract transition  $(j, E, j')$  if for every  $k, \bar{k} \in \{1, \dots, m\}$  the following conditions hold:

$$k = \bullet \in E \implies q_k = b, \quad \bullet = k \in E \implies b = q'_k, \quad k = \bar{k} \in E \implies q_k = q'_{\bar{k}}.$$

► **Proposition 2.12.** *For every triple  $((j, q), b, (j', q')) \in \bar{Q} \times \mathbb{A} \times \bar{Q}$ , we have*

$$(j, q) \xrightarrow{b} (j', q') \text{ in } \bar{A} \text{ iff } ((j, q), b, (j', q')) \text{ is consistent with some } (j, E, j') \in \text{abs}(\delta).$$

► **Definition 2.13.** An *abstract run* in  $\bar{A}$  is a sequence  $(j_0, E_1, j_1, E_2, j_2, \dots, E_n, j_n)$  such that  $j_0 \in J_I$  and  $j_{r-1} \xrightarrow{E_r} j_r$  for  $r = 1, \dots, n$ . It is *accepting* if  $j_n \in J_F$ .

► **Notation 2.14.** Given an abstract run  $(j_0, E_1, j_1, E_2, j_2, \dots, E_n, j_n)$ , we inductively define the predicates  $\text{Eq}_k^{(i)}$  ( $i \in \{1, \dots, n\}$ ,  $k \in \{1, \dots, m\}$ ) on the set  $\{1, \dots, n\}$ :

1. if  $\bullet = k$  in  $E_i$  then  $\text{Eq}_k^{(i)}(i)$ ;
2. if  $r < n$  and  $k = \bar{k}$  in  $E_{r+1}$  and  $\text{Eq}_{\bar{k}}^{(i)}(r)$  then  $\text{Eq}_k^{(i)}(r+1)$ .

Informally,  $\text{Eq}_k^{(i)}(r)$  asserts that  $1 \leq i \leq r \leq n$  and that in every run in  $\bar{A}$  of length  $r$  whose transitions are consistent with  $E_1, \dots, E_r$ , the  $i$ -th input letter equals the content of register  $k$  after  $r$  steps. The accepted language may be characterized using these predicates:

► **Proposition 2.15.** *The NOFRA  $\bar{A}$  accepts the word  $b_1 \dots b_n \in \mathbb{A}^*$  iff there exists an accepting abstract run of length  $n$  (with induced predicates  $\text{Eq}_k^{(i)}$ ) such that for  $i, r \in \{1, \dots, n\}$ ,*

$$r < n \text{ and } k = \bullet \text{ in } E_{r+1} \text{ and } \text{Eq}_k^{(i)}(r) \text{ for some } k \implies b_i = b_{r+1}. \quad (2.1)$$

As a first application of this result, we identify an important difference between NOFA and NOFRA concerning the power of guessing data values during the computation:

► **Definition 2.16.** A NOFA/NOFRA is *non-guessing* if each initial state has empty support and for each transition  $q \xrightarrow{a} q'$  one has  $\text{supp } q' \subseteq \text{supp } q \cup \{a\}$ .

The NOFA-recognizable language  $L_0$  from the Introduction is not recognizable by any non-guessing NOFA [17, Ex. 1]. Note that  $L_0$  is not positive; in fact, it is necessarily so, since for positive languages guessing does not add to the expressive power of automata:

► **Theorem 2.17.** *Every positive NOFA-recognizable language is accepted by some non-guessing NOFRA, hence by some non-guessing NOFA.*

To make a NOFRA non-guessing, one keeps track (via the state) of those registers containing data values forced by abstract transitions. The other registers then may be modified arbitrarily, which allows the elimination of guessing transitions.

### 3 Positive Register Automata

We now relate positive NOFA-recognizable languages to register automata, a.k.a. finite-memory automata, originally introduced by Kaminski and Francez [17]; we follow the equivalent presentation by Bojańczyk et al. [6]. A *register automaton* is a quintuple  $A = (C, m, \delta, I, F)$  where  $C$  is a finite set of control states,  $m \in \mathbb{N}$  is the number of registers (numbered from 1 to  $m$ ),  $I, F \subseteq C$  are sets of initial and final states, and  $\delta \subseteq C \times \text{Bool}(\Phi) \times C$  is the set of transitions. Here,  $\text{Bool}(\Phi)$  denotes the set of boolean formulas over the atoms  $\Phi = (\{1, \dots, m\} \times \{\text{before}\} \cup \{\bullet\} \cup \{1, \dots, m\} \times \{\text{after}\})^2$ . Elements of  $\Phi$  are called *equations*; we write  $x = y$  for  $(x, y) \in \Phi$ . Moreover, we denote  $(c, \varphi, c') \in \delta$  by  $c \xrightarrow{\varphi} c'$ . A

configuration of  $A$  is a pair  $(c, r)$  of a state  $c \in C$  and a word  $r \in (\mathbb{A} \cup \{\perp\})^m$  corresponding to a partial assignment of data values to the registers. The initial configurations are  $(c, \perp^m)$  for  $c \in I$ . Given an input  $a \in \mathbb{A}$  and configurations  $(c, r), (c', r')$  we write  $(c, r) \xrightarrow{a} (c', r')$  if this move is consistent with some transition  $c \xrightarrow{\varphi} c'$ , that is, the formula  $\varphi$  is true under the assignment making an atom  $x = y \in \Phi$  true iff the corresponding data values are defined and equal. For instance,  $(k, \text{before}) = \bullet$  is true iff  $r_k \neq \perp$  and  $r_k = a$ , and  $(k, \text{before}) = (\bar{k}, \text{after})$  is true iff  $r_k, r'_k \neq \perp$  and  $r_k = r'_k$ . A word  $w = a_1 \dots a_n \in \mathbb{A}^*$  is *accepted* by  $A$  if it admits an accepting run, viz. a sequence of moves  $(c_0, r_0) \xrightarrow{a_1} (c_1, r_1) \xrightarrow{a_2} \dots \xrightarrow{a_n} (c_n, r_n)$  where  $(c_0, r_0)$  is initial and  $c_n \in F$ . The *accepted language*  $L(A) \subseteq \mathbb{A}^*$  is the set of accepted words.

As shown by Bojańczyk et al. [6], register automata accept the same languages as NOFAs. To capture positive languages, we restrict to register automata with positive transitions:

► **Definition 3.1.** A register automaton is *positive* if for each transition  $c \xrightarrow{\varphi} c'$  the formula  $\varphi$  is positive:  $\varphi = \text{true}$  or  $\varphi$  uses the boolean operations  $\vee$  and  $\wedge$  only.

► **Theorem 3.2.** A data language is positive and NOFA-recognizable iff it is accepted by some positive register automaton.

Here, the approach is to regard a configuration of a positive register automaton as a state of a NOFRA. Conversely, an abstract transition  $j \xrightarrow{E} j'$  of a NOFA can be transformed into a transition  $j \xrightarrow{\varphi} j'$  of a register automaton for the conjunction  $\varphi$  of all equations in  $E$ , identifying  $k = \bullet, \bullet = k, k = \bar{k}$  with  $(k, \text{before}) = \bullet, \bullet = (k, \text{after}), (k, \text{before}) = (\bar{k}, \text{after})$ . A tweak of the initial states accounts for the requirement that registers are initially empty.

► **Remark 3.3.** Just like register automata are equivalent to finite-memory automata, positive register automata correspond to a restricted version of finite-memory automata called *finite-state unification-based automata (FSUBA)* [18, 32]. The original definition of the latter involves a fixed initial register assignment, which enables acceptance of non-positive languages. However, FSUBA with empty initial registers are equivalent to positive register automata; see the full paper for details. This implies in particular that positive register automata admit a decidable inclusion problem, in contrast to the case of unrestricted register automata [25]. Indeed, FSUBA translate into a more general model called *RNNA* [29, Sec. 6], for which inclusion is decidable. Tal [32] has given a direct decidability proof for FSUBA.

## 4 Monadic Second-Order Logic with Positive Equality Tests

As motivated in the Introduction, positive data languages are considered as expressing properties of data words involving positive statements about equality of data values. In the following we make this idea precise. For this purpose, we employ monadic second-order logic with equality tests, abbreviated  $\text{MSO}^\sim$  [4, 9, 25]. Its formulae are given by the grammar

$$\varphi, \psi := x < y \mid x \sim y \mid X(x) \mid \neg\varphi \mid \varphi \vee \psi \mid \varphi \wedge \psi \mid \exists x. \varphi \mid \exists X. \varphi \mid \forall x. \varphi \mid \forall X. \varphi,$$

where  $x, y$  range over first-order variables and  $X$  over monadic second-order variables. A formula is interpreted over a fixed data word  $w = a_1 \dots a_n \in \mathbb{A}^*$ . First-order variables represent positions, i.e. elements of the set  $\{1, \dots, n\}$ , and second-order variables represent subsets of  $\{1, \dots, n\}$ . The atomic formula  $x < y$  means “position  $x$  comes before position  $y$ ”, and  $x \sim y$  means “the same data value occurs at positions  $x$  and  $y$ ”. The interpretation of the remaining constructs is standard. A *sentence* is a formula without free variables. We write  $L(\varphi) \subseteq \mathbb{A}^*$  for the set of data words satisfying the sentence  $\varphi$ . For example, the languages  $L_0$  and  $L_1$  from the Introduction are defined by  $\varphi_0 = \forall y. \text{last}(y) \Rightarrow (\forall x. x < y \Rightarrow \neg(x \sim y))$ , where  $\text{last}(y) = \neg\exists z. y < z$  and  $\psi \Rightarrow \xi = \neg\psi \vee \xi$ , and by  $\varphi_1 = \exists x. \exists y. x < y \wedge x \sim y$ .

Recall that by standard rules of negation, every formula is equivalent to one in *negation normal form (NNF)*, where for each subformula  $\neg\varphi$  the formula  $\varphi$  is atomic.

► **Definition 4.1.** An  $\text{MSO}^\sim$  formula lies in  $\text{MSO}^{\sim,+}$  (*monadic second-order logic with positive equality tests*) if it admits an NNF containing no subformula of the form  $\neg(x \sim y)$ . A data language is  *$\text{MSO}^{\sim,+}$ -definable* if it is of the form  $L(\varphi)$  for an  $\text{MSO}^{\sim,+}$  sentence  $\varphi$ .

The above sentence  $\varphi_1$  lies in  $\text{MSO}^{\sim,+}$  but  $\varphi_0$  does not. The following is immediate:

► **Proposition 4.2.** *Every  $\text{MSO}^{\sim,+}$ -definable language is positive.*

► **Remark 4.3.** The logic  $\text{MSO}^\sim$  is more expressive than NOFAs [25], and the same holds for  $\text{MSO}^{\sim,+}$ : the language defined by the  $\text{MSO}^{\sim,+}$  sentence  $\varphi = \forall x. \exists y. (x < y \vee y < x) \wedge x \sim y$  (“no data value occurs only once”) is not NOFA-recognizable. However, within the class of NOFA-recognizable languages, positive and  $\text{MSO}^{\sim,+}$ -definable languages coincide:

► **Theorem 4.4.** *A NOFA-recognizable language is positive iff it is  $\text{MSO}^{\sim,+}$ -definable.*

Indeed, one can express the abstract acceptance condition of Proposition 2.15 in  $\text{MSO}^{\sim,+}$ .

## 5 Toposes for Names

In the remainder, we investigate positive data languages and their automata from a more conceptual perspective. Some familiarity with basic category theory (functors, natural transformations, (co-)limits, adjunctions) is required; see Mac Lane [22] for a gentle introduction.

Nominal sets and nominal renaming sets (Section 2.1) were initially introduced as a convenient abstract framework for reasoning about names, and related issues such as freshness, binding, and substitution. An alternative, and more general, approach uses the presheaf categories  $\mathbf{Set}^{\mathbb{A}}$  [31] and  $\mathbf{Set}^{\mathbb{A}^{\text{ren}}}$  [10]. The intuition behind each of these categories  $\mathcal{C}$  is very similar: one thinks of  $X \in \mathcal{C}$  as a collection of finitely supported objects, equipped with a renaming operation that extends renamings  $\rho: \mathbb{A} \rightarrow \mathbb{A}$  to the level of elements of  $X$ . The difference between the four categories lies in whether elements admit a *least* support, or just some finite support, and in whether renamings  $\rho$  are injective or arbitrary maps; see Figure 2. The last column classifies the respective finitely presentable objects, which underly automata. We now recall the latter concept and describe the categories in more detail.

**Finitely presentable objects.** A diagram  $D: I \rightarrow \mathcal{C}$  in a category  $\mathcal{C}$  is *directed* if its scheme  $I$  is a directed poset: every finite subset of  $I$  has an upper bound. A *directed colimit* is a colimit of a directed diagram. An object  $X$  of  $\mathcal{C}$  is *finitely presentable* if its hom-functor  $\mathcal{C}(X, -): \mathcal{C} \rightarrow \mathbf{Set}$  to the category of sets and functions preserves directed colimits. In many categories, finitely presentable objects correspond to the objects with a finite description. For example, the finitely presentable objects of  $\mathbf{Set}$  are precisely finite sets, and if  $\mathcal{C}$  is a variety of algebras (e.g. monoids, groups, rings), an algebra is a finitely presentable object of  $\mathcal{C}$  iff it is presentable by finitely many generators and relations [2, Thm. 3.12].

**Nominal (renaming) sets.** We let  $\mathbf{Nom}$  denote the category of nominal sets and  $\text{Perm}(\mathbb{A})$ -equivariant maps, and  $\mathbf{RnNom}$  the category of nominal renaming sets and  $\text{Fin}(\mathbb{A})$ -equivariant maps. Both categories are toposes, that is, they are finitely complete (with limits formed as in  $\mathbf{Set}$ ), cartesian closed, and admit a subobject classifier. Note that  $\mathbf{Nom}$  is a boolean topos (its subobject classifier is  $2 = \{0, 1\}$  with the trivial group action), which is not true for  $\mathbf{RnNom}$  [12, Sec. 5]. The next proposition provides a categorical description of orbit-finite nominal (renaming) sets; for nominal sets this result is well-known, see [26, Prop. 2.3.7] or [27, Thm. 5.16], and the statement for nominal renaming sets may be deduced from it.

Category	Objects	Least supp.	Renamings	Finitely pres. objects
<b>Nom</b>	nominal sets	yes	injective	orbit-finite sets
<b>RnNom</b>	nominal renaming sets	yes	arbitrary	orbit-finite sets
<b>Set<sup>ℐ</sup></b>	presheaves over ℐ	no	injective	super-finitary presheaves
<b>Set<sup>ℱ</sup></b>	presheaves over ℱ	no	arbitrary	super-finitary presheaves

■ **Figure 2** Toposes that model sets of finitely supported objects.

► **Proposition 5.1.** *A nominal (renaming) set is orbit-finite iff it is a finitely presentable object of **Nom** or **RnNom**, respectively.*

The forgetful functor  $U: \mathbf{RnNom} \rightarrow \mathbf{Nom}$  given by restricting the  $\text{Fin}(\mathbb{A})$ - to a  $\text{Perm}(\mathbb{A})$ -action has a left adjoint  $F: \mathbf{Nom} \rightarrow \mathbf{RnNom}$  [24, Thm. 2.6]. We refer to *op. cit.* for its explicit description, but remark that  $F(\mathbb{A}^{\#n}) = \mathbb{A}^n$  for every  $n \in \mathbb{N}$  [24, Thm. 3.7].

**Presheaves.** A (covariant) presheaf over a small category  $\mathcal{C}$  is a functor  $P: \mathcal{C} \rightarrow \mathbf{Set}$ . We write  $\mathbf{Set}^{\mathcal{C}}$  for the category of presheaves and natural transformations. We specifically consider presheaves over  $\mathbb{F}$  and  $\mathbb{I}$ , the categories whose objects are finite subsets  $S \subseteq_f \mathbb{A}$  and whose morphisms  $\rho: S \rightarrow T$  are functions or injective functions, respectively. The categories **Nom** and **RnNom** form full reflective subcategories of  $\mathbf{Set}^{\mathbb{I}}$  and  $\mathbf{Set}^{\mathbb{F}}$  via embeddings

$$I_*: \mathbf{Nom} \hookrightarrow \mathbf{Set}^{\mathbb{I}} \quad \text{and} \quad J_*: \mathbf{RnNom} \hookrightarrow \mathbf{Set}^{\mathbb{F}}.$$

Here,  $I_*$  is given for  $X \in \mathbf{Nom}$ ,  $S \subseteq_f \mathbb{A}$ ,  $\rho: S \rightarrow T$  in  $\mathbb{I}$  and  $f: X \rightarrow Y$  in **Nom** by

$$(I_*X)S = \{x \in X : \text{supp } x \subseteq S\}, \quad (I_*X)\rho(x) = \bar{\rho} \cdot x, \quad (I_*f)_S(x) = f(x),$$

where  $\bar{\rho} \in \text{Perm}(\mathbb{A})$  is any permutation extending the injective map  $\rho$ . The embedding  $J_*$  is defined analogously. In both cases, the essential image of the embedding consists precisely of the presheaves preserving pullbacks of injective maps, see [27, Thm. 6.8] and [12, Thm. 38]. Informally, a presheaf  $P \in \mathbf{Set}^{\mathcal{C}}$ , where  $\mathcal{C} \in \{\mathbb{I}, \mathbb{F}\}$ , specifies a set  $PS$  of  $S$ -supported objects for every  $S \subseteq_f \mathbb{A}$ , and the pullback preservation property asserts precisely that every object admits a least support. A presheaf  $P \in \mathbf{Set}^{\mathcal{C}}$  is *super-finitary* if there exists  $S \subseteq_f \mathbb{A}$  such that (i)  $PS'$  is a finite set for all  $S' \subseteq S$ , and (ii) for every  $T \subseteq_f \mathbb{A}$  and  $x \in PT$ , there exists  $S' \subseteq S$  and  $\rho \in \mathcal{C}(S', T)$  such that  $x \in P\rho[PS']$ . (This implies that  $PT$  is finite.) Such an  $S$  is called a *generating set* for  $P$ . The next proposition shows that super-finitary presheaves are the analogue of orbit-finite sets; see [1, Cor. 3.34] for the case  $\mathcal{C} = \mathbb{F}$ :

► **Proposition 5.2.** *For  $\mathcal{C} \in \{\mathbb{I}, \mathbb{F}\}$  and  $P \in \mathbf{Set}^{\mathcal{C}}$ , the following are equivalent: (i)  $P$  is super-finitary; (ii)  $P$  is finitely presentable; (iii) there exists an epimorphism (a componentwise surjective natural transformation)  $\coprod_{i \in I} \mathcal{C}(S_i, -) \twoheadrightarrow P$  with  $I$  finite and  $S_i \subseteq_f \mathbb{A}$ . Moreover, super-finitary presheaves are closed under sub-presheaves and finite products.*

To relate the two presheaf categories  $\mathbf{Set}^{\mathbb{I}}$  and  $\mathbf{Set}^{\mathbb{F}}$ , recall that every functor  $E: \mathcal{C} \rightarrow \mathcal{D}$  between small categories induces an adjunction (5.1), where the right adjoint  $E^*$  is given by  $E^*(P) = P \circ E$ , and the left adjoint sends a presheaf  $P \in \mathbf{Set}^{\mathcal{C}}$  to its *left Kan extension*  $\text{Lan}_E P$ . For the inclusion functor  $E: \mathbb{I} \hookrightarrow \mathbb{F}$ , we obtain the commutative diagram (5.2) of adjunctions. Here,  $I^*$  and  $J^*$  are the reflectors, i.e. the left adjoints of  $I_*$  and  $J_*$ .

$$\begin{array}{ccc} \mathbf{Set}^{\mathcal{C}} & \xleftarrow[\text{Lan}_E]{E^*} & \mathbf{Set}^{\mathcal{D}} \\ & & \end{array} \quad (5.1) \qquad \begin{array}{ccc} \mathbf{Set}^{\mathbb{I}} & \xleftarrow[\top]{E^*} & \mathbf{Set}^{\mathbb{F}} \\ I_* \uparrow \vdash I^* & \xrightarrow[\text{Lan}_E]{} & J_* \downarrow \dashv J_* \\ \mathbf{Nom} & \xleftarrow[U]{F} & \mathbf{RnNom} \end{array} \quad (5.2)$$

► **Proposition 5.3.** *All functors in (5.2) preserve finitely presentable objects.*

Hence, the adjunctions (5.2) restrict to the full subcategories of finitely presentable objects.

## 6 Nondeterministic Automata in a Category

Our aim is to investigate nondeterministic automata and their languages in the toposes of Figure 2, and to compare their expressive power. To this end, we first introduce the required automata-theoretic concepts uniformly at the level of abstract categories.

► **Assumptions 6.1.** Fix a category  $\mathcal{C}$  with finite limits and (strong epi, mono)-factorizations. We assume that strong epimorphisms are stable under finite products (that is,  $e \times e'$  is a strong epimorphism whenever  $e$  and  $e'$  are) and pullbacks (that is, in every pullback square  $e \circ \bar{f} = f \circ \bar{e}$ , the morphism  $\bar{e}$  is a strong epimorphism whenever  $e$  is).

The (strong epi, mono)-factorization  $f = (A \xrightarrow{e} I \xrightarrow{m} B)$  of a morphism  $f: A \rightarrow B$  in  $\mathcal{C}$  is its *image factorization*, and the subobject represented by  $m$  is the *image* of  $f$ .

► **Example 6.2.** Every topos satisfies Assumptions 6.1, including **Set**, **Nom**, **RnNom**, **Set<sup>II</sup>** and **Set<sup>F</sup>**. Note that in a topos all epimorphisms are strong. In the five categories above, epi- and monomorphisms are the (componentwise) surjective and injective morphisms, resp. Pullbacks and finite products are formed (componentwise) at the level of underlying sets.

► **Definition 6.3.** A *language* over  $\Sigma \in \mathcal{C}$  is a family of subobjects of  $\Sigma^n$  for each  $n \in \mathbb{N}$ :

$$L = (m_n^{(L)}: L^{(n)} \rightarrow \Sigma^n)_{n \in \mathbb{N}}.$$

We write  $L \leq L'$  iff  $L^{(n)} \leq L'^{(n)}$  for all  $n$ , using the partial order  $\leq$  on subobjects of  $\Sigma^n$ .

► **Remark 6.4.** If  $\mathcal{C}$  is countably extensive (e.g. a topos with countable coproducts), languages correspond bijectively to subobjects of  $\Sigma^* = \coprod_{n \in \mathbb{N}} \Sigma^n$ . Indeed, every language  $L$  yields the subobject  $\coprod_n m_n^{(L)}: \coprod_n L^{(n)} \rightarrow \Sigma^*$ , and conversely every subobject of  $\Sigma^*$  is of this form. In particular, this holds in the categories of Example 6.2.

► **Definition 6.5.** A *nondeterministic  $\mathcal{C}$ -automaton* is a quintuple  $A = (Q, \Sigma, \delta, I, F)$  consisting of an object  $Q \in \mathcal{C}$  of *states*, an *input alphabet*  $\Sigma \in \mathcal{C}$ , and subobjects

$$m_\delta: \delta \rightarrow Q \times \Sigma \times Q, \quad m_I: I \rightarrow Q, \quad m_F: F \rightarrow Q,$$

representing *transitions*, *initial states*, and *final states*, respectively. A *morphism*  $h: A' \rightarrow A$  of nondeterministic  $\mathcal{C}$ -automata is given by a pair of morphisms  $h_s: Q' \rightarrow Q$  and  $h_a: \Sigma' \rightarrow \Sigma$  of  $\mathcal{C}$  that restrict as shown below (note that  $h_t$ ,  $h_i$  and  $h_f$  are uniquely determined):

$$\begin{array}{ccccc} \delta' & \xrightarrow{\quad h_t \quad} & \delta & & I' & \xrightarrow{\quad h_i \quad} & I & & F' & \xrightarrow{\quad h_f \quad} & F \\ m_{\delta'} \downarrow & & \downarrow m_\delta & & m_{I'} \downarrow & & \downarrow m_I & & m_{F'} \downarrow & & \downarrow m_F \\ Q' \times \Sigma' \times Q' & \xrightarrow{\quad h_s \times h_a \times h_s \quad} & Q \times \Sigma \times Q & & Q' & \xrightarrow{\quad h_s \quad} & Q & & Q' & \xrightarrow{\quad h_s \quad} & Q \end{array} \quad (6.1)$$

We write  $\mathbf{NAut}(\mathcal{C})$  for the category of nondeterministic automata in  $\mathcal{C}$  and their morphisms, and  $\mathbf{NAut}_{\text{fp}}(\mathcal{C})$  for its full subcategory given by *nondeterministic fp-automata*, viz. automata where  $Q, \Sigma, \delta, I, F$  are finitely presentable objects of  $\mathcal{C}$ .

► **Definition 6.6.** For every nondeterministic  $\mathcal{C}$ -automaton  $A = (Q, \Sigma, \delta, I, F)$ , its *accepted language* is the language  $L(A)$  over  $\Sigma$  given as follows:

1.  $m_{L(A)}^{(0)}: L^{(0)}(A) \rightarrow 1 = \Sigma^0$  is the image of the unique morphism  $I \cap F \xrightarrow{!} 1$ , where  $1$  is the terminal object of  $\mathcal{C}$  and  $I \cap F$  is the intersection (pullback) of  $m_I$  and  $m_F$ .

2. For  $n > 0$ , the subobject  $m_{L(A)}^{(n)}: L^{(n)}(A) \rightarrow \Sigma^n$  is defined via the commutative diagram

$$\begin{array}{ccccc} L^{(n)}(A) & \xleftarrow{e_{n,A}} & \text{AccRun}_A^{(n)} & \xrightarrow{\bar{d}_{n,A}} & \delta^n \\ m_{L(A)}^{(n)} \downarrow & & \downarrow \bar{m}_\delta^{(n)} & & \downarrow m_\delta^n \\ \Sigma^n & \xleftarrow{p_{n,A}} & I \times (\Sigma \times Q)^{n-1} \times \Sigma \times F & \xrightarrow{d_{n,A}} & (Q \times \Sigma \times Q)^n \end{array}$$

Here, letting  $\Delta: Q \rightarrow Q \times Q$  denote the diagonal,  $d_{n,A}$  is the monomorphism

$$I \times (\Sigma \times Q)^{n-1} \times \Sigma \times F \xrightarrow{m_I \times (\text{id} \times \Delta)^{n-1} \times \text{id} \times m_F} Q \times (\Sigma \times Q \times Q)^{n-1} \times \Sigma \times Q \cong (Q \times \Sigma \times Q)^n,$$

the morphisms  $\bar{d}_{n,A}$  and  $\bar{m}_\delta^{(n)}$  form the pullback of  $d_{n,A}$  and  $m_\delta^n$ , the morphism  $p_{n,A}$  is the projection, and  $e_{n,A}$  and  $m_{L(A)}^{(n)}$  form the image factorization of  $p_{n,A} \circ \bar{m}_\delta^{(n)}$ .

► **Example 6.7.**

1. A nondeterministic fp-automaton in **Set** is a classical nondeterministic finite automaton. The pullback  $\text{AccRun}_A^{(n)}$  is the set of accepting runs of length  $n$ , hence  $L(A)$  is the usual accepted language: the set of words with an accepting run.
2. A nondeterministic fp-automaton in **Nom** or **RnNom** with alphabet  $\Sigma = \mathbb{A}$  is a NOFA or NOFRA, respectively. The two notions of accepted language in Definition 2.3 and Definition 6.6 match, that is,  $L(A)$  is the set of words with an accepting run.
3. In the next section, we will also look into nondeterministic **Set<sup>I</sup>**- and **Set<sup>F</sup>**-automata.

► **Remark 6.8.** Readers familiar with coalgebras [28] may note that if  $\mathcal{C}$  is a topos, the final states and transitions of a nondeterministic  $\mathcal{C}$ -automaton correspond to a coalgebra  $\gamma: Q \rightarrow \Omega \times (\mathcal{P}Q)^\Sigma$  where  $\Omega$  is the subobject classifier and  $\mathcal{P}: \mathcal{C} \rightarrow \mathcal{C}$  is the covariant power object functor [16, Sec. A.2.3]. We expect our above definition of accepted language to match the one given by coalgebraic trace semantics [15, 30], with the required arguments relying on the internal logic of the topos  $\mathcal{C}$ . Details are left for future work; we have found that the present relational approach to automata leads to shorter and more direct proofs.

► **Proposition 6.9.** *Let  $h: A' \rightarrow A$  be an  $\mathbf{NAut}(\mathcal{C})$ -morphism where  $\Sigma' = \Sigma$  and  $h_a = \text{id}_\Sigma$ .*

1. *The accepted language of  $A'$  is contained in that of  $A$ , that is,  $L(A') \leq L(A)$ .*
2. *If  $h_s$  is strongly epic in  $\mathcal{C}$  and the squares (6.1) are pullbacks, then  $L(A') = L(A)$ .*

Hence, the construction  $A \mapsto A'$  of Remark 2.6 indeed yields an equivalent NOFA.

► **Proposition 6.10.** *Let  $\mathcal{C}$  and  $\mathcal{D}$  be categories satisfying the Assumptions 6.1.*

1. *Every functor  $G: \mathcal{C} \rightarrow \mathcal{D}$  lifts to a functor  $\bar{G}: \mathbf{NAut}(\mathcal{C}) \rightarrow \mathbf{NAut}(\mathcal{D})$  defined by*

$$\bar{G}(Q, \Sigma, \delta, I, F) = (GQ, G\Sigma, \overline{G\delta}, \overline{GI}, \overline{GF}) \quad \text{and} \quad \bar{G}f = Gf.$$

*Here,  $\overline{G\delta}$ ,  $\overline{GI}$ ,  $\overline{GF}$  are the images of the morphisms shown below, with  $\text{can}$  denoting the canonical morphism induced by the product projections:*

$$G\delta \xrightarrow{Gm_\delta} G(Q \times \Sigma \times Q) \xrightarrow{\text{can}} GQ \times G\Sigma \times GQ, \quad GI \xrightarrow{Gm_I} GQ, \quad GF \xrightarrow{Gm_F} GQ.$$

2. *Every adjunction  $L \dashv R: \mathcal{C} \rightarrow \mathcal{D}$  lifts to an adjunction  $\bar{L} \dashv \bar{R}: \mathbf{NAut}(\mathcal{C}) \rightarrow \mathbf{NAut}(\mathcal{D})$ .*

In particular, the adjunctions (5.2) lift to adjunctions between the respective categories of nondeterministic automata, which in turn restrict to fp-automata by Proposition 5.3:

$$\begin{array}{ccc}
\mathbf{NAut}_{\text{fp}}(\mathbf{Set}^{\mathbb{I}}) & \xleftarrow[\perp]{\bar{E}^*} & \mathbf{NAut}_{\text{fp}}(\mathbf{Set}^{\mathbb{F}}) \\
\tilde{I}_* \uparrow \downarrow \tilde{I}^* & \xrightarrow[\text{Lan}_E]{\perp} & \tilde{J}^* \downarrow \uparrow \tilde{J}_* \\
\mathbf{NAut}_{\text{fp}}(\mathbf{Nom}) & \xleftarrow[\bar{U}]{\bar{F}} & \mathbf{NAut}_{\text{fp}}(\mathbf{RnNom})
\end{array} \tag{6.2}$$

The positive closure  $A \mapsto \bar{A}$  of Construction 2.7, which is key to our results in Sections 2 through 4, is an instance of the proposition since  $\bar{A} = \bar{F}A$  for the left adjoint  $F: \mathbf{Nom} \rightarrow \mathbf{RnNom}$ .

## 7 Nondeterministic Presheaf Automata

We proceed to relate the expressive power of the four automata models in (6.2). Specifically, for  $\mathcal{C} \in \{\mathbb{I}, \mathbb{F}\}$  we consider nondeterministic  $\mathbf{Set}^{\mathcal{C}}$ -automata  $A = (Q, \Sigma, \delta, I, F)$  with a super-finitary (= finitely presentable) presheaf  $Q$  of states and input alphabet  $\Sigma = V_{\mathcal{C}} \in \mathbf{Set}^{\mathcal{C}}$ , for the inclusion functor  $V_{\mathcal{C}}(S) = S$ . (This implies that  $\delta$ ,  $I$  and  $F$  are super-finitary by Proposition 5.2.) Note that  $V_{\mathcal{C}}$  corresponds to the input alphabet  $\mathbb{A}$  used for NOF(R)As:

$$V_{\mathbb{I}} = I_*(\mathbb{A}) \quad \text{and} \quad V_{\mathbb{F}} = J_*(\mathbb{A}) = \text{Lan}_E(V_{\mathbb{I}}).$$

A language in  $\mathbf{Set}^{\mathcal{C}}$  is a sub-presheaf  $L \subseteq V_{\mathcal{C}}^*$ , or equivalently a family of sub-presheaves  $L^{(n)} \subseteq V_{\mathcal{C}}^n$  for  $n \in \mathbb{N}$  (Definition 6.3 and Remark 6.4). Here,  $V_{\mathcal{C}}^*(S) = S^*$ , the set of words over the finite alphabet  $S \subseteq_f \mathbb{A}$ , and  $V_{\mathcal{C}}^n(S) = S^n$ , the subset of words of length  $n$ .

► **Remark 7.1.** For the sake of distinction, we refer to languages in  $\mathbf{Set}^{\mathcal{C}}$  as *presheaf languages*, and to subsets of  $\mathbb{A}^*$  as *word languages*. Both concepts are closely related: Every presheaf language  $L \subseteq V_{\mathbb{I}}^*$  in  $\mathbf{Set}^{\mathbb{I}}$  induces a  $\text{Perm}(\mathbb{A})$ -equivariant word language  $W(L) \subseteq \mathbb{A}^*$  given by  $W(L) = \bigcup_{S \subseteq_f \mathbb{A}} L(S)$ , and, conversely, every  $\text{Perm}(\mathbb{A})$ -equivariant word language  $K \subseteq \mathbb{A}^*$  induces a presheaf language  $P(K) \subseteq V_{\mathbb{I}}^*$  given by  $[P(K)]S = K \cap S^*$  for  $S \subseteq_f \mathbb{A}$ . Analogously for presheaf languages in  $\mathbf{Set}^{\mathbb{F}}$  and  $\text{Fin}(\mathbb{A})$ -equivariant word languages. In both cases, these translations almost yield a bijective correspondence: one has  $K = W(P(K))$ , but generally only  $L \subseteq P(W(L))$ . For instance, for  $L \subseteq V_{\mathbb{F}}^*$  given by  $L(\emptyset) = \emptyset$  and  $L(S) = \{\varepsilon\}$  for  $S \neq \emptyset$  one has  $[P(W(L))]\emptyset = \{\varepsilon\}$ , so  $L \subsetneq P(W(L))$ . The equality  $L = P(W(L))$  holds iff  $L$  is *downwards closed*, that is,  $L(S') = L(S) \cap (S')^*$  for all  $S' \subseteq S \subseteq_f \mathbb{A}$ .

The presheaf version of positive word languages and positive closures is as follows:

► **Definition 7.2.** Let  $L \subseteq V_{\mathbb{I}}^*$  be a presheaf language in  $\mathbf{Set}^{\mathbb{I}}$ .

1. The language  $L$  is *positive* if  $L = KE$  for some (unique) language  $K \subseteq V_{\mathbb{F}}^*$  in  $\mathbf{Set}^{\mathbb{F}}$ .
2. A *positive closure* of  $L$  is a language  $\bar{L}$  in  $\mathbf{Set}^{\mathbb{F}}$  such that  $L \subseteq \bar{L}E$  and  $\bar{L}$  is minimal with that property, that is,  $\bar{L} \subseteq K$  for every language  $K \subseteq V_{\mathbb{F}}^*$  in  $\mathbf{Set}^{\mathbb{F}}$  such that  $L \subseteq KE$ .

A positive closure is clearly unique; its existence is ensured by the next proposition, which is proved using the universal property of left Kan extensions.

► **Proposition 7.3.** *The positive closure of  $L \subseteq V_{\mathbb{I}}^*$  is given by the image of the morphism*

$$\varphi: \text{Lan}_E(L) \xrightarrow{\text{Lan}_E(\iota)} \text{Lan}_E(V_{\mathbb{I}}^*) \cong \coprod_k \text{Lan}_E(V_{\mathbb{I}}^k) \xrightarrow{\coprod_k \text{can}_k} \coprod_k \text{Lan}_E(V_{\mathbb{I}})^k = \coprod_k V_{\mathbb{F}}^k = V_{\mathbb{F}}^*$$

where  $\iota: L \hookrightarrow V_{\mathbb{I}}^*$  is the inclusion, the isomorphism witnesses preservation of coproducts by the left adjoint  $\text{Lan}_E$ , and  $\text{can}_k$  is the canonical map induced by the product projections.

► **Remark 7.4.** A presheaf  $P \in \mathbf{Set}^{\mathbb{I}}$  is *strong* if  $P = I_*(X)$  for a strong nominal set  $X$ . Since  $I_*$  preserves coproducts, (super-finitary) strong presheaves are exactly (finite) coproducts  $\coprod_{j \in J} \mathbb{I}(S_j, -)$  of representable presheaves. By Proposition 5.2 and Proposition 6.9, every super-finitary  $\mathbf{Set}^{\mathbb{I}}$ -automaton is equivalent to one whose presheaf of states is strong. Given such an automaton  $A$  with states  $Q = \coprod_{j \in J} \mathbb{I}(S_j, -)$ , applying the lifted left adjoint  $\overline{\mathbf{Lan}}_E$  yields a super-finitary  $\mathbf{Set}^{\mathbb{F}}$ -automaton  $\bar{A}$  with states  $\mathbf{Lan}_E(Q) = \coprod_{j \in J} \mathbb{F}(S_j, -)$ , using that  $\mathbf{Lan}_E$  preserves coproducts and representables (see e.g. [22, Ex. X.3.2]). This is the analogue of Construction 2.7 for presheaf automata. Similar to Proposition 2.8, we have

► **Proposition 7.5.** *For every super-finitary nondeterministic  $\mathbf{Set}^{\mathbb{I}}$ -automaton  $A$  with a strong presheaf of states, the  $\mathbf{Set}^{\mathbb{F}}$ -automaton  $\bar{A} = \overline{\mathbf{Lan}}_E(A)$  accepts the language  $\overline{L(A)}$ .*

While by definition nondeterministic presheaf automata accept presheaf languages, using Remark 7.1 we can also naturally associate a word language semantics to them:

► **Definition 7.6.**

1. The word language *accepted* by a nondeterministic  $\mathbf{Set}^{\mathcal{C}}$ -automaton  $A$  is  $W(L(A)) \subseteq \mathbb{A}^*$ , the word language induced by the presheaf language of  $A$ .
2. A word language  $L \subseteq \mathbb{A}^*$  is  *$\mathbf{Set}^{\mathcal{C}}$ -recognizable* if there exists a super-finitary nondeterministic  $\mathbf{Set}^{\mathcal{C}}$ -automaton accepting it.

This enables a classification of the expressive power of nondeterministic  $\mathbf{Set}^{\mathcal{C}}$ -automata:

► **Theorem 7.7.**

1. *A word language is NOFA-recognizable iff it is  $\mathbf{Set}^{\mathbb{I}}$ -recognizable.*
2. *A word language is positive and NOFA-recognizable iff it is  $\mathbf{Set}^{\mathbb{F}}$ -recognizable.*

For item 1 one shows that the functors  $\bar{I}_*$  and  $\bar{I}^*$  of (6.2) preserve the accepted word languages of automata. For item 2 one uses Proposition 7.5 and the observation that every nondeterministic  $\mathbf{Set}^{\mathbb{F}}$ -automaton accepts a positive word language.

This shows that the theory of data languages can be based on presheaves rather than nominal sets [6]. In particular, the conceptual difference between the two approaches (viz. existence of least supports) is largely inessential from the perspective of automata theory.

## 8 Conclusions and Future Work

We have characterized positive data languages recognizable by NOFAs in terms of register automata, logic, and category theory; see Figure 1 for a summary of our contributions. Our results underline the phenomenon that weak classes of data languages tend to have a rich theory and admit many equivalent perspectives, paralleling classical regular languages over finite alphabets. For example, a similar observation has been made for data languages recognizable by orbit-finite nominal monoids [4, 8, 9].

The logic  $\text{MSO}^{\sim,+}$  defines positive data languages, but is more expressive than NOFAs. Identifying a suitable syntactic fragment of  $\text{MSO}^{\sim,+}$  that captures precisely the positive NOFA-recognizable languages remains an open problem. The same holds for the decidability of the satisfiability problem for  $\text{MSO}^{\sim,+}$ , which is known to be undecidable for  $\text{MSO}^{\sim}$  [20]. On a related note, it might be interesting to characterize the expressive power of full  $\text{MSO}^{\sim,+}$ . Specifically, does it capture precisely the  $\text{MSO}^{\sim}$ -definable positive languages?

Finally, besides register automata, a number of further automata models for data languages have been proposed, most notably pebble automata [25] and data automata [5, 7]. In general, these models differ in their expressive power. However, it is conceivable that some or all of them may become equivalent when restricted to positive data languages.

## Abstract

---

*Pursuit-evasion games* have been intensively studied for several decades due to their numerous applications in artificial intelligence, robot motion planning, database theory, distributed computing, and algorithmic theory. COPS AND ROBBER (CNR) is one of the most well-known pursuit-evasion games played on graphs, where multiple *cops* pursue a single *robber*. The aim is to compute the *cop number* of a graph,  $k$ , which is the minimum number of cops that ensures the *capture* of the robber.

From the viewpoint of parameterized complexity, CNR is W[2]-hard parameterized by  $k$  [Fomin et al., TCS, 2010]. Thus, we study structural parameters of the input graph. We begin with the *vertex cover number* (vcn). First, we establish that  $k \leq \frac{vcn}{3} + 1$ . Second, we prove that CNR parameterized by vcn is FPT by designing an exponential kernel. We complement this result by showing that it is unlikely for CNR parameterized by vcn to admit a polynomial compression. We extend our exponential kernels to the parameters *cluster vertex deletion number* and *deletion to stars number*, and design a linear vertex kernel for *neighborhood diversity*. Additionally, we extend all of our results to several well-studied variations of CNR.

## 1 Introduction

In *pursuit-evasion*, a set of agents, called *pursuers*, plan to catch one or multiple *evaders*. Classically, pursuit-evasion games were played on geometric setups, where pursuers and evaders move on the plane [35, 49]. Parsons [48] formulated pursuit-evasion on graphs to model the search for a person trapped in caves, giving rise to the field of graph searching. Since then, pursuit-evasion has been studied extensively, having applications in artificial intelligence [36], robot motion planning [16, 40], constraint satisfaction and database theory [31, 32, 33], distributed computing [4, 18] and network decontamination [45], and significant implications in graph theory and algorithms [1, 25, 30, 54].

COPS AND ROBBER (CNR) is one of the most intensively studied pursuit-evasion games on graphs, where a set of cops pursue a single robber. Players move in discrete time steps alternately, starting with the cops. In each move, a player can move to an adjacent vertex, and the cops win by *capturing* the robber (i.e., if a cop and the robber occupy the same vertex). The goal is to compute the *cop number* of a graph  $G$ , denoted  $c(G)$ , which is the minimum number of cops required to win in  $G$ . We define the game formally in Section 2. CNR is well studied in the artificial intelligence literature under the name MOVING TARGET

PURSUIT (MTP) [37], where we consider sub-optimal but faster strategies from an applicative point of view. The results have found numerous applications in game design, police chasing, path planning, and robot motion planning [5, 44, 56].

Determining the parameterized complexity of games is a well-studied research topic [10, 11, 52]. Most pursuit-evasion games are AW[\*]-hard [53]. In particular, CNR is W[2]-hard parameterized by  $c(G)$  [27]. Thus, we consider structural parameterizations, focusing on *kernelization*, polynomial-time preprocessing with a parametric guarantee. Due to its profound impact, kernelization was termed “the lost continent of polynomial time” [26]. We begin with the most studied structural parameter: the *vertex cover number* ( $\text{vcn}$ ) of the input graph. We bound  $c(G)$  in terms of  $\text{vcn}$ , as well as achieve both positive and negative results concerning the kernelization complexity of CNR parameterized by  $\text{vcn}$ . We generalize our kernelization results to the smaller parameters *cluster vertex deletion number* ( $\text{cvd}$ ) and *deletion to stars number* ( $\text{dts}$ ), as well as to the parameter *neighborhood diversity* ( $\text{nd}$ ). Furthermore, we extend all our results to several well-studied variants of CNR.

The choice of  $\text{vcn}$  to study pursuit-evasion games is natural due to various scenarios where  $\text{vcn}$  is significantly smaller than the graph size. For example, this includes scenarios where we model the existence of one or few (possibly interconnected) central hubs – for illustration, suppose an intruder is hiding in a system of buildings where we have only few corridors but a large number of rooms, or suppose we have few virtual servers with many stations (e.g., of private users) that can communicate only with the servers. Furthermore,  $\text{vcn}$  is one of the most efficiently computable parameters from both approximation [55] and parameterized [17] points of view, making it fit from an applicative perspective even when a vertex cover is not given along with the input. Moreover,  $\text{vcn}$  is the best choice for proving negative results – indeed, our negative result on the kernelization complexity of CNR for  $\text{vcn}$  implies the same for many other well-known smaller parameters such as treewidth, treedepth and feedback vertex set [28]. One shortcoming of  $\text{vcn}$  as a parameter is that it is large for some simple (and easy to resolve) dense graphs like cliques. However, we generalize our kernel to  $\text{cvd}$ , which is small for these dense graphs, and to  $\text{dts}$ . Furthermore, we design a *linear* kernel for the well-studied parameter  $\text{nd}$ . We further discuss the utility of our kernels in the Conclusion.

**Brief Survey.** CNR was independently introduced by Quilliot [51] and Nowakowski and Winkler [46] with exactly one cop.<sup>1</sup> Aigner and Fromme [2] generalized CNR to multiple cops and defined the *cop number* of a graph. We refer to the book [9] for details.

The computational complexity of CNR is a challenging research subject. On the positive side, Berarducci and Intrigila [6] gave a backtracking algorithm to decide if  $G$  is  $k$ -copwin in  $\mathcal{O}(n^{2k+1})$  time. On the negative side, Fomin et al. [27] proved that CNR is NP-hard, and W[2]-hard parameterized by  $k$ . Moreover, Mamino [43] showed that CNR is PSPACE-hard, and later, Kinnersley [39] proved that CNR is, in fact, EXPTIME-complete. Recently, Brandt et al. [14] proved that, conditioned on (*Strong*) *Exponential Time Hypothesis*, the time complexity of any algorithm for CNR is  $(\Omega(n^{k-o(1)})) 2^{\Omega(\sqrt{n})}$ . Since CNR admits an XP-time algorithm, it is sensible to bound the cop number for various graph classes or by structural parameters. Nowadays, we know that the cop number is at most 3 for toroidal graphs [41], 9 for unit-disk graphs [7], 13 for string graphs [20], and bounded for bounded genus graphs [12] and minor-free graphs [3]. Moreover,  $c(G) \leq \frac{\text{tw}(G)}{2} + 1$  [38] and  $c(G) \leq \text{cw}(G)$  [27], where  $\text{tw}(G)$  and  $\text{cw}(G)$  are the treewidth and the cliquewidth of  $G$ , respectively.

---

<sup>1</sup> In fact, a specific instance of CNR was given as a puzzle in the book [24] already in 1917.

**Our Contribution.** We conduct a comprehensive analysis of CNR parameterized by  $\text{vcn}$ . Due to space constraints, the proofs of the claims marked by (\*) and the claims for which we only provide a proof sketch are deferred to the full version [29].

We start by bounding the cop number of a graph:

► **Theorem 1.** *For a graph  $G$ ,  $c(G) \leq \frac{\text{vcn}}{3} + 1$ .*

The proof is based on the application of three reduction rules. Each of our rules controls its own cop, which guards at least three vertices from the vertex cover. Once our rules are no longer applicable, we exhibit that the remaining unguarded part of the graph is of a special form, and the usage of only two additional cops suffices. We complement Theorem 1 with an argument that it might be difficult to improve this bound further using techniques similar to ours.

Second, we prove that CNR parameterized by  $\text{vcn}$  is FPT by designing a kernelization algorithm:

► **Theorem 2.** *CNR parameterized by  $\text{vcn}$  admits a kernel with at most  $\text{vcn} + \frac{2^{\text{vcn}}}{\sqrt{\text{vcn}}}$  vertices.*

Our kernel is also based on the application of reduction rules. However, these rules are very different than those used for the proof of Theorem 1. While our main rule is quite standard in kernelization (involving the removal of false twins), the proof of its correctness is (arguably) not. Theorem 2, Theorem 1, and the XP-algorithm (Proposition 12) yield the following corollary:

► **Corollary 3.** *CNR is FPT parameterized by  $\text{vcn}$ , and solvable in  $(\text{vcn} + \frac{2^{\text{vcn}}}{\sqrt{\text{vcn}}})^{\frac{\text{vcn}}{3} + 2} \cdot n^{\mathcal{O}(1)}$  time.*

We complement our kernel by showing that it is unlikely for CNR to admit polynomial compression, by providing a *polynomial parameter transformation* from RED-BLUE DOMINATING SET. Our reduction makes non-trivial use of a known construction of a special graph having high girth and high minimum degree.

► **Theorem 4.** *CNR parameterized by  $\text{vcn}$  does not admit polynomial compression, unless  $NP \subseteq \text{coNP}/\text{poly}$ .*

We also present a linear vertex kernel parameterized by  $\text{nd}$  for CNR, LAZY CNR, and COPS AND ATTACKING ROBBER, and a quadratic vertex kernel for COPS AND FAST ROBBER and FULLY ACTIVE CNR:

► **Theorem 5 (\*)**. *CNR, LAZY CNR, and COPS AND ATTACKING ROBBER parameterized by  $\text{nd}$  admits a kernel with at most  $\text{nd}$  vertices. Moreover, COPS AND FAST ROBBER and FULLY ACTIVE CNR parameterized by  $\text{nd}$  admit a kernel with at most  $\text{nd}^2$  vertices.*

On the positive side, we extend our exponential kernel to smaller parameters,  $\text{cvd}$  and  $\text{dts}$ :

► **Theorem 6.** *CNR parameterized by  $\text{cvd}$  admits a kernel with at most  $2^{2^{\text{cvd}} + \sqrt{\text{cvd}}}$  vertices. Moreover, CNR parameterized by  $\text{dts}$  admits a kernel with at most  $2^{2^{\text{dts}} + \text{dts}^{1.5}}$  vertices.*

Several variants of CNR have been studied due to their copious applications. We extend our results, parameterized by  $\text{vcn}$ , to some of the most well-studied ones. We define these variants (and used notations) in Section 2. We first bound the cop number of these variants by  $\text{vcn}$ :

► **Theorem 7 (\*)**. For a graph  $G$ : (1)  $c_{\text{lazy}} \leq \frac{\text{vcn}}{2} + 1$ ; (2)  $c_{\text{attack}} \leq \frac{\text{vcn}}{2} + 1$ ; (3)  $c_{\text{active}}(G) \leq \text{vcn}$ ; (4)  $c_{\text{surround}}(G) \leq \text{vcn}$ ; (5)  $c_s(G) \leq \text{vcn}$  (for any value of  $s$ ); (6) for a strongly connected orientation  $\vec{G}$  of  $G$ ,  $c(\vec{G}) \leq \text{vcn}$ .

We also extend our exponential kernel to these variants:

► **Theorem 8**. COPS AND ATTACKING ROBBER and LAZY CNR parameterized by  $\text{vcn}$  admit a kernel with at most  $\text{vcn} + \frac{2^{\text{vcn}}}{\sqrt{\text{vcn}}}$  vertices. Moreover, CNR on strongly connected directed graphs admits a kernel with at most  $3^{\text{vcn}} + \text{vcn}$  vertices.

Then, we present a slightly more general kernelization that works for most variants of the game:

► **Theorem 9**. FULLY ACTIVE CNR, COPS AND FAST ROBBER, and SURROUNDING CNR parameterized by  $\text{vcn}$  admit a kernel with at most  $\text{vcn} + \text{vcn} \cdot 2^{\text{vcn}}$  vertices.

We complement our exponential kernels for these variants by arguing about their compressibility:

► **Theorem 10 (\*)**. LAZY CNR, COPS AND ATTACKING ROBBER, COPS AND FAST ROBBER, FULLY ACTIVE CNR, and CNR on strongly connected directed and oriented graphs parameterized by  $\text{vcn}$  do not admit a polynomial compression, unless  $\text{NP} \subseteq \text{coNP}/\text{poly}$ .

## 2 Preliminaries

For  $\ell \in \mathbb{N}$ , let  $[\ell] = \{1, \dots, \ell\}$ . Whenever we mention  $\frac{a}{b}$ , we mean  $\lceil \frac{a}{b} \rceil$ .

**Graph Theory.** We only consider finite, connected<sup>2</sup>, and simple graphs. For a graph  $G$ , we denote  $|V(G)|$  by  $n$ . Let  $v \in V(G)$ . Then,  $N(v) = \{u \mid uv \in E(G)\}$  and  $N[v] = N(v) \cup \{v\}$ . For  $X \subseteq V(G)$ , let  $N_X(v) = N(v) \cap X$  and  $N_X[v] = N[v] \cap X$ . We say that  $v$  dominates  $u$  if  $u \in N[v]$ . The *girth* of  $G$  is the length of a shortest cycle contained in  $G$ . A  $u, v$ -path is a path with endpoints  $u$  and  $v$ . A path is *isometric* if it is a shortest path between its endpoints. For a directed graph  $\vec{G}$ , let  $N^+(u)$  and  $N^-(u)$  denote the set of out-neighbors and in-neighbors of  $u$ , respectively.

Let  $G$  be a graph and  $U \subseteq V(G)$ . Then,  $G[U]$  denotes the subgraph of  $G$  induced by  $U$ . A set  $U \subseteq V(G)$  is a *vertex cover* if  $G[V(G) \setminus U]$  is an independent set. The minimum cardinality of a vertex cover of  $G$  is its *vertex cover number* ( $\text{vcn}$ ). Moreover,  $U$  is a *cluster vertex deletion set* if  $G[V(G) \setminus U]$  is a disjoint union of cliques. The minimum size of a cluster vertex deletion set of a graph is its *cluster vertex deletion number* ( $\text{cvd}$ ). Additionally,  $U$  is a *deletion to stars set* if  $G[V(G) \setminus U]$  is a disjoint union of star graphs. The minimum size of a deletion to stars set of a graph is its *deletion to stars number* ( $\text{dts}$ ). Two vertices  $u, v \in V(G)$  have the *same type* if and only if  $N(v) \setminus \{u\} = N(u) \setminus \{v\}$ . A graph  $G$  has *neighborhood diversity* at most  $w$  if there exists a partition of  $V(G)$  into at most  $w$  sets, such that all the vertices in each set have the same type.

<sup>2</sup> The cop number of a disconnected graph is the sum of the cop numbers of its components; hence, we assume connectedness.

**CnR.** CnR is a two-player perfect information pursuit-evasion game played on a graph. One player is referred as *cop player* and controls a set of *cops*, and the other player is referred as *robber player* and controls a single *robber*. The game starts with the cop player placing each cop on some vertex of the graph, and multiple cops may simultaneously occupy the same vertex. Then, the robber player places the robber on a vertex. Afterwards, the cop player and the robber player make alternate moves, starting with the cop player. In the cop player move, the cop player, for each cop, either moves it to an adjacent vertex (along an edge) or keeps it on the same vertex. In the robber player move, the robber player does the same for the robber. For simplicity, we will say that the cops (resp., robber) move in a cop (resp., robber) move instead of saying that the cop (resp., robber) player moves the cops (resp., robber). Throughout, we denote the robber by  $\mathcal{R}$ .

A situation where one of the cops, say,  $\mathcal{C}$ , occupies the same vertex as  $\mathcal{R}$  is a *capture*. The cops win if they have a strategy to capture  $\mathcal{R}$ , and  $\mathcal{R}$  wins if it has a strategy to evade a capture indefinitely. A graph  $G$  is *k-copwin* if  $k$  cops have a winning strategy in  $G$ . The *cop number* of  $G$ , denoted  $c(G)$ , is the minimum  $k$  such that  $G$  is  $k$ -copwin. For brevity,  $G$  is said to be *copwin* if it is 1-copwin (i.e.  $c(G) = 1$ ). Given a graph  $G$  and  $k \in \mathbb{N}$ , CnR asks whether  $G$  is  $k$ -copwin.

If a cop  $\mathcal{C}$  occupies a vertex  $v$ , then  $\mathcal{C}$  *attacks*  $N[v]$ . A vertex  $u$  is *safe* if it is not being attacked by any cop. If  $\mathcal{R}$  is on a vertex that is not safe, then  $\mathcal{R}$  is *under attack*. We say that some cops *guard* a subgraph  $H$  of  $G$  if  $\mathcal{R}$  cannot enter  $H$  without getting captured by one of these cops in the next cop move. We shall use the following result:

► **Proposition 11** ([2]). *One cop can guard an isometric path  $P$  after a finite number of cop moves.*

Currently, the best known algorithm to decide whether  $G$  is  $k$ -copwin is by Petr et al. [50]:

► **Proposition 12** ([50]). *CnR is solvable in  $\mathcal{O}(kn^{k+2})$  time.*

**Variations of CnR.** Several variations of CnR have been studied in the literature, differing mainly in the rules of movements of agents, the definition of the capture, and the capabilities of the agents. We provide below the definitions of the games considered in this paper here. A detailed overview of these games is provided in the full version [29].

**Lazy CnR.** In LAZY CnR [47], the cops are *lazy*, i.e., at most one cop can move during the cops' turn. The cop number in this game is denoted by  $c_{\text{lazy}}(G)$ .

**Cops and Attacking Robber.** In COPS AND ATTACKING ROBBER [8], if on a robber's turn, there is a cop in its neighborhood, then  $\mathcal{R}$  can attack the cop and *eliminate* it from the game. However, if more than one cop occupy a vertex and  $\mathcal{R}$  attacks them, then only one of the cops gets eliminated, and  $\mathcal{R}$  gets captured by one of the remaining cops. Here, the cop number is denoted by  $c_{\text{attack}}(G)$ .

**Fully Active CnR.** In FULLY ACTIVE CnR [34], in a cop/robber move, each cop/robber must move to an adjacent vertex. Here, the cop number is denoted by  $c_{\text{active}}(G)$ .

**Surrounding CnR.** SURROUNDING CnR [15] differs in the definition of capture. Here, a cop and  $\mathcal{R}$  can occupy the same vertex during the game, but  $\mathcal{R}$  cannot end its turn by remaining at a vertex occupied by some cop. The cops win by *surrounding*  $\mathcal{R}$ , i.e., if  $\mathcal{R}$  occupies a vertex  $v$ , then there is a cop at each vertex  $u \in N(v)$ . The *surrounding cop number* for  $G$  is denoted as  $c_{\text{surround}}(G)$ .

**Cops and Fast Robber.** In COPS AND FAST ROBBER [27],  $\mathcal{R}$  can move faster than the cops. If  $\mathcal{R}$  has speed  $s$ , then it can move along a path with at most  $s$  edges not containing any cop. The minimum number of cops that ensures capture of a fast robber with speed  $s$  in a graph  $G$  is denoted by  $c_s(G)$ . For  $s \geq 2$ , deciding whether  $c_s(G) \leq k$  is W[2]-hard parameterized by  $k$  even when input graph  $G$  is restricted to be a split graph [27].

**CnR on Directed Graphs.** In the game of CNR on directed graphs [42, 13, 21], the players can only move along the orientation of the arcs.

**An XP Algorithm for Variants.** For graph searching, there is a standard technique to get an  $n^{\mathcal{O}(k)}$  time XP algorithm. This technique involves generating a *game graph* where each vertex represents a possible placement of all the agents (game states) on the vertices of  $G$ . Petr et al. [50] implemented this algorithm for CNR in  $\mathcal{O}(kn^{k+2})$  time. It is not difficult to see that this algorithm can be made to work for all the variants we discussed (by changing the rules to navigate between game states). We discuss these extensions in the full version [29].

► **Proposition 13.** *Any variant of CNR considered in this paper is solvable in  $\mathcal{O}(kn^{k+2})$  time.*

**Parameterized Complexity.** In the framework of parameterized complexity, each problem instance is associated with a non-negative integer, called a *parameter*. A parameterized problem  $\Pi$  is *fixed-parameter tractable* (FPT) if there is an algorithm that, given an instance  $(I, k)$  of  $\Pi$ , solves it in time  $f(k) \cdot |I|^{\mathcal{O}(1)}$  for some computable function  $f(\cdot)$ . Two instances  $I$  and  $I'$  are *equivalent* when  $I$  is a Yes-instance if and only if  $I'$  is a Yes-instance. A *compression* of a parameterized problem  $\Pi_1$  into a (possibly non-parameterized) problem  $\Pi_2$  is a polynomial-time algorithm that maps each instance  $(I, k)$  of  $\Pi_1$  to an equivalent instance  $I'$  of  $\Pi_2$  such that size of  $I'$  is bounded by  $g(k)$  for some computable function  $g(\cdot)$ . If  $g(\cdot)$  is polynomial, then the problem is said to admit a *polynomial compression*. A *kernelization algorithm* is a compression where  $\Pi_1 = \Pi_2$ . Here, the output instance is called a *kernel*. Let  $\Pi_1$  and  $\Pi_2$  be two parameterized problems. A *polynomial parameter transformation* from  $\Pi_1$  to  $\Pi_2$  is a polynomial-time algorithm that, given an instance  $(I, k)$  of  $\Pi_1$ , generates an equivalent instance  $(I', k')$  of  $\Pi_2$  such that  $k' \leq p(k)$ , for some polynomial  $p(\cdot)$ . It is well-known that if  $\Pi_1$  does not admit a polynomial compression, then  $\Pi_2$  does not admit a polynomial compression [17]. We refer to the books [17, 28] for details on parameterized complexity.

### 3 Bounding the Cop Number

We will use the following lemma to derive upper bounds on  $c(G)$  for several graph parameters.

► **Lemma 14** (\*). *Let  $G$  be a graph and let  $U \subseteq V(G)$  be a set of vertices such that for each connected component  $H$  of  $G[V(G) \setminus U]$ ,  $c(H) \leq \ell$ . Then,  $c(G) \leq \frac{|U|}{2} + \ell$ .*

Since star graphs and complete graphs are copwin, Lemma 14 implies the following theorem.

► **Theorem 15.** *Let  $G$  be a graph and  $t = \min\{\text{cvd}, \text{dts}\}$ . Then,  $c(G) \leq \frac{t}{2} + 1$ .*

**Bounding Cop Number by vcn.** Let  $U$  be a vertex cover of size  $t$  in  $G$  and  $I$  be the independent set  $V(G) \setminus U$ . Lemma 14 implies that  $c(G) \leq \lceil \frac{t}{2} \rceil + 1$ . In this section, we improve this bound. First, we provide the following reduction rules.

► **Reduction Rule 1 (RR1).** *If there is a vertex  $v \in I$  such that  $|N(v)| \geq 3$ , then place a cop at  $v$  and delete  $N[v]$ .*

► **Reduction Rule 2 (RR2).** *If there is a vertex  $v \in U$  such that  $|N[v] \cap U| \geq 3$ , then place a cop at  $v$  and delete  $N[v]$ .*

► **Reduction Rule 3 (RR3).** *If there is an isometric path  $P$  such that  $P$  contains at least three vertices from  $U$ , then guard  $P$  using one cop and delete  $V(P)$  (see Proposition 11).*

We note the following.

► **Note 16.** In the application of RR1-RR3, whenever a set of vertices  $X \subseteq V(G)$  is deleted by the application of RR1-RR3, it implies that each vertex  $x \in X$  is being guarded by some cop, and hence, is not accessible to  $\mathcal{R}$ . We do not actually delete the vertices, and this deletion part is just for the sake of analysis. Hence, from the cop player's perspective, the graph remains connected.

Next, we argue that, after an exhaustive application of RR1-RR3 on  $G$ , each connected component has a special structure and is 2-copwin.

► **Lemma 17 (\*).** *Once we cannot apply RR1-RR3 anymore, let  $\mathcal{R}$  be in a connected component  $H$  of  $G$ . Then,  $c(H) \leq 2$ .*

Finally, we have the following theorem.

► **Theorem 1.** *For a graph  $G$ ,  $c(G) \leq \frac{vcn}{3} + 1$ .*

**Proof Sketch.** The proof follows from Lemma 17 and the fact that in each application of RR1-RR3, we use one cop to remove (or guard) at least three new vertices from  $U$ . ◀

We note that a similar technique will fail if we try to “remove” four vertices in each reduction rule [29].

## 4 Exponential Kernels

**Exponential Kernel by vcn.** Let  $G$  be a graph where a vertex cover  $U$  of size  $t$  is given. If no such vertex cover is given, then we can compute a vertex cover  $U$  of size  $t \leq 2 \cdot vcn$  using a polynomial-time approximation algorithm [55]. Let  $I$  be the independent set  $V(G) \setminus U$ . Our kernelization algorithm is based on the exhaustive application of the following reduction rules.

► **Reduction Rule 4 (RR4).** *If  $k > \frac{t}{3}$ , then answer positively.*

► **Reduction Rule 5 (RR5).** *If  $k = 1$ , then apply an  $\mathcal{O}(n^3)$  time algorithm (Proposition 12) to check whether  $G$  is copwin.*

► **Reduction Rule 6 (RR6).** *If there are two distinct vertices  $u, v \in I$  such that  $N(u) \subseteq N(v)$ , then delete  $u$ .*

The safeness of RR4 follows from Theorem 1. The following lemma proves the safeness of RR6. We note that Lemma 18 can also be derived from [6, Corollary 3.3], but we give a self-contained proof for the sake of completeness.

► **Lemma 18.** *Let  $u$  and  $v$  be two distinct vertices of  $G$  such that  $N(u) \subseteq N(v)$ . Consider the subgraph  $H$  of  $G$  induced by  $V(G) \setminus \{u\}$ . Let  $k \geq 2$ . Then,  $G$  is  $k$ -copwin if and only if  $H$  is  $k$ -copwin.*

■ **Figure 1** Illustration for Lemma 18. Here,  $\mathcal{R}$  is at vertex  $u$  and  $\mathcal{C}_1$  is at vertex  $v$ .

**Proof.** First, let  $G$  be  $k$ -copwin. Then, for the graph  $H$ , the  $k$  cops borrow the winning strategy that they have for  $G$ , with the only difference that whenever a cop has to move to the vertex  $u$  in  $G$ , it moves to  $v$  (in  $H$ ) instead. Since  $N(u) \subseteq N(v)$ , the cop can make the next move as it does in the winning cop strategy for  $G$ . Note that using this strategy, the cops can capture  $\mathcal{R}$  if  $\mathcal{R}$  is restricted to  $V(H)$  in  $G$ . Therefore, using this strategy,  $k$  cops will capture  $\mathcal{R}$  in  $H$  as well.

Second, we show that if  $H$  is  $k$ -copwin, then  $G$  is  $k$ -copwin. Here, for each vertex  $x \neq u$  of  $G$ , we define  $I(x) = x$ , and for  $u$ , we define  $I(u) = v$ . Observe that for each  $x \in V(G)$ ,  $I(x)$  is restricted to  $H$  and if  $xy \in E(G)$ , then  $I(x)I(y) \in E(H)$ . Therefore, every valid move of a player from a vertex  $x$  to  $y$  in  $G$  can be translated to a valid move from  $I(x)$  to  $I(y)$  in  $H$ . Now, the cops have the following strategy. If the robber is on a vertex  $x$ , the cops consider the *image* of the robber on the vertex  $I(x)$ . Since the robber's image is restricted to  $H$ , the cops can use the winning strategy for  $H$  to capture the image of the robber in  $G$ . Once the image is captured, if the robber is not on the vertex  $u$ , then the robber is also captured. Otherwise, the robber is on the vertex  $u$ , and at least one cop is on  $v$ . See Figure 1 for an illustration. So, one cop, say  $\mathcal{C}_1$ , stays on  $v$  and this prevents the robber from ever leaving  $u$ . Indeed this follows because  $N(u) \subseteq N(v)$ , and so, if  $\mathcal{R}$  ever leaves  $u$ , it will be captured by  $\mathcal{C}_1$  in the next cop move. Finally, since  $k > 1$ , some other cop, say  $\mathcal{C}_2$ , can use a finite number of moves to reach  $u$  and capture the robber. ◀

Note that the requirement for  $k \geq 2$  in Lemma 18 is crucial. Otherwise, we can get an  $H$  such that  $c(H) = 1$ , but  $c(G) > 1$ . For example, consider  $C_4$ , where any two non-adjacent vertices satisfy the property in RR6, and if we remove one of them, the cop number reduces from 2 to 1. However, this does not harm our algorithm because if we are given  $k = 1$ , then RR5 is applied (before RR6).

Two sets  $A$  and  $B$  are *incomparable* if neither  $A \subseteq B$  nor  $B \subseteq A$ . We shall use the following proposition that follows from Sperner's Theorem and Stirling's approximation.

► **Proposition 19.** *Let  $X$  be a set of cardinality  $N$ . Moreover, let  $Y$  be a set of subsets of  $X$  such that for each  $a, b \in Y$ ,  $a$  and  $b$  are incomparable. Then,  $|Y| \leq \frac{2^N}{\sqrt{N}}$ .*

Once we cannot apply RR4-RR6 anymore, we claim that the size of the reduced graph  $G'$  is bounded by a function of  $t$ . Let  $U' = U \cap V(G')$  and  $I' = I \cap V(G')$ . Clearly,  $|U'| \leq t$ . Now, each vertex  $u \in I'$  is associated with a neighborhood  $N(u)$  such that  $N(u) \subseteq U'$ . Moreover, for any two vertices  $u, v \in I'$ , the sets  $N(u)$  and  $N(v)$  are incomparable. Hence, due to Proposition 19,  $|I'| \leq \frac{2^t}{\sqrt{t}}$ , and therefore,  $|V(G')| \leq t + \frac{2^t}{\sqrt{t}}$ , which proves the following theorem.

► **Theorem 2.** *CNR parameterized by  $\text{vcn}$  admits a kernel with at most  $\text{vcn} + \frac{2^{\text{vcn}}}{\sqrt{\text{vcn}}}$  vertices.*

The details for exponential kernels for other parameters and variants can be found in [29]. Here, we present only our reduction rules and the essential claims that lead to our results.

**Kernel by  $\text{cvd}$ .** Let  $U$  be a cluster vertex deletion set of size  $t$ . Let  $S = V(G) \setminus U$ , and  $C_1, \dots, C_\ell$  be the set of disjoint cliques in  $G[S]$ . We have the following reduction rules along with RR 5.

► **Reduction Rule 7 (RR7).** *If  $k > \frac{t}{2}$ , then answer positively.*

► **Reduction Rule 8 (RR8).** *Let  $u$  and  $v$  be vertices of some clique  $C \in G[S]$  such that  $N[u] \subseteq N[v]$ . Then, delete  $u$ .*

► **Reduction Rule 9 (RR9).** *Let  $C_i$  and  $C_j$  be two cliques in  $G[S]$  such that for each vertex  $u \in V(C_i)$ , there exists a vertex  $v \in V(C_j)$  such that  $N_U(u) \subseteq N_U(v)$ . Then, delete  $V(C_i)$ .*

RR7 is safe due to Theorem 15. The safeness of RR8 is proved by the following Lemma, whose proof is similar to the proof of Lemma 18.

► **Lemma 20 (\*).** *Let  $u$  and  $v$  be vertices of some clique  $C$  of  $G[S]$ . If  $N_U(u) \subseteq N_U(v)$ , then  $c(G) = c(G[V(G) \setminus \{u\}])$ .*

The safeness of RR9 is proved by the following Lemma.

► **Lemma 21 (\*).** *Let  $C_i$  and  $C_j$  be two cliques in  $G[S]$  such that for each vertex  $u \in V(C_i)$ , there exists a vertex  $v \in V(C_j)$  such that  $N_U(u) \subseteq N_U(v)$ . Then, for  $k > 1$ ,  $G$  is  $k$ -copwin if and only if  $G[V(G) \setminus V(C_i)]$  is  $k$ -copwin.*

Finally, we use the following lemma to bound the size of the desired kernel from Theorem 6.

► **Lemma 22 (\*).** *After an exhaustive application of RR7-RR9, the size of the reduced graph is at most  $2^{2^t + \sqrt{t}}$ .*

**Kernel by  $\text{dts}$ .** Using similar ideas, we can also get a kernel for CNR parameterized by  $\text{dts}$ . Let  $U$  be a deletion to stars vertex set of size  $t$ . Also, let  $S = V(G) \setminus U$ , and let  $X_1, \dots, X_\ell$  be the stars in the graph  $G[S]$ . Specifically, we have the following reduction rules along with RR7.

► **Reduction Rule 10 (RR10).** *Let  $u$  and  $v$  be two leaves of a star  $X$  in  $G[S]$  such that  $N_U(u) \subseteq N_U(v)$ . Then, delete  $u$ .*

► **Reduction Rule 11 (RR11).** *Let  $X$  and  $Y$  be two stars in  $G[S]$  such that  $V(X) = x, x_1, \dots, x_p$  and  $V(Y) = y, y_1, \dots, y_q$ , where  $x$  and  $y$  are center vertices of  $X$  and  $Y$ , respectively. If  $N_U(x) \subseteq N_U(y)$  and for each vertex  $x_i$  (for  $i \in [p]$ ), there is a vertex  $y_j$  (for  $j \in [q]$ ) such that  $N_U(x_i) \subseteq N_U(y_j)$ , then delete  $X$ .*

The following lemma establishes that RR10 and RR11 are safe. (RR7 is safe due to Theorem 15.)

► **Lemma 23 (\*).** *Assuming  $k > 1$ , RR10 and RR11 are safe.*

Using calculations similar to ones used in our previous kernels and Proposition 19, we can establish that (see [29]), once we cannot apply RR10 and RR11 anymore, the size of the reduced graph can be at most  $\frac{2^{2^t}}{\sqrt{2^t}} \cdot 2^t \cdot (\frac{2^t}{\sqrt{t}} + 1)$ , giving us the desired kernel from Theorem 6.

### Kernels for Different Variants

**Lazy CnR and Cops and Attacking Robber.** For these variants, we have the following reduction rules along with RR6, which we apply before applying RR6.

- ▶ **Reduction Rule 12** (RR12). *If  $k \geq \frac{t}{2} + 1$ , then answer positively (Theorem 7).*
- ▶ **Reduction Rule 13** (RR13). *If  $k = 1$ , then apply the  $\mathcal{O}(n^3)$  time algorithm from Proposition 13.*

The next lemma proves safeness of RR6 for both variants.

- ▶ **Lemma 24** (\*). *Let  $u$  and  $v$  be two distinct vertices of  $G$  such that  $N(u) \subseteq N(v)$ . Consider the graph  $H$  induced by  $V(G) \setminus \{u\}$ . Then for  $k > 1$  and for  $x \in \{\text{lazy, attack}\}$ ,  $c_x(G) \leq k$  if and only if  $c_x(H) \leq k$ .*

The size of the kernel, by using these reduction rules, is dependent on RR6. Therefore, we get the desired kernels for these variants as claimed in Theorem 8.

**CnR on Directed Graphs.** Next, we consider the game of CnR on directed graphs. We have the following lemma.

- ▶ **Lemma 25** (\*). *Let  $u$  and  $v$  be two distinct vertices of a strongly connected directed graph  $\vec{G}$  such that  $N^+(u) \subseteq N^+(v)$  and  $N^-(u) \subseteq N^-(v)$ . Let  $\vec{H}$  be the graph induced by  $V(\vec{G}) \setminus \{u\}$ . Then, for  $k > 1$ ,  $\vec{H}$  is  $k$ -copwin if and only if  $\vec{G}$  is  $k$ -copwin.*

Let  $G$  be a graph with a vertex cover  $U$  of size  $t$ , and let  $I = V(G) \setminus U$ . Let  $\vec{G}$  be a strongly connected orientation of  $G$ . We apply the following reduction rules.

- ▶ **Reduction Rule 14** (RR14). *If  $k \geq t$ , then answer positively.*
- ▶ **Reduction Rule 15** (RR15). *If  $k = 1$ , then apply the  $\mathcal{O}(n^3)$  time algorithm (Proposition 13) to check if  $\vec{G}$  is copwin.*
- ▶ **Reduction Rule 16** (RR16). *If  $u$  and  $v$  are two distinct vertices in  $I$  such that  $N^+(u) \subseteq N^+(v)$  and  $N^-(u) \subseteq N^-(v)$ , then delete  $u$ .*

Safeness of RR14 and RR16 follow from Theorem 7 and Lemma 25, respectively. Once we cannot apply RR16, observe that each vertex  $u \in I$  has a unique neighborhood ( $N^+(u) \cup N^-(u)$ ), and there are three choices for a vertex  $v \in U$  to appear in the neighborhood of  $u$ , i.e., either  $v \in N^+(u)$ , or  $v \in N^-(u)$ , or  $v \notin N^+(u) \cup N^-(u)$ . Thus,  $|I| \leq 3^t$ , giving the desired kernel as claimed in Theorem 8.

**General Kernelization.** Here, we provide a general reduction rule that works for most variants of CnR parameterized by vcn. Let  $U$  be a vertex cover of size  $t$  in  $G$  and  $I$  be the independent set  $V(G) \setminus U$ . For each subset  $S \subseteq U$ , we define the following equivalence class:  $\mathcal{C}_S = \{v \in I : N(v) = S\}$ . We have the following reduction rule along with RR14.

- ▶ **Reduction Rule 17** (RR17). *If there is an equivalence class  $\mathcal{C}_S$  such that  $|\mathcal{C}_S| > k + 1$ , then keep only  $k + 1$  arbitrary vertices from  $\mathcal{C}_S$  in  $G$ , and delete the rest.*

The following lemma proves the safeness of RR17.

► **Lemma 26** (\*). *Let  $G$  be a graph with a vertex cover  $U$  of size  $t$ . Let  $\mathcal{C}_S$  (for  $S \subseteq U$ ) be an equivalence class such that  $|\mathcal{C}_S| = \ell > k + 1$ . Moreover, let  $H$  be a subgraph formed by deleting  $\ell - k - 1$  arbitrary vertices of  $\mathcal{C}_S$  from  $G$ . Then,*

1.  $c_{\text{active}}(H) \leq k$  if and only if  $c_{\text{active}}(G) \leq k$ .
2.  $c_s(H) \leq k$  if and only if  $c_s(G) \leq k$ , for any  $s \geq 1$ .
3.  $c_{\text{surround}}(H) \leq k$  if and only if  $c_{\text{surround}}(G) \leq k$ .

**Proof Sketch.** Here, we present a sketch of the proof for (3). Let  $\mathcal{C}_S = \{v_1, \dots, v_\ell\}$ . WLOG, let the vertices  $v_1, \dots, v_{k+1}$  belong to the graph  $H$  and vertices  $v_{k+2}, \dots, v_\ell$  are deleted. Note that  $\mathcal{R}$  cannot be surrounded at a vertex in  $S$  in  $G$  since each vertex in  $S$  has at least  $k + 1$  neighbours.

The proof of  $c_{\text{surround}}(H) \leq c_{\text{surround}}(G)$  is similar to the proof of Lemma 18.

For the other direction, let  $c_{\text{surround}}(H) \leq k$ . Since we have only  $k$  cops, at any time, there is at least one vertex in  $\{v_1, \dots, v_{k+1}\}$  that is not occupied by any cop. Let us call this vertex a *free vertex* (there might be multiple free vertices). For each vertex  $x \in V(G)$ , if  $x \in V(H)$ , then we define  $I(x) = x$ ; else, if  $x \in \{v_{k+1}, \dots, v_\ell\}$ , then we define  $I(x) = y$ , where  $y$  is a free vertex at that instance. Whenever  $\mathcal{R}$  moves to a vertex  $x \in V(G)$ , we say that the *image of the robber*, denoted  $\mathcal{I}_{\mathcal{R}}$ , moves to  $I(x)$ . Recall that, in this variant, although some cop and  $\mathcal{R}$  can be at the same vertex,  $\mathcal{R}$  cannot end its move at the same vertex as one of the cops. Cops use this capability to force  $\mathcal{R}$  to move from a vertex. Therefore, we also have to argue that whenever cops force  $\mathcal{R}$  to move, they force  $\mathcal{I}_{\mathcal{R}}$  to move as well. To this end, observe that  $\mathcal{I}_{\mathcal{R}}$  and  $\mathcal{R}$  are on different vertices only if  $\mathcal{R}$  is on some vertex  $x \in \{v_{k+1}, \dots, v_\ell\}$  and  $\mathcal{I}_{\mathcal{R}}$  is on a free vertex, say,  $y$ . Notice that if, in the strategy for  $H$ ,  $\mathcal{R}$  was occupying  $y$  and the cop player wants to force  $\mathcal{R}$  to move out of  $y$ , then it does so by moving a cop, say,  $\mathcal{C}$ , from a vertex  $w \in N(y)$  to  $y$ . Cop player adapts this strategy in  $G$  by moving  $\mathcal{C}$  from  $w$  to  $x$  instead of  $w$  to  $y$  (it is possible because  $N(x) = N(y)$ ). Thus,  $\mathcal{R}$ , as well as  $\mathcal{I}_{\mathcal{R}}$ , are forced to move as they would have been forced to move in the winning strategy of  $k$  cops in  $H$ .

Hence,  $\mathcal{I}_{\mathcal{R}}$  is restricted to  $V(H)$  in  $G$ . Thus, cops will surround  $\mathcal{I}_{\mathcal{R}}$  in a finite number of rounds. The only thing to observe now is that if  $\mathcal{I}_{\mathcal{R}}$  is surrounded in  $V(H)$ , then  $\mathcal{R}$  is surrounded in  $G$ . ◀

Lemma 26 and the following lemma imply Theorem 9.

► **Lemma 27** (\*). *Let  $G$  be a graph with a vertex cover  $U$  of size  $t$ . After an exhaustive application of RR14 and RR17, the reduced graph has at most  $t + t \cdot 2^t$  vertices.*

## 5 Incompressibility

In this section, we show that it is unlikely for CNR parameterized by  $\text{vcn}$  to admit a polynomial compression. For this purpose, we first define the following problem. In RED-BLUE DOMINATING SET, we are given a bipartite graph  $G$  with a vertex bipartition  $V(G) = T \cup N$  and a non-negative integer  $k$ . A set of vertices  $N' \subseteq N$  is said to be an *RBDS* if each vertex in  $T$  has a neighbor in  $N'$ . The aim of RED-BLUE DOMINATING SET is to decide whether there exists an *RBDS* of size at most  $k$  in  $G$ . We shall use the following result.

► **Proposition 28** ([23]). *RED-BLUE DOMINATING SET parameterized by  $|T| + k$  does not admit a polynomial compression, unless  $NP \subseteq \text{coNP}/\text{poly}$ .*

We show that CNR parameterized by  $\text{vcn}$  does not have a polynomial compression by developing a polynomial parameter transformation from RED-BLUE DOMINATING SET parameterized by  $|T| + k$  to CNR parameterized by  $\text{vcn}$ .

**Bipartite Graphs with Large Degree and Girth.** For our reduction, we borrow a construction by Fomin et al. [27] of bipartite graphs having high girth and high minimum degree, which they used to prove NP-hardness (and  $W[2]$ -hardness for the solution size  $k$ ) of CNR. For positive integers  $p, q$ , and  $r$ , we can construct a bipartite graph  $H(p, q, r)$  with  $rqp^2$  edges and a bipartition  $(X, Y)$ , with  $|X| = |Y| = pq$ . The set  $X$  is partitioned into sets  $U_1, \dots, U_p$ , and the set  $Y$  is partitioned into sets  $W_1, \dots, W_p$ , with  $|U_i| = |W_i| = q$ . By  $H_{i,j}$  we denote the subgraph of  $H(p, q, r)$  induced by  $U_i \cup W_j$ , and by  $\deg_{i,j}(z)$  we denote the degree of vertex  $z$  in  $H_{i,j}$ . Fomin et al. [27] provided the following construction:

► **Proposition 29** ([27]). *Let  $q \geq 2p(r+1) \frac{(p(r+1)-1)^6-1}{(p(r+1)-1)^2-1}$ . Then, we can construct  $H(p, q, r)$  in time  $\mathcal{O}(r \cdot q \cdot p^2)$  with the following properties.*

1. *The girth of  $H(p, q, r)$  is at least 6.*
2. *For every vertex  $z \in V(H_{i,j})$  and every  $i, j \in [p]$ , we have  $r-1 \leq \deg_{i,j}(z) \leq r+1$ .*

**Polynomial Parameter Transformation.** Let  $(G, k)$  be an instance of RED-BLUE DOMINATING SET with  $V(G) = T \cup N$ . First, we construct a graph  $G'$  with  $V(G') = T' \cup N'$  from  $G$  by introducing two new vertices,  $x$  and  $y$ , such that  $T' = T \cup \{x\}$  and  $N' = N \cup \{y\}$ , and  $E(G') = E(G) \cup \{xy\}$ . We have the following observation.

► **Observation 30.**  *$G$  has an RBDS of size at most  $k$  if and only if  $G'$  has an RBDS of size at most  $k+1$ . Moreover, any RBDS of  $G'$  contains  $y$ .*

Now, we present the main construction for our reduction. Denote the vertex set  $V(T')$  by  $\{v_1, v_2, \dots, v_{p'}, x\}$ . Moreover, let  $p = p' + 1$ ,  $\ell = k + 1$ ,  $r = \ell + 2$ , and  $q = \lceil 2p(r+1) \frac{(p(r+1)-1)^6-1}{(p(r+1)-1)^2-1} \rceil$ .

We construct  $H(p, q, r)$  such that each of  $U_i$  and  $W_i$ , for  $0 < i \leq p'$ , contains  $q$  copies of vertex  $v_i$ , and each of  $U_p$  and  $W_p$  contains  $q$  copies of vertex  $x$ . Now, we obtain a graph  $G''$  by adding one more set of vertices  $P$  to  $H(p, q, r)$  such that  $V(P) = V(N')$ . Moreover, if there is an edge between a vertex  $u \in N'$  and a vertex  $v_i \in T'$ , then we add an edge between  $u$  and every vertex of  $U_i$ , and also between  $u$  and every vertex of  $W_i$ . Similarly, we add an edge between  $y$  and every vertex of  $U_p$ , and between  $y$  and every vertex of  $W_p$ . Finally, we make the vertex  $y$  adjacent to every vertex of  $P$ . See Figure 2 for reference. For correctness, we have the following lemma.

► **Lemma 31.**  *$G'$  has an RBDS of size at most  $\ell$  if and only if  $G''$  is  $\ell$ -copwin.*

**Proof.** First, we show that if  $G'$  has an RBDS of size  $\ell$ , then  $\ell$  cops have a winning strategy in  $G''$ . Let  $S \subseteq N'$  be an RBDS in  $G'$  of size at most  $\ell$ . The cops begin by choosing the vertices corresponding to  $S$  in  $P$ . Observe that the vertex  $y$  has to be present in  $S$ . Since vertex  $y$  dominates each vertex in  $P$ , the robber cannot safely enter a vertex in  $P$ . Additionally, due to the construction of  $G''$ , the vertices of  $S$  dominate each vertex in  $H$ . Hence, the robber cannot safely enter a vertex in  $H$ . Therefore, the robber will be captured in the first move of the cops.

Next, we show that if there is no RBDS of size  $\ell$  in  $G'$ , then  $\ell$  cops do not have a winning strategy. We prove this by giving a winning strategy for the robber. First, we show that the robber can safely enter the graph. In the beginning, let there be  $\ell_1 \leq \ell$  cops in  $P$  and  $\ell_2 \leq \ell$  cops in  $H$ . Since there is no RBDS of size  $\ell$  in  $G'$ , for every placement of at most  $\ell$  cops in  $P$ , there exists at least one pair of  $U_i$  and  $W_i$  such that no vertex of  $U_i$  and  $W_i$  is dominated by the cops from  $P$ . Let  $U_i$  and  $W_i$  be one such pair of sets such that no vertex of  $U_i$  and  $W_i$  is dominated by the cops from  $P$ . Moreover, since each vertex of  $H$  can dominate at

■ **Figure 2** Illustration for  $H(p, q, r)$  and  $P$ . If a vertex  $u$  is connected to  $v_j$  in  $G$ , then  $u$  is connected to every vertex of  $W_j \cup U_j$ . Moreover, for every  $i, j$ , each vertex in  $U_i$  has at least  $r - 1$  neighbors in  $U_j$ .

most  $p(r + 1)$  vertices in  $H$ ,  $\ell_2$  cops can dominate at most  $\ell \cdot p(r + 1)$  vertices. Since  $U_i$  (and  $W_i$  also) contains  $q$  vertices, and  $q > \ell \cdot p(r + 1)$ , the  $\ell_2$  cops in  $H$  cannot dominate all vertices of  $U_i$ , and hence the robber can safely enter a vertex of  $U_i$ .

Now, whenever the robber is under attack, it does the following. Without loss of generality, let us assume that the robber is in  $U_i$  (the case of  $W_i$  is symmetric). Since there are at most  $\ell$  cops in  $P$ , there is always a  $W_j$  such that no vertex of  $W_j$  is dominated by cops from  $P$ . Since each vertex in  $U_i$  has at least  $r - 1 = \ell + 1$  neighbours in  $W_j$ , the robber can move to at least  $\ell + 1$  vertices of  $W_j$ . Since the girth of  $H$  is at least 6, no vertex from  $H$  can dominate two vertices of  $W_j$  that are adjacent to the robber; else, we get a cycle on four vertices. Hence, at most  $\ell$  cops from  $H$  can dominate at most  $\ell$  neighbors of the robber in  $W_j$ , and the robber has at least  $\ell + 1$  neighbors in  $W_j$ . Hence, the robber can move to a safe vertex in  $W_j$ . Since the graph  $H$  is symmetric, the robber can move safely from  $W_j$  to  $W_{j'}$  also. The robber follows this strategy to avoid capture forever. ◀

Next, we have the following observation to show that there exists a vertex cover  $U$  of  $G''$  such that  $|U| = \text{poly}(|T|, k)$ .

► **Observation 32.**  $V(H) \cup \{y\}$  is a vertex cover of  $G''$ . Therefore, the vertex cover number of  $G''$  is at most  $2 \cdot p \cdot q + 1 = 1 + 2p \cdot \lceil 2p(k + 3) \frac{(p(k+3)-1)^6 - 1}{(p(k+3)-1)^2 - 1} \rceil$ , where  $p = |T| + 1$ .

This completes the proof of the argument that CNR parameterized by vcn is unlikely to admit a polynomial compression. Thus, we have the following theorem as a result of Lemma 31, Observation 32 and Proposition 28.

► **Theorem 4.** CNR parameterized by vcn does not admit polynomial compression, unless  $NP \subseteq \text{coNP}/\text{poly}$ .

## 6 Conclusion and Future Directions

To achieve our kernelization results, the rules we used concerned removing (false or true) twins from the graph. These rules are easy to implement and hence can be used to reduce the complexity of the input graph, even when the input graph is far from the considered

parameters. For example, for cographs and grids, none of the considered parameters is constant/bounded, but cographs and grids can be reduced to a single vertex with the operation of removing twins, and hence, our reduction rules give an alternate proof that the cop number of cographs and grids is at most two [38, 19] for several variants. Moreover, MTP is well-studied with the motivation of designing computer games. Some examples of these variants include: multiple targets and multiple pursuer search [56] with applications in controlling non-player characters in video games; MTP from the robber’s perspective with faster cops [44] where the strategies were tested on Baldur’s Gate; MTP modeled with edge weights and different speeds of agents [36] with the specific examples of Company of Heroes and Supreme Commander. Moreover, the PACMAN game’s movement can be considered as an instance of FULLY ACTIVE CNR on a partial grid. One of the key aspects of designing these games is to come up with scenarios that are solvable but look complex and challenging. Our reduction rule can there. One can begin with an easy-to-resolve instance of CNR, and then keep adding twins to this instance (recursively) to get an instance that looks sufficiently complex but has the same complexity.

Finally, we define (formally defined in the full version [29]) a new variant of CNR, named GENERALIZED CNR, that generalizes many well-studied variants of CNR. Here the input is  $(G, \mathcal{C}_1, \dots, \mathcal{C}_k, \mathcal{R})$  where each cop  $\mathcal{C}_i$  has *speed*  $s_i$  and  $\mathcal{R}$  has speed  $s_R$ . Moreover, each cop can be either forced to be *active* (have to move in each turn), *lazy* (at most one lazy cop moves in each turn), or *flexible*. Furthermore, each cop  $\mathcal{C}_i$  can have *reach*  $\lambda_i$ . (Think of  $\mathcal{C}_i$  having a gun with range  $\lambda_i$ , and if  $\mathcal{R}$  is ever at a vertex that is at a distance at most  $\lambda_i$  from  $\mathcal{C}_i$ , it gets shot.) In the full version [29], we show that RR17 provides a kernel for GENERALIZED CNR as well. This gives hope that RR17 can be used to get kernels for many practical variants not explicitly studied in this paper. Also, RR17 has been used to provide kernelization algorithm for HUNTER AND RABBIT game parameterized by  $\text{vcn}$  [22].

Still, many questions on the parameterized complexity of CNR remain open. We list some of these questions below.

► **Question 33.** *Does there exist an FPT algorithm for CNR parameterized by  $\text{vcn}$  with running time  $2^{\mathcal{O}(\text{vcn})} \cdot n^{\mathcal{O}(1)}$ ?*

► **Question 34.** *Does there exist a better bound for the cop number with respect to  $\text{vcn}$ ? In particular, is  $c(G) = o(\text{vcn})$ ?*

► **Question 35.** *Does CNR parameterized by  $\text{vcn}$  admit a polynomial  $\alpha$ -approximate kernel?*

► **Question 36.** *Study CNR with respect to the following parameters: (1) feedback vertex set (2) treewidth (3) treedepth. In particular, is CNR FPT parameterized by treewidth?*

## Abstract

The minimum branch vertices spanning tree problem consists in finding a spanning tree  $T$  of an input graph  $G$  having the minimum number of branch vertices, that is, vertices of degree at least three in  $T$ . This  $NP$ -hard problem has been widely studied in the literature and has many important applications in network design and optimization. Algorithmic and combinatorial aspects of the problem have been extensively studied and its fixed parameter tractability has been recently considered. In this paper we focus on modular-width and show that the problem of finding a spanning tree with the minimum number of branch vertices is FPT with respect to this parameter.

**2012 ACM Subject Classification** Theory of computation  $\rightarrow$  Parameterized complexity and exact algorithms; Mathematics of computing  $\rightarrow$  Graph theory

**Keywords and phrases** Spanning Trees, Branch vertices, Fixed-parameter tractable algorithms, Modular-width

## 1 Introduction

Let  $G = (V, E)$  be an undirected graph where  $V$  is the set of vertices and  $E$  is the set of edges. Given a spanning tree  $T$  of  $G$ , a *branch vertex* is a vertex having degree at least three in  $T$ . If  $G$  is a connected graph, we denote by  $b(G)$  the smallest number of branch vertices in any spanning tree of  $G$ . We study the following problem:

MINIMUM BRANCH VERTICES (MBV)

**Instance:** A connected graph  $G = (V, E)$ .

**Goal:** Find a spanning tree of  $G$  having  $b(G)$  branch vertices.

Notice that a spanning tree of  $G$  without branch vertices is a Hamilton path, that is,  $b(G) = 0$  if and only if  $G$  admits a Hamilton path.

The problem of determining a spanning tree with a bounded number of branch vertices, while a natural theoretical question, was introduced to solve a problem related to wavelength-division multiplexing technology in optical networks, where one wants to minimize the number of light-splitting switches in a light-tree [11]. Also for Cognitive Radio Networks other than for 5G technologies, that operate with a wide range of frequencies, bounding the switching costs due to the switching between different service providers has high importance both in terms of delay and energy consumption [16, 24]. MBV has been then widely studied, both from the algorithmic and the graph-theoretic point of view. Gargano *et al.* [12] proved that it is NP-complete to decide whether a graph  $G$  admits a spanning tree with at most  $k$  branch vertices, for given  $G$  and  $k$ , even in cubic graphs. Salamon [23] proved the existence of an algorithm that finds a spanning tree with  $O(\log |V(G)|)$  branch vertices whenever the

degree of each vertex of the input graph is  $\Omega(n)$ ; moreover, an approximation factor better than  $O(\log |V(G)|)$  would imply that  $NP \subseteq DTIME(n^{O(\log \log n)})$ . Sufficient conditions for a connected claw-free graph to have a spanning tree with  $k$  branch vertices are given in [20]. Integer linear formulations of MBV and some variants are presented in [5–7], together with different relaxations of them; the authors also provide numerical result comparison of the considered relaxations. In [26] hybrid integer linear programs for MB are considered and solved with branch-and-cut algorithms. In [18, 21, 22] decomposition methods of graphs are used to solve the MBV problem. Other heuristics are presented in [19, 25, 27]. In [8] a complementary formulation of MBV is investigated. It is called maximum path-node spanning tree (MPN), where the goal is to find a spanning tree that maximizes the number of vertices with degree at most two; the authors prove that MPN is APX-hard and present an approximation algorithm with ratio 6/11. Related gathering processes are considered in [2–4, 13, 14].

## 1.1 Parameterized Complexity

Parameterized complexity is a refinement to classical complexity theory in which one takes into account not only the input size, but also other aspects of the problem given by a parameter  $p$ . A problem with input size  $n$  and parameter  $p$  is called *fixed parameter tractable* (FPT) if it can be solved in time  $f(p) \cdot n^c$ , where  $f$  is a computable function only depending on  $p$  and  $c$  is a constant.

In this paper we are interested in assessing the complexity of MBV when parameterized by modular-width. It was recently proven that MBV is FPT when parameterized either by treewidth [1] or by neighborhood diversity [15]. On the other hand, it was shown in [9] that the problem is  $W[1]$ -hard when parameterized by clique-width. Specifically, in [9] it was proven that the (MBV special case) hamiltonian path problem is  $W[1]$ -hard when parameterized by clique-width. See Figure 1 for a relation among the above parameters.

■ **Figure 1** A summary of the relations holding among some popular parameters. We use  $mw(G)$ ,  $tw(G)$ ,  $cw(G)$ ,  $nd(G)$ , and  $vc(G)$  to denote modular-width, treewidth, cliquewidth, neighborhood diversity, and minimum vertex cover of a graph  $G$ , respectively. Solid arrows denote generalization, e.g., modular-width generalizes neighborhood diversity. Dashed arrows denote that the generalization may exponentially increase the parameter.

## 1.2 Modular-width

Modular-width was introduced in [10] as graph parameter which could cover dense graphs but still allows FPT algorithms for the problems lost to clique-width.

► **Definition 1** (Modular-width [10]). Consider graphs that can be obtained from an algebraic expression that uses the following operations:

- (O1) Create an isolated vertex;
- (O2) the disjoint union of 2 graphs denoted by  $G_1 \oplus G_2$ , i.e.,  $G_1 \oplus G_2$  is the graph with vertex set  $V(G_1) \cup V(G_2)$  and edge set  $E(G_1) \cup E(G_2)$ ;
- (O3) the complete join of 2 graphs denoted by  $G_1 \otimes G_2$ , i.e.,  $G_1 \otimes G_2$  is the graph with vertex set  $V(G_1) \cup V(G_2)$  and edge set  $E(G_1) \cup E(G_2) \cup \{\{v, w\} : v \in V(G_1) \text{ and } w \in V(G_2)\}$ ;
- (O4) the substitution operation with respect to some graph  $G$  with vertex set  $\{1, 2, \dots, n\}$  i.e., for graphs  $G_1, \dots, G_n$  the substitution of the vertices of  $G$  by the graphs  $G_1, \dots, G_n$ , denoted by  $G(G_1, \dots, G_n)$ , is the graph with vertex set  $\bigcup_{i=1}^n V(G_i)$  and edge set  $\bigcup_{i=1}^n E(G_i) \cup \{\{u, v\} \mid u \in V(G_i), v \in V(G_j), \{i, j\} \in E(G)\}$ . Hence,  $G(G_1, \dots, G_n)$  is obtained from  $G$  by substituting every vertex  $i \in V(G)$  with the graph  $G_i$  and adding all edges between the vertices of a graph  $G_i$  and the vertices of a graph  $G_j$  whenever  $\{i, j\} \in E(G)$ .

Let  $A$  be an algebraic expression that uses only the operations (O1)–(O4). The width of  $A$  is the maximum number of operands used by any occurrence of the operation (O4) in  $A$ . The modular-width of a graph  $H$ , denoted  $\text{mw}(H)$ , is the least integer  $m$  such that  $H$  can be obtained from such an algebraic expression of width at most  $m$ .

We recall that an algebraic expression of width  $\text{mw}(G)$  can be constructed in linear time [28].

Given a graph  $H = G(G_1, \dots, G_n)$ , we will refer to the graphs  $G_1, \dots, G_n$  also as the modules of  $H$ . Notice that given the graph  $H = G(G_1, \dots, G_n)$ , by the operations O(1)–(O4), one has that all the vertices of  $G_i$  share the same neighborhood outside  $G_i$ ; indeed,

$$\begin{aligned} \{\{u, v\} \mid u \in V(G_i), v \in V(G_j)\} \subseteq E(H) & \quad \text{if } \{i, j\} \in E(G) \\ \{\{u, v\} \mid u \in V(G_i), v \in V(G_j)\} \cap E(H) = \emptyset & \quad \text{if } \{i, j\} \notin E(G) \end{aligned} \quad (1)$$

for each  $i, j = 1, \dots, n$  with  $i \neq j$ .

### 1.3 Graph Partitioning

A *spider* is a tree with at most one branch vertex. The *center* of the spider is the branch vertex, if it exists, and is any vertex otherwise. A *path-spider cover* of a graph  $G$  is a set composed by one spider and some paths that are pair-wise (vertex-)disjoint and whose union contains every vertex of  $G$ . We denote by  $\text{spi}(G)$  the least integer  $p$  such that  $G$  has a path-spider cover with  $p - 1$  paths.

In order to solve MBV, we define and study the following problem that can be of its own interest:

PATH-SPIDER COVER (PSC)

**Instance:** A graph  $G = (V, E)$ .

**Goal:** Find a path-spider cover of  $G$  with  $\text{spi}(G) - 1$  paths.

Moreover, we will need the following Partitioning into Paths problem that was proven to be FPT with respect to modular-width in [10]. A *partition of a graph  $G$  into paths* is a set of (vertex-)disjoint paths of  $G$  whose union contains every vertex of  $G$ . We denote by  $\text{ham}(G)$  the least integer  $p$  such that  $G$  has a partition into  $p$  paths. Notice that  $\text{spi}(G) \leq \text{ham}(G)$ .

PARTITIONING INTO PATHS (PP)

**Instance:** A graph  $G = (V, E)$ .

**Goal:** Find a partition of  $G$  into  $\text{ham}(G)$  paths.

As originally defined in [10], the PARTITIONING INTO PATHS problem only asks for the value  $\text{ham}(G)$ , while we ask for the actual path partitioning of  $G$ .

In the following we will denote by  $\mathcal{P}_{ham(G)}$  a partition of  $G$  into  $ham(G)$  paths, and by  $\mathcal{P}_{spi(G)}$  a path-spider cover of  $G$  with  $spi(G) - 1$  paths.

Given a path  $P$  in  $G$ , we will denote by  $f(P)$  and  $s(P)$  the two end-points of  $P$ ; we will distinguish them as *the first and the second end-point of  $P$* , respectively. Furthermore, if  $P$  denotes a spider in  $G$  then we will equally use either  $f(P)$  or  $s(P)$  to denote *the center of  $P$* .

## 2 Our Results

We present an FPT algorithm for MBV parameterized by modular-width. To this aim, we also design a FPT algorithm for PSC parameterized by modular-width.

Let  $H$  be the input graph. Consider the parse-tree of an algebraic expression describing  $H$ , according to the rules (O1)-(O4) in Section 1.3. We take a look at the operation corresponding to the root: Operation (O1) is trivial and (O2) yields a disconnected graph, therefore we suppose the last operation is either (O3) or (O4). Hence, we can see the input graph as  $H = G(G_1, \dots, G_n)$  where  $G$  is a graph with  $n \leq mw(H)$  vertices and  $G_1, \dots, G_n$  are graphs.

The algorithm that finds a spanning tree of an input graph  $H$  with  $b(H)$  branch vertices goes through the following steps 1) and 2).

- 1) An FPT algorithm for PSC and PP parameterized by the modular-width of the input graph  $H$ . Namely, for each vertex  $\hat{H} = \hat{G}(\hat{G}_1, \dots, \hat{G}_n)$  of the parse-tree of  $H$ , we show how to compute the triple

$$(ham(\hat{H}), spi(\hat{H}), |V(\hat{H})|) \text{ together with } \mathcal{P}_{ham(\hat{H})} \text{ and } \mathcal{P}_{spi(\hat{H})},$$

where  $\mathcal{P}_{ham(\hat{H})}$  is a partition of  $\hat{H}$  into  $ham(\hat{H})$  paths and  $\mathcal{P}_{spi(\hat{H})}$  is a path-spider cover of  $\hat{H}$  with  $spi(\hat{H}) - 1$  paths.

- 2) Compute a spanning tree of  $H = G(G_1, \dots, G_n)$  with  $b(H)$  branch vertices by using the values, computed at step 1), for the graphs  $G_1, \dots, G_n$ , that is,

$$(ham(G_i), spi(G_i), |V(G_i)|), \mathcal{P}_{ham(G_i)}, \text{ and } \mathcal{P}_{spi(G_i)},$$

for  $i = 1, \dots, n$ ,

The computation in step 2) is only done once, i.e., for the root vertex of the parse tree, corresponding to the input graph  $H = G(G_1, \dots, G_n)$ . It is shown in Section 3, which is devoted to prove the following theorem.

► **Theorem 2.** MINIMUM BRANCH VERTICES *parameterized by modular-width is fixed-parameter tractable.*

The computation in step 1) is presented in Section 4. Following [10], we use a bottom-up dynamic programming approach along the parse-tree to compute for every vertex a record of data, using those already computed for its children. Since the operations of type (O1)-(O3) can be replaced by one operation of type (O4) that uses at most 2 operands, we only focus on the computation (and the time it requires) of a record of data for a vertex of type (O4) in the parse-tree. Namely, in Section 4 we prove the following theorem.

► **Theorem 3.** PATH-SPIDER COVER *parameterized by modular-width is fixed-parameter tractable.*

### 3 The MBV algorithm

In this section we give an algorithm that finds a spanning tree of graph  $H$  with  $b(H)$  branch vertices. We assume here that for each vertex  $\hat{H} = \hat{G}(\hat{G}_1, \dots, \hat{G}_n)$  of the parse-tree of  $H$ , we already have

the triple  $(\text{ham}(\hat{H}), \text{spi}(\hat{H}), |V(\hat{H})|)$  together with  $\mathcal{P}_{\text{ham}(\hat{H})}$  and  $\mathcal{P}_{\text{spi}(\hat{H})}$ .

We start by giving a characterization of a spanning tree with the minimum number of branch vertices in terms of the modular decomposition of  $H$ .

► **Lemma 4.** *Let  $H = G(G_1, \dots, G_n)$  be a connected graph. There exists a spanning tree of  $H$  with  $b(H)$  branch vertices that has at most one branch vertex belonging to  $G_i$  for each  $i = 1, \dots, n$ . Hence,  $b(H) \leq n \leq \text{mw}(H)$ .*

**Proof.** Let  $T$  be a spanning tree of  $H$  with  $b(H)$  branch vertices. Denote by  $B$  the set of vertices of  $H$  that are branch vertices in  $T$  and by  $N_T(v)$  the set of neighbors of  $v$  in  $T$ , for any vertex  $v$ . Assume that  $|V(G_i) \cap B| \geq 2$  for some  $i \in \{1, \dots, n\}$ . We show how to transform  $T$  so to satisfy the lemma. The transformation consists of two phases.

■ **Phase 1.** For each  $i = 1, \dots, n$ , we denote by  $B_i$  the set of branch vertices in  $V(G_i)$  that have in  $T$  at least two neighbors outside  $V(G_i)$ , that is,

$$B_i = \{v \mid v \in V(G_i) \cap B \text{ and } |N_T(v) \cap (\cup_{j \neq i} V(G_j))| \geq 2\}.$$

In this phase we transform  $T$  so that  $|B_i| \leq 1$ , for each  $i$ . We proceed as follows.

For each  $i$  such that  $|B_i| \geq 2$ ,

- let  $v$  be any node in  $B_i$ ;
- for each  $w \in B_i$  with  $w \neq v$ , consider the path connecting  $v$  and  $w$  in  $T$ , say  $v, \dots, w', w$ , and modify  $T$  as follows: For any  $x \in (N_T(w) - V(G_i)) - \{w'\}$ , substitute in  $T$  the edge  $\{w, x\}$  by the edge  $\{v, x\}$ .  
(Notice that this is possible by (1) and implies  $B_i = \{v\}$ ).

■ **Phase 2.** We know that each  $G_i$  contains at most one branch vertex with at least two neighbors outside  $V(G_i)$ , that is now  $|B_i| \leq 1$  for each  $i$ .

If there exists  $i$  such that  $G_i$  contains at least 2 branch vertices, we modify the spanning tree so that only one remains. We proceed as follows.

While there exists  $i$  such that  $|V(G_i) \cap B| \geq 2$ .

- Choose any  $j \neq i$  such that  $\{i, j\} \in E(G)$  and let

$$w \in \begin{cases} B_j & \text{if } B_j = \{w\}, \\ V(G_j) \cap B & \text{if } B_j = \emptyset \text{ and } V(G_j) \cap B \neq \emptyset \\ V(G_j) & \text{otherwise.} \end{cases}$$

- For each branch vertex  $v \in V(G_i) \cap B$  with  $v \neq w$ , perform the following step.
  - \* Consider the path connecting  $v$  and  $w$  in  $T$ , say  $v, v', \dots, w$ , and modify  $T$  as follows: For any  $x \in N_T(v) \cap V(G_i)$  and  $x \neq v'$ , substitute in  $T$  the edge  $\{v, x\}$  by the edge  $\{w, x\}$ .  
(This is possible by (1). Moreover, even if now  $w$  becomes a new branch vertex, we know that  $|V(G_j) \cap B| = 1$ ; finally,  $|B_j| \leq 1$ ,  $|V(G_i) \cap B| \leq 1$ , and the number of branch vertices does not increase.

By iterating the above steps, one can obtain the desired spanning tree of  $H$  with at most one branch vertex in each  $V(G_i)$ . ◀

In the remaining part of this section, we present an algorithm that computes a spanning tree of  $H = G(G_1, \dots, G_n)$  with  $b(H)$  branch vertices, if  $b(H) > 0$ . In Section 4.2 we deal with the case  $b(H) = 0$ , that is, we show how to find a Hamiltonian path of  $H$ , if any exists.

By exploiting Lemma 4, the algorithm proceeds by considering all the subsets  $B_G \subseteq \{1, \dots, n\}$  with  $|B_G| \geq 1$ , ordered by size, and checking whether there exists a spanning tree of  $H$  with  $|B_G|$  branch vertices, so that exactly one branch vertex belongs to each  $V(G_i)$  with  $i \in B_G$  and none to each  $V(G_i)$  with  $i \notin B_G$ .

The identification of the spanning tree of  $H$  goes through the solution of an Integer Linear Program that uses the values  $ham(G_i)$ ,  $spi(G_i)$ ,  $|V(G_i)|$ , for  $i = 1, \dots, n$ , and exploits property (1). Namely, if the ILP does not admit a solution for  $B_G$ , then the set is discarded; if for  $B_G$  the ILP admits a solution, we will show how to use the partition of  $G_i$  given in  $\mathcal{P}_{ham(G_i)}$  and  $\mathcal{P}_{spi(G_i)}$  to construct a spanning tree of  $H$  having exactly  $|B_G|$  branch vertices (recall that the sets  $B_G$  are considered by increasing size). The optimal spanning tree will be indeed shown to correspond to the smallest  $B_G$  for which the ILP admits a solution.

### 3.1 The Integer Linear Program

Let  $B_G \subseteq \{1, \dots, n\}$ , with  $|B_G| \geq 1$ . Construct a digraph

$$G_{B_G} = (\{1, \dots, n\} \cup \{s\}, A_{B_G}),$$

where  $s \notin V(H)$  is an additional vertex that will be called the source.  $G_{B_G}$  is obtained from  $G$  by replacing each edge  $\{i, j\} \in E(G)$  by the two directed arcs  $(i, j)$  and  $(j, i)$ , and then adding a directed arc  $(s, r)$  where  $r$  is an arbitrary vertex in  $B_G$ . Formally,

$$A_{B_G} = \{(s, r)\} \cup \{(i, j), (j, i) \mid \text{there exists an edge between } i \text{ and } j \text{ in } E(G)\}.$$

For sake of clearness, we will refer to the vertices of  $G$  as *module indices* and reserve the term vertex to those in  $H$ .

We use the solution of the following Integer Linear Programming (ILP) to select arcs of  $G_{B_G}$  that will help to construct the desired spanning tree in  $H$ .

$$x_{sr} = 1 \tag{2}$$

$$\sum_{j:(j,i) \in A_{B_G}} x_{ji} \leq |V(G_i)| \quad \forall i \in \{1, \dots, n\} \tag{3}$$

$$\sum_{j:(j,i) \in A_{B_G}} x_{ji} \geq spi(G_i) \quad \forall i \in B_G \tag{4}$$

$$\sum_{j:(j,i) \in A_{B_G}} x_{ji} \geq ham(G_i) \quad \forall i \in \{1, \dots, n\} - B_G \tag{5}$$

$$\sum_{\ell:(i,\ell) \in A_{B_G}} x_{i\ell} - \sum_{j:(j,i) \in A_{B_G}} x_{ji} \leq 0 \quad \forall i \in \{1, \dots, n\} - B_G \tag{6}$$

$$y_{sr} = n \tag{7}$$

$$\sum_{j:(j,i) \in A_{B_G}} y_{ji} - \sum_{\ell:(i,\ell) \in A_{B_G}} y_{i\ell} = 1 \quad \forall i \in \{1, \dots, n\} \tag{8}$$

$$y_{ij} \leq n x_{ij} \quad \forall (i, j) \in A_{B_G} \tag{9}$$

$$y_{ij}, x_{ij} \in \mathbb{N} \quad \forall (i, j) \in A_{B_G} \tag{10}$$

For each arc  $(i, j) \in A_{B_G}$ , the non negative decision variable  $x_{ij}$  represents the load to be put on  $(i, j)$ . The load of the arc  $(s, r)$  is set to 1. The total incoming load at module index  $i \in \{1, \dots, n\}$  has to be at most  $|V(G_i)|$  and at least  $spi(G_i)$  in case  $i \in B_G$  (to be sure that the spider and all the  $spi(G_i) - 1$  paths in  $G_i$  are reached) and at least  $ham(G_i)$  in case  $i \notin B_G$  (to be sure that all the  $ham(G_i)$  paths in  $G_i$  are reached). Constraints (3), (4) and (5) correspond to this requirement.

Constraint (6) binds the relation between the total incoming and outgoing loads at any  $i \notin B_G$ , namely  $i$  must have an outgoing load upper bounded by its incoming load.

Constraints (7) and (8) use a single commodity flow in which  $s$  is used as the source and the other module indices are demand vertices. For each arc  $(i, j) \in A_{B_G}$ , the non negative decision variable  $y_{ij}$  represents the quantity of flow from  $i$  to  $j$ .

Each  $i \in \{1, \dots, n\}$  has demand of one unit; therefore, the difference between the inflow and the outflow must be exactly one. Meanwhile, the supply quantity at the source  $s$  has to be exactly  $n$ , in order to reach each of the module index in  $\{1, \dots, n\}$ .

Constraint (9) stresses variable  $y_{ij} = 0$  whenever  $x_{ij} = 0$ ; thus if no load is put on  $(i, j)$  then  $j$  cannot be reached through  $i$ .

Given an integer solution  $(y, x)$ , if any, to the above ILP, the values of variables  $y$  imply that each module index  $i \in \{1, \dots, n\} - \{r\}$  is reached from the source  $s$ . Then, by the construction of the digraph  $G_{B_G}$ , each module index  $i \in \{1, \dots, n\}$  is reached from module index  $r$ . Furthermore, by the relation between variables  $x$  and  $y$  (constraint (9)), we know that each module index  $i \in \{1, \dots, n\}$  gets incoming load from at least one of its neighbors.

▷ Claim 5. The subgraph  $G_x$  of  $G_{B_G}$  with vertex set  $\{1, \dots, n\}$  and arc set  $\{(i, j) \mid x_{ij} \geq 1\}$  contains a directed path from  $r$  to any other module index .

We stress that the constraints involving variables  $y$  only assure that a spanning tree in  $G_x$  exists. A more sophisticated approach is necessary to find a spanning tree of  $H$  with branch vertices in  $B_G$  only.

### 3.2 The spanning tree construction

Our algorithm constructs a spanning tree  $T$  of  $H$  with  $|B_G|$  branch vertices, one in each  $V(G_i)$  with  $i \in B_G$ . To this aim, it uses the values of variables  $x$  and the path-spider cover  $\mathcal{P}_{spi(G_i)}$  for  $i \in B_G$  and the partition into disjoint paths  $\mathcal{P}_{ham(G_i)}$  for  $i \notin B_G$ .

Denote by  $In(i)$  the set of the module indices for which there exist arcs in  $G_x$  toward  $i$ , that is,  $In(i) = \{j \mid x_{ji} \geq 1\}$ , and by

$$\alpha_i = \sum_{j:j \in In(i)} x_{ji} \tag{11}$$

the number of vertices of  $V(G_i)$  whose parent in  $T$  is a vertex outside  $V(G_i)$ .

Let  $\mathcal{P}^i = \{P_1^i, P_2^i, \dots, P_{\alpha_i}^i\}$  be

- the path-spider cover of  $G_i$  obtained from those in  $\mathcal{P}_{spi(G_i)}$  by removing  $\alpha_i - spi(G_i)$  arbitrary edges in case  $i \in B_G$  (notice that by constraint (4), it holds  $\alpha_i \geq spi(G_i)$ ), or
- the partition of  $G_i$  into disjoint paths obtained from those in  $\mathcal{P}_{spi(G_i)}$  by removing  $\alpha_i - ham(G_i)$  arbitrary edges in case  $i \notin B_G$  (notice that by (4), it holds  $\alpha_i \geq ham(G_i)$ ).

Furthermore, denote by

$$f(\mathcal{P}^i) = \{f(P_1^i), f(P_2^i), \dots, f(P_{\alpha_i}^i)\}$$

the sets of the first end-points in the partition  $\mathcal{P}^i$  and by

$$s(\mathcal{P}^i) = \{s(P_1^i), s(P_2^i), \dots, s(P_{\alpha_i}^i)\}$$

the sets of the second end-points in  $\mathcal{P}^i$ . In case  $i \in B_G$ , we assume that  $P_1^i \in \mathcal{P}^i$  is the spider and  $f(P_1^i) = s(P_1^i)$  is the center in  $P_1^i$ .

We also denote by

$$\beta_i = \begin{cases} \sum_{\ell: i \in I_n(\ell)} x_{i\ell} & \text{if } i \notin B_G \\ 1 & \text{if } i \in B_G \end{cases} \quad (12)$$

the number of vertices of  $V(G_i)$ , that will be the parent of some vertex in  $\bigcup_{\ell: i \in I_n(\ell)} V(G_\ell)$ .

Our algorithm ensures that the  $\alpha_i$  vertices in  $f(\mathcal{P}^i)$  are the vertices in  $G_i$  whose parent in  $T$  is outside  $V(G_i)$ , and that  $\beta_i$  vertices among those in  $s(\mathcal{P}^i)$  are chosen to be parents of vertices outside  $V(G_i)$ . Notice that by Claim 5 ( $\alpha_i \geq 1$ ) and constraint (6), it follows that  $\alpha_i \geq \beta_i$  for each  $i \in \{1, \dots, n\}$ .

Figure 2 shows the partition of graph  $G_i$  (whose vertices are grouped in the dotted circle) into  $\alpha_i$  disjoint paths if  $i \notin B_G$  and into a spider plus  $\alpha_i - 1$  disjoint paths if  $i \in B_G$ .

■ **Figure 2** The vertices of graph  $G_i$ , grouped in the dotted circle, as partitioned in  $\alpha_i$  disjoint paths if  $i \notin B_G$  and in a spider plus  $\alpha_i - 1$  disjoint paths if  $i \in B_G$ . Vertex  $f(P_j^i)$  is the only vertex in  $P_j^i$  whose parent in  $T$  is outside  $G_i$  and vertex  $s(P_j^i)$  is the only vertex in  $P_j^i$  that can have a children in  $T$  outside  $G_i$ .

The algorithm TREE constructs a spanning tree of  $H = G(G_1, \dots, G_n)$  iteratively by exploring unexplored vertices of  $H$ , until possible, and maintains a main subtree  $T$  and a forest whose roots are progressively connected to  $T$  to assemble the spanning tree. The process stops when all the vertices of  $H$  are explored. A similar idea was used in [15] in the special case in which each graph  $G_i$  is either a clique or an independent set.

The algorithm uses a queue  $Q$  to enqueue the explored vertices and maintains a set  $R$  of the roots of trees of explored vertices that wait to be connected to the main tree  $T$ . The forest structure is described through the parent function  $\pi$ .

At the beginning the set  $R$  is empty. The exploration starts with the center  $f(P_1^r)$  of the spider in the path-spider cover of  $G_r$  (recall that by construction  $r \in B_G$ ); the procedure EXPLORE( $f(P_1^r)$ ) carries out the construction of the main tree  $T$  rooted at  $f(P_1^r)$  and marks as explored all the reached vertices (adding them to the set  $Ex$ ). Clearly, for each explored vertex  $v$  there is a path in  $T$  joining  $f(P_1^r)$  to  $v$ .

However, it can occur that some of the vertices have not been explored (i.e.,  $V(H) - Ex \neq \emptyset$ ). In such a case an explored vertex  $w \in f(\mathcal{P}^j) \cap Ex$  is chosen so that it belongs to some  $V(G_j)$  which also contains at least a unexplored vertex  $u \in (f(\mathcal{P}^j) - Ex) - R$  which is able to explore at least one unexplored neighbour outside  $G_j$ , that is,  $\beta_j \geq 1$  (the existence of such a set  $V(G_j)$  is assured by Lemma 7). By using (1) and knowing that the parents of vertices in  $f(\mathcal{P}^j)$  are outside  $V(G_j)$ , the algorithm makes:

- the parent of  $w$  (recall that  $w$  is explored) become the parent of  $u$ , and
- $w$  (the root of a subtree of explored vertices) is added to  $R$  and removed from  $Ex$  (this allows to later explore  $w$  and add it, together with its subtree, to the main tree  $T$ ), and
- EXPLORE( $u$ ) is called to start a new exploration from  $u$ .

Notice that the algorithm modifies the forest by assigning to  $u$  the parent of  $w$  and only later (after adding  $u$  and some descendants of  $u$ ) adding again the subtree rooted in  $w$  to the main tree  $T$ . This allows connecting new vertices in  $V(H) - Ex$  to the main tree  $T$ ; the particular choice of  $u$  and  $w$  will be shown to avoid the possibility that the algorithm fails, due to the fact that no arc can be added to  $T$  without forming a cycle or creating an extra branch vertex. The process is iterated as long as there are unexplored vertices, i.e.  $V(H) - Ex \neq \emptyset$ .

The procedure  $\text{EXPLORE}(u)$  starts exploring  $u = f(P_k^j)$  together with the whole  $P_k^j$ \*, then putting in  $Q$  only the vertex  $s(P_k^j)$  and successively padding the main tree  $T$  (recall that (unless  $u = f(P_1^r)$ ) the parent of  $u$  is a vertex already in  $T$ , thus we construct a subtree rooted at  $u$  spanning on all the newly explored vertices).  $\text{EXPLORE}(u)$  uses for each module index  $i$  the values of  $\alpha_i$  and  $\beta_i$  that are initially defined as in (11) and (12), and the partition  $\mathcal{P}^i = \{P_1^i, P_2^i, \dots, P_{\alpha_i}^i\}$  of  $G_i$ . The value  $\alpha_i = \sum_{j: j \in \text{In}(i)} x_{ji}$  counts the number of vertices of  $V(G_i)$  that must be assigned a parent outside  $V(G_i)$ , they are the vertices in  $f(\mathcal{P}^i) = \{f(P_1^i), f(P_2^i), \dots, f(P_{\alpha_i}^i)\}$ ; in particular,  $x_{ji}$  vertices of  $f(\mathcal{P}^i)$  have to be explored by vertices in  $V(G_j)$ , for  $j \in \text{In}(i)$ . The value  $\beta_i$  counts the number of vertices of  $V(G_i)$  that have to explore other vertices in some other  $V(G_\ell)$ , for  $\ell: i \in \text{In}(\ell)$ ; in particular,

- if  $i \in B_G$  then exactly  $\beta_i = 1$  vertex in  $V(G_i)$ , that is  $s(P_1^i)$  (i.e., the center of the spider  $P_1^i$ ), becomes a branch vertex in  $T$ : it is set as the parent of  $x_{i\ell}$  unexplored vertices in  $f(\mathcal{P}^\ell)$  for each  $\ell$  such that  $x_{i\ell} \geq 1$  (i.e.,  $i \in \text{In}(\ell)$ ), and
- if  $i \notin B_G$  then  $\beta_i = \sum_{\ell: i \in \text{In}(\ell)} x_{i\ell}$  vertices in  $s(\mathcal{P}^i) = \{s(P_1^i), s(P_2^i), \dots, s(P_{\alpha_i}^i)\}$  are chosen and each one becomes the parent of one unexplored vertex in  $f(\mathcal{P}^\ell)$ .

Recall that, by the ILP constraints, we know that  $\alpha_i \geq \beta_i$ .

The vertices in  $s(\mathcal{P}^i)$  for  $i \in \{1, \dots, n\}$  are the only one to be enqueued in  $Q$ . When a vertex  $v \in s(\mathcal{P}^i)$  is dequeued from  $Q$  in  $\text{EXPLORE}(u)$  then the value of  $\beta_i$  is decreased by one if  $v$  explores (i.e., if  $\beta_i \geq 1$ ). In this case, for each explored vertex  $f(P_h^\ell)$ , with  $i \in \text{In}(\ell)$ , the whole  $P_h^\ell$  is also explored. Furthermore, the value  $\alpha_\ell$  is decreased by the number of vertices in  $s(\mathcal{P}^\ell)$  that  $v$  explores, for  $i \in \text{In}(\ell)$ . Hence, at the beginning of each iteration of the while loop in  $\text{EXPLORE}(u)$  the values of  $\alpha_i$  represents the number of vertices in  $f(\mathcal{P}^i)$  that remain to be explored while  $\beta_i$  is the number of vertices in  $s(\mathcal{P}^i)$  that already have to explore. Note that when a vertex  $v \in s(\mathcal{P}^i)$  is dequeued from  $Q$  in  $\text{EXPLORE}(u)$ , with  $u \neq f(P_1^r)$ , and  $\beta_i \geq 1$ , the algorithm checks if the neighbour  $v' \in f(\mathcal{P}^\ell)$ , that  $v$  explores, is in  $R$  (i.e.,  $v'$  is a root of a tree in the forest). In this case  $v'$ , with the tree rooted at it, is connected to the main tree  $T$  (since it was already explored in the past).

► **Lemma 6.** *At the end of  $\text{EXPLORE}(f(P_1^r))$  the function  $\pi$  describes a tree, rooted at  $f(P_1^r)$ , spanning the set  $Ex \subseteq V(H)$  of explored vertices. The vertices in  $B \cap Ex$  are the branch vertices.*

**Proof.** When  $\text{EXPLORE}(f(P_1^r))$  is called, the whole spider  $P_1^r$  is explored (i.e.  $Ex = Ex \cup P_1^r$  and so added to  $T$ ) and its center  $s(P_1^r)$  is enqueued in  $Q$ . After that, each time a vertex  $v \in s(\mathcal{P}^i)$  is dequeued from  $Q$  (recall,  $v \in Ex$ , i.e., it is an explored vertex), the algorithm can either stop its exploration (i.e.,  $\beta_i = 0$ ) or explore one or more unexplored neighbor of  $v$  together with the path/spider it belongs. Indeed, we can prove that  $v$  has the needed number of unexplored neighbors. If  $\beta_i = 0$  then  $v$  is a leaf in  $T$ ; hence, we only have to consider the case  $\beta_i \geq 1$ . If  $i \notin B_G$  then  $v$  has  $\beta_i \geq 1$  unexplored neighbors and one of them, say  $f(P_h^\ell)$

\* Assume that when in the algorithm  $P \in \mathcal{P}^j$  is explored, that is  $Ex = Ex \cup P$ , then the parent function  $\pi$  is set going through all the vertices in  $P$  from  $f(P)$  to  $s(P)$  in case  $P$  is a path, and from the center  $f(P) = s(P)$  to the leaves in case  $P$  is a spider.

■ **Algorithm 1** TREE( $H, G_1, \dots, G_n, r, B_G$ ).

```

1:  $R = \emptyset, B = \emptyset, Ex = \emptyset$ 
2:  $\pi(u) = \text{nhil}$  for each  $u \in V(H)$ 
3: EXPLORE( $f(P_1^r)$ )
4: while  $V(H) - Ex \neq \emptyset$  do
5:   - Let  $G_j$  be any graph s.t.  $((f(\mathcal{P}^j) - Ex) - R \neq \emptyset \neq f(\mathcal{P}^j) \cap Ex)$  and  $\beta_j \geq 1$ 
6:   - Let  $w \in f(\mathcal{P}^j) \cap Ex$  and  $u \in (f(\mathcal{P}^j) - Ex) - R$ 
7:   - Set  $\pi(u) = \pi(w), Ex = Ex - \{w\}, R = R \cup \{w\}$ 
8:   - EXPLORE( $u$ )
9: end while
10: return  $\pi, B$ 

```

---

for  $i \in In(\ell)$ , can be added to  $T$  as child of  $v$ . If  $i \in B_G$  then  $v$  is the first vertex of  $V(G_i)$  that explores and  $x_{i\ell}$  vertices in  $f(\mathcal{P}_\ell)$  are unexplored and can be added to  $T$  as children of  $v$ , for each  $\ell$  such that  $x_{i\ell} \geq 1$ . Hence  $v$  becomes a branch vertex in  $T$  and is put in  $B$ . Since  $R = \emptyset$  (i.e. no tree is in the forest), each time a neighbor of  $v$  is explored, say  $f(P_h^\ell)$ , then the whole path/spider  $P_h^\ell$  is added to  $T$  and  $s(P_h^\ell)$  is enqueued in  $Q$ . Hence, any explored vertex has  $f(P_1^r)$  as ancestor, i.e., the function  $\pi$  describes a path joining any explored vertex to  $f(P_1^r)$ . Noticing that no vertex can be enqueued twice in  $Q$  (since any enqueued vertex is also marked as explored), we have that the function  $\pi$  does not create cycles. ◀

We can also prove the following result.

► **Lemma 7.** *Let  $Ex$  be the set of explored vertices at the beginning of any iteration of the while loop in algorithm TREE. If  $V(H) - Ex \neq \emptyset$  then there exists a module index  $j$  such that  $(f(\mathcal{P}^j) - Ex) - R \neq \emptyset \neq f(\mathcal{P}^j) \cap Ex$  and  $\beta_j \geq 1$ .*

► **Lemma 8.** *After each call of EXPLORE( $u$ ) the function  $\pi$  describes a forest spanning the vertices in  $Ex \cup R$  of explored vertices and consisting of  $|R| + 1$  trees respectively rooted at  $f(P_1^r)$  and at the vertices in  $R$ . The vertices in  $B$  are the only branch vertices in the forest.*

**Proof.** When EXPLORE( $u$ ) is called, the function  $\pi$  describes a forest, spanning the current set  $Ex \cup R$ , whose roots are the vertices in  $\{f(P_1^r)\} \cup R$  and where  $R \subset V(H) - Ex$ . We notice that by Lemma 6, this is true the first time EXPLORE is called, that is, after the call to EXPLORE( $f(P_1^r)$ ) (at that time  $R = \emptyset$ ).

We prove that the claim is also true at the end of each call to EXPLORE( $u$ ). When EXPLORE( $u$ ) is called,  $Q$  is empty; vertex  $u$  is explored (i.e. it is added to  $Ex$ ) and enqueued in  $Q$ . Then EXPLORE( $u$ ) proceeds, exactly as in EXPLORE( $f(P_1^r)$ ), dequeuing vertices from  $Q$  and exploring their unexplored neighbors, so constructing a subtree of the main tree  $T$  rooted at  $u$  described by function  $\pi$ . The only difference with EXPLORE( $f(P_1^r)$ ) is when one of the vertices explored is  $v' \in R$ . Vertex  $v' \in R$  is removed from  $R$  (see lines 11, 22) and connected to the main tree  $T$  through the function  $\pi$  and marked as explored exactly as any other explored vertex. However  $v'$  is not enqueued in  $Q$  since it has already explored its neighbors; hence,  $v'$  is connected to  $T$  together with its subtree of explored vertices. ◀

We are now able to prove the following result.

► **Lemma 9.** *The algorithm TREE returns a spanning tree of  $H$ , described by function  $\pi$ , with branch vertex set  $B$ .*

**Proof.** By using Lemma 6 we know that algorithm TREE constructs, through procedure EXPLORE( $f(P_1^r)$ ), a main tree  $T$ , described by  $\pi$ . In case  $T$  does not span all the vertices in  $V(H)$  then, Lemma 7 assures that the algorithm finds a graph  $G_j$  with an explored vertex

---

**Algorithm 2** EXPLORE( $u$ ).

$w \in f(\mathcal{P}^j) \cap Ex$  and an unexplored vertex  $u \in (f(\mathcal{P}^j) - Ex) - R$ . Disconnecting  $w$  (together with its subtree) from the main tree  $T$ , the algorithm let  $w$  become one of the roots of trees in  $R$ . Furthermore, since the parent of  $w$  in  $T$  is a vertex outside  $V(G_j)$  and, since  $u$  and  $w$  share the same neighborhood outside  $G_j$  (by (1)), the algorithm let  $u$  be connected to the vertex that was the parent of  $w$  in  $T$  (thus, connecting  $u$  to  $T$ ). Considering that  $u \notin R$  and  $\beta_j \geq 1$ , the algorithm starts a new exploration from  $u$  (recall that  $u \in f(\mathcal{P}^j) - Ex$ ) calling EXPLORE( $u$ ). By Lemma 8, this allows padding  $T$  with the subtree rooted at  $u$ . The lemma follows by iterating the above procedure until no unexplored vertex exists in  $V(H)$ . ◀

### 3.3 The algorithm complexity

Summarizing, given the triple  $(\text{ham}(G_i), \text{spi}(G_i), |V(G_i)|)$  together with  $\mathcal{P}_{\text{ham}(G_i)}$  and  $\mathcal{P}_{\text{spi}(G_i)}$ , for each  $i \in \{1, \dots, n\}$ , the proposed method to construct the spanning tree of  $H = G(G_1, \dots, G_n)$  works as follows.

For each  $B_G \subseteq \{1, \dots, n\}$  with  $|B_G| \geq 1$ , selected in order of increasing size, the algorithm executes the following steps:

- solve the corresponding ILP
- if a solution exists for the current set  $B_G$ , use algorithm TREE to construct a spanning tree of  $H = G(G_1, \dots, G_n)$  with  $|B_G|$  branch vertices.

Jansen and Rohwedder [17] have recently showed that the time needed to find a feasible solution of an ILP with  $p$  integer variables and  $q$  constraints is  $O(\sqrt{q}\Delta)^{(1+o(1))q} + O(qp)$ , where  $\Delta$  is the largest absolute value of any coefficient in the ILP. Denoted by  $m$  the number of edges of  $G$ , our ILP has  $q = 3n + 2m + 1$  constraints,  $p = 2(m + 1)$  variables and  $\Delta = n$ . Hence the time to solve it is  $O(n\sqrt{n+m})^{(1+o(1))(3n+2m+1)} + O(n(n+m))$ . Using the solution  $(y, x)$  of the ILP, the algorithm TREE returns the spanning tree of  $H$  in time  $O(|V(H)|^2)$ . Overall, the algorithm requires time

$$2^n [O(n\sqrt{n+m})^{(1+o(1))(3n+2m+1)} + O(n(n+m))] + O(|V(H)|^2).$$

Recall that  $n \leq mw$ , and therefore  $m \leq nw^2$ .

### 3.4 Optimality

It is possible to show that if no set  $B_G \subseteq \{1, \dots, n\}$ , of size  $k$  exists for which the ILP admits a solution then any spanning tree of  $H = G(G_1, \dots, G_n)$  has  $b(H) \geq k + 1$  branch vertices. This allows to say that the optimal spanning tree in  $H$  corresponds to the smallest set  $B_G \subseteq \{1, \dots, n\}$  for which the ILP admits a solution, if any. Namely, we can prove the following result.

► **Lemma 10.** *Given the graphs  $G_1, \dots, G_n$  and  $\text{ham}(G_i), \text{spi}(G_i), |V(G_i)|$  for each  $i = 1, \dots, n$ , if there exists a spanning tree in  $H = G(G_1, \dots, G_n)$  with  $k \geq 1$  branch vertices then there exist a set  $B_G \subseteq \{1, \dots, n\}$  with  $|B_G| = k$ , for which ILP admits a solution  $(x, y)$ .*

## 4 The triple and partition computation

In this section we show how to compute the record of data for any vertex  $\hat{H} = \hat{G}(\hat{G}_1, \dots, \hat{G}_{\hat{n}})$  of the parse-tree. Namely, given the triple  $(\text{ham}(\hat{G}_i), \text{spi}(\hat{G}_i), |V(\hat{G}_i)|)$ ,  $\mathcal{P}_{\text{ham}(\hat{G}_i)}$  and  $\mathcal{P}_{\text{spi}(\hat{G}_i)}$ , for each  $i = 1, \dots, \hat{n}$ , we have to compute

the triple  $(\text{ham}(\hat{H}), \text{spi}(\hat{H}), |V(\hat{H})|)$  together with  $\mathcal{P}_{\text{ham}(\hat{H})}$  and  $\mathcal{P}_{\text{spi}(\hat{H})}$ ,

Clearly,  $|V(\hat{H})| = \sum_{i=1}^{\hat{n}} |V(\hat{G}_i)|$ . We show below how to compute  $\text{spi}(\hat{H})$  and  $\mathcal{P}_{\text{spi}(\hat{H})}$ , and also  $\text{ham}(\hat{H})$  and  $\mathcal{P}_{\text{ham}(\hat{H})}$ ,

For a graph  $\hat{H}$  and an integer  $\ell$ , we denote by  $\hat{H} \otimes \ell$  the graph obtained from  $\hat{H}$  by adding  $\ell$  vertices and connecting them to every vertex in  $\hat{H}$ ; formally,  $\hat{H} \otimes \ell$  has vertex set  $V(\hat{H}) \cup \{v_1, \dots, v_\ell\}$  and edge set  $E(\hat{H}) \cup \{\{u, v_j\} \mid u \in V(\hat{H}), 1 \leq j \leq \ell\}$ . We notice that, since  $\hat{H} = \hat{G}(\hat{G}_1, \dots, \hat{G}_{\hat{n}})$  then the graph  $\hat{H} \otimes \ell$ , for each  $2 \leq \ell \leq |V(\hat{H})|$ , is equal to the graph  $\hat{G}'(\hat{G}_1, \dots, \hat{G}_{\hat{n}}, I_\ell)$  where  $\hat{G}'$  is the graph obtained from  $\hat{G}$  by adding the vertex  $\hat{n} + 1$  (i.e.,  $V(\hat{G}') = \{1, \dots, \hat{n}, \hat{n} + 1\}$ ) and making it adjacent to all the other vertices of  $\hat{G}$  (i.e.,  $E(\hat{G}') = \{(i, \hat{n} + 1) \mid 1 \leq i \leq \hat{n}\}$ ), and  $I_\ell$  is the independent set with  $\ell$  vertices  $\{v_1, \dots, v_\ell\}$ .

#### 4.1 Computing $\text{spi}(\hat{H})$ and $\mathcal{P}_{\text{spi}(\hat{H})}$

In order to compute the values  $\text{spi}(\hat{H})$  and  $\mathcal{P}_{\text{spi}(\hat{H})}$ , we first need a preliminary result.

► **Proposition 11.** *Let  $\hat{H}$  be a graph and*

$$s(\hat{H}) = \min\{\ell \mid \hat{H} \otimes (\ell - 1) \text{ has a spanning spider with center in } \hat{H}\}.$$

Then  $\text{spi}(\hat{H}) = s(\hat{H})$ .

**Proof.** We first show that  $s(\hat{H}) \leq \text{spi}(\hat{H})$ . Let  $P_1, P_2, \dots, P_{\text{spi}(\hat{H})}$  be the path-spider cover of  $\hat{H}$  and let  $f(P_1)$  be the center of spider  $P_1$  and,  $f(P_i)$  be the first end-point of path  $P_i$  for  $i = 2, \dots, \text{spi}(\hat{H})$ . Hence, the graph  $\hat{H} \otimes (\text{spi}(\hat{H}) - 1)$  contains the spider with center  $f(P_1)$  obtained connecting  $f(P_1)$  to the vertex  $i$  and then connecting vertex  $i$  to  $f(P_i)$  for each for  $i = 1, \dots, \text{spi}(\hat{H}) - 1$ . Now, we prove that  $\text{spi}(\hat{H}) \leq s(\hat{H})$ . Let  $S$  be a spider in  $\hat{H} \otimes (s(\hat{H}) - 1)$  with the center  $u \in V(\hat{H})$ . Then, removing from  $S$  the vertices in  $\{1, \dots, s(\hat{H}) - 1\}$  we have a path-spider cover with center  $u$  and  $s(\hat{H}) - 1$  path pairwise disjoint. ◀

Recall that the graph  $\hat{H} \otimes (\ell - 1)$  is equal to  $\hat{G}'(\hat{G}_1, \dots, \hat{G}_n, I_{\ell-1})$  and notice that

$$\text{ham}(I_{\ell-1}) = \text{spi}(I_{\ell-1}) = \ell - 1 \text{ and } \mathcal{P}_{\text{ham}(I_{\ell-1})} = \mathcal{P}_{\text{spi}(I_{\ell-1})} = I_{\ell-1}.$$

We can then take into account the values  $\text{ham}(\hat{G}_i)$ ,  $\text{spi}(\hat{G}_i)$ ,  $|V(\hat{G}_i)|$ , and the sets  $\mathcal{P}_{\text{ham}(\hat{G}_i)}$  and  $\mathcal{P}_{\text{spi}(\hat{G}_i)}$ , for all  $i \in \{1, \dots, \hat{n}\}$ . For each  $B_{\hat{G}_i} = \{j\}$ , for  $j = 1, \dots, \hat{n}$ , we can follow the lines of Section 3.1 to verify whether the corresponding ILP is feasible. In the positive case, following the construction given in Section 3.2, one can obtain a spider of  $\hat{H} \otimes (\ell - 1)$  centered in  $V(\hat{G}_i)$

The minimum  $\ell$  for which the above occurs, gives  $\text{spi}(\hat{H})$  as well as the spider  $T$  covering  $\hat{H} \otimes (\text{spi}(\hat{H}) - 1)$  with center in  $V(\hat{H})$ . The arguments used in Section 2.3 allows to obtain the time complexity of this computation (here,  $\hat{m}$  represents the number of edges of  $\hat{G}$ )

$$\text{spi}(\hat{H}) \hat{n} [O(\hat{n}\sqrt{\hat{n} + \hat{m}})^{(1+o(1))(3\hat{n}+2\hat{m}+1)} + O(\hat{n}(\hat{n} + \hat{m}))] + O(|V(\hat{H})|^2).$$

Clearly, the subgraph of  $T$  induced by  $V(\hat{H})$  returns the path-spider cover  $\mathcal{P}_{\text{spi}(\hat{H})}$  of  $\hat{H}$ , thus concluding the proof of Theorem 3.

#### 4.2 Computing $\text{ham}(\hat{H})$ and $\mathcal{P}_{\text{ham}(\hat{H})}$

Using an approach similar to the one in the proof of Proposition 11, we can prove the following result.

► **Proposition 12.** *Let  $\hat{H}$  be a graph and*

$$h(\hat{H}) = \min\{\ell \mid \hat{H} \otimes \ell \text{ has a hamiltonian path with an end-point in } \{v_1, \dots, v_\ell\}\}.$$

Then  $\text{ham}(\hat{H}) = h(\hat{H})$ .

By Proposition 12, the value  $\text{ham}(\hat{H})$  is equal to the minimum positive integer  $\ell$  with  $1 \leq \ell \leq |V(\hat{H})|$  such that the graph

$$\hat{H} \otimes \ell \text{ has a hamiltonian path with an end-point not in } \{v_1, \dots, v_\ell\}. \quad (13)$$

To verify if graph  $\hat{H} \otimes \ell$  has a hamiltonian path and eventually find it, we can proceed as in Section 3. Indeed, considering that  $\hat{H} \otimes \ell = \hat{G}'(\hat{G}_1, \dots, \hat{G}_n, I_\ell)$ , and that  $\text{ham}(I_\ell) = \ell$  and  $\mathcal{P}_{\text{ham}(I_\ell)} = I_\ell$ , then given the values  $\text{ham}(\hat{G}_i)$ ,  $|V(\hat{G}_i)|$  and the set  $\mathcal{P}_{\text{ham}(\hat{G}_i)}$ , for each

$i \in \{1, \dots, \hat{n}\}$ , we can consider the corresponding ILP as in Section 3.1 choosing  $B_{\hat{G}_r} = \emptyset$  and  $r = \hat{n} + 1$  (i.e.,  $\hat{G}_r = I_\ell$ ). If the ILP admits a solution, we can construct the hamiltonian path  $P$  of  $\hat{H} \otimes \ell = \hat{G}'(\hat{G}_1, \dots, \hat{G}_{\hat{n}}, I_\ell)$  following the construction in Section 3.2 choosing any vertex in  $\hat{G}_r = I_\ell$  as end-point (i.e., root). Finally, we notice that everything was proved in Section 3.2 holds also in this case (i.e.,  $\hat{G}'(\hat{G}_1, \dots, \hat{G}_{\hat{n}}, I_\ell)$ ,  $B_{\hat{G}_r} = \emptyset$  and  $\hat{G}_r = I_\ell$ ) and that, as in Section 3.4, it can be proved that if there exists a hamiltonian path of  $\hat{G}'(\hat{G}_1, \dots, \hat{G}_{\hat{n}}, I_\ell)$  with an end-point in  $I_\ell$  then exists a solution  $(x, y)$  of the corresponding ILP (the same arguments used in the proof of Lemma 10 holds rooting the hamiltonian path at the end-point in  $I_\ell$ ).

The minimum  $\ell$  for which (13) occurs, gives  $ham(\hat{H})$  and also the hamiltonian path  $P$  of  $\hat{H} \otimes ham(\hat{H})$  with one end-point in  $I_{ham(\hat{H})}$ . The arguments used in Section 2.3 allows to have the time complexity of this computation

$$ham(\hat{H}) [O(\hat{n}\sqrt{\hat{n} + \hat{m}})^{(1+o(1))(3\hat{n}+2\hat{m}+1)} + O(\hat{n}(\hat{n} + \hat{m}))] + O(|V(\hat{H})|^2).$$

Obviously, the subgraph of  $P$  induced by  $V(\hat{H})$  will return the partition in  $ham(\hat{H})$  disjoint paths of  $\hat{H}$ ,  $\mathcal{P}_{ham(\hat{H})}$ .

We stress that  $ham(\hat{H}) = 1$  iff the graph  $\hat{H}$  has a hamiltonian path.

## Abstract

What is the  $\Sigma_3^2$ -circuit complexity (depth 3, bottom-fanin 2) of the  $2n$ -bit inner product function? The complexity is known to be exponential  $2^{\alpha n}$  for some  $\alpha_n = \Omega(1)$ . We show that the limiting constant  $\alpha := \limsup \alpha_n$  satisfies

$$0.847\dots \leq \alpha \leq 0.965\dots$$

Determining  $\alpha$  is one of the seemingly-simplest open problems about depth-3 circuits. The question was recently raised by Golovnev, Kulikov, and Williams (ITCS 2021) and Frankl, Gryaznov, and Talebanfard (ITCS 2022), who observed that  $\alpha \in [0.5, 1]$ . To obtain our improved bounds, we analyse a covering LP that captures the  $\Sigma_3^2$ -complexity up to polynomial factors. In particular, our lower bound is proved by constructing a feasible solution to the dual LP.

## 1 Introduction

A  $\Sigma_3$ -circuit is an unbounded-fanin depth-3 boolean circuit with an  $\vee$ -gate at the top. That is, the circuit computes an OR of CNFs. A foremost open problem in circuit complexity is to prove a lower bound of  $2^{\omega(\sqrt{n})}$  on the  $\Sigma_3$ -circuit complexity of an explicit  $n$ -bit boolean function. Current techniques can prove at best a bound of  $2^{\Omega(\sqrt{n})}$  [7, §11].

For the more restricted class of  $\Sigma_3^k$ -circuits that have fanin  $k$  at the bottom (that is, ORs of  $k$ -CNFs), we can hope for improved bounds. For example, the famous satisfiability coding lemma [14] implies that the  $n$ -bit parity function has  $\Sigma_3^k$ -circuit complexity at least  $2^{n/k}$  and this is tight up to polynomial factors (for constant  $k$ ). Even stronger, for  $k = 2$ , Paturi, Saks, and Zane [12] exhibit a function with near-maximal  $\Sigma_3^2$ -complexity  $2^{n-o(n)}$ . No such near-maximal lower bounds are currently known for  $k = 3$ .

**Inner product.** A natural function whose  $\Sigma_3^k$ -complexity remains unknown (up to  $\text{poly}(n)$  factors) is the *inner product* function  $\text{IP}_n$ , defined on  $2n$ -bit inputs  $(x, y) \in (\{0, 1\}^n)^2$  by

$$\text{IP}_n(x, y) := \langle x, y \rangle \bmod 2.$$

Recently, Golovnev, Kulikov, and Williams [2] asked to determine the  $\Sigma_3^k$ -complexity of  $\text{IP}_n$  in case  $k = 3$ . Curiously enough, Frankl, Gryaznov, and Talebanfard [1] point out that the problem is nontrivial already in case  $k = 2$ , and they obtained partial results towards resolving it. It has been known that the  $\Sigma_3^2$ -complexity of  $\text{IP}_n$  is between  $2^{n/2}$  and  $2^n$  [14, 2].

## 1.1 Our result

Our main result is to prove improved upper and lower bounds for inner product.

► **Theorem 1** (Main result). *Write the  $\Sigma_3^2$ -complexity of  $\text{IP}_n$  as  $2^{\alpha n}$  for some  $\alpha_n \geq 0$ . Then*

$$\alpha := \limsup \alpha_n \in [0.847\dots, 0.965\dots].$$

It remains an intriguing problem to determine  $\alpha$  precisely. It is surprising (for us, at least) that neither of the previous bounds  $\alpha \in [0.5, 1]$  were tight, especially because the problem is seemingly one of the simplest open questions about depth-3 circuits.

Studying exact exponents of  $\Sigma_3^k$ -circuit complexities is a relatively unexplored research direction, and we believe it could foster the development of new lower bound techniques. In particular, a major motivation for this comes from *depth reduction* results. For example, in case  $k = 16$ , Golovnev, Kulikov, and Williams [2] have shown that proving near-maximal  $2^{n-o(n)}$  bounds for  $\Sigma_3^{16}$ -circuits would already yield new improved lower bounds for *unrestricted* (unbounded depth) circuits. Their result extends classical connections discovered by Valiant [15]; see also the monograph [16, §3].

## 1.2 Overview of techniques

To obtain our improved bounds on  $\alpha$  in Theorem 1 – both upper and lower bounds – we study a fractional covering problem, formulated as a linear program (LP), that captures the  $\Sigma_3^2$ -circuit complexity up to  $\text{poly}(n)$  factors.

To our knowledge, LPs have not been widely employed in analysing depth-3 circuits. They are, however, routinely used to prove strong lower bounds in the related area of *communication complexity* [9]. Many such LP-based methods are catalogued by Jain and Klauck [6]. Moreover, Lee and Shraibman [10] give a monograph-length treatment on how to use LP duality to prove communication lower bounds. In one of the earliest examples, Karchmer, Kushilevitz, and Nisan [8] characterised nondeterministic communication complexity via a fractional covering problem. The formulation we use is a straightforward adaptation of this for depth-3 circuits. A similar formulation also appeared in the work of Hirahara [4] that connects depth-3 complexity with one-sided CNF approximations.

**Covering LP.** The size of a  $\Sigma_3^2$ -circuit is determined (up to  $O(n^2)$  factors) by the fanin of the top  $\vee$ -gate. Suppose a circuit with top-fanin  $m$  computes a function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ . We can view the circuit as expressing the set of 1-inputs  $f^{-1}(1)$  as a union of  $m$  sets,

$$f^{-1}(1) = \bigcup_{i \in [m]} \phi_i^{-1}(1), \tag{1}$$

where each  $\phi_i^{-1}(1)$  is the set of inputs accepted by a 2-CNF formula  $\phi_i$ . The least top-fanin needed to compute  $f$  is then captured by the optimal *integer solutions* to the following covering LP. In this LP, we assign a fractional weight  $w_\phi \in [0, 1]$  for each 2-CNF  $\phi$  that is *consistent* with  $f$ , meaning that  $\phi(x) \leq f(x)$  for every input  $x \in \{0, 1\}^n$ . We let  $\Phi$  denote the set of all 2-CNFs consistent with  $f$ .

$$\begin{array}{ll} \min & \sum_{\phi \in \Phi} w_\phi \\ \text{subject to} & \sum_{\phi \in \Phi} w_\phi \phi(x) \geq 1, \quad \forall x \in f^{-1}(1) \\ & w_\phi \in [0, 1], \quad \forall \phi \in \Phi \end{array} \tag{LP}$$

A classic result of Lovász [11] says that the integrality gap of a covering LP is small.

► **Lemma 2** (Lovász [11]). *Let  $\text{Opt}$  and  $\text{Opt}^{\mathbb{Z}}$  denote the value of (LP) optimised over fractional solutions ( $w_\phi \in [0, 1]$ ) and integral solutions ( $w_\phi \in \{0, 1\}$ ), respectively. Then*

$$\text{Opt} \leq \text{Opt}^{\mathbb{Z}} \leq O(n) \cdot \text{Opt}.$$

Consequently, to determine the  $\Sigma_3^2$ -complexity of  $f = \text{IP}_n$  we only need to solve the fractional (LP). We will use the (LP) in Section 2 to construct circuits for  $\text{IP}_n$  that witness the upper bound  $\alpha \leq 0.965\dots$

**Dual LP.** A common method to prove a depth-3 lower bound is to estimate the number of accepting inputs for any consistent CNF, say, by  $\max_{\phi \in \Phi} |\phi^{-1}(1)| \leq C$ , and then conclude that the top-fanin must be at least  $|f^{-1}(1)|/C$ . Such arguments are standard in the *top-down* circuit lower bound literature [3, 14, 12, 13, 5].

An important generalisation of this method is to first choose a hard distribution  $\mathcal{D}$  over the 1-inputs  $f^{-1}(1)$  and then measure the size of  $\phi^{-1}(1)$  relative to  $\mathcal{D}$ . If we can show  $\max_{\phi \in \Phi} \Pr_{x \sim \mathcal{D}}[\phi(x) = 1] \leq p$ , then the top-fanin must be at least  $1/p$ . Indeed, the following optimisation problem captures the best lower bound provable with this method.

$$\begin{aligned} & \max && 1/p \\ & \text{subject to} && \sum_{x \in f^{-1}(1)} \mathcal{D}(x) \phi(x) \leq p, && \forall \phi \in \Phi \\ & && \sum_{x \in f^{-1}(1)} \mathcal{D}(x) = 1, \\ & && \mathcal{D}(x) \in [0, 1], && \forall x \in f^{-1}(1) \end{aligned} \quad (\text{Dual LP})$$

This program is not written in standard LP format as we are seemingly optimising a nonlinear function. However, it is equivalent<sup>1</sup> to  $\max \sum_x A(x)$  s.t.  $\sum_x A(x) \phi(x) \leq 1$  and  $A(x) \geq 0$ , which is the canonical dual to (LP). Hence, by strong duality, we can always prove a tight lower bound (up to polynomial factors) on depth-3 complexity by finding the right hard distribution  $\mathcal{D}$ .

**Hard distribution for IP.** What hard distribution  $\mathcal{D}$  should we choose to prove a strong lower bound for  $\text{IP}_n$ ? If we choose  $\mathcal{D}$  to be the uniform distribution over  $\text{IP}_n^{-1}(1)$ , then prior work [1, Thm 28] showed that this only yields the bound  $\alpha \geq \log \frac{4}{3} = 0.415\dots$  If we choose  $\mathcal{D}$  by sampling a pair  $(x, 1^n)$  where  $x$  is uniform random in  $\{0, 1\}^n$ , then we have effectively reduced  $\text{IP}_n$  to  $n$ -bit parity and we obtain  $\alpha \geq 0.5$  [2], which is tight for parity.

To get our improved lower bound on  $\alpha$ , we analyse a more general distribution.

**(Section 3)** We consider a distribution where the  $2n$  input bits are *iid*, that is,  $\mathcal{D}$  is the binomial distribution with some parameter  $p \in (0, 1)$ . (Note that while  $\mathcal{D}$  is not supported on  $\text{IP}_n^{-1}(1)$  it does place a constant probability mass on it.) We prove a structure lemma for consistent 2-CNFs and characterise those that have the highest acceptance probability under  $\mathcal{D}$ . Optimising the choice of  $p$ , we will obtain  $\alpha \geq \log \frac{9}{5} = 0.847\dots$

<sup>1</sup> If  $\mathcal{D}, p$  is feasible for (Dual LP), then  $A(x) := \mathcal{D}(x)/p$  is feasible and has the same objective function value in the other program. In the other direction, set  $p := 1/\sum_y A(y)$  and  $\mathcal{D}(x) := p \cdot A(x)$ .

### 1.3 Discussion and open problems

The challenge in proving a better lower bound in Theorem 1 is that our techniques rely heavily on the hard distribution having independence between the  $n$  coordinates. One way we could try to improve the lower bound is to consider a slightly more general *coordinate-wise iid* distribution. That is, we choose a distribution  $\mu$  over one coordinate pair  $(x_i, y_i) \in \{0, 1\}^2$  and then define a product distribution by  $\mathcal{D} := \mu^n := \mu \times \cdots \times \mu$ . We carried out this approach (using computer-aided calculations) only to find out that we get no improvement this way: the hardest  $\mathcal{D}$  is still the bit-wise *iid* that we consider in Section 3. A candidate for the absolute hardest distribution (not necessarily coordinate-wise *iid*) is merely a *symmetric* distribution that is invariant under permuting the  $n$  coordinates. We leave it as an open problem to analyse such non-*iid* distributions.

Another open problem that could be amenable to an LP-based attack is to determine the  $\Sigma_3^k$ -circuit complexity of inner product in case  $k = 3$ , as was originally asked by Golovnev, Kulikov, and Williams [2]. The best lower bound known is  $2^{n/3}$  [14], and one could hope to show an improved lower bound even relative to an *iid* distribution. Here the obvious challenge is that 3-CNFs are notoriously much more difficult (even NP-hard) to analyse than 2-CNFs. Our overall approach in this paper is still applicable even for  $k > 2$ . Namely, one needs to “merely” prove an analogue of our structure lemma (Lemma 7) for  $k$ -CNFs.

## 2 Upper bound

In this section, we prove the upper bound  $\alpha \leq 0.965\dots$  as claimed in Theorem 1. The circuit will be constructed in two parts. To explain this, we denote, for an input  $(x, y) \in \{0, 1\}^{2n}$  and a 2-bit pattern  $s \in \{0, 1\}^2$ , the fraction of occurrences of this pattern by

$$p_s(x, y) := \frac{1}{n} |\{i \in [n] : (x_i, y_i) = s\}|.$$

We use one  $\Sigma_3^2$ -circuit to accept every input  $(x, y) \in \text{IP}_n^{-1}(1)$  with  $p_{11}(x, y) \leq p$  where  $p$  is a carefully chosen threshold, and another  $\Sigma_3^2$ -circuit to accept those inputs with  $p_{11}(x, y) \geq p$ .

The following two lemmas (proved in Sections 2.1 and 2.2) record the two types of circuits we will construct. To state these lemmas, recall that a circuit  $C$  is *consistent* with  $\text{IP}_n$  if  $C(x, y) \leq \text{IP}_n(x, y)$  for all inputs  $(x, y)$ . We let  $H(p) := -p \log p - (1-p) \log(1-p)$  denote the binary entropy function. Moreover, we let  $\mathbb{H}(X)$  denote the usual Shannon entropy of a random variable  $X$ . Finally, for  $p \in [0, 1]$ , we define a random variable  $X_p \in \{0, 1\}^2$  such that  $\Pr[X_p = 11] = p$  and  $\Pr[X_p = s] = (1-p)/3$  for  $s \in \{00, 01, 10\}$ .

► **Lemma 3.** *For every  $p \in [0, \frac{1}{2}]$  there exists a  $\Sigma_3^2$ -circuit of size  $2^{nH(p)+o(n)}$  that is consistent with  $\text{IP}_n$  and that accepts all  $(x, y) \in \text{IP}_n^{-1}(1)$  with  $p_{11}(x, y) \leq p$ .*

► **Lemma 4.** *For every  $p \in [\frac{1}{4}, 1]$  there exists a  $\Sigma_3^2$ -circuit of size  $2^{\frac{1}{2}n\mathbb{H}(X_p)+o(n)}$  that is consistent with  $\text{IP}_n$  and that accepts all  $(x, y) \in \text{IP}_n^{-1}(1)$  with  $p_{11}(x, y) \geq p$ .*

The final  $\Sigma_3^2$ -circuit for  $\text{IP}_n$  is the OR of the two  $\Sigma_3^2$ -circuits above. It is easy to see that using any constant  $p \in (\frac{1}{4}, \frac{1}{2})$  we get a circuit of size  $2^{\beta n}$  with  $\beta < 1$ . We can further optimise the choice of  $p$  by equating the two circuit size expressions, solving for  $p$  numerically (using any numerical computation software), which comes to  $p := 0.3909\dots$ , and then plugging this value of  $p$  into the size expressions to get a circuit of size  $2^{0.965\dots n+o(n)}$ , as desired.

It remains to prove Lemmas 3 and 4, which we do in the rest of this section.

### 2.1 Proof of Lemma 3

In this lemma we focus on finding efficient  $\Sigma_3^2$ -circuits accepting inputs  $(x, y) \in \text{IP}^{-1}(1)$  with a small value of  $p_{11}(x, y) \leq p \leq 1/2$ . Given a subset  $I \subseteq [n]$ , define the *brute-force CNF* by

$$\phi_{\text{BF}}^{(I)} := \bigwedge_{i \in I} (x_i \wedge y_i) \wedge \bigwedge_{i \in [n] \setminus I} (\neg x_i \vee \neg y_i).$$

Note that  $\phi_{\text{BF}}^{(I)}$  accepts an input  $(x, y)$  iff  $I$  equals the set of all  $i$  such that  $(x_i, y_i) = (1, 1)$ . Hence, to accept every input with  $p_{11}(x, y) \leq p$ , our  $\Sigma_3^2$ -circuit will consider all suitable  $I$ :

$$C := \bigvee_{\substack{I \subseteq [n] \\ |I| \leq pn \\ |I| \text{ odd}}} \phi_{\text{BF}}^{(I)}. \tag{2}$$

The size of  $C$  is at most  $\binom{n}{\leq pn} \cdot O(n)$  where  $\binom{n}{\leq pn} := \sum_{i=0}^{pn} \binom{n}{i}$  can be estimated from above via Stirling’s approximation by  $2^{nH(p)+o(n)}$  for all  $p \leq 1/2$ . Finally, it is clear from the construction that  $C$  is consistent with  $\text{IP}_n$ . This concludes the proof of Lemma 3. ◀

### 2.2 Proof of Lemma 4

In this lemma we focus on finding efficient  $\Sigma_3^2$ -circuits accepting inputs  $(x, y) \in \text{IP}_n^{-1}(1)$  with a large value of  $p_{11}(x, y) \geq p \geq 1/4$ . To illustrate our idea, we first construct a circuit for a simpler related function, and then explain how to modify it to get circuits for  $\text{IP}_n$ .

**Simple warm-up circuit.** We first describe a circuit that computes the following partial function (which is consistent with  $\neg \text{IP}_n$ , but we will address this later):

$$f_n(x, y) := \begin{cases} 0 & \text{if } n \cdot p_{11}(x, y) \text{ is odd,} \\ 1 & \text{if } n \cdot p_s(x, y) \text{ is even for all } s \in \{0, 1\}^2, \text{ and } p_{11}(x, y) \geq p, \\ * & \text{otherwise.} \end{cases}$$

The interesting case here is when  $n$  is even, as otherwise  $f_n(x, y) \in \{0, *\}$  for all  $(x, y)$ . Let  $M \subseteq \binom{[n]}{2} := \{e \subseteq [n] : |e| = 2\}$  be a *perfect matching* of  $[n]$  (that is, partition of  $[n]$  into pairs). We define the *collision CNF* associated with  $M$  by

$$\phi_{\text{Coll}}^{(M)} := \bigwedge_{\{i, j\} \in M} (x_i \leftrightarrow x_j) \wedge (y_i \leftrightarrow y_j).$$

This is a 2-CNF since we can write an equivalence as  $a \leftrightarrow b \equiv (a \vee \neg b) \wedge (\neg a \vee b)$ . Note that a collision CNF accepts iff for every pair  $\{i, j\} \in M$  we have  $(x_i, y_i) = (x_j, y_j)$ . Hence it only accepts inputs where  $n \cdot p_s(x, y)$  is even for all  $s \in \{0, 1\}^2$ . Thus  $\phi_{\text{Coll}}^{(M)}$  is consistent with  $f_n$ .

To construct a  $\Sigma_3^2$ -circuit for  $f_n$ , it is enough, as discussed in Section 1.2, to design a feasible solution to the (LP) associated with  $f_n$ . (We note that the (LP) formulation works equally well for partial functions.) To this end, we calculate in the following claim (proved in Section 2.3) the probability that a *random* collision CNF accepts a fixed 1-input of  $f_n$ .

▷ **Claim 5.** Let  $(x, y) \in f_n^{-1}(1)$ . For a uniformly chosen perfect matching  $M \subseteq \binom{[n]}{2}$ ,

$$\Pr_M [\phi_{\text{Coll}}^{(M)}(x, y) = 1] \geq 2^{-\frac{1}{2}n\mathbb{H}(X_p)-o(n)} =: L(p).$$

## 51:6 Depth-3 Circuits for Inner Product

We now construct a feasible solution to (LP) for  $f_n$ . Let  $\Phi_{\text{Coll}}$  denote the set of all collision CNFs, one for each perfect matching of  $[n]$ . Consider the weight assignment corresponding to the uniform distribution over  $\Phi_{\text{Coll}}$ ; namely, set  $w_\phi := 1/|\Phi_{\text{Coll}}|$  for every  $\phi \in \Phi_{\text{Coll}}$  and  $w_\phi := 0$  for all the rest. Note that the objective function value is  $\sum_\phi w_\phi = 1$ . However, the assignment may not be feasible: for a covering constraint indexed by  $(x, y) \in f_n^{-1}(1)$ , we are only guaranteed a weak lower bound (much smaller than 1):

$$\sum_\phi w_\phi \phi(x, y) = \Pr_M [\phi_{\text{Coll}}^{(M)}(x, y) = 1] \geq L(p).$$

We can, however, transform this weight assignment into a feasible one by scaling all the weights up by a factor of  $1/L(p)$  (and truncating any resulting weight  $> 1$  to 1). In the scaled assignment, the objective function value is at most  $1/L(p)$ . We conclude (using Lemma 2) that  $f_n$  has a circuit of size  $O(n)/L(p) = 2^{\frac{1}{2}n\mathbb{H}(X_p)+o(n)}$ .

It remains to explain how a circuit of this size can also be constructed for  $\text{IP}_n$ .

**Actual circuit for  $\text{IP}$ .** To prove Lemma 4, we would like to use the  $\Sigma_3^2$ -circuit we constructed above for  $f_n$  to design a circuit for the partial function

$$\text{IP}_n^{(p)}(x, y) := \begin{cases} 0 & \text{if } n \cdot p_{11}(x, y) \text{ is even,} \\ 1 & \text{if } n \cdot p_{11}(x, y) \text{ is odd, and } p_{11}(x, y) \geq p, \\ * & \text{otherwise.} \end{cases}$$

Consider the following nondeterministic algorithm for  $\text{IP}_n^{(p)}$ . On input  $(x, y) \in \{0, 1\}^{2n}$ :

1. Nondeterministically guess a subset  $S \subseteq \{0, 1\}^2$  where  $11 \in S$ . The intention is that patterns in  $S$  should appear in  $(x, y)$  an odd number of times.
2. For each  $s \in S$ , guess a coordinate  $i(s) \in [n]$ .
3. For each  $s \in S$ , check that  $(x_{i(s)}, y_{i(s)}) = s$ . If not, reject.
4. Output the same as the function  $f_{n-|S|}$  on input  $(x_i, y_i)_{i \in [n] \setminus i(S)}$ .

It is straightforward to check that this computes  $\text{IP}_n^{(p)}$  correctly. (A minor technical detail is that when computing  $f_{n-|S|}$ , the  $p_{11}$  value may slightly drop because we remove one occurrence of the 11-pattern. However, this is not really a problem since the slight drop will not affect the asymptotics of the circuit size.) The question remains: How can it be implemented as a  $\Sigma_3^2$ -circuit? We do it as follows. Consider any guess outcome  $O := (S, (i(s))_{s \in S})$ . We can modify the circuit  $C$  for  $f_{n-|S|}$  (applied to the input bits  $(x_i, y_i)_{i \in [n] \setminus i(S)}$ ) to perform the check in Item 3 by adding to each 2-CNF in  $C$  the singleton terms  $(x_{i(s)} = s_1)$  and  $(y_{i(s)} = s_2)$  for all  $s = (s_1, s_2) \in S$ . Call the resulting circuit  $C_O$ . Our final  $\Sigma_3^2$ -circuit computes the OR of all circuits  $C_O$ . Since there are only  $O(n^4)$  many different guess outcomes, the resulting circuit is only a factor  $O(n^4)$  larger than our circuit for  $f_n$ . This concludes the proof of Lemma 4.  $\blacktriangleleft$

### 2.3 Proof of Claim 5

*Proof.* Write  $n!! := \prod_{i=0}^{\lfloor n/2 \rfloor} (n - 2i)$  for the double factorial. The number of perfect matchings on  $[n]$  is well-known to be given by  $(n - 1)!!$  when  $n$  is even. Therefore,  $(np_s - 1)!!$  gives the number of ways to match the coordinates with pattern  $s$ . We have

$$\Pr_M [\phi_{\text{Coll}}^{(M)}(x, y) = 1] = \frac{\prod_{s \in \{0,1\}^2} (np_s - 1)!!}{(n - 1)!!}. \quad (3)$$

Taking logarithms and using Stirling's approximation ( $\log n! = \frac{1}{2}n \log n - \frac{1}{2}n \pm o(n)$ ) we get

$$\begin{aligned} \log \Pr_M [\phi_{\text{Coll}}^{(M)}(x, y) = 1] &= \frac{1}{2} \sum_s np_s \log(np_s) - \frac{1}{2}n \log n \pm o(n) \\ &= \frac{1}{2}n \cdot \sum_s p_s \log p_s \pm o(n) \\ &= -\frac{1}{2}n \cdot \mathbb{H}(P) \pm o(n). \end{aligned}$$

Here  $P \in \{0, 1\}^2$  is the random variable defined by  $\Pr[P = s] = p_s$ . We ask: which random variable  $X \in \{0, 1\}^2$  maximises the entropy  $\mathbb{H}(X)$  subject to the constraint  $\Pr[X = 11] = p^*$ ? By the concavity of  $\mathbb{H}$  and symmetry (we can relabel outcomes without affecting the entropy), it is the random variable  $X_{p^*}$  such that

$$\Pr[X_{p^*} = 11] = p^*, \quad \Pr[X_{p^*} = 00] = \Pr[X_{p^*} = 10] = \Pr[X_{p^*} = 01] = (1 - p^*)/3.$$

The univariate map  $p^* \mapsto \mathbb{H}(X_{p^*})$  is also concave. It is maximised at  $p^* = 1/4$  (when  $X_{p^*}$  is uniform), and decreasing for  $p^* > 1/4$ . This means that, since  $1/4 \leq p \leq p_{11}$ , we have that  $\mathbb{H}(X_p) \geq \mathbb{H}(X_{p_{11}}) \geq \mathbb{H}(P)$ . Hence we obtain the claimed lower bound:

$$\log \Pr_M [\phi_{\text{Coll}}^{(M)}(x, y) = 1] \geq -\frac{1}{2}n \cdot \mathbb{H}(X_p) - o(n). \quad \triangleleft$$

### 3 Lower bound

In this section, we prove the lower bound  $\alpha \geq \log \frac{9}{5} = 0.847\dots$  as claimed in Theorem 1. We will follow the Dual LP strategy discussed in Section 1.2. Namely, we will choose a hard distribution over  $\text{IP}_n^{-1}(1)$  and then bound the acceptance probability of any 2-CNF consistent with  $\text{IP}_n$ . In fact, it is convenient to prove a slightly stronger statement and bound the acceptance probability of any 2-CNF consistent with  $\text{IP}_n$  or  $\neg\text{IP}_n$ . Indeed, we let  $\Phi_n$  denote the set of 2-CNFs consistent with  $\text{IP}_n$  or  $\neg\text{IP}_n$ .

**Hard distribution.** As the hard distribution, we consider the binomial distribution  $\mathcal{D}_p$  with parameter  $p \in (0, 1)$ , whose choice we will optimise later. That is,  $(X, Y) \sim \mathcal{D}_p$  is such that all bits are *iid*: they are independent and have identical distribution,  $\Pr[X_i = 1] = \Pr[Y_i = 1] = p$ . Note that  $\mathcal{D}_p$  is not in fact supported on  $\text{IP}_n^{-1}(1)$ , but it still places  $\Omega(1)$  probability mass on this set. Consequently, any  $\Sigma_3^2$ -circuit will have to cover  $\Omega(1)$  fraction of  $\mathcal{D}_p$  with its CNFs, so we can still use  $\mathcal{D}_p$  for proving a lower bound.

**Max-probability formulas.** Our goal will be to argue that any  $\phi \in \Phi_n$  has an acceptance probability dominated by one of two “maximum probability formulas” (*max-formulas*, for short). Namely, our first max-formula is the collision CNF (used in our upper bound in Section 2.2 and specialised here for one matching) and our second formula has a NAND constraint for each coordinate.

$$\text{1st max-formula: } \phi_{\text{Coll}}^{(n)} := \bigwedge_{i \in [n/2]} (x_{2i-1} \leftrightarrow x_{2i}) \wedge (y_{2i-1} \leftrightarrow y_{2i}) \quad \text{where } n \text{ is even,}$$

$$\text{2nd max-formula: } \phi_{\text{Nand}}^{(n)} := \bigwedge_{i \in [n]} (\neg x_i \vee \neg y_i).$$

Writing  $\Pr_{\mathcal{D}}[\phi] := \Pr_{(X,Y) \sim \mathcal{D}}[\phi(X, Y) = 1]$  for short, it is straightforward to see that

$$\Pr_{\mathcal{D}_p}[\phi_{\text{Coll}}^{(n)}] = (p^2 + (1-p)^2)^n \quad \text{and} \quad \Pr_{\mathcal{D}_p}[\phi_{\text{Nand}}^{(n)}] = (1-p^2)^n. \quad (4)$$

Equating these probabilities and solving for  $p$  yields our optimal choice  $p = p^* := 2/3$ . The following lemma states that these formulas have, for  $p = p^*$ , higher acceptance probabilities than any 2-CNF consistent with  $\text{IP}_n$  (or  $\neg\text{IP}_n$ ).

► **Lemma 6.**  $\Pr_{\mathcal{D}_{p^*}}[\phi] \leq M_{p^*}^{(n)} := \max \{ \Pr_{\mathcal{D}_{p^*}}[\phi_{\text{Coll}}^{(n)}], \Pr_{\mathcal{D}_{p^*}}[\phi_{\text{Nand}}^{(n)}] \}$  for any  $\phi \in \Phi_n$ .

Using Lemma 6 it is easy to complete our proof. We get for any  $\phi \in \Phi_n$ ,

$$\Pr_{\mathcal{D}_{p^*}}[\phi] \leq M_{2/3}^{(n)} = (1 - (2/3)^2)^n = 2^{-\log(9/5) \cdot n} = 2^{-0.847\dots n}.$$

As per Dual LP, the reciprocal of this probability yields the claimed circuit lower bound.

It remains to prove Lemma 6, which we do in the rest of this section.

### 3.1 Proof of Lemma 6

To help us analyse acceptance probabilities, we first prove a *structure lemma* for any consistent 2-CNF formula  $\phi$ . This lemma will find some “structured” formula  $\phi'$  that is (semantically) implied by  $\phi$ , denoted  $\phi \models \phi'$  (that is,  $\phi^{-1}(1) \subseteq \phi'^{-1}(1)$ ). The formula  $\phi'$  comes from a set of structured formulas  $\mathcal{S}_n$ , which we will carefully define in Section 3.2. For now, it suffices for us to know that each structured formula  $\phi^{(k)} \in \mathcal{S}_n$  only mentions variables among  $(x_i, y_i)_{i \in I}$  for some subset  $I \subseteq [n]$  of size  $|I| = k$  (possibly  $k \ll n$ ).

► **Lemma 7 (Structure lemma).** *Let  $\phi \in \Phi_n$  be a 2-CNF consistent with  $\text{IP}_n$  or  $\neg\text{IP}_n$ . Then there is some structured 2-CNF formula  $\phi^{(k)} \in \mathcal{S}_n$  such that  $\phi \models \phi^{(k)}$ .*

We can now formulate a “localised” version of Lemma 6 for structured formulas. It allows us to locally compare the acceptance probability of  $\phi^{(k)}$  with our max-formulas  $\phi_{\text{Coll}}^{(k)}$  and  $\phi_{\text{Nand}}^{(k)}$ , now defined naturally over  $k$  many coordinates. Our original definition of  $\phi_{\text{Coll}}^{(n)}$  was actually assuming  $n$  is even. For technical convenience, for odd  $n$ , we define  $\phi_{\text{Coll}}^{(n)} := \phi_{\text{Coll}}^{(n-1)} \wedge (x_n \leftrightarrow y_n)$ . The bounds in (4) continue to hold for this extended definition.

► **Lemma 8.**  $\Pr_{\mathcal{D}_{p^*}}[\phi^{(k)}] \leq M_{p^*}^{(k)} := \max \{ \Pr_{\mathcal{D}_{p^*}}[\phi_{\text{Coll}}^{(k)}], \Pr_{\mathcal{D}_{p^*}}[\phi_{\text{Nand}}^{(k)}] \}$  for any  $\phi^{(k)} \in \mathcal{S}_n$ .

Using Lemmas 7 and 8 (proved below) it is now easy to prove Lemma 6:

**Proof of Lemma 6.** We prove this by induction on  $n$ . The base case  $n = 0$  is vacuously true under the convention that  $\Pr[\phi_{\perp}] = M_{p^*}^{(0)} = 1$  for the empty formula  $\phi_{\perp}$ . For the inductive case  $n \geq 1$ , let  $\phi \in \Phi_n$  be arbitrary. Apply the structure lemma (Lemma 7) to find some  $\phi^{(k)} \in \mathcal{S}_n$  such that  $\phi \models \phi^{(k)}$ . Suppose for notational convenience  $\phi^{(k)}$  involves the first  $k \leq n$  coordinates. Let  $\mathcal{D}_{p^*}^{(k)}$  denote our binomial distribution over  $\{0, 1\}^{2k}$ . Then

$$\Pr_{\mathcal{D}_{p^*}^{(n)}}[\phi] \leq \sum_{\substack{a, b \in \{0, 1\}^k \\ \phi^{(k)}(a, b) = 1}} \Pr_{\mathcal{D}_{p^*}^{(k)}}[(a, b)] \cdot \Pr_{\mathcal{D}_{p^*}^{(n-k)}}[\phi|_{a, b}],$$

where  $\phi|_{a, b}$  is obtained from  $\phi$  by restricting the first  $k$  coordinates to values  $(a, b)$ . We note that restricting values in a formula consistent with  $\text{IP}_n$  might yield a formula consistent with  $\neg\text{IP}_{n-k}$  (and vice versa). We now apply Lemma 6 inductively for  $\phi|_{a, b}$  to conclude

$$\Pr_{\mathcal{D}_{p^*}^{(n)}}[\phi] \leq M_{p^*}^{(n-k)} \cdot \sum_{a, b} \Pr_{\mathcal{D}_{p^*}^{(k)}}[(a, b)] = M_{p^*}^{(n-k)} \cdot \Pr_{\mathcal{D}_{p^*}^{(k)}}[\phi^{(k)}] \leq M_{p^*}^{(n-k)} M_{p^*}^{(k)} = M_{p^*}^{(n)},$$

where the last inequality is Lemma 8 and the final equality follows from (4). ◀

The rest of this section is organised as follows. We first define our family of structured formulas  $\mathcal{S}_n$  in Section 3.2. Then we will prove Lemmas 7 and 8 in Sections 3.3 and 3.4.

### 3.2 Structured formulas in $\mathcal{S}_n$

We now proceed to define our family of structured formulas  $\mathcal{S}_n$ . The family will be closed under *symmetries of  $\text{IP}_n$* , as we now explain. The value of inner product  $\text{IP}_n$  remains unchanged if we permute its  $n$  coordinates (e.g., swap  $(x_i, y_i)$  with  $(x_j, y_j)$ ) or transpose two variables inside a single coordinate (i.e., swap  $(x_i, y_i)$  with  $(y_i, x_i)$ ). These permutations generate the group of symmetries of  $\text{IP}_n$ . We say that two CNFs  $\phi$  and  $\phi'$  are *isomorphic* if there is some symmetry  $\pi$  of  $\text{IP}_n$  that, when applied to  $\phi$  to yield  $\phi^\pi$ , makes the two formulas equivalent,  $\phi^\pi \equiv \phi'$ , that is, to accept the same set of inputs.

**Structured family  $\mathcal{S}_n$ .** To define  $\mathcal{S}_n$ , we list below its various members. Each formula is defined over some  $k \leq n$  pairs of literals  $L_k := \{\tilde{x}_1, \tilde{y}_1, \dots, \tilde{x}_k, \tilde{y}_k\}$  where  $\tilde{x}_i \in \{x_i, \neg x_i\}$  and  $\tilde{y}_i \in \{y_i, \neg y_i\}$ . Each item defines a type of 2-CNF with the understanding that each of its isomorphic copies is included in  $\mathcal{S}_n$ . See Figure 1 for illustrations. We start with two cases corresponding to our max-formulas.

1. **Nand** is  $\phi_{\text{Nand}}^{(1)} = (\neg x_1 \vee \neg y_1)$ . This is case  $n = 1$  of our second max-formula.
2. **Matching** is defined relative to a perfect matching  $M \subseteq \binom{L_k}{2}$  by

$$\phi_{\text{Match}}^{(k)} = \bigwedge_{\{\ell, \ell'\} \in M} (\ell \leftrightarrow \ell').$$

Note that this is a generalisation of our first max-formula (where the literals are positive and the perfect matching is more structured).

The final type of formula will be an extension of the following “ladder” formula

$$\psi^{(k)} = \bigwedge_{i=1}^{k-1} (\tilde{y}_i \leftrightarrow \tilde{x}_{i+1}) \quad \text{where } k \geq 2.$$

We also define two types of “terminal” constraints (where  $\ell, \ell' \in L_k$ ),

$$\begin{aligned} \text{Back-edge:} \quad \psi_{\text{B}}^{\text{left}} &= (\tilde{x}_1 \leftrightarrow \ell), & \psi_{\text{B}}^{\text{right}} &= (\tilde{y}_k \leftrightarrow \ell') \quad \text{where } \ell \neq \tilde{x}_1 \text{ and } \ell' \neq \tilde{y}_k, \\ \text{Positive:} \quad \psi_{\text{P}}^{\text{left}} &= (y_1 \rightarrow x_1), & \psi_{\text{P}}^{\text{right}} &= (x_k \rightarrow y_k). \end{aligned}$$

3. **Ladder** is given by choosing terminal types  $(L, R) \in \{\text{B}, \text{P}\}^2$  and defining

$$\phi_{LR}^{(k)} = \psi^{(k)} \wedge \psi_L^{\text{left}} \wedge \psi_R^{\text{right}}.$$

► **Remark 9.** It can be shown that this list is *irredundant* in that, for each type, there is a formula  $\phi^{(k)} \in \mathcal{S}_n$  of that type and  $\phi \in \Phi_n$  such that  $\phi \models \phi^{(k)}$  but  $\phi \not\models \phi'$  for every  $\phi' \in \mathcal{S}_n$  of type different than  $\phi^{(k)}$ . This means that we need all three types for our structure lemma.

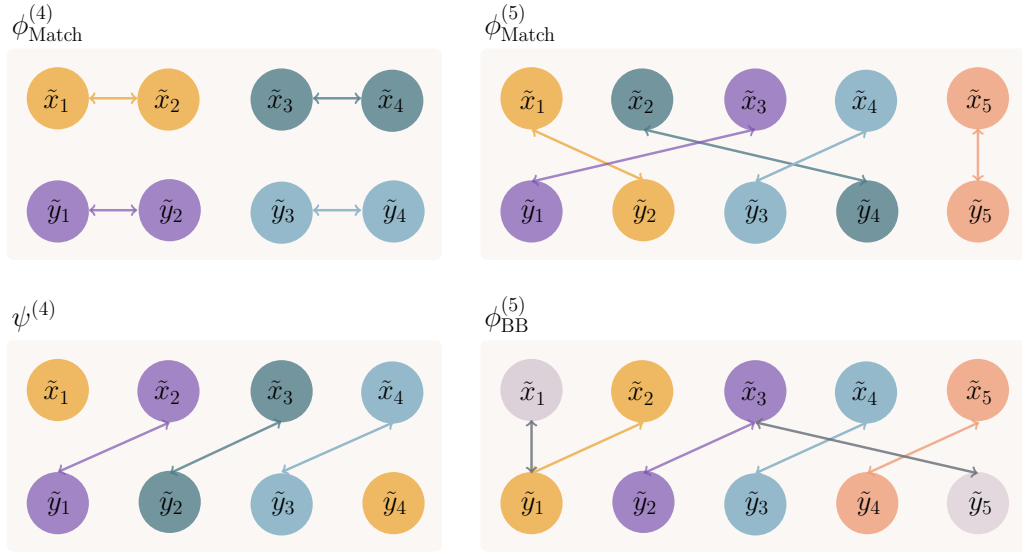

### 3.3 Proof of Structure lemma (Lemma 7)

In the proof of Lemma 7, we use the standard notion of an implication graph of a 2-CNF.

**Implication graphs.** Given a 2-CNF  $\phi$  over  $k$  variables  $\{x_1, y_1, \dots, x_k, y_k\}$ , its *implication graph*  $G_\phi = (V, E)$  is the directed graph given by

$$\begin{aligned} V &:= \{x_1, \neg x_1, y_1, \neg y_1, \dots, x_k, \neg x_k, y_k, \neg y_k\}, \\ E &:= \{(u, v) \in V^2 : u \neq v \text{ and } \phi \models (u \rightarrow v)\}. \end{aligned}$$

## 51:10 Depth-3 Circuits for Inner Product

■ **Figure 1** Examples of Matching and Ladder CNFs.

We note that implication graphs are sometimes defined more syntactically: For each clause  $(u \vee v)$  of  $\phi$ , include the edges  $(\neg u, v)$  and  $(\neg v, u)$  in  $G_\phi$ , and moreover, for each singleton clause  $(u)$  of  $\phi$ , include the edges  $(v, u)$  in  $G_\phi$  for all  $v$ . Taking the transitive closure (add edge  $(u, v)$  if there is a directed path from  $u$  to  $v$ ) of this graph yields the graph in our (semantic) definition above.

We call a strongly connected component of  $G_\phi$  a *strong-component* for short. We say that a variable  $x_i$  is fixed by  $\phi$  if there is some  $b \in \{0, 1\}$  such that for every  $(x, y) \in \phi^{-1}(1)$  we have  $x_i = b$ . The following lemma will be used several times.

► **Lemma 10.** *Let  $\phi \in \Phi_n$  and suppose  $y_1$  lies in a strong-component of size 1 in  $G_\phi$ . Then we have  $\phi \models x_1 \rightarrow \tilde{y}_1$  for some  $\tilde{y}_1 \in \{y_1, \neg y_1\}$ .*

**Proof.** We may assume that  $y_1$  is not fixed by  $\phi$ , as otherwise the lemma is trivially true. We assume that  $\phi \not\models x_1 \rightarrow \neg y_1$  and hope to show  $\phi \models x_1 \rightarrow y_1$ . Thus, there is some satisfying assignment  $(x', y') \in \phi^{-1}(1)$  such that  $(x'_1, y'_1) = (1, 1)$ . Denote by  $N_{\text{in}} \subseteq V$  the in-neighbours of  $y_1$ , that is, all the literals from which there exists an edge (equivalently, directed path, as  $G_\phi$  is transitively closed) to  $y_1$ . Note that  $\{\ell, \neg \ell\} \not\subseteq N_{\text{in}}$  for every literal  $\ell$ , as otherwise one of  $\ell$  or  $\neg \ell$  would always be set to 1, forcing  $y_1$  to always be 1, contradicting that  $y_1$  is not fixed. Modify  $(x', y')$  by setting literals in  $N_{\text{in}}$  to 0. By the properties listed above, it follows that the new assignment, call it  $(x'', y'')$ , still satisfies  $\phi$ . Moreover,  $(x'', y'')$  has the property that we may flip the value of all the literals in the strong-component of  $y_1$  – which is just  $y_1$  itself – and still remain a satisfying assignment. Since we can flip  $y_1$  in isolation, we must have that  $x''_1 = 0$  (otherwise we would change the parity of the 11 pattern, which contradicts  $\phi \in \Phi_n$ ). But since  $x'_1 = 1$  we must have that  $x_1 \in N_{\text{in}}$ , meaning that  $(x_1, y_1)$  is an edge, and hence  $\phi \models x_1 \rightarrow y_1$ , as desired. ◀

We now proceed to prove Lemma 7 in two cases by considering  $G_\phi$  for  $\phi \in \Phi_n$ .

**Case 1.** *Every strong-component is of size 1.* Applying Lemma 10 twice, the second time with roles of  $x_1$  and  $y_1$  swapped, we learn that  $\phi \models x_1 \rightarrow \tilde{y}_1$  and  $\phi \models y_1 \rightarrow \tilde{x}_1$ . If  $\phi \models x_1 \rightarrow \neg y_1$  or  $\phi \models y_1 \rightarrow \neg x_1$  holds then we have  $\phi \models \phi_{\text{Nand}}^{(1)}$ , as desired. In the remaining case, both  $\phi \models x_1 \rightarrow y_1$  and  $\phi \models y_1 \rightarrow x_1$  hold, which implies  $\phi \models \phi_{\text{Match}}^{(1)}$ .

**Case 2.** *There exists a strong-component of size at least 2.* Suppose by symmetry that  $y_1$  lies in a strong-component of size at least 2. If  $y_1$  is bidirectionally connected to  $\tilde{x}_1$ , that is,  $\phi \models (y_1 \leftrightarrow \tilde{x}_1)$ , then this means that  $\phi \models \phi_{\text{Match}}^{(1)}$  and we are done.

Assume henceforth that  $y_1$  is bidirectionally connected to some literal other than  $\tilde{x}_1$ , say by symmetry  $y_1 \leftrightarrow \tilde{x}_2$ . Consider  $y_2$ : is it bidirectionally connected to a literal in coordinate greater than 2? If yes, say by symmetry  $y_2 \leftrightarrow \tilde{x}_3$ . Consider  $y_3$ , etc. By this “unravelling” process, we are exposing the bidirectional edges of a ladder formula  $\psi^{(k)}$ . This process must eventually end at step  $k \leq n$  in one of the following two cases.

- **Subcase 2-1:**  $y_k$  is bidirectionally connected to some literal  $\ell'$  in coordinate  $\leq k$ . Here we have  $\phi \models (y_k \leftrightarrow \ell') = \psi_{\text{B}}^{\text{right}}$ .
- **Subcase 2-2:**  $y_k$  lies in a singleton strong-component. In this case, we apply Lemma 10 to learn that  $\phi \models x_k \rightarrow \tilde{y}_k$ . If  $\phi \models x_k \rightarrow \neg y_k$ , then we would have found a copy of  $\phi_{\text{Nand}}^{(1)}$  in coordinate  $k$  and we are done. Otherwise  $\phi \models x_k \rightarrow y_k$ , which means  $\phi \models \psi_{\text{P}}^{\text{right}}$ .

That is, in both cases (if we did not outright prove the lemma) we found either  $\phi \models \psi_{\text{B}}^{\text{right}}$  or  $\phi \models \psi_{\text{P}}^{\text{right}}$ . By a similar argument, we can start unravelling edges starting at  $x_1$  to find either  $\phi \models \psi_{\text{B}}^{\text{left}}$  or  $\phi \models \psi_{\text{P}}^{\text{left}}$ . This will allow us to terminate the left side of the ladder, which completes the proof that  $\phi \models \phi_{\text{LR}}^{(k)}$ .

### 3.4 Proof of Lemma 8

We show the inequalities for every  $\phi \in \mathcal{S}_n$ .

- $\phi_{\text{Nand}}^{(1)}$ : This is true by definition of  $M_p^{(1)}$ .
- $\phi_{\text{Match}}^{(k)}$ : First note that the structure of the perfect matching for  $\phi_{\text{Match}}^{(k)}$  will not change the acceptance probability because all input bits are *iid*. Moreover, when both  $\ell$  and  $\ell'$  are positive,  $\Pr[\ell \leftrightarrow \ell'] = p^2 + (1-p)^2$ ; otherwise,  $\Pr[\ell \leftrightarrow \ell'] = \max\{2p(1-p), p^2 + (1-p)^2\} \leq p^2 + (1-p)^2$  for all  $p \in [0, 1]$ . Therefore, we have that  $\Pr_{\mathcal{D}_p}[\phi_{\text{Match}}^{(k)}] \leq \Pr_{\mathcal{D}_p}[\phi_{\text{Coll}}^{(k)}]$ .
- $\phi_{\text{BB}}^{(k)}$ : We show in the above that  $\Pr[\ell \leftrightarrow \ell'] \leq p^2 + (1-p)^2$  for any literals  $\ell$  and  $\ell'$ ; we can similarly show that, for any literals  $\ell, \ell'$  and  $\ell''$ ,  $\Pr[\ell \leftrightarrow \ell', \ell \leftrightarrow \ell''] \leq p^3 + (1-p)^3$ . Replacing all literals in  $\phi_{\text{BB}}^{(k)}$  by their positive analogues to get a new CNF  $\phi$ , we have that  $\Pr_{\mathcal{D}_p}[\phi_{\text{BB}}^{(k)}] \leq \Pr_{\mathcal{D}_p}[\phi]$ . Let  $M$  be the perfect matching associated with  $\phi$ . Define  $M' := M \cup \{(x_1, y_k)\}$ . Observe that  $M'$  is a perfect matching for all  $2k$  literals. Let  $\phi'$  be the matching CNF constructed from  $M'$ . Let  $P$  be the acceptance probability of  $\phi$ . We know that  $\Pr_{\mathcal{D}_p}[\phi'] = P \cdot \frac{[(1-p)^2 + p^2]^3}{[(1-p)^3 + p^3]^2} \geq P$  since  $\frac{[(1-p)^2 + p^2]^3}{[(1-p)^3 + p^3]^2} \geq 1$  for  $p \in [0, 1]$ .
- $\phi_{\text{PP}}^{(k)}$ : Similarly, we can replace all literals in  $\phi_{\text{PP}}^{(k)}$  with their positive analogues and get  $\phi$ . Let  $M$  be the perfect matching associated with  $\phi$ . Define  $M' := M \cup \{(x_1, y_k)\}$ . Observe that  $M'$  is a perfect matching for all  $2k$  literals. Let  $\phi'$  be the matching CNF constructed from  $M'$ . Let  $P$  be the acceptance probability of  $\phi$ . If  $k = 2$  then we have that  $P = (1-p)^2 + p^4 = [(1-p)^2 + p^2]^2 = \Pr_{\mathcal{D}_p}[\phi']$  for  $p = \frac{2}{3}$ . If  $k > 2$ , we know that  $\Pr_{\mathcal{D}_p}[\phi'] = P \cdot \frac{[(1-p)^2 + p^2]^3}{[(1-p)^2 + p^3]^2} > P$  since  $\frac{[(1-p)^2 + p^2]^3}{[(1-p)^2 + p^3]^2} > 1$  for  $p = \frac{2}{3}$ .
- $\phi_{\text{BP}}^{(k)}$ : As we have seen before, we can replace all literals in  $\phi_{\text{BP}}^{(k)}$  with their positive analogues and get  $\phi$ . Let  $M$  be the perfect matching associated with  $\phi$ . Define  $M' := M \cup \{(x_1, y_k)\}$ . Observe that  $M'$  is a perfect matching for all  $2k$  literals. Let  $\phi'$  be the

matching CNF constructed from  $M'$ . Let  $P$  be the acceptance probability of  $\phi$ . If  $k = 2$  then we have that  $P = (1 - p)^3 + p^4 < [(1 - p)^2 + p^2]^2 = \Pr_{\mathcal{D}_p}[\phi']$  for  $p = \frac{2}{3}$ . If  $k > 2$ , we know that  $\Pr_{\mathcal{D}_p}[\phi'] = P \cdot \frac{((1-p)^2+p^2)^3}{((1-p)^2+p^3)[(1-p)^3+p^3]} > P$  since  $\frac{((1-p)^2+p^2)^3}{((1-p)^2+p^3)[(1-p)^3+p^3]} > 1$  for  $p = \frac{2}{3}$ .

## Abstract

---

This paper introduces a generic framework that provides sufficient conditions for guaranteeing polynomial-time decidability of fixed-negation fragments of first-order theories that adhere to certain fixed-parameter tractability requirements. It enables deciding sentences of such theories with arbitrary existential quantification, conjunction and a fixed number of negation symbols in polynomial time. It was recently shown by Nguyen and Pak [*SIAM J. Comput.* 51(2): 1–31 (2022)] that an even more restricted such fragment of Presburger arithmetic (the first-order theory of the integers with addition and order) is NP-hard. In contrast, by application of our framework, we show that the fixed negation fragment of weak Presburger arithmetic, which drops the order relation from Presburger arithmetic in favour of equality, is decidable in polynomial time.

## 1 Introduction

It is well-known that even the simplest first-order theories are computationally difficult to decide [12]. In particular, it follows from a result of Stockmeyer that every theory with a non-trivial predicate such as equality is PSPACE-hard to decide [24]. Even when restricting to existential fragments or fragments with a fixed number of quantifier alternations, deciding such fragments is NP-hard at best. There are two further kinds of restrictions that may lead to tractability. First, restricting the Boolean structure of the matrix of formulae in prenex form yields tractable fragments of, e.g., the Boolean satisfiability problem. For instance, the Horn and XOR-fragments of propositional logic are decidable in polynomial time, and this even applies to quantified Boolean Horn formulae, see e.g. [7]. Second, restricting the number of variables can also lead to tractable fragments of a first-order theory, especially for structures over infinite domains such as Presburger arithmetic, the first-order theory of the structure  $(\mathbb{Z}, 0, 1, +, \leq)$ . While the existential fragment of Presburger arithmetic is NP-complete in general [5, 25], it becomes polynomial-time decidable when additionally fixing the number of variables [22]; this is a consequence of polynomial-time decidability of integer programming when the dimension is fixed [18]. Already when moving to an  $\exists\forall$  quantifier prefix, Presburger arithmetic becomes NP-hard [23]. On the first sight, this result seems to preclude any possibility of further restrictions that may lead to tractable fragments of

Presburger arithmetic. However, another tractable fragment was identified in the context of investigating the complexity of the classical *Frobenius problem*. Given positive integers  $a_1, \dots, a_n \in \mathbb{N}$ , this problem is to determine the largest integer that cannot be obtained as a non-negative linear combination of the  $a_i$ , which is called the *Frobenius number*. For any fixed  $n > 0$ , deciding whether the Frobenius number exceeds a given threshold can be reduced to the so-called *short fragment* of Presburger arithmetic, a highly restricted fragment in which everything, the number of atomic formulae and the number of variables (and *a fortiori* the number of quantifier alternations), is fixed – except for the coefficients of variables appearing in linear terms of atomic inequalities. Kannan [15] showed that the  $\forall^k \exists^\ell$ -fragment of short Presburger arithmetic is decidable in polynomial time for all fixed  $k, \ell$ , which implies that the decision version of the Frobenius problem is in polynomial time for fixed  $n$ . However, in a recent breakthrough, Nguyen and Pak showed that there are fixed  $k, \ell, m$  such that the  $\exists^k \forall^\ell \exists^m$ -fragment of short Presburger arithmetic is NP-hard, and adding further (fixed) quantifier alternations allows the logic to climb the polynomial hierarchy [20].

The main contribution of this paper is to develop an algorithmic framework that enables us to show that *fixed negation fragments* of certain first-order theories are decidable in polynomial time. Formulae in this fragment are generated by the following grammar, where  $\Psi$  are atomic formulae of the underlying first-order theory, and an arbitrary but a priori fixed number of negation symbols is allowed to occur:

$$\Phi ::= \exists x \Phi \mid \neg \Phi \mid \Phi \wedge \Phi \mid \Psi.$$

We give sufficient conditions for the fixed negation fragment of a first-order theory to be decidable in polynomial time. Observe that this fragment is more permissive than the “short fragments” of Kannan, as it allows for an unbounded number of quantified variables and an unbounded number of conjunctions. However, it implicitly fixes the number of quantifier alternations as well as the number of disjunctions.

As a main application of our framework, we show that, unlike full Presburger arithmetic, the fixed negation fragment of weak Presburger arithmetic (weak PA) is polynomial-time decidable. Weak PA is the strictly less expressive substructure  $(\mathbb{Z}, 0, 1, +, =)$  (which is, in fact, the structure Presburger studied in his seminal article [21]). It was recently shown that weak PA has the same complexity as Presburger arithmetic [9]. Bodirsky et al. showed that the weak PA fragment of (an unbounded number of) existential linear Horn equations  $\bigwedge_{i \in I} (A_i \cdot \mathbf{x} = b_i) \rightarrow (C_i \cdot \mathbf{x} = d_i)$  over  $\mathbb{Z}$  can be decided in PTIME [4]. It follows from the generic results in this paper that the quantified versions of those formulae with the number of quantifier alternations and  $|I|$  fixed is also polynomial-time decidable. This is the best possible such result, since one can show that, for  $I$  unbounded, the  $\exists \forall$  fragment of linear Horn equations in 2 variables is NP-hard (a proof of this is given in Appendix A). Our framework not only allows for deciding satisfiability (and validity) of fixed negation formulae of Weak PA in PTIME, but also to compute a representation of the set of solutions of a given formula.

Our algorithmic framework is parametric on a concrete representation of the sets definable within the first-order theory  $\mathcal{T}$  under consideration and only requires a sensible representation of solution sets for conjunctions of atomic formulae. From this representation, the framework guides us to the definition of a companion structure  $\mathcal{R}$  for the theory  $\mathcal{T}$  in which function symbols and relations in  $\mathcal{R}$  are interpreted as reductions from parametrised complexity theory, e.g. UXP reductions, see e.g. [11, Chapter 15]. By requiring mild conditions on the types of reductions and parameters that the functions and relations in  $\mathcal{R}$  must have, we are able to give a general theorem for the tractability of the fixed negation satisfiability

and entailment problems for  $\mathcal{T}$ . One technical issue we show how to overcome in a general way is how to treat negation, which is especially challenging when the initial representation provided to the framework is not closed under complementation (as it is the case in our treatment of weak PA). We resolve this issue by reducing it to the problem of completing a prelattice under relative complement, which we analyse computationally. Our main source of inspiration here is the notion of the so-called *difference normal form* of propositional logic, a rather unorthodox normal form introduced by Hausdorff [13, Ch. 1§5].

## 2 Preliminaries

We assume familiarity with basic concepts from first-order logic, set theory and abstract algebra. This section focuses on notation and simple definitions that might be non-standard to some readers.

**Sets and functions.** We write  $\text{seq}(A)$  for the set of all finite tuples over a set  $A$ , and denote by  $()$  the empty tuple. This definition corresponds to the standard notion of Kleene star  $A^*$  of a set  $A$ . The discrepancy in notation is introduced to avoid writing  $(\Sigma^*)^*$  for the domain of all tuples of finite words over an alphabet  $\Sigma$ , as in formal languages the Kleene star comes equipped with the axiom  $(\Sigma^*)^* = \Sigma^*$ . We denote this domain by  $\text{seq}(\Sigma^*)$ .

We write  $f : \subseteq X \rightarrow Y$  (resp.  $f : X \rightarrow Y$ ) to denote a *partial* (resp. *total*) function from  $X$  to  $Y$ . The domain of  $f$  is denoted with  $\text{dom}(f)$ . We write  $\text{id}_A : A \rightarrow A$  for the identity function on  $A$ . Given  $f : \subseteq A \rightarrow B$ ,  $g : \subseteq B \rightarrow C$  and  $h : \subseteq D \rightarrow E$ , we denote by  $(g \circ f) : \subseteq A \rightarrow C$  and  $(f \times h) : \subseteq A \times D \rightarrow B \times E$  the *composition* and the *Cartesian product* of functions.

**Structures with indexed families of functions.** We consider an expansion to the traditional definition of structure from universal algebra that accommodate for a potentially infinite number of functions. As usual, a *structure*  $\mathcal{A} = (A, \sigma, I)$  consists of a *domain*  $A$  (a set), a *signature*  $\sigma$ , and an *interpretation function*  $I$ ; however in our case the signature is a quadruple  $\sigma = (\mathcal{F}, \mathcal{G}, \mathcal{R}, \text{ar})$  containing not only a set of *function symbols*  $\mathcal{F}$ , a set of *relation symbols*  $\mathcal{R}$ , and the *arity function*  $\text{ar} : \mathcal{F} \uplus \mathcal{R} \uplus \mathcal{G} \rightarrow \mathbb{N}$ , but also a set of (indexed) *families of function symbols*  $\mathcal{G}$ . Each element of  $\mathcal{G}$  is a pair  $(g, X)$  where  $g$  is a function symbol and  $X$  is a countable set of indices. The interpretation function  $I$  associates to every  $f \in \mathcal{F}$  a map  $f^{\mathcal{A}} : A^{\text{ar}(f)} \rightarrow A$ , to every  $(g, X) \in \mathcal{G}$  a map  $g^{\mathcal{A}} : X \times A^{\text{ar}(g)} \rightarrow A$ , and to every  $R \in \mathcal{R}$  a relation  $R^{\mathcal{A}} \subseteq A^{\text{ar}(R)}$  which we often see as a function  $R^{\mathcal{A}} : A^{\text{ar}(R)} \rightarrow \{\top, \perp\}$ .

The standard notions of *homomorphism*, *embedding* and *isomorphism of structures*, as well as the notions of *congruence for a structure* and *quotient structure* extend in a natural way to structures having families of functions. For instance, a *homomorphism* from  $\mathcal{A} = (A, \sigma, I)$  into  $\mathcal{B} = (B, \sigma, J)$  is a map  $h : A \rightarrow B$  that *preserves* all functions, families of functions and relations; so in particular given  $(g, X) \in \mathcal{G}$ , the map  $h$  satisfies  $g^{\mathcal{B}}(x, h(a_1), \dots, h(a_{\text{ar}(g)})) = h(g^{\mathcal{A}}(x, a_1, \dots, a_{\text{ar}(g)}))$  for every  $x \in X$  and  $a_1, \dots, a_{\text{ar}(g)} \in A$ .

We denote structures in calligraphic letters  $\mathcal{A}, \mathcal{B}, \dots$  and their domains in capital letters  $A, B, \dots$ . When the arity function  $\text{ar}$  and the interpretation  $I$  are clear from the context, we write  $(A, f_1^{\mathcal{A}}, \dots, f_j^{\mathcal{A}}, (g_1^{\mathcal{A}}, X_1), \dots, (g_\ell^{\mathcal{A}}, X_\ell), R_1^{\mathcal{A}}, \dots, R_k^{\mathcal{A}})$ , and often drop the superscript  $\mathcal{A}$ , for a structure  $\mathcal{A} = (A, \sigma, I)$  with  $\sigma = (\{f_1, \dots, f_j\}, \{(g_1, X_1), \dots, (g_\ell, X_\ell)\}, \{R_1, \dots, R_k\}, \text{ar})$ . A structure  $\mathcal{A} = (A, \sigma, I)$  is said to be an *algebra of sets* whenever  $A$  is a family of sets and the symbols in  $\sigma$  are taken from  $\{\emptyset, \cup, \cap, \setminus, \subseteq, =\}$  and interpreted as the canonical operations on sets. Since  $\mathcal{A}$  is a structure, the set  $A$  is closed under all set operations in  $\sigma$ .

► **Example 1.** To understand the notion of families of function, consider the structure  $\mathcal{A} = (\mathbb{Z}, (\text{mul}, \mathbb{N}))$ . Here, the family of functions  $(\text{mul}, \mathbb{N})$ , interpreted as  $\text{mul}^{\mathcal{A}}(n, x) = n \cdot x$  for all  $n \in \mathbb{N}$  and  $x \in \mathbb{Z}$ , uniformly define multiplication by a non-negative constant  $n$ .

**First-order theories (finite tuples semantics).** The first-order (FO) language of the signature  $\sigma = (\mathcal{F}, \mathcal{G}, \mathcal{R}, ar)$  is the set of formulae  $\Phi, \Psi, \dots$  built from the grammar

$$\Phi, \Psi := r(t_1, \dots, t_{ar(r)}) \mid \neg\Phi \mid \Phi \wedge \Psi \mid \exists x. \Phi, \quad t := x \mid f(t_1, \dots, t_{ar(f)}) \mid g(i, t_1, \dots, t_{ar(g)}),$$

where  $x \in \mathbb{V}$  is a first-order variable,  $r \in \mathcal{R}$ ,  $f \in \mathcal{F}$ ,  $(g, X) \in \mathcal{G}$  and  $i \in X$  (more precisely,  $i$  belongs to a representation of  $X$ , see Section 3). Lexemes of the form  $r(t_1, \dots, t_{ar(r)})$  are the *atomic formulae* of the language. Throughout the paper, we implicitly assume an order on the variables in  $\mathbb{V}$ , and write  $x_j$  for the  $j$ -th variable (indexed from 1).

For our purposes it comes handy to define the FO theory of a structure  $\mathcal{A} = (A, \sigma, I)$  using tuples instead of the more standard approach of having maps from variables to values. The two definitions are equivalent. Given an atomic formula  $r(t_1, \dots, t_{ar(r)})$  having  $x_n$  as the largest appearing variable, we write  $\llbracket r(t_1, \dots, t_{ar(r)}) \rrbracket_{\mathcal{A}} \subseteq A^n$  for the set of  $n$ -tuples, corresponding to values of the first  $n$  variables, that makes  $r(t_1, \dots, t_{ar(r)})$  true under the given interpretation  $I$ . Let  $\mathbf{I} := \{(i_1, \dots, i_k) \in \text{seq}(\mathbb{N}) : i_1, \dots, i_k \text{ all distinct}\}$ . The *first-order theory* of  $\mathcal{A}$  is the structure  $\text{FO}(\mathcal{A}) := (\llbracket \mathcal{A} \rrbracket_{\text{FO}}, \perp, \top, \vee, \wedge, -, (\pi, \mathbf{I}), (\pi^{\forall}, \mathbf{I}), \leq)$ , where:

1.  $\llbracket \mathcal{A} \rrbracket_{\text{FO}}$  is the least set that contains  $\llbracket r(t_1, \dots, t_{ar(r)}) \rrbracket_{\mathcal{A}}$ , for each formula  $r(t_1, \dots, t_{ar(r)})$ , and that is closed under the functions  $\perp, \top, \vee, \wedge, -, (\pi, \mathbf{I})$  and  $(\pi^{\forall}, \mathbf{I})$ , defined below;
2.  $\perp$  is interpreted as  $\emptyset$ ,  $\top$  is interpreted as  $\{\}$ , and given  $S \subseteq A^n$  and  $T \subseteq A^m$ ,

$$\begin{aligned} S \vee T &:= \{(a_1, \dots, a_{\max(n,m)}) : (a_1, \dots, a_n) \in S \text{ or } (a_1, \dots, a_m) \in T\}, \\ S \wedge T &:= \{(a_1, \dots, a_{\max(n,m)}) : (a_1, \dots, a_n) \in S \text{ and } (a_1, \dots, a_m) \in T\}, \\ S - T &:= \{(a_1, \dots, a_{\max(n,m)}) : (a_1, \dots, a_n) \in S \text{ and } (a_1, \dots, a_m) \notin T\}, \\ \pi((i_1, \dots, i_k), X) &:= \{\gamma \in A^n : \text{there is } \mathbf{a} \in A^k \text{ such that } \gamma[(i_1, \dots, i_k) \leftarrow \mathbf{a}] \in X\}, \\ \pi^{\forall}((i_1, \dots, i_k), X) &:= \{\gamma \in A^n : \text{for every } \mathbf{a} \in A^k, \gamma[(i_1, \dots, i_k) \leftarrow \mathbf{a}] \in X\}, \\ S \leq T &\text{ if and only if } S \times A^m \subseteq T \times A^n, \end{aligned}$$

where  $\gamma[(i_1, \dots, i_k) \leftarrow \mathbf{a}]$  is the tuple obtained from the  $n$ -tuple  $\gamma$  by replacing its  $i_j$ -th component with the  $j$ -th component of  $\mathbf{a}$ , for every  $j \in [1, \min(k, n)]$ .

The semantics  $\llbracket \cdot \rrbracket_{\mathcal{A}}$  of the first-order language of  $\sigma$  is extended to non-atomic formulae via  $\text{FO}(\mathcal{A})$ . As usual, for negation, conjunction and existential quantification, we have  $\llbracket \neg\Phi \rrbracket_{\mathcal{A}} := \top - \llbracket \Phi \rrbracket_{\mathcal{A}}$ ,  $\llbracket \Phi \wedge \Psi \rrbracket_{\mathcal{A}} := \llbracket \Phi \rrbracket_{\mathcal{A}} \wedge \llbracket \Psi \rrbracket_{\mathcal{A}}$ , and  $\llbracket \exists x_i. \Phi \rrbracket_{\mathcal{A}} := \pi((i), \llbracket \Phi \rrbracket_{\mathcal{A}})$ . We remark that  $\text{FO}(\mathcal{A})$  contains operators whose syntactic counterpart is absent from the FO language of  $\sigma$ , such as the universal projection  $\pi^{\forall}$ . This is done for algorithmic purposes, as the framework we introduce in Section 4 treats these operators as first-class citizens.

We let  $\text{AC}(\sigma)$  be the set of all conjunctions of atomic formulae in the FO language of  $\sigma$ .

**Fixed negation fragments.** Fix  $k \in \mathbb{N}$ . The  $k$ -negations fragment of the FO language of a signature  $\sigma$  is the set of all formulae having at most  $k$  negations  $\neg$ . Note that, following the grammar of FO languages provided above, this restriction also bounds the number of disjunctions and alternations between existential and universal quantifiers that formulae can have. Given a structure  $\mathcal{A} = (A, \sigma, I)$ , we are interested in the following problem:

$k$  NEGATIONS SATISFIABILITY: given a formula  $\Phi$  with at most  $k$  negations, decide  $\llbracket \Phi \rrbracket_{\mathcal{A}} \neq \emptyset$ .

### 3 Representations and parametrised complexity of signatures

Per se, a structure  $\mathcal{A}$  cannot be analysed algorithmically, in particular because the elements of  $A$  do not have a notion of size. A standard way to resolve this issue is defining computability via the notion of representations (as it is done for instance in computable analysis [26]).

**Representations.** A *representation* for a set  $A$  is a surjective partial map  $\rho : \subseteq \Sigma^* \rightarrow A$ , where  $\Sigma$  is a finite alphabet. Words  $w \in \Sigma^*$  are naturally equipped with a notion of *size*, i.e., their length, denoted by  $|w|$ . Not all words are valid representations for elements of  $A$  ( $\rho$  is partial) and each element from  $A$  can be represented in several ways ( $\rho$  is not assumed to be injective). Given a representation  $\rho : \subseteq \Sigma^* \rightarrow A$ , we write  $(\approx_\rho) \subseteq \Sigma^* \times \Sigma^*$  for the equivalence relation  $\{(w_1, w_2) : w_1, w_2 \in \text{dom}(\rho) \text{ and } \rho(w_1) = \rho(w_2)\}$  and define  $h_\rho : \text{dom}(\rho)/\approx_\rho \rightarrow A$  to be the bijection satisfying  $h_\rho([w]_{\approx_\rho}) = \rho(w)$ , for every  $w \in \text{dom}(\rho)$ . Here,  $\text{dom}(\rho)/\approx_\rho$  is the set of all equivalence classes  $[w]_{\approx_\rho}$  of words  $w \in \text{dom}(\rho)$ .

It is often more practical to represent elements of  $A$  by objects that are more sophisticated than words in  $\Sigma^*$ , such as tuples, automata, graphs, etc. Taking these representations does not change the notion of computability or complexity, because they can be easily encoded as words (over a bigger alphabet, if necessary). In our setting, of particular interest are representations as tuples of words. The notion of size for words trivially extends to tuples:  $|(w_1, \dots, w_n)| := n + \sum_{i=1}^n |w_i|$ . Given representations  $\rho : \subseteq \Sigma^* \rightarrow A$  and  $\rho' : \subseteq \Pi^* \rightarrow A'$ , we rely on the following operations on representations:

- The Cartesian product  $\rho \times \rho'$  of representations, defined as in Section 2.
- The representation  $\text{seq}(\rho) : \subseteq \text{seq}(\Sigma^*) \rightarrow \text{seq}(A)$  returning  $(\rho(w_1), \dots, \rho(w_n))$  on tuples  $(w_1, \dots, w_n) \in \text{dom}(\rho)^n$ , for every  $n \in \mathbb{N}$ .
- Given a map  $\oplus : S \times S \rightarrow S$  with  $S \supseteq A$ , the representation  $\text{fold}[\oplus](\rho)$  recursively defined as  $\text{fold}[\oplus](\rho)(()) := \emptyset$ , and  $\text{fold}[\oplus](\rho)((w_1, \dots, w_n)) := \rho(w_1) \oplus \text{fold}[\oplus](\rho)((w_2, \dots, w_n))$ .

We also require representations for basic objects such as  $\mathbb{N}$ ,  $\mathbb{Z}$  and so on. Specifically, we assume to have *canonical representations*  $\nu_X$  for the following countable domains  $X$ :

- $X = \mathbb{N}$  or  $X = \mathbb{Z}$ , so that  $\nu_X$  denote a representation of  $\mathbb{N}$  or  $\mathbb{Z}$ , respectively.
- $X$  is any finite set, e.g., we assume to have a representation  $\nu_{\mathbb{B}}$  for the Booleans  $\mathbb{B} = \{\top, \perp\}$ ,
- $X = \Sigma^*$  where  $\Sigma$  is any finite alphabet. In this case,  $\nu_{\Sigma^*} := \text{id}_{\Sigma^*}$ .

**Implementations and computability.** Let  $\rho : \subseteq \Pi^* \rightarrow A$  and  $\rho_1, \dots, \rho_n$  be representations, with  $\rho_i : \subseteq \Sigma_i^* \rightarrow A_i$ . A function  $f : A_1 \times \dots \times A_n \rightarrow A$  is said to be  $(\rho_1 \times \dots \times \rho_n, \rho)$ -*computable* if there is a computable function (in the usual sense of Turing machines)  $F : \text{dom}(\rho_1) \times \dots \times \text{dom}(\rho_n) \rightarrow \text{dom}(\rho)$  such that  $\rho(F(w_1, \dots, w_n)) = f(\rho_1(w_1), \dots, \rho_n(w_n))$  for all  $w_i \in \text{dom}(\rho_i)$ ,  $i \in [1, n]$ . The function  $F$  is said to be a  $(\rho_1 \times \dots \times \rho_n, \rho)$ -*implementation* of  $f$ . It is convenient to avoid mentioning the representations of a computable function when it operates on canonical types. Given sets  $A, A_1, \dots, A_n$  admitting canonical representations, a function  $f : A_1 \times \dots \times A_n \rightarrow A$  is said to be *computable* whenever it is  $(\nu_{A_1} \times \dots \times \nu_{A_n}, \nu_A)$ -*computable* ( $\nu_{A_i}$  and  $\nu_A$  are the canonical representations of  $A_i$  and  $A$ ).

Let  $\mathcal{A} = (A, \sigma, I)$  be a structure and  $\rho : \subseteq \Sigma^* \rightarrow A$  be a representation. Let  $\mathcal{M} := (\text{dom}(\rho), \sigma, J)$  be a structure where the interpretation function  $J$  associates computable functions to each function, family of functions and relations in  $\sigma$ , and makes  $\approx_\rho$  a congruence for  $\mathcal{M}$ . The structure  $\mathcal{M}$  is said to be a  $\rho$ -*implementation* of  $\mathcal{A}$  whenever  $\rho$  is a homomorphism between  $\mathcal{M}$  and  $\mathcal{A}$ . We highlight the fact that, compared to a standard homomorphism between structures, an implementation is always surjective (since  $\rho$  is surjective) and forces  $J$  to give an interpretation to functions and relations in  $\sigma$  in terms of computable functions.

► **Example 2.** The addition function  $+: \mathbb{Z}^2 \rightarrow \mathbb{Z}$  is  $(\nu_{\mathbb{Z}}^2, \nu_{\mathbb{Z}})$ -computable. Since  $\nu_{\mathbb{Z}}$  is the canonical representation of  $\mathbb{Z}$ , we simply say that  $+$  is *computable*. This is the standard notion of computability over  $\mathbb{Z}$ . The structure  $(\text{dom}(\nu_{\mathbb{Z}}), +)$  is a  $\nu_{\mathbb{Z}}$ -implementation of  $(\mathbb{Z}, +)$ .

**Parametrised complexity of signatures.** The framework we define in the next section requires the introduction of a notion of parametrised complexity for the signature of a structure (which we call a *UXP signature*) which we now formulate. First, let us recall the standard notion of UXP reduction from parametrised complexity theory [11, Chapter 15]. Let  $\Gamma$  and  $\Pi$  be two finite alphabets, and  $D \subseteq \Gamma^*$ . A *parameter function* is a map  $\eta: \Gamma^* \rightarrow \mathbb{N}$  such that  $\eta(w) \geq 1$  for every  $w \in \Gamma^*$ . A computable function  $F: D \rightarrow \Pi^*$  is said to be a *uniform slicewise polynomial reduction* for two parameter functions  $\eta$  and  $\theta$ , or  $(\eta, \theta)$ -UXP reduction in short, whenever there is an increasing map  $G: \mathbb{N} \rightarrow \mathbb{N}$  such that for every  $w \in \Gamma^*$ ,  $F(w)$  runs in time  $|w|^{G(\eta(w))}$  (w.l.o.g. assume  $|w| \geq 2$ ) and  $\theta(F(w)) \leq G(\eta(w))$ .

As usual in computability theory, functions  $F$  with multiple arguments are handled by introducing a special symbol to the alphabet  $\Gamma$ , say  $\#$ , to separate the arguments, thus seeing  $F$  as a function in one input. For instance, an operator  $\oplus: \Sigma_1^* \times \Sigma_2^* \rightarrow \Sigma^*$  can be interpreted by a computable function taking as inputs words  $w_1 \# w_2$  with  $(w_1, w_2) \in \Sigma_1^* \times \Sigma_2^*$ . The product  $(\eta_1 \cdot \eta_2)(w_1 \# w_2) := \eta_1(w_1) \cdot \eta_2(w_2)$  of parameter functions  $\eta_1: \Sigma_1^* \rightarrow \mathbb{N}$  and  $\eta_2: \Sigma_2^* \rightarrow \mathbb{N}$  can be used to refine the complexity analysis of  $\oplus$  to each of its two arguments. We write  $\mathbf{1}$  for the trivial parameter function defined as  $\mathbf{1}(w) := 1$  for all  $w \in \Sigma^*$ .

Let  $\mathcal{A} = (A, \sigma, I)$  be a structure,  $\sigma = (\mathcal{F}, \mathcal{G}, \mathcal{R}, ar)$ ,  $\rho: \Sigma^* \rightarrow A$  be a representation, and  $\eta: \Sigma^* \rightarrow \mathbb{N}$  be a parameter function. We say that  $\mathcal{A}$  has a  $(\rho, \eta)$ -UXP signature whenever there is an interpretation function  $J$  such that (i)  $(\text{dom}(\rho), \sigma, J)$  is a  $\rho$ -implementation of  $\mathcal{A}$  and (ii)  $J$  associates a  $(\eta^{ar(f)}, \eta)$ -UXP reduction to every  $f \in \mathcal{F}$ , a  $(\mathbf{1} \cdot \eta^{ar(g)}, \eta)$ -UXP reduction to every  $(g, X) \in \mathcal{G}$ , and a  $(\eta^{ar(R)}, \mathbf{1})$ -UXP reduction to every  $R \in \mathcal{R}$ .

► **Example 3.** Consider the structure  $(L, \cup, \cap, (\cdot)^c)$  where  $L$  is the set of all regular languages over a finite alphabet  $\Sigma$  and  $\cup, \cap$ , and  $(\cdot)^c$  are the canonical operations of union, intersection and complementation of languages, respectively. This structure has a tractable signature for the representation of regular languages as deterministic finite automata (DFAs), as all operations can be implemented in PTIME on DFAs. However, it does not have a tractable signature for the representation of regular languages as non-deterministic finite automata (NFAs), because computing  $(\cdot)^c$  on NFAs requires first to determinise the automaton.

As in the case of representations, it is often more practical to have parameter functions from objects that are more sophisticated than words. Given a parameter function  $\theta: \Sigma^* \rightarrow \mathbb{N}$ , in this paper we consider the following operations  $\text{len}(\theta): \text{seq}(\Sigma^*) \rightarrow \mathbb{N}$ ,  $\text{max}(\theta): \text{seq}(\Sigma^*) \rightarrow \mathbb{N}$  and  $\text{depth}(\theta): \text{seq}(\text{seq}(\Sigma^*)) \rightarrow \mathbb{N}$  on parameter functions (below,  $\mathbf{w} = (w_1, \dots, w_n)$ ):

$$\text{len}(\theta)(\mathbf{w}) := \sum_{i=1}^n \theta(w_i), \quad \text{max}(\theta)(\mathbf{w}) := \max_{i=1}^n \theta(w_i), \quad \text{depth}(\theta) := \text{len}(\text{len}(\theta)).$$

## 4 A framework for the fixed negation fragment of first-order theories

Fix a structure  $\mathcal{A} = (A, \sigma, I)$  and consider  $\text{FO}(\mathcal{A}) := ([\mathcal{A}]_{\text{FO}}, \perp, \top, \vee, \wedge, -, (\pi, \mathbf{I}), (\pi^\vee, \mathbf{I}), \leq)$ . In this section, we describe a framework that can be employed to show that the  $k$  negation satisfiability problem for  $\text{FO}(\mathcal{A})$  is in PTIME. Part of our framework is generic, i.e., applies to any first-order theory, while other parts are necessarily specific to the theory under study. This section covers the former part and highlights the latter.

To understand the framework it is helpful to take a moment to consider how we can exploit the fact that we only consider formulae with a fixed number of negations. For simplicity, let us focus for the time being on *quantified Boolean formulae* (QBF) in prenex

form. A first key question is whether bringing the quantifier-free part  $\Phi$  of a QBF formula in a particular normal form can be computationally beneficial. Of course, due to our restrictions,  $\Phi$  can be brought into DNF in PTIME. However, because of quantifier alternation together with the unbounded number of conjunctions, choosing this normal form comes with several intricacies. Another option we might try is to put  $\Phi$  into a form where all but a fixed amount of constraints are in Horn form, and then try to rely on the algorithm to solve quantified Horn Boolean satisfiability in PTIME [17]. This works for the Boolean case, but not for an arbitrary theory. For instance, the quantified Horn satisfiability problem for the FO theory of  $\mathcal{Z} = (\mathbb{Z}, 0, 1, +, =)$ , i.e. weak Presburger arithmetic, is already NP-hard for the alternation prefix  $\exists\forall$  and 2 variables, as we briefly sketch in Appendix A, and NEXPTIME-hard in general [9]. It turns out that a suitable normal form for  $\Phi$  is given by formulae of the form  $\Phi_1 - (\Phi_2 - (\dots - (\Phi_{k-1} - \Phi_k)))$ , where each  $\Phi_i$  is a negation-free formula in DNF, and  $\Psi_1 - \Psi_2$  is the relative complementation  $\Psi_1 \wedge \neg\Psi_2$ . As we will see in this section, this atypical normal form (introduced by Hausdorff in [13] and called *difference normal form* in [14]) not only fully makes use of our restriction on the number of negations, but also exhibits nice properties in relation to quantification.

A second key question is what representation of  $\llbracket \mathcal{A} \rrbracket_{\text{FO}}$  works best for our purposes, as formulae might not be the right “data structure”. Though the difference normal form already sets how to treat disjunctions and negations, we have the flexibility to vary the representation of conjunctions of atomic formulae. Let us be a bit more precise. Consider a domain  $D \subseteq \llbracket \mathcal{A} \rrbracket_{\text{FO}}$  containing *at least* the sets  $\llbracket \Psi \rrbracket_{\mathcal{A}}$ , for all  $\Psi \in \text{AC}(\sigma)$ . We define  $\text{un}(D)$  to be the closure of  $D$  under the disjunction  $\vee$ , and  $\text{diffnf}(D)$  to be the smallest set containing  $\text{un}(D)$  and being closed under relative complements  $X - Y$ , with  $X \in \text{un}(D)$  and  $Y \in \text{diffnf}(D)$ . From the notion of difference normal form we conclude that  $\{\llbracket \Phi \rrbracket_{\mathcal{A}} : \Phi \text{ quantifier free}\} \subseteq \text{diffnf}(D)$ . Now, given a representation  $\rho : \subseteq \Sigma^* \rightarrow D$ , the partial functions  $\text{un}(\rho) : \subseteq \text{seq}(\Sigma^*) \rightarrow \text{un}(D)$  and  $\text{diffnf}(\rho) : \subseteq \text{seq}(\text{seq}(\Sigma^*)) \rightarrow \text{diffnf}(D)$ , defined as  $\text{un}(\rho) := \text{fold}[\vee](D)$  and  $\text{diffnf}(\rho) := \text{fold}[-](\text{un}(\rho))$  are representations of  $\text{un}(D)$  and  $\text{diffnf}(D)$ , respectively. When  $\rho$  is a representation encoding  $D$  as conjunctions of atomic formulae, then  $\text{diffnf}(\rho)$  is encoding  $\text{diffnf}(D)$  in the difference normal form [13]. The key point is that the representation  $\rho$  can be selected so that  $D$  is encoded as something other than formulae. For instance, for linear arithmetic theories, alternative encodings are given by automata [6] or geometrical objects [10]. In Section 6 we will use the latter. Of course, selecting representations other than formulae requires an efficient way of changing representation, as stressed in the forthcoming Proposition 4 (see the map  $F$ ). One last observation: above, we introduced  $D$  so that it could include sets beyond  $\llbracket \Psi \rrbracket_{\mathcal{A}}$ , where  $\Psi \in \text{AC}(\sigma)$ . Further sets might be required in order to make  $\text{diffnf}(D)$  closed under (universal) projection. For instance, in weak integer arithmetic, the formula  $\exists y : x = 2 \cdot y$ , stating that  $x$  is even, cannot be expressed with a quantifier-free formula, hence  $\llbracket \exists y : x = 2 \cdot y \rrbracket_{\mathcal{Z}}$  must be added to  $D$ .

The following proposition formalises the observations done in the last two paragraphs. We recall that an algorithm is said to be in  $\chi$ -UXP, for a parameter  $\chi : \Sigma^* \rightarrow \mathbb{N}$ , if it runs in time  $|w|^{G(\chi(w))}$  for every  $w \in \Sigma^*$ , for some function  $G : \mathbb{N} \rightarrow \mathbb{N}$  not depending on  $w$ . A decision problem is in  $\chi$ -UXP whenever there is a  $\chi$ -UXP algorithm solving that problem.

► **Proposition 4.** *Fix  $k \in \mathbb{N}$ . Assume the following objects to be defined:*

- a representation  $\rho$  of  $D := \bigcup_{n \in \mathbb{N}} D_n$ , where, for all  $n \in \mathbb{N}$ ,  $D_n \subseteq \mathcal{P}(A^n)$  is such that  $\llbracket \Psi \rrbracket_{\mathcal{A}} \in D_n$  for every  $\Psi \in \text{AC}(\sigma)$  having maximum variable  $x_n$ ,
  - a  $(\xi, \theta)$ -UXP reduction  $F : \text{AC}(\sigma) \rightarrow \text{dom}(\rho)$  s.t.  $(\rho \circ F)(\Psi) = \llbracket \Psi \rrbracket_{\mathcal{A}}$  for all  $\Psi \in \text{AC}(\sigma)$ .
- If  $\mathcal{D} = (\text{diffnf}(D), \perp, \top, \vee, \wedge, -, (\pi, \mathbf{I}), (\pi^\forall, \mathbf{I}), \leq)$  has  $(\text{diffnf}(\rho), \text{depth}(\theta))$ -UXP signature,
- the  $k$  negations satisfiability problem for  $\text{FO}(\mathcal{A})$  is in  $\xi$ -UXP (PTIME, if  $\xi = \mathbf{1}$ ), and
  - there is a  $\xi$ -UXP (PTIME, if  $\xi = \mathbf{1}$ ) algorithm that, given a formula  $\Phi$  of  $\text{FO}(\mathcal{A})$  having at most  $k$  negations, returns  $X$  in  $\text{dom}(\text{diffnf}(\rho))$  such that  $\text{diffnf}(\rho)(X) = \llbracket \Phi \rrbracket_{\mathcal{A}}$ .

By virtue of what we said above, Proposition 4 should not be surprising: the reduction  $F$  enables an efficient conversion from  $\text{AC}(\sigma)$  to elements in  $\text{dom}(\rho)$ , and (since  $\mathcal{D}$  is a structure)  $\text{diffnf}(\mathcal{D})$  is closed under all the operations in the signature and thus it is equal to  $\llbracket \mathcal{A} \rrbracket_{\text{FO}}$ . Consequently,  $\text{FO}(\mathcal{A})$  has a  $(\text{diffnf}(\rho), \text{depth}(\theta))$ -UXP signature, and one can efficiently use  $\text{diffnf}(\rho)$  as a data structure to carry out the algorithm to decide satisfiability, by simply invoking the various UXP reductions implementing the functions and relations in  $\mathcal{D}$ . We remark that the sole purpose of the parameter  $\theta$  is to factor in the parameter  $\xi$ , and can be thought as  $\theta := \mathbf{1}$  in the case of  $\xi := \mathbf{1}$  (i.e., the case yielding PTIME algorithms).

Whereas the choice of  $\mathcal{D}$  and  $F$  highly depends on the FO theory at hand, we show that a significant portion of the work required to prove that  $\mathcal{D}$  has the desired UXP signature can be treated in a general way, thanks to the notion of difference normal form. This “automation” can be seen as the core of our framework, which provides a minimal set of subproblems that are sufficient to conclude that  $\mathcal{D}$  has a  $(\text{diffnf}(\rho), \text{depth}(\theta))$ -UXP signature. Below, we divide those subproblems into two steps, one for Boolean connectives and one for quantification. One significant result in this context is that negation can be treated in a general way.

► **Step 1** (Boolean connectives).

1. Show that the structure  $(\mathcal{D}, \wedge, \leq)$  has a  $(\rho, \theta)$ -UXP signature.
2. Show that the structure  $(\text{un}(\mathcal{D}), \leq)$  has a  $(\text{un}(\rho), \text{len}(\theta))$ -UXP signature.

Step 1 asks to provide algorithms for solving typical computational problems that are highly domain-specific: Item 1 considers the intersection and inclusion problems for elements of  $\mathcal{D}$ , with respect to the representation  $\rho$ , whereas Item 2 deals with the inclusion problem for unions of elements in  $\mathcal{D}$ , with respect to the representation  $\text{un}(\rho)$ . In the case of unions, we highlight the parameter  $\text{len}(\theta)$  which fixes the length of the union.

Once Step 1 is established, we are able to show that the full Boolean algebra (including relative complementation) of  $\text{diffnf}(\mathcal{D})$  has a UXP signature that is suitable for Proposition 4.

► **Lemma 5.** *Under the assumption that Step 1 is established,  $(\text{diffnf}(\mathcal{D}), \perp, \top, \vee, \wedge, -, \leq)$  has a  $(\text{diffnf}(\rho), \text{depth}(\theta))$ -UXP signature.*

The proof of this lemma boils down to the definition of suitable UXP reductions implementing the binary operations  $\wedge$ ,  $\vee$  and  $-$ . We will give further insights on how this is achieved in Section 5, where we study algorithmic aspects of the difference normal form.

Moving forward, we now consider projection and universal projection. Again, the goal is to minimise the efforts needed to add support for these operations. In this sense, the decision to adopt the difference normal becomes now crucial. First, we need to introduce a variant of the universal projection which we call relative universal projection. Given  $Z \subseteq A^m$ ,  $X \subseteq A^n$  and  $\mathbf{i} = (i_1, \dots, i_k) \in \mathbf{I}$ , the *relative universal projection*  $\pi_Z^\forall(\mathbf{i}, X)$  of  $X$  with respect to  $Z$  is defined as follows (where  $M := \max(m, n)$ ):

$$\pi_Z^\forall(\mathbf{i}, X) := \{(a_1, \dots, a_M) \in A^M : \mathbf{a} := (a_1, \dots, a_m) \in \pi(\mathbf{i}, Z) \text{ and for all } \mathbf{b} \in A^k \\ \text{if } \mathbf{a}[\mathbf{i} \leftarrow \mathbf{b}] \in Z \text{ then } (a_1, \dots, a_n)[\mathbf{i} \leftarrow \mathbf{b}] \in X\}.$$

Informally speaking,  $\pi_Z^\forall(\mathbf{i}, X)$  acts as a universal projection for the part of  $X$  that lies inside  $Z$ . Note that one can retrieve the universal projection as  $\pi^\forall(\mathbf{i}, X) = \pi_Z^\forall(\mathbf{i}, X)$ .

The lemma below outlines a key “mutual distribution” property of projection and relative universal projection over relative complement. In the context of the difference normal form, this property allows us to disregard complementation when adding support for quantification.

► **Lemma 6.** *We have  $\pi(\mathbf{i}, X - Y) = \pi(\mathbf{i}, X) - \pi_X^\forall(\mathbf{i}, Y)$  and  $\pi_Z^\forall(\mathbf{i}, X - Y) = \pi_Z^\forall(\mathbf{i}, X) - \pi(\mathbf{i}, Y)$ , for every  $X \subseteq A^n$ ,  $Y \subseteq A^m$ ,  $Z \subseteq A^r$ , and  $\mathbf{i} \in \mathbf{I}$ .*

For instance,  $\pi(\mathbf{i}, W - (X - (Y - Z))) = \pi(\mathbf{i}, W) - (\pi_W^\forall(\mathbf{i}, X) - (\pi(\mathbf{i}, Y) - \pi_Y^\forall(\mathbf{i}, Z)))$ .

Below, let us write  $\hat{\pi}$  for the restriction of the projection operator  $\pi$  on inputs  $(\mathbf{i}, X)$  where  $X \in \mathbf{D}$ , and write  $\hat{\pi}^{\forall}$  for the restriction of the relativised universal projection  $\pi^{\forall}$  on inputs  $(Z, \mathbf{i}, X)$  where  $Z \in \overline{\mathbf{D}}$  and  $X \in \text{un}(\mathbf{D})$ . Thanks to Lemma 6, adding to Step 1 the following step is sufficient to conclude that  $\mathcal{D}$  has the UXP signature required by Proposition 4.

► **Step 2** (Projection and universal projection).

1. Show that  $\hat{\pi}(\mathbf{i}, X) \in \text{diffnf}(\mathbf{D})$ , for every  $X \in \mathbf{D}$  and  $\mathbf{i} \in \mathbf{I}$ .
2. Show that  $\hat{\pi}_Z^{\forall}(\mathbf{i}, X) \in \text{diffnf}(\mathbf{D})$ , for every  $Z \in \mathbf{D}$ ,  $\mathbf{i} \in \mathbf{I}$  and  $X \in \text{un}(\mathbf{D})$ .
3. Show a  $(\mathbf{1} \cdot \theta, \text{depth}(\theta))$ -UXP reduction that  $(\nu_{\mathbf{I}} \times \rho, \text{diffnf}(\rho))$ -implements  $\hat{\pi}$ .
4. Show a  $(\theta \cdot \mathbf{1} \cdot \text{len}(\theta), \text{depth}(\theta))$ -UXP reduction that  $(\rho \times \nu_{\mathbf{I}} \times \text{un}(\rho), \text{diffnf}(\rho))$ -implements  $\hat{\pi}^{\forall}$ .

► **Lemma 7.** Under the assumption that Steps 1 and 2 are established, the structure  $\mathcal{D}$  from Proposition 4 has a  $(\text{diffnf}(\rho), \text{depth}(\theta))$ -UXP signature.

## 5 Closing prelattices under relative complement

Let us go back to the notion of difference normal form, which again are formulae of the form  $\Phi_1 - (\Phi_2 - (\dots - \Phi_k))$ , where each  $\Phi_i$  is negation-free and in DNF. Our framework is based on the idea of using these syntactic chains of relative complementations, let us call them *decreasing sequences*, as a way of closing a structure (not just formulae) under complement. Doing this allows the domain  $\mathbf{D}$  to not be necessarily closed under complement. Then, one natural question to ask is under which assumptions do structures admit a computable notion of decreasing sequences. We give an answer to this question by showing that any prelattice  $\mathcal{A}$  that is well-founded *or* distributive has a well-defined algebra over decreasing sequences (SDS algebra). We study computational aspects of SDS algebras that allows us to establish Lemma 5. When  $\mathcal{A}$  is both well-founded and distributive, we also show that the SDS algebra act as a completion of  $\mathcal{A}$  under relative complement (this result is not required for Lemma 5).

**Prelattices.** We assume familiarity with the order theoretic definition of a *lattice*. A structure  $\mathcal{A} = (A, \vee, \wedge, \leq)$  is said to be a *prelattice* whenever  $\leq$  is a *preorder*, and the quotient structure  $\mathcal{A}/\approx := (A/\approx, \vee/\approx, \wedge/\approx, \leq/\approx)$  of  $\mathcal{A}$  under the congruence  $(\approx) := (\leq \cap \leq^{-1})$  is a lattice. Roughly speaking, a prelattice is a lattice that may not satisfy antisymmetry, i.e., distinct elements of  $A$  are allowed to be equal under  $\leq$ . If  $\leq/\approx$  has a least element  $L$ , we often add to the signature of  $\mathcal{A}$  a constant symbol  $\perp$  interpreted as an element  $a \in A$  such that  $[a]_{\approx} = L$ . As usual,  $\mathcal{A}$  is *well-founded* if there are no infinite sequences of elements that are strictly decreasing with respect to  $\leq$ , and it is *distributive* whenever  $a \wedge (b \vee c) \approx (a \wedge b) \vee (a \wedge c)$ , for every  $a, b, c \in A$ . A (pre)lattice  $(L, \leq)$  is said to be *closed under relative complement* whenever, for every  $x, y \in L$  there is an element  $[x \setminus y] \in L$  satisfying  $y \wedge [x \setminus y] = \perp$  and  $x \leq y \vee [x \setminus y]$ . (Pre)lattices may not be closed under relative complement, see for example the three elements lattice  $(\{\perp, p, \top\}, \leq)$  with  $\perp < p < \top$ .

**Decreasing sequences and SDS algebras.** Fix a prelattice  $\mathcal{A} = (A, \perp, \vee, \wedge, \leq)$  that is well-founded or distributive. Let  $\approx$  and  $<$  be the equivalence relation and strict partial order induced by  $\leq$ , respectively. We write  $\text{SDS}(\mathcal{A})$  for the set of all *strictly decreasing sequences* (SDS) over  $A$ , i.e., those (possibly empty) finite tuples  $(a_1, \dots, a_n) \in \text{seq}(A)$  satisfying  $a_{i+1} < a_i$  for every  $i \in [1, n-1]$ . Let  $X := (a_1, \dots, a_n), Y := (b_1, \dots, b_m) \in \text{SDS}(\mathcal{A})$ . Given  $a \in A$  and  $X' \in \text{SDS}(\mathcal{A})$ , we write  $X = \langle a; X' \rangle$  whenever  $a = a_1$  and  $X' = (a_2, \dots, a_n)$ . We write  $X \approx Y$  whenever  $n = m$  and  $a_i \approx b_i$  for all  $i \in [1, n]$ , or  $X, Y \in \{(), a : a \in A \text{ and } a \approx \perp\}$ . We recursively define the *cons* operator  $(:): A \times \text{SDS}(\mathcal{A}) \rightarrow \text{SDS}(\mathcal{A})$  as follows:

$$a : X := \begin{cases} a & \text{if } X \in \{(), b : b \in A \text{ and } b \approx \perp\} \\ (a, a_1, \dots, a_n) & \text{else if } a_1 < a \\ a : ((a \wedge a_1) : (a_2, \dots, a_n)) & \text{else if } a \wedge a_1 < a \\ \perp & \text{else if } n = 1 \text{ (here, } a \leq a_1) \\ (a \wedge a_2) : (a_3, \dots, a_n) & \text{otherwise} \end{cases}$$

Intuitively, on input  $(a, X)$ ,  $(:)$  returns an SDS that represents the relative complement of  $a$  and  $X$ . With a simple induction on the length of  $X$  one can show that  $(:)$  is well-defined.

The *SDS algebra* of  $\mathcal{A}$  is the structure  $(\text{SDS}(\mathcal{A}), \emptyset, \gamma, \lambda, -, \preceq)$ . In this structure,  $\emptyset$  is the constant function returning  $\perp^{\mathcal{A}}$  from  $\mathcal{A} \subseteq \text{SDS}(\mathcal{A})$ , the (*inclusion*)  $\preceq$  is defined as  $X \preceq Y \stackrel{\text{def}}{=} (X - Y) \approx \emptyset$ , and the functions  $\gamma$  (*union*),  $\lambda$  (*intersection*) and  $-$  (*difference*), having arity two, are interpreted following the mutually recursive definitions (where, whenever their length is non-zero, we assume  $X = \langle a; X' \rangle$  and  $Y = \langle b; Y' \rangle$ ):

$$\begin{aligned} X \wedge Y &:= \begin{cases} \emptyset & \text{if } X \approx \emptyset \text{ or } Y \approx \emptyset, \\ (a \wedge b) : (X' \gamma Y') & \text{else} \end{cases} & X \gamma Y &:= \begin{cases} Y & \text{if } X \approx \emptyset, \\ X & \text{else if } Y \approx \emptyset, \\ a : (X' - Y) & \text{else if } b \leq a, \\ (a \vee b) : ((X' \gamma Y') - ((a \wedge b) : (X' \lambda Y'))) & \text{else.} \end{cases} \\ X - Y &:= \begin{cases} X & \text{if } X \approx \emptyset \text{ or } Y \approx \emptyset, \\ a : (X' \gamma Y') & \text{else} \end{cases} \end{aligned}$$

The definitions of  $\lambda$ ,  $\gamma$  and  $-$  observe validities of elementary set theories, and follow the idea that  $\langle a; X' \rangle$  should represent the element  $a - X'$ . For instance, the last line in the definition of  $X - Y$ , where  $X = \langle a; X' \rangle$ , relies on the set validity  $(E - F) - G = E - (F \cup G)$ .

► **Lemma 8.** *Suppose that  $\mathcal{A}$  is well-founded or distributive. Then, the functions  $\gamma, \lambda, - : \text{SDS}(\mathcal{A}) \times \text{SDS}(\mathcal{A}) \rightarrow \text{SDS}(\mathcal{A})$  and  $\preceq : \text{SDS}(\mathcal{A}) \times \text{SDS}(\mathcal{A}) \rightarrow \mathbb{B}$  are well-defined.*

For  $\mathcal{A}$  well-founded, this lemma is proven by induction on the lexicographic ordering built from  $\leq^{\mathcal{A}}$  and the total ordering on  $\mathbb{N}$ . For  $\mathcal{A}$  distributive, one notes that the closure  $C$  of a finite set of elements  $\{\perp, a_1, \dots, a_n\} \subseteq A$  under  $\vee$  and  $\wedge$  is a prelattice that is finite up to  $\approx$ , making  $\leq^{\mathcal{A}}/\approx$  a well-founded relation when restricted to elements in  $C$ . These elements are the only ones computed by  $\gamma$ ,  $\lambda$  and  $-$ . The lemma then follows as in the well-founded case.

The following proposition clarifies the intention behind SDS algebras.

► **Proposition 9.** *Any well-founded and distributive lattice  $\mathcal{A}$  embeds in  $(\text{SDS}(\mathcal{A}), \emptyset, \gamma, \lambda, \preceq)$ , which is a well-founded distributive prelattice closed under relative complement.*

Showing that  $\mathcal{A}$  embeds in  $(\text{SDS}(\mathcal{A}), \emptyset, \gamma, \lambda, \preceq)$  is simple. To show that the latter structure is closed under relative complement we rely on Birkhoff's representation theorem, a theorem that allows to construct set algebras isomorphic to  $\mathcal{A}$ . Birkhoff's representation theorem is usually given for *finite* distributive lattices. However, an inspection of its proof shows that finiteness can be replaced with well-foundedness in a simple way.

► **Theorem 10** ([3]). *Let  $\mathcal{A} = (A, \perp, \vee, \wedge, \leq)$  be a well-founded distributive lattice. There is an algebra of sets  $\mathcal{B} = (B, \emptyset, \cup, \cap, \subseteq)$  that is isomorphic to  $\mathcal{A}$ .*

Let  $\mathcal{N} = (N, \emptyset, \cup, \cap, \setminus, \subseteq)$  be the algebra of sets obtained by closing the structure  $\mathcal{B}$  above under the set difference  $\setminus$ . Thanks to Theorem 10, to show the closure under relative complement required by Proposition 9 it suffices providing a surjective homomorphism from the SDS algebra of  $\mathcal{B}$  to the structure  $\mathcal{N}$ . The map  $h : \text{SDS}(\mathcal{B}) \rightarrow N$  defined as  $h(X) := \emptyset$  for  $X \approx \emptyset$ , and otherwise as  $h(X) := a \setminus h(X')$  for  $X = \langle a; X' \rangle$ , is such a homomorphism.

**UXP signatures for SDS algebras.** We move to the computational aspects of SDS algebras. Let  $\mathcal{A} = (A, \perp, \vee, \wedge, \leq)$  be a distributive (not necessarily well-founded) prelattice and  $\rho : \subseteq \Sigma^* \rightarrow A$  be a representation. Let  $\text{SDS}(\rho) : \subseteq \text{seq}(\Sigma^*) \rightarrow \text{SDS}(\mathcal{A})$  be the representation of  $\text{SDS}(\mathcal{A})$  defined as  $\text{SDS}(\rho)(w_1, \dots, w_n) := \rho(w_1) : (\dots : (\rho(w_n)))$  for every  $n \in \mathbb{N}$  and  $w_1, \dots, w_n \in \text{dom}(\rho)$ , and undefined otherwise. Below,  $\text{len}(\eta)$  is defined as in Section 3.

► **Theorem 11.** *Let  $\mathcal{A} = (A, \perp, \vee, \wedge, \leq)$  be a distributive prelattice with a  $(\rho, \eta)$ -UXP signature. The SDS algebra of  $\mathcal{A}$  has a  $(\text{SDS}(\rho), \text{len}(\eta))$ -UXP signature.*

For the proof of this theorem, one considers the  $\rho$ -implementation  $\mathcal{R}$  of  $\mathcal{A}$  in which the functions  $\vee$  and  $\wedge$  are  $(\eta \cdot \eta, \eta)$ -UXP reductions and the relation  $\leq$  is a  $(\eta \cdot \eta, \mathbf{1})$ -UXP reduction. The structure  $\mathcal{R}$  is a distributive prelattice, hence it has a well-defined SDS algebra  $(\text{SDS}(\mathcal{R}), \emptyset, \Upsilon, \lambda, -, \preceq)$ . By following the above definitions of  $\Upsilon, \lambda, -$  and  $\preceq$ , one can provide  $(\text{len}(\eta)^2, \text{len}(\eta))$ -UXP and  $(\text{len}(\eta) \cdot \text{len}(\eta), \mathbf{1})$ -UXP reductions for the functions and relations of the structure  $\mathcal{S} = (\text{dom}(\text{SDS}(\rho)), \emptyset, \Upsilon, \lambda, -, \preceq)$  that  $\text{SDS}(\rho)$ -implements the SDS algebra of  $\mathcal{A}$ .

Theorem 11 gives us what we need to prove Lemma 5. Step 1 of the framework implies that  $\mathcal{U} = (\text{un}(\mathcal{D}), \perp, \vee, \wedge, \leq)$  is a distributive prelattice with a  $(\text{un}(\rho), \text{len}(\theta))$ -UXP signature. By Theorem 11, the SDS algebra of  $\mathcal{U}$  has a  $(\text{SDS}(\text{un}(\rho)), \text{depth}(\theta))$ -UXP signature. So, Lemma 5 follows as one provides a surjective homomorphism from the SDS algebra of  $\mathcal{U}$  to  $(\text{diffnf}(\mathcal{D}), \perp, \top, \vee, \wedge, -, \preceq)$ . This surjective homomorphism is obtained by updating map  $h$  used in the proof of Proposition 9 so that it uses the operator  $-$  instead of the set difference  $\setminus$ .

## 6 Weak linear integer arithmetic

In this section, we briefly discuss how to instantiate the framework of Section 4 to weak Presburger arithmetic (weak PA), i.e. the FO theory of the structure  $\mathcal{Z} = (\mathbb{Z}, 0, 1, +, =)$ .

**Setup.** According to Proposition 4, instantiating the framework requires first to define the domain  $\mathcal{D}$ , its representation  $\rho$  and the change of representation  $F : \text{AC}(\sigma) \rightarrow \text{dom}(\rho)$ . In weak PA, conjunctions of atomic formulae are systems of affine equations, which over  $\mathbb{Z}$  define shifted integer lattices (SL), which are not necessarily fully dimensional. We let  $\mathcal{D}_n$  be the set of all shifted (integer) lattices of  $\mathbb{Z}^n$ , so that  $\mathcal{D}$  is the set of all shifted lattices of  $\mathbb{Z}^n$  for some  $n$ . We represent elements in  $\mathcal{D}$  with the standard representation of a SL as a base point and an independent periodic set. Recall that we write  $\nu_{\mathbb{Z}^n}$  for the canonical representation of  $\mathbb{Z}^n$  (see Section 3). Formally, for every  $n \in \mathbb{N}$ , if  $v_0$  represents a vector in  $\mathbb{Z}^n$ , and  $v_1, \dots, v_k$  represent linearly independent vectors in  $\mathbb{Z}^n$ , then we let

$$\rho_{\text{SL}}(n, v_0, \dots, v_k) := \nu_{\mathbb{Z}^n}(v_0) + \text{span}_{\mathbb{Z}}\{\nu_{\mathbb{Z}^n}(v_1), \dots, \nu_{\mathbb{Z}^n}(v_k)\}.$$

A PTIME function  $F$  allowing to change representation from conjunctions of atomic formulae to elements in  $\text{dom}(\rho_{\text{SL}})$  can be obtained thanks to the following well-known algorithm.

► **Proposition 12** ([16]). *There is a PTIME algorithm to compute the Hermite normal form, along with the transformation matrices, of a given matrix with integer entries.*

Since  $F$  runs in PTIME, the parameter  $\xi$  in Proposition 4 equals  $\mathbf{1}$ , and we need to show that  $\mathcal{D}$  has a  $(\text{diffnf}(\rho_{\text{SL}}), \text{depth}(\theta))$ -UXP signature for  $\theta := \mathbf{1}$ , by establishing Steps 1 and 2.

**Step 1.** Both the problems of computing intersections and testing inclusions for two shifted lattices represented as in  $\rho_{\text{SL}}$  reduces to solving systems of linear equations over  $\mathbb{Z}$ , which can be done in PTIME again thanks to Proposition 12. This establishes Item 1 of Step 1.

Item 2 asks for an algorithm to solve inclusion between union of shifted lattices. This is a computationally expensive operation. Roughly speaking, one first notices that it suffices to be able to test  $Z \leq X$  where  $Z \subseteq \mathbb{Z}^k$  is a SL and  $X := \bigvee_{i \in I} X_i \subseteq \mathbb{Z}^k$ , where all  $X_i$  are SL. This inclusion testing can be performed by checking that  $|Z \cap [0, d)^k| = |(Z \wedge X) \cap [0, d)^k|$  for a well-chosen value of  $d \in \mathbb{N}$ . Hence, inclusion reduces to a counting problem for lattice points in a box, which in turn reduces to computing lattice determinants:

► **Lemma 13.** *Let  $L \subseteq \mathbb{Z}^k$  be a lattice and  $d > 0$  such that  $d\mathbb{Z}^k \subseteq L$ , then  $|L \cap [0, d)^k| = \frac{d^k}{\det(L)}$ .*

To extend the above lemma to union of shifted lattices, we rely on an inclusion-exclusion formula which requires the algorithm to consider all possible  $2^{|I|}$  intersections between the  $X_i$ . This leads to a procedure that is exponential in the number of elements in the union, which is however sufficient to establish Item 2, since it asks for an algorithm that runs in PTIME when the length of the union is fixed; see the parameter  $\text{len}(\theta)$ .

► **Lemma 14.** *There is an algorithm that given  $z \in \text{dom}(\rho_{\text{SL}})$  and  $x \in \text{dom}(\text{un}(\rho_{\text{SL}}))$  decides  $\rho_{\text{SL}}(z) \leq \text{un}(\rho_{\text{SL}})(x)$  in time  $2^{\text{len}(\mathbf{1})(x)} \text{poly}(|x|, |z|)$ . In particular, Item 2 of Step 1 holds.*

**Step 2.** Establishing Items 1 and 3 is simple: thanks to our choice of representation, i.e.  $\rho_{\text{SL}}$ , given  $X \in \text{dom}(\rho_{\text{SL}})$  and  $\mathbf{i} \in \mathbf{I}$ ,  $\pi(\mathbf{i}, X)$  can be computed by simply crossing out the entries of all vectors of  $X$  corresponding to the indices in  $\mathbf{i}$ . On the contrary, the algorithm for universal projections  $\pi_{\mathbb{Z}}^{\forall} X$  required by Items 2 and 4 turns out to be challenging to compute. Intuitively, similarly to inclusion testing, we need to count points in unions of SL but in a parametric way. This means that given  $X = \bigvee_{\ell \in L} X_{\ell}$ , where all  $X_{\ell}$  are SL, every intersection  $\bigwedge_{j \in J} X_j$  ( $J \subseteq L$ ) in the inclusion-exclusion formula may or may not need to be counted, depending on the value of a parameter  $f$  belonging of a certain set of parameters  $\mathcal{F}$  (see lemma below). The algorithm therefore considers all possible ways in which intersections may or may not be taken, which is roughly  $2^{2^{|L|}}$ . This allows us to conclude a rather surprising fact: the relative universal projection can be expressed as a complex combination of unions, intersections, projections and relative complementations that are exclusively applied to the initial sets in input. The number of these operations only depend on the length  $|L|$ .

► **Lemma 15.** *Consider  $X = \bigvee_{\ell \in L} X_{\ell}$ , where  $X_{\ell} \in \text{D}$  for all  $\ell \in L$ , and let  $Z \in \text{D}$  and  $\mathbf{i} \in \mathbf{I}$ . Then, there is a set of parameters  $\mathcal{F} \subseteq (2^L \rightarrow \{0, 1\})$  such that*

$$\pi_{\mathbb{Z}}^{\forall}(\mathbf{i}, X) = \bigvee_{f \in \mathcal{F}} \left( \left( \bigwedge_{J: f(J)=1} \bigwedge_{j \in J} \pi(\mathbf{i}, X_j \wedge Z) \right) - \left( \bigvee_{J: f(J)=0} \bigwedge_{j \in J} \pi(\mathbf{i}, X_j \wedge Z) \right) \right).$$

*Given  $z, (x_{\ell})_{\ell \in L} \in \text{dom}(\rho_{\text{SL}})$  s.t.  $\rho_{\text{SL}}(z) = Z$  and  $\rho_{\text{SL}}(x_{\ell}) = X_{\ell}$ , the set  $\mathcal{F}$  can be computed in time  $\text{poly}(|z|, \max_{\ell \in L}(|x_{\ell}|), 2^{2^{|L|} + |L|})$ . In particular, Items 2 and 4 of Step 2 hold.*

To clarify, since the parameter  $\text{len}(\theta)$  in Item 4 fixes the length  $|L|$ , the right-hand side of the above equation only has a fixed number of operations, and can thus be evaluate efficiently thanks to the other steps of the framework. Then, by Lemma 7 and Proposition 4, we get:

► **Theorem 16.** *Fix  $k \in \mathbb{N}$ . The  $k$  negations satisfiability problems for weak PA is in PTIME.*

By Proposition 4 we also conclude that there is a PTIME procedure that given a formula  $\Phi$  from  $\text{FO}(\mathcal{Z})$  with  $k$  negations returns an element of  $\text{dom}(\text{diff}(\text{un}(\rho_{\text{SL}})))$  representing  $\llbracket \Phi \rrbracket_{\mathcal{Z}}$ .

## 7 Final remarks

We developed a framework to establish polynomial-time decidability of fixed negation sentences of first-order theories whose signatures enjoy certain (parametrised) complexity properties. A key feature of the framework is that it treats complementation in a general way, and considers universal projection as a first-class citizen. Note that, a priori, the latter operation might be easier than the former to decide, as shown for instance in [8].

We instantiated our framework to show that the fixed negation fragment of weak PA is in PTIME, in sharp contrast with (standard) PA [20]. Due to space constraints, we did not provide further instantiation of our framework. We know that it can be used to show that the fixed negation fragment of weak linear real arithmetic is in PTIME. We believe that the framework provides a sensible approach to study fixed negation fragments of FO extensions of, e.g., certain abstract domains. While the framework obviously works for interval arithmetic, the case of linear octagon arithmetic [19], whose full FO theory is PSPACE-complete [2], seems already non-trivial. More generally, since the various steps required to instantiate the framework only consider natural computational problems (inclusions and projections), our hope is to also tackle theories outside the world of arithmetic.

## A Hardness of quantified weak PA Horn formulas

In this appendix, we complement the tractability result for the  $k$ -negation fragment of weak PA established in Section 6 with an NP lower bound for (quantified) weak PA Horn formulas. This lower bound only requires two variables  $x$  and  $y$ , where  $x$  is quantified existentially and  $y$  is quantified universally. The matrix of such a 2-variable formula is of the form

$$\bigwedge_{1 \leq i \leq n} (a_i \cdot x + b_i \cdot y = c_i \rightarrow a'_i \cdot x + b'_i \cdot y = c'_i).$$

We show this result by a reduction from the problem of deciding a univariate system of non-congruences  $\bigwedge_{i=1}^k x \not\equiv r_i \pmod{m_i}$ , where  $m_i \geq 2$  and  $r_i \in [0, m_i - 1]$  for every  $i \in [1, k]$ . This problem is shown NP-hard in [1, Theorem 5.5.7]. The reduction directly follows from the following equivalence: for every  $x \in \mathbb{Z}$ ,

$$\bigwedge_{i=1}^k x \not\equiv r_i \pmod{m_i} \iff \forall y : \bigwedge_{i=1}^k (x - r_i = m_i \cdot y \rightarrow y = 3 \cdot x + 1).$$

First, consider  $x \in \mathbb{Z}$  satisfying the left-hand side. Pick  $y \in \mathbb{Z}$ . We have  $x - r_i \neq m_i \cdot y$  for every  $i \in [1, k]$ . So, every antecedent of the implications in  $\bigwedge_{i=1}^k (x - r_i = m_i \cdot y \rightarrow y = 3 \cdot x + 1)$  is false, showing the right-hand side. For the other direction, consider an  $x \in \mathbb{Z}$  satisfying the right-hand side. It suffices to show that, for every  $i \in [1, k]$  and  $y \in \mathbb{Z}$ , if  $x - r_i = m_i \cdot y$  then  $y \neq 3 \cdot x + 1$ . This implies that, for the right-hand side to hold, it must be the case that  $x - r_i \neq m_i \cdot y$  for every  $i \in [1, k]$  and  $y \in \mathbb{Z}$ ; proving the left-hand side. *Ad absurdum*, suppose that  $x - r_i = m_i \cdot y$  and  $y = 3 \cdot x + 1$  hold. Then,  $x = -\frac{r_i + m_i}{3 \cdot m_i - 1}$ . However,  $0 < \frac{r_i + m_i}{3 \cdot m_i - 1} \leq \frac{2 \cdot m_i - 1}{3 \cdot m_i - 1} < 1$ , as  $m_i \geq 2$  and  $r_i \in [0, m_i - 1]$ , contradicting that  $x$  is an integer.

► **Proposition 17.** *Deciding  $\exists \forall$  weak PA Horn sentences in two variables is NP-hard.*

# The Covering Canadian Traveller Problem Revisited

Niklas Hahn

## Abstract

In this paper, we consider the  $k$ -Covering Canadian Traveller Problem ( $k$ -CCTP), which can be seen as a variant of the Travelling Salesperson Problem. The goal of  $k$ -CCTP is finding the shortest tour for a traveller to visit a set of locations in a given graph and return to the origin. Crucially, unknown to the traveller, up to  $k$  edges of the graph are blocked and the traveller only discovers blocked edges online at one of their respective endpoints. The currently best known upper bound for  $k$ -CCTP is  $O(\sqrt{k})$  which was shown in [Huang and Liao, ISAAC '12]. We improve this polynomial bound to a logarithmic one by presenting a deterministic  $O(\log k)$ -competitive algorithm that runs in polynomial time. Further, we demonstrate the tightness of our analysis by giving a lower bound instance for our algorithm.

## 1 Introduction

The Canadian Traveller Problem (CTP) was introduced in 1991 by Papadimitriou and Yannakakis [26] as an extension of the Shortest Path Problem and has applications in online route planning in road networks. The goal of the problem is to find a shortest path between a source and a destination in an unreliable graph, in which some edges may become unavailable. This can only be observed in an online manner, i.e., when reaching one of the endpoints of such an edge. More specifically, consider a connected, undirected graph  $G = (V, E)$  with a source node  $s \in V$ , a destination node  $t \in V$  and a non-negative cost function  $c: E \rightarrow \mathbb{R}^+$  representing the cost to traverse each edge. A traveller seeks to find a path with minimum cost from  $s$  to  $t$ . However, one or more edges might be blocked, and thus cannot be traversed. The traveller only learns that an edge is blocked when reaching one of its endpoints. When the number of blocked edges is bounded by  $k$ , the variant is called  $k$ -Canadian Traveller Problem or  $k$ -CTP [6].

This work studies a generalization of CTP, defined in [22], which is called the Covering Canadian Traveller Problem (CCTP). In CCTP, one attempts to develop an efficient tour for a traveller that visits all vertices in a graph and returns to the origin (source) under the same uncertainty as that of CTP. When the number of blocked edges is bounded by  $k$ , the problem is called  $k$ -CCTP, analogous to the  $k$ -CTP variant of CTP.

We make two assumptions on the underlying graph model, similar to [22]. First, we assume that the graph remains connected even if all blocked edges are removed. Second, the state of an edge, i.e., whether it is blocked or not, does not change after the traveller learns about it. The problem has practical uses in dynamic routing systems that prioritize efficient travel routes and aim to avoid traffic congestion. Since Huang and Liao introduced CCTP [22], there has been a notable amount of work on similar problems in the literature [1, 30, 36, 37]. For example, Zhang et al. [35] studied the Steiner Travelling Salesperson Problem in which the salesperson instantly learns about new blocked edges. Shiri et al. [29] focused on how to allocate and route search-and-rescue teams to areas with trapped victims, considering the uncertainty about road conditions which may delay the operations.

The motivation behind CCTP stems from other similar optimization problems, such as dynamic TSP and online TSP. Dynamic TSP has been studied for various different types of dynamic change, such as the addition or removal of locations, and changing pairwise distances between locations in the underlying space [21, 32]. On the other hand, Ausiello et al. [4] introduced the online TSP in which the input arrives over time, i.e., during the travel new requests (locations) appear that have to be visited by the algorithm. The problem has many practical applications, e.g., in logistics and robotics [2, 27]. Since its introduction, a series of papers has been published on the subject [3, 10, 19].

As is usual in the literature on online problems, we measure the performance of our algorithm by its competitive ratio [11]. This means that its performance is compared to the performance of an algorithm for the corresponding offline problem. In our setting, this would be an algorithm which knows the complete graph structure, including all blocked edges.

### Our Contribution

In this paper, we focus on  $k$ -CCTP. Currently, the best known deterministic algorithm for  $k$ -CCTP is the CYCLIC ROUTING algorithm by Huang and Liao [22] with competitive ratio  $O(\sqrt{k})$ . We improve this bound to  $O(\log k)$  by making a connection with the Online Graph Exploration problem. In the Online Graph Exploration problem, a searcher starts from a source vertex and aims to visit all vertices of an unknown but fixed graph. Upon reaching a new vertex, the server learns all incident edges and their costs. The reduction we give allows us to get a polynomial time algorithm for  $k$ -CCTP using an algorithm for the Exploration problem. Finally, we show that our analysis of the  $O(\log k)$ -competitive algorithm is tight.

## 2 Related Work

### Online Graph Exploration Problem

In the Online Graph Exploration problem, defined in [20], an agent has to explore an unknown graph by starting at a given vertex, visiting all other vertices, and returning to the starting one. The agent can only move along the edges of the graph and has to pay a cost for each traversed edge.

A simple and fast algorithm that solves the problem is the Nearest Neighbor (NN) algorithm. The algorithm selects an unexplored vertex that is cheapest to reach from the current one and visits it, repeating this process until all vertices are visited. This algorithm has been shown to have a competitive ratio of  $\Theta(\log n)$  for arbitrary graphs in the Online Graph Exploration Problem [28], which is a tight bound even on planar unit-weight graphs [15, 18]. Note that although the analysis in [28] deals with the offline problem, the nearest neighbor can always be identified even in the online scenario and the same analysis

applies. The second algorithm that achieves the  $\Theta(\log n)$  bound, which is the best known upper bound for arbitrary graphs, is the hierarchical Depth First Search algorithm (HDFS) in [23].

On the other hand, obtaining constant-competitive tours is known only for special cases of graphs, such as graphs with  $k$  distinct weights, graphs with bounded genus, cycles, tadpole graphs and cactus graphs [12, 15, 20, 23, 24]. Conversely, the best known lower bound on the competitive ratio of an online algorithm is just  $10/3$  [9], and despite efforts, it is still unclear whether there exists an  $o(\log n)$  or even  $O(1)$ -competitive exploration algorithm for general graphs.

### Canadian Traveller Problem

CTP has been proven to be PSPACE-complete [26]. For the  $k$ -CTP variant, Bar-Noy and Schieber proposed a polynomial time algorithm that minimizes the maximum travel length [6]. Westphal developed a simple deterministic online algorithm for  $k$ -CTP that is  $(2k + 1)$ -competitive and proved that no deterministic online algorithm can have a (strictly) better competitive ratio [33]. Furthermore, he showed a lower bound of  $k + 1$  for any randomized algorithm, even if all  $s - t$  paths are node disjoint. Xu et al. [34] proposed a deterministic algorithm that is also  $(2k + 1)$ -competitive for  $k$ -CTP and proved that a natural greedy strategy based on the available blockage information is exponential in  $k$ . On graphs where all  $s - t$  paths are node-disjoint, a  $(k + 1)$ -competitive randomized online algorithm is known [7, 31]. Demaine et al. [14] proposed a polynomial time randomized algorithm that improves the deterministic lower bound of  $2k + 1$  by an  $o(1)$  factor for arbitrary graphs. They also showed that the competitive ratio is even better if the randomized algorithm runs in pseudo-polynomial time. Recently, Bergé et al. [8] proved that the competitive ratio of any randomized algorithm using a specific set of strategies called memoryless cannot be better than  $2k + O(1)$ . Over the last few years, various other variants of CTP have been investigated [5, 17, 25].

### Covering Canadian Traveller Problem

The best known algorithm for  $k$ -CCTP is the one proposed in [22] with a competitive ratio of  $O(\sqrt{k})$ . The algorithm, called CYCLIC ROUTING, decomposes the entire route into several rounds. In each round, the traveller attempts to visit as many vertices as possible in the graph following the visiting order (or the reverse order) of the tour derived by Christofides' algorithm [13].

## 3 Preliminaries

In this section, we give some basic definitions. We start by giving a formal definition of the problem we study, before defining the Online Graph Exploration Problem, the performance measure and restating Christofides' algorithm for completeness. In what follows, we will denote by  $G = (V, E)$  a weighted, undirected graph. We will interchangeably use the notion of “cost” and “length” for the weight of an edge. For example, a shortest tour is a tour of minimum cost.

### Definition of $k$ -CCTP

The formal definition of CCTP is as follows. Given a complete metric graph  $G = (V, E)$  with a source vertex  $s \in V$ , a traveller aims, beginning from  $s$ , to visit every other vertex in  $V$  at least once and return to  $s$  with as little cost as possible. However, the traveller

discovers online that some edges are blocked once reaching one of their endpoints. Moreover, as mentioned earlier, two assumptions are made. First, the blocked edges cannot isolate vertices of  $G$ , i.e.,  $G$  remains connected, and second, edges remain in their state (i.e., whether they are blocked or not) forever. In this paper, we consider its variant  $k$ -CCTP where the number of blocked edges is bounded by  $k$ .

### Definition of the Online Graph Exploration Problem

The problem can be formalized as follows. Let  $G = (V, E)$  be a weighted, undirected graph with  $|V| = n$  vertices. The agent starts at a vertex  $s \in V$  and has to visit every vertex in the graph and return to  $s$ . Note that the agent can visit a vertex more than once. At each step, the agent is located at a vertex  $u$  and can choose to move to any of the neighboring vertices of  $u$ . The agent incurs a cost equal to the cost of the edge traversed. Upon arriving at a vertex  $v$ , the agent learns all the edges incident to  $v$  and their costs.

### Competitive Ratio

A deterministic online algorithm  $ALG$  for  $k$ -CCTP is  $c$ -competitive if the total cost  $|ALG(\sigma)|$  accrued by  $ALG$  for input  $\sigma$  is at most  $c \cdot |OPT(\sigma)|$ . Here,  $|OPT(\sigma)|$  is the total cost of an optimal tour for  $\sigma$  which is computed by an offline algorithm that already knows all blocked edges.

### Christophides' algorithm

We also remind the reader how Christophides' algorithm works. Christophides' algorithm on a complete metric graph  $G$  can be described as follows [16]:

1. Create a minimum spanning tree  $T$  of  $G$ .
2. Find a minimum-weight perfect matching  $M$  in the subgraph of  $G$  that is induced by the vertices with odd degrees in  $T$ .
3. Combine the edges of  $M$  and  $T$  to form a connected multigraph  $H$ .
4. Form a Eulerian cycle in  $H$ .
5. Make the circuit found in the previous step into a Hamiltonian cycle by skipping repeated vertices.

## 4 Solving $k$ -CCTP via Graph Exploration

In this section, we present the results of our work. First, we show a connection between CCTP and the Online Graph Exploration problem (Theorem 1). This is the crucial step to improve the upper bound of  $O(\sqrt{k})$ .

The idea behind our reduction is that CCTP can be solved by an algorithm that solves the Online Graph Exploration Problem. This is possible since at every step, the traveller locally learns the real edges in both problems. The challenge here is that the algorithms for the Online Graph Exploration for arbitrary graphs have competitive ratios depending on the number of vertices  $n$ .

So, how can we reduce the size of the graph in which we run an algorithm for Graph Exploration to something of size  $O(k)$ ? First, we try to follow an approximately optimal TSP tour, skipping vertices when edges are discovered to be blocked. Similar to the idea in CYCLIC ROUTING of [22], we use a function SHORTCUT to achieve this. After that, we return to the starting vertex. This way, we visit at least  $n - k$  vertices of  $G$ . Since they do not have to be visited again, we can then use the information gathered to reduce the number of vertices in the graph on which we will run the algorithm for Graph Exploration to  $O(k)$ . Formally, we have the following theorem.

► **Theorem 1.** *If there exists an  $f(k)$ -competitive algorithm for the Online Graph Exploration problem on graphs with at most  $k + 1$  nodes and an  $\alpha$ -approximation algorithm for metric TSP, then there exists an  $(f(k) + 2\alpha)$ -competitive algorithm for  $k$ -CCTP.*

**Proof.** Suppose that we have ALGOEXPLORATION, an  $f(k)$ -competitive algorithm for the Online Graph Exploration problem on arbitrary graphs with at most  $k + 1$  nodes, and ALGOTSP, an  $\alpha$ -approximation algorithm for metric TSP. Then, we will prove that the algorithm COMPRESSANDEXPLORE that uses these algorithms as subroutines has a competitive ratio of at most  $f(k) + 2\alpha$  for  $k$ -CCTP (for pseudocode, see Algorithm 1).

First, the algorithm runs ALGOTSP on the input graph  $G$  to compute a TSP tour  $P$ . For simplicity, we relabel the vertices with respect to the tour, i.e., we assume that the tour  $P$  has the order  $s = v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_n \rightarrow v_1$ . If an edge  $\{v_i, v_j\}$  is blocked, the traveller tries to go to the next vertex in the order determined by  $P$ , i.e.,  $v_{j+1}$ , or  $v_1$  for  $j = n$  (for pseudocode of this subroutine, see Function SHORTCUT on page 8). This procedure is possible since the original graph is complete. By the triangle inequality, the cost of the tour is upper bounded by the cost of tour  $P$ . If the traveller reaches vertex  $s$ , then SHORTCUT terminates. If  $s$  is not reachable directly because of a blocked edge, the traveller returns to  $s$  by retracing their steps. Since  $\text{cost}(P)$  is an  $\alpha$ -approximation for metric TSP, we have that  $\text{cost}(\text{SHORTCUT}) \leq 2 \cdot \text{cost}(P) \leq 2\alpha \cdot |\text{OPT}|$ , where  $\text{OPT}$  is an optimal offline TSP tour on graph  $G$ .

The traveller learns about all blocked edges which are adjacent to the vertices that are visited during SHORTCUT. In the procedure, all edges that are discovered to be blocked are collected in the set  $E_b$ . Thus, the traveller knows the whole graph (with all blocks) except for the induced (complete) subgraph formed by the unvisited vertices  $U$ . Let  $\kappa$  be the number of vertices which remain unvisited by  $ALG$  after SHORTCUT, i.e., the size of the set  $U$ . Then, the traveller has discovered at least  $\kappa$  blocked edges, i.e.,  $|E_b| \geq \kappa$ .

Next, the traveller, being at  $s$ , has to visit the vertices in  $U$ . Since the true edges of the graph except for those of the induced subgraph formed by vertices in  $U$  are known, it suffices to consider only the vertices in the set  $U_s = U \cup \{s\}$ . While the vertices in  $V \setminus U_s$  themselves are not required, a shortest path between two vertices  $x, y \in U_s$  might include vertices from the set  $V \setminus U_s$  as intermediate nodes. This can occur when currently unknown edges between unvisited nodes are blocked. More specifically, the algorithm runs the function COMPRESS (for pseudocode, see Function COMPRESS on page 9). For every pair of vertices  $x, y \in U_s$ , the function creates a new edge  $P_{x,y}$  representing a shortest path between  $x$  and  $y$  such that the path consists only of edges that are known not to be blocked, i.e., edges in which at least one node has already been visited before – if such a shortest path exists. Note that this phase of the algorithm does not incur any cost in terms of competitive ratio. Thus, the procedure creates a multigraph  $G'$  which consists of vertex set  $U_s$ , the initial edges that connect these vertices and the “shortest-path” edges as described above. To better explain the steps of the algorithm we present an example of an execution of algorithm COMPRESSANDEXPLORE below (see Example 1).

Finally, the algorithm runs ALGOEXPLORATION on  $G'$  and visits the remaining vertices.<sup>1</sup> Every time the traveller visits a vertex, they learn all incident edges. This includes the newly added “shortest-path” edges, of which we know that they are feasible. If the traveller uses

<sup>1</sup> ALGOEXPLORATION solves the Exploration problem on arbitrary graphs, but  $G'$  is a multigraph with at most two edges per pair of vertices. However, this does not cause a problem, since the algorithm can always select a shortest edge out of the two and the optimal solution can be computed while keeping only one edge per pair.

such a “shortest-path” edge, then in the final computed tour in the original graph we expand it, meaning that we use the real path that corresponds to this edge. The cost of an optimal TSP tour  $OPT_{G'}$  on multigraph  $G'$  is at most the cost of an optimal TSP tour  $OPT_G(U_s)$  that only has to visit the vertex set  $U_s$ , i.e., the vertices that are also in  $G'$ , but inside the input graph  $G$ . To see that this holds, consider an optimal tour  $OPT_G(U_s)$ . Assume that it visits the vertices in  $U_s$  in the order  $s = x_1 \rightarrow x_2 \rightarrow \dots \rightarrow x_{|U_s|} \rightarrow x_1$ . Between any vertices  $x_i, x_{i+1} \in U_s$  for  $i \in \{1, \dots, |U_s| - 1\}$  (or  $x_{|U_s|}, x_1$ ) that are visited one after the other,  $OPT_G(U_s)$  uses a shortest path. Each of these shortest paths starts in  $U_s$ . If it then uses an edge to another vertex in  $U_s$ , this edge will also be in  $G'$  as each direct edge between two vertices of  $U_s$  will either be blocked in both  $G$  and  $G'$  or not be blocked in both. Hence, we can assume that an edge  $\{u, v\}$  from  $u \in U_s$  to a vertex  $v \notin U_s$  is taken. This is an already discovered edge, as  $v$  has already been visited during **SHORTCUT**. Eventually, the path will re-enter into the set  $U_s$  by using another already discovered edge  $\{v', u'\}$  for some  $v' \notin U_s$  and  $u' \in U_s$ . In between leaving and re-entering, all edges that were taken are also already discovered and this partial path has exactly the same length as the shortest-path edge  $P_{u,u'}$  between  $u, u' \in U_s$ .<sup>2</sup> Continuing this argument, eventually the target vertex in  $U_s$  is reached. All intermediate partial paths are inside  $G'$ , either since they are regular edges that also exist in  $G$ , or since they have been added as shortest-path edges during **SHORTCUT**.

The multigraph  $G'$  has  $\kappa + 1$  vertices and at least  $\kappa$  blocks have already been discovered. The number of blocked edges is at most  $k$ , and thus there are at most  $k + 1$  vertices in  $G'$ . So, from the hypothesis the cost incurred by **ALGOEXPLORATION** on  $G'$  is at most  $f(k) \cdot |OPT_{G'}|$ . Since an optimal solution for visiting a subset of vertices  $OPT_G(U_s)$  has cost at most  $|OPT|$ , we get the following

$$\text{cost}(\text{ALGOEXPLORATION}) \leq f(k) \cdot |OPT_{G'}| \leq f(k) \cdot |OPT_G(U_s)| \leq f(k) \cdot |OPT| .$$

Overall, the algorithm has a total cost for the traveller of

$$\begin{aligned} \text{cost}(\text{COMPRESSANDEXPLORE}) &= \text{cost}(\text{SHORTCUT}) + \text{cost}(\text{ALGOEXPLORATION}) \\ &\leq (f(k) + 2\alpha) \cdot |OPT| . \end{aligned}$$

Consequently, **COMPRESSANDEXPLORE** is an  $(f(k) + 2\alpha)$ -competitive algorithm for  $k$ -CCTP. Note that the knowledge of  $k$  does not affect the performance of the algorithm. ◀

► **Remark.** In the proof, we allow  $k \geq n - 1$  as long as the resulting graph remains connected. The analysis of the competitive ratio of  $O(\sqrt{k})$  in [22] requires  $k < n - 1$ .

► **Example 1.** *Fig. 1 shows an example of **COMPRESSANDEXPLORE**. The traveller begins at vertex  $s = v_1$  and moves in a counterclockwise direction. The given TSP tour by **ALGOTSP** here is  $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_{16} \rightarrow v_1$ . The solid lines represent the tour that the traveller follows during **SHORTCUT** due to the discovered blocked edges (red dashed lines). The traveller follows the shortcut path  $v_1 \rightarrow v_2 \rightarrow v_4 \rightarrow v_5 \rightarrow v_9 \rightarrow v_{10} \rightarrow v_{11} \rightarrow v_{14} \rightarrow v_{16}$  and after visiting vertex  $v_{16}$ , they return back to  $s$  following the same path backwards. Next, the algorithm runs **COMPRESS** and gets  $G'$ . Multigraph  $G'$  contains  $s$ , the remaining unvisited vertices and at most two edges between each pair of these vertices. Between  $v_i$  and  $v_j$  there is the edge  $\{v_i, v_j\}$  (which may be blocked) and possibly the “shortest-path” edge  $P_{i,j}$ . The cost of  $P_{i,j}$*

<sup>2</sup> There might be several shortest paths with the same length, which is why the shortest path chosen for  $P_{u,u'}$  and the described shortest path might differ. Still, their lengths are equal by definition.

■ **Algorithm 1** COMPRESSANDEXPLORE(ALGOTSP, ALGOEXPLORATION).

---

**Input** : A complete metric graph  $G = (V, E)$  with  $n$  vertices; a starting vertex  $s \in V$ ;

**Output** : A tour that visits every vertex in  $V$ ;

**Parameter**: ALGOTSP( $G_1$ ): An algorithm that returns a TSP tour on a metric graph  $G_1$ ; The tour has the form  $s = v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_n \rightarrow v_1$ ;  
 ALGOEXPLORATION( $G_2$ ): An algorithm that solves the Online Graph Exploration problem on an arbitrary graph  $G_2$  and returns a tour;

- 1  $P \leftarrow$  ALGOTSP( $G$ );
- 2  $G^*, U, P_1 \leftarrow$  SHORTCUT( $G, P$ );
- 3  $G' \leftarrow$  COMPRESS( $G^*, U, G$ );
- 4  $P_2 \leftarrow$  ALGOEXPLORATION( $G'$ );
- 5  $P' \leftarrow (P_1 \rightarrow P_2)$ ;

/\* Concatenate  $P_1$  and  $P_2$ , i.e., visit the vertices according to  $P_1$ , then according to  $P_2$ . \*/

6 **return**  $P'$ ;

---

■ **Figure 1** An example of algorithm COMPRESSANDEXPLORE.

is the cost of the shortest path from  $v_i$  to  $v_j$  in which each edge has at least one endpoint outside of  $G'$ . In the example, a possible case for  $i = 1$  and  $j = 3$  is shown on the right with  $P_{1,3}$  being the path  $v_1 \rightarrow v_4 \rightarrow v_3$ .

Finally, the algorithm runs ALGOEXPLORATION on  $G'$ . The traveller visits all remaining vertices, returns to  $s$  and the algorithm terminates.

Now, we can use COMPRESSANDEXPLORE with Christophides' algorithm for metric TSP and the Nearest Neighbor for the Online Graph Exploration problem. Since this algorithm uses Christophides' algorithm and then Nearest Neighbor, we refer to it by CNN.

► **Corollary 2.** CNN has a competitive ratio of  $O(\log k)$  for  $k$ -CCTP.

**Proof.** Christophides' algorithm gives a  $3/2$ -approximation for metric TSP. On the other hand, NN yields a competitive ratio of  $O(\log n)$  for the Graph Exploration problem in an arbitrary graph, where  $n$  is the number of vertices in the graph. Thus, from Theorem 1 we get that CNN has a competitive ratio of  $3 + O(\log(k + 1)) = O(\log k)$ . ◀

```

---

To demonstrate that the above analysis is tight, the following theorem presents a family of instances that achieves a competitive ratio of  $\Omega(\log k)$  and therefore proves the analysis to be tight.

► **Theorem 3.** *There exists a family of instances for which CNN has a competitive ratio of the  $\Omega(\log k)$ .*

**Proof.** We will use the graph presented in [18] to lower bound the competitive ratio of the Nearest Neighbor algorithm. For an integer  $p \geq 1$ , the graph  $G_p = (V_p, E_p)$  consists of a chain of  $2^p - 1$  triangles.  $G_p$  has  $2^p$  vertices in its lower level, and  $2^p - 1$  vertices in its upper level. The left-most vertex in the lower level is denoted by  $l_p$ , the right-most by  $r_p$  and the central vertex in the upper level is denoted by  $m_p$ . All edges in  $G_p$  have an equal cost of 1.

For our instance, we slightly modify the graph by adding another vertex  $u$  to the left of  $l_p$  with an edge  $\{u, l_p\}$  of cost 1. We also set  $s = l_p$  as the starting vertex. Since the input for  $k$ -CCTP is a complete graph, we also need to add some more edges. All edges from  $u$  to the other vertices have a cost of 1, and all other new edges have a cost of 2. All these edges will be blocked edges. We call this new graph  $G_p^+$ .

The resulting graph has  $k = \Theta(n^2)$  blocked edges and clearly satisfies the triangle inequality. We illustrate the non-blocked part of  $G_p^+$  for  $p = 3$  in Fig. 2.

In the first step of Christophides' algorithm, a minimal spanning tree is constructed. One possible MST  $T$  is a path from  $u$  to  $r_p$ . The nodes with uneven degree in  $T$  are the nodes  $u$  and  $r_p$ , so for the matching, the edge between  $u$  and  $r_p$  is added. This results in a simple cycle of all nodes. The MST and the matching edge are illustrated in Fig. 3.

■ **Figure 2** Graph  $G_p^+$  (for  $p = 3$ ).  $G_p^+$  is used to show tightness of the  $O(\log k)$ -competitive ratio.

The TSP-tour can then be chosen to be  $s = l_3 \rightarrow u \rightarrow r_3 \rightarrow \dots \rightarrow l_3$ . This means that in **SHORTCUT**, only node  $u$  would be visited besides  $l_p$  as the direct edges from  $u$  to any other node (besides  $l_p$ ) are blocked. At the end of **SHORTCUT**, the traveller returns to  $l_p$ .

After **SHORTCUT**, the remaining graph would thus be the original graph  $G_p$  from [18]. We use the following lemma to prove that there exists a TSP-tour in  $G_p$  which starts (and ends) in  $l_p$  which is found by NN that has a length of  $(p + 4) \cdot 2^{p-1} - 2$ . We will prove the lemma below.

► **Lemma 4** (Based on [18, Lemma 1]). *There exists a NN-based TSP tour on  $G_p$  which starts in  $l_p$  and visits  $m_p$  as final vertex before returning back to  $l_p$ . The tour has length  $(p + 4) \cdot 2^{p-1} - 2$ .*

Using this result, the total cost of the described TSP-tour is  $(p + 4)2^{p-1}$ , whereas an optimal TSP-tour has cost  $2 + 3(2^p - 1)$ , namely visiting  $u$  and optimally visiting  $G_p$  by going in a zig-zag motion from left to right (as shown in the MST in Fig. 3) and returning using the lower edges of the triangle, thereby using each edge of the triangles exactly once.

■ **Figure 3** The MST and the matching edge (dashed line) in  $G_3^+$ .

This gives us a ratio of

$$\frac{(p+4) \cdot 2^{p-1}}{2+3 \cdot (2^p-1)} = \frac{(p+4) \cdot 2^{p-1}}{6 \cdot 2^{p-1}-1} \geq \frac{p+4}{6} = \Omega(p) = \Omega(\log n) . \quad \blacktriangleleft$$

**Proof of Lemma 4.** We split the tour into two parts. In the first part, all vertices are visited, and in the second part, the traveller returns to  $l_p$ .

The second part has length  $1 + 2^{p-1} - 1 = 2^{p-1}$ . This is true because the whole graph has been discovered and the traveller can take the shortest path from  $m_p$  to  $l_p$ , which is going down to the left point of the middle triangle and then traversing the  $2^{p-1} - 1$  many triangles on the left side to reach  $l_p$ .

Hence, to show the Lemma, it remains to show that there exists a NN-route to visit all vertices in  $G_p$  which has length  $(p+3) \cdot 2^{p-1} - 2 = (p+4) \cdot 2^{p-1} - 2 - 2^{p-1}$ , starting at  $l_p$  and ending at  $m_p$ . We prove this by induction. For  $p=1$ ,  $G_p$  consists of a single triangle, and the route  $l_1 \rightarrow r_1 \rightarrow m_1$  has length  $2 = (1+3) \cdot 2^{1-1} - 2$ .

For the inductive step, we observe that  $G_p$  can be constructed from two copies of  $G_{p-1}$  and an additional vertex  $m_p$  (and three additional edges). Let  $G_{p-1}^{(l)}$  be the left copy and  $G_{p-1}^{(r)}$  be the right copy. Then, the new edges are  $\{r_{p-1}^{(l)}, l_{p-1}^{(r)}\}$ ,  $\{r_{p-1}^{(l)}, m_p\}$  and  $\{l_{p-1}^{(r)}, m_p\}$ . This is illustrated in Fig. 4. By the induction hypothesis, there exists an NN-route in  $G_{p-1}^{(l)}$  starting in  $l_p = l_{p-1}^{(l)}$  and ending in  $m_{p-1}^{(l)}$  with length  $(p-1+3) \cdot 2^{p-1-1} - 2$ . The two nearest unvisited neighbors to  $m_{p-1}^{(l)}$  are  $m_p$  and  $l_{p-1}^{(r)}$  with equal distance  $2^{p-2} + 1$ . By going to  $l_{p-1}^{(r)}$ , the sub-route from  $l_{p-1}^{(r)}$  to  $m_{p-1}^{(r)}$  of length  $(p+2) \cdot 2^{p-2} - 2$  can then be found by NN. Note that throughout this route,  $m_p$  will never be closer to the current vertex than any other unvisited vertex in the current sub-route and thus will not be visited before  $m_{p-1}^{(r)}$ . Finally,  $m_p$  needs to be visited, which requires an additional cost of  $2^{p-2} + 1$ . Overall, there exists an NN-route from  $l_p$  to  $m_p$  with length

$$2 \cdot ((p+2) \cdot 2^{p-2} - 2) + 2 \cdot (2^{p-2} + 1) = (p+2) \cdot 2^{p-1} - 4 + 2^{p-1} + 2 = (p+3) \cdot 2^{p-1} - 2 .$$

This concludes the proof. ◀

Finally, we remark that CNN takes polynomial time. The procedures SHORTCUT and COMPRESS run in polynomial time as the required shortest paths can be computed in polynomial time. Since Christophides' algorithm and Nearest Neighbor also have polynomial time complexity, so does CNN.

## 5 Concluding Remarks

In this work, we considered the Covering Canadian Traveller Problem with up to  $k$  blocked edges. We improved the upper bound to  $O(\log k)$  by drawing an interesting connection to the Online Graph Exploration problem. Further, we showed the tightness of our analysis.

■ **Figure 4** Graph  $G_p$  (for  $p = 3$ ) constructed from two copies of  $G_{p-1}$ , with the joining edges denoted by the dashed lines.

Our reduction implies immediate consequences of future work on the respective other problem. For one, it allows an improvement of the lower bound on the Graph Exploration problem using a general lower bound on  $k$ -CCTP. Currently, the best known bound for the Graph Exploration problem is  $10/3$ . Tightening this gap would be a very interesting result. Second, an improved algorithm for the Graph Exploration problem immediately gives rise to a better algorithm and upper bound on  $k$ -CCTP.

Nevertheless, already an improved algorithm for  $k$ -CCTP or a lower bound on the Graph Exploration problem would be of independent interest without exploiting our reduction and thus provides another challenging direction of future research.

## Abstract

We initiate a study of the complexity of MSM-MEDIAN, the problem of computing a median of a set of  $k$  real-valued time series under the move-split-merge distance. This distance measure is based on three operations: moves, which may shift a data point in a time series; splits, which replace one data point in a time series by two consecutive data points of the same value; and merges, which replace two consecutive data points of equal value by a single data point of the same value. The cost of a move operation is the difference of the data point value before and after the operation, the cost of split and merge operations is defined via a given constant  $c$ .

Our main results are as follows. First, we show that MSM-MEDIAN is NP-hard and W[1]-hard with respect to  $k$  for time series with at most three distinct values. Under the Exponential Time Hypothesis (ETH) our reduction implies that a previous dynamic programming algorithm with running time  $|I|^{\mathcal{O}(k)}$  [Holznigenkemper et al., Data Min. Knowl. Discov. '23] is essentially optimal. Here,  $|I|$  denotes the total input size. Second, we show that MSM-MEDIAN can be solved in  $2^{\mathcal{O}(d/c)} \cdot |I|^{\mathcal{O}(1)}$  time where  $d$  is the total distance of the median to the input time series.

## 1 Introduction

Computing an exact or approximate consensus of a set of real-valued time series is a critical task in many applications like nearest-neighbor classification and clustering of time series [1, 8, 10]. The algorithmic task in this problem is to compute for a given set  $X$  of time series some time series  $x$  which has a small distance to the members of  $X$ . Naturally, the quality of the computed consensus time series for the above-mentioned applications and the difficulty of computing such a consensus depend highly on the underlying time series distance function.

The best results in terms of quality and robustness of the computed distances is achieved by elastic distance measures [11]. Informally, when computing an elastic distance measure for two time series, each time series may be stretched or compressed. This ensures that the best-fitting parts are aligned. Elastic distance measures allow for comparison of time series of different lengths, are translation invariant and robust to temporal misalignment [9]. The high quality of elastic measures however comes at a high running time cost [11].

Consider for example the most popular elastic measure, the *dynamic time warping* (DTW) distance. The DTW distance of two time series of length  $n$  and  $m$  can be computed in  $\mathcal{O}(nm)$  time by a simple dynamic programming (DP) algorithm. Under the SETH, a fairly common complexity-theoretic assumption, this cannot be improved to  $\mathcal{O}(n^{2-\epsilon})$  time even when both time series have length  $n$  [3]. DTW-MEAN, the problem of computing a mean under the DTW distance measure, that is, a time series that minimizes the sum of squared DTW distances to the input time series, can be solved in  $\mathcal{O}(n^{2k+1}2^k k)$  time [2]. Here,  $n$  is the maximum time series length and  $k$  is the number of input time series. While this running time is polynomial for a constant number of strings, it grows rapidly with  $k$  making the algorithm impractical for  $k \geq 4$ . DTW-MEAN is NP-hard [4], so a polynomial-time algorithm cannot be expected. Moreover, DTW-MEAN is W[1]-hard with respect to  $k$  and thus an FPT algorithm for  $k$ , that is, an algorithm with running time  $f(k) \cdot n^{\mathcal{O}(1)}$  is presumably impossible [4]. Altogether, the complexity of distance and mean computation under the DTW measure are fairly well-understood by now.

DTW is by far not the only elastic distance measure. In this work, we study the *Move-Split-Merge* (MSM) distance [12]. Here, one time series is transformed into another using three types of operations. A *move* shifts one value in a time series, a *split* replaces one point of a time series by two subsequent points of the same value and a *merge* replaces two subsequent points of the same value by a single point of the same value. In contrast to DTW, the MSM distance fulfills the properties of a metric. Moreover, it achieves high accuracy in 1-NN classification tasks [9, 11]. This highly motivates an algorithmic study of distance computation and median finding problems. Initially, the distance computation for the MSM metric was found to be much slower than for DTW [11]. Recent progress showed that, on the practical side, the MSM distance computation can be improved so that it is competitive with state-of-the-art algorithms for DTW [5]. For MSM-MEDIAN, the problem of computing a time series that minimizes the sum of the MSM-distances to a given set  $X$  of time series, the running times are even better than for DTW-MEAN<sup>1</sup>: There is a DP algorithm that solves MSM-MEDIAN in  $\mathcal{O}(n^{k+3}2^k k^3)$  time [6].<sup>2</sup> As in the DTW-MEAN algorithm, this is a polynomial running time for fixed number of input sequences but the running time dependence on  $k$  is better. This running time advantage was also confirmed in an experimental evaluation [6]. Given the high quality of MSM-based classifications, it would be very desirable to push this running time advantage even further by finding better algorithms for MSM-MEDIAN. At this point, it should be noted that apart from the above-mentioned DP, nothing is known about the complexity of MSM-MEDIAN. This work aims at filling this gap. In particular, we study whether there is hope for substantial improvements over the current DP algorithm.

**Our Results.** We present two main results. First, we show that MSM-MEDIAN is NP-hard, W[1]-hard when parameterized by  $k$ , and cannot be solved in  $f(k) \cdot |I|^{\mathcal{O}(k)}$  time for any computable function  $f$ , unless the ETH fails. Here,  $|I|$  denotes the total input size of MSM-MEDIAN. These hardness results hold even if the total number of distinct values in the input time series is three. This implies that the previous DP algorithm for MSM-MEDIAN [6]

<sup>1</sup> It may seem inappropriate to directly compare a mean finding problem with a median finding problem. However, in the DTW-MEAN problem, the DTW distance measure is defined as a square root of a warping past cost [2]. Consequently, the DTW mean minimizes the sum of warping path costs and is thus in fact a median for this distance measure.

<sup>2</sup> Previously, the problem was called MSM-MEAN. Following a reviewer suggestion, we now use the name MSM-MEDIAN since the aim is to minimize the sum of distances instead of the sum of squared distances.

is close to optimal. Second, we show that MSM-MEDIAN can be solved in  $2^{\mathcal{O}(d/c)} \cdot |I|^{\mathcal{O}(1)}$  time where  $c$  is the constant cost for a merge or split operation and  $d$  is a bound on the total distance of the median  $x^*$  to the input time series in  $X$ . Due to space constraints, proofs of statements marked with (\*) are deferred to a full version.

## 2 Preliminaries

A *time series* of length  $n$  is a sequence  $x = (x[1], \dots, x[n])$ , where each *data point*, in short *point*,  $x[i]$  is a real number. For  $i \in [1, n]$  and  $j \in [i, n]$ , we denote by  $x[i, j]$  the contiguous subsequence of  $x$  starting at  $i$  and ending at  $j$ . A contiguous subsequence  $x[i, j]$  is an  $\alpha$ -run if  $x[\ell] = \alpha$  for each  $\ell \in [i, j]$ . Similarly, we call  $x[i, j]$  a *binary run* if  $x[\ell] \in \{0, 1\}$  for each  $\ell \in [i, j]$ . For a set of time series  $X = \{x_1, \dots, x_k\}$ , the  $i$ th point of the  $j$ th time series of  $X$  is denoted by  $x_j[i]$ ;  $V(X) = \{x[i] \mid x \in X, i \in [1, |x|]\}$  denotes the set of all values of points in the time series of  $X$ .

**Move-Split-Merge Operations.** We now define the MSM metric, following the notation of Stefan et al. [12], and the MSM-MEDIAN problem. The MSM metric allows three types of operations to transfer one time series into another: *move*, *split*, and *merge*. For time series  $x = (x[1], \dots, x[n])$ , a move transforms a point  $x[i]$  into  $x[i] + w$  for some  $w \in \mathbb{R}$ , that is,  $\text{Move}_{i,w}(x) := (x[1], \dots, x[i-1], x[i] + w, x[i+1], \dots, x[n])$ , with cost  $\text{Cost}(\text{Move}_{i,w}) = |w|$ . Informally, we say that there is a *move at point  $x[i]$  to another point  $x[i] + w$* . The split operation splits the  $i$ th element of  $x$  into two consecutive points. A split at point  $x[i]$  is defined as  $\text{Split}_i(x) := (x[1], \dots, x[i-1], x[i], x[i], x[i+1], \dots, x[n])$ . A merge operation may be applied to two consecutive points of equal value. For  $x[i] = x[i+1]$ , it is given by  $\text{Merge}_i(x) := (x[1], \dots, x[i-1], x[i+1], \dots, x[n])$ . We say that  $x[i]$  and  $x[i+1]$  *merge*. Split and merge operations are inverse operations. Their costs are assumed to be equal and determined by a given nonnegative constant  $c =: \text{Cost}(\text{Split}_i) = \text{Cost}(\text{Merge}_i)$ .

A *transformation sequence*  $\mathbb{S}$  is a tuple  $(S_1, \dots, S_s)$  with  $S_j \in \{\text{Move}_{i_j, w_j}, \text{Split}_{i_j}, \text{Merge}_{i_j}\}$ . A *transformation*  $\mathbf{T}(x, \mathbb{S})$  of a time series  $x$  for a given transformation sequence  $\mathbb{S}$  is defined recursively via  $\mathbf{T}(x, \mathbb{S}) := \mathbf{T}(S_1(x), (S_2, \dots, S_s))$  and  $\mathbf{T}(x, \emptyset) := x$ . We say that  $\mathbb{S}$  transforms  $x$  to  $y$  if  $\mathbf{T}(x, \mathbb{S}) = y$ . The cost of a transformation sequence  $\mathbb{S}$  is the sum of all individual operation costs, that is,  $\text{Cost}(\mathbb{S}) := \sum_{S \in \mathbb{S}} \text{Cost}(S)$ . A transformation is *optimal* if it has minimal cost. The *MSM distance*  $d_{\text{MSM}(c)}(x, y)$  between two time series  $x$  and  $y$  is the cost of an optimal transformation. If  $c$  is clear from context, we may only write  $d_{\text{MSM}}$ . We let  $D_{\text{MSM}(c)}(X, y) := \sum_{x \in X} d_{\text{MSM}(c)}(x, y)$  denote the distance of a sequence  $X$  of time series to a time series  $y$ . A *median*  $x^*$  of a set of time series  $X$  is a time series with minimum distance to  $X$ . The decision problem of computing a median is defined as follows.

MSM-MEDIAN

**Input:** A constant  $c > 0$ , a sequence  $X := (x_1, \dots, x_k)$  of time series, and an integer  $d$ .

**Question:** Is there a time series  $x^*$  such that  $D_{\text{MSM}(c)}(X, x^*) \leq d$ ?

**Transformations Graphs.** We further recall the concept of *transformation graphs* to describe the structure of a transformation between time series  $x$  and  $x^*$  [6, 12]. The *transformation graph* of  $\mathbf{T}(x, \mathbb{S}) = x^*$  is a directed acyclic graph  $G_{\mathbb{S}}(x, x^*)$  with *source nodes*  $N(x) = \{u[1], \dots, u[m]\}$  and *sink nodes*  $N(x^*) = \{u^*[1], \dots, u^*[n]\}$ , where a node  $u[i]$  represents the point  $x[i]$  and a node  $u^*[j]$  represents the point  $x^*[j]$ . The nodes which are neither source nor sink nodes are called *intermediate nodes*. All nodes have in-degree and out-degree at most 2. If there is a directed path from one node  $\alpha$  to another node  $\beta$ , we say that  $\alpha$  is *aligned*

■ **Figure 1** An optimal transformation graph between  $x := (4, 5, 5, 10)$  and  $y := (10, 7, 8)$  with  $c = 0.1$ . Move edges are red. There are two merge operations, one split operation, and move operations of total cost 8. Hence,  $d(x, y) = 8.3$ .

to  $\beta$ . The nodes of  $N(x)$  that align to the same node  $\alpha$  correspond to consecutive points in  $x$ . Each node in the node set  $V$  of  $G_{\mathbb{S}}(x, x^*)$  is associated with a value given by a function  $\text{val} : V \rightarrow \mathbb{R}$ . For source and sink nodes we have  $\text{val}(u[i]) = x[i]$  and  $\text{val}(u^*[j]) = x^*[j]$ . Each intermediate node is also associated with a value. The edges represent the transformation operations of  $\mathbb{S}$ . To create a transformation graph, for each operation in  $\mathbb{S}$ , a respective *move edge* or two *split* edges, or two *merge edges* are added to the graph. If a node  $\alpha$  has outdegree 2 and is connected to a node  $\beta$  by a split edge and  $\beta$  is a child of  $\alpha$ , then there exists a node  $\gamma \neq \beta$  to which  $\alpha$  is connected by a split edge and which is a child of  $\alpha$ . If the nodes  $\alpha$  and  $\beta$  are connected by a merge edge,  $\alpha$  is a parent of  $\beta$ , and  $\beta$  has indegree 2, then there exists a node  $\gamma \neq \alpha$  which is connected to  $\beta$  by a merge edge and is a parent of  $\beta$ . Moreover, for the split and the merge case, it holds that  $\text{val}(\alpha) = \text{val}(\beta) = \text{val}(\gamma)$ . A move edge can be further specified as an *increasing (inc-)* or *decreasing (dec-)* edge if the move operation adds a (not necessarily strictly) positive or negative value to the value of the parent node, respectively.

A *transformation path*, in short *path*, in  $G_{\mathbb{S}}(x, x^*)$  is a directed path from a source node  $u[i] \in N(x)$  to a sink node  $u^*[j] \in N(x^*)$ . A transformation path is *monotonic* if the move edges on this path are only inc- or only dec-edges. A transformation graph is *optimal* if it belongs to an optimal transformation. There exists an optimal transformation graph  $G_{\mathbb{S}}(x, x^*)$  which can be decomposed into a sequence of distinct *trees*  $(T_1, \dots, T_t)$  with the following properties [6]: 1) The sink and source nodes of each tree  $T_i$  form a contiguous subsequence of  $x$  and  $y$ , respectively. 2) For all  $i \in [1, t - 1]$ , the source and sink nodes of  $T_i$  precede the source and sink nodes of  $T_{i+1}$ , respectively. 3) Each path in each  $T_i$  is monotonic. For  $i \in [1, n]$  and  $j \in [i, n]$ , we denote by  $u[i, j]$  a contiguous subsequence of nodes of  $x$ .

The *cost of a tree*  $T$  is the sum of the cost of the tree edges and denoted by  $\text{Cost}_c(T)$ . If the merge/split cost  $c$  is clear from the context, we may omit the subscript. If a tree contains two nodes  $\alpha$  and  $\beta$ , its cost are at least  $|\alpha - \beta|$ . If a tree contains a split or merge edge, its cost are at least  $c$ . We call an optimal transformation graph decomposed into a sequence of trees as an *optimal transformation forest*. Figure 1 shows an example where the transformation graph consists of two trees.

► **Observation 1 (\*)**. *Let  $X$  be a set of time series, let  $x^*$  be a time series, and let  $i \in [1, |x^*| - 1]$ . If for each time series  $x \in X$ , there is some optimal transformation graph containing a tree  $T_x$  such that both  $u^*[i]$  and  $u^*[i + 1]$  are sinks of  $T_x$ , then there is a time series  $y^*$  such that for each time series  $x \in X$ ,  $d_{\text{MSM}(c)}(x, x^*) > d_{\text{MSM}(c)}(x, y^*)$ .*

Let  $x$  and  $y$  be time series of the same length. We define  $d_{\text{Move}}(x, y) := \sum_{i=1}^{|x|} |x[i] - y[i]|$  as the *move distance* between  $x$  and  $y$ . The move distance describes the cost of a transformation forest between  $x$  and  $y$  that only uses move operations. Hence,  $d_{\text{Move}}(x, y) = d_{\text{MSM}(c)}(x, y)$  if and only if some optimal transformation between  $x$  and  $y$  uses only move operations.

**Circular Consensus String.** Our negative results are obtained by a reduction from BINARY CIRCULAR CONSENSUS STRING [4]. Let  $s$  be a string of length  $n$  and let  $\delta \in [1, n]$ . The *circular shift of  $s$  by  $\delta$*  is the string  $s^{\leftarrow\delta}$  of length  $n$  with  $s^{\leftarrow\delta}[i] := s[1 + (i - 1 + \delta) \bmod n]$  for each  $i \in [1, n]$ . We denote the *Hamming distance* of strings  $s_1$  and  $s_2$  by  $d_{\text{Ham}}(s_1, s_2)$ .

BINARY CIRCULAR CONSENSUS STRING

**Input:** A set  $S := \{s_1, \dots, s_k\}$  of binary strings of length  $n$  and an integer  $d$ .

**Question:** Is there a binary string  $s^*$  of length  $n$  and a  $k$ -tuple  $(\delta_1, \dots, \delta_k) \in [0, n-1]^k$  such that  $\sum_{i \in [1, k]} d_{\text{Ham}}(s_i^{\leftarrow\delta_i}, s^*) \leq d$ ?

The Exponential Time Hypothesis (ETH) [7] implies that 3-SAT cannot be solved in  $2^{o(|F|)}$  time where  $F$  is the input formula. Assuming the ETH, BINARY CIRCULAR CONSENSUS STRING cannot be solved in  $f(k) \cdot n^{o(k)}$  time for any computable function  $f$  [4].

### 3 Finding an MSM-Median is Hard

In this section we prove our main hardness results for MSM-MEDIAN.

► **Theorem 2.** *For  $c = 1$ , MSM-MEDIAN is NP-hard, W[1]-hard when parameterized by  $k$ , and cannot be solved in  $f(k) \cdot |I|^{o(k)}$  time for any computable function  $f$ , unless the ETH fails. This holds even if  $|V(X)| = 3$ .*

To show the hardness results, we present a reduction from the BINARY CIRCULAR CONSENSUS STRING-problem which is NP-hard, W[1]-hard when parameterized by  $k$ , and cannot be solved in  $f(k) \cdot n^{o(k)}$  time for any computable function  $f$ , unless the ETH fails [4].

Let  $I := (S, d)$  be an instance of BINARY CIRCULAR CONSENSUS STRING and let  $n$  denote the length of each binary strings of  $S := \{s_1, \dots, s_k\}$  with  $k := |S|$ . If  $d \geq n \cdot k$ , then  $I$  is a trivial yes-instance. Hence, we assume that  $d \leq n \cdot k$ . We can assume that  $k \leq n$  as otherwise  $I$  can be solved in FPT-time for  $k$ . We now describe how to construct in polynomial time an equivalent instance  $I' := (c = 1, X, d')$  of MSM-MEDIAN such that  $|X| = |S|$  and  $|I'| \in n^{\mathcal{O}(1)}$ . Each point in each time series of  $X$  has value either 0, 1, or  $A := 2d + 3$ . Let  $g : \{0, 1\}^* \rightarrow \{0, 1, A\}^*$  be the function where  $g(0) := (0, A)$  and  $g(1) := (1, A)$ , and for any binary string  $y$  of length at least 2 we have  $g(y) := g(y[1]) \circ \dots \circ g(y[|y|])$ .

For each  $i \in [1, k]$ , we define a time series  $x'_i := g(s_i)$ . Let  $R := k \cdot (n \cdot (A + 2) + 1)$ . We set  $X := (x_1, \dots, x_k)$ , where for each  $i \in [1, k]$ ,  $x_i$  is the concatenation of  $R$  copies of  $x'_i$ , that is,  $x_i := (x'_i)^R = (g(s_i))^R = g((s_i)^R)$ . Finally, we set  $d' := (R - 1) \cdot d + k \cdot (n \cdot (A + 2) + 1) = (R - 1) \cdot d + k \cdot (n \cdot (2d + 5) + 1)$ . This completes the construction of  $I'$ .

Note that  $|X| = k$  and that  $|I'| \in |I|^{\mathcal{O}(1)} \subseteq n^{\mathcal{O}(1)}$  since we assumed that  $k \leq n$  and  $d \leq n \cdot k$ . Hence, to show the statement, it remains to show that  $I$  is a yes-instance of BINARY CIRCULAR CONSENSUS STRING if and only if  $I'$  is a yes-instance of MSM-MEDIAN.

**$I'$  is a yes-instance if  $I$  is a yes-instance.** Let  $s^*$  be a binary string of length  $n$  and let  $(\delta_1, \dots, \delta_k) \in [0, n - 1]^k$  be a  $k$ -tuple such that  $\sum_{i \in [1, k]} d_{\text{Ham}}(s_i^{\leftarrow\delta_i}, s^*) \leq d$ . We define a time series  $x'$  as  $x' := g(s^*)$ . Let  $x^*$  be the concatenation of  $R - 1$  copies of  $x'$ , that is,

$$x^* := (x')^{R-1} = (g(s^*))^{R-1} = g((s^*)^{R-1}).$$

We show that  $D_{\text{MSM}}(X, x^*) \leq d'$ . More precisely, we show that  $d_{\text{MSM}}(x_i, x^*) \leq (R - 1) \cdot d_{\text{Ham}}(s_i^{\leftarrow\delta_i}, s^*) + n \cdot (A + 2) + 1$  for each  $i \in [1, k]$ . Since  $\sum_{s_i \in S} d_{\text{Ham}}(s_i^{\leftarrow\delta_i}, s^*) \leq d$  and  $D_{\text{MSM}}(X, x^*) = \sum_{x_i \in X} d_{\text{MSM}}(x_i, x^*)$ , this then implies that  $D_{\text{MSM}}(X, x^*) \leq (R - 1) \cdot d + k \cdot (n \cdot (A + 2) + 1) = d'$ . Informally, we obtain the bound on  $d_{\text{MSM}}(x_i, x^*)$  via the

■ **Figure 2** Left: An instance of CCS for three strings  $s_1, s_2, s_3$  with the consensus string  $s^*$ . Red rectangles show the shift  $\delta_i$ ,  $i \in [1, 3]$ . Right: Corresponding MSM-MEDIAN problem with input time series  $x_1, x_2$ , and  $x_3$  and the median  $x^*$ . Blue parts in the input time series align via merge-and-move edges to  $x^*$ . Red parts align via move edges from the input time series to  $x^*$ .

following transformation: For the middle  $(R-1) \cdot 2 \cdot n$  points of  $x_i$ , only move operations are applied. All other points at the beginning and end of each time series in  $X$  merge to the first or last point in  $x^*$ , respectively. Figure 2 shows an example.

The above-mentioned set of middle points of  $x_i$  is defined as follows. The string  $(s_i)^R$  contains the substring  $(s_i^{\leftarrow \delta_i})^{R-1}$  starting at index  $\delta_i + 1$ . Hence,  $x_i = g((s_i)^R)$  contains the substring  $\tilde{x}_i := g((s_i^{\leftarrow \delta_i})^{R-1}) = g(s_i^{\leftarrow \delta_i})^{R-1}$  starting at index  $2 \cdot \delta_i + 1$ . The time series  $\tilde{x}_i$  comprises exactly these middle points. We now bound the distance of  $x_i$  to  $\tilde{x}_i$  and the distance of  $\tilde{x}_i$  to  $x^*$ .

First, we show that  $d_{\text{MSM}}(x_i, \tilde{x}_i) \leq n \cdot (A+2) + 1$ . To this end, we describe a transformation graph  $G_i$  between  $x_i$  and  $\tilde{x}_i$  that consists of  $(R-1) \cdot 2 \cdot n$  trees. The first tree  $T_1$  contains the first  $2 \cdot \delta_i + 1$  points of  $x_i$  as source nodes and the first point of  $\tilde{x}_i$  as the unique sink node. Similarly, the last tree  $T_{(R-1) \cdot 2 \cdot n}$  contains the last  $2 \cdot (n - \delta_i) + 1$  points of  $x_i$  as source nodes and the last point of  $\tilde{x}_i$  as the unique sink node. For each  $\ell \in [2, (R-1) \cdot 2 \cdot n - 1]$ , the tree  $T_\ell$  consists of a single edge from the source  $u_i[2 \cdot \delta_i + \ell]$  to the sink  $\tilde{u}_i[\ell]$ . Since  $x_i$  contains the substring  $\tilde{x}_i$  starting at index  $2 \cdot \delta_i + 1$ , for each  $\ell \in [2, (R-1) \cdot 2 \cdot n - 1]$ , we have  $x_i[2 \cdot \delta_i + \ell] = \tilde{x}_i[\ell]$  which implies  $\text{Cost}(T_\ell) = 0$ . Hence, it remains to show that  $\text{Cost}(T_1) + \text{Cost}(T_{(R-1) \cdot 2 \cdot n}) \leq n \cdot (A+2) + 1$ . The following lemma upper-bounds the costs of these trees independent of the concrete binary values of their respective sources and sinks. For each  $\alpha \in \{0, 1, A\}$ , we use  $\alpha$  as shortcut for the length-one time series  $(\alpha)$ .

► **Lemma 3 (\*)**. *Let  $y$  be a binary string. It holds that*

- $d_{\text{MSM}}(A \circ g(y), A) \leq |y| \cdot (A+2)$  and
- for each  $\alpha_1 \in \{0, 1\}$  and each  $\alpha_2 \in \{0, 1\}$ ,  $d_{\text{MSM}}(g(y) \circ \alpha_1, \alpha_2) \leq |y| \cdot (A+2) + 1$ .

Recall that sink nodes of  $T_1$  are nodes in  $x^*$ . Since the unique sink node of  $T_1$  has value either 0 or 1, Lemma 3 implies  $\text{Cost}(T_1) \leq (\delta_i) \cdot (A+2) + 1$ . Moreover, since the unique sink node of  $T_{(R-1) \cdot 2 \cdot n}$  has value  $A$ , Lemma 3 implies  $\text{Cost}(T_{(R-1) \cdot 2 \cdot n}) \leq (n - \delta_i) \cdot (A+2)$ . Hence,  $d_{\text{MSM}}(x_i, \tilde{x}_i) \leq \text{Cost}(T_1) + \text{Cost}(T_{(R-1) \cdot 2 \cdot n}) \leq n \cdot (A+2) + 1$ .

Second, we show that  $d_{\text{MSM}}(\tilde{x}_i, x^*) \leq (R-1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*)$ . Recall that  $\tilde{x}_i$  and  $x^*$  have the same length  $((R-1) \cdot 2 \cdot n)$ . Hence, it is sufficient to show that  $d_{\text{Move}}(\tilde{x}_i, x^*) \leq (R-1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*)$ . Since  $\tilde{x}_i[\ell] = x_i^*[\ell] = A$  for each even  $\ell \in [1, |x^*|]$ , we conclude

$$\begin{aligned}
 d_{\text{Move}}(\tilde{x}_i, x^*) &= \sum_{\text{odd } \ell \in [1, |x^*|]} |\tilde{x}_i[\ell] - x^*[\ell]| = \sum_{\ell \in [1, (R-1) \cdot n]} |\tilde{x}_i[2\ell - 1] - x^*[2\ell - 1]| \\
 &= (R-1) \cdot \sum_{\ell \in [1, n]} |\tilde{x}_i[2\ell - 1] - x^*[2\ell - 1]| \\
 &= (R-1) \cdot \sum_{\ell \in [1, n]} d_{\text{Ham}}(\tilde{x}_i[2\ell - 1], x^*[2\ell - 1])
 \end{aligned}$$

$$\begin{aligned}
 &= (R - 1) \cdot \sum_{\ell \in [1, n]} d_{\text{Ham}}(s_i^{\leftarrow \delta_i}[\ell], s^*[\ell]) \\
 &= (R - 1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*).
 \end{aligned}$$

Recall that  $\tilde{x}_i = (g(s_i^{\leftarrow \delta_i}))^{R-1}$  and  $x^* = (g(s^*))^{R-1}$ . The second to last equation holds since by definition of  $g$ , for each  $j \in [1, n]$ ,  $g(s_i^{\leftarrow \delta_i})[2j - 1] = s_i^{\leftarrow \delta_i}[j]$  and  $g(s^*)[2j - 1] = s^*[j]$ . Hence,  $d_{\text{MSM}}(\tilde{x}_i, x^*) \leq d_{\text{Move}}(\tilde{x}_i, x^*) = (R - 1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*)$ .

Since  $d_{\text{MSM}}$  is a metric, we obtain

$$d_{\text{MSM}}(x_i, x^*) \leq d_{\text{MSM}}(x_i, \tilde{x}_i) + d_{\text{MSM}}(\tilde{x}_i, x^*) \leq (R - 1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*) + n \cdot (A + 2) + 1.$$

Hence,  $d_{\text{MSM}}(x_i, x^*) \leq (R - 1) \cdot d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*) + n \cdot (A + 2) + 1$  for each time series  $x_i \in X$  and thus  $D_{\text{MSM}}(X, x^*) \leq d'$ . Consequently,  $I'$  is a yes-instance of MSM-MEDIAN.

**$I'$  is a no-instance if  $I$  is a no-instance.** If  $I$  is a no-instance, then for each binary string  $s^*$  of length  $n$  and each  $k$ -tuple  $(\delta_1, \dots, \delta_k) \in [0, n - 1]^k$ ,  $\sum_{i \in [1, k]} d_{\text{Ham}}(s_i^{\leftarrow \delta_i}, s^*) \geq d + 1$ . Let  $x^*$  be a time series that minimizes  $D_{\text{MSM}}(X, x^*)$ . We show that  $D_{\text{MSM}}(X, x^*) \geq R \cdot (d + 1) = d' + d > d$ . We can assume that  $x^*$  uses only values of  $V(X) = \{0, 1, A\}$  [6]. For each  $i \in [1, k]$ , let  $G_{S_i}(x_i, x^*)$  be an optimal transformation graph between  $x_i$  and  $x^*$ . Moreover, let  $\mathcal{T}_i$  be the collection of all trees of  $G_{S_i}(x_i, x^*)$ . We can assume that each value in each such tree is from  $V(X) = \{0, 1, A\}$  [6]. For a collection of trees  $\mathfrak{T}$ , we denote  $\text{Cost}(\mathfrak{T}) := \sum_{T \in \mathfrak{T}} \text{Cost}(T)$ . To show that  $D_{\text{MSM}}(X, x^*) > d'$ , we first introduce some notation.

We say that a move edge  $(u_1, u_2)$  of any tree is *heavy* if  $|\text{val}(u_1) - \text{val}(u_2)| > 1$ . Analogously, we call path  $P$  in any tree *heavy* if at least one move edge of  $P$  is heavy. Since each node of each tree between  $X$  and  $x^*$  has a value from  $\{0, 1, A\}$ , a tree  $T$  contains a heavy path if and only if  $T$  contains at least one node with value  $A$  and at least one node with value either 0 or 1. In other words, if a tree  $T$  contains no heavy path, then a) the value of each node in  $T$  is  $A$  or b) the value of each node in  $T$  is from  $\{0, 1\}$ . Since  $A = 2d + 3$ , the cost of a tree with a heavy path is at least  $A - 1 = 2(d + 1)$ .

In the following, we take the time series  $x_1 \in X$  as a pivot and regard the partial alignment of a prefix of  $x_1$  to a prefix of  $x^*$ . Then, we analyze the cost of all other time series  $x \in X \setminus \{x_1\}$  aligning to this prefix of  $x^*$ .

For each  $i \in [0, R]$ , let  $b_i$  be the largest number of  $[0, |x^*|]$  such that  $u^*[b_i]$  is the sink of a tree of  $\mathcal{T}_1$  containing no source nodes of  $u_1[2ni + 1, 2nR]$ . Note that  $b_0 = 0$  and that if the tree of  $\mathcal{T}_1$  that has  $u_1[1]$  as a source node also has a source node  $u_1[2ni + 1]$  for some  $i \in [1, R - 1]$ , then  $b_j = 0$  for each  $j \in [0, i]$ . For each  $i \in [0, R]$  let  $\mathcal{B}_i$  be set of trees between any time series  $x$  of  $X$  and  $x^*$  containing only sinks of  $u^*[1, b_i]$ . Figure 3 depicts examples of trees belonging to  $\mathcal{B}_i$  and a tree not belonging to  $\mathcal{B}_i$ . For  $i \in [1, R]$ , the  $i$ th block is defined as  $\mathcal{Q}_i = \mathcal{B}_i \setminus \mathcal{B}_{i-1}$ . That is, each tree  $T$  in a block  $\mathcal{Q}_i$  contains only sinks of  $u^*[1, b_i]$  and at least one sink of  $u^*[b_{i-1} + 1, b_i]$ . The  $i$ th block  $\mathcal{Q}_i$  is a *cut* if  $\mathcal{Q}_i \cap \mathcal{T}_1$  has exactly the set of source nodes  $u_1[2n(i - 1) + 1, 2ni]$ . Figure 4 depicts two examples

■ **Figure 3** Two time series  $x_j$  and  $x_l$  with a median  $x^*$  of  $X$ ;  $T'$  is not in  $\mathcal{B}_i$ ,  $T''$  and  $T'''$  are in  $\mathcal{B}_i$ .

■ **Figure 4** The upper time series shows  $x_1$ , the lower time series shows the median  $x^*$ . The first example is not a cut since the tree  $T$  has source nodes  $u_1[j]$  with  $j > 2in$ . The second example is not a cut since the tree  $T$  has source nodes  $u_1[j]$  with  $j \leq 2(i-1)n$ . The third example is a cut.

of blocks not being cuts and one example of a cut. The idea behind the definitions of cuts is as follows: If a block  $\mathcal{Q}_i$  is not a cut, then some tree  $T \in \mathcal{T}_1$  with at least two sources contains  $u_1[2n(i-1)]$  or  $u_1[2ni+1]$  as a source. We say that  $\mathcal{Q}_i$  is a *light cut* if for each tree  $T \in \mathcal{Q}_i \cap \mathcal{T}_1$ ,  $T$  contains no heavy path. Hence, if  $\mathcal{Q}_i$  is a light cut, then for each source node  $\hat{u}$  in  $u_1[2n(i-1)+1, 2ni]$ , the tree of  $\mathcal{T}_1$  containing  $\hat{u}$  contains no heavy path. Note that a light cut  $\mathcal{Q}_i$  may still contain trees with heavy paths but these trees are not contained in  $\mathcal{T}_1$ .

We further describe the structure of a light cut. By construction, every copy of  $x_1$  starts with a binary value followed by an  $A$ , followed by a binary value and so on. All paths in trees of a light cut  $\mathcal{Q}_i$  are light. That is, an  $A$  in  $x_1$  aligns to one or multiple  $A$  in  $x^*$  and a binary number in  $x_1$  aligns to one or multiple binary numbers in  $x^*$ . That is, we have  $n$  non-empty binary runs  $(r_{\text{bin}}^1, \dots, r_{\text{bin}}^n)$  and  $n$  non-empty  $A$ -runs  $(r_A^1, \dots, r_A^n)$  such that

$$x^*[b_{i-1}+1, b_i] = (r_{\text{bin}}^1 \circ r_A^1 \circ r_{\text{bin}}^2 \circ r_A^2 \circ \dots \circ r_{\text{bin}}^n \circ r_A^n).$$

We now show that each block  $\mathcal{Q}_i$  has amortized cost at least  $d+1$ . This implies that the total cost of the transformation forest exceeds  $d' < R \cdot (d+1)$  and thus  $I'$  is a no-instance of MSM-MEDIAN. Let  $i \in [1, R]$ . We say that a set  $J \subseteq [i, R]$  with  $i \in J$  is *right-dominated* by a set  $J' \subseteq [i, R]$  if  $J \subseteq J'$  and  $[\max(J), \max(J')] \subseteq J'$ .

► **Lemma 4 (\*)**. *Let  $i \in [1, R]$  such that the block  $\mathcal{Q}_i$  is not a light cut. Moreover, let  $J \subseteq [i, R]$  such that  $i \in J$  and for each  $j \in J$ , the block  $\mathcal{Q}_j$  is not a light cut. Then, there is some  $J' \subseteq [i, R]$  such that  $J$  is right-dominated by  $J'$  and  $\text{Cost}(\cup_{j \in J'} \mathcal{Q}_j \cap \mathcal{T}_1) \geq |J'| \cdot (d+1)$ .*

► **Lemma 5**. *Let  $I$  be a no-instance of BINARY CIRCULAR CONSENSUS STRING and let  $i \in [0, R-1]$ . If  $\text{Cost}(\mathcal{B}_i) \geq i \cdot (d+1)$ , then there is some  $j > i$  such that  $\text{Cost}(\mathcal{B}_j) \geq j \cdot (d+1)$ .*

**Proof.** Considering the next block  $\mathcal{Q}_{i+1}$ , we distinguish whether  $\mathcal{Q}_{i+1}$  is a light cut.

**Case 1: Block  $\mathcal{Q}_{i+1}$  is not a light cut.** Let  $J = \{i+1\}$ . By Lemma 4, there is some  $J' \subseteq [i+1, R]$  with  $J \subseteq J'$  and  $[\max(J), \max(J')] = [i+1, \max(J')] \subseteq J'$  such that  $\text{Cost}(\cup_{j \in J'} \mathcal{Q}_j \cap \mathcal{T}_1) \geq |J'| \cdot (d+1)$ . For  $j = \max(J')$  we have  $\text{Cost}(\mathcal{B}_j \setminus \mathcal{B}_i) \geq \text{Cost}(\cup_{j \in J'} \mathcal{Q}_j \cap \mathcal{T}_1) \geq |J'| \cdot (d+1) = (j-i) \cdot (d+1)$ . We get

$$\begin{aligned} \text{Cost}(\mathcal{B}_j) &= \text{Cost}((\mathcal{B}_j \setminus \mathcal{B}_i) \cup \mathcal{B}_i) = \text{Cost}(\mathcal{B}_j \setminus \mathcal{B}_i) + \text{Cost}(\mathcal{B}_i) \\ &\geq (j-i) \cdot (d+1) + i \cdot (d+1) = j \cdot (d+1). \end{aligned}$$

Hence, the statement holds for  $j$ .

**Case 2: Block  $\mathcal{Q}_{i+1}$  is a light cut.** Recall that since  $\mathcal{Q}_{i+1}$  is a light cut, there are  $n$  non-empty binary runs  $(r_{\text{bin}}^1, \dots, r_{\text{bin}}^n)$  and  $n$  non-empty  $A$ -runs  $(r_A^1, \dots, r_A^n)$  such that

$$x^*[b_i+1, b_{i+1}] = (r_{\text{bin}}^1 \circ r_A^1 \circ r_{\text{bin}}^2 \circ r_A^2 \circ \dots \circ r_{\text{bin}}^n \circ r_A^n).$$

First, we show two properties of transformation graphs from each time series of  $X$  to  $x^*$  which directly imply  $\text{Cost}(\mathcal{B}_j) \geq j \cdot (d + 1)$  for some  $j \geq i + 1$ . Afterward, we show that transformation graphs without these properties then resembles circular shifts of the binary input strings of  $I$ . Because  $I$  is a no-instance of BINARY CIRCULAR CONSENSUS STRING, we then get  $\text{Cost}(\mathcal{Q}_{i+1}) \geq d + 1$  which implies  $\text{Cost}(\mathcal{B}_{i+1}) \geq (i + 1) \cdot (d + 1)$ .

▷ **Claim 6 (\*)**. Let  $i \in [0, R - 1]$  such that  $\mathcal{Q}_{i+1}$  is a light cut. If there is some tree  $T$  in  $\mathcal{B}_R \setminus \mathcal{T}_1$  that contains at least one sink node of  $u^*[b_i + 1, b_{i+1}]$  and where any of the following holds:

1.  $T$  is contained in  $\mathcal{Q}_{i+1}$  and contains a heavy path or
  2. the values of the sinks of  $T$  contain at least one  $A$  and at least one binary value,
- then there is some  $j > i$  such that  $\text{Cost}(\mathcal{B}_j \setminus \mathcal{B}_i) \geq (j - i) \cdot (d + 1)$ .

Hence, if Condition 1 or Condition 2 holds, then there is some  $j \geq i + 1$  such that  $\text{Cost}(\mathcal{B}_j \setminus \mathcal{B}_i) \geq (j - i) \cdot (d + 1)$ . Consequently,  $\text{Cost}(\mathcal{B}_j) = \text{Cost}(\mathcal{B}_j \setminus \mathcal{B}_i) + \text{Cost}(\mathcal{B}_i) \geq j \cdot (d + 1)$  which implies that the statement holds for  $j$ . In the following, we thus assume that neither Condition 1 or Condition 2 holds. This implies that

- each tree of  $\mathcal{Q}_{i+1}$  has only one source node (otherwise, Condition 1 holds) and
- each tree with at least one sink node of  $x^*[b_i + 1, b_{i+1}]$  has either a) only sinks with binary values or b) only sinks with value  $A$  (otherwise, Condition 2 holds).

Note that the latter implies that each tree with at least one sink node of  $x^*[b_i + 1, b_{i+1}]$  has either a) only sinks with binary values or b) only sinks with value  $A$ . Since Condition 1 does not hold, this further implies that each tree  $T$  of  $\mathcal{Q}_{i+1}$

- has only sinks with binary values, if the value of the unique source of  $T$  is binary and
- has only sinks with value  $A$ , if the unique source of  $T$  has value  $A$ .

Next, we show that the statement holds for  $j = i + 1$ . To this end, we show that  $\text{Cost}(\mathcal{Q}_{i+1}) \geq d + 1$ . For each  $q \in [1, n]$ , let  $\text{last}^q$  denote the index of the last binary value of  $r_{\text{bin}}^q$  in the median. Let  $s^*$  be the length- $n$  string such that  $s^*[q] = x^*[\text{last}^q]$  for each  $q \in [1, n]$ .

▷ **Claim 7**. For each  $p \in [1, k]$ , there is some even index  $\delta'_p$  such that for each  $q \in [1, n]$  there is a tree  $T_p^q$  satisfying the following properties:

- (i)  $T_p^q$  is contained in  $\mathcal{Q}_{i+1} \cap \mathcal{T}_p$ ,
- (ii)  $u_p[\delta'_p + 2 \cdot q - 1]$  is the unique source node of  $T_p^q$ , and
- (iii)  $u^*[\text{last}^q]$  is a sink node of  $T_p^q$ .

*Proof.* Let  $p \in [1, k]$ . We prove this statement in an inductive way. First, we show that there is an even index  $\delta'_p$  such that there is a tree  $T_p^n$  satisfying Properties (i)–(iii). Afterward, we show that if for some  $\ell \in [2, n]$ , there is a tree  $T_p^\ell$  satisfying Properties (i)–(iii), then the tree  $T_p^{\ell-1}$  satisfies Properties (i)–(iii). This then implies the statement.

Let  $T_p^n$  be the tree of  $\mathcal{T}_p$  having  $u^*[\text{last}^n]$  as a sink node and let  $T'$  be the tree of  $\mathcal{T}_p$  having  $u^*[\text{last}^n + 1]$  as a sink node. Note that  $T_p^n$  satisfies Property (iii). Since  $\text{last}^q$  is the index of the last value of the  $n$ th binary run of  $\mathcal{Q}_{i+1}$ , we have  $x^*[\text{last}^n + 1] = A$ . Moreover, since each tree containing at least one sink node in  $x^*[b_i + 1, b_{i+1}]$  has either a) only sinks with binary values or b) only sinks with value  $A$ ,  $T_p^n$  and  $T'$  are distinct trees. Hence, since  $\text{last}^n + 1 \leq b_{i+1}$ ,  $T_p^n$  is contained in  $\mathcal{Q}_{i+1}$ . This implies that  $T_p^n$  satisfies Property (i). Moreover, since no tree in  $\mathcal{Q}_{i+1}$  contains a heavy path, the values of the source nodes and the values of the sink nodes of  $T_p^n$  are all binary values. Hence, since each tree of  $\mathcal{Q}_{i+1}$  has only one source node,  $T_p^n$  has a unique source and this unique source has a binary value. Since  $x_p$  contains binary values only on odd positions, there is some even  $\delta'_p$  such that  $u_p[\delta'_p + 2 \cdot n - 1]$  is the unique source of  $T_p^n$ . Hence,  $T_p^n$  satisfies Properties (i)–(iii) for  $\delta'_p$ .

Now assume by induction that the statement holds for  $T_p^\ell$ . We show that the tree  $T_p^{\ell-1}$  satisfies Properties (i)–(iii) as well. Since  $r_A^{\ell-1}$  is a non-empty  $A$ -run and each tree of  $\mathcal{Q}_{i+1}$  has either a) only sinks with binary values or b) only sinks with value  $A$ ,  $T_p^\ell$  is not the first tree of  $\mathcal{T}_p$ . Hence, since  $\delta'_p$  is even,  $\delta'_p + 2 \cdot \ell - 1 \geq 3$ . Let  $T'$  be the tree of  $\mathcal{T}_p$  having  $u_p[\delta'_p + 2 \cdot \ell - 2]$  as a source node, and let  $T_p^{\ell-1}$  be the tree of  $\mathcal{T}_p$  having  $u_p[\delta'_p + 2 \cdot \ell - 3] = u_p[\delta'_p + 2 \cdot (\ell - 1) - 1]$  as a source node. Since no tree of  $\mathcal{Q}_{i+1}$  contains a heavy path, the values of all sink nodes of  $T_p^\ell$  and  $T_p^{\ell-1}$  are binary and the values of all sink nodes of  $T'$  are  $A$ . Hence,  $T_p^\ell$  contains exactly the  $\ell$ th binary run as sink nodes, as otherwise,  $T_p^\ell$  contains a sink with value  $A$  or  $T'$  contains a sink with a binary value. Hence,  $T'$  contains the node of the last  $A$  of the  $(\ell - 1)$ th  $A$ -run as a sink node. Since  $T_p^\ell$  is contained in  $\mathcal{Q}_{i+1}$ , this further implies that  $T'$  is also contained in  $\mathcal{Q}_{i+1}$ . Thus, similarly to the above,  $T'$  contains exactly the  $(\ell - 1)$ th  $A$ -run as sink nodes, as otherwise,  $T'$  contains a sink with binary value or  $T_p^{\ell-1}$  contains a sink with value  $A$ . Hence,  $T_p^{\ell-1}$  contains the node  $u^*[\text{last}^{\ell-1}]$  as a sink node and thus fulfills Property (iii). Since  $T_p^\ell$  is contained in  $\mathcal{Q}_{i+1}$ , this further implies that  $T_p^{\ell-1}$  is also contained in  $\mathcal{Q}_{i+1}$ . Hence,  $T_p^{\ell-1}$  fulfills Property (i). By the fact that each tree in  $\mathcal{Q}_{i+1}$  contains only one source node, this then implies that  $u_p[\delta'_p + 2 \cdot (\ell - 1) - 1]$  is the unique source node of  $T_p^{\ell-1}$ . Hence,  $T_p^{\ell-1}$  satisfies Properties (i)–(iii).

Moreover, the above proof also shows that  $\delta'_p + 2 \cdot \ell - 1 \geq 3$  for each  $\ell \in [2, n]$ , which implies that  $\delta'_p \geq 0$ . Additionally, the proof also shows that for each  $\ell \in [2, n]$ ,

- $T_p^\ell$  of  $\mathcal{T}_p$  contains exactly the  $\ell$ th binary run as sink nodes and
- the tree of  $\mathcal{T}_p$  containing  $u_p[\delta'_p + 2 \cdot \ell - 2]$  as unique source node, contains exactly the  $(\ell - 1)$ th  $A$ -run as sink nodes.<sup>3</sup>  $\triangleleft$

For each  $p \in [1, k]$ , let  $\delta'_p$  be the index fulfilling the properties of Claim 7. Moreover, for each  $p \in [1, k]$  and for each  $q \in [1, n]$ , let  $T_p^q$  be the tree fulfilling the properties of Claim 7 with respect to  $\delta'_p$ . Finally, let  $\mathfrak{T} := \{T_p^q \mid p \in [1, k], q \in [1, n]\}$  denote the set of these trees. We show that  $\text{Cost}(\mathfrak{T}) \geq d + 1$ . Due to Property (i) of Claim 7,  $\mathfrak{T} \subseteq \mathcal{Q}_{i+1}$ . Hence,

$$\begin{aligned} \text{Cost}(\mathcal{B}_{i+1}) &= \text{Cost}((\mathcal{B}_{i+1} \setminus \mathcal{B}_i) \cup \mathcal{B}_i) = \text{Cost}(\mathcal{Q}_{i+1}) + \text{Cost}(\mathcal{B}_i) \\ &\geq (d + 1) + i \cdot (d + 1) \geq (i + 1) \cdot (d + 1). \end{aligned}$$

To show that  $\text{Cost}(\mathfrak{T}) \geq d + 1$ , we use the fact that for each binary string  $\hat{s}$  of length  $n$  and each  $k$ -tuple  $(\delta_1, \dots, \delta_k)$ ,  $\sum_{p \in [1, k]} d_{\text{Ham}}(s_p^{\leftarrow \delta_p}, \hat{s}) \geq d + 1$ . In particular, this holds for  $s^*$ , the string of length  $n$  where for each index  $q \in [1, n]$ ,  $s^*[q] = x^*[\text{last}^q]$ . For each  $p \in [1, k]$ , we set  $\delta_p := \frac{\delta'_p \bmod (2n)}{2} = \frac{\delta'_p}{2} \bmod n$ . Next, we show that for each  $p \in [1, k]$ ,  $\text{Cost}(\mathfrak{T}_p) \geq d_{\text{Ham}}(s_p^{\leftarrow \delta_p}, s^*)$ , where  $\mathfrak{T}_p := \mathfrak{T} \cap \mathcal{T}_p = \{T_p^q \mid q \in [1, n]\}$ .

Let  $p \in [1, k]$ . Recall that  $x_p = (g(s_p))^R = g((s_p)^R)$ . Hence, by definition of  $g$  and  $s_p^{\leftarrow \delta_p}$ , for each  $q \in [1, n]$ ,

$$\begin{aligned} s_p^{\leftarrow \delta_p}[q] &= s_p[1 + (\delta_p + q - 1) \bmod n] = (s_p)^R[\delta_p + q] \\ &= x_p[2 \cdot (\delta_p + q) - 1] = x_p[2 \cdot \delta_p + 2 \cdot q - 1] = x_p[\delta'_p + 2 \cdot q - 1]. \end{aligned}$$

Since for each  $q \in [1, n]$ ,  $T_p^q$  contains the source  $u_p[\delta'_p + 2 \cdot q - 1]$  of value  $x_p[\delta'_p + 2 \cdot q - 1] = s_p^{\leftarrow \delta_p}[q]$  and the sink  $u^*[\text{last}^q]$  of value  $s^*[q]$ , we conclude  $\text{Cost}(T_p^q) \geq |s_p^{\leftarrow \delta_p}[q] - s^*[q]| \geq d_{\text{Ham}}(s_p^{\leftarrow \delta_p}[q], s^*[q])$ . Hence,  $\text{Cost}(\mathfrak{T}_p) = \sum_{q=1}^n \text{Cost}(T_p^q) \geq \sum_{q=1}^n d_{\text{Ham}}(s_p^{\leftarrow \delta_p}[q], s^*[q]) = d_{\text{Ham}}(s_p^{\leftarrow \delta_p}, s^*)$ .

Since  $\sum_{p=1}^k d_{\text{Ham}}(s_p^{\leftarrow \delta_p}, s^*) \geq d + 1$ , we conclude  $\text{Cost}(\mathcal{Q}_{i+1}) \geq \text{Cost}(\mathfrak{T}) \geq d + 1$ . This then implies  $\text{Cost}(\mathcal{B}_{i+1}) \geq (i + 1) \cdot (d + 1)$ . Hence, the statement holds for  $j = i + 1$ .  $\blacktriangleleft$

<sup>3</sup> Recall that  $x^*$  minimizes  $D_{\text{MSM}}(X, x^*)$  and that for each  $i \in [1, k]$ ,  $G_i$  is a transformation graph between  $x_i$  and  $x^*$ . By Observation 1, this implies that for each  $\ell \in [2, n]$ , the  $\ell$ th binary run and the  $(\ell - 1)$ th  $A$ -run each have length 1. This then implies  $(x^*[\text{last}^1], \dots, x^*[\text{last}^n + 1]) = g(s^*)$ .

Note that  $\text{Cost}(\mathcal{B}_0) = \text{Cost}(\emptyset) = 0 \geq 0 \cdot (d+1)$ . Hence, due to Lemma 5, one can show via induction that  $\text{Cost}(\mathcal{B}_R) \geq R \cdot (d+1)$ . Since  $R = k \cdot (n \cdot (A+2) + 1)$ ,

$$R \cdot (d+1) = (R-1) \cdot d + R + d = (R-1) \cdot d + k \cdot (n \cdot (A+2) + 1) + d = d' + d.$$

Hence  $D_{\text{MSM}}(X, x^*) = \text{Cost}(\mathcal{B}_R) \geq R \cdot (d+1) > d'$  and  $I'$  is a no-instance of MSM-MEDIAN. This completes the proof of the equivalence of  $I$  and  $I'$  and thus the proof of Theorem 2. With the hardness for  $c = 1$  at hand, we may also show hardness for arbitrary values of  $c$ .

► **Theorem 8 (\*)**. *For every constant  $c > 0$ , MSM-MEDIAN is NP-hard, W[1]-hard when parameterized by  $k$ , and cannot be solved in  $f(k) \cdot |I|^{o(k)}$  time for any computable function  $f$ , unless the ETH fails. This holds even if  $|V(X)| = 3$ .*

## 4 Parameterized Algorithms for MSM-Median

The algorithms presented in the following extend the DP algorithm of Holznigenkemper et al. [6]. Given a sequence  $X$  of time series of length at most  $n$  each and some  $m \in \mathbb{N}$ , this DP computes in time  $\mathcal{O}(n^{|X|+2} \cdot 2^{|X|} \cdot |X|^2 \cdot m)$  a time series  $x^*$  of length at most  $m$  that contains only points of  $V(X)$  and has minimum distance to  $X$  among all such time series.

**Allowing Weights.** Let  $X := (x_1, \dots, x_k)$  be a sequence of time series. Moreover, let  $X' := \{x_i \mid 1 \leq i \leq k\}$  be the set of time series of  $X$  and let  $\omega : X' \rightarrow \mathbb{N}^+$  be the function where for each  $x \in X'$ ,  $\omega(x)$  is the number of occurrences of  $x$  in  $X$ . We call  $(X', \omega)$  the *weighted equivalent* of  $X$ . We denote by  $D_{\text{MSM}(c)}^\omega(X', y) := \sum_{x \in X'} (\omega(x) \cdot d_{\text{MSM}(c)}(x, y))$  the *weighted MSM-distance* between  $X'$  and  $y$ .

► **Observation 9.** *Let  $X := (x_1, \dots, x_k)$  be a sequence of time series and let  $(X', \omega)$  be the weighted equivalent of  $X$ . Then, for each time series  $x^*$ ,  $D_{\text{MSM}(c)}(X, x^*) = D_{\text{MSM}(c)}^\omega(X', x^*)$ .*

► **Lemma 10.** *Let  $X$  be a set of time series of length at most  $n$  each, let  $\omega : X \rightarrow \mathbb{N}^+$  be a weight function, and let  $m \in \mathbb{N}$ . In time  $\mathcal{O}(n^{|X|+2} \cdot 2^{|X|} \cdot |X|^2 \cdot m)$  one can find a time series  $x^*$  that contains only points of  $V(X)$ , has length at most  $m$ , and minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*)$ .*

**Proof.** We adapt the algorithm by Holznigenkemper et al. [6] by inserting the weights of the time series as follows: We fill a  $(k+2)$ -dimensional table  $D$  with entries  $D[\mathbf{p}, \ell, s]$ , where  $\mathbf{p} = (p_1, \dots, p_k)$  indicates the *current positions* of  $X$ , the index  $\ell \in [1, m]$  indicates the *current position* of  $x^*$ , and  $s$  is a point in  $V(X)$ . The entry  $D[\mathbf{p}, \ell, s]$  stores the minimal cost needed to transform the partial time series  $(x_1[1, p_1], \dots, x_k[1, p_k])$  to any time series  $x^*$  of length exactly  $\ell$  where  $x^*[\ell] = s$  and  $x^*$  uses only values from  $V(X)$ . Since all time series are weighted, all partial time series are also weighted. Hence, the cost of all transformation operations regarding the weighted partial time series also have to be weighted.

In the DP recurrence, we distinguish two cases: Merges are applied (to the last positions of a subset of  $X$ ) or splits or moves are applied (to the last positions of all time series in  $X$ ). When merges are applied, the position of  $x^*$  does not change in the recurrences, this case is denoted by  $A_{ME}$ . When moves and splits are applied, then the position of  $x^*$  decreases, this case is denoted  $A_{MS}$ . In the recurrence, we consider the best of these two cases:

$$D[\mathbf{p}, \ell, s] = \min\{A_{MS}[\mathbf{p}, \ell, s], A_{ME}[\mathbf{p}, \ell, s]\}.$$

To present the recurrence for the two cases, we use index sets  $I_{MO}$ ,  $I_{SP}$ , and  $I_{ME}$  representing the time series indices for which move, split, and merge operations are applied, respectively.

## 54:12 On the Complexity of Computing Time Series Medians Under the MSM Metric

All index sets are subsets of  $[1, k]$  and  $I_{MO} \cup I_{SP} = [1, k]$ . For an index set  $I$ , let  $\bar{\mathbf{p}}_I = (\bar{p}_1, \dots, \bar{p}_k)$  where  $\bar{p}_i = p_i - 1$  for all  $i \in I$  and  $\bar{p}_i = p_i$  for all  $i \in [1, k] \setminus I$ . For merge operations, the recursive call of the function does not decrease the current position of  $x^*$ :

$$A_{ME}[\mathbf{p}, \ell, s] = \min_{I_{ME}} (D[\bar{\mathbf{p}}_{I_{ME}}, \ell, s] + \sum_{i \in I_{ME}} (\omega(x_i) \cdot C(x_i[p_i], x_i[p_i - 1], s))),$$

$$\text{where } C(u, v, w) = \begin{cases} c & \text{if } v \leq u \leq w \text{ or } v \geq u \geq w \\ c + \min(|u - v|, |u - w|) & \text{otherwise.} \end{cases}$$

For move and split operations, the recursive call of the function decreases the current position of  $x^*$ :

$$A_{MS}[\mathbf{p}, \ell, s] = \min_{s' \in V(X)} \left\{ \min_{I_{MO}, I_{SP}} (D[\bar{\mathbf{p}}_{I_{MO}}, \ell - 1, s']) + \sum_{i \in I_{MO}} (\omega(x_i) \cdot |x_i[p_i] - s|) + \sum_{i \in I_{SP}} (\omega(x_i) \cdot C(s, x_i[p_i], s')) \right\}.$$

Each single entry of  $A_{MS}$  and  $A_{ME}$  can be computed in time  $2^{|X|} \cdot (|X| + n + d/c + m)^{\mathcal{O}(1)}$ . For the last recursion step, the entries  $D[(1, \dots, 1), 1, s]$  are computed by  $D[(1, \dots, 1), 1, s] = \sum_{i=1}^k (\omega(x_i) \cdot |x_i[1] - s|)$ . All entries  $D[\mathbf{p}, \ell, s]$  for which  $p_i < 1$  for some  $i \in [1, k]$  are set to  $+\infty$ . If  $\ell = 1$  and  $p_i > 1$  for all  $i \in [1, k]$ , then only merge operations may be applied since the position of  $x^*$  can not be decreased anymore:  $D[\mathbf{p}, 1, s] = A_{ME}[\mathbf{p}, \ell, s]$ .

The minimum distance  $D_{\text{MSM}(c)}^\omega(X', x^*)$  to any time series  $x^*$  of length at most  $m$  that uses only points of  $V(X)$  can be computed by  $\min_{\ell \in [m], s \in V(X)} (D[\mathbf{p}, \ell, s])$ , where  $\mathbf{p} := (|x_1|, \dots, |x_k|)$ . Since the previous DP [6] runs in the desired running time and we only added weights to the DP but did not change the table structure, the running time stays the same. The corresponding time series can be found via traceback.  $\blacktriangleleft$

► **Lemma 11 (\*)**. *Let  $X$  be a set of time series of length at most  $n$  each and let  $\omega : X \rightarrow \mathbb{N}^+$ . Then, each time series  $x^*$  that minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*)$  has length at most  $n \cdot |X|$ .*

**Improving the Dynamic Program with a Cost-Bound.** Next, we establish an intermediate FPT algorithm with the parameters  $|X|$  and  $d/c$ .

► **Theorem 12.** *Let  $X$  be a set of time series each of length at most  $n$ , let  $\omega : X \rightarrow \mathbb{N}^+$  be a weight function, let  $d \in \mathbb{R}$ , and let  $m \in \mathbb{N}$ . In time  $4^{|X|} \cdot 3^{d/c} \cdot (|X| + n + d/c + m)^{\mathcal{O}(1)}$  one can find a time series  $x^*$  that contains only points of  $V(X)$ , has length at most  $m$ , and minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*)$  or correctly output that there is no such time series  $x^*$  with  $D_{\text{MSM}(c)}^\omega(X, x^*) \leq d$ .*

The main idea is that when given a cost budget  $d$ , we may be able to limit the number of entries in the DP-table that do not exceed a cost of  $d$ . That is, we only need to compute the entries in the DP-table that are close to the diagonal.

► **Lemma 13 (\*)**. *Let  $\mathbf{p} = (p_1, \dots, p_k) \in \mathbb{N}^k$ , let  $\ell \in \mathbb{N}$ , and let  $s \in \mathbb{R}$ . If  $\sum_{i=1}^k |p_i - \ell| > d/c$ , then  $D[\mathbf{p}, \ell, s] > d$ .*

We now adapt the DP-table described in the proof of Lemma 10 as follows. The table entries now have a slightly different interpretation: If the minimal cost needed to transform the partial time series  $(x_1[1, p_1], \dots, x_k[1, p_k])$  to any time series  $x^*$  of length  $\ell$  with  $x^*[\ell] = s$  that only uses points from  $V(X)$  is at most  $d$ , then the value of  $D[\mathbf{p}, \ell, s]$  is exactly this number. Otherwise,  $D[\mathbf{p}, \ell, s]$  may hold an arbitrary value larger than  $d$ , for example  $d + 1$ .

For each  $\ell \in [1, m]$  and each  $s \in V(X)$ , we only compute the table entries  $D[(p_1, \dots, p_k), \ell, s]$  with  $\sum_{i=1}^k |p_i - \ell| \leq d/c$ . Moreover, whenever a sum required to compute an entry of  $D[\mathbf{p}', \ell', s']$  depends on the value of an entry  $D[\mathbf{p}, \ell, s]$  with  $\sum_{i=1}^k |p_i - \ell| > d/c$ , then this sum is not computed but replaced by  $d+1$  since the sum is at least  $D[\mathbf{p}, \ell, s] > d$  as well. This is correct since each entry of  $D$  is obtained by minimizing sums of non-negative numbers. Finally, we compute  $d^* := \min_{\ell \in [1, m]} \min_{s \in V(X)} D[(|x_1|, \dots, |x_k|), \ell, s]$ . If  $d^* > d$ , we output that there is no time series  $x^*$  with the desired properties. Otherwise, we find some time series  $x^*$  with  $D_{\text{MSM}(c)}^\omega(X, x^*) = d^*$  via traceback and output this time series.

To show that this modified algorithm has the running time promised in Theorem 12, we bound the number of vectors  $(p_1, \dots, p_k) \in \mathbb{N}^k$  with  $\sum_{i=1}^k |p_i - \ell| \leq d/c$ .

► **Observation 14 (\*)**. *Let  $\mathbf{q} = (q_1, \dots, q_k) \in \mathbb{Z}^k$  be a vector and let  $\alpha \in \mathbb{N}$ . In time  $\mathcal{O}(2^k \cdot 3^\alpha \cdot \alpha \cdot k)$ , one can enumerate all vectors  $\mathbf{p} = (p_1, \dots, p_k) \in \mathbb{Z}^k$  with  $\sum_{i=1}^k |q_i - p_i| \leq \alpha$ .*

By setting  $\alpha = d/c$  and  $q_i = \ell$  for each  $i \in [1, k]$ , Observation 14 implies that we have to compute at most  $2^{|X|} \cdot 3^{d/c} \cdot (|X| + n + d/c + m)^{\mathcal{O}(1)}$  entries of  $D$  to compute  $d^* := \min_{\ell \in [1, m]} \min_{s \in V(X)} D[(|x_1|, \dots, |x_k|), \ell, s]$ . Since each entry can be computed in time  $2^{|X|} \cdot (|X| + n + d/c + m)^{\mathcal{O}(1)}$ , we obtain the stated running time. If  $d^* \leq d$ , the corresponding time series can be found via traceback in the same running time. This shows Theorem 12.

**An FPT-algorithm for the Distance Bound.** In this section, we now obtain an FPT algorithm for the parameter  $d/c$ , removing the running time dependence on  $|X|$ .

► **Theorem 15**. *MSM-MEDIAN can be solved in time  $2^{\mathcal{O}(d/c)} \cdot |I|^{\mathcal{O}(1)}$ . Moreover, when given a yes-instance of MSM-MEDIAN, one can find a median in the same running time.*

For a time series  $x$ , we define  $X_{\text{Close}}(x) := \{y \in X \mid |y| = |x| \text{ and } d_{\text{MSM}(c)}(x, y) \leq 3 \cdot c/2\}$ .

► **Lemma 16**. *Let  $X$  be a set of time series, let  $x \in X$ , and let  $x^*$  be any time series with  $d_{\text{MSM}(c)}(x, x^*) < c/2$ , then*

- $|x^*| = |x|$ ,
- for each  $y \in X_{\text{Close}}(x)$ ,  $d_{\text{MSM}(c)}(y, x^*) = d_{\text{Move}}(y, x^*)$ , and
- for each  $z \in X \setminus X_{\text{Close}}(x)$ ,  $d_{\text{MSM}(c)}(z, x^*) \geq c$ .

**Proof.** First, note that since  $d_{\text{MSM}(c)}(x, x^*) < c/2$ , each optimal transformation forest between  $x$  and  $x^*$  uses only move edges. Hence,  $|x^*| = |x|$ .

Next, we show that for each  $y \in X_{\text{Close}}(x)$ ,  $d_{\text{MSM}(c)}(y, x^*) = d_{\text{Move}}(y, x^*)$ . By the triangle inequality,  $d_{\text{MSM}(c)}(y, x^*) \leq d_{\text{MSM}(c)}(y, x) + d_{\text{MSM}(c)}(x, x^*) < 3 \cdot c/2 + c/2 = 2c$ . Hence, since  $|y| = |x| = |x^*|$ , each transformation forest between  $y$  and  $x^*$  contains the same number of split and merge operations. Since  $d_{\text{MSM}(c)}(y, x^*) < 2c$ , each optimal transformation forest between  $y$  and  $x^*$  uses only move edges which implies that  $d_{\text{MSM}(c)}(y, x^*) = d_{\text{Move}}(y, x^*)$ .

Finally, we show that for each  $z \in X \setminus X_{\text{Close}}(x)$ ,  $d_{\text{MSM}(c)}(z, x^*) \geq c$ . Let  $z \in X \setminus X_{\text{Close}}(x)$ . If  $|z| \neq |x|$ , then since  $|x| = |x^*|$ , each transformation forest between  $z$  and  $x^*$  contains at least one split or merge operation. Consequently,  $d_{\text{MSM}(c)}(z, x^*) \geq c$ . Otherwise, that is, if  $|z| = |x|$ , then  $3 \cdot c/2 < d_{\text{MSM}(c)}(z, x)$  since  $z \notin X_{\text{Close}}(x)$ . By the triangle inequality,  $d_{\text{MSM}(c)}(z, x) \leq d_{\text{MSM}(c)}(z, x^*) + d_{\text{MSM}(c)}(x, x^*) < d_{\text{MSM}(c)}(z, x^*) + c/2$ . Hence,  $3 \cdot c/2 < d_{\text{MSM}(c)}(z, x^*) + c/2$  which implies  $d_{\text{MSM}(c)}(z, x^*) > c$ . ◀

**Proof of Theorem 15.** Let  $I := (X', d)$  be an instance of MSM-MEDIAN where each time series of  $X'$  has length at most  $n$  and let  $(X, \omega)$  be the weighted equivalent of  $X'$ . There is a median that only uses values of  $V(X)$  [6, Lemma 10]. We describe how to find in the stated running time a time series  $x^*$  with this property that minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*)$  or correctly detect that no such time series exists with  $D_{\text{MSM}(c)}^\omega(X, x^*) \leq d$ . We distinguish two cases.

**Case 1:**  $d/c \geq |X|/2$ . Hence,  $|X| \leq 2 \cdot d/c$ . By Lemma 11, the sought time series  $x^*$  has length at most  $n \cdot |X|$ . Due to Theorem 12, we can find a time series with the desired properties that has length at most  $n \cdot |X|$  in time  $4^{|X|} \cdot 3^{d/c} \cdot (|X| + n + d/c)^{\mathcal{O}(1)} \leq 4^{2 \cdot d/c} \cdot 3^{d/c} \cdot (|X| + n + d/c)^{\mathcal{O}(1)} = 48^{d/c} \cdot (|X| + n + d/c)^{\mathcal{O}(1)}$  or detect that no such time series exists with  $D_{\text{MSM}(c)}^\omega(X, x^*) \leq d$ . Hence, if such a time series  $x^*$  is found, we can correctly output that  $I$  is a yes-instance of MSM-MEDIAN and return the found time series. Otherwise, by the above, we can correctly output that  $I$  is a no-instance of MSM-MEDIAN.

**Case 2:**  $d/c < |X|/2$ . The idea is as follows: If  $I$  is a yes-instance of MSM-MEDIAN, then there is a median  $x^*$  with  $D_{\text{MSM}(c)}^\omega(X, x^*) \leq d$  and some time series  $\tilde{x} \in X$  with  $d_{\text{MSM}(c)}(\tilde{x}, x^*) \leq d/|X| < c/2$ . Lemma 16 now implies: for each time series  $y \in X_{\text{Close}}(\tilde{x})$ ,  $d_{\text{MSM}(c)}(y, x^*) = d_{\text{Move}}(y, x^*)$  and for each time series  $z \in X \setminus X_{\text{Close}}(\tilde{x})$ ,  $d_{\text{MSM}(c)}(z, x^*) \geq c$ . This implies that  $Z := X \setminus X_{\text{Close}}(\tilde{x})$  contains at most  $d/c$  time series. Hence, to find a median, the main algorithmic difficulty lies in finding a time series of length  $|\tilde{x}|$  that uses only points of  $V(X)$  and minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*) = D_{\text{MSM}(c)}^\omega(Z, x^*) + \sum_{y \in X_{\text{Close}}(\tilde{x})} (\omega(y) \cdot d_{\text{Move}}(y, x^*))$ . We show that this can be done in time  $4^{|\tilde{x}|} \cdot 3^{d/c} \cdot (|X| + n + d/c)^{\mathcal{O}(1)}$  by modifying the DP of Theorem 12. Essentially the idea is that since for each time series  $y \in X_{\text{Close}}(\tilde{x})$ ,  $d_{\text{MSM}(c)}(y, x^*) = d_{\text{Move}}(y, x^*)$ , the transformation forest between  $y$  and  $x^*$  is fixed and we do not need to store current positions of time series in  $X_{\text{Close}}(\tilde{x})$  as dimensions in the DP-table.

▷ **Claim 17 (\*)**. Let  $Z$  be a set of time series of length at most  $n_Z$  each, let  $Y$  be a non-empty set of time series of length  $n_Y$  each, let  $\omega : Z \cup Y \rightarrow \mathbb{N}^+$ , and let  $d \in \mathbb{R}$ . In time  $4^{|Z|} \cdot 3^{d/c} \cdot (|Z \cup Y| + \max(n_Z, n_Y) + d/c)^{\mathcal{O}(1)}$  one can find a time series  $x^*$  that

- contains only points of  $V(Z) \cup V(Y)$ , has length  $n_Y$ , and
- minimizes  $d_{Z,Y}(x^*) := D_{\text{MSM}(c)}^\omega(Z, x^*) + \sum_{y \in Y} (\omega(y) \cdot d_{\text{Move}}(y, x^*))$

or correctly output that there is no such time series  $x^*$  with  $d_{Z,Y}(x^*) \leq d$ .

The algorithm for  $d/c < |X|/2$  now works as follows: Branch into all possibilities for  $\tilde{x}$ . That is, iterate over all time series  $x \in X$  and compute the sets  $Y := X_{\text{Close}}(x)$  and  $Z := X \setminus Y$ . If  $|Z| > d/c$ , then continue with the next time series since  $x$  is no candidate for  $\tilde{x}$ . Otherwise, apply the algorithm behind Claim 17 for the sets  $Z$  and  $Y$ . If this algorithm returns that there is no time series  $x^*$  with the desired property, then  $x$  is not a candidate for  $\tilde{x}$  or  $I$  is a no-instance of MSM-MEDIAN. Otherwise, store the time series  $x^*$  that minimizes  $D_{\text{MSM}(c)}^\omega(Z, x^*) + \sum_{y \in Y} (\omega(y) \cdot d_{\text{MSM}(c)}(y, x^*)) \leq d$ . After iterating over all time series of  $X$ , output the stored time series  $x^*$  that minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*)$ . If no such time series was found, output that  $I$  is a no-instance of MSM-MEDIAN.

By the above, this algorithm is correct. It remains to show the running time. Since for any two time series  $x$  and  $y$ ,  $d_{\text{MSM}(c)}(x, y)$  can be computed in  $\mathcal{O}(|x| \cdot |y|)$  time [12], each individual step of this algorithm runs in  $|I|^{\mathcal{O}(1)}$  time. For each time series  $x$  with  $|X \setminus X_{\text{Close}}(x)| \leq d/c$ , the algorithm behind Claim 17 can be applied in time  $4^{|X \setminus X_{\text{Close}}(x)|} \cdot 3^{d/c} \cdot |I|^{\mathcal{O}(1)} \leq 12^{d/c} \cdot |I|^{\mathcal{O}(1)}$ . Consequently, this algorithm runs in time  $12^{d/c} \cdot |I|^{\mathcal{O}(1)}$ .

Since in both cases the running time is at most  $48^{d/c} \cdot |I|^{\mathcal{O}(1)}$ , the statement holds. ◀

Finally, let us observe that the concrete value of  $d$  need not be known in advance.

► **Corollary 18.** *Let  $X$  be a sequence of time series of length at most  $n$  each, then we can find in time  $2^{\mathcal{O}(d/c)} \cdot (|X| + n + d/c)^{\mathcal{O}(1)}$  a time series  $x^*$  that minimizes  $D_{\text{MSM}(c)}^\omega(X, x^*) = d$ .*

## Abstract

Selection of a group of representatives satisfying certain fairness constraints, is a commonly occurring scenario. Motivated by this, we initiate a systematic algorithmic study of a *fair* version of HITTING SET. In the classical HITTING SET problem, the input is a universe  $\mathcal{U}$ , a family  $\mathcal{F}$  of subsets of  $\mathcal{U}$ , and a non-negative integer  $k$ . The goal is to determine whether there exists a subset  $S \subseteq \mathcal{U}$  of size  $k$  that *hits* (i.e., intersects) every set in  $\mathcal{F}$ . Inspired by several recent works, we formulate a fair version of this problem, as follows. The input additionally contains a family  $\mathcal{B}$  of subsets of  $\mathcal{U}$ , where each subset in  $\mathcal{B}$  can be thought of as the group of elements of the same *type*. We want to find a set  $S \subseteq \mathcal{U}$  of size  $k$  that (i) hits all sets of  $\mathcal{F}$ , and (ii) does not contain *too many* elements of each type. We call this problem FAIR HITTING SET, and chart out its tractability boundary from both classical as well as multivariate perspective. Our results use a multitude of techniques from parameterized complexity including classical to advanced tools, such as, methods of representative sets for matroids, FO model checking, and a generalization of best known kernels for HITTING SET.

## 1 Introduction

Imagine a scenario of selecting a committee of size  $k$  from a group of people  $\mathcal{U}$ . We need a committee of people with some given attributes. These kinds of “attribute hitting” scenarios is modeled by a family  $\mathcal{F}$  over  $\mathcal{U}$ , where for each attribute  $\mathcal{A}$ , we have a set  $\mathcal{F}$  containing

people in  $\mathcal{U}$  who have the attribute  $\mathcal{A}$ . As is life, not always every set of people can work collectively. In particular, the committee cannot operate smoothly if we select more than the desired number of people from a set  $B \subseteq \mathcal{U}$ . These conflicts are modeled by another family,  $\mathcal{B}$  over  $\mathcal{U}$ , and a function  $f : \mathcal{B} \rightarrow \mathbb{N}$ , which says that  $f(B)$  is the maximum number of people from a set  $B \in \mathcal{B}$  that can serve on the committee. Specifically, we want a committee that is a hitting set for attributes and has a set of people who are “conflict free”. This paper aims to undertake a systematic study of a generalization of Hitting Set, which models such scenarios, and study this problem in the realm of parameterized complexity.

Indeed, HITTING SET is one of the 21 problems proven to be NP-complete by [6]. Recall, in this problem, we are given a set system  $(\mathcal{U}, \mathcal{F})$ , and an integer  $k$ . Here,  $\mathcal{U}$  is a finite set of elements known as *universe* and  $\mathcal{F}$  is a family of subsets of  $\mathcal{U}$ . The objective is to determine whether there exists a subset  $S \subseteq \mathcal{U}$  such that  $S$  *hits* all sets in  $\mathcal{F}$ , i.e., for every  $F_i \in \mathcal{F}$ ,  $S \cap F_i \neq \emptyset$ . HITTING SET is closely related to the SET COVER problem. These two problems, along with a particularly interesting special case thereof, namely that of VERTEX COVER, are some of the most extensively studied problems in the field of approximation algorithms and parameterized complexity. HITTING SET problem is of a particular interest, because many combinatorial problems can be modeled as instances of HITTING SET.

Motivated from real-life applications, there has been a growing interest on the fairness aspect of various problems and algorithms developed. This has led to the whole new field of algorithmic fairness. Depending on the specific application, there are numerous ways to define the notion of *fairness*. One of the earliest definitions of fairness comes from [8], who defined fair versions of edge deletion problems. This was motivated from the following scenario. Suppose the graph models a communication network, with each edge being a link between a pair of nodes. In order to achieve acyclicity in the network, some links need to be disconnected. However, from the perspective of each node, it is desirable that fewest possible links incident to it are disconnected. Thus, we wish to disconnect links in a fair or equitable manner for the nodes.

Subsequently, this notion was extended by [11, 7] to define fair versions of vertex deletion problems. In this model, we want to delete a subset of vertices in order to achieve a certain graph property, such that each vertex has fewest possible neighbors deleted. As a concrete example, in a fair version of VERTEX COVER in this model, we want to find a vertex cover  $S$ , such that each vertex outside  $S$  has fewest neighbors in  $S$ . Recently, [1] studied a generalization of this, called SPARSE HITTING SET. The input to SPARSE HITTING SET consists of  $(\mathcal{U}, \mathcal{F}, \mathcal{B})$ , where  $\mathcal{U}$  is the universe, and  $\mathcal{F}$  and  $\mathcal{B}$  are two families of subsets of  $\mathcal{U}$ . The goal is to find a hitting set  $S \subseteq \mathcal{U}$  for  $\mathcal{F}$  such that  $k := \max_{B_i \in \mathcal{B}} |B_i \cap S|$  is minimized. Here,  $k$  is called the *sparseness* of the solution. Note that SPARSE HITTING SET generalizes FAIR VERTEX COVER as defined above. Along a similar line, [5] considered *conflict-free* versions of various problems, including HITTING SET. In CONFLICT FREE  $d$ -HITTING SET, we are given an instance  $(\mathcal{U}, \mathcal{F}, k)$  of HITTING SET, and a conflict graph  $H = (\mathcal{U}, E)$ , and the goal is to find a hitting set  $S \subseteq \mathcal{U}$  of size at most  $k$ , such that  $S$  induces an independent set in the conflict graph  $H$ .

## Our Problem

Along the same line of work, we define a fair version of HITTING SET, which captures all of the aforementioned problems, and much more. Formally, the problem is defined as follows.

**FAIR HITTING SET**

**Input.** An instance  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$ , where  $\mathcal{U} = \{u_1, u_2, \dots, u_n\}$  is the universe;  $\mathcal{B}$  and  $\mathcal{F}$  are two families of subsets of  $\mathcal{U}$ , where  $\mathcal{F} = \{F_1, F_2, \dots, F_m\}$ , and  $\mathcal{B} = \{B_1, B_2, \dots, B_\ell\}$ , and  $k$  is a positive integer.

**Task.** Determine whether there exists  $S \subseteq \mathcal{U}$ , with the following properties.

- $|S| \leq k$ ,
- $S$  is a *hitting set* for  $\mathcal{F}$ , i.e., for every  $F_i \in \mathcal{F}$ ,  $S \cap F_i \neq \emptyset$ , and
- For every  $B_j \in \mathcal{B}$ ,  $|S \cap B_j| \leq f(B_j)$ .

We refer to a set  $S \subseteq \mathcal{U}$  satisfying the above properties as a *fair hitting set* for  $\mathcal{F}$ , and use  $|\mathcal{I}|$  to denote the size of the instance  $\mathcal{I}$ .

We note that FAIR HITTING SET generalizes SPARSE HITTING SET. Given an instance  $(\mathcal{U}, \mathcal{F}, \mathcal{B})$  of SPARSE HITTING SET, we iteratively solve instances  $\mathcal{I}_i$  of FAIR HITTING SET for  $i = 1, 2, \dots$ . Here, an instance  $\mathcal{I}_i$  of FAIR HITTING SET is given by  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f_i, |\mathcal{U}|)$ , where  $f_i(B_j) = i$  for all  $B_j \in \mathcal{B}$ . For the smallest  $i$  such that  $\mathcal{I}_i$  is a yes-instance of FAIR HITTING SET, we stop and conclude that  $i$  is the optimal sparseness of the given instance of SPARSE HITTING SET. We note that FAIR HITTING SET also generalizes the setting considered by [5].

## 1.1 Our Results, Techniques, and Relation to Hitting Set

First, we observe that FAIR HITTING SET is a generalization of HITTING SET, by setting  $\mathcal{B} = \emptyset$ . Thus, FAIR HITTING SET inherits all lower bound results from HITTING SET, namely, in general the problem is NP-hard as well as W[2]-hard parameterized by  $k$ , the solution size [2]. However, note that in the hard instances of HITTING SET, the sets in  $\mathcal{F}$  can intersect arbitrarily. Indeed, consider an extreme case, when the sets in  $\mathcal{F}$  are pairwise disjoint. In this setting HITTING SET is trivial to solve – an optimal solution must contain exactly one element from each set of  $\mathcal{F}$ . In contrast, we show that FAIR HITTING SET remains NP-hard, as well as W[1]-hard w.r.t.  $k$  – and thus unlikely to be FPT – even in this simple setting. In particular, we show the following lower bound results, which are proved formally in the full version.

► **Theorem 1.** FAIR HITTING SET remains NP-hard when (1) the sets in  $\mathcal{F}$  are pairwise disjoint, (2) each element appears in at most two distinct  $B_i$ 's in  $\mathcal{B}$ , and (3) each  $B_i \in \mathcal{B}$  has size exactly 2. Furthermore, assuming ETH, it is not possible to solve FAIR HITTING SET in time  $2^{o(t)}$ , where  $t = \max\{|\mathcal{U}|, |\mathcal{F}|, |\mathcal{B}|\}$ .

FAIR HITTING SET is W[1]-hard when parameterized by  $k$ , even when the sets in  $\mathcal{F}$  are pairwise disjoint, and each  $B_i \in \mathcal{B}$  has size exactly 2.

The first result is obtained via a reduction from a problem of finding a “rainbow matching” on a path, and for the second result we give a parameter preserving reduction from  $k$ -MULTICOLORED INDEPENDENT SET. Given these lower bound results (Theorem 1), we study FAIR HITTING SET under specific assumptions on the instance  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f, k)$ . A natural question is: *under which assumptions?* To answer this we look at the known fixed-parameter tractability results for HITTING SET.

### Hitting Set in Parameterized Complexity

HITTING SET is known to be W[2]-complete parameterized by the solution size in general. In other words, under widely believed complexity theoretic assumptions, it does not admit an FPT algorithm parameterized by the solution size. This motivates the study of HITTING SET in special cases. One particularly interesting case is VERTEX COVER when the size of each set in  $\mathcal{F}$  is exactly two. VERTEX COVER is the most extensively studied problem in the parameterized complexity with a number of results in the FPT algorithms and kernelization in general graphs as well as special classes of graphs. Many of the techniques and results developed for VERTEX COVER also extend  $d$ -HITTING SET, where each set in  $\mathcal{F}$  has size at most  $d$ , for some constant  $d$ . More generally, HITTING SET is known to be FPT and admits a polynomial kernel in the case when the incidence graph  $G_{\mathcal{U},\mathcal{F}}$ , which is the bipartite graph on the vertex set  $\mathcal{U} \uplus \mathcal{F}$  with edges denoting the set-containment, is  $K_{i,j}$ -free. That is, no  $i$  sets in  $\mathcal{F}$  contain  $j$  elements in common, where  $i$  and  $j$  are assumed to be constants. This setting generalizes all the above settings as well as when the  $G_{\mathcal{U},\mathcal{F}}$  is  $d$ -degenerate (since such graphs are  $K_{d+1,d+1}$ -free).

### Our Algorithmic Results

Notably, we are able to extend almost all of the fixed-parameter tractability results for HITTING SET mentioned in the previous paragraph, under suitable assumptions on the set system  $(\mathcal{U}, \mathcal{B})$ . We give a summary of our results in Figure 1.

More specifically, we obtain our results in the following steps. Consider a special case FAIR HITTING SET, when the sets in  $\mathcal{F}$  are pairwise disjoint, and each element appears in at most  $q$  sets in  $\mathcal{B}$ . Note that the first part of Theorem 1 implies that the problem is NP-hard even when  $q = 2$ . On the other hand, when  $q = 1$ , i.e., when both  $\mathcal{F}$  and  $\mathcal{B}$  are families of pairwise disjoint sets, then we observe FAIR HITTING SET can be solved in polynomial time. Thus,  $q = 1$  to  $2$  is a sharp transition between the tractability of the problem. Although the problem is NP-hard even for constant values of  $q$ , the following results are interesting in this setting. In particular, we show that the problem is FPT, and admits a polynomial kernel parameterized by  $k$ , if  $q$  is a constant.

► **Theorem 2.** *Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. Then, FAIR HITTING SET can be solved in time  $2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$  time, when every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and any pair of sets in  $\mathcal{F}$  are pairwise disjoint. Further, FAIR HITTING SET admits a kernel of size  $\mathcal{O}(kq^2 \binom{kq}{q} \log k)$ .*

Next we generalize Theorem 2 to a scenario where every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and at most  $d$  sets in  $\mathcal{F}$ .

► **Theorem 3.** *Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. Then, FAIR HITTING SET can be solved in time  $k^{\mathcal{O}(dk)} 2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$  time, when every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and at most  $d$  sets in  $\mathcal{F}$ .*

These results, Theorems 2 and 3, are obtained by the key observation that the problem can be modeled as finding a hitting set for  $\mathcal{F}$  that is also an independent set in a suitably defined partition matroid that encodes the constraints imposed by  $(\mathcal{U}, \mathcal{B}, f)$ . This enables us to use the representative sets toolkit developed for matroids. This result is discussed in Section 3.

Next we consider a generalization of the above setting, where (1) each element appears in at most  $q$  sets in  $\mathcal{B}$ , and (2) the  $G_{\mathcal{U},\mathcal{F}}$  is  $K_{d,d}$ -free. In this case, we combine the techniques developed in HITTING SET literature in the  $K_{d,d}$ -free setting, as well as, the representative sets based techniques developed in Section 3, to obtain the following result.

► **Theorem 4.** *Given an instance  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f, k)$  of FAIR HITTING SET, such that  $G_{\mathcal{U}, \mathcal{F}}$  is  $K_{d,d}$ -free, and the frequency of each element in  $\mathcal{B}$  is bounded by  $q$ , one can find an equivalent instance  $\mathcal{I}' = (\mathcal{U}', \mathcal{F}', \mathcal{B}', f', k')$  of FAIR HITTING SET in polynomial time, such that  $|\mathcal{U}'| = \mathcal{O}(k^{d^2+q}d^dq^q)$ ,  $|\mathcal{F}'| \leq dk^d$ , and  $|\mathcal{B}'| = \mathcal{O}(k^{d^2+q} \cdot d^dq^{q+1})$ , where  $d$  and  $q$  are assumed to be constants.*

Finally, we reach our most general case, where suppose (1) the  $(\mathcal{U}, \mathcal{B})$  incidence graph is “nowhere dense” (defined formally in the full version; this class includes planar, excluded minor, bounded degree, and bounded expansion graphs), and (2) the  $(\mathcal{U}, \mathcal{F})$  incidence graph is  $K_{d,d}$ -free. In this case, we obtain an FPT algorithm, parameterized by  $k$  and  $d$ . This result is in two steps. First, we proceed as prior to the case when each element appears in  $f(k, d)$  sets of  $\mathcal{F}$  (cf. Theorem 4). Next, since  $(\mathcal{U}, \mathcal{B})$  incidence graph is nowhere dense, we reduce the problem of finding a FAIR HITTING SET to FO model checking procedure on nowhere dense graphs, which is known to be FPT in the size of the formula. In particular, we show that the problem can be encoded by a variant of INDUCED SUBGRAPH ISOMORPHISM on nowhere dense graphs, where the size of the host graph we are searching for can be bounded by a function of  $k$ ,  $d$  and the graph class.

► **Theorem 5.** *Let  $\mathcal{G}$  be a nowhere dense graph class. Let  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f, k)$  be an instance of FAIR HITTING SET such that the incidence graph  $G := G_{\mathcal{U}, \mathcal{B}} \in \mathcal{G}$ , and  $G_{\mathcal{U}, \mathcal{F}}$  is  $K_{d,d}$ -free for some  $d \geq 1$ . Then, one can solve FAIR HITTING SET on  $\mathcal{I}$  in time  $h(k, d) \cdot |\mathcal{I}|^{\mathcal{O}(1)}$ , for some function  $h(\cdot, \cdot)$ .*

## 2 Preliminaries

For an integer  $\ell \geq 1$ , we use the notation  $[\ell] := \{1, 2, \dots, \ell\}$ . Let  $\mathcal{R} = (\mathcal{U}, \mathcal{S})$  be a *set system*, where  $\mathcal{U}$  is a finite set of elements (also called the *ground set* or the *universe*), and  $\mathcal{S}$  is a family of subsets of  $\mathcal{U}$ . For an element  $u \in \mathcal{U}$ , and any  $\mathcal{S}' \subseteq \mathcal{S}$ , we use the notation  $\mathcal{S}'(u) := \{S \in \mathcal{S}' : u \in S\}$ , i.e.,  $\mathcal{S}'(u)$  is the sub-family of sets from  $\mathcal{S}'$  that contain  $u$ . For a subset  $R \subseteq \mathcal{U}$ , we denote  $\mathcal{S} - R := \{S \setminus R : S \in \mathcal{S}\}$ . We use  $G_{\mathcal{U}, \mathcal{S}}$  to denote the incidence graph corresponding to the set system  $(\mathcal{U}, \mathcal{S})$ , i.e.,  $G_{\mathcal{U}, \mathcal{S}}$  is a bipartite graph with bipartition  $\mathcal{U} \uplus \mathcal{S}$ , such that there is an edge between an element  $e \in \mathcal{U}$  and a set  $S \in \mathcal{S}$  iff  $e \in S$ .

In this paper, we work with finite, simple, undirected graphs. We use the standard graph theoretic notation and terminology, as defined in [3].

## 3 FPT Algorithm and Kernel Based on Representative Sets

In this section we design an algorithm and a kernel for a special case of FAIR HITTING SET, using methods based on representative sets [4, 10]. Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. The first special case we consider is the following: every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and any pair of sets in  $\mathcal{F}$  are pairwise disjoint.

Before this, however, we consider the special case of  $q = 1$ , i.e., when any pair of sets in  $\mathcal{B}$ , as well as that in  $\mathcal{F}$  are disjoint. In this case, we can solve the problem in polynomial time, by reducing it to the problem of finding maximum flow in an auxiliary directed graph, defined as follows. The vertices of the graph are  $\mathcal{B} \uplus \mathcal{U} \uplus \mathcal{F} \uplus \{s, t\}$ . First, we add arcs (i.e., directed edges) from source  $s$  to each  $B_j \in \mathcal{B}$ , with capacity  $f(B_j)$ . Next, for every  $u \in B_j$ , we add an arc  $(B_j, u)$  of capacity 1. Similarly, for each  $u \in F_i$ , we add an arc  $(u, F_i)$ , of capacity 1. Finally, we add arcs  $(F_i, t)$  of capacity  $\infty$ . It is straightforward to show that there exists a flow of value  $k$  in the graph iff there exists a fair hitting set of size  $k$ . We omit the details.

No.	$\mathcal{G}_{\mathcal{U},\mathcal{B}}$	$\mathcal{G}_{\mathcal{U},\mathcal{F}}$	Results

■ **Figure 1** An overview of different results obtained in this paper. In the second (resp. third) column, we state the assumption on the set system  $(\mathcal{U}, \mathcal{B})$  (resp.  $(\mathcal{U}, \mathcal{F})$ ). In rows 1-5 (resp. rows 1-4)  $q$  (resp.  $d$ ) denotes the maximum frequency of an element in  $\mathcal{B}$  (in  $\mathcal{F}$ ). In the last column, we mention our results in the respective settings, and give corresponding references. Note that some of the references can be found in the full version.

■ **Figure 2** A Hasse diagram of the settings considered in Figure 1, where the number in each node corresponds to the row in the table. An arrow from node  $i$  to node  $j$  indicates that the setting in row  $i$  generalizes the setting in row  $j$ . Nodes colored in green, orange (resp. red) color indicate that the setting is solvable in polynomial, FPT time (resp. is  $W[1]$ -hard).

Note that  $q \geq 2$ , but the sets in  $\mathcal{F}$  are pairwise disjoint, the problem is NP-hard. In this case, To design both our algorithm and the kernel we first embed the fairness constraints imposed by  $\mathcal{B}$  in a combinatorial object called a *partition matroid*. A partition matroid is a set system  $\mathcal{M} = (E, \mathcal{I})$ , defined as follows. The ground set  $E$  is partitioned into  $\ell$  subsets  $E_1 \uplus E_2 \uplus \dots \uplus E_\ell$ , such that a set  $S \subseteq E$  belongs to the family  $\mathcal{I}$  iff for each  $1 \leq j \leq \ell$ , it holds that  $|E_j \cap S| \leq k_j$ , where  $k_1, k_2, \dots, k_\ell$  are non-negative integers.

It might be observed that the definition of a partition matroid closely resembles the fairness constraints, i.e., for each  $B_j$ , the hitting set  $H$  must satisfy  $|H \cap B_j| \leq f(B_j)$ . However, this idea does not quite work, since the sets  $B_j \in \mathcal{B}$  are not disjoint – indeed, otherwise we could solve the problem in polynomial time, as discussed earlier. Nevertheless, we can salvage the situation by making  $q$  distinct copies of every element  $u \in \mathcal{U}$ , and replacing each of the occurrences of  $u$  in  $q$  distinct  $B_j$ 's with a unique copy. The resulting set system is a partition matroid that exactly captures the fairness constraints. Correspondingly, in each set of  $\mathcal{F}$ , we replace an original element with all of its  $q$  copies. Recall that we want to find a hitting set for  $\mathcal{F}$ ; however, in the new formulation, we must now ensure that if we pick *at least* one copy of element in the solution, we pick *all* of its copies in the solution.

Thus, our solution is an independent set of  $\mathcal{M}$  that (1) is a hitting set for  $\mathcal{F}$ , and (2) picks either 0 or  $q$  copies of every element. To find such a solution in time FPT in  $k$  and  $q$  (resp. to reduce the size of the instance), we use a sophisticated tool developed in parameterized complexity, called *representative sets*. Later, we generalize this idea to the case where every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and at most  $d$  sets in  $\mathcal{F}$ . In the next section, we formally define the partition matroid, and in the subsequent sections, we apply the toolkit of representative sets to design our FPT algorithm and the kernel.

### 3.1 Partition Matroid and Our Solution

In a partition matroid we have a universe  $\tilde{U}$ , partitioned into  $\tilde{U}_1, \dots, \tilde{U}_\ell$ , together with positive integers  $k_1, \dots, k_\ell$ , and a family of independent sets  $\mathcal{I}$ , such that  $X \subseteq \tilde{U}$  is in  $\mathcal{I}$  if and only if  $|X \cap \tilde{U}_i| \leq k_i, i \in [\ell]$ .

Let  $(\mathcal{U}, \mathcal{B})$  be the given set system such that each element  $u \in \mathcal{U}$  appears in *at most*  $q$  sets of  $\mathcal{B}$ . For an element  $u \in \mathcal{U}$ , let  $q(u) \leq q$  denote the number of sets in  $\mathcal{B}$ , that  $u$  appears in. Further, for an element  $u \in \mathcal{U}$ , let  $\text{copies}(u) = \{u^1, u^2, \dots, u^{q(u)}\}$ . We define

$$\tilde{U} = \bigcup_{u \in \mathcal{U}} \text{copies}(u).$$

Next, we need to define a partition of  $\tilde{U}$ . Towards this, we use the information about the sets in  $\mathcal{B}$ . We know that each element  $u \in \mathcal{B}$  appears in  $q(u)$  sets and we have made  $q(u)$  copies of  $u$ , thus we use *distinct* and *unique* copy of  $u$  in each sets in  $\mathcal{B}$  in which  $u$  appears. This results in  $\tilde{\mathcal{B}} = \{\tilde{B}_i : B_i \in \mathcal{B}\}$ , where  $\tilde{B}_i$  is the set corresponding to an original set  $B_i$ , after replacing elements with their copies. Observe that for every pair of indices  $i \neq j$  we have that  $\tilde{B}_i \cap \tilde{B}_j = \emptyset$  and  $\cup_i \tilde{B}_i = \tilde{U}$ . This immediately gives a partition of  $\tilde{U}$ . Finally, we define  $k_i = f(B_i)$ . This completes the description of the partition matroid we will be using. We will call this matroid as  $\mathcal{M} = (\tilde{U}, \mathcal{I})$

Given a subset  $X \subseteq \tilde{U}$ , we define a set associated with  $X$ , called  $\text{projection}(X)$  as follows. The set  $\text{projection}(X) \subseteq \mathcal{U}$ , contains an element  $u \in \mathcal{U}$  if and only if  $\text{copies}(u) \cap X \neq \emptyset$ . Similarly, we define a notion of embedding. For a set  $A \subseteq \mathcal{U}$ , let  $\text{embed}(A) = \cup_{u \in A} \text{copies}(u)$ . This brings us to the following lemma which relates our problem and finding an independent set in the matroid.

► **Lemma 6.** *An input  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  is a yes-instance if and only if there exists an independent set  $X \in \mathcal{I}$  of the matroid  $\mathcal{M} = (\tilde{\mathcal{U}}, \mathcal{I})$  such that (1)  $|\text{projection}(X)| \leq k$ , (2)  $X = \text{embed}(\text{projection}(X))$ , and (3)  $\text{projection}(X)$  is a hitting set for  $\mathcal{F}$ .*

**Proof.** In the forward direction, let  $S \subseteq \mathcal{U}$  be a solution to the original problem. Suppose  $S = \{s_1, s_2, \dots, s_k\}$ . Consider  $X = \text{embed}(S)$ . Observe that by definition,  $S = \text{projection}(X)$ . So  $|\text{projection}(X)| = k$  and  $\text{projection}(X)$  is a hitting set for  $\mathcal{F}$ . We claim that  $X$  is an independent set because if not, there exists a part  $\tilde{B}_i$  which satisfies that  $|X \cap \tilde{B}_i| > k_i = f(B_i)$ . As  $S = \text{projection}(X)$  and for every  $u \in \tilde{B}_i$ ,  $B_i$  contains a  $v$  such that  $u \in \text{copies}(v)$ , this results in  $|S \cap B_i| > k_i$  implying  $|S \cap B_i| > f(B_i)$  which contradicts that  $S$  is a valid solution to the original problem.

In the reverse direction, let  $X \in \mathcal{I}$  be an independent set satisfying both the conditions. Let  $S = \text{projection}(X)$ . We claim that,  $S$  is a solution for the original instance because if not, there exist a part  $B_i$  which satisfies that  $|S \cap B_i| > f(B_i) = k_i$ . As  $X = \text{embed}(S)$  and for every  $u \in B_i$ , an unique copy from  $\text{copies}(u)$  is contained in  $\tilde{B}_i$ , which results in  $|X \cap \tilde{B}_i| > k_i$  which contradicts that  $X$  is an independent set. ◀

### 3.2 Computation of the Desired Independent Set

In this section we give an algorithm to compute an independent set  $X \in \mathcal{I}$  of the matroid  $\mathcal{M} = (\tilde{\mathcal{U}}, \mathcal{I})$  such that  $|\text{projection}(X)| \leq k$  and  $\text{projection}(X)$  is a hitting set for  $\mathcal{F}$  (as given by Lemma 6). We will design a dynamic programming algorithm based on representative families to compute the desired independent set. Towards this we first give the required definitions. We start with the definition of an  $\ell$ -representative family.

► **Definition 7** ( $\ell$ -Representative Family). *Given a matroid  $M = (E, \mathcal{I})$  and a family  $\mathcal{S}$  of subsets of  $E$ , we say that a subfamily  $\hat{\mathcal{S}} \subseteq \mathcal{S}$  is  $\ell$ -representative for  $\mathcal{S}$  if the following holds: for every set  $Y \subseteq E$  of size at most  $\ell$ , if there is a set  $X \in \mathcal{S}$  disjoint from  $Y$  with  $X \cup Y \in \mathcal{I}$ , then there is a set  $\hat{X} \in \hat{\mathcal{S}}$  disjoint from  $Y$  with  $\hat{X} \cup Y \in \mathcal{I}$ . If  $\hat{\mathcal{S}} \subseteq \mathcal{S}$  is  $\ell$ -representative for  $\mathcal{S}$  we write  $\hat{\mathcal{S}} \subseteq_{rep}^{\ell} \mathcal{S}$ .*

In other words if some independent set in  $\mathcal{S}$  can be extended to a larger independent set by adding  $\ell$  new elements, then there is a set in  $\hat{\mathcal{S}}$  that can be extended by the same  $\ell$  elements. We say that a family  $\mathcal{S} = \{S_1, \dots, S_t\}$  of sets is a  $p$ -family if each set in  $\mathcal{S}$  is of size  $p$ .

► **Proposition 8** ([4, 9, Theorem 3.8, Theorem 1.3]). *Let  $M = (E, \mathcal{I})$  be a partition matroid,  $\mathcal{S} = \{S_1, \dots, S_t\}$  be a  $p$ -family of independent sets. Then there exists  $\hat{\mathcal{S}} \subseteq_{rep}^{\ell} \mathcal{S}$  of size  $\binom{p+\ell}{p}$ . Furthermore, given a representation  $A_M$  of  $M$  over a field  $\mathbb{F}$ , there is a deterministic algorithm computing  $\hat{\mathcal{S}} \subseteq_{rep}^{\ell} \mathcal{S}$  of size at most  $\binom{p+\ell}{p}$  in  $\mathcal{O}\left(\binom{p+\ell}{p} t p^{\omega} + t \binom{p+\ell}{p}^{\omega-1} + \|A_M\|^{\mathcal{O}(1)}\right)$  operations over  $\mathbb{F}$ , where  $\|A_M\|$  denotes the length of  $A_M$  in the input.*

For the purpose of this article, it is enough to know that partition matroids are “representable” [10, Proposition 3.5] and a “truncation” of partition matroids are computable in deterministic polynomial time [9, Theorem 1.3]. This results in Proposition 8, which we will use for our algorithm without giving further definitions of representation and truncation [4, 9, 10].

Let  $\mathcal{F} = \{F_1, F_2, \dots, F_m\}$  be the subsets of  $\mathcal{U}$ ,  $k$  be a positive integer. Since, the sets in  $\mathcal{F}$  are pairwise disjoint, the number of sets in  $\mathcal{F}$  is upper bounded by  $k$ . We call a set  $S \subseteq \mathcal{U}$ , a *potential solution*, if for all  $j \in [\ell]$ ,  $|S \cap B_j| \leq f(B_j)$ . Let

$$\mathcal{S}_i := \{S : S \text{ is a potential solution, } |S| = i \text{ and for all } j \in [i] |S \cap F_j| = 1\}.$$

Given  $\mathcal{S}_i$ , we define  $\mathcal{S}_i^{\text{emb}}$  as  $\{\text{embed}(S) \mid S \in \mathcal{S}_i\}$ . Observe that  $\mathcal{S}_i^{\text{emb}} \subseteq \mathcal{I}$  and each set has size at most  $qi$ . Notice that, each set in  $\mathcal{S}$  has size *exactly*  $i$ , but the same can not be said about the sets in  $\mathcal{S}_i^{\text{emb}}$ . However, since each element occurs in at most  $q$  sets of  $\mathcal{B}$ , we have that each set in  $\mathcal{S}_i^{\text{emb}}$  has size at most  $qi$ .

Our algorithm checks whether  $\mathcal{S}_k$  is non-empty or not. Towards that first observe that  $\mathcal{S}_k$  is non-empty if and only if  $\mathcal{S}_k^{\text{emb}}$  is non-empty. So the testing of non-emptiness of  $\mathcal{S}_k$  boils down to checking whether  $\mathcal{S}_k^{\text{emb}}$  is non-empty or not. We test whether  $\mathcal{S}_k^{\text{emb}}$  is non-empty by computing  $\widehat{\mathcal{S}}_k^{\text{emb}} \subseteq_{\text{rep}}^0 \mathcal{S}_k^{\text{emb}}$  and checking whether  $\widehat{\mathcal{S}}_k^{\text{emb}}$  is non-empty. To argue the correctness of the algorithm, first we have the following observation.

► **Observation 9.**  $\mathcal{S}_k^{\text{emb}} \neq \emptyset$  iff  $\widehat{\mathcal{S}}_k^{\text{emb}} \neq \emptyset$ .

**Proof.** Since  $\widehat{\mathcal{S}}_k^{\text{emb}} \subseteq \mathcal{S}_k^{\text{emb}}$ , the reverse direction is immediate. Now we argue the forward direction. Suppose  $\mathcal{S}_k^{\text{emb}}$ , then it contains some set  $A$ . Note that  $A$  trivially satisfies  $A \cap \emptyset = \emptyset$ . Therefore, since  $\widehat{\mathcal{S}}_k^{\text{emb}} \subseteq_{\text{rep}}^0 \mathcal{S}_k^{\text{emb}}$ , there must exist a set  $\hat{A} \in \widehat{\mathcal{S}}_k^{\text{emb}}$  such that  $\hat{A} \cap \emptyset = \emptyset$ , i.e.,  $\widehat{\mathcal{S}}_k^{\text{emb}} \neq \emptyset$ . ◀

Thus, having computed the representative family  $\widehat{\mathcal{S}}_k^{\text{emb}}$  all we need to do is to check whether it is non-empty. All that remains is an algorithm that computes the representative family  $\widehat{\mathcal{S}}_k^{\text{emb}}$ .

Let  $\mathcal{Z}$  be a family of sets and  $\ell$  be an integer, then  $\mathcal{Z}[\ell]$  is a subset of  $\mathcal{Z}$  that contains *all the sets of*  $\mathcal{Z}$  of size *exactly*  $\ell$ . We describe a dynamic programming based algorithm. Let  $\mathcal{D}$  be an array indexed from integers in  $\{0, 1, \dots, k\}$ . The entry  $\mathcal{D}[i]$  stores the following for all  $j \in \{i, \dots, qi\}$ ,  $\widehat{\mathcal{S}}_i^{\text{emb}}[j] \subseteq_{\text{rep}}^{qk-j} \mathcal{S}_i^{\text{emb}}[j]$ .

We fill the entries in the matrix  $\mathcal{D}$  in the increasing order of indexes. For  $i = 0$ ,  $\mathcal{D}[0] = \emptyset$ . Suppose, we have filled all the entries until the index  $i$ . Then consider the set

$$\mathcal{N}^{i+1} = \{X' = X \cup \text{embed}(\{u\}) : X \in \mathcal{D}[i], u \in F_{i+1}, \text{projection}(X') \text{ is a potential solution}\}$$

We partition sets in  $\mathcal{N}^{i+1}$  based on sizes. Let  $\mathcal{N}^{i+1}[j]$  denote all the sets in  $\mathcal{N}^{i+1}$  of size  $j$ .

▷ **Claim 10.** For all  $j \in \{i+1, \dots, q(i+1)\}$ ,  $\mathcal{N}^{i+1}[j] \subseteq_{\text{rep}}^{qk-j} \mathcal{S}_{i+1}^{\text{emb}}[j]$ .

**Proof.** Let  $S \in \mathcal{S}_{i+1}^{\text{emb}}[j]$  and  $Y$  be a set of size at most  $qk - j$  (which is essentially an independent set of the matroid  $\mathcal{M} = (\widetilde{U}, \mathcal{I})$ ) such that  $S \cap Y = \emptyset$  and  $S \cup Y \in \mathcal{I}$ . We will show that there exists a set  $S' \in \mathcal{N}^{i+1}[j]$  such that  $S' \cap Y = \emptyset$  and  $S' \cup Y \in \mathcal{I}$ . This will imply the desired result. Since  $S \in \mathcal{S}_{i+1}^{\text{emb}}[j]$  there exists an element  $u \in F_{i+1}$  such that

$$S = (S \setminus \text{embed}(\{u\})) \cup \text{embed}(\{u\}).$$

Let  $S_i = (S \setminus \text{embed}(\{u\}))$ . Since,  $S$  is an independent set of the matroid  $\mathcal{M} = (\widetilde{U}, \mathcal{I})$ , we have that  $S_i$  is an independent set of the matroid  $\mathcal{M} = (\widetilde{U}, \mathcal{I})$  (hereditary property). Further,  $|\text{projection}(S_i)| = i$  and  $\text{projection}(S_i)$  is a hitting set for  $F_1, \dots, F_i$ . This implies that  $S_i \in \mathcal{S}_i^{\text{emb}}$ . Let  $Y_i = Y \cup \text{embed}(\{u\})$ . Notice that since  $S \cap Y = \emptyset$  and  $S \cup Y \in \mathcal{I}$ , we have that  $Y_i$  is an independent set and  $S_i \cup Y_i = S \cup Y \in \mathcal{I}$ . Let  $|S_i| = j'$ . Then, we know that  $\mathcal{D}[i]$  contains  $\widehat{\mathcal{S}}_i^{\text{emb}}[j'] \subseteq_{\text{rep}}^{qk-j'} \mathcal{S}_i^{\text{emb}}[j']$ . This implies that there exists a set  $S'_i \in \widehat{\mathcal{S}}_i^{\text{emb}}[j']$  such that  $S'_i \cup Y_i \in \mathcal{I}$ . This implies that  $S'_i \cup \text{embed}(\{u\})$  is in  $\mathcal{N}^{i+1}$ . Further, since  $|S| = \sum_{x \in \text{projection}(S)} |\text{embed}(\{x\})|$ , we have that  $|S'_i \cup \text{embed}(\{u\})| = |S_i| = j$ . This implies that  $S'_i \cup \text{embed}(\{u\})$  is in  $\mathcal{N}^{i+1}[j]$ . Thus, we can take  $S' = S'_i \cup \text{embed}(\{u\})$ . This completes the proof. ◀

We fill the entry for  $\mathcal{D}[i+1]$  as follows. We first compute  $\mathcal{N}^{i+1}$ . Observe that the sets in  $\mathcal{N}^{i+1}$  have sizes ranging from  $i+1$  to  $q(i+1)$ . Now we apply Proposition 8 on each of  $\mathcal{N}^{i+1}[j]$ ,  $j \in \{i+1, \dots, q(i+1)\}$ , and compute  $qk-j$  representative. That is, we compute  $\widehat{\mathcal{N}}^{i+1}[j] \subseteq_{rep}^{qk-j} \mathcal{N}^{i+1}[j]$ . We set

$$\mathcal{D}[i+1] = \bigcup_{j=i+1}^{q(i+1)} \widehat{\mathcal{N}}^{i+1}[j].$$

Observe that the number of sets in  $\mathcal{D}[i]$  of size  $j$  is upper bounded by  $\binom{q(k-i)+j}{j} \leq \binom{qk}{di} \leq 2^{\mathcal{O}(qk)}$ . Hence, the time taken to compute  $\mathcal{D}[i]$  is upper bounded by  $2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$ . Thus, the time taken to compute  $\mathcal{D}[i+1]$  requires at most  $qk$  invocations of Proposition 8. This itself takes  $2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$  time. This completes the proof, resulting in the following result.

► **Theorem 2.** *Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. Then, FAIR HITTING SET can be solved in time  $2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$  time, when every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and any pair of sets in  $\mathcal{F}$  are pairwise disjoint. Further, FAIR HITTING SET admits a kernel of size  $\mathcal{O}(kq^2 \binom{kq}{q} \log k)$ .*

Theorem 2 can be generalized to the scenario where every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and at most  $d$  sets in  $\mathcal{F}$ . Observe that if each element appear in at most  $d$  sets of  $\mathcal{F}$ , then the total number of sets that a subset of size  $k$  of  $\mathcal{U}$  can hit is upper bounded by  $dk$ , else we immediately return that given instance is a NO-instance. Let  $S = \{u_1, \dots, u_k\}$  be a hypothetical solution to our problem. Now, with the help of  $S$ , we partition  $\mathcal{F}$  as follows. Let  $\mathcal{F}_i$  denote all sets in  $\mathcal{F}$  that contain  $u_i$  and none of  $\{u_1, \dots, u_{i-1}\}$ . Clearly,  $\mathcal{F}_i$ ,  $i \in [k]$ , partitions  $\mathcal{F}$ . Now we can design a dynamic programming algorithm similar to the one employed in Theorem 2, where in each iteration we grow our representative family by elements that only hit sets in  $\mathcal{F}_i$  and not in  $\mathcal{F}_j$ ,  $j > i$ . This will result in the following theorem, whose proof can be found in the full version.

► **Theorem 3.** *Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. Then, FAIR HITTING SET can be solved in time  $k^{\mathcal{O}(dk)} 2^{\mathcal{O}(qk)} n^{\mathcal{O}(1)}$  time, when every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and at most  $d$  sets in  $\mathcal{F}$ .*

### 3.3 A Kernel for a Special Case of Fair Hitting Set using Matroids

In this section we design a polynomial kernel for the same special case of FAIR HITTING SET, that we considered in the last section. Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET and assume that every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and any pair of sets in  $\mathcal{F}$  are pairwise disjoint. To design our kernel we will again use Lemma 6 that says that an input  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  is a yes-instance if and only if there exists an independent set  $X \in \mathcal{I}$  of the matroid  $\mathcal{M} = (\tilde{\mathcal{U}}, \mathcal{I})$  such that  $|\text{projection}(X)| \leq k$  and  $\text{projection}(X)$  is a hitting set for  $\mathcal{F}$ .

Let  $\mathcal{F} = \{F_1, F_2, \dots, F_m\}$  be the subsets of  $\mathcal{U}$ , and  $k$  be a positive integer. Since, the sets in  $\mathcal{F}$  are pairwise disjoint, the number of sets in  $\mathcal{F}$  is upper bounded by  $k$ . In particular, we assume that  $m = k$ . We define  $\mathcal{F}_i^{\text{emb}} = \{\text{embed}(\{u\}) \mid u \in F_i\}$ . For our kernel we apply the following reduction rules. We start with some simple reduction rules.

- **Reduction Rule 1.** Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET.
- If there exists an element  $u \in \mathcal{U}$ , such that  $u$  does not appear in any sets in  $\mathcal{F}$  then delete it from  $\mathcal{U}$  and all the sets in  $\mathcal{B}$  that it appears in.
  - If there exists a set  $B \in \mathcal{B}$  such that  $B = \emptyset$ , then delete  $B$ , and take  $f$  as the restriction of  $f$  on  $\mathcal{B} \setminus \{B\}$ .

- If there exists a set  $B \in \mathcal{B}$  such that  $f(B) = 0$ , then we do as follows:  $\mathcal{U} := \mathcal{U} \setminus \{B\}$ ; delete all the elements of  $B$  from all the sets in  $\mathcal{B}$  and  $\mathcal{F}$  that it appears in. If some set in  $\mathcal{F}$  becomes empty then return a trivial NO-instance. Else, take  $f$  as the restriction of  $f$  on  $\mathcal{B} \setminus \{B\}$  and keep the integer  $k$  unchanged.

Soundness of Reduction Rule 1 is obvious and hence omitted. The next reduction rule is the main engine of our kernel.

► **Reduction Rule 2.** Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET. If there exists a pair of integers  $i \in [k]$  and  $j \in [q]$  such that  $|\mathcal{F}_i^{\text{emb}}[j]| > \binom{kq}{j}$ , then do as follows. Compute  $\widehat{\mathcal{F}}_i^{\text{emb}}[j] \subseteq_{\text{rep}}^{qk-j} \mathcal{F}_i^{\text{emb}}[j]$ . Let  $F \in \mathcal{F}_i^{\text{emb}}[j]$  that do not appear in  $\widehat{\mathcal{F}}_i^{\text{emb}}[j]$ . Then obtain a reduced instance as follows.

- $\mathcal{U} := \mathcal{U} \setminus \text{projection}(F)$
- Delete  $\text{projection}(F)$  from all the sets in  $\mathcal{B}$  and  $\mathcal{F}$  that it appears in.
- The function  $f$  and  $k$  remains the same.

► **Lemma 11.** *Reduction Rule 2 is sound.*

**Proof.** Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET, and let  $(\mathcal{U}', \mathcal{F}', \mathcal{B}', f : \mathcal{B}' \rightarrow \mathbb{N}, k)$  be the reduced instance, after an application of Reduction Rule 2. It is easy to see that a solution to the reduced instance can directly be lifted to the input instance. Thus, we focus on forward direction.

In the forward direction, let  $S$  be a solution to  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$ . Then, by Lemma 6, it implies that  $\text{embed}(S) \in \mathcal{I}$  (of the matroid  $\mathcal{M} = (\widetilde{\mathcal{U}}, \mathcal{I})$ ) and  $|S| \leq k$  and  $S = \text{projection}(\text{embed}(S))$  is a hitting set for  $\mathcal{F}$ . Let  $u = \text{projection}(F)$ . Then, we have that  $\mathcal{U} := \mathcal{U} \setminus \{u\}$ . If  $u \notin S$ , then  $S$  is also the solution to  $(\mathcal{U}', \mathcal{F}', \mathcal{B}', f : \mathcal{B}' \rightarrow \mathbb{N}, k)$ . So we assume that  $u \in S$ .

Observe that  $F = \text{embed}(\{u\})$ ,  $|F| = j$ , and  $u$  belongs to  $F_i$ . Further, since every set in  $\mathcal{F}$  are pairwise disjoint we have that the only job of  $u$  is to hit the set  $F_i$ . Consider,  $Y = \text{embed}(S) \setminus \text{embed}(\{u\})$ . Since,  $\text{embed}(S) \in \mathcal{I}$ , we have that  $Y \in \mathcal{I}$  (hereditary property of the matroid), and the size of  $Y$  is upper bounded by  $qk - j$ . The last assertion follows from the fact that for any element  $v \in \mathcal{U}$ , the size of  $\text{embed}(\{v\})$  is upper bounded by  $q$  and  $|\text{embed}(S)| = \sum_{x \in S} |\text{embed}(\{x\})| \leq qk$ . This implies that there exists  $F' \in \widehat{\mathcal{F}}_i^{\text{emb}}[j] \subseteq_{\text{rep}}^{qk-j} \mathcal{F}_i^{\text{emb}}[j]$  such that  $Y \cup \{F'\} \in \mathcal{I}$ . Since,  $|\text{projection}(\text{embed}(S))| \leq k$ , we have that  $|\text{projection}(Y)| \leq k - 1$ . Thus,  $|\text{projection}(Y \cup \{F'\})| \leq k$ . Now we need to show that  $\text{projection}(Y \cup \{F'\})$  is a hitting set for  $\mathcal{F}$ . This follows from the fact that  $u' = \text{projection}(F') \in F_i$ . In other words, we have shown that  $S' = S \setminus \{u\} \cup \{u'\}$  is a desired hitting set for  $\mathcal{F}$ . This concludes the proof. ◀

Finally, we get the following kernel.

► **Theorem 12.** *Let  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  be an instance of FAIR HITTING SET such that every element in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$  and any pair of sets in  $\mathcal{F}$  are pairwise disjoint. Then, FAIR HITTING SET admits a kernel of size  $\mathcal{O}(kq^2 \binom{kq}{q} \log k)$ .*

**Proof.** For our algorithm we apply Reduction Rules 1 and 2 exhaustively. If any application of these rules return that the input is a NO-instance, we return the same. The correctness of the algorithm follows from the correctness of Reduction Rules 1 and 2. Further it is clear that the algorithm runs in polynomial time. What remains to show is that the reduced instance is upper bounded by the claimed function.

For convenience we assume that the reduced instance is also denoted by  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$ . Since, Reduction Rule 2 is not applicable we have that each set  $F_i$ ,  $i \in [k]$ , is upper bounded by  $\sum_{j=1}^q \binom{kq}{j} \leq q \binom{kq}{q}$ . This implies that  $|\mathcal{U}| \leq kq \binom{kq}{q}$ . Further, since every element

in  $\mathcal{U}$  appears in at most  $q$  sets in  $\mathcal{B}$ , we have that the number of non-empty sets in  $\mathcal{B}$  is upper bounded by  $q|\mathcal{U}| \leq kq^2 \binom{kq}{q}$ . Since, Reduction Rule 1 is not applicable we have that there are no empty-sets and hence  $|\mathcal{B}| \leq kq^2 \binom{kq}{q}$ . Further, to represent the function  $f$  we need at most  $\mathcal{O}(|\mathcal{B}| \log k) \leq \mathcal{O}(kq^2 \binom{kq}{q} \log k)$  bits. This completes the proof.  $\blacktriangleleft$

#### 4 Reduction from $K_{d,d}$ -free $G_{\mathcal{U},\mathcal{F}}$ to Bounded Frequency in $\mathcal{F}$

In Section 4.1, we consider a special case of the above setting: (1)  $G_{\mathcal{U},\mathcal{F}}$  is  $K_{d,d}$ -free, and (2) each element in  $\mathcal{U}$  has frequency at most  $q$  in  $\mathcal{B}$ . For this case, we design a polynomial kernel. For the sake of brevity, we give a detailed, yet informal, overview of the kernelization, and defer the formal details to the full version.

A part of the kernelization procedure can also be used to bound the frequency of an element in  $\mathcal{F}$  by a function of  $k$  and  $d$ . We give an alternate, self-contained proof of this theorem in the full version. This reduction is used as the first step in some of our results, such as Section 5.

#### 4.1 Polynomial Kernel for $K_{d,d}$ -free $G_{\mathcal{U},\mathcal{F}}$ and Bounded Frequency in $\mathcal{B}$

Consider an input  $(\mathcal{U}, \mathcal{F}, \mathcal{B}, f : \mathcal{B} \rightarrow \mathbb{N}, k)$  of FAIR HITTING SET. In this section we design a polynomial kernel for FAIR HITTING SET problem when  $G_{\mathcal{U},\mathcal{F}}$  is  $K_{d,d}$ -free and frequency of each element in  $\mathcal{B}$  is at most  $q$ . We fix  $d$  and  $q$  for the rest of the section. Without loss of generality we assume that  $d \geq 2$ ,  $k \geq 2$ . We also assume that we do not have multisets in  $\mathcal{F}$  and  $\mathcal{B}$ .

Under these assumptions, the kernelization algorithm consists of two phases. In the first phase we apply some reduction rules to bound the size of  $|\mathcal{F}|$ . In the second phase, we use the partition matroid  $\mathcal{M} = (\tilde{\mathcal{U}}, \mathcal{I})$ , as defined in Section 3.1 using  $\mathcal{B}$  to design a reduction rule to bound the number of elements. Now we discuss each of these phases in more detail.

##### Phase 1

We first define the following easy reduction rules that handle some of the easy cases

- We can delete an empty set from  $\mathcal{B}$  without affecting the instance.
- We can delete an element  $u \in \mathcal{U}$  that is not contained in any set in  $\mathcal{F}$ .
- If there exists a set  $B \in \mathcal{B}$  with  $f(B) = 0$ , then we consider two cases.
  1. If there exists some  $F \in \mathcal{F}$  such that  $F \subseteq B$ , then we have a no-instance.
  2. Otherwise, we can delete  $B$  from  $\mathcal{B}$ , and delete all elements of  $B$  from the universe  $\mathcal{U}$  as well as the corresponding sets in  $\mathcal{F}$ .

Each such rule can be implemented in polynomial time. We emphasize that these reduction rules are repeatedly applied in this order, after each application of subsequent rules.

Next, we consider the following case. If there exists an element  $u \in \mathcal{U}$  contained in at least  $dk^{d-1}$  sets of  $\mathcal{F}$ , then in *polynomial time* we can find a non-empty set  $X \subseteq \mathcal{U}$  of size at most  $d-1$  with the following properties: (1)  $X$  intersects with *every* fair hitting set of size at most  $k$ , and (2) the number of sets in  $\mathcal{F}$  that contain  $X$  as a subset is *large*, i.e., at least  $dk^{d-1}$ . This is where we crucially use the fact that  $G_{\mathcal{U},\mathcal{F}}$  is  $K_{d,d}$ -free. Now, we can use such a set  $X$  to reduce the size of instance, by either finding some  $u \in \mathcal{U}$ , or some  $F_i \in \mathcal{F}$  that can be deleted without affecting the instance.

Note that since we reduce the size of instance in each application of the rule, this rule is applicable only polynomially many times. Furthermore, when the rule is not applicable, it follows that every element of  $\mathcal{U}$  is contained in at most  $dk^{d-1}$  sets of  $\mathcal{F}$ . Here, we observe that

we did not make any specific assumptions about the hypergraph  $(\mathcal{U}, \mathcal{B})$ , except that we may delete an element of  $\mathcal{U}$  or a set from  $\mathcal{B}$ . Thus, the resulting hypergraph is a sub-hypergraph of the original hypergraph  $(\mathcal{U}, \mathcal{B})$ . Thus, if  $G_{\mathcal{U}, \mathcal{B}}$  satisfies some hereditary property  $\Pi$ , then the resulting incidence graph continues to satisfy  $\Pi$ . Thus, phase 1 constitutes a proof of .

At this step, if the number of sets in  $\mathcal{F}$  is larger than  $dk^d$ , no subset of size  $k$  can hit all sets in  $\mathcal{F}$ . Thus, we simply conclude that such an instance is a no-instance of the problem. This concludes Phase 1.

Suppose in the original instance  $G_{\mathcal{U}, \mathcal{B}}$  satisfied that the frequency of every element in  $\mathcal{B}$  is at most  $q$ . Then, at this step, we can use an approach similar to Theorem 3 to design an FPT algorithm that runs in time  $d^k k^{kd} \cdot 2^{\mathcal{O}(kq)} \cdot |\mathcal{I}|^{\mathcal{O}(1)}$ . Now, we proceed to Phase 2, where we further reduce the size of an instance to design a kernel under the assumption when the frequency in  $\mathcal{B}$  is bounded by  $q$ .

## Phase 2

We observe that the number of elements in  $\mathcal{U}$  with frequency at least  $d$  in  $\mathcal{F}$  is bounded by  $\binom{|\mathcal{F}|}{d} \cdot d$ . Let  $\mathcal{U}'$  denote the elements that are contained in at most  $d - 1$  sets of  $\mathcal{F}$ . We define equivalence classes of  $\mathcal{U}'$ , such that all elements in the same class belong to all the sets of  $\mathcal{Y}$ , where  $\mathcal{Y} \subseteq \mathcal{F}$  is a sub-family of size at most  $d - 1$ . Let us denote such a subset by  $\text{ExactNbr}(\mathcal{Y})$ .

We use the matroid-based techniques developed in the previous section, in order to reduce the number of distinct elements in  $\text{ExactNbr}(\mathcal{Y})$  that we need to remember. In particular, we show that for every  $\mathcal{Y} \subseteq \mathcal{F}$ , we only need to remember at most  $\binom{kq}{q}$  distinct elements, and we may delete the rest in a careful manner.

Thus, at the end, we have the following. The number of elements with degree (i.e., frequency) at most  $d - 1$  in  $G_{\mathcal{U}, \mathcal{F}}$  is bounded by  $d \cdot \binom{|\mathcal{F}|}{d} \cdot \binom{kq}{q}$ . Accounting for the elements with large degree, the total number of elements in  $\mathcal{U}$  is bounded by  $\mathcal{O}(k^{\mathcal{O}(d^2+q)} d^d q^q)$ . Since each element has degree at most  $q$  in  $G_{\mathcal{U}, \mathcal{B}}$ , we can also bound the number of sets in  $\mathcal{B}$ . Observe that each of our reduction rules can be applied in polynomial time and only polynomially many times. Thus, we prove the following theorem.

► **Theorem 4.** *Given an instance  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f, k)$  of FAIR HITTING SET, such that  $G_{\mathcal{U}, \mathcal{F}}$  is  $K_{d,d}$ -free, and the frequency of each element in  $\mathcal{B}$  is bounded by  $q$ , one can find an equivalent instance  $\mathcal{I}' = (\mathcal{U}', \mathcal{F}', \mathcal{B}', f', k')$  of FAIR HITTING SET in polynomial time, such that  $|\mathcal{U}'| = \mathcal{O}(k^{d^2+q} d^d q^q)$ ,  $|\mathcal{F}'| \leq dk^d$ , and  $|\mathcal{B}'| = \mathcal{O}(k^{d^2+q} \cdot d^d q^{q+1})$ , where  $d$  and  $q$  are assumed to be constants.*

## 5 Parameterization by $k + d$ when $G_{\mathcal{U}, \mathcal{B}}$ is nowhere dense and $G_{\mathcal{U}, \mathcal{F}}$ is $K_{d,d}$ -free

We give a brief overview of the following theorem, a formal proof can be found in the full version.

► **Theorem 5.** *Let  $\mathcal{G}$  be a nowhere dense graph class. Let  $\mathcal{I} = (\mathcal{U}, \mathcal{F}, \mathcal{B}, f, k)$  be an instance of FAIR HITTING SET such that the incidence graph  $G := G_{\mathcal{U}, \mathcal{B}} \in \mathcal{G}$ , and  $G_{\mathcal{U}, \mathcal{F}}$  is  $K_{d,d}$ -free for some  $d \geq 1$ . Then, one can solve FAIR HITTING SET on  $\mathcal{I}$  in time  $h(k, d) \cdot |\mathcal{I}|^{\mathcal{O}(1)}$ , for some function  $h(\cdot, \cdot)$ .*

First, we reduce the given instance, where  $G_{\mathcal{U}, \mathcal{F}}$  is  $K_{d,d}$ -free, to an instance where the size of  $|\mathcal{F}|$  is bounded by  $d \cdot k^d$ . Thus, it suffices to design an FPT algorithm parameterized by  $k, d$  and  $m := |\mathcal{F}|$ . The rest of the section focuses on designing such an algorithm. We

prove Theorem 5 by reducing the problem to FO model checking on  $G$ .<sup>1</sup> Due to lack of space, the necessary definitions and background pertaining to nowhere dense graph classes and first-order logic is given in the full version.

We reduce the problem of deciding whether  $\mathcal{I}$  is a yes-instance of FAIR HITTING SET to the problem of First-Order (FO) model checking. We first “guess” the structure of a hypothetical solution (i.e.,  $S \subseteq \mathcal{U}$  such that  $S$  is a fair hitting set for  $\mathcal{F}$ ), if any. More specifically, we guess the exact size  $k'$  of a hypothetical solution, and the exact subset of  $\mathcal{F}$  that is hit by each element of the solution. Note that there are at most  $2^{\mathcal{O}(km)}$  possible guesses. For each such guess, we create a first-order logic formula that is true if and only if such a solution is a fair hitting set, i.e., it hits all the sets in  $F$ , and for each  $B_j \in \mathcal{B}$ , the size of the intersection of  $B_j$  with the solution is at most  $f(B_j)$ . We show that the size of the formula is upper bounded by a function of  $k$  and  $|\mathcal{F}|$ . Finally, since model checking of first-order logic formulas can be decided in polynomial time on nowhere dense graphs, the theorem follows.

## Abstract

---

FEEDBACK VERTEX SET (FVS) is one of the most studied vertex deletion problems in the field of graph algorithms. In the decision version of the problem, given a graph  $G$  and an integer  $k$ , the question is whether there exists a set  $S$  of at most  $k$  vertices in  $G$  such that  $G - S$  is acyclic. It is one of the first few problems which were shown to be NP-complete, and has been extensively studied from the viewpoint of approximation and parameterized algorithms. The best-known polynomial time approximation algorithm for FVS is a 2-factor approximation, while the best known deterministic and randomized FPT algorithms run in time  $\mathcal{O}^*(3.460^k)$  and  $\mathcal{O}^*(2.7^k)$  respectively.<sup>1</sup>

In this paper, we contribute to the newly established area of parameterized approximation, by studying FVS in this paradigm. In particular, we combine the approaches of parameterized and approximation algorithms for the study of FVS, and achieve an approximation guarantee with a factor better than 2 in randomized FPT running time, that improves over the best known parameterized algorithm for FVS. We give three simple randomized  $(1 + \epsilon)$  approximation algorithms for FVS, running in times  $\mathcal{O}^*(2^{\epsilon k} \cdot 2.7^{(1-\epsilon)k})$ ,  $\mathcal{O}^*\left(\left(\left(\frac{4}{1+\epsilon}\right)^{(1+\epsilon)} \cdot \left(\frac{\epsilon}{3}\right)^\epsilon\right)^k\right)$ , and  $\mathcal{O}^*(4^{(1-\epsilon)k})$  respectively for every  $\epsilon \in (0, 1)$ . Combining these three algorithms, we obtain a factor  $(1 + \epsilon)$  approximation algorithm for FVS, which has better running time than the best-known (randomized) FPT algorithm for every  $\epsilon \in (0, 1)$ . This is the first attempt to look at a parameterized approximation of FVS to the best of our knowledge. Our algorithms are very simple, and they rely on some well-known reduction rules used for arriving at FPT algorithms for FVS.

## 1 Introduction

Vertex deletion problems are one of the most basic and well-studied classes of graph editing problems. In the decision version of these problems, given a graph  $G$  and integer  $k$ , we are asked whether we can delete at most  $k$  vertices from  $G$  such that the resulting graph satisfies certain properties. When we want the resulting graph to be empty or acyclic, then the vertex deletion problem corresponds to the well-known VERTEX COVER and FEEDBACK VERTEX SET problems respectively. These were two of the first few problems to be shown NP-complete and appear in Karp’s list of 21 NP-complete problems. In this paper, we concentrate on the FEEDBACK VERTEX SET problem, in the realm of parameterized approximation. The problem is formally defined as follows.

FEEDBACK VERTEX SET (FVS)	<b>Parameter:</b> $k$
<b>Input:</b> A graph $G = (V, E)$ and a positive integer $k$ .	
<b>Question:</b> Does there exist a set $S \subseteq V(G)$ such that $ S  \leq k$ and $G - S$ is acyclic?	

Parameterized approximation combines the fields of parameterized and approximation algorithms, where we try to get the best of both worlds by achieving a better guarantee than that of the best-known approximation algorithm (running in polynomial time), while the algorithm takes FPT time, but beats the best known exact algorithm for the problem. Such algorithms are termed “parameterized approximation” algorithms in the literature. An even more ambitious goal can be to get a parameterized approximation scheme, where for every  $\epsilon \in (0, \alpha - 1)$  (where  $\alpha$  is the best-known approximation factor for polynomial-time algorithms), we get a factor  $(1 + \epsilon)$  approximation algorithm, that runs in FPT time and is faster than the best known parameterized algorithm for the problem.

Probably the best example for this approach is the MIN  $k$ -CUT problem (delete a minimum number of edges to get at least  $k$  connected components), which is not expected to be FPT when parameterized by  $k$  since it is W[1]-hard. The best-known approximation factor, that is possible in polynomial time, for this is 2 [20]. Gupta et al. [11] showed that we can get an approximation ratio better than 2 by allowing FPT running time, and in a recent breakthrough result, Lokshtanov et al. [19] designed a *parameterized approximation scheme* for the problem, which means that for every  $\epsilon > 0$ , there is an algorithm running in FPT time which gives a factor  $(1 + \epsilon)$  approximation for MIN  $k$ -CUT. There are a few of lower bounds results in the field as well [3, 5, 6, 17], which show that this approach does not work for certain problems.

In addition to problems that are not expected to be FPT, researchers have also studied problems that are FPT from the lens of parameterized approximation. For these problems, we try to get a better approximation factor (than what is known in polynomial time) by allowing faster FPT running time (as compared to the best FPT algorithm for the problem). This approach has been applied to many problems including VERTEX COVER,  $d$ -HITTING SET [10, 4, 15], classical cut problems like DIRECTED-FVS, MULTICUT [18] etc. For a comprehensive overview of the current state of parameterized approximation, we refer to the recent survey by Feldmann et al. [9], as well as the surveys conducted by Kortsarz [14] and Marx [21].

In this paper, we look at FEEDBACK VERTEX SET (FVS), which is one of the most studied problems in the field of parameterized complexity, from the parameterized approximation lens. For FVS, the best-known approximation factor that can be achieved in polynomial time is 2 [1], and this is the best approximation factor that we can hope for FVS in polynomial time under the famous Unique Games Conjecture [13]. On the other side, the fastest known deterministic and randomized FPT algorithms for FVS run in times  $\mathcal{O}^*(3.460^k)$  [12] and

$\mathcal{O}^*(2.7^k)$  [16] respectively. We want to design a parameterized approximation scheme for FVS. This turns out to be a harder task than designing such schemes for problems like VERTEX COVER. For VERTEX COVER, there is a simple branching algorithm, that picks an edge and branches on its endpoints, but no such simple algorithm exists for FVS because the forbidden subgraph for FVS, a cycle, can be very large. For designing a good parameterized approximation scheme for VERTEX COVER or  $d$ -HITTING SET, there are two ways to achieve it: i) pick disjoint copies of edges or sets in the solution and then run the fastest FPT algorithm on the remaining instance, and ii) do branching for some steps, and then run an approximation algorithm on the remaining instance. These seem difficult to achieve for FVS because the cycles can be very big, and hence the approximation guarantee in i) and the branching factor in ii) are not bounded. In this paper, we overcome these difficulties using ideas from known randomized algorithms and obtain the following result.

► **Theorem 1.** *There exists a randomized algorithm that, given an instance  $(G, k)$  of FVS and  $\epsilon \in (0, 1)$ , either reports a failure or finds a feedback vertex set in  $G$  of size at most  $(1 + \epsilon)k$  in time*

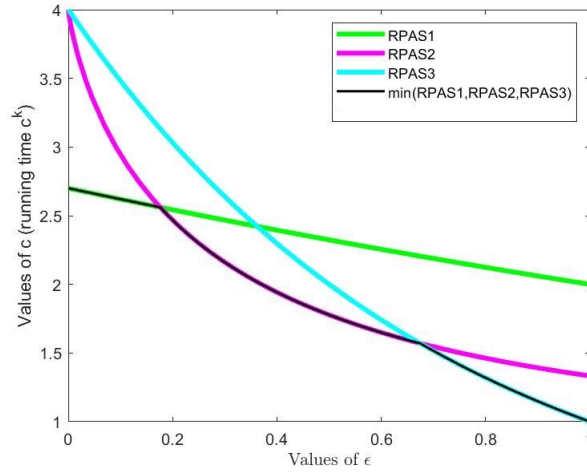

$$\mathcal{O}^* \left( \min \left\{ 2^{\epsilon k} \cdot 2.7^{(1-\epsilon)k}, \left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^k, 4^{(1-\epsilon)k} \right\} \right).$$

Moreover, if  $G$  has a feedback vertex set of size at most  $k$ , the algorithm returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $1/e$ .

**Our methods.** For proving Theorem 1, we make use of two randomized algorithms, the first being one of the oldest algorithms for FVS that runs in time  $\mathcal{O}^*(4^k)$  [2], and the other being the currently best known randomized algorithm for FVS running in time  $\mathcal{O}^*(2.7^k)$  [16]. We give three different algorithms to get the running time mentioned in Theorem 1, where each of the three algorithms outperforms the other two in some range of  $\epsilon$  in the interval  $[0, 1]$ . For a clearer view, we provide a graph depicting the running times of the three algorithms for different values of  $\epsilon$  in Figure 1. We observe that for every  $\epsilon \in (0, 1)$ , the algorithm of Theorem 1 gives a randomized  $(1 + \epsilon)$  approximation and runs in time better than  $\mathcal{O}^*(2.7^k)$ . All our algorithms make use of some simple reduction rules for FVS, which have been extensively applied to obtain FPT algorithms for the problem. The useful property of the rules is that if none of them are applicable, then the graph has a minimum degree of at least 3.

The first algorithm that we design uses the property that in a graph with a minimum degree of at least 3, at least half the edges are incident on any feedback vertex set of the graph [2]. It picks some edges randomly, adds the endpoints of the edges to the solution, and then it runs the  $\mathcal{O}^*(2.7^k)$  time algorithm of [16] on the remaining graph. This gives an algorithm running in time  $\mathcal{O}^*(2.7^{(1-\epsilon)k})$  and succeeding (giving a factor  $(1 + \epsilon)$  approximation for every  $\epsilon \in (0, 1)$ ) with probability  $c \cdot 2^{-\epsilon k}$  for some  $c \geq \frac{1}{2}$ . We repeat this algorithm  $\frac{1}{c} \cdot 2^{\epsilon k}$  times to get a constant probability of success, and the final running time is  $\mathcal{O}^*(2^{\epsilon k} \cdot 2.7^{(1-\epsilon)k})$ .

The second algorithm that we design also uses the same property, but it picks one of the endpoints randomly from a randomly picked edge in the solution (instead of both endpoints in the first algorithm). We keep doing that till we either exhaust our budget or the graph becomes acyclic. Using the techniques of [15], we show that this algorithm succeeds with probability  $\left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^{-k}$ . Repeating this  $\left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^k$  times, we get constant success probability. The running time of this algorithm is better than the first algorithm for  $\epsilon \in (0.176, 1)$ .

■ **Figure 1** A graph showing running times of the three algorithms, which we name RPAS1, RPAS2, and RPAS3.

The third algorithm, instead of picking the vertices like the second algorithm does till the budget is exhausted, picks vertices up to a certain threshold, and then applies the 2-approximation algorithm of [1] on the remaining graph. This algorithm succeeds with probability  $4^{-(1-\epsilon)k}$ , which gives the running time of  $\mathcal{O}^*(4^{(1-\epsilon)k})$  for constant success probability. This algorithm performs better than the first two algorithms for  $\epsilon \in (0.674, 1)$ .

The main purpose of this article is to put forward a proof of concept for designing FPT approximation algorithms for problems for which the forbidden sets are of unbounded size. All our algorithms are randomized, and getting a deterministic FPT approximation scheme for FVS is an interesting open problem.

## 2 Preliminaries

In this section, we give the notations and definitions, along with some known results and reduction rules which are used in the paper.

For a graph  $G = (V, E)$ , we denote the set of vertices of the graph by  $V(G)$  and the set of edges of the graph by  $E(G)$ . For a set  $S \subseteq V(G)$ , the subgraph of  $G$  induced by  $S$  is denoted by  $G[S]$  and it is defined as the subgraph of  $G$  with vertex set  $S$  and edge set  $\{\{u, v\} \in E(G) : u, v \in S\}$  and the subgraph obtained after deleting  $S$  (and the edges incident to the vertices in  $S$ ) is denoted as  $G - S$ . We say a graph  $G$  is acyclic if there is no cycle in the graph. For ease of notation, we will use  $uv$  to denote an edge of a graph instead of  $\{u, v\}$ . We denote the degree of a vertex  $v \in V(G)$  as  $d(v)$  and it is equal to the number of edges incident on  $v$ . In case of a self-loop on  $v$ , the self-loop contributes 2 to  $d(v)$ . The minimum degree of a graph  $G$  is denoted as  $\delta(G)$  and it is defined as  $\delta(G) = \min\{d(v) : v \in V(G)\}$ . For a graph  $G$ , a set  $S \subseteq V(G)$  is called a *feedback vertex set* of  $G$  if  $G - S$  is acyclic. An instance  $(G, k)$  of FVS is said to be a **Yes** instance if there is a feedback vertex set of size at most  $k$  in  $G$ . Given a **Yes** instance  $(G, k)$  of FVS and an  $\epsilon \in (0, 1)$  as an input, we say that an algorithm  $\mathcal{A}$  *succeeds* if it outputs a feedback vertex set of  $G$  of size at most  $(1 + \epsilon)k$ . We denote the size of a minimum-sized feedback vertex set of a graph  $G$  by  $\text{fvs}(G)$ .

Let us state the following reduction rules that we will use in this paper to make the minimum degree of the graph at least 3.

1. [8] If there is a self-loop at a vertex  $v$ , delete  $v$  from the graph and decrease  $k$  by 1.
2. [8] If there is an edge of multiplicity larger than 2, reduce its multiplicity to 2.
3. [8] If there is a vertex  $v$  of degree at most 1, delete  $v$ .
4. [8] If there is a vertex  $v$  of degree 2, delete  $v$  and connect its two neighbors by a new edge.

If none of the above four reduction rules are applicable to a graph  $G$  then we can assume that  $\delta(G) \geq 3$ . We will also use the following lemma to ensure that if  $\delta(G) \geq 3$  then any random endpoint of a random edge of the graph is part of any feedback vertex set of  $G$  with probability at least  $\frac{1}{4}$ .

► **Lemma 2** ([8]). *Let  $G$  be a multigraph on  $n$  vertices, with minimum degree at least 3. Then, for every feedback vertex set  $X$  of  $G$ , at least half of the edges of  $G$  have at least one endpoint in  $X$ .*

### 3 Algorithm 1

In this section, we present the first randomized  $(1 + \epsilon)$  approximation algorithm for FVS for every  $\epsilon \in (0, 1)$ . Given an instance  $(G, k)$  of FVS, we first apply reduction rules 2-4 on the graph. After applying the reduction rules, we pick all the vertices having a self-loop into the set  $S_1$  and we decrease the parameter by the number of vertices picked into  $S_1$ . If no vertex has a self-loop, then we pick an edge  $uv$  uniformly at random and add both  $u$  and  $v$  into  $S_1$  if none of the reduction rules are applicable and  $G - S_1$  is not acyclic. We decrease the parameter by 1 in this case. We do that because with good probability that one of these vertices belongs to any feedback vertex set of the graph, and hence we decrease  $\text{fvs}(G)$  by one with good probability. Then we delete  $S_1$  from the graph and repeat the same process until  $G - S_1$  becomes acyclic or the parameter decreases by at least  $\epsilon k$ . Next, we check whether  $G - S_1$  is acyclic and  $|S_1| \leq (1 + \epsilon)k$ . If yes, then we just return  $S_1$  as a solution. Otherwise, we apply the randomized FPT algorithm of [16] for FVS on the graph  $G - S_1$  with the remaining parameter. If the randomized FPT algorithm of [16] returns a solution  $S_2$ , then we return  $S_1 \cup S_2$  as a solution, otherwise, we return No. We describe the algorithm formally in Algorithm 1. Now we state the main result of this section.

► **Theorem 3.** *There exists a randomized algorithm running in  $\mathcal{O}^*(2^{\epsilon k} \cdot 2.7^{(1-\epsilon)k})$  time such that, given an FVS instance  $(G, k)$  and  $\epsilon \in (0, 1)$ , it either reports a failure or finds a feedback vertex set of  $G$  of size at most  $(1 + \epsilon)k$ . Moreover, if the algorithm is given a Yes-instance, it returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $1/e$ .*

Let us call the algorithm of Theorem 3 RPAS1. It is obtained by repeating Algorithm 1 multiple times to get a constant success probability. So before we give the proof of Theorem 3, we prove a couple of lemmas about Algorithm 1.

► **Lemma 4.** *If Algorithm 1 returns a set  $S$  then  $S$  is a feedback vertex set in  $G$  of size at most  $(1 + \epsilon)k$ .*

**Proof.** The returned solution is either of the form  $S_1$  or of the form  $S_1 \cup S_2$  for some vertex sets  $S_1$  and  $S_2$ . If it consists of only  $S_1$ , then by line 15 of the algorithm it is clear that  $G - S_1$  is acyclic and  $|S_1| \leq (1 + \epsilon)k$ .

Now, if the returned solution is of the form  $S_1 \cup S_2$ , then by the correctness of the randomized FPT algorithm of [16] for FVS, we can say that  $S_2$  is a feedback vertex set of  $G - S_1$ , and this implies that  $S = S_1 \cup S_2$  is a feedback vertex set of  $G$ . Also, if the parameter is decreased by  $\beta$  inside the while loop when Algorithm 1 returns a solution of the form  $S_1 \cup S_2$ , then observe that  $|S_1| \leq \beta + \epsilon k$  and  $|S_2| \leq k - \beta$ . Thus, we get  $|S| = |S_1| + |S_2| \leq \beta + \epsilon k + k - \beta = (1 + \epsilon)k$ . ◀

---

**Input** : An instance  $(G, k)$  of FVS and a  $\epsilon \in (0, 1)$ .

- 1 *Fix*  $l' = k$ ;
- 2 *Fix*  $l = (1 - \epsilon)k$ ;
- 3 *Initialize*,  $S_1 \leftarrow \emptyset$ ;
- 4 **while**  $k > l$  &  $G - S_1$  is not acyclic **do**
- 5     apply reduction rules 2-4 exhaustively to  $G - S_1$ ;
- 6     **if** there is a self-loop **then**
- 7          $S_1 = S_1 \cup \{v : \text{there is a loop on } v\}$ ;
- 8          $k \leftarrow k - |\{v : \text{there is a loop on } v\}|$ ;
- 9     **else**
- 10         pick an edge  $e = uv$  uniformly at random from  $E(G - S_1)$ ;
- 11          $S_1 = S_1 \cup \{u, v\}$ ;
- 12          $k \leftarrow k - 1$ ;
- 13     **end**
- 14 **end**
- 15 **if**  $G - S_1$  is acyclic &  $|S_1| \leq (1 + \epsilon)l'$  **then**
- 16     return  $S_1$ ;
- 17 **end**
- 18 apply the randomized FPT algorithm of [16] for FVS on  $(G - S_1, k)$ ;
- 19 **if** Above algorithm returns a solution  $S_2$  **then**
- 20     return  $S_1 \cup S_2$ ;
- 21 **else**
- 22     return No;
- 23 **end**

---

► **Lemma 5.** *Given an Yes-instance of FVS, Algorithm 1 returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $c \cdot 2^{-\epsilon k}$  for some constant  $c \geq \frac{1}{2}$ .*

**Proof.** Let  $(G, k)$  be a given Yes-instance for FVS. Notice that, inside the while loop, the parameter decreases when we pick vertices having a self-loop on them or when we choose an edge uniformly at random and add both of its endpoints to  $S_1$ . We do the latter only if none of the reduction rules are applicable.

Now, when we pick vertices having a self-loop into the set  $S_1$ , by the correctness of reduction rule 1, there must exist a feedback vertex set  $F$  of  $G$  of size at most  $k$  (as the given instance is a Yes-instance) containing those vertices having self-loops. Then we choose an edge  $uv$  uniformly at random and add both its endpoints  $u$  and  $v$  to  $S_1$  only if none of the reduction rules are applicable and thus the minimum degree of the graph is at least 3. Then by Lemma 2, at least one of  $u$  and  $v$  is in  $F$  with probability at least  $\frac{1}{2}$ . Thus, when the parameter decreases by one, we add at least one vertex of  $F$  to  $S_1$  with probability at least  $\frac{1}{2}$  (the statement is true with probability 1 when we are adding the vertices having self-loops to  $S_1$ ). If the parameter decreases by  $\beta$  (note that  $\beta \geq \epsilon k$ ) inside the while loop, then  $S_1$  contains at least  $\beta$  vertices of  $F$  with probability at least  $\frac{1}{2^{\epsilon k}}$  (as we choose an edge uniformly at random inside the while loop for at most  $\epsilon k$  steps). Also, if  $S_1$  contains at least  $\beta$  vertices from  $F$ , then  $(G - S_1, k - \beta)$  is a Yes-instance and the randomized FPT algorithm of [16] will find feedback vertex set in  $G - S_1$  of size at most  $k - \beta$  with probability at least  $c$  for some constant  $c \geq \frac{1}{2}$ . Thus, given a Yes-instance  $(G, k)$  of FVS, Algorithm 1 returns a feedback vertex set of size at most  $(1 + \epsilon)k$  with probability at least  $c \cdot 2^{-\epsilon k}$ . ◀

■ **Algorithm 2** Second randomized  $(1 + \epsilon)$  approximation algorithm for FVS.

---

**Input** : An instance  $(G, k)$  of FVS and  $\epsilon \in (0, 1)$ .

- 1 *Initialize*,  $S \leftarrow \emptyset$ ;
- 2 **while**  $|S| < (1 + \epsilon)k$  &  $G - S$  is not acyclic **do**
- 3     apply reduction rules 2-4 exhaustively to  $G - S$ ;
- 4     **if** there is a self-loop **then**
- 5          $S = S \cup \{v : \text{there is a self-loop on } v\}$ ;
- 6     **else**
- 7         pick an edge  $e$  u.a.r from  $E(G - S)$ ;
- 8         pick a vertex  $v$  u.a.r. from the endpoints of  $e$  ;
- 9          $S = S \cup \{v\}$ ;
- 10    **end**
- 11    **if**  $G - S$  is acyclic &  $|S| \leq (1 + \epsilon)k$  **then**
- 12        return  $S$ ;
- 13    **end**
- 14 **end**
- 15 return No;

---

**Proof of Theorem 3.** The randomized FPT algorithm of [16] for FVS runs in  $\mathcal{O}^*(2.7^{k'})$  time for an instance  $(G, k')$  of FVS. Notice that, when Algorithm 1 calls the algorithm of [16], the parameter is at most  $(1 + \epsilon)k$ . Thus Algorithm 1 takes  $\mathcal{O}^*(2.7^{(1+\epsilon)k})$  time when it calls the algorithm of [16]. Except for this step, all other steps in Algorithm 1 can be done in polynomial time. So overall Algorithm 1 runs in time  $\mathcal{O}^*(2.7^{(1+\epsilon)k})$ . Also, due to Lemma 5, given a Yes-instance of FVS it outputs a solution of size at most  $(1 + \epsilon)k$  with probability at least  $c \cdot 2^{-\epsilon k}$ . The algorithm of Theorem 3 (which we call RPAS1) repeats Algorithm 1 at most  $\frac{1}{c} \cdot 2^{\epsilon k}$  times. The first time Algorithm 1 returns a solution, RPAS1 returns the same solution and stops. Otherwise, if all the  $\frac{1}{c} \cdot 2^{\epsilon k}$  runs of Algorithm 1 return No, then RPAS1 returns No as well. This gives the running time of RPAS1 to be  $\mathcal{O}^*(2^{\epsilon k} \cdot 2.7^{(1+\epsilon)k})$ . We have already seen in Lemma 4 that Algorithm 1 either fails or returns a solution of size at most  $(1 + \epsilon)k$ , so this is true for RPAS1 as well. For showing the second part of Theorem 3, we observe that RPAS1 fails if and only if each of the runs of Algorithm 1 fails. Hence, RPAS1 succeeds with probability at least  $1 - (1 - c \cdot 2^{-\epsilon k})^{\frac{1}{c} \cdot 2^{\epsilon k}} \geq 1/e$ . This finishes the proof of the theorem. ◀

#### 4 Algorithm II

In this section, we present our second randomized  $(1 + \epsilon)$  approximation algorithm for FVS for every  $\epsilon \in (0, 1)$ . Given an instance  $(G, k)$  of FVS, like before, we first apply reduction rules 2-4 on the graph. When none of the reduction rules 2-4 are applicable, we pick all the vertices with self-loops into the set  $S$ . If no vertex has a self-loop, then we pick an edge uniformly at random and then we pick an endpoint (say  $v$ ) of this edge uniformly at random. We add this vertex  $v$  into  $S$ . Then we delete  $S$  from the graph and repeat the same process until  $G - S$  becomes acyclic or the size of  $S$  crosses  $(1 + \epsilon)k$ . If  $G - S$  becomes acyclic before the size of  $S$  crosses  $(1 + \epsilon)k$ , then we return  $S$  as a solution, otherwise, we return No. We describe the algorithm formally in Algorithm 2. Now we state the main result of this section.

► **Theorem 6.** *There exists a randomized algorithm running in  $\mathcal{O}^* \left( \left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^k \right)$  time such that, given an FVS instance  $(G, k)$  and  $\epsilon \in (0, 1)$ , it either reports a failure or finds a feedback vertex set of  $G$  of size at most  $(1 + \epsilon)k$ . Moreover, if the algorithm is given a Yes-instance, it returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $1/e$ .*

Let us call the algorithm of Theorem 6 RPAS2. Just like RPAS1, it is obtained by repeating Algorithm 2 multiple times to get a constant success probability. So before we give the proof of Theorem 6, we need to show some results about the success probability of Algorithm 2. We first make the following observation which follows directly from line 11 of the algorithm.

► **Observation 7.** *If Algorithm 2 returns a solution  $S$  for a given instance  $(G, k)$  of FVS then  $S$  is a feedback vertex set in  $G$  of size at most  $(1 + \epsilon)k$ .*

Let  $T(b, k, n) : \mathbb{Z} \times \mathbb{N} \times \mathbb{N} \rightarrow [0, 1]$  be defined as follows.

$$T(b, k, n) := \min_{G: |V(G)| \leq n, \text{fvs}(G) \leq k} \{ \rho \mid \text{Algorithm 2 returns a feedback vertex set of } G \text{ of size at most } b \text{ with probability } \rho \}$$

If we can show a lower bound on  $T(b, k, n)$  where  $b = (1 + \epsilon)k$ , and  $k$  and  $\epsilon$  are as in the input of Algorithm 2, then that will give a lower bound for the success probability of Algorithm 2. We first make the following observation.

► **Observation 8.**  *$T(b, k, n) \leq T(b, k, n - 1)$  and  $T(b, k, n) \leq T(b, k - 1, n)$ .*

**Proof.** The first part of the observation follows from the fact that the set of graphs considered for  $T(b, k, n - 1)$  while taking the minimum in the definition is a subset of the set of graphs considered for  $T(b, k, n)$ . The second part also follows by a similar reasoning on the size of the feedback vertex set. ◀

Now, let us see what happens when Algorithm 2 adds  $v_i$  to  $S$ . Let  $E_1$  denote the event when this  $v_i$  belongs to some feedback vertex set of  $G$  of size at most  $k$ , and let  $E_2$  denote the event when  $v_i$  is not part of any feedback vertex set of  $G$  of size at most  $k$ . The probability of success of Algorithm 2 on  $G$  with parameter  $k$  and budget  $b$  is at least  $T(b - 1, k - 1, n - 1)$  and  $T(b - 1, k, n - 1)$  respectively in case  $E_1$  or  $E_2$  happens. This gives us the following.

$$T(b, k, n) \geq \Pr[E_1] \cdot T(b - 1, k - 1, n - 1) + \Pr[E_2] \cdot T(b - 1, k, n - 1).$$

Now, if we add  $v_i$  to  $S$  from line 5 of Algorithm 2 and  $G$  has a feedback vertex set of size at most  $k$ , then there must exist a feedback vertex set  $F$  of  $G$  of size at most  $k$  that contains  $v_i$ . Else, if  $v_i$  is added to  $S$  from line 9, then none of the reduction rules are applicable and by Lemma 2, we have that,  $\Pr[E_1] \geq \frac{1}{4}$ . That is,  $\Pr[E_1] = \frac{1}{4} + c_i$  for some  $c_i \geq 0$ . We also know that  $\Pr[E_1] + \Pr[E_2] = 1$ . Hence, the recurrence relation of success probability is

$$T(b, k, n) \geq \left( \frac{1}{4} + c_i \right) \cdot T(b - 1, k - 1, n - 1) + \left( \frac{3}{4} - c_i \right) \cdot T(b - 1, k, n - 1).$$

Now, using Observation 8, we can write

$$T(b, k, n) \geq \frac{1}{4} \cdot T(b - 1, k - 1, n) + \frac{3}{4} \cdot T(b - 1, k, n). \quad (1)$$

Since  $n$  is an invariant in the above recurrence relation, we can rewrite 1 as

$$T(b, k) \geq \frac{1}{4} \cdot T(b-1, k-1) + \frac{3}{4} \cdot T(b-1, k). \quad (2)$$

It can be easily seen that two trivial base cases of the recurrence 2 are the following.

i)  $T(b, k) = 0$  when  $b < 0$ , and ii)  $T(b, k) = 1$  when  $k = 0$  and  $b \geq 0$ .

#### 4.1 Solution of recurrence relation 2 and proof of Theorem 6

To solve the recurrence 2, we make use of the results in [15]. Let, a recurrence relation define a function  $p : \mathbb{Z} \times \mathbb{N} \rightarrow [0, 1]$  satisfying the following equations.

$$\begin{aligned} p(b, k) &= \min_{\{1 \leq j \leq N \mid \bar{k}^j \leq k\}} \sum_{i=1}^{r_j} \bar{\gamma}_i^j \cdot p\left(b - \bar{b}_i^j, k - \bar{k}_i^j\right) \\ p(b, k) &= 0 && \forall b < 0, k \in \mathbb{N} \\ p(b, 0) &= 1 && \forall b \geq 0, \end{aligned} \quad (3)$$

where  $N \in \mathbb{N}$ , and for any  $1 \leq j \leq N$  the following hold:  $\bar{b}^j \in \mathbb{N}_+^{r_j}$ ,  $\bar{k}^j \in \mathbb{N}^{r_j}$  and  $\bar{\gamma}^j \in \mathbb{R}_+^{r_j}$  with  $\sum_{i=1}^{r_j} \bar{\gamma}_i^j = 1$ . We say that  $\bar{k}^j \leq k$  if  $\bar{k}_i^j \leq k, \forall 1 \leq i \leq r_j$ . We refer to the recurrence relation in 3 as the composite recurrence of  $\{(\bar{b}^j, \bar{k}^j, \bar{\gamma}^j) \mid 1 \leq j \leq N\}$ . Note that for the recurrence to be properly defined, there must be  $1 \leq j \leq N$  such that  $\bar{k}^j \leq 1$  (otherwise the min operation in 3 may be taken over an empty set). Also notice that the recurrence 2 is a composite recurrence with  $N = 1$  (and thus  $j = 1$ ),  $r_j = r = 2$ ,  $\bar{\gamma}_1 = \frac{1}{4}$ ,  $\bar{\gamma}_2 = \frac{3}{4}$ ,  $\bar{b}_1 = 1$ ,  $\bar{b}_2 = 1$ ,  $\bar{k}_1 = 1$  and  $\bar{k}_2 = 0$ . Throughout this subsection, we use the word term when referring to triples of the form  $(\bar{b}^j, \bar{k}^j, \bar{\gamma}^j)$ .

We say that a vector  $\bar{q} \in \mathbb{R}_{\geq 0}^r$  is a distribution if  $\sum_{i=1}^r \bar{q}_i = 1$  and use  $D(\cdot \parallel \cdot)$  to denote **Kullback-Leibler divergence** [7]<sup>2 3</sup>.

To state the main result of [15], we need the next definition. For short, associate the term  $(\bar{b}, \bar{k}, \bar{\gamma})$  with the expression  $\sum_{i=1}^r \bar{\gamma}_i \cdot p(b - \bar{b}_i, k - \bar{k}_i)$ .

► **Definition 9.** Let  $\bar{b} \in \mathbb{N}_+^r$ ,  $\bar{k} \in \mathbb{N}^r$  and  $\bar{\gamma} \in \mathbb{R}_{\geq 0}^r$  with  $\sum_{i=1}^r \bar{\gamma}_i = 1$ . Then for  $\alpha > 0$ , the  $\alpha$  branching number of the term  $(\bar{b}, \bar{k}, \bar{\gamma})$  is the optimal value  $M^*$  of the following minimization problem over  $\bar{q} \in \mathbb{R}_{\geq 0}^r$  :

$$M^* = \min \left\{ \frac{1}{\sum_{i=1}^r \bar{q}_i \cdot \bar{k}_i} D(\bar{q} \parallel \bar{\gamma}) \mid \sum_{i=1}^r \bar{q}_i \cdot \bar{b}_i \leq \alpha \sum_{i=1}^r \bar{q}_i \cdot \bar{k}_i, \bar{q} \text{ is a distribution} \right\}.$$

If the optimization above does not have a feasible solution then  $M^* = \infty$ .

The main result of [15] is the following.

► **Theorem 10** ([15]). Let  $p$  be the composite recurrence of  $\{(\bar{b}^j, \bar{k}^j, \bar{\gamma}^j) \mid 1 \leq j \leq N\}$ , and  $\alpha > 0$ . Denote by  $M_j$  the  $\alpha$ -branching number of  $(\bar{b}^j, \bar{k}^j, \bar{\gamma}^j)$ , and let  $M = \max \{M_j \mid 1 \leq j \leq N\}$ . If  $M < \infty$  then

$$\lim_{k \rightarrow \infty} \frac{\log p(\lfloor \alpha k \rfloor, k)}{k} = -M.$$

<sup>2</sup> Formally, for  $\bar{c}, \bar{d} \in \mathbb{R}^k$  define  $D(\bar{c} \parallel \bar{d}) = \sum_{i=1}^k \bar{c}_i \log \frac{\bar{c}_i}{\bar{d}_i}$ .

<sup>3</sup> Throughout the paper we refer by log to the natural logarithm.

## 56:10 Parameterized Approximation Scheme for Feedback Vertex Set

As said earlier, for the recurrence 2, we have  $N = 1$ , and thus,  $j$  will always have only one value, so we just ignore  $j$ . Also, we have  $r_j = r = 2$ ,  $\bar{\gamma}_1 = \frac{1}{4}$ ,  $\bar{\gamma}_2 = \frac{3}{4}$ ,  $\bar{b}_1 = 1$ ,  $\bar{b}_2 = 1$ ,  $\bar{k}_1 = 1$  and  $\bar{k}_2 = 0$ . The  $\alpha$ -branching number of  $(\bar{b}, \bar{k}, \bar{\gamma})$  is,

$$M = \min \left\{ \frac{1}{\sum_{i=1}^2 \bar{q}_i \cdot \bar{k}_i} D(\bar{q} \| \bar{\gamma}) \mid \sum_{i=1}^2 \bar{q}_i \cdot \bar{b}_i \leq \alpha \sum_{i=1}^2 \bar{q}_i \cdot \bar{k}_i, \bar{q} \text{ is a distribution} \right\}.$$

So, we have to minimize

$$\frac{1}{\sum_{i=1}^2 \bar{q}_i \cdot \bar{k}_i} D(\bar{q} \| \bar{\gamma}) \quad (4)$$

with respect to the constraint,

$$\sum_{i=1}^2 \bar{q}_i \cdot \bar{b}_i \leq \alpha \sum_{i=1}^2 \bar{q}_i \cdot \bar{k}_i \quad (5)$$

Also, since  $\bar{q}$  is a distribution, we have

$$\bar{q}_1 + \bar{q}_2 = 1 \quad (6)$$

So, using 6 in 5 we get,

$$\bar{q}_1 + \bar{q}_2 \leq \alpha \bar{q}_1 \implies \bar{q}_1 \geq \frac{1}{\alpha} \quad (7)$$

Now, from 4, we get,

$$\frac{1}{\sum_{i=1}^2 \bar{q}_i \cdot \bar{k}_i} D(\bar{q} \| \bar{\gamma}) = \frac{1}{\bar{q}_1} \left( \bar{q}_1 \log \frac{\bar{q}_1}{\bar{\gamma}_1} + \bar{q}_2 \log \frac{\bar{q}_2}{\bar{\gamma}_2} \right) = \left( \log 4\bar{q}_1 + \frac{(1 - \bar{q}_1)}{\bar{q}_1} \log \frac{4(1 - \bar{q}_1)}{3} \right).$$

Notice that, the above expression is a function of  $\bar{q}_1$  only. Let us consider the function,  $f : [\frac{1}{\alpha}, 1] \rightarrow \mathbb{R}$  such that,

$$f(x) = \left( \log 4x + \frac{1-x}{x} \log \frac{4(1-x)}{3} \right).$$

Since we want a factor  $(1 + \epsilon)$  approximation for every  $\epsilon \in (0, 1)$ , we are interested for  $1 < \alpha < 2$  only and in this range of  $\alpha$ ,  $\frac{1}{\alpha} > \frac{1}{2}$ . Now, to compute  $M$ , we need to minimize  $f(x)$ .

Here, derivative of  $f(x)$ ,

$$f'(x) = -\frac{1}{x^2} \log \frac{4(1-x)}{3} \geq 0, \forall x \in \left[ \frac{1}{4}, 1 \right].$$

This implies that the function  $f$  is a monotonically increasing function on the domain of our interest ( i.e., where  $\frac{1}{\alpha} > \frac{1}{2}$ ). Hence,  $f(x)$  is minimum at  $x = \frac{1}{\alpha}$  and this implies

$$M = f\left(\frac{1}{\alpha}\right) = \log \left( \frac{4}{\alpha} \left( \frac{4}{3\alpha} (\alpha - 1) \right)^{(\alpha-1)} \right).$$

By Theorem 10,

$$p(\alpha k, k) = \left( \frac{4}{\alpha} \left( \frac{4}{3\alpha} (\alpha - 1) \right)^{(\alpha-1)} \right)^{-k}.$$

Now, from recurrence relation 2 and putting  $\alpha = (1 + \epsilon)$ , we get,

$$T((1 + \epsilon)k, k) \geq \left( \left( \frac{4}{1 + \epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^{-k}.$$

**Proof of Theorem 6.** Showing that  $T(b, k, n) \geq \left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^{-k}$  shows that given a Yes-instance  $(G, k)$  of FVS, Algorithm 2 succeeds with probability at least  $\left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^{-k}$ . Now, the proof follows along the lines of the proof of Theorem 3, and by repeating Algorithm 2  $\left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^k$  times, we get success probability at least  $1/e$ . Since Algorithm 2 runs in polynomial time, the running time of RPAS2 is  $\mathcal{O}^* \left( \left( \left( \frac{4}{1+\epsilon} \right)^{(1+\epsilon)} \cdot \left( \frac{\epsilon}{3} \right)^\epsilon \right)^k \right)$ . ◀

## 5 Algorithm III

In this section, we present the third randomized  $(1 + \epsilon)$  approximation algorithm for FVS for every  $\epsilon \in (0, 1)$ . Given an instance  $(G, k)$  of FVS, we first apply reduction rules 2-4 on the graph. After this, we pick all the vertices with self-loops into the set  $S_1$ . If no vertex has a self-loop, then we pick an edge uniformly at random, select an endpoint  $v$  of this edge uniformly at random, and add this vertex  $v$  into  $S_1$ . Then we delete  $S_1$  from the graph and repeat the same process until  $G - S_1$  becomes acyclic or the size of  $S_1$  crosses  $(1 - \epsilon)k$ . Next, we check whether  $G - S_1$  is acyclic and  $|S_1| \leq (1 + \epsilon)k$ . If yes, then we just return  $S_1$  as a solution. Otherwise, we apply a 2-approximation algorithm [1] for FVS on the graph  $G - S_1$ . If the 2-approximate solution, say  $S_2$ , of  $G - S_1$  is of size at most  $2(k - |S_1|)$  then we return  $S_1 \cup S_2$  as a solution, otherwise we return No. We describe the algorithm formally in Algorithm 3. Now we state the main result of this section.

▶ **Theorem 11.** *There exists a randomized algorithm running in  $\mathcal{O}^*(4^{(1-\epsilon)k})$  time such that, given an FVS instance  $(G, k)$  and  $\epsilon \in (0, 1)$ , it either reports a failure or finds a feedback vertex set of  $G$  of size at most  $(1 + \epsilon)k$ . Moreover, if the algorithm is given a Yes-instance, it returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $1/e$ .*

Let us call the algorithm of Theorem 6 RPAS3. Just like RPAS1 and RPAS2, it is obtained by repeating Algorithm 3 multiple times to get a constant success probability. So before we give the proof of Theorem 11, we need to prove some lemmas about Algorithm 3.

▶ **Lemma 12.** *If Algorithm 3 returns a set  $S$  then  $S$  is a feedback vertex set in  $G$  of size at most  $(1 + \epsilon)k$ .*

**Proof.** The returned solution will be either of the form  $S_1$  or of the form  $S_1 \cup S_2$  for some vertex set  $S_1$ , and  $S_2$ . If it is only  $S_1$ , then by the algorithm, it is clear that  $G - S_1$  is acyclic and  $|S_1| \leq (1 + \epsilon)k$ .

Now, if the returned solution is of the form  $S_1 \cup S_2$ , then  $S_2$  is a 2-approximate solution for the graph  $G - S_1$ . Thus, by the correctness of 2-approximation algorithm for FEEDBACK VERTEX SET, we can say  $S_2$  is a feedback vertex set in  $G - S_1$ , and this implies,  $S = S_1 \cup S_2$  is a feedback vertex set in  $G$ .

Now from Algorithm 3, we can see,  $|S_1| \geq (1 - \epsilon)k$ . Again, Algorithm 3 returns a solution of the form  $S_1 \cup S_2$  only when  $|S_2| \leq 2(k - |S_1|)$ . Thus, we get,

$$|S| = |S_1| + |S_2| \leq |S_1| + 2(k - |S_1|) = 2k - |S_1| \leq 2k - (1 - \epsilon)k = (1 + \epsilon)k. \quad \blacktriangleleft$$

▶ **Lemma 13.** *Given an Yes-instance of FVS, Algorithm 3 returns a solution of size at most  $(1 + \epsilon)k$  with probability at least  $4^{-(1-\epsilon)k}$ .*

■ **Algorithm 3** Third randomized  $(1 + \epsilon)$ -approximation algorithm for FVS.

---

**Input** : An instance  $(G, k)$  of FVS and  $\epsilon \in (0, 1)$ .

- 1 *Initialize*,  $S_1 \leftarrow \emptyset$ ;
- 2 **while**  $|S_1| < (1 - \epsilon)k$  &  $G - S_1$  is not acyclic **do**
- 3     apply reduction rules 2-4 exhaustively to  $G - S_1$ ;
- 4     **if** there is a self-loop **then**
- 5          $S_1 = S_1 \cup \{v : \text{there is a self-loop on } v\}$ ;
- 6     **else**
- 7         pick an edge  $e$  u.a.r from  $E(G - S_1)$ ;
- 8         pick a vertex  $v$  u.a.r. from the endpoints of  $e$ ;
- 9          $S_1 = S_1 \cup \{v\}$ ;
- 10    **end**
- 11    **if**  $G - S_1$  is acyclic &  $|S_1| \leq (1 + \epsilon)k$  **then**
- 12        return  $S_1$ ;
- 13    **end**
- 14 **end**
- 15 apply 2-approximation for FVS on  $G - S_1$ ;
- 16 Let  $S_2$  be returned solution;
- 17 **if**  $|S_2| > 2(k - |S_1|)$  **then**
- 18     return No;
- 19 **else**
- 20     return  $S_1 \cup S_2$ ;
- 21 **end**

---

**Proof.** Let the given instance  $(G, k)$  be a **Yes** instance, that is, there is a feedback vertex set in  $G$  of size at most  $k$ . Let  $S_1^1$  and  $S_1^2$  be the set of vertices we add in  $S$  by the line number 5 and 9 of Algorithm 3, respectively. Notice that we add vertices to  $S_1^1$  only when there are some self-loops in the graph (i.e., reduction rule 1 is applicable). By the correctness of reduction rule 1, if  $(G, k)$  is a **Yes** instance, then there exists a feedback vertex set of size at most  $k$  containing  $S_1^1$ . Now, when we add a vertex in  $S_1^2$ , from the pseudocode of Algorithm 3, we can see none of the reduction rules are applicable and thus, we can assume the minimum degree of the graph to be at least 3. Now if we pick an edge uniformly at random and then we pick one of its endpoints,  $v$  uniformly at random into  $S_1^2$  then Lemma 2 says that,  $v$  is a part of any feedback vertex set with probability at least  $\frac{1}{4}$ . Thus, for some feedback vertex set  $F$  of size at most  $k$ ,  $pr[S_1 = S_1^1 \cup S_1^2 \subseteq F] \geq \frac{1}{4} \cdot \frac{1}{4} \cdot \frac{1}{4} \cdots \frac{1}{4} (|S_1^2| \text{ times}) = \frac{1}{4^{|S_1^2|}}$ . Since, Algorithm 3 adds at most one vertex to  $S_1^2$  at every execution of the while loop and the while loop runs for at most  $(1 - \epsilon)k$  steps, so,  $|S_1^2| \leq (1 - \epsilon)k$ . Therefore,  $pr[S_1 = S_1^1 \cup S_1^2 \subseteq F] \geq \frac{1}{4^{(1-\epsilon)k}}$ . If  $S_1 = F$ , then  $S_1$  is a feedback vertex set in  $G$  and  $|S_1| \leq k \leq (1 + \epsilon)k$  and Algorithm 3 will return a solution. Else if  $S_1 \subset F$  then  $F \setminus S_1$  is a feedback vertex set in  $G - S_1$  of size  $k - |S_1|$ . Hence, the size of the 2-approximate solution  $S_2$  will be at most  $2(k - |S_1|)$  and Algorithm 3 will return a solution  $S = S_1 \cup S_2$ . So, if the given instance  $(G, k)$  is a yes-instance then for some feedback vertex set  $F$  in  $G$  of size at most  $k$ ,  $S_1 \subseteq F$  with probability at least  $\frac{1}{4^{(1-\epsilon)k}}$  and when  $S_1 \subseteq F$ , Algorithm 3 always returns a solution. Hence the proof. ◀

**Proof of Theorem 11.** There is a polynomial time 2-approximation algorithm for FVS that can be found in [1]. Also, every step under the while loop in Algorithm 3 takes only polynomial time and the while loop runs for at most  $(1 - \epsilon)k$  times. So, overall Algorithm 3

runs in polynomial time. RPAS3 calls Algorithm 3 for  $4^{(1-\epsilon)k}$  times to achieve constant success probability, and the remainder of the proof follows from Lemma 12 and Lemma 13 along the lines of proofs of Theorem 3 and Theorem 6. ◀

## 6 Comparison of RPAS1, RPAS2, and RPAS3, and proof of Theorem 1

In this section we compare the running times of the algorithms in Theorem 3, Theorem 6, and Theorem 11, which we have named RPAS1, RPAS2, and RPAS3 respectively. We observe that each of RPAS1, RPAS2 and RPAS3 performs better than the other two when  $\epsilon$  lies in the intervals  $(0, 0.176)$ ,  $(0.176, 0.674)$ , and  $(0.674, 1)$  respectively. For  $\epsilon = 0.176$ , the running times of RPAS1 and RPAS2 are the same, while for  $\epsilon = 0.674$ , the running times of RPAS2 and RPAS3 turn out to be the same. The following table gives the running time of the three algorithms for different values of  $\epsilon$  for comparison. Now we are ready to give the proof of Theorem 1.

No.	$\epsilon$	Approximation factor	RPAS1 run time	RPAS2 run time	RPAS3 run time	Better run time
1	0.05	1.05	$2.66^k$	$3.319^k$	$3.732^k$	$2.66^k$
2	0.10	1.10	$2.62^k$	$2.945^k$	$3.482^k$	$2.62^k$
3	0.15	1.15	$2.581^k$	$2.676^k$	$3.482^k$	$2.581^k$
4	0.176	1.176	$2.561^k$	$2.561^k$	$3.134^k$	$2.561^k$
5	0.20	1.20	$2.543^k$	$2.467^k$	$3.031^k$	$2.467^k$
6	0.25	1.25	$2.505^k$	$2.3^k$	$2.828^k$	$2.3^k$
7	0.30	1.30	$2.468^k$	$2.16^k$	$2.639^k$	$2.16^k$
8	0.35	1.35	$2.431^k$	$2.043^k$	$2.462^k$	$2.043^k$
9	0.40	1.40	$2.395^k$	$1.942^k$	$2.297^k$	$1.942^k$
10	0.45	1.45	$2.359^k$	$1.855^k$	$2.144^k$	$1.855^k$
11	0.50	1.50	$2.324^k$	$1.778^k$	$2^k$	$1.778^k$
12	0.55	1.55	$2.289^k$	$1.71^k$	$1.866^k$	$1.71^k$
13	0.60	1.60	$2.255^k$	$1.649^k$	$1.741^k$	$1.649^k$
14	0.65	1.65	$2.222^k$	$1.595^k$	$1.624^k$	$1.595^k$
15	0.674	1.674	$2.206^k$	$1.571^k$	$1.571^k$	$1.571^k$
16	0.70	1.70	$2.188^k$	$1.546^k$	$1.516^k$	$1.516^k$
17	0.75	1.75	$2.156^k$	$1.502^k$	$1.414^k$	$1.414^k$
18	0.80	1.80	$2.124^k$	$1.462^k$	$1.32^k$	$1.32^k$
19	0.85	1.85	$2.092^k$	$1.426^k$	$1.231^k$	$1.231^k$
20	0.9	1.90	$2.061^k$	$1.392^k$	$1.149^k$	$1.149^k$
21	0.95	1.95	$2.03^k$	$1.362^k$	$1.072^k$	$1.072^k$

**Proof of Theorem 1.** Given an instance  $(G, k)$  and an  $\epsilon \in (0, 1)$ , the algorithm runs one of RPAS1, RPAS2, and RPAS3 depending upon which of them performs the best for that value of  $\epsilon$  (for  $\epsilon = 0.176$ , we can choose either of RPAS1 or RPAS2 and for  $\epsilon = 0.674$ , we can choose either of RPAS2 or RPAS3). The running time and the correctness follows from Theorem 3, Theorem 6, and Theorem 11. ◀

## Abstract

---

For any finite set  $\mathcal{H} = \{H_1, \dots, H_p\}$  of graphs, a graph is  $\mathcal{H}$ -subgraph-free if it does not contain any of  $H_1, \dots, H_p$  as a subgraph. In recent work, meta-classifications have been studied: these show that if graph problems satisfy certain prescribed conditions, their complexity can be classified on classes of  $\mathcal{H}$ -subgraph-free graphs. We continue this work and focus on problems that have polynomial-time solutions on classes that have bounded treewidth or maximum degree at most 3 and examine their complexity on  $H$ -subgraph-free graph classes where  $H$  is a connected graph. With this approach, we obtain comprehensive classifications for (INDEPENDENT) FEEDBACK VERTEX SET, CONNECTED VERTEX COVER, COLOURING and MATCHING CUT. This resolves a number of open problems.

We highlight that, to establish that INDEPENDENT FEEDBACK VERTEX SET belongs to this collection of problems, we first show that it can be solved in polynomial time on graphs of maximum degree 3. We demonstrate that, with the exception of the complete graph on four vertices, each graph in this class has a minimum size feedback vertex set that is also an independent set.

## 1 Introduction

A graph  $G$  contains a graph  $H$  as a *subgraph* if  $H$  can be obtained from  $G$  by vertex deletions and edge deletions; else  $G$  is said to be  *$H$ -subgraph-free*. If  $H$  can be obtained from  $G$  using *only* vertex deletions, then  $H$  is an *induced* subgraph of  $G$ , and if not then  $G$  is  *$H$ -free*. There are few studies of complexity classifications of graph problems for  $H$ -subgraph-free graphs (compare the greater attention given to problems on  $H$ -free graphs). There are results for INDEPENDENT SET, DOMINATING SET and LONGEST PATH [1], Max-Cut [13] and LIST COLOURING [10] (see also [11] for a shorter alternative proof of the result for INDEPENDENT SET). In these papers, complete classifications are presented giving the complexity of the problems even for  $\mathcal{H}$ -subgraph-free graphs, where  $\mathcal{H}$  is any finite set of graphs (for a set of

graphs  $\mathcal{H}$ , a graph  $G$  is  $\mathcal{H}$ -subgraph-free if  $G$  is  $H$ -subgraph-free for every  $H \in \mathcal{H}$ ). Such classifications seem difficult to obtain. For example, for COLOURING, there is only a partial classification [11]. For this reason – and also noting that the classifications for the problems above were all the same – a systematic approach was developed in [12] with the introduction of a new framework which we will describe after introducing some terminology.

For an integer  $k \geq 1$ , the  $k$ -subdivision of an edge  $e = uv$  of a graph replaces  $e$  by a path of length  $k + 1$  with endpoints  $u$  and  $v$  (and  $k$  new vertices). The  $k$ -subdivision of a graph  $G$  is the graph obtained from  $G$  after  $k$ -subdividing each edge. For a graph class  $\mathcal{G}$  and an integer  $k$ , let  $\mathcal{G}^k$  consist of the  $k$ -subdivisions of the graphs in  $\mathcal{G}$ . Let  $\Pi$  be a graph problem. We say that  $\Pi$  is NP-complete under edge subdivision of subcubic graphs if there exists an integer  $k \geq 1$  such that the following holds for the class of subcubic graphs  $\mathcal{G}$ : if  $\Pi$  is NP-complete for  $\mathcal{G}$ , then  $\Pi$  is NP-complete for  $\mathcal{G}^{kp}$  for every integer  $p \geq 1$ . A graph problem  $\Pi$  is a C123-problem (belongs to the framework) if it satisfies the three conditions:

- C1.  $\Pi$  is polynomial-time solvable for every graph class of bounded treewidth;
- C2.  $\Pi$  is NP-complete for the class of subcubic graphs; and
- C3.  $\Pi$  is NP-complete under edge subdivision of subcubic graphs.

As shown in [12], C123-problems allow for full complexity classifications for  $\mathcal{H}$ -subgraph-free graphs (as long as  $\mathcal{H}$  has finite size). A subdivided claw is a graph obtained from a claw (4-vertex star) after subdividing, separately, each of its edges zero or more times. The disjoint union of two vertex-disjoint graphs  $G_1$  and  $G_2$  has vertex set  $V(G_1) \cup V(G_2)$  and edge set  $E(G_1) \cup E(G_2)$ . The set  $\mathcal{S}$  consists of the graphs that are disjoint unions of subdivided claws and paths. Now, let  $\Pi$  be a C123-problem. For a finite set  $\mathcal{H}$ , the problem  $\Pi$  on  $\mathcal{H}$ -subgraph-free graphs is polynomial-time solvable if  $\mathcal{H}$  contains a graph from  $\mathcal{S}$  and NP-complete otherwise. [12].

Examples of C123-problems include INDEPENDENT SET, DOMINATING SET, LIST COLOURING, ODD CYCLE TRANSVERSAL, MAX CUT and STEINER TREE; see [12] for a comprehensive list. Thus we see the power of the framework to aid progress in deciding the complexity of problems on  $\mathcal{H}$ -subgraph-free graphs. But there are still many graph problems that are not C123. In [15], results were obtained for problems that satisfy C1 and C2 but not C3. Such problems are called C12-problems and include  $k$ -INDUCED DISJOINT PATHS,  $C_5$ -COLOURING, HAMILTON CYCLE and STAR 3-COLOURING [15]. We consider the research question:

*How do C13-problems – that is, problems that satisfy C1 and C3 but not C2 – behave for  $\mathcal{H}$ -subgraph-free graphs? Can we still classify their computational complexity?*

Let us immediately note some redundancy in the definition of C13-problems: if a problem does not satisfy C2, then C3 is implied. Nevertheless we retain the terminology to preserve the link to the approach of [12]. To show a problem is a C13 problem there are two requirements: that the problem is polynomial-time solvable both on classes of bounded treewidth and on subcubic classes. In fact, the tractable cases for C123 problems rely on that the problems satisfy C1.

► **Theorem 1** ([12]). *Let  $\Pi$  be a problem that satisfies C1. For a finite set  $\mathcal{H}$ , the problem  $\Pi$  on  $\mathcal{H}$ -subgraph-free graphs is polynomial-time solvable if  $\mathcal{H}$  contains a graph from  $\mathcal{S}$ .*

As an important step towards a full dichotomy for C13 problems, we restrict ourselves to considering  $H$ -subgraph-free graphs where  $H$  is connected. We focus on five well-known NP-complete problems that we will see are not C123 but C13-problems: FEEDBACK VERTEX SET, INDEPENDENT FEEDBACK VERTEX SET, CONNECTED VERTEX COVER and MATCHING CUT. We introduce these problems below. With one exception, we can recognize that they are C13 problems using known results.

For a graph  $G = (V, E)$ , a set  $W \subseteq V$  is a *feedback vertex set* of  $G$  if every cycle in  $G$  contains a vertex of  $W$ . Moreover,  $W$  is an *independent feedback vertex set* if  $W$  is an independent set. We note that  $G$  has a feedback vertex set of size  $k$  if and only if the 2-subdivision of  $G$  has an independent feedback vertex set of size  $k$ . A graph  $G$  might contain no independent feedback vertex set: consider, for example, a complete graph on four or more vertices. The (INDEPENDENT) FEEDBACK VERTEX SET problem is to decide if a graph  $G$  has an (independent) feedback vertex set of size at most  $k$  for some given integer  $k$ .

A set  $W \subseteq V$  is a *connected vertex cover* of  $G$  if every edge of  $E$  is incident with a vertex of  $W$ , and moreover  $W$  induce a connected subgraph. The CONNECTED VERTEX COVER problem is to decide if a graph  $G$  has a connected vertex cover of size at most  $k$  for a given integer  $k$ . A  $k$ -colouring of  $G$  is a function  $c : V \rightarrow \{1, \dots, k\}$  such that for each edge  $uv \in E$ ,  $c(u) \neq c(v)$ . The COLOURING problem is to decide if a graph  $G$  has a  $k$ -colouring for some given integer  $k$ . A *matching cut* of a connected graph is a matching (set of pairwise non-adjacent edges) that is also an edge cut, i.e., its removal creates a disconnected graph. The MATCHING CUT problem is to decide if a connected graph has a matching cut.

## 1.1 Our Results

Both FEEDBACK VERTEX SET and INDEPENDENT FEEDBACK VERTEX SET satisfy C1 [21]. Whereas FEEDBACK VERTEX SET does have a polynomial-time algorithm on subcubic graphs [22] and thus does not satisfy C2, a polynomial-time algorithm for INDEPENDENT FEEDBACK VERTEX SET on subcubic graphs was not previously known. In Section 2, we prove the following result addressing this gap in the literature.

► **Theorem 2.** *A minimum size independent feedback vertex set of every connected subcubic graph  $G \neq K_4$  is also a minimum size feedback vertex set of  $G$ . Moreover, it is possible to find a minimum independent feedback vertex set of  $G$  in polynomial time.*

Hence, both FEEDBACK VERTEX SET and INDEPENDENT FEEDBACK VERTEX SET are C13. The other problems are also C13. Namely, CONNECTED VERTEX COVER satisfies C1 [2] and is polynomial-time solvable on subcubic graphs [22] so does not satisfy C2, while COLOURING also satisfies C1 [2] but not C2 due to Brooks' Theorem [4]. Finally, MATCHING CUT satisfies C1 [3] but not C2, due to a polynomial-time algorithm for subcubic graphs [5].

The *star*  $K_{1,s}$  is the connected graph that contains a vertex of degree  $s$  whose neighbours each have degree 1. A *subdivided star* is obtained from a star by subdividing one or more of its edges.

► **Definition 3.** *An  $S_{w,x,y,z}$  is a graph formed by subdividing each edge of a  $K_{1,4}$ ,  $w - 1$ ,  $x - 1$ ,  $y - 1$ , and  $z - 1$  times. Each of the subdivided edges is called a tentacle. The vertex of degree 4 is the centre.*

In Section 3, we investigate the structure of  $H$ -subgraph-free graphs when  $H$  is a subdivided star and use this in Section 4 to show a general approach to C13 problems that requires some additional properties (that they can be solved componentwise after, possibly, the removal of bridges). This is sufficient to obtain the following result.

► **Theorem 4.** *Let  $q$  and  $r$  be positive integers. The following problems can be solved in polynomial time on  $S_{1,1,q,r}$ -subgraph-free graphs: FEEDBACK VERTEX SET, INDEPENDENT FEEDBACK VERTEX SET, CONNECTED VERTEX COVER, COLOURING and MATCHING CUT.*

In Section 5, we obtain a hardness result.

► **Theorem 5.** *FEEDBACK VERTEX SET and INDEPENDENT FEEDBACK VERTEX SET are NP-complete on the class of  $S_{2,2,2,2}$ -subgraph free graphs that have maximum degree 4.*

## 1.2 State-of-the-Art Summaries

We now state complexity classifications for each of the problems. These results, proved in Section 6, combine the results above with a number of other results from [5, 7, 8, 9, 11, 14, 17, 19, 20]. None of these papers presented general results for C13 problems. However, we note, for example, that hardness when  $H$  contains a cycle follows from past results on classes of bounded girth which were proved separately for each problem, but often using a similar technique. There are other results that just apply to one or two of the problems.

► **Theorem 6.** *Let  $H$  be a connected graph. On  $H$ -subgraph-free graphs, FEEDBACK VERTEX SET and INDEPENDENT FEEDBACK VERTEX SET are solvable in polynomial time if  $H \in \mathcal{S} \cup \{S_{1,1,q,r} \mid q \geq r \geq 1\}$ . They are NP-complete if  $H$  contains a cycle or more than one vertex of degree at least 3 or  $H \in \{K_{1,5}, S_{2,2,2,2}\}$ .*

► **Theorem 7.** *Let  $H$  be a connected graph. On  $H$ -subgraph-free graphs, CONNECTED VERTEX COVER is solvable in polynomial time if  $H \in \mathcal{S} \cup \{S_{1,1,q,r} \mid q \geq r \geq 1\}$ . It is NP-complete if  $H$  contains a cycle or  $H = K_{1,5}$ .*

The following result refers to trees defined in Figure 1.

► **Theorem 8.** *Let  $H$  be a connected graph. On  $H$ -subgraph-free graphs, COLOURING is solvable in polynomial time if  $H \in \mathcal{S} \cup \{S_{1,1,q,r} \mid q \geq r \geq 1\}$  or if  $H$  is a forest with maximum degree 4 and at most seven vertices. It is NP-complete if  $H$  contains a cycle, or  $H \in \{K_{1,5}, S_{2,2,2,2}\}$ , or if  $H$  contains a subdivision of the tree  $T_1$  as a subgraph, or  $H$  contains as a subgraph the tree obtained from  $T_2$  after subdividing the edge  $st$   $p$  times,  $0 \leq p \leq 9$ , or  $H$  contains one of the trees  $S_{2,2,2,2}, T_4, T_5, T_6$  as a subgraph.*

■ **Figure 1** Illustration of the trees  $T_1, \dots, T_6$  reproduced from [11]; note that  $T_3 = S_{2,2,2,2}$ .

► **Theorem 9.** *Let  $H$  be a connected graph. On  $H$ -subgraph-free graphs, MATCHING CUT is solvable in polynomial time if  $H \in \mathcal{S} \cup \{S_{1,1,q,r} \mid q \geq r \geq 1\}$ . It is NP-complete if  $H$  contains a cycle or  $H = K_{1,5}$ .*

## 2 Independent Feedback Vertex Sets of Subcubic Graphs

In [22], Ueno, Kajitani and Gotoh gave a polynomial-time algorithm for FEEDBACK VERTEX SET on subcubic graphs. In this section, we prove Theorem 2 by showing that INDEPENDENT FEEDBACK VERTEX SET is also polynomial-time solvable on subcubic graphs by demonstrating that the problems are alike as, for any subcubic graph, one can find a minimum size feedback vertex set that is also an independent set (with a single exceptional case). As the problems can be solved componentwise, we consider only connected graphs.

In fact, we are going to prove a result that is an expansion of Theorem 2 that will come in handy later. We need some definitions. A *cactus* is a graph in which no two cycles have an edge in common. A cactus is *nice* if no two cycles have a vertex in common (every subcubic cactus is nice since if two cycles share a vertex but not an edge, we can find a vertex of degree at least 4). A cactus is *very nice* if every vertex belongs to exactly one cycle.

► **Theorem 10.** *Let  $G \neq K_4$  be a connected subcubic graph. Then a minimum size independent feedback vertex set of  $G$  is also a minimum size feedback vertex set of  $G$ . Moreover, there is a minimum size independent feedback vertex set of  $G$  that contains only vertices of degree 3 if and only if  $G$  is not a very nice cactus. There is a polynomial-time algorithm to find a minimum size independent feedback vertex set and if  $G$  is not a very nice cactus it finds a set that contains only vertices of degree 3.*

We observe that the theorem fails if  $G = K_4$ .

**Proof.** It will be seen that the proof implies a polynomial-time algorithm for finding an independent feedback vertex set of the size no greater than a given feedback vertex set.

A feedback vertex set of  $K_4$  must contain at least two vertices and so  $K_4$  has no independent feedback vertex set. In a very nice cactus, the minimum size of a feedback vertex set is equal to the number of cycles and one can easily find such a set that is independent if one permits the inclusion of degree 2 vertices. (For example, pick an arbitrary vertex  $v$  and form an independent feedback vertex set by taking the vertex in each cycle that is farthest from  $v$ .) If there are  $k$  (disjoint) cycles, then, considering the tree-like structure of a very nice cactus, there are  $2(k - 1)$  vertices of degree 3 that can be considered as  $k - 1$  adjacent pairs. Thus no set of  $k$  vertices of degree 3 is independent.

So suppose that  $G \neq K_4$  is not a very nice cactus. Of course, we may also assume that  $G$  is not a tree, else the empty set is an independent feedback vertex set. Let  $F$  be a feedback vertex set of  $G$ . To prove the theorem, we must show that we can find an independent feedback vertex set of  $G$  that is no larger than  $F$ . We can assume that  $F$  contains only vertices of degree 3 since any vertex of degree 2 can be replaced by a nearest vertex of degree 3. As  $G$  is neither a tree nor a cycle (a cycle is a very nice cactus), we know that  $G$  has vertices of degree 3.

Let  $J = \emptyset$ . Our approach is to add vertices to  $J$  until it forms an independent feedback vertex set. We make some trivial but useful statements:

1.  $F$  is a feedback vertex set containing only vertices of degree 3,
2.  $J \subseteq F$ , and
3.  $J$  is a nonseparating independent set of  $G$ ; that is, no pair of vertices of  $J$  are joined by an edge and  $G - J$  is connected.

We will repeatedly modify  $F$  and  $J$  in such a way that these three statements remain true and the size of  $F$  does not increase and it remains a feedback vertex set. We can make the following changes without contradicting the three statements.

- We can add a vertex  $x \in F \setminus J$  to  $J$  if  $x$  has no neighbour in  $J$  and is not a cutvertex in  $G - J$ .
- If  $x \in F \setminus J$ , we can redefine  $F$  as  $(F \setminus \{x\}) \cup \{y\}$  if  $y$  is a vertex that belongs to every cycle of  $G - (F \setminus \{x\})$  and has degree 3 (that is,  $y$  belongs to every cycle of  $G$  that contains  $x$  but no other vertex of  $F$ ).

Our initial aim is to make changes so that  $G - J$  is a graph where no two cycles have a vertex in common; that is, it is a nice cactus.

▷ **Claim 11.** We can modify  $F$  and  $J$  until  $G - J$  is a nice cactus.

Proof. Assume  $G - J$  contains two cycles with a common vertex, and, therefore, as  $G$  is subcubic, a common edge, else we are done. Consider a subgraph  $K$  induced by two cycles of  $G - J$  that have a common edge (so  $K$  is 2-connected and has no cutvertex). Of course,  $F$  must contain at least one vertex of  $K$ ; let  $r$  be such a vertex.

If  $r$  has degree 3 in  $K$ , then we can add it to  $J$  since it has three neighbours in  $G - J$  (so none in  $J$ ) and is not a cutvertex in  $G - J$  since  $K - \{r\}$  is connected.

Otherwise  $r$  has degree 2 in  $K$ . Traversing edges of  $K$  away from  $r$  in either direction, let  $p$  and  $q$  be the first vertices of degree 3 in  $K$  that are reached (and  $p \neq q$  by the definition of  $K$ ). Let  $r'$  be the first vertex of degree 3 in  $G$  reached from  $r$  on the path in  $K$  towards  $p$ .

If  $r$  has a neighbour  $j \in J$ , then we can redefine  $F$  as  $F \setminus \{r\} \cup \{r'\}$  since every cycle in  $G$  containing  $r$  also contains either  $j$  or  $r'$ . Suppose instead that  $r$  has no neighbour in  $J$ . Let  $r''$  be the neighbour of  $r$  in  $G - J$  but not  $K$ . If  $r$  is not a cutvertex in  $G - J$ , then we can add  $r$  to  $J$ . If  $r$  is a cutvertex in  $G - J$ , then no cycle of  $G - J$  includes the edge  $rr''$ . Thus, again, we can redefine  $F$  as  $F \setminus \{r\} \cup \{r'\}$ .

So we either add a vertex to  $J$  or modify  $F$  by replacing a vertex with another that is closer in  $K$  to  $p$ . By repetition, we either add a vertex to  $J$  or modify  $F$  to include  $p$  in which case, as noted above, we can add  $p$  to  $J$ . Therefore, if  $G - J$  contains two cycles with a common edge, we can increase the size of  $J$  and so, ultimately, we can assume that  $G - J$  contains no such pair of cycles and is a nice cactus. This completes the proof of Claim 11.  $\triangleleft$

Let  $H = G - J$ . By Claim 11, the cycles of  $H$  are vertex disjoint and the graph has a treelike structure: if one replaces each cycle by a single vertex, then a tree is obtained. As  $F$  must contain at least one vertex of each cycle of  $H$ , if we add to  $J$  one vertex chosen from each cycle of  $H$  (in any way), it will be no larger than  $F$ . If we can do this in such a way that  $J$  is an independent set and each vertex has degree 3, then the proof will be complete. Thus we must describe how to choose a degree 3 vertex from each cycle of  $H$  such that the union of these vertices and  $J$  is an independent set, possibly after some further minor modifications. The reasoning about these modifications will require that  $H$  is connected so the requirement above that  $J$  be nonseparating was needed.

If  $H$  contains no cycles, then  $J$  is already an independent feedback vertex set and there is nothing to prove. Otherwise, let  $C$  be a cycle of  $H$ . Let  $S(C)$  be the set of vertices that contains, for each cycle  $C'$  of  $H$  other than  $C$ , the vertex of  $C'$  that is nearest to  $C$  in  $H$ . See Figure 2. Each vertex  $v$  of  $S(C)$  has degree 3 in  $H$  since it has two neighbours in a cycle  $C'$  and a neighbour not in  $C'$  on the path from  $v$  to  $C$ . Thus no vertex of  $S(C)$  has a neighbour in  $J$ . Moreover, clearly  $S(C)$  is an independent set. Thus  $J \cup S(C)$  is an independent set that covers every cycle of  $G$  except  $C$ . For a vertex  $v$  in  $C$ , let  $F(v) = J \cup S(C) \cup \{v\}$ . If we can find a cycle  $C$  that contains a vertex  $v$  of degree 3 not adjacent to  $J$  or to another cycle in  $H$ , then  $F(v)$  is an independent feedback vertex set and we are done.

Suppose instead that no such cycle can be found. Notice that this implies that every vertex of  $H$  belongs to a cycle. (If there was a vertex  $w$  not in a cycle, then let  $v$  be a nearest vertex to  $w$  in a cycle and then  $F(v)$  is an independent feedback vertex set of degree 3 vertices; again, see Figure 2.) So  $H$  is a very nice cactus and, by assumption,  $J \neq \emptyset$ .

Let  $j$  be a vertex in  $J$  with neighbours  $v_1, v_2$  and  $v_3$  in  $H$ . Suppose that these three vertices are in the same cycle  $C$  of  $H$ . If  $C$  is a 3-cycle, then  $\{j, v_1, v_2, v_3\}$  induces  $K_4$ , a contradiction. So we can assume that  $v_1$  and  $v_2$  are not adjacent. Then  $J_1 = J \setminus \{j\} \cup \{v_1, v_2\} \cup S(C)$  is an independent feedback vertex set of degree 3 vertices and  $|J_2| = |F|$ . Quick check: all cycles are covered by  $J_1$  since  $v_1$  and  $S(C)$  cover the cycles of  $H$  and every cycle containing  $j$  includes at least one of  $v_1$  and  $v_2$ ;  $J_1$  is independent as  $v_1$  and  $v_2$  have degree 2 in  $H$  so no other neighbour in  $J$  and are not adjacent to vertices, such as those of  $S(C)$ , that do not belong to  $C$ , and the vertices of  $S(C)$  have degree 3 in  $H$  so no neighbours in  $J$ .

■ **Figure 2** A nice subcubic cactus. The central 5-cycle is denoted  $C$  and the white vertices form the set  $S(C)$ . Note that  $w$  does not belong to any cycle and  $v$  is the nearest vertex to  $w$  in a cycle. Thus  $S(C) \cup \{v\}$  is an independent feedback vertex set for the graph.

Suppose instead that  $v_1, v_2$  and  $v_3$  do not all belong to the same cycle. Let  $C$  be the cycle that contains  $v_1$  and suppose that  $v_2$  and  $v_3$  do not belong to the same cycle as each other (one might belong to  $C$ ). Then  $J_2 = J \setminus \{j\} \cup \{v_1\} \cup S(C)$  is an independent feedback vertex set of degree 3 vertices and  $|J_2| = |F| - 1$ . Quick check: all cycles are covered by  $J_2$  since  $v_1$  and  $S(C)$  cover the cycles of  $H$  and every cycle containing  $j$  includes either  $v_1$  or both  $v_2$  and  $v_3$  and all the paths from  $v_2$  to  $v_3$  (that do not include  $j$ ) go through either a vertex of  $J$  or a vertex of  $S(C)$  as they are in different cycles in  $H$ ;  $J_2$  is independent as  $v_1$  has degree 2 in  $H$  so, as before, no other neighbour in  $J$  or  $S(C)$ , and the vertices of  $S(C)$  have degree 3 in  $H$  so no neighbours in  $J$ . ◀

### 3 Graphs Excluding Subdivided Stars as a Subgraph: Structure

Recall that the treedepth of a graph  $G$  is the minimum height of a forest  $F$  such that for every pair of adjacent vertices in  $G$ , one is the ancestor of the other in  $F$ . It is well-known that the treewidth of a graph is at most its treedepth. In this section, we aim to show that  $H$ -subgraph-free graphs, for certain  $H$ , have bounded treedepth. Then we know that problems that are tractable on classes of bounded treewidth are also tractable on these classes. Before presenting our results, we need the following result from [18].

► **Theorem 12** ([18]). *Let  $G$  be a graph of treedepth at least  $d$ . Then  $G$  has a subgraph isomorphic to a path of length at least  $d$ .*

Our next two theorems consider graphs  $S_{w,x,y,z}$ . By Definition 3, this graph is four paths sharing an endvertex. In a small abuse of terminology, we will use *leaf* to mean only a vertex of degree 1 that is adjacent to the centre.

► **Proposition 13.** *Let  $r$  be a positive integer. Then the subclass of connected  $S_{1,1,1,r}$ -subgraph-free graphs that are not subcubic has bounded treedepth.*

**Proof.** Let  $G$  be a connected  $S_{1,1,1,r}$ -subgraph-free graph that is not subcubic so contains a vertex  $v_0$  with neighbours  $v_1, v_2, v_3, v_4$ . We will show that  $G$  has treedepth at most  $2r + 2$ . Suppose instead that the treedepth of  $G$  is at least  $2r + 3$ . The graph  $G \setminus \{v_0, v_1, v_2, v_3, v_4\}$  must have treedepth at least  $2r - 2$  (since adding a vertex to a graph cannot increase the

treedepth by more than one), and therefore, by Theorem 12, it must contain a path  $P$  of length  $2r - 2$ . Let  $Q$  be a shortest path in  $G$  between  $P$  and  $v_0$  (which must exist as  $G$  is connected). Let  $z$  be the vertex where  $P$  and  $Q$  meet. Let  $P'$  be the longest subpath of  $P$  of which  $z$  is an endvertex. As  $P'$  is at least half the length of  $P$ , and  $Q$  contains at least one edge, the path  $P' \cup Q$  contains at least  $r$  edges. Thus there exists in  $G$  a subgraph isomorphic to  $S_{1,1,1,r}$ ; the centre is  $v_0$ ,  $P' \cup Q$  is the tentacle of length  $r$ , and three of  $v_1, v_2, v_3, v_4$  are the three leaves (since at most one of these four vertices can belong to  $Q$  and none belong to  $P'$ ). This contradiction completes the proof. ◀

The assumption that the graphs are connected is needed: the class of all graphs that are each a disjoint union of a path and a  $K_{1,4}$  is not subcubic but has unbounded treedepth.

Consider now the class of all connected graphs that are each obtained from a  $K_{1,4}$  after subdividing exactly one of its edges zero or more times. This is a class of graphs that are connected, not subcubic and  $S_{1,1,q,r}$ -subgraph-free for all  $r \geq q \geq 2$  and again has unbounded treedepth. Thus, in the following analogue of Proposition 13, we need an additional property. A bridge is *proper* if neither incident vertex has degree 1. A graph is *quasi-bridgeless* if it contains no proper bridge.

► **Theorem 14.** *Let  $q$  and  $r$  be positive integers. Then the subclass of connected  $S_{1,1,q,r}$ -subgraph-free graphs that are not subcubic and are quasi-bridgeless has bounded treedepth.*

**Proof.** Let  $G$  be a connected quasi-bridgeless  $S_{1,1,q,r}$ -subgraph-free graph that is not subcubic so contains a vertex  $v_0$  with neighbours  $v_1, v_2, v_3, v_4$ . We will show that  $G$  has treedepth at most  $2(q+r+3)^2 + 6$ . Suppose instead that the treedepth of  $G$  is at least  $2(q+r+3)^2 + 7$ . The graph  $J = G \setminus \{v_0, v_1, v_2, v_3, v_4\}$  must have treedepth at least  $2(q+r+3)^2 + 2$  and therefore, by Theorem 12, it must contain a path  $P$  of length  $2(q+r+3)^2 + 2$ . Let  $z$  be the middle vertex of  $P$ . We prove the following claim.

▷ **Claim 15.** If there is a cycle  $C$  in  $G$  that contains  $z$  and also a vertex  $v \neq z$  that has two neighbours  $a$  and  $b$  not on  $C$ , then  $G$  contains a subgraph isomorphic to  $S_{1,1,q,r}$ .

**Proof.** A *big adorned cycle* is a graph that contains a cycle with at least  $q+r+1$  edges and two further vertices each joined by an edge to the same vertex on the cycle; the latter vertex is called the centre. If we find a big adorned cycle in  $G$  we are done as it contains a subgraph isomorphic to  $S_{1,1,q,r}$  (the centre is the same and it is obtained by deleting one or more edges of the cycle). Let  $C^+$  be the union of  $C$  and the vertices  $a$  and  $b$  and the edges  $va$  and  $vb$ . If  $|C| \geq q+r+1$ , then  $C^+$  is a big adorned cycle.

So suppose that  $|C| \leq q+r$ . Consider the intersections of  $P$  with  $V(C^+)$ . A maximal subpath of  $P$  whose internal vertices are not in  $V(C^+)$  is called an *interval* of  $P$ . Note that  $P$  has at most  $|C^+| + 1 \leq q+r+3$  intervals. If all intervals of  $P$  have length at most  $q+r-1$ , then  $P$  itself has length at most  $(q+r+3)(q+r-1) < (q+r+3)^2$ , a contradiction. Hence, at least one of the intervals has length at least  $q+r$ ; we call such an interval *long*. See Figure 3 for an illustration.

Suppose that there is a long interval  $L$  of which both endvertices  $x$  and  $y$  are in  $V(C^+)$ . Then there are shortest (possibly trivial) paths  $S$  and  $T$  on  $C^+$  from  $v$  to  $x$  and  $y$  respectively that are vertex disjoint except for  $v$ . As  $x$  and  $y$  are distinct, the union of  $L$ ,  $S$  and  $T$  is a cycle on at least  $q+r+1$  edges. As  $v$  has four neighbours in  $C^+$ , two of them do not belong to this cycle and considering these two neighbours (and the incident edges that join them to  $v$ ) with the cycle, we have a big adorned cycle centred at  $v$ .

Hence, there is no long interval with both endvertices in  $V(C^+)$  and we can assume any long interval has just one endvertex in  $V(C^+)$ . Suppose that there are two long intervals  $L_1$  and  $L_2$  whose endvertices in  $C^+$  are  $x$  and  $y$  respectively. If  $x = y$ , then  $L_1$  and  $L_2$  are

■ **Figure 3** The cycle  $C$  and path  $P$  from the proof of Claim 15 illustrating the three cases (a) there is a long interval with both endvertices in  $P$ , (b) there are two vertex-disjoint long intervals, and (c) there are two long intervals that meet in a single vertex.

the only intervals and their union is  $P$ . This implies that  $P$  only intersects  $C^+$  in  $x$  and so we must have  $x = z$ . Then there exists in  $G$  a subgraph isomorphic to an  $S_{1,1,q,r}$  with  $z$  as its centre, the neighbours of  $z$  on  $C$  as the leaves and subpaths of  $L_1$  and  $L_2$  as the tentacles. If  $x \neq y$ , then there are shortest paths  $S, T$  on  $C^+$  from  $v$  to  $x$  and  $y$  respectively that are vertex disjoint except for  $v$ . Then there exists in  $G$  a subgraph isomorphic to an  $S_{1,1,q,r}$  with  $v$  as its centre, the paths  $S$  and  $T$ , possibly extended by subpaths of  $L_1$  and  $L_2$ , as the tentacles and two neighbours of  $v$  in  $C^+$  that do not belong to  $S$  or  $T$  as the leaves.

Hence, there is only one long interval  $L$ . As the other intervals are short, they have total length at most  $|C^+| \cdot (q+r) < (q+r+3)^2$ . Hence,  $L$  has length at least  $(q+r+3)^2 + 2$ . As  $L$  contains more than half the vertices of  $P$ , the middle vertex of  $P$  is an internal vertex of  $L$  and so does not belong to  $C^+$ . This contradicts that  $z$  is the middle vertex of  $P$  and completes the proof of the claim.  $\triangleleft$

We now apply the claim. Note that  $v_0$  and  $z$  are distinct as  $z$  belongs to  $J$  but  $v_0$  does not. Since  $G$  is quasi-bridgeless and neither  $v_0$  nor  $z$  has degree 1, it follows from Menger's Theorem [16] that there exist two edge-disjoint paths  $S, T$  from  $v_0$  to  $z$ . If  $S$  and  $T$  are internally vertex-disjoint paths, then their union forms a cycle that contains  $z$ . We can assume that each of  $S$  and  $T$  contain only one neighbour of  $v_0$  else we can find shortcuts and redefine them. Hence,  $v_0$  has two neighbours not in the cycle and we can apply Claim 15. If  $S$  and  $T$  are not internally vertex-disjoint, let  $v'$  be a vertex of  $(V(S) \cap V(T)) \setminus \{z\}$  that is furthest from  $v_0$  on  $T$ . Consider the subpath  $T'$  of  $T$  from  $v'$  to  $z$  and the subpath  $S'$  of  $S$  from  $v'$  to  $z$ . Since  $T'$  does not intersect  $S$  by definition,  $S'$  and  $T'$  are internally vertex disjoint. Hence, their union forms a cycle that contains  $z$ . Moreover,  $v'$  has degree at least four, of which two neighbours are not on  $S'$  or  $T'$ . Hence, we can apply Claim 15.  $\blacktriangleleft$

#### 4 Graphs Excluding Subdivided Stars as a Subgraph: Algorithms

We present several applications of the structural results of the previous section.

We note that FEEDBACK VERTEX SET, INDEPENDENT FEEDBACK VERTEX SET and COLOURING can be solved componentwise. In a sense, so can CONNECTED VERTEX COVER and MATCHING CUT since disconnected graphs are no instances (except possibly for CONNECTED VERTEX COVER instances with edgeless components but these can be ignored).

► **Theorem 16.** *Let  $r$  be a positive integer. A problem  $\Pi$  can be solved in polynomial time on  $S_{1,1,1,r}$ -subgraph-free graphs if the following hold:*

- i)  $\Pi$  can be solved in polynomial time on subcubic graphs,
- ii)  $\Pi$  can be solved in polynomial time on graphs of bounded treedepth, and
- iii)  $\Pi$  can be solved componentwise on disconnected graphs.

**Proof.** Let  $C$  be a connected component of a  $S_{1,1,1,r}$ -subgraph-free graph  $G$ . If  $C$  is subcubic, then the problem can be solved in polynomial time. Otherwise, by Proposition 13,  $C$  has bounded treedepth and again the problem can be solved in polynomial time. Finally, the solutions for its connected components can be merged in polynomial time. ◀

► **Theorem 17.** *Let  $q$  and  $r$  be positive integers. A problem  $\Pi$  can be solved in polynomial time on  $S_{1,1,q,r}$ -subgraph-free graphs if the following hold:*

- i)  $\Pi$  can be solved in polynomial time on subcubic graphs,
- ii)  $\Pi$  can be solved in polynomial time on graphs of bounded treedepth, and
- iii)  $\Pi$  can be solved on graphs with proper bridges using a polynomial-time reduction to a family of instances on graphs that are either of bounded treedepth or subcubic.

**Proof.** Let  $H$  be one of the family of instances obtained from an instance  $G$  of  $\Pi$ . As  $H$  is either of bounded treedepth or subcubic, the problem can be solved in polynomial time. As we have a reduction, once solved on all the family of instances, we can solve  $\Pi$  on  $G$ . ◀

The simplest way to apply Theorem 17 is to show that if it is possible to solve  $\Pi$  on each of the family of components obtained by deleting the proper bridges of an instance, then these solutions combine to provide a solution for the initial instance (since the components are quasi-bridgeless and so certainly either of bounded treedepth or subcubic by Theorem 14.)

We now use Theorem 17 to prove Theorem 4. We do not apply Theorem 16 in this paper, as the results it would give us would just be special cases of those we have obtained using Theorem 17. Nevertheless, there are potential applications of Theorem 16 as there might be C13 problems that can be solved componentwise but cannot be solved by finding the reduction required by Theorem 17. We will see, in the proof below, that to solve INDEPENDENT FEEDBACK VERTEX SET via a reduction requires an intricate argument and the careful analysis of possible solutions on subcubic graphs that was provided by Theorem 10.

► **Theorem 4 (restated).** *Let  $q$  and  $r$  be positive integers. The following problems can be solved in polynomial time on  $S_{1,1,q,r}$ -subgraph-free graphs: FEEDBACK VERTEX SET, INDEPENDENT FEEDBACK VERTEX SET, CONNECTED VERTEX COVER, COLOURING and MATCHING CUT.*

**Proof.** To show that the result follows immediately from Theorem 17, we can show that the problems can be solved by deleting bridges and considering the resulting graph componentwise; this will be trivial for some problems, but for others we will need to find a different reduction.

For FEEDBACK VERTEX SET, as bridges do not belong to cycles, the problem is unchanged when they are deleted.

For INDEPENDENT FEEDBACK VERTEX SET such a straightforward approach is not possible as if we simply delete bridges and solve the problem on the components, the merged solution might not be independent (since we might choose both endvertices of a deleted bridge). We must argue a little more carefully. Let  $G$  be a  $S_{1,1,q,r}$ -subgraph-free graph and consider the treelike structure of  $G$  when thinking of its blocks – the connected components when the bridges are deleted. In fact, consider a subgraph of  $G$  that is a block plus all its incident bridges. Some of these subgraphs might be subcubic; let us call these *C-type*. For those that are not, we can assume, by Theorem 14, that there is a constant  $c$  such that their treewidth is at most  $c$ ; let us call these subgraphs *T-type* (note that this is a weaker claim than the Theorem 14 provides, as we could assume that the treedepth was bounded). If such a subgraph is both subcubic and has treewidth at most  $c$ , we will think of it as T-type. We can assume  $c \geq 3$  so a very nice cactus (with pendant edges) is T-type. If subgraphs of

the same type overlap (because they are joined by a bridge), we observe that their union is also of that type (since the union is also either, respectively, subcubic or of treewidth at most  $c$ ). So, merging overlapping subgraphs of the same type as much as possible we can consider  $G$  as being made up of C- and T-type subgraphs and bridges that each join a C-type subgraph to a T-type subgraph. As INDEPENDENT FEEDBACK VERTEX SET can be solved in polynomial time on graphs of bounded treewidth [21] as well as on subcubic graphs by Theorem 2, we can solve it on these subgraphs. Before we solve it on a C-type subgraph, we can delete pendant bridges (that link to a T-type subgraph in  $G$ ) so the incident vertex now has degree at most 2. As a very nice cactus is being considered as a T-type subgraph, we know, by Theorem 10, that the solutions we find for C-type subgraphs do not use the vertices incident with the bridges. Thus the solutions can be merged for a solution for  $G$  that is also independent.

For CONNECTED VERTEX COVER, let  $G$  be a  $S_{1,1,q,r}$ -subgraph-free graph. Clearly, we may assume  $G$  is connected, or it has no connected vertex cover. As for INDEPENDENT FEEDBACK VERTEX SET consider each subgraph  $J$  that is a block of  $G$  and also include the bridges of  $G$  incident with the block. Observe that  $J$  is quasi-bridgeless and  $S_{1,1,q,r}$ -subgraph-free. Noticing that a connected vertex cover  $W$  of  $G$  must contain both vertices incident with any proper bridge, we see that the restriction of  $W$  to the vertices of  $J$  is a connected vertex cover of  $J$  that includes vertices incident with bridges of  $G$ . And the construction of  $J$  means its connected vertex covers will include these vertices adjacent to bridges in  $G$ . Thus we see that have a reduction and can solve the problem on  $G$ .

For COLOURING if, for a graph  $G$ , we colour the components of the graph obtained by deleting bridges, then we can merge these into a colouring of  $G$ . If the two endvertices of a bridge have been coloured alike, then we just permute the colours on one of the components. This might create new clashes, but we move to the adjacent components and permute there. By the definition of bridge, we will never have to permute the colours on a component more than once so the process terminates.

For MATCHING CUT, if a graph contains a bridge, then we have immediately that it is a yes instance. ◀

## 5 Graphs Excluding Subdivided Stars as a Subgraph: Hardness

We prove Theorem 5.

► **Theorem 5 (restated).** FEEDBACK VERTEX SET and INDEPENDENT FEEDBACK VERTEX SET are NP-complete on the class of  $S_{2,2,2,2}$ -subgraph free graphs that have maximum degree 4.

**Proof.** Both problems belong to NP. We shall show a reduction from the following NP-complete problem 2P1N-3SAT [6].

2P1N-3SAT

*Instance:* A CNF formula  $\Phi$  where each clause contains at most three literals and each variable occurs twice positively and once negatively.

*Question:* Does  $\Phi$  have a satisfying assignment?

Given an instance of 2P1N-3SAT with on variables  $\{v_1, \dots, v_n\}$ , we construct a graph  $G$  as follows. For each variable  $v_i$ , we construct the gadget shown in Figure 4. The triangles  $xx'a$  and  $yy'b$  represent the positive occurrences of the variable, while the diamond  $zstc$  represents the negative occurrence. For each clause  $C_j$ , we construct a hexagon if the clause has size 3 and a square if the clause has size 2 (we may assume that no clause has size 1).

■ **Figure 4** The variable and clause gadgets (for clauses of size 3) from the proof of Theorem 5. The vertices  $x$ ,  $y$ , and  $z$  of a variable gadget will be identified with the (labeled) vertices of clause gadgets.

Alternate vertices of this clause gadget represent literals and are identified with a vertex  $x$ ,  $y$  or  $z$  of the corresponding variable gadget. Clearly this can be done in such a way each vertex  $x$  and  $y$  of each variable gadget is identified with exactly one vertex from a clause gadget that represents a positive literal, and each vertex  $z$  of each variable gadget is identified with exactly one vertex from a clause gadget that represents a negative literal. Note that  $G$  has maximum degree 4.

▷ **Claim 18.**  $G$  does not contain  $S_{2,2,2,2}$  as a subgraph.

*Proof.* Let us consider where we might find the centre vertex of a  $S_{2,2,2,2}$  in  $G$ . Clearly a vertex  $v$  cannot be the centre vertex if its 2-neighbourhood in  $G$  contains a cut of size 3 (that is, if there are 3 vertices each of distance at most 2 from  $v$  that form a cut in  $G$ ). The centre vertex cannot be the vertices  $p$  or  $q$  of a variable gadget, because the set  $\{a, b, c\}$  of the same gadget forms a cut of size 3 in the 2-neighbourhood of  $p$  and  $q$ . The centre vertex cannot be the vertices  $a$ ,  $b$ , or  $c$  of a variable gadget either, because  $\{x, p, q\}$ ,  $\{y, p, q\}$  and  $\{z, p, q\}$  respectively form cuts of size 3 in their 2-neighbourhoods. The vertices  $x$ ,  $y$ , and  $z$  cannot be the centre vertex as in their 2-neighbourhood is a cut of size 3 that contains their two neighbours in a clause gadget and, respectively,  $a$ ,  $b$  and  $c$ . The remaining vertices of  $G$  have degree less than 4. The claim is proved. ◁

Any feedback vertex set of a variable gadget has size at least 4, because it contains four disjoint cycles. So any feedback vertex set of  $G$  must contain at least  $4n$  vertices. It only remains to show that  $G$  has an (independent) feedback vertex set of size at most  $4n$  if and only if  $\Phi$  is satisfiable.

Assume that  $\Phi$  has a satisfying assignment. We construct a feedback vertex set  $F$  of  $G$ . If a variable is true, then the vertices  $x$ ,  $y$ ,  $p$ , and  $t$  of the variable gadget belong to  $F$ . If a variable is false, then instead  $z$ ,  $a$ ,  $b$ , and  $c$  belong to  $F$ . Thus  $F$  is an independent set (vertices of distinct variable gadgets are not adjacent) and its size is exactly  $4n$ .

▷ **Claim 19.**  $F$  is a feedback vertex set.

*Proof.* Notice that if a literal of a clause is satisfied, then, in the clause gadget, the corresponding vertex is in  $F$ . Thus, as clause is satisfied, each cycle contained in a single variable or clause gadget contains a vertex of  $F$ . Consider a cycle of  $G$  that is not contained within a single gadget. It must include a non-trivial path of some variable gadget where the

endvertices are two of  $\{x, y, z\}$ . If it includes  $x$  it must also include  $a$  and if it includes  $y$  it must also include  $b$ . But  $F$  contains one of  $\{x, a\}$  and one of  $\{y, b\}$  so such a cycle also intersects  $F$ . Thus  $F$  intersects all the cycles of  $G$ .  $\triangleleft$

Conversely, suppose that  $G$  has a feedback vertex set  $F$  of size at most  $4n$ . Again, each variable gadget contains at least four vertices of  $F$  and so contains exactly four vertices of  $F$ . Notice that  $F$  cannot contain either  $\{x, z\}$  or  $\{y, z\}$  as, in each case, there are three disjoint cycles of the gadget that would need to be covered by just two vertices.

Let us describe a satisfying assignment of  $\Phi$ . If, for a variable gadget, either  $x$  or  $y$  belongs to  $F$ , we let the variable be true. If  $z$  belongs to  $F$ , we let it be false. By the preceding argument, there is no possibility that we must set a variable to be both true and false. If none of  $\{x, y, z\}$  belong to  $F$ , we set the value of the variable arbitrarily. This is a satisfying assignment as every clause gadget (which is a cycle) must have at least one vertex in  $F$  and the corresponding variable is satisfied.  $\blacktriangleleft$

## 6 Proofs of the Classifications

We prove Theorems 6–9. Noting that the theorems contain some analogous results, and wishing to avoid repetition, we make a few general comments that apply to all proofs.

We state again that the five problems under consideration are C13 problems. Thus when  $H \in \mathcal{S}$ , each theorem follows from Theorem 1. When  $H = S_{1,1,q,r}$ , we apply Theorem 4. Thus, except for Theorem 8 on COLOURING, the following proofs need only cover the NP-complete cases.

**Proof of Theorem 6.** We note again that FEEDBACK VERTEX SET reduces to INDEPENDENT FEEDBACK VERTEX SET after subdividing each edge so here we consider only the former.

By Poljak’s construction [19], for every integer  $g \geq 3$ , FEEDBACK VERTEX SET is NP-complete for graphs of girth at least  $g$  (the girth of a graph is the length of its shortest cycle). Thus FEEDBACK VERTEX SET is NP-complete for  $H$ -subgraph-free graphs whenever  $H$  contains a cycle.

Suppose that  $H$  has  $m$  vertices and more than one vertex of degree at least 3. From any graph  $G$ , if we we subdivide each edge  $m$  times, we obtain a graph  $J$  that is  $H$ -subgraph free since the distance between any pair of vertices of degree more than 2 is at least  $m + 1$ . In finding a minimum size feedback vertex set of  $J$ , we may as well restrict ourselves to selecting vertices of  $G$ . This implies that FEEDBACK VERTEX SET is NP-complete for  $H$ -subgraph-free graphs.

The problem is NP-complete on planar graphs of maximum degree 4 [20] (so for  $K_{1,5}$ -subgraph-free graphs).

Theorem 5 completes the proof.  $\blacktriangleleft$

**Proof of Theorem 7.** For every integer  $g \geq 3$ , CONNECTED VERTEX COVER is NP-complete for graphs of girth at least  $g$  [17], so also for  $H$ -subgraph-free graphs whenever  $H$  contains a cycle. It is NP-complete on graphs of maximum degree 4 [8], so for  $K_{1,5}$ -subgraph-free graphs.  $\blacktriangleleft$

**Proof of Theorem 8.** For every integer  $g \geq 3$ , COLOURING is NP-complete for graphs of girth at least  $g$  [14], so also for  $H$ -subgraph-free graphs whenever  $H$  contains a cycle. In [9], it was shown that COLOURING is NP-complete on (planar) graphs of maximum degree 4, and so too for  $K_{1,5}$ -subgraph-free graphs. The other cases are all proved in [11]  $\blacktriangleleft$

**Proof of Theorem 9.** For every integer  $g \geq 3$ , MATCHING CUT is NP-complete for graphs of girth at least  $g$  [7], so also for  $H$ -subgraph-free graphs whenever  $H$  contains a cycle. It is NP-complete on graphs of maximum degree 4 [5], so for  $K_{1,5}$ -subgraph-free graphs. ◀

## 7 Conclusions

We made significant progress towards classifying the complexity of five well-known C13-problems on  $H$ -subgraph-free graphs, extending previously known results. In particular, we identified a gap in the literature, and provided a polynomial-time algorithm for INDEPENDENT FEEDBACK VERTEX SET for subcubic graphs.

If  $H$  is connected, then we narrowed the gap for these problems to the open case where  $H = S_{1,p,q,r}$ , so  $H$  is a subdivided star with one short leg and three arbitrarily long legs. To obtain a result for connected  $S_{1,p,q,r}$ -subgraph-free graphs similar to our previous results, we would need the graphs to be 3-edge-connected. Indeed, the statement is false without this assumption. Consider the class of all graphs that are each the union of a path and a  $K_{1,4}$  two of whose leaves are identified with distinct end-vertices of the path and whose other two leaves are made adjacent. This is a class of graphs that are bridgeless, not subcubic and  $S_{1,p,q,r}$ -subgraph-free and again has unbounded treedepth. It is not yet clear whether a suitably modified theorem statement would indeed hold. In addition, it is unclear whether this would yield a result that could be applied in the same way as Proposition 13 and Theorem 14 were above. We leave the case  $H = S_{1,p,q,r}$  as future research.

Finally, we also leave determining the complexity of CONNECTED VERTEX COVER and MATCHING CUT on  $S_{2,2,2,2}$ -subgraph-free graphs as an open problem.

## Abstract

Finding a *maximum* cardinality common independent set in two matroids (also known as MATROID INTERSECTION) is a classical combinatorial optimization problem, which generalizes several well-known problems, such as finding a maximum bipartite matching, a maximum colorful forest, and an arborescence in directed graphs. Enumerating all *maximal* common independent sets in two (or more) matroids is a classical enumeration problem. In this paper, we address an “intersection” of these problems: Given two matroids and a threshold  $\tau$ , the goal is to enumerate all maximal common independent sets in the matroids with cardinality at least  $\tau$ . We show that this problem can be solved in polynomial delay and polynomial space. We also discuss how to enumerate all maximal common independent sets of two matroids in non-increasing order of their cardinalities.

## 1 Introduction

The bipartite matching problem is arguably one of the most famous combinatorial optimization problems, which asks to find a maximum cardinality matching in a bipartite graph. By polynomial-time algorithms for the maximum flow problems, this problem can be solved in polynomial time. This problem is naturally generalized for non-bipartite graphs, which is also solvable in polynomial time [9].

Another natural generalization of the bipartite matching problem is MATROID INTERSECTION. In this problem, we are given two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$ , where  $\mathcal{I}_1 \subseteq 2^S$  and  $\mathcal{I}_2 \subseteq 2^S$  are the set of independent sets of  $M_1$  and  $M_2$ , respectively, and asked to find a maximum cardinality *common independent set* of  $M_1$  and  $M_2$ , that is, a maximum cardinality set in  $\mathcal{I}_1 \cap \mathcal{I}_2$ . When both  $M_1$  and  $M_2$  are partition matroids, this problem is equivalent to the bipartite  $b$ -matching problem, which is a generalization of the bipartite matching problem. A famous matroid intersection theorem [10] shows a min-max formula and also gives a polynomial-time algorithm for MATROID INTERSECTION [23].

These classical results give efficient algorithms to find a *single* best (bipartite) matching in a graph or common independent set in two matroids. This type of objective serves as the gold standard in many algorithmic and computational studies. However, such a single best solution may not be appropriate for real-world problems due to the complex nature of them [11].

One possible remedy to this issue is to enumerate *multiple* solutions instead of a single best one. From the point of view of enumeration, the problems of enumeration *maximal* and *maximum* (bipartite) matchings and its generalization are studied in the literature [6, 29–31]. Enumerating maximal independent sets in a graph is one of the best-studied problems in this area and is solvable in polynomial delay and polynomial space [6, 29]. Due to the correspondence between matchings in a graph and independent sets in its line graph, we can enumerate all maximal matchings in polynomial delay and polynomial space as well. Moreover, several algorithms that are specialized to (bipartite) matchings are known [30, 31].

Enumeration algorithms for matroids are also frequently studied in the literature [3, 12, 16, 17, 22]. Lawler et al. [22] showed that all maximal common independent sets in  $k$  matroids can be enumerated in polynomial delay when  $k$  is constant. For general  $k$ , this problem is highly related to DUALIZATION (or equivalently, minimal transversal enumeration, minimal hitting set enumeration), which can be solved in output quasi-polynomial time<sup>1</sup> [3]. Apart from common independent sets, enumeration problems related to matroids are studied [15, 17], such as minimal multiway cuts [17] and minimal Steiner forests in graphs [15].

In this paper, we consider an “intersection” of the above two worlds, optimization and enumeration, for MATROID INTERSECTION. More specifically, given two matroids  $M_1$  and  $M_2$  and an integer  $\tau$ , we consider the problem of enumerating all *maximal* common independent sets of  $M_1$  and  $M_2$  with cardinality at least  $\tau$ . We refer to this problem as LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION. By setting  $\tau = 0$ , we can enumerate all maximal common independent sets of  $M_1$  and  $M_2$ , and by setting  $\tau = \text{opt}$ , we can enumerate all maximum common independent sets of  $M_1$  and  $M_2$ , where  $\text{opt}$  is the optimal value of MATROID INTERSECTION. We would like to mention that simultaneously handling two constraints, maximality and cardinality, would make enumeration problems more difficult (see [18–20], for other enumeration problems). We show that LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION can be solved in polynomial delay and space. This extends the results of enumerating maximum common independent sets due to [12] and enumerating maximal common independent sets due to [22]. Our enumeration algorithm allows us to enumerate several combinatorial objects with maximality and cardinality constraints, such as bipartite  $b$ -matchings, colorful forests, and degree-constraint subdigraphs.

To prove this, we devise a reverse search algorithm [1] to enumerate all maximal common independent sets of  $M_1$  and  $M_2$ . This algorithm enumerates the solutions in a depth first manner. To completely enumerate all the solutions without duplicates, we carefully design its search strategy. We exploit a famous augmenting path theorem for MATROID INTERSECTION [23]. This enables us to design a “monotone” search strategy, yielding a polynomial-delay and polynomial-space enumeration algorithm. A similar idea is used in [19] for enumerating maximal matchings with cardinality at least  $\tau$  but we need several nontrivial lemmas to obtain our result.

Although our algorithm enumerates all maximal common independent sets of two matroids with cardinality at least  $\tau$ , solutions may not be generated in a sorted order, which is of great importance in database community [8, 26]. A *ranked enumeration algorithm* is an algorithm

---

<sup>1</sup> An enumeration algorithm runs in output quasi-polynomial time if it runs in time  $N^{(\log N)^c}$ , where  $c$  is a constant and  $N$  is the combined size of the input and output.

enumerates all the solutions in a non-increasing order of their cardinality (or more generally objective value). We discuss how to convert our enumeration algorithm to the one that enumerates in a ranked manner with a small overhead in the running time.

## 2 Preliminaries

Let  $S$  be a finite set. We denote the cardinality of  $S$  as  $n$ . For two sets  $X$  and  $Y$ , the symmetric difference of  $X$  and  $Y$  is defined as  $X \triangle Y := (X \setminus Y) \cup (Y \setminus X)$ . A pair  $M = (S, \mathcal{I})$  is called a *matroid* if  $M$  satisfies the following conditions:

- $\emptyset \in \mathcal{I}$ ,
- if  $I \in \mathcal{I}$  and  $J \subseteq I$ , then  $J \in \mathcal{I}$ , and
- if  $I, J \in \mathcal{I}$  and  $|I| < |J|$ , then  $I \cup \{e\} \in \mathcal{I}$  for some  $e \in J \setminus I$ .

A subset  $S'$  of  $S$  is called an *independent set* of  $M$  (or *independent* in  $M$ ) if  $S'$  is contained in  $\mathcal{I}$  and  $S'$  is called a *dependent set* of  $M$  (or *dependent* in  $M$ ) otherwise. An inclusion-wise maximal independent set of  $M$  is called a *base* of  $M$ , and an inclusion-wise minimal dependent set of  $M$  is called a *circuit* of  $M$ . For two distinct circuits  $C_1$  and  $C_2$  of  $M$  with  $C_1 \cap C_2 \neq \emptyset$  and  $e \in C_1 \cap C_2$ , there always exists a circuit  $C_3$  of  $M$  such that  $C_3 \subseteq (C_1 \cup C_2) \setminus \{e\}$ . This property is called the (*weak*) *circuit elimination axiom* [25]. For a matroid  $M = (S, \mathcal{I})$  and a subset  $X \subseteq S$ , the pair  $(X, \mathcal{J})$  is the *restriction* of  $M$  to  $X$ , where  $\mathcal{J} = \{Y \subseteq X : Y \in \mathcal{I}\}$ . We denote it as  $M \upharpoonright X$ . Similarly, the pair  $(S \setminus X, \mathcal{J}')$  is the *deletion* of  $X$  from  $M$ , where  $\mathcal{J}' = \{Y \setminus X : Y \in \mathcal{I}\}$ . We denote it as  $M \setminus X$ . Moreover, the pair  $(S \setminus X, \mathcal{J}'' )$  is the *contraction* of  $X$  from  $M$ , where  $\mathcal{J}'' = \{Y \subseteq S \setminus X : M \upharpoonright X \text{ has a base } B \text{ such that } Y \cup B \in \mathcal{I}\}$ . We denote it as  $M/X$ . Similarly, It is known that for a matroid  $M = (S, \mathcal{I})$  and  $X \subseteq S$ ,  $M/X$ ,  $M \upharpoonright X$ , and  $M \setminus X$  are all matroids [25]. For two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$  defined on the same set  $S$ , a subset  $T \subseteq S$  is a *common independent set* of  $M_1$  and  $M_2$  if  $T \in \mathcal{I}_1$  and  $T \in \mathcal{I}_2$ .

Let  $I_1$  and  $I_2$  be distinct independent sets of  $M$ . In our algorithm, we frequently consider a matroid obtained from  $M$  by restricting to  $I_1 \cup I_2$  and then contracting  $I_1 \cap I_2$ . This matroid is defined on  $I_1 \triangle I_2$  and has some properties shown below.

► **Proposition 1.** *Let  $I_1$  and  $I_2$  be independent sets of  $M$  and let  $M' = (M \upharpoonright (I_1 \cup I_2)) / (I_1 \cap I_2)$ .  $I \subseteq I_1 \triangle I_2$  is independent in  $M'$  if and only if  $I \cup (I_1 \cap I_2)$  is independent in  $M$ .*

**Proof.** Suppose that  $I$  is independent in  $M'$ . As  $M'$  is a contraction of  $I_1 \cap I_2$  from  $M \upharpoonright (I_1 \cup I_2)$ ,  $I \cup (I_1 \cap I_2)$  is independent in  $M \upharpoonright (I_1 \cup I_2)$  and hence in  $M$ . The converse direction is analogous. ◀

► **Proposition 2.** *Let  $I_1$  and  $I_2$  be maximal common independent sets of  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$ . Then, both  $I_1 \setminus I_2$  and  $I_2 \setminus I_1$  are maximal common independent sets of two matroids  $M'_1 = (M_1 \upharpoonright (I_1 \cup I_2)) / (I_1 \cap I_2)$  and  $M'_2 = (M_2 \upharpoonright (I_1 \cup I_2)) / (I_1 \cap I_2)$ .*

**Proof.** By symmetry, it suffices to show that  $I_1 \setminus I_2$  is a maximal common independent set of  $M'_1$  and  $M'_2$ . By Proposition 1,  $(I_1 \setminus I_2) \cup (I_1 \cap I_2) = I_1$  is independent in  $M_1$  if and only if  $I_1 \setminus I_2$  is independent in  $M'_1$ . Similarly,  $I_1$  is independent in  $M_2$  if and only if  $I_1 \setminus I_2$  is independent in  $M'_2$ . Thus,  $I_1 \setminus I_2$  is a common independent set of  $M'_1$  and  $M'_2$ . To see the maximality, suppose that there is  $e \in I_2 \setminus I_1$  such that  $(I_1 \setminus I_2) \cup \{e\}$  is a common independent set of  $M'_1$  and  $M'_2$ . By Proposition 1,  $I_1 \cup \{e\}$  is a common independent set of  $M_1$  and  $M_2$ , contradicting the maximality of  $I_1$ . ◀

We next define some notations for directed graphs. In this paper, we assume that directed graphs have no self-loops. For a directed graph  $D = (V, A)$ , we say that a vertex  $v$  is an *out-neighbor* of  $u$  ( $u$  is an *in-neighbor* of  $v$ ) in  $D$  if  $D$  has an arc  $(u, v)$ . The set of

out-neighbors of  $v$  is denoted by  $N^+(v)$ , and the set of in-neighbors of  $v$  is denoted by  $N^-(v)$ . A sequence  $(v_1, \dots, v_k)$  of distinct vertices is a *directed path* if there is an arc  $(v_i, v_{i+1})$  for  $1 \leq i < k$ . A directed path  $(v_1, \dots, v_k)$  in  $D$  is called a *directed path without shortcuts* if  $D$  has no arc from  $v_i$  to  $v_j$  for any  $1 \leq i < j \leq k$  with  $i + 1 < j$ .

We measure the time complexity of enumeration algorithms with delay complexity [13]. The *delay* of an enumeration algorithm is the maximum time elapsed between two consecutive outputs, including preprocessing and post-processing time. An enumeration algorithm is called a *polynomial-delay enumeration algorithm* if its delay is upper bounded by a polynomial of the size of an input. An enumeration algorithm is called a *linear incremental-time enumeration algorithm* if, for any  $i \leq N$ , an algorithm outputs at least  $i$  solutions in time  $O(i \cdot \text{poly}(n))$ , where  $N$  is the number of solutions [4].

Now, we formally define our problems. Throughout the paper, we assume that matroids are given as *independence oracles*, that is, for a matroid  $M = (S, \mathcal{I})$ , we can test whether a subset  $X \subseteq S$  belongs to  $\mathcal{I}$  by accessing an oracle for  $M$ . Moreover, we assume that independence oracles can be evaluated in  $Q$  time and in  $\hat{Q}$  space. We say that an enumeration algorithm runs in polynomial delay (resp. polynomial space) if the delay (resp. space) is upper bounded by a polynomial in  $n + Q$  (resp.  $n + \hat{Q}$ ).

► **Definition 3.** Given two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$  represented by independence oracles and an integer  $\tau$ , **LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION** asks to enumerate all maximal common independent sets of  $M_1$  and  $M_2$  with cardinality at least  $\tau$ .

► **Definition 4.** Given two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$  represented by independence oracles, **RANKED MAXIMAL COMMON INDEPENDENT SET ENUMERATION** asks to enumerate all maximal common independent sets of  $M_1$  and  $M_2$  in a non-increasing order with respect to cardinality.

## 2.1 Overview of an algorithm for finding a maximum common independent set

Our proposed algorithm for **LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION** leverages a well-known property used in an algorithm for finding a maximum common independent set in two matroids. In this paper, we refer to a particular algorithm given by Lawler [23].

Let  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$  be matroids. In Lawler's algorithm [23], we start with an arbitrary common independent set  $I$  of  $M_1$  and  $M_2$  (e.g.,  $I := \emptyset$ ), update  $I$  to a larger common independent set  $I'$  in some "greedy way". This update procedure is based on the following auxiliary directed graph  $D_{M_1, M_2}(I) = (S \cup \{s, t\}, A)$ .

Let  $I \subseteq S$  be a common independent set of  $M_1$  and  $M_2$ . The set  $A = A_1 \cup A_2 \cup A_3 \cup A_4$  of arcs in  $D_{M_1, M_2}(I)$  consists of the following four types of arcs. The first type of arcs is defined as

$$A_1 = \{(e, f) : e \in I, f \in S \setminus I, I \cup \{f\} \notin \mathcal{I}_1, (I \cup \{f\}) \setminus \{e\} \in \mathcal{I}_1\},$$

that is, an arc  $(e, f) \in A_1$  indicates that  $I \Delta \{e, f\}$  is independent in  $M_1$ . Symmetrically, the second type of arcs is defined as

$$A_2 = \{(f, e) : e \in I, f \in S \setminus I, I \cup \{f\} \notin \mathcal{I}_2, (I \cup \{f\}) \setminus \{e\} \in \mathcal{I}_2\},$$

that is, an arc  $(f, e)$  indicates that  $I \Delta \{e, f\}$  is independent in  $M_2$ . The third and fourth types of arcs are defined as

$$A_3 = \{(s, f) : f \in S \setminus I, I \cup \{f\} \in \mathcal{I}_1\}$$

$$A_4 = \{(f, t) : f \in S \setminus I, I \cup \{f\} \in \mathcal{I}_2\},$$

■ **Figure 1** This figure depicts an example of the auxiliary graph  $D_{M_1, M_2}(\{1, 2, 3\})$ . Let  $M_1$  and  $M_2$  be matroids with the same ground set  $\{1, \dots, 7\}$  that defined by five bases  $\{1, 2, 3, 4\}$ ,  $\{1, 2, 3, 5\}$ ,  $\{1, 3, 5, 6\}$ ,  $\{1, 2, 5, 6\}$ ,  $\{1, 2, 5, 7\}$  and six bases  $\{1, 2, 3, 6\}$ ,  $\{1, 2, 3, 7\}$ ,  $\{1, 2, 5, 6\}$ ,  $\{1, 3, 5, 6\}$ ,  $\{1, 2, 5, 7\}$ ,  $\{2, 3, 4, 6\}$ , respectively. In this example,  $D_{M_1, M_2}(\{1, 2, 3\})$  has a directed  $s$ - $t$  path  $P = (s, 5, 2, 6, t)$  without shortcuts and  $\{1, 3, 5, 6\}$  is a common independent set of  $M_1$  and  $M_2$ .

respectively. Arcs  $(s, f)$  and  $(f, t)$  indicate that  $I \cup \{f\}$  is independent in  $M_1$  and in  $M_2$ , respectively. We illustrate a concrete example of  $D_{M_1, M_2}(I)$  in Figure 1. In the following, we simply write  $D(I)$  to denote  $D_{M_1, M_2}(I)$ .

Let  $P$  be a directed path from  $s$  to  $t$  in  $D(I)$  without shortcuts. By the definition of  $D(I)$ ,  $|V(P) \cap I|$  is one less than  $|V(P) \setminus I|$ . Moreover, we can prove that  $I \Delta (V(P) \setminus \{s, t\})$  is a common independent set of  $M_1$  and  $M_2$  [23], meaning that the common independent set  $I \Delta (V(P) \setminus \{s, t\})$  of  $M_1$  and  $M_2$  is strictly larger than  $I$ . It is easy to see that  $D(I)$  has a directed path from  $s$  to  $t$  without shortcuts if and only if  $D(I)$  has a directed path from  $s$  to  $t$ . The following lemma summarizes the above discussion and also proves that the converse direction also holds.

► **Lemma 5** (Corollary 3.2 in [23]). *Let  $I$  be a common independent set in two matroids  $M_1$  and  $M_2$  and  $D(I)$  be the auxiliary directed graph. Then,  $I$  is a maximum common independent set in  $M_1$  and  $M_2$  if and only if  $D(I)$  has no directed  $s$ - $t$  path.*

Such a path  $P$  in  $D(I)$  is called an *augmenting path*. Lemma 5 is helpful to design an algorithm for enumerating all large maximal common independent sets in two matroids.

### 3 Enumeration of maximum common independent sets

We first consider the problem of enumerating all *maximum* common independent sets of two matroids, which is indeed a special case of LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION, where  $\tau = \text{opt}$ .<sup>2</sup> It is known that this problem can be solved in amortized polynomial time using the algorithm in [12]. However, an analysis of the delay of this algorithm is not explicitly given in their paper. In order to show an explicit delay bound, we give a polynomial-delay algorithm for MAXIMUM COMMON INDEPENDENT SET ENUMERATION, using a simple flashlight search technique (also known as binary partition and backtracking) [2, 27].

In this technique, an algorithm enumerates solutions by recursively picking one element  $e$  in  $S$  and partitioning the set of solutions into two subsets; One set consists of solutions including  $e$ , and the other set consists of solutions excluding  $e$ . After partitioning according to  $e$ , the algorithm repeats this partitioning process until all the elements in  $S$  are picked. It is easy to see that each solution set obtained in this process contains at most one solution. If a solution set contains a solution, then we just output it. To upper bound the running time of this recursive algorithm, we need to check whether a current solution set is empty

<sup>2</sup> By  $\text{opt}$ , we mean the maximum cardinality of a common independent set of  $M_1$  and  $M_2$ .

in the recursive partition process. We call such a subproblem an *extension problem*. To enumerate maximum common independent sets of matroids, we define MAXIMUM COMMON INDEPENDENT SET EXTENSION as follows.

► **Definition 6.** *Given two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$ , and two disjoint subsets  $In, Ex \subseteq S$ . MAXIMUM COMMON INDEPENDENT SET EXTENSION asks to find a maximum common independent set  $I$  of  $M_1$  and  $M_2$  that satisfies  $In \subseteq I$  and  $Ex \cap I = \emptyset$ .*

In what follows, we call conditions  $In \subseteq I$  and  $Ex \cap I = \emptyset$  the *inclusion condition* and *exclusion condition*, respectively. Note that for any matroid  $M$ ,  $M \setminus Ex$  and  $M / In$  are matroids. The following proposition is straightforward but essential for solving the extension problem.

► **Proposition 7.** *Let  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$  be two matroids, and  $In$  and  $Ex$  be disjoint subsets of  $S$ . Suppose that  $In$  is a common independent set of  $M_1$  and  $M_2$ . Let  $M'_1 = (M_1 / In) \setminus Ex$  and  $M'_2 = (M_2 / In) \setminus Ex$ . Then, there is a maximum common independent set  $I$  of  $M_1$  and  $M_2$  that satisfies  $In \subseteq I$  and  $Ex \cap I = \emptyset$  if and only if there is a common independent set  $I'$  of  $M'_1$  and  $M'_2$  with the cardinality  $|I| - |In|$ .*

By the above proposition, we can solve MAXIMUM COMMON INDEPENDENT SET EXTENSION in polynomial time by using a polynomial-time algorithm for finding a maximum common independent set of two matroids [28]. Note that by using oracles for  $M_1$  and  $M_2$ , we can check whether a subset of  $S$  is independent in  $M'_1$  and in  $M'_2$  in time  $O(n + Q)$  and space  $O(n + \hat{Q})$ .

Now, we design a simple flashlight search algorithm, which is sketched as follows. Let  $\mathcal{S}(In, Ex)$  be the set of maximum common independent sets of  $M_1$  and  $M_2$  that satisfy both the inclusion and exclusion conditions. Clearly, the set of all maximum common independent sets of  $M_1$  and  $M_2$  corresponds to  $\mathcal{S}(\emptyset, \emptyset)$ . By solving the extension problem, we can determine whether  $\mathcal{S}(In, Ex)$  is empty or not in polynomial time. Moreover, for an element  $e \in S \setminus (In \cup Ex)$ ,  $\{\mathcal{S}(In \cup \{e\}, Ex), \mathcal{S}(In, Ex \cup \{e\})\}$  is a partition of  $\mathcal{S}(In, Ex)$ . Thus, we can enumerate all maximum common independent sets in  $\mathcal{S}(In, Ex)$  by recursively enumerating  $\mathcal{S}(In \cup \{e\}, Ex)$  and  $\mathcal{S}(In, Ex \cup \{e\})$ . We give a pseudo-code of our algorithm in Algorithm 1. Finally, we consider the delay of this algorithm. Let  $\mathcal{T}$  be a recursion tree defined by the execution of Algorithm 1. As we output a maximum common independent set of  $M_1$  and  $M_2$  at each leaf node in  $\mathcal{T}$ , the delay of the algorithm is upper bounded by the “distance” of two leaf nodes times the running time required to processing each node in  $\mathcal{T}$ . The distance between the root and a leaf node of  $\mathcal{T}$  is at most  $n$  and thus, the distance between two leaf nodes in  $\mathcal{T}$  is upper bounded by linear in  $n$ . The time complexity of each node in  $\mathcal{T}$  is bounded by  $O(\text{poly}(n))$ . Hence, the delay of Algorithm 1 is polynomial in  $n$ . By using an  $O(\text{opt}^{3/2}nQ)$ -time and  $O(n^2 + \hat{Q})$ -space algorithm for finding a maximum common independent set of two matroids [7], the following theorem follows.

► **Theorem 8.** *We can enumerate all maximum common independent sets of  $M_1$  and  $M_2$  in  $O(\text{opt}^{3/2}n^2Q)$  delay and  $O(n^2 + \hat{Q})$  space.*

#### 4 Enumeration of large maximal common independent sets

We propose a polynomial-delay and polynomial-space algorithm for enumerating maximal common independent sets of two matroids  $M_1$  and  $M_2$  with the cardinality at least  $\tau$ , namely LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION. From Theorem 8, if  $\tau = \text{opt}$ , we can enumerate all maximum common independent sets of  $M_1$  and  $M_2$  in polynomial delay and polynomial space. Thus, in this section, we assume that  $\tau < \text{opt}$ .

■ **Algorithm 1** A polynomial-delay and polynomial-space algorithm for enumerating all maximum common independent sets in two matroids.

   |   both  $In \subseteq I'$  and  $(Ex \cup \{e\}) \cap I' = \emptyset$  then
9   |   | RecMaximum( $M_1, M_2, In, Ex \cup \{e\}$ )

```

---

Our proposed algorithm is based on *reverse search* [1], which is one of the frequently used techniques to design efficient enumeration algorithms [14, 19, 21, 24, 29]. One may expect that a flashlight search algorithm similar to that described in the previous section could be designed for LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION, because finding a *maximal* solution is usually easier than finding a *maximum* solution. However, this intuitive phenomenon does not hold for extension problems. In particular, the problem of finding a maximal matching in a bipartite graph that satisfies an exclusion condition is NP-complete [5, 19]. As the set of all matchings in a bipartite graph can be described as the set of common independent sets of matroids, the extension problem for LARGE MAXIMAL COMMON INDEPENDENT SET ENUMERATION is NP-complete.

Before delving into our algorithm, we briefly sketch an overview of the reverse search technique. Let  $\mathcal{S}$  be the set of solutions. In the reverse search technique, we define a set of “special solutions”  $\mathcal{R} \subseteq \mathcal{S}$  and a rooted forest (i.e., a set of rooted trees) on  $\mathcal{S}$  whose roots belong to  $\mathcal{R}$ . Suppose that we can enumerate  $\mathcal{R}$  efficiently. Then, we can enumerate all solutions in  $\mathcal{S}$  by solely traversing the rooted forest from each root solution in  $\mathcal{R}$ . To this end, for a non-root solution  $X$  in  $\mathcal{S} \setminus \mathcal{R}$ , it suffices to define its parent  $\text{par}(X)$  in an appropriate manner. More specifically, to define a rooted forest on  $\mathcal{S}$ , this parent-child relation must have no cycles. Moreover, to traverse this rooted forest, we need to efficiently enumerate the children of each internal node in the rooted forest.

Now, we turn back to our problem. In the following, we may simply refer to maximal common independent sets of  $M_1$  and  $M_2$  with cardinality at least  $\tau$  as *solutions*. We define the set of maximum common independent sets of  $M_1$  and  $M_2$  as the root solutions  $\mathcal{R}$ . We can efficiently enumerate  $\mathcal{R}$  by Theorem 8. To define the parent of a solution not in  $\mathcal{R}$ , fix an arbitrary maximum common independent set  $R$  of  $M_1$  and  $M_2$ . Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$ . We consider two matroids  $M_1(R, I) := (M_1 \mid (R \cup I)) / (R \cap I)$  and  $M_2(R, I) := (M_2 \mid (R \cup I)) / (R \cap I)$  as well as the auxiliary directed graph  $D(R, I) := D_{M_1(R, I), M_2(R, I)}(I \setminus R)$ . Let us note that the vertex set of  $D(R, I)$  is  $(R \triangle I) \cup \{s, t\}$ . Since  $R$  and  $I$  are independent in both  $M_1$  and  $M_2$ , by Proposition 1,  $R \setminus I$  and  $I \setminus R$  are independent in  $M_1(R, I)$  and  $M_2(R, I)$  as well. Moreover, as  $|R| > |I|$ , we have  $|R \setminus I| > |I \setminus R|$ . Thus, by Lemma 5,  $D(R, I)$  has a directed  $s$ - $t$  path. Let  $P$  be a directed  $s$ - $t$  path  $(v_1 = s, v_2, \dots, v_{2k+1} = t)$  in  $D(R, I)$  without shortcuts. We first show that  $I \triangle \{v_2, v_3\}$  is a common independent set of  $M_1$  and  $M_2$ .

► **Lemma 9.** *Let  $P = (v_1 = s, \dots, v_{2k+1} = t)$  be a directed  $s$ - $t$  path without shortcuts in  $D(R, I)$ . Then  $P$  has at least four vertices and  $I \triangle \{v_2, v_3\}$  is also a common independent set of  $M_1$  and  $M_2$ .*

**Proof.** We first show that  $P$  has at least four vertices. As  $s$  is not adjacent to  $t$  in  $D(R, I)$ ,  $P$  has at least three vertices. If  $P = (v_1 = s, v_2, v_3 = t)$ , then  $(I \setminus R) \cup \{v_2\}$  is a common independent set of  $M_1(R, I)$  and  $M_2(R, I)$ . However, by Proposition 2,  $I \setminus R$  is a maximal common independent set of  $M_1(R, I)$  and  $M_2(R, I)$ , a contradiction.

We next show that  $I \triangle \{v_2, v_3\}$  is also a common independent set of  $M_1$  and  $M_2$ . By the definition of  $D(R, I)$ ,  $v_2 \in R \setminus I$  and  $v_3 \in I \setminus R$ . This implies that  $v_2 \notin I$  and  $v_3 \in I$ . Moreover, since  $D(R, I)$  has arcs  $(s, v_2)$  and  $(v_2, v_3)$ ,  $(I \setminus R) \cup \{v_2\}$  is independent in  $M_1(R, I)$  and  $(I \setminus R) \triangle \{v_2, v_3\}$  is independent in  $M_2(R, I)$ . By Proposition 1,  $I \cup \{v_2\}$  and  $I \triangle \{v_2, v_3\}$  are independent in  $M_1$  and in  $M_2$ , respectively. As  $I \triangle \{v_2, v_3\} = (I \setminus \{v_3\}) \cup \{v_2\}$  is a subset of  $I \cup \{v_2\}$ ,  $I \triangle \{v_2, v_3\}$  is a common independent set of  $M_1$  and  $M_2$ . ◀

We define the parent  $\text{par}(I)$  of  $I$  as follows. To ensure the consistency of defining its parent, we choose a path  $P$  from  $s$  to  $t$  without shortcuts in  $D(R, I)$  in a certain way, and hence the path  $P$  is determined solely by the pair  $R$  and  $I$ . We define the parent of  $I$  (under  $R$ ) as  $\mu(I \triangle \{v_2, v_3\})$ , where  $\mu(X)$  is an arbitrary maximal common independent set of  $M_1$  and  $M_2$  containing  $X$  for a common independent set  $X$  of  $M_1$  and  $M_2$ . Similarly, we choose a maximal common independent set  $\mu(X)$  in a certain way, and hence  $\mu(X)$  is determined solely by  $X$ . Therefore, by Lemmas 5 and 9, for a maximal common independent set  $I$  of  $M_1$  and  $M_2$  with  $|I| < |R|$ , the parent of  $I$  (under  $R$ ) is uniquely determined and we denote it as  $\text{par}(I)$ . In the following, we claim that this parent-child relation defines a rooted forest on the solutions whose roots belong to  $\mathcal{R}$ . A key to this is a certain “monotonicity”, which will be proven in Lemma 11: For any solution  $I$  with  $|I| < |R|$ , it holds that  $|R \triangle I| > |R \triangle \text{par}(I)|$ . Given these, from any solution  $I$  with  $|I| < |R|$ , we can “reach” a maximum common independent set of  $M_1$  and  $M_2$  (not necessarily to be  $R$ ) by iteratively taking its parent at most  $n$  times as  $|R \triangle I| \leq n$ . To show this monotonicity, we give the following technical lemma, whose proof is deferred to the end of this section.

► **Lemma 10.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$  and  $e \in I$  and  $f \in S \setminus I$ . If  $D(I)$  has two arcs  $(s, f)$  and  $(f, e)$ , then  $I \triangle \{e, f\}$  is a common independent set of  $M_1$  and  $M_2$ . Moreover,  $|\mu(I \triangle \{e, f\})| \leq |I| + 1$ .*

Now, we prove the aforementioned “monotonicity”.

► **Lemma 11.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$ . Then, the following three properties on  $\text{par}(I)$  are satisfied.*

- $|I| \leq |\text{par}(I)|$ ,
- $|R \triangle I| > |R \triangle \text{par}(I)|$ , and
- $|I \triangle \text{par}(I)| \leq 3$ .

**Proof.** As  $|R \setminus I| > |I \setminus R|$ , by Lemma 5, there is a directed path  $P = (v_1, \dots, v_{2k+1})$  from  $s = v_1$  to  $t = v_{2k+1}$  without shortcuts in  $D(R, I)$ . By Lemma 9,  $I' = I \triangle \{v_2, v_3\}$  is a common independent set of  $M_1$  and  $M_2$ . The first property  $|I| \leq |\text{par}(I)|$  follows from

$$|\text{par}(I)| = |\mu(I \triangle \{v_2, v_3\})| \geq |I \triangle \{v_2, v_3\}| = |I|,$$

as  $v_2 \notin I$  and  $v_3 \in I$ . Since  $v_2 \in R \setminus I$  and  $v_3 \in I \setminus R$ , we have  $|R \triangle I'| = |R \triangle I| - 2$ . If  $D(I)$  has arcs  $(s, v_2)$  and  $(v_2, v_3)$ , by Lemma 10,  $|\mu(I')| \leq |I| + 1$ , which yields that

$$|R \triangle \text{par}(I)| = |R \triangle \mu(I')| \leq |R \triangle I'| + 1 = |R \triangle I| - 1,$$

where the inequality  $|R \triangle \mu(I')| \leq |R \triangle I'| + 1$  follows from  $|\mu(I')| \leq |I| + 1 = |I'| + 1$ , meaning that  $\mu(I') \setminus I'$  contains at most one element. This also shows that

$$|I \triangle \text{par}(I)| = |I \triangle \mu(I')| \leq |I \triangle I'| + 1 \leq |I \triangle (I \triangle \{v_2, v_3\})| + 1 = 3.$$

Thus, it suffices to show that  $D(I)$  has these arcs  $(v_2, v_3)$  and  $(s, v_2)$ . Let  $M_1(R, I) = (M_1 \mid (R \cup I)) / (R \cap I)$  and  $M_2(R, I) = (M_2 \mid (R \cup I)) / (R \cap I)$ . As  $D(R, I)$  has the arc  $(v_2, v_3)$ ,  $(I \setminus R) \cup \{v_2\}$  and  $((I \setminus R) \cup \{v_2\}) \setminus \{v_3\}$  are dependent and independent in  $M_2(R, I)$ , respectively. By Proposition 1,

$$\begin{aligned} ((I \setminus R) \cup \{v_2\}) \cup (R \cap I) &= I \cup \{v_2\} \text{ and} \\ (((I \setminus R) \cup \{v_2\}) \setminus \{v_3\}) \cup (R \cap I) &= (I \cup \{v_2\}) \setminus \{v_3\} \end{aligned}$$

are dependent and independent in  $M_2$ , respectively. This implies that  $D(I)$  has an arc  $(v_2, v_3)$ . A similar argument for  $(s, v_2)$  and  $M_1(R, I)$  proves that  $D(I)$  has arc  $(s, v_2)$ , completing the proof of this lemma.  $\blacktriangleleft$

Now, we are ready to describe our algorithm, which is also shown in Algorithm 2. We assume that the size of a maximum common independent set of  $M_1$  and  $M_2$  is at least  $\tau$  as otherwise we do nothing. We first enumerate the set  $\mathcal{R}$  all maximum common independent sets of  $M_1$  and  $M_2$ . This can be done in polynomial delay and polynomial space using the algorithm in Theorem 8. We choose an arbitrary  $R \in \mathcal{R}$  and for each  $I \in \mathcal{R}$ , we enumerate all solutions that belong to the component containing  $I$  in the rooted forest defined by the parent-child relation. This is done by calling  $\text{RecMaximal}(M_1, M_2, I, R, \tau)$ . The procedure  $\text{RecMaximal}(M_1, M_2, I, R, \tau)$  recursively generates solutions  $I'$  with  $I = \text{par}(I')$ . We would like to emphasize that the algorithm only generates solutions  $I'$  with  $|I'| \geq \tau$ .

We first claim that all the solutions are generated by this algorithm. To see this, consider an arbitrary solution  $I$ . Define a value  $v(I)$  as

$$v(I) = \begin{cases} 0 & \text{if } |I| = |R| \\ |I \triangle R| & \text{otherwise.} \end{cases}$$

We prove the claim by induction on  $v(I)$ . Suppose that  $v(I) = 0$ . In this case,  $I$  is a maximum common independent set of  $M_1$  and  $M_2$ , as  $|I \triangle R| = 0$  if and only if  $I = R$ . Then,  $I$  is obviously generated as we call  $\text{RecMaximal}(M_1, M_2, I, R, \tau)$  for all  $I \in \mathcal{R}$ . Suppose that  $v(I) > 0$ . Then,  $I$  is a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$ . We assume that all the solutions  $I'$  with  $v(I') = |R \triangle I'| < |R \triangle I|$  is generated by the algorithm. By Lemma 11, we have  $|\text{par}(I)| \geq |I| \geq \tau$  and  $|R \triangle \text{par}(I)| < |R \triangle I|$ , which implies that  $\text{par}(I)$  is generated by the algorithm. By the definition of parent, we have  $\text{par}(I) = \mu(I \triangle \{u, v\})$  and  $|\text{par}(I) \triangle I| \geq 2$  for some  $u, v \in S$ . Moreover, by Lemma 11,  $|I \triangle \text{par}(I)| \leq 3$ , the child  $I$  of  $\text{par}(I)$  is computed at line 7. Thus,  $I$  is generated by the algorithm as well.

We next claim that all the solutions are generated without duplication. Since we only call  $\text{RecMaximal}(M_1, M_2, I', R, \tau)$  for  $I = \text{par}(I')$ , it holds that  $v(I) < v(I')$ . As  $v(I) \leq n$  for every solution  $I$ , by the uniqueness of the parent of non-maximum solutions, the algorithm generates each solution exactly once. This concludes that the algorithm correctly enumerates all maximal common independent sets of  $M_1$  and  $M_2$  of cardinality at least  $\tau$ .

Finally, we discuss the running time of the algorithm. We first enumerate all maximum common independent sets of  $M_1$  and  $M_2$ . This can be done in time  $O(n^{7/2}Q)$  delay. For each solution  $I$ , we compute  $\text{par}(I)$  as follows. We construct the graph  $D(R, I)$  that has  $n + 2$  nodes and  $O(n^2)$  arcs. This can be done by using  $O(n^2Q)$  queries to the oracles for

■ **Algorithm 2** A polynomial-delay and polynomial-space algorithm for enumerating all maximal common independent sets of  $M_1$  and  $M_2$  with the cardinality at least  $\tau$ .

---

```

1 Procedure Maximal( $M_1 = (S, \mathcal{I}_1), M_2 = (S, \mathcal{I}_2), \tau$ )
2   | Choose arbitrary  $R \in \mathcal{R}$ 
3   | foreach  $I \in \mathcal{R}$  do RecMaximal( $M_1, M_2, I, R, \tau$ )           // Use Algorithm 1.
4 Procedure RecMaximal( $M_1, M_2, I, R, \tau$ )
5   | Output  $I$ 
6   | foreach  $X \in \binom{S}{3} \cup \binom{S}{2}$  do
7   |   |  $I' \leftarrow I \Delta X$ 
8   |   | if  $I'$  is a maximal common independent set of  $M_1$  and  $M_2$  such that
9   |   |   |  $\tau \leq |I'| < |R|$  and  $I = \text{par}(I')$  then
9   |   |   |   | RecMaximal( $M_1, M_2, I', R, \tau$ )

```

---

$M_1$  and  $M_2$ . To find the path  $P$  from  $s$  to  $t$  without shortcuts, we just compute a shortest path from  $s$  to  $t$ , which can be done in  $O(n^2)$  time. Thus, we can compute  $I \Delta \{v_2, v_3\}$  in  $O(n^2Q)$  time as well. From  $I \Delta \{v_2, v_3\}$ ,  $\mu(I \Delta \{v_2, v_3\})$  can be computed in  $O(nQ)$  time. Thus, we can compute  $\text{par}(I)$  from  $I$  in time  $O(n^2Q)$ .

For each call  $\text{RecMaximal}(M_1, M_2, I, R, \tau)$ , we output exactly one solution. Moreover, the running time of computing all children of  $I$  is  $O(n^5Q)$ . This can be seen as there are  $O(n^3)$  candidates  $I'$  of children and we can check in  $O(n^2Q)$  time whether a candidate  $I'$  is in fact a child of  $I$ . Thus the delay of the algorithm is upper bounded by the time elapsed between two consecutive calls. As the depth of the rooted forest defined by recursive calls is at most  $n$ , this can be upper bounded by  $O(n^6Q)$ . As for the space complexity, by Theorem 8, we can enumerate all maximum common independent sets of  $M_1$  and  $M_2$  in  $O(n^2 + \hat{Q})$  space. In  $\text{RecMaximal}$ , we need to store local variables  $I$  and  $X$  in each recursive call, which can be done in space  $O(n)$ . As the depth of the rooted forest is at most  $n$ , the space usage for local variables is  $O(n^2)$  in total. For each candidate  $I'$ , we can check in  $O(n^2 + \hat{Q})$  whether  $I'$  is a maximal common independent set of  $M_1$  and  $M_2$  and whether  $I = \text{par}(I')$ . Overall, we have the following theorem.

► **Theorem 12.** *There is an  $O(n^6Q)$ -delay and  $O(n^2 + \hat{Q})$ -space algorithm for enumerating maximal common independent sets in two matroids with the cardinality at least  $\tau$ .*

#### 4.1 Proof of Lemma 10

To complete our proof of Theorem 12, we need to show the correctness of Lemma 10. To this end, we focus on  $D(I)$ . Since  $I$  is a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$ ,  $D(I)$  has a directed  $s$ - $t$  path  $P = (v_1 = s, v_2 = f, v_3 = e, \dots, v_{2k+1} = t)$ . By the definition of  $D(I)$ ,  $I \Delta \{e, f\}$  is a common independent set of  $M_1$  and  $M_2$ . We first show that  $I \Delta \{e, f\}$  becomes dependent in  $M_1$  when we add an element  $f'$  in  $N_{D(I)}^+(e)$ .

► **Lemma 13.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$ ,  $e$  be an element in  $I$ , and  $f_1$  and  $f_2$  be distinct two elements in  $N_{D(I)}^+(e)$ . Then,  $I' := (I \setminus \{e\}) \cup \{f_1, f_2\}$  is dependent in  $M_1$ .*

**Proof.** Since  $D(I)$  has arcs  $(e, f_1)$  and  $(e, f_2)$ , both  $(I \setminus \{e\}) \cup \{f_1\}$  and  $(I \setminus \{e\}) \cup \{f_2\}$  are independent in  $M_1$ , and  $I \cup \{f_1\}$  and  $I \cup \{f_2\}$  are dependent in  $M_1$ . Thus,  $M_1$  has two circuits  $C_1$  and  $C_2$  that contain  $\{e, f_1\}$  and  $\{e, f_2\}$ , respectively. By the circuit elimination axiom, there is a circuit  $C_3 \subseteq (C_1 \cup C_2) \setminus \{e\}$ . Since  $I'$  contains  $(C_1 \cup C_2) \setminus \{e\}$ , it also contains  $C_3$  and hence is dependent in  $M_1$ . ◀

► **Lemma 14.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$ ,  $e$  be an element in  $I$ , and  $f_1$  and  $f_2$  be distinct two elements in  $N_{D(I)}^-(e)$ . Then,  $I' := (I \setminus \{e\}) \cup \{f_1, f_2\}$  is dependent in  $M_2$*

**Proof.** Since  $D(I)$  has arcs  $(f_1, e)$  and  $(f_2, e)$ , both  $I \Delta \{e, f_1\}$  and  $I \Delta \{e, f_2\}$  are independent in  $M_2$  and  $I \cup \{f_1\}$  and  $I \cup \{f_2\}$  are dependent in  $M_2$ . Thus,  $M_2$  has two circuits  $C_1$  and  $C_2$  that contain  $\{e, f_1\}$  and  $\{e, f_2\}$ , respectively. By the circuit elimination axiom, there is a circuit  $C_3 \subseteq (C_1 \cup C_2) \setminus \{e\}$ . Since  $I'$  contains  $(C_1 \cup C_2) \setminus \{e\}$ , it also contains  $C_3$  and hence is dependent in  $M_2$ . ◀

We show that  $\mu(I \Delta \{e, f\})$  does not contain any element in  $S \setminus (I \cup N_{D(I)}^+(e) \cup N_{D(I)}^-(e))$ .

► **Lemma 15.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$ ,  $e$  be an element in  $I$ , and  $f$  be an element in  $S \setminus (I \cup N_{D(I)}^+(e) \cup N_{D(I)}^-(e))$ . Then,  $I \Delta \{e, f\}$  is dependent in at least one of  $M_1$  or in  $M_2$ .*

**Proof.** From the maximality of  $I$ ,  $I \cup \{f\}$  is dependent in at least one of  $M_1$  or  $M_2$ . Suppose that  $I \cup \{f\}$  is dependent on  $M_2$ . Then,  $I \cup \{f\}$  contains at least one circuit  $C$  of  $M_2$  containing  $f$ . We show that  $I \cup \{f\}$  contains only one circuit of  $M_2$ . If  $I \cup \{f\}$  contains another circuit  $C'$  with  $f \in C'$ , by the circuit elimination axiom,  $(C \cup C') \setminus \{f\}$  contains a circuit, which contradicts the fact that  $I$  is independent in  $M_2$ . Thus,  $M_2$  has the unique circuit  $C$ , which is contained in  $I \cup \{f\}$ . Observe that  $N_{D(I)}^+(f) \cap I = C \setminus \{f\}$ , since  $(I \cup \{f\}) \setminus \{e\}$  is independent in  $M_2$  for  $e' \in C$  due to the minimality of  $C$ . As  $f \in S \setminus (I \cup N_{D(I)}^+(e) \cup N_{D(I)}^-(e))$ , we have  $e \notin C$ . Hence,  $(I \setminus \{e\}) \cup \{f\}$  contains  $C$ , that is,  $(I \setminus \{e\}) \cup \{f\}$  is dependent in  $M_2$ . When  $I \cup \{f\}$  is dependent in  $M_1$ ,  $(I \setminus \{e\}) \cup \{f\}$  is also dependent in  $M_1$  from a similar discussion. ◀

Now we are ready to prove Lemma 10.

► **Lemma 10.** *Let  $I$  be a maximal common independent set of  $M_1$  and  $M_2$  with  $|I| < |R|$  and  $e \in I$  and  $f \in S \setminus I$ . If  $D(I)$  has two arcs  $(s, f)$  and  $(f, e)$ , then  $I \Delta \{e, f\}$  is a common independent set of  $M_1$  and  $M_2$ . Moreover,  $|\mu(I \Delta \{e, f\})| \leq |I| + 1$ .*

**Proof.** By the definition of  $D(I)$ ,  $I \Delta \{e, f\}$  is a common independent set since  $D(I)$  has two arcs  $(s, f)$  and  $(f, e)$ . Thus,  $\mu(I \Delta \{e, f\})$  is a maximal common independent set of  $M_1$  and  $M_2$ . We show that  $|\mu(I \Delta \{e, f\})| \leq |I| + 1$ . Since  $f$  is contained in  $N_{D(I)}^-(e)$ ,  $\mu(I \Delta \{e, f\})$  does not contain elements in  $N_{D(I)}^-(e)$  except for  $f$  by Lemma 14. Moreover, by Lemma 13,  $\mu(I \Delta \{e, f\})$  contains at most one element in  $N_{D(I)}^+(e)$ . Finally,  $\mu(I \Delta \{e, f\})$  does not contain any element in  $S \setminus (I \cup N_{D(I)}^+(e) \cup N_{D(I)}^-(e))$  by Lemma 15. Therefore,  $\mu(I \Delta \{e, f\}) \setminus (I \Delta \{e, f\})$  contains at most one element. Since  $|I \Delta \{e, f\}| = |I|$ ,  $|\mu(I \Delta \{e, f\})| \leq |I| + 1$ . ◀

## 5 Ranked enumeration

In this section, we give a ranked enumeration algorithm for enumerating maximal common independent sets of two matroids  $M_1 = (S, \mathcal{I}_1)$  and  $M_2 = (S, \mathcal{I}_2)$ . Recall that an enumeration algorithm is called a *ranked enumeration algorithm* if the algorithm enumerates solutions in a non-increasing order of their cardinality. We do this in a slightly general manner.

In what follows, we consider the following abstract problem. Let  $S$  be a finite set and  $\mathcal{F}$  be a subset of  $2^S$ . Let  $\mathcal{A}(\tau)$  be an algorithm that outputs all sets in  $\mathcal{F}$  with the cardinality at least  $\tau$ . We denote the maximum delay complexity and the space complexity from  $\mathcal{A}(\tau)$  to  $\mathcal{A}(1)$  as  $t(n)$  and  $s(n)$ , respectively. Moreover, we denote the number of outputs of  $\mathcal{A}(\tau)$  as  $\#\mathcal{A}(\tau)$ . Under this problem setting, we construct a ranked enumeration algorithm that outputs the  $i$ -th solution in  $O(i \cdot n \cdot t(n))$  time with  $O(s(n))$  space as follows.

Our idea is simply to execute  $\mathcal{A}$  from  $\mathcal{A}(n)$  to  $\mathcal{A}(1)$ . When  $\mathcal{A}(k)$  outputs a solution with cardinality more than  $k$ , we just ignore it. In other words, when we execute  $\mathcal{A}(i)$ , all solutions in  $\mathcal{F}$  with cardinality exactly  $i$  are output. Clearly, we can enumerate all solutions in  $\mathcal{F}$  in a non-increasing order of their cardinality. We consider the time and space complexity of this method. It is easy to see that the space complexity of this algorithm is  $O(s(n))$  as we just execute  $\mathcal{A}$  in order. Thus, we estimate the running time required to output the first  $i$  solutions for  $i \leq |\mathcal{F}|$ . Let  $j \geq 1$  be the maximum integer such that  $\#\mathcal{A}(j)$  is less than  $i$ . Since the delay of  $\mathcal{A}$  is bounded by  $t(n)$  and  $\#\mathcal{A}(j-1)$  is at least  $i$ ,  $\mathcal{A}(j-1)$  outputs the  $i$ -th solution in  $O(i \cdot t(n))$  time. Since the total running time is bounded by  $O((n-j+1) \cdot \#\mathcal{A}(j) \cdot t(n) + i \cdot t(n)) = O(i \cdot n \cdot t(n))$  time, this algorithm outputs the first  $i$  solutions in  $O(i \cdot n \cdot t(n))$  time.

► **Theorem 16.** *Let  $S$  be a finite set and  $\mathcal{F}$  be a subset of  $2^S$ . For any  $1 \leq k \leq \tau$ , suppose that we have an algorithm  $\mathcal{A}(k)$  that enumerates all sets in  $\mathcal{F}$  with the cardinality at least  $k$  for any  $1 \leq k \leq \tau$  in  $t(n)$  delay and  $s(n)$  space. Then, there is an algorithm enumerating all subsets in  $\mathcal{I}$  in non-increasing order of their cardinality that outputs the first  $i$  solutions in  $O(i \cdot n \cdot t(n))$  time using  $O(s(n))$  space for  $i \leq |\mathcal{F}|$ .*

We obtain a linear incremental-time and polynomial-space ranked enumeration algorithm for maximal common independent sets of two matroids by combining Theorems 12 and 16.

► **Theorem 17.** *There is a linear incremental-time and polynomial-space algorithm for enumerating all maximal common independent sets in two matroids in non-increasing order. This algorithm outputs the first  $i$  solutions in  $O(i \cdot n^7 Q)$  time.*

## 6 Applications of our algorithms

Due to an expressive power of MATROID INTERSECTION, Theorems 12 and 17 give enumeration algorithms for various combinatorial objects in a unified way. An example of such objects is to enumerate maximal  $b$ -matchings in bipartite graphs. It is known that an intersection of two matroids can represent all objects in the following theorem. See the appendix for details on representing these objects by an intersection of two matroids.

► **Theorem 18.** *There are polynomial delay and space enumeration algorithms for*

- *maximal bipartite  $b$ -matchings with cardinality at least  $\tau$ ,*
- *maximal colorful forests with cardinality at least  $\tau$ , and*
- *maximal degree constrained subgraphs in digraphs with cardinality at least  $\tau$ ,*

*Moreover, there are linear incremental-time and polynomial-space ranked enumeration algorithms for the above problems.*

## Abstract

We propose a framework for certified computation on hyperspaces by formalizing various higher-order data types and operations in a constructive dependent type theory. Our approach builds on our previous work on axiomatization of exact real computation where we formalize nondeterministic first-order partial computations over real and complex numbers. Based on the axiomatization, we first define open, closed, compact and overt subsets in an abstract topological way that allows short and elegant proofs with computational content coinciding with standard definitions in computable analysis. From these proofs we extract programs for testing inclusion, overlapping of sets, et cetera.

To improve extracted programs, our framework specializes the Euclidean space  $\mathbb{R}^m$  making use of metric properties. To define interesting operations over hyperspaces of Euclidean space, we introduce a nondeterministic version of a continuity principle valid under the standard type-2 realizability interpretation. Instead of choosing one of the usual formulations, we define it in a way similar to an interval extension operator, which often is already available in exact real computation software.

We prove that the operations on subsets preserve the encoding, and thereby define a small calculus to build new subsets from given ones, including limits of converging sequences with regards to the Hausdorff metric. From the proofs, we extract programs that generate drawings of subsets of  $\mathbb{R}^m$  with any given precision efficiently. As an application we provide a function that constructs fractals, such as the Sierpinski triangle, from iterated function systems using the limit operation, resulting in certified programs that errorlessly draw such fractals up to any desired resolution.

## 1 Introduction

In exact real computation, real numbers are often presented as abstract data type hiding tedious multi-precision computations used to eliminate rounding errors in the background from the user. Extensionally to the user, the real numbers resemble the classical structure of real

numbers which makes reasoning procedures more intuitive, emancipating the programmers from tracking artificial numerical errors. The theoretical framework to study computability of algorithms in this context is computable analysis [16, 28]. Recent developments in implementations demonstrate the usefulness of this approach in practice [1, 20, 15].

The project cAERN [14] aims to provide an axiomatic formalization of exact real number computations in a constructive type theory, modeling real numbers similar as observed by users of exact real computation software; cf., [2, 25] where explicit representations are required for computations. Instead of being constructed as sequences of approximations, real numbers are axiomatized in a way that two reals are provably equal when they represent the same numbers; cf., [3, 9, 26]. This can be regarded as a modification of the classical real numbers by replacing uncomputable operations (e.g., rounding to nearest integers) and computably invalid axioms (e.g., the law of trichotomy) with their computable variants. As the axiomatization is representation irrelevant, reals appear similar to the classical real numbers allowing many classical results to be transported into our setting (see [14, Section 6]). At the same time, by allowing only computably valid axioms, it admits a program extraction mechanism built on top of an existing exact real computation framework.

The extraction is achieved by mapping the axiomatic real type  $\mathbb{R}$  to the abstract data type of real numbers  $\mathbf{CReal}$  and axioms to primitive operations in AERN, a Haskell library for exact real number computation which is being developed by one of the authors [15]. Thus, we do not need to focus on the concrete representation of real numbers and its efficient implementation which is challenging on its own (see e.g. [19]).

More concretely, in our system a proof of a theorem of the form

$$\Pi(x : \mathbb{R}). M\Sigma(y : \mathbb{R}). P x y$$

yields a nondeterministic AERN function of type  $\mathbf{CReal} \rightarrow \mathbf{CReal}$ . Here,  $M : \mathbf{Type} \rightarrow \mathbf{Type}$  formalizes nondeterminism, which is an inevitable effect of identifying real numbers extensionally [17].<sup>1</sup>

The theory formalized in cAERN is sufficient to build interesting first-order nondeterministic functions [13]. Many applications in exact real computation, e.g. reachability questions for dynamical systems, computing integrals and solving differential equations, however deal with higher order objects such as hyperspaces of functions and subsets as primitive data type [8]. Such applications are often safety-critical and a framework for formally proving correctness of algorithms on such higher-order objects is thus highly desirable.

In this paper, we extend our previous axiomatic formalization towards higher-order exact real computations. Based on the axiomatization of real numbers, partial lazy Boolean, and nondeterminism, we define various higher-order types including Euclidean spaces, classical subsets, open subsets, closed subsets, compact subsets and overt subsets. Furthermore, we provide various operations on these sets, including limit operations on compact sets based on Hausdorff distance. We further provide a rich theory of subsets of Euclidean spaces and operations on them, encoding them in a way that lets us efficiently generate verified drawings.

An important fact in computable analysis is that every computable function is continuous. When we operate on higher-order objects, this fact becomes computationally relevant. To make continuity available in our system, we include an axiomatic formalization of the continuity principle saying that any function from real numbers *nondeterministically* admits a modulus of continuity function. As the goal of the project is to use axioms to model

---

<sup>1</sup> Nondeterminism in this context is also called multivaluedness [28] or non-extensionality [5].

functionality that is typically available in exact real computation, instead of assuming a continuity principle by saying that any functional  $(\mathbb{N} \rightarrow \mathbb{N}) \rightarrow \mathbb{N}$  is continuous and then derive various continuity lemmas on  $X \rightarrow Y$  by reasoning on specific constructions of the types  $X$  and  $Y$ , decomposing them to the natural numbers, we formalize the continuity principle directly on our axiomatic types in terms of an interval extension. Such an operation is natural in exact real computation software and our continuity principle can be extracted to a simple operation in AERN.

Using the continuity principle, we show that our efficient encoding of euclidean subsets is computationally equivalent to a more general way to represent subsets. We further show that it can be used to generate verified drawings of images of functions on certain subsets.

As an application we devise a general construction of fractals defined by a recurrence relation on compact sets. The recurrence relation can be used to define the structure, which then can be drawn exactly up to any desired resolution using the drawing operation. We further can use the limit operator for a simple and elegant formulation of the theorem.

This paper is organized as follows. In Section 2 we briefly summarize the background from our previous work, introduce notations used throughout the paper and explain some extensions to the theory necessary for the current work. In Section 3 we define the continuity principle and prove some of its consequences. We define open, closed, compact and overt subsets in a generic setting and prove some of the properties in Section 4. We consider subsets of Euclidean space for which we use specialized encodings in Section 5 and finally show some applications to generate certified drawings of two-dimensional sets in Section 6.

All statements in this paper except for those in Appendix A have been implemented and fully formally verified in the Coq proof assistant as part of the cAERN library<sup>2</sup>. We extend the program extraction mechanism so that the newly added axioms, including the continuity principle, are mapped to appropriate AERN functions. The constructive content of the proofs can thus be extracted to AERN programs using Coq’s Haskell program extraction functionality and mapping axiomatically defined operations to basic operations in AERN providing a certified module in AERN for defining and manipulating higher-order objects.

## 2 Preliminaries

### 2.1 Type Theory and Realizability

As in [14] we assume to work in a simple type theory with basic types  $0, 1, 2, \mathbb{N}, \mathbb{Z}$ , a universe of classical propositions  $\mathbf{Prop}$ , and a universe of types  $\mathbf{Type}$ . We assume that the identity types  $=$  are in  $\mathbf{Prop}$  and that  $\mathbf{Prop}$  is a type universe closed under  $\rightarrow, \times, \vee, \exists, \Pi$ , containing two types  $\mathbf{True}, \mathbf{False} : \mathbf{Prop}$  which are the unit and the empty type respectively. We denote by  $P \vee Q : \mathbf{Prop}$  the classical fact that  $P$  or  $Q$  holds, and by  $P + Q : \mathbf{Type}$  the fact that there is a computational procedure deciding if  $P$  or  $Q$  holds. Similarly, when we have a family of classical propositions  $P : X \rightarrow \mathbf{Prop}$ , the type  $\exists(x : X). P x : \mathbf{Prop}$  denotes the classical existence of  $x : X$  satisfying  $P x$  while the ordinary dependent pair type (also called  $\Sigma$ -type),  $\Sigma(x : X). P x : \mathbf{Type}$  denotes the constructive existence.

We assume enough axioms that make  $\mathbf{Prop}$  indeed a universe of classical propositions and that are valid under this interpretation. That includes the law of excluded middle

$$\Pi(P : \mathbf{Prop}). P \vee \neg P$$

<sup>2</sup> <https://github.com/holgerthies/coq-aern>

where  $\neg P$  is defined by  $P \rightarrow \text{False}$  and propositional extensionality

$$\Pi(P, Q : \text{Prop}). (P \rightarrow Q) \rightarrow (Q \rightarrow P) \rightarrow P = Q.$$

These axioms allow us to reason classically when we are dealing with classical statements such as  $\exists(x : X). P x : \text{Prop}$ . Furthermore, we assume a general (dependent) function extensionality

$$\Pi(P : X \rightarrow \text{Type}). \Pi(f, g : \Pi(x : X). P x). (\Pi(x : X). f x = g x) \rightarrow f = g.$$

Based on this foundational setting of a constructive type theory we axiomatically formalize various types and operations for real number computation that are briefly introduced in the next subsections. The soundness of the basic setting of type theory and the newly introduced axioms are justified by extending a realizability interpretation in the category of assemblies over Kleene's second algebra [11, 23] by mapping each axiom to a computable operation in computable analysis.

## 2.2 Kleenean and Sierpinski Spaces

One important characteristic of exact real computation, besides exact operations, is nontermination. As real numbers are expressed exactly using infinite representations, comparing real numbers is a partial operation where testing  $x < y$  does not terminate when  $x = y$  regardless of the specific representations that are used [28, Theorem 4.1.16]. To deal with such partiality, instead of making computations continue indefinitely when the same numbers are compared, AERN and other exact real computation software provide a data type for lazy Boolean  $\{\text{ff}, \text{tt}, \perp\}$ , generalizing Booleans by adding a third element  $\perp$  as an explicit state of divergence. The third value  $\perp$  is an admissible value that a variable can store whose nontermination is delayed until it is required to test whether the value is  $\text{tt}$  or  $\text{ff}$ .

Observing that the space satisfies the algebraic structure of Kleene's three-valued logic where  $\perp$  is the third truth value for indeterminacy, the data type is also often called *Kleenean*. In particular, we assume that there are three distinct constants  $\text{true}, \text{false}, \text{bot} : \mathbb{K}$ , although we do not assume that they are the only elements by adding an induction rule. We write  $[k]$  for  $k = \text{true}$ .

Later we often need to deal with infinite sequences of Kleenean expressions. This has not yet been considered in our previous work and requires to characterize the Kleeneans further by assuming some additional axioms. The *nondeterministic countable choice principle* is an axiom of the following type:

$$\Pi(x : \mathbb{N} \rightarrow \mathbb{K}). (\exists(n : \mathbb{N}). [x\ n]) \rightarrow \text{M}\Sigma(n : \mathbb{N}). [x\ n]. \quad (1)$$

Here,  $\text{M}$  is a nondeterminism monad such that for any type  $X : \text{Type}$ , we automatically get a type  $\text{M}X : \text{Type}$  modelling the result of a nondeterministic computation in  $X$ . The axiom says whenever we have a sequence of Kleenean terms  $x$  and know that there (classically) is at least one index  $n$  such that  $x\ n$  is  $\text{true}$ , then we can nondeterministically find such an index.

Sometimes we only need to know if there is an element of the sequence that is  $\text{true}$ . For this, we add the following axiom.

$$\Pi(x : \mathbb{N} \rightarrow \mathbb{K}). \Sigma(k : \mathbb{K}). ([k] \leftrightarrow \exists(n : \mathbb{N}). [x\ n]).$$

That is, we can find a  $k : \mathbb{K}$  that is  $\text{true}$  iff any of the sequence elements is  $\text{true}$  and can be  $\text{false}$  or  $\text{bot}$  otherwise. To see that the axiom is valid, it suffices to show that such a  $k$  is computable which can be done by iterating over all the outputs of the realizers of  $x\ n$  in parallel.

A space similar to the Kleenean that is more commonly used in computability theory is the Sierpinski space. Sierpinski space is the topological space  $\{\downarrow, \uparrow\}$  whose only nontrivial open is  $\{\downarrow\}$ . In a certain way,  $\mathbf{K}$  can be seen as an extension of Sierpinski space by adding another decidable element `false`. However, as the type of Kleenean  $\mathbf{K}$  already exists in our system, we instead consider Sierpinski as a subtype of  $\mathbf{K}$  by defining it as

$$S := \Sigma(b : \mathbf{K}). b \neq \text{false}$$

and name  $\downarrow := (\text{true}, t_{\downarrow})$  and  $\uparrow := (\text{bot}, t_{\uparrow})$  where the  $t_{\downarrow}$  is the unique proof term for `true`  $\neq$  `false` and  $t_{\uparrow}$  is the unique proof term for `⊥`  $\neq$  `false`. The uniqueness of the proof terms is due to the `Prop` axioms. From the computational point of view,  $S$  can be thought of as  $\mathbf{K}$  where it is promised that `false` does not appear.

As a further axiom, we assume that the first projection  $\text{proj}_1 : S \rightarrow \mathbf{K}$  admits a retraction  $\text{KtoS} : \mathbf{K} \rightarrow S$ . Observe that the assumption can be validated by a program on the Kleenean that on its input  $b : \mathbf{K}$  checks if  $b = \text{true}$  or `false` and simply diverges when  $b = \text{false}$ .

### 2.3 Real Numbers and Euclidean Space

We assume real numbers by declaring that there is a type  $\mathbf{R}$  for real numbers containing two distinct constants 0 and 1, the standard arithmetical operators and a semi-decidable  $\mathbf{K}$ -valued comparison operator. From this axiomatization we can define further operations such as  $\max(x, y)$ ,  $|x|$ , etc. Again, the full axiomatization can be found in [14]. For any  $m : \mathbf{N}$  we further define the type  $\mathbf{R}^m$  simply as an  $m$ -element list of  $\mathbf{R}$  with maximum norm  $\|\cdot\|$ , and define the vector space operations point-wise.

We often approximate real numbers by elements of a countable dense subset. We call a type  $X$  enumerable if there exists a map  $f : \mathbf{N} \rightarrow X$  that is surjective in the classical sense. We define dyadic numbers by pairs  $\mathbf{D} := \mathbf{Z} \times \mathbf{N}$  and identify the pair  $(z, n)$  with the real  $z \cdot 2^{-n}$ . It is not hard to show that  $\mathbf{D}$  is enumerable. Similarly we write  $\mathbf{D}^m$  for the  $m$ -element list of  $\mathbf{D}$  when  $m : \mathbf{N}$  and suppose that the trivial coercion from  $\mathbf{D}^m$  to  $\mathbf{R}^m$  is taken implicitly.

We use dyadic numbers to approximate real numbers. In our theory, we can prove that  $\mathbf{D}$  is indeed dense in  $\mathbf{R}$  in the sense that for any real number  $x$ , we can nondeterministically find a dyadic rational approximation up to any prescribed error  $2^{-p}$ . More generally, we can prove the following statement in the Euclidean space:

$$\Pi(x : \mathbf{R}^m). \Pi(p : \mathbf{N}). \text{M}\Sigma(d : \mathbf{D}^m). \|x - d\| \leq 2^{-p}.$$

## 3 Continuity

Exact real computation software often internally represents real numbers by converging sequences of intervals with dyadic rational endpoints. Thus, for any function  $f : \mathbf{R} \rightarrow \mathbf{S}$ , whenever  $(f\ x)\downarrow$ , there is some dyadic interval containing  $x$  that made the software computing  $f\ x$  return  $\top$ . We thus formulate continuity on an abstract level similar to the above without referring to specific constructions of continuous types.

The Sierpinski space has two open subsets  $\{\downarrow\}$  and  $\{\downarrow, \uparrow\}$ . An interval extension of a function  $f : \mathbf{R} \rightarrow \mathbf{S}$  is a discrete function that indicates in which of the two open sets all values for  $f$  lie for any dyadic interval. As there are exactly two values, we can represent  $\{\downarrow\}$  and  $\{\downarrow, \uparrow\}$  space by the Boolean constants `true` and `false`, respectively. We can then see a map  $\hat{f}$  of type  $\mathbf{D} \times \mathbf{N} \rightarrow \mathbf{B}$  as a set-valued function from dyadic intervals:  $\hat{f}$  returns a subset of Sierpinski space on its argument  $(d, n) : \mathbf{D} \times \mathbf{N}$  representing the interval  $(d - 2^{-n}, d + 2^{-n}) \subset \mathbb{R}$ .

## 59:6 Formalizing Hyperspaces for Extracting Efficient Exact Real Computation

For a map  $f : \mathbb{R} \rightarrow \mathbb{S}$ , we say that a set-valued function on dyadic intervals  $\hat{f}$  is an interval extension of  $f$  when it satisfies the inclusion property:

$$\text{incl } \hat{f} := \Pi(d : \mathbb{D}). \Pi(n : \mathbb{N}). \hat{f}(d, n) = \text{true} \rightarrow (\Pi(x : \mathbb{R}). |x - d| \leq 2^{-n} \rightarrow (f x) \downarrow).$$

In words, whenever the interval extension  $\hat{f}$  of  $f$  returns true on the pair  $(d, n)$ ,  $(f x) \downarrow$  for all  $x \in (d - 2^{-n}, d + 2^{-n})$ .

However, not all interval extensions are interesting as the inclusion property holds also for the trivial map  $\hat{f}$  that returns false for all inputs. We say that a map  $\hat{f} : \mathbb{D} \times \mathbb{N} \rightarrow \mathbb{B}$  seen as an interval extension of  $f : \mathbb{R} \rightarrow \mathbb{S}$  is tight if whenever  $(f x) \downarrow$ , there (classically) exists an interval containing  $x$  for which  $\hat{f}$  indicates that  $\downarrow$  is the only valid answer on that interval:

$$\text{tight } \hat{f} := \Pi(x : \mathbb{R}). (f x) \downarrow \rightarrow \exists(d : \mathbb{D}). \exists(n : \mathbb{N}). |x - d| < 2^{-n} \wedge \hat{f}(d, n) = \text{true}$$

Our continuity principle is the following axiom saying that for any map  $f : \mathbb{R} \rightarrow \mathbb{S}$ , there nondeterministically exists an interval extension of it that is tight:

$$\Pi(f : \mathbb{R} \rightarrow \mathbb{S}). \text{M}\Sigma(\hat{f} : \mathbb{D} \times \mathbb{N} \rightarrow \text{bool}). \text{incl } \hat{f} \wedge \text{tight } \hat{f}.$$

It is realized by the trivial operation that given  $f$  extracts the realizer  $\hat{f}$  of  $f$  assuming that the underlying exact real computation is done via dealing real numbers by converging sequences of intervals with dyadic rational endpoints. Since a single function admits several different realizers, the procedure of extracting realizers is nondeterministic.

From the above, we can derive the more standard form of the continuity principle which says that there exists a modulus function:

$$\Pi(f : \mathbb{R} \rightarrow \mathbb{S}). \Pi(x : \mathbb{R}). (f x) \downarrow \rightarrow \text{M}\Sigma(n : \mathbb{N}). \Pi(y : \mathbb{N}). |x - y| < 2^{-n} \rightarrow (f y) \downarrow.$$

To derive this version of the principle, assume that we are given  $x$  with  $f x \downarrow$ . Due to the continuity axiom, we further have nondeterministically a tight interval extension  $\hat{f}$ . From the tightness, we then know that there (classically) exist  $d, n$  such that  $|d - x| < 2^{-n}$  and  $\hat{f}(d, n) = \text{true}$ . Though  $\hat{f}$  is Boolean-valued, we can post-compose the embedding from  $\mathbb{B}$  to  $\mathbb{S}$  and use the nondeterministic countable choice principle in Equation (1) to nondeterministically find such  $d$  and  $n$ . We then (again nondeterministically) choose some  $m$  such that  $2^{-m} < 2^{-n} - |x - d|$ . As for any  $y$  with  $|x - y| < 2^{-m}$ ,  $|y - d| < 2^{-n}$  holds, it is guaranteed that  $f y \downarrow$  by the properties of the interval extension. Thus, any such  $m$  fulfills the condition.

Further, we can derive a continuity principle for real valued functions  $f : \mathbb{R} \rightarrow \mathbb{R}$ :

$$\Pi(x : \mathbb{R}). \Pi(m : \mathbb{N}). \text{M}\Sigma(n : \mathbb{N}). \Pi(y : \mathbb{N}). |x - y| < 2^{-n} \rightarrow |(f x) - (f y)| < 2^{-m}$$

To prove that this continuity principle holds, take any  $f : \mathbb{R} \rightarrow \mathbb{R}$ ,  $x : \mathbb{R}$ , and  $m : \mathbb{N}$ , and define a function  $g_{x,m} : \mathbb{R} \rightarrow \mathbb{S}$  by  $g_{x,m} := \lambda(y : \mathbb{R}). |(f x) - (f y)| < 2^{-m}$ . Here, we let  $(x < y)$  be the embedding of the Kleenean valued comparison to Sierpinski space, i.e. such that  $(x < y) \downarrow$  if and only if  $x < y$  holds. The continuity principle on Sierpinski valued functions yields

$$|(f x) - (f x)| < 2^{-m} \rightarrow \text{M}\Sigma(n : \mathbb{N}). \Pi(y : \mathbb{R}). |x - y| < 2^{-n} \rightarrow |(f x) - (f y)| < 2^{-m}.$$

As  $|(f x) - (f x)| < 2^{-m}$  is trivially true, we get the desired bound.

As a last application, consider any discrete type  $X$  having decidable equality  $\Pi(x, y : X). (x = y) + (x \neq y)$ . We can then prove that any  $f : \mathbb{R} \rightarrow X$  is constant:  $\Pi(x : \mathbb{R}). \Pi(y : \mathbb{R}). f x = f y$ . Similarly as above, assuming  $x : \mathbb{R}$ , we define a function  $g_x$  where  $(g_x y)$  is defined if  $(f x) = (f y)$  and undefined if  $(f x) \neq (f y)$ , constructed based on the decidability of elements of  $X$ . Again, applying the continuity principle, we get

$$\text{M}\Sigma(n : \mathbb{N}). \Pi(y : \mathbb{R}). |x - y| < 2^{-n} \rightarrow (f x) = (f y) .$$

Since we can prove that any locally constant function from  $\mathbb{R}$  is constant in the classical part of our system, we can conclude that  $f$  is constant.

All results can be easily generalized to arbitrary Euclidean space  $\mathbb{R}^m$  by replacing the absolute value with the maximum norm and proofs are contained in our formal development.

## 4 Subsets

For any type  $X$ , we first express subsets classically as predicates  $X \rightarrow \text{Prop}$ . That is, we set

$$\text{csubset}(X) := X \rightarrow \text{Prop}$$

and define classical operations on classical subsets such as  $\in, \cup, \cap, \subseteq, \dots$  in the obvious way. For example,  $(x \in S) := S x$ ,  $S \cap T := \lambda(x : X). x \in S \wedge x \in T$ , and so on.

Our goal is to assign computational content to classically defined subsets which in turn allows to extract programs that perform operations on these sets. In computable analysis, computational content is given by defining representations for certain spaces of subsets [22, 8] and perform computations on these representations. This can be done in a very general setting without restricting to specific spaces, although the computational procedures are usually extremely inefficient and not useful for practical applications.

While we are mostly interested in subsets of Euclidean spaces for which we can specialize the theorems and get more efficient algorithms, the general results are still interesting mathematically and can be used for basic facts that are not meant to be used computationally.

Classically, a subset  $A \subseteq X$  of a topological space  $X$  is open iff its characteristic function  $\chi_A : X \rightarrow \mathbb{S}$  is continuous. We thus identify open sets with their characteristic function:

$$\text{open } A := \Sigma(f : X \rightarrow \mathbb{S}). \Pi(x : X). (f x) \downarrow \leftrightarrow x \in A .$$

Similarly, we define closed sets as their complement

$$\text{closed } A := \Sigma(f : X \rightarrow \mathbb{S}). \Pi(x : X). (f x) \downarrow \leftrightarrow x \notin A .$$

Computationally for an open set we can verify (i.e. semi-decide) if a point is contained in the set and for a closed set we can verify if a point is outside.

We state some simple properties of open and closed sets. We omit the proofs here, but pen and paper proofs can e.g. be found in [22] and full formal proofs can be found in our Coq development.

1. If  $(A_i)_{i \in \mathbb{N}}$  are open then so is the countable union  $\bigcup A_i$ .
2. If  $A$  and  $B$  are open then so is their finite intersection  $A \cap B$ .
3. If  $A$  and  $B$  are closed then so is their finite union  $A \cup B$ .
4. If  $(A_i)_{i \in \mathbb{N}}$  are closed then so is the countable intersection  $\bigcap A_i$ .

Other classes of subsets that are often considered in computable analysis are the compact and overt subsets. (Computably) compact subsets are those for which we can effectively verify that an open set covers them. That is, a subset  $A \subseteq X$  is compact iff

$$\Sigma(f : \text{open } X \rightarrow \mathbb{S}). \Pi(U : \text{open } X). (f U) \downarrow \leftrightarrow A \subseteq U .$$

Overtness is a dual notion to compactness. For a (computably) overt subset, we can effectively verify if an open set touches it. That is, a subset  $A \subseteq X$  is overt iff

$$\Sigma(f : \text{open } X \rightarrow \mathbb{S}). \Pi(U : \text{open } X). (f U) \downarrow \leftrightarrow A \cap U \neq \emptyset.$$

The notion of overtness is less known to classical mathematicians as it does not carry any information outside a constructive or computational context (i.e. any set is classically overt).

Another way to look at these notions is that for a compact subset  $A$  it can be verified that a semidecidable property  $P$  holds for each point, i.e. if  $\forall x \in A, P x$  and for an overt subset it can be verified that it holds for at least one point, i.e. if  $\exists x \in A, P x$ .

Similar as for open and closed sets, we prove several properties of compact and overt sets in our Coq development but omit the details here for space reasons.

## 5 Subsets of Euclidean Space

Using basic properties of the Kleenean and Sierpinski spaces, we get short and elegant proofs for simple properties of open sets. However, from the point of view of doing actual computations, using Sierpinski valued functions to represent basic objects is often far from optimal and programs extracted from the proofs are inefficient. As we are interested in extracting exact real computation programs, our main focus is on subsets of Euclidean spaces. Most statements in this section can be proven in a much more general setting (and our Coq development contains some of them). However, the proofs in this section are optimized to encode efficient algorithms by making use of particular properties of the representation.

### 5.1 Characterization of Euclidean Subsets

We prove the following characterization for subsets  $A \subseteq \mathbb{R}^m$  of Euclidean space:

$$\begin{aligned} \text{open } A &\leftrightarrow \text{M}\Sigma(F : \mathbb{N} \rightarrow \mathbb{R}^m \times \mathbb{R}). \\ &\quad \Pi(n : \mathbb{N}). \text{B}((F n)) \subseteq A \\ &\quad \wedge \quad \Pi(x : \mathbb{R}^m). x \in A \rightarrow \exists(n : \mathbb{N}). x \in \text{B}((F n)). \end{aligned}$$

Here,  $\text{B}(x, r)$  encodes a ball with radius  $r$  around  $x$ . That is, a subset  $A \subseteq \mathbb{R}^m$  is open iff we can find a sequence of (possibly empty) balls, all contained in  $A$ , that eventually cover all  $A$ .

To show the equivalence let us call the statement on the right of the equivalence Euclidean open. Thus, first assume that  $A$  is open in the sense of the previous section, that is, there is a function  $f : \mathbb{R}^m \rightarrow \mathbb{S}$  such that  $(f x) \downarrow$  iff  $x \in A$ . We can enumerate all possible inputs  $\mathbb{D}^d \times \mathbb{N}$  and define a sequence of balls by choosing  $\text{B}(d, 2^{-n})$  whenever  $(\hat{f} d n) = \text{True}$ . By the properties of the interval extension, any such ball is contained in  $A$  and for any  $x \in A$  we will find at least one ball that contains  $x$ .

Now assume  $A$  is Euclidean open. For any  $x, y, r$ , testing if  $x \in \text{B}(y, r)$  is semidecidable as we only need to check if  $d(x, y) < r$ . Thus, given  $x : \mathbb{R}$  we define a sequence  $s : \mathbb{N} \rightarrow \mathbb{S}$  such that  $(s n) \downarrow$  iff  $x \in \text{B}((F n))$ . Then  $\exists(n : \mathbb{N}). (s n) \downarrow \leftrightarrow x \in A$ , i.e., we need to check if there is at least one element in the sequence that is defined, which is again semidecidable.

For practical purposes, we are mostly interested in Euclidean subsets that are both compact and overt. Such sets (and some variations) have been considered in constructive mathematics and computable analysis under different names, sometimes using the same terminology for slightly different concepts. In Bishop's constructive mathematics, a set is compact if it is closed and totally bounded [10]. Here, totally bounded means that it can be covered by finitely many subsets of fixed size. Brattka and Weihrauch [4] define a representation  $\nu_{\text{min-cover}}$  for compact sets based on such coverings.

We only consider subsets of Euclidean space that are classically closed and characterize their subsets in terms of “drawings” with arbitrary precision, meaning that for each  $n$  we can generate a picture of  $A$  in terms of “pixels” (i.e. small boxes or closed balls) of size  $2^{-n}$ . It turns out that subsets for which such drawings exist are precisely those that are both compact and overt. It can further shown that they coincide with the *located* subsets, i.e., the subsets for which the distance of the set and a real number is computable (cf. [27, §12] and [24]). We thus use the term *located* for these subsets. We can define a closed ball  $B(c, r) \subseteq \mathbb{R}^m$  with center  $c$  and radius  $r$  (w.r.t. the maximum norm) simply as the tuple  $(c, r) : \mathbb{R}^m \times \mathbb{R}$ . We denote the type of all such balls by  $B$  and use  $[B]$  to denote finite lists of balls. For any  $b : B$  we further let  $\|b\|$  denote its radius. We then formally define the located sets by

$$\begin{aligned} \text{located } A &:\equiv \Pi(n : \mathbb{N}). \Sigma(L : [B]). \\ &\quad \Pi(b \in L). \|b\| \leq 2^{-n} \quad (\text{fast convergence}) \\ &\quad \wedge \Pi(b \in L). b \cap A \neq \emptyset \quad (\text{intersection}) \\ &\quad \wedge \bigcup_{b \in L} b \supseteq A \quad (\text{cover}). \end{aligned}$$

Thus, a set is located if for each  $n$  we get a finite list of closed balls, each with radius at most  $2^{-n}$  so that their union covers the whole set  $A$  and such that each ball intersects  $A$ . Note that we need to restrict to classically closed subsets as the coverings only define a set up to its closure. The empty set is located as we allow closed balls to be empty (encoded by a negative radius).

We call the set defined by the union of the elements of the  $n$ -th list of the sequence the  $n$ -th approximation or the  $n$ -th covering of  $A$  and denote it by  $A_n$ .

For  $A \subseteq \mathbb{R}^m$  and  $x \in \mathbb{R}^m$ , let us write  $d(x, A)$  for  $\inf_{y \in A} \|x - y\|$ .

The Hausdorff distance  $d_H(A, B)$  of two sets is defined by

$$d_H(X, Y) = \max \left\{ \sup_{x \in X} d(x, Y), \sup_{y \in Y} d(X, y) \right\}.$$

Note that the set defined by the  $n$ -th approximation has Hausdorff distance at most  $2^{-n}$  to the set that is approximated. In fact, the other direction also holds, i.e. we can show

$$\text{located } A \leftrightarrow \Pi(n : \mathbb{N}). \Sigma(L : [B]). d_H(A, \bigcup_{b \in L} b) \leq 2^{-n}.$$

To see this, assume for each  $n \in \mathbb{N}$  we can get a list of balls  $L$  such that  $d_H(A, \bigcup_{b \in L} b) \leq 2^{-n}$ . We take the  $(n + 1)$ -st list and double the radius of each of the balls. This guarantees that the resulting set covers  $A$  while still being small enough.

Note that center and radius of the balls can be arbitrary real numbers, as in the context of exact real computation it is more convenient to work with real numbers than with rationals. However, decidable equality on balls can be useful. Restricting to only dyadic rationals for center and radius does not make a difference as we can approximate real numbers arbitrarily well by dyadic rationals and thus can convert any real covering to a dyadic covering.

It can be shown that a set is located if and only if it is compact and overt. Although a formal proof of the equivalence could be used to prove that some of the subset operations preserve locatedness, recall that the main goal of our project is to extract efficient programs from proofs. It is thus reasonable to have different proofs using the more efficient representation, and a formal proof of the equivalence is less important. While the algorithmic content of the proofs is rather simple, showing correctness of the procedures needs some facts from classical analysis complicating the formalization of the proof. We therefore only give a pen and paper proof of the equivalence in Appendix A and state the fact as a meta-theorem.

## 5.2 Operations on located subsets

Let us first show that we can effectively get the distance of a point and a located set. For any nonempty located sets we can compute the distance function. That is,

$$\text{located } A \wedge A \neq \emptyset \rightarrow \Pi(x : \mathbb{R}^m). \Sigma(r : \mathbb{R}). r = d(x, A).$$

For any ball  $b = B(c, r)$ , the distance  $d(b, x)$  is given by  $\max\{0, \|x - c\| - r\}$ . We choose the  $n$ -th approximation and take the minimum over all  $d(b, x)$ . This gives a  $2^{-n}$  approximation of  $d(A, x)$ . Taking the limit of all the approximations for each  $n$  thus corresponds to  $d(A, x)$ .

Let us next show that several standard operations on located subsets preserve locatedness. Although the results already follow from located sets being both compact and overt, our proofs encode more efficient algorithms, making use of the representation of located sets. The extracted programs can be used as a small calculus to combine subsets using set operations.

The properties stated below mostly can be shown by directly applying the operations on the coverings. We thus state them without proof.

1. For located sets  $A, B$  their union  $A \cup B$  is located.
2. For a located set  $A$  and any  $\lambda > 0$ , the scaled set  $\lambda A := \{\lambda x : x \in A\}$  is located.
3. For a located set  $A$  and any  $v : \mathbb{R}^m$ , the set  $A + v := \{x + v : x \in A\}$  is located.

Using the continuity principle on real numbers we can generalize the above to images of arbitrary real functions. For any set  $A \subseteq \mathbb{R}^m$ , and function  $f : \mathbb{R}^m \rightarrow \mathbb{R}^k$  let us define the image  $f[A] \subseteq \mathbb{R}^k$  by  $y \in f[A] :\leftrightarrow \exists(x : A). f(x) = y$ . Then we can show that the image of located sets is again located:

$$\Pi(A \subseteq \mathbb{R}^m). \Pi(f : \mathbb{R}^m \rightarrow \mathbb{R}^k). \text{located } A \rightarrow \text{located } f[A]$$

To show this, for each  $n \in \mathbb{N}$ , we need to find a covering of  $f[A]$  with balls with radius at most  $2^{-n}$ . We can use the continuity principle on real functions to define an extension  $\hat{f}$  that maps balls  $b \subseteq \mathbb{R}^m$  to balls (with possibly infinite radius)  $b' \subseteq \mathbb{R}^k$  such that  $f[b] \subseteq b'$ . We can further show that the radius of  $\hat{f}(b)$  goes to zero when the radius of  $b$  goes to zero. Thus we generate all coverings, apply  $\hat{f}$  to each of the balls of the coverings and check if the radius of each of them is bounded by  $2^{-n}$  which we know will eventually happen. While generating images under arbitrary functions is very powerful, the procedure is obviously quite inefficient and thus generating sets using the above specialized operations is preferred.

Another very useful operation that lets us easily generate more complicated sets from simple ones is the limit operation. Here, by limit operation we mean that we are given a sequence of located sets which converge to another set in terms of Hausdorff distance. That is, a set  $K$  is defined to be the limit of a sequence of located sets if

$$\text{isLim } K := \Pi(n : \mathbb{N}). \Sigma(X : \text{located } \mathbb{R}^m). d_H(X, K) \leq 2^{-n}$$

holds. We can show that the limit of a sequence of located sets is again located, i.e.

$$\text{isLim } K \rightarrow \text{located } K.$$

To see this, let  $X_i$  denote the  $i$ -th set in the sequence and  $X_{i,j}$  denote its  $j$ -th covering. As  $d_H(X_i, K) \leq 2^{-i}$  and  $d(X_{i,j}, X_i) \leq 2^{-j}$  it suffices to take  $X_{n+1, n+1}$  and double the radius of each of the balls to guarantee that the resulting set covers  $K$ .

■ **Figure 1** Approximations of the triangle.

## 6 Examples

From a proof that a set is located in our Coq implementation, we can extract an AERN program that computes the coverings. We implemented the examples below in Coq and extracted programs to generate for each  $n$  a finite list of real numbers, encoding the center and radii of each ball in the  $n$ -th covering. We can then use AERN to give us arbitrarily exact rational approximations of these real numbers, which we in turn can output and visualize by drawing the approximate boxes.

### 6.1 A Simple Triangle

Let us start with a simple example. We define a triangle  $T \subseteq \mathbb{R}^2$  by

$$(x, y) \in T \leftrightarrow x \geq 0 \wedge y \geq 0 \wedge x + y \leq 1.$$

To show that the set is located, let  $b_{i,j,n} := B((\frac{2i+1}{2^{n+1}}, \frac{2j+1}{2^{n+1}}), 2^{-n})$ . We define the  $n$ -th covering as the list  $L$  containing all  $b_{i,j,n}$  with  $i + j < 2^n$ . Figure 1 shows the coverings defined by this procedure. All of the balls have radius  $2^{-n}$  by definition and each ball intersects the triangle as  $i + j < 2^n$  implies  $\frac{2i+1+2j+1}{2^{n+1}} \leq 1$ . Each point of the triangle is contained in one of the  $b_{i,j,n}$  as for any  $x \in [0, 1]$  and  $n \in \mathbb{N}$  we can find some  $k \in \mathbb{N}$  such that  $2^{-n}k \leq x < 2^{-n}(k+1)$ . We can thus find such coordinates  $(i, j)$  for a point  $(x, y) \in T$  and as  $x + y \leq 1$  it follows that  $i + j < 2^n$  as claimed.

### 6.2 Fractals

As a more interesting application, let us look at a procedure to generate certified drawing of fractals. We consider simple self-similar fractals generated by iterated function systems (IFPs) without rotation. For simplicity we only consider fractals that are contained in the unit cube  $[0, 1]^m$ . For a finite set of points  $D := (d_1, d_2, \dots, d_k) \subseteq [0, 1]^m$  we define a classical subset  $\mathcal{I}(D) \subseteq \mathbb{R}^m$  as the smallest subset such that

1.  $D \subseteq \mathcal{I}(D)$ , and
2.  $\Pi(x : \mathcal{I}(D)). \Pi(d : D). \frac{x+d}{2} \in \mathcal{I}(D)$ .

Classically it can be shown that there is a unique compact subset with these properties. We show that any set defined in this way is located. To do so, we need to define a sequence of coverings of the set. We start with the first covering  $L_0$  being the list containing only the unit disc. As each  $d \in D$  is contained in the unit disc, the intersection and covering properties hold. We then recursively define the covering  $L_{n+1}$  from the previous covering  $L_n$  by following the construction rule, i.e., by making for each  $d \in D$  a copy of the previous covering where the center of each ball is moved halfway towards  $d$  and has half the radius.

■ **Figure 2** Approximations of the Sierpinski triangle.

Obviously, each of the balls in  $L_{n+1}$  has radius  $2^{-(n+1)}$ . To show that this procedure preserves the intersection property, let  $b \in L_{n+1}$ . Then there is some  $b' \in L_n$  and  $d \in D$  such that  $x \in b$  iff there is an  $x' \in b'$  with  $x = \frac{x'+d}{2}$ . As  $L_n$  has the intersection property, there is some  $x' \in b'$  with  $x' \in \mathcal{I}(D)$ . By definition of  $\mathcal{I}(D)$ , then  $\frac{x'+d}{2} \in \mathcal{I}(D)$ , i.e.,  $b \cap \mathcal{I}(D) \neq \emptyset$ . Similarly, to show that the covering property is preserved, assume  $x \in \mathcal{I}(D)$ . Then by definition either  $x = d$  for some  $d \in D$  or there is some  $x' \in \mathcal{I}(D)$  and some  $d \in D$  such that  $x = \frac{x'+d}{2}$ . Any  $d \in D$  is contained in  $L_{n+1}$  as  $d \in L_n$  and  $d = \frac{d+d}{2}$ . In the other case, there is some  $b \in L_n$  such that  $x' \in b$  as  $L_n$  is a covering. But then by definition of the procedure, there is some  $b' \in L_{n+1}$  that contains  $x$ .

A more elegant way to prove the locatedness of  $\mathcal{I}(D)$  is using the limit operation. We can define a sequence of located sets  $(T_i)_{i \in \mathbb{N}}$  by letting  $T_0$  be the unit disc and then applying the iteration given by the IFP. It is not hard to show that each  $T_i$  has Hausdorff distance at most  $2^{-i}$  to the fractal and thus applying the limit operation suffices. However the extracted program is slightly less efficient than the direct encoding as the limit uses  $T_{n+1}$  to get the  $n$ -th approximations and increases the radius leading to coverings where balls overlap.

As an application of the result, consider the Sierpinski triangle which is defined as the two dimensional subset  $\mathcal{I}(D)$  with  $D = \{(-1, -1), (1, -1), (0, \sqrt{3} - 1)\}$ .

From the above we get a proof that the set is located, from which we can extract a Haskell program computing the coverings. Figure 2 is a plot of the output of the extracted program for increasing  $n$ . To generate the plot, AERN has been used to approximate the real numbers for center and radius in the  $n$ -th approximation with error bounded by  $2^{-n}$ . The overlap at the top and bottom of the boxes is due to the approximation of the real number  $\sqrt{3} - 1$ .

## 7 Conclusion and future work

We considered procedures to work with different classes of subsets in a computational setting. Currently, we only consider simple operations on subsets to build new subsets and extract programs for certified drawings up to any desired resolution. Producing coverings yields a representation that is easy to manipulate computationally and efficient if our goal is to draw the whole set or do other operations that require global knowledge. However, naturally the size of the list of coverings grows exponentially when increasing the precision. One might argue that high precision approximations are more useful locally, i.e. instead of getting a picture of the whole set one might want to zoom into a small part of the set and draw it with arbitrarily high precision.

Instead of outputting the whole set, the list can be replaced by a nondeterministic test function, that tests whether a ball is close enough to the set or not:

$$\Pi(x : \mathbb{R}^d). \Pi(r : \mathbb{R}). M((d(x, A) < r) + (d(x, A) > 2r)).$$

That is, given a ball with center  $x$  and radius  $r$ , the function tells us if the ball intersects the set or not, but it is allowed to slightly over-approximate the set, i.e., both answers are possible if a ball with twice the radius intersects the set. Similar representations are often used in complexity theory (e.g. [6, 7]). In future work, we plan to include such representations in our development and show the equivalence to the covering representation for located sets.

More interesting operations can be achieved from computing images of arbitrary functions. Currently, we only have a simple implementation using the continuity principle on real numbers which is not efficient enough to be used in actual applications. Similar to the representations of Euclidean subsets, we can think of more efficient representations for the space of real functions. One possibility that comes to mind is using polynomial models such as Taylor models [18]. This would also allow for extensions to more advanced operations like integration and solution operators for ordinary differential equations [12, 21].

## A Equivalence of representations

We prove that a classically closed set is located if and only if it is both compact and overt. Since the *if* part is straightforward, let us focus on the *only if* direction.

Let us assume that  $A$  is compact and overt and show that  $A$  is located as well. We need to find for any natural  $n$  a finite set of balls of radius at most  $2^{-n}$ , each intersecting  $A$ , and collectively covering  $A$ . We will also assume  $n \geq 1$  and assign to  $n = 0$  the same set of balls as for  $n = 1$ .

As  $A$  is computationally compact, we can find a ball containing  $A$ . Without loss of generality, assume  $A \subseteq B(0, 1)$ .

Let  $J$  be the set of all  $d$ -dimensional integer vectors  $j$  whose integer components  $j_i$  satisfy  $-m \leq j_i \leq m$  where  $m = 3 \cdot 2^{n-1}$ . The points  $c_j = j/m$  for  $j \in J$  form a uniform grid over the (max-norm) unit ball  $B(0, 1)$ . Therefore the union of balls of radius  $r = 1/2m$  around  $c_j$  covers  $B(0, 1)$  and therefore  $A$ :

$$A \subseteq B(0, 1) \subset \bigcup_{j \in J} \overline{B}(c_j, r) \tag{2}$$

We will apply compact  $A$  and overt  $A$  on open and closed sets, respectively, derived from the above cover of  $A$ , except that we increase the radius to  $3r = 3/2m = 2^{-n}$ . This will make the cover sufficiently redundant to compensate for potential non-termination of the compactness and overtness applications on specific sets.

For each  $j \in J$ , let

$$\begin{aligned} \text{disjoint}_j &= \text{compact } A \ (A \cap \overline{B}(c_j, 3r)) \\ \text{intersects}_j &= \text{overt } A \ (A \cap B(c_j, 3r)) \\ \text{haveinfo}_j &= \text{empty}_j \sqcup \text{nonempty}_j \end{aligned}$$

Note that as  $\text{disjoint}_j, \text{intersects}_j, \text{haveinfo}_j \in \mathcal{S}$ , their computation may not terminate. Moreover,  $\text{haveinfo}_j$  terminates iff either of the other two terminate.

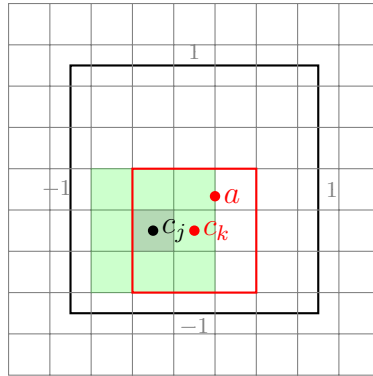

We compute all  $\text{haveinfo}_j$  computations in parallel until enough of them succeed to cover  $A$ , more precisely, until for the set of terminated indices  $J_T \subseteq J$ , it holds:

$$B(0, 1) \subseteq \bigcup_{j \in J_T} \overline{B}(c_j, 3r) \quad (3)$$

Once Equation (3) holds, the set  $\{\overline{B}(c_j, 3r) \mid j \in J_T \wedge \text{intersects}_j\}$  is the desired covering, namely, the balls have sufficiently small radius, each of them intersects  $A$ , and their union covers  $A$  thanks to Equation (3) and the definition of  $\text{disjoint}_j$ , which means that we omit only balls that are disjoint from  $A$ .

It remains to prove that Equation (3) must hold in finite time. This will follow from Equation (2) when we show that for each  $j \in J$  the ball  $\overline{B}(c_j, r)$  is covered by some  $\overline{B}(c_k, 3r)$  such that  $\text{haveinfo}_k$  terminates. Note that the ball  $\overline{B}(c_j, r)$  is covered by  $\overline{B}(c_k, 3r)$  for all  $k \in J$  with  $\|j - k\| \leq 1$ , i.e., the “neighbouring” indices in addition to  $j$  itself.

Now, if  $\text{haveinfo}_j$  does not terminate, i.e., if both  $\text{empty}_j$  and  $\text{nonempty}_j$  do not terminate, the ball  $\overline{B}(c_j, 3r)$  is not disjoint from  $A$  but its interior is disjoint from  $A$ . This means that there is  $a \in A$  with  $\|c_j - a\| = 3r$  as illustrated in Figure 3.

■ **Figure 3**  $\overline{B}(c_j, r)$  covered by  $\overline{B}(c_k, 3r)$ ;  $n = 1, m = 3, r = 1/6, j = (-1, -1)$ .

Let us define the vector  $k$  component-wise as follows:

$$k_i = \begin{cases} j_i + 1 & a_i - (c_j)_i = 3r \\ j_i - 1 & a_i - (c_j)_i = -3r \\ j_i & |a_i - (c_j)_i| < 3r \end{cases} \quad (4)$$

Note that  $k$  is a “neighbour” of index  $j$ . Now,  $k \in J$  because if it was not, some component  $k_i$  would be outside the interval  $[-m, m]$ , which would mean that either  $a_i = 1 + 3r$  or  $a_i = -1 - 3r$ , which would contradict  $A \subseteq B(0, 1)$ .

## 59:16 Formalizing Hyperspaces for Extracting Efficient Exact Real Computation

Using the same three cases as in Equation (4), we get:

$$|a_i - (c_k)_i| = \begin{cases} |a_i - (c_j)_i - 1/m| = 3r - 1/m < 3r & k_i = j_i + 1 \\ |a_i - (c_j)_i + 1/m| = |-3r + 1/m| < 3r & k_i = j_i - 1 \\ |a_i - (c_j)_i| < 3r & k_i = j_i \end{cases} \quad (5)$$

In all three cases we have  $|(c_k)_i - a_i| < 3r$ . Over all  $i$ , we get  $a \in B(c_k, 3r)$ .

Finally,  $a \in B(c_k, r)$  implies that  $\text{nonempty}_k$  terminates, and therefore  $\overline{B}(c_j, r)$  is covered by  $\overline{B}(c_k, 3r)$  in Equation (3) as illustrated in Figure 3.

# Set Semantics for Asynchronous TeamLTL: Expressivity and Complexity

## Abstract

We introduce and develop a set-based semantics for asynchronous TeamLTL. We consider two canonical logics in this setting: the extensions of TeamLTL by the Boolean disjunction and by the Boolean negation. We relate the new semantics with the original semantics based on multisets and establish one of the first positive complexity theoretic results in the temporal team semantics setting. In particular we show that both logics enjoy normal forms that can be utilised to obtain results related to expressivity and complexity (decidability) of the new logics.

## 1 Introduction

Linear temporal logic (LTL) is one of the most prominent logics for the specification and verification of reactive and concurrent systems. The core idea in model checking, as introduced in 1977 by Amir Pnueli [22], is to specify the correctness of a program as a set of infinite sequences, called traces, which define the acceptable executions of the system. In LTL-model checking one is concerned with trace sets that are definable by an LTL-formula. Ordinary LTL and its progeny are well suited for specification and verification of *trace properties*. These are properties of systems that can be checked by going through all executions of the system in isolation. A canonical example here is *termination*; a system terminates if each run of the system terminates. However not all properties of interest are trace properties. Many properties that are of prime interest, e.g., in information flow security, require a richer framework. The term *hyperproperty* was coined by Clarkson and Schneider [3] to refer to properties which relate multiple execution traces. A canonical example is *bounded termination*; one cannot check whether a system terminates in bounded time by only checking traces in isolation. Checking hyperproperties is vital in information flow security where dependencies between secret inputs and publicly observable outputs of a system are considered potential security violations. Commonly known properties of that type are noninterference [24, 20] and observational determinism [30]. Hyperproperties are not limited to the area of information flow control; e.g., distributivity and other system properties like fault tolerance can be expressed as hyperproperties [5].

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

During the past decade, the need for being able to formally specify hyperproperties has led to the creation of families of new logics for this purpose, since LTL and other established temporal logics can only specify trace properties. The two main families of the new logics are the so-called *hyperlogics* and logics that adopt *team semantics*. In the former approach temporal logics such as LTL, computation tree logic (CTL), and quantified propositional temporal logic (QPTL) are extended with explicit trace and path quantification, resulting in logics like HyperLTL [2], HyperCTL\* [2], and HyperQPTL [23, 4]. The latter approach (which we adopt here) is to lift the semantics of temporal logics to sets of traces directly by adopting team semantics yielding logics such as TeamLTL [15, 7] and TeamCTL [14, 7].

Krebs et al. [15] introduced two versions of LTL with team semantics: a synchronous semantics and an asynchronous variant that differ on how the evolution of time is linked between computation traces when temporal operators are evaluated. In the synchronous semantics time proceeds in lock-step, while in the asynchronous variant time proceeds independently on each trace. For example the formula “F terminate” (here F denotes the future-operator and “terminate” is a proposition depicting that a trace has terminated) defines the hyperproperty “bounded termination” under synchronous semantics, while it expresses the trace property “termination” under asynchronous semantics. The elegant definition of bounded termination exemplifies one of the main distinguishing factors of team logics from hyperlogics; namely the ability to refer directly to unbounded number of traces. Each hyperlogic-formula has a fixed number of trace quantifiers that delineate the traces involved in the evaluation of the formula. Another distinguishing feature of team logics lies in their ability to enrich the logical language with novel atomic formulae for stating properties of teams. The most prominent of these are the *dependence atom*  $\text{dep}(\bar{x}, \bar{y})$  (stating that the values of the variables  $\bar{x}$  functionally determine the values of  $\bar{y}$ ) and *inclusion atom*  $\bar{x} \subseteq \bar{y}$  (expressing the inclusion dependency that all the values occurring for  $\bar{x}$  must also occur as a value for  $\bar{y}$ ).

As an example, let  $o_1, \dots, o_n$  be public observables and assume that  $c$  reveals confidential information. The atom  $(o_1, \dots, o_n, c) \subseteq (o_1, \dots, o_n, \neg c)$  expresses a form of non-inference by stating that an observer cannot infer the value of the confidential bit from the outputs.

While HyperLTL and other hyperlogics have been studied extensively, many of the basic properties of TeamLTL are still not well understood. Krebs et al. [15] showed that synchronous TeamLTL and HyperLTL are incomparable in expressivity and that the asynchronous variant collapses to LTL. Not much was known about the complexity aspects of TeamLTL until Lück [18] showed that the complexity of satisfiability and model checking of synchronous TeamLTL with Boolean negation  $\sim$  is equivalent to the decision problem of third-order arithmetic. Subsequently, Virtema et al. [29] embarked for a more fine-grained analysis of the complexity of synchronous TeamLTL and discovered a decidable syntactic fragment (the so-called *left-flat fragment*) and established that already a very weak access to the Boolean negation suffices for undecidability. They also showed that synchronous TeamLTL and its extensions can be translated to  $\text{HyperQPTL}^+$ , which is an extension of HyperLTL by (non-uniform) quantification of propositions. Kontinen and Sandström [12] defined translations between extensions of TeamLTL and the three-variable fragment of first-order team logic to utilize the better understanding of first-order team semantics. They also showed that any logic effectively residing between synchronous TeamLTL extended with the Boolean negation and second-order logic inherits the complexity properties of the extension of TeamLTL with the Boolean negation. Finally, Gutsfeld et al. [7] reimagined the setting of temporal team semantics to be able to model richer forms of (a)synchronicity by developing the notion of time-evaluation functions. In addition to reimagining the framework, they discovered

decidable logics which however relied on restraining time-evaluation functions to be either *k-context-bounded* or *k-synchronous*. It is worth noting that recently asynchronous hyperlogics have been considered also in several other articles (see, e.g., [8, 1]).

Almost all complexity theoretic results previously obtained for TeamLTL have been negative, and the few positive results have required drastic restrictions in syntax or semantics. In this article we take a fresh look at expressive extensions of asynchronous TeamLTL. Recent works on synchronous TeamLTL have revealed that quite modest extensions of synchronous TeamLTL are undecidable. Thus, our study of asynchronous TeamLTL partly stems from our desire to discover decidable but expressive logics for hyperproperties. Until now, all the papers on temporal team semantics have explicitly or implicitly adopted a semantics based on multisets of traces. In the team semantics literature, this often carries the name *strict semantics*, in contrast to *lax semantics* which is de-facto set-based semantics. In database theory, it is ubiquitous that tasks that are computationally easy under set based semantics become untractable in the multiset case. In the team semantics setting this can be already seen in the model checking problem of propositional inclusion logic  $PL(\subseteq)$  which is P-complete under lax semantics, but NP-complete under strict semantics [10]. Our new set-based framework offers a setting that drops the accuracy that accompanies adoption of multiset semantics in favour of better computational properties. Consider the following formula expressing a form of strong non-inference in parallel computation:  $G((o_1, \dots, o_n, c) \subseteq (o_1, \dots, o_n, \neg c))$ , where  $o_1, \dots, o_n$  are observable outputs and  $c$  is confidential. In the synchronous setting, the formula expresses that during a synchronous computation, at any given time, an observer cannot infer the value of the secret  $c$  from the outputs. In the asynchronous setting, the formula states a stronger property that the above property holds for all computations (not only synchronous). In the multiset setting the number of parallel computation nodes is fixed, while in the new lax semantics, we drop that restriction, and consider an undefined number of computation nodes. The condition is stronger in lax semantics; and intuitively easier to falsify, which makes model checking in practice easier.

**Our contribution.** We introduce and develop a set-based semantics for asynchronous TeamLTL, which we name *lax semantics* and write  $\text{TeamLTL}^l$ . We consider two canonical logics in this setting: the extensions of  $\text{TeamLTL}^l$  by the Boolean disjunction  $\text{TeamLTL}^l(\vee)$  and by the Boolean negation  $\text{TeamLTL}^l(\sim)$ . By developing the basic theory of lax asynchronous TeamLTL, we discover some fascinating connections between the strict and lax semantics. We discover that both of the logics enjoy normal forms that can be utilised to obtain expressivity and complexity results. Tables 1 and 2 summarise our results. For comparison, Table 3 summarises the known results on complexity of synchronous TeamLTL.

## 2 Preliminaries

Fix a set AP of *atomic propositions*. The set of formulae of LTL (over AP) is generated by the grammar:  $\varphi ::= p \mid \neg p \mid \varphi \vee \psi \mid \varphi \wedge \psi \mid \bigcirc \varphi \mid G \varphi \mid \varphi \text{U} \psi$ , where  $p \in \text{AP}$ . We adopt the convention that formulae are given in negation normal form, i.e.,  $\neg$  is allowed only in front of atomic propositions. Note that this is an expressively complete set of LTL-formulae. The logical constants  $\top, \perp$  and the operators F and W can be defined in the usual way:  $\perp := p \wedge \neg p$ ,  $\top := p \vee \neg p$ ,  $F \varphi := \top \text{U} \varphi$ , and  $\varphi \text{W} \psi := (\varphi \text{U} \psi) \vee G \varphi$ . Note also the equivalences  $\neg \bigcirc \varphi \equiv \bigcirc \neg \varphi$ ,  $\neg F \varphi \equiv G \neg \varphi$ , and  $\neg(\varphi \text{U} \psi) \equiv (\neg \varphi \text{W}(\neg \psi \wedge \neg \varphi))$ .

A *trace*  $t$  over AP is an infinite sequence from  $(2^{\text{AP}})^\omega$ . For a natural number  $i \in \mathbb{N}$ , we denote by  $t[i]$  the  $(i + 1)$ th letter of  $t$  and by  $t[i, \infty]$  the postfix  $(t[j])_{j \geq i}$  of  $t$ . Semantics of LTL is defined in the usual manner (see e.g., [21]). For example,  $t \models p$  iff  $p \in t[0]$  and  $t \models \bigcirc \varphi$  iff  $t[1, \infty] \models \varphi$ . The *truth value* of a formula  $\varphi$  on a trace  $t$  is denoted by  $\llbracket \varphi \rrbracket_t \in \{0, 1\}$ .

■ **Table 1** Expressivity hierarchy of the asynchronous logics considered in the paper. Logics with lax or strict semantics are here referred with the superscripts  $l$  and  $s$ , respectively. For the definitions of left flatness, quasi flatness, and left downward closure, we refer to Definitions 7 and 13. †: This follows since only  $\text{TeamLTL}^l(\otimes)$  is downward closed (cf. Theorem 8 and Definition 13). Theorem 8 implies that for  $\text{TeamLTL}(\sim)$ -formulae in quasi-flat form the strict and lax semantics coincide.

Next we present the so-called asynchronous team semantics for LTL introduced in [15]. In [15], the release operator was defined slightly erroneously; we fix the issue here by taking  $G$  as primitive and defining  $R$  using  $G$  and  $U$ . Informally, a multiset of traces  $T$  is a collection of traces with possible repetitions. Formally, we represent  $T$  as a set of pairs  $(i, t)$ , where  $i$  is an *index* (from some suitable large set) and  $t$  is a trace. We stipulate that the elements of a multiset have distinct indices. From now on, we will always omit the index and write  $t$  instead of  $(i, t)$ . For multisets  $T$  and  $S$ ,  $T \uplus S$  denotes the disjoint union of  $T$  and  $S$  (obtained by stipulating that traces in  $S$  and  $T$  have disjoint sets of indices). Note that all the functions  $f$  with domain  $T$  are actually of the form  $f((i, t))$  and may map different copies of the trace  $t$  differently. A *team* (*multiteam*, resp.) is a set (multiset, resp.) of traces. If  $f: T \rightarrow \mathbb{N}$  is a function, we define the updated team  $T[f, \infty] := \{t[f(t), \infty] \mid t \in T\}$ , where  $f$  determines for each trace a point in time it updates to. For functions  $f$  and  $f'$  as above, we write  $f' < f$ , if  $f'(t) < f(t)$  for all  $t \in T$ . The underlying team support( $T$ ) :=  $\{t \mid (i, t) \in T\}$  of a multiteam  $T$  is called the *support* of  $T$ .

► **Definition 1** (Team Semantics for LTL). *Let  $T$  be a multiteam, and  $\varphi$  and  $\psi$  LTL-formulae. The asynchronous team semantics of TeamLTL is defined as follows.*

$$\begin{array}{ll}
T \models l & \Leftrightarrow t \models l \text{ for all } t \in T, \text{ where } l \in \{p, \neg p \mid p \in \text{AP}\} \text{ is a literal} \\
T \models \varphi \wedge \psi & \Leftrightarrow T \models \varphi \text{ and } T \models \psi \\
T \models \varphi \vee \psi & \Leftrightarrow \exists T_1, T_2 \text{ s.t. } T_1 \uplus T_2 = T \text{ and } T_1 \models \varphi \text{ and } T_2 \models \psi \\
T \models \bigcirc \varphi & \Leftrightarrow T[1, \infty] \models \varphi, \text{ where } 1 \text{ is the constant function } t \mapsto 1 \\
T \models G\varphi & \Leftrightarrow \forall f: T \rightarrow \mathbb{N} \quad T[f, \infty] \models \varphi \\
T \models \varphi U \psi & \Leftrightarrow \exists f: T \rightarrow \mathbb{N} \quad T[f, \infty] \models \psi \text{ and } \forall f' < f: T'[f', \infty] \models \varphi, \\
& \text{where } T' := \{t \in T \mid f(t) \neq 0\}
\end{array}$$

The synchronous variant of the semantics is obtained by allowing  $f$  to range only over constant functions. We take the asynchronous semantics as the standard semantics and write TeamLTL for asynchronous TeamLTL.

We also consider the *Boolean disjunction*  $\otimes$  and *Boolean negation*  $\sim$  interpreted as usual:  $T \models \varphi \otimes \psi$  iff  $(T \models \varphi \text{ or } T \models \psi)$ , and  $T \models \sim \varphi$  iff  $T \not\models \varphi$ .

Next we define some important semantic properties of formulae studied in the literature. A logic has one of the properties if every formula of the logic has the property. It is easy to check that TeamLTL has all the properties listed [15] whereas its extension with the Boolean disjunction has all but flatness and the extension with Boolean negation has none.

**(Downward closure)** If  $T \models \varphi$  and  $S \subseteq T$ , then  $S \models \varphi$ .

**(Empty team property)**  $\emptyset \models \varphi$ .

**(Flatness)**  $T \models \varphi$  iff  $\{t\} \models \varphi$  for all  $t \in T$ .

**(Singleton equivalence)**  $\{t\} \models \varphi$  iff  $t \models \varphi$ .

We will now justify our choice of semantics. The semantic rules for literals, conjunction, and disjunction are the standard ones in team semantics, and which have been motivated numerous times in the literature [26]. Two important properties for the logic to have, for it to be a conservative extension of LTL, are flatness and singleton equivalence. These properties also motivated the original definition of asynchronous TeamLTL [15]. The given semantics for  $\bigcirc$  is the only possible one that satisfies flatness. The same is true for  $F$  (i.e.,  $\top U \varphi$ ) and  $G$ ; moreover the semantics clearly capture the intuitive meanings of asynchronously in the future and asynchronously globally, respectively. The given semantics for  $U$  preserves flatness

and singleton equivalence, and adequately captures the intuitive meaning of asynchronous until. The framework of asynchronous TeamLTL then allows us to define different variants of the familiar temporal operators. E.g.,  $\varphi W_1 \psi := G \varphi \vee \varphi U \psi$  and  $\varphi W_2 \psi := G \varphi \otimes \varphi U \psi$  define different variants of *weak until*; the first of which is flat, while the second is not.

$$\begin{aligned} T \models \varphi W_1 \psi & \Leftrightarrow \exists T_1, T_2 \text{ s.t. } T_1 \uplus T_2 = T, T_1 \models G \varphi \text{ and } T_2 \models \varphi U \psi \\ T \models \varphi W_2 \psi & \Leftrightarrow T \models G \varphi \text{ or } T \models \varphi U \psi \end{aligned}$$

Similarly  $\varphi R_1 \psi := \psi U((\psi \wedge \varphi) \vee G \psi)$  and  $\varphi R_2 \psi := \psi U((\psi \wedge \varphi) \otimes G \psi)$  give rise to different variants of *release*. Moreover, with  $\sim$  one can define additional dual operators.

A defining feature of team semantics is the ability to enrich logics with novel atomic statements describing properties of teams in a modular fashion. For example, *dependence atoms*  $\text{dep}(\varphi_1, \dots, \varphi_n, \psi)$  and *inclusion atoms*  $\varphi_1, \dots, \varphi_n \subseteq \psi_1, \dots, \psi_n$ , with  $\varphi_1, \dots, \varphi_n, \psi, \psi_1, \dots, \psi_n$  being LTL-formulae, have been studied extensively in first-order and modal team semantics. The dependence atom states that the truth value of  $\psi$  is functionally determined by that of  $\varphi_1, \dots, \varphi_n$  whereas the inclusion atom states that each value combination of  $\varphi_1, \dots, \varphi_n$  must also occur as a value combination for  $\psi_1, \dots, \psi_n$ . Formally:

$$T \models \text{dep}(\varphi_1, \dots, \varphi_n, \psi) \text{ iff } \forall t, t' \in T : \left( \bigwedge_{1 \leq j \leq n} \llbracket \varphi_j \rrbracket_t = \llbracket \varphi_j \rrbracket_{t'} \right) \Rightarrow \llbracket \psi \rrbracket_t = \llbracket \psi \rrbracket_{t'}$$

$$T \models \varphi_1, \dots, \varphi_n \subseteq \psi_1, \dots, \psi_n \text{ iff } \forall t \in T \exists t' \in T : \bigwedge_{1 \leq j \leq n} \llbracket \varphi_j \rrbracket_t = \llbracket \psi_j \rrbracket_{t'}$$

Consider the following exemplary formula:  $G \text{dep}(i_1, i_2, o) \vee G \text{dep}(i_2, i_3, o)$ . The formula states that the executions of the system can be decomposed into two parts; in the first part, the output  $o$  is determined by the inputs  $i_1$  and  $i_2$ , and in the second part,  $o$  is determined by the inputs  $i_2$  and  $i_3$ .

If  $\mathcal{A}$  is a collection of atoms and connectives,  $\text{TeamLTL}(\mathcal{A})$  denotes the extension of TeamLTL with the atoms and connectives in  $\mathcal{A}$ . It is straightforward to see (in analogy to the modal team semantics setting [11]) that any dependency such as the ones above is determined by a finite set of  $n$ -ary Boolean relations. Let  $B$  be a set of  $n$ -ary Boolean relations. We define the property  $[\varphi_1, \dots, \varphi_n]_B$  for an  $n$ -tuple  $(\varphi_1, \dots, \varphi_n)$  of LTL-formulae:

$$T \models [\varphi_1, \dots, \varphi_n]_B \text{ iff } \{(\llbracket \varphi_1 \rrbracket_t, \dots, \llbracket \varphi_n \rrbracket_t) \mid t \in T\} \in B.$$

Expressions of the form  $[\varphi_1, \dots, \varphi_n]_B$  are *generalised atoms*. It was shown in [29] that, in the synchronous setting,  $\text{TeamLTL}(\sim)$  is expressively complete with respect to all generalised atoms, whereas the extension of  $\text{TeamLTL}(\otimes)$  with the so-called *flattening operator* can express any downwards closed generalised atoms. These results readily extend to the asynchronous setting. Moreover the flattening operator renders itself unnecessary due to flatness of asynchronous TeamLTL. The results imply, e.g, that the (downwards closed) dependence atoms can be expressed in both of the logics  $\text{TeamLTL}(\sim)$  and  $\text{TeamLTL}(\otimes)$ , and inclusion atoms in turn are expressible in  $\text{TeamLTL}(\sim)$ . The proof of the following theorem is essentially the same as the proof of [28, Proposition 17]. Below  $L \equiv L'$  denotes the equiexpressivity of the logics  $L$  and  $L'$ .

► **Theorem 2.** *Let  $\mathcal{A}, \mathcal{D}$  be the sets of all generalised atoms, and all downward closed generalised atoms. Then  $\text{TeamLTL}(\mathcal{D}, \otimes) \equiv \text{TeamLTL}(\otimes)$  and  $\text{TeamLTL}(\mathcal{A}, \sim) \equiv \text{TeamLTL}(\sim)$ .*

### 3 Set-based semantics for TeamLTL

Next we define a relaxed version of the asynchronous semantics. We call it *lax* semantics as it corresponds to the so-called lax semantics of first-order team semantics (see e.g., [6]). From now on we refer to the semantics of Definition 1 as strict semantics. The possibility of considering lax semantics for TeamLTL was suggested by Lück already in [19] but the full definition was not given. Intuitively, lax semantics can always be obtained from a strict one by checking what strict semantics would yield if multiteams were enriched with unbounded many copies of each of its traces. One of the defining features of lax semantics is that it is unable to distinguish multiplicities, which is formalised by Proposition 4 below.

We need some notation for the new definition. We write  $\mathcal{P}(\mathbb{N})^+$  to denote  $\mathcal{P}(\mathbb{N}) \setminus \{\emptyset\}$ . For a team  $T$  and function  $f: T \rightarrow \mathcal{P}(\mathbb{N})^+$ , we set  $T[f, \infty] := \{t[s, \infty] \mid t \in T, s \in f(t)\}$ . For  $T' \subseteq T$ ,  $f: T \rightarrow \mathcal{P}(\mathbb{N})^+$ , and  $f': T' \rightarrow \mathcal{P}(\mathbb{N})^+$ , we define that  $f' < f$  if and only if

$$\forall t \in T': \min(f'(t)) \leq \min(f(t)) \text{ and, if } \max(f(t)) \text{ exists, } \max(f'(t)) < \max(f(t)).$$

► **Definition 3** (TeamLTL<sup>l</sup>). *Let  $T$  be a team, and  $\varphi$  and  $\psi$  TeamLTL-formulae. The lax semantics is defined as follows. We only list the cases that differ from the strict semantics.*

$$\begin{aligned} T \models^l \varphi \vee \psi &\Leftrightarrow \exists T_1, T_2 \text{ s.t. } T_1 \cup T_2 = T \text{ and } T_1 \models \varphi \text{ and } T_2 \models \psi \\ T \models^l \mathbf{G} \varphi &\Leftrightarrow \forall f: T \rightarrow \mathcal{P}(\mathbb{N})^+ \text{ it holds that } T[f, \infty] \models^l \varphi \\ T \models^l \varphi \cup \psi &\Leftrightarrow \exists f: T \rightarrow \mathcal{P}(\mathbb{N})^+ \text{ such that } T[f, \infty] \models^l \psi \text{ and} \\ &\quad \forall f': T' \rightarrow \mathcal{P}(\mathbb{N})^+ \text{ s.t. } f' < f, \text{ it holds that } T'[f', \infty] \models^l \varphi \text{ or } T' = \emptyset, \\ &\quad \text{where } T' := \{t \in T \mid \max(f(t)) \neq 0\} \end{aligned}$$

In the context we will be considering in this article, the subformulae  $\varphi$  in the definition of the until operator  $\mathbf{U}$  always have the empty team property and thus we disregard the possibility that the team  $T'$  is empty in our proofs, as that case follows from the empty team property.

The above set-based semantics can also be viewed in terms of multisets. In that case functions  $f$  are quantified uniformly, i.e. we restrict our consideration to functions where  $f(i, t) = f(j, t)$ . Furthermore, the semantics for disjunction is defined in a way that omits references to multiplicities. In order to relate our new logics to the old multiteam based ones, we extend the lax semantics to multiteams  $T$  by stipulating that  $T \models^l \varphi$  iff  $\text{support}(T) \models^l \varphi$ .

The following proposition shows that TeamLTL<sup>l</sup>( $\sim$ ) satisfies the so-called *locality* property, see full version of this article [13] for the proof. For a trace  $t$  over  $\text{AP}'$  and  $\text{AP} \subseteq \text{AP}'$ , the *reduction* of  $t$  to  $\text{AP}$ ,  $t_{\uparrow \text{AP}}$ , is a sequence from  $(2^{\text{AP}})^\omega$  such that  $p \in t[i]$  if and only if  $p \in t_{\uparrow \text{AP}}[i]$ , for all  $p \in \text{AP}$  and  $i \in \mathbb{N}$ . For a team  $T$  over  $\text{AP}'$  we define the *reduction* of  $T$  to  $\text{AP}$  by  $T_{\uparrow \text{AP}} = \{t_{\uparrow \text{AP}} \mid t \in T\}$ .

► **Proposition 4.** *Let  $T$  be a team and  $\varphi$  a TeamLTL<sup>l</sup>( $\sim$ )-formula with variables in  $\text{AP}$ . Now  $T \models^l \varphi$  iff  $T_{\uparrow \text{AP}} \models^l \varphi$ .*

The next theorem displays that lax semantics enjoys the same fundamental properties as its strict counterpart. The proof via a straightforward induction, see full version of this article [13] for details.

► **Theorem 5.** *TeamLTL<sup>l</sup> satisfies downward closure, empty team property, singleton equivalence, and flatness.*

The following example establishes that the new lax semantics differs from the strict semantics, and that in the old semantics multiplicities matter. Moreover, we obtain TeamLTL<sup>l</sup> < TeamLTL<sup>l</sup>( $\otimes$ ) by showing that the latter is not flat.

► **Example 6.** Let  $\varphi$  be the formula  $G(p \otimes q)$ ,  $T_1 := \{t\}$  and  $T_2 := \{(1, t), (2, t)\}$ , where  $t := \{p\}\{q\}^\omega$ . It is easy to check that  $T_1 \models \varphi$  but  $T_1 \not\models^l \varphi$  (which is witnessed by  $T[f, \infty] \not\models^l p \otimes q$  for  $f(t) := \{0, 1\}$ ). Likewise  $T_2 \not\models \varphi$ . Moreover  $\{s_i\} \models^l \varphi$ , for  $i \in \{1, 2\}$ , but  $\{s_1, s_2\} \not\models^l \varphi$ , where  $s_1 := \{p\}^\omega$  and  $s_2 := \{q\}^\omega$ .

We will also consider the following fragments of  $\text{TeamLTL}(\otimes)$  and  $\text{TeamLTL}(\sim)$ .

► **Definition 7.** A formula  $\varphi$  of  $\text{TeamLTL}(\otimes)$  is called *left-flat*, if in all of its subformulae of the form  $G\psi$  and  $\psi \cup \theta$ , the subformula  $\psi$  is an LTL-formula. A formula  $\varphi$  of  $\text{TeamLTL}(\sim, \otimes)$  is called *left-downward closed*, if in all of its subformulae of the form  $G\psi$  and  $\psi \cup \theta$ , the subformula  $\psi$  is an  $\text{TeamLTL}(\otimes)$ -formula.

We will later show that the above syntactic restriction for flatness could be replaced by a semantic restriction (see Corollary 11). The proof of the following theorem is in the full version of this article [13].

► **Theorem 8.** For all  $\varphi \in \text{TeamLTL}^l(\otimes)$  the following two claims hold:

1.  $\varphi$  is downward closed and has the empty team property, and
2. if  $\varphi$  is left-flat, then  $T \models \varphi$  iff  $\text{support}(T) \models^l \varphi$  for all multiteams  $T$ .

The restriction to left-flat formulae in case (2) above is necessary by Example 6.

## 4 Normal Forms for TeamLTL with Boolean Disjunction and Negation

In this section we develop normal forms for our logics, which we then utilise to obtain strong expressivity and complexity results.

► **Definition 9.** A formula  $\varphi$  is in  $\otimes$ -disjunctive normal form if it is of the form  $\bigvee_{i \in I} \alpha_i$ , where  $\alpha_i$  are LTL-formulae.

Every formula of  $\text{TeamLTL}^l(\otimes)$  can be transformed into an equivalent  $\otimes$ -disjunctive normal form. This result is similar to the one proved in [27] for team-based modal logic  $\text{ML}(\otimes)$ . In the following  $|\varphi|$  denotes the length of the formula  $\varphi$ .

► **Theorem 10.** Every  $\varphi \in \text{TeamLTL}^l(\otimes)$  is logically equivalent to a formula  $\varphi^* = \bigvee_{i \in I} \alpha_i$  in  $\otimes$ -disjunctive normal form, where  $|\alpha_i| \leq |\varphi|$  and  $|I| = 2^k$ , where  $k$  is the number of  $\otimes$  in  $\varphi$ .

**Proof.** The proof proceeds by induction on the structure of formulae. Note that atomic formulae are already in the normal form and that the case for  $\otimes$  is trivial. The remaining cases are defined as follows:

$$\begin{aligned} (\psi \wedge \theta)^* &:= \bigvee_{i \in I, j \in J} (\alpha_i^\psi \wedge \alpha_j^\theta) & (\psi \vee \theta)^* &:= \bigvee_{i \in I, j \in J} (\alpha_i^\psi \vee \alpha_j^\theta) \\ (\bigcirc \psi)^* &:= \bigvee_{i \in I} \bigcirc \alpha_i^\psi & (G\psi)^* &:= \bigvee_{i \in I} G \alpha_i^\psi \\ (\psi \cup \theta)^* &:= \bigvee_{i \in I, j \in J} (\alpha_i^\psi \cup \alpha_j^\theta). \end{aligned}$$

where  $\alpha_i^\psi$  and  $\alpha_j^\theta$  are the flat formulae in the disjunctive normal forms of  $\psi$  and  $\theta$  respectively, and  $I$  and  $J$  are the respective index sets.

Suppose  $\varphi = \psi \wedge \theta$  and that  $\psi \equiv \bigvee_{i \in I} \alpha_i^\psi$  and  $\theta \equiv \bigvee_{j \in J} \alpha_j^\theta$  (induction hypothesis). Now  $T \models^l \varphi$  if and only if  $T \models^l \psi$  and  $T \models^l \theta$ . The latter holds, if and only if  $T \models^l \alpha_k^\psi$  and  $T \models^l \alpha_{k'}^\theta$ , for some  $k$  and  $k'$ . This can be equivalently expressed as  $T \models^l \bigvee_{i, j} (\alpha_i^\psi \wedge \alpha_j^\theta)$ , i.e.  $T \models^l \varphi^*$ .

Suppose  $\varphi = \psi \vee \theta$  and that  $\psi \equiv \bigvee_{i \in I} \alpha_i^\psi$  and  $\theta \equiv \bigvee_{j \in J} \alpha_j^\theta$ . By definition  $T \models^l \varphi$  if and only if there exists  $T' \cup T'' = T$  such that  $T' \models^l \psi$  and  $T'' \models^l \theta$ . By the induction hypothesis the latter is equivalent with  $T' \models^l \bigvee_{i \in I} \alpha_i^\psi$  and  $T'' \models^l \bigvee_{j \in J} \alpha_j^\theta$ . By definition this holds if and only if there are  $k'$  and  $k''$  such that  $T' \models^l \alpha_{k'}^\psi$  and  $T'' \models^l \alpha_{k''}^\theta$ , which is equivalent with  $T \models^l \alpha_{k'}^\psi \vee \alpha_{k''}^\theta$ , for some  $k'$  and  $k''$ , by definition. Equivalently then  $T \models^l \bigvee_{i \in I, j \in J} (\alpha_i^\psi \vee \alpha_j^\theta)$ .

Suppose  $\varphi = \bigcirc \psi$  and that  $\psi \equiv \bigvee_{i \in I} \alpha_i^\psi$ . By definition  $T \models^l \varphi$  is equivalent with  $T[1, \infty] \models^l \psi$ . By the induction hypothesis the latter holds if and only if  $T[1, \infty] \models^l \bigvee_{i \in I} \alpha_i^\psi$ , which by definition is equivalent with  $T[1, \infty] \models^l \alpha_k^\psi$  for some  $k \in I$ . The latter holds if and only if  $T \models^l \bigcirc \alpha_k^\psi$  for some  $k \in I$ , which is equivalent with  $T \models^l \bigvee_{i \in I} \bigcirc \alpha_i^\psi$ .

Suppose  $\varphi = \mathbf{G} \psi$  and that  $\psi \equiv \bigvee_{i \in I} \alpha_i^\psi$ . Suppose that  $T \models^l \varphi$ . By definition for all functions  $f: T \rightarrow \mathcal{P}(\mathbb{N})^+$  it holds that  $T[f, \infty] \models^l \psi$ . By the induction hypothesis  $T[f, \infty] \models^l \bigvee_{i \in I} \alpha_i^\psi$  for all  $f$ . Especially this holds for the total function defined for every  $t \in T$  by  $f_{max}(t) := \mathbb{N}$ . Thus  $T[f_{max}, \infty] \models^l \alpha_k^\psi$  for some  $k$ . By downward closure it holds that  $T[f', \infty] \models^l \alpha_k^\psi$  for all  $f': T \rightarrow \mathcal{P}(\mathbb{N})^+$ . Hence  $T \models^l \mathbf{G} \alpha_k^\psi$ , and thus  $T \models^l \bigvee_{i \in I} \mathbf{G} \alpha_i^\psi$ . The other direction is analogous.

Suppose  $\varphi = \psi \mathbf{U} \theta$  and that  $\psi \equiv \bigvee_{i \in I} \alpha_i^\psi$  and  $\theta \equiv \bigvee_{j \in J} \alpha_j^\theta$ . Suppose  $T \models^l \varphi$ . By definition there exists a function  $f: T \rightarrow \mathcal{P}(\mathbb{N})^+$  such that  $T[f, \infty] \models^l \theta$  and for all functions  $f': T' \rightarrow \mathcal{P}(\mathbb{N})^+$  such that  $f' < f$ ,  $T'[f', \infty] \models^l \psi$ , where  $T' := \{t \in T \mid f(t) \neq 0\}$ . Hence by the induction hypothesis  $T[f, \infty] \models^l \bigvee_{j \in J} \alpha_j^\theta$ , which is equivalent with  $T[f, \infty] \models^l \alpha_k^\theta$  for some  $k \in J$ , and, for the function  $f_{max}(t) := \{n \in \mathbb{N} \mid n < m, \text{ for some } m \in f(t)\}$  (which is well-defined, as  $f(t)$  is non-empty for  $t \in T'$ ), it holds that  $T[f_{max}, \infty] \models^l \bigvee_{i \in I} \alpha_i^\psi$ , which in turn is equivalent with  $T[f_{max}, \infty] \models^l \alpha_{k'}^\psi$  for some  $k' \in I$ . By downward closure the latter holds for all intermediary functions, and thus  $T \models^l \alpha_{k'}^\psi \mathbf{U} \alpha_k^\theta$  and finally  $T \models^l \bigvee_{i \in I, j \in J} (\alpha_i^\psi \mathbf{U} \alpha_j^\theta)$  as wanted. The converse is analogous.

For showing the size estimates stated in the theorem, it suffices to note that our translation to  $\bigcirc$ -disjunctive normal form can be equivalently stated:  $\varphi \equiv \bigvee_{i \in I} \alpha_i^\psi = \bigvee_{f \in F} \varphi^f$ , where  $F$  is the set of all selection functions  $f$  that select, separately for each occurrence, either the left disjunct  $\psi$  or the right disjunct  $\theta$  of each subformula of the form  $\psi \bigcirc \theta$  of  $\varphi$ , and  $\varphi^f$  denotes the formula obtained from  $\varphi$  by substituting each occurrence of a subformula of type  $(\psi \bigcirc \theta)$  by  $f(\psi \bigcirc \theta)$ . The size estimates follow immediately from this observation.  $\blacktriangleleft$

Proofs for the following two corollaries can be found in the full version of this article [13].

► **Corollary 11.** *For every flat TeamLTL<sup>l</sup>( $\bigcirc$ )-formula there exists an equivalent TeamLTL<sup>l</sup>-formula.*

► **Corollary 12.**  $\text{TeamLTL}^l(\bigcirc) < \text{TeamLTL}(\bigcirc)$ .

A normal form, similar to the one in Theorem 10, can also be obtained for TeamLTL( $\sim$ ). However, since the extension is not downward closed, it only holds for a specific fragment of the logic. The following normal form has been introduced and used in [17, 16] to analyse the complexity of modal team logic and FO<sup>2</sup> in the team semantics context. Below  $\varphi^d$  denotes a formula obtained by transforming  $\neg \varphi$  into negation normal form in the standard way in LTL.

► **Definition 13.** *A formula  $\varphi$  is quasi-flat if  $\varphi$  is of the form:  $\bigvee_{i \in I} (\alpha_i \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j})$ , where  $\alpha_i$  and  $\beta_{i,j}$  are LTL-formulae, and  $\exists \beta_{i,j}$  is an abbreviation for the formula  $\sim \beta_{i,j}^d$ .*

Note that, for LTL-formulae  $\alpha$  and  $\beta$ , we have  $T \models^l \alpha$  if and only if  $t \models \alpha$ , for all  $t \in T$ . Moreover  $T \models^l \exists \beta$ , if and only if there exists some trace  $t \in T$  such that  $t \models \beta$ .

► **Theorem 14.** *Every left-downward closed formula  $\varphi \in \text{TeamLTL}^l(\sim, \otimes)$  is logically equivalent to a quasi-flat formula  $\varphi^*$ .*

**Proof.** Proof by induction over the structure of  $\varphi$ . Atoms are flat, and hence are in the normal form. The translations and the proofs of correctness for the cases of conjunction, disjunction, and Boolean negation are analogous to the simpler modal framework of [17, 16].

Suppose  $\varphi = \psi \wedge \theta$  and assume that  $\psi$  is equivalent to  $\bigotimes_{i \in I} (\alpha_i^\psi \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j}^\psi)$  and  $\theta$  to  $\bigotimes_{i \in I'} (\alpha_i^\theta \wedge \bigwedge_{j \in J'_i} \exists \beta_{i,j}^\theta)$ . By the distributive laws of conjunction and disjunction,  $\varphi$  is clearly equivalent to

$$\bigotimes_{i \in I, k \in I'} (\alpha_i^\psi \wedge \alpha_k^\theta \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j}^\psi \wedge \bigwedge_{j \in J'_k} \exists \beta_{k,j}^\theta).$$

Suppose  $\varphi = \psi \vee \theta$ . By the induction hypothesis and an argument analogous to the disjunction case of the proof of Theorem 10,  $\varphi$  is equivalent to

$$\bigotimes_{i \in I, k \in I'} ((\alpha_i^\psi \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j}^\psi) \vee (\alpha_k^\theta \wedge \bigwedge_{j \in J'_k} \exists \beta_{k,j}^\theta)). \quad (1)$$

The above formula expresses that  $T$  can be split into two parts:  $T_1$  in which each trace satisfies  $\alpha_i$  and the subformulae  $\beta_{i,j}$  are satisfied by some traces, and  $T_2$  in which each trace satisfies  $\alpha_k$  and the subformulae  $\beta_{k,j}$  are satisfied by some traces. But this is equivalent to saying that  $T$  can be split into two parts:  $T_1$  in which each trace satisfies  $\alpha_i$ , and  $T_2$  in which each trace satisfies  $\alpha_k$ ; and the subformulae  $\alpha_i \wedge \beta_{i,j}$  and  $\alpha_k \wedge \beta_{k,j}$  are satisfied by some traces in  $T$ , and thus the formula (1) is equivalent with

$$\bigotimes_{i \in I, k \in I'} ((\alpha_i^\psi \vee \alpha_k^\theta) \wedge \bigwedge_{j \in J_i} \exists (\alpha_i^\psi \wedge \beta_{i,j}^\psi) \wedge \bigwedge_{j \in J'_k} \exists (\alpha_k^\theta \wedge \beta_{k,j}^\theta))$$

that is in the normal form.

Suppose  $\varphi = \sim \psi$  and assume that  $\psi$  is equivalent to  $\bigotimes_{i \in I} (\alpha_i \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j})$ . Now  $\varphi$  is clearly equivalent to  $\bigwedge_{i \in I} (\exists \alpha_i^d \otimes \bigotimes_{j \in J_i} \beta_{i,j}^d)$ . This formula can be expanded back to the normal form with exponential blow-up using the distributivity law of propositional logic.

Suppose  $\varphi = \bigcirc \psi$  and assume that  $\psi$  is equivalent to  $\bigotimes_{i \in I} (\alpha_i \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j})$ . It is now easy to check that  $\varphi$  is equivalent to  $\bigotimes_{i \in I} (\bigcirc \alpha_i \wedge \bigwedge_{j \in J_i} \exists \bigcirc \beta_{i,j})$ .

Suppose  $\varphi = \mathbf{G} \psi$ . Since  $\varphi$  is left-downward closed,  $\psi$  is equivalent with a formula of the form  $\bigotimes_i \alpha_i$ , which can be transformed to the normal form by Theorem 10.

Suppose  $\varphi = \psi \mathbf{U} \theta$ . By assumption  $\varphi$  is left-downward closed hence  $\psi$  is equivalent with a formula of the form  $\bigotimes_{i \in I} \alpha_i^\psi$  (by the previous theorem) and  $\theta$  is equivalent to  $\bigotimes_{k \in I'} (\alpha_k^\theta \wedge \bigwedge_{j \in J_k} \exists \beta_{k,j}^\theta)$ . Now using the fact that  $\psi$  is downward closed, it is easy to see that  $\varphi$  is logically equivalent with the formula:

$$\bigotimes_{i \in I, k \in I'} (\alpha_i^\psi \mathbf{U} (\alpha_k^\theta \wedge \bigwedge_{j \in J_k} \exists \beta_{k,j}^\theta)). \quad (2)$$

It now suffices to show that the disjuncts (for any  $i \in I, k \in I'$ ) of (2) can be equivalently expressed as:

$$(\alpha_i^\psi \mathbf{U} \alpha_k^\theta \wedge \bigwedge_{j \in J_k} \exists (\alpha_i^\psi \mathbf{U} (\alpha_k^\theta \wedge \beta_{k,j}^\theta))). \quad (3)$$

We will show the logical implication from (3) to (2). Assume

$$T \models^l (\alpha_i^\psi \mathbf{U} \alpha_k^\theta \wedge \bigwedge_{j \in J_k} \exists (\alpha_i^\psi \mathbf{U} (\alpha_k^\theta \wedge \beta_{k,j}^\theta))).$$

Let  $f$  be such that  $T[f, \infty] \models^l \alpha_k^\theta$  and that  $T[g, \infty] \models^l \alpha_i^\psi$ , for all  $g < f$ . In order to show

$$T \models^l \alpha_i^\psi \text{U}(\alpha_k^\theta \wedge \bigwedge_{j \in J_k} \exists \beta_{k,j}^\psi), \quad (4)$$

we need to make sure that traces witnessing the truth of the formulae  $\exists \beta_{k,j}^\psi$  can be found in  $T[f, \infty]$ . Here we can use the assumption that  $T \models^l \bigwedge_{j \in J_k} \exists(\alpha_i^\psi \text{U}(\alpha_k^\theta \wedge \beta_{k,j}^\psi))$  implying that for each  $j \in J_k$  there exists  $t_j \in T$  such that  $t_j \models \alpha_i^\psi \text{U}(\alpha_k^\theta \wedge \beta_{k,j}^\psi)$ . Let now  $n_j$  be such that  $t_j[n_j, \infty] \models \alpha_k^\theta \wedge \beta_{k,j}^\psi$  and that  $t_j[l, \infty] \models \alpha_i^\psi$  for all  $l < n_j$ . Now by the flatness of the formulae  $\alpha_i^\psi$ ,  $\alpha_k^\theta$ , and  $\beta_{k,j}^\psi$ , the function  $f'$  defined by

$$f'(t) := \begin{cases} f(t) \cup \{t_j[n_j, \infty]\} & \text{if } t = t_j, \text{ for some } j \in J_k \\ f(t) & \text{otherwise} \end{cases}$$

witnesses (4). The converse is proved analogously.  $\blacktriangleleft$

The following example indicates that the restriction to left-downward closed formulae is necessary for the proof to work in the above theorem. An alternate proof that does not require the restriction to left-downward closed formulae may still exist.

► **Example 15.** Let  $\varphi$  be the formula  $\text{G}(\exists p_1 \otimes \exists p_2)$  and  $T := \{t\}$ , where  $t := (\{p_1\}\{p_2\})^\omega$ . It is now easy to check that  $T \models^l \varphi$  but  $T \not\models^l \text{G} \exists p_i$  for  $i \in \{1, 2\}$ .

## 5 Computational Properties

In this section we analyse the computational properties of the logics studied in the previous section. We focus on the complexity of the model checking and satisfiability problems.

For the model checking problem one has to determine whether a team of traces generated by a given finite Kripke structure satisfies a given formula. We consider Kripke structures of the form  $K := (W, R, \eta, w_0)$ , where  $W$  is a finite set of states,  $R \subseteq W^2$  a left-total transition relation,  $\eta: W \rightarrow 2^{\text{AP}}$  a labelling function, and  $w_0 \in W$  an initial state of  $W$ . A path  $\sigma$  through  $K$  is an infinite sequence  $\sigma \in W^\omega$  such that  $\sigma[0] := w_0$  and  $(\sigma[i], \sigma[i+1]) \in R$  for every  $i \geq 0$ . The *trace of  $\sigma$*  is defined as  $t(\sigma) := \eta(\sigma[0])\eta(\sigma[1]) \cdots \in (2^{\text{AP}})^\omega$ . A Kripke structure  $K$  then *generates* the trace set  $\text{Traces}(K) := \{t(\sigma) \mid \sigma \text{ is a path through } K\}$ .

► **Definition 16.** *The model checking problem of a logic  $\mathcal{L}$  is the following decision problem: Given a formula  $\varphi \in \mathcal{L}$  and a Kripke structure  $K$  over AP, determine whether  $\text{Traces}(K) \models \varphi$ . The (countable) satisfiability problem of a logic  $\mathcal{L}$  is the following decision problem: Given a formula  $\varphi \in \mathcal{L}$ , determine whether  $T \models \varphi$  for some (countable)  $T \neq \emptyset$ .*

Below we will use the fact that the model checking and satisfiability problems of LTL are PSPACE-complete [25]. Furthermore, we use the facts that the satisfiability problem of propositional team logic  $\text{PL}(\sim)$  is  $\text{ATIME-ALT}(\text{exp}, \text{poly})$ -complete [9], and that the complexity of modal team logic is complete for the class  $\text{TOWER}(\text{poly}) := \text{TIME}(\text{exp}_{n \circ (1)}(1))$ , where  $\text{exp}_0(1) := 1$  and  $\text{exp}_{k+1}(1) := 2^{\text{exp}_k(1)}$  [17, 16].

► **Theorem 17.**

1. *The model checking and satisfiability problems of  $\text{TeamLTL}^l(\otimes)$  are PSPACE-complete.*
2. *The model checking and satisfiability problems of the left-flat fragment of  $\text{TeamLTL}(\otimes)$  are PSPACE-complete.*

3. The model checking problem of the left-downward closed fragment of  $\text{TeamLTL}^l(\sim, \otimes)$  is PSPACE-hard and it is contained in  $\text{TOWER}(\text{poly})$ .
4. The satisfiability problem of the left-downward closed fragment of  $\text{TeamLTL}^l(\sim, \otimes)$  is ATIME-ALT( $\text{exp}, \text{poly}$ )-hard and it is contained in  $\text{TOWER}(\text{poly})$ .

**Proof.** Let us first consider the proofs of claims 1 and 2. Note that PSPACE-hardness holds already for LTL-formulae, hence it suffices to show containment in PSPACE. Furthermore, note that 2 follows immediately from 1 and Theorem 8. Assume a formula  $\varphi \in \text{TeamLTL}^l(\otimes)$  and a Kripke structure  $K$  is given as input. By Theorem 10,  $\varphi$  is logically equivalent with a formula of the form  $\bigvee_{f \in F} \varphi^f$ , where  $f$  varies over selection functions selecting, separately for each occurrence, either the left disjunct  $\psi$  or the right disjunct  $\theta$  of each subformula of the form  $\psi \otimes \theta$  of  $\varphi$ . Now, without constructing the full formula  $\bigvee_{f \in F} \varphi^f$ , using polynomial space with respect to the size of  $\varphi$  it is possible to check whether  $\text{Traces}(K) \models \varphi_f$  for some  $f \in F$ . Hence the upper bound follows from the fact that LTL model checking is in PSPACE. The upper bound for satisfiability follows analogously.

Let us then consider the proof of claim (4). The proof of claim (3) is analogous. For the lower bound it suffices to note that propositional team logic  $\text{PL}(\sim)$  is a fragment of the left-downward closed fragment of  $\text{TeamLTL}^l(\sim, \otimes)$  and hence its satisfiability problem can be trivially reduced to the satisfiability problem of the left-downward closed fragment. Therefore ATIME-ALT( $\text{exp}, \text{poly}$ )-hardness follows by the result of [9].

For the upper bound we first transform an input formula  $\varphi$  into an equivalent quasi-flat formula of the form  $\bigvee_{i \in I} (\alpha_i \wedge \bigwedge_{j \in J_i} \exists \beta_{i,j})$ . Analogously to [17, 16], this formula can be computed in time  $\text{TIME}(\text{exp}_{O(|\varphi|)}(1))$ . It is now easy to see that the quasi-flat formula is satisfiable iff there exists  $i \in I$ , such that  $\text{SAT}(\alpha_i \wedge \beta_{i,j}) = 1$  for all  $j \in J_i$ . Since LTL-satisfiability checking is contained in  $\text{PSPACE} \subseteq \text{TIME}(2^{n^{O(1)}})$ , the overall complexity of the above procedure is in  $\text{TIME}(\text{exp}_{(|\varphi|^{O(1)})}(1))$ . ◀

## 6 Conclusion

We introduced a novel set-based semantics for asynchronous TeamLTL. We showed several results on the expressive power and complexity of the extensions of  $\text{TeamLTL}^l$  by the Boolean disjunction  $\text{TeamLTL}^l(\otimes)$  and by the Boolean negation  $\text{TeamLTL}^l(\sim)$ . In particular, our results show that the complexity properties of the former logic are comparable to that of LTL and that the left-downward closed fragment of the latter has also decidable model-checking and satisfiability problems. See Table 1 on page 4 for an overview of our expressivity results and Table 2 for our complexity results. We obtained these results on  $\text{TeamLTL}^l(\otimes)$  and  $\text{TeamLTL}^l(\sim)$  via normal forms that also allowed us to relate the expressive power of these logics to the corresponding logics in the strict semantics. Our results show that, while the synchronous TeamLTL can be viewed as a fragment of second-order logic, the asynchronous  $\text{TeamLTL}(\otimes)$  under the lax semantics is a sublogic of HyperLTL (see [2] for a definition). Furthermore, our decidability results show, e.g, that it will probably be possible to devise a complete proof system for the logic. The full version of this article [13] relates and applies our results to recently defined logics whose asynchronicity is formalised via time evaluation functions [7]. We conclude with open questions:

- Does Theorem 14 extend to all formulae of  $\text{TeamLTL}^l(\sim)$ ? Note that any quasi-flat- $\text{TeamLTL}(\sim)$ -formula can be rewritten in HyperLTL.
- Can the result (iii) of Theorem 17 be accompanied by an matching lower bound (i.e.,  $\text{TOWER}(\text{poly})$ -hardness result)?

- Can a syntactic characterisation (similar to Corollary 11) be obtained for the downward closed fragment of  $\text{TeamLTL}^l(\sim)$ ? We believe that  $\text{TeamLTL}^l(\otimes)$  is a promising candidate, as its extensions with infinite conjunctions and disjunctions suffices for all downward closed properties of teams.
- What is the complexity of model checking for  $\text{TeamLTL}(\otimes)$  under the strict semantics?

---

## Abstract

For a graph class  $\mathcal{G}$ , we define the  $\mathcal{G}$ -modular cardinality of a graph  $G$  as the minimum size of a vertex partition of  $G$  into modules that each induces a graph in  $\mathcal{G}$ . This generalizes other module-based graph parameters such as neighborhood diversity and iterated type partition. Moreover, if  $\mathcal{G}$  has bounded modular-width, the  $W[1]$ -hardness of a problem in  $\mathcal{G}$ -modular cardinality implies hardness on modular-width, clique-width, and other related parameters. Several FPT algorithms based on modular partitions compute a solution table in each module, then combine each table into a global solution. This works well when each table has a succinct representation, but as we argue, when no such representation exists, the problem is typically  $W[1]$ -hard. We illustrate these ideas on the generic  $(\alpha, \beta)$ -domination problem, which is a generalization of known domination problems such as BOUNDED DEGREE DELETION,  $k$ -DOMINATION, and  $\alpha$ -DOMINATION. We show that for graph classes  $\mathcal{G}$  that require arbitrarily large solution tables, these problems are  $W[1]$ -hard in the  $\mathcal{G}$ -modular cardinality, whereas they are fixed-parameter tractable when they admit succinct solution tables. This leads to several new positive and negative results for many domination problems parameterized by known and novel structural graph parameters such as clique-width, modular-width, and cluster-modular cardinality.

## 1 Introduction

Modular decompositions of graphs have played an important role in algorithms since their inception [23]. In the world of parameterized complexity [11, 13], Gajarský et. al. [22] proposed the notion of *modular-width*, or *mw* for short, which can be defined as the maximum degree of a prime node in the modular decomposition tree of  $G$ . Unlike other structural parameters such as treewidth [4], *mw* can be bounded on certain classes of dense graphs, making it comparable to the clique-width (*cw*) parameter [10]. In fact, *cw* is at most *mw* plus two, and *mw* can sometimes be arbitrarily larger than *cw*. It is known that several problems that are hard in *cw* are fixed-parameter tractable (FPT) in *mw*, with popular examples including HAMILTONIAN CYCLE, GRAPH COLORING [16, 18, 22], and METRIC DIMENSION [2, 5]. In particular in [22], the main technique used to design such algorithms is dynamic programming over the modular decomposition. In essence, the values of an optimal solution are found recursively in each module of the graph  $G$ , which are then combined into a solution for the graph itself, often using small integer linear programs based on the prime graph of  $G$ . Another technique was recently introduced in [19], where the authors show that the number of potential maximal cliques of a graph is at most  $O^*(1.73^{mw})$ , a fact that can be combined with results of [6, 20] to obtain FPT algorithms for a family of problems.

■ **Figure 1** Relation among the parameters clique-width ( $cw$ ), modular-width ( $mw$ ), **cograph**-modular cardinality (**cograph- $mc$** ), iterated type partitions ( $itp$ ), **stars**-modular cardinality (**stars- $mc$** ), **cluster**-modular cardinality (**cluster- $mc$** ), neighborhood diversity ( $nd$ ), and **linear forest**-modular cardinality (**linear forest- $mc$** ). Arrows indicate generalizations, e.g. modular-width( $mw$ ) generalizes **cograph**-modular cardinality and thus is bounded by (a function of) **cograph**-modular cardinality.

Despite these efforts, there are still several problems that are known to be hard on  $cw$ , for instance MAX-CUT [17] and BOUNDED DEGREE DELETION [3, 24], but unknown to be hard or FPT in  $mw$ . Recently, an XP algorithm is given for  $k$ -DOMINATION in parameter treewidth ( $tw$ ) [34], but the W-hardness for  $k$ -DOMINATION in parameter  $tw$ ,  $cw$  or  $mw$  is unknown. Also, the authors of [22] conclude with the question of whether EDGE DOMINATING SET and PARTITION INTO TRIANGLES are FPT in  $mw$ , which are 10 years-old questions that are still unanswered. One promising direction to gain knowledge and tools for  $mw$  algorithms is to study some of its related parameters. We consider such variants in which the graph must be decomposed into modules that each induces a subgraph belonging to a specific graph class. Notable examples include neighborhood diversity ( $nd$ ) [31], in which each module must induce an edgeless graph or a clique, and iterated type partition ( $itp$ ) [9], in which each module must induce a cograph. This idea was also used in [25] from which we borrow our terminology, where a partition into modules inducing cliques is used to obtain linear kernels for the cluster editing problem. Meanwhile, as Knop wrote in [29], ‘another important task in this area is to understand the boundary between modular-width on one side, and neighborhood diversity, twin-cover number, and clique-width on the other side’.

Our work resides in this boundary, as we propose to generalize the above ideas by restricting modules to a given graph class  $\mathcal{G}$ . That is, we define the  $\mathcal{G}$ -modular cardinality of a graph  $G$ , denoted  $\mathcal{G}\text{-}mc(G)$ , as the size of the smallest partition of its vertices into modules that each induces a subgraph in  $\mathcal{G}$ . If  $\mathcal{G}$  has bounded modular-width (e.g. cographs), the hardness of a problem in  $\mathcal{G}$ -modular cardinality implies its hardness in  $mw$  (and thus  $cw$ ). On the other hand, FPT techniques for  $\mathcal{G}\text{-}mc$  may shed light towards developing better algorithms for  $mw$ . Also, by considering graph classes of unbounded modular-width (e.g. paths, grids),  $\mathcal{G}\text{-}mc$  may be incomparable with  $mw$  or even  $cw$ , leading to FPT algorithms for novel types of graphs. To the best of our knowledge, such a generalization had not been studied, although it is worth mentioning that in [27], the authors propose a similar concept for treewidth, where some bags of a tree decomposition are allowed to be in some graph class.

**Our contributions.** We first establish that if  $\mathcal{G}$  is hereditary and has bounded  $mw$ , then  $mw(G)$  is at most  $\mathcal{G}\text{-}mc(G)$  for a graph  $G \notin \mathcal{G}$ , allowing the transfer of hardness results. We then show that for many graph classes, namely those that are *easily mergeable*, there is a polynomial-time algorithm to compute  $\mathcal{G}\text{-}mc$  and obtain a corresponding modular partition.

We then introduce techniques to obtain W[1]-hardness results and FPT algorithms for the  $\mathcal{G}\text{-}mc$  parameter. In essence, we argue that the dynamic programming technique on  $mw$  algorithms works well when a small amount of information from each module is sufficient to obtain a solution for the whole graph (for instance, the algorithms of [22] require only a

■ **Table 1** Our results for the  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION  $((\alpha, \beta)$ -LDD) on different parameters (the mark \* is implied by [3, 24]). Results in boldface are those proved directly in this paper (other entries are implied by these results). Recall that  $\alpha = 0$  is equivalent to the  $k$ -DOMINATION,  $\alpha = 1$  to the BOUNDED DEGREE DELETION (BDD), and  $\alpha \in (0, 1)$  to the  $\alpha$ -DOMINATION. Not shown in the table: BDD is FPT in parameters **linear forest- $mc$**  and **binary forest- $mc$** .

single integer from each module). Such *succinct solution tables* from each module can often be combined using integer programs with few integer variables [21, 28, 33]. Conversely, when too much information is required from each module (e.g. linear in the size of the modules) to obtain a final solution, we are unable to use integer programming and this typically leads to W[1]-hardness. This occurs when *arbitrary solution tables* are possible in each module.

We use a large class of domination problems to illustrate these techniques. Specifically, for a real number  $\alpha \in [0, 1]$  and integer  $\beta$  (possibly negative), we introduce the  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION problem. Given a graph  $G$  and an integer  $q$ , this problem asks for a  $X \subseteq V(G)$  of size at most  $q$  such that, for each  $v \in V(G) \setminus X$ , we have  $|N(v) \cap X| \geq \alpha|N(v)| + \beta$ . In other words, each unchosen vertex has at least a fraction  $\alpha$  of its neighbors dominating it, plus some number  $\beta$ . The problem is equivalent to the BOUNDED DEGREE DELETION (BDD) [3, 24] if  $\alpha = 1$  and  $\beta \leq 0$ ; equivalent to the  $k$ -DOMINATION [8, 32] if  $\alpha = 0$  and  $\beta \geq 1$ ; and equivalent to the  $\alpha$ -DOMINATION [1, 12, 14, 35] if  $\alpha \in (0, 1)$  and  $\beta = 0$ .

Table 1 illustrates the main results of this paper. The hardness results follow from a more general result on arbitrary solution tables (Theorem 7). It is slightly technical, so we describe its high-level implication on the case  $\alpha = 1$  (BDD). In this problem, a possible solution table is a function  $f : [n] \rightarrow \mathbb{N}$  such that  $f(i)$  is the minimum maximum degree achievable in  $G$  after deleting  $i$  vertices. The theorem states that for graph class  $\mathcal{G}$ , if for any such  $f$  we can construct a graph in  $\mathcal{G}$  whose solution table is  $f$ , then BDD is W[1]-hard in  $\mathcal{G}$ -modular cardinality. We show that the class of disjoint stars satisfies this property, which implies several other hardness results. On the other hand, several positive results for the BDD make use of succinct solution tables. In essence, when  $f$  can be represented by a constant number of linear functions, or by a convex function, then we can use integer programming to merge these tables and obtain positive results. Finally, additional results not shown in the table can be deduced easily from this technique. We show that BDD is FPT in **linear forest-modular cardinality** and **binary forest-modular cardinality** as parameters, which are of interest since they are incomparable with modular-width. Due to space constraints, we refer the reader to the full version of this paper [30] for definitions and complete proofs.

## 2 Preliminary notions

For an integer  $n$ , denote  $[n] = \{1, \dots, n\}$ . The maximum degree of a graph  $G$  is denoted by  $\Delta(G)$ .  $\overline{G}$  denotes the *complement* graph of  $G$ . The neighborhood of  $v \in V(G)$  is  $N(v)$ . The set of connected components of a graph  $G$  is denoted  $CC(G)$ . For  $X \subseteq V(G)$ ,  $G[X]$  denotes the subgraph of  $G$  induced by  $X$  and  $G - X = G[V(G) \setminus X]$ . If  $X = \{v\}$ , we may write  $G - v$ . Slightly abusing notation, we may also write  $v \in G$  instead of  $v \in V(G)$ ,  $|G|$  instead of  $|V(G)|$ , and  $X \cap G$  instead of  $X \cap V(G)$ .

A *graph class*  $\mathcal{G}$  is a (possibly infinite) set of graphs containing at least one non-empty graph. We say that  $\mathcal{G}$  is *hereditary* if, for any  $G \in \mathcal{G}$ , any induced subgraph of  $G$  is also in  $\mathcal{G}$ . Note that if  $\mathcal{G}$  is hereditary, the graph consisting of an isolated vertex is in  $\mathcal{G}$ . We say that  $\mathcal{G}$  is a *polynomial-time recognition graph class* if there is a polynomial-time algorithm that decides whether a given graph  $G$  is in  $\mathcal{G}$ . Some popular graph classes that we will use throughout this paper:  $\mathcal{I}$  is the set of all edgeless graphs;  $\mathcal{K}$  is the set of all complete graphs; **cluster** is the set of graphs in which every connected component induces a complete graph; **stars** is the set of graphs in which every connected component is a star graph; **cograph** is the set of cographs, where a cograph is either a single vertex, or a graph obtained by applying either a join or a disjoint union of two cographs [7]. Observe that  $\mathcal{I} \subseteq \mathbf{stars} \subseteq \mathbf{cograph}$ .

**Modular parameters.** For a graph  $G = (V, E)$ , a *module* of  $G$  is a  $M \subseteq V$  such that for every  $v \in V \setminus M$ , either  $M \subseteq N(v)$  or  $M \cap N(v) = \emptyset$ . The empty set,  $V$ , and every  $\{v\}$  for  $v \in V$  are called the *trivial modules*. In a *prime* graph, all modules are trivial. A *factor* is a subgraph induced by a module. A module  $M$  is *strong* if for any module  $M'$  of  $G$ , either  $M' \subseteq M$ ,  $M \subseteq M'$ , or  $M \cap M' = \emptyset$ .  $M$  is *maximal* if  $M \subsetneq V$  and there is no module  $M'$  such that  $M \subsetneq M' \subsetneq V$ . A partition  $\mathcal{M}$  of  $V(G)$  is called a *modular partition* if every element of  $\mathcal{M}$  is a module of  $G$ . If  $\mathcal{M}$  only contains maximal strong modules, then it is a *maximal modular partition*. This partition is unique. Two modules  $M$  and  $M'$  are *adjacent* in  $G$  if every vertex of  $M$  is adjacent to every vertex of  $M'$ , and *non-adjacent* otherwise. For a modular partition  $\mathcal{M}$  of  $V$ , the *quotient graph*  $G_{/\mathcal{M}}$  is defined by  $V(G_{/\mathcal{M}}) = \{v_M : M \in \mathcal{M}\}$  and  $v_{M_1}v_{M_2} \in E(G_{/\mathcal{M}})$  if and only if  $M_1, M_2$  are adjacent.

We call  $MD(G)$  the *modular decomposition tree* of  $G$ , in which each vertex  $v_M$  corresponds to a strong module  $M$ . More specifically, each leaf  $v_{\{v\}}$  of the inclusion tree corresponds to a vertex  $v$  of  $G$  and the root vertex  $v_V$  corresponds to  $V$ . Moreover, for any two strong modules  $M$  and  $M'$ ,  $M'$  is a proper subset of  $M$  if and only if  $v_{M'}$  is a descendant of  $v_M$  in  $MD(G)$ . An internal vertex  $v_M$  of  $MD(G)$  is *parallel* if  $G[M]$  is disconnected, is *series* if  $\overline{G[M]}$  is disconnected, and is *prime* otherwise. The *modular-width* of  $G$  is the maximum number of children of a prime vertex in  $MD(G)$  (see [26] for more). Our variant follows.

► **Definition 1.** Let  $\mathcal{G}$  be a graph class. For a graph  $G$  (not necessarily in  $\mathcal{G}$ ), a module  $M$  of  $G$  is a  $\mathcal{G}$ -module if  $G[M]$  belongs to  $\mathcal{G}$ . A modular partition  $\mathcal{M} = \{M_1, \dots, M_k\}$  of a graph  $G$  is called a  $\mathcal{G}$ -modular partition if each  $M_i$  is a  $\mathcal{G}$ -module. The  $\mathcal{G}$ -modular cardinality of  $G$ , denoted by  $\mathcal{G}\text{-mc}(G)$ , is the minimum cardinality of a  $\mathcal{G}$ -modular partition of  $G$ .

The neighborhood diversity (*nd*) is equivalent to the  $(\mathcal{K} \cup \mathcal{I})$ -modular cardinality. The iterated type partition (*itp*) parameter [9] is the number of vertices of the graph obtained through the following process: start with the smallest modular partition into cliques and edgeless graphs; contract each module into a single vertex; repeat until no more contraction is possible. It can be shown that the remaining vertices represent modules that are cographs. Thus,  $itp(G)$  is not smaller than the **cograph**-modular cardinality of  $G$ .

### 3 Properties and tractability of $\mathcal{G}$ -modular cardinality

In this section, we state two basic results regarding  $\mathcal{G}$ - $mc$ . First,  $mw$  is not larger than  $\mathcal{G}$ - $mc$  for graph classes of bounded modular-width. This allows hardness results on  $\mathcal{G}$ - $mc$  to also apply to  $mw$ . Second,  $\mathcal{G}$ - $mc$  is polynomial-time computable for “easily mergeable” graph classes. The first is relatively easy using modular partitions and induction.

► **Theorem 2.** *Let  $\mathcal{G}$  be an hereditary graph class and define  $\omega_{\mathcal{G}} := \max_{H \in \mathcal{G}} mw(H)$ . Then for any graph  $G$ ,  $mw(G) \leq \max(\mathcal{G}\text{-}mc(G), \omega_{\mathcal{G}})$ .*

Let us note that the above bound is tight, in the sense that  $mw(G)$  can be at least as large as either  $\mathcal{G}\text{-}mc(G)$  or  $\omega(G)$ . For instance, if  $G \notin \mathcal{G}$  is a prime graph, then  $mw(G) = \mathcal{G}\text{-}mc(G)$ , and if  $G = \arg \max_{H \in \mathcal{G}} mw(H)$ , then  $mw(G) = \omega_{\mathcal{G}}$ .

Let us now state the second result. A graph  $G$  is a  $\mathcal{G}$ -join if  $\overline{G}$  is disconnected and  $G[C] \in \mathcal{G}$  for each  $C \in CC(\overline{G})$ . Likewise,  $G$  is a  $\mathcal{G}$ -union if  $G$  is disconnected and  $G[C] \in \mathcal{G}$  for each  $C \in CC(G)$ . If  $G$  is a  $\mathcal{G}$ -join (resp.  $\mathcal{G}$ -union), a  $\mathcal{G}$ -merge is a  $\mathcal{G}$ -modular partition  $\mathcal{M}$  of  $G$  such that for each  $C \in CC(\overline{G})$  (resp.  $C \in CC(G)$ ), there is some  $M \in \mathcal{M}$  that contains  $C$ . We say that  $\mathcal{M}$  is a *minimum*  $\mathcal{G}$ -merge if no other  $\mathcal{G}$ -merge has a size strictly smaller than  $\mathcal{M}$ . We say that a graph class  $\mathcal{G}$  is *easily mergeable* if there exists a polynomial time algorithm that, given a graph  $G$  such that  $G$  is either a  $\mathcal{G}$ -join or a  $\mathcal{G}$ -union, outputs a minimum  $\mathcal{G}$ -merge of  $G$ . We say that  $\mathcal{G}$  is *trivially mergeable* if, for any  $\mathcal{G}$ -join or  $\mathcal{G}$ -union  $G$ , one of  $\{V(G)\}, CC(G)$ , or  $CC(\overline{G})$  is a minimum  $\mathcal{G}$ -merge of  $G$ .

► **Theorem 3.** *Suppose that  $\mathcal{G}$  is a hereditary graph class. Suppose further that  $\mathcal{G}$  is polynomial-time recognizable and easily mergeable. Then a  $\mathcal{G}$ -modular partition of  $G$  of minimum size can be obtained in polynomial time.*

The above implies that for  $\mathcal{G} \in \{\mathcal{I}, \mathcal{K}, \text{cograph}, \text{cluster}\}$ , a  $\mathcal{G}$ -modular partition of minimum size of a graph  $G$  can be computed in polynomial time. It is not hard to show that  $\mathcal{I}, \mathcal{K}$ , and  $\text{cograph}$  are trivially mergeable. For  $\text{cluster}$ , if  $G$  is a  $\text{cluster}$ -join, then  $G \in \text{cluster}$ . If  $G$  is a  $\text{cluster}$ -union, one may show that we can merge all the connected components of  $\overline{G}$  that contain one clique into a single clique, and the other connected components are left intact.

Note that not all graph classes are equally easy to merge. Consider the class “graphs with at most 100 vertices”. Merging such graphs amounts to solving a bin packing problem with a fixed capacity of 100, and current polynomial-time algorithms require time in the order of  $n^{100}$ . This is easily mergeable nonetheless, and it would be interesting to find graph classes that are hereditary and polynomial-time recognizable, but not easily mergeable.

### 4 Hardness of domination problems with arbitrary solution tables

Let us recall our generic domination problem of interest. For  $\alpha \in [0, 1]$  and  $\beta \in \mathbb{Z}$  we define:

The  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION problem

**Input:** a graph  $G = (V, E)$  and a non-negative integer  $q$ ;

**Question:** does there exist a subset  $X \subseteq V$  of size at most  $q$  such that for every  $v \in V \setminus X$ ,  $|N(v) \cap X| \geq \alpha|N(v)| + \beta$ ?

In the above, the vertex set  $X$  is called a  $(\alpha, \beta)$ -linear degree dominating set of  $G$ . In addition, for convenience, we also call  $X$  the deletion part of  $G$ . For any vertex  $v \in V(G - X)$ , the degree of  $v$  in  $X$ , denoted by  $\deg(v, G, X)$ , equals the number of vertices in  $X \cap V(G)$  adjacent to  $v$ . The minimum degree of  $G - X$  in  $X$  equals  $\min\{\deg(v, G, X) : v \in G - X\}$ , which is denoted by  $\delta(G - X, X)$ .

■ **Figure 2** The degree deletion function of a  $(a_0, I, c)$ -degree deletion graph. The  $x$ -axis represents the number of vertices to delete, while the  $y$ -axis represents the minimum maximum degree achievable by deleting  $x$  vertices. The first point of the  $(i + 1)$ -th horizontal vertex set is  $(c(a_i), a_i)$  for  $0 \leq i \leq |I|$ , and the last point of the  $(i + 1)$ -th horizontal vertex set is  $(c(a_{i+1}) - 1, a_i)$  for  $0 \leq i \leq |I| - 1$ . Disjoint stars are used as an example here since the graph class **stars** admits arbitrary deletion tables. The number of stars with  $a_i$  leaves is  $c(a_{i+1}) - c(a_i)$  for  $0 \leq i \leq |I| - 1$ . The degree deletion process removes the internal vertices of stars from large to small.

Our goal is to formalize the intuition that graph classes with arbitrary solution tables lead to  $W[1]$ -hardness in  $\mathcal{G}$ - $mc$ . For  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION, this takes the form of *arbitrary deletion tables* for  $\alpha \in (0, 1]$  and *arbitrary retention tables* for  $\alpha = 0$ .

► **Definition 4.** Let  $(a_0, I, c)$  be a triple with  $\{a_0\} \cup I \subseteq \mathbb{N}$  and  $c : \mathbb{N} \rightarrow \mathbb{N}$ . We call  $c$  a cost function. We say that  $(a_0, I, c)$  is decreasing valid if, by listing the elements  $a_1, \dots, a_{|I|}$  of  $I$  in decreasing order, we have  $a_0 > a_1 > \dots > a_{|I|} > 1$ , and  $0 = c(a_0) < c(a_1) < \dots < c(a_{|I|})$ .

For a decreasing valid triple  $(a_0, I, c)$ , we say that a graph  $G = (V, E)$  is a  $(a_0, I, c)$ -degree deletion graph if all of the following conditions hold:

1.  $G$  has maximum degree  $a_0$  and at most  $(a_0 c(a_{|I|}))^{10}$  vertices;
2. for any  $a_i \in I$ , there exists  $X \subseteq V$  of size  $c(a_i)$  such that  $G - X$  has maximum degree  $a_i$ ;
3. for any  $a_i \in I$  and any  $X \subseteq V$  of size strictly less than  $c(a_i)$ ,  $G - X$  has maximum degree at least  $a_{i-1}$ .

In addition, if  $G \in \mathbf{stars}$  and satisfies the above three conditions, then we say that  $G$  is a  $(a_0, I, c)$ -degree deletion star graph.

We say that a graph class  $\mathcal{G}$  admits arbitrary degree deletion tables if, for any decreasing valid triple  $(a_0, I, c)$ , one can construct in time polynomial in  $a_0 c(a_{|I|})$  a graph  $G \in \mathcal{G}$  such that  $G$  is a  $(a_0, I, c)$ -degree deletion graph. Note that the size of  $G$  is only required to be a polynomial function of  $a_0 c(a_{|I|})$ , but we fix it to  $(a_0 c(a_{|I|}))^{10}$  for convenience. For an integer  $x \in [0, |V|]$ , we call  $f(x) = \min\{\Delta(G - X) : |X| = x\}$  the *degree deletion function* of  $G$ , where  $X$  is a subset of  $V$ . Figure 2 demonstrates the degree deletion function of a  $(a_0, I, c)$ -degree deletion graph. The intuition behind degree deletion graphs is that their deletion function has a stepwise behavior with many steps.

The above notion of an arbitrary solution table works well for  $\alpha \in (0, 1]$ . For  $\alpha = 0$ , we need to replace “deletion” with “retention”. This is useful for the  $\alpha = 0$  case, where the set  $X$  must contain at least  $\beta$  neighbors of each unchosen vertex. Hence, the steps of the table describe, for each number  $x$  of vertices to include in  $X$ , the maximum possible  $\delta(G - X, X)$  that can be achieved with a subset of size  $x$ .

► **Definition 5.** Let  $(a_0, I, c)$  be a triple with  $\{a_0\} \cup I \subseteq \mathbb{N}$  and  $c : \mathbb{N} \rightarrow \mathbb{N}$ . We call  $c$  a cost function. We say that  $(a_0, I, c)$  is increasing valid if, by listing the elements  $a_1, \dots, a_{|I|}$  of  $I$  in decreasing order, we have  $a_0 > a_1 > \dots > a_{|I|} > 100$ ,<sup>1</sup> and  $c(a_0) > c(a_1) > \dots > c(a_{|I|}) = 0$ .

For a increasing valid triple  $(a_0, I, c)$ , we say that a graph  $G = (V, E)$  is a  $(a_0, I, c)$ -degree retention graph above  $(p, l)$ , where  $p$  and  $l$  are positive integers and  $l < 100$ , if all of the following conditions hold:

1.  $G$  has maximum degree  $a_0$ , at most  $(a_0 c(a_0))^{10}$  vertices, and  $p$  vertices of degree less than  $l$ ;
2. for any  $a_i \in \{a_0\} \cup I$ , there exists  $X \subseteq V$  of size  $p + c(a_i)$  such that the minimum degree of  $G - X$  in  $X$  is  $a_i$ ;
3. for any  $a_i \in \{a_0\} \cup I$  and any  $X \subseteq V$  of size strictly less than  $p + c(a_i)$ , the minimum degree of  $G - X$  in  $X$  is at most  $a_{i+1}$ , where here we define  $a_{|I|+1} = l$ .

We say that a graph class  $\mathcal{G}$  admits arbitrary degree retention tables if, for any increasing valid triple  $(a_0, I, c)$ , there exist integers  $p$  and  $l$  such that one can construct in time polynomial in  $c(a_0)a_0$  a graph  $G \in \mathcal{G}$  such that  $G$  is a  $(a_0, I, c)$ -degree retention graph above  $(p, l)$ . Note that condition 2 of Definition 5 imply that  $p + c(a_0) < |V| \leq (c(a_0)a_0)^{10}$ . For any integer  $x \in [0, |V| - 1]$ , we call  $f(x) = \max\{\delta(G - X, X) : |X| = x\}$  the degree retention function of  $G$ , where  $X$  is a subset of  $V$ . Importantly, **stars** admit both types of tables.

► **Proposition 6.** The graph class **stars** admits arbitrary deletion tables and arbitrary retention tables.

► **Theorem 7.** The  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION problem is  $W[1]$ -hard in the following cases:

1.  $\alpha = 0$ ,  $\beta$  is in the input, and the parameter is the  $(\mathcal{G} \cup \mathcal{I})$ -modular cardinality, where  $\mathcal{G}$  is any graph class that admits arbitrary degree retention tables;
2.  $\alpha$  is any fixed constant in the interval  $(0, 1)$ ,  $\beta$  is any fixed constant in  $\mathbb{Z}$ , and the parameter is the **stars**-modular cardinality;
3.  $\alpha = 1$ ,  $\beta$  is in the input, and the parameter is the  $(\mathcal{G} \cup \mathcal{I})$ -modular cardinality, where  $\mathcal{G}$  is any graph class that admits arbitrary degree deletion tables.

The proof of the Theorem 7 is quite long and can be found in [30]. The proof of the three cases all use the same construction and the same set of claims, but most claims require an argument for each case. The next section illustrates the main techniques on the case  $\alpha = 1$ . Using the relationship demonstrated in Figure 1 we have the following.

► **Corollary 8.** The  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION problem parameterized by either clique-width, modular-width, **cograph**-modular cardinality, iterated type partition, and **stars**-modular cardinality, is  $W[1]$ -hard in the following cases:

1.  $\alpha = 0$ ,  $\beta$  is in the input;
2.  $\alpha$  is any fixed constant in the interval  $(0, 1)$ ,  $\beta$  is any fixed constant in  $\mathbb{Z}$ ;
3.  $\alpha = 1$ ,  $\beta$  is in the input.

In particular, **BOUNDED DEGREE DELETION** problem,  $k$ -**DOMINATION** problem, and  $\alpha$ -**DOMINATION** problem are  $W[1]$ -hard in all these parameters.

One can show that these problems are in XP parameterized by **stars**-modular cardinality. Indeed, one can choose, for each **stars** module  $M$ , a number in  $[|M|] \cup \{0\}$  of vertices to delete in  $M$ , and apply these deletions greedily. There are at most  $|V(G)|^{\mathcal{G}\text{-}mc(G)}$  combinations

<sup>1</sup> In fact, any large constant here is enough for our proof in this paper, we fix it to be 100 for convenience.

of choices, and it suffices to try each of them. This works because the greedy strategy is applicable to stars, and it remains to study the XP complexity for other parameters. The next proposition is not related to the above hardness results, but allows us to fill in some of the gaps that the above leaves in our results table. In section 6, we will also show that for  $\alpha = 1$  and  $\beta$  in the input, the problem is FPT in `cluster`-modular cardinality.

► **Proposition 9.** *The  $(\alpha, \beta)$ -LINEAR DEGREE DOMINATION problem is FPT in the following cases:*

1.  $\alpha \in [0, 1]$ ,  $\beta$  is in the input, and the parameter is the neighborhood diversity;
2.  $\alpha \in \{0, 1\}$ ,  $\beta$  is a constant, and the parameter is the clique-width.

The first case requires some work, whereas the second is a simple application of Courcelle's theorem [10], as the problem admits a constant-length MSO<sub>1</sub> formula.

## 5 $(1, \beta)$ -Linear Degree Domination (BDD)

We sketch the proof of the W[1]-hardness of  $(1, \beta)$ -LINEAR DEGREE DOMINATION problem, which is enough to demonstrate the main idea of the reduction technique. Recall that we assume that  $\alpha = 1$  and  $\beta < 0$ , which is the BOUNDED DEGREE DELETION problem. That is, we must delete at most  $q$  vertices such that the resulting subgraph has maximum degree at most  $|\beta|$ . Furthermore, in the  $(1, \beta)$ -LINEAR DEGREE DOMINATION problem, we also call  $X$ , the  $(1, \beta)$ -linear degree dominating set of  $G$ , the deletion part of  $G$ .

We provide a reduction from the SYMMETRIC MULTICOLORED CLIQUE problem, which we define as follows. A symmetric multicolored graph  $G = (V^1 \cup V^2 \dots \cup V^k, E)$  is a connected graph such that, for all distinct  $i, j \in [k]$ ,

1.  $V^i = \{v_1^i, \dots, v_n^i\}$ , where  $n \geq k$ ;
2. all the vertices of  $V^i$  are colored by color  $i$ ;
3. if  $v_r^i v_s^j \in E(G)$ , then  $v_s^j v_r^i \in E(G)$  as well.

Then, for the SYMMETRIC MULTICOLORED CLIQUE problem, the input is a symmetry multicolored graph  $G$  and an integer  $k$ , and the objective is to decide whether  $G$  contains a  $k$ -clique with vertices of all  $k$  colors. We also call  $v_r^i v_s^j$  and  $v_s^i v_r^j$  symmetry edges.

The reduction in [15, Lemma 1], which proves the W[1]-hardness of the multicolored clique problem, actually produces a symmetric multicolored graph. Hence, SYMMETRIC MULTICOLORED CLIQUE is W[1]-hard. We now sketch the following.

► **Lemma 10.** *Case 3 for the W[1]-hardness results in Theorem 7 is correct.*

Let  $(G, k)$  be an instance of SYMMETRIC MULTICOLORED CLIQUE, where  $G = (V^1 \cup V^2 \cup \dots \cup V^k, E)$ . Without loss of generality, suppose  $k \geq 100$ , otherwise, the problem can be solved in polynomial time. We will construct a corresponding instance  $(H, \beta, q)$  of  $(1, \beta)$ -LINEAR DEGREE DOMINATION, where  $H$  is a graph whose  $\mathcal{G}$ -modular cardinality will be bounded by  $O(k^2)$ ,  $\beta = -(nk)^{10000}$ , and  $q$  is the maximum allowed size of  $X$ , the desired deletion part of  $H$  (to be specified later). Before proceeding, we will make use of a 2-sumfree-set, which is a set of positive integers in which every couple of elements has a distinct sum. That is,  $I$  is a 2-sumfree set if, for any  $(a, b), (a', b') \in I \times I$ ,  $a + b = a' + b'$  if and only if  $\{a, b\} = \{a', b'\}$  (note that  $a = b$  is possible). It is known that one can construct in time  $O(n^3)$  a 2-sumfree-set  $I$  of cardinality  $n$  in which the maximum value is  $n^4$ , which can be achieved with a greedy procedure (this is because  $(n+1)^4 - n^4 > n^3$  and  $a_i + a_j - a_r$  has at most  $n^3$  different values). We thus assume that we have built a 2-sumfree set  $I = \{a_1, \dots, a_n\}$  for  $H$ , where  $n^4 \geq a_1 > \dots > a_n \geq 1$ . Without loss of generality, we may multiply each  $a_i \in I$  by an

■ **Figure 3** Illustration of the construction of  $H$ .

integer  $r$ , where here we choose  $r = 2(k-1)^2k^3$ . Then, we have that  $n^4r \geq a_1 > \dots > a_n \geq r$  for the updated  $I$ . Moreover, for any distinct pair  $(a, b), (a', b') \in I \times I$ , we have that the absolute value of  $a + b - a' - b'$  is at least  $r$ .

For each color class  $V^i = \{v_1^i, \dots, v_n^i\}$  of  $G$ , we provide a bijection  $f_i$  from  $V^i$  to  $I$ , such that  $f_i(v_s^i) = a_s$  for every  $s \in [n]$ . Clearly, we can use  $f_i^{-1}(a_s)$  to denote the unique vertex  $v_s^i$  of  $V^i$  associated with  $a_s \in I$ . We have that, for all  $s, t \in [n]$ , each pair of  $a_s, a_t \in I$  has a unique sum. For distinct  $i, j$  and any  $u \in V^i, w \in V^j$  such that  $uw \in E(G)$ , if  $f_i(u) + f_j(w) = a_s + a_t$ , then edge  $uw$  is either  $v_s^i v_t^j$  or  $v_t^i v_s^j$ . Moreover, for any distinct color classes  $V^i, V^j$ , edges  $v_s^i v_t^j$  and  $v_t^i v_s^j$ , together, are both in  $E(G)$  or both not in  $E(G)$ . Hence, by looking at a sum in  $I$ , we will be able to tell whether it is corresponding to a pair of symmetry edges between  $V^i$  and  $V^j$ , or not.

Next, we define  $s = n^{10}$ ,  $q = ks + \binom{k}{2}s$ ,  $a_0 = q + 1$ , and  $a_{n+1} = a_n - 1$ . We construct  $H$  as in Figure 3. First, for each color class  $V^i$  of  $G$ , add three factors  $R_i, S_i, T_i$  to  $H$ , where:

- $R_i$  is an edgeless graph of size  $|\beta| - s$ .
- $S_i$  is a  $(a_0, I \cup \{a_{n+1}\}, c)$ -degree deletion graph, where we put the costs  $c(a_j) = s - \frac{1}{2}a_j$  for  $a_j \in I$  and  $c(a_{n+1}) = a_0$ .
- $T_i$  is an edgeless graph of size  $s$ .

We then make  $S_i$  adjacent with  $R_i$  and  $T_i$ . Secondly, for each pair of color classes  $V^i, V^j$  with  $i < j$ , we add another two factors  $U_{ij}, R_{ij}$ , where:

- $R_{ij}$  is an edgeless graph of size  $|\beta| - 2s$ .
- $U_{ij}$  is built as follows. Suppose integer set  $I_{ij}$  consists of all  $a + b$  such that  $a, b \in I$  and symmetry edges  $f_i^{-1}(b)f_j^{-1}(a), f_i^{-1}(a)f_j^{-1}(b) \in E(G)$ . Let  $\ell_{ij} = \min(I_{ij})$ .

Then  $U_{ij}$  is a  $(a_0, I_{ij} \cup \{\ell_{ij} - 1\}, c_{ij})$ -degree deletion graph, where we put the cost  $c_{ij}(a + b) = s - \frac{1}{2(k-1)}(a + b)$ , and we put  $c_{ij}(\ell_{ij} - 1) = a_0$ .

We then make  $U_{ij}$  adjacent with  $R_{ij}$ , and adjacent with  $T_i$  and  $T_j$ . To avoid cumbersome notation, we define  $U_{ij} = U_{ji}$ ,  $R_{ij} = R_{ji}$ ,  $c_{ij} = c_{ji}$ , and  $I_{ij} = I_{ji}$ . This completes the construction of  $H$ . It is easy to see that  $H$  can be constructed in polynomial time and the number of factors in  $H$  is a polynomial function in  $k$ .

All that remains is to argue that the objective instance is equivalent to the original one. The following lemma gives the forward direction. We only provide a sketch here.

► **Lemma 11.** *Suppose that  $G$  contains a multicolored clique  $C$  of size  $k$ . Then there is  $X \subseteq V(H)$  of size at most  $q = ks + \binom{k}{2}s$  such that  $\Delta(H - X) \leq |\beta|$ .*

**Proof sketch.** For  $i \in [k]$ , let  $f_i^{-1}(\hat{a}_i)$  be the vertex of  $V^i$  that belongs to the multicolored clique  $C$ , where  $\hat{a}_i \in I$  is the number associated with the vertex. For any  $i \neq j$ , we know that vertices  $f_i^{-1}(\hat{a}_i)$  and  $f_j^{-1}(\hat{a}_j)$  are in  $C$ , which means that  $f_i^{-1}(\hat{a}_i)f_j^{-1}(\hat{a}_j) \in E(G)$ . This

## 61:10 Parameterized Complexity of Domination Problems

implies that  $\hat{a}_i + \hat{a}_j$  is in the  $I_{ij}$  list that was used to construct  $U_{ij}$ . We then show how to construct the vertex set  $X$  for  $H$ . The intersection of each  $R_i$  and  $X$  is empty. For each  $T_i$ , add  $\hat{a}_i$  vertices to  $X$ . For each  $S_i$ , add  $c(\hat{a}_i) = s - \frac{1}{2}\hat{a}_i$  vertices to  $X$ . This can be done so that  $S_i - X$  has maximum degree  $\hat{a}_i$  according to Definition 4. The intersection of each  $R_{ij}$  and  $X$  is empty. For each  $U_{ij}$ , we can add  $c_{ij}(\hat{a}_i + \hat{a}_j) = s - \frac{\hat{a}_i + \hat{a}_j}{2(k-1)}$  vertices to  $X$  so that  $U_{ij} - X$  has maximum degree  $\hat{a}_i + \hat{a}_j$  according to Definition 4. It is not hard to verify that  $X$  with exactly  $q$  vertices satisfies that  $\Delta(H - X) \leq |\beta|$ . ◀

The converse direction is much more difficult.

► **Lemma 12.** *Suppose that there is  $X \subseteq V(H)$  with  $|X| \leq q$  such that  $H - X$  has maximum degree at most  $|\beta|$ . Then  $G$  contains a multicolored clique of size  $k$ .*

**Proof sketch.** Let  $X \subseteq V(H)$  be of size at most  $q$  such that  $H - X$  has maximum degree  $|\beta|$  or less. To ease notation slightly, for a factor  $M$  of  $H$ , we will write  $X(M) := X \cap V(M)$  and  $\chi(M) := |X(M)|$ . The proof is divided into a series of claims. ◀

▷ **Claim 13.** For each  $i \in [k]$ , we may assume that  $\chi(R_i) = 0$ . Moreover for each distinct  $i, j \in [k]$ , we may assume that  $\chi(R_{ij}) = 0$ .

The rough idea is that a vertex of  $X(R_i)$  can always be replaced by a vertex of  $T_i \setminus X$  if the latter is non-empty. If  $V(T_i) \setminus X$  is empty, then after an unavoidable at least  $c(a_1)$  vertices deletion from  $S_i$ , no deletion in  $R_i$  is needed since each remaining vertex of  $S_i$  in  $H - X$  has maximum degree at most  $|\beta| - s + a_1 < |\beta|$ . The idea for  $\chi(R_{ij}) = 0$  goes the same way.

▷ **Claim 14.** For any  $i \in [k]$ , we may assume  $\Delta(S_i - X) \in \{a_1, \dots, a_n\}$ , and that  $\chi(S_i) = c(\Delta(S_i - X))$ .

The rough idea is that Case 2 of Definition 4 states that we can delete  $c(a_j)$  vertices from  $S_i$  to make  $\Delta(S_i - X) = a_j$ , where  $0 \leq j \leq n + 1$ . In fact, this is the smallest maximum degree we can achieve in  $S_i$  by deleting between  $c(a_j)$  and  $c(a_{j+1}) - 1$  vertices, because of the stepwise behavior of arbitrary deletion tables. Moreover, we already know that  $\chi(R_i) = 0$  based on Claim 13. So, if  $\Delta(S_i - X) = a_0$  there is a vertex in  $S_i - X$  with degree  $|\beta| - s + a_0 > |\beta|$ , and if  $\Delta(S_i - X) = a_n - 1$  or less then  $c(a_n - 1) = a_0 > q$  vertices have to be deleted from  $S_i$ .

▷ **Claim 15.** For any distinct  $i, j \in [k]$ , we may assume that  $\Delta(U_{ij} - X) \in I_{ij}$ , and that  $\chi(U_{ij}) = c_{ij}(\Delta(U_{ij} - X))$ .

The idea for proving this claim is similar to that of Claim 14. Our next step is to argue that the degree chosen by  $U_{ij}$  must be the sum of the degrees chosen by  $S_i$  and  $S_j$ . More specifically, for  $i \in [k]$ , we say that  $S_i$  chose  $a_j \in I$  if  $\Delta(S_i - X) = a_j$  and  $\chi(S_i) = c(a_j)$ . Likewise, for distinct  $i, j \in [k]$ , we say that  $U_{ij}$  chose  $a, b \in I$  if  $\Delta(U_{ij} - X) = a + b$  and  $\chi(U_{ij}) = c_{ij}(a + b)$ . Note that by Claim 14, each  $S_i$  chooses one  $a_j$  and by Claim 15, each  $U_{ij}$  chooses one pair  $a, b$  such that symmetry edges  $f_i^{-1}(b)f_j^{-1}(a), f_i^{-1}(a)f_j^{-1}(b) \in E(G)$ . The point to make is that if  $S_i$  and  $S_j$  chose  $a$  and  $b$ , respectively, then  $U_{ij}$  must have chosen  $a, b$ .

▷ **Claim 16.** For each  $i \neq j$ , if  $S_i$  chose  $a \in I$  and  $S_j$  chose  $b \in I$ , then  $U_{ij}$  chose  $a, b$ .

We sketch it as follows. For each  $i \in [k]$ , we will denote by  $\hat{a}_i$  the element of  $I$  that  $S_i$  chose. We divide the  $U_{ij}$ 's into three groups:

$$U^< = \{U_{ij} : U_{ij} \text{ chose } a', b' \text{ such that } a' + b' < \hat{a}_i + \hat{a}_j\}$$

$$U^= = \{U_{ij} : U_{ij} \text{ chose } a', b' \text{ such that } a' + b' = \hat{a}_i + \hat{a}_j\}$$

$$U^> = \{U_{ij} : U_{ij} \text{ chose } a', b' \text{ such that } a' + b' > \hat{a}_i + \hat{a}_j\}$$

To prove the claim, it suffices to show that  $U^<$  and  $U^>$  are empty (this is because  $U_{ij} \in U^=$  is only possible if  $U_{ij}$  chose  $\hat{a}_i, \hat{a}_j$ , since all the sum pairs are distinct). The rough idea is as follows. If each  $U_{ij}$  chose the correct  $\hat{a}_i, \hat{a}_j$ , then each of them will incur a deletion cost of  $c_{ij}(\hat{a}_i + \hat{a}_j) = s - \frac{\hat{a}_i + \hat{a}_j}{2^{(k-1)}}$  and end up cancelling the deletion costs of the  $S_i$  and  $T_i$  factors. If  $U^<$  is non-empty, it incurs extra deletion cost with respect to  $c_{ij}(\hat{a}_i + \hat{a}_j)$  with no real benefit. The complicated case is when  $U^>$  is non-empty. In this case,  $U_{ij} - X$  has higher degree than if it had chosen  $\hat{a}_i, \hat{a}_j$  and incurs less deletions than  $c_{ij}(\hat{a}_i + \hat{a}_j)$ . However, this needs to be compensated with extra deletions in  $T_i$  and  $T_j$ . By using a charging argument, we can show that the sum of extra deletions required for all the  $U^>$  members outweighs the deletions saved in the  $U_{ij}$ 's of  $U^>$ .

We can now construct a multicolored clique. Define  $C = \{f_i^{-1}(\hat{a}_i) : i \in [k] \text{ and } S_i \text{ chose } \hat{a}_i\}$ . We claim that  $C$  is a clique. By Claim 14, each  $S_i$  chooses some  $\hat{a}_i$  and thus  $|C| = k$ . Now let  $f_i^{-1}(\hat{a}_i), f_j^{-1}(\hat{a}_j)$  be two vertices of  $C$ , where  $i < j$ . Then  $\hat{a}_i, \hat{a}_j$  were chosen by  $S_i$  and  $S_j$ , respectively, and by Claim 15 we know that  $U_{ij}$  chose  $\hat{a}_i + \hat{a}_j$ . By the construction of the  $U_{ij}$  solution table, this is only possible if symmetry edges  $f_i^{-1}(\hat{a}_i)f_j^{-1}(\hat{a}_j), f_i^{-1}(\hat{a}_j)f_j^{-1}(\hat{a}_i) \in E(G)$ . Therefore,  $f_i^{-1}(\hat{a}_i)f_j^{-1}(\hat{a}_j) \in E(G)$  and  $C$  is a clique.

## 6 FPT algorithms for succinct solution tables

In this section, we study the BOUNDED DEGREE DELETION problem (i.e.  $\alpha = 1, \beta < 0$ ) on graph classes that admit succinct solution tables. Let  $G = (V, E)$  be a graph. Assume  $\mathbb{S}_x \subseteq 2^V$  consists of all subsets of  $V$  with size  $x \in [0, |V|]$ .  $X \in \mathbb{S}_x$  is called an  $x$ -deletion set of  $G$  if  $\Delta(G - X) = \min\{\Delta(G - Y) : Y \in \mathbb{S}_x\}$ . An  $x$ -deletion of  $G$  is the process of deleting all vertices of an  $x$ -deletion set from  $G$ . Clearly, the degree deletion function  $f(x)$  of  $G$  is the maximum degree of  $G$  after an  $x$ -deletion. A *piecewise linear function*  $g : \mathbb{R} \rightarrow \mathbb{R}$  is a continuous function defined on a sequence of intervals, such that the function is linearly restricted to each of the intervals (each such linear function is called a *sub-function* of  $g$ ). In addition, a *constant piecewise linear function* is a piecewise linear function that consists of a constant number of linear sub-functions.

► **Definition 17.** Let  $\mathcal{G}$  be a polynomial-time recognizable graph class. For  $G \in \mathcal{G}$ , suppose that  $f^G(x)$  is the degree deletion function of  $G = (V, E)$ , where  $x \in [0, |V|]$ . We say that  $\mathcal{G}$  admits a succinct solution table for BOUNDED DEGREE DELETION if, for every  $G \in \mathcal{G}$ , there exists a function  $g^G : \mathbb{R} \rightarrow \mathbb{R}$  that satisfies at least one of the following conditions:

1.  $g^G$  is a constant piecewise linear function such that  $f^G(x) = g^G(x)$  for every integer  $x \in [0, |V(G)|]$ ,
2.  $g^G$  is a piecewise convex linear function such that  $f^G(x) = \lceil g^G(x) \rceil$  for every integer  $x \in [0, |V(G)|]$ .

Moreover,  $g^G$  can be described and constructed in polynomial time with respect to  $|V(G)|$ .

A graph class admits a succinct solution table of type  $t$  for BOUNDED DEGREE DELETION if we refer to the condition  $t$ , where  $t \in \{1, 2\}$ . Type 1 implies the solution table can be divided into a constant number of blocks, each of which can be encoded into a small number of bits

## 61:12 Parameterized Complexity of Domination Problems

(note that for any fixed graph class, the upper bound on the constant should be fixed as well). In type 2, the solution table could be convex, but could also be *non-convex* with a larger number of blocks, but we can reduce this special non-convex function to a convex function using ceilings (this occurs with `cluster-mc`). As we show, these definitions capture the intuition of solution tables that can be merged in FPT time.

► **Theorem 18.** *Let  $\mathcal{G}$  be a graph class that admits a succinct solution table for BOUNDED DEGREE DELETION. Assume a minimum  $\mathcal{G}$ -modular partition is given. Then, BOUNDED DEGREE DELETION is FPT parameterized by  $\mathcal{G}$ -modular cardinality.*

**Application.** Let graph class BDT include all graphs with bounded degree and treewidth. We prove BDT and `cluster` admit succinct solution tables of type 1 and type 2, respectively. Thus, BOUNDED DEGREE DELETION is FPT in parameter *BDT-mc* or *cluster-mc*. Clearly, *BDT-mc* is bounded by a function of vertex cover number and is incomparable with *mw* (*linear forest* has unbounded *mw*). Moreover, `cluster-mc` is a parameter with size at most *nd* and at least *mw*.

► **Theorem 19.** *BDT admits a succinct solution table for BOUNDED DEGREE DELETION. Therefore, the BOUNDED DEGREE DELETION is FPT in parameter *BDT-mc*.*

**Proof sketch.** For every  $G \in \text{BDT}$ , the degree deletion function of  $G$  can be represented by an efficiently computable step function with a constant number of steps. ◀

► **Lemma 20.** *Assume cluster graph  $H$  contains  $b$  complete graphs  $K_a$ , where  $K_a$  is the maximum size complete graph in  $H$ . Let  $q \in [b, |V(H)|]$ . Suppose  $R$  is obtained from  $H$  by deleting exactly one vertex from every  $K_a$  of  $H$ . Then,  $H$  has a  $q$ -deletion such that the maximum degree of the remaining graph is  $h$  if and only if  $R$  has a  $(q - b)$ -deletion such that the maximum degree of the remaining graph is  $h$ .*

► **Theorem 21.** *Cluster admits a succinct solution table for BOUNDED DEGREE DELETION. Therefore, the BOUNDED DEGREE DELETION is FPT in parameter `cluster-mc`.*

**Proof sketch.** Let  $G$  be a cluster graph and  $f^G(x)$  be the degree deletion function of  $G$ . We can construct a piecewise convex linear function  $g^G$  based on the structure of  $G$ , and prove that  $f^G(x) = \lceil g^G(x) \rceil$  by using the properties of the two functions and Lemma 20. ◀

**Open problems.** We conclude with some interesting problems.

- Can we characterize graph classes that are easily mergeable? For instance, is the class of  $H$ -free graphs easily mergeable, for any fixed graph  $H$ ?
- Is BOUNDED DEGREE DELETION fixed-parameter tractable in parameter  $(K_{1,t}$ -free)-modular cardinality, where  $t \geq 3$  is either fixed or a parameter?
- Is  $k$ -DOMINATION FPT in parameter `cluster`-modular cardinality, where  $\beta$  is related to the input size?
- Is  $\alpha$ -DOMINATION FPT in parameter `cluster`-modular cardinality?
- The RED-BLUE CAPACITATED DOMINATING SET problem is  $W[1]$ -hard in *cw* [17]. It is not hard to prove it to be FPT in *mw* using succinct solution tables. Does the same hold for the RED-BLUE EXACT SATURATED CAPACITATED DOMINATING SET?
- Are EDGE DOMINATING SET, MAX-CUT, and PARTITION INTO TRIANGLES FPT in parameter `cograph`-modular cardinality?

## Abstract

Given a graph  $G$  and an integer  $k$ , MAX MIN FVS asks whether there exists a minimal set of vertices of size at least  $k$  whose deletion destroys all cycles. We present several results that improve upon the state of the art of the parameterized complexity of this problem with respect to both structural and natural parameters.

Using standard DP techniques, we first present an algorithm of time  $\text{tw}^{O(\text{tw})}n^{O(1)}$ , significantly generalizing a recent algorithm of Gaikwad et al. of time  $\text{vc}^{O(\text{vc})}n^{O(1)}$ , where  $\text{tw}, \text{vc}$  denote the input graph's treewidth and vertex cover respectively. Subsequently, we show that both of these algorithms are essentially optimal, since a  $\text{vc}^{o(\text{vc})}n^{O(1)}$  algorithm would refute the ETH.

With respect to the natural parameter  $k$ , the aforementioned recent work by Gaikwad et al. claimed an FPT branching algorithm with complexity  $10^k n^{O(1)}$ . We point out that this algorithm is incorrect and present a branching algorithm of complexity  $9.34^k n^{O(1)}$ .

## 1 Introduction

We consider a MaxMin version of the well-studied feedback vertex set problem where, given a graph  $G = (V, E)$  and a target size  $k$ , we are asked to find a set of vertices  $S$  with the following properties: (i) every cycle of  $G$  contains a vertex of  $S$ , that is,  $S$  is a feedback vertex set (ii) no proper subset of  $S$  is a feedback vertex set, that is,  $S$  is minimal (iii)  $|S| \geq k$ . Although much less studied than its minimization cousin, MAX MIN FVS has recently attracted attention in the literature as part of a broader study of MaxMin versions of standard problems, such as MAX MIN VERTEX COVER and UPPER DOMINATING SET. The main motivation of this line of research is the search for a deeper understanding of the performance of simple greedy algorithms: given an input, we would like to compute what is the worst possible solution that would still not be improvable by a simple heuristic, such as removing redundant vertices. Nevertheless, over recent years MaxMin problems have been found to possess an interesting combinatorial structure of their own and have now become an object of more widespread study (we survey some such results below).

It is not surprising that MAX MIN FVS is known to be NP-complete and is in fact significantly harder than MINIMUM FVS in most respects, such as its approximability or its amenability to algorithms solving special cases. Given the problem’s hardness, in this paper we focus on the parameterized complexity of MAX MIN FVS, since parameterized complexity is one of the main tools for dealing with computational intractability<sup>1</sup>. We consider two types of parameterizations: the natural parameter  $k$ ; and the parameterization by structural width measures, such as treewidth. In order to place our results into perspective, we first recall the current state of the art.

**Previous work.** MAX MIN FVS was first shown to be NP-complete even on graphs of maximum degree 9 by Mishra and Sikdar [32]. This was subsequently improved to NP-completeness for graphs of maximum degree 6 by Dublois et al. [20], who also present an approximation algorithm with ratio  $n^{2/3}$  and proved that this is optimal unless  $P=NP$ . A consequence of the polynomial time approximation algorithm of [20] was the existence of a kernel of order  $O(k^3)$ , which implied that the problem is fixed-parameter tractable with respect to the natural parameter  $k$ . Some evidence that this kernel size may be optimal was later given by [2]. We note also that the problem can easily be seen to be FPT parameterized by treewidth (indeed even by clique-width) as the property that a set is a minimal feedback vertex set is  $\text{MSO}_1$ -expressible, so standard algorithmic meta-theorems apply.

Given the above, the state of the art until recently was that this problem was known to be FPT for the two most well-studied parameterizations (by  $k$  and by treewidth), but concrete FPT algorithms were missing. An attempt to advance this state of the art and systematically study the parameterized complexity of the problem was recently undertaken by Gaikwad et al. [23], who presented exact algorithms for this problem running in time  $10^k n^{O(1)}$  and  $\text{vc}^{O(\text{vc})} n^{O(1)}$ , where  $\text{vc}$  is the input graph’s vertex cover, which is known to be a (much) more restrictive parameter than treewidth. Leveraging the latter algorithm, [23] also present an FPT approximation scheme which can  $(1 - \varepsilon)$ -approximate the problem in time  $2^{O(\text{vc}/\varepsilon)} n^{O(1)}$ , that is, single-exponential time with respect to  $\text{vc}$ .

**Our contribution.** We begin our work by considering MAX MIN FVS parameterized by the most standard structural parameter, treewidth. We observe that, using standard DP techniques, we can obtain an algorithm running in time  $\text{tw}^{O(\text{tw})} n^{O(1)}$ , that is, slightly super-exponential with respect to treewidth. Note that this slightly super-exponential running time is already present in the  $\text{vc}^{O(\text{vc})} n^{O(1)}$  algorithm of [23], despite the fact that vertex cover is a much more severely restricted parameter. Hence, our algorithm generalizes the algorithm of [23] without a significant sacrifice in the running time.

Despite the above, our main contribution with respect to structural parameters is not our algorithm for parameter treewidth, but an answer to a question that is naturally posed given the above: can the super-exponential dependence present in both our algorithm and the algorithm of [23] be avoided, that is, can we obtain a  $2^{O(\text{tw})} n^{O(1)}$  algorithm? We show that this is likely impossible, as the existence of an algorithm running in time  $\text{vc}^{o(\text{vc})} n^{O(1)}$  is ruled out by the ETH (and hence also the existence of a  $\text{tw}^{o(\text{tw})} n^{O(1)}$  algorithm). This result is likely to be of wider interest to the parameterized complexity community, where one of the most exciting developments of the last fifteen years has arguably been the development of the Cut&Count technique (and its variations). One of the crowning achievements of this

---

<sup>1</sup> Throughout the paper we assume that the reader is familiar with the basics of parameterized complexity, as given in standard textbooks [16].

technique is the design of single-exponential algorithms for connectivity problems – indeed an algorithm running in time  $3^{\text{tw}}n$  for MINIMUM FVS is given in [17]. It has therefore been of much interest to understand which connectivity problems admit single-exponential algorithms using such techniques (see e.g. [7] and the references within). Curiously, even though several cousins of MINIMUM FEEDBACK VERTEX SET have been considered in this context (such as SUBSET FEEDBACK VERTEX SET and RESTRICTED EDGE-SUBSET FEEDBACK EDGE SET), for MAX MIN FVS, which is arguably a very natural variant, it was not known whether a single-exponential algorithm for parameter treewidth is possible. Our work thus adds to the literature a natural connectivity problem where Cut&Count can provably not be applied (under standard assumptions). Interestingly, our lower bound even applies to the case of vertex cover, which is rare, as most problems tend to become rather easy under this very restrictive parameter.

We then move on to consider the parameterization of the problem by  $k$ , the size of the sought solution. Observe that a  $k^{O(k)}n^{O(1)}$  algorithm can easily be obtained by the results sketched above and a simple win/win argument: start with any minimal feedback vertex set  $S$  of the given graph  $G$ : if  $|S| \geq k$  we are done; if not, then  $\text{tw}(G) \leq k$  and we can solve the problem using the algorithm for treewidth. It is therefore only interesting to consider algorithms with a single-exponential dependence on  $k$ . Such an algorithm, with complexity  $10^k n^{O(1)}$ , was claimed by [23]. Unfortunately, as we explain in detail in Section 5, this algorithm contains a significant flaw<sup>2</sup>.

Our contribution is to present a corrected version of the algorithm of [23], which also achieves a slightly better running time of  $9.34^k n^{O(1)}$ , compared to the  $10^k n^{O(1)}$  of the (flawed) algorithm of [23]. Our algorithm follows the same general strategy of [23], branching and placing vertices in the forest or the feedback vertex set. However, we have to rely on a more sophisticated measure of progress, because simply counting the size of the selected set is not sufficient. We therefore measure our progress towards a restricted special case we identify, namely the case where the undecided part of the graph induces a linear forest. Though this special case sounds tantalizingly simple, we show that the problem is still NP-complete under this restriction, but obtaining an FPT algorithm is much easier. We then plug in our algorithm to a more involved branching procedure which aims to either reduce instances into this special case, or output a certifiable minimal feedback vertex set of the desired size.

Finally, motivated by the above we note that a blocking point in the design of algorithms for MAX MIN FVS seems to be the difficulty of the extension problem: given a set  $S_0$ , decide if a minimal fvs  $S$  that extends  $S_0$  exists. As mentioned, Casel et al. [13] showed that this problem is W[1]-hard parameterized by  $|S_0|$ . Intriguingly, however, it is not even known if this problem is in XP, that is, whether it is solvable in polynomial time for fixed  $k$ . We show that this is perhaps not surprising, as obtaining a polynomial time algorithm in this case would imply the existence of a polynomial time algorithm for the notorious  $k$ -IN-A-TREE problem: given  $k$  terminals in a graph, find an induced tree that contains them. Since this problem was solved for  $k = 3$  in a breakthrough by Chudnovsky and Seymour [15], the complexity for fixed  $k \geq 4$  has remained a big open problem (for example [29] states that “Solving it in polynomial time for constant  $k$  would be a huge result”). It is therefore perhaps not surprising that obtaining an XP algorithm for the extension problem for minimal feedback vertex sets of fixed size is challenging, since such an algorithm would settle another long-standing problem.

---

<sup>2</sup> Saket Saurabh, one of the authors of [23], confirmed so via private communication with Michael Lampis.

**Other relevant work.** As mentioned, MAX MIN FVS is an example of a wider class of MaxMin problems which have recently attracted much attention in the literature, among the most well-studied of which are MAXIMUM MINIMAL VERTEX COVER [2, 11, 12, 34] and UPPER DOMINATING SET (which is the standard name for MAXIMUM MINIMAL DOMINATING SET) [1, 3, 5, 21]. Besides these problems, MaxMin or MinMax versions of cut and separations problems [19, 26, 30], knapsack problems [22, 24], matching problems [14], and coloring problems [6] have also been studied.

The question of which connectivity problems admit single-exponential algorithms parameterized by treewidth has been well-studied over the last decade. As mentioned, the main breakthrough was the discovery of the Cut&Count technique [16], which gave randomized  $2^{O(\text{tw})}n^{O(1)}$  algorithms for many such problems, such as STEINER TREE, HAMILTONICITY, CONNECTED DOMINATING SET and others. Follow-up work also provided deterministic algorithms with complexity  $2^{O(\text{tw})}n^{O(1)}$  [8]. It is important to note that the discovery of these techniques was considered a surprise at the time, as the conventional wisdom was that connectivity problems probably require  $\text{tw}^{O(\text{tw})}$  time to be solved [31]. Naturally, the topic was taken up with much excitement, in an attempt to discover the limits of such techniques, including problems for which they cannot work. In this vein, [33] gave a meta-theorem capturing many tractable problems, and also an example problem that cannot be solved in time  $2^{o(\text{tw}^2)}n^{O(1)}$  under the ETH. Several other examples of connectivity problems which require slightly super-exponential time parameterized by treewidth are now known [4, 27], with the most relevant to our work being the feedback vertex set variants studied in [7, 10], as well as the digraph version of the minimum feedback vertex set problem (parameterized by the treewidth of the underlying graph) [9]. The results of our paper seem to confirm the intuition that the Cut&Count technique is rather fragile when applied to feedback vertex set problems, since in many variations or generalizations of this problem, a super-exponential dependence on treewidth is inevitable (assuming the ETH).

## 2 Preliminaries

Throughout the paper, we use standard graph notation [18]. Moreover, for vertex  $u \in V(G)$ , let  $\deg_X(u)$  denote its degree in  $G[X \cup \{u\}]$ , where  $X \subseteq V(G)$ . A *multigraph*  $G$  is a graph which is permitted to have multiple edges with the same end nodes, thus, two vertices may be connected by more than one edge. Given a (multi)graph  $G$ , where  $e = \{u, v\} \in E(G)$  is a not necessarily unique edge connecting distinct vertices  $u$  and  $v$ , the *contraction* of  $e$  results in a new graph  $G'$  such that  $V(G') = (V(G) \setminus \{u, v\}) \cup \{w\}$ , while for each edge  $\{u, x\}$  or  $\{v, x\}$  in  $E(G)$ , there exists an edge  $\{w, x\}$  in  $E(G')$ . Any edge  $e \in E(G)$  not incident to  $u, v$  also belongs to  $E(G')$ . If  $u$  and  $v$  were additionally connected by an edge apart from  $e$ , then  $w$  has a self loop.

For  $i \in \mathbb{N}$ ,  $[i]$  denotes the set  $\{1, \dots, i\}$ . A feedback vertex set  $S$  of  $G$  is minimal if and only if  $\forall s \in S$ ,  $G[(V(G) \setminus S) \cup \{s\}]$  contains a cycle, namely a *private cycle* of  $s$  [21]. Lastly, we make use of a weaker version of ETH, which states that 3-SAT cannot be determined in time  $2^{o(n)}$ , where  $n$  denotes the number of the variables [28].

Finally, note that the proofs of all lemmas and theorems marked with  $(\star)$  are present in the full version of the paper.

## 3 Treewidth Algorithm

Here we will present an algorithm for MAX MIN FVS parameterized by the treewidth of the input graph, arguably the most well studied structural parameter. As a corollary of the lower bound established in Section 4, it follows that the running time of the algorithm is essentially optimal under the ETH.

► **Theorem 1.** ( $\star$ ) *Given an instance  $\mathcal{I} = (G, k)$  of MAX MIN FVS, as well as a nice tree decomposition of  $G$  of width  $tw$ , there exists an algorithm that decides  $\mathcal{I}$  in time  $tw^{O(tw)}n^{O(1)}$ .*

**Proof sketch.** The main idea lies on performing standard dynamic programming on the nodes of the nice tree decomposition. To this end, for each node, we will consider all the partial solutions, corresponding to (not necessarily minimal) feedback vertex sets of the subgraph induced by the vertices of the nodes of the corresponding subtree of the tree decomposition. We will try to extend such a feedback vertex set to a minimal feedback vertex set of  $G$ , that respects the partial solution. For each partial solution, it is imperative to identify, apart from the vertices of the bag that belong to the feedback vertex set, the connectivity of the rest of the vertices in the potential final forest. In order to do so, we consider a coloring indicating that, same colored vertices of the forest of the partial solution, should be in the same connected component of the potential final forest. Moreover, we keep track of which vertices of the forest of the partial solution are connected via paths containing forgotten vertices. Finally, for each vertex of the feedback vertex set of the partial solution, we need to identify one of its private cycles. To do so, we first guess the connected component of the potential final forest that “includes” such a private cycle, while additionally keeping track of the number of edges between the vertex and said component. ◀

#### 4 ETH Lower Bound

In this section we present a lower bound on the complexity of solving MAX MIN FVS parameterized by vertex cover. Starting from a 3-SAT instance on  $n$  variables, we produce an equivalent MAX MIN FVS instance on a graph of vertex cover  $O(n/\log n)$ , hence any algorithm solving the latter problem in time  $vc^{o(vc)}n^{O(1)}$  would refute the ETH. As already mentioned, vertex cover is a very restrictive structural parameter, and due to known relationships of vertex cover with more general parameters, such as treedepth and treewidth, analogous lower bounds follow for these parameters. We first state the main theorem.

► **Theorem 2.** *There is no  $vc^{o(vc)}n^{O(1)}$  time algorithm for MAX MIN FVS, where  $vc$  denotes the size of the minimum vertex cover of the input graph, unless the ETH fails.*

Before we present the details of our construction, let us give some high-level intuition. Our goal is to “compress” an  $n$ -variable instance of 3-SAT, into an MAX MIN FVS instance with vertex cover roughly  $n/\log n$ . To this end, we will construct  $\log n$  choice gadgets, each of which is supposed to represent  $n/\log n$  variables, while contributing only  $n/\log^2 n$  to the vertex cover. Hence, each vertex of each such gadget must be capable of representing roughly  $\log n$  variables.

Our choice gadget may be thought of as a variation of a bipartite graph with sets  $L, R$ , of size roughly  $n/\log^2 n$  and  $\sqrt{n}$  respectively. If one naively tries to encode information in such a gadget by selecting which vertices of  $L \cup R$  belong in an optimal solution, this would only give 2 choices per vertex, which is not efficient enough. Instead, we engineer things in a way that all vertices of  $L \cup R$  must belong in the forest in an optimal solution, and the interesting choice for a vertex  $\ell$  of  $L$  is with which vertex  $r$  of  $R$  we will place  $\ell$  in the same component. In this sense, a vertex  $\ell$  of  $L$  has  $|R|$  choices, which is sufficient to encode the assignment for  $\Omega(\log n)$  variables. What remains, then, is to add machinery that enforces this basic setup, and then clause checking vertices which for each clause verify that the clause is satisfied by testing if an  $\ell$  vertex that represents one of its literals is in the same component as an  $r$  vertex that represents a satisfying assignment for the clause.

## 4.1 Preliminary Tools

Before we present the construction that proves Theorem 2, we give a variant of 3-SAT from which it will be more convenient to start our reduction, as well as a basic force gadget that we will use in our construction to ensure that some vertices must be placed in the forest in order to achieve an optimal solution.

**3P3SAT.** We first define a constrained version of 3-SAT, called 3-PARTITIONED-3-SAT (3P3SAT for short), and establish its hardness under the ETH.

### 3-PARTITIONED-3-SAT

**Input:** A formula  $\phi$  in 3-CNF form, together with a partition of the set of its variables  $V$  into three disjoint sets  $V_1, V_2, V_3$ , with  $|V_i| = n$ , such that no clause contains more than one variable from each  $V_i$ .

**Task:** Determine whether  $\phi$  is satisfiable.

► **Theorem 3.** ( $\star$ ) 3-PARTITIONED-3-SAT cannot be decided in time  $2^{o(n)}$ , unless the ETH fails.

**Force gadgets.** We now present a gadget that will ensure that a vertex  $u$  must be placed in the forest in any solution that finds a large minimal feedback vertex set. In the remainder, suppose that  $A$  is a sufficiently large value (we give a concrete value to  $A$  in the next section). When we say that we attach a *force gadget* to a vertex  $u$ , we introduce  $A + 1$  new vertices  $\bar{u}, u_1, \dots, u_A$  to the graph such that the vertices  $u_i$  form an independent set, while there exist edges  $\{u, u_i\}, \{\bar{u}, u_i\}$  for all  $i \in [A]$ , as well as the edge  $\{u, \bar{u}\}$ . We refer to vertex  $\bar{u}$  as the *gadget twin* of  $u$ , while the rest of the vertices will be referred to as the *gadget leaves* of  $u$ . Intuitively, the idea here is that if  $u$  (or  $\bar{u}$ ) is contained in a minimal feedback vertex set, then none of the  $A$  leaves of the gadget can be taken, because these vertices cannot have private cycles. Hence, setting  $A$  to be sufficiently large will allow us to force  $u$  to be in the forest.

■ **Figure 1** Force gadget attached to vertex  $u$ .

## 4.2 Construction

Let  $\phi$  be a 3P3SAT instance of  $m$  clauses, where  $|V_p| = n$  for  $p \in [3]$  and, without loss of generality, assume that  $n$  is a power of 4 (this can be achieved by adding dummy variables to the instance if needed). Partition each variable set  $V_p$  to  $\log n$  subsets  $V_p^q$  of size at most  $\lceil \frac{n}{\log n} \rceil$ , where  $p \in [3]$  and  $q \in [\log n]$ . Let  $L = \lceil \frac{n}{\log^2 n} \rceil$ . Moreover, partition each variable subset  $V_p^q$  into  $2L$  subsets  $\mathcal{V}_\alpha^{p,q}$  of size as equal as possible, where  $\alpha \in [2L]$ . In the following

we will omit  $p$  and  $q$  and instead use the notation  $\mathcal{V}_\alpha$ , whenever  $p, q$  are clear from the context. Define  $R = \sqrt{n}$ ,  $A = n^2 + m$  and  $k = (4AL + AR + 2LR) \cdot 3 \log n + m$ . We will proceed with the construction of a graph  $G$  such that  $G$  has a minimal feedback vertex set of size at least  $k$  if and only if  $\phi$  is satisfiable.

For each variable subset  $V_p^q$ , we define the choice gadget graph  $G_p^q$  as follows:

- $V(G_p^q) = \{\ell_i, \ell'_i, \kappa_i, \lambda_i \mid i \in [2L]\} \cup \{r_j \mid j \in [R]\} \cup \{m_j^i \mid i \in [2L], j \in [R]\}$ ,
- all the vertices  $\ell_i, \ell'_i$  and  $r_j$  have an attached force gadget,
- for  $i \in [2L]$ ,  $N(\kappa_i) = M_i \cup \{\lambda_i\}$  and  $N(\lambda_i) = M_i \cup \{\kappa_i\}$ , where  $M_i = \{m_j^i \mid j \in [R]\}$ ,
- for  $i \in [2L]$  and  $j \in [R]$ ,  $m_j^i$  has an edge with  $\ell_i, \ell'_i$  and  $r_j$ .

We will refer to the set  $X_i = M_i \cup \{\kappa_i, \lambda_i\}$  as the *choice set*  $i$ .

Intuitively, one can think of this gadget as having been constructed as follows: we start with a complete bipartite graph that has on one side the vertices  $\ell_i$  and on the other the vertices  $r_j$ ; we subdivide each edge of this graph, giving the vertices  $m_j^i$ ; for each  $i \in [2L]$  we add  $\ell'_i, \kappa_i, \lambda_i$ , connect them to the same  $m_j^i$  vertices that  $\ell_i$  is connected to and connect  $\kappa_i$  to  $\lambda_i$ ; we attach force gadgets to all  $\ell_i, \ell'_i, r_j$ . Hence, as sketched before, the idea of this gadget is that the choice of a vertex  $\ell_i$  is to pick an  $r_j$  with which it will be in the same component in the forest, and this will be expressed by picking one  $m_j^i$  that will be placed in the forest.

(a) Part of the construction concerning  $X_i$ . (b) The whole choice gadget graph  $G_p^q$ .

■ **Figure 2** Black vertices have a force gadget attached.

Each vertex  $\ell_\alpha$  of  $G_p^q$  is used to represent a variable subset  $\mathcal{V}_\alpha^{p,q} \subseteq V_p^q$  containing at most

$$|\mathcal{V}_\alpha^{p,q}| \leq \left\lceil \frac{|V^{p,q}|}{2L} \right\rceil \leq \left\lceil \frac{\lceil \frac{n}{\log n} \rceil}{2L} \right\rceil = \left\lceil \frac{n}{2L \log n} \right\rceil \leq \left\lceil \frac{n}{2 \frac{n}{\log^2 n} \log n} \right\rceil = \left\lceil \frac{\log n}{2} \right\rceil = \frac{\log n}{2}$$

variables of  $\phi$ , where we used Theorem 3.10 of [25], for  $f(x) = x/2L$ . We fix an arbitrary one-to-one mapping so that every vertex  $m_\beta^\alpha$ , where  $\beta \in [R]$ , corresponds to a different assignment for this subset, which is dictated by which element of  $M_\alpha$  was not included in the final feedback vertex set. Since  $R = 2^{\log n/2} = \sqrt{n}$ , the size of  $M_\alpha$  is sufficient to uniquely encode all the different assignments of  $\mathcal{V}_\alpha$ .

Finally, introduce vertices  $c_i$ , where  $i \in [m]$ , each of which corresponds to a clause of  $\phi$ , and define graph  $G$  as the union of these vertices as well as all graphs  $G_p^q$ , where  $p \in [3]$  and  $q \in [\log n]$ . For a clause vertex  $c$ , add an edge to  $\ell_\alpha$  when  $\mathcal{V}_\alpha$  contains a variable appearing in  $c$ , as well as to the vertices  $r_\beta$  for each such  $\ell_\alpha$ , such that  $m_\beta^\alpha \notin S$  corresponds to an assignment of  $\mathcal{V}_\alpha$  satisfying  $c$ , where  $S$  denotes a minimal feedback vertex set. Notice

that since no clause contains multiple variables from the same variable set  $V_i$ , due to the refinement of the partition of the variables, it holds that all the variables of a clause will be represented by vertices appearing in distinct  $G_p^q$ .

### 4.3 Correctness

Having constructed the previously described instance  $(G, k)$  of MAX MIN FVS, it remains to prove its equivalence with the initial 3-PARTITIONED-3-SAT instance.

► **Lemma 4.** ( $\star$ ) *Any minimal feedback vertex set  $S$  of  $G$  of size at least  $k$  has the following properties:*

- (i)  $S$  does not contain any vertex attached with a force gadget or its gadget twin,
  - (ii)  $|M_i \setminus S| \leq 1$ , for every  $G_p^q$  and  $i \in [2L]$ ,
  - (iii)  $|S \cap V(G_p^q)| = 4AL + AR + 2LR$ ,
- where  $p \in [3]$  and  $q \in [\log n]$ .

► **Lemma 5.** ( $\star$ ) *If  $\phi$  has a satisfying assignment, then  $G$  has a minimal feedback vertex set of size at least  $k$ .*

► **Lemma 6.** ( $\star$ ) *If  $G$  has a minimal feedback vertex set of size at least  $k$ , then  $\phi$  has a satisfying assignment.*

► **Lemma 7.** ( $\star$ ) *It holds that  $\text{vc}(G) = O(n/\log n)$ .*

Using the previous lemmas, we can prove Theorem 2.

**Proof of Theorem 2.** Let  $\phi$  be a 3-PARTITIONED-3-SAT formula. In polynomial time, we can construct a graph  $G$  such that, due to Lemmas 5 and 6, deciding if  $G$  has a minimal feedback vertex set of size at least  $k$  is equivalent to deciding if  $\phi$  has a satisfying assignment. In that case, assuming there exists a  $\text{vc}^{o(\text{vc})}$  algorithm for MAX MIN FVS, one could decide 3-PARTITIONED-3-SAT in time

$$\text{vc}^{o(\text{vc})} = \left( \frac{n}{\log n} \right)^{o(n/\log n)} = 2^{(\log n - \log \log n)o(n/\log n)} = 2^{o(n)},$$

which contradicts the ETH due to Theorem 3. ◀

Since for any graph  $G$  it holds that  $\text{tw}(G) \leq \text{vc}(G)$ , the following corollary holds.

► **Corollary 8.** *There is no  $\text{tw}^{o(\text{tw})}n^{O(1)}$  time algorithm for MAX MIN FVS, where  $\text{tw}$  denotes the treewidth of the input graph, unless the ETH fails.*

## 5 Natural Parameter Algorithm

In this section we will present an FPT algorithm for MAX MIN FVS parameterized by the natural parameter, i.e. the size of the maximum minimal feedback vertex set  $k$ . The main theorem of this section is the following.

► **Theorem 9.** *MAX MIN FVS can be solved in time  $9.34^k n^{O(1)}$ .*

**Structure of the Section.** In Section 5.1 we define the closely related ANNOTATED MMFVS problem, and prove that it remains NP-hard, even on some instances of specific form, called *path restricted instances*. Subsequently, we present an algorithm dealing with this kind of instances, which either returns a minimal feedback vertex set of size at least  $k$  or concludes that this is a No instance of ANNOTATED MMFVS. Afterwards, in Section 5.2, we solve MAX MIN FVS by producing a number of instances of ANNOTATED MMFVS and utilizing the previous algorithm, therefore proving Theorem 9.

**Oversight of [23].** The algorithm of [23] performs a branching procedure which marks vertices as either belonging in the feedback vertex set or the remaining forest. The flaw is that the algorithm ceases the branching once  $k$  vertices have been identified as vertices of the feedback vertex set. However, this is not correct, since deciding if a given set  $S_0$  can be extended into a minimal feedback vertex set  $S \supseteq S_0$  is NP-complete and even W[1]-hard parameterized by  $|S_0|$  [13]. Hence, identifying  $k$  vertices of the solution is not, in general, sufficient to produce a feasible solution and the algorithm of [23] is incomplete, because it does not explain how the guessed part of the feedback vertex set can be extended into a feasible minimal solution. Intuitively, the pitfall here is that, unlike other standard maximization problems, such as MAX CLIQUE, MAX MIN FVS is not monotone, that is, a graph that contains a feasible solution of size  $k$  is not guaranteed to contain a feasible solution of size  $k - 1$  (consider, for instance, a  $K_{2,n}$ ).

## 5.1 Annotated MMFVS and Path Restricted Instances

First, we define the following closely related problem, denoted by ANNOTATED MMFVS for short.

ANNOTATED MAXIMUM MINIMAL FEEDBACK VERTEX SET

**Input:** A graph  $G = (V, E)$ , disjoint sets  $S, F \subseteq V$  where  $S \cup F$  is a feedback vertex set of  $G$ , as well as an integer  $k$ .

**Task:** Determine whether there exists a minimal feedback vertex set  $S'$  of  $G$  of size  $|S'| \geq k$  such that  $S' \supseteq S$  and  $S' \cap F = \emptyset$ .

**Remarks.** Notice that if  $F$  is not a forest, then the corresponding instance always has a negative answer. For the rest of this section, let  $U = V(G) \setminus (S \cup F)$ . Moreover, let  $H = \{s \in S \mid \deg_F(s) \geq 2 \text{ and } \deg_U(s) \leq 1\}$  denote the set of *good vertices* of  $S$ . An *interesting path* of  $G[U]$  is a connected component of  $G[U]$  such that for every vertex  $u$  belonging to said component, it holds that  $\deg_{F \cup U}(u) = 2$ . If every connected component of  $G[U]$  is an interesting path, then this is a *path restricted instance*. Furthermore, given an instance  $\mathcal{I}$ , let  $\text{ammfvs}(\mathcal{I})$  be equal to 1 if it is a Yes instance and 0 otherwise.

Let  $\mathcal{I} = (G, S, F, k)$  be a path restricted instance of ANNOTATED MMFVS. We will present an algorithm that either returns a minimal feedback vertex set  $S' \subseteq S \cup U$  of  $G$  of size at least  $k$  or concludes that this is a No instance of ANNOTATED MMFVS. Notice that ANNOTATED MMFVS remains NP-hard even on such instances, as dictated by Theorem 10. Therefore, we should not expect to solve path restricted instances of ANNOTATED MMFVS in polynomial time.

► **Theorem 10.** ( $\star$ ) ANNOTATED MMFVS is NP-hard on path restricted instances, even if all the paths are of length 2.

## 62:10 Parameterized Max Min Feedback Vertex Set

We proceed by presenting the main algorithm of this subsection, which will be essential in proving Theorem 9.

► **Theorem 11.** ( $\star$ ) *Let  $\mathcal{I} = (G, S, F, k)$  be a path restricted instance of ANNOTATED MMFVS, and let  $g$  denote the number of its good vertices. There is an algorithm running in time  $O(3^{k-g}n^{O(1)})$  which either returns a minimal feedback vertex set  $S' \subseteq S \cup U$  of  $G$  of size at least  $k$  or concludes that  $\mathcal{I}$  is a No instance of ANNOTATED MMFVS.*

**Proof sketch.** The main idea of the algorithm lies on the fact that we can efficiently handle instances where either  $k = 0$  or  $S = \emptyset$ . Towards this, we will employ a branching strategy that, as long as  $S$  remains non empty, new instances with reduced  $k$  are produced. Prior to performing branching, we first observe that we can efficiently deal with the good vertices. Afterwards, by employing said branching strategy, in every step we decide which vertex will be counted towards the  $k$  required, thereby reducing parameter  $k$  on each iteration. If at some point  $k = 0$  or  $S = \emptyset$ , it remains to decide whether this comprises a viable solution  $S'$ . Notice that  $S'$  may not be a solution for the annotated instance, since even if  $|S'| \geq k$ , it does not necessarily hold that  $S' \supseteq S$ . ◀

### 5.2 Algorithm for Max Min FVS

We start by presenting a high level sketch of the algorithm for MAX MIN FVS. The starting point is a minimal feedback vertex set  $S_0$  of  $G$ . Note that such a set can be obtained in polynomial time, while if it is of size at least  $k$ , we are done. Therefore, assume that  $|S_0| < k$ . Then, assuming there exists a minimal feedback vertex set  $S^*$ , where  $|S^*| \geq k$  and  $F^* = V(G) \setminus S^*$ , we will guess  $S_0 \cap S^*$ , thereby producing instances  $\mathcal{I}_0 = (G, S_0 \cap S^*, S_0 \cap F^*, k)$  of ANNOTATED MMFVS. Subsequently, we will establish a number of *safe* reduction rules, which do not affect the answer of the instances. We will present a measure of progress  $\mu$ , which guarantees that if an instance  $\mathcal{I} = (G, S, F, k)$  of ANNOTATED MMFVS has  $\mu(\mathcal{I}) \leq 1$ , then  $G$  has a minimal feedback vertex set  $S' \subseteq S \cup U$  of size at least  $k$ . Then, we will employ a branching strategy which, given  $\mathcal{I}_i$ , will produce instances  $\mathcal{I}_{i+1}^1, \mathcal{I}_{i+1}^2$  of lesser measure of progress, such that  $\mathcal{I}_i$  is a Yes instance if and only if at least one of  $\mathcal{I}_{i+1}^1, \mathcal{I}_{i+1}^2$  is also a Yes instance. If we can no further apply our branching strategy, and the measure of progress remains greater than 1, then it holds that  $\mathcal{I}$  is a path restricted instance and Theorem 11 applies.

**Measure of progress.** Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS. We define as  $\mu(\mathcal{I}) = k + cc(F) - g - p$  its *measure of progress*, where

- $cc(F)$  denotes the number of connected components of  $F$ ,
- $g$  denotes the number of good vertices of  $S$ ,
- $p$  denotes the number of interesting paths of  $G[U]$ .

It holds that if  $\mu(\mathcal{I}) \leq 1$ , then the underlying MAX MIN FVS instance has a positive answer, which does not necessarily respect the constraints dictated by the annotated version.

► **Lemma 12.** ( $\star$ ) *Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS, where  $\mu(\mathcal{I}) \leq 1$ . Then,  $G$  has a minimal feedback vertex set  $S' \subseteq S \cup U$  of size at least  $k$ .*

**Reduction rules.** In the following, we will describe some reduction rules which do not affect the answer of an instance of ANNOTATED MMFVS, while not increasing its measure of progress.

► **Lemma 13.** ( $\star$ ) *Let  $G = (V, E)$  be a (multi)graph and  $uv \in E(G)$ . Then,  $G$  is acyclic if and only if  $G/uv$  is acyclic.*

**Rule 1.** Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS,  $u, v \in F$  and  $uv \in E$ . Then, replace  $\mathcal{I}$  with  $\mathcal{I}' = (G', S, F', k)$ , where  $G' = G/uv$  occurs from the contraction of  $u$  and  $v$  into  $w$ , while  $F' = (F \cup \{w\}) \setminus \{u, v\}$ .

**Rule 2.** Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS,  $u \in U$  and  $\deg_{F \cup U}(u) = 0$ . Then, replace  $\mathcal{I}$  with  $\mathcal{I}' = (G - u, S, F, k)$ .

**Rule 3.** Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS,  $u \in U$  and  $\deg_{F \cup U}(u) = 1$ , while  $v \in N(u) \cap (F \cup U)$ . Then, replace  $\mathcal{I}$  with  $\mathcal{I}' = (G', S, F', k)$ , where  $G' = G/uv$  occurs from the contraction of  $u$  and  $v$  into  $w$ , while  $F' = (F \cup \{w\}) \setminus \{v\}$  if  $v \in F$ , and  $F' = F$  otherwise.

► **Lemma 14.** ( $\star$ ) *Applying rules 1, 2 and 3 does not change the outcome of the algorithm and does not increase the measure of progress.*

After exhaustively applying the aforementioned rules, it holds that  $\forall u \in U$ ,  $\deg_{F \cup U}(u) \geq 2$ , i.e.  $G[U]$  is a forest containing trees, all the leaves of which have at least one edge to  $F$ . Moreover,  $G[F]$  comprises an independent set. We proceed with a branching strategy that produces instances of ANNOTATED MMFVS of reduced measure of progress. If at some point  $\mu \leq 1$ , then Lemma 12 can be applied.

**Branching strategy.** Let  $\mathcal{I} = (G, S, F, k)$  be an instance of ANNOTATED MMFVS, on which all of the reduction rules have been applied exhaustively, thus, it holds that a)  $\forall u \in U$ ,  $\deg_{F \cup U}(u) \geq 2$  and b)  $F$  is an independent set.

Define  $u \in U$  to be an *interesting* vertex if  $\deg_{F \cup U}(u) \geq 3$ . As already noted,  $G[U]$  is a forest, the leaves of which all have an edge towards  $F$ , otherwise Rule 3 could still be applied. Consider a root for each tree of  $G[U]$ . For some tree  $T$ , let  $v$  be an interesting vertex at maximum distance from the corresponding root, i.e.  $v$  is an interesting vertex of maximum height. Notice that such a tree cannot be an interesting path. We branch depending on whether  $u$  is in the feedback vertex set or not. Towards this end, let  $S' = S \cup \{v\}$  and  $F' = F \cup \{v\}$ , while  $\mathcal{I}_1 = (G, S', F, k)$  and  $\mathcal{I}_2 = (G, S, F', k)$ . It holds that  $\mathcal{I}$  is a Yes instance if and only if at least one of  $\mathcal{I}_1, \mathcal{I}_2$  is a Yes instance, while if  $G[F']$  contains a cycle,  $\mathcal{I}_2$  is a No instance and we discard it. We replace  $\mathcal{I}$  with the instances  $\mathcal{I}_1$  and  $\mathcal{I}_2$ .

► **Lemma 15.** ( $\star$ ) *The branching strategy produces instances of reduced measure of progress, without reducing the number of good vertices. Additionally, whenever the branching places a vertex on the feedback vertex set, this vertex is good.*

**Complexity.** Starting from an instance  $(G, k)$  of MAX MIN FVS, we produce a minimal feedback vertex set  $S_0$  of  $G$  in polynomial time. If  $|S_0| \geq k$ , we are done. Alternatively, we produce instances of ANNOTATED MMFVS by guessing the intersection of  $S_0$  with some minimal feedback vertex set of  $G$  of size at least  $k$ . Let  $\mathcal{I} = (G, S, F, k)$  be one such instance. It holds that  $\mu(\mathcal{I}) \leq k + c$ , where  $c = cc(F)$ , therefore the branching will perform at most  $k + c$  steps. Notice that, at any step of the branching procedure, the number of good vertices never decreases. Now, consider a path restricted instance  $\mathcal{I}' = (G', S', F', k)$  resulting from branching starting on  $\mathcal{I}$ , on which branching, exactly  $\ell$  times a vertex was placed in the

## 62:12 Parameterized Max Min Feedback Vertex Set

feedback vertex set, therefore  $|S'| - |S| = \ell$ . There are at most  $\binom{k+c}{\ell}$  different such instances, each of which has at least  $\ell$  good vertices, thus Theorem 11 requires time at most  $3^{k-\ell}n^{O(1)}$ . Since  $0 \leq \ell \leq k+c$ , and there are at most  $\binom{k}{c}$  different instances  $\mathcal{I}$ , the algorithm runs in time  $9.34^k n^{O(1)}$ , since

$$\begin{aligned} \sum_{c=0}^k \binom{k}{c} \sum_{\ell=0}^{k+c} \binom{k+c}{\ell} 3^{k-\ell} &= 3^k \sum_{c=0}^k \binom{k}{c} \sum_{\ell=0}^{k+c} \binom{k+c}{\ell} 3^{-\ell} = 3^k \sum_{c=0}^k \binom{k}{c} \left(\frac{4}{3}\right)^{k+c} \\ &= 4^k \sum_{c=0}^k \binom{k}{c} \left(\frac{4}{3}\right)^c = 4^k \left(\frac{7}{3}\right)^k \leq 9.34^k. \end{aligned}$$

### 6 The Extension Problem

In this section we consider the following extension problem:

MINIMAL FVS EXTENSION

**Input:** A graph  $G = (V, E)$  and a set  $S \subseteq V$ .

**Task:** Determine whether there exists  $S^* \supseteq S$  such that  $S^*$  is a minimal feedback vertex set of  $G$ .

Observe that this is a special case of ANNOTATED MMFVS, since we essentially set  $F = \emptyset$  and do not care about the size of the produced solution, albeit with the difference that now we will not focus on the case where  $V \setminus S$  is already acyclic. This extension problem was already shown to be W[1]-hard parameterized by  $|S|$  by Casel et al. [13]. One question that was left open, however, was whether it is solvable in polynomial time for fixed  $|S|$ , that is, whether it belongs in the class XP. Superficially, this seems somewhat surprising, because for the closely related MAXIMUM MINIMAL VERTEX COVER and UPPER DOMINATING SET problems, membership of the extension problem in XP is almost trivial: it suffices to guess for each  $v \in S$  a private edge or vertex that is only dominated by  $v$ , remove from consideration other vertices that dominate this private edge or vertex, and then attempt to find any feasible solution. The reason that this strategy does not seem to work for feedback vertex set is that for each  $v \in S$  we would have to guess a private cycle. Since a priori we have no bound on the length of such a cycle, there is no obvious way to achieve this task in  $n^{f(k)}$  time.

Though we do not settle the complexity of the extension problem for fixed  $k$ , we provide evidence that obtaining a polynomial time algorithm would be a challenging task, because it would imply a similar algorithm for the  $k$ -IN-A-TREE problem. In the latter, we are given a graph  $G$  and a set  $T$  of  $k$  terminals and are asked to find a set  $T^*$  such that  $T \subseteq T^*$  and  $G[T^*]$  is a tree [15, 29].

► **Theorem 16.**  *$k$ -IN-A-TREE parameterized by  $k$  is fpt-reducible to MINIMAL FVS EXTENSION parameterized by the size of the given set.*

**Proof.** Consider an instance  $G = (V, E)$  of  $k$ -IN-A-TREE, with terminal set  $T$ . Let  $T = \{t_1, \dots, t_k\}$ . We add to the graph  $k-1$  new vertices,  $s_1, \dots, s_{k-1}$  and connect each  $s_i$  to  $t_i$  and to  $t_{i+1}$ , for  $i \in [k-1]$ . We set  $S = \{s_1, \dots, s_{k-1}\}$ . This completes the construction. Clearly, this reduction preserves the value of the parameter.

To see correctness, suppose first that a tree  $T^* \supseteq T$  exists in  $G$ . We set  $S_1 = S \cup (V \setminus T^*)$  in the new graph.  $S_1$  is a feedback vertex set, because removing it from the graph leaves  $T^*$ , which is a tree.  $S_1$  contains  $S$ . Furthermore, if  $S_1$  is not minimal, we greedily remove from it arbitrary vertices until we obtain a minimal feedback vertex set  $S_2$ . We claim that  $S_2$  must

still contain  $S$ . Indeed, each vertex  $s_i$ , for  $i \in [k - 1]$  has a private cycle, since its neighbors  $t_i, t_{i+1} \in T^*$ . For the converse direction, if there exists in the new graph a minimal feedback vertex set  $S^*$  that contains  $S$ , then the remaining forest  $F^* = V \setminus S^*$  must contain  $T$ , since each vertex of  $S$  must have a private cycle in the forest, and vertices of  $S$  have degree 2. Furthermore, all vertices of  $T$  must be in the same component of  $F^*$ , because to obtain a private cycle for  $s_i$ , we must have a path from  $t_i$  to  $t_{i+1}$  in  $F^*$ , for all  $i \in [k - 1]$ . Therefore, in this case we have found an induced tree in  $G$  that contains all terminals. ◀

## 7 Conclusions and Open Problems

We have precisely determined the complexity of MAX MIN FVS with respect to structural parameters from vertex cover to treewidth as being slightly super-exponential. One natural question to consider would then be to examine if the same complexity can be achieved when the problem is parameterized by clique-width. Regarding the complexity of the extension problem for sets of fixed size  $k$ , we have shown that this is at least as hard as the well-known (and wide open)  $k$ -IN-A-TREE problem. Barring a full resolution of this question, it would also be interesting to ask if the converse reduction also holds, which would prove that the two problems are actually equivalent.

## Abstract

The generation and verification of quantum states are fundamental tasks for quantum information processing that have recently been investigated by Irani, Natarajan, Nirkhe, Rao and Yuen [CCC 2022], Rosenthal and Yuen [ITCS 2022], Metger and Yuen [QIP 2023] under the term *state synthesis*. This paper studies this concept from the viewpoint of quantum distributed computing, and especially distributed quantum Merlin-Arthur (dQMA) protocols. We first introduce a novel task, on a line, called state generation with distributed inputs (SGDI). In this task, the goal is to generate the quantum state  $U|\psi\rangle$  at the rightmost node of the line, where  $|\psi\rangle$  is a quantum state given at the leftmost node and  $U$  is a unitary matrix whose description is distributed over the nodes of the line. We give a dQMA protocol for SGDI and utilize this protocol to construct a dQMA protocol for the Set Equality problem studied by Naor, Parter and Yegorov [SODA 2020], and complement our protocol by showing classical lower bounds for this problem. Our second contribution is a dQMA protocol, based on a recent work by Zhu and Hayashi [Physical Review A, 2019], to create EPR-pairs between adjacent nodes of a network without quantum communication. As an application of this dQMA protocol, we prove a general result showing how to convert any dQMA protocol on an arbitrary network into another dQMA protocol where the verification stage does not require any quantum communication.

## 1 Introduction

While quantum computational complexity has so far mostly investigated the complexity of classical problems (e.g., computing Boolean functions) in the quantum setting, recent works [1, 16, 20, 24, 29, 35] have started investigating the complexity of *quantum* problems (e.g., generating quantum states). For instance, Ji, Liu and Song [20] and Kretschmer [24]

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

have investigated the concept of quantum pseudorandom states from complexity-theoretic and cryptographic perspectives. Irani, Natarajan, Nirkhe, Rao, and Yuen [16] have made in-depth investigations of the complexity of the *state synthesis problem* in a setting first introduced by Aaronson [1] where the goal is to generate a quantum state by making queries to a classical oracle encoding the state. Rosenthal and Yuen [35] and Metger and Yuen [29] have considered interactive proofs for synthesizing quantum states (and also for implementing unitaries). Here the main goal is to generate complicated quantum states (e.g., quantum states described by an exponential-size generating quantum circuit) efficiently with the help of an all-powerful but untrusted prover. Note that in settings where an all-powerful prover is present, the task of quantum state synthesis is closely related to the task of quantum state verification (since the prover can simply send the quantum state that needs to be synthesized).

In this paper, we investigate the task of state generation and verification in the setting of quantum distributed computing. Quantum distributed computing is a fairly recent research topic: despite early investigations in the 2000s and the 2010s [3, 8, 9, 13, 36], it is only in the past five years that significant advances have been done in understanding the power of quantum distributed algorithms [2, 10, 17, 18, 25, 27, 37]. Fraigniaud, Le Gall, Nishimura, and Paz [10], in particular, have investigated the power of distributed quantum proofs in distributed computing, which is the natural quantum version of the concept of distributed classical proofs (also called locally-checkable proofs [14] or proof-labeling schemes [23]): each node of the network receives, additionally to its input, a quantum state (called a quantum proof) from an all-powerful but untrusted party called the prover. The main result from [10] shows that there exist classical problems that can be solved by quantum protocols using quantum proofs of length exponentially smaller than in the classical case.

We present two main results about state generation and verification in the setting where an all-powerful but untrusted prover helps the nodes in a non-interactive way, and apply these results to design new quantum protocols for concrete problems studied recently in [10, 33].

## 1.1 First result and applications: State Generation with Distributed Inputs

One of the main conceptual contributions of this paper is introducing the following problem: In a network of  $r + 1$  nodes  $v_0, v_1, \dots, v_r$ , node  $v_0$  is given as input an  $n$ -qubit quantum state  $|\psi\rangle$ . The goal is to generate the quantum state  $U|\psi\rangle$  at node  $v_r$ , where  $U$  is a unitary matrix whose description is distributed over the nodes of the network. For concreteness, in this paper we focus on the case where the network is a path of length  $r$  and the nodes  $v_0, v_r$  are both extremities of the path.<sup>1</sup>

Here is the precise description of the problem. The parties  $v_0, v_1, \dots, v_r$  are the nodes of a line graph of length  $r$ : the left-end extremity is  $v_0$ , the right-end extremity is  $v_r$ , and nodes  $v_j$  and  $v_{j+1}$  are connected for  $j = 0, 1, \dots, r - 1$ . Node  $v_0$  receives as input the classical description of an  $n$ -qubit state  $|\psi\rangle$ , as a  $2^n$ -dimensional vector.<sup>2</sup> The other nodes  $v_j$  for  $j = 1, 2, \dots, r$  receive as input the description of an  $n$ -qubit unitary transformation: each node  $v_j$  receives the description of a unitary transformation  $U_j$  acting on  $n$  qubits. In this setting, the aim is to generate the quantum state

<sup>1</sup> In distributed computing it is standard to first investigate the complexity of computational problems on simple network topologies such as a path or a ring. A solution on the path can often be extended to networks of more complex topology, or be used as a building block for solving problems on network of arbitrary topology.

<sup>2</sup> Our protocol actually only requires  $v_0$  to be able to generate many copies of  $|\psi\rangle$ , and thus also works when the input is a description of a quantum circuit generating  $|\psi\rangle$ , or even a black box generating  $|\psi\rangle$ .

$$|\varphi_r\rangle := U_r \cdots U_1 |\psi\rangle$$

at the right-end extremity  $v_r$ . We call this problem  $n$ -qubit *State Generation with Distributed Inputs* on the line of length  $r$  ( $n$ -qubit  $\text{SGDI}_r$ ). Without a prover, this problem is clearly not solvable in less than  $r$  rounds of communications between neighbors (this can be seen easily by considering the case where  $U_1 = \cdots = U_r = I$ ).

We consider the setting where a prover (an all-powerful but untrusted party) helps the nodes in a non-interactive way: at the very beginning of the protocol the prover sends to node  $v_j$  a quantum state  $\rho_j$  of at most  $s_c$  qubits, for each  $j \in \{0, 1, \dots, r\}$ . Here  $s_c$  is called the certificate size of the protocol and the state  $\rho_j$  is called the certificate to  $v_j$ . The nodes then run a one-round<sup>3</sup> distributed quantum algorithm (called the verification algorithm). More precisely, the nodes first perform one round of (synchronous) communication: each node sends one quantum message of at most  $s_m$  qubits to its neighbors ( $s_m$  is called the message size of the protocol). Each node then decides to either accept or reject. Such protocols, which have been introduced and studied in [10], are called distributed Quantum Merlin-Arthur (dQMA) protocols (see Section 2 for details). Additionally, when considering dQMA protocols for  $n$ -qubit  $\text{SGDI}_r$ , we add the requirement that node  $v_r$  outputs an  $n$ -qubit quantum state at the end of the protocol.

Here is our main result:

► **Theorem 1.** *For any constant  $\varepsilon > 0$ , there exists a dQMA protocol for  $n$ -qubit  $\text{SGDI}_r$  with certificate size  $O(n^2 r^5)$  and message size  $O(nr^2)$  satisfying the following: (**completeness**) There are certificates  $\rho_0, \dots, \rho_r$  such that all the nodes accept and node  $v_r$  outputs  $|\varphi_r\rangle$  with probability 1; (**soundness**) If all the nodes accept with probability at least  $\varepsilon$ , then the output state  $\rho$  of node  $v_r$  satisfies  $\langle \varphi_r | \rho | \varphi_r \rangle \geq 1 - \varepsilon$ .*

The protocol of Theorem 1 is a dQMA protocol with perfect completeness and soundness  $\varepsilon$ . Indeed, when receiving appropriate certificates from the prover, all nodes accept with probability 1 and node  $v_r$  outputs the state  $|\varphi_r\rangle$ . On the other hand, if the state  $\rho$  is far from  $|\varphi_r\rangle$ , the soundness condition guarantees that for any certificates  $\rho_0, \dots, \rho_r$  received from the prover (including the case of entangled certificates), the probability that at least one node rejects is at least  $1 - \varepsilon$  (remember that the quantity  $\langle \varphi_r | \rho | \varphi_r \rangle$  represents the square root of the fidelity between  $|\varphi_r\rangle\langle \varphi_r|$  and  $\rho$ ).

As an application of Theorem 1, we construct a quantum protocol for a concrete computational task called Set Equality, which was introduced in Ref. [33]. Here is the formal definition over a network of arbitrary topology (represented by an arbitrary graph  $G = (V, E)$ ).

► **Definition 1** ( $\text{SetEquality}_{\ell, U}$  [33]). *Let  $\ell$  be a positive integer and  $U$  be a finite set. Each node  $u$  of a graph  $G = (V, E)$  holds two lists of  $\ell$  elements  $(a_{u,1}, \dots, a_{u,\ell})$  and  $(b_{u,1}, \dots, b_{u,\ell})$  as input, where  $a_{u,i}, b_{u,i} \in U$  for all  $i \in \{1, 2, \dots, \ell\}$ . Define  $A = \{a_{u,i} \mid u \in V, i \in \{1, 2, \dots, \ell\}\}$  and  $B = \{b_{u,i} \mid u \in V, i \in \{1, 2, \dots, \ell\}\}$ . The output of  $\text{SetEquality}_{\ell, U}$  is 1 (yes), if  $A = B$  as multisets and 0 (no) otherwise.*

Using Theorem 1 we obtain the following result:

<sup>3</sup> As in almost all prior works on (classical or quantum) distributed proofs, in this paper we consider only one-round verification algorithms.

► **Theorem 2.** *For any small enough constant  $\varepsilon > 0$ , there exists a dQMA protocol for  $\text{SetEquality}_{\ell,U}$  on the line graph of length  $r$  with completeness  $1 - \varepsilon$  and soundness  $\varepsilon$  that has certificate size  $O(r^5 \log^2(\ell r) \log^2 |U|)$  and message size  $O(r^2 \log(\ell r) \log |U|)$ .*

While Ref. [33] considered the special case of  $\text{SetEquality}_{\ell,U}$  and showed efficient distributed *interactive* protocols with small certificate and message size (see Section 1.4), no (nontrivial) classical dMA protocol (or lower bound) is known before this paper to our best knowledge. We complement the result in Theorem 2 by showing classical lower bounds and upper bounds of distributed Merlin-Arthur (dMA) protocols for  $\text{SetEquality}_{\ell,U}$ .

► **Theorem 3.** *For any dMA protocol for  $\text{SetEquality}_{\ell,U}$  on a line graph of length  $r$  with certificate size  $s_c$ , completeness  $3/4$ , and soundness  $1/4$ ,*

- *if  $|U| < \ell$ , then  $s_c = \Omega(|U| \log(\ell/|U|))$ ;*
- *if  $|U| = \Omega(\ell)$ , then  $s_c = \Omega(\ell)$ ;*
- *if  $|U| = \Omega(r\ell)$ , then  $s_c = \Omega(r\ell)$ .*

► **Theorem 4.** *There exists a dMA protocol for  $\text{SetEquality}_{\ell,U}$  on a line graph of length  $r$  with completeness 1 and soundness 0 whose certificate size and message size are both  $O(\min\{r\ell \log |U|, |U| \log(r\ell)\})$ .*

Although the dependence in  $r$  is worse than in the classical dMA protocol of Theorem 4, the dependence of the dQMA protocol of Theorem 2 in  $\ell$  (the number of elements each node receives) and  $|U|$  (the size of the universal set) are polylogarithmic. On the other hand, in classical case, we have linear lower bounds with respect to  $\ell$  and  $|U|$  as in Theorem 3. Therefore Theorem 2 gives a significant improvement for sufficiently large  $\ell$  and  $|U|$ . This assumption about the input parameters seems reasonable when considering applications similar to those of the dQMA protocol for the equality problem proposed in Ref. [10]. Note that our bounds of classical certificate size in Theorem 3 and Theorem 4 are tight up to  $\text{poly} \log(\ell, |U|, r)$  factors when  $|U| < \ell$  or  $|U| = \Omega(r\ell)$ .

## 1.2 Second result and applications: EPR-pairs generation and LOCC dQMA protocols

Our second contribution is a protocol, based on a recent work by Zhu and Hayashi [41], to create EPR-pairs between adjacent nodes of a network without quantum communication in the same setting as above, where a prover helps the nodes in a non-interactive way. As an application of this protocol, we prove a general result showing how to convert any dQMA protocol on an arbitrary network into another dQMA protocol where the verification algorithm uses only classical communication (instead as quantum communication, as allowed in the definition of dQMA protocols and used in all dQMA protocols of Ref. [10] and Theorems 1 and 2 above).

More precisely, we say a dQMA protocol is an LOCC (Local Operation and Classical Communication) dQMA protocol if the verification algorithm can be implemented only by local operations at each node and classical communication between neighboring nodes (i.e., no quantum communication is allowed). Our protocol for generating EPR-pairs enables us to show the following theorem:

► **Theorem 5.** *For any constants  $p_c$  and  $p_s$  such that  $0 \leq p_s < p_c \leq 1$ , let  $\mathcal{P}$  be a dQMA protocol for some problem on a network  $G$  with completeness  $p_c$ , soundness  $p_s$ , certificate size  $s_c^{\mathcal{P}}$  and message size  $s_m^{\mathcal{P}}$ . For any small enough constant  $\gamma > 0$ , there exists an LOCC dQMA protocol  $\mathcal{P}'$  for the same problem on  $G$  with completeness  $p_c$ , soundness  $p_s + \gamma$ , certificate size  $s_c^{\mathcal{P}'} + O(d_{\max} s_m^{\mathcal{P}} s_{tm}^{\mathcal{P}'})$ , and message size  $O(s_m^{\mathcal{P}} s_{tm}^{\mathcal{P}'})$ , where  $d_{\max}$  is the maximum degree of  $G$ , and  $s_{tm}^{\mathcal{P}'}$  is the total number of qubits sent in the verification stage of  $\mathcal{P}'$ .*

As an application of Theorem 5, we consider the equality problem studied in Ref. [10]. In this problem, denoted  $\text{EQ}_n^t$ , a collection of  $n$ -bit strings  $x_1, x_2, \dots, x_t$  is given as input to  $t$  specific nodes  $u_1, u_2, \dots, u_t$  (called terminals) of an arbitrary network  $G = (V, E)$  as follows: node  $u_i$  receives  $x_i$ , for  $i \in \{1, 2, \dots, t\}$ . The goal is to check whether the  $t$  strings are equal, i.e., whether  $x_1 = \dots = x_t$ . By applying Theorem 5 to the main result in Ref. [10] (a dQMA protocol for  $\text{EQ}_n^t$  with certificate size  $O(tr^2 \log n)$  and message size  $O(tr^2 \log(n+r))$ ), we obtain the following corollary:

► **Corollary 1.** *For any small enough constant  $\varepsilon > 0$ , there is an LOCC dQMA protocol for  $\text{EQ}_n^t$  with completeness 1, soundness  $\varepsilon$ , certificate size  $O(d_{\max}|V|t^2r^4 \log^2(n+r))$  and messages size  $O(|V|t^2r^4 \log^2(n+r))$ , where  $r$  is the radius of the set of the  $t$  terminals and  $|V|$  is the number of nodes of the network  $G = (V, E)$ .*

We can also apply Theorem 5 to the dQMA protocol of Theorem 2, leading to the following corollary:

► **Corollary 2.** *For any small enough constant  $\varepsilon > 0$ , there is an LOCC dQMA protocol for  $\text{SetEquality}_{\ell, U}$  on the line graph of length  $r$  with completeness  $1 - \varepsilon$ , soundness  $\varepsilon$ , certificate size  $O(r^5 \log^2(\ell r) \log^2 |U|)$  and messages size  $O(r^5 \log^2(\ell r) \log^2 |U|)$ .*

Note that these LOCC dQMA protocols still have good dependence in the main parameters we are interested in: the parameter  $n$  for  $\text{EQ}_n^t$  (for which the dependence is still exponentially better than any classical dMA protocols) and the parameters  $\ell$  and  $|U|$  for  $\text{SetEquality}_{\ell, U}$  (for which the dependence is still exponentially better than any classical dMA protocols, due to Theorem 3).

### 1.3 Overview of our proofs

To explain the proof idea of Theorem 1, we only consider the simplified case  $U_1 = \dots = U_r = I$ . The general case can be proved similarly by a slightly more complicated analysis.

The dQMA protocol to prove Theorem 1 is based on the dQMA protocol on the line of length  $r$  by Fraigniaud et al. [10]. In the setting of Ref. [10], the left-end extremity  $v_0$  has an  $n$ -bit string  $x$ , the right-end extremity  $v_r$  has an  $n$ -bit string  $y$ , and the other intermediate nodes have no input. The goal is to verify whether  $x = y$ . The dQMA protocol in Ref. [10] checks whether the fingerprint state  $|\psi_0\rangle = |\psi_x\rangle$  [5] prepared by  $v_0$  is equal to the fingerprint state  $|\psi_r\rangle = |\psi_y\rangle$  prepared by  $v_r$  ( $x = y$ ), or  $|\psi_0\rangle$  is almost orthogonal to  $|\psi_r\rangle$  ( $x \neq y$ ). For this, node  $v_j$  ( $2 \leq j \leq r-1$ ) receives a subsystem whose reduced state is  $\rho_j$  as a certificate from the prover. At the verification stage, any node (except for  $v_r$ ) chooses keeping its certificate by itself, or sending it to the right neighboring node with probability  $1/2$  to check if the reduced states of the two neighboring nodes,  $\rho_j$  and  $\rho_{j+1}$ , are close, which can be checked by the SWAP test [5]. If  $x = y$ , then the prover can send  $|\psi_0\rangle$  ( $= |\psi_r\rangle$ ) for every intermediate node to pass all the SWAP tests done at the verification stage, which means accept. Otherwise, the SWAP test done at some node rejects with a reasonable probability since  $|\psi_x\rangle$  is very far from  $|\psi_y\rangle$ , and hence the distance between  $\rho_j$  and  $\rho_{j+1}$  should be far at some  $j$ .

Now the case that  $U_1 = \dots = U_r = I$  (which means that all nodes except  $v_0$  have no input) in the setting of  $\text{SGDI}_r$  (then the goal state  $|\varphi_r\rangle$  at  $v_r$  is the same as the state  $|\psi\rangle$  of  $v_0$ ) is similar to the setting of Ref. [10], except that  $v_r$  also has no input. The difficulty is that  $v_r$  has no state that can be generated by itself, and thus the analysis of Ref. [10] cannot be used as it is.

To overcome this difficulty, we utilize an idea from the verification of graph states [15, 32], in particular, the idea by Morimae, Takeuchi, and Hayashi [32]. They used the following basic idea for their protocol in order to verify an arbitrary graph state  $|G\rangle$  sent from the prover (or prepared by a malicious party): (i) the verifier receives  $(m + k + 1)$  subsystems, in which each subsystem ideally contains  $|G\rangle$ , from the prover; (ii) the verifier chooses  $m$  subsystems uniformly at random, and discards them; (iii) the verifier chooses one subsystem, and some test that  $|G\rangle$  should pass (stabilizer test) is done for each of the remaining  $k$  subsystems; and (iv) if all the tests passed, the chosen subsystem in (iii) should be close to  $|G\rangle$ , which is proved by using a quantum de Finetti theorem with some measurement condition [28] (exponentially better in the dimension of the subsystem than the standard quantum de Finetti theorem [6]). Note that (ii) and (iii) are necessary since the assumption that the total system is permutation-invariant is needed to apply the quantum de Finetti theorem.

Our protocol applies the idea of Ref. [32] to the verification protocol of Ref. [10] explained above. Namely, the parties  $v_1, v_2, \dots, v_r$  first receives  $(m + k + 1)$  subsystems, where each subsystem ideally contains  $|\psi\rangle^{\otimes r}$ , sent from the prover. For  $k$  subsystems that are randomly chosen, we apply the verification protocol of Ref. [10]. Actually, we have a subtle problem with the corresponding steps of (ii) and (iii) in the idea of Ref. [32], since  $v_0, v_1, \dots, v_r$  do not have any shared randomness, and thus those steps cannot be implemented jointly. Fortunately, this problem can be overcome since the permutation-invariant property is satisfied by the random permutations of  $(m + k + 1)$  subsystems on *each* party.

The dQMA protocol for Theorem 2 is based on the distributed interactive protocol by Naor, Parter, and Yogev [33] using shared randomness<sup>4</sup>. In our setting (line of length  $r$ ), the distributed interactive protocol of Ref. [33] is as follows with two polynomials  $\alpha_j(x) := \prod_i (x - a_{j,i})$  and  $\beta_j(x) := \prod_i (x - b_{j,i})$ : with shared randomness  $s$  (taken from a large field), (i)  $v_0$  prepares  $A_0(s) := \alpha_0(s)$  and  $B_0(s) := \beta_0(s)$ ; (ii)  $v_j$  ( $j = 1, 2, \dots, r$ ) ideally receives  $A_j(s) := \alpha_0(s) \cdots \alpha_j(s)$  and  $B_j(s) := \beta_0(s) \cdots \beta_j(s)$  from the prover; (iii)  $A_j(s) = \alpha_j(s)A_{j-1}(s)$  and  $B_j(s) = \beta_j(s)B_{j-1}(s)$  are checked for consistency by communication from  $v_{j-1}$  to  $v_j$ . We can see that when  $A = B$ ,  $A_r(s) = B_r(s)$  for any  $s$ , and thus this protocol accepts with probability 1 by the ideal certificates from the prover, while when  $A \neq B$ ,  $A_r(s) \neq B_r(s)$  for most of  $s$ , and thus some node rejects with reasonable probability.

Actually, neither interaction nor shared randomness is available in our setting. Instead, we reduce the protocol by Naor et al. to  $\text{SGDI}_r$  with  $|\psi\rangle = |\psi_A\rangle \otimes |\psi_B\rangle$  where  $|\psi_A\rangle = \sum_s |s\rangle |\alpha_0(s)\rangle$ , and  $|\psi_B\rangle = \sum_s |s\rangle |\beta_0(s)\rangle$ , and  $U = U_{j,A} \otimes U_{j,B}$ , where  $U_{j,A}$  roughly<sup>5</sup> maps  $|s\rangle |t\rangle$  to  $|s\rangle |\alpha_j(s)t\rangle$  ( $j = 1, 2, \dots, r$ ) and  $U_{j,B}$  roughly maps  $|s\rangle |t\rangle$  to  $|s\rangle |\beta_j(s)t\rangle$  ( $j = 1, 2, \dots, r$ ). Then, Theorem 1 guarantees that  $v_r$  receives  $\sum_s |s\rangle |A_r(s)\rangle$  and  $\sum_s |s\rangle |B_r(s)\rangle$  with high fidelity as long as every node accepts with at least the probability guaranteed by Theorem 1. The SWAP test between these at  $v_r$  checks if  $A = B$  with high probability.

For the classical lower bound of  $\text{SetEquality}_{\ell,U}$  in Theorem 3, we utilize the lower bound for  $\text{EQ}_n^2$  of [10]. Ref. [10] showed that for any classical protocol for  $\text{EQ}_n^2$  on the line graph, at least one internal node requires a certificate of linear size. We show that  $\text{EQ}_n^2$  can be reduced to  $\text{SetEquality}_{\ell,U}$  in three cases depending on the size of  $U$ . Here we explain the simplest case:  $|U| = \Omega(\ell)$ . For a line graph with the left-end extremity  $v$  and the right-end extremity  $v'$ , let  $x = x_1 x_2 \cdots x_n$  be the input of  $\text{EQ}_n^2$  for  $v$  and  $y = y_1 y_2 \cdots y_n$  be the input of  $\text{EQ}_n^2$  for  $v'$ . Then we consider an injection  $f$  from  $\{0, 1\}^n$  to the set of  $3\ell$ -bit strings with

<sup>4</sup> While there is no shared randomness in their setting, shared randomness can be simulated by two interactions between the prover and the verifier.

<sup>5</sup> We actually need some modifications for  $U_{j,A}$  to be unitary.

Hamming weight  $\ell$  such that the input list  $(a_{v,1}, \dots, a_{v,\ell})$  of  $\text{SetEquality}_{\ell,U}$  for  $v$  includes the  $j$ -th element of the universal set  $U$  for  $|U| > 3\ell$  if and only if  $f(x)_j = 1$ , and the input list  $(b_{v',1}, \dots, b_{v',\ell})$  of  $\text{SetEquality}_{\ell,U}$  for  $v'$  includes the  $j$ -th element of the universal set  $U$  if and only if  $f(y)_j = 1$ . Now these two sets are identical if and only if  $x = y$ , which means a reduction from  $\text{EQ}_n^2$  to  $\text{SetEquality}_{\ell,U}$  for  $\ell = \Theta(n)$ . We thus get a lower bound of  $\Omega(\ell)$  from the  $\Omega(n)$  lower bound of  $\text{EQ}_n^2$  mentioned above.

The classical upper bound of  $\text{SetEquality}_{\ell,U}$  in Theorem 4 is fairly simple: the prover can send all of inputs  $A$  and  $B$  to each node to achieve the first upper bound  $O(r\ell \log |U|)$ . For the second upper bound  $O(|U| \log(r\ell))$ , the node  $v_i$  on the line graph  $\{v_0, \dots, v_r\}$  is given the information of inputs of  $v_j, j \in \{0, \dots, i-1\}$  as the certificate in the form of the number of each element of  $U$  in the corresponding inputs.

The basic proof idea of Theorem 5 is standard: we replace one qubit communicated between any two nodes  $u$  and  $v$  by two bits using quantum teleportation [4], assuming that they share an EPR pair  $|\Phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$  sent from the prover. The problem is that the prover may be malicious, and  $u$  and  $v$  should then verify that the pair sent from the prover is  $|\Phi^+\rangle$ . In order to obtain  $|\Phi^+\rangle$  with high fidelity, we actually ask the prover to send  $N+1$  copies of the EPR pairs. An honest prover will send the state  $|\Phi^+\rangle^{\otimes(N+1)}$ , but a malicious prover may naturally send an arbitrary state. Nodes  $u$  and  $v$  use  $N$  among the  $N+1$  pairs for the verification. If the verification succeeds, they are guaranteed that the remaining pair has high fidelity with  $|\Phi^+\rangle$ .

This type of verification of  $|\Phi^+\rangle$  in an adversarial scenario by the malicious prover was considered in a remarkable work by Zhu and Hayashi [41]. Extending the previous result [34] in a less adversarial scenario, they showed that by taking  $N = O(\frac{1}{\varepsilon} \log(\frac{1}{\delta}))$ , if the verification test succeeds with probability at least  $\delta$ , the state  $\sigma$  of the last pair has a high fidelity with  $|\Phi^+\rangle$  such that  $\langle \Phi^+ | \sigma | \Phi^+ \rangle \geq 1 - \varepsilon$ . Furthermore, the measurements in their verification protocol (essentially the same as those in Ref. [34]) are local, namely, they do not need any entangled measurement between the two qubits of each pair.

Now the proof idea of Theorem 5 uses the verification protocol of Ref. [41] in our setting. To do so, we first observe that the amount of classical communication needed between  $u$  and  $v$  can be upper-bounded by  $O(N)$  (which is the same as the certificate size from the prover), by rewriting the protocol of Ref. [41] with a slight modification in our setting. Then we replace the quantum bits sent among the nodes in the original dQMA protocol  $\mathcal{P}$  by classical communication. However, it needs not only a single EPR pair but a lot of EPR pairs to be verified. Thus, we need further analysis to convert  $\mathcal{P}$  into an LOCC dQMA protocol and to evaluate the message size of classical communication and the certificate size.

## 1.4 Related work

The concept of *distributed Merlin-Arthur protocols* (dMA), which is very similar to the concept of *randomized proof-labeling schemes* [12] was introduced by [11] as a randomized version of locally checkable proofs (LCPs). In a dMA protocol, as in LCPs, the prover assigns each node a short certificate. The nodes then perform a 1-round distributed algorithm, i.e., exchange messages with their neighbors through incident edges. The difference is that in dMA, this algorithm can be a randomized algorithm, instead of a deterministic algorithm as in LCPs. This randomization is helpful to reduce the size of certificates for some problems.

The recent paper [22] introduced the interactive extension of dMA, *distributed interactive proofs*, in which the prover and the verifier can perform more interaction. They showed that interaction is also useful to reduce the size of certificates. This concept has recently been explored in depth by several studies: distributed interactive proofs that utilize quantum certificates [26], the role of shared and private randomness [7, 30], and more efficient protocols

for concrete problems [19, 31, 33]. In particular, [33] introduced  $\text{SetEquality}_{\ell,U}$ , which is one of the problems we study in this paper, and showed efficient interactive protocols for  $\text{SetEquality}_{\ell,U}$  when  $\ell = |V|$  and  $|U| = O(|V|)$  that require two interactions between the prover and the verifier with certificate size<sup>6</sup>  $O(\log |V|)$ , and five interactions between the prover and the verifier with certificate size  $O(\log \log |V|)$ .

The technique we used in this paper from Refs. [32, 41] belongs to a broad and hot topic called “state certification (state verification)” [21, 38]. One conceptual contribution of this paper is providing the first concrete example of the effective use of these techniques for quantum distributed verification.

## 2 dQMA protocols

We consider a decision problem on a connected graph (called the network)  $G = (V, E)$ , where  $t$  inputs  $x_1, x_2, \dots, x_t$  are assigned to  $t$  nodes  $v_1, v_2, \dots, v_t \in V$ . We interpret the decision problem as a Boolean function  $f$ , where  $f(x_1, x_2, \dots, x_t) = 1$  is interpreted as “yes” and  $f(x_1, x_2, \dots, x_t) = 0$  is interpreted as “no”.

The concept of distributed quantum Merlin-Arthur (dQMA) protocols on a graph  $G = (V, E)$  is a quantum version of the concept of distributed Merlin-Arthur (dMA) protocols. The aim of a dMA protocol is to verify whether  $f(x_1, x_2, \dots, x_t) = 1$  or not. As briefly explained in Section 1.1, the nodes of  $G$  (which correspond to the verifier) first receive a message from a powerful but possibly malicious party (the prover). The nodes then enter a verification phase, in which they communicate together (but do not communicate with the prover anymore). The communication is possible only if two nodes are connected: each node can send one message to each of its neighbors. In the case of dQMA protocols, the only difference is that the message from the prover and the communication among the nodes may be quantum. Note that neither randomness nor entanglement are shared among the nodes in advance.

Formally, in a dQMA protocol  $\mathcal{P}$  on  $G = (V, E)$ , each node  $u \in V$  first receives a quantum register  $M_u$  from the prover. Then the nodes move to the verification stage, which consists of the following steps: (i)  $u$  applies a local quantum (or classical) operation on the composite system of  $M_u$  and its private register  $V_u$ ; (ii)  $u$  sends a quantum (or classical) register  $M_{uv}$  to any neighboring node  $v$ , and (iii)  $u$  applies a local quantum (or classical) operation on  $M_u$ ,  $V_u$ , and  $\otimes_{v \in N(u)} M_{vu}$ , and either accepts or rejects (we call this the decision of  $u$ ), where  $N(u)$  denotes the set of nodes that are neighbors of  $u$ . When local operations at each node and communication among the nodes in the verification stage are classical, the dQMA protocol is called *LOCC (Local Operation and Classical Communication)*.

The two main complexity measures of  $\mathcal{P}$  are the certificate size and the message size. The certificate size of  $\mathcal{P}$ , denoted as  $s_c^{\mathcal{P}}$ , is the maximum number of qubits that are sent to each node from the prover, that is,  $s_c^{\mathcal{P}} := \max_{u \in V} |M_u|$ , where  $|R|$  denotes the number of qubits of  $R$ . The message size of  $\mathcal{P}$ , denoted as  $s_m^{\mathcal{P}}$ , is the maximum number of qubits sent on edges of  $G$ , namely,  $s_m^{\mathcal{P}} := \max_{(u,v) \in E} (|M_{uv}| + |M_{vu}|)$ .

A dQMA protocol  $\mathcal{P}$  for a decision problem  $f$  on  $G$  with completeness  $p_c$  and soundness  $p_s$  is defined as a dQMA protocol satisfying the following two conditions:

**(completeness)** If  $f(x_1, x_2, \dots, x_t) = 1$ , there exists some quantum state  $|\chi\rangle$  on  $M := \otimes_{u \in V} M_u$  such that  $\Pr[\text{all nodes accept}] \geq p_c$ ;

**(soundness)** If  $f(x_1, x_2, \dots, x_t) = 0$ , for any quantum state  $|\chi\rangle$  on  $M$ ,  $\Pr[\text{all nodes accept}] \leq p_s$ .

<sup>6</sup> For  $\text{SetEquality}_{\ell,U}$ , the certificate size of their protocol can be written as  $O(\log |U| + \log(\ell|V|))$ .

In this paper, we consider the problem of generating a quantum state  $|\varphi\rangle$  on a network  $G = (V, E)$ . In this problem, some initially specified nodes  $w_1, \dots, w_\kappa$  not only make their decisions (accept or reject) but also output the quantum state  $|\varphi\rangle$  jointly (if they accept). In our specific problem, the  $n$ -qubit  $\text{SGDI}_r$ , all nodes of the line graph with nodes  $v_0, v_1, \dots, v_r$  have an input ( $v_0$  has a classical description of  $|\psi\rangle$  and  $v_j$  for  $j = 1, 2, \dots, r$  has a classical description of  $U_j$ ),  $|\varphi\rangle = |\varphi_r\rangle$  ( $:= U_r \cdots U_1 |\psi\rangle$ ),  $\kappa = 1$ , and  $w_1 = v_r$ .

In a dQMA protocol for the problem of generating  $|\varphi\rangle$  on  $G$ , the completeness and soundness conditions are slightly different from the case of decision problems. For our purpose we actually only need to discuss perfect-completeness protocols. We say that the dQMA protocol has perfect completeness and  $(\delta, \varepsilon)$ -soundness if the following completeness and soundness are satisfied:

**(completeness)** There exists a quantum state  $|\chi\rangle$  on  $M$  such that

$$\Pr[\text{all nodes accept and } w_1, \dots, w_\kappa \text{ output } |\varphi\rangle \text{ jointly}] = 1;$$

**(soundness)** If all nodes accept with probability at least  $\delta$ , then the output  $\tilde{\rho}$  of  $w_1, \dots, w_\kappa$  (under the condition that all nodes accept) satisfies

$$\langle \varphi | \tilde{\rho} | \varphi \rangle \geq 1 - \varepsilon.$$

The soundness condition is regarded as a kind of hypothesis testing (i.e., if the verifier's test passes with probability greater than a threshold, then the state would be close to the ideal one). A similar completeness-soundness condition is used for the interactive proofs for synthesizing quantum states [35].

### 3 dQMA Protocol for State Generation with Distributed Inputs

In this section we present our dQMA protocol for the  $n$ -qubit State Generation with Distributed Inputs over the line of length  $r$  ( $n$ -qubit  $\text{SGDI}_r$ ) and prove Theorem 1.

#### 3.1 dQMA protocol for SGDI

The following is our dQMA protocol for  $n$ -qubit  $\text{SGDI}_r$ .

**Protocol  $\mathcal{P}_{\text{SGDI}}$ :** Let  $k = 144cr^{2+\eta}$  and  $m = 2cnk^2(r+1)^{1+\eta}$  for any constant  $c > 0$  and any small constant  $\eta \geq 0$ .

1.  $v_0$  prepares  $(m+k+1)$  copies of  $|\psi\rangle$  in  $n$ -qubit registers  $R_{0,j}$  ( $j = 1, 2, \dots, m+k+1$ ).
2. The prover sends each  $v_l$ , where  $l = 1, 2, \dots, r$ ,  $(m+k+1)$   $n$ -qubit registers  $R_{l,1}, R_{l,2}, \dots, R_{l,m+k+1}$ .
3. Each  $v_l$  ( $l = 1, 2, \dots, r$ ) permutes the  $(m+k+1)$  registers  $R_{l,1}, R_{l,2}, \dots, R_{l,m+k+1}$  by a permutation  $\pi$  on  $\{1, 2, \dots, m+k+1\}$  taken uniformly at random, and renames  $R_{l,j} := R_{l,\pi(j)}$ .
4. The parties  $v_0, v_1, \dots, v_r$  implement the following subprotocol  $\mathcal{P}_{\text{SGDIV}}$  (a modification of the verification steps in Ref. [10]) on registers  $R_{0,j}, R_{1,j}, \dots, R_{r,j}$  for each  $j = 2, 3, \dots, k+1$  in order. If some party rejects for some  $j$ , the protocol rejects.
5.  $v_r$  outputs  $R_{r,1}$ .

**Protocol  $\mathcal{P}_{\text{SGDIV}}$ :** Assume that  $v_0$  has  $|\psi\rangle$  on  $n$ -qubit register  $R_0$ , and  $v_l$  ( $l = 1, 2, \dots, r$ ) receives  $n$ -qubit register  $R_l$ .

1. For every  $j = 0, 1, \dots, r - 1$ , party  $v_j$  chooses a bit  $b_j$  uniformly at random, and sends its register  $R_j$  to the right neighbor  $v_{j+1}$  whenever  $b_j = 0$ .
2. For every  $j = 1, 2, \dots, r$ , if  $v_j$  receives a register from the left neighbor  $v_{j-1}$ , and if  $b_j = 1$ , then  $v_j$  applies  $U_j$  on register  $R_{j-1}$ , and performs the SWAP test on the registers  $(R_{j-1}, R_j)$ , and accepts or rejects accordingly; Otherwise,  $v_j$  accepts.

We can show the following theorem, which induces Theorem 1 by a special case with  $\eta = 0$ .

► **Theorem 6.** *Protocol  $\mathcal{P}_{\text{SGDI}}$  has perfect completeness and  $(\frac{1}{(cr^\eta)^{1/4}}, \frac{1}{(cr^\eta)^{1/4}})$ -soundness. The certificate size of  $\mathcal{P}_{\text{SGDI}}$  is  $O(n^2r^{5+3\eta})$  and the message size is  $O(nr^{2+\eta})$ .*

### 3.2 Proof of Theorem 6

We can see that the certificate size of  $\mathcal{P}_{\text{SGDI}}$  is  $(m + k + 1)n = O(n^2r^{5+3\eta})$  from step 2 of  $\mathcal{P}_{\text{SGDI}}$ . Since  $\mathcal{P}_{\text{SGDI}}$  implements  $\mathcal{P}_{\text{SGDIV}}$   $(k + 1)$  times, and the message size of  $\mathcal{P}_{\text{SGDI}}$  is  $O(n)$ , the message size of  $\mathcal{P}_{\text{SGDI}}$  is  $O(nk) = O(nr^{2+\eta})$ .

The completeness clearly holds: since the prover honestly sends

$$|\varphi_l\rangle := U_l \cdots U_1 |\psi\rangle$$

as the content of  $R_{l,j}$  for each  $j \in \{1, 2, \dots, m + k + 1\}$  and then all the SWAP tests in  $\mathcal{P}_{\text{SGDIV}}$  accept with probability 1.

The proof of the soundness can be found in the full version.

## 4 Application: dQMA Protocol for Set Equality

In this section we prove Theorem 2 by constructing a protocol for  $\text{SetEquality}_{\ell,U}$  based on the protocol for  $\text{SGDI}_r$  developed in Section 3.

**Proof of Theorem 2.** We consider  $\text{SetEquality}_{\ell,U}$  (Definition 1) for the line graph of length  $r$  with nodes  $v_0, v_1, \dots, v_r$ , where  $v_j$  has  $a_{j,1}, \dots, a_{j,\ell}$  and  $b_{j,1}, \dots, b_{j,\ell}$ . Let  $\alpha_j(s) := \prod_{i \in \{1, 2, \dots, \ell\}} (s - a_{j,i})$  and  $\beta_j(s) := \prod_{i \in \{1, 2, \dots, \ell\}} (s - b_{j,i})$  for each  $j \in \{0, 1, \dots, r\}$ . We identify  $a_{u,i}, b_{u,i}$  as elements in a finite field  $\mathbb{F}$  with size  $|\mathbb{F}| \geq \tilde{c}\ell(r + 1)2^{\log|U|}$  for some (sufficiently large) constant  $\tilde{c} > 0$ . Our goal is the same as of the interactive protocol of [33] – the node  $v_r$  checks if two polynomials  $p_A(s) := \prod_{j \in \{0, 1, \dots, r\}} \alpha_j(s)$  and  $p_B(s) := \prod_{j \in \{0, 1, \dots, r\}} \beta_j(s)$  take the same value for uniform randomly chosen  $s \in \mathbb{F}$ , where  $s$  is distributed by the interaction. In order to implement this idea in a non-interactive way, we utilize the framework of  $\text{SGDI}$  as follows: Let

$$|\psi\rangle := \frac{1}{\sqrt{|\mathbb{F}|}} \sum_{s \in \mathbb{F}} |s\rangle |\alpha_0(s)\rangle$$

be the initial state that the node  $v_0$  can locally produce. Each node  $v_j, j \in \{1, 2, \dots, r\}$  has a unitary transformation  $U_j$  which maps  $|s\rangle |\alpha_{j-1}(s)\rangle$  to  $|s\rangle |\alpha_j(s)\rangle$  (to be precise, we also need to deal with the case where  $\alpha_j(s)$  is a zero polynomial). Using the protocol for  $\text{SGDI}$  in Theorem 1, the node  $v_r$  outputs the state  $|\varphi_r\rangle = U_r \cdots U_1 |\psi\rangle$ , which is the uniform

superposition of  $|s\rangle|p_A(s)\rangle$  over all  $s \in \mathbb{F}$ . Similarly,  $v_r$  also outputs the uniform superposition of  $|s\rangle|p_B(s)\rangle$  over all  $s \in \mathbb{F}$ . Finally,  $v_r$  does the SWAP test for these states, which accepts with high probability if and only if two polynomials are identical (i.e.,  $A = B$  as multisets) since the two polynomials  $p_A(s)$  and  $p_B(s)$  take different values for most  $s \in \mathbb{F}$  if  $A \neq B$ . In the full version we complete the proof by describing the details of the protocol (which we denote  $\mathcal{P}_{\text{seteq}}$ ) and analyzing it rigorously. ◀

#### 4.1 Classical bounds for SetEquality $_{\ell,U}$

Here we prove the classical lower bounds shown in Theorem 3. The proof of Theorem 4 is deferred to the full version.

**Proof of Theorem 3.** In order to prove our lower bounds for SetEquality $_{\ell,U}$ , we utilize reductions from EQ $_n^2$  to SetEquality $_{\ell,U}$ , then apply the following lower bound of EQ $_n^2$  that appears in [10].

► **Lemma 1** (Theorem 9 of [10]). *Let  $r \geq 3$  be a positive integer. Consider an instance of EQ $_n^2$  where the two nodes  $v_0$  and  $v_r$  on a line graph  $v_0, \dots, v_r$  are provided with inputs  $x \in \{0, 1\}^n$  and  $y \in \{0, 1\}^n$ . Then, for any dMA protocol that solves EQ $_n^2$  for this instance with completeness  $1-p$  and soundness  $1-2p-\varepsilon$  for any  $p, \varepsilon > 0$ , there exists  $i \in \{1, \dots, r-1\}$  such that the certificate size of  $v_i$  is  $\Omega(n)$ .*

We show three different reductions depending on the size of  $|U|$ . Due to space constraints, we only show the simplest case:  $|U| = \Omega(\ell)$ . The reductions for the other two cases are deferred to the full version.

Let  $\mathcal{P}$  be a dMA protocol for SetEquality $_{\ell,U}$  with the certificate size  $s_c$  which appears in the statement of the theorem. We consider the following instance of EQ $_n^2$  on a line graph  $v_0, \dots, v_r$  of length  $r \geq 3$ : the node  $v_0$  is provided with  $x$ , and the node  $v_r$  is provided with  $y$ . Let  $\ell$  be the minimum integer satisfying  $\binom{3\ell}{\ell} \geq 2^n$ . Since  $\binom{3\ell}{\ell} = 2^{3\ell H(1/3) - O(\log \ell)}$  where  $H(\cdot)$  is the binary entropy function, we have  $\ell = \Theta(n)$ . Let  $S = \{s \in \{0, 1\}^{3\ell} : |s| = \ell\}$  be the set of  $3\ell$ -bit strings so that  $|S| = \binom{3\ell}{\ell}$ . We arbitrarily choose one injection  $f : \{0, 1\}^n \rightarrow S$  (this kind of injection exists since we have  $|S| \geq 2^n$ ). The network constructs the following instance of SetEquality $_{\ell,U}$  for the universal set  $U = \{0, 1, 2, \dots, 3\ell\}$  without communication:

- The inputs  $x$  and  $y$  are converted to  $f(x), f(y) \in S$ . Let  $X = \{i : f(x)_i = 1\}$  and  $Y = \{i : f(y)_i = 1\}$  be two sets of  $\ell$  elements from the universal set  $\{1, 2, \dots, 3\ell\}$ .  $X$  and  $Y$  are regarded as the inputs  $(a_{v_0,1}, \dots, a_{v_0,\ell})$  and  $(b_{v_r,1}, \dots, b_{v_r,\ell})$  of SetEquality $_{\ell,U}$ . Furthermore, we set  $(b_{v_0,1}, \dots, b_{v_0,\ell}) = (a_{v_r,1}, \dots, a_{v_r,\ell}) = (0, \dots, 0)$ .
- The inputs to each internal node  $v_1, \dots, v_{r-1}$  are set to  $(0, \dots, 0), (0, \dots, 0)$ .

Now the set  $A$  and  $B$  of this instance of SetEquality $_{\ell,U}$  are identical as multisets if and only if  $f(x) = f(y)$ . Since  $f$  is an injection, we have  $f(x) = f(y) \Leftrightarrow x = y$  and thus the output of SetEquality $_{\ell,U}$  on this instance is identical to that of EQ $_n^2$  on the input  $x$  and  $y$ . Now we can use the protocol  $\mathcal{P}$  to solve EQ $_n^2$  for  $n = \Theta(\ell)$ . Thus by Lemma 1, we have  $s_c = \Omega(\ell)$ . ◀

## 5 Conversion of dQMA protocols into LOCC dQMA protocols

In this section we show how to create an EPR pair  $|\Phi^+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$  between two parties without quantum communication in the setting where a prover helps the nodes in a non-interactive way. Our protocol is based on the verification protocol of the EPR pair in the adversarial setting proposed by Zhu and Hayashi [41] (see also [39, 40]), who showed that a verifier  $V$  can check whether a two-qubit state sent from a (possibly malicious) prover is  $|\Phi^+\rangle$ .

The following is the verification protocol given in Ref. [41].

**Protocol  $\mathcal{P}_{\text{ZH}}$ :** Let  $R_1, R_2, \dots, R_N, R_{N+1}$  be  $(N+1)$  two-qubit registers from the prover. Here,  $|+\rangle := \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$ ,  $|-\rangle := \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$ ,  $|+\prime\rangle := \frac{1}{\sqrt{2}}(|0\rangle + i|1\rangle)$  and  $|-\prime\rangle := \frac{1}{\sqrt{2}}(|0\rangle - i|1\rangle)$ .

1. Perform a random permutation  $\pi$  on the  $(N+1)$  two-qubit registers, and rename  $R_j := R_{\pi(j)}$  for  $j = 1, 2, \dots, N+1$ .
2. For each  $j = 1, 2, \dots, N$ , the verifier  $V$  does one of the following three POVMs on register  $R_j$  with probability  $1/3$  for each:
  - $M_1 = \{E_1, I - E_1\}$  with  $E_1 = |00\rangle\langle 00| + |11\rangle\langle 11|$ .
  - $M_2 = \{E_2, I - E_2\}$  with  $E_2 = |++\rangle\langle ++| + |--\rangle\langle --|$ .
  - $M_3 = \{E_3, I - E_3\}$  with  $E_3 = |+\prime-\prime\rangle\langle +\prime-\prime| + |-\prime+\prime\rangle\langle -\prime+\prime|$ .
3. Reject if the second components in the POVMs are obtained. Otherwise, the test passes and outputs  $R_{N+1}$ .

Ref. [41] describes  $E_1 = \frac{I+Z^{\otimes 2}}{2}$ ,  $E_2 = \frac{I+X^{\otimes 2}}{2}$  and  $E_3 = \frac{I-Y^{\otimes 2}}{2}$ , where

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \text{ and } Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

while we rewrite them as above (which is a similar expression to the protocol in Ref. [34]) since it would be easy to see for our purpose. Importantly, step 2 implements the POVM  $\{\Omega, I - \Omega\}$  on  $R_j$  with  $\Omega = \frac{2}{3}|\Phi^+\rangle\langle\Phi^+| + \frac{1}{3}I$  for each  $j$ , but it is implemented by local measurements on each qubit of  $R_j$ .

The following result was shown for the protocol  $\mathcal{P}_{\text{ZH}}$  in Ref. [41].

► **Theorem 7 (Zhu-Hayashi).** *There is a number  $N = O(\frac{1}{\varepsilon} \log(\frac{1}{\delta}))$  such that if the test passed with probability at least  $\delta$ , then the output state  $\tilde{\sigma}$  of  $\mathcal{P}_{\text{ZH}}$  (under the condition that the test passes) satisfies  $\langle\Phi^+|\tilde{\sigma}|\Phi^+\rangle \geq 1 - \varepsilon$ .*

The protocol  $\mathcal{P}_{\text{ZH}}$  uses only local measurements, and thus, it can be used for verifying the sharing of an EPR pair by two parties who only use local operations and classical communication (LOCC).

Let  $V_1$  and  $V_2$  be neighboring parties who expect to receive  $|\Phi^+\rangle$  jointly from the prover. The following protocol is a simple implementation of  $\mathcal{P}_{\text{ZH}}$  with LOCC by  $V_1$  and  $V_2$ .

**Protocol  $\mathcal{P}_{\text{ZHLOCC}}$ :** Let  $R_{1,1}, \dots, R_{N,1}, R_{N+1,1}$  be  $(N+1)$  one-qubit registers from the prover to  $V_1$ , and  $R_{1,2}, \dots, R_{N,2}, R_{N+1,2}$  be  $(N+1)$  one-qubit registers from the prover to  $V_2$ , respectively.

1.  $V_1$  chooses a random permutation  $\pi$  on  $\{1, 2, \dots, N+1\}$  and sends it to  $V_2$ , and then both perform  $\pi$  on the  $(N+1)$  two-qubit registers  $(R_{1,1}, R_{1,2}), \dots, (R_{N,1}, R_{N,2}), (R_{N+1,1}, R_{N+1,2})$ . Rename  $R_{j,1} := R_{\pi(j),1}$  and  $R_{j,2} := R_{\pi(j),2}$ .
2.  $V_1$  chooses  $N$  random numbers  $k_1, k_2, \dots, k_N \in \{1, 2, 3\}$  and sends them to  $V_2$ . For each  $j = 1, 2, \dots, N$ ,  $V_1$  and  $V_2$  implement one of the POVMs  $M_1, M_2, M_3$  on register  $(R_{j,1}, R_{j,2})$  jointly as follows.
  - when  $k_j = 1$ , they jointly implement  $M_1 = \{E_1, I - E_1\}$ ;  $V_1$  and  $V_2$  measure  $R_{j,1}$  and  $R_{j,2}$  in the  $Z$  basis  $\{|0\rangle, |1\rangle\}$ , respectively, and  $V_1$  sends the measurement value to  $V_2$ , who rejects iff it differs from the measurement value of  $V_2$ .

- when  $k_j = 2$ , they jointly implement  $M_2 = \{E_2, I - E_2\}$ ;  $V_1$  and  $V_2$  measure  $R_{j,1}$  and  $R_{j,2}$  in the  $X$  basis  $\{|+\rangle, |-\rangle\}$ , respectively, and  $V_1$  sends the measurement value to  $V_2$ , who rejects iff it differs from the measurement value of  $V_2$ .
  - when  $k_j = 3$ , they jointly implement  $M_3 = \{E_3, I - E_3\}$ ;  $V_1$  and  $V_2$  measure  $R_{j,1}$  and  $R_{j,2}$  in the  $Y$  basis  $\{|+\rangle, |-\rangle\}$ , respectively, and  $V_1$  sends the measurement value to  $V_2$ , who rejects iff it is same as the measurement value of  $V_2$ .
3. The test passes and  $V_1$  and  $V_2$  output  $R_{N+1,1}$  and  $R_{N+1,2}$ , respectively.

It is easy to see that  $\mathcal{P}_{\text{ZHLOCC}}$  simulates  $\mathcal{P}_{\text{ZH}}$  exactly in a distributed manner. The protocol  $\mathcal{P}_{\text{ZHLOCC}}$  does not use any quantum communication between  $V_1$  and  $V_2$ , while the amount of classical communication used between  $V_1$  and  $V_2$  is  $\lceil \log(N+1)! \rceil + \lceil \log 3^N \rceil + N = O(N \log N)$ .

Furthermore, we can replace a random permutation  $\pi$  in step 1 of  $\mathcal{P}_{\text{ZHLOCC}}$  by switching the  $j$ th two-qubit register  $(R_{j,1}, R_{j,2})$  and the  $(N+1)$ th register  $(R_{N+1,1}, R_{N+1,2})$  by choosing  $j$  uniformly at random from  $\{1, 2, \dots, N+1\}$  (actually, doing nothing when  $j = N+1$ ) since the output state by such change is the same as protocol  $\mathcal{P}_{\text{ZHLOCC}}$ . We call the protocol by such change  $\mathcal{P}_{\text{ZHLOCC}}^+$ . Now the amount of classical communication used between  $V_1$  and  $V_2$  in  $\mathcal{P}_{\text{ZHLOCC}}^+$  is improved to  $\lceil \log(N+1) \rceil + \lceil \log 3^N \rceil + N = O(N)$ .

Thus the following theorem holds for  $\mathcal{P}_{\text{ZHLOCC}}^+$ .

► **Theorem 8.** *For the same number  $N = O(\frac{1}{\varepsilon} \log(\frac{1}{\delta}))$  as Theorem 7, if the test passed with at least probability  $\delta$ , then the two-qubit state  $\tilde{\sigma}$  output by  $V_1$  and  $V_2$  in  $\mathcal{P}_{\text{ZHLOCC}}^+$  satisfies  $\langle \Phi^+ | \tilde{\sigma} | \Phi^+ \rangle \geq 1 - \varepsilon$ .*

In the full version, we prove Theorem 5 by showing how to use the protocol  $\mathcal{P}_{\text{ZHLOCC}}^+$ .

---

## Abstract

The (PERFECT) MATCHING CUT problem is to decide if a graph  $G$  has a (perfect) matching cut, i.e., a (perfect) matching that is also an edge cut of  $G$ . Both MATCHING CUT and PERFECT MATCHING CUT are known to be NP-complete, leading to many complexity results for both problems on special graph classes. A perfect matching cut is also a matching cut with maximum number of edges. To increase our understanding of the relationship between the two problems, we introduce the MAXIMUM MATCHING CUT problem. This problem is to determine a largest matching cut in a graph. We generalize and unify known polynomial-time algorithms for MATCHING CUT and PERFECT MATCHING CUT restricted to graphs of diameter at most 2 and to  $(P_6 + sP_2)$ -free graphs. We also show that the complexity of MAXIMUM MATCHING CUT differs from the complexities of MATCHING CUT and PERFECT MATCHING CUT by proving NP-hardness of MAXIMUM MATCHING CUT for  $2P_3$ -free quadrangulated graphs of diameter 3 and radius 2 and for subcubic line graphs of triangle-free graphs. In this way, we obtain full dichotomies of MAXIMUM MATCHING CUT for graphs of bounded diameter, bounded radius and  $H$ -free graphs.

**2012 ACM Subject Classification** Mathematics of computing → Graph algorithms

**Keywords and phrases** matching cut, perfect matching,  $H$ -free graph, diameter, radius, dichotomy

## 1 Introduction

A *matching*  $M$  (i.e., a set of pairwise disjoint edges) of a connected graph  $G = (V, E)$  is a *matching cut* if  $V$  can be partitioned into a set of blue vertices  $B$  and a set of red vertices  $R$ , such that  $M$  consists of all the edges with one end-vertex in  $B$  and the other one in  $R$ . Graphs with matching cuts were introduced in 1970 by Graham [20] (as *decomposable* graphs) to solve a problem on cube numbering. Other relevant applications include ILFI networks [13], WDM networks [1], graph drawing [33] and surjective graph homomorphisms [18].

The decision problem is called MATCHING CUT: does a given connected graph have a matching cut? In 1984, Chvátal [11] proved that it is NP-complete even for graphs of maximum degree at most 4. Afterwards, parameterized and exact algorithms were given [2, 8, 17, 19, 24, 25]. A variant called DISCONNECTED PERFECT MATCHING “does a connected graph have a perfect matching that contains a matching cut?” has also been studied [7, 15, 31], and the problem was generalized, for every  $d \geq 1$ , to  $d$ -CUT “does a connected graph have an edge cut where each vertex has at most  $d$  neighbours across the cut?” [3, 19]. But, in particular, many results have appeared where the input for MATCHING CUT was restricted to some special graph class, and this is what we do in our paper as well. We first discuss related work, restricting ourselves mainly to those classes relevant to our paper (see, for example, [8] for a more comprehensive overview):

■ **Figure 1** The graphs  $H_1^*$  (left) and  $H_i^*$  (right).

- graphs of bounded diameter;
- graphs of bounded radius;
- hereditary graph classes; in particular  $H$ -free graphs.

The *distance* between two vertices  $u$  and  $v$  in a connected graph  $G$  is the *length* (number of edges) of a shortest path between  $u$  and  $v$  in  $G$ . The *eccentricity* of a vertex  $u$  is the maximum distance between  $u$  and any other vertex of  $G$ . The *diameter*, denoted by  $\text{diameter}(G)$ , and *radius*, denoted by  $\text{radius}(G)$ , are the maximum and minimum eccentricity, respectively, over all vertices of  $G$ ; note that  $\text{radius}(G) \leq \text{diameter}(G) \leq 2 \cdot \text{radius}(G)$  for every graph  $G$ .

The MATCHING CUT problem is polynomial-time solvable for graphs of diameter at most 2 [6, 26]. This result was extended to graphs of radius at most 2 [30]. In contrast, the problem is NP-complete for graphs of diameter at most 3 [26], yielding two dichotomies:

► **Theorem 1** ([26, 30]). *For an integer  $d \geq 1$ , MATCHING CUT for graphs of diameter  $d$  and for graphs of radius  $d$  is polynomial-time solvable if  $d \leq 2$  and NP-complete if  $d \geq 3$ .*

A class of graphs is *hereditary* if it is closed under vertex deletion. Hereditary graph classes include many well-known classes, such as those that are  $H$ -free for some graph  $H$ . A graph  $G$  is  $H$ -free if  $G$  does not contain  $H$  as an *induced* subgraph, that is,  $G$  cannot be modified into  $H$  by a sequence of vertex deletions. For a set of graphs  $\mathcal{H}$ , a graph  $G$  is  $\mathcal{H}$ -free if  $G$  is  $H$ -free for every  $H \in \mathcal{H}$ . If  $\mathcal{H} = \{H_1, \dots, H_p\}$  for some  $p \geq 1$ , we also say that  $G$  is  $(H_1, \dots, H_p)$ -free. Note that a class of graphs  $\mathcal{G}$  is hereditary if and only if there is a set of graphs  $\mathcal{H}$ , such that every graph in  $\mathcal{G}$  is  $\mathcal{H}$ -free. Hence, for a *systematic* complexity study, it is natural to first focus on the case where  $\mathcal{H}$  has size 1; see, e.g., [9, 10, 12, 16, 22, 35].

For an integer  $r \geq 1$ , let  $P_r$  denote the path on  $r$  vertices,  $K_{1,r}$  the star on  $r + 1$  vertices, and  $K_{1,r} + e$  the graph obtained from  $K_{1,r}$  by adding one edge (between two leaves). The graph  $K_{1,3}$  is also known as the *claw*. For  $s \geq 3$ , let  $C_s$  denote the cycle on  $s$  vertices. Let  $H_1^*$  be the graph that looks like the letter “H”, and for  $i \geq 2$ , let  $H_i^*$  be the graph obtained from  $H_1^*$  by subdividing the middle edge of  $H_1^*$  exactly  $i - 1$  times; see also Figure 1. We denote the *disjoint union* of two graphs  $G_1$  and  $G_2$  by  $G_1 + G_2 = (V(G_1) \cup V(G_2), E(G_1) \cup E(G_2))$ . We denote by  $sG$  the disjoint union of  $s$  copies of  $G$ , for  $s \geq 1$ .

Polynomial-time algorithms for MATCHING CUT exist for *subcubic* graphs (graphs of maximum degree at most 3) [11],  $K_{1,3}$ -free graphs [5],  $P_6$ -free graphs [30],  $(K_{1,4}, K_{1,4} + e)$ -free graphs [25] and *quadrangulated* graphs, i.e.,  $(C_5, C_6, \dots)$ -free graphs [32]; the latter class contains the class of *chordal* graphs, i.e.,  $(C_4, C_5, C_6, \dots)$ -free graphs. Moreover, if MATCHING CUT is polynomial-time solvable for  $H$ -free graphs, then it is so for  $(H + P_3)$ -free graphs [30]. The problem is NP-complete even for graphs of maximum degree at most 4 [11];  $K_{1,4}$ -free graphs [11] (see [5, 25]); planar graphs of girth 5 [5];  $K_{1,5}$ -free bipartite graphs [28]; graphs of girth at least  $g$ , for every  $g \geq 3$  [15];  $(3P_5, P_{15})$ -free graphs [31] (improving a result of [14]); bipartite graphs where the vertices in one bipartition class all have degree exactly 2 [32] and thus for  $H_i^*$ -free graphs for every odd  $i \geq 1$ ; and for  $H_i^*$ -free graphs for every even  $i \geq 2$  [15]. Even more recently, Le and Le [27] proved that MATCHING CUT is NP-complete even for  $(3P_6, 2P_7, P_{14})$ -free graphs.

The above results imply the following partial complexity classification, which leaves open only a number of cases where  $H$  is a *linear forest*, that is, the disjoint union of one or more paths. For two graphs  $H$  and  $H'$ , we write  $H \subseteq_i H'$  if  $H$  is an induced subgraph of  $H'$ .

► **Theorem 2** ([5, 11, 15, 27, 31, 30, 32]). *For a graph  $H$ , MATCHING CUT on  $H$ -free graphs is*

- *polynomial-time solvable if  $H \subseteq_i sP_3 + K_{1,3}$  or  $sP_3 + P_6$  for some  $s \geq 0$ , and*
- *NP-complete if  $H \supseteq_i K_{1,4}, P_{14}, 3P_5, 2P_7, C_r$  for some  $r \geq 3$  or  $H_j^*$  for some  $j \geq 1$ .*

■ **Figure 2** The graph  $P_6$  with a matching cut of size 2 (left), another matching cut of size 2 (middle) and a perfect matching cut (right). In each figure, thick edges denote matching cut edges.

### 1.1 Our Focus

We already mentioned the known generalization of MATCHING CUT (i.e. 1-CUT) to  $d$ -CUT. In our paper, we consider a different kind of generalization, namely MAXIMUM MATCHING CUT, which is to determine a *largest* matching cut of a connected graph (if a matching cut exists). So far, this problem has only been studied for the extreme case, where the task is to decide if a connected graph has a *perfect* matching cut, that is, a matching cut that saturates every vertex; see also Figure 2. This variant was introduced as PERFECT MATCHING CUT by Heggernes and Telle [21], who proved it was NP-complete. We briefly discuss some very recent results for PERFECT MATCHING CUT on special graph classes below.

It is readily seen that the gadget in the NP-hardness reduction of Heggernes and Telle [21] has diameter 6 and radius 3. More recently Le and Le [27] gave a reduction with a graph of diameter 4. It is also known that PERFECT MATCHING CUT is polynomial-time solvable for graphs of radius (and thus also diameter) at most 2 [31]. Hence, we only obtain a partial complexity classification for graphs of bounded diameter in this case.

► **Theorem 3** ([21, 31]). *For integers  $d$  and  $r$ , PERFECT MATCHING CUT for graphs of diameter  $d$  and for graphs of radius  $r$  is polynomial-time solvable if  $d \leq 2$  or  $r \leq 2$ , respectively, and NP-complete if  $d \geq 4$  or  $r \geq 3$ , respectively.*

For  $1 \leq h \leq i \leq j$ , the graph  $S_{h,i,j}$  is the tree of maximum degree 3 with exactly one vertex  $u$  of degree 3, whose leaves are at distance  $h$ ,  $i$  and  $j$ , respectively, from  $u$ ; note  $S_{1,1,1} = K_{1,3}$ .

It is known that PERFECT MATCHING CUT is polynomial-time solvable for  $S_{1,2,2}$ -free graphs (and thus for  $K_{1,3}$ -free graphs) [29];  $P_6$ -free graphs [31]; and for pseudo-chordal graphs [29] (and thus for chordal graphs, i.e.,  $(C_4, C_5, \dots)$ -free graphs). Moreover, PERFECT MATCHING CUT is polynomial-time solvable for  $(H + P_4)$ -free graphs if it is polynomial-time solvable for  $H$ -free graphs [31]. It is also known that PERFECT MATCHING CUT is NP-complete even for 3-connected cubic planar bipartite graphs [4],  $(3P_6, 2P_7, P_{14})$ -free graphs [27],  $K_{1,4}$ -free bipartite graphs of girth  $g$  for every  $g \geq 3$  [29] and for  $H_i^*$ -free graphs for every  $i \geq 1$  [15]. This gives us a partial complexity classification:

► **Theorem 4** ([15, 27, 29, 31]). *For a graph  $H$ , PERFECT MATCHING CUT on  $H$ -free graphs is*

- *polynomial-time solvable if  $H \subseteq_i sP_4 + S_{1,2,2}$  or  $sP_4 + P_6$  for some  $s \geq 0$ , and*
- *NP-complete if  $H \supseteq_i K_{1,4}, P_{14}, 3P_6, 2P_7, C_r$  for some  $r \geq 3$  or  $H_j^*$  for some  $j \geq 1$ .*

From Theorem 4 it can be seen that again only cases where  $H$  is a linear forest remain open. However, the number of open cases is smaller than for MATCHING CUT. So far, all known complexities for MATCHING CUT and PERFECT MATCHING CUT on special graph classes coincide except for (sub)cubic graphs. We note that whenever MAXIMUM MATCHING CUT is polynomial-time solvable for some graph class, then so are MATCHING CUT and PERFECT MATCHING CUT. Similarly, if one of the latter two problems is NP-complete, then MAXIMUM MATCHING CUT is NP-hard. For instance, this immediately yields a complexity dichotomy for graphs of maximum degree at most  $\Delta$ . Namely, as MAXIMUM MATCHING CUT is trivial if  $\Delta = 2$  and PERFECT MATCHING CUT is NP-complete if  $\Delta = 3$ , we have a complexity jump from  $\Delta = 2$  to  $\Delta = 3$ , just like PERFECT MATCHING CUT; recall that for MATCHING CUT this jump appears from  $\Delta = 3$  to  $\Delta = 4$ . We consider the following research question:

*For which graph classes is MAXIMUM MATCHING CUT harder than MATCHING CUT and PERFECT MATCHING CUT and for which graph classes do the complexities coincide?*

## 1.2 Our Results

In Section 4 we show that MAXIMUM MATCHING CUT is NP-hard for  $2P_3$ -free quadrangulated graphs of diameter 3 and radius 2. We note that the restrictions to radius 2 and diameter 3 are not redundant: consider, for example, the  $P_6$ , which is  $2P_3$ -free but which has radius 3 and diameter 5. In the same section, we also show NP-hardness for subcubic line graphs of triangle-free graphs, or equivalently, subcubic  $(K_{1,3}, \text{diamond})$ -free graphs (the diamond is obtained from the  $K_4$  after removing an edge). These NP-hardness results are in stark contrast to the situation for MATCHING CUT and PERFECT MATCHING CUT, as evidenced by Theorems 1–4. Recall also that MATCHING CUT is polynomial-time solvable for quadrangulated graphs [32].

Before proving these results, we first show in Section 3 that MAXIMUM MATCHING CUT is polynomial-time solvable for graphs of diameter 2, generalizing the known polynomial-time algorithms for MATCHING CUT and PERFECT MATCHING CUT for graphs of diameter at most 2. Hence, all three problems have the same dichotomies for graphs of bounded diameter.

We also prove in Section 3 that MAXIMUM MATCHING CUT is polynomial-time solvable for  $P_6$ -free graphs, generalizing the previous polynomial-time results for MATCHING CUT and PERFECT MATCHING CUT for  $P_6$ -free graphs. Due to the hardness result for  $2P_3$ -free graphs, we cannot show polynomial-time solvability for “ $+P_4$ ” (as for PERFECT MATCHING CUT) or “ $+P_3$ ” (as for MATCHING CUT). However, we can prove that if MAXIMUM MATCHING CUT is polynomial-time solvable for  $H$ -free graphs, then it is so for  $(H + P_2)$ -free graphs; again, see Section 3. The common proof technique for our polynomial-time results is as follows:

1. Translate the problem into a colouring problem. We pre-colour some vertices either red or blue, and try to extend the pre-colouring to a red-blue colouring of the whole graph via reduction rules. This technique has been used for MATCHING CUT and PERFECT MATCHING CUT, but our analysis is different. In particular, the algorithms for MATCHING CUT and PERFECT MATCHING CUT on  $P_6$ -free graphs use an algorithm for graphs of radius at most 2 as a subroutine (shortcut). We cannot do this for MAXIMUM MATCHING CUT, as we will show NP-hardness for radius 2.
2. Reduce the set of uncoloured vertices, via a number of branching steps, to an independent set, and then translate the problem into a matching problem. This is a new proof ingredient. The matching problem is to find a largest matching that saturates every vertex of the independent set of uncoloured vertices. Plesník [34] gave a polynomial time algorithm for this, which we will use as subroutine.<sup>1</sup>

---

<sup>1</sup> The polynomial-time algorithm of Plesník [34] solves a more general problem. It takes as input a

The above polynomial-time and NP-hardness results yield the following three dichotomies for MAXIMUM MATCHING CUT proven in Section 5; in particular we have obtained a complete complexity classification of MAXIMUM MATCHING CUT for  $H$ -free graphs (whereas such a classification is only partial for the other two problems, as shown in Theorems 2 and 4).

► **Theorem 5.** *For an integer  $d$ , MAXIMUM MATCHING CUT on graphs of diameter  $d$  is*

- polynomial-time solvable if  $d \leq 2$ , and
- NP-hard if  $d \geq 3$ .

► **Theorem 6.** *For an integer  $r$ , MAXIMUM MATCHING CUT on graphs of radius  $r$  is*

- polynomial-time solvable if  $r \leq 1$ , and
- NP-hard if  $r \geq 2$ .

► **Theorem 7.** *For a graph  $H$ , MAXIMUM MATCHING CUT on  $H$ -free graphs is*

- polynomial-time solvable if  $H \subseteq_i sP_2 + P_6$  for some  $s \geq 0$ , and
- NP-hard if  $H \supseteq_i K_{1,3}$ ,  $2P_3$  or  $H \supseteq_i C_r$  for some  $r \geq 3$ .

Finally, in Section 6 we pose a number of open problems.

## 2 Preliminaries

We consider finite, undirected graphs without multiple edges and self-loops. Let  $G = (V, E)$  be a connected graph. For  $u \in V$ , the set  $N(u) = \{v \in V(G) \mid uv \in E(G)\}$  is the *neighbourhood* of  $u$  in  $G$ , where  $|N(u)|$  is the *degree* of  $u$ . For  $S \subseteq V$ , the *neighbourhood* of  $S$  is the set  $N(S) = \bigcup_{u \in S} N(u) \setminus S$ . The graph  $G[S]$  is the subgraph of  $G$  induced by  $S \subseteq V(G)$ , that is,  $G[S]$  is the graph obtained from  $G$  after deleting the vertices not in  $S$ . We say that  $S$  is a *dominating* set of  $G$ , and that  $G[S]$  *dominates*  $G$  if every vertex of  $V(G) \setminus S$  has at least one neighbour in  $S$ . The *domination number* of  $G$  is the size of a smallest dominating set of  $G$ . The set  $S$  is an *independent set* if no two vertices in  $S$  are adjacent and  $S$  is a *clique* if every two vertices in  $S$  are adjacent. A matching  $M$  is  *$S$ -saturating* if every vertex in  $S$  is an end-vertex of an edge in  $M$ . An  $S$ -saturating matching is *maximum* if there is no  $S$ -saturating matching of  $G$  with more edges. We will use the following result.

► **Theorem 8** ([34]). *For a graph  $G$  and set  $S \subseteq V(G)$ , it is possible in polynomial time to find a maximum  $S$ -saturating matching or conclude that  $G$  has no  $S$ -saturating matching.*

The *line graph* of  $G$  is the graph  $L(G)$  whose vertices are the edges of  $G$ , such that for every two vertices  $e$  and  $f$ , there exists an edge between  $e$  and  $f$  in  $L(G)$  if and only if  $e$  and  $f$  share an end-vertex in  $G$ . A bipartite graph with non-empty partition classes  $V_1$  and  $V_2$  is *complete* if there is an edge between every vertex of  $V_1$  and every vertex of  $V_2$ . If  $|V_1| = k$  and  $|V_2| = \ell$ , then we denote the complete bipartite graph by  $K_{k,\ell}$ . We will need the following theorem.

► **Theorem 9** ([36]). *A graph  $G$  on  $n$  vertices is  $P_6$ -free if and only if each connected induced subgraph of  $G$  contains a dominating induced  $C_6$  or a dominating (not necessarily induced) complete bipartite graph. We can find such a dominating subgraph of  $G$  in  $O(n^3)$  time.*

A *red-blue colouring* of a connected graph  $G$  colours every vertex of  $G$  either red or blue. If every vertex of a set  $S \subseteq V$  has the same colour (red or blue), then  $S$ , and also  $G[S]$ , are called *monochromatic*. An edge with a blue and a red end-vertex is *bichromatic*. A red-blue

---

graph  $G$  with an edge weighting  $w$ , a vertex subset  $S$  and two integers  $a$  and  $b$ . It then finds a maximum weight matching over all matchings that saturate  $S$  and whose cardinality is between  $a$  and  $b$ .

colouring is *valid* if every blue vertex has at most one red neighbour; every red vertex has at most one blue neighbour; and both colours red and blue are used at least once. For a valid red-blue colouring of  $G$ , we let  $R$  be the *red* set consisting of all vertices coloured red and  $B$  be the *blue* set consisting of all vertices coloured blue (so  $V(G) = R \cup B$ ). Moreover, the *red interface* is the set  $R' \subseteq R$  consisting of all vertices in  $R$  with a (unique) blue neighbour, and the *blue interface* is the set  $B' \subseteq B$  consisting of all vertices in  $B$  with a (unique) red neighbour in  $R$ . The *value* of a valid red-blue colouring is its number of bichromatic edges, or equivalently, the size of its red (or blue) interface. A valid red-blue colouring is *maximum* if there is no valid red-blue colouring of the graph with larger value. The notion of a red-blue colouring has been used before (see e.g. [14, 30]), and the next observations are easy to see.

► **Observation 10.** *For every connected graph  $G$  and integer  $k$ , it holds that  $G$  has a matching cut with at least  $k$  edges if and only if  $G$  has a valid red-blue colouring of value at least  $k$ .*

► **Observation 11.** *Every complete graph  $K_r$  with  $r \geq 3$  and every complete bipartite graph  $K_{r,s}$  with  $\min\{r, s\} \geq 2$  and  $\max\{r, s\} \geq 3$  is monochromatic.*

We omitted the proof of our next lemma; it is very similar to the proofs of corresponding lemmas for MATCHING CUT [14] and PERFECT MATCHING CUT [31]. On an aside, the lemma implies that MAXIMUM MATCHING CUT is in XP when parameterized by the domination number of a graph.

► **Lemma 12.** *For a connected  $n$ -vertex graph  $G$  with domination number  $g$ , it is possible to find a maximum red-blue colouring (if a red-blue colouring exists) in  $O(2^g n^{g+2})$  time.*

To handle “partial” red-blue colourings that we want to extend to maximum valid red-blue colourings, we slightly modify some terminology from [31] to work for maximum matching cuts as well.

Let  $G = (V, E)$  be a connected graph and  $S, T, X, Y \subseteq V$  be four non-empty sets with  $S \subseteq X$ ,  $T \subseteq Y$  and  $X \cap Y = \emptyset$ . A *red-blue  $(S, T, X, Y)$ -colouring* of  $G$  is a red-blue colouring of the vertices in  $X \cup Y$ , with a red set containing  $X$ ; a blue set containing  $Y$ ; a red interface containing  $S$  and a blue interface containing  $T$ . To obtain a red-blue  $(S, T, X, Y)$ -colouring, we start with two disjoint subsets  $S''$  and  $T''$  of  $V$ , called a *starting pair*, such that

- (i) every vertex of  $S''$  is adjacent to at most one vertex of  $T''$ , and vice versa, and
- (ii) at least one vertex in  $S''$  is adjacent to a vertex in  $T''$ .

Let  $S^*$  consist of all vertices of  $S''$  with a (unique) neighbour in  $T''$ , and let  $T^*$  consist of all vertices of  $T''$  with a (unique) neighbour in  $S''$ ; so, every vertex in  $S^*$  has a unique neighbour in  $T^*$ , and vice versa. We call  $(S^*, T^*)$  the *core* of  $(S'', T'')$ . Note that  $|S^*| = |T^*| \geq 1$ .

We now colour every vertex in  $S''$  red and every vertex in  $T''$  blue. Propagation rules will try to extend  $S''$  to a set  $X$ , and  $T''$  to a set  $Y$ , by finding new vertices whose colour must always be either red or blue. That is, we place new red vertices in the set  $X$ , which already contains  $S''$ , and new blue vertices in the set  $Y$ , which already contains  $T''$ . If a red and blue vertex are adjacent, then we add the red one to a set  $S \subseteq X$  and the blue one to a set  $T \subseteq Y$ . So initially,  $S := S^*$ ,  $T := T^*$ ,  $X := S''$  and  $Y := T''$ . We let  $Z := V \setminus (X \cup Y)$ .

Our task is to try to extend the partial red-blue colouring on  $X \cup Y$  to a *maximum* valid red-blue  $(S, T, X, Y)$ -colouring of  $G$ , that is, a valid red-blue  $(S, T, X, Y)$ -colouring that has largest value over all valid red-blue  $(S, T, X, Y)$ -colourings of  $G$ . In order to do this, we present three propagation rules, which indicate necessary implications of previous choices.

We start with rules R1 and R2, which together correspond to the five rules from [26]. Rule R1 detects cases where we cannot extend the partial red-blue colouring defined on  $X \cup Y$ . Rule R2 tries to extend the sets  $S, T, X, Y$  as much as possible. While the sets  $S, T, X, Y$  grow, Rule R2 ensures that we keep constructing a (maximum) valid red-blue  $(S, T, X, Y)$ -colouring (assuming  $G$  has a valid red-blue  $(S, T, X, Y)$ -colouring).

- R1. Return no (i.e.,  $G$  has no red-blue  $(S, T, X, Y)$ -colouring) if a vertex  $v \in Z$  is
- (i) adjacent to a vertex in  $S$  and to a vertex in  $T$ , or
  - (ii) adjacent to a vertex in  $S$  and to two vertices in  $Y \setminus T$ , or
  - (iii) adjacent to a vertex in  $T$  and to two vertices in  $X \setminus S$ , or
  - (iv) adjacent to two vertices in  $X \setminus S$  and to two vertices in  $Y \setminus T$ .
- R2. Let  $v \in Z$ .
- (i) If  $v$  is adjacent to a vertex in  $S$  or to two vertices of  $X \setminus S$ , then move  $v$  from  $Z$  to  $X$ . If  $v$  is also adjacent to a vertex  $w$  in  $Y$ , then add  $v$  to  $S$  and  $w$  to  $T$ .
  - (ii) If  $v$  is adjacent to a vertex in  $T$  or to two vertices of  $Y \setminus T$ , then move  $v$  from  $Z$  to  $Y$ . If  $v$  is also adjacent to a vertex  $w$  in  $X$ , then add  $v$  to  $T$  and  $w$  to  $S$ .

Assume that exhaustively applying rules R1 and R2 on a starting pair  $(S'', T'')$  does not lead to a no-answer but to a tuple  $(S', T', X', Y')$ . Then, we call  $(S', T', X', Y')$  an *intermediate tuple*; see also Figure 3. A propagation rule is *safe* if for every integer  $\nu$  the following holds:  $G$  has a valid red-blue  $(S, T, X, Y)$ -colouring of value  $\nu$  before the application of the rule if and only if  $G$  has a valid red-blue  $(S, T, X, Y)$ -colouring of value  $\nu$  after the application of the rule. Le and Le [26] proved the following lemma, which shows that R1 and R2 can be used safely and which is not difficult to verify. The fact that the value  $\nu$  is preserved in Lemma 13 (ii) below is implicit in their proof.

► **Lemma 13** ([26]). *Let  $G$  be a connected graph with a starting pair  $(S'', T'')$  with core  $(S^*, T^*)$ , and with an intermediate tuple  $(S', T', X', Y')$ . The following holds:*

- (i)  $S^* \subseteq S'$ ,  $S'' \subseteq X'$  and  $T^* \subseteq T'$ ,  $T'' \subseteq Y'$  and  $X' \cap Y' = \emptyset$ ,
- (ii) *For every integer  $\nu$ ,  $G$  has a valid red-blue  $(S^*, T^*, S'', T'')$ -colouring of value  $\nu$  if and only if  $G$  has a valid red-blue  $(S', T', X', Y')$ -colouring of value  $\nu$  (note that the backward implication holds by definition), and*
- (iii) *every vertex in  $S'$  (resp.  $T'$ ) has exactly one neighbour in  $Y'$  (resp. in  $X'$ ), which belongs to  $T'$  (resp.  $S'$ ); every vertex in  $X' \setminus S'$  (resp.  $Y' \setminus T'$ ) has no neighbour in  $Y'$  (resp.  $X'$ ); and every vertex of  $V \setminus (X' \cup Y')$  has no neighbour in  $S' \cup T'$ , at most one neighbour in  $X' \setminus S'$ , and at most one neighbour in  $Y' \setminus T'$ .*

Moreover,  $(S', T', X', Y')$  is obtained in polynomial time.

Let  $(S', T', X', Y')$  be an intermediate tuple of a graph  $G$ . Let  $Z = V \setminus (X' \cup Y')$ . A red-blue  $(S', T', X', Y')$ -colouring of  $G$  is *monochromatic* if all connected components of  $G[Z]$  are monochromatic. We say that an intermediate tuple  $(S', T', X', Y')$  is *monochromatic* if every connected component of  $G[V \setminus (X' \cup Y')]$  is monochromatic in every valid red-blue  $(S', T', X', Y')$ -colouring of  $G$ . A propagation rule is *mono-safe* if for every integer  $\nu$  the following holds:  $G$  has a valid monochromatic red-blue  $(S, T, X, Y)$ -colouring of value  $\nu$  before the application of the rule if and only if  $G$  has a valid monochromatic red-blue  $(S, T, X, Y)$ -colouring of value  $\nu$  after the application of the rule.

■ **Figure 3** An example (from [31]) of a red-blue  $(S', T', X', Y')$ -colouring of a graph with an intermediate 4-tuple  $(S', T', X', Y')$ .

We now present Rule R3 (used implicitly in [26]) and prove that R3 is mono-safe.

**R3.** If there are two distinct vertices  $u$  and  $v$  in a connected component  $D$  of  $G[Z]$  with a common neighbour  $w \in X \cup Y$ , then colour every vertex of  $D$  with the colour of  $w$ .

► **Lemma 14.** *Rule R3 is mono-safe.*

**Proof.** Say  $w \in X \cup Y$  is in  $X$ , so  $w$  is red. Then, at least one of  $x$  and  $y$  must be coloured red. Hence, as  $D$  must be monochromatic, every vertex of  $D$  must be coloured red. Note that the value of a maximum monochromatic red-blue  $(S, T, X, Y)$ -colouring (if it exists) is not affected. ◀

Suppose that exhaustively applying rules R1–R3 on an intermediate tuple  $(S', T', X', Y')$  does not lead to a no-answer but to a tuple  $(S, T, X, Y)$ . We call  $(S, T, X, Y)$  the *final* tuple. The following lemma can be proved by a straightforward combination of the arguments of the proof of Lemma 13 with Lemma 14 and the observation that an application of R3 takes polynomial time, just as a check to see if R3 can be applied.

► **Lemma 15.** *Let  $G$  be a connected graph with a monochromatic intermediate tuple  $(S', T', X', Y')$  and a resulting final tuple  $(S, T, X, Y)$ . The following three statements hold:*

- (i)  $S' \subseteq S$ ,  $X' \subseteq X$ ,  $T' \subseteq T$ ,  $Y' \subseteq Y$ , and  $X \cap Y = \emptyset$ ,
- (ii) *For every integer  $\nu$ ,  $G$  has a valid (monochromatic) red-blue  $(S', T', X', Y')$ -colouring of value  $\nu$  if and only if  $G$  has a valid monochromatic red-blue  $(S, T, X, Y)$ -colouring of value  $\nu$  (note that the backward implication holds by definition), and*
- (iii) *every vertex in  $S$  (resp.  $T$ ) has exactly one neighbour in  $Y$  (resp.  $X$ ), which belongs to  $T$  (resp.  $S$ ); every vertex in  $X \setminus S$  (resp.  $Y \setminus T$ ) has no neighbour in  $Y$  (resp.  $X$ ) and no two neighbours in the same connected component of  $G[V \setminus (X \cup Y)]$ ; and every vertex of  $V \setminus (X \cup Y)$  has no neighbour in  $S \cup T$ , at most one neighbour in  $X \setminus S$ , and at most one neighbour in  $Y \setminus T$ .*

Moreover,  $(S, T, X, Y)$  is obtained in polynomial time.

### 3 Polynomial-Time Results

The following lemma uses Theorem 8 and is the final step in *all* our polynomial-time results.

■ **Figure 4** A  $U$ -saturating matching (left) and the corresponding valid red-blue colouring (right). Note that not every vertex in  $X \cup Y$  belongs to  $W$ .

► **Lemma 16.** *Let  $G = (V, E)$  be a connected graph with a monochromatic intermediate tuple  $(S', T', X', Y')$  and a final tuple  $(S, T, X, Y)$ . If  $V \setminus (X \cup Y)$  is an independent set, then it is possible to find in polynomial time either a maximum valid red-blue  $(S, T, X, Y)$ -colouring of  $G$  or conclude that  $G$  has no such colouring.*

**Proof.** Let  $Z = V \setminus (X \cup Y)$  and  $W = N(Z)$ . As  $Z$  is independent, every vertex of  $W$  belongs to  $(X \setminus S) \cup (Y \setminus T)$  due to Lemma 15-(iii). Let  $U \subseteq Z$  consist of all vertices of  $Z$  with a neighbour in both  $X \setminus S$  and  $Y \setminus T$ . We claim that the set of bichromatic edges of every valid red-blue  $(S, T, X, Y)$ -colouring is the union of a  $U$ -saturating matching in  $G[W \cup Z]$  (if it exists) and the set of edges with one end-vertex in  $S$  and the other one in  $T$ .

First suppose that  $G[W \cup Z]$  has a  $U$ -saturating matching  $M$ . We colour every vertex in  $X$  red and every vertex in  $Y$  blue. Let  $z \in Z$ . First assume that  $z$  is incident to an edge  $zw \in M$ . If  $w \in X \setminus S$ , then colour  $z$  blue. If  $w \in Y \setminus T$ , then colour  $z$  red. Now suppose  $z$  is not incident to an edge in  $M$ . Then  $z \notin U$ , as  $M$  is  $U$ -saturating. Hence, either every neighbour of  $z$  belongs to  $X \setminus S$  and is coloured red, in which case we colour  $z$  red, or every neighbour of  $z$  belongs to  $Y \setminus T$  and is coloured blue, in which case we colour  $z$  blue. This gives us a valid red-blue  $(S, T, X, Y)$ -colouring of  $G$ . See also Figure 4.

Now suppose that  $G$  has a valid red-blue  $(S, T, X, Y)$ -colouring. By definition, every vertex of  $X$  is coloured red, and every vertex of  $Y$  is coloured blue. By Lemma 15-(iii), every edge with an end-vertex in  $S$  and the other one in  $T$  is bichromatic, and there are no other bichromatic edges in  $G[X \cup Y]$ . Let  $M$  be the set of other bichromatic edges. Then, every vertex of  $M$  has one vertex in  $Z$  and the other one in  $W$ . Moreover, if  $z \in U$ , then  $z$  has a red neighbour (its neighbour in  $X \setminus S$ ) and a blue neighbour (its neighbour in  $Y \setminus T$ ). Hence, no matter what colour  $z$  has itself,  $z$  is incident to a bichromatic edge of  $M$ . We conclude that  $M$  is  $U$ -saturating, and the claim is proven.

From the above claim, it follows that all we have to do is to find a maximum  $U$ -saturating matching in  $G[W \cup Z]$ . By Theorem 8, this takes polynomial time. ◀

We are now ready to present our first result.

► **Theorem 17.** *MAXIMUM MATCHING CUT is solvable in polynomial time for  $P_6$ -free graphs.*

**Proof.** Let  $G = (V, E)$  be a connected  $P_6$ -free graph. By Observation 10 it suffices to find a maximum valid red-blue colouring of  $G$ . We know from Theorem 9 that  $G$  has a dominating induced  $C_6$  or a dominating (not necessarily induced) complete bipartite graph  $K_{r,s}$ , which can be found in polynomial time. If  $G$  has a dominating induced  $C_6$ , then  $G$  has domination number at most 6, and we apply Lemma 12. Suppose  $G$  has a dominating complete bipartite graph  $F$  with partition classes  $\{u_1, \dots, u_r\}$  and  $\{v_1, \dots, v_s\}$ , where  $r \leq s$ . If  $s \leq 2$ , then  $G$  has domination number at most 4, and we apply Lemma 12 again. So we assume that  $s \geq 3$ .

If  $r \geq 2$ , then  $V(F)$  must be monochromatic in any valid red-blue colouring of  $G$  by Observation 11. In this case we colour every vertex of  $V(F)$  blue. If  $r = 1$ , then we may assume without loss of generality that  $N(u_1) = \{v_1, \dots, v_s\}$ . In this case we colour  $u_1$  blue, and we branch over all  $O(n)$  options of colouring at most one vertex of  $N(u_1)$  red.

So, now we consider a red-blue colouring of  $F$ . It might be that  $F$  is monochromatic (in particular, this will be the case if  $r \geq 2$ ). If  $F$  is monochromatic, then every vertex of  $F$  is blue. In order to get a starting pair with a non-empty core, we branch over all  $O(n^2)$  options of choosing a bichromatic edge (one end-vertex of which may belong to  $F$ ). Let  $D$  be the set of all coloured vertices, that is,  $D$  contains  $V(F)$  and possibly one or two other vertices. By construction, exactly one vertex of  $D$  is coloured red, and all other vertices of  $D$  are blue.

Let  $S^* = S''$  be the set containing the red vertex of  $D$ . Let  $T^*$  be the singleton set containing the blue neighbour of the vertex in  $S^*$ . Let  $T''$  be the set of blue vertices, so  $T^* \subseteq T''$ . We exhaustively apply rules R1 and R2 on the starting pair  $(S'', T'')$ . By Lemma 13

■ **Figure 5** The situation in Claim 17.3 where two connected components  $Z_1, Z_2$  of  $G[Z]$ , each with at least two vertices, are both coloured red. This will always yield an induced path on at least six vertices, even if  $w_1$  and  $w_2$  are not adjacent, as at most one of  $z'_1, z'_2$  is adjacent to  $w_3$ .

we either find in polynomial time that  $G$  has no valid red-blue  $(S^*, T^*, S'', T'')$ -colouring, and we discard the branch, or we obtain an intermediate tuple  $(S', T', X', Y')$  of  $G$ . Suppose the latter case holds. Let  $Z' = V \setminus (X' \cup Y')$  be the set of uncoloured vertices.

▷ **Claim 17.1.** Every vertex  $z \in Z'$  has a neighbour in  $Y' \setminus T'$  that belongs to  $F$ .

Proof. As  $F$  is dominating,  $z$  has a neighbour in  $F$ . Since  $D \supseteq V(F)$  contains exactly one red vertex  $x$ , which has a blue neighbour in  $D$ , all neighbours of  $x$  in  $G - D$  are coloured red, that is, belong to  $X$ . As  $z \in G - D$  belongs to  $Z'$ , this means that  $x$  and  $z$  are non-adjacent. So, the neighbour of  $z$  in  $F$  must belong to  $Y' \setminus T'$  (as else we could have applied R2). ◁

▷ **Claim 17.2.** The intermediate tuple  $(S', T', X', Y')$  is monochromatic.

Proof. Suppose for a contradiction that there is an edge  $uv \in E(G[Z'])$  such that  $u$  is blue and  $v$  is red. Then  $v$  has two blue neighbours by Claim 17.1, a contradiction. ◁

Since Claim 17.2 holds, we may now exhaustively apply R1–R3 to the intermediate tuple  $(S', T', X', Y')$ . By Lemma 15 we either find in polynomial time that  $G$  has no valid red-blue  $(S', T', X', Y')$ -colouring, and thus no valid red-blue  $(S^*, T^*, S', T')$ -colouring, and we discard the branch, or we obtain a final tuple  $(S, T, X, Y)$  of  $G$ . Again, we let  $Z = V \setminus (X \cup Y)$ . By the same lemma and Claim 17.1, the following holds for every (uncoloured) vertex  $w \in Z$ :

- $w$  has at most one neighbour in  $X \setminus S$ ,
- $w$  has exactly one neighbour in  $Y \setminus T$ , which belongs to  $F$ , and
- if  $w'$  is in the same connected component of  $G[Z]$  as  $w$ , then  $w$  and  $w'$  do not share a neighbour in  $G - Z$ .

▷ **Claim 17.3.** In any valid red-blue  $(S, T, X, Y)$ -colouring at most one red component may have more than one vertex.

Proof. For a contradiction, assume that  $Z_1$  and  $Z_2$  are connected components of size at least 2 that are both coloured red. For  $i = 1, 2$ , let  $z_i$  and  $z'_i$  be two adjacent vertices in  $Z_i$ , and let  $w_i$  be the blue neighbour of  $z_i$  in  $F$  (which exists due to Claim 17.1). Note that  $w_1$  is not adjacent to any vertex of  $\{z'_1, z_2, z'_2\}$ , and  $w_2$  is not adjacent to any vertex of  $\{z_1, z'_1, z'_2\}$ . Moreover,  $w_1$  and  $w_2$  are distinct vertices, and do not have any other neighbours in  $Z_1 \cup Z_2$ . If  $w_1$  and  $w_2$  are adjacent, then  $z'_1 z_1 w_1 w_2 z_2 z'_2$  is an induced  $P_6$ . As  $G$  is  $P_6$ -free, this is not possible. Hence,  $w_1$  and  $w_2$  are not adjacent.

We now use the fact that  $w_1$  and  $w_2$  both belong to  $F$  and that  $F$  is complete bipartite. As  $w_1 w_2 \notin E$ , the latter means there is a vertex  $w_3 \in V(F)$  adjacent to both  $w_1$  and  $w_2$ , so  $w_3$  is blue as well. As  $z'_1$  and  $z'_2$  are both coloured red, at most one of  $z'_1, z'_2$  can be adjacent

to  $w_3$ . Hence, we may assume without loss of generality that  $w_3$  is not adjacent to  $z'_1$ . As  $z_1$  and  $z_2$  have  $w_1$  and  $w_2$ , respectively, as their matching partner,  $w_3$  is adjacent neither to  $z_1$  nor to  $z_2$ . Now,  $z'_1 z_1 w_1 w_3 w_2 z_2$  is an induced  $P_6$ , a contradiction. See also Figure 5.  $\triangleleft$

We then exhaustively apply rules R1-R3 again. This takes polynomial time. In essence, we merely pre-coloured some more vertices red. So, in the end we either find a new tuple of  $G$  with the same properties as those listed in Lemma 15, or we find that  $G$  has not such a tuple, in which case we discard the branch. Suppose we have not discarded the branch. Now the set of uncoloured vertices form an independent set. Hence, we can apply Lemma 16 to find in polynomial time a red-blue colouring of  $G$  that is a maximum red-blue  $(S^*, T^*, S'', T'')$ -colouring due to Lemmas 13-(ii) and 15-(ii).

If somewhere in the above process we discarded a branch, that is, if  $G$  has no valid red-blue  $(S^*, T^*, S'', T'')$ -colouring, we consider the next one. Else remember the value of the maximum red-blue  $(S^*, T^*, S'', T'')$ -colouring that we found. Afterwards, we pick one with the largest value to obtain a maximum valid red-blue colouring of  $G$ .

The correctness of our algorithm follows from its description. The running time is polynomial: each of the in total  $O(n^3)$  branches takes polynomial time to process.  $\blacktriangleleft$

The proof of our next result combines Lemma 16 with arguments from the proof that MATCHING CUT is polynomial-time solvable for  $(H + P_3)$ -free graphs if it is so for  $H$ -free graphs [30]. We omit the proof.

► **Theorem 18.** *Let  $H$  be a graph. If MAXIMUM MATCHING CUT is polynomial-time solvable for  $H$ -free graphs, then it is so for  $(H + P_2)$ -free graphs.*

We now show our third polynomial-time result; we will again apply Lemma 16.

► **Theorem 19.** *MAXIMUM MATCHING CUT is solvable in polynomial time for graphs with diameter at most 2.*

**Proof sketch.** Let  $G = (V, E)$  be a graph of diameter at most 2. If  $G$  has diameter 1, then the problem is trivial to solve. Assume that  $G$  has diameter 2. By Observation 10 it suffices to find a maximum valid red-blue colouring of  $G$ . By definition, such a colouring has at least one bichromatic edge (has value at least 1). We branch over all  $O(n^2)$  options of choosing the bichromatic edge.

Consider a branch, where  $e = uv$  is the bichromatic edge, say  $u$  is blue and  $v$  is red. All other neighbours of  $u$  must be coloured blue. Let  $D = \{u\} \cup N(u)$ . Then  $D$  dominates  $G$ , as  $G$  has diameter 2. Set  $S^* = \{u\}$ ,  $T^* = \{v\}$ ,  $S'' = \{u\}$  and  $T'' = N(u)$ . This gives us a starting pair  $(S'', T'')$  with core  $(S^*, T^*)$ . We exhaustively apply R1 and R2 on  $(S'', T'')$ . By Lemma 13 we either find in polynomial time that  $G$  has no valid red-blue  $(S^*, T^*, S'', T'')$ -colouring, and we discard the branch, or we obtain an intermediate tuple  $(S', T', X', Y')$ . Say the latter holds. Let  $Z' = V \setminus (X' \cup Y')$  be the set of uncoloured vertices. We show the following claim (proof omitted).

▷ **Claim 19.1.** The intermediate tuple  $(S', T', X', Y')$  is monochromatic.

By Claim 19.1, we may exhaustively apply R1–R3 to the intermediate tuple  $(S', T', X', Y')$ . By Lemma 15 we either find in polynomial time that  $G$  has no valid red-blue  $(S', T', X', Y')$ -colouring, and thus no valid red-blue  $(S^*, T^*, S', T')$ -colouring, and we discard the branch, or we obtain a final tuple  $(S, T, X, Y)$  of  $G$ . We let  $Z = V \setminus (X \cup Y)$ . We show the following claims (proofs omitted).

▷ **Claim 19.2.** Every vertex  $w \in Z$  has exactly one neighbour in  $X \setminus S$ .

■ **Figure 6** A graph  $G$  (left) where the thick red edges form a maximum edge cut, and the graph  $G'$  (right) from the proof of Theorem 20, where the thick red edges form a maximum matching cut.

▷ **Claim 19.3.** If  $G[Z]$  contains two connected components  $F_1$  and  $F_2$  of size at least 2, then  $G[Z] = F_1 + F_2$ .

We use Claim 19.2 to prove Claim 19.3, from which it follows that  $G[Z]$  has at most two components with more than one vertex, which are both monochromatic in every valid red-blue  $(S, T, X, Y)$ -colouring of  $G$  (if such a colouring exists) due to Claim 19.1. Hence, we can branch over all possible colourings of these connected components (there are at most four branches).

For each branch, we propagate the obtained partial red-blue colouring by exhaustively applying rules R1–R3. This takes polynomial time. In essence, we merely pre-coloured some more vertices red or blue. So, in the end we either find a new tuple of  $G$  with the same properties as those listed in Lemma 15, or we find that  $G$  has not such a tuple, in which case we discard the branch. Suppose not. Now the set of uncoloured vertices form an independent set. Hence, we can apply Lemma 16 to find in polynomial time a red-blue colouring of  $G$  that is a maximum red-blue  $(S^*, T^*, S'', T'')$ -colouring due to Lemmas 13-(ii) and 15-(ii).

If we discarded a branch, that is, if  $G$  has no valid red-blue  $(S^*, T^*, S'', T'')$ -colouring, we consider the next one. If we did not discard the branch, then we remember the value of the maximum red-blue  $(S^*, T^*, S'', T'')$ -colouring that we found. Afterwards, we pick one with the largest value to obtain a maximum valid red-blue colouring of  $G$ .

The correctness of our branching algorithm follows from its description. The running time is polynomial: each of the in total  $O(n^2)$  branches takes polynomial time to process. ◀

## 4 Hardness Results

We sketch the two hardness proofs. For the first one we reduce from MAXIMUM CUT, which is NP-complete even for subcubic graphs [37]: does a subcubic graph  $G$  have an edge cut of size at least  $k$  for some integer  $k$ ?

► **Theorem 20.** MAXIMUM MATCHING CUT is NP-hard for subcubic line graphs of triangle-free graphs.

**Proof sketch.** Let  $(G, k)$  be an instance of MAXIMUM CUT, where  $G$  is subcubic. Build a graph  $G'$  as follows (see also Figure 6). Replace every vertex  $v \in V(G)$  by a triangle  $C_v$ . For every edge  $uv \in E(G)$ , add an edge between a vertex in  $C_v$  and a vertex in  $C_u$ , such that every vertex in  $C_v$  has at most one neighbour outside  $C_v$ . This is possible, as  $G$  is subcubic. The graph  $G'$  is also subcubic, as every vertex in  $G'$  has two neighbours inside a triangle and at most one neighbour outside. Moreover,  $G'$  is  $(K_{1,3}, \text{diamond})$ -free, so the line graph of a triangle-free graph. We can show that  $G$  has an edge cut of size at least  $k$  if and only if  $G'$  has a maximum matching cut of size at least  $k$ . ◀

■ **Figure 7** The graph  $G$  for  $X = \{x_1, \dots, x_6\}$  and  $\mathcal{S} = \{\{x_1, x_2, x_4\}, \{x_2, x_4, x_5\}, \{x_3, x_5, x_6\}\}$ . The vertices in the rectangle form a clique. The set  $\mathcal{S}' = \{\{x_1, x_2, x_4\}, \{x_3, x_5, x_6\}\}$  is an exact 3-cover of  $X$ . The thick red edges in the graph show the corresponding maximum matching cut.

An *exact 3-cover* of a set  $X$  is a collection  $\mathcal{C}$  of 3-element subsets of  $X$ , such that every  $x \in X$  is in exactly one 3-element subset of  $\mathcal{C}$ . We now reduce from EXACT 3-COVER, which is to decide if a collection  $\mathcal{S}$  of 3-element subsets of a set  $X$  with  $q$  elements has an *exact 3-cover* of  $X$  (which will be of size  $q$ ). This problem is NP-complete (see [23]).

► **Theorem 21.** MAXIMUM MATCHING CUT is NP-hard for  $2P_3$ -free quadrangulated graphs of radius at most 2 and diameter at most 3.

**Proof sketch.** Let  $(X, \mathcal{S})$  be an instance of EXACT 3-COVER where  $X = \{x_1, \dots, x_{3q}\}$  and  $\mathcal{S} = \{S_1, \dots, S_k\}$ , such that each  $S_i$  contains exactly three elements of  $X$ . From  $(X, \mathcal{S})$  we construct a graph  $G$  as follows (see also Figure 7). We first define a clique  $K_X = \{x_1, \dots, x_{3q}\}$ . For each  $S \in \mathcal{S}$ , we do as follows. Let  $S = \{x_h, x_i, x_j\}$ . We add a triangle  $K_S$  on vertices  $x_h^S, x_i^S$  and  $x_j^S$ . We add an edge between a vertex  $x_i \in K_X$  and a vertex  $u \notin K_X$  if and only if  $u = x_i^S$  for some  $S \in \mathcal{S}$ . This completes the construction of  $G$ . Note that  $G$  is  $2P_3$ -free, quadrangulated as well as that the radius of  $G$  is at most 2 and the diameter of  $G$  is at most 3. We can show that  $\mathcal{S}$  contains an exact 3-cover of  $X$  if and only if  $G$  has a matching cut of size  $3q$ . ◀

## 5 The Proofs of Theorems 5–7

We first note that Theorem 5 immediately follows from Theorems 19 and 21.

The first part of Theorem 6 follows from the fact that a graph of radius 1 has a dominating vertex, and thus it has a matching cut if and only if it has a vertex of degree 1, which can be checked in polynomial time. The second part of Theorem 6 follows from Theorem 21.

To prove Theorem 7, let  $H$  be a graph. If  $H$  contains a cycle, then MATCHING CUT, and thus MAXIMUM MATCHING CUT, is NP-hard due to Theorem 2. Now suppose  $H$  has no cycle, so  $H$  is a forest. If  $H$  contains a vertex of degree at least 3, then the class of  $H$ -free graphs contains the class of  $K_{1,3}$ -free graphs. The latter class contains the class of line graphs, and thus we apply Theorem 20. Now suppose  $H$  is a forest of maximum degree at most 2, that is,  $H$  is a linear forest. If  $H \subseteq_i sP_2 + P_6$  for some  $s \geq 0$ , then we apply Theorem 17. Else  $H$  has an induced  $2P_3$ . We apply Theorem 21. This completes the proof.

## 6 Conclusions

We considered the optimization version MAXIMUM MATCHING CUT of the classical MATCHING CUT problem after first observing that the PERFECT MATCHING CUT problem is a special case of the former problem. We generalized known algorithms for graphs of diameter at most 2

and  $P_6$ -free graphs from MATCHING CUT and PERFECT MATCHING CUT to MAXIMUM MATCHING CUT. We also showed that the latter problem is computationally harder (assuming  $P \neq NP$ ) than MATCHING CUT and PERFECT MATCHING CUT for various graph classes. Our results led to three new dichotomy results, including a complete computational complexity classification of MAXIMUM MATCHING CUT for  $H$ -free graphs. The latter classification is still unsettled for the other two problems, as can be observed from Theorems 2 and 4. Below we discuss some other open problems.

We first recall that the complexity of PERFECT MATCHING CUT has not been fully classified for graphs of diameter at most  $d$ . What is the complexity of PERFECT MATCHING CUT in the remaining open case where  $d = 3$ ? We showed that MAXIMUM MATCHING CUT is NP-hard for  $2P_3$ -free quadrangulated graphs of diameter 3 and radius 2, whereas MATCHING CUT is polynomial-time solvable for quadrangulated graphs [32]. We recall an interesting open problem of Le and Telle [29] who asked, after proving polynomial-time solvability for chordal graphs: what is the complexity of PERFECT MATCHING CUT for quadrangulated graphs, or more general,  $k$ -chordal graphs for  $k \geq 4$ ? Here, a graph is  $k$ -chordal for some  $k \geq 3$  if it is  $(C_{k+1}, C_{k+2}, \dots)$ -free, so 3-chordal graphs are the chordal graphs.

## Abstract

---

Finite-state dimension, introduced early in this century as a finite-state version of classical Hausdorff dimension, is a quantitative measure of the lower asymptotic *density of information* in an infinite sequence over a finite alphabet, as perceived by finite automata. Finite-state dimension is a robust concept that now has equivalent formulations in terms of finite-state gambling, lossless finite-state data compression, finite-state prediction, entropy rates, and automatic Kolmogorov complexity. The 1972 Schnorr-Stimm dichotomy theorem gave the first automata-theoretic characterization of normal sequences, which had been studied in analytic number theory since Borel defined them in 1909. This theorem implies, in present-day terminology, that a sequence (or a real number having this sequence as its base- $b$  expansion) is normal if and only if it has finite-state dimension 1. One of the most powerful classical tools for investigating normal numbers is the 1916 Weyl's criterion, which characterizes normality in terms of exponential sums. Such sums are well studied objects with many connections to other aspects of analytic number theory, and this has made use of Weyl's criterion especially fruitful. This raises the question whether Weyl's criterion can be generalized from finite-state dimension 1 to arbitrary finite-state dimensions, thereby making it a quantitative tool for studying data compression, prediction, etc. i.e., *Can we characterize all compression ratios using exponential sums?*

This paper does exactly this. We extend Weyl's criterion from a characterization of sequences with finite-state dimension 1 to a criterion that characterizes every finite-state dimension. This turns out *not* to be a routine generalization of the original Weyl criterion. Even though exponential sums may diverge for non-normal numbers, finite-state dimension can be characterized in terms of the *dimensions* of the *subsequence limits* of the exponential sums. In case the exponential sums are convergent, they converge to the Fourier coefficients of a probability measure whose *dimension* is precisely the finite-state dimension of the sequence.

This new and surprising connection helps us bring Fourier analytic techniques to bear in proofs in finite-state dimension, yielding a new perspective. We demonstrate the utility of our criterion by substantially improving known results about preservation of finite-state dimension under arithmetic. We strictly generalize the results by Aistleitner and Doty, Lutz and Nandakumar for finite-state dimensions under arithmetic operations. We use the method of exponential sums and our Weyl criterion to obtain the following new result: *If  $y$  is a number having finite-state strong dimension 0, then  $\dim_{FS}(x + qy) = \dim_{FS}(x)$  and  $\text{Dim}_{FS}(x + qy) = \text{Dim}_{FS}(x)$  for any  $x \in \mathbb{R}$  and  $q \in \mathbb{Q}$ .* This generalization uses recent estimates obtained in the work of Hochman [17] regarding the entropy of convolutions of probability measures.

## 1 Introduction

Finite-state compressibility [34], or equivalently, finite-state dimension [10, 2, 5] is a quantification of the information rate in data as measured by finite-state automata. This formulation, initially motivated by practical constraints, has proved to be rich and mathematically robust, having several equivalent characterizations. In particular, the finite state-dimension of a sequence is equal to the compression ratio of the sequence using information lossless finite-state compressors ([10, 2]). Finite-state dimension has unexpected connections to areas such as number theory, information theory, and convex analysis [20, 12]. Schnorr and Stimm [28] establish a particularly significant connection by showing that a number is Borel normal in base  $b$  (see for example, [24, 6, 8]) if and only if its base  $b$  expansion has finite-state compressibility equal to 1, *i.e.*, is incompressible (see also: [3, 5, 13, 15]). Equivalently, a number  $x \in [0, 1)$  is normal if and only if  $\dim_{FS}(x)$ , the finite-state dimension of  $x$  is equal to 1. A celebrated characterization of Borel normality in terms of exponential sums, provided by Weyl's criterion [32], has proved to be remarkably effective in the study of normality. Weyl's criterion on uniformly distributed sequences modulo 1 yields a characterization that a real number  $r$  is normal to base  $b$  if and only if for every integer  $k$ ,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k (b^j r)} = 0. \quad (1)$$

This tool was used by Wall [31] in his pioneering thesis to show that normality is preserved under certain operations like selection of subsequences along arithmetic progressions, and multiplication with non-zero rationals. Weyl's criterion facilitates the application of tools from Fourier analysis in the study of Borel normality. Weyl's criterion is used in several important constructions of normal numbers including those given by Cassels [7], Erdős and Davenport [11] etc. The criterion was also instrumental in obtaining the construction of absolutely normal numbers given by Schmidt in [27].

The finite-state compression ratio/dimension of an arbitrary sequence is a quantity in  $[0,1]$ . The classical Weyl's criterion provides a characterization of numbers having finite-state dimension equal to 1 in terms of exponential sums. This leads us to the natural question - *Can we characterize arbitrary compression ratios using exponential sums?* This question turns out to be highly non-trivial. It is not easy to generalize Weyl's criterion to study arbitrary finite-state compression ratios/dimension. The major conceptual hurdle arises from the fact that for non-normal numbers, the Weyl sum averages in (1) need not converge. The Weyl averages need not converge even when the finite-state dimension and the strong dimension of a sequence are equal.

We demonstrate this by explicitly constructing such a sequence in Lemma 19. Using a new construction method involving the controlled concatenation of two special sequences, we demonstrate the existence of a sequence  $x \in \Sigma^\infty$  with non-convergent Weyl averages, while having finite-state dimension and strong dimension both equal to  $\frac{1}{2}$ . The proof that this constructed sequence satisfies the required properties uses new techniques, which might be

of independent interest. Due to the existence of such sequences, it is unclear how to *extract* the finite-state dimension of a sequence from non-convergent Weyl averages. Indeed, it was unclear whether any generalization of the Weyl’s criterion to arbitrary finite-state dimensions even exists.

Our paper rescues this approach and gives such a characterization of arbitrary finite-state compressibility/dimension by introducing one important viewpoint, that turns out to be the major theoretical insight. Even when the exponential sums diverge, the theory of *weak convergence* of probability measures ([4]) enables us to consider the collection of all probability measures having Fourier coefficients equal to the subsequence limits of the Weyl averages. The *dimensions* of the measures in the set of subsequence weak limit measures gives a generalization of Weyl’s criterion. For any  $x$ , let  $\dim_{FS}(x)$  and  $\text{Dim}_{FS}(x)$  denote the finite-state dimension and finite-state strong dimension [2] of  $x$  respectively. We now informally state our Weyl’s criterion for finite-state dimension.

► **Theorem** (Informal statement of Theorem 22). *Let  $x \in [0, 1)$ . If for any subsequence  $\langle n_m \rangle_{m=0}^\infty$  of natural numbers, there exist complex numbers  $c_k$  such that for every  $k \in \mathbb{Z}$ ,  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k (b^j x)} = c_k$ , then, there exists a probability measure  $\mu$  on  $[0, 1)$  such that for every  $k$ ,  $c_k = \int e^{2\pi i k y} d\mu$ . Let  $\mathcal{W}_x$  be the collection of all such probability measures  $\mu$  on  $[0, 1)$  that can be obtained as the subsequence limits of Weyl averages. Then,  $\dim_{FS}(x) = \inf_{\mu \in \mathcal{W}_x} H^-(\mu)$  and  $\text{Dim}_{FS}(x) = \sup_{\mu \in \mathcal{W}_x} H^+(\mu)$ .*

The *correct* notion of *dimensions* of the subsequence weak limit measures in  $\mathcal{W}_x$  which yields the finite-state dimensions of  $x$  turns out to be  $H^-$  and  $H^+$ , the *lower* and *upper average entropies* of  $\mu$  as defined in [2]<sup>1</sup>. Therefore, this new characterization enables us to *extract* the finite-state compressibility/dimension by studying the behavior of the Weyl sum averages, thereby extending Weyl’s criterion for normality to arbitrary finite-state dimensions.

An interesting special case of our criterion is when the exponential averages of a sequence are convergent. In this case, the averages  $\langle c_k \rangle_{k \in \mathbb{Z}}$  are precisely the *Fourier coefficients* of a *unique* limiting measure, whose *dimension* is precisely the finite-state dimension of the sequence. This relates two different notions of dimension to each other. We give the informal statement of our criterion for this special case.

► **Theorem** (Informal statement of Theorem 23). *Let  $x \in [0, 1)$ . If there exist complex numbers  $c_k$  for  $k \in \mathbb{Z}$  such that  $\frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k (b^j x)} \rightarrow c_k$  as  $n \rightarrow \infty$ , then, there exists a unique measure  $\mu$  on  $[0, 1)$  such that for every  $k$ ,  $c_k = \int e^{2\pi i k y} d\mu$ . Furthermore,  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = H^-(\mu) = H^+(\mu)$ .*

Our results also show that in case there is a unique weak limit measure, the exponential sums (1) converge for every  $k \in \mathbb{Z}$ . These give the first known relations between Fourier coefficients and finite-state compressibility/dimension. The proof of Weyl’s criterion for finite-state dimension is not a routine generalization of the available proofs of Weyl’s criterion for normality (see [32, 14], [30]) and requires several facts from the theory of weak convergence of probability measures and new relationships involving the exponential sums, the *dimensions* of weak limit measures and the finite-state dimension of the given sequence. We overcome certain additional technical difficulties in working with two different topologies - the topology on the torus  $\mathbb{T}$  where Fourier coefficients uniquely determine a measure, and another, Cantor space, which is required for studying combinatorial properties of sequences, like normality.

<sup>1</sup> These are analogues of the well-known *Rényi upper and lower dimensions* of measures as defined in [25]. See the remark following Definition 5.

## 1.1 Applications of our criterion

We illustrate how this framework can be applied in sections 6. These results justify that this framework pioneers a new, powerful, approach to data compression. It is not very surprising that when the Weyl averages converge, our criterion has applications. Importantly, even in situations where the Weyl averages do not converge, it is possible to derive non-trivial consequences. We apply our techniques to substantially improve known results about the preservation of finite-state dimension under arithmetic and combinatorial operations.

Doty, Lutz and Nandakumar [12] show that if  $x$  is any real and  $q$  is any non-zero rational, then the finite-state dimensions and strong dimensions of  $x$ ,  $qx$  and  $x + q$  are equal. When  $x$  is normal, a generalization is obtained by Aistleitner [1], which can be described as follows. Let  $y$  be any real such that the asymptotic density of zeroes in its expansion is one. Then, for any rational  $q$ , we have  $x + qy$  is normal. We generalize these results by allowing both the following conditions simultaneously,

1.  $x$  is allowed to be any real, obtaining a result for all finite-state dimensions rather than only for normals as in Aistleitner [1] and
2.  $y$  is allowed to be any real with finite-state strong dimension 0 which satisfies a natural independence condition. This generalizes both the restrictions in Doty, Lutz and Nandakumar [12] and Aistleitner [1],

and show that for any rational  $q \in \mathbb{Q}$ ,  $\dim_{FS}(x + qy) = \dim_{FS}(x)$  and  $\text{Dim}_{FS}(x + qy) = \text{Dim}_{FS}(x)$  if  $x$  and  $y$  are *independent* (see Definition 30) and  $\text{Dim}_{FS}(y) = 0$ .

Using our Weyl criterion along with the results in Hochman [17], we obtain the following. Let  $x$  and  $y$  be real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent. Then for any  $d, e \in \mathbb{Z}$ ,  $\dim_{FS}(dx + ey) \geq \max\{\dim_{FS}(dx), \dim_{FS}(ey)\}$  and  $\dim_{FS}(dx + ey) \leq \dim_{FS}(dx) + \text{Dim}_{FS}(ey)$ . Similarly,  $\text{Dim}_{FS}(dx + ey) \geq \max\{\text{Dim}_{FS}(dx), \text{Dim}_{FS}(ey)\}$  and  $\text{Dim}_{FS}(dx + ey) \leq \text{Dim}_{FS}(dx) + \text{Dim}_{FS}(ey)$ . Our main results are consequences of these inequalities.

There are several known techniques for explicit constructions of normal numbers (see [20, 6]), but constructions of those with finite-state dimension  $s \in [0, 1)$  follow two techniques: first, to start with a normal sequence, and to *dilute* it with an appropriate fraction of simple patterns, as we did in Section 4, and second, to start with a coin with bias  $p$  such that  $-p \log_2 p - (1 - p) \log_2(1 - p) = s$ , and consider any typical sequence drawn from this distribution (see also [23]). We note that our Weyl criterion along with techniques from Mance and Madritsch [22] yields new methods for the explicit construction of numbers having a specified finite-state dimension.

Lossless data compression is practically significant, and theoretically sophisticated. We show how one of the major tools of modern mathematics, Fourier analysis, can be brought to bear to study compressibility of individual data sequences. We hope that our criterion will facilitate the application of more powerful Fourier analytic tools in future works involving finite-state compression/dimension.

After the preliminary sections, section 3 gives Weyl's criterion on Cantor space using weak convergence of measures. Next, we show the necessity and the sufficiency of passing to *subsequences* of sequences of measures in order to generalize Weyl's criterion for finite-state dimension. In section 6 we show the applications of our Weyl criterion to yield new, general results regarding the preservation of finite-state dimension under arithmetic and combinatorial operations.

## 2 Preliminaries

For any natural number  $b > 1$ ,  $\Sigma_b$  denotes the alphabet  $\{0, 1, 2, \dots, b-1\}$ . Throughout this paper, we work with base 2, but our results generalize to all bases. We use  $\Sigma$  to denote the binary alphabet  $\Sigma_2$ . We denote the set of finite binary strings by  $\Sigma^*$  and the set of infinite sequences by  $\Sigma^\infty$ . For any  $w \in \Sigma^*$ , let  $C_w$  be the set of infinite sequences with  $w$  as a prefix, called a *cylinder*. For any sequence  $x = x_0x_1x_2\dots$  in  $\Sigma^\infty$ , we denote the substring  $x_ix_{i+1}\dots x_j$  of  $x$ , by  $x_i^j$ . The Borel  $\sigma$ -algebra generated by the set of all cylinder sets is denoted by  $\mathcal{B}(\Sigma^\infty)$ . Let  $\mathbb{T}$  denote the one-dimensional torus or unit circle. i.e.,  $\mathbb{T}$  is the unit interval  $[0, 1)$  with the metric  $d(r, s) = \min\{|r - s|, 1 - |r - s|\}$ .  $\mathbb{T}$  is a compact metric space. The Borel  $\sigma$ -algebra generated by all open sets in  $\mathbb{T}$  is denoted by  $\mathcal{B}(\mathbb{T})$ . For any base  $b$ , let  $v_b$  be the *evaluation map* which maps any  $x \in \Sigma^\infty$  to its *value* in  $\mathbb{T}$  which is  $\sum_{i=0}^\infty \frac{x_i}{b^{i+1}} \bmod 1$ . We use the simplified notation  $v$  to denote the base 2 evaluation map  $v_2$ . Let  $T$  be the left shift transformation  $T(x_0x_1x_2\dots) = x_1x_2x_3\dots$  on  $\Sigma^\infty$ . For any base  $b$  and  $w \in \Sigma_b^*$ , let  $I_w^b$  denote the interval  $[v_b(w0^\infty), v_b(w0^\infty) + b^{-|w|})$  in  $\mathbb{T}$ . We use the simplified notation  $I_w$  to refer to  $I_w^2$ . Let  $\mathbb{D}$  be the set of all dyadic rationals in  $\mathbb{T}$ . It is easy to see that  $v : \Sigma^\infty \rightarrow \mathbb{T}$  has a well-defined inverse, denoted  $v^{-1}$ , over  $\mathbb{T} \setminus \mathbb{D}$ . For any measure  $\mu$  on  $\mathbb{T}$  (or  $\Sigma^\infty$ ), we refer to the collection of complex numbers  $\int e^{2\pi iky} d\mu$  where  $k$  ranges over  $\mathbb{Z}$  as the *Fourier coefficients of measure*  $\mu$ . For measures over  $\Sigma^\infty$ , the function  $e^{2\pi iky}$  inside the integral is replaced with  $e^{2\pi ikv(y)}$ . For every measure  $\mu$  on  $\mathbb{T}$ , we define the corresponding lifted measure on  $\Sigma^\infty$  as follows.

► **Definition 1** (Lift  $\hat{\mu}$  of a measure  $\mu$  on  $\mathbb{T}$ ). *If  $\mu$  is a measure on  $\mathbb{T}$ , then we define the lift  $\hat{\mu}$  of  $\mu$  to be the unique measure on  $\Sigma^\infty$  satisfying  $\hat{\mu}(C_w) = \mu(I_w)$  for every string  $w \in \Sigma^*$ .*<sup>2</sup>

► **Definition 2.** *Let  $x \in \Sigma^*$  have length  $n$ . We define the sliding count probability of  $w \in \Sigma^*$  in  $x$  denoted  $P(x, w)$ , and the disjoint block probability of  $w$  in  $x$ , denoted  $P^d(x, w)$ , as follows.*

$$P(x, w) = \frac{|\{i \in [0, n - |w|] : x_i^{i+|w|-1} = w\}|}{n - |w| + 1} \quad \text{and} \quad P^d(x, w) = \frac{|\{i \in [0, \frac{n}{|w|}] : x_{|w|i}^{|w|(i+1)-1} = w\}|}{n/|w|}$$

Now, we define normal sequences in  $\Sigma^\infty$  and normal numbers on  $\mathbb{T}$ .

► **Definition 3.** *A sequence  $x \in \Sigma^\infty$  is normal if for every  $w \in \Sigma^*$ ,  $\lim_{n \rightarrow \infty} P(x_0^{n-1}, w) = 2^{-|w|}$ .  $r \in \mathbb{T}$  is normal if and only if  $r \notin \mathbb{D}$  and  $v^{-1}(r)$  is a normal sequence in  $\Sigma^\infty$ .*

Equivalently, we can formulate normality using disjoint probabilities [20]. The following is the block entropy characterization of finite-state dimension from [5], which we use instead of the original formulation using  $s$ -gales (see [10],[2],[21]).

► **Definition 4** ([10, 5]). *For a given block length  $l$ , we define the sliding block entropy over  $x_0^{n-1}$  as  $H_l(x_0^{n-1}) = -\frac{1}{l} \sum_{w \in \Sigma^l} P(x_0^{n-1}, w) \log(P(x_0^{n-1}, w))$ . The finite-state dimension of  $x \in \Sigma^\infty$ , denoted  $\dim_{FS}(x)$ , and finite-state strong dimension of  $x$ , denoted  $\text{Dim}_{FS}(x)$ , are defined as follows.  $\dim_{FS}(x) = \inf_l \liminf_{n \rightarrow \infty} H_l(x_0^{n-1})$  and  $\text{Dim}_{FS}(x) = \inf_l \limsup_{n \rightarrow \infty} H_l(x_0^{n-1})$ .*<sup>3</sup>

<sup>2</sup> The uniqueness of  $\hat{\mu}$  follows from routine measure theoretic arguments

<sup>3</sup> The fact that  $\dim_{FS}(x)$  and  $\text{Dim}_{FS}(x)$  are equivalent to the lower and upper finite-state compressibilities of  $x$  using lossless finite-state compressors, follows immediately from the results in [34] and [10].

Disjoint block entropy  $H_l^d$  is defined similarly by replacing  $P$  with  $P^d$ . Bourke, Hitchcock and Vinodchandran [5], based on the work of Ziv and Lempel [34], demonstrated the entropy characterization of finite-state dimension using  $H_l^d$  instead of  $H_l$ . Kozachinskiy and Shen ([19]) proved that the finite-state dimension of a sequence can be equivalently defined using sliding block entropies (as in Definition 4) instead of disjoint block entropies. It is clear from the definition that, for any  $x \in \Sigma^\infty$ ,  $\dim_{FS}(x) \leq \text{Dim}_{FS}(x)$ . Any  $x$  with  $\dim_{FS}(x) = \text{Dim}_{FS}(x)$  is called a *regular sequence*. Upper and lower average entropies were defined in [2] for measures constructed out of infinite bias sequences. We extend these notions to the set of all measures on  $\Sigma^\infty$  below.

► **Definition 5.** For any probability measure  $\mu$  on  $\Sigma^\infty$ , let  $\mathbf{H}_n(\mu) = -\sum_{w \in \Sigma^n} \mu(C_w) \log(\mu(C_w))$ . The upper average entropy of  $\mu$ , denoted  $H^+(\mu)$ , and its lower average entropy, denoted  $H^-(\mu)$ , are respectively the limit superior and the limit inferior as  $n$  tends to  $\infty$  of  $H_n(\mu)/n$ .

Upper and lower average entropies are the Cantor space analogues of Rényi upper and lower dimensions of measures on  $[0,1]$  which were originally defined for measures on the real line in [25]. For any  $x \in \mathbb{T}$  (or  $x \in \Sigma^\infty$ ), let  $\delta_x$  denote the Dirac measure at  $x$ . i.e,  $\delta_x(A) = 1$  if  $x \in A$  and 0 otherwise for every  $A \in \mathcal{B}(\mathbb{T})$  (or  $A \in \mathcal{B}(\Sigma^\infty)$ ). Given a sequence  $\langle x_n \rangle_{n=0}^\infty$  of numbers in  $\mathbb{T}$  (or  $\Sigma^\infty$ ), we investigate the behavior of exponential averages  $\frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k x_j}$  by studying the weak convergence of sequences of averages of Dirac measures.

► **Definition 6.** Given a sequence  $\langle x_n \rangle_{n=0}^\infty$  in  $\mathbb{T}$  (or elements in  $\Sigma^\infty$ ), we say that  $\langle \nu_n \rangle_{n=1}^\infty$  is the sequence of averages of Dirac measures over  $\mathbb{T}$  (or over  $\Sigma^\infty$ ) constructed out of the sequence  $\langle x_n \rangle_{n=0}^\infty$  if,  $\nu_n = n^{-1} \sum_{i=0}^{n-1} \delta_{x_i}$  for each  $n \in \mathbb{N}$ .

### 3 Weyl's criterion and weak convergence

Schnorr and Stimm [28] (see also [3, 5]) showed a central connection between normal numbers and finite-state compressibility, or equivalently, finite-state dimension: a sequence  $x \in \Sigma^\infty$  is normal if and only if its finite-state dimension is 1. Any  $x \in \Sigma^\infty$  has finite-state dimension (equivalently, finite-state compressibility) between 0 and 1. In this sense, finite-state dimension is a generalization of the notion of normality. Another celebrated characterization of normality, in terms of exponential sums, was provided by Weyl in 1916. This characterization has resisted attempts at generalization. In the present section, we show that the theory of weak convergence of measures yields a generalization of Weyl's characterization for arbitrary dimensions. We demonstrate the utility of this new characterization to finite-state compressibility/finite-state dimension, in subsequent sections. Weyl criterion for normal numbers on  $\mathbb{T}$  is the following.

► **Theorem 7** (Weyl's criterion [32]). A number  $r \in \mathbb{T}$  is normal if and only if for every  $k \in \mathbb{Z}$ ,  $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k (2^j r)} = 0$ .

The insight in this theorem is the connection between a number  $x$  being normal, and the concept of the collection of its shifts being uniformly distributed in the unit interval. It is the latter concept which leads to the cancellation of the exponential sums of all orders. The following is a formulation of this criterion on Cantor space, which we require in our work.

► **Theorem 8** (Weyl's criterion on  $\Sigma^\infty$ ). A sequence  $x \in \Sigma^\infty$  is a normal sequence if and only if for every  $k \in \mathbb{Z}$ ,  $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k (v(T^j x))} = 0$ .

The key to generalizing Weyl’s criterion to sequences with finite-state dimension less than 1 is to characterize convergence of subsequences of exponential sums using weak convergence of probability measures on  $\Sigma^\infty$  (see Billingsley [4]). Over  $\mathbb{T}$ , this equivalent characterization is well-known (see Section 4.4 from [14]). Obtaining the same equivalence over  $\Sigma^\infty$  involves some technical hurdles due to the fact that continuous functions over  $\Sigma^\infty$  need not have a uniform approximation using trigonometric polynomials. In order to overcome these, we need to carefully study the relationship between the convergence of Weyl averages and weak convergence over  $\Sigma^\infty$ . We develop these relationships in the following lemmas. At the end of this section we characterize Theorem 8 in terms of weak convergence of a sequence of measures over  $\Sigma^\infty$ .

► **Definition 9.** A sequence  $\langle \nu_n \rangle_{n \in \mathbb{N}}$  of probability measures on a metric space  $(X, d)$  converges weakly to a probability  $\mu$  on  $(X, d)$ , denoted  $\nu_n \Rightarrow \mu$ , if for every bounded continuous function  $f : X \rightarrow \mathbb{C}$ , we have  $\lim_{n \rightarrow \infty} \int f d\nu_n = \int f d\mu$ .

If a sequence of measures  $\langle \nu_n \rangle_{n \in \mathbb{N}}$  on a metric space  $(X, d)$  has a weak limit measure, then the weak limit must be unique (see Theorem 1.2 from [4]). Since  $\mathbb{T}$  and  $\Sigma^{\infty 4}$  are compact metric spaces, using Prokhorov’s Theorem (see Theorem 5.1 from [4]) we get that any sequence of measures  $\langle \nu_n \rangle_{n \in \mathbb{N}}$  on  $\mathbb{T}$  (or  $\Sigma^\infty$ ), has a measure  $\mu$  on  $\mathbb{T}$  (or  $\Sigma^\infty$ ) and a subsequence  $\langle \nu_{n_m} \rangle_{m \in \mathbb{N}}$  such that  $\nu_{n_m} \Rightarrow \mu$ . We first establish a relationship between weak convergence of measures on  $\mathbb{T}$  and the convergence of measures of dyadic intervals in  $\mathbb{T}$ . Since the set of all finite unions of dyadic intervals in  $\mathbb{T}$  is closed under finite intersections, we obtain the following lemma using Theorem 2.2 from [4].

► **Lemma 10.** If for every dyadic interval  $I$  in  $\mathbb{T}$ ,  $\lim_{n \rightarrow \infty} \nu_n(I) = \mu(I)$ , then  $\nu_n \Rightarrow \mu$ .

The Portmanteau theorem (Theorem 2.1 from [4]) gives the following partial converse.

► **Lemma 11.** Let  $\nu_n \Rightarrow \mu$ . Then  $\lim_{n \rightarrow \infty} \nu_n(I) = \mu(I)$  for dyadic interval  $I = [d_1, d_2)$  if  $\mu(\{d_1\}) = \mu(\{d_2\}) = 0$ .

We characterize convergence of exponential sums in terms of weak convergence of probability measures, first on  $\mathbb{T}$  and then on the Cantor space  $\Sigma^\infty$ . Unlike Theorem 7, the result on  $\Sigma^\infty$  does not follow immediately from that on  $\mathbb{T}$ . On  $\mathbb{T}$ , the following theorem holds due to Prokhorov theorem, the fact that continuous functions on  $\mathbb{T}$  can be approximated uniformly using trigonometric polynomials, and that Fourier coefficients of measures over  $\mathbb{T}$  are unique due to Bochner’s theorem (see Theorem 4.19 from [16]).

► **Theorem 12.** Let  $r \in \mathbb{T}$  and let  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures constructed out of  $\langle 2^n r \bmod 1 \rangle_{n=0}^\infty$ . Let  $\langle n_m \rangle_{m \in \mathbb{N}}$  be any subsequence of natural numbers. Then for every  $k \in \mathbb{Z}$ , there is a  $c_k \in \mathbb{C}$  such that  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k (2^j r)} = c_k$  if and only if there is a unique measure  $\mu$  such that  $\nu_{n_m} \Rightarrow \mu$ . Furthermore, if any of the above conditions are true, then  $c_k = \int e^{2\pi i k y} d\mu$  for every  $k \in \mathbb{Z}$  and  $\mu$  is the unique measure on  $\mathbb{T}$  having Fourier coefficients  $\langle c_k \rangle_{k \in \mathbb{Z}}$ .

We require an analogue of this theorem for Cantor space. But the proof above cannot be adapted because on Cantor space, there are continuous functions which cannot be approximated uniformly using trigonometric polynomials. For example, consider  $\chi_{C_0}$ . Observe that  $\chi_{C_0}(0^\infty) = 1 \neq 0 = \chi_{C_0}(1^\infty)$ . But since  $v(0^\infty) = v(1^\infty)$ , every trigonometric polynomial

<sup>4</sup> The metric on  $\Sigma^\infty$  is  $d(x, y) = 2^{-\min\{i | x_i \neq y_i\}}$ .

has the same value on  $0^\infty$  and  $1^\infty$ . However, we recover the analogue by handling dyadic rational sequences and other sequences in separate cases. Since the set of all finite unions of cylinder sets in  $\Sigma^\infty$  is closed under finite intersections and since the characteristic functions of cylinder sets are continuous on the Cantor space, we get the following analogue of Lemma 10 and 11 using Theorem 2.2 from [4].

► **Lemma 13.** *For a sequence of measures  $\langle \nu_n \rangle_{n \in \mathbb{N}}$  on  $\Sigma^\infty$ ,  $\nu_n \Rightarrow \mu$  iff  $\lim_{n \rightarrow \infty} \nu_n(C_w) = \mu(C_w)$  for every  $w \in \Sigma^*$ .*

In the following theorems we relate the convergence of measures of cylinder sets to the convergence of Weyl averages on the Cantor space using Theorem 12 and Lemma 13. We state these theorems for convergence along any subsequence, since we require these more general results for studying the subsequence limits of Weyl averages.

► **Theorem 14.** *Let  $x \in \Sigma^\infty$  and  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures on  $\Sigma^\infty$  constructed out of  $\langle T^n x \rangle_{n=0}^\infty$ . Let  $\langle n_m \rangle_{m \in \mathbb{N}}$  be any subsequence of natural numbers. If  $\lim_{m \rightarrow \infty} \nu_{n_m}(C_w) = \mu(C_w)$  for every  $w \in \Sigma^*$ , then for every  $k \in \mathbb{Z}$  we have  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k v(T^j x)} = \int e^{2\pi i k v(y)} d\mu$ .*

Observe that  $\frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k v(T^j x)} = \int e^{2\pi i k v(y)} d\nu_{n_m}$ . Hence, the above claim follows from Lemma 13 and the definition of weak convergence since for every  $k \in \mathbb{Z}$ ,  $e^{2\pi i k v(y)}$  is a continuous function on  $\Sigma^\infty$ <sup>5</sup>. While Fourier coefficients uniquely determine measures over  $\mathbb{T}$ , Bochner's Theorem does not hold over  $\Sigma^\infty$ . For example let  $\mu_1 = \delta_{0^\infty}$  and let  $\mu_2 = \delta_{1^\infty}$ . Then  $\mu_1 \neq \mu_2$ , but it is easy to verify that for any  $k \in \mathbb{Z}$ ,  $\int e^{2\pi i k v(y)} d\mu_1 = e^{2\pi i k v(0^\infty)} = 1 = \int e^{2\pi i k v(y)} d\mu_2$ . The following lemma leads to a converse of Theorem 14.

► **Lemma 15.** *Let  $x \in \Sigma^\infty$  such that  $v(x) \notin \mathbb{D}$  and let  $\langle \nu'_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures on  $\mathbb{T}$  constructed out of the sequence  $\langle 2^n v(x) \bmod 1 \rangle_{n=0}^\infty$ . Let  $d$  be any non-zero dyadic rational. If  $\nu'_{n_m} \Rightarrow \mu'$  for some subsequence of natural numbers  $\langle n_m \rangle_{m \in \mathbb{N}}$ , then  $\mu'(\{d\}) = 0$ .*

Using the above results we obtain the following partial converse of Theorem 14.

► **Theorem 16.** *Let  $x \in \Sigma^\infty$  and let  $\langle n_m \rangle_{m \in \mathbb{N}}$  be any subsequence of natural numbers. Let  $\langle c_k \rangle_{k \in \mathbb{Z}}$  be complex numbers such that  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k v(T^j x)} = c_k$  for every  $k \in \mathbb{Z}$ . Then there exists a unique measure  $\mu$  on  $\mathbb{T}$  having Fourier coefficients  $\langle c_k \rangle_{k \in \mathbb{Z}}$  and  $\lim_{m \rightarrow \infty} \nu_{n_m}(C_w) = \hat{\mu}(C_w)$  for every  $w \in \Sigma^*$  such that  $w \neq 1^{|w|}$  and  $w \neq 0^{|w|}$ .*

For any  $x \in \Sigma^\infty$ , let  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures on  $\Sigma^\infty$  constructed out of the sequence  $\langle T^n x \rangle_{n=0}^\infty$ . Now, for any  $A \in \mathcal{B}(\Sigma^\infty)$ ,  $\nu_n(A)$  is the proportion of elements in the finite sequence  $x, Tx, T^2x, \dots, T^{n-1}x$  which falls inside the set  $A$ . From this remark, and the definitions of  $\nu_n$  and the sliding count probability  $P$ , the following lemma follows easily.

► **Lemma 17.** *Let  $w$  be any finite string in  $\Sigma^*$  and let  $l = |w|$ . Let  $x$  be any element in  $\Sigma^\infty$ . If  $\langle \nu_n \rangle_{n=1}^\infty$  is the sequence of averages of Dirac measures over  $\Sigma^\infty$  constructed out of the sequence  $\langle T^n x \rangle_{n=0}^\infty$ . Then for any  $n$ ,  $\nu_n(C_w) = P(x_0^{n+l-2}, w)$ .*

We now give a new characterization of Weyl's criterion on Cantor Space (Theorem 8) in terms of weak convergence of measures.

<sup>5</sup> This follows easily by observing that the valuation map  $v : \Sigma^\infty \rightarrow \mathbb{T}$  is a continuous function on  $\Sigma^\infty$ .

► **Theorem 18** (Weyl's criterion on  $\Sigma^\infty$  and weak convergence). *Let  $x \in \Sigma^\infty$ , and  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures constructed out of  $\langle T^n x \rangle_{n=0}^\infty$ , and  $\mu$  be the uniform measure on  $\Sigma^\infty$ . Then the following are equivalent.*

1.  $x$  is normal.
2. For every  $w \in \Sigma^*$ , the sliding block frequency  $P(x_0^{n-1}, w) \rightarrow 2^{-|w|}$  as  $n \rightarrow \infty$ .
3. For every  $k \in \mathbb{Z}$ ,  $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k v(T^j x)} = 0$ .
4.  $\nu_n \Rightarrow \mu$ .

#### 4 Divergence of exponential sums for non-normal numbers

Weyl's criterion says that when  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = 1$  the averages of the exponential sums for every  $k$  converges to 0. However for  $x$  with  $\dim_{FS}(x) < 1$ , the situation is different. It is easy to construct a sequence  $a$  with  $\dim_{FS}(a) < 1$  and a  $k \in \mathbb{Z}$  such that the sequence of Weyl averages with parameter  $k$  do not converge. It is natural to ask if the condition  $\dim_{FS}(x) = \text{Dim}_{FS}(x)$  is sufficient to guarantee convergence of the exponential sum averages. But we construct an  $x$  with  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = \frac{1}{2}$  such that for some  $k$ , the sequence  $\langle \sum_{j=0}^{n-1} e^{2\pi i k v(T^j x)} \rangle_{n=1}^\infty$  diverges. Entropy rates converging to a limit does not imply that the empirical probability measures converge to a limiting distribution, and it is the latter notion which is necessary for exponential sums to converge.

► **Lemma 19.** *There exists  $x \in \Sigma^\infty$  with  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = \frac{1}{2}$  such that for some  $k \in \mathbb{Z}$ , the sequence  $\langle \sum_{j=0}^{n-1} e^{2\pi i k v(T^j x)} \rangle_{n=1}^\infty$  is not convergent.*

Generalizing the construction of diluted sequences in [10], we define an  $x$  with  $v(x) \in \mathbb{T} \setminus \mathbb{D}$  and  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = 1/2$ , but where for some  $k \in \mathbb{Z}$ , the sequences of Weyl sum averages diverge. The idea of dilution is as follows. Let  $y \in \Sigma^\infty$  be normal. Define  $a \in \Sigma^\infty$  by  $a_{2n} = 0$ ,  $a_{2n+1} = y_n$ ,  $n \in \mathbb{N}$ . Then  $\dim_{FS}(a) = \text{Dim}_{FS}(a) = 1/2$ . Note that  $b \in \Sigma^\infty$  defined by  $b_{4n} = b_{4n+3} = 0$ , and  $b_{4n+1} = y_{2n}$ ,  $b_{4n+2} = y_{2n+1}$ ,  $n \in \mathbb{N}$  is also a regular sequence with  $\dim_{FS}(b) = \text{Dim}_{FS}(b) = 1/2$ . But, the sliding block frequency of 01 in  $a$  is  $1/4$ , whereas it is  $3/16$  in  $b$ . We leverage the existence of such distinct sequences with equal dimension. The disjoint blocks of  $x$  alternate between the above two patterns in a controlled manner to satisfy the following conditions.

1.  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = 1/2$
2. There is an increasing sequence of indices  $\langle n_i \rangle_{i=1}^\infty$  such that  $\lim_{i \rightarrow \infty} P(x_0^{n_i-1}, 01) = 1/4$ .
3. There is an increasing sequence of indices  $\langle n_j \rangle_{j=1}^\infty$  such that  $\lim_{j \rightarrow \infty} P(x_0^{n_j-1}, 01) = 3/16$ .

Let  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures constructed out of  $\langle T^n x \rangle_{n=0}^\infty$ , and  $\langle \nu'_n \rangle_{n=1}^\infty$ , those from  $\langle 2^n v(x) \bmod 1 \rangle_{n=0}^\infty$ . Assume that  $\langle n^{-1} \sum_{j=0}^{n-1} e^{2\pi i k v(T^j x)} \rangle_{n=1}^\infty$  converge for every  $k \in \mathbb{Z}$ . Using the same steps in the proof of Theorem 16, we get that  $\nu'_n \Rightarrow \mu'$  where  $\mu'$  is the unique measure on  $\mathbb{T}$  having Fourier coefficients equal to the limits of the Weyl averages. Since  $v(x) \in \mathbb{T} \setminus \mathbb{D}$ , Theorem 16 implies that  $\nu(C_{01})$  is convergent. Using Lemma 17, we infer that  $\lim_{n \rightarrow \infty} P(x_0^{n-1}, 01)$  exists. But, we know from conditions 2 and 3 that  $P(x_0^{n-1}, 01)$  is not convergent. Hence, we arrive at a contradiction. Therefore, for some  $k \in \mathbb{Z}$ , the Weyl averages  $\langle n^{-1} \sum_{j=0}^{n-1} e^{2\pi i k v(T^j x)} \rangle_{n=1}^\infty$  diverge. The above construction is easily adapted to show that for any rational number  $p/q \in (0, 1)$ , there exists  $x \in \Sigma^\infty$  with  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = p/q$  such that some Weyl average of  $x$  diverges.

## 5 Weyl's criterion for finite-state dimension

We saw in Lemma 19 that Weyl averages may diverge for  $x$  having finite-state dimension less than 1, even if  $x$  is regular. Hence, it is necessary for us to deal with divergent Weyl averages and obtain their relationship with the finite-state dimension of  $x$ . We know from Theorem 18 that Weyl's criterion for normality (Theorem 8) is equivalently expressed in terms of weak convergence of a sequence of measures over  $\Sigma^\infty$ . In section 5.1, we generalize the weak convergence formulation to handle arbitrary finite state dimension. Applying this, in section 5.2, we generalize the exponential sum formulation.

### 5.1 Weak convergence and finite-state dimension

We know from Theorem 18 that  $x \in \Sigma^\infty$  is normal (equivalently,  $\dim_{FS}(x) = 1$ ) if and only if  $\nu_n \rightarrow \mu$ , where  $\mu$  is the uniform distribution over  $\Sigma^\infty$ . In this subsection we give a generalization of this formulation of Weyl's criterion which applies for  $x$  having any finite-state dimension. Lemma 19 and Theorem 14 together imply that  $\nu_n$ 's need not be weakly convergent even if  $x$  is guaranteed to be regular. However, studying the subsequence limits of  $\langle \nu_n \rangle_{n=1}^\infty$  gives us the following generalization of Weyl's criterion for arbitrary  $x \in \Sigma^\infty$ .

► **Theorem 20.** *Let  $x \in \Sigma^\infty$ . Let  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures on  $\Sigma^\infty$  constructed out of the sequence  $\langle T^n x \rangle_{n=0}^\infty$ . Let  $\mathcal{W}_x$  be the collection of all subsequence weak limits of  $\langle \nu_n \rangle_{n=1}^\infty$ . i.e.,  $\mathcal{W}_x = \{\mu \mid \exists \langle n_m \rangle_{m=0}^\infty \text{ such that } \nu_{n_m} \Rightarrow \mu\}$ . Then,  $\dim_{FS}(x) = \inf_{\mu \in \mathcal{W}_x} H^-(\mu)$  and  $\text{Dim}_{FS}(x) = \sup_{\mu \in \mathcal{W}_x} H^+(\mu)$ .*

The following is an equivalent version of Theorem 20 which we require in section 5.2. From the definition of lower average entropy, Theorem 20 shows that,  $\dim_{FS}(x) = \inf_{\mu \in \mathcal{W}_x} \liminf_{l \rightarrow \infty} \mathbf{H}_l(\mu)/l$ . This  $\liminf$  can be replaced by an infimum.

► **Lemma 21.**  $\dim_{FS}(x) = \inf_{\mu \in \mathcal{W}_x} \inf_l \mathbf{H}_l(\mu)/l$

### 5.2 Weyl averages and finite-state dimension

We now obtain the main result of the paper by relating subsequence limits of Weyl averages and finite-state dimension. In case the Weyl averages converge, we show that the sequence is regular. In particular, when the Weyl averages converge to 0, then the regular sequence is normal. We know from Lemma 19 that there exist regular sequences with non-convergent Weyl averages. In the absence of limits, we investigate the subsequence limits of Weyl averages in order to obtain a relationship with the finite-state dimension. If for some  $x \in \Sigma^\infty$ , there exist a sequence of natural numbers  $\langle n_m \rangle_{m \in \mathbb{N}}$  and constants  $\langle c_k \rangle_{k \in \mathbb{Z}}$  such that  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k v(T^j x)} = c_k$ . Then, using Theorem 16, we get that there exists a measure  $\mu$  on  $\mathbb{T}$  such that  $c_k = \int e^{2\pi i k y} d\mu$  and  $\lim_{m \rightarrow \infty} \nu_{n_m}(C_w) = \hat{\mu}(C_w)$  for every  $w \neq 0^{|w|}$  and  $w \neq 1^{|w|}$ . But,  $\nu_{n_m}(C_{0^l})$  and  $\nu_{n_m}(C_{1^l})$  need not converge. Simple examples of such strings can be obtained by concatenating increasingly large runs of 0's and 1's in an alternating stage wise manner. However, the probabilities of the strings  $0^l$  and  $1^l$  have negligible effect on the finite-state dimension as  $l$  gets large. Using Theorem 20 we obtain the following.

► **Theorem 22** (Weyl's criterion for finite-state dimension). *Let  $x \in \Sigma^\infty$ . If for any  $\langle n_m \rangle_{m=0}^\infty$  there exist constants  $c_k$  for  $k \in \mathbb{Z}$  such that  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k v(T^j x)} = c_k$ , for every  $k \in \mathbb{Z}$ , then there exists a measure  $\mu$  on  $\mathbb{T}$  such that for every  $k$ ,  $c_k = \int e^{2\pi i k y} d\mu$ . Let  $\widehat{\mathcal{W}}_x$  be the collection of the lifted measures  $\hat{\mu}$  on  $\Sigma^\infty$  for all  $\mu$  on  $\mathbb{T}$  that can be obtained as subsequence limits of Weyl averages. Then,  $\dim_{FS}(x) = \inf\{H^-(\hat{\mu}) \mid \hat{\mu} \in \widehat{\mathcal{W}}_x\}$  and  $\text{Dim}_{FS}(x) = \sup\{H^+(\hat{\mu}) \mid \hat{\mu} \in \widehat{\mathcal{W}}_x\}$*

**Proof of Theorem 22.** If  $v(x)$  is a dyadic rational in  $\mathbb{T}$ , then it can be easily verified that the Weyl averages are convergent to 1. The unique measure having all Fourier coefficients equal to 1 over  $\mathbb{T}$  is  $\delta_0$ . Since  $\tilde{\delta}_0 = \delta_{0^\infty}$ , it can be easily verified that  $\dim_{FS}(x) = H^-(\delta_{0^\infty}) = H^+(\delta_{0^\infty}) = \text{Dim}_{FS}(x) = 0$ . Hence, we consider the case when  $v(x)$  is not a dyadic rational. We first define analogues of finite-state dimension by avoiding the strings  $0^l$  and  $1^l$  for all  $l$  in calculating the sliding entropies. We define  $\tilde{H}_l(x_0^{n-1})$  to be the normalized sliding entropy over  $x_0^{n-1}$  as in the definition of  $H_l(x_0^{n-1})$ , except that the summation is taken over  $\Sigma^l \setminus \{0^l, 1^l\}$  instead of  $\Sigma^l$ . Using this notion, we define  $\widetilde{\dim}_{FS}(x) = \liminf_{l \rightarrow \infty} \liminf_{n \rightarrow \infty} \tilde{H}_l(x_0^{n-1})$  and  $\widetilde{\text{Dim}}_{FS}(x) = \liminf_{l \rightarrow \infty} \limsup_{n \rightarrow \infty} \tilde{H}_l(x_0^{n-1})$ . Since,  $\tilde{H}_l(x_0^{n-1}) \leq H_l(x_0^{n-1}) \leq \tilde{H}_l(x_0^{n-1}) + 2/l$ , it can be shown using routine arguments that  $\dim_{FS}(x) = \widetilde{\dim}_{FS}(x)$  and  $\text{Dim}_{FS}(x) = \widetilde{\text{Dim}}_{FS}(x)$ . Similarly we define  $\tilde{H}^+$  and  $\tilde{H}^-$  by reducing the range of the sum in the definition of  $H_l$  to  $\Sigma^l \setminus \{0^l, 1^l\}$  instead of  $\Sigma^l$ . Using a similar argument as in the case of sliding entropy, it can be shown that  $\tilde{H}^+$  and  $\tilde{H}^-$  are the same as  $H^+$  and  $H^-$  for any measure on  $\Sigma^\infty$ . Let  $\langle \nu_n \rangle_{n=1}^\infty$  be the sequence of averages of Dirac measures on  $\Sigma^\infty$  constructed out of the sequence  $\langle T^n x \rangle_{n=0}^\infty$ . Let  $\mathcal{W}_x$  be the set of all weak limits of  $\nu_n$  as constructed in Theorem 20. Since  $v(x)$  is not a dyadic rational, using Prokhorov's theorem for weak convergence of  $\mathbb{T}$  and weak convergence over  $\Sigma^\infty$ , it can be shown that,  $\inf_{\mu \in \mathcal{W}_x} H^-(\mu) = \inf_{\hat{\mu} \in \widehat{\mathcal{W}}_x} H^-(\hat{\mu})$  and  $\sup_{\mu \in \mathcal{W}_x} H^+(\mu) = \sup_{\hat{\mu} \in \widehat{\mathcal{W}}_x} H^+(\hat{\mu})$ . The claim now follows from Theorem 20. ◀

Hence, the finite-state dimension and finite-state strong dimension are related to the lower and upper average entropies of the subsequence limits of the Weyl averages. Using the above result, we get the following theorem in the case when the Weyl averages are convergent.

► **Theorem 23** (Weyl's criterion for convergent Weyl averages). *Let  $x \in \Sigma^\infty$ . If there exist  $c_k \in \mathbb{C}$  for  $k \in \mathbb{Z}$  such that  $\frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k(v(T^j x))} \rightarrow c_k$  as  $n \rightarrow \infty$ , then, there exists a unique measure  $\mu$  on  $\mathbb{T}$  such that for every  $k$ ,  $c_k = \int e^{2\pi i k y} d\mu$ . Furthermore,  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = H^-(\hat{\mu}) = H^+(\hat{\mu})$ .*

As a special case, we derive Weyl's criterion for normality, i.e, for sequences  $x$  such that  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = 1$  as a special case of Theorem 20 and Theorem 23.

► **Theorem 24.** *Let  $x \in \Sigma^\infty$ . Then  $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k(v(T^j x))} = 0$  for every  $k \in \mathbb{Z}$  if and only  $\dim_{FS}(x) = \text{Dim}_{FS}(x) = 1$ .*

The conclusion of Theorem 23 says that  $\dim_{FS}(x) = \text{Dim}_{FS}(x)$ . i.e,  $x$  is a regular sequence. Hence, Lemma 19 and Theorem 23 together yield the following.

► **Corollary 25.** *If for each  $k \in \mathbb{Z}$ ,  $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k(v(T^j x))} = c_k$  for a sequence of complex numbers  $\langle c_k \rangle_{k \in \mathbb{Z}}$ . Then,  $x$  is a regular sequence. But there exist regular sequences having non-convergent Weyl averages.*

## 6 Preservation of finite-state dimension under real arithmetic

In this section, we demonstrate the utility of our framework by proving the most general results yet regarding the preservation of finite-state dimension under arithmetic operations like addition with reals satisfying a natural independence condition, and multiplication with non-zero rationals. These results strictly generalize all known results regarding the preservation of finite-state dimension including those of Doty, Lutz and Nandakumar [12] and Aistleitner [1]. Our Weyl criterion plays a pivotal role in these extensions. We combine our Weyl criterion along with recent estimates by Hochman [17] for the entropy of convolution of probability measures. It is easier to analyze addition and multiplication as operations

over  $\mathbb{T}$ . Hence we first obtain an equivalent Weyl's criterion for finite-state dimension in terms of measures over  $\mathbb{T}$ . We now define the analogues of upper and lower average entropies for measures over  $\mathbb{T}$ . This turns out to be the notion of Rényi dimension as defined by Alfréd Rényi in [25]. Recall that for any  $m$  and  $w \in \Sigma_m^n$ ,  $I_w^m$  denotes the interval  $[v_m(w0^\infty), v_m(w0^\infty) + m^{-|w|}]$  in  $\mathbb{T}$ .

► **Definition 26** (Rényi Dimension). *For any probability measure  $\mu$  on  $\mathbb{T}$  and partition factor  $m$ , let  $\mathbf{H}_n^m(\mu) = -\sum_{w \in \Sigma_m^n} \mu(I_w^m) \log(\mu(I_w^m))$ . The Rényi upper and lower dimensions (see [25] and [33]) are defined as follows,  $\overline{\dim}_R^m(\mu) = \limsup_{n \rightarrow \infty} \frac{\mathbf{H}_n^m(\mu)}{n \log m}$  and  $\underline{\dim}_R^m(\mu) = \liminf_{n \rightarrow \infty} \frac{\mathbf{H}_n^m(\mu)}{n \log m}$ . If  $\overline{\dim}_R^m(\mu) = \underline{\dim}_R^m(\mu)$  then the Rényi dimension of  $\mu$  is  $\dim_R^m(\mu) = \overline{\dim}_R^m(\mu) = \underline{\dim}_R^m(\mu)$ .*

From the above definition, it seems as if the notion of Rényi dimension is dependent on the choice of the partition factor  $m$ . However, Rényi upper and lower dimensions are quantities that are independent of the partition factor<sup>6</sup>. Hence, we suppress the partition factor  $m$  in the notations  $\overline{\dim}_R^m(\mu)$ ,  $\underline{\dim}_R^m(\mu)$  and  $\dim_R^m(\mu)$  and use  $\overline{\dim}_R(\mu)$ ,  $\underline{\dim}_R(\mu)$  and  $\dim_R(\mu)$  to refer to the corresponding quantities for a measure  $\mu$  on  $\mathbb{T}$ . Now, we state an equivalent Weyl's criterion for finite-state dimension for  $r \in \mathbb{T}$  in terms of weak limit measures over  $\mathbb{T}$  and Rényi dimension of measures over  $\mathbb{T}$ .

► **Theorem 27** (Restatement of Weyl's criterion for finite-state dimension (Theorem 22)). *Let  $r \in \mathbb{T}$ . If for any  $\langle n_m \rangle_{m=0}^\infty$  there exist  $c_k$  for  $k \in \mathbb{Z}$  such that  $\lim_{m \rightarrow \infty} \frac{1}{n_m} \sum_{j=0}^{n_m-1} e^{2\pi i k 2^j r} = c_k$  for every  $k \in \mathbb{Z}$ , then there exists a measure  $\mu$  on  $\mathbb{T}$  such that for every  $k$ ,  $c_k = \int e^{2\pi i k y} d\mu$ . Let  $\mathcal{W}_r$  be the collection of all  $\mu$  on  $\mathbb{T}$  that can be obtained as subsequence limits of Weyl averages. Then,  $\dim_{FS}(r) = \inf\{\underline{\dim}_R(\mu) \mid \mu \in \mathcal{W}_r\}$  and  $\text{Dim}_{FS}(r) = \sup\{\overline{\dim}_R(\mu) \mid \mu \in \mathcal{W}_r\}$ .*

D. D. Wall in his thesis [31] proved that if  $r \in [0, 1]$  and  $q$  is any non-zero rational number, then  $r$  is a normal number if and only if  $qr$  and  $q + r$  are normal numbers. Doty, Lutz and Nandakumar [12] generalized this result to arbitrary finite-state dimensions and proved that the finite-state dimension and finite-state strong dimension of any number are preserved under multiplication and addition with rational numbers.

► **Theorem 28** ([12]). *Let  $r \in \mathbb{T}$  and  $q$  be any non-zero rational number. Then for any base  $b$ ,  $\dim_{FS}^b(r) = \dim_{FS}^b(q + r) = \dim_{FS}^b(qr)$  and  $\text{Dim}_{FS}^b(r) = \text{Dim}_{FS}^b(q + r) = \text{Dim}_{FS}^b(qr)$ .*

In the above  $\dim^b$  and  $\text{Dim}^b$  denotes the finite-state dimension and finite-state strong dimension of the number  $r$  calculated by considering the sequence representing the base- $b$  expansion of  $r$ <sup>8</sup>. In the specific case of normal sequences, Wall's result has been generalized by Aistleitner in the following form. Let  $\mathcal{C}$  be the set of reals  $y = 0.y_0y_1\dots$  such that the ratio  $P(y_0^{n-1}, 0)$  goes to 1 as  $n$  tends to  $\infty$ . Then we have the following.

► **Theorem 29**. *If  $y \in \mathcal{C}$ , then for any normal  $r \in \mathbb{T}$  and  $q \in \mathbb{Q}$ , the number  $r + qy$  is normal.*

We strictly generalize all these above results by formulating a natural independence notion between two reals. We describe the framework below. Given strings  $x$  and  $y$  in  $\Sigma^\infty$  and strings  $u, w \in \Sigma^\ell$  for some  $\ell \geq 1$ , we define the *joint occurrence count* of  $u$  and  $w$

<sup>6</sup> This important fact regarding Rényi dimension is a folklore result.

<sup>7</sup> The  $2^j$  term in limit expression must be replaced with  $b^j$  while investigating the above criterion in any arbitrary base  $b$

<sup>8</sup> For  $r$  having multiple base  $b$  expansions, this does not cause any ambiguity since in this case the finite-state dimensions of  $r$  are 0 with respect to any of the two possible expansions.

in  $x$  and  $y$  up to  $n$  as,  $N_{u,w}(x_0^{n-1}, y_0^{n-1}) = |\{i \in [0, n - \ell] : x_i^{i+\ell-1} = u \text{ and } y_i^{i+\ell-1} = w\}|$ . And, then the *joint occurrence probability* of  $u$  and  $w$  in  $x$  and  $y$  up to  $n$  is defined as  $P_{u,w}(x_0^{n-1}, y_0^{n-1}) = \frac{N_{u,w}(x_0^{n-1}, y_0^{n-1})}{n-\ell+1}$ .

Informally, we define two infinite strings  $x$  and  $y$  to be independent if for infinitely many lengths  $l$ , the occurrence probability distributions of  $l$ -length strings within  $x$  and  $y$  are *independent* in the limit. The straightforward formulation of independence between  $x$  and  $y$  is  $\lim_{n \rightarrow \infty} P_{u,w}(x_0^{n-1}, y_0^{n-1}) = \lim_{n \rightarrow \infty} P(x_0^{n-1}, u)P(y_0^{n-1}, w)$ . But these limits need not exist for general  $x$  and  $y$ . Hence, the more admissible and useful definition is the following.

► **Definition 30.** Any two strings  $x$  and  $y$  in  $\Sigma^\infty$  are said to be independent if for infinitely many  $\ell \geq 1$  and for every  $u, w \in \Sigma^\ell$ ,  $\lim_{n \rightarrow \infty} |P_{u,w}(x_0^{n-1}, y_0^{n-1}) - P(x_0^{n-1}, u)P(y_0^{n-1}, w)| = 0$ .

For any measures  $\mu_1$  and  $\mu_2$  on  $\mathbb{T}$ , let  $\mu_1 * \mu_2$  denote the convolution of these two measures (see [26] or [16]). A basic intuition for our approach can be viewed as follows. A standard result in probability theory (see for example, Shiryaev [29], 2nd. edition, Section II.8) is that, if  $X$  and  $Y$  are two independent random variables, then the distribution of  $X + Y$  is the convolution of the distributions of  $X$  and  $Y$ . Moreover, the Fourier coefficients of the convolution is the product of the Fourier coefficients of the individual distributions. Our result may be viewed as an analogous result using sequences. The following theorem gives an important connection between the exponential averages of the sum of independent reals and the exponential averages of the individual reals which is crucial in proving the main results in this section.

► **Theorem 31.** If  $x$  and  $y$  are real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30, then for any integers  $d, e$  and  $q \in \mathbb{Q}$ ,

$$\lim_{n \rightarrow \infty} \left| \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k 2^j (dx+ey)} - \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k 2^j dx} \frac{1}{n} \sum_{j=0}^{n-1} e^{2\pi i k 2^j ey} \right| = 0.$$

The proofs of the following bounds on Rényi dimension of convolutions crucially employ results from Hochman [17] along with the data processing inequality ([9, 18]).

► **Lemma 32.** For any measures  $\mu_1$  and  $\mu_2$  on  $\mathbb{T}$ ,

1.  $\underline{\dim}_R(\mu_1 * \mu_2) \geq \max\{\underline{\dim}_R(\mu_1), \underline{\dim}_R(\mu_2)\}$  and  $\underline{\dim}_R(\mu_1 * \mu_2) \leq \underline{\dim}_R(\mu_1) + \overline{\dim}_R(\mu_2)$
2.  $\overline{\dim}_R(\mu_1 * \mu_2) \geq \max\{\overline{\dim}_R(\mu_1), \overline{\dim}_R(\mu_2)\}$  and  $\overline{\dim}_R(\mu_1 * \mu_2) \leq \overline{\dim}_R(\mu_1) + \underline{\dim}_R(\mu_2)$

The following is our main result.

► **Theorem 33.** Let  $x$  and  $y$  be real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30. Then for any  $d, e \in \mathbb{Z}$ ,

1.  $\dim_{FS}(dx + ey) \geq \max\{\dim_{FS}(dx), \dim_{FS}(ey)\}$  and  $\dim_{FS}(dx + ey) \leq \dim_{FS}(dx) + \text{Dim}_{FS}(ey)$ .
2.  $\text{Dim}_{FS}(dx + ey) \geq \max\{\text{Dim}_{FS}(dx), \text{Dim}_{FS}(ey)\}$  and  $\text{Dim}_{FS}(dx + ey) \leq \text{Dim}_{FS}(dx) + \dim_{FS}(ey)$ .

The following technical lemmas that are consequences of Theorem 31 are required for proving Theorem 33.

► **Lemma 34.** Let  $x$  and  $y$  be real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30 and let  $d, e \in \mathbb{Z}$ . Then, for any  $\mu \in \mathcal{W}_{dx+ey}$  there exist  $\mu_1 \in \mathcal{W}_{dx}$  and  $\mu_2 \in \mathcal{W}_{ey}$  such that  $\mu = \mu_1 * \mu_2$ .

► **Lemma 35.** *If  $x$  and  $y$  are real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30. Let  $d, e \in \mathbb{Z}$  and  $q \in \mathbb{Q}$ . Then, for any  $\mu_1 \in \mathcal{W}_{dx}$  there exist  $\mu \in \mathcal{W}_{dx+ey}$  and  $\mu_2 \in \mathcal{W}_{ey}$  such that  $\mu = \mu_1 * \mu_2$ .*

Now we prove Theorem 33.

**Proof of Theorem 33.** Consider any  $\mu \in \mathcal{W}_{dx+ey}$ . Using Lemma 34 we get that there exists  $\mu_1 \in \mathcal{W}_{dx}$  and  $\mu_2 \in \mathcal{W}_{ey}$  such that  $\mu = \mu_1 * \mu_2$ . Now, it follows from Lemma 32 that  $\underline{\dim}_R(\mu) = \underline{\dim}_R(\mu_1 * \mu_2) \geq \underline{\dim}_R(\mu_1)$ . On applying Theorem 27 for  $dx \in \mathbb{T}$ , we get  $\underline{\dim}_R(\mu) \geq \dim_{FS}(dx)$ . Since  $\mu$  was arbitrary, applying Theorem 27 for  $dx + ey \in \mathbb{T}$ , we obtain  $\dim_{FS}(dx + ey) \geq \dim_{FS}(dx)$ . The proof of  $\dim_{FS}(dx + ey) \geq \dim_{FS}(ey)$  is similar. This completes the proof of the first inequality. In order to show the second inequality, consider any  $\mu_1 \in \mathcal{W}_{dx}$ . Using Lemma 35, there exist  $\mu \in \mathcal{W}_{dx+ey}$  and  $\mu_2 \in \mathcal{W}_{ey}$  such that  $\mu = \mu_1 * \mu_2$ . Now using Lemma 32, it follows that  $\underline{\dim}_R(\mu) = \underline{\dim}_R(\mu_1 * \mu_2) \leq \underline{\dim}_R(\mu_1) + \underline{\dim}_R(\mu_2)$ . On applying Theorem 27 for the points  $dx + ey \in \mathbb{T}$  and  $ey \in \mathbb{T}$ , we get  $\dim_{FS}(dx + ey) \leq \underline{\dim}_R(\mu_1) + \text{Dim}_{FS}(ey)$ . Since  $\mu_1$  was arbitrary, applying Theorem 27 for  $dx \in \mathbb{T}$ , we obtain  $\dim_{FS}(dx + ey) \leq \dim_{FS}(dx) + \text{Dim}_{FS}(ey)$ . 2 follows similarly. ◀

The following is an immediate corollary of the Theorem 33.

► **Corollary 36.** *If  $x$  and  $y$  are real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30, then for any  $q \in \mathbb{Q}$ ,*

1.  $\dim_{FS}(x+qy) \geq \max\{\dim_{FS}(x), \dim_{FS}(y)\}$  and  $\dim_{FS}(x+qy) \leq \dim_{FS}(x) + \text{Dim}_{FS}(y)$ .
2.  $\text{Dim}_{FS}(x + qy) \geq \max\{\text{Dim}_{FS}(x), \text{Dim}_{FS}(y)\}$  and  $\text{Dim}_{FS}(x + qy) \leq \text{Dim}_{FS}(x) + \text{Dim}_{FS}(y)$

On considering the case when  $\text{Dim}_{FS}(y) = 0$ , we obtain the following corollaries, generalizing earlier results by Doty, Lutz, Nandakumar [12] and Aistleitner [1], regarding the preservation of finite-state dimension under addition with an independent sequence having zero finite-state strong dimension.

► **Corollary 37.** *If  $x$  and  $y$  are real numbers in  $\mathbb{T}$  such that  $x$  and  $y$  are independent in the sense of condition 30 with  $\text{Dim}_{FS}(y) = 0$ , then for any  $q \in \mathbb{Q}$ ,  $\dim_{FS}(x + qy) = \dim_{FS}(x)$  and  $\text{Dim}_{FS}(x + qy) = \text{Dim}_{FS}(x)$ .*

It is easy to verify that any string in  $\mathcal{C}$  is independent of any other string  $x \in \Sigma^\infty$ . Thus we obtain the following generalization of Aistleitner's result to every dimension [1].

► **Corollary 38.** *If  $y$  is any real number in  $\mathcal{C}$ , then for any  $x \in \mathbb{T}$  and  $q \in \mathbb{Q}$ ,  $\dim_{FS}(x + qy) = \dim_{FS}(x)$  and  $\text{Dim}_{FS}(x + qy) = \text{Dim}_{FS}(x)$ .*

# On the Complexity Dichotomy for the Satisfiability of Systems of Term Equations over Finite Algebras

Peter Mayr  

Department of Mathematics, University of Colorado Boulder, CO, USA  
Institute for Algebra, Johannes Kepler Universität Linz, Austria

---

## Abstract

For a fixed finite algebra  $\mathbf{A}$ , we consider the decision problem  $\text{SysTerm}(\mathbf{A})$ : does a given system of term equations have a solution in  $\mathbf{A}$ ? This is equivalent to a constraint satisfaction problem (CSP) for a relational structure whose relations are the graphs of the basic operations of  $\mathbf{A}$ . From the complexity dichotomy for CSP over fixed finite templates due to Bulatov [4] and Zhuk [18], it follows that  $\text{SysTerm}(\mathbf{A})$  for a finite algebra  $\mathbf{A}$  is in P if  $\mathbf{A}$  has a not necessarily idempotent Taylor polymorphism and is NP-complete otherwise. More explicitly, we show that for a finite algebra  $\mathbf{A}$  in a congruence modular variety (e.g. for a quasigroup),  $\text{SysTerm}(\mathbf{A})$  is in P if the core of  $\mathbf{A}$  is abelian and is NP-complete otherwise. Given  $\mathbf{A}$  by the graphs of its basic operations, we show that this condition for tractability can be decided in quasi-polynomial time.

## 1 Introduction

How hard is it to check whether a system of term equations is solvable in an algebra? The *System of Term Equations Satisfiability Problem* over a fixed algebra  $\mathbf{A}$  is the following decision problem:

$\text{SysTerm}(\mathbf{A})$   
Input: terms  $s_1, t_1, \dots, s_m, t_m$  in the signature of  $\mathbf{A}$   
Problem: Does  $s_1 \approx t_1, \dots, s_m \approx t_m$  have a solution in  $\mathbf{A}$ ?

For example,  $\text{SysTerm}$  for the ring of integers  $(\mathbb{Z}, +, \cdot, 1)$  is Hilbert's tenth problem and undecidable by Matiyasevich's theorem. In this note we only consider  $\text{SysTerm}$  for finite algebras (meaning algebraic structures of finite size and finite signature), which clearly can be solved in non-deterministic polynomial time (NP).

Obviously  $\text{SysTerm}(\mathbf{A})$  has always a positive answer if  $\mathbf{A}$  has a trivial subalgebra  $\{o\}$  by setting all variables to  $o$ . Hence it is trivial for most classical algebras like groups, rings (without 1 as basic operation), lattices, and semigroups with idempotents<sup>1</sup>. This is one reason why the related problem  $\text{SysPol}$ , the satisfiability problem for a system of polynomial equations (allowing also constants), has received more attention in the past. Note that  $\text{SysPol}$  can be considered as the restriction of  $\text{SysTerm}$  to algebras for which each constant

---

<sup>1</sup> Rings with 1, quasigroups, more generally magmas, and  $G$ -sets are some of the few named algebras without trivial subalgebras. However, among finite algebras with randomly chosen operations, almost none have trivial subalgebras by a result of Murskii [2, Theorem 6.16].

is a basic operation. We will show that for any finite  $\mathbf{A}$  there exists some algebra  $\mathbf{A}'$  (the core of  $\mathbf{A}$ ) such that  $\text{SysTerm}(\mathbf{A})$  and  $\text{SysPol}(\mathbf{A}')$  are equivalent under logspace reductions (see Lemmas 6 and 7).

Goldmann and Russell [11] showed that  $\text{SysPol}$  (which they denote as  $\text{EQN}^*$ ) is in  $\text{P}$  for abelian and  $\text{NP}$ -complete for non-abelian finite groups. Klíma, Tesson and Thérien [14] investigated  $\text{SysPol}$  over finite semigroups and showed that it is in  $\text{P}$  for commutative monoids that are unions of their subgroups and  $\text{NP}$ -complete for other monoids. Larose and Zádori [15] studied  $\text{SysPol}$  over finite algebras in general and observed that they are logspace-equivalent to constraint satisfaction problems (CSP) of a specific form. They showed in particular that  $\text{SysPol}$  for any finite  $\mathbf{A}$  in a congruence modular variety (including most classical algebras like groups, modules, rings, quasigroups, lattices but not semigroups) is in  $\text{P}$  if  $\mathbf{A}$  is abelian (meaning the operations of  $\mathbf{A}$  are affine functions over an abelian group) and  $\text{NP}$ -complete otherwise. By using the universal algebraic definition of commutators and abelianness, this generalizes the previously mentioned result of Goldmann and Russell. Broniek [3] investigated  $\text{SysPol}$  and  $\text{SysTerm}$  for unary algebras (where all basic operations are unary). He showed in particular that  $\text{SysTerm}$  for unary algebras of size at most 3 is in  $\text{P}$  or  $\text{NP}$ -complete.

Our goal in this note is first to explicitly state the connections between  $\text{SysTerm}$ ,  $\text{SysPol}$  and  $\text{CSP}$  by a straightforward adaptation of the approach of Larose and Zádori in Section 3. From the celebrated complexity dichotomy for  $\text{CSP}$  by Bulatov [4] and Zhuk [18], we then obtain immediately that  $\text{SysTerm}$  for any finite algebra is either in  $\text{P}$  or  $\text{NP}$ -complete in Theorem 1. For finite  $\mathbf{A}$  in a congruence modular variety, we give an algebraic criterion for when  $\text{SysTerm}(\mathbf{A})$  is tractable in Theorem 2. Finally we show that this criterion can be decided in quasi-polynomial time for  $\mathbf{A}$  given by the graphs of its operations in Theorem 3.

For the precise statement of our results we recall some notions that play an important role in the classification of  $\text{CSP}$ s and algebras. For a structure  $\mathcal{C}$  (possibly with function and relation symbols) define *polymorphisms* of  $\mathcal{C}$  as the homomorphisms from finite powers of  $\mathcal{C}$  to  $\mathcal{C}$  and denote the set of polymorphisms as

$$\text{Pol}(\mathcal{C}) := \bigcup_{n \in \mathbb{N}} \text{Hom}(\mathcal{C}^n, \mathcal{C}).$$

For example, the polymorphisms of a vector space  $\mathbf{A}$  are just the linear maps from  $\mathbf{A}^n$  to  $\mathbf{A}$  for  $n \in \mathbb{N}$ .

Let  $f: A^n \rightarrow A$  for  $n > 1$ . Then  $f$  is *Taylor* if it satisfies  $n$  identities in distinct variables  $x, y$  of the form

$$f(\dots, x_i, \dots) \approx f(\dots, y_i, \dots) \text{ for all } i \in \{1, \dots, n\}$$

where the omitted variables on either side may be  $x$  or  $y$ . These identities were chosen so that no projection map on a non-trivial domain can satisfy them.

Next  $f: A^4 \rightarrow A$  is *Siggers* if it satisfies

$$f(a, r, e, a) \approx f(r, a, r, e).$$

For example, a binary commutative operation  $f$  is Taylor by virtue of  $f(x, y) \approx f(y, x)$ . By adding two fictitious variables we also obtain a Siggers operation from  $f$ . Clearly every Siggers operation is Taylor. In fact, every finite structure  $\mathcal{C}$  has a Taylor polymorphism of some arity iff  $\mathcal{C}$  has a Siggers polymorphism [13, 17].

As in [1] we do not require that Taylor and Siggers operations are idempotent like in older literature (see Lemma 8 for the relation with their idempotent version). This allows for a convenient formulation of the dichotomy for  $\text{CSP}$  and consequently the dichotomy for  $\text{SysTerm}$ .

► **Theorem 1.** *Let  $\mathbf{A}$  be a finite algebra. Then  $\text{SysTerm}(\mathbf{A})$  is in P if  $\mathbf{A}$  has a (not necessarily idempotent) Taylor (equivalently Siggers) polymorphism; else  $\text{SysTerm}(\mathbf{A})$  is NP-complete.*

We will show Theorem 1 in Section 3 by encoding  $\text{SysTerm}$  over an algebra as CSP over a relational structure and invoking the dichotomy for CSPs.

We already observed that  $\text{SysTerm}$  for  $\mathbf{A}$  with a trivial subalgebra  $\{o\}$  is trivial. Still to put this into the context of Theorem 1, note that such an algebra has  $f(x, y) := o$  as a Taylor polymorphism. For a less obvious example,  $\mathbf{A} = (\mathbb{Z}_2, +, 0, 1)$  has  $x + y + z$  as Taylor polymorphism and consequently tractable  $\text{SysTerm}$ .

Theorem 1 generalizes all the dichotomy results for  $\text{SysPol}$  in [11, 14, 15] mentioned above and fully settles the P/NP-complete dichotomy for  $\text{SysTerm}$ . Still it would be desirable to describe its boundary in more explicit structural terms of the algebra  $\mathbf{A}$  than by the existence of certain polymorphisms. We manage to do this under the assumption of additional structural properties on  $\mathbf{A}$ .

Here we just review the bare minimum of notions from universal algebra that we need to state our results. For more details we refer to [2, 5, 16] and Section 2 below. A *variety* is a class of algebras of fixed signature that is defined by identities. For example, groups form a variety with a binary operation  $\cdot$ , a unary  $^{-1}$  and constant 1 satisfying the usual group axioms. Varieties are usually classified by so-called Mal'cev conditions, essentially the term identities they satisfy. We list the conditions which occur in this note in increasing strength.

- A variety  $V$  is *Taylor* if it has a term  $t$  which induces an idempotent Taylor operation on all its algebras. Here idempotent means that  $V$  satisfies  $t(x, \dots, x) \approx x$ .

For example, semilattices form a Taylor variety with Taylor term  $t(x, y) := xy$  but (commutative) semigroups and  $G$ -sets do not.

- A variety  $V$  is *congruence modular* if every algebra  $\mathbf{A}$  in  $V$  has a modular congruence lattice.

Most classical algebras, in particular those that have (quasi)group operations, like groups, modules, rings, loops, ... or lattice operations, like lattices, Boolean algebras, Heyting algebras, ... are members of congruence modular varieties. On the other hand, semilattices and more generally semigroups do not form congruence modular varieties.

- A variety is *congruence distributive* if all its algebras have distributive congruence lattices. Every algebra with lattice operations is contained in a congruence distributive variety but non-trivial groups are not.

Since distributivity implies modularity for lattices, congruence distributive varieties are congruence modular. Further congruence modular varieties are Taylor.

There exist various generalizations of commutators from groups to arbitrary algebras. These may differ in general but most of them lead to the same concept of abelianness in Taylor varieties (see [9, 12]). In particular, a finite algebra  $\mathbf{A}$  in a Taylor variety is *abelian* (with respect to the standard term condition commutator) iff all its basic operations are affine functions of some commutative group  $(A, +, -, 0)$ . Although such an abelian algebra  $\mathbf{A}$  may not have  $+$  or  $-$  as term operations, the ternary function  $x - y + z$  is a term operation and is called the *Mal'cev term operation* of  $\mathbf{A}$ . A group is abelian in this sense iff it is abelian in the classical group theoretic sense. A loop is abelian iff it is an abelian group. Since for a ring the commutator of congruences corresponds to the product of ideals, a ring is abelian iff its multiplication is 0. For a lattice or any algebra in a congruence distributive variety, the commutator of two congruences is just their intersection. Hence these algebras are abelian iff they are trivial.

Next we extend some established notions and facts on relational structures to the setting of algebras. A finite structure  $\mathcal{C}$  (possibly with function and relational symbols) is a *core* if every endomorphism of  $\mathcal{C}$  is an embedding (equivalently, an automorphism). It is well-known

and not hard to see that if  $h$  is an endomorphism of a finite structure  $\mathcal{C}$  such that  $h(\mathcal{C})$  is minimal with respect to inclusion among all endomorphic images of  $\mathcal{C}$ , then  $h(\mathcal{C})$  is a core. Moreover this core is unique up to isomorphism and hence called *the core of  $\mathcal{C}$* . An algebra has trivial core iff it has a trivial subalgebra. An algebra expanded with all constants is its own core. For a non-degenerate example, the core of the symmetric group  $(S_3, \cdot, (1, 2))$  expanded with the additional constant  $(1, 2)$  is isomorphic to  $(\mathbb{Z}_2, +, 0, 1)$ .

We will prove the following generalization of a result by Larose and Zádori on the complexity of systems of polynomial equations [15, Corollary 3.14] in Section 4.

► **Theorem 2.** *Let  $\mathbf{A}$  be a finite algebra in a congruence modular variety. Then  $\text{SysTerm}(\mathbf{A})$  is in P if the core of  $\mathbf{A}$  is abelian; else  $\text{SysTerm}(\mathbf{A})$  is NP-complete.*

Since any non-trivial ring with 1 is non-abelian by the discussion of commutators above, it follows that its  $\text{SysTerm}$  is NP-complete.

Also, since non-trivial algebras in congruence distributive varieties are non-abelian, Theorem 2 yields that  $\text{SysTerm}(\mathbf{A})$  for such a finite  $\mathbf{A}$  is NP-complete unless  $\mathbf{A}$  has a trivial subalgebra and hence trivial core, in which case  $\text{SysTerm}(\mathbf{A})$  is trivial.

A natural follow-up to the dichotomy results above is the metaquestion of deciding for a given algebra  $\mathbf{A}$  whether it has tractable  $\text{SysTerm}$ . Or, for practical purposes, how much preprocessing is necessary on a given algebra  $\mathbf{A}$  with abelian core such that one can solve  $\text{SysTerm}$  for  $\mathbf{A}$  in polynomial time in the size of the system of equations? Here and in the following we assume that algebras are given by the graphs of their basic operations.

Recall that a finite structure has a (not necessarily idempotent) Taylor polymorphism iff it has a (not necessarily idempotent) 4-ary Siggers polymorphism. The latter condition can clearly be decided in NP. So the metaquestion for  $\text{SysTerm}$ , i.e., deciding whether a given finite algebra  $\mathbf{A}$  has a (not necessarily idempotent) Taylor polymorphism, is in NP.

Chen and Larose showed that the metaquestion for CSP, i.e., deciding whether a given finite relational structure  $\mathbb{A}$  has a (not necessarily idempotent) Taylor polymorphism, is actually NP-complete [6]. Klíma, Tesson and Thérien constructed for every finite relational structure  $\mathbb{A}$  a finite semigroup  $\mathbf{A}$  such that  $\text{CSP}(\mathbb{A})$  is polynomial time equivalent to  $\text{SysPol}(\mathbf{A})$  [14, Theorem 8]. Similarly, Broniek constructed for every finite relational structure  $\mathbb{A}$  a finite unary algebra  $\mathbf{A}$  such that  $\text{CSP}(\mathbb{A})$  is polynomial time equivalent to  $\text{SysTerm}(\mathbf{A})$  [3, Theorem 3.4]. However, for both these constructions, the size of the algebra  $\mathbf{A}$  is exponential in the size of relational structure  $\mathbb{A}$ . Hence they do not allow to transfer the NP-hardness of the metaquestion for CSP to the metaquestion for  $\text{SysTerm}$ . To the best of our knowledge, it may be easier to decide for algebras whether they have a Taylor polymorphism than for relational structures.

In particular, for an algebra in a congruence modular variety, the existence of a (not necessarily idempotent) Taylor polymorphism can be decided in quasi-polynomial time by the following slightly stronger result, which we will prove in Section 5. Recall that congruence modular varieties are Taylor.

► **Theorem 3.** *There exists a quasi-polynomial time algorithm that, given a finite algebra  $\mathbf{A}$  in a Taylor variety, decides if the core of  $\mathbf{A}$  is abelian, in which case the core of  $\mathbf{A}$  and the graph of its Mal'cev term operation can also be computed in quasi-polynomial time.*

Thus given a finite algebra  $\mathbf{A}$  in a Taylor variety, we can compute its core  $\mathbf{C}$  in quasi-polynomial time if  $\mathbf{C}$  is abelian. Moreover, if the core  $\mathbf{C}$  is abelian, we can use its Mal'cev term operation  $x - y + z$  to reduce  $\text{SysTerm}(\mathbf{A})$  to a linear system of equations over the abelian group  $(C, +)$ . If a system of term equations over abelian  $\mathbf{C}$  (equivalently over  $\mathbf{A}$ ) has a solution, then we can also find it in polynomial time in the size of the system.

We do not know whether the quasi-polynomial time algorithms in Theorem 3 can be improved to polynomial time.

Of course one can also ask how hard it is to check the assumptions of Theorem 3 in case that the idempotent Taylor term operation of  $\mathbf{A}$  is not given as part of the input. For that Freese and Valeriote showed that deciding whether a given finite algebra  $\mathbf{A}$  is in a Taylor variety or whether it is in a congruence modular variety is EXPTIME-complete [10, Corollary 9.3] but that these problems are in P for idempotent  $\mathbf{A}$ , i.e., if all basic operations  $f$  of  $\mathbf{A}$  satisfy  $f(x, \dots, x) \approx x$  [10, Theorem 6.2, 6.3].

## 2 Preliminaries

We review the algebraic results that we will need. For standard universal algebraic background we refer the reader to [2, 5, 9, 12, 16].

### 2.1 Algebras and varieties

An *algebra*  $\mathbf{A} = (A, \{f^{\mathbf{A}} : f \in F\})$  is a pair where  $A$  is a non-empty set (the *universe* of  $\mathbf{A}$ ),  $F$  is a set of function symbols equipped with a map *arity*:  $F \rightarrow \mathbb{N}$  that assigns to each function symbol its arity (the *signature* of  $\mathbf{A}$ ), and  $f^{\mathbf{A}}$  are the interpretations of the symbols  $f \in F$  as operations of the corresponding arity on  $A$  (the *basic operations* of  $\mathbf{A}$ ). We say  $\mathbf{A}$  is *finite* if its universe and its signature are finite. An algebra is *trivial* if its universe has size 1.

*F*-terms or *terms in the signature* of  $\mathbf{A}$  are constructed from function symbols  $F$  and variables  $x_1, x_2, \dots$  in the usual way: every variable is an *F*-term, and if  $f \in F$  is  $k$ -ary and  $t_1, \dots, t_k$  are *F*-terms, then  $f(t_1, \dots, t_k)$  is an *F*-term. Every *F*-term  $t$  in variables  $x_1, \dots, x_k$  induces a  $k$ -ary *term function*  $t^{\mathbf{A}}: A^k \rightarrow A$  by interpreting a variable  $x_i$  as the  $i$ -th projection from  $A^k$  onto  $A$  and interpreting function symbols  $f$  as  $f^{\mathbf{A}}$ .

*Polynomials* over  $\mathbf{A}$  are defined like terms except that additionally for every element  $a \in A$  there is a constant polynomial  $a$ . Again every polynomial  $p$  in variables  $x_1, \dots, x_k$  induces a  $k$ -ary *polynomial function*  $p^{\mathbf{A}}: A^k \rightarrow A$  via the interpretation of function symbols in  $F$  on  $A$  and the interpretation of a constant  $a$  as the corresponding element  $a \in A$ . Two algebras  $\mathbf{A}_1 = (A, F_1)$  and  $\mathbf{A}_2 = (A, F_2)$  on the same universe are *polynomially equivalent* if  $\mathbf{A}_1$  and  $\mathbf{A}_2$  have the same set of polynomial functions of all arities.

An *identity* is a pair of terms  $(s, t)$ , which we usually write as  $s \approx t$ . For  $k$ -ary terms  $s, t$ , the  $k$ -tuple  $(a_1, \dots, a_k) \in A^k$  is a *solution* of  $s(x_1, \dots, x_k) \approx t(x_1, \dots, x_k)$  if  $s^{\mathbf{A}}(a_1, \dots, a_k) = t^{\mathbf{A}}(a_1, \dots, a_k)$ . An algebra  $\mathbf{A}$  *satisfies* an identity  $s \approx t$  if  $s^{\mathbf{A}} = t^{\mathbf{A}}$ .

A *variety*  $V$  is a class of algebras over the same fixed signature  $F$  that is defined by a set of identities  $\Sigma$ , that is,  $V = \{\mathbf{A} : \mathbf{A} \text{ satisfies } \Sigma\}$ . Birkhoff showed that the variety generated by a class  $K$  of algebras over  $F$  consists of all homomorphic images of subalgebras of direct powers of elements in  $K$ .

A variety  $V$  is *locally finite* if all its finitely generated algebras are finite. For example, the variety generated by a finite algebra  $\mathbf{A}$  is locally finite.

### 2.2 Commutators

Commutators have been generalized from normal subgroups of groups to congruences of general algebras by Smith, Hagemann, Herrmann, Gumm, Freese, McKenzie and others. See [9] for the history and overview of their development.

For congruences  $\alpha, \beta$  of an algebra  $\mathbf{A}$ , let  $M_{\mathbf{A}}(\alpha, \beta)$  be the subalgebra of  $\mathbf{A}^{2 \times 2}$  that is generated by all elements of the form

$$\begin{bmatrix} a & a \\ b & b \end{bmatrix}, \begin{bmatrix} c & d \\ c & d \end{bmatrix} \quad \text{for } a\alpha b, c\beta d.$$

Writing quadruples as  $2 \times 2$  tables is just a notational convenience here. The operations of  $\mathbf{A}$  simply apply componentwise. The *commutator*  $[\alpha, \beta]$  is the smallest congruence  $\gamma$  of  $\mathbf{A}$  such that

$$\forall \begin{bmatrix} x & y \\ z & w \end{bmatrix} \in M_{\mathbf{A}}(\alpha, \beta): x\gamma y \Rightarrow z\gamma w.$$

For an algebra  $\mathbf{A}$  let  $1_A$  denote the total congruence and  $0_A$  denote the trivial congruence (equality). Then  $\mathbf{A}$  is *abelian* if  $[1_A, 1_A] = 0_A$ .

Abelianess has strong structural consequences of an algebra. Assume  $\mathbf{A}$  is a finite abelian algebra in a Taylor variety. Then  $\mathbf{A}$  is polynomially equivalent to a module by [12, 9]. More explicitly, there exist operation  $+, -, 0$  such that  $(A, +, -, 0)$  is an abelian group with a set of endomorphisms  $R$ . Every  $k$ -ary basic operation  $f^{\mathbf{A}}$  of  $\mathbf{A}$  can be represented in the form

$$f^{\mathbf{A}}(x_1, \dots, x_k) = \sum_{i=1}^k r_i(x_i) + c$$

for some endomorphisms  $r_1, \dots, r_k \in R$  and some constant  $c \in A$ . Given a term  $t$  of  $\mathbf{A}$  it can be rewritten iteratively as a sum of endomorphisms of  $(A, +, -, 0)$  and constants in polynomial time as well. Hence  $\text{SysTerm}(\mathbf{A})$  reduces to solving a system of linear equations over  $(A, +, -, 0)$ , which is clearly in P.

### 2.3 Tame congruence theory

For congruence  $\alpha, \beta$  of an algebra  $\mathbf{A}$  we say  $\alpha$  is *covered* by  $\beta$  (written  $\alpha \prec \beta$ ) if  $\alpha$  is strictly contained in  $\beta$  and there is no congruence strictly between  $\alpha$  and  $\beta$ .

A finite non-trivial algebra is *minimal* if all its unary polynomial operations are either constant or permutations. Pálffy showed that every minimal algebra is polynomially equivalent to an algebra of one the following five types:

1. a  $G$ -set (i.e., an algebra all of whose basic operations are permutations);
2. a vector space;
3. the Boolean algebra of size 2;
4. the lattice of size 2;
5. the semilattice of size 2.

Tame congruence theory (TCT) as developed by Hobby and McKenzie in [12] associates with any pair of congruences  $\alpha \prec \beta$  of a finite algebra  $\mathbf{A}$  a set of minimal algebras all of which have the same type 1-5. The precise construction is quite technical and will not be needed in this paper. Hence we will not discuss it beyond stating that every pair  $\alpha \prec \beta$  is labelled with a unique type. The set of all types of pairs  $\alpha \prec \beta$  of  $\mathbf{A}$  is denoted by  $\text{typ}\{\mathbf{A}\}$ . For a variety  $V$  the set of all types of  $\alpha \prec \beta$  of all finite algebras  $\mathbf{A}$  in  $V$  is denoted by  $\text{typ}\{V\}$ .

There are deep connections between the typeset of a variety  $V$ , that is, the local behaviour of polynomial functions on its finite members, and the identities that hold in  $V$ . For example:

- [12, Theorem 9.6] A locally finite variety  $V$  is Taylor iff  $1 \notin \text{typ}\{V\}$ .
- [12, Theorem 8.5] If a locally finite variety  $V$  is congruence modular, then  $\text{typ}\{V\} \subseteq \{2, 3, 4\}$ .

### 3 SysTerm, SysPol and CSP

In this section we collect easy facts on the correspondence between systems of equations and constraint satisfaction problems that may be known at least implicitly in one form or the other. Still we hope it is useful to provide an explicit and consistent overview for the reader.

#### 3.1 Reduction to CSP

First we reduce a system of equations to a particular constraint satisfaction problem. The *Constraint Satisfaction Problem* over a fixed relational structure  $\mathbb{A}$  is the decision problem:

CSP( $\mathbb{A}$ )  
 Input: a structure  $\mathbb{X}$  in the signature of  $\mathbb{A}$   
 Problem: Is there a homomorphism from  $\mathbb{X}$  to  $\mathbb{A}$ ?

Many classical decision problems like 3-SAT, graph coloring, solvability of linear systems... can be formulated as CSP for an appropriately chosen structure  $\mathbb{A}$ . For background on CSP on fixed templates we refer to the survey [1] by Barto, Krokhn and Willard.

Denote the *graph* of a  $k$ -ary operation  $f: A^k \rightarrow A$  by the  $k+1$ -ary relation

$$f^\circ := \{(x_1, \dots, x_k, f(x_1, \dots, x_k)) : x_1, \dots, x_k \in A\}.$$

For an algebra  $\mathbf{A} = (A, F)$  with universe  $A$  and basic operations  $F$ , let  $\mathbb{A}^\circ := (A, \{f^\circ : f \in F\})$  denote the relational structure with the graphs of the basic operations as relations.

Larose and Zádori observed the following correspondence between SysPol and CSP. The proof for systems of term equations is essentially the same and added here for the convenience of the reader.

► **Lemma 4** ([15, cf. Theorem 2.2]). *Let  $\mathbf{A}$  be a finite algebra. Then  $\text{SysTerm}(\mathbf{A})$  is logspace-equivalent to  $\text{CSP}(\mathbb{A}^\circ)$ .*

**Proof.** For a  $\text{CSP}(\mathbb{A}^\circ)$ -instance  $\mathbb{X}$ , each constraint  $(x_{i_1}, \dots, x_{i_{k+1}}) \in f^\circ$  can be reformulated as  $f(x_{i_1}, \dots, x_{i_k}) \approx x_{i_{k+1}}$  in constant time. Clearly the conjunction of constraints is satisfiable iff the system of corresponding equations is solvable in  $\mathbf{A}$ .

Conversely, for a  $\text{SysTerm}(\mathbf{A})$ -instance  $s_1 \approx t_1, \dots, s_m \approx t_m$ , rewrite each occurring term  $t = f(u_1, \dots, u_k)$  for a basic operation  $f$  of  $\mathbf{A}$  as a sequence of constraints  $(y_{u_1}, \dots, y_{u_k}, y_t) \in f^\circ$  in variables  $y$  indexed by subterms and correspondingly for the subterms  $u_1, \dots, u_k$ . If  $t = x$  is a variable, just write  $y_t = x$ . All these constraints together with  $y_s = y_t$  for every given equation  $s \approx t$  form a  $\text{CSP}(\mathbb{A}^\circ)$ -instance which is satisfiable iff the original system of equations over  $\mathbf{A}$  is solvable. This rewriting creates as many new variables as there are function symbols and variables in  $s_1, t_1, \dots, s_m, t_m$  and can be done in logarithmic space. ◀

It is straightforward to check that the polymorphisms of  $\mathbf{A}$  are the same as those of  $\mathbb{A}^\circ$ .

► **Lemma 5.**  $\text{Pol}(\mathbf{A}) = \text{Pol}(\mathbb{A}^\circ)$  for every algebra  $\mathbf{A}$ .

**Proof.** Let  $h: A^n \rightarrow A$ ,  $f: A^k \rightarrow A$  and  $x_1 = (x_{11}, \dots, x_{1n}), \dots, x_k = (x_{k1}, \dots, x_{kn})$  in  $A^n$ . Then  $hf(x_1, \dots, x_k) = f(h(x_1), \dots, h(x_k))$  with  $f$  acting on  $A^n$  componentwise iff

$$h \left( \left[ \begin{array}{c} x_{11} \\ \vdots \\ x_{k1} \\ f(x_{11}, \dots, x_{k1}) \end{array} \right], \dots, \left[ \begin{array}{c} x_{1n} \\ \vdots \\ x_{kn} \\ f(x_{1n}, \dots, x_{kn}) \end{array} \right] \right) \in f^\circ.$$

Hence  $h$  is a polymorphism of the algebra  $(A, f)$  iff  $h$  is a polymorphism of the relational structure  $(A, f^\circ)$ . The assertion follows. ◀

The previous two lemmas are already enough to obtain the complexity dichotomy for SysTerm from that for CSP.

**Proof of Theorem 1.** By Lemma 4 and 5 it suffices to consider  $\text{CSP}(\mathbb{A}^\circ)$ . Then the hardness part only uses that 3-SAT reduces to  $\text{CSP}(\mathbb{A}^\circ)$  if  $\mathbb{A}^\circ$  has no Taylor polymorphism [1, Theorem 40].

The tractability part follows from the celebrated result by Bulatov [4] and Zhuk [18] that  $\text{CSP}(\mathbb{A})$  for a finite relational structure  $\mathbb{A}$  is in P if  $\mathbb{A}$  has a (not necessarily idempotent) Taylor polymorphism. ◀

### 3.2 Cores

As for CSP, it suffices to investigate SysTerm for cores  $\mathbf{A}$  by the next observation.

► **Lemma 6.**  $\text{SysTerm}(\mathbf{A}) = \text{SysTerm}(h(\mathbf{A}))$  for each endomorphism  $h$  of  $\mathbf{A}$ .

**Proof.** Let  $h$  be an endomorphism of  $\mathbf{A}$ . Obviously, if a system of term identities  $\Sigma$  has a solution in the subalgebra  $h(\mathbf{A})$  of  $\mathbf{A}$ , then also in  $\mathbf{A}$ . Conversely, if  $\Sigma$  has a solution in  $\mathbf{A}$ , then clearly also in its homomorphic image  $h(\mathbf{A})$ . ◀

It is well-known that a CSP over a core relational structure is equivalent to the CSP over its expansion with singletons. Correspondingly, systems of term equations over a core algebra  $\mathbf{A}$  are equivalent to systems of polynomial equations over  $\mathbf{A}$ . We give a direct proof of this fact since it is short and makes the reduction from SysPol to SysTerm more apparent.

► **Lemma 7.** Let  $\mathbf{A}$  be a finite algebra that is a core. Then  $\text{SysPol}(\mathbf{A})$  is logspace-equivalent to  $\text{SysTerm}(\mathbf{A})$ .

**Proof.**  $\text{SysTerm}(\mathbf{A})$  reduces trivially to  $\text{SysPol}(\mathbf{A})$ . For the converse, the crucial observation is that the graphs of endomorphisms of  $\mathbf{A}$  are the solutions of a system of term equations. By definition a map  $h: A \rightarrow A$  is an endomorphism of  $\mathbf{A}$  iff for all  $f \in F$ , say  $k$ -ary, and for all  $a_1, \dots, a_k \in A$

$$f(h(a_1), \dots, h(a_k)) = h(f(a_1, \dots, a_k)).$$

Hence  $\{(a, h(a)) : a \in A\}$  is the graph of an endomorphism of  $\mathbf{A}$  iff  $y_a = h(a)$  for  $a \in A$  is a solution of the system of term equations

$$f(y_{a_1}, \dots, y_{a_k}) \approx y_{f(a_1, \dots, a_k)} \quad \text{for } f \in F \text{ (} k\text{-ary), } a_1, \dots, a_k \in A. \quad (1)$$

Given an instance of  $\text{SysPol}(\mathbf{A})$  with variables  $x_1, \dots, x_n$ , we introduce  $|A|$  new variables  $y_a$  for  $a \in A$  and replace every occurrence of a constant  $a$  in a polynomial equation by  $y_a$ . To the resulting set of term equations we also add the equations (1) to obtain an instance of  $\text{SysTerm}(\mathbf{A})$ . Note that the added system (1) does not depend on the original input, only on  $\mathbf{A}$ . Hence the new term system can be obtained from the original polynomial system in logspace by rewriting any occurring constant  $a$  as variable  $y_a$ .

If the original polynomial system has a solution, then clearly the new term system has a solution with  $y_a = a$ . Conversely, if the new system has a solution  $x_1 = b_1, \dots, x_n = b_n$  and  $y_a = h(a)$  for  $a \in A$ , then  $h$  is an endomorphism of  $\mathbf{A}$ . Since  $\mathbf{A}$  is a core by assumption,  $h$  is in fact an automorphism. Hence  $x_1 = h^{-1}(b_1), \dots, x_n = h^{-1}(b_n)$  and  $y_a = a$  for  $a \in A$  is also a solution of the new system. Thus  $x_1 = h^{-1}(b_1), \dots, x_n = h^{-1}(b_n)$  is a solution of the original polynomial system. ◀

### 3.3 Polymorphisms satisfying height-1 identities

An identity has *height* 1 if it is of the form  $f(u_1, \dots, u_k) \approx g(v_1, \dots, v_\ell)$  for operation symbols  $f, g$  and not necessarily distinct variables  $u_1, \dots, u_k, v_1, \dots, v_\ell$ .

For example, commutativity of a binary operation  $f$  is expressed by a height-1 identity but associativity is not since that requires nested applications of  $f$ .

Since the identities for a Taylor operation all have height 1, the next lemma yields that a structure has a (not necessarily idempotent) Taylor polymorphism iff its core has the corresponding idempotent polymorphism. For relational structures this is well-known and the same easy proof applies to general structures.

► **Lemma 8** ([6, cf. Lemma 6.4]). *Let  $\Sigma$  be a set of height-1 identities. Then a finite structure  $\mathcal{C}$  (possibly with function and relation symbols) has polymorphisms satisfying  $\Sigma$  iff the core of  $\mathcal{C}$  has idempotent polymorphisms satisfying  $\Sigma$ .*

**Proof.** Let  $h$  be an endomorphism of  $\mathcal{C}$  such that  $h(\mathcal{C})$  is the core of  $\mathcal{C}$ .

If  $F$  is a set of polymorphisms of  $h(\mathcal{C})$  satisfying  $\Sigma$ , then  $f'(x_1, \dots, x_k) := f(h(x_1), \dots, h(x_k))$  for  $f \in F$  ( $k$ -ary) are polymorphisms of  $\mathcal{C}$  and still satisfy the same height-1 identities.

Conversely, let  $F$  be polymorphisms of  $\mathcal{C}$  satisfying  $\Sigma$ . For  $f \in F$  ( $k$ -ary), let  $f^*(x_1, \dots, x_k)$  be the restriction of  $hf(x_1, \dots, x_k)$  to the substructure  $h(\mathcal{C})$ . Then  $\{f^* : f \in F\}$  is a set of polymorphism of  $h(\mathcal{C})$  which still satisfies the height-1 identities of  $\Sigma$ . Moreover, for every  $f \in F$ , we have that  $f_1(x) := f^*(x, \dots, x)$  is an endomorphism of  $h(\mathcal{C})$ , hence an automorphism. Thus  $f_1^{-1}f^*$  is an idempotent polymorphism of  $h(\mathcal{C})$ . If  $f^*(u_1, \dots, u_k) \approx g^*(v_1, \dots, v_\ell)$  is in  $\Sigma$ , then  $f_1 = g_1$  and consequently  $f_1^{-1}f^*(u_1, \dots, u_k) \approx g_1^{-1}g^*(v_1, \dots, v_\ell)$  holds on  $h(\mathcal{C})$ . Hence  $f_1^{-1}f^*$  for  $f \in F$  are idempotent polymorphisms of  $h(\mathcal{C})$  that still satisfy  $\Sigma$ . ◀

## 4 Systems over algebras in congruence modular varieties

Larose and Zádori explicitly characterized finite algebras without congruences  $\alpha \prec \beta$  of TCT type 5 in Taylor varieties that have idempotent Taylor polymorphisms.

► **Theorem 9** ([15, Theorem 3.12]). *Let  $\mathbf{A}$  be a finite algebra in a Taylor variety such that  $5 \notin \text{typ}\{\mathbf{A}\}$ . Then  $\mathbf{A}$  has an idempotent Taylor polymorphism iff  $\mathbf{A}$  is abelian.*

Note that there exist non-abelian algebras with idempotent Taylor term operations that commute with themselves, e.g., semilattices. Hence the assumption  $5 \notin \text{typ}\{\mathbf{A}\}$  cannot be omitted in Theorem 9.

Theorem 9 yields an explicit characterization of the complexity of SysTerm over cores that parallels those of SysPol by Larose and Zádori.

► **Corollary 10** ([15, cf. Corollary 3.13]). *Let  $\mathbf{A}$  be a finite algebra in a Taylor variety such that  $5 \notin \text{typ}\{\mathbf{A}\}$ . Then  $\text{SysTerm}(\mathbf{A})$  is in P if the core of  $\mathbf{A}$  is abelian; else  $\text{SysTerm}(\mathbf{A})$  is NP-complete.*

**Proof.** If the core  $h(\mathbf{A})$  of  $\mathbf{A}$  is abelian, then  $h(\mathbf{A})$  is polynomially equivalent to a module with group operations  $+, -$  by [12]. Further  $\text{SysTerm}(h(\mathbf{A}))$  reduces to a system of linear equations over that module. Then  $d(x, y, z) = x - y + z$  is a polymorphism of  $h(\mathbf{A})$  and also of the corresponding relational structure  $h(\mathbf{A}^\circ)$  by Lemma 5. Hence  $\text{CSP}(h(\mathbf{A}^\circ))$  is a so-called general subgroup problem and can be solved in polynomial time by a result of Feder and Vardi [8, Theorem 33]. Then  $\text{SysTerm}(\mathbf{A})$  is in P by Lemmas 4 and 6.

## 66:10 Satisfiability of Systems of Term Equations

Else if the core of  $\mathbf{A}$  is not abelian, then it has no idempotent Taylor polymorphism by Theorem 9. Hence  $\text{SysTerm}(\mathbf{A})$  is NP-complete by the hardness of CSP over structures without Taylor polymorphisms and Lemma 6. ◀

The proof of Corollary 10 does not require the full strength of the CSP-dichotomy by Bulatov and Zhuk but only that linear systems over modules are in P. Moreover, for an abelian algebra  $\mathbf{A}$  in a Taylor variety we can give a parametrization of all solutions of a system of term equations and determine their number by linear algebra in polynomial time. All of this applies in particular to algebras in congruence modular varieties.

**Proof of Theorem 2.** Let  $\mathbf{A}$  be a finite algebra in a congruence modular variety. Then the variety  $V$  generated by  $\mathbf{A}$  is locally finite and congruence modular. By [12, Theorem 8.5]  $V$  omits types 1 (i.e.,  $V$  is Taylor) and 5. In particular  $\mathbf{A}$  itself has no congruences  $\alpha \prec \beta$  of type 5. Hence the result is a special case of Corollary 10. ◀

### 5 Metaquestions about the complexity dichotomy

In the following we assume that algebras  $(A, f_1, \dots, f_m)$  are given by the graphs of their basic operations  $f_1, \dots, f_m$ . So, for  $n$  the maximum arity of  $f_1, \dots, f_m$ , this representation has size at least  $|A|^n$ .

We give a quasi-polynomial time algorithm to decide whether a given algebra in a Taylor variety has abelian core.

**Proof of Theorem 3.** Let  $\mathbf{A}$  be a finite algebra in a Taylor variety. First we claim that the core of  $\mathbf{A}$  is abelian iff there exists a homomorphism from the maximal abelian quotient  $\bar{\mathbf{A}} := \mathbf{A}/[1, 1]$  of  $\mathbf{A}$  to  $\mathbf{A}$ .

For the “only if”-direction, assume that the core  $h(\mathbf{A})$  for some endomorphism  $h$  of  $\mathbf{A}$  is abelian. By the Homomorphism Theorem  $h(\mathbf{A})$  is isomorphic to the quotient of  $\mathbf{A}$  by the kernel  $\ker h := \{(x, y) \in A^2 : h(x) = h(y)\}$  of  $h$ . In particular  $\mathbf{A}/\ker h$  is abelian as well. By the definition of the commutator,  $[1, 1]$  is the unique smallest congruence of  $\mathbf{A}$  such that  $\mathbf{A}/[1, 1]$  is abelian. Hence  $[1, 1] \leq \ker h$ . Let  $x/[1, 1]$  denote the class of  $x$  modulo  $[1, 1]$  in  $\bar{\mathbf{A}}$ . Then  $\bar{h}: \bar{\mathbf{A}} \rightarrow \mathbf{A}$ ,  $x/[1, 1] \mapsto h(x)$ , is a well-defined homomorphism.

Conversely, for the “if”-direction, assume we have a homomorphism  $\bar{h}: \bar{\mathbf{A}} \rightarrow \mathbf{A}$ . Then  $\bar{h}$  lifts to an endomorphism  $h: \mathbf{A} \rightarrow \mathbf{A}$ ,  $x \mapsto \bar{h}(x/[1, 1])$ . Clearly the images of  $h$  and  $\bar{h}$  are the same and the kernel  $\ker h$  contains  $[1, 1]$ . So by the Homomorphism Theorem  $h(\mathbf{A})$  is isomorphic to a quotient of  $\bar{\mathbf{A}}$ . Note that  $\bar{\mathbf{A}}$  is abelian in a Taylor variety and hence has a Mal’cev term operation  $d$  by [12, Theorem 9.6]. Hence  $\bar{\mathbf{A}}$  is polynomially equivalent to a module and all its quotients are abelian as well by [9] (We note in passing that outside of Taylor varieties, unfortunately quotients of abelian algebras may not be abelian again). In particular  $h(\mathbf{A})$  is abelian. While  $h(\mathbf{A})$  may not be the core of  $\mathbf{A}$ , all images  $g(\mathbf{A})$  for an endomorphism  $g$  of  $\mathbf{A}$  that are contained in  $h(\mathbf{A})$  are subalgebras of an abelian algebra, thus abelian themselves (This holds for arbitrary algebras by the definition of the commutator). Since the core of  $\mathbf{A}$  is isomorphic to a minimal such image  $g(\mathbf{A})$ , it is abelian.

Hence it suffices to check whether there exists a homomorphism from  $\bar{\mathbf{A}}$  to  $\mathbf{A}$ . Recall that the commutator  $[1, 1]$  can be enumerated in polynomial time by an algorithm due to Willard [7, Proposition 4.1]. Thus computation in  $\bar{\mathbf{A}}$  effectively reduces to computation in  $\mathbf{A}$  in the following steps.

Using the description of the structure of abelian algebras in congruence modular varieties from [9], we see that the subalgebra  $M_{\bar{\mathbf{A}}}(1, 1)$  of  $\bar{\mathbf{A}}^{2 \times 2}$  that is generated by all elements of the form

$$\begin{bmatrix} a & a \\ b & b \end{bmatrix}, \begin{bmatrix} c & d \\ c & d \end{bmatrix} \quad \text{for } a, b, c, d \in \bar{A}$$

has the universe

$$M_{\bar{\mathbf{A}}}(1, 1) = \left\{ \begin{bmatrix} y & x \\ z & d(x, y, z) \end{bmatrix} : x, y, z \in \bar{A} \right\}.$$

Hence the Mal'cev term operation  $d$  on  $\bar{\mathbf{A}}$  is unique and its graph can be computed by enumerating the elements in  $M_{\bar{\mathbf{A}}}(1, 1)$  by a straightforward closure algorithm in polynomial time. More specifically for any fixed element  $u_0 \in \bar{A}$ , the operations  $x + y := d(x, u_0, y)$  and  $-x := d(u_0, x, u_0)$  on  $\bar{A}$  yield an abelian group  $(\bar{A}, +, -, u_0)$  with zero element  $u_0$ . Further  $d(x, y, z) = x - y + z$  for all  $x, y, z \in \bar{A}$ . Now we can grow a generating set  $u_1, \dots, u_n$  of  $(\bar{A}, +)$  with  $n \leq \log_2 |\bar{A}|$  as follows. If  $u_0, \dots, u_i$  are fixed and the generated subgroup  $B_i := \langle u_0, \dots, u_i \rangle$  of  $(\bar{A}, +)$  is not all of  $\bar{A}$ , then pick some  $u_{i+1} \in \bar{A} \setminus B_i$ . Note that the index of  $B_i$  in  $B_{i+1}$  is at least 2 by Lagrange's Theorem. So the process stops with  $B_n = \bar{A}$  after  $n \leq \log_2 |\bar{A}|$  steps each of which requires only polynomial time in  $|A|$ . Finally we have obtained a generating set  $u_0, u_1, \dots, u_n$  for  $(\bar{A}, x - y + z)$  and in particular for  $\bar{\mathbf{A}}$  in polynomial time in  $|A|$ .

Clearly every homomorphism  $h: \bar{\mathbf{A}} \rightarrow \mathbf{A}$  is uniquely determined by its images on the generators  $u_0, \dots, u_n$ . For  $v_0, \dots, v_n \in A$  we can enumerate

$$\langle (u_0, v_0), \dots, (u_n, v_n) \rangle \leq \bar{\mathbf{A}} \times \mathbf{A}$$

in polynomial time to see whether the partial map with  $h(u_i) := v_i$  for  $i \in \{0, \dots, n\}$  extends to a homomorphism from  $\bar{\mathbf{A}}$  to  $\mathbf{A}$ . Checking the  $|A|^{n+1} \leq 2^{(\log |A|)^2 + \log |A|}$  potential images of  $u_0, \dots, u_n$  yields an algorithm that decides the existence of a homomorphism from  $\bar{\mathbf{A}}$  to  $\mathbf{A}$  in quasi-polynomial time in  $|A|$ .

If such a homomorphism exists, then the homomorphism with smallest image maps  $\bar{\mathbf{A}}$  to the abelian core of  $\mathbf{A}$  with Mal'cev term operation induced by  $d$  on  $\bar{\mathbf{A}}$ . Thus the universe of the core of  $\mathbf{A}$  can be obtained in quasi-polynomial time as well.  $\blacktriangleleft$

# Parallel Enumeration of Parse Trees

Margarita Mikhelson ✉

Department of Mathematics and Computer Science, Saint Petersburg State University, Russia

Alexander Okhotin ✉ 

Department of Mathematics and Computer Science, Saint Petersburg State University, Russia

---

## Abstract

A parallel algorithm for enumerating parse trees of a given string according to a fixed context-free grammar is defined. The algorithm computes the number of parse trees of an input string; more generally, it applies to computing the weight of a string in a weighted grammar. The algorithm is first implemented on an arithmetic circuit of depth  $O((\log n)^2)$  with  $O(n^6)$  elements. Then, it is improved using fast matrix multiplication to use only  $O(n^{5.38})$  elements, while preserving depth  $O((\log n)^2)$ .

## 1 Introduction

The classical cubic-time Cocke–Kasami–Younger parsing algorithm can be adapted to solving such problems as counting the number of parse trees of an input string, or computing the probability of an input string in a probabilistic grammar – and, more generally, computing the weight of a string in a weighted grammar. This is possible, because the algorithm considers the substrings in a certain predictable order, and investigates each partition of each substring exactly once, and hence never enumerates the same parse tree twice.

Another classical parsing algorithm discovered by Valiant [9] computes the same values in the time of matrix multiplication  $O(n^\omega)$ , where  $\omega < 3$ . In spite of quite a nontrivial order of processing the substrings and their partitions, it maintains the same property: every partition of every substring is considered only once, there is no double counting. Hence, the algorithm can be applied to computing weights in any ring [2], see Okhotin [6] for an elementary presentation.

These are the sequential parsing algorithms. Yet another classical parsing method is a parallel algorithm discovered independently by Brent and Goldschlager [3] and by Rytter [7]. Their algorithm, if implemented on a parallel architecture with concurrent reads and exclusive writes, works in time  $O((\log n)^2)$  and uses  $O(n^6)$  processors. If implemented on a uniform family of Boolean circuits (the model of parallel computation assumed in this paper), the algorithm by Brent, Goldschlager and Rytter uses circuits of depth  $O((\log n)^2)$  with  $O(n^6 \log n)$  elements, that is, NC<sup>2</sup>-circuits.

What is important to know about the Brent–Goldschlager–Rytter parallel parsing algorithm is that it *considers the same trees multiple times*, and this happens in different branches of parallel computation: each tree is obtained in different ways by combining different subtrees. An example of this is given in Figure 1: here the input string is  $a_1a_2a_3a_4$ , and the algorithm obtains its single parse tree in two ways. One way is to produce a subtree of  $a_1a_2$  with root  $A$ , another tree with root  $S$  with a “hole” instead of  $A$  and with the

■ **Figure 1** Multiple partitions of a tree into a “tree with a hole” and a subtree.

leaves  $a_3a_4$  to the right of the hole, and then to fill this hole with the former subtree, see Figure 1(left). The other way is similar, using a subtree of  $a_3a_4$  with root  $D$  to fill a hole in another “tree with a hole”. The algorithm will construct these subtrees in different branches of parallel computation, each time deducing the existence of a parse tree of  $a_1a_2a_3a_4$ . If the algorithm were modified to count the number of trees, then the tree in the figure will be counted twice, as the algorithm has no means to check whether these trees were the same or not. Hence, the algorithm can only determine the existence of a tree, but cannot compute a reliable count of the number of trees, as well as cannot compute the weight of the input string in most semirings.

In a recent paper by Bakinova et al. [1], a simple variant of the Brent–Goldschlager–Rytter algorithm for computing *the number of trees modulo two* was presented: the algorithm uses a Boolean circuit of the same depth  $O((\log n)^2)$ , whereas the number of elements is  $O(n^7)$ . This algorithm considers each tree only once, and therefore it can be adapted to compute the precise number of trees, if the Boolean circuit is replaced with an arithmetic circuit. In the same way, one can compute the weight in any semiring. This raises a natural question: could the number of elements in  $(\log n)^2$ -depth circuits solving this problem be reduced to  $O(n^6)$  or below?

This paper presents a new parallel algorithm for enumerating all parse trees of an input string, which maintains the same circuit depth  $O(\log^2 n)$ , and is more efficient in terms of the number of elements. First, in Section 3, the problem is solved using a circuit with  $O(n^6)$  elements. The algorithm is formulated as computing the number of trees, and then it is adapted to compute the weight of an input string in any semiring.

Next, in Section 4, this algorithm is improved by using fast matrix multiplication. The algorithm elaborates the algorithm in Section 3 in the same way as Valiant’s [9] algorithm elaborates the Cocke–Kasami–Younger algorithm: it computes the same values as the original algorithm, but rearranges the order of computation so that the arithmetical operations are combined into matrix multiplications. As compared to Valiant’s [9] algorithm, the proposed algorithm has to handle trees with holes, which require a more difficult rearrangement of the computation.

By abuse of notation, let  $\omega \geq 2$  be a number, such that for every  $n$  and for every ring there is a circuit of depth  $O(\log n)$  with  $O(n^\omega)$  elements computing operations in the ring, which multiplies any two  $n \times n$  matrices. Strassen’s algorithm [8] can be implemented on such a circuit. Also it is known that the Coppersmith–Winograd [4] algorithm can be implemented on a logarithmic-depth circuit as well – see, e.g., Gazit and Miller [5]. Then

the new algorithm for enumerating parse trees maintains circuit depth  $O(\log^2 n)$ , whereas the number of elements in it is reduced to  $O(n^{\omega+3})$ , that is, does not exceed  $O(n^{5.38})$ . The algorithm is applicable to computing the weight of a string in any ring.

## 2 Definitions

► **Definition 1.** *A grammar in the Chomsky normal form is a quadruple  $G = (\Sigma, N, R, S)$ , where  $\Sigma$  is a finite alphabet;  $N$  is a finite set of nonterminal symbols;  $R$  is a finite set of grammar rules, each of the form  $A \rightarrow BC$ , with  $A, B, C \in N$ , or  $A \rightarrow a$ , with  $A \in N$  and  $a \in \Sigma$ ;  $S \in N$  is the initial symbol.*

► **Definition 2.** *Let  $G = (\Sigma, N, R, S)$  be a grammar in the Chomsky normal form. A parse tree in  $G$  is a tree, in which the root is labelled with  $S$ , every internal vertex is labelled with any nonterminal symbol  $A \in N$ , and every leaf is labelled with a symbol  $a \in \Sigma$ . Every vertex  $A \in N$  may either have two sons labelled  $B$  and  $C$ , for some rule  $A \rightarrow BC$ , or one son labelled  $a$ , if there is a rule  $A \rightarrow a$ . Vertices with two sons have their sons ordered, which induces an order on the leaves. If  $w \in \Sigma^+$  is the string formed by the leaves of a tree, this is a parse tree of  $w$ .*

*The language defined by the grammar, denoted by  $L(G)$  is the set of all strings  $w \in \Sigma^+$  that have at least one parse tree.*

Under this definition, it is easy to generalize grammars to weighted grammars over a semiring.

► **Definition 3.** *Let  $G = (\Sigma, N, R, S)$  be a grammar in the Chomsky normal form, let  $\mathcal{S}$  be a semiring, and let  $\Phi: R \rightarrow \mathcal{S}$  be a function assigning weights in  $\mathcal{S}$  to rules. The triple  $(G, \mathcal{S}, \Phi)$  is called a weighted grammar.*

*Then, the weight of a parse tree is the product of weights of all rules used in the tree. The weight of a string  $w \in \Sigma^*$  is the sum of weights of all parse trees of  $w$ . The grammar defines a mapping from  $\Sigma^*$  to  $\mathcal{S}$ .*

If  $\mathcal{S}$  is the Boolean semiring and all rules have weight 1, then a weighted grammar become an ordinary grammar, which defines the language  $\{w \mid w \text{ has weight } 1\}$ ; and if  $\mathcal{S}$  is a two-element field, the weighted grammar becomes a GF(2)-grammar. If  $\mathcal{S}$  is the set of non-negative integers with addition and multiplication, and all rules have weight 1, then the weighted grammar defines the number of parse trees in  $G$ . If  $\mathcal{S}$  is the set of probabilities in  $[0, 1]$  with addition and multiplication, this is a probabilistic grammar.

This paper uses arithmetic circuits as a model of parallel computation.

► **Definition 4.** *An arithmetic circuit over natural numbers  $\mathbb{N} = \{0, 1, 2, \dots\}$  is a directed acyclic graph, in which all nodes with no incoming arcs are called the inputs and are labelled with distinct input variables, and each of the rest of the nodes, called elements, has two incoming arcs and is labelled either with addition, or with multiplication. Input variables are natural numbers, each element computes a function of the input variables. The circuit is said to compute the function computed in a designated output element.*

*An arithmetic circuit over integers  $\mathbb{Z}$  additionally may use the subtraction operation. Arithmetic circuits over a semiring  $\mathcal{S}$  and over a ring  $\mathcal{R}$  generalize these circuits by computing values in the corresponding algebraic structures.*

*The depth of a circuit is the length of the longest path.*

A parsing algorithm is implemented on a circuit, which is constructed for a fixed grammar  $G = (\Sigma, N, R, S)$  and a fixed length of input strings  $n$ . The circuit has  $|\Sigma| \cdot n$  inputs, each indicating whether there is a particular symbol in a particular position. The output element gives the number of parse trees of the given string.

Since a different circuit is needed for each input length, the following standard uniformity condition is assumed.

► **Definition 5.** A family of arithmetic circuits is uniform, if there exists a deterministic logarithmic-space Turing machine that, for every input length  $n$  given in unary notation, produces the circuit for input strings of length  $n$ .

### 3 A circuit with $O(n^6)$ elements

► **Theorem 6.** For every grammar  $G = (\Sigma, N, R, S)$  in the Chomsky normal form there is a uniform family of arithmetic circuits, for each length of input strings  $n \geq 1$ , which computes the number of parse trees of an input string of length  $n$ , has at most  $|N|^2 \cdot |R| \cdot n^6$  elements and is of depth at most  $21 \log_2^2 n + 7 \log_2 n \log_2 |R|$ .

**Proof.** Denote  $w = a_1 \dots a_n$ . The circuit consists of the following elements.

- An element  $A(i, j)$ , for all  $A \in N$  and  $i, j$ , with  $0 \leq i < j \leq n$ , computes the number of parse trees from  $A$  for the string  $a_{i+1} \dots a_j$ ; these trees are schematically presented as in Figure 2(left).

An example of such a tree for  $A(0, 2)$  can be seen in Figure 1(left).

- An element  $\frac{A}{D}(i, k, \ell, j)$ , for all  $A, D \in N$  and  $0 \leq i \leq k < \ell \leq j \leq n$ , computes the number of parse trees for the string  $a_{i+1} \dots a_j$  from  $A$ , with a hole instead of a subtree  $a_{k+1} \dots a_\ell$  from  $D$ , depicted as in Figure 2(middle).

Such a “tree with a hole” for  $\frac{S}{A}(0, 0, 2, 4)$  can be seen in Figure 1(left).

- An element  $\frac{A}{D}|_q(i, k, \ell, j)$ , for all  $A, D \in N$  and  $0 \leq i \leq k < \ell \leq j \leq n$ , with  $(k - i) + (j - \ell) > 0$  and  $q \geq 0$ , computes the number of parse trees for the string  $a_{i+1} \dots a_j$  from  $A$ , with a hole instead of a subtree  $a_{k+1} \dots a_\ell$  from  $D$ , such that at the first branching the subtree with the hole contains at most  $q$  leaves, as shown in Figure 2(right).

The tree in the earlier Figure 1(left) is too small to illustrate this, because after the first branching the subtree with the hole is empty (that is, contains 0 leaves).

- Some extra elements are used to compute the values of the named elements listed above: e.g., each element  $A(i, j)$  is computed by a circuit that consists of  $O(n^3)$  extra elements, etc.

■ **Figure 2** (left)  $A(i, j)$ ; (middle)  $\frac{A}{D}(i, k, \ell, j)$ ; (right)  $\frac{A}{D}|_q(i, k, \ell, j)$ .

Figure 3 (left) Intermediate vertex  $E$  in a tree  $A(i, j)$ ; (right) Intermediate vertex  $E$  on the path to the hole in a tree  $\frac{A}{D}(i, k, \ell, j)$ .

Denote the inputs of the circuit by  $In(a, i)$ , for all  $a \in \Sigma$  and  $1 \leq i \leq n$ , where  $In(a, i) = 1$  if the  $i$ -th symbol of an input string is equal to  $a$  and  $In(a, i) = 0$  otherwise. Elements of the circuit corresponding to one-symbol strings are initialized directly from the inputs as  $A(i - 1, i) = \sum_{A \rightarrow a \in R} In(a, i)$ , for all  $A \in N$  and  $1 \leq i \leq n$ . Also, trees with a hole containing no leaves are defined for every pair of positions:  $\frac{A}{D}(i, i, j, j) = 1$ , for  $A, D \in N$  and  $0 \leq i < j \leq n$ .

The desired number of parse trees of  $w$  is computed by the element  $S(0, n)$ .

Consider an arbitrary parse tree  $\tau$ , corresponding to  $A(i, j)$  which has  $j - i$  leaves. Denote by  $E$  the deepest vertex having more than  $\frac{2}{3}(j - i)$  leaves in its subtree. Such a vertex exists, moreover it is unique. Denote by  $B$  and  $C$  the children of  $E$ . Suppose that the subtree of  $B$  corresponds to leaves  $a_{k+1} \dots a_m$ , and the subtree of  $C$  corresponds to leaves  $a_{m+1} \dots a_\ell$ , as illustrated in Figure 3(left). Taking into account that  $E$  is the deepest vertex with more than  $\frac{2}{3}(j - i)$  leaves, both  $B$  and  $C$  may only have at most  $\frac{2}{3}(j - i)$  leaves each, in other words,  $\ell - k > \frac{2}{3}(j - i)$  and  $\max(m - k, \ell - m) \leq \frac{2}{3}(j - i)$ .

Hence, the number of parse trees for  $A(i, j)$  can be calculated as

$$A(i, j) = \sum_{\substack{E \rightarrow BC \in R \\ k, \ell, m: i \leq k < m < \ell \leq j \\ \ell - k > \frac{2}{3}(j - i) \\ \max(m - k, \ell - m) \leq \frac{2}{3}(j - i)}} \frac{A}{E}(i, k, \ell, j) \cdot B(k, m) \cdot C(m, \ell)$$

Every parse tree  $\tau$  has been taken into account, because there is such a vertex  $E$  in every tree. Furthermore, the vertex  $E$  is unique for the given parse tree  $\tau$ , therefore every  $\tau$  is taken into account only once.

The above formula for  $A(i, j)$  is implemented on a circuit as follows. For each triple  $(k, \ell, m)$ , one extra element is used to multiply  $\frac{A}{E}(i, k, \ell, j)$  by  $B(k, m)$ , and another extra element multiplies the result by  $C(m, \ell)$ . It remains to sum up the resulting products: as there are  $O(n^3)$  of them, up to  $O(n^3)$  extra elements are needed, and they are organized into a tree of logarithmic depth.

Similar arguments allow us to deduce a formula for  $\frac{A}{D}(i, k, \ell, j)$  and to implement it on a circuit. Denote by  $E$  the deepest vertex on the path from  $A$  to  $D$  with more than  $\frac{2}{3}(k - i + j - \ell)$  leaves in its subtree, and denote these leaves by  $a_{s+1} \dots a_k$  and  $s_{\ell+1} \dots s_t$ , see Figure 3(right). Then

$$\frac{A}{D}(i, k, \ell, j) = \sum_{\substack{E \in N \\ s: i \leq s \leq k \\ t: \ell \leq t \leq j \\ k-s+t-\ell > \frac{2}{3}(k-i+j-\ell)}} \frac{A}{E}(i, s, t, j) \cdot \frac{E}{D} \Big|_{\frac{2}{3}(k-i+j-\ell)}(s, k, \ell, t)$$

Indeed, the intermediate positions  $s$  and  $t$  are chosen so that the subtree  $E$  has more than  $\frac{2}{3}(k - i + j - \ell)$  leaves. On the other hand, the definition of  $\frac{E}{D} \Big|_{\frac{2}{3}(k-i+j-\ell)}$  guarantees that no other vertex on the path from  $E$  to  $D$  has more than  $\frac{2}{3}(k - i + j - \ell)$  leaves. Hence,  $E$  is indeed the deepest vertex on the path from  $A$  to  $D$  with more than  $\frac{2}{3}(k - i + j - \ell)$  leaves. Since such a vertex is unique for each tree, every parse tree for  $\frac{A}{D}(i, k, \ell, j)$  is counted only once.

A circuit computing  $\frac{A}{D}(i, k, \ell, j)$  by the above formula uses  $O(n^2)$  extra elements.

In order to compute  $\frac{E}{D} \Big|_q(s, k, \ell, t)$ , let us consider the rule used at the root  $E$  of a tree with a hole  $D$ . Let  $E \rightarrow BC$  be this rule, and let  $m$  be the position in the input such that leaves up to  $a_m$  belong to subtree  $B$ , and leaves beginning with  $a_{m+1}$  belong to subtree  $C$ . Then  $\frac{E}{D} \Big|_q(s, k, \ell, t)$  can be computed as follows:

$$\frac{E}{D} \Big|_q(s, k, \ell, t) = \sum_{\substack{E \rightarrow BC \in R \\ m: s < m \leq k \\ k-m+t-\ell \leq q}} B(s, m) \cdot \frac{C}{D}(m, k, \ell, t) + \sum_{\substack{E \rightarrow BC \in R \\ m: \ell \leq m < t \\ k-s+m-\ell \leq q}} \frac{B}{D}(s, k, \ell, m) \cdot C(m, t)$$

A circuit computing an element  $\frac{E}{D} \Big|_q(s, k, \ell, t)$  by this formula uses  $O(n)$  extra elements.

The entire circuit consists of all the above elements and computes the desired values.

**Number of elements in the circuit.** There are  $O(n^2)$  elements  $A(i, j)$  and computing each of them takes  $O(n^3)$  extra elements. Similarly, each of the  $O(n^4)$  elements  $\frac{A}{D}(i, k, \ell, j)$  takes  $O(n^2)$  extra elements to compute, whereas the computation of each of the  $O(n^5)$  elements  $\frac{E}{D}(s, k, \ell, t) \Big|_q$  takes  $O(n)$  extra elements. This accounts for  $O(n^6)$  elements in the entire circuit; the calculation of the dependence on the grammar is omitted due to space constraints.

**Depth of the circuit.** The elements  $A(i, j)$  directly depend on elements, which have at most  $\frac{2}{3}(j - i)$  leaves in their subtrees.

For each element  $\frac{A}{D}(i, k, \ell, j)$ , let  $\alpha = k - i + j - \ell$  be the number of leaves in its subtree. Then it directly depends on elements  $\frac{E}{D}(\cdot, \cdot, \cdot, \cdot)$  with at most  $\frac{1}{3}\alpha$  leaves, and elements  $\frac{E}{D} \Big|_q(\cdot, \cdot, \cdot, \cdot)$  with at most  $\alpha$  leaves, and with  $q \leq \frac{2}{3}\alpha$ . The latter element depends on  $B(\cdot, \cdot)$  with at most  $\alpha$  leaves, and on  $\frac{C}{D}(\cdot, \cdot, \cdot, \cdot)$  with at most  $\frac{2}{3}\alpha$ . Overall,  $\frac{A}{D}$  depends on elements with at most  $\frac{2}{3}\alpha$  leaves in three steps.

Each element  $\frac{E}{D} \Big|_q(s, k, \ell, t)$  depends on elements  $\frac{A}{D}$  and  $B$  with fewer than  $\alpha$  leaves.

Thus, for an element of every type, whether it is  $A(\cdot, \cdot)$ ,  $\frac{E}{D} \Big|_q(\cdot, \cdot, \cdot, \cdot)$  or  $\frac{A}{D}(\cdot, \cdot, \cdot, \cdot)$ , after a quadruple application of the rules, the number of leaves is reduced at least by a factor of  $\frac{3}{2}$ .

At each level of these dependencies, a sum of multiple values is computed using a binary tree of logarithmic depth in the number of arguments, whence overall depth  $O(\log^2 n)$ . ◀

The above circuit actually performs operations in the ring of natural numbers, adding constant 1 for each parse tree accounted for. This can be generalized to compute the value of a string in a weighted grammar over every semiring.

► **Theorem 7.** *For every weighted grammar  $G = (\Sigma, N, R, S)$  in the Chomsky normal form, with weights in a semiring  $\mathcal{S}$ , there is a uniform family of arithmetic circuits computing elements over  $\mathcal{S}$ , for each length of input strings  $n \geq 1$ , which computes the value of an input string of length  $n$  in the semiring, has  $O(n^6)$  elements and is of depth  $O(\log^2 n)$ .*

## 4 A smaller circuit using fast matrix multiplication

In the circuit constructed in Theorem 6, all elements  $A(\cdot, \cdot)$  are computed using  $\Theta(n^5)$  operations in total, and computation of elements of both types  $\frac{A}{D}$  and  $\frac{A}{D}|_q$  takes  $\Theta(n^6)$  operations. Hence, in order to reduce the total number of elements in the circuit, computation of elements  $\frac{A}{D}$  and  $\frac{A}{D}|_q$  should be optimized. It turns out that such an optimization could be done via fast matrix multiplication.

### 4.1 Matrix multiplication for $\frac{A}{D}$

Let us show how fast matrix multiplication can be used to compute the same values  $\frac{A}{D}(i, k, \ell, j)$  using fewer elements.

In the following, matrices with rows and columns indexed by *substrings*, that is, pairs of two positions in the string, will be considered. Denote  $I = (i, j)$  and  $|I| = j - i$ ; similarly, let  $K = (k, \ell)$ ,  $|K| = \ell - k$ ,  $S = (s, t)$ ,  $|S| = t - s$ . For every pair of non-terminal symbols  $A, D$  let us define a matrix of size  $\frac{n(n+1)}{2} \times \frac{n(n+1)}{2}$ , consisting of elements  $\frac{A}{D}[I][K] = \frac{A}{D}(i, k, \ell, j)$  with  $i \leq k < \ell \leq j$  and  $\frac{A}{D}[I][K] = 0$  otherwise. Then the formula for computing the value  $\frac{A}{D}(i, k, \ell, j)$  can be rewritten in the new notation as follows.

$$\frac{A}{D}[I][K] = \sum_{\substack{E \in N \\ S: K \subset S \subset I \\ |S| - |K| > \frac{2}{3}(|I| - |K|)}} \frac{A}{E}[I][S] \cdot \frac{E}{D}|_{\frac{2}{3}(|I| - |K|)}[S][K]$$

In this notation, the formula resembles a matrix product, and suggests that some elements of a matrix  $\frac{A}{D}[I][K]$ , with rows indexed by  $I$  and columns indexed by  $K$ , could be computed as a product of some submatrices of  $\frac{A}{E}$  and of  $\frac{E}{D}|_{\frac{2}{3}(|I| - |K|)}$  (as long as  $|I| - |K|$  is fixed). However, an algorithm cannot compute the product of these matrices in one step, since the elements corresponding to the longer substrings indirectly depend on the elements corresponding to the shorter substrings. For this reason, those matrices shall be split into several submatrices, which shall be multiplied separately at different stages of the computation.

The matrix  $\frac{A}{D}[I][K]$  is split into submatrices with fixed  $|I|$  and  $|K|$ . The submatrix with  $|I| = \alpha$  and  $|K| = \beta$ , is denoted by  $\left\{ \frac{A}{D}[I][K] \right\}_{|I|=\alpha, |K|=\beta}$ , and is of size  $(n - \alpha + 1) \times (n - \beta + 1)$ . This submatrix is computed as the following sum of matrix products.

$$\left\{ \frac{A}{D}[I][K] \right\}_{\substack{|I|=\alpha \\ |K|=\beta}} = \sum_{\substack{E \in N \\ \gamma: \frac{2}{3}\alpha + \frac{1}{3}\beta < \gamma < \alpha}} \left\{ \frac{A}{E}[I][S] \right\}_{\substack{|I|=\alpha \\ |S|=\gamma}} \cdot \left\{ \frac{E}{D}|_{\frac{2}{3}(\alpha - \beta)}[S][K] \right\}_{\substack{|S|=\gamma \\ |K|=\beta}}$$

(the condition  $\frac{2}{3}\alpha + \frac{1}{3}\beta < \gamma < \alpha$  is obtained from the inequalities  $|S| - |K| > \frac{2}{3}(|I| - |K|)$  and  $|S| < |I|$ )

■ **Figure 4** The computation of  $\frac{E}{D}\Big|_q(s, k, \ell, t)$  in the case of branching to the left.

The submatrices being multiplied include some elements  $\frac{A}{E}[I][S]$  with  $S \subsetneq I$ , and  $\frac{E}{D}\Big|_{\frac{2}{3}(\alpha-\beta)}[S][K]$  with  $K \subsetneq S$ , which are not in the formula for  $\frac{A}{D}[I][K]$ ; however, since these elements are zero by the definition of the matrices, these unintended terms in the sums have no effect on the result.

Also note that the computation of the element  $\frac{A}{D}[I][K]$  with  $\alpha - \beta$  leaves, requires only the elements  $\frac{A}{E}[\cdot][\cdot]$  with at most  $\frac{1}{3}(\alpha - \beta)$  leaves, and the elements  $\frac{E}{D}\Big|_q[\cdot][\cdot]$  with at most  $\alpha - \beta$  leaves. The overall order of computation will be set accordingly, so that by the time the product is computed, its arguments will have already been computed.

## 4.2 Matrix multiplication for elements $\frac{E}{D}\Big|_q$

Let us now consider the elements  $\frac{E}{D}\Big|_q(s, k, \ell, t)$ . As it was mentioned above, each of these elements can be calculated as

$$\frac{E}{D}\Big|_q(s, k, \ell, t) = \sum_{\substack{E \rightarrow BC \in R \\ m: s < m \leq k \\ k - m + t - \ell \leq q}} B(s, m) \cdot \frac{C}{D}(m, k, \ell, t) + \sum_{\substack{E \rightarrow BC \in R \\ m: \ell \leq m < t \\ k - s + m - \ell \leq q}} \frac{B}{D}(s, k, \ell, m) \cdot C(m, t)$$

Let us show how fast matrix multiplication can be used in order to compute the first sum. The second sum is computed similarly.

For each element  $\frac{E}{D}\Big|_q(s, k, \ell, t)$ , define a value  $p$ , which equals  $p = k + t - \ell$ , as it is shown in Figure 4. The proposed order of computations is designed in a such way that elements  $\frac{E}{D}\Big|_q$  with the same  $p$  are calculated together.

Let us fix  $p > 0$  and consider computations of  $\frac{E}{D}\Big|_q(s, k, \ell, t)$  with  $t - \ell + k = p$ . Denote a matrix  $U^{p,B}$  of size  $p \times p$ , such that for all  $s, m = 0, 1, \dots, p-1$ ,  $U^{p,B}[s][m] = B(s, m)$  if  $s < m$ , and  $U[s][m] = 0$  otherwise. In other words,  $U$  is a top-left corner of the matrix  $B$ . Also denote a matrix  $W^{p,q,C,D}$  of size  $p \times n^2$ , where the first coordinate is  $m = 0, 1, \dots, p-1$ , and the second is a triple of  $k, \ell, t$ , such that  $k + t - \ell = p$ , and  $W^{p,q,C,D}[m][k, \ell, t] = \frac{C}{D}(m, k, \ell, t)$  if  $m \leq k \leq \ell \leq t$  and  $m \geq p - q$ , and  $W^{p,q,C,D}[m][k, \ell, t] = 0$  otherwise.

It is claimed that the product of  $U^{p,B}$  and  $W^{p,q,C,D}$  contains the exact values needed for the computation of  $\frac{E}{D}\Big|_q$ .

$$(U^{p,B} \cdot W^{p,q,C,D})[s][k, \ell, t] = \sum_{m=0}^{p-1} U^{p,B}[s][m] \cdot W^{p,q,C,D}[m][k, \ell, t]$$

This sum has  $U^{p,B}[s][m] = 0$  for  $m \leq s$ , and  $W^{p,q,C,D}[m][k, \ell, t] = 0$  for  $m \geq k$  and for  $m \leq p - q$ . Since  $p = k + t - \ell \geq k$ , the upper limit  $m < p$  becomes redundant. Therefore, the range of the sum can be reduced as follows.

$$\begin{aligned} (U^{p,B} \cdot W^{p,q,C,D})[s][k, \ell, t] &= \sum_{m=0}^{p-1} U^{p,B}[s][m] \cdot W^{p,q,C,D}[m][k, \ell, t] = \\ &= \sum_{\substack{s < m \leq k \\ p-q \leq m}} B(s, m) \cdot \frac{C}{D}(m, k, \ell, t) \end{aligned}$$

Hence, in order to compute all elements  $\frac{E}{D}|_q(s, k, \ell, t)$  with  $t - \ell + k = p$ , it is needed to iterate over all pairs of non-terminals  $B, C$ , such that  $E \rightarrow BC \in R$ , construct the corresponding matrices  $U^{p,B}$  and  $W^{p,q,C,D}$ , and sum up their products. However, elements in each of these matrices indirectly depend on each other, so it is again impossible to build and multiply these matrices in one step. For this reason, matrices  $U^{p,B}$  and  $W^{p,q,C,D}$  are never built wholly, and their products are gradually calculated by multiplying their submatrices of various size. The higher the value of  $p$ , the later the entire product  $U^{p,B} \cdot W^{p,q,C,D}$  will be obtained. Let us also mention that both matrices  $U^{p,B}$  and  $W^{p,q,C,D}$ , consist of elements  $B, \frac{C}{D}$  and  $\frac{E}{D}|_q$  or zeros, and so does their product  $U^{p,B} \cdot W^{p,q,C,D}$ . Hence, there is no need to actually store these matrices – it is only a way to represent computations performed over the named elements.

► **Remark 8.** From the definition of  $U^{p,B}$  it follows that an arbitrary element  $U^{p,B}[s][m]$  has  $m - s$  leaves in its subtree. In other words, the elements with  $\alpha$  leaves in their subtrees lay on the  $\alpha$ -th diagonal, in the numeration where the main diagonal has number 0.

► **Remark 9.** Similarly, every element  $W^{p,q,C,D}[m][k, \ell, t]$  has  $\min(k - m + t - \ell, q) = \min(p - m, q)$  leaves in its subtree. In other words, the elements in the  $\alpha$ -th row from the bottom of  $W^{p,q,C,D}$  have  $\min(\alpha, q)$  leaves in their subtrees.

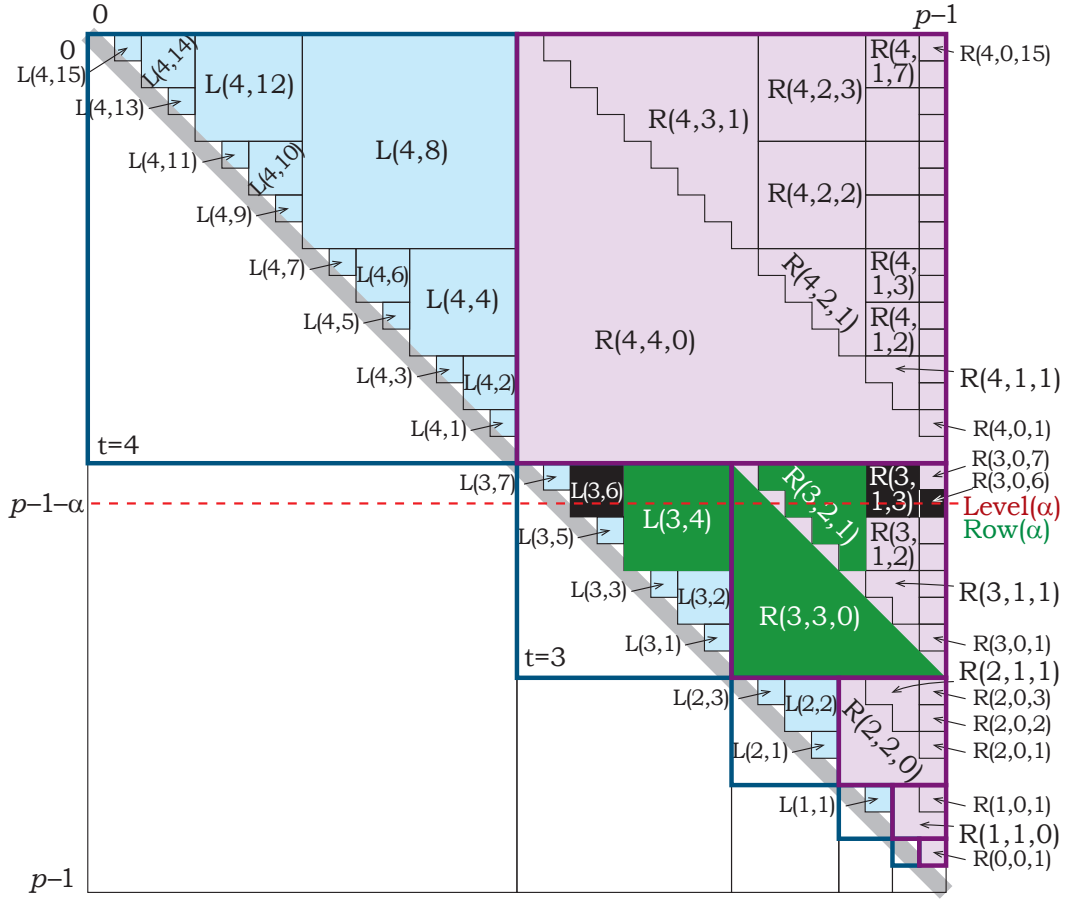

For a fixed value of  $p$ , the matrix  $U^{p,B}$  is split into disjoint submatrices, which will be multiplied by the algorithm. These matrices are denoted by  $L(t, j)$  and  $R(t, \ell, j)$ , where the number  $t$  refers to a large square of size  $2^t \times 2^t$ , in which the corresponding submatrix is contained. The L-matrices are in the large squares centered at the main diagonal, whereas the R-matrices are in the large squares to the right of the main diagonal. This decomposition is illustrated in Figure 5.

It is important to note that even though the matrices  $U^{p,B}$  for different  $p$  are corners of the same matrix  $B$ , the matrix  $U^{p,B}$  is split anew for each  $p$ , and there is no relation between the decompositions for different  $p$ .

► **Definition 10.** For all  $t = 0, \dots, \log_2 p - 1$  and  $j = 1, \dots, 2^t - 1$ , let  $n_j$  be the maximal power of two that divides  $j$ . Denote by  $L(t, j)$  the submatrix of matrix  $U^{p,B}$  of size  $n_j \times n_j$  with left bottom corner at  $(p - 2^t - j - 1, p - 2^t - j)$ .

$$L(t, j) = U^{p,B}[p - 2^t - j - n_j, \dots, p - 2^t - j - 1][p - 2^t - j, \dots, p - 2^t - j + n_j - 1]$$

Each  $L(t, j)$  is in the  $t$ -th large square, its left corner is next to the main diagonal, and  $j$  is the number of the row within the large square, numbered from the bottom.

■ **Figure 5** Partition of  $U^{p,B}$ , with  $p = 32$ , and the sets  $Level(\alpha)$  and  $Row(\alpha)$  for  $\alpha = 14$ .

► **Definition 11.** For all  $t = 0, \dots, \log_2 p - 1$ ,  $\ell = 0, \dots, t - 1$  and  $j = 1, \dots, 2^{t-\ell} - 1$  denote by  $R(t, \ell, j)$  the submatrix of matrix  $U^{p,B}$  of size  $2^\ell \times 2^\ell$  with left bottom corner in  $(p - 2^t - 2^\ell j - 1, p - 2^{\ell+1} + 1)$ .

$$R(t, \ell, j) = U[p - 2^t - 2^\ell(j + 1), \dots, p - 2^t - 2^\ell j - 1][p - 2^{\ell+1} + 1, \dots, p - 2^\ell]$$

Here, if  $j = 1$ , then all the entries below the main diagonal in matrix  $R(t, \ell, j)$  are set to zero.

In addition to that, for all  $t = 0, \dots, \log_2 p - 1$  denote by  $R(t, t, 0)$  the submatrix of matrix  $U^{p,B}$  of size  $2^t \times 2^t$  with left top corner at  $(p - 2^{t+1}, p - 2^t)$ , where all the entries above the main diagonal are set to zero. If  $0 \leq a, b < 2^t$  are the indices of this submatrix, then

$$R(t, t, 0)[a][b] = \begin{cases} U[p - 2^{t+1} + a][p - 2^t + b], & a \geq b \\ 0, & a < b \end{cases}$$

The lower triangular part of the  $t$ -th R-square is  $R(t, t, 0)$ . An R-square is split into blocks of columns, with each  $\ell$ -th block from the right of width  $2^\ell$ . Then, a submatrix  $R(t, \ell, j)$  is the  $j$ -th submatrix down in the  $\ell$ -th block of columns. The bottom submatrix in each block of columns (one with  $j = 1$ ) is upper triangular. All these details are illustrated in the figure. Submatrices  $L(\cdot, \cdot)$  and  $R(\cdot, \cdot, \cdot)$  form a partition of the upper triangle of matrix  $U$ , which is the non-zero part of  $U$ .

For each  $\alpha = 0, \dots, p-1$  denote by  $Row(\alpha)$  the set of all submatrices in the partition, which do intersect with the  $(p-1-\alpha)$ -th row of  $U^{p,B}$  (that is, the  $(\alpha+1)$ -th row from the bottom). The product of each of these matrices by the corresponding stripe of  $W^{p,q,C,D}$  is required for the computation of  $(p-1-\alpha)$ -th row of  $U \cdot W$ .

► **Definition 12.** Let  $\alpha = 2^t + r$  with  $0 \leq r < 2^t$ . Let  $r$  be represented as a sequence of binary digits as  $r = \sum_{i=1}^k 2^{r_i}$ , where  $r_1 < \dots < r_k$  are the numbers of all positive bits. Then  $Row(\alpha)$  consists of  $k$  matrices  $L(t, \cdot)$  and  $\lfloor \log_2 r \rfloor + 2$  matrices  $R(t, \cdot, \cdot)$ . To be more precise,

$$Row(\alpha) = \left\{ L \left( t, \sum_{i=s}^k 2^{r_i} \right) \mid s = 1, \dots, k \right\} \cup \left\{ R \left( t, \ell, \left\lfloor \frac{r}{2^\ell} \right\rfloor \right) \mid \ell = 0, \dots, \lfloor \log_2 r \rfloor \right\} \cup \{R(t, t, 0)\}$$

Let us now denote by  $Level(\alpha)$  the set of all matrices from  $Row(\alpha)$  whose bottom row intersects with the  $(p-1-\alpha)$ -th row of  $U^{p,B}$ . All matrices from  $Level(\alpha)$  are to be multiplied by the corresponding stripes of  $W$  simultaneously at a certain level of the circuit.

► **Definition 13.** For each  $\alpha = 1, \dots, p-1$ , let  $\alpha = 2^t + r$  with  $0 \leq r < 2^t$ . If  $r > 0$ , then the set of matrices  $Level(\alpha)$  consists of the following matrices.

$$Level(\alpha) = \{L(t, r)\} \cup \left\{ R \left( t, \ell, \frac{r}{2^\ell} \right) \mid \ell = 0, \dots, \lfloor \log_2 r \rfloor, r : 2^\ell \right\}$$

And if  $r = 0$ , then  $Level(\alpha)$  contains only the big lower-triangular matrix  $R$ .

$$Level(\alpha) = \{R(t, t, 0)\}$$

In Figure 5, the sets  $Row(\alpha)$  and  $Level(\alpha)$  are illustrated for  $\alpha = 14$ .

- **Lemma 14.** Every matrix of the partition lies in exactly one set  $Level(\alpha)$ .
- **Lemma 15.** Every element of every matrix from  $Level(\alpha)$  has at most  $\alpha$  leaves.
- **Lemma 16.** Every matrix from  $Level(\alpha)$  is multiplied by some elements of  $W$ , each having at most  $\min(\alpha, q)$  leaves.
- **Lemma 17.** For every  $\alpha$ , every matrix from  $Row(\alpha)$  lies in set  $Level(\beta)$ , for some  $\beta \leq \alpha$ .

In other words, in the circuit, every matrix from the partition shall be multiplied by the corresponding stripe of  $W$  before their product would be needed.

### 4.3 Circuit

The circuit is organized into  $6 \lceil \log_{\frac{3}{2}} n \rceil$  levels, each of depth at most  $\log n$ . At each group of six levels numbered  $6t, 6t+1, \dots, 6t+5$ , all elements with  $\alpha$  in the range  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$  are computed. This is done in six stages, according to the following plan.

0. At the level  $\tau = 6t$ , elements  $A(\cdot, \cdot)$  with  $\alpha$  leaves, where  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$  are computed directly via summation. These elements depend on  $B, C$  and  $\frac{A}{E}$  with  $\beta < \left(\frac{3}{2}\right)^t$  leaves – each of which was computed at a level  $6t'$  or  $6t'+3$ , where  $t' < t$ .
1. At the level  $\tau = 6t+1$  for all such  $\alpha$  that  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$  matrices from  $Level^{p,B}(\alpha)$  are multiplied by the corresponding strips of the matrix  $W^{p,q,C,D}$ ; this is done separately for each  $p$ . As it was mentioned in Lemma 15, all elements of the matrix  $U^{p,B}$  involved in this computation have at most  $\alpha < \left(\frac{3}{2}\right)^{t+1}$  leaves, so these elements were computed at levels  $6t'$  with  $t' \leq t$ . At the same time, as it follows from Lemma 16, the elements

## 67:12 Parallel Enumeration of Parse Trees

of  $W^{p,q,C,D}$  involved in the computation have at most  $\min(q, \alpha) < \left(\frac{3}{2}\right)^t$  leaves, so these elements were computed at levels  $6t' + 3$  with  $t' < t$ . All in all, the elements computed at level  $\tau = 6t + 1$  depend only on elements from earlier levels.

2. At the level  $\tau = 6t + 2$ , elements  $\frac{E}{D}|_q(\cdot, \cdot, \cdot, \cdot)$  with  $q < \left(\frac{3}{2}\right)^t$  and with  $\alpha$  leaves, where  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$ , are computed. For each  $\alpha$ , the earlier computed products of matrices from the set  $Row^{p,B}(\alpha)$  by the corresponding stripes of  $W^{p,q,C,D}$  are taken, all their  $\alpha$ -th rows are summed up. Next, a sum of the resulting rows is taken over all rules  $E \rightarrow BC$ . Since submatrices from  $Row^{p,B}(\alpha)$  form a partition of the non-zero part of  $\alpha$ -th row of matrix  $U^{p,B}$ , the sum is exactly the value of  $\frac{E}{D}|_q$ . As it was proven in Lemma 17, each matrix from  $Row^{p,B}(\alpha)$  lies in one of the sets  $Level^{p,B}(\beta)$  with  $\beta \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$ . Hence, the elements from level  $\tau = 6t + 2$  depend on elements from levels  $6t' + 1$ , with  $t' \leq t$ .
3. At the level  $\tau = 6t + 3$ , according to the formulas from Section 4.1, elements  $\frac{A}{D}(\cdot, \cdot, \cdot, \cdot)$  with  $\alpha$  leaves are computed, where  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$ .  
To be more precise, for all  $\alpha$  in this range and for all  $\zeta = 1 \dots n - \alpha$ , the following matrix products are computed simultaneously:

$$\left\{ \frac{A}{D}[I][K] \right\}_{\substack{|I|=\zeta+\alpha \\ |K|=\zeta}} = \sum_{\substack{E \in N \\ \gamma: \frac{2}{3}\alpha + \zeta < \gamma < \zeta + \alpha}} \left\{ \frac{A}{E}[I][S] \right\}_{\substack{|I|=\zeta+\alpha \\ |S|=\gamma}} \cdot \left\{ \frac{E}{D} \right\}_{\frac{2}{3}\alpha} [S][K]_{\substack{|S|=\gamma \\ |K|=\zeta}}$$

In the left part of the equation there are exactly the elements  $\frac{A}{D}$  with  $\alpha$  leaves. They depend on elements  $\frac{A}{E}$  with at most  $\frac{1}{3}\alpha < \left(\frac{3}{2}\right)^t$  leaves, which were computed at some levels  $6t' + 3$  with  $t' < t$ . Also there is a dependency on elements  $\frac{E}{D}|_q$  with fewer than  $\alpha < \left(\frac{3}{2}\right)^{t+1}$  leaves, where  $q = \frac{2}{3}\alpha < \left(\frac{3}{2}\right)^t$ . These elements were computed at levels  $\{6t' + 2 | t' \leq t\} \cup \{6t' + 5 | t' < t\}$ . Overall, the elements from level  $\tau = 6t + 3$  depend on elements from levels  $6t' + 3$  and  $6t' + 5$  with  $t' < t$ , as well as on elements from levels  $6t' + 2$  with  $t' \leq t$ .

4. At the level  $\tau = 6t + 4$ , matrices from the sets  $Level^{p,B}(\alpha)$ , with  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$ , are multiplied by the corresponding strips of matrices  $W^{p,q,C,D}$ , and for all  $q \geq \left(\frac{3}{2}\right)^t$ . The computations are the same as at level  $6t + 1$ , with the only difference that  $\min(q, \alpha) < \left(\frac{3}{2}\right)^{t+1}$ . So, the elements from level  $\tau = 6t + 4$  depend on elements from levels  $6t'$  and  $6t' + 3$  with  $t' \leq t$ .
5. At the level  $\tau = 6t + 5$ , the elements  $\frac{E}{D}|_q$  with  $q \geq \left(\frac{3}{2}\right)^t$  are computed for all  $\alpha$  with  $\left(\frac{3}{2}\right)^t \leq \alpha < \left(\frac{3}{2}\right)^{t+1}$ . This is done similarly to the level  $6t + 2$ , with the computations depending on the elements from levels  $6t' + 4$  with  $t' \leq t$ .

► **Theorem 18.** *For every grammar  $G = (\Sigma, N, R, S)$  in the Chomsky normal form and for every string length  $n$ , there exists an arithmetic circuit of depth  $O((\log n + \log |R|) \log n)$  and with  $O(|N|^2 \cdot |R| \cdot n^{\omega+3})$  elements, which computes the number of parse trees of an input string of length  $n$ . (where  $\omega \geq 2$  is a number, such that for every  $n$  there is an arithmetic circuit of depth  $O(\log n)$  and with  $O(n^\omega)$  elements that computes the product of two  $n \times n$  integer matrices)*

**Proof.**

**Depth.** Since the elements at every level  $\tau$  depend only on elements from earlier levels, there are no cycles in the circuit, and the depth of the logical dependencies between elements does not exceed the number of levels, which is  $6\lceil \log_{\frac{3}{2}} n \rceil$ . At each level, each element is computed either as a sum of at most  $n^3|R|$  values, or as a part of a matrix product involving matrices of

size at most  $n \times n$ . Sums are computed in depth  $O(\log n + \log |R|)$  by the standard method. Matrix products are computed in depth  $O(\log n)$  using fast matrix multiplication. Hence, the entire circuit has depth  $O((\log n + \log |R|) \log n)$ .

**Number of elements.** Elements  $B(\cdot, \cdot)$  are computed as sums of  $O(|N| \cdot |R| \cdot n^5)$  elements, which is less than  $O(|N|^2 \cdot |R| \cdot n^{3+\omega})$ .

The computations of all elements  $\frac{A}{D}(\cdot, \cdot, \cdot, \cdot)$  are performed at levels  $6t + 3$ , see stage 3 above. For fixed  $\alpha$  and  $\zeta$ , there are  $\alpha + \zeta - (\frac{2}{3}\alpha + \zeta) = \frac{1}{3}\alpha$  different of  $\gamma$ , and for each  $\gamma$  there are  $|N|^3$  matrix multiplications corresponding to different nonterminals  $A$ ,  $D$  and  $E$ , where each matrix is not larger than  $n \times n$ . Summing up over all  $\alpha$ ,  $\zeta$ ,  $A$ ,  $D$  and  $E$  gives the following upper bound on the number of operations.

$$\text{const} \cdot \sum_{A, D, E \in N} \sum_{\zeta=1}^{n-1} \sum_{\alpha=1}^{n-\zeta} \frac{1}{3} \alpha n^\omega = \text{const} \cdot |N|^3 \cdot n(n^2 - 1)n^\omega = O(|N|^3 \cdot n^{3+\omega})$$

It remains to prove that all matrix multiplications required to compute  $\frac{E}{D}|_q(\cdot, \cdot, \cdot, \cdot)$  can be done using  $O(|N|^2 \cdot |R| \cdot n^{3+\omega})$  elements.

Let firstly fix the parameters  $p, q$ , the rule  $E \rightarrow BC$  and the nonterminal  $D$ , and estimate the number of elements used to compute the product of matrices  $U^{p,B} \cdot W^{p,q,C,D}$  for these  $p, q$ ,

Denote the width of the matrix  $W^{p,q,C,D}$  by  $M$ , it is  $O(n^2)$ . Fix  $t \in \{0, \dots, \log_2 p\}$  and consider the partition of matrices  $U^{p,B}[p - 2^{t+1}, \dots, p - 2^t - 1][p - 2^{t+1}, \dots, p - 2^t - 1]$  (the large square of size  $2^t \times 2^t$  on the main diagonal in Figure 5) and  $U^{p,B}[p - 2^{t+1}, \dots, p - 2^t - 1][p - 2^t, \dots, p - 1]$  (the large square of size  $2^t \times 2^t$  to the right of the main diagonal in Figure 5). The first matrix has  $2^{k-j-1}$  submatrices  $L(t, \cdot)$  of size  $2^j \times 2^j$ , and the second one has  $2^{k-j} - 1$  submatrices  $R(t, j, \cdot)$  of size  $2^j \times 2^j$ . So, among the matrices  $\{L(t, \cdot)\} \cup \{R(t, \cdot, k) \mid k > 0\}$  there are  $2^{t-j-1} + 2^{t-j} - 1$  matrices of size  $2^j \times 2^j$ , and each of them is multiplied by a strip of size  $2^t \times M$  of the matrix  $W^{p,q,C,D}$ ; to be more precise, this product is computed by splitting the stripe into  $\frac{M}{2^j}$  square matrices of size  $2^t \times 2^t$  each. Each product of square matrices of size  $2^j \times 2^j$  is computed using  $O(2^{j\omega})$  arithmetic operations, and therefore the total number of operations is bounded by constant times the following expression.

$$\begin{aligned} \sum_{j=0}^{t-1} (2^{t-j} + 2^{t-j-1} - 1) \frac{M}{2^j} 2^{j\omega} &\leq \sum_{j=0}^{t-1} \frac{3}{2} 2^{t-j} \frac{M}{2^j} 2^{j\omega} = \frac{3}{2} M \sum_{j=0}^{t-1} 2^{t-j} 2^{j\omega-j} = \\ &= \frac{3}{2} 2^t M \sum_{j=0}^{t-1} 2^{j(\omega-2)} \approx \text{const} \cdot 2^t M \cdot 2^{t(\omega-2)} = \text{const} \cdot 2^{t(\omega-1)} M \end{aligned}$$

In addition to that, there is one more matrix  $R(t, t, 0)$  of size  $2^t \times 2^t$ , which is multiplied by the strip of the matrix  $W^{p,q,C,D}$  of size  $2^t \times M$ , implemented as  $\frac{M}{2^t}$  multiplications by a square matrix, which gives  $O(2^{t\omega}) \cdot \frac{M}{2^t} = O(M2^{t(\omega-1)})$  additional operations.

All in all,  $O(M2^{t(\omega-1)})$  elements are required for a given  $t$ . The sum of the number of elements for  $t = 0, \dots, \log_2 p$  is then bounded by

$$\text{const} \cdot \sum_{t=0}^{\log p} M \cdot 2^{t(\omega-1)} \approx \text{const} \cdot M \cdot 2^{(\omega-1) \log p} = \text{const} \cdot p^{\omega-1} M$$

Hence, for a given  $p$  and  $q$  all matrices from the partition of  $U^{p,B}$  are multiplied using  $O(Mp^{\omega-1})$  elements, where  $M = O(n^2)$ . Since  $p \leq n$ , this value is not more than  $O(n^{\omega+1})$ .

The last step is to sum the number of elements for all  $p, q = 1, \dots, n$  and for all rules  $E \rightarrow BC$  and nonterminals  $D$ , and obtain the desired upper bound  $O(|N| \cdot |R| \cdot n^{\omega+3})$  on the number of elements in the circuit. ◀

Like the simple circuit with  $O(n^6)$  elements, the new circuit can also be adapted to compute the value of a string in a weighted grammar. Since fast matrix multiplication requires matrices over a ring, this restriction makes its way into the theorem.

► **Theorem 19.** *For every weighted grammar  $G = (\Sigma, N, R, S)$  in the Chomsky normal form, with weights in a ring  $\mathcal{R}$ , there is a uniform family of arithmetic circuits computing elements over  $\mathcal{R}$ , for each length of input strings  $n \geq 1$ , which computes the value of an input string of length  $n$  in the ring, has  $O(|N|^2 \cdot |R| \cdot n^{\omega+3})$  elements and is of depth  $O((\log n + \log |R|) \log n)$ . (where  $\omega \geq 2$  is a number, such that for every  $n$  there is a an arithmetic circuit of depth  $O(\log n)$  and with  $O(n^\omega)$  elements that computes the product of two  $n \times n$  matrices over  $\mathcal{R}$ )*

## 5 Future work

The smaller of the two proposed circuits for enumerating parse trees uses  $O(n^{3+\omega})$  elements. On the other hand, in the Boolean case, where only the existence of a parse tree is determined, it should be sufficient to use only  $O(n^{2\omega})$  elements, see Brent and Goldschlager [3, Sect. 6]. Perhaps the enumeration of parse trees might also be done using asymptotically fewer than  $n^{\omega+3}$  elements, and this looks like an interesting subject for future research.

---

## Abstract

---

We study a two-player game on a graph between an attacker and a defender. To begin with, the defender places guards on a subset of vertices. In each move, the attacker attacks an edge. The defender must move at least one guard across the attacked edge to defend the attack. The defender wins if and only if the defender can defend an infinite sequence of attacks. The smallest number of guards with which the defender has a winning strategy is called the eternal vertex cover number of a graph  $G$  and is denoted by  $\text{evc}(G)$ . It is clear that  $\text{evc}(G)$  is *at least*  $\text{mvc}(G)$ , the size of a minimum vertex cover of  $G$ . We say that  $G$  is *Spartan* if  $\text{evc}(G) = \text{mvc}(G)$ . The characterization of Spartan graphs has been largely open. In the setting of bipartite graphs on  $2n$  vertices where every edge belongs to a perfect matching, an easy strategy is to have  $n$  guards that always move along perfect matchings in response to attacks. We show that these are essentially the only Spartan bipartite graphs.

## 1 Introduction

A *vertex cover* of a graph  $G$  is a subset  $S$  of vertices such that every edge in  $G$  has at least one of its endpoints in  $S$ . An *optimal* vertex cover of a graph  $G$  is a vertex cover of the smallest possible size and the size of this optimal vertex cover is denoted by  $\text{mvc}(G)$ . A *bipartite graph*  $G = (V, E)$  is a graph whose vertex set can be partitioned into two independent sets, say  $V = (A \cup B)$ , that is every edge is between a vertex in  $A$  and one in  $B$ . Clearly, both  $A$  and  $B$  are vertex covers of  $G$ . If a bipartite graph  $G = (A \cup B, E)$  is connected and its *only* optimal vertex covers are  $A$  and  $B$ , then we say that  $G$  is *elementary*. If every connected component of a bipartite graph is elementary, then we call it *essentially elementary*.

Klostermeyer and Mynhardt [8] introduced the notion of the *eternal vertex cover* number of a graph  $G$ . There are two players – an *attacker* and a *defender*, who are playing on a simple, undirected graph  $G$ . In the beginning, the defender can choose to place guards on some of the vertices of  $G$ . The attacker’s move involves choosing an edge to “attack”. The defender is able to “defend” this attack if she can move the guards along the edges of the graph in such a way that at least one guard moves along the attacked edge. If both the

endpoints of the attacked edge have guards on them, the guards can simply exchange their places and the attack is defended as well as the original configuration of guards is restored. Note that any number of guards can move after an attack, but each guard can move only one “step”, i.e., just along a single edge. If such a movement is not possible, then the attacker wins. If the defender can defend the graph against an infinite sequence of attacks, then the defender wins (see Figure 1). The minimum number of guards with which the defender has a winning strategy is called the *eternal vertex cover number* of the graph  $G$  and is denoted by  $\text{evc}(G)$ .

There are two variations of this game, one where only one guard can be present per vertex at a given time and a variant where more than one guard can be present on a vertex at a given time. Our results apply to both the variants of the game.

■ **Figure 1** An attack that is defended by moving two guards.

If  $S_\ell$  is the subset of vertices that have guards on them after the defender has played her  $\ell$ -th move, and  $S_\ell$  is not a vertex cover of  $G$ , then the attacker can target any of the uncovered edges to win the game. Therefore, when the defender has a winning strategy, it implies that she can always “reconfigure” one vertex cover into another in response to any attack, where the reconfiguration is constrained by the rules of how the guards can move and the requirement that at least one of these guards needs to move along the attacked edge. It follows that  $\text{evc}(G) \geq \text{mvc}(G)$ , where  $\text{mvc}(G)$  is the size of the smallest vertex cover for any graph  $G$ .

We call graphs  $G$  which enjoy  $\text{evc}(G) = \text{mvc}(G)$  *Spartan*, to indicate that these graphs can manage attacks without using “additional” guards. Understanding Spartan graphs for several special cases have been addressed in the literature (see, for instance, [3]). However, the characterization of bipartite graphs that are Spartan has been left open. We show that bipartite graphs are Spartan if and only if they are essentially elementary.

We also consider a natural extension of the eternal vertex cover problem: where the guards are allowed to move two or more steps on each turn instead of one, without retracing. An attack is defended only if the guard moves along the attacked edge on their first step. We show that with just one additional step, we need either just as many guards as the size of the smallest vertex cover or one more: so in this variant all graphs are “almost” Spartan. We also show that the extra guard is needed only if the graph has a degree one vertex not contained in any minimum vertex cover. Finally, we show that allowing for more than one extra step is the same as allowing exactly one extra step.

**Related Work.** Among characterizations related to Spartan graphs, we have the following. Let the graph class  $\mathcal{F}$  denote the class of all connected graphs  $G$  for which each minimum vertex cover of  $G$  that contains all the cut vertices of  $G$  induces a connected subgraph in  $G$ .

(A cut vertex is a vertex whose removal disconnects the graph.) Let  $G(V, E)$  be a graph that belongs to  $\mathcal{F}$ , with at least two vertices, and  $X \subset V$  be the set of cut vertices of  $G$ . Then Babu et al. [2] showed that  $G$  is Spartan if and only if for every vertex  $v \in V \setminus X$ , there exists a minimum vertex cover  $S_v$  of  $G$  such that  $X \cup \{v\} \subset S_v$ . Klostermeyer and Mynhardt [7] also study graphs for which the eternal vertex cover number coincides with the eternal domination number, a closely related notion. This is a similar game, except that the attacks happen on vertices and if the attacked vertex does not have a guard already, then a guard from a neighbouring vertex must come to the attacked vertex. All other guards can stay on their initial position or move to a neighbouring vertex. The minimum number of guards required to protect the graph from an infinite sequence of attacks is called the *eternal domination number*.

Note that twice as many vertices as the  $\text{mvc}(G)$  always suffice to defend against any sequence of attacks – by placing guards on both endpoints of any maximum matching to begin with and after any attack, reconfiguring the guards to obtain another maximum matching. Using this strategy, a 2-approximation algorithm for ETERNAL VERTEX COVER was obtained by Fomin et al. [5]. This also implies  $\text{mvc}(G) \leq \text{evc}(G) \leq 2\text{mvc}(G)$ . [8] gave a characterization of the graphs for which the upper bound is achieved. The notion of elementary graphs was considered by Lovász and Plummer [9] and several useful characterizations were given by Heteyi [6]. We adapt these definitions to suit the context of bipartite graphs.

## Methodology

Recall that a *matching* is a collection of vertex disjoint edges, and a matching which contains one edge incident to each vertex of a graph is called a *perfect matching*. We say that an edge is *allowed* if it is contained in some perfect matching. A graph  $G$  is said to be *elementary* if and only if it is connected and every edge is allowed.

It turns out that a connected bipartite graph  $G = (A \cup B, E)$  is elementary if and only if its *only* optimal vertex covers are  $A$  and  $B$ , as we make explicit in the proposition below.

► **Proposition 1** ([6]). *The following are equivalent for any connected bipartite graph  $G = (A \cup B, E)$ .*

1.  $A$  and  $B$  are the only minimum vertex covers of  $G$ , and in particular  $|A| = |B|$ .
2. Every edge in  $G$  is allowed.

Notice that it is easy to see that for bipartite graphs, if  $G$  is elementary then it is Spartan (see also Lemma 2 and Araki, Fujito, and Inoue [1]). Indeed, we start by placing guards on all vertices of  $A$ . If the edge  $e$  is attacked, then we move guards to  $B$  along the edges of the perfect matching  $M$  that contains the edge  $e$ . Future attacks can be similarly defended, so the guards alternate between occupying  $A$  and  $B$  in response to edge attacks.

What we focus on demonstrating in this contribution is the converse, namely that if a connected bipartite graph  $G$  does not have this structure, then it is also not Spartan: in some sense, the trivial scenario is the only one in which we can hope to manage without employing any “extra” guards.

**Spartan  $\implies$  Perfect Matching.** To begin with, notice that if  $G = (A \cup B, E)$  is connected and does not have a perfect matching, we already need more than  $\text{mvc}(G)$  guards (see also Proposition 4). In particular, let  $M$  be a maximum matching in  $G$ . Recall that  $|M| = \text{mvc}(G)$  by König’s theorem. Without loss of generality, let  $b \in B$  be a vertex not incident to any edge of  $M$ . Since  $G$  is connected,  $b$  has some neighbor  $a \in A$ , which must belong to any vertex cover of  $G$ . In particular, the defender is forced to position a guard on

## 68:4 Spartan Bipartite Graphs Are Essentially Elementary

$a$  in the initial configuration. If the edge  $ab$  is attacked, the guard on  $a$  is forced to move to  $b$ . This creates a situation where  $|M| - 1$  guards have to reposition themselves to protect all the edges of  $M$  – which is impossible since the edges of  $M$  are disjoint.

Therefore, a necessary condition for a connected bipartite graph to be Spartan is that it must admit a perfect matching. This is, however, evidently not sufficient: indeed, there are connected bipartite graphs with perfect matchings that are not Spartan (see also Figure 2).

■ **Figure 2** A graph with a perfect matching where  $\text{mvc}(G)$  many guards do not suffice. For each choice of  $\text{mvc}(G)$  many guards at the initial configuration, attacking the dashed edge shown in the figure leads to an indefensible position in one or two steps.

**Spartan  $\implies$  No Degree One Vertices.** We observe that a connected bipartite Spartan graph  $G = (A \cup B, E)$  on at least three vertices cannot have a degree one vertex (see also Proposition 5 and Babu et al. [2]). Assume to the contrary that  $G$  has a degree one vertex, say  $a \in A$ . Let  $b$  denote  $a$ 's unique neighbor in  $G$ . Since  $G$  has at least one vertex other than  $a$  and  $b$ , and  $G$  is connected,  $b$  must have another neighbor in  $G$ : say  $a'$ . Now, if the initial configuration has a guard on  $a$ , then attack the edge  $ba'$ ; otherwise attack the edge  $ab$  to force a guard on  $a$  and then attack  $ba'$ . Both cases lead to a scenario where both endpoints of the edge  $ab$  have guards on them. However, since  $G$  is Spartan, it has a perfect matching  $M$ . Further, since  $a$  is a degree one vertex,  $M$  is forced to contain the edge  $ab$ . This in turn implies that at least  $|A| - 1$  guards are required to defend the rest of the graph, contradicting the assumption that  $G$  is Spartan.

**Proof by Structure-Preserving Contractions.** So far, we have seen that a connected bipartite graph  $G = (A \cup B, E)$  which is Spartan must have a perfect matching and no degree one vertices. Fix an arbitrary perfect matching  $M$ , and let  $ab \in M$ . Let  $P$  be a maximal walk (without repeating edges) starting at  $a$ , alternating between edges of  $M$  and  $E \setminus M$ . The terminal vertex of  $P$  is either  $a$ , or a vertex  $v$  which must have a neighbor on  $P$ , since  $G$  has no degree one vertices. So from  $P$ , we can derive a cycle whose edges alternate between  $M$  and  $E \setminus M$  (see also Proposition 17).

At a high level (see Figure 3), our proof relies on “contracting” each such cycle to a single matching edge and arguing that the resulting graph remains Spartan provided the original graph was also Spartan. In particular, we show the following. If  $G$  is Spartan to begin with, and  $M$  is a perfect matching with  $S$  is a set of endpoints of  $M' \subseteq M$  such that  $G[S]$  is elementary, then “replacing”  $G[S]$  with a single edge until this operation is no longer possible; keeps the graph Spartan (see also Lemma 13). Here it is useful that any bipartite graph obtained by adding edges to a cycle (while preserving the bipartite-ness) is elementary, a fact that we establish separately (see also Proposition 7) – thus we can simply keep contracting along cycles  $C$ . The idea of the proof is then the following. Consider what happens once we are stuck, i.e., we cannot contract any further: we either have an edge, or we have a graph that is not an edge but must have a degree one vertex (if not, note that we would not

■ **Figure 3** Proof idea: The sequence of forward contractions preserves “Spartan-ness” overall (i.e.,  $G_t$  is Spartan if  $G_0$  is Spartan) while the backward expansions preserve “elementary-ness”.

be stuck). But from our previous discussion, we know that a connected bipartite Spartan graph on at least three vertices cannot have a degree one vertex. So in this situation, we have transformed the Spartan graph we started with into one that is not Spartan, and in particular, there is an attack that  $\text{mvc}(\cdot)$  many guards will not be able to defend on the “contracted” graph. It turns out that this attack can be mimicked on the graph we started with, contradicting our assumption that the original graph is Spartan. Thus, our process must end at a single edge.

To conclude the proof, we show that if we take an elementary bipartite graph  $G$  and “inject” an elementary graph into it by substituting an edge with an elementary graph, then the resulting graph is also elementary. This lets us run the contraction operations on  $G$  in reverse, starting from the edge that we ended up with; and since an edge is elementary, we conclude that  $G$  must have also been elementary (see also Lemma 15).

When  $G$  is not connected, the arguments we made can be made independently of every connected component of  $G$ . This leads to our final characterization: that a bipartite graph  $G$  is Spartan if and only if each of its components are elementary. Since it is straightforward to check if a bipartite graph  $G = (A \cup B, E)$  is elementary (for instance, by checking if  $G \setminus \{u, v\}$  admits a perfect matching for every  $uv \in E$ ), our result also implies a polynomial-time recognition algorithm for bipartite Spartan graphs. We note that, in contrast to  $\text{mvc}(G)$ , determining  $\text{evc}(G)$  is known to be NP-hard even for bipartite graphs.

In Section 2, we describe the proofs of the claims mentioned in the outline here in greater detail. Our notation largely follows conventions from Diestel [4]. The proofs for statements marked with a  $(\star)$  can be found in the full version of this paper.

## 2 Spartan Bipartite Graphs are Essentially Elementary

We begin with the (easy) forward implication, which was also observed by [1] – we provide an explicit proof in the full version in the interest of completeness.

► **Lemma 2**  $(\star)$ . *If a bipartite graph  $G$  is essentially elementary,  $\text{evc}(G) = |V(G)|/2 = \text{mvc}(G)$ , i.e.,  $G$  is Spartan.*

It turns out that we may assume, without loss of generality, that  $G$  is connected (we refer the reader to the full version for a more explicit explanation). Therefore, our goal amounts to showing the following.

► **Lemma 3**  $(\star)$ . *If  $G$  is a connected bipartite graph that is Spartan, then it is elementary.*

We first argue that any connected Spartan bipartite graph must have a perfect matching.

► **Proposition 4**. *If  $G$  is a Spartan connected bipartite graph, it admits a perfect matching.*

**Proof.** Let  $G$  be a connected Spartan bipartite graph with bipartition  $(A, B)$  where  $A = \{a_1, \dots, a_p\}$  and  $B = \{b_1, \dots, b_q\}$  (see also Figure 4). For the sake of contradiction, assume that  $G$  does *not* admit a perfect matching, i.e., without loss of generality let  $q > k$ . Let  $S$  be

68:6 Spartan Bipartite Graphs Are Essentially Elementary

a minimum vertex cover in  $G$  of size  $k$  such that the guards are placed on  $S$  in the initial configuration. Let  $M$  be any maximum matching. Without loss of generality, let the edges of  $M$  be given by:

$$\{e_1 = (a_1, b_1), \dots, e_i = (a_i, b_i), e_{i+1} = (a_{i+1}, b_{i+1}), \dots, e_k = (a_k, b_k)\},$$

where  $S \cap A = \{a_1, \dots, a_i\}$  and  $S \cap B = \{b_{i+1}, \dots, b_k\}$ .

Since  $M$  is not a perfect matching,  $|V(G)| > 2k$  i.e. there exists a vertex in  $G$  which is not an endpoint of any edge in  $M$ . Without loss of generality, let this vertex be  $b_q$ . Since  $b_q$  is not an isolated vertex, it must have a neighbour on the  $A$  side. Since  $S$  is a vertex cover, this neighbour must lie in  $S \cap A$ . Without loss of generality, let this neighbour be  $a_1$ . If the attacker attacks  $a_1 b_q$ , the guard on  $a_1$  must come to  $b_q$  and cannot move further. Now there are  $k - 1$  guards on the vertices of  $M$  to protect  $k$  matching edges. So no matter how these guards arrange themselves, at least one edge of  $M$  must be vulnerable before the next attack. The attacker attacks this edge in the next move and wins thus contradicting the fact that  $G$  is Spartan. Therefore, the graph  $G$  must admit a perfect matching. ◀

(a) A graph which does not have a perfect matching and the red edge is attacked.

(b) After defending the attack, there are only  $k - 1$  guards to protect  $k$  matching edges. So an edge will remain vulnerable.

■ **Figure 4** Demonstrating that Spartan connected bipartite graphs must have perfect matching towards a proof of Proposition 4.

So we now have that connected Spartan bipartite graphs  $G$  have at least one perfect matching. From now on we denote the bipartitions of  $G$  by  $A = \{a_1, a_2, \dots, a_n\}$  and  $B = \{b_1, b_2, \dots, b_n\}$  where each  $a_i$  and  $b_i$  have an edge between them so that we have a perfect matching  $M = \bigcup_{i=1}^n \{a_i b_i\}$ . Since  $G$  is connected, these bipartitions are unique upto permutations. We now show that connected bipartite graphs that are Spartan do not have degree one vertices. This follows from known results (for example, as shown by [2]), however, our argument is more direct and we make it explicit to make our presentation self-contained.

► **Proposition 5** (No Degree One Vertex). *Let  $G$  be a connected bipartite graph with  $|V(G)| > 2$  and with a perfect matching. If  $\text{evc}(G) = \text{mvc}(G)$ , then  $G$  has no degree one vertex.*

From Lemma 2 and Proposition 5, we have the following.

► **Corollary 6.** *Let  $G$  be a connected bipartite graph with more than two vertices. If  $G$  is elementary, then  $G$  cannot have a degree one vertex.*

Next, we show that a bipartite graph with a cycle that visits every vertex is elementary.

► **Proposition 7** (Adding edges to cycles). *Consider a connected bipartite graph  $G = (A \cup B, E)$  which is a cycle  $a_1 b_1 a_2 b_2 \dots a_k b_k a_1$  (where  $k > 1$ ). The graph  $G'$  formed after adding any number of edges between  $A$  and  $B$  (preserving bipartiteness) will be elementary.*

**Proof.** Let  $G$  be a connected bipartite graph  $G$  which is a cycle  $a_1 b_1 a_2 b_2 \dots a_k b_k a_1$ , where  $k > 1$  (see also Figure 5). Here the two sides of the bipartition are  $A = \{a_1, a_2, \dots, a_k\}$  and  $B = \{b_1, b_2, \dots, b_k\}$ .

The graph  $G$  has two perfect matchings which are given by  $M = \{a_1 b_1, a_2 b_2, \dots, a_k b_k\}$  and  $M' = \{b_1 a_2, b_2 a_3, \dots, b_{k-1} a_k, b_k a_1\}$ . It is easily seen that any edge of  $G$  lies in one of these two perfect matchings.

Suppose we add some edges from  $A$  to  $B$ . Notice that the vertex set of the new graph  $G'$  is same as the vertex set of  $G$ . In order to prove that  $G'$  is elementary, it is sufficient to show that each of the newly added edges belongs to a perfect matching of  $G'$ .

Consider a newly added edge  $a_i b_j$ . This clearly preserves bipartiteness. Here,  $i \neq j, j + 1$  because the edges  $a_i b_i$  and  $a_i b_{i-1}$  were already in  $G$ .

First, let  $i > j + 1$ . Consider the matching:

$$M_1 = \{a_i b_j, b_i a_{i+1}, b_{i+1} a_{i+2}, \dots, b_{k-1} a_k, b_k a_1, b_1 a_2, \dots, b_{j-1} a_j, a_{j+1} b_{j+1}, a_{j+2} b_{j+2}, \dots, a_{i-1} b_{i-1}\}.$$

Clearly  $M_1$  is a perfect matching containing  $a_i b_j$ .

Now let  $i < j$ . Let  $N_1 = \{a_i b_j, b_i a_{i+1}, b_{i+1} a_{i+2}, \dots, b_{j-1} a_j\}$ ;  $N_2 = \{a_1 b_1, \dots, a_{i-1} b_{i-1}\}$ ; and  $N_3 = \{a_{j+1} b_{j+1}, \dots, a_k b_k\}$ .

Consider the matching  $M_2$  given by  $N_1 \cup N_2 \cup N_3$ . Clearly  $M_2$  is a perfect matching containing  $a_i b_j$ .

This concludes our argument showing that  $G'$  is elementary. ◀

(a) This figure shows a cycle with  $k = 4$ .

(b) Each newly added edge is allowed: Suppose  $a_1 b_2$  is the new edge, it can be combined with the existing edges to form the perfect matching denoted by the dashed purple lines.

■ **Figure 5** An example of a bipartite graph with a spanning cycle.

We now introduce the terminology “special subset” to indicate that we are working with a subset of endpoints of some edges in a perfect matching.

► **Definition 8 (Special Subset).** Let  $G$  be a connected bipartite graph with a perfect matching  $M = \{a_1 b_1, a_2 b_2, \dots, a_n b_n\}$ . Consider:  $S = \{a_{i_1}, b_{i_1}, a_{i_2}, b_{i_2}, \dots, a_{i_k}, b_{i_k}\}$  for some distinct  $i_1, i_2, \dots, i_k \in [n]$  and  $2 \leq k \leq n$ . Then  $S$  is said to be a **special subset** of  $V(G)$ .

A “special induced subgraph” is a subgraph induced by a special subset.

► **Definition 9 (Special Induced Subgraph).** Let  $G$  be a connected bipartite graph with a perfect matching and  $S$  be a special subset of  $V(G)$ . The subgraph  $G[S]$  induced by  $S$  is called a **special induced subgraph** of  $G$ .

We now note that edges allowed in special induced subgraphs of a graph  $G$  are also allowed in  $G$ .

► **Proposition 10 (Allowed Edge).** Let  $G$  be a connected bipartite graph with a perfect matching  $M$ . Let  $S$  be a special subset of  $G$  and  $H = G[S]$  be the corresponding special induced subgraph. An edge which is allowed in  $H$  is also allowed in  $G$ .

**Proof.** If  $S = V(G)$ , we are done. Otherwise without loss of generality, let  $S$  be the set  $\{a_1, b_1, a_2, b_2, \dots, a_k, b_k\}$ . Consider an edge  $a_i b_j$  which is allowed in  $H$  for some  $i, j \in [k]$ . Consider the matching  $M_H$  which is a perfect matching of  $H$  containing  $a_i b_j$ . Consider  $M' = M_H \cup \{a_{i+1} b_{i+1}, \dots, a_k b_k\}$ . Clearly  $M'$  is a perfect matching of  $G$  containing  $a_i b_j$ . Thus,  $a_i b_j$  is allowed in  $G$ . ◀

We now turn to a key definition: one of “contracting” a special elementary subset to a single edge. We refer the reader to Figure 6 for an example of an application of this operation.

► **Definition 11 (Matching Contraction Graph).** Consider a connected bipartite graph  $G$  with bipartition  $A$  and  $B$  and a perfect matching  $M$ . Let  $S$  and  $H = G[S]$  be a special subset of  $V(G)$  and the corresponding special induced subgraph of  $G$ . If  $H$  is elementary, replace  $A \cap S$  by a new vertex  $\alpha$  and  $B \cap S$  by a new vertex  $\beta$  in  $G$ . Add an edge  $\alpha\beta$  in the new graph. For an edge  $ab$  where  $a \in A \setminus S$  and  $b \in S$ , add an edge  $a\beta$  to the new graph. Similarly for an edge  $ab$  where  $a \in S$  and  $b \in B \setminus S$ , add an edge  $\alpha b$  to the new graph. Keep all the other edges and vertices of  $G$  unchanged. If there are any parallel edges, replace them by a single edge. The new graph  $G_S$  thus obtained is called the **matching contraction graph** of  $G$  w.r.t.  $S$  and the procedure of obtaining a matching contraction graph is called as **contraction**.

■ **Figure 6** Demonstrating the operation of contracting a special elementary subset to a single edge. For a more elaborate example involving a sequence of contractions, see Figure 12.

Note that if  $G$  is a connected bipartite graph and  $S$  is a special subset, then the matching contraction graph  $G_S$  is also connected and bipartite.

It can be seen that if the special subset  $S$  has size  $2k$ , then the matching contraction graph has  $2(n - k + 1)$  vertices, a perfect matching of size  $n - k + 1$  and thus a minimum vertex cover of size  $n - k + 1$ .

► **Definition 12** (Special elementary subset). *Let  $G$  be a connected bipartite graph with a perfect matching. A special subset  $S$  such that  $G[S]$  is elementary is called a **special elementary subset**.*

We consider a series of contractions over a graph  $G$ . Each time we contract a special elementary subset  $S$  of  $G$ . We rename each vertex in the new graph as the largest indexed vertex in the original graph. We associate a label with each vertex, which carries the names of the vertices of the original graph that were contracted to this new vertex. We keep on repeating this procedure until we reach a graph which cannot be contracted further. We denote this graph by  $G_{\bar{S}}$ . We fix a perfect matching  $M$  in  $G$  and in each contracted graph, we get a matching given by  $M \setminus E(G[S]) \cup \{\alpha\beta\}$  where  $\alpha$  and  $\beta$  denote the newly obtained vertices on the  $A$  and  $B$  side respectively. Whenever we say “matched partner” or “matching edge” in the new graph, unless mentioned otherwise, we will be referring to this matching.

► **Lemma 13** (Matching Contraction Graph Property). *Suppose that  $G$  is a connected bipartite graph with a perfect matching  $M$ . Then, if  $G$  is Spartan, then  $G_{\bar{S}}$  is Spartan.*

**Proof.** If  $G_{\bar{S}}$  is a single edge, then  $G$  was elementary to begin with, as each expansion preserves the “elementary-ness” by Lemma 15. And since a single edge is Spartan,  $G_{\bar{S}}$  is Spartan in this case.

## 68:10 Spartan Bipartite Graphs Are Essentially Elementary

Consider the case where  $G_{\bar{s}}$  is not a single edge. Now by Proposition 18,  $G_{\bar{s}}$  must have a degree-1 vertex. Without loss of generality, we assume that this degree-1 vertex is on the B side and let us denote this vertex by  $\beta_1$  and its matched partner by  $\alpha_1$ . Also, note that  $G_{\bar{s}}$  is not Spartan by Proposition 5. We show that  $G$  was also not Spartan in this case.

Let  $B_1$  be the set of vertices in  $G$  in the label of  $\beta_1$ , i.e, which were contracted to get  $\beta_1$  and similarly  $A_1$  be the set of vertices in  $A$  which were contracted to get  $\alpha_1$  and let  $|A_1| = |B_1| = k$ . Note that this contraction may not have happened in one step, but over a series of steps. Notice that  $G \setminus \{A_1 \cup B_1\}$  is non-empty, as  $G_{\bar{s}}$  is not a single edge. Note that no vertex in  $B_1$  can be adjacent to a vertex in  $A \setminus A_1$ . Suppose some vertex  $b \in B_1$  is adjacent to a vertex  $a \in A \setminus A_1$ , this will result in an edge  $a\beta_1$  in  $G_{\bar{s}}$  which contradicts the fact that  $\beta_1$  is a degree-1 vertex. Also, we know that after a series of contractions,  $G[A_1 \cup B_1]$  got contracted to a single edge. By Lemma 15,  $G[A_1 \cup B_1]$  is elementary. Therefore, any minimum sized vertex cover of  $G$  will contain all the  $k$  vertices of  $A_1$  and no vertex from  $B_1$  or all the  $k$  vertices of  $B_1$  and no vertex from  $A_1$ . Now consider any initial configuration of guards on  $G$  with  $n$  guards. As seen above, either all the vertices of  $B_1$  have guards or all the vertices of  $A_1$  have guards and only one of these can happen. If all the vertices of  $A_1$  are occupied by guards, the attacker attacks a matched edge  $a_i b_i$  such that  $a_i \in A_1$ . The guard on  $a_i$  is forced to move to  $b_i$  and cannot move any further. If all the guards cannot reconfigure to form a vertex cover, then  $G$  is not Spartan and hence we are done. Otherwise, all the guards must reconfigure in such a way that all the vertices in  $B_1$  have guards and all the vertices in  $A_1$  do not have guards. Thus without loss of generality, we can assume that all the vertices in  $B_1$  have guards and all the vertices in  $A_1$  do not have guards.

Now recall that no vertex in  $B_1$  has a neighbour in  $A \setminus A_1$ . Since  $G$  is connected, there exists  $a_p \in A_1$  and  $b_q \in B \setminus B_1$  such that  $a_p b_q \in E(G)$ . Since  $a_p$  does not have a guard,  $b_q$  must have a guard as the guards are occupying a vertex cover. Now suppose the attacker attacks the edge  $a_p b_q$ , the guard on  $b_q$  must move to  $a_p$ . Since all the vertices in  $B_1$  have guards but none of them has a neighbour in  $A \setminus A_1$  and no vertex in  $A_1$  had a guard before this guard just moved to  $a_p$ , now no guard can move from  $\{A_1 \cup B_1\}$  to  $V(G) \setminus A_1$ . Thus there will be  $k + 1$  guards on  $k$  matching edges in  $G[A_1 \cup B_1]$ . Therefore, some edge in  $G[V(G) \setminus \{A_1 \cup B_1\}]$  will be vulnerable and can be attacked in the next move. Hence,  $G$  is not Spartan.  $\blacktriangleleft$

► **Remark.** We have actually shown that any bipartite graph  $G$  which is not “essentially elementary” can be destroyed by the attacker in at most three moves when the defender has  $\text{mvc}(G)$  many guards.

► **Definition 14 (Maximal Contraction Graph).** *Let  $G$  be a connected bipartite graph with a perfect matching and there does not exist any special elementary subset  $S$  of  $V(G)$ . Then  $G$  is said to be a **maximal contraction graph**.*

Note that by definition the size of a special subset is always more than 2 and hence if  $|V(G)| = 2$ , i.e.,  $G$  is a single edge, then  $G$  is a maximal contraction graph as  $G$  has no special subset and hence no special elementary subset. Note that the sequence of contractions above ends in a maximal contraction graph that is in fact an edge.

► **Lemma 15 (Maximal Contraction Graph).** *Let  $G$  be a connected bipartite graph with a perfect matching  $M$ . Let  $S$  be a special elementary subset of  $V(G)$  and  $G_S$  be the corresponding matching contraction graph. Then, if  $G_S$  is elementary, then  $G$  is also elementary.*

**Proof.** Let  $G = (A \cup B, E)$ . To show that  $G$  is elementary, we show that  $A$  and  $B$  are the only optimal vertex covers of  $G$ . We assume that the edges of the perfect matching in  $G$  are  $\{a_1b_1, a_2b_2, \dots, a_nb_n\}$  and that the special subset  $S$  is induced by the vertices based on the edges  $\{a_1b_1, \dots, a_kb_k\}$ . Let  $\alpha$  and  $\beta$  denote the endpoints of the edge in  $G_S$  created by the contraction of  $S$ . Finally, let  $(A', B')$  denote the partition of  $G_S$ .

Note that  $G[S]$  is assumed to be elementary. If  $X$  is an optimal vertex cover for  $G$ , then  $X \cap S$  is a vertex cover for  $G[S]$  of size  $k$ , since  $G \setminus S$  has a matching of size  $(n - k)$ . Observe that:

- either  $X \cap A = \{a_1, \dots, a_k\}$  and  $X \cap B = \emptyset$ , or
- $X \cap A = \emptyset$  and  $X \cap B = \{b_1, \dots, b_k\}$ ,

because any other subset of  $k$  vertices that forms a valid vertex cover for  $G[S]$  would contradict the assumption that  $G[S]$  is elementary.

Now assume that  $G$  has a vertex cover  $X$  such that  $X \neq A$  and  $X \neq B$ . Without loss of generality, assume that  $X \cap A = \{a_1, \dots, a_k\}$  (the argument for the other case is symmetric). We let  $X_A := X \cap \{a_{k+1}, \dots, a_n\}$  and  $X_B = X \cap \{b_{k+1}, \dots, b_n\}$ . Note that  $X_B \neq \emptyset$  because  $X \neq A$ .

We now claim that  $X' := X_A \cup X_B \cup \{\alpha\}$  is an optimal vertex cover in  $G_S$  that is different from both  $A'$  and  $B'$ . It is clear that  $|X'| = (n - k + 1)$ , thus the size of  $X'$  is  $\text{mvc}(G_S)$ . Further, since  $\alpha \in A'$  and  $X_B \neq \emptyset$ ,  $X' \neq A'$  and  $X' \neq B'$ . It remains to be shown that  $X'$  covers all edges in  $G_S$ .

Note that if any edge  $a_ib_j$  in  $G_S[\{a_{k+1}, \dots, a_n\} \cup \{b_{k+1}, \dots, b_n\}]$  is not covered by  $X'$ , then the  $a_ib_j$  is also not covered by  $X$  in  $G$ . All edges incident on  $\alpha$  are also covered. Now suppose an edge of the form  $\beta a_\ell$  is not covered by  $X'$  for some  $\ell \in \{a_{k+1}, \dots, a_n\}$ . Note that for this edge to be present in  $G_S$ , by the definition of the contraction operation, there must have been an edge of the form  $b_ia_\ell$ , for some  $i \in [k]$ . Note that if  $\beta a_\ell$  is not covered by  $X'$  then  $b_ia_\ell$  is not covered by  $X$  in  $G$  either, which contradicts our assumption that  $X$  was a vertex cover in  $G$ .

This shows that  $G_S$  has an optimal vertex cover different from both  $A'$  and  $B'$ , but this contradicts our assumption that  $G_S$  was elementary to begin with. Therefore it must be the case that  $G$  is also elementary. ◀

► **Definition 16** (Alternating cycle). *Let  $G$  be a connected bipartite graph with no degree 1 vertex and a perfect matching  $M = \{a_1b_1, a_2b_2, \dots, a_nb_n\}$ . We define a cycle  $a_{i_1}b_{i_1}a_{i_2}b_{i_2} \dots b_{i_k}a_{i_k}a_{i_1}$  in  $G$  as an **alternating cycle** where  $i_1, i_2, \dots, i_k \in [n]$  and  $2 \leq k \leq n$ .*

► **Proposition 17** (No alternating cycle). *Let  $G$  be a maximal contraction graph. Then  $G$  cannot contain any alternating cycle.*

**Proof.** Let  $G$  be a maximal contraction graph. It is clear that  $G$  is a connected bipartite graph with a perfect matching. Let  $M = \{a_1b_1, a_2b_2, \dots, a_nb_n\}$  be a perfect matching of  $G$ . If  $n = 1$ ,  $G$  cannot contain any cycle and hence cannot contain any alternating cycle. Let  $n \geq 2$  and let  $C = a_{i_1}b_{i_1}a_{i_2}b_{i_2} \dots b_{i_k}a_{i_k}a_{i_1}$  be an alternating cycle in  $G$ . Let  $S = V(C)$ . Clearly  $S$  is a special subset of  $V(G)$  and by Proposition 7 and Proposition 10,  $S$  is a special elementary subset of  $V(G)$ . This contradicts the fact that  $G$  is a maximal contraction graph. Thus  $G$  cannot have an alternating cycle. ◀

► **Proposition 18** (Structure of the Maximal Contraction). *Let  $G$  be a maximal contraction graph. Then  $G$  must have a degree 1 vertex.*

## 68:12 Spartan Bipartite Graphs Are Essentially Elementary

**Proof.** Let  $G$  be a maximal contraction graph. It is clear that  $G$  is a connected bipartite graph with a perfect matching. Let  $M = \{a_1b_1, a_2b_2, \dots, a_nb_n\}$  be a perfect matching of  $G$ . If  $n = 1$ , then  $G$  is a single edge and thus  $G$  has a degree 1 vertex. Now let  $n \geq 2$  and assume that  $G$  has no degree 1 vertices. Consider the set  $S = \{a_1, b_1\}$ . Since  $b_1$  is not a degree 1 vertex, we are done. So there exists  $a_{i_1} \neq a_1$  which is a neighbor of  $b_1$ . Add  $a_{i_1}$  and  $b_{i_1}$  to  $S$ . Now for each  $b_{i_p}$  for  $p = 1, 2, \dots$ , there exists  $a_{p+1}$  which is a neighbor of  $b_{i_p}$  because  $G$  has no degree 1 vertex or alternating cycle. Add  $a_{p+1}$  and  $b_{p+1}$  to  $S$ . Thus  $S$  will be an infinite set. But  $S \subset V(G)$  which is finite. Hence we have a contradiction. Thus  $G$  must have a degree 1 vertex. ◀

To sum up the proof of Lemma 3: consider any connected bipartite graph  $G$ . First we have shown that if  $G$  is Spartan, it must have a perfect matching and no degree one vertices. Therefore, a maximal contraction graph derived from  $G$  must be an edge. But note that an edge is elementary, and running the contractions in reverse to recover  $G$  preserves the property of the graph being elementary, and we have the desired conclusion. We remark that our proof shows that every connected bipartite graph with a Hamiltonian cycle is Spartan. However, it turns out that the converse is not true in the sense that there exist connected bipartite graphs that are Spartan but do not have Hamiltonian cycles: for instance, Figure 7 presents an example of a connected bipartite Spartan graph that is not Hamiltonian.

■ **Figure 7** An example of an elementary bipartite graph where the two independent sets are  $A = \{a_1, a_2, a_3, a_4\}$  and  $B = \{b_1, b_2, b_3, b_4\}$  and all the edges belong to one of the three perfect matchings:  $M_1 = \{a_1b_1, a_2b_2, a_3b_3, a_4b_4\}$ ,  $M_2 = \{a_1b_3, a_3b_2, a_2b_1, a_4b_4\}$  or  $M_3 = \{a_1b_1, a_2b_4, a_4b_3, a_3b_2\}$ . It can be verified that this graph does not have a Hamiltonian cycle.

### 3 EVC with Extra Steps

Almost all of the proofs in the previous sections rely crucially on the fact that a guard can only move one step after each attack. This gives rise to the question that what happens if multiple moves are allowed? If retracing of steps is allowed, then any guard can clean up an attack and come back to their original position. Thus this problem will be the same as the vertex cover problem and hence it is not so interesting.

We define a variant of the ETERNAL VERTEX COVER problem that we call *New Eternal Vertex Cover*. Again we have a two player game with one player as “the attacker” and the other player as “the defender”. Just like the ETERNAL VERTEX COVER problem, the defender initially places the guards on some of the vertices of the graph (of his choice). The attacker attacks an edge. In response to the attack, the defender can move each guard for at most *two* steps without retracing. The constraint is however that the defense of the attacked edge must happen in the first move itself, i.e., after the attack, at least one guard who was present on one of the endpoints of the graph must move across the attacked edge. If such a movement is not possible after a finite sequence of attacks, the attacker wins; otherwise, if

the defender has a strategy to defend the graph  $G$  against an infinite sequence of attacks, the defender wins. There can only be one guard per vertex in the configuration before the attack and the configuration after the attack is defended. However, more than one guard can cross a vertex during the reconfiguration.

We define the *New Eternal Vertex Cover Number* of a graph  $G$  as the smallest number of guards required in this new setting such that the defender has a winning strategy. We denote this number by  $\text{nevc}(G)$ . It is clear that since the defense must happen in the first step of a guard, if the vertices occupied by guards do not form a vertex cover, the attacker wins. Therefore, we have  $\text{mvc}(G) \leq \text{nevc}(G)$  for any graph  $G$ . Also, since  $\text{evc}(G)$  many guards can defend an infinite sequence of attacks on a graph  $G$  with each guard moving just one step after each attack, it can be seen that for any graph  $G$ , we have  $\text{nevc}(G) \leq \text{evc}(G)$ .

► **Remark.** These two inequalities imply that for any Spartan graph  $G$ , we have  $\text{mvc}(G) = \text{nevc}(G) = \text{evc}(G)$ . However, there are graph classes where these inequalities are not strict.

We show that computing the *New Eternal Vertex Cover* number for a given graph  $G$  is NP-hard in the next lemma. We use a reduction from the *Vertex Cover* problem. Given an input instance  $(G, k)$  (where  $|V(G)| = n$  and  $k < n - 1$ ) of the *Vertex Cover* problem, we construct an equivalent instance of the *New Eternal Vertex Cover* problem by adding a global vertex  $\star$  to the graph  $G$ , i.e., make the new vertex  $\star$  adjacent to every other vertex in  $G$ . It turns out that  $G$  has a vertex cover of size  $k$  if and only if the defender has a winning strategy in the new setting using  $k + 1$  guards. The proof of equivalence is deferred to the full version due to lack of space.

► **Lemma 19** ( $\star$ ). *The New Eternal Vertex Cover problem is NP-hard.*

► **Lemma 20.** *For any connected graph  $G$ , the defender has a winning strategy using  $\text{mvc}(G) + 1$  guards, i.e.,  $\text{nevc}(G) \leq \text{mvc}(G) + 1$  for any graph  $G$ .*

**Proof.** For any graph  $G$ , we give a winning strategy for the defender in the new setting using  $\text{mvc}(G) + 1$  guards.

Let  $\text{mvc}(G) = k$  and let  $C_1, C_2, \dots, C_q$  be the connected components of the subgraph induced by the vertices of a  $k$ -sized vertex cover of  $G$ . Place one guard on each of these vertices of this vertex cover (say  $S$ ) and one guard in the independent set (say on the vertex  $w$ ).

Now suppose some edge is attacked such that both its endpoints have guards, then the guards can exchange places and the configuration is restored.

Suppose some edge  $uv$  is attacked such that  $u \in S$  and  $v \in V(G) \setminus S$ . Then the guard on  $u$  moves to  $v$ . Suppose  $w$  is adjacent to some vertex which lies in the same connected component of  $S$  as  $w$ , then the guards can each move one step along a path from  $w$  to  $u$  such that there is a guard on  $u$  and all the vertices of  $S$  at the end of this movement and now no guard on  $w$ . But we still have all the vertices of  $S$  with one guard each and one guard in the independent set (now on  $v$ ). Thus we have a configuration just like the initial configuration and each strategy can be implemented here accordingly.

Suppose  $u$  and any neighbour of  $w$  do not lie in the same connected component of  $S$ . As  $G$  is connected, there is a path from  $w$  to  $u$  in  $G$  and this path contains some vertices of  $V(G) \setminus S$ . Let this path be  $w = u_1 u_2 \dots u_\ell = u$ . We trigger a movement of guards along this path as follows: If  $u_{\ell-1}$  has a guard, this guard moves to  $u$ , otherwise  $u_{\ell-2}$  must have a guard because  $S$  is a vertex cover. This guard moves to  $u_{\ell-1}$  and then to  $u$ . Similarly for each  $u_i \in S$  where  $i \in \{\ell - 2, \ell - 3, \dots, 2\}$ , if  $u_{i-1}$  has a guard, the guard on  $u_{i-1}$  moves to  $u_i$ . Otherwise  $u_{i-2}$  must have a guard (because  $S$  is a vertex cover) which moves to  $u_{i-1}$

and then to  $u_i$ . It can be observed that at the end of this movement, all vertices in  $S$  have a guard and  $v$  has a guard and  $w$  does not have a guard. Therefore, we have the same situation as before where all the vertices in the vertex cover have a guard and one guard outside the vertex cover. Thus we have shown that  $\text{mvc}(G) + 1$  many guards are sufficient to defend  $G$  against any sequence of attacks in this new setting. ◀

► **Lemma 21.** *If  $G$  is any graph without a degree-1 vertex, then  $\text{nevc}(G) = \text{mvc}(G)$ .*

**Proof.** It is sufficient to show that  $\text{nevc}(G) \leq \text{mvc}(G)$ , i.e., the defender has a winning strategy using  $\text{mvc}(G)$  many guards. Also it is sufficient to only look at connected graphs.

Let  $\text{mvc}(G) = k$  and let  $S$  be a minimum sized vertex cover of  $G$ . The defender places one guard on each vertex of  $S$ . If any edge with both endpoints in  $S$  is attacked, then the guards exchange their positions and we are back to the same configuration.

Suppose any edge  $uv$  such that  $u \in S$  and  $v \notin S$  is attacked. The guard on  $u$  moves to  $v$ . Since  $v$  is not a degree 1 vertex, it must have a neighbour  $w$  other than  $u$ . Depending on whether  $w$  and  $u$  lie in the same connected component in  $G[S]$  or not, we can trigger a movement of guards just like the proof of Lemma 20 such that each guard moves at most two steps and there is no guard on  $v$  at the end of this movement and there is a guard on  $u$ . Thus the vertex cover  $S$  is restored and we have a winning strategy using  $\text{mvc}(G)$  many guards. ◀

► **Lemma 22.** *For any graph  $G$ ,  $\text{nevc}(G) = \text{mvc}(G)$  if and only if for each degree-1 vertex  $v$  of  $G$ , there exists a minimum sized vertex cover  $S_v$  of  $G$  which contains  $v$ .*

**Proof.** Let  $G$  be a graph such that  $\text{mvc}(G) = k$  and there exists a degree-1 vertex  $v$  such that no  $k$ -sized vertex cover of  $G$  contains  $v$ . Let  $u$  be the neighbour of  $v$ , then any minimum sized vertex cover of  $G$  must contain  $u$ . Therefore, in the initial configuration there must be a guard on  $u$  and no guard on  $v$ . If the attacker attacks the edge  $uv$ , then the defender must move the guard on  $u$  to  $v$ . Since  $v$  has no other neighbour than  $u$  and retracing is not allowed, the guard on  $v$  cannot move anywhere else. Now since there is no vertex cover of size  $k$  which contains  $v$ , the guards cannot reconfigure to form a vertex cover, no matter how the other guards arrange themselves. Thus  $\text{mvc}(G)$  many guards are not sufficient to protect  $G$  and thus  $\text{nevc}(G) \neq \text{mvc}(G)$ .

Now suppose that for every degree-1 vertex  $v$  of  $G$ , there exists a minimum sized vertex cover  $S_v$  of  $G$  which contains  $v$ . Let the size of the minimum sized vertex cover of  $G$  be  $k$ . We now describe a strategy to defend an attack on  $G$  with  $k$  guards. Place each guard on a vertex of a minimum sized vertex cover (say  $S$ ) of  $G$ . Without loss of generality, we assume that some edge  $uv$  such that  $u \in S$  and  $v \notin S$  is attacked. The guard on  $u$  is forced to move to  $v$ . If  $v$  is a vertex with degree 2 or more, then we mimic the strategy in Lemma 20 to get all the guards back on  $S$ . If  $v$  is a degree-1 vertex, we show that it is possible to transfer the guards from  $S$  to  $S_v$  (where  $S_v$  is the minimum sized vertex cover containing  $v$ ).

Denote  $S \cap S_v$  by  $P$  and  $(V(G) \setminus S \cap S_v) \setminus \{v\}$  by  $Q$ . Here  $P$  are the vertices which need to retain a guard and  $Q$  are the vertices which need to gain a guard in order to reconfigure from  $S$  to  $S_v$ . Let  $|P| = p$  and  $|Q| = q$ . Clearly  $p + q + 1 = k$ , i.e.,  $k - p = q + 1$ . Therefore  $|S \setminus P| = |Q \cup \{v\}|$ . We show that there is a perfect matching between these two sets. Notice that there cannot be an edge with both endpoints in  $S \setminus P$  because these vertices are not in  $S_v$  and  $S_v$  is a vertex cover. Suppose there is no perfect matching between  $S \setminus P$  and  $Q \cup \{v\}$ , then there exists a set  $A \in S \setminus P$  such that  $|N(A) \cap (Q \cup \{v\})| < |A|$ . But this is not possible as  $(S \setminus P) \setminus A \cup N(A)$  will be a vertex cover of  $G$  of size less than  $k$ . Thus there exists a perfect matching between  $S \setminus P$  and  $Q \cup \{v\}$  which can be used to reconfigure the guards from  $S$  to  $S_v$ . ◀

► **Corollary 23** ( $\star$ ). *There exists a polynomial time algorithm for finding the New Eternal Vertex Cover number on bipartite graphs.*

Note that if we allow the guards to move for an arbitrary number of steps without retracing after each attack, Lemma 22 still holds, i.e., there are families of graphs (for instance, star graphs) such that even allowing the guards to move for an arbitrary number of steps does not make them “Spartan” in the new setting. Thus the power of one extra step subsumes the power of any number of additional steps.

## 4 Concluding Remarks

We showed that a natural sufficient condition for when a graph is Spartan (i.e, when  $\text{evc}(G) = \text{mvc}(G)$ ) is also necessary in the context of bipartite graphs. Motivated by our proof we extend the notion of eternal vertex cover to a variant where the guards are allowed to move more than one step on their turn, and completely characterize the number of guards needed in terms of  $\text{mvc}$ : indeed, we show that one extra guard suffices, and is needed only if the graph has a degree one vertex that is not contained in any minimum vertex cover.

It would be interesting to see what happens if the defense can happen in the second step of a guard. We also showed that while the new variant remains computationally hard, unlike the original problem, it is in fact solvable in polynomial time on bipartite graphs. Generalizing our structural results beyond bipartite graphs is an interesting direction for future work.

# On the Finite Variable-Occurrence Fragment of the Calculus of Relations with Bounded Dot-Dagger Alternation

Yoshiki Nakamura  

Tokyo Institute of Technology, Japan

---

## Abstract

We introduce the *k*-variable-occurrence fragment, which is the set of terms having at most *k* occurrences of variables. We give a sufficient condition for the decidability of the equational theory of the *k*-variable-occurrence fragment using the finiteness of a monoid. As a case study, we prove that for Tarski's calculus of relations with bounded dot-dagger alternation (an analogy of quantifier alternation in first-order logic), the equational theory of the *k*-variable-occurrence fragment is decidable for each *k*.

## 1 Introduction

Since *the satisfiability problem of first-order logic* is undecidable [8, 30] in general, (un-)decidable classes of first-order logic are widely studied [7]; for example, the undecidability holds even for the *Kahr–Moore–Wang (KMW) class*<sup>1</sup>  $[\forall\exists\forall, (0, \omega)]$  [14], but it is decidable for the *Bernays–Schönfinkel–Ramsey (BSR) class*  $[\exists^*\forall^*, \text{all}] = [3, 27]$ . The calculus of relations (CoR) [28], revived by Tarski, is an algebraic system on binary relations; its expressive power is equivalent to that of the three-variable fragment of first-order logic with equality [28, 29], w.r.t. binary relations. The equational theory of CoR is undecidable [28, 29]<sup>2</sup> in general, which follows from the undecidability of the KMW class, but, for example, it is decidable for the *(existential) positive fragment* [2, 26] and the *existential fragment* [22] of CoR, which follows from the decidability of the BSR class. On the undecidability of CoR, the undecidability holds even for the 1-variable fragment [16] and even for the 1-variable fragment only with union, composition, and complement [19], where the *k*-variable fragment denotes the set of terms having at most *k* variables.

---

<sup>1</sup> Recall the notation for *prefix-vocabulary classes* [7, Def. 1.3.1]. E.g.,  $[\forall\exists\forall, (0, \omega)]$  denotes the set of prenex sentences  $\varphi$  of first-order logic without equality, function symbols, nor constants such that the quantifier prefix of  $\varphi$  is  $\forall\exists\forall$ ;  $\varphi$  has  $\omega$  (countably infinitely many) binary relation symbols and  $\varphi$  does not have 1- nor *i*-ary relation symbols for  $i \geq 3$ .

<sup>2</sup> In [29], the undecidability of the equational theory is shown for more general classes of relation algebras.

Then, from the undecidability result for the 1-variable fragment of CoR [16, 19] above, the following natural question arises – Is it decidable for the  $k$ -variable-occurrence fragment of CoR? Here, the  $k$ -variable-occurrence fragment denotes the set of terms having at most  $k$  occurrences of variables. For example, when  $a, b$  are variables and  $1$  is a constant, the term  $(a \cdot b) \cdot (1 \cdot (a \cdot b))$  has 4 occurrences of variables and 1 occurrence of constants; thus, this term is in the 4-variable-occurrence fragment (cf. the term is in the 2-variable fragment since the variables  $a, b$  occur). While one may seem that this restriction immediately implies the decidability, the equational theory of the  $k$ -variable-occurrence fragment on some (single) algebra is undecidable in general even when  $k = 0$  (Remark 2).

Our contribution is to prove that the equational theory of the  $k$ -variable-occurrence fragment is decidable for CoR *with bounded dot-dagger alternation*, where the dot-dagger alternation [20, 21] is an analogy of the quantifier alternation in first-order logic. Note that the equational theory of the  $k$ -variable fragment is undecidable in general for CoR [16, 19] (even with bounded dot-dagger alternation (Prop. 24)).

Our strategy is to prove that the number of terms in the  $k$ -variable-occurrence fragment is finite up to the semantic equivalence relation. To this end, (1) we decompose terms as much as possible; and then (2) we show that each decomposed part is finite up to the semantic equivalence relation by collecting valid equations. By the preprocessing of (1), one can see that for (2), essentially, it suffices to prove the finiteness of some monoid (using the method of Sect. 2). Its finiteness is not clear, as it is undecidable whether a (finitely presented) monoid is finite in general; but, fortunately, we can prove the finiteness (Thm. 25) by finding valid equations (Fig. 1).

The rest of this paper is structured as follows. Sect. 2 introduces the  $k$ -variable-occurrence fragment for general algebras and gives a framework to prove the decidability from the finiteness of a monoid. Sect. 3 recalls the syntax and semantics of CoR and the dot-dagger alternation hierarchy. In Sect. 4, based on Sect. 2, we prove that the equational theory of CoR with bounded dot-dagger alternation is decidable. Sect. 5 concludes this paper.

We write  $\mathbb{N}$  for the set of all non-negative integers. For  $l, r \in \mathbb{N}$ , we write  $[l, r]$  for the set  $\{i \in \mathbb{N} \mid l \leq i \leq r\}$ . For a set  $A$ , we write  $\#A$  for the cardinality of  $A$  and  $\wp(A)$  for the power set of  $A$ . For a set  $A$  and an equivalence relation  $\sim$  on  $A$ , we write  $A/\sim$  for the quotient set of  $A$  by  $\sim$  and  $[a]_{\sim}$  for the equivalence class of an element  $a \in A$  on  $\sim$ .

## 2 On the $k$ -variable-occurrence fragment

We fix  $\Sigma$  as a non-empty *finite* set of variables. We fix  $S$  as a *finite* algebraic signature;  $S$  is a map from a finite domain (of functions) to  $\mathbb{N}$ . For each  $\langle f, n \rangle \in S$ , we write  $f^{(n)}$ ; it is the function symbol  $f$  with arity  $n$ . We also let  $S^{(n)} \triangleq \{f^{(m)} \in S \mid m = n\}$ . The set  $\mathbf{T}$  of  $S$ -terms over  $\Sigma$  is defined as the minimal set closed under the following two rules:  $a \in \Sigma \implies a \in \mathbf{T}$ ;  $(f^{(n)} \in S \text{ and } t_1, \dots, t_n \in \mathbf{T}) \implies f(t_1, \dots, t_n) \in \mathbf{T}$ .

An  $S$ -algebra  $A$  is a tuple  $\langle |A|, \{f^A\}_{f^{(n)} \in S} \rangle$ , where  $|A|$  is a non-empty finite set and  $f^A: |A|^n \rightarrow |A|$  is an  $n$ -ary map for each  $f^{(n)} \in S$ . A *valuation*  $\mathbf{v}: \Sigma \rightarrow |A|$  on an  $S$ -algebra  $A$  is a map; we write  $\hat{\mathbf{v}}: \mathbf{T} \rightarrow |A|$  for the unique homomorphism extending  $\mathbf{v}$ . For a class  $\mathcal{C}$  of  $S$ -algebras, the equivalence relation  $\sim_{\mathcal{C}}$  on  $\mathbf{T}$  is defined by:  $t \sim_{\mathcal{C}} s \iff \hat{\mathbf{v}}(t) = \hat{\mathbf{v}}(s)$  for all valuations  $\mathbf{v}$  on all algebras in  $\mathcal{C}$ . For a set  $T \subseteq \mathbf{T}$ , the equational theory of  $T$  over  $\mathcal{C}$  is the set  $\{\langle t, s \rangle \in T^2 \mid t \sim_{\mathcal{C}} s\}$ .

► **Definition 1** (*k*-variable-occurrence fragment). For an *S*-term  $t$ , let  $\text{vo}(t)$  be the number of occurrences of variables in  $t$ :  $\text{vo}(t) \triangleq \begin{cases} 1 & (t \in \Sigma) \\ \sum_{i=1}^n \text{vo}(t_i) & (t = f(t_1, \dots, t_n)) \end{cases}$ . For each set  $T$  of *S*-terms, the *k*-variable-occurrence fragment  $T_{(\text{vo} \leq k)}$  is the set  $\{t \in T \mid \text{vo}(t) \leq k\}$ . (Similarly, let  $T_{(\text{vo} = k)} \triangleq \{t \in T \mid \text{vo}(t) = k\}$ .) Clearly,  $T = \bigcup_{k \in \mathbb{N}} T_{(\text{vo} \leq k)}$ .

► **Remark 2.** The equational theory of the *k*-variable-occurrence fragment is undecidable in general, even when  $k = 0$ . It follows from the reduction from the word problem for monoids. Let  $M = \langle |M|, \circ^M, \mathbf{1}^M \rangle$  be a (finitely) presented monoid with finite generators  $C = \{c_1, \dots, c_l\}$  such that the word problem for  $M$  is undecidable (by Markov [17] and Post [25]). We define  $S \triangleq \{c_1^{(1)}, \dots, c_l^{(1)}\} \cup \{\mathbf{1}^{(0)}\}$  and the *S*-algebra  $A \triangleq \langle |A|, \{f^A\}_{f^{(n)} \in S} \rangle$  by:  $|A| = |M|$ ;  $c_i^A(x) = c_i \circ^M x$  for  $i \in [1, l]$ ;  $\mathbf{1}^A = \mathbf{1}^M$ . By definition, for all two words  $a_1 \dots a_n, b_1 \dots b_m$  over  $C$ : they are equivalent in  $M$  iff  $a_1(a_2(\dots a_n(\mathbf{1}) \dots)) \sim_{\{A\}} b_1(b_2(\dots b_m(\mathbf{1}) \dots))$ .

In the rest of this section, we fix  $\mathcal{C}$  as a class of *S*-algebras.

## 2.1 On the finiteness of *k*-variable-occurrence fragment: from 1 to *k*

How can we show the decidability of the equational theory of the *k*-variable-occurrence fragment? We consider proving it from the finiteness up to the semantic equivalence relation:

► **Proposition 3** (Cor. of [5, 15] for the complexity). Let  $T \subseteq \mathbf{T}$  be a subterm-closed<sup>3</sup> set. If the set  $T/\sim_{\mathcal{C}}$  is finite, the equational theory of  $T$  over  $\mathcal{C}$  is decidable. Moreover, it is decidable in DLOGTIME-uniform NC<sup>1</sup> if the input is given as a well-bracketed string.

**Proof Sketch.** Because  $\mathcal{C}$  is fixed and  $T/\sim_{\mathcal{C}}$  is finite, for each  $t \in T$ , one can calculate the index of the equivalence class of  $t$  on  $\sim_{\mathcal{C}}$  by using the (finite and possibly partial) Cayley table of each operator; thus, the equational theory is decidable. Moreover, according to this algorithm, if the input is given as a well-bracketed string, one can also construct a parenthesis context-free grammar such that for all  $t, s \in T$ , the well-bracketed string encoding the equation  $t = s$  is in the language iff  $t \sim_{\mathcal{C}} s$ . Hence, the complexity is shown because every language recognized by a parenthesis context-free grammar is in ALOGTIME [5, 6] (ALOGTIME is equivalent to DLOGTIME-uniform NC<sup>1</sup> [18]). ◀

For the *k*-variable-occurrence fragment, the finiteness of  $T_{(\text{vo} \leq 1)}$  (with Prop. 3) can imply the decidability of the equational theory of  $T_{(\text{vo} \leq k)}$  (Lem. 6) by the following decomposition lemma. Here, we write  $t[s/a]$  for the term  $t$  in which each  $a$  has been replaced with  $s$ .

► **Lemma 4.** Let  $T \subseteq \mathbf{T}$  be a subterm-closed set. Let  $k \geq 2$ ,  $a \in \Sigma$ . Then, for all  $t \in T_{(\text{vo} = k)}$ , there are  $t_0 \in T_{(\text{vo} \leq 1)}$ ,  $f^{(n)} \in S$ ,  $t_1, \dots, t_n \in T_{(\text{vo} \leq k-1)}$  such that  $t = t_0[f(t_1, \dots, t_n)/a]$ .

**Proof.** By induction on  $t$ . Since  $k \geq 2$ , there are  $g^{(m)} \in S$ ,  $s_1, \dots, s_m \in T$  s.t.  $t = g(s_1, \dots, s_m)$  and  $\sum_{i=1}^m \text{vo}(s_i) = k$ . Case  $\text{vo}(s_i) \leq k-1$  for all  $i$ : By letting  $t_0 \triangleq a$ , we have  $t = t_0[g(s_1, \dots, s_m)/a]$ . Otherwise: Let  $i$  be s.t.  $\text{vo}(s_i) = k$ . Since  $s_i \in T_{(\text{vo} = k)}$ , let  $u \in T_{(\text{vo} \leq 1)}$ ,  $f^{(n)} \in S$ ,  $t_1, \dots, t_n \in T_{(\text{vo} \leq k-1)}$  be the ones obtained by IH w.r.t.  $s_i$ , so that  $s_i = u[f(t_1, \dots, t_n)/a]$ . By letting  $t_0 \triangleq g(s_1, \dots, s_{i-1}, u, s_{i+1}, \dots, s_m)$ , we have:

<sup>3</sup> A set  $T \subseteq \mathbf{T}$  is subterm-closed if for every  $t \in T$ , if  $s$  a subterm of  $t$ , then  $s \in T$ .

$$\begin{aligned}
 t_0[f(t_1, \dots, t_n)/a] &= g(s_1, \dots, s_{i-1}, u, s_{i+1}, \dots, s_m)[f(t_1, \dots, t_n)/a] \\
 &= g(s_1, \dots, s_{i-1}, u[f(t_1, \dots, t_n)/a], s_{i+1}, \dots, s_m) \quad (\text{vo}(s_j) = 0 \text{ if } j \neq i) \\
 &= g(s_1, \dots, s_{i-1}, s_i, s_{i+1}, \dots, s_m) = t. \quad (s_i = u[f(t_1, \dots, t_n)/a])
 \end{aligned}$$

Hence, this completes the proof.  $\blacktriangleleft$

► **Example 5** (of Lem. 4). If  $S = \{\circ^{(2)}, \text{l}^{(0)}\}$  and  $a, b, c \in \Sigma$ , the term  $t = \text{l} \circ ((a \circ (b \circ c)) \circ \text{l}) \in \mathbf{T}_{(\text{vo} \leq 3)}$  has the following decomposition:  $t = (\text{l} \circ (a \circ \text{l})) [a \circ (b \circ c) / a]$ . Then  $\text{l} \circ (a \circ \text{l}) \in \mathbf{T}_{(\text{vo} \leq 1)}$  and  $a, (b \circ c) \in \mathbf{T}_{(\text{vo} \leq 2)}$ . The following is an illustration of the decomposition, where the number written in each subterm  $s$  denotes  $\text{vo}(s)$ :

Using this decomposition iteratively, we have the following:

► **Lemma 6.** *Let  $T \subseteq \mathbf{T}$  be a subterm-closed set. Assume that  $T_{(\text{vo} \leq 1)} / \sim_c$  is finite. Then, for each  $k \in \mathbb{N}$ , the set  $T_{(\text{vo} \leq k)} / \sim_c$  is finite.*

**Proof.** It suffices to prove: for all  $k \geq 2$ ,  $T_{(\text{vo} = k)} / \sim_c$  is finite. By induction on  $k$ . We have:

$$\begin{aligned}
 &\#(T_{(\text{vo} = k)} / \sim_c) \\
 &\leq \#(\{t_0[f(t_1, \dots, t_n)/a] \mid f^{(n)} \in S, t_1, \dots, t_n \in T_{(\text{vo} \leq k-1)}, t_0 \in T_{(\text{vo} \leq 1)}\} / \sim_c) \quad (\text{Lem. 4}) \\
 &\leq \sum_{f^{(n)} \in S} \#(\{t_0[f(t_1, \dots, t_n)/a] \mid t_1, \dots, t_n \in T_{(\text{vo} \leq k-1)}, t_0 \in T_{(\text{vo} \leq 1)}\} / \sim_c).
 \end{aligned}$$

Then the set  $\{t_0[f(t_1, \dots, t_n)/a] \mid t_1, \dots, t_n \in T_{(\text{vo} \leq k-1)}, t_0 \in T_{(\text{vo} \leq 1)}\} / \sim_c$  is finite because  $T_{(\text{vo} \leq k-1)} / \sim_c$  is finite (by IH) and  $\sim_c$  satisfies the congruence law. Thus, the last term above is finite since  $S$  is finite. Hence  $T_{(\text{vo} = k)} / \sim_c$  is finite.  $\blacktriangleleft$

## 2.2 The monoid of the 1-variable-occurrence fragment

Thanks to Lem. 6, we can focus on the 1-variable-occurrence fragment. For the 1-variable-occurrence fragment, it suffices to consider a monoid. For a set  $A$  of characters, we write  $A^*$  for the set of all words (i.e., finite sequences) over the alphabet  $A$ . We write  $wv$  for the concatenation of words  $w$  and  $v$  and write  $\varepsilon$  for the empty word. We write  $\|w\|$  for the length of a word  $w$ .

► **Definition 7.** *Let  $\dot{\Sigma}$  be the (possibly infinite) set of characters defined by:*

$$\dot{\Sigma} \triangleq \bigcup_{f^{(n)} \in S, i \in [1, n]} \{f(t_1, \dots, t_{i-1}, \_, t_{i+1}, \dots, t_n) \mid \forall j \in [1, n] \setminus \{i\}, t_j \in \mathbf{T}_{(\text{vo} \leq 0)}\}.$$

( $\_$  denotes “blank”.) For a word  $w \in \dot{\Sigma}^*$  and a term  $t \in \mathbf{T}$ , let  $w[t]$  be the term defined by:

$$w[t] \triangleq \begin{cases} f(t_1, \dots, t_{i-1}, w'[t], t_{i+1}, \dots, t_n) & (w = f(t_1, \dots, t_{i-1}, \_, t_{i+1}, \dots, t_n)w') \\ t & (w = \varepsilon) \end{cases}.$$

► **Example 8** (of Def. 7). If  $S = \{\circ^{(2)}, \mathbf{l}^{(0)}\}$ , then  $\dot{\Sigma} = \{(\mathbf{l} \circ \_), ((\mathbf{l} \circ \mathbf{l}) \circ \_), \dots (\_ \circ \mathbf{l}), \dots\}$ . For example, if  $w = ((\mathbf{l} \circ \mathbf{l}) \circ \_)(\_ \circ \mathbf{l})(\mathbf{l} \circ \_)$ , we have:

$$\begin{aligned} w[a] &= (((\mathbf{l} \circ \mathbf{l}) \circ \_)(\_ \circ \mathbf{l})(\mathbf{l} \circ \_)[a]) = (\mathbf{l} \circ \mathbf{l}) \circ ((\_ \circ \mathbf{l})(\mathbf{l} \circ \_)[a]) \\ &= (\mathbf{l} \circ \mathbf{l}) \circ (((\mathbf{l} \circ \_)[a]) \circ \mathbf{l}) \\ &= (\mathbf{l} \circ \mathbf{l}) \circ ((\mathbf{l} \circ \varepsilon[a]) \circ \mathbf{l}) = (\mathbf{l} \circ \mathbf{l}) \circ ((\mathbf{l} \circ a) \circ \mathbf{l}). \end{aligned}$$

► **Proposition 9.** For all  $t \in \mathbf{T}_{(\mathbf{v}_0 \leq 1)}$ , there are  $w \in \dot{\Sigma}^*$  and  $s \in S^{(0)} \cup \Sigma$  s.t.  $t = w[s]$ .

**Proof.** By easy induction on  $t$ . ◀

► **Definition 10.** Let  $\sim_{\mathcal{C}}$  be the equivalence relation on  $\dot{\Sigma}^*$  defined by:

$$w \sim_{\mathcal{C}} v \iff w[a] \sim_{\mathcal{C}} v[a] \text{ where } a \in \Sigma \text{ is any variable.}$$

► **Lemma 11.** If  $\dot{\Sigma}^*/\sim_{\mathcal{C}}$  is finite, then  $\mathbf{T}_{(\mathbf{v}_0 \leq 1)}/\sim_{\mathcal{C}}$  is finite.

**Proof.** By Prop. 9 (and that the set  $S^{(0)} \cup \Sigma$  is finite). ◀

Moreover, if  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}}$  is finite, it suffices to consider a finite subset of  $\dot{\Sigma}$ , as follows:

► **Lemma 12.** Assume that  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}}$  is finite. Let  $T_0 = \{t_1, \dots, t_n\} \subseteq \mathbf{T}_{(\mathbf{v}_0 \leq 0)}$  be such that  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}} = \{[t_1]_{\sim_{\mathcal{C}}}, \dots, [t_n]_{\sim_{\mathcal{C}}}\}$ . Let  $\dot{\Sigma}_0 \subseteq \dot{\Sigma}$  be the finite set defined by:

$$\dot{\Sigma}_0 \triangleq \bigcup_{f^{(n)} \in S, i \in [1, n]} \{f(t_1, \dots, t_{i-1}, \_, t_{i+1}, \dots, t_n) \mid \forall j \in [1, n] \setminus \{i\}, t_j \in T_0\}.$$

Then  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite  $\implies \dot{\Sigma}^*/\sim_{\mathcal{C}}$  is finite.

**Proof.** For every  $a \in \dot{\Sigma}$ , there is  $b \in \dot{\Sigma}_0$  s.t.  $a \sim_{\mathcal{C}} b$ . By the congruence law of  $\sim_{\mathcal{C}}$ , for every  $w \in \dot{\Sigma}^*$ , there is some  $v \in \dot{\Sigma}_0^*$  s.t.  $w \sim_{\mathcal{C}} v$ . Since  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite, this completes the proof. ◀

► **Example 13** (of Lem. 12). If  $S = \{\circ^{(2)}, \mathbf{l}^{(0)}\}$  (so,  $\dot{\Sigma} = \{(\mathbf{l} \circ \_), ((\mathbf{l} \circ \mathbf{l}) \circ \_), \dots (\_ \circ \mathbf{l}), \dots\}$ ) and  $\mathcal{C}$  is the class of all monoids, we have:  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}} = \{[\mathbf{l}]_{\sim_{\mathcal{C}}}\}$ . Thus the set  $\dot{\Sigma}_0 = \{(\mathbf{l} \circ \_), (\_ \circ \mathbf{l})\}$  is sufficient for considering the finiteness of  $\dot{\Sigma}^*/\sim_{\mathcal{C}}$ .

Thus, to prove the finiteness of  $\mathbf{T}_{(\mathbf{v}_0 \leq k)}/\sim_{\mathcal{C}}$ , it suffices to prove that both  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}}$  and  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  are finite:

► **Lemma 14.** If  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}}$  and  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  are finite, then for each  $k \in \mathbb{N}$ , the set  $\mathbf{T}_{(\mathbf{v}_0 \leq k)}/\sim_{\mathcal{C}}$  is finite (hence, the equational theory of  $\mathbf{T}_{(\mathbf{v}_0 \leq k)}$  over  $\mathcal{C}$  is decidable).

**Proof.** We have:  $\mathbf{T}_{(\mathbf{v}_0 \leq 0)}/\sim_{\mathcal{C}}$  and  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  are finite  $\implies \dot{\Sigma}^*/\sim_{\mathcal{C}}$  is finite (by Lem. 12)  $\implies \mathbf{T}_{(\mathbf{v}_0 \leq 1)}/\sim_{\mathcal{C}}$  is finite (by Lem. 11)  $\implies \mathbf{T}_{(\mathbf{v}_0 \leq k)}/\sim_{\mathcal{C}}$  is finite (by Lem. 6). (The decidability is obtained from Prop. 3.) ◀

### 2.3 Finiteness from finding equations

For languages  $L, K$ , we write  $LK$  for the concatenation of  $L$  and  $K$ :  $LK = \{wv \mid w \in L, v \in K\}$ . For words  $w_i$  ( $i \in I$ ), we write  $\bigcup_{i \in I} w_i$  for the language  $\{w_i \mid i \in I\}$ .

For the finiteness of  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$ , we consider finding equations  $\{\langle w_i, v_i \rangle \mid i \in I\}$  and then applying the following:

► **Lemma 15.** *Let  $\dot{\Sigma}_0 \subseteq \dot{\Sigma}$  be a finite set. Let  $\langle \cdot \rangle \subseteq (\dot{\Sigma}_0^*)^2$  be a well-founded relation s.t.*

- $\langle \cdot \rangle$  satisfies the congruence law (i.e.,  $v < v' \implies wv < wv'$ );
- $\langle \cdot \rangle$  has no infinite antichains.<sup>4</sup>

Then, the following are equivalent:

1. There is a finite set  $\{\langle w_i, v_i \rangle \mid i \in I\} \subseteq \langle \cdot \rangle \cap (\sim_{\mathcal{C}})$  such that the language  $\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$  over the alphabet  $\dot{\Sigma}_0$  is cofinite.<sup>5</sup>
2.  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite.

**Proof.**  $1 \implies 2$ : By induction on the well-founded relation  $\langle \cdot \rangle$ , we prove: For every  $w \in \dot{\Sigma}_0^*$ , there is some  $v \in \dot{\Sigma}_0^* \setminus (\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*)$  such that  $w \sim_{\mathcal{C}} v$ . If  $w \in \dot{\Sigma}_0^* \setminus (\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*)$ , by letting  $v = w$ . Otherwise, since  $w \in \dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$ , there are  $i \in I$  and  $w', w'' \in \dot{\Sigma}_0^*$  such that  $w = w'v_iw''$ . By  $w'w_iw'' < w'v_iw''$  (the congruence law of  $\langle \cdot \rangle$ ) and IH, there is  $v \in \dot{\Sigma}_0^* \setminus (\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*)$  s.t.  $w'w_iw'' \sim_{\mathcal{C}} v$ . We also have  $w'v_iw'' \sim_{\mathcal{C}} w'w_iw''$  (by  $v_i \sim_{\mathcal{C}} w_i$  with the congruence law of  $\sim_{\mathcal{C}}$ ). Thus  $w'v_iw'' \sim_{\mathcal{C}} v$  (by transitivity of  $\sim_{\mathcal{C}}$ ).

$2 \implies 1$ : Let  $W \triangleq \bigcup_{X \in \dot{\Sigma}_0^*/\sim_{\mathcal{C}}} \{w \in X \mid w \text{ is minimal w.r.t. } \langle \cdot \rangle \cap X^2\}$ . Let  $\text{Subw}(W)$  be the subword closure of  $W$  (i.e., the minimal set  $W' \supseteq W$  s.t.  $w'ww'' \in W' \implies w \in W'$ ). Let  $V \triangleq (\text{Subw}(W)\dot{\Sigma}_0) \setminus \text{Subw}(W)$ . Then  $(\dot{\Sigma}_0^*V\dot{\Sigma}_0^*) = \dot{\Sigma}_0^* \setminus \text{Subw}(W)$  holds, as follows. For  $\subseteq$ : Let  $w \in \dot{\Sigma}_0^*$ ,  $v \in V$ ,  $w' \in \dot{\Sigma}_0^*$ . If we assume  $wv < wv'$ , then  $v \in \text{Subw}(W)$ , but this contradicts  $v \in V$ ; thus,  $wv < wv' \notin \text{Subw}(W)$ . For  $\supseteq$ : By induction on the length of  $w \in \dot{\Sigma}_0^* \setminus \text{Subw}(W)$ . If  $w \in V$ , clear. If  $w \notin V$ , let  $w = w'a$  (note that  $w \neq \varepsilon$ , because  $\varepsilon \in \text{Subw}(W)$  always by that  $W$  is not empty). Then,  $w' \in \dot{\Sigma}_0^* \setminus \text{Subw}(W)$  (if not, since  $w' \in \text{Subw}(W)$  and  $w \notin \text{Subw}(W)$ ,  $w \in V$ , reaching a contradiction). Thus by IH,  $w' \in \dot{\Sigma}_0^*V\dot{\Sigma}_0^*$ ; thus  $w \in \dot{\Sigma}_0^*V\dot{\Sigma}_0^*$ . Hence, we have  $\dot{\Sigma}_0^* \setminus (\dot{\Sigma}_0^*V\dot{\Sigma}_0^*) = \text{Subw}(W)$ . Now, the set  $W$  is finite because  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite and for each  $X \in \dot{\Sigma}_0^*/\sim_{\mathcal{C}}$ , the number of minimal elements  $w$  is finite (because  $\langle \cdot \rangle$  has no infinite antichains); thus  $\text{Subw}(W)$  is finite; thus  $V$  is finite. Let  $V = \{v_1, \dots, v_n\}$ . For every  $i \in [1, n]$ , there is  $w_i \in W \cap [v_i]_{\sim_{\mathcal{C}}}$  s.t.  $w_i < v_i$ , because  $v_i$  is not minimal w.r.t.  $\langle \cdot \rangle \cap [v_i]_{\sim_{\mathcal{C}}}^2$ . Hence,  $\{\langle w_i, v_i \rangle \mid i \in [1, n]\}$  is the desired set. ◀

The *shortlex order* (aka *length-lexicographical order*) is an example of  $\langle \cdot \rangle$  in Lem. 15 (because it is a well-ordering [4, Def. 2.2.3] and it satisfies the congruence law).

► **Example 16** (toy example of Lem. 15 ( $1 \implies 2$ )). Let  $S = \{\circ^{(2)}, \text{I}^{(0)}, -^{(1)}\}$  and  $\mathcal{C}$  be the class of groups. Let  $\dot{\Sigma}_0 = \{\text{I} \circ \_, (\_ \circ \text{I}), \_ -\}$ . Then, we have the following 3 equations:

$$\varepsilon \sim_{\mathcal{C}} (\text{I} \circ \_) \qquad \varepsilon \sim_{\mathcal{C}} (\_ \circ \text{I}) \qquad \varepsilon \sim_{\mathcal{C}} (\_ -)(\_-).$$

(This is because  $a \sim_{\mathcal{C}} (\text{I} \circ a)$ ,  $a \sim_{\mathcal{C}} (a \circ \text{I})$ , and  $a \sim_{\mathcal{C}} (a^-)^-$  hold, respectively.) Then, the language  $(\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*) = \dot{\Sigma}_0^* \setminus \{\varepsilon, \_ -\}$  is cofinite. Thus, from the 3 equations, we have that  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite. (Use a shortlex order as  $\langle \cdot \rangle$  in Lem. 15.)

<sup>4</sup> This assumption is used only in the direction of  $2 \implies 1$ .

<sup>5</sup> A language  $L$  over an alphabet  $A$  is cofinite if its complemented language  $A^* \setminus L$  is finite.

While it is undecidable whether a given (finitely presented) monoid  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite [17] (see also [4, Thm. 7.3.7 with Def. 7.3.2(b)]) in general (cf. 2 of Lem. 15), it is decidable (in linear time) whether the language of a given regular expression of the form  $\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$  is cofinite (cf. 1 of Lem. 15):

► **Proposition 17.** *The following is decidable in linear time (more precisely,  $\mathcal{O}(n)$  time on a random-access machine for  $n$  the number of symbols in the given regular expression): Given a regular expression of the form  $\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$  over the alphabet  $\dot{\Sigma}_0$ , is its language cofinite?*

**Proof Sketch.** By the Aho-Corasick algorithm, we can construct a deterministic finite automaton (DFA) from a given regular expression of the form  $\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$  in linear time [1, Sect. 8]. By taking the complemented language of the DFA, it suffices to show that the following problem is in  $\mathcal{O}(n)$  time: given a DFA with  $n$  states, is its language finite? Then we can give the following algorithm: From the graph induced by the DFA, remove all the states not reachable from the starting state and remove all the states not reachable to any accepting states by using the depth-first search; check whether there exists some cycle in the graph by the depth-first search. ◀

Thus, thanks to  $1 \implies 2$  of Lem. 15, we can focus on finding a finite set of equations. While it is undecidable in general whether there exists such a set, we give a possibly non-terminating pseudo-code in Algorithm 1, which can help to find equations (e.g., Fig. 1).<sup>6</sup>

■ **Algorithm 1** Possibly non-terminating pseudo-code for ensuring the finiteness of  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$ .

---

**Require:** Given  $S, \Sigma, \sim_{\mathcal{C}}, \dot{\Sigma}_0$ . ▷  $\dot{\Sigma}_0$  is a finite alphabet of Lem. 12.  
**Ensure:** Is  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  finite?  
1:  $\Gamma \leftarrow \emptyset$  ▷ We use  $I, w_i, v_i$  to denote  $\Gamma = \{\langle w_i, v_i \rangle \mid i \in I\}$ .  
2: **while** the language  $\dot{\Sigma}_0^*(\bigcup_{i \in I} v_i)\dot{\Sigma}_0^*$  over  $\dot{\Sigma}_0$  is not cofinite **do**  
3:    $\langle w, v \rangle \leftarrow$  a fresh pair in  $\dot{\Sigma}_0^* \times \dot{\Sigma}_0^*$  ▷  $<$  is a binary relation in (Lem. 15).  
4:   **if**  $w < v$  and  $w \sim_{\mathcal{C}} v$  **then**  $\Gamma \leftarrow \Gamma \cup \{\langle w, v \rangle\}$   
5:   **end if**  
6: **end while**  
7: **return** True

---

► **Remark 18.** If “given  $w, v$ , does  $w \sim_{\mathcal{C}} v$  hold” is decidable, then Algorithm 1 is a semi-algorithm (i.e., if  $\dot{\Sigma}_0^*/\sim_{\mathcal{C}}$  is finite, it is terminated and returns True; otherwise, not terminated). This is because  $2 \implies 1$  of Lem. 15 also holds.

### 3 The calculus of relations with bounded dot-dagger alternation

In the remaining part of this paper, as a case study of the  $k$ -variable-occurrence fragment presented in Sect. 2, we consider the calculus of relations with bounded dot-dagger alternation. In this section, we recall the definitions of the calculus of relations (CoR) and the dot-dagger alternation hierarchy.

<sup>6</sup> Usually, to calculate  $\sim_{\mathcal{C}}$  is a bottleneck. For relaxing this problem, for example, hashing words by using some algebras in  $\mathcal{C}$  is practically useful for reducing the number of  $\sim_{\mathcal{C}}$  calls (since if the hash of two words  $w, v$  are different, then we immediately have that  $w, v$  are not equivalent w.r.t.  $\sim_{\mathcal{C}}$ ).

### 3.1 CoR: syntax and semantics

We fix  $\Sigma$  as a non-empty *finite* set of variables. Consider the finite algebraic signature  $S^{\text{CoR}} \triangleq \{\perp^{(0)}, \top^{(0)}, -^{(1)}, \cup^{(2)}, \cap^{(2)}, \text{I}^{(0)}, \text{D}^{(0)}, \cdot^{(2)}, \dagger^{(2)}\} \cup \{\pi^{(1)} \mid \pi \text{ is a map in } [1, 2]^{[1, 2]}\}$  (we consider algebras of binary relations and each  $\pi$  is used for a projection of binary relations). The set  $\mathbf{T}^{\text{CoR}}$  of CoR terms is defined as follows:

$$\mathbf{T}^{\text{CoR}} \ni t, s, u ::= a \mid \perp \mid \top \mid s \cup u \mid s \cap u \mid s^- \\ \mid \text{I} \mid \text{D} \mid s \cdot u \mid s \dagger u \mid s^\pi \quad (a \in \Sigma, \pi \in [1, 2]^{[1, 2]}).$$

Additionally, for a term  $t$ , we use  $t^\sim$  to denote the term  $t^\sim \triangleq t^{\{1 \rightarrow 2, 2 \rightarrow 1\}}$ . Here, we use the infix notation for binary operators, the superscript notation for unary operators, and parenthesis in ambiguous situations, as usual.

For binary relations  $R, S$  on a set  $W$ , the *identity relation*  $\text{I}_W$  on  $W$ , the *difference relation*  $\text{D}_W$  on  $W$ , the *(relational) composition (relative product)*  $R \cdot S$ , the *dagger (relative sum)*  $R \dagger S$ , and the *projection*  $R^\pi$  are defined by:

$$\begin{aligned} \text{I}_W &\triangleq \{\langle x, y \rangle \in W^2 \mid x = y\} && \text{(identity)} \\ \text{D}_W &\triangleq \{\langle x, y \rangle \in W^2 \mid x \neq y\} && \text{(difference)} \\ R \cdot S &\triangleq \{\langle x, y \rangle \in W^2 \mid \exists z \in W, \langle x, z \rangle \in R \wedge \langle z, y \rangle \in S\} && \text{(relative product)} \\ R \dagger S &\triangleq \{\langle x, y \rangle \in W^2 \mid \forall z \in W, \langle x, z \rangle \in R \vee \langle z, y \rangle \in S\} && \text{(relative sum)} \\ R^\pi &\triangleq \{\langle x_1, x_2 \rangle \in W^2 \mid \langle x_{\pi(1)}, x_{\pi(2)} \rangle \in R\} && \text{(projection)}. \end{aligned}$$

A structure  $\mathfrak{A}$  is a tuple  $\langle |\mathfrak{A}|, \{a^\mathfrak{A}\}_{a \in \Sigma} \rangle$ , where  $|\mathfrak{A}|$  is a non-empty set and  $a^\mathfrak{A} \subseteq |\mathfrak{A}|^2$  is a binary relation for each  $a \in \Sigma$ . For a structure  $\mathfrak{A}$ , the *binary relation map*  $\llbracket \_ \rrbracket_{\mathfrak{A}} : \mathbf{T}^{\text{CoR}} \rightarrow \wp(|\mathfrak{A}|^2)$  is the unique homomorphism extending  $\llbracket a \rrbracket_{\mathfrak{A}} = a^\mathfrak{A}$  w.r.t. the set-theoretic operators and the aforementioned binary relation operators; i.e.,  $\llbracket t \rrbracket_{\mathfrak{A}}$  is defined as follows:

$$\begin{aligned} \llbracket a \rrbracket_{\mathfrak{A}} &\triangleq a^\mathfrak{A} \quad (a \in \Sigma) & \llbracket \perp \rrbracket_{\mathfrak{A}} &\triangleq \emptyset & \llbracket \top \rrbracket_{\mathfrak{A}} &\triangleq |\mathfrak{A}|^2 & \llbracket \text{I} \rrbracket_{\mathfrak{A}} &\triangleq \text{I}_{|\mathfrak{A}|} & \llbracket \text{D} \rrbracket_{\mathfrak{A}} &\triangleq \text{D}_{|\mathfrak{A}|} \\ \llbracket t \cup s \rrbracket_{\mathfrak{A}} &\triangleq \llbracket t \rrbracket_{\mathfrak{A}} \cup \llbracket s \rrbracket_{\mathfrak{A}} & \llbracket t \cap s \rrbracket_{\mathfrak{A}} &\triangleq \llbracket t \rrbracket_{\mathfrak{A}} \cap \llbracket s \rrbracket_{\mathfrak{A}} & \llbracket t^- \rrbracket_{\mathfrak{A}} &\triangleq |\mathfrak{A}|^2 \setminus \llbracket t \rrbracket_{\mathfrak{A}} \\ \llbracket t \cdot s \rrbracket_{\mathfrak{A}} &\triangleq \llbracket t \rrbracket_{\mathfrak{A}} \cdot \llbracket s \rrbracket_{\mathfrak{A}} & \llbracket t \dagger s \rrbracket_{\mathfrak{A}} &\triangleq \llbracket t \rrbracket_{\mathfrak{A}} \dagger \llbracket s \rrbracket_{\mathfrak{A}} & \llbracket t^\pi \rrbracket_{\mathfrak{A}} &\triangleq \llbracket t \rrbracket_{\mathfrak{A}}^\pi. \end{aligned}$$

It is well-known that w.r.t. binary relations, CoR has the same expressive power as the three-variable fragment of first-order logic with equality:<sup>7</sup>

► **Proposition 19** ([28, 29, 11]). *W.r.t. binary relations, the expressive power of  $\mathbf{T}^{\text{CoR}}$  is equivalent to that of the three-variable fragment of first-order logic with equality.*

Let  $\text{REL}$  be the class of all structures. Let  $\text{REL}_{\geq m}$  (resp.  $\text{REL}_{\leq m}$ ) be the class of structures  $\mathfrak{A}$  of  $\#|\mathfrak{A}| \geq m$  (resp.  $\#|\mathfrak{A}| \leq m$ ). For  $\mathcal{C} \subseteq \text{REL}$ , the equivalence relation  $\sim_{\mathcal{C}}$  on  $\mathbf{T}^{\text{CoR}}$  is defined by:  $t \sim_{\mathcal{C}} s \iff \llbracket t \rrbracket_{\mathfrak{A}} = \llbracket s \rrbracket_{\mathfrak{A}}$  for every  $\mathfrak{A} \in \mathcal{C}$ . For  $T \subseteq \mathbf{T}^{\text{CoR}}$ , the equational theory of  $T$  over  $\mathcal{C}$  is the set  $\{\langle t, s \rangle \in T^2 \mid t \sim_{\mathcal{C}} s\}$ . We mainly consider  $\sim_{\text{REL}}$ : the equational theory over  $\text{REL}$ . The following are some instances w.r.t.  $\sim_{\text{REL}}$ :

$$\begin{aligned} a \cdot (b \cdot c) &\sim_{\text{REL}} (a \cdot b) \cdot c & a \cap (b \cup c) &\sim_{\text{REL}} (a \cap b) \cup (a \cap c) & (a^\sim)^\sim &\sim_{\text{REL}} a \\ a \cdot a^\sim &\not\sim_{\text{REL}} a^\sim \cdot a & a \cdot (b \dagger c) &\not\sim_{\text{REL}} (a \cdot b) \dagger c & a^{\{1 \rightarrow 1, 2 \rightarrow 1\}} &\sim_{\text{REL}} (a \cap \text{I}) \cdot \top. \end{aligned}$$

<sup>7</sup> Namely, for every formula  $\varphi$  with two distinct free variables  $z_1, z_2$  in the three-variable fragment of first-order logic with equality, there is  $t \in \mathbf{T}^{\text{CoR}}$  such that for all  $\mathfrak{A}$ ,  $\llbracket \lambda z_1 z_2. \varphi \rrbracket_{\mathfrak{A}} = \llbracket t \rrbracket_{\mathfrak{A}}$ . Conversely, for every  $t \in \mathbf{T}^{\text{CoR}}$ , there is  $\varphi$  such that for all  $\mathfrak{A}$ ,  $\llbracket t \rrbracket_{\mathfrak{A}} = \llbracket \lambda z_1 z_2. \varphi \rrbracket_{\mathfrak{A}}$ . Here,  $\llbracket \lambda z_1 z_2. \varphi \rrbracket_{\mathfrak{A}} \triangleq \{\langle x, y \rangle \in |\mathfrak{A}|^2 \mid \varphi \text{ is true on } \mathfrak{A} \text{ if } z_1, z_2 \text{ are mapped to } x, y, \text{ respectively}\}$ .

The following propositions hold because for each  $m \in \mathbb{N}$ , the number of structures  $\mathfrak{A}$  of  $\#\mathfrak{A} \leq m$  is finite up to isomorphism and each structure is finite.

► **Proposition 20.** *For each  $m \in \mathbb{N}$ ,  $\mathbf{T}^{\text{CoR}}/\sim_{\text{REL}_{\leq m}}$  is finite.*

► **Proposition 21.** *Let  $T \subseteq \mathbf{T}^{\text{CoR}}$  be a subterm-closed set and  $m \geq 1$ . Then,  $T/\sim_{\text{REL}}$  is finite  $\iff T/\sim_{\text{REL}_{\geq m}}$  is finite. Additionally, the equational theory of  $T$  over  $\text{REL}$  is decidable  $\iff$  the equational theory of  $T$  over  $\text{REL}_{\geq m}$  is decidable.*

**Proof.** Because  $t \sim_{\text{REL}} s \iff t \sim_{\text{REL}_{\leq m-1}} s \wedge t \sim_{\text{REL}_{\geq m}} s$ . By Prop. 20 with Prop. 3,  $T/\sim_{\text{REL}_{\leq m-1}}$  is finite and the equational theory of  $T$  over  $\text{REL}_{\leq m-1}$  is decidable. ◀

### 3.2 The dot-dagger alternation hierarchy

► **Definition 22** (the dot-dagger alternation hierarchy [21]). *The sets,  $\{\Sigma_n^{\text{CoR}}, \Pi_n^{\text{CoR}}\}_{n \in \mathbb{N}}$ , are the minimal sets satisfying the following:*

- $\Sigma_0^{\text{CoR}} = \Pi_0^{\text{CoR}} = \{t \in \mathbf{T}^{\text{CoR}} \mid t \text{ does not contain } \cdot \text{ nor } \dagger\}$ ;
- For  $n \geq 0$ ,  $\Sigma_n^{\text{CoR}} \cup \Pi_n^{\text{CoR}} \subseteq \Sigma_{n+1}^{\text{CoR}} \cap \Pi_{n+1}^{\text{CoR}}$ ;
- For  $n \geq 1$ , if  $s, u \in \Sigma_n^{\text{CoR}}$ , then  $s \cup u, s \cap u, s \cdot u, s^\pi \in \Sigma_n^{\text{CoR}}$  and  $s \dagger u \in \Pi_{n+1}^{\text{CoR}}$ ;
- For  $n \geq 1$ , if  $s, u \in \Pi_n^{\text{CoR}}$ , then  $s \cup u, s \cap u, s \dagger u, s^\pi \in \Pi_n^{\text{CoR}}$  and  $s \cdot u \in \Sigma_{n+1}^{\text{CoR}}$ .

For example,  $a \cdot b \in \Sigma_1^{\text{CoR}}$  and  $a \cdot (b \dagger c) \in \Sigma_2^{\text{CoR}}$  (the term  $a \cdot b$  means that for some  $z$ ,  $a(x, z)$  and  $b(z, y)$ ). The term  $a \cdot (b \dagger c)$  means that for some  $z$ , for every  $w$ ,  $a(x, z)$  and  $(b(z, w)$  or  $c(w, y))$ . Here,  $x$  and  $y$  indicate the source and the target, respectively, and each  $a'(x', y')$  denotes that there is an  $a'$ -labelled edge from  $x'$  to  $y'$ ). The dot-dagger alternation hierarchy is an analogy of the quantifier alternation hierarchy in first-order logic (by viewing  $\cdot$  as  $\exists$  and  $\dagger$  as  $\forall$ ). This provides a fine-grained analogy of Prop. 19 w.r.t. the number of quantifier alternations, as follows:

► **Proposition 23** ([21, Cor. 3.14]; cf. Prop. 19). *W.r.t. binary relations, the expressive power of  $\Sigma_n^{\text{CoR}}$  (resp.  $\Pi_n^{\text{CoR}}$ ) is equivalent to that of the level  $\Sigma_n$  (resp.  $\Pi_n$ ) in the quantifier alternation hierarchy of the three-variable fragment of first-order logic with equality.*

Because there are recursive translations for Prop. 23 [21], the following (un-)decidability results follow from those in first-order logic.

► **Proposition 24.** *The equational theory of  $\Sigma_n^{\text{CoR}}$  (resp.  $\Pi_n^{\text{CoR}}$ ) is decidable if  $n \leq 1$  and is undecidable if  $n \geq 2$ .*

**Proof Sketch.** When  $\Sigma$  is a countably infinite set, they follow from the BSR class  $[\exists^* \forall^*, \text{all}] = [3, 27]$  and the reduction class  $[\forall \exists \wedge \forall^3, (\omega, 1)]$  [7, Cor. 3.1.19]. We can strengthen this result even if  $\#\Sigma = 1$  by using a variant of the translation in [19, Lem. 11] for encoding countably infinitely many variables by one variable. (See [23] for more details.) ◀

## 4 On the $k$ -variable-occurrence fragment of $\Sigma_n^{\text{CoR}}$

We now consider  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$ : the  $k$ -variable-occurrence fragment of the level  $\Sigma_n^{\text{CoR}}$  in the dot-dagger alternation hierarchy. Clearly,  $\Sigma_n^{\text{CoR}} = \bigcup_{k \in \mathbb{N}} (\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$ . While the equational theory of  $\Sigma_n^{\text{CoR}}$  is undecidable in general (Prop. 24), we show that the equational theory of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  is decidable (Cor. 26). Our goal in this section is to show the following:

► **Theorem 25.** For each  $n, k \in \mathbb{N}$ ,  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  is finite.

Combining with Prop. 3 yields the following decidability and complexity upper bound. The complexity lower bound is because the equational theory can encode the *boolean sentence value problem* [5] (even if  $n = k = 0$ ), as a given boolean sentence  $\varphi$  is true iff  $t \sim_{\text{REL}} \top$ , where  $t$  is the term obtained from  $\varphi$  by replacing  $\wedge, \vee, \top, \text{F}$  with  $\cap, \cup, \top, \perp$ , respectively.

► **Corollary 26.** For  $n, k \in \mathbb{N}$ , the equational theory of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  over REL is decidable. Moreover, it is complete for DLOGTIME-uniform  $\text{NC}^1$  under DLOGTIME reductions if the input is given as a well-bracketed string.

To prove Thm. 25, we consider the finiteness of  $\mathbf{T}_{(\text{vo} \leq 0)}^{\text{CoR}} / \sim_{\text{REL}}$  in Sect. 4.1 and the finiteness of a monoid for  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  in Sect. 4.2, respectively (cf. Lem. 14).

#### 4.1 On the finiteness of $\mathbf{T}_{(\text{vo} \leq 0)}^{\text{CoR}}$

For the finiteness of  $\mathbf{T}_{(\text{vo} \leq 0)}^{\text{CoR}} / \sim_{\text{REL}}$ , by Prop. 21, it suffices to show the following:

► **Lemma 27.**  $\mathbf{T}_{(\text{vo} \leq 0)}^{\text{CoR}} / \sim_{\text{REL}_{\geq 3}} = \{[\perp]_{\sim_{\text{REL}_{\geq 3}}}, [\top]_{\sim_{\text{REL}_{\geq 3}}}, [I]_{\sim_{\text{REL}_{\geq 3}}}, [D]_{\sim_{\text{REL}_{\geq 3}}}\}$ .

**Proof.** W.r.t.  $\sim_{\text{REL}_{\geq 3}}$ , we prove that the four elements are closed under each operator. For the operators  $\cap, -, \cdot, \smile$ , this is shown by the following Cayley tables:

$\cap$	$\top$	$\perp$	$I$	$D$
$\top$	$\top$	$\perp$	$I$	$D$
$\perp$	$\perp$	$\perp$	$\perp$	$\perp$
$I$	$I$	$\perp$	$I$	$\perp$
$D$	$D$	$\perp$	$\perp$	$D$

$-$	$\diagdown$
$\top$	$\perp$
$\perp$	$\top$
$I$	$D$
$D$	$I$

$\cdot$	$\top$	$\perp$	$I$	$D$
$\top$	$\top$	$\perp$	$\top$	$\top$
$\perp$	$\perp$	$\perp$	$\perp$	$\perp$
$I$	$\top$	$\perp$	$I$	$D$
$D$	$\top$	$\perp$	$D$	$\top$

$\smile$	$\diagdown$
$\top$	$\top$
$\perp$	$\perp$
$I$	$I$
$D$	$D$

Note that  $D \cdot D \sim_{\text{REL}_{\geq 3}} \top$  holds thanks to “ $\geq 3$ ”. When  $\#(|\mathfrak{A}|) \geq 3$ , we have:  $\langle x, y \rangle \in \llbracket D \cdot D \rrbracket_{\mathfrak{A}}$  iff  $(\exists z \in |\mathfrak{A}|, z \neq x \wedge z \neq y) \text{ iff } |\mathfrak{A}| \setminus \{x, y\} \neq \emptyset \text{ iff True}$  (cf. Remark 28). (Similarly for  $D \cdot \top \sim_{\text{REL}_{\geq 2}} \top$ .) For the other operators ( $\cup, \dagger, \pi$ ), they can be expressed by using  $\cap, -, \cdot, \smile$  as follows:  $t \cup s \sim_{\text{REL}} (t^- \cap s^-)^-$ ,  $t \dagger s \sim_{\text{REL}} (t^- \cdot s^-)^-$ ,  $t^{\{1 \rightarrow 1, 2 \rightarrow 2\}} \sim_{\text{REL}} t$ ,  $t^{\{1 \rightarrow 1, 2 \rightarrow 1\}} \sim_{\text{REL}} (t \cap I) \cdot \top$ ,  $t^{\{1 \rightarrow 2, 2 \rightarrow 2\}} \sim_{\text{REL}} \top \cdot (t \cap I)$ , and  $t^{\{1 \rightarrow 2, 2 \rightarrow 1\}} = t^\smile$ . Hence, this completes the proof. ◀

► **Remark 28.**  $D \cdot D \not\sim_{\text{REL}} \top$ , whereas  $D \cdot D \sim_{\text{REL}_{\geq 3}} \top$ . For example when  $\#|\mathfrak{A}| = 1$ , since  $\llbracket D \rrbracket_{\mathfrak{A}} = \llbracket \perp \rrbracket_{\mathfrak{A}}$ , we have  $\llbracket D \cdot D \rrbracket_{\mathfrak{A}} = \emptyset \neq |\mathfrak{A}| = \llbracket \top \rrbracket_{\mathfrak{A}}$ . ( $D \cdot D$  is not equivalent to neither one of the four constants w.r.t.  $\sim_{\text{REL}}$ ; thus, there are many constants w.r.t.  $\sim_{\text{REL}}$ .)

#### 4.2 Monoid for $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$

Next, we decompose terms, and then we reduce the finiteness of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  to that of a monoid (cf. Sect. 2.2).

► **Lemma 29.** For each  $n, k \in \mathbb{N}$ , if  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite,  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  is finite.

**Proof.** By specializing  $T$  with  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  and  $\mathcal{C}$  with REL, in Prop. 3 and Lem. 6. ◀

► **Lemma 30.** For each  $n, k \in \mathbb{N}$ ,  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  is finite iff  $(\Pi_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  is finite.

**Proof.**  $\Leftarrow$ : For every term  $t$  in  $(\Pi_n^{\text{CoR}})_{(\text{vo} \leq k)}$ , there is some  $s$  in  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  such that  $t \sim_{\text{REL}} s^-$ . Such  $s$  can be obtained from the term  $t^-$  by taking the complement normal form using the following equations:

$$\begin{array}{ccccccc} \top^- \sim_{\text{REL}} \perp & & \perp^- \sim_{\text{REL}} \top & & \top^- \sim_{\text{REL}} \text{D} & & \text{D}^- \sim_{\text{REL}} \top \\ (s \cup u)^- \sim_{\text{REL}} s^- \cap u^- & & (s \cap u)^- \sim_{\text{REL}} s^- \cup u^- & & (s^-)^- \sim_{\text{REL}} s & & (s^\pi)^- \sim_{\text{REL}} (s^-)^\pi. \end{array}$$

$\Rightarrow$ : As with  $\Leftarrow$ . ◀

► **Lemma 31** (cf. Lem. 4). Let  $a \in \Sigma$ . For all  $n \geq 2$ ,  $t \in (\Sigma_n^{\text{CoR}})_{(\text{vo} \leq 1)}$ , there are  $t_0 \in (\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)}$  and  $t_1 \in (\Pi_{n-1}^{\text{CoR}})_{(\text{vo} \leq 1)}$  such that  $t \sim_{\text{REL}_{\geq 3}} t_0[t_1/a]$ .

**Proof.** By induction on the pair of  $n$  and  $t$ . We distinguish the following cases. Case  $t \in (\Sigma_{n-1}^{\text{CoR}})_{(\text{vo} \leq 1)}$ : Clear, by IH ( $\cdot: \Pi_{n-2}^{\text{CoR}} \subseteq \Pi_{n-1}^{\text{CoR}}$ ). Case  $t \in (\Pi_{n-1}^{\text{CoR}})_{(\text{vo} \leq 1)}$ : By letting  $t_0 = a$  and  $t_1 = t$ . Case  $t = s \cup u$ : By  $\text{vo}(t) = 1$ ,  $\text{vo}(s) = 0$  or  $\text{vo}(u) = 0$  holds. Sub-case  $\text{vo}(s) = 0$ : By Lem. 27, let  $s' \in \{\perp, \top, \text{I}, \text{D}\}$  be s.t.  $s \sim_{\text{REL}_{\geq 3}} s'$ . By IH w.r.t.  $u$ , let  $u_0 \in (\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)}$ ,  $u_1 \in (\Pi_{n-1}^{\text{CoR}})_{(\text{vo} \leq 1)}$  be s.t.  $u \sim_{\text{REL}_{\geq 3}} u_0[u_1/a]$ . By letting  $t_0 = s' \cup u_0$  and  $t_1 = u_1$ , we have  $t \sim_{\text{REL}_{\geq 3}} t_0[t_1/a]$ . Sub-case  $\text{vo}(u) = 0$ : As with Sub-case  $\text{vo}(s) = 0$ . Case  $t = s \cap u, s \cdot u, s^\pi$ : As with Case  $t = s \cup u$ . ◀

The following is an illustrative example of the decomposition of Lem. 31:

► **Lemma 32.** For each  $n \in \mathbb{N}$ , if  $(\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite,  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite.

**Proof.** By induction on  $n$ . Case  $n \leq 1$ : By the assumption (note that  $(\Sigma_0^{\text{CoR}})_{(\text{vo} \leq 1)} \subseteq (\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)}$ ). Case  $n \geq 2$ : By the assumption,  $(\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite. By IH with Lem. 30,  $(\Pi_{n-1}^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite. Combining them with Lem. 31 (and Prop. 21 for changing  $\sim_{\text{REL}}$  and  $\sim_{\text{REL}_{\geq 3}}$  mutually) yields that  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite. ◀

For  $S \subseteq S^{\text{CoR}}$ , let  $\mathbf{T}^S \subseteq \mathbf{T}^{\text{CoR}}$  be the set of all terms over the signature  $S$ . Then we have:

► **Lemma 33.** If  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}} / \sim_{\text{REL}}$  is finite, then  $(\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite.

**Proof sketch.** Note that  $t, s \in \Sigma_1^{\text{CoR}} ::= u \mid t \cup s \mid t \cap s \mid t \cdot s \mid t^\pi$  (where  $u \in \Sigma_0^{\text{CoR}}$ ,  $\pi \in [1, 2]^{[1, 2]}$ ) and  $u, u' \in \Sigma_0^{\text{CoR}} ::= a \mid u \cup u' \mid u \cap u' \mid u^- \mid \top \mid \perp \mid u^\pi$  (where  $a \in \Sigma$ ,  $\pi \in [1, 2]^{[1, 2]}$ ). By taking the complement ( $-$ ) and projection ( $\pi$ ) normal form and replacing  $\perp$  with  $\text{I} \cap \text{D}$  and  $\top$  with  $\text{I} \cup \text{D}$ , for each  $t \in (\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)}$  and  $a \in \Sigma$ , there are  $t_0 \in \mathbf{T}_{(\text{vo} \leq 1)}^{\{\cup, \cap, \cdot, \text{I}, \text{D}\}}$  and  $t_1 \in \mathbf{T}_{(\text{vo} \leq 1)}^{\{-\} \cup \{\pi \mid \pi \in [1, 2]^{[1, 2]}\}}$  such that  $t \sim_{\text{REL}} t_0[t_1/a]$ . Moreover, by the distributive law of  $\cup$  w.r.t.  $\cdot$  and  $\cap$ , for each  $t \in \mathbf{T}_{(\text{vo} \leq 1)}^{\{\cup, \cap, \cdot, \text{I}, \text{D}\}}$ , there are  $n \in \mathbb{N}$  and  $t_1, \dots, t_n \in \mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}}$  such that  $t \sim_{\text{REL}} t_1 \cup \dots \cup t_n$ . Because  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}} / \sim_{\text{REL}}$  is finite (by the assumption) and  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{-\} \cup \{\pi \mid \pi \in [1, 2]^{[1, 2]}\}} / \sim_{\text{REL}}$  is clearly finite,  $(\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)} / \sim_{\text{REL}}$  is finite. Hence, this completes the proof. (See [23] for more details of the proof.) ◀

## 69:12 On the Finite Variable-Occurrence Fragment of the Calculus of Relations

Combining Lems. 29, 32, and 33 yields that to prove that  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)} / \sim_{\text{REL}}$  is finite, it suffices to prove that  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}} / \sim_{\text{REL}}$  is finite.

Let  $\dot{\Sigma}$  be the set of characters of Def. 7 from the signature  $\{\cap^{(2)}, \cdot^{(2)}, \text{I}^{(0)}, \text{D}^{(0)}, \smile^{(1)}\}$ . That is,  $\dot{\Sigma} \triangleq \{(\_ \cap t), (t \cap \_), (\_ \cdot t), (t \cdot \_) \mid t \in (\mathbf{T}_{(\text{vo} \leq 0)}^{\{\cap, \cdot, \text{I}, \text{D}, \smile\}}) \cup \{\smile\}$ . (While  $\smile$  does not occur in  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}}$ , we introduce  $\smile$  for replacing the primitive character  $(\text{D} \cdot \_)$  with  $\smile (\_ \cdot \text{D})$ . This is not essential but is useful for reducing the number of equations and for simplifying the notation (Def. 35).) Let  $\dot{\sim}_{\text{REL}_{\geq 5}}$  be the equivalence relation on  $\dot{\Sigma}^*$  defined by:  $w \dot{\sim}_{\text{REL}_{\geq 5}} v \iff w[a] \sim_{\text{REL}_{\geq 5}} v[a]$  where  $a \in \Sigma$  is any variable (recall Def. 10).<sup>8</sup>

► **Lemma 34.** *If  $\dot{\Sigma}^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  is finite, then  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}} / \sim_{\text{REL}}$  is finite.*

**Proof.** Since  $\dot{\Sigma}^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  is finite, we have that  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}, \smile\}} / \sim_{\text{REL}_{\geq 5}}$  is finite (Lem. 11); thus,  $\mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, \text{I}, \text{D}\}} / \sim_{\text{REL}_{\geq 5}}$  is finite. Hence by Prop. 21, this completes the proof. ◀

We consider the following finite subset  $\dot{\Sigma}_0$  of  $\dot{\Sigma}$  (cf. Lem. 12):

► **Definition 35.** *Let  $\dot{\Sigma}_0 \subseteq \dot{\Sigma}$  be the finite set  $\{\cap_{\text{I}}, \cap_{\text{D}}, \cdot_{\text{D}}, \smile\}$ , where  $\cap_{\text{I}}, \cap_{\text{D}}, \cdot_{\text{D}}$  are abbreviations of  $(\_ \cap \text{I}), (\_ \cap \text{D}), (\_ \cdot \text{D})$ , respectively.*

► **Lemma 36.** *If  $\dot{\Sigma}_0^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  is finite, then  $\dot{\Sigma}^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  is finite.*

**Proof.** It suffices to prove the following: for every  $a \in \dot{\Sigma}$ , there is  $w \in \dot{\Sigma}_0^*$  such that  $a \dot{\sim}_{\text{REL}_{\geq 5}} w$ . Case  $a = (\_ \cap t), (\_ \cdot t)$ : Since  $\text{vo}(t) = 0$ , by using Lem. 27, they are shown by distinguishing the following four sub-cases, as follows:

	$t \sim_{\text{REL}_{\geq 3}} \perp$	$t \sim_{\text{REL}_{\geq 3}} \top$	$t \sim_{\text{REL}_{\geq 3}} \text{I}$	$t \sim_{\text{REL}_{\geq 3}} \text{D}$
$a = (\_ \cap t)$	$\cap_{\text{I}} \cap_{\text{D}}$	$\varepsilon$	$\cap_{\text{I}}$	$\cap_{\text{D}}$
$a = (\_ \cdot t)$	$\cap_{\text{I}} \cap_{\text{D}}$	$\cdot_{\text{D}} \cdot_{\text{D}}$	$\varepsilon$	$\cdot_{\text{D}}$

Case  $a = (t \cap \_), (t \cdot \_)$ : By  $(t \cap \_) = \smile (\_ \cap t)$  and applying the above case analysis for  $(\_ \cap t)$ , this case can be proved (similarly for  $(t \cdot \_)$ ). Case  $a = \smile$ : Since  $\smile \in \dot{\Sigma}_0$ . ◀

Thus, our goal is to prove that  $\dot{\Sigma}_0^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  is finite.

### 4.3 On the finiteness of the monoid

For the finiteness of  $\dot{\Sigma}_0^* / \dot{\sim}_{\text{REL}_{\geq 5}}$  (cf. Lem. 15), we present the 21 equations in Fig. 1.<sup>9</sup> For  $i \in [1, 21]$ , let  $w_i, v_i$  be words such that  $w_i = v_i$  denotes the  $i$ -th equation.

► **Lemma 37** (soundness). *For each  $i \in [1, 21]$ ,  $w_i \dot{\sim}_{\text{REL}_{\geq 5}} v_i$ .*

**Proof Sketch.** We prove  $w_i[a] \sim_{\text{REL}_{\geq 5}} v_i[a]$ , where  $a$  is any variable. This equation can be translated to the validity of a first-order sentence via the standard translation [28]. Here, we add the formula  $\exists x_1, \dots, x_5, \wedge_{i,j \in [1,5]; i \neq j} x_i \neq x_j$  as an axiom, for forcing  $\dot{\sim}_{\text{REL}_{\geq 5}}$ . Thanks to this encoding, each of them can also be tested by using ATP/SMT systems. Nevertheless, in

<sup>8</sup> The condition “ $\geq 5$ ” is needed for some equations in Fig. 1.

<sup>9</sup> The most technical part of the paper is to collect these equations. They are obtained by running a program based on Algorithm 1 using ATP/SMT systems.

$$\begin{array}{llll}
\cap_l = \cap_l \cap_l & (1) & \varepsilon = \smile \smile & (7) & \cdot_D \cdot_D = \cdot_D \cdot_D \cdot_D & (13) \\
\cap_D = \cap_D \cap_D & (2) & \cap_D \cap_l = \cdot_D \cap_l \cap_D & (8) & \cdot_D \cdot_D \cap_D = \cdot_D \cdot_D \cap_l \cdot_D & (14) \\
\cap_l = \cap_l \smile & (3) & \cap_D \cap_l = \cap_l \cdot_D \cap_l & (9) & \cap_D \cdot_D \cdot_D = \cdot_D \cap_l \cdot_D \cdot_D & (15) \\
\cap_l = \smile \cap_l & (4) & \cap_l \cdot_D = \cap_l \cdot_D \cap_D & (10) & \smile \cdot_D \cap_l = \cap_D \smile \cdot_D \cap_l & (16) \\
\cap_l \cap_D = \cap_D \cap_l & (5) & \cdot_D \cap_l = \cap_D \cdot_D \cap_l & (11) & \cdot_D \smile \cdot_D \smile = \smile \cdot_D \smile \cdot_D & (17) \\
\cap_D \smile = \smile \cap_D & (6) & \cdot_D \cdot_D = \cdot_D \cap_D \cdot_D & (12) & \smile \cdot_D \cap_l \cdot_D = \cap_D \smile \cdot_D \cdot_D \cap_D & (18) \\
& & & & \cdot_D \smile \cdot_D \cdot_D \smile = \smile \cdot_D \cdot_D \smile \cdot_D & (19) \\
\cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile \cdot_D \cap_D \smile & (20) \\
\cdot_D \cap_l \cdot_D \smile \cdot_D \cap_l \cdot_D \smile \cdot_D \smile \cdot_D \cap_l \cdot_D \smile \cdot_D \cap_l \cdot_D \smile \cdot_D & (21)
\end{array}$$

■ **Figure 1** Equations for the finiteness.

the following, as an example, we give explicit proof for Equation (13). By using the standard translation, Equation (13) is translated into the following formula in first-order logic, where  $x_0, y_0$  are free variables:

$$\begin{aligned}
& (\exists y_1, (\exists y_2, a(x_0, y_2) \wedge y_2 \neq y_1) \wedge y_1 \neq y_0) \\
\leftrightarrow & (\exists y_1, (\exists y_2, (\exists y_3, a(x_0, y_3) \wedge y_3 \neq y_2) \wedge y_2 \neq y_1) \wedge y_1 \neq y_0).
\end{aligned}$$

This formula is valid under  $\text{REL}_{\geq 5}$ , which can be shown by using the axiom above (notice that under  $\text{REL}_{\geq 5}$ ,  $y_1$  on the left and  $y_1, y_2$  on the right always exist, by taking a vertex not assigned by any variable occurring in each formula; thus, both formulas are equivalent to the formula  $\exists y, a(x_0, y)$ ). Even without the encoding to first-order logic, this equation can also be shown as follows:

$$\begin{aligned}
(\cdot_D \cdot_D)[a] &= (a \cdot D) \cdot D = a \cdot (D \cdot D) && \text{(associativity law)} \\
&= a \cdot \top && (\top \sim_{\text{REL}_{\geq 3}} D \cdot D) \\
&= a \cdot (D \cdot D \cdot D) && (\top \sim_{\text{REL}_{\geq 3}} \top \cdot D \text{ and } \top \sim_{\text{REL}_{\geq 3}} D \cdot D) \\
&= ((a \cdot D) \cdot D) \cdot D = (\cdot_D \cdot_D \cdot_D)[a]. && \text{(associativity law)}
\end{aligned}$$

See [23, 24] for all the equations. ◀

► **Lemma 38.** *The language  $\bigcup_{i \in [1, 21]} \dot{\Sigma}_0^* v_i \dot{\Sigma}_0^*$  over  $\dot{\Sigma}_0$  is cofinite.*

**Proof Sketch.** It suffices to prove that for some  $n \in \mathbb{N}$ , the following hold: there is no word  $w \in \dot{\Sigma}_0^* \setminus (\bigcup_{i \in [1, 21]} \dot{\Sigma}_0^* v_i \dot{\Sigma}_0^*)$  such that  $\|w\| \geq n$  (since the set  $\{w \in \dot{\Sigma}_0^* \mid \|w\| \leq n - 1\}$  is finite). This holds when  $n \geq 29$ , which can be tested by using Z3 (an ATP/SMT system) [9] and can be checked by drawing its DFA (see [23, 24], for more details). ◀

Thus, we have obtained the following:

► **Lemma 39.**  *$\dot{\Sigma}^* / \sim_{\text{REL}_{\geq 5}}$  is finite.*

**Proof.** By Lems. 37 and 38, we can apply Lem. 15, where  $<$  is the shortlex order on  $\dot{\Sigma}_0^*$  induced by:  $\cap_l < \cap_D < \cdot_D < \smile$ . By the form,  $w_i < v_i$  is clear for each  $i \in [1, 21]$ . ◀

Finally, Thm. 25 is obtained as follows:

**Proof of Thm. 25.** We have:  $\dot{\Sigma}_0^*/\sim_{\text{REL}_{\geq 5}}$  is finite (Lem. 39)  $\implies \dot{\Sigma}^*/\sim_{\text{REL}_{\geq 5}}$  is finite (Lem. 36)  $\implies \mathbf{T}_{(\text{vo} \leq 1)}^{\{\cap, \cdot, !, \text{D}\}}/\sim_{\text{REL}}$  is finite (Lem. 34)  $\implies (\Sigma_1^{\text{CoR}})_{(\text{vo} \leq 1)}/\sim_{\text{REL}}$  is finite (Lem. 33)  $\implies (\Sigma_n^{\text{CoR}})_{(\text{vo} \leq 1)}/\sim_{\text{REL}}$  is finite (Lem. 32)  $\implies (\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}/\sim_{\text{REL}}$  is finite (Lem. 29).  $\blacktriangleleft$

$\blacktriangleright$  Remark 40. The finite axiomatizability of the equational theory of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  over REL immediately follows from the finiteness of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}/\sim_{\text{REL}}$ .

## 5 Conclusion

We have introduced the *k-variable-occurrence fragment* and presented an approach for showing the decidability of the equational theory from the finiteness. As a case study, we have proved that the equational theory of  $(\Sigma_n^{\text{CoR}})_{(\text{vo} \leq k)}$  is decidable, whereas that of  $\Sigma_n^{\text{CoR}}$  is undecidable in general. We leave the decidability open for the equational theory of CoR with *full dot-dagger alternation* (i.e.,  $\mathbf{T}_{(\text{vo} \leq k)}^{\text{CoR}}$ , in this paper). Our approach may apply to some other algebras/logics. It would be interesting to consider the finite variable-occurrence fragment for other systems (e.g., CoR with antidomain [13, 10], dynamic logics [12], relation algebras). It would also be interesting to extend our result to *first-order logic with equality* (cf. Prop. 19) – for example, is the *k-atomic-predicate-occurrence fragment* of the *m-variable fragment* of first-order logic with equality decidable?

---

## Abstract

We establish that constructive continued fraction dimension originally defined using  $s$ -gales [20] is robust, but surprisingly, that the effective continued fraction dimension and effective (base- $b$ ) Hausdorff dimension of the same real can be unequal in general.

We initially provide an equivalent characterization of continued fraction dimension using Kolmogorov complexity. In the process, we construct an optimal lower semi-computable  $s$ -gale for continued fractions. We also prove new bounds on the Lebesgue measure of continued fraction cylinders, which may be of independent interest.

We apply these bounds to reveal an unexpected behavior of continued fraction dimension. It is known that feasible dimension is invariant with respect to base conversion [8]. We also know that Martin-Löf randomness and computable randomness are invariant not only with respect to base conversion, but also with respect to the continued fraction representation [20]. In contrast, for any  $0 < \varepsilon < 0.5$ , we prove the existence of a real whose effective Hausdorff dimension is less than  $\varepsilon$ , but whose effective continued fraction dimension is greater than or equal to 0.5. This phenomenon is related to the “non-faithfulness” of certain families of covers, investigated by Peres and Torbin [22] and by Alberverio, Ivanenko, Lebid and Torbin [1].

We also establish that for any real, the constructive Hausdorff dimension is at most its effective continued fraction dimension.

**2012 ACM Subject Classification** Theory of computation → Computability; Mathematics of computing → Information theory

**Keywords and phrases** Algorithmic information theory, Kolmogorov complexity, Continued fractions, Effective Hausdorff dimension

## 1 Introduction

The concept of an individual random sequence, first defined by Martin-Löf using constructive measure [15], is well-established and mathematically robust - very different approaches towards the definition identify precisely the same sequences as random. These include Kolmogorov incompressibility (Levin [10], Chaitin [3]) and unpredictability by martingales [24]. While the theory of Martin-Löf randomness *classifies* sequences into random and non-random, it does not *quantify* the information rate in a non-random sequence. Lutz effectivized the classical notions of Hausdorff and packing dimensions [12], surprisingly extending it to individual infinite binary sequences [13], yielding a notion of information density in sequences. This definition also has several equivalent definitions in terms of Kolmogorov compression

rates [16], unpredictability by  $s$ -gales, and using covers [12, 13]. These definitions have led to a rich variety of applications in various domains of computability and complexity theory (see for example, Downey and Hirschfeldt [5], Nies [21]).

Recently, settings more general than the Cantor space of infinite binary (or in general, infinite sequences from a finite alphabet) have been studied by Lutz and Mayordomo [14], and Mayordomo [17, 18]. Prominent among them is Mayordomo’s definition of effective Hausdorff dimension for a very general class of metric spaces [17, 18]. Nandakumar and Vishnoi [20] and Vishnoi [28] define the notion of effective dimension of continued fractions, which involves a countably infinite alphabet, and is thus a setting which cannot be studied using Mayordomo’s framework. This latter setting is interesting topologically since the space of continued fractions is non-compact, and interesting measure-theoretically since the natural shift invariant measure, the Gauss measure, is a non-product measure.

Nandakumar and Vishnoi [20] use the notion of an  $s$ -gale on the space of continued fractions to define effective dimension. Vishnoi [28] introduced the notion of Kolmogorov complexity of finite continued fraction strings using a one to one binary encoding. Vishnoi [28] also shows that the notion of Kolmogorov complexity is invariant under computable 1-1 encodings, upto an additive constant.

In this work, we first establish the mathematical robustness of the notion of effective dimension, by proving an equivalent characterization using Kolmogorov complexity of continued fractions. The characterization achieves the necessary equivalence by choosing a binary encoding of continued fractions which has a compelling geometric intuition, and then applying Mayordomo’s characterization of effective (binary) Hausdorff dimension using Kolmogorov complexity [16]. In the process, analogous to the notion of an optimal constructive supergale on the Cantor space defined by Lutz [13], we provide the construction of a lower semi-computable  $s$ -gale that is optimal for continued fractions. We also prove new bounds on the Lebesgue measure of continued fraction cylinders using the digits of the continued fraction expansion, a result which may be of independent interest.

The topological and measure-theoretic intricacies involved in this setting imply that some, but not all, “natural” properties of randomness and dimension carry over from the binary setting. For example, while Martin-Löf and computable randomness are invariant with respect to the conversion between the base- $b$  and continued fraction expansion of the same real [19, 20], Vandehey [26] and Scheerer [23] show that other notions of randomness like absolute normality and normality for continued fractions are not identical.

Staiger [25] showed that the Kolmogorov complexity of a base  $b$  expansion of a real  $\alpha, 0 \leq \alpha \leq 1$ , is independent of the chosen base  $b$ . Aligning with this, Hitchcock and Mayordomo [8] establish that feasible dimension of a real is the same when converting between one base to another. Hitherto, it was unknown whether effective dimension is invariant with respect to conversion between base- $b$  and continued fraction representations. Since we can convert between the representations efficiently, it is possible that these are equal. We show this is true in one direction, that the effective base  $b$  dimension is a lower bound for effective continued fraction dimension.

However, using the technique of diagonalization against the optimal lower semicomputable continued fraction  $s$ -gale and using set covering techniques used in recent works by Peres and Torbin [22], Albeverio, Ivanenko, Lebid and Torbin [1] and Albeverio, Kondratiev, Nikiforov and Torbin [2] to show the “non-faithfulness” of certain families of covers, we show that the reverse direction does not hold, in general. We prove the following result: for every  $0 < \varepsilon < 0.5$ , there is a real whose effective (binary) Hausdorff dimension is less than  $\varepsilon$  while its effective continued fraction dimension is at least 0.5. By the result of Hitchcock and

Mayordomo [8], this also implies that the effective base- $b$  dimension of this real is less than  $\varepsilon$  in every base- $b$ ,  $b \geq 2$ . Thus, surprisingly, there is a sharp gap between the effective (base- $b$ ) dimension of a real and its effective continued fraction dimension, highlighting another significant difference in this setting.

## 2 Preliminaries

We denote the binary alphabet by  $\Sigma$ . The set of strings of a particular length  $n$  is denoted  $\Sigma^n$ . The set of all finite binary strings is denoted  $\Sigma^*$  and infinite binary sequences is denoted  $\Sigma^\infty$ . For a binary string  $v \in \Sigma^n \setminus \{0^n \cup 1^n\}$ ,  $v - 1$  denotes the string occurring just before  $v$  lexicographically, and  $v + 1$  the string occurring just after  $v$  lexicographically. We use  $\mathbb{N}$  to denote the set of positive integers. The set of finite continued fractions is denoted  $\mathbb{N}^*$  and the set of all infinite continued fractions, as  $\mathbb{N}^\infty$ .

We adopt the notation  $[a_1, a_2, \dots]$  for the continued fraction

$$\frac{1}{a_1 + \frac{1}{a_2 + \dots}}$$

and similarly,  $[a_1, a_2, \dots, a_n]$  for finite continued fractions.

If a finite binary string  $x$  is a prefix of a finite string  $z$  or an infinite binary sequence  $Z$ , then we denote this by  $x \sqsubseteq z$  or  $x \sqsubseteq Z$  respectively. If  $x$  is a proper prefix of a finite string  $z$ , we denote it by  $x \sqsubset z$ . We adopt the same notation for denoting that a finite continued fraction  $v$  is a prefix of another continued fraction. For a  $v \in \mathbb{N}^*$ , the *cylinder set* of  $v$ , denoted  $C_v$ , is defined by  $C_v = \{Y \in \mathbb{N}^\infty \mid v \sqsubset Y\}$ . For a  $w \in \Sigma^*$ ,  $C_w$  is defined similarly. For a continued fraction string  $v = [a_1 \dots a_n]$ ,  $P(v)$  denotes the string  $[a_1, \dots, a_{n-1}]$ .  $\lambda$  denotes the empty string and we define  $P(\lambda) = \lambda$ .

For  $v \in \mathbb{N}^*$ ,  $\mu(v)$  refers to the Lebesgue measure of the continued fraction cylinder  $C_v$ .  $\gamma(v)$  refers to the Gauss measure of the continued fraction cylinder  $C_v$ , defined by  $\gamma(v) = \int_{C_v} \frac{1}{1+x} dx$ . We use the same notation for a binary cylinder  $w \in \Sigma^*$ . It is well-known that the Gauss measure is absolutely continuous with respect to the Lebesgue measure, and is invariant with respect to the left-shift transformation on continued fractions (see for example, [4], or [6]). Wherever there is no scope for confusion, for a  $v \in \mathbb{N}^*$ , we use  $\mu(v)$  and  $\gamma(v)$  to represent  $\mu(C_v)$  and  $\gamma(C_v)$  respectively. The same holds for a  $v \in \Sigma^*$ . We also use the notation  $\mu^s(v)$  and  $\gamma^s(v)$  to denote  $(\mu(v))^s$  and  $(\gamma(v))^s$  respectively. For a continued fraction string  $v = [a_1, \dots, a_n]$ , we call  $n$  as the rank of  $v$ , and we denote it using  $\text{rank}(v)$ .  $[v, i]$  denotes the continued fraction  $[a_1, \dots, a_n, i]$ . For an infinite continued fraction string  $Y = [a_1, a_2, \dots]$ ,  $Y \upharpoonright n$  denotes the continued fraction string corresponding to the first  $n$  entries of  $Y$ , that is  $Y \upharpoonright n = [a_1, a_2 \dots a_n]$ . For  $k \in \mathbb{N}$ ,  $\mathbb{N}^{\leq k}$  refers to the set of continued fraction strings having rank less than or equal to  $k$ . All logarithms in the work have base 2, unless specified otherwise. For any sets  $A$  and  $B$ ,  $A \Delta B$  denotes the symmetric set difference operator, defined by  $(A \setminus B) \cup (B \setminus A)$ . In this work, for ease of notation,  $Y \in \mathbb{N}^*$  denotes an infinite continued fraction and  $X \in \Sigma^\infty$  denotes an infinite binary sequence.

### 2.1 Constructive dimension of binary sequences

Lutz [13] defines the notion of effective (equivalently, constructive) dimension of an individual infinite binary sequence using the notion of the success of  $s$ -gales.

► **Definition 1** (Lutz [13]). For  $s \in [0, \infty)$ , a binary  $s$ -gale is a function  $d : \Sigma^* \rightarrow [0, \infty)$  such that  $d(\lambda) < \infty$  and for all  $w \in \Sigma^*$ ,  $d(w)[\mu(C_w)]^s = \sum_{i \in \{0,1\}} d(wi)[\mu(C_{wi})]^s$ .

The success set of  $d$  is  $S^\infty(d) = \left\{ X \in \mathbb{N}^\infty \mid \limsup_{n \rightarrow \infty} d(X \upharpoonright n) = \infty \right\}$ .

For  $\mathcal{F} \subseteq [0, 1]$ ,  $\mathcal{G}(\mathcal{F})$  denotes the set of all  $s \in [0, \infty)$  such that there exists a lower semicomputable binary  $s$ -gale  $d$  with  $\mathcal{F} \subseteq S^\infty(d)$ .

The constructive dimension or effective Hausdorff dimension of  $\mathcal{F} \subseteq [0, 1]$  is  $\text{cdim}(\mathcal{F}) = \inf \mathcal{G}(\mathcal{F})$  and the constructive dimension of a sequence  $X \in \Sigma^\infty$  is  $\text{cdim}(X) = \text{cdim}(\{X\})$ .

### 3 Effective Continued Fraction Dimension using $s$ -gales

Nandakumar and Vishnoi [20] formulate the notion of effective dimension of continued fractions using the notion of lower semicomputable continued fraction  $s$ -gales. Whereas a binary  $s$ -gale bets on the digits of the binary expansion of a number, a continued fraction  $s$ -gale places bets on the digits of its continued fraction expansion.

► **Definition 2** (Nandakumar, Vishnoi [20]). For  $s \in [0, \infty)$ , a continued fraction  $s$ -gale is a function  $d : \mathbb{N}^* \rightarrow [0, \infty)$  such that  $d(\lambda) < \infty$  and for all  $w \in \mathbb{N}^*$ , the following holds.

$$d(w)[\gamma(C_w)]^s = \sum_{i \in \mathbb{N}} d(wi)[\gamma(C_{wi})]^s.$$

The success set of  $d$  is  $S^\infty(d) = \left\{ Y \in \mathbb{N}^\infty \mid \limsup_{n \rightarrow \infty} d(Y \upharpoonright n) = \infty \right\}$ .

In this paper, we deal with the notion of effective or equivalently, constructive dimension. In order to effectivize the notion of  $s$ -gales, we require them to be *lower semicomputable*.

► **Definition 3.** A function  $d : \mathbb{N}^* \rightarrow [0, \infty)$  is called lower semicomputable if there exists a total computable function  $\hat{d} : \mathbb{N}^* \times \mathbb{N} \rightarrow \mathbb{Q} \cap [0, \infty)$  such that the following two conditions hold.

- **Monotonicity:** For all  $w \in \mathbb{N}^*$  and for all  $n \in \mathbb{N}$ , we have  $\hat{d}(w, n) \leq \hat{d}(w, n+1) \leq d(w)$ .
- **Convergence:** For all  $w \in \mathbb{N}^*$ ,  $\lim_{n \rightarrow \infty} \hat{d}(w, n) = d(w)$ .

For  $\mathcal{F} \subseteq [0, 1]$ ,  $\mathcal{G}_{CF}(\mathcal{F})$  denotes the set of all  $s \in [0, \infty)$  such that there exists a lower semicomputable continued fraction  $s$ -gale  $d$  with  $\mathcal{F} \subseteq S^\infty(d)$ .

► **Definition 4** (Nandakumar, Vishnoi [20]). The effective continued fraction dimension of  $\mathcal{F} \subseteq [0, 1]$  is

$$\text{cdim}_{CF}(\mathcal{F}) = \inf \mathcal{G}_{CF}(\mathcal{F}).$$

The effective continued fraction dimension of a sequence  $Y \in \mathbb{N}^\infty$  is defined by  $\text{cdim}_{CF}(\{Y\})$ , the effective continued fraction dimension of the singleton set containing  $Y$ .

#### 3.1 Conversion of binary $s$ -gales into continued fraction $s$ -gales

In this subsection, from a continued fraction  $s'$ -gale  $d : \mathbb{N}^* \rightarrow [0, \infty)$ , for any  $s > s'$ , we construct a binary  $s$ -gale  $h : \Sigma^* \rightarrow [0, \infty)$  which succeeds on all the reals on which  $d$  succeeds. The construction proceeds in multiple steps. We first mention some technical lemmas which we use in the proof.

The following lemma is an easy consequence of the fact that the Gauss measure is absolutely continuous with respect to the Lebesgue measure (see for example, Nandakumar and Vishnoi [20]).

► **Lemma 5.** For any interval  $B \subseteq (0, 1)$ , we have

$$\frac{1}{2 \ln 2} \mu(B) \leq \gamma(B) \leq \frac{1}{\ln 2} \mu(B).$$

In the construction that follows, we formulate betting strategies on binary cylinders based on continued fraction cylinders. In order to do this conversion, we require the following bounds on the relationships between the lengths of continued fraction cylinders and binary cylinders.

► **Lemma 6** (Nandakumar, Vishnoi [20]). For any  $0 \leq a < b \leq 1$ , let  $[\frac{m}{2^k}, \frac{m+1}{2^k})$ , where  $0 \leq m \leq 2^k - 1$  be one of the largest dyadic intervals which is a subset of  $[a, b)$ , then  $\frac{1}{2^k} \geq \frac{1}{4}(b - a)$ .

► **Lemma 7** (Falconer [7]). For any  $0 \leq a < b \leq 1$ , let  $[\frac{m}{2^k}, \frac{m+1}{2^k})$ ,  $[\frac{m+1}{2^k}, \frac{m+2}{2^k})$ , where  $0 \leq m \leq 2^k - 2$ , be the smallest consecutive dyadic intervals whose union covers  $[a, b)$ . Then  $\frac{1}{2^k} \leq 2(b - a)$ .

The following lemma is a generalization of the Kolmogorov inequality for continued fraction martingales (Vishnoi [27]) to  $s$ -gales. The lemma states that an equality holds in the case of decompositions using prefix-free subcylinder sets upto a finite depth.

► **Lemma 8.** Let  $d : \mathbb{N}^* \rightarrow [0, \infty)$  be a continued fraction  $s$ -gale. Let  $v \in \mathbb{N}^*$  and for some  $k \in \mathbb{N}$ , let  $A$  be a prefix free set of elements in  $\mathbb{N}^{\leq k}$  such that  $\cup_{w \in A} C_w = C_v$ . Then, we have  $d(v)\gamma^s(v) = \sum_{w \in A} d(w)\gamma^s(w)$ .

In the construction of a binary  $s$ -gale from continued fraction gales, The first step is the following decomposition of a binary cylinder into a set of prefix free continued fraction cylinders.

► **Lemma 9** (Vishnoi [27]). For every  $w \in \Sigma^*$ , there exists a set  $I(w) \subseteq \mathbb{N}^*$  and a constant  $k \in \mathbb{N}$  such that,

1.  $y \in \mathbb{N}^{\leq k}$  for every  $y \in I(w)$ .
2.  $(\cup_{y \in I(w)} C_y) \Delta C_w \subseteq \{\inf(C_w), \sup(C_w)\}$
3.  $I(w0) \cup I(w1) = I(w)$
4.  $I(w0) \cap I(w1) = \phi$

Moreover, given  $w \in \Sigma^*$ , Vishnoi [27] gives a division algorithm to compute  $I(w)$ . It is also clear from the division algorithm that for all  $w \in \Sigma^*$ , there exists a  $u \in I(w)$  such that for all  $v \in (I(w0) \cup I(w1)) \setminus I(w)$ , we have  $u \sqsubset v$ . This  $u \in I(w)$  is the continued fraction cylinder for which the mid point of  $w$ ,  $m(w)$  is an interior point in  $C_u$  and therefore gets divided.

From a continued fraction martingale, Vishnoi [27] uses the decomposition  $I(w)$  to construct a binary martingale that places the same aggregate bets on an interval. We generalize this construction to the setting of  $s$ -gales. Given a continued fraction  $s'$ -gale  $d : \mathbb{N}^* \rightarrow [0, \infty)$ , using the decomposition  $I(w)$ , we construct a binary  $s'$ -gale  $H_d$  from  $d$ .

► **Definition 10.** Given any continued fraction  $s'$ -gale  $d : \mathbb{N}^* \rightarrow [0, \infty)$ , define the Proportional binary  $s'$ -gale of  $d$ ,  $H_d : \Sigma^* \rightarrow [0, \infty)$  as follows:

$$H_d(w) = \sum_{y \in I(w)} d(y) \left( \frac{\gamma(y)}{\mu(w)} \right)^{s'}.$$

## 70:6 Effective Continued Fraction Dimension

For a  $w \in \Sigma^*$ , let  $I'(w) = I(w0) \cup I(w1)$ . Then we have,

$$H_d(w0) + H_d(w1) = 2^{s'} \sum_{y \in I'(w)} d(y) \left( \frac{\gamma(y)}{\mu(w)} \right)^{s'}.$$

Let  $u \in I(w)$  such that for all  $v \in I'(w) \setminus I(w)$ ,  $u \sqsubset v$ . Hence, by Lemma 8, it follows that  $\sum_{y \in I'(w)} d(y) \gamma^{s'}(y) = \sum_{y \in I(w)} d(y) \gamma^{s'}(y)$ . Therefore, we have  $H_d(w0) + H_d(w1) = 2^{s'} H_d(w)$ , so  $H_d$  is an  $s'$ -gale. Also as  $\gamma(\lambda) = 1$ , we have that  $H_d(\lambda) = d(\lambda)$ .

As  $I(w)$  is computably enumerable, it follows that  $H_d$  is lower semicomputable if  $d$  is lower semicomputable.

The construction by Vishnoi [27] proceeds using the *savings-account trick* for martingales. In the setting of  $s$ -gales, however, the concept of a savings account does not work directly. Therefore, we require additional constructions in this setting.

Using ideas from the construction given in Lemma 3.1 in Hitchcock and Mayordomo [8], we construct a “smoothed”  $s$ -gale  $H_h : \Sigma^* \rightarrow [0, \infty)$  from the proportional  $s'$ -gale constructed in Definition 10.

► **Definition 11.** For a  $w \in \Sigma^*$ , and an  $n > |w|$ , we define

$$\begin{aligned} F_n(w) &= \{u \in \{0^n \cup 1^n\} \mid w \sqsubseteq u\} \cup \{u \in \Sigma^n \setminus \{0^n \cup 1^n\} \mid w \sqsubseteq u + 1 \text{ and } w \sqsubseteq u - 1\}, \\ H_n(w) &= \{u \in \Sigma^n \mid w \sqsubseteq u \text{ or } w \sqsubseteq u + 1 \text{ or } w \sqsubseteq u - 1\} \setminus F_n. \end{aligned}$$

► **Definition 12.** Given an  $s'$ -gale  $h : \Sigma^* \rightarrow [0, \infty)$ , for any  $s > s'$  and for each  $n \in \mathbb{N}$ , define:

$$h_n(w) = \begin{cases} 2^{s|w|} \left( \sum_{u \in H_n(w)} \frac{1}{2} h(u) + \sum_{u \in F_n(w)} h(u) \right) & \text{if } |w| < n \\ 2^{(s-1)(|w|-n+1)} h_n(w[0 \dots n-2]) & \text{otherwise.} \end{cases}$$

Define  $S_h : \Sigma^* \rightarrow [0, \infty)$  by

$$S_h(w) = \sum_{n=0}^{\infty} 2^{-sn} h_n(w).$$

We call  $S_h$  as the smoothed  $s$ -gale of  $h$ .

Consider a string  $w \in \Sigma^n$  other than  $0^n$  and  $1^n$ . In  $h_n$ , a factor of half the capital of  $w$  gets assigned to its immediate parent  $w'$ . The other half is assigned to the neighbor of  $w'$  to which  $w$  is adjacent to.

It is straightforward to verify that each  $h_n$  is an  $s$ -gale.  $S_h$  is a combination of  $s$ -gales, and hence is a valid  $s$ -gale. Note that  $h_n(\lambda) = \sum_{u \in \Sigma^n} h(u) = 2^{s'n}$ . Therefore as  $s > s'$ ,  $S_h(\lambda) = \sum_{n \in \mathbb{N}} 2^{(s'-s)n}$  is finite. If  $h$  is lower semicomputable, it follows that  $S_h$  is lower semicomputable.

Combining the constructions given in the section, for any  $s > s'$ , we show the construction of a binary  $s$ -gale from a continued fraction  $s'$ -gale, satisfying certain bounds on the capital acquired.

This construction helps to establish a lower bound on effective continued fraction dimension using effective binary dimension. It is also central in formulating a Kolmogorov complexity characterization for continued fraction dimension.

► **Lemma 13.** *For  $s' \in (0, \infty)$ , let  $d : \mathbb{N}^* \rightarrow [0, \infty)$  be a continued fraction  $s'$ -gale. Then, for any  $s > s'$ , there exists a binary  $s$ -gale  $h : \Sigma^* \rightarrow [0, \infty)$  such that for any  $v \in \mathbb{N}^*$  and for any  $b \in \Sigma^*$  such that  $C_b \cap C_v \neq \emptyset$  and  $\frac{1}{16}\mu(v) \leq \mu(b) \leq 2\mu(v)$ , we have*

$$h(b) \geq c_s d(v),$$

where  $c_s$  is a constant that depends on  $s$ . Moreover, if  $d$  is lower semicomputable, then  $h$  is lower semicomputable.

#### 4 Kolmogorov Complexity characterization of Continued Fraction Dimension

Mayordomo [16] extended the result by Lutz [11] to show that effective dimension of a binary sequence  $X \in \Sigma^\infty$  can be characterized in terms of the Kolmogorov complexity of the finite prefixes of  $X$ .

► **Theorem 14** (Mayordomo [16] and Lutz [11]). *For every  $X \in \Sigma^\infty$ ,*

$$\text{cdim}(X) = \liminf_{n \rightarrow \infty} \frac{K(X \upharpoonright n)}{n}.$$

We provide a similar characterization for effective continued fraction dimension. To obtain the Kolmogorov complexity of a continued fraction string, we use the Kolmogorov complexity of one of its binary encodings.

The idea of encoding a finite continued fraction using a 1-1 binary encoding is present in Vishnoi [28]. The author presents an invariance theorem stating that every computable binary 1-1 encoding of continued fractions defines the same Kolmogorov complexity, up to an additive constant. Hence in this work, we use a new binary encoding to define Kolmogorov complexity of continued fractions, which helps us establish the characterization of effective dimension of continued fractions in a fairly simple manner while having intuitive geometric meaning.

► **Definition 15** (Many-one binary encoding). *For a continued fraction string  $v \in \mathbb{N}^*$ , let  $b_v$  be the leftmost maximal binary cylinder which is enclosed by  $C_v$ . We define  $E(v) = b_v$ .*

► **Lemma 16.** *For any  $b \in \Sigma^*$ , there exists at most three  $v \in \mathbb{N}^*$  such that  $E(v) = b$ .*

Therefore for any  $b \in \Sigma^*$ , at most three continued fraction cylinders, say  $[v]$ ,  $[v, i]$  and  $[v, i, j]$  get mapped to  $b$ . Therefore we pad two additional bits of information to  $E(v)$ , say  $b_1(v).b_2(v)$  to identify the continued fraction cylinder that  $E(v)$  corresponds to.

► **Definition 17** (One-one binary encoding). *For  $v \in \mathbb{N}^*$ , let  $\mathcal{E}(v) = E(v).b_1(v).b_2(v)$ . This forms a one to one binary encoding of  $v$ .*

We define Kolmogorov complexity of continued fraction string  $v \in \mathbb{N}^*$  as the Kolmogorov complexity of  $\mathcal{E}(v)$ .

► **Definition 18** (Kolmogorov complexity of continued fraction strings). *For any  $v \in \mathbb{N}^*$ , define  $K_{\mathcal{E}}(v) = K(\mathcal{E}(v))$ .*

**Notation.** By the invariance theorem of Vishnoi [28], for any  $v \in \Sigma^*$ ,  $K_{\mathcal{E}}$  is at most an additive constant more than the complexity of  $v$  as defined in [28]. Hence, we drop the suffix and denote the above complexity as  $K(v)$ .

In the proof of Theorem 14, Mayordomo [16] provides the construction of an  $s$ -gale that succeeds on all  $X$  for which  $s > s' > \liminf_{n \rightarrow \infty} \frac{K(X \upharpoonright n)}{n}$ . We extend the construction to the setting of continued fractions.

Additionally, we take a convex combination of gales to remove the dependence of the  $s$ -gale on the parameter  $s'$ . Due to this, we obtain the notion of an optimal lower semicomputable continued fraction  $s$ -gale. This notion is crucial in the proofs we use in the upcoming sections.

► **Definition 19.** Given  $0 < s' < s \leq 1$  let

$$G_{s'} = \{w \in \mathbb{N}^* \mid K(w) \leq -s' \log(\mu(w))\}.$$

Consider the following function  $d_{s'} : \mathbb{N}^* \rightarrow [0, \infty)$  defined by

$$d_{s'}(v) = \frac{1}{\gamma^s(v)} \left( \sum_{w \in G_{s'}; v \sqsubseteq w} \gamma^{s'}(w) + \sum_{w \in G_{s'}; w \sqsubset v} \gamma^{s'}(w) \frac{\gamma(v)}{\gamma(w)} \right).$$

Now for each  $i \in \mathbb{N}$ , let  $s_i = s(1 - 2^{-i})$ . Finally, define  $d^* : \mathbb{N}^* \rightarrow [0, \infty)$  by

$$d^*(v) = \sum_{i=1}^{\infty} 2^{-i} d_{s_i}(v).$$

We now go on to show that the function  $d^*$  given in Definition 19 is a lower semicomputable  $s$ -gale. Additionally, it succeeds on all continued fraction sequences  $Y$  for which the Kolmogorov complexity of its prefixes,  $K(Y \upharpoonright n)$  dips below  $s \times -\log(\mu(Y \upharpoonright n))$  infinitely often.

► **Lemma 20.** For any  $0 < s \leq 1$ , there exists a lower semicomputable continued fraction  $s$ -gale  $d^* : \mathbb{N}^* \rightarrow [0, \infty)$  that succeeds on all  $Y \in \mathbb{N}^{\infty}$  such that  $\liminf_{n \rightarrow \infty} \frac{K(Y \upharpoonright n)}{-\log(\mu(Y \upharpoonright n))} < s$ .

We refer to Downey and Hirschfeldt's (Theorem 13.3.4 [5]) proof of the lower bound on constructive dimension using Kolmogorov complexity. The proof fundamentally uses properties of the universal lower semicomputable super-martingale.

For any real having continued fraction dimension less than  $s$ , we obtain a lower semicomputable binary  $s$ -gale that succeeds on it from Lemma 13. We use the success of this binary  $s$ -gale along with the same properties of the universal lower semicomputable super-martingale, to prove the following lemma.

► **Lemma 21.** For any  $Y \in \mathbb{N}^{\infty}$  and any  $s > \text{cdim}_{CF}(Y)$ , we have  $\liminf_{n \rightarrow \infty} \frac{K(Y \upharpoonright n)}{-\log(\mu(Y \upharpoonright n))} \leq s$ .

Therefore, we have the following Kolmogorov complexity based characterization of effective continued fraction dimension.

► **Theorem 22.** For any  $Y \in \mathbb{N}^{\infty}$ ,

$$\text{dim}_{CF}(Y) = \liminf_{n \rightarrow \infty} \frac{K(Y \upharpoonright n)}{-\log(\mu(Y \upharpoonright n))}.$$

**Proof.** For any  $Y \in \mathbb{N}^{\infty}$ , let  $s^* = \liminf_{n \rightarrow \infty} \frac{K(Y \upharpoonright n)}{-\log(\mu(Y \upharpoonright n))}$ .

For any  $s > s^*$ , from Lemma 20, it follows that there exists a lower semicomputable  $s$ -gale  $\mathcal{D}$  that succeeds on  $Y$ . Hence  $\text{dim}_{CF}(Y) \leq s^*$ .

For any  $s > \text{dim}_{CF}(Y)$ , from Lemma 21, we have that  $s^* \leq s$ . Therefore, we have  $s^* \leq \text{dim}_{CF}(Y)$ . ◀

#### 4.1 Optimal gales and effective continued fraction dimension of a set

Lutz [13] utilizes the notion of the optimal constructive subprobability supermeasure  $\mathbf{M}$  on the Cantor space [29] to provide a notion of an optimal constructive supergale.

We note that using Theorem 22, the gale that we obtain from Lemma 20 leads to an analogous notion in the continued fraction setting. We call the continued fraction  $s$ -gale  $d^*$  thus obtained as the *optimal lower semicomputable continued fraction  $s$ -gale*.

► **Lemma 23.** *For any  $s > 0$ , there exists a lower semicomputable continued fraction  $s$ -gale  $d^* : \mathbb{N}^* \rightarrow [0, \infty)$  such that for all  $Y \in \mathbb{N}^\infty$  with  $\text{cdim}_{CF}(Y) < s$ ,  $d^*$  succeeds on  $Y$ .*

**Proof.** For all  $Y \in \mathbb{N}^*$  such that  $\text{cdim}_{CF}(Y) < s$ , from Theorem 22, it follows that  $\liminf_{n \rightarrow \infty} \frac{K(Y \upharpoonright n)}{-\log(\mu(Y \upharpoonright n))} < s$ . Now applying Lemma 20, we see that the given lemma holds. ◀

Lutz (Theorem 4.1 in [13]) shows that the effective dimension of a set is precisely the supremum of effective dimensions of individual elements in the set, that is for all  $X \subseteq [0, 1]$ ,  $\text{cdim}(X) = \sup_{S \in X} \text{cdim}(S)$ . Using the notion of the optimal lower semicomputable continued fraction  $s$ -gale from Lemma 23, we extend this result to continued fraction dimension.

► **Theorem 24.** *For all  $\mathcal{F} \subseteq [0, 1]$ ,  $\text{cdim}_{CF}(\mathcal{F}) = \sup_{Y \in \mathcal{F}} \text{cdim}_{CF}(Y)$ .*

**Proof.** For any  $s > \text{cdim}_{CF}(\mathcal{F})$ , for all  $Y \in \mathcal{F}$  there exists a lower semicomputable continued fraction  $s$ -gale that succeeds on  $Y$ . Thus we have  $\sup_{Y \in \mathcal{F}} \text{cdim}_{CF}(Y) \leq s$ .

Take any any  $s > \sup_{Y \in \mathcal{F}} \text{cdim}_{CF}(Y)$ . It follows that for all  $Y \in \mathcal{F}$ ,  $\text{cdim}_{CF}(Y) < s$ . Therefore from Lemma 23, we have that there exists a lower semicomputable continued fraction  $s$ -gale  $d^* : \mathbb{N}^* \rightarrow [0, \infty)$  that succeeds on all  $Y \in \mathcal{F}$ . Therefore,  $\text{cdim}_{CF}(\mathcal{F}) \leq s$ . ◀

## 5 Reals with unequal Effective Dimension and Effective Continued Fraction Dimension

In this section, we show that for any set of reals  $\mathcal{F} \subseteq [0, 1]$ , the effective Hausdorff effective dimension of  $\mathcal{F}$  cannot exceed its effective continued fraction dimension. We show that this cannot be improved to an equality. Hence, this inequality is strict in general. We show this by proving the existence of a real such that its effective continued fraction dimension is strictly greater its effective dimension.

### 5.1 Effective Hausdorff dimension is at most the effective continued fraction dimension

► **Theorem 25.** *For any  $\mathcal{F} \subseteq [0, 1]$ ,  $\text{cdim}(\mathcal{F}) \leq \text{cdim}_{CF}(\mathcal{F})$ .*

**Proof.** Let  $s > s' > \text{cdim}_{CF}(\mathcal{F})$ . By definition, there exists a lower semicomputable continued fraction  $s'$ -gale  $d : \mathbb{N}^* \rightarrow [0, \infty)$  such that  $\mathcal{F} \subseteq S^\infty[d]$ .

Take any  $Y \in S^\infty[d]$ . Let  $X \in \Sigma^\infty$  be the corresponding binary representation of  $Y$ . By definition, for any  $m \in \mathbb{N}$ , there exists an  $n \in \mathbb{N}$  such that  $d(Y \upharpoonright n) > m$ . Let  $v = Y \upharpoonright n$ .

Using Lemma 7, we get two binary cylinders  $w_1$  and  $w_2$  such that  $C_v \subseteq C_{w_1} \cup C_{w_2}$  such that  $\mu(w_1) = \mu(w_2) \leq 2\mu(v)$ . We have that since  $v \sqsubseteq Y$ ,  $w_1 \sqsubseteq X$  or  $w_2 \sqsubseteq X$ . Without loss of generality assume that  $w_1 \sqsubseteq X$ .

From Lemma 13, we obtain a lower semicomputable  $s$ -gale  $h$  such that  $h(w_1) \geq c_s \cdot d(v) \geq c_s \cdot m$  for some positive constant  $c_s$ .

Since  $m$  is arbitrary, we see that  $h$  succeeds on  $X$ . ◀

## 5.2 Reals with unequal effective Hausdorff and effective continued fraction dimensions

We now provide the main construction of the paper, utilizing the results we show in previous sections.

We first require some technical lemmas about the estimation of Lebesgue measure of a continued fraction cylinder in terms of digits of the continued fraction. Some of the bounds derived in this section may be of independent interest.

In combinatorial arguments, the Gauss measure is often difficult to deal with directly, and it is convenient to use the Lebesgue measure, and derive inequalities.

The following equation, Proposition 1.2.7 in Kraaikamp and Iosifescu [9], is extremely useful in deriving an estimate for the Lebesgue measure of continued fraction cylinders. We derive consequences of this Lemma below, and these are crucial in estimating the dimension of the continued fraction we construct in Section 5. Note that the bounds for Gauss measure are not simple to derive directly.

► **Lemma 26** (Kraaikamp, Iosifescu [9]). *For any  $v = [a_1, \dots, a_n]$  and  $i \in \mathbb{N}$ ,*

$$\frac{\mu([v, i])}{\mu([v])} = \frac{s_n + 1}{(s_n + i)(s_n + i + 1)}$$

where  $s_n = [a_n, \dots, a_1]$  is the rational corresponding to the reverse of string  $v$ .

The lemma given above gives the following bounds on the Lebesgue measure of a continued fraction cylinder in terms of the digits of the continued fraction.

► **Lemma 27.** *For any  $v = [a_1, \dots, a_k] \in \mathbb{N}^k$  we have*

$$\prod_{i=1}^k \frac{1}{(a_i + 1)(a_i + 2)} \leq \mu(v) \leq \prod_{i=1}^k \frac{2}{a_i (a_i + 1)}$$

► **Lemma 28.** *Let  $v = [a_1 \dots a_k] \in \mathbb{N}^*$ . Then for any  $a, b \in \mathbb{N}$  such that  $b > a$ ,*

$$\mu\left(\bigcup_{i=a}^b [v, i]\right) \leq \frac{2}{a} \prod_{i=1}^k \frac{2}{a_i (a_i + 1)}$$

The following lemma is a direct constructive extension of the proof by Lutz [12]. Using this technique, we convert a set of computably enumerable prefix free binary covers into a lower semicomputable binary  $s$ -gale.

► **Lemma 29** (Lutz [12]). *For all  $n \in \mathbb{N}$ , and  $\mathcal{F} \subseteq [0, 1]$ , if there is a computably enumerable prefix free binary cover  $\{B_i^n\}$  of  $\mathcal{F}$ , such that  $\sum_i |B_i^n|^s < 2^{-n}$ , then there exists a lower semicomputable binary  $s$ -gale that succeeds on  $\mathcal{F}$ .*

We now proceed to show the construction of the set  $\mathcal{F}$ . The definition uses a parameter  $\mathbf{s}$ . We later go on to show that for all such  $\mathcal{F}$ , there exists an element  $Y \in \mathcal{F}$  such that the effective continued fraction dimension of  $Y$  is greater than 0.5. We also go on to show that  $\text{cdim}(F) \leq \mathbf{s}$ .

We first provide the stage-wise construction of a set  $\mathcal{F}_k \subseteq [0, 1]$ , such that for each  $k \in \mathbb{N}$   $\mathcal{F}_{k+1} \subseteq \mathcal{F}_k$ . We then define the set  $\mathcal{F}$  using an infinite intersection of the sets  $\mathcal{F}_k$ .

► **Definition 30.** Let  $0 < s < 0.5$ . Define  $a_1 = 1$ . For any  $k \in \mathbb{N}$ , such that  $k > 1$ , define  $a_k$  inductively as:

$$a_k = 2 \left( k \prod_{i=1}^{k-1} 100a_i \right)^{1/s}.$$

For any  $k \in \mathbb{N}$ , define  $b_k = 50 \cdot a_k$ . Take  $\mathcal{F}_0 = \lambda$ .

Let  $\mathcal{F}_k = \{[v_1 \dots v_k] \in \mathbb{N}^k \text{ such that } v_i \in [a_i, b_i] \text{ for } i \in 1 \text{ to } k\}$ . Finally define

$$\mathcal{F} = \bigcap_{k=1}^{\infty} \mathcal{F}_k.$$

We use the bounds obtained from Lemma 26, along with basic properties of harmonic numbers to prove the following property of measures of continued fraction sub cylinders.

► **Lemma 31.** For any  $x \in \mathbb{N}^*$ ,  $s \leq 0.5$  and  $a_k, b_k \in \mathbb{N}$  such that  $b_k = 50 \cdot a_k$ ,

$$\sum_{i=a_k}^{b_k} \gamma^s([x, i]) > c \gamma^s([x]) \text{ for some } c > 1.$$

Using the bound derived above, we show that for  $s = 0.5$ , the optimal  $s$ -gale  $d^*$  formulated in Section 4.1 does not succeed on some sequence in  $Y \in \mathcal{F}$ . Using this we establish that  $\text{cdim}_{CF}(Y) \geq 0.5$ .

► **Lemma 32.** There exists a  $Y \in \mathcal{F}$  such that  $\text{cdim}_{CF}(Y) \geq 0.5$ .

**Proof.** Let  $s = 0.5$ . Consider the continued fraction  $s$ -gale  $d^*$  from Lemma 23. It follows that for all  $Y \in \mathbb{N}^*$ , if  $d^*$  does not succeed on any  $Y \in \mathbb{N}^*$ , then  $\text{cdim}_{CF}(Y) \geq s$ .

Consider any  $v \in \mathbb{N}^*$ , let  $\text{rank}(v) = k$ . From lemma 31, we have that for some  $c > 1$ ,

$$\sum_{i=a_k}^{b_k} \gamma^s([v, i]) > c \cdot \gamma^s([v]).$$

Now if  $\forall i \in [a_k, b_k]$ ,  $d^*([v, i]) \geq \frac{1}{c} \cdot d^*(v)$ , from the  $s$ -gale condition it follows that  $d^*(v) \gamma^s(v) \geq \frac{d^*(v)}{c} \sum_{i=a_k}^{b_k} \gamma^s([v, i]) > d^*(v) \gamma^s(v)$ , which is a contradiction.

Therefore, it follows that for all  $v \in \mathbb{N}^*$ , there exists some  $n_v \in [a_k, b_k]$  such that  $d^*([v, i]) < \frac{1}{c} \cdot d^*(v)$ .

Let  $v_0 = \lambda$ , for each  $i \in \mathbb{N}$ , we define  $v_i = [v_{i-1}, n_{v_{i-1}}]$ . Take  $Y = \bigcap_{i=1}^{\infty} C_{v_i}$ , it follows that  $Y \in \mathcal{F}$ . Taking  $d^*(\lambda) = k$  we get  $d^*(Y \upharpoonright n) < \frac{k}{c^n}$ . Therefore the continued fraction  $s$ -gale  $d^*$  does not succeed on  $Y$ . Hence  $\text{cdim}_{CF}(Y) \geq 0.5$ . ◀

From this, it follows that the constructive dimension of the entire set  $\mathcal{F}$  is also greater than or equal to 0.5.

► **Lemma 33.**  $\text{cdim}_{CF}(\mathcal{F}) \geq 0.5$ .

**Proof.** From Theorem 24, we get that  $\text{cdim}_{CF}(\mathcal{F}) = \sup_{Y \in \mathcal{F}} \text{cdim}_{CF}(Y)$ . From Lemma 32, it follows that there exists a  $Y \in \mathcal{F}$  such that  $\text{cdim}_{CF}(Y) \geq 0.5$ . Combining these two, we get that  $\text{cdim}_{CF}(\mathcal{F}) \geq 0.5$ . ◀

Now we show that the effective Hausdorff dimension of all points in the set  $\mathcal{F}$  is less than  $s$ . Using ideas from [2], we devise a set of covers  $S_k$  for  $\mathcal{F}$ , by combining adjacent continued fraction cylinders into a single cover.

Using the bounds derived on Lebesgue measure of continued fraction cylinders, we show that for the set of covers  $S_k$  for  $\mathcal{F}$ , the  $s$ -dimensional Hausdorff measure shrinks arbitrarily small.

## 70:12 Effective Continued Fraction Dimension

► **Lemma 34.** For  $k \in \mathbb{N}$ , let  $S_k = \{ \bigcup_{i=a_k}^{b_k} [v, i] \text{ for } v \in \mathcal{F}_{k-1} \}$ . Then,  $\sum_{S \in S_k} \mu^{\mathbf{s}}(S) \leq 1/k$ .

**Proof.** The largest element in  $S_k$  is  $I = [(a_1 \dots a_{k-1}, a_k), [(a_1 \dots a_{k-1}, b_k)]$ . The number of elements in  $S_k$  equals  $\prod_{i=1}^{k-1} (b_i - a_i)$ . Additionally, we have  $b_i = 50a_i$  for all  $i \in \mathbb{N}$ . Therefore,

$$\sum_{S \in S_k} \mu^{\mathbf{s}}(S) \leq \mu^{\mathbf{s}}(I) \prod_{i=1}^{k-1} 50a_i.$$

From Lemma 28, it follows that  $\mu(I) \leq \frac{2}{a_k} \prod_{i=1}^{k-1} \frac{2}{a_i(a_i+1)}$ . Therefore,

$$\begin{aligned} \sum_{S \in S_k} \mu^{\mathbf{s}}(S) &\leq \left( \frac{2}{a_k} \prod_{i=1}^{k-1} \frac{2}{a_i^2} \right)^{\mathbf{s}} \prod_{i=1}^{k-1} (50a_i) \\ &\leq \frac{2^{\mathbf{s}}}{a_k^{\mathbf{s}}} \prod_{i=1}^{k-1} 100a_i \end{aligned}$$

Since  $a_k = 2(k \prod_{i=1}^{k-1} 100a_i)^{1/\mathbf{s}}$ , this value is less than  $1/k$ . ◀

To show that the constructive dimension of  $\mathcal{F}$  is less than  $\mathbf{s}$ , we construct a lower semicomputable binary  $\mathbf{s}$ -gale that succeeds on  $\mathcal{F}$ . Using standard techniques, we first convert the covers obtained in Lemma 34 to a set of binary covers of  $\mathcal{F}$ . Finally applying Lemma 29, we convert the binary covers into a semicomputable  $\mathbf{s}$ -gale that succeeds on  $\mathcal{F}$ .

► **Lemma 35.**  $\text{cdim}(\mathcal{F}) \leq \mathbf{s}$ .

**Proof.** Given  $k \in \mathbb{N}$ , from Lemma 34, we have that for  $S_k = \{ \bigcup_{i=a_k}^{b_k} [v, i] \text{ for } v \in \mathcal{F}_{k-1} \}$ ,  $\sum_{S \in S_k} \mu^{\mathbf{s}}(S) \leq 1/k$ . For each  $S \in S_k$ , using Lemma 7, we get that for the two smallest consecutive binary cylinders say  $b_1(S)$  and  $b_2(S)$  that cover  $S$ , we have that  $\mu(b_1) = \mu(b_2) \leq 2\mu(S)$ .

Hence the set  $B_k = \{ \{b_1(S)\} \cup \{b_2(S)\} \text{ such that } S \in S_k \}$  forms a binary cover of  $S_k$ . Also from Lemma 7, we have that  $\sum_{b \in B_k} \mu^{\mathbf{s}}(b) \leq 2^{1+\mathbf{s}} \sum_{S \in S_k} \mu^{\mathbf{s}}(S) \leq 2^{1+\mathbf{s}}/k$ .

Note that the set  $S_k$  is computable as  $a_k$  and  $b_k$  are computable for all  $k$ . Given any interval  $S$ ,  $b_1(S)$  and  $b_2(S)$  are also computable. Hence the set  $B_k$  is computable.

Since  $B_k$  is a finite set, we can remove all  $v \in B_k$  such that  $u \sqsubset v$  for some  $u \in B_k$ , to make  $B_k$  prefix free.

For an  $n \in \mathbb{N}$ , taking  $k = \lceil 2^{1+\mathbf{s}} \cdot 2^n \rceil$ , the set  $B_k$  forms a computably enumerable prefix free binary cover of  $\mathcal{F}$  such that  $\sum_{b \in B_k} \mu^{\mathbf{s}}(b) \leq 2^{-n}$ .

Applying Lemma 29, we get that there exists a lower semicomputable  $\mathbf{s}$ -gale that succeeds on  $\mathcal{F}$ . Hence the lemma holds. ◀

We sum up the results from Lemma 32 and Lemma 35 into the following theorem.

► **Theorem 36.** Given any  $0 < \varepsilon < 0.5$ , there exists a  $Y \in \mathbb{N}^*$  such that  $\text{cdim}_{CF}(Y) \geq 0.5$  and  $\text{cdim}(Y) \leq \varepsilon$ .

**Proof.** Given  $0 < \varepsilon < 0.5$ , taking  $\mathbf{s} = \varepsilon$ , construct the set  $\mathcal{F}$  given in Definition 30.

From Lemma 32, it follows that there exists a  $Y \in \mathcal{F}$  such that  $\text{cdim}_{CF}(Y) \geq 0.5$ .

From Lemma 35, it follows that for all  $X \in \mathcal{F}$ ,  $\text{cdim}(X) \leq \varepsilon$ . Hence  $\text{cdim}(Y) \leq \varepsilon$ . ◀

## A Appendix

### A.1 Proof of Lemma 13

**Proof.** Given an  $s'$ -gale  $d : \mathbb{N}^* \rightarrow [0, \infty)$ , let  $h' = H_d$ , the proportional binary  $s'$ -gale of  $d$  given in Definition 10.

For a  $v \in \mathbb{N}^*$ , consider the smallest  $w_1, w_2 \in \Sigma^*$  such that  $C_v \subseteq C_{w_1} \cup C_{w_2}$ . Also we can see that there exists a  $S \subseteq I(w_1) \cup I(w_2)$  such that  $C_v = \cup_{u \in S} C_u$ .

Therefore from Lemma 8, we get  $h'(w_1) + h'(w_2) \geq d(v) \frac{\gamma^{s'}(v)}{\mu^{s'}(w_1)}$ . From Lemma 7, we get that  $\mu(w_1) = \mu(w_2) \leq 2\mu(v)$ . Also from Lemma 5, we have that  $\gamma(v) \leq (\ln 2)^{-1} \mu(v)$ . Therefore,  $h'(w_1) + h'(w_2) \geq (2 \ln 2)^{-s'} d(v)$ . Now for any  $s > s'$ , we have that  $h'(w_1) + h'(w_2) \geq c_1 d(v)$ , where  $c_1 = 1/(2 \ln 2)^s$ .

Now for any  $s > s'$ , consider the smoothed  $s$ -gale  $h = S_{H_d}$  of the  $s'$ -gale  $H_d$  given in Definition 11.

Let  $|w_1| = n$ , and let  $W_1 = P(P(w_1))$  be the parent cylinder of parent of  $w_1$ . Similarly let  $W_2 = P(P(w_2))$ . We see that for any  $W \in \{W_1, W_2\}$ ,  $h_n(W) \geq 2^{s(n-2)} \frac{h'(w_1) + h'(w_2)}{2} \geq c_2 \cdot 2^{sn} \cdot d(v)$ , where  $c_2 = 2^{-(2s+1)} c_1$ .

Take any any  $b \in \Sigma^*$  such that  $C_b \cap C_v \neq \emptyset$  and  $2 \cdot \mu(v) \geq \mu(b) \geq \frac{1}{16} \mu(v)$ . Since  $\mu(b) \leq 2\mu(v)$  and  $\mu(v) \leq 2\mu(w_1)$ , it follows that for some  $W \in \{W_1, W_2\}$ ,  $W \sqsubseteq b$ . Also since  $\mu(b) \geq \frac{1}{16} \mu(v)$ , we have that,  $\mu(b) \geq \frac{1}{32} \mu(w_1)$ .

Therefore, we have that  $h_n(b) \geq 2^{5(s-1)} h_n(W) \geq c_3 \cdot 2^{sn} \cdot d(v)$ , where  $c_3 = c_2 \cdot 2^{5(s-1)}$ .

Since  $h(b) \geq 2^{-sn} h_n(b)$ , we have that  $h(b) \geq c_3 \cdot d(v)$ . ◀

### A.2 Proof of Lemma 31

**Proof.** From Lemma 26, it follows that

$$\begin{aligned} \sum_{a_n}^{b_k} \frac{\mu^s([x, i])}{\mu^s([x])} &= \sum_{a_n}^{b_k} \left( \frac{s_k + 1}{(s_k + i)(s_k + i + 1)} \right)^s \\ &\geq \sum_{a_k}^{b_k} \left( \frac{1}{(i + 1)(i + 2)} \right)^s \end{aligned}$$

The second inequality follows from the fact that  $s_k \in [0, 1]$ .

Using Lemma 5, we get that

$$\sum_{a_n}^{b_k} \frac{\gamma^s([x, i])}{\gamma^s([x])} \geq \sum_{a_k}^{b_k} \left( \frac{1}{2(i+1)(i+2)} \right)^s$$

Putting  $b_k = 50a_k$  and  $s \leq 0.5$ , we get

$$\begin{aligned} \sum_{a_n}^{b_k} \frac{\gamma^s([x, i])}{\gamma^s([x])} &\geq \frac{1}{2} \sum_{a_k}^{50a_k} \frac{1}{i+2} \\ &= 0.5(H(50a_k + 2) - H(a_k + 1)). \end{aligned}$$

where  $H_n$  is the  $n^{\text{th}}$  Harmonic number. From the fact that  $\ln n \leq H_n \leq \ln n + 1$ , we have

$$\begin{aligned} H(50a_k + 2) - H(a_k + 1) &\geq \ln(50a_k) - \ln(2a_k) - 1 \\ &= \ln(25) - 1. \end{aligned}$$

The lemma holds as  $0.5(\ln 25 - 1)$  is greater than 1. ◀

# On the Expressive Power of Regular Expressions with Backreferences

## Abstract

---

A *rewb* is a regular expression extended with a feature called *backreference*. It is broadly known that backreference is a practical extension of regular expressions, and is supported by most modern regular expression engines, such as those in the standard libraries of Java, Python, and more. Meanwhile, *indexed languages* are the languages generated by indexed grammars, a formal grammar class proposed by A.V.Aho. We show that these two models' expressive powers are related in the following way: every language described by a rew b is an indexed language. As the smallest formal grammar class previously known to contain rewbs is the class of context sensitive languages, our result strictly improves the known upper-bound. Moreover, we prove the following two claims: there exists a rew b whose language does not belong to the class of stack languages, which is a proper subclass of indexed languages, and the language described by a rew b without a captured reference is in the class of nonerasing stack languages, which is a proper subclass of stack languages. Finally, we show that the hierarchy investigated in a prior study, which separates the expressive power of rewbs by the notion of nested levels, is within the class of nonerasing stack languages.

## 1 Introduction

A *rewb* is a regular expression empowered with a certain extension, called *backreference*, that allows preceding substrings to be used later. It is closer to practical regular expressions than the pure ones, and supported by the standard libraries of most modern programming languages. A typical example of a rew b follows:

► **Example 1.** Let  $\Sigma$  be the alphabet  $\{a, b\}$ . The language  $L(\alpha)$  described by the rew b  $\alpha = ({}_1(a + b)^*)_1 \setminus 1$  is  $\{ww \mid w \in \Sigma^*\}$ . Intuitively,  $\alpha$  first *captures* a preceding string  $w \in L((a + b)^*)$  by  $({}_1)_1$ , and second *references* that  $w$  by following  $\setminus 1$ . Therefore,  $\alpha$  matches  $ww$ . Because this  $L(\alpha)$  is a textbook example of a non-context-free language (and therefore non-regular), the expressive power of rewbs exceeds that of the pure ones.

In 1968, A.V.Aho discovered indexed languages with characterizations by two equivalent models: indexed grammars and (one-way<sup>1</sup> nondeterministic, or 1N) nested stack automata (NSA) [1, 2]. The class of indexed languages is a proper superclass of context free languages (CFL), and a proper subclass of context sensitive languages (CSL) [1].

---

<sup>1</sup> “One-way” means that the input cursor will not move back to left. The antonym is “two-way.”

Berglund and van der Merwe [4], and Câmpeanu et al. [5] have shown that the class of rewbs is incomparable with the class of CFLs and is a proper subclass of CSLs. As the first main contribution of this paper, we prove that the language described by a rewb is an indexed language. Since the class of CSLs was the previously known best upper-bound of rewbs, our result gives a novel and strictly tighter upper-bound.

Meanwhile, there is a class of the languages called stack languages [8, 7]. This class corresponds to the model (1N) stack automata (SA), a restriction of NSA. Hence, it trivially follows that the class of stack languages is a subclass of indexed languages. Actually, this containment is known to be proper [2]. Furthermore, a model called nonerasing stack automata (NESA) has been studied in papers such as [8, 11, 14], and its language class is known to be a proper subclass of stack languages [14].

In this paper, we show that every rewb without a captured reference (that is, one in which no reference  $\backslash i$  appears as a subexpression of an expression of the form  $(\alpha)_j$ ) describes a nonerasing stack language. Given our result, the following question is natural: does every rewb describe a (nonerasing) stack language? We show that the answer is no. Namely, we show a rewb that describes a non-stack language. Finally, Larsen [12] has proposed a notion called *nested levels* of a rewb and showed that they give rise to a concrete increasing hierarchy of expressive powers of rewbs by exhibiting, for each nested level  $i \in \mathbb{N}$ , a language  $L_i$  that is expressible by a rewb at level  $i$  but not at any levels below  $i$ . We show that this hierarchy is within the class of nonerasing stack languages, that is, there exists an NESA  $A_i$  recognizing  $L_i$  for every nested level  $i$ . Below, we summarize the main contributions of the paper.

- (a) Every rewb describes an indexed language. (Section 4, Corollary 16)
- (b) Every rewb without a captured reference describes a nonerasing stack language. (Section 4, Corollary 17)
- (c) There exists a rewb that describes a non-stack language. (Section 5, Theorem 18)
- (d) The hierarchy given by Larsen [12] is within the class of nonerasing stack languages. (Section 6, Theorem 20)

Note that by (b) and (c), it follows that there is a rewb that *needs* capturing of references (Section 5, Corollary 19). See also Figure 2 for a summary of the results.

The rest of the paper is organized as follows. Section 2 discusses related work. Section 3 defines preliminary notions used in the paper such as the syntax and semantics of rewb, SA, NESA, and NSA. Sections 4, 5, and 6 formally state and prove the paper’s main contributions listed above. Section 7 concludes the paper with a discussion on future work. For space, the proofs are in the full paper [13].

## 2 Related Work

First, we discuss related work on rewbs. There are several variants of the syntax and semantics of rewbs since they first appeared in the seminal work by Aho [3]. A recent study by Berglund and van der Merwe [4] summarizes the variants and the relations between them. In sum, there are two variants of the syntax, whether or not a same label may appear as the index of more than one capture (“may repeat labels”, “no label repetitions”), and two variants of the semantics, whether an unbound reference is interpreted as the empty string or an undefined factor ( $\varepsilon$ -semantics,  $\emptyset$ -semantics). As shown in [4], there is no difference in the expressive powers between these two semantics under the “may repeat labels” syntax (therefore, there are three classes with different expressive powers, namely “no label repetitions” with  $\emptyset$ -semantics, “no label repetitions” with  $\varepsilon$ -semantics, and “may repeat labels”). In this paper, we focus on the “may repeat labels” formalization, which has

the highest expressive power of the three and is often studied in formal language theory. We adopt the  $\varepsilon$ -semantics as the semantics of rewbs. Note that the pioneering formalization of rewbs given by Aho [3] has the equivalent expressive power as this class. The rewbs with “may repeat labels” with  $\varepsilon$ -semantics was recently proposed by Schmid with the notion of ref-words and dereferences [15]. Simultaneously, he proposed a class of automata called *memory automata* (MFA), and showed that its expressive power is equivalent to that of rewbs. Freydenberger and Schmid extended MFA to *MFA with trap-state* [6]. Berglund and van der Merwe [4] showed that the class of Schmid’s rewbs is a proper subclass of CSLs, and is incomparable with the class of CFLs. Note that there is a pumping lemma for the formalization given by C ampeanu et al. [5] but it is known not to work for Schmid’s rewbs. As mentioned above, Larsen introduced the notion of nested levels and showed that increase in the levels increases the expressive powers of rewbs [12].

Next, we discuss related work on the three automata used throughout the paper, namely SA, NESA, and NSA. Ginsburg et al. introduced SA as a mathematical model that is more powerful than pushdown automaton (PDA), and NESA as a restricted version of SA [8]. Hopcroft and Ullman discovered a type of Turing machine corresponding to the class of two-way NESA [11]. Ogden proposed a pumping lemma for stack languages and nonerasing stack languages [14]. Aho proposed NSA with a proof of the fact that (1N) NSA and indexed grammars given by himself in [1] are equivalent in their expressive powers, and recognized PDA and SA as special cases of NSA [2]. Aho also showed that the class of indexed languages is a proper superclass of CFLs, and a proper subclass of CSLs [1]. Hayashi proposed a pumping lemma for indexed languages [9].

### 3 Preliminaries

In this section, we formalize the syntax and the semantics of rewbs following the formalization given in [6]. We begin with the syntax. Let  $\Sigma_\varepsilon = \Sigma \uplus \{\varepsilon\}$  and  $[k] = \{1, 2, \dots, k\}$ , where the symbol  $\uplus$  denotes a disjoint union.

► **Definition 2.** For each natural number  $k \geq 1$ , the set of  $k$ -rewbs over  $\Sigma$ , written  $REWB_k$ , and the mapping  $\text{var} : REWB_k \rightarrow \mathcal{P}([k])$  are defined as follows, where  $a \in \Sigma_\varepsilon$  and  $i \in [k]$ :

$$\begin{aligned} (\alpha, \text{var}(\alpha)) ::= & (a, \emptyset) \mid (\backslash i, \{i\}) \mid (\alpha_0 \alpha_1, \text{var}(\alpha_0) \cup \text{var}(\alpha_1)) \mid (\alpha_0 + \alpha_1, \text{var}(\alpha_0) \cup \text{var}(\alpha_1)) \\ & \mid (\alpha_0^*, \text{var}(\alpha_0)) \mid ((\alpha_0)_j, \text{var}(\alpha_0) \uplus \{j\}) \text{ where } j \in [k] \setminus \text{var}(\alpha_0). \end{aligned}$$

We also write  $REWB_0$  for the set REG of regular expressions over  $\Sigma$ , and  $REWB$  for the set of all rewbs, namely  $\bigcup_{k \geq 0} REWB_k$ .

► **Example 3.** For example,  $\varepsilon$ ,  $a$ ,  $\backslash 1$ ,  $a^* \backslash 1$ ,  $(1a^*)_1$ ,  $((1a^*)_1)^*$ ,  $(2a^*)_2 \backslash 2$ ,  $(1a^*)_1 (2b^*)_2 (\backslash 1 + \backslash 2)$ ,  $(2(1(a+b)^*)_1 \backslash 1)_2 \backslash 2 (2 \backslash 1)_2^*$ ,  $((1 \backslash 4 a)_1 (2 \backslash 3)_2 (3 \backslash 2 a)_3 (4 \backslash 1 \backslash 3)_4)^*$  are rewbs. On the other hand,  $(1(1a^*)_1)_1$ ,  $(1a^* \backslash 1)_1$ ,  $(1(2(1a^*)_1)_2)_1$  are not rewbs.

Note that this syntax allows multiple occurrences of captures with the same label, that is, we adopt the “may repeat labels” convention. Next, we define the semantics.

► **Definition 4.** Let  $B_k = \{[i, ]_i \mid i \in [k]\}$ . The mapping  $\mathcal{R}_k : REWB_k \rightarrow \mathcal{P}((\Sigma \uplus B_k \uplus [k])^*)$  is defined as follows, where  $a \in \Sigma_\varepsilon$  and  $i \in [k]$ :

$$\begin{aligned} \mathcal{R}_k(a) &= \{a\}, \quad \mathcal{R}_k(\backslash i) = \{i\}, \quad \mathcal{R}_k(\alpha_0 \alpha_1) = \mathcal{R}_k(\alpha_0) \mathcal{R}_k(\alpha_1), \\ \mathcal{R}_k(\alpha_0 + \alpha_1) &= \mathcal{R}_k(\alpha_0) \cup \mathcal{R}_k(\alpha_1), \quad \mathcal{R}_k(\alpha^*) = \mathcal{R}_k(\alpha)^*, \quad \mathcal{R}_k((\alpha)_i) = \{[i] \mathcal{R}_k(\alpha) [i]\}. \end{aligned}$$

We let  $\Sigma_k^{[*]}$  denote  $\bigcup_{\alpha \in REWB_k} \mathcal{R}_k(\alpha)$ .

► **Example 5.**  $\mathcal{R}_k((1(a+b)^*)_1 \setminus 1) = \{[1] \{a, b\}^* [1] \{1\}\} = \{[1 w]_1 1 \mid w \in \{a, b\}^*\}$ .

That is, we first regard a rewb  $\alpha$  over  $\Sigma$  as a regular expression over  $\Sigma \uplus B_k \uplus [k]$ , deducing the language  $\mathcal{R}_k(\alpha)$ . The second step, described next, is to apply the *dereferencing (partial) function*  $\mathcal{D}_k : (\Sigma \uplus B_k \uplus [k])^* \rightarrow \Sigma^*$  to each of its element.

We give an intuitive description of  $\mathcal{D}_k$ . First,  $\mathcal{D}_k$  scans its input string from the beginning toward the end, seeking  $i \in [k]$ . If such  $i$  is found,  $\mathcal{D}_k$  replaces this  $i$  with the substring obtained by removing the brackets in  $v$  that comes from the preceding  $[i v]_i$  if  $[i$  exists (if this  $[i$  has no corresponding  $]_i$ ,  $\mathcal{D}_k$  becomes undefined). Otherwise,  $\mathcal{D}_k$  replaces this  $i$  with  $\varepsilon$ . The dereferencing function  $\mathcal{D}_k$  repeats this procedure until all elements of  $[k]$  appearing in the string are exhausted, then removes all remaining brackets. We let  $v_{[r]}$  denote the string which  $\mathcal{D}_k$  scans at the  $r^{\text{th}}$  number  $n_r \in [k]$  at the  $r^{\text{th}}$  loop (see the full version [13] for the formal definitions of  $\mathcal{D}_k$  and  $v_{[r]}$ ).

1.  $[1a [2b]_2 2]_1 1$ . In this example,  $\mathcal{D}_k$  encounters  $n_1 = 2$  first, and this 2 corresponds the preceding  $[2b]_2$ , therefore this 2 is replaced with  $v_{[1]} = b$ . As a result, the input string becomes  $[1a [2b]_2 b]_1 1$ .  $\mathcal{D}_k$  repeats this process again. Now,  $\mathcal{D}_k$  locates  $n_2 = 1$  corresponding the preceding  $[1a [2b]_2 b]_1$ , so this 1 is replaced with  $v_{[2]} = a[2b]_2 b$  but with the brackets erased. Therefore we gain  $[1a [2b]_2 b]_1 abb$ . Finally,  $\mathcal{D}_k$  removes all remaining brackets and produces  $abbabb$ . Here is the diagram:  $[1a [2b]_2 2]_1 1 \rightarrow [1a [2b]_2 b]_1 1 \rightarrow [1a [2b]_2 b]_1 abb \rightarrow abbabb$ .
2.  $[1a]_1 1 [1bb]_1 1$ . In this example,  $n_1 = n_2 = 1$ ,  $v_{[1]} = a$ ,  $v_{[2]} = bb$ , and

$$[1a]_1 1 [1bb]_1 1 \rightarrow [1a]_1 a [1bb]_1 1 \rightarrow [1a]_1 a [1bb]_1 bb \rightarrow aabbbb.$$

3.  $abc12$ . In this example,  $n_1 = n_2 = 1$ ,  $v_{[1]} = v_{[2]} = \varepsilon$ , and  $abc12 \rightarrow abc2 \rightarrow abc$ .

Note that an unbound reference is replaced with the empty string  $\varepsilon$ , that is, we adopt the  $\varepsilon$ -semantics. However, as mentioned in Section 2, this semantics' expressive power is equivalent to that of the  $\emptyset$ -semantics under the “may repeat labels” convention (see [4] for the proof). We define the language  $L(\alpha)$  denoted by a  $k$ -rewb  $\alpha \in REWB_k$  to be  $\mathcal{D}_k(\mathcal{R}_k(\alpha)) = \{\mathcal{D}_k(v) \mid v \in \mathcal{R}_k(\alpha)\}$  (Lemmas 6 and 8 ensure that  $L(\alpha)$  is well-defined).

Let  $g : (\Sigma \uplus B_k)^* \rightarrow \Sigma^*$  denote the free monoid homomorphism where  $g(x)$  is  $x$  for each  $x \in \Sigma$ , and  $\varepsilon$  for each  $x \in B_k$ . Every  $v \in (\Sigma \uplus B_k \uplus [k])^*$  can be written uniquely in the form  $v = v_0 n_1 v_1 \cdots n_m v_m$ , where  $m \geq 0$  (denoted by  $\text{cnt } v$ ), and  $v_r \in (\Sigma \uplus B_k)^*$  and  $n_r \in [k]$  for each  $r \in \{0, \dots, m\}$ . Here, let  $y_0 \triangleq v_0$  and for each  $r \in \{1, \dots, m\}$ ,  $y_r \triangleq v_0 n_1 v_1 \cdots n_r v_r$ . A string  $v = v_0 n_1 v_1 \cdots n_m v_m$  over  $\Sigma \uplus B_k \uplus [k]$  is said to be *matching* if

$$\forall r \in \{1, \dots, m\}. \forall x_1, x_2. y_{r-1} = x_1 [n_r x_2 \implies (\exists x'_2, x_3. x_2 = x'_2]_{n_r} x_3 \wedge x'_2 \notin ]_{n_r}]_{n_r}$$

holds. Intuitively, a string  $v$  being matching means that for all  $n_r \in [k]$  in  $v$ , if there exists a left bracket  $[n_r$  in the string immediately before  $n_r$ , then there is a right bracket  $]_{n_r}$  in between this  $[n_r$  and  $n_r$ . The following three lemmas follow.

► **Lemma 6.** *Given a matching string  $v$ ,  $\mathcal{D}_k(v) = g(v_0) g(v_{[1]}) g(v_1) \cdots g(v_{[m]}) g(v_m)$ .*

► **Lemma 7.** *A prefix of a matching string is matching. That is, if we decompose a string  $v$  into  $v = xy$ ,  $x$  is matching. Moreover,  $x_{[r]} = v_{[r]}$  holds for each  $r = 1, \dots, \text{cnt } x (\leq \text{cnt } v)$ .*

► **Lemma 8.** *Every  $v \in \Sigma_k^{[*]}$  is matching.*

Next, we recall the notions of SA, NESAs, and NSAs. In this paper, we unify their definitions based on [2, 7] to clarify the different capabilities of these models. First, we review NFA. Here is the definition in the textbook by Hopcroft et al. [10]:

► **Definition 9** ([10], p.57). A *nondeterministic finite automaton*  $N$  is a 5-tuple  $(Q, \Sigma, \delta, q_0, F)$ , where  $Q$  is a finite set of states,  $\Sigma$  a finite set of input symbols (also called alphabet),  $q_0 \in Q$  a start state,  $F \subseteq Q$  a set of final states, and  $\delta : Q \times \Sigma \rightarrow \mathcal{P}(Q)$  a transition function.

As well known, the transition function  $\delta$  can be *extended* to  $\hat{\delta} : Q \times \Sigma^* \rightarrow \mathcal{P}(Q)$  where  $\hat{\delta}(q, w)$  represents the set of all states reachable from  $q$  via  $w$ . Let  $q \xrightarrow{a}_N q'$  denote  $q' \in \delta(q, a)$ , and  $q \xrightarrow{w}_N q'$  denote  $q' \in \hat{\delta}(q, w)$ . With this notation, the language of an NFA  $N$  can be written as follows:  $L(N) = \left\{ w \in \Sigma^* \mid \exists q_f \in F. q_0 \xrightarrow{w}_N q_f \right\}$ .

A pushdown automaton (PDA) is an NFA equipped with a *stack* such that the PDA may write and read its *stack top* with a transition. A *stack automaton* (SA) is “an extended PDA”, which can reference not only the top but inner content of the stack. That is, while the *stack pointer* of a PDA is fixed to the top, an SA allows its pointer to move left and right and read a stack symbol pointed to by the pointer. However, the only place on the stack that can be rewritten is the top, as in PDA. Formally, a (1N) SA  $A$  is a 9-tuple  $(Q, \Sigma, \Gamma, \delta, q_0, Z_0, \#, \$, F)$  satisfying the following conditions: the components  $Q, \Sigma, q_0$  and  $F$  are the same as those of NFA.  $\Gamma (\neq \emptyset)$  is a finite set of stack symbols, and  $Z_0 \in \Gamma$  is an initial stack symbol. The stack symbol  $\# \notin \Sigma \cup \Gamma$  (resp.  $\$ \notin \Sigma \cup \Gamma$ ) is always and only written at the leftmost (bottom) (resp. the right most (top)) of the stack.<sup>2</sup> The transition function  $\delta$  has the following two modes, where  $L, S, R \notin (\Sigma \cup \Gamma) \uplus \{\#, \$\}$ ,  $\Delta_i \triangleq \{S, R\}$ , and  $\Delta_s \triangleq \{L, S, R\}$ :

- (i) (pushdown mode)  $Q \times \Sigma \times \Gamma \$ \rightarrow \mathcal{P}(Q \times \Delta_i \times \Gamma^* \$)$ ,
- (ii) (stack reading mode) (a)  $Q \times \Sigma \times \Gamma \$ \rightarrow \mathcal{P}(Q \times \Delta_i \times \{L\})$ , (b)  $Q \times \Sigma \times \Gamma \rightarrow \mathcal{P}(Q \times \Delta_i \times \Delta_s)$ ,  
(c)  $Q \times \Sigma \times \{\#\} \rightarrow \mathcal{P}(Q \times \Delta_i \times \{R\})$ .

Intuitively,  $\delta$  works as follows (Definition 10 provides the formal semantics). (i) The statement  $(q', d, w \$) \in \delta(q, a, Z \$)$  says that whenever the current state is  $q$ , the input symbol is  $a$ , and the pointer references the top symbol  $Z$ , the machine can move to the state  $q'$ , move the input cursor along  $d$ , and replace  $Z$  with the string  $w$ . (ii) The statement (b)  $(q', d, e) \in \delta(q, a, Z)$  says that whenever the current state is  $q$ , the input symbol is  $a$ , and the pointer references the symbol  $Z$ , the machine can move to the state  $q'$ , move the input cursor along  $d$ , and move the pointer along  $e$ . The statements (a) and (c) are similar to (b) except that the direction in which the pointer can move is restricted lest the pointer go out of the stack. In particular, an SA that cannot erase a symbol once written on the stack is called a *nonerasing stack automaton* (NESAs). That is, a (1N) nonerasing stack automaton is an SA whose transition function  $\delta$  satisfies the condition that, in (i) (pushdown mode),  $(q', d, w \$) \in \delta(q, a, Z \$)$  implies  $w \in Z\Gamma^*$ . To formally describe how SA works, we define a tuple called *instantaneous description* (ID), which consists of a state, an input string, and a string representation of the stack, and define the binary relation  $\vdash_A$  over the set of these tuples. Let  $\bar{L} = -1$ ,  $\bar{S} = 0$ , and  $\bar{R} = 1$ .

► **Definition 10.** Let  $A$  be an SA  $(Q, \Sigma, \Gamma, \delta, q_0, \#, \$, F)$ . An element of the set  $I = Q \times \Sigma^* \times \{\#\}(\Gamma \uplus \{1\})^* \{\$\}$  is called *instantaneous description*, where the stack symbol  $1 \notin \Gamma$  stands for the position of stack pointer. Moreover, let  $\vdash_A$  (or  $\vdash$  when  $A$  is clear) be the smallest binary relation over  $I$  satisfying the following conditions:

<sup>2</sup> These special symbols  $\#, \$$  representing “bottom” and “top” of the stack respectively do not appear in [7] and are introduced anew in this paper to define NESAs and NSAs, which will be defined later, in the style of [2]. In fact, SA defined in [7] is not capable of directly discerning whether the stack pointer is at the top or not. Although it is not difficult to see that directly adding the ability does not increase the expressive power of SA, the ability is directly in NESAs as seen in [11, 14]. Therefore, to make it easy to see that NESAs is a restriction of SA, we define SA to also directly have the ability.

- (i)  $(q, a_i \cdots a_k, \#yZ\uparrow\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#yw\uparrow\$)$  if  $(q', d, w\$) \in \delta(q, a_i, Z\$)$ .<sup>3</sup>
- (ii) (a)  $(q, a_i \cdots a_k, \#yZ\uparrow\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#y\uparrow Z\$)$  if  $(q', d, L) \in \delta(q, a_i, Z\$)$ .  
 (b) if  $(q', d, e) \in \delta(q, a_i, Z)$  and  $Z = Z_j$ ,  $1 \leq j < n$ , then  
 $(q, a_i \cdots a_k, \#Z_1 \cdots Z_j \uparrow \cdots Z_n\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#Z_1 \cdots Z_{j+\bar{e}} \uparrow \cdots Z_n\$)$ .  
 (c)  $(q, a_i \cdots a_k, \#\uparrow Zy\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#Z\uparrow y\$)$  if  $(q', d, R) \in \delta(q, a_i, \#)$ .

Note that  $L \notin \Delta_i$ , which means the input cursor will not move back to left. We say that  $A$  accepts  $w \in \Sigma^*$  if there exist  $y_1, y_2 \in \Gamma^*$ , and  $q_f \in F$  such that  $(q_0, w, \#Z_0\uparrow\$) \vdash_A^* (q_f, \varepsilon, \#y_1\uparrow y_2\$)$ . Let  $L(A)$  denote the set of all strings accepted by  $A$ .

We next define *nested stack automaton* (NSA) which is SA extended with the capability to create and remove substacks. For instance, suppose that the stack is  $\#a_1a_2\uparrow a_3\$$  and we are to create a new substack containing  $b_1b_2$ :

$$\#a_1\underline{c}b_1b_2\uparrow\$a_2a_3\$ \tag{1}$$

Note that the new substack  $c b_1 b_2 \$$  is embedded below the symbol  $a_2$  indicated by the stack pointer, and the pointer moves to the top of the created substack. The creation of the inner substack narrows the range within which the stack pointer can move as indicated by the underlined part  $\#a_1\underline{c}b_1b_2\uparrow\$$ . While the bottom of the entire stack is always fixed by the leftmost symbol  $\#$ , the top of the embedded substack is regarded as the top of the entire stack. The inner substacks are allowed to be embedded endlessly and everywhere, whereas the writing in the pushdown mode is still restricted to the top of the stack:

$$\#a_1\underline{c}b_1b_2\uparrow\$a_2a_3\$ \xrightarrow{L} \#a_1\underline{c}b_1\uparrow b_2\$a_2a_3\$ \xrightarrow{\text{create}} \#a_1\underline{c}c_1c_2\uparrow\$b_1b_2\$a_2a_3\$ \tag{2}$$

$$\#a_1\underline{c}b_1b_2\uparrow\$a_2a_3\$ \xrightarrow{L} \#a_1\uparrow\underline{c}b_1b_2\$a_2a_3\$ \xrightarrow{\text{create}} \#\underline{c}c_1c_2\uparrow\$a_1\underline{c}b_1b_2\$a_2a_3\$ \tag{3}$$

We must empty the inner substack and then remove itself in advance whenever we want to reference the right side of the inner substack such as  $a_2, a_3$ . For example, let us empty the inner substack by popping twice from (1) and then removing it:

$$\#a_1\underline{c}b_1b_2\uparrow\$a_2a_3\$ \xrightarrow{\text{pop}} \#a_1\underline{c}b_1\uparrow\$a_2a_3\$ \xrightarrow{\text{pop}} \#a_1\underline{c}\uparrow\$a_2a_3\$ \xrightarrow{\text{destruct}} \#a_1a_2\uparrow a_3\$ \tag{4}$$

Notice that the stack pointer moves to the right after removing the inner substack. We now define NSA formally. A (1N) nested stack automaton  $A$  is a 10-tuple  $(Q, \Sigma, \Gamma, \delta, q_0, Z_0, \#, c, \$, F)$  satisfying the following conditions: the components  $Q, \Sigma, \Gamma, q_0, Z_0, \#, \$$  and  $F$  are the same as those of SA. The stack symbol  $c \notin \Sigma \cup \Gamma$  represents the bottom of a substack.<sup>4</sup> The transition function  $\delta$  has the following four modes, where  $\Gamma' \triangleq \Gamma \uplus \{c\}$ :

- (i) (pushdown mode)  $Q \times \Sigma \times \Gamma\$ \rightarrow \mathcal{P}(Q \times \Delta_i \times \Gamma*\$)$ .
- (ii) (stack reading mode) (a)  $Q \times \Sigma \times \Gamma'\$ \rightarrow \mathcal{P}(Q \times \Delta_i \times \{L\})$ , (b)  $Q \times \Sigma \times \Gamma' \rightarrow \mathcal{P}(Q \times \Delta_i \times \Delta_s)$ ,  
 (c)  $Q \times \Sigma \times \{\#\} \rightarrow \mathcal{P}(Q \times \Delta_i \times \{R\})$ .
- (iii) (stack creation mode)  $Q \times \Sigma \times (\Gamma' \uplus \Gamma'\$) \rightarrow \mathcal{P}(Q \times \Delta_i \times \{c\} \Gamma*\$)$ .
- (iv) (stack destruction mode)  $Q \times \Sigma \times \{c\}\$ \rightarrow \mathcal{P}(Q \times \Delta_i)$ .

Moreover, we define how NSA works with ID and  $\vdash$  in the same manner as SA. Given an NSA  $A = (Q, \Sigma, \Gamma, \delta, q_0, Z_0, \#, c, \$, F)$ , we define ID,  $\vdash_A$ , and  $L(A)$  in the same way as Definition 10 (however, we let  $I$  be  $Q \times \Sigma^* \times \{\#\} (\Gamma \uplus \{c, \$, \uparrow\})^* \{\$\}$ ). Here, we only give the rules corresponding to (iii) and (iv) in the definition of  $\delta$  (the others are essentially the same as those of SA):

<sup>3</sup> We regard  $a_{k+1} \cdots a_k$  as  $\varepsilon$ .

<sup>4</sup> Note that the bottom of the entire stack is always represented by  $\#$  and not  $c$ , as mentioned above.

- (iii) if  $(q', d, cw\$) \in \delta(q, a_i, Z)$  and  $Z = Z_j$ ,  $1 \leq j < n$ , then  
 $(q, a_i \cdots a_k, \#Z_1 \cdots Z_j \uparrow \cdots Z_n\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#Z_1 \cdots cw \uparrow \$Z_j \cdots Z_n\$)$ ,  
and  $(q, a_i \cdots a_k, \#yZ \uparrow \$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#y cw \uparrow \$Z\$)$  if  $(q', d, cw\$) \in \delta(q, a_i, Z\$)$ .
- (iv)  $(q, a_i \cdots a_k, \#y_1 c \uparrow \$Zy_2\$) \vdash_A (q', a_{i+\bar{d}} \cdots a_k, \#y_1 Z \uparrow y_2\$)$  if  $(q', d) \in \delta(q, a_i, c\$)$ .

#### 4 Every rewb describes an indexed language

As described above, to obtain the language  $L(\alpha)$  described by a  $k$ -rewb  $\alpha$ , we derive the regular language  $\mathcal{R}_k(\alpha)$  over the alphabet  $\Sigma \uplus B_k \uplus [k]$  first, then apply the dereferencing function  $\mathcal{D}_k$  to every element of  $\mathcal{R}_k(\alpha)$ . Using this observation, we construct an NSA  $A_\alpha$  recognizing the language  $L(\alpha)$  as follows.

The NSA  $A_\alpha$  is based on an NFA  $N$  recognizing the language  $\mathcal{R}_k(\alpha)$ , in the sense that each transition in  $A_\alpha$  comes from a corresponding transition of  $N$ . The NFA  $N$  has the alphabet  $\Sigma \uplus B_k \uplus [k]$ , and so handles three types of characters. For each transition  $q \xrightarrow[N]{a} q'$  with  $a \in \Sigma$ , i.e., moving from  $q$  to  $q'$  by an input symbol  $a$ ,  $A_\alpha$  also has the same transition except pushing  $a$  to the stack, denoted by  $q \xrightarrow{a/\$ \rightarrow a\$} q'$ . For each transition  $q \xrightarrow[N]{b} q'$  with  $b \in B_k$ , i.e., moving by a bracket  $b$ ,  $A_\alpha$  has the transition pushing  $b$  without consuming input symbols, denoted by  $q \xrightarrow{\varepsilon/\$ \rightarrow b\$} q'$ .<sup>5</sup> For each transition  $q \xrightarrow[N]{i} q'$  with  $i \in [k]$ ,  $A_\alpha$  has a large “transition” that consists of several transitions. In this “transition,”  $A_\alpha$  first seeks the left bracket  $[_i$  of the bracketed string  $[_i v]_i$  within the stack, and checks if the input from the cursor position matches  $v$  character by character while consuming the input, and finally moves to  $q'$  if all characters of  $v$  matched.

A difficult yet interesting point is that NSA cannot check  $v$  against the stack and push  $v$  onto the stack at the same time, that is, after checking a character  $c$  of  $v$ , if  $A_\alpha$  wants to push  $c$  to the stack,  $A_\alpha$  must leave from  $v$ , climb up the stack toward the top, and write  $c$ . However, after the push,  $A_\alpha$  becomes lost by not knowing where to go back to. How about marking the place where  $A_\alpha$  should return in advance? Unfortunately, that does not work; NSA can insert such marks anywhere by creating substacks, but due to the restriction of NSA, it cannot go above the position of the mark, much less climb up to the top. Therefore, NSA cannot directly push the result of a dereference onto the stack.

We cope with this problem as follows. We allow  $j \in [k]$  to appear in  $v$ , and for each appearance of  $j$  in the checking of  $v$ ,  $A_\alpha$  pauses the checking and puts a substack containing the current state as a marker at the stack pointer position. Then,  $A_\alpha$  searches down the stack for the corresponding bracketed string  $]_j v']_j$ , and begins checking  $v'$  if it is found. By repeating this process,  $A_\alpha$  eventually reaches a string  $v'' \in (\Sigma \uplus B_k)^*$  containing no characters of  $[k]$ . Once done with the check of  $v''$ ,  $A_\alpha$  climbs up toward the stack top, finds a marker  $p$  denoting the state to return to, and resumes from  $p$  after deleting the substack containing the marker. By repeating this, if  $A_\alpha$  returns to the position where it initially found  $j$ , it has successfully consumed the substring of the input string corresponding to the dereference of  $j$ . The following lemma is immediate.

► **Lemma 11.** *Let  $k \geq 1$  and  $\alpha \in \text{REWB}_k$ . There exists an NFA  $(Q, \Sigma \uplus B_k \uplus [k], \delta, q_0, F)$  over  $\Sigma \uplus B_k \uplus [k]$  recognizing  $\mathcal{R}_k(\alpha)$  all of whose states can reach some final state, that is,  $\forall q \in Q. \exists w \in (\Sigma \uplus B_k \uplus [k])^*. \exists q_f \in F. q \xrightarrow[N]{w} q_f$ .*

<sup>5</sup> Strictly speaking, our NFA (cf. Definition 9) does not allow consuming the empty string  $\varepsilon$ . However, we can realize the transition  $q \xrightarrow{\varepsilon/\$ \rightarrow b\$} q'$  alternatively by adding  $q \xrightarrow{c/\$ \rightarrow b\$,S} q'$  for each  $c \in \Sigma$ , i.e., moving by  $c$  with the input cursor fixed.

► **Corollary 12.** *Let  $N$  be the NFA in Lemma 11. For all  $q \in Q$  and for all  $w \in (\Sigma \uplus B_k \uplus [k])^*$ , if  $q_0 \xrightarrow{w}_N q$  then  $w$  is matching (see the full version [13] for the proof).*

We show the main theorem (the proof sketch is coming later):

► **Theorem 13.** *For every rewb  $\alpha \in REWB$ , there exists an NSA that recognizes  $L(\alpha)$ .*

The claim obviously holds when  $\alpha$  is a pure regular expression (i.e.,  $\alpha \in REWB_0$ ). Suppose that  $\alpha \in REWB_k$  with  $k \geq 1$ . By Lemma 11, there is an NFA  $N = (Q_N, \Sigma \uplus B_k \uplus [k], \delta_N, q_0, F)$  that recognizes  $\mathcal{R}_k(\alpha)$  and satisfies Corollary 12. We construct an NSA  $A_\alpha = (Q, \Sigma, \Gamma, \delta, q_0, Z_0, \#, \mathfrak{c}, \mathfrak{S}, F)$  as follows. Let  $Q \triangleq Q_N \uplus \{c_i, e_i, r_i \mid i \in [k]\} \uplus \{W_q \mid q \in Q_N\} \uplus \{E_{p,i}, L_{p,i} \mid p \in Q_N \uplus \{e_i \mid i \in [k]\}, i \in [k]\}$ ,  $\Gamma \triangleq \Sigma \uplus B_k \uplus [k] \uplus Q \uplus \{Z_0\}$ , and let  $\delta$  be the smallest relation that, for all  $a \in \Sigma$ ,  $b \in B_k$ ,  $c \in \Sigma$ ,  $i, j \in [k]$ ,  $q, q' \in Q_N$ ,  $Z \in \Gamma$  and  $p \in Q_N \uplus \{e_i \mid i \in [k]\}$ , satisfies the following conditions:

- |  |  |
|--|--|
| (1) $\delta_N(q, a) \ni q' \implies \delta(q, a, Z\mathfrak{S}) \ni (q', R, Za\mathfrak{S})$     | (10) $\delta(e_i, c, [j]) = \{(e_i, S, R)\}$ where $i \neq j$  |
| (2) $\delta_N(q, b) \ni q' \implies \delta(q, c, Z\mathfrak{S}) \ni (q', S, Zb\mathfrak{S})$     | (11) $\delta(e_i, c, [j]) = \begin{cases} \{(r_i, S, R)\} & (i = j) \\ \{(e_i, S, R)\} & (i \neq j) \end{cases}$ |
| (3) $\delta_N(q, i) \ni q' \implies \delta(q, c, Z\mathfrak{S}) \ni (W_{q'}, S, Zi\mathfrak{S})$ | (12) $\delta(e_i, c, j) = \{(c_j, S, \mathfrak{c}e_i\mathfrak{S})\}$ where $i \neq j$                            |
| (4) $\delta(W_q, c, i\mathfrak{S}) = \{(c_i, S, \mathfrak{c}q\mathfrak{S})\}$                    | (13) $\delta(r_i, c, Z) = \{(r_i, S, R)\}$   |
| (5) $\delta(c_i, c, p\mathfrak{S}) = \{(c_i, S, L)\}$  | (14) $\delta(r_i, c, p\mathfrak{S}) = \{(E_{p,i}, S, \mathfrak{S})\}$  |
| (6) $\delta(c_i, c, Z) = \{(c_i, S, L)\}$ where $Z \neq [i, Z_0]$                                | (15) $\delta(E_{p,i}, c, \mathfrak{c}\mathfrak{S}) = \{(L_{p,i}, S)\}$   |
| (7) $\delta(c_i, c, Z_0) = \{(r_i, S, R)\}$  | (16) $\delta(L_{e_j,i}, c, i) = \{(e_j, S, R)\}$   |
| (8) $\delta(c_i, c, [i]) = \{(e_i, S, R)\}$  | (17) $\delta(L_{q,i}, c, i\mathfrak{S}) = \{(q, S, S)\}$   |
| (9) $\delta(e_i, a, a) = \{(e_i, R, R)\}$  |  |

Rule (1) translates  $q \xrightarrow{a}_N q'$  into  $q \xrightarrow{a/\mathfrak{S} \rightarrow a\mathfrak{S}} q'$ , (2) translates  $q \xrightarrow{b}_N q'$  into  $q \xrightarrow{\varepsilon/\mathfrak{S} \rightarrow b\mathfrak{S}} q'$ , and rules (3)–(17) translate  $q \xrightarrow{i}_N q'$  into a large “transition” to consume the string that corresponds to the dereference of  $i$ . The details of the “transition” are as follows. By looking at the underlying  $N$  with rule (3),  $A_\alpha$  finds a state  $q'$  that it should go back to after going throughout the “transition,” and goes to the state  $W_{q'}$  by pushing  $i$  to the stack. At  $W_{q'}$ , by rule (4),  $A_\alpha$  inserts  $\mathfrak{c}q'\mathfrak{S}$  just below  $i$ , and goes to the state  $c_i$ . The state  $c_i$  represents the *call mode* in which  $A_\alpha$  looks for the left-nearest  $[i$  by rules (5) and (6) and proceeds to the state  $e_i$  (*execution mode*) by (8) if it finds  $[i$ . Otherwise (i.e., the case when  $A_\alpha$  arrives at the bottom of the stack), it proceeds to the state  $r_i$  (*return mode*) by rule (7). At  $e_i$ ,  $A_\alpha$  consumes input symbols by checking them against the symbols on the stack (rules (9)–(12)). In particular, rule (9) handles the case when the symbols match. Rules (10) and (11) handle the cases when brackets are read from the stack. The first case of (11) handles the case when the right bracket  $]_i$  is read, and the rules handle the other brackets (i.e.,  $[_j$  or  $]_j$  with  $i \neq j$ ) by simply skipping them (note that  $]_j = [i$  cannot happen since we started from the left-nearest  $[i$ ). Reading  $j \in [k]$ , by rule (12),  $A_\alpha$  inserts  $\mathfrak{c}e_i\mathfrak{S}$  just below  $j$  and goes to  $c_j$  to locate the corresponding  $]_j$  (here,  $j \neq i$  holds by the definition of the syntax). At  $r_i$ ,  $A_\alpha$  proceeds to return to the state  $p$  that passed the control to  $c_i$  (rules (13)–(17)). Since this  $p$  was pushed at the stack top,  $A_\alpha$  first climbs up to the stack top by rule (13), transits to the state  $E_{p,i}$  popping  $p$  by (14), then goes to  $L_{p,i}$  removing the embedded substack by (15), and finally goes back to  $p$  by (16) and (17). A subtle point in the last step is that where the stack pointer should be placed depends on whether  $p$  is a state  $e_j$  (for some  $j \in [k]$ ) or in  $Q_N$ . In the former case, after (15) removes the embedded substack  $\mathfrak{c}e_j\mathfrak{S}$  that was created just below the call to  $i$ , the stack pointer points to  $i$ . However, the stack pointer should shift one more to the right, lest  $A_\alpha$  begins to repeat the call reading  $i$  again by (12). Therefore, (16) correctly handles the case by doing the shift. In the latter case, as stipulated by (17), the stack pointer should point to the stack top symbol  $i$  since  $p$  is the state stored at (3).

We state two lemmas used to prove Theorem 13. Let  $\vdash_{(n)}$  denote the subrelation of  $\vdash$  derived from the rule  $(n)$ . The following lemma is immediate from the definition of  $\vdash_{(n)}$ .

► **Lemma 14.** For all  $q, q' \in Q_N$ ,  $w, w' \in \Sigma^*$ ,  $\gamma, \gamma' \in \Gamma^*$ ,

(a) 1. for each  $a \in \Sigma$ ,  $(q, aw, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(1)} (q', w, \#Z_0\gamma a\uparrow\mathbb{S})$  if  $q \xrightarrow{a}_N q'$ ,  
 2.  $\exists a \in \Sigma. q \xrightarrow{a}_N q' \wedge w = aw' \wedge \beta = Z_0\gamma a\uparrow$  if  $(q, w, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(1)} (q', w', \#\beta\mathbb{S})$ ,

(b) 1. for each  $b \in B_k$ ,  $(q, w, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(2)} (q', w, \#Z_0\gamma b\uparrow\mathbb{S})$  if  $q \xrightarrow{b}_N q'$ ,  
 2.  $\exists b \in B_k. q \xrightarrow{b}_N q' \wedge w = w' \wedge \beta = Z_0\gamma b\uparrow$  if  $(q, w, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(2)} (q', w', \#\beta\mathbb{S})$ .

In particular, letting  $\vdash_{(1),(2)} = \vdash_{(1)} \uplus \vdash_{(2)}$ , we obtain the following statement by repeating  $(a)_1$  and  $(b)_1$  zero or more times: For all  $v \in (\Sigma \uplus B_k)^*$ ,  $(q, g(v)w, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(1),(2)}^* (q', w, \#Z_0\gamma v\uparrow\mathbb{S})$  if  $q \xrightarrow{v}_N q'$ .

► **Lemma 15.** Suppose that  $q \xrightarrow{i}_N q'$ , and  $\gamma i$  is matching. Let  $m = \text{cnt}(\gamma i)$ . For all  $p \in Q_N$ ,  $w, w' \in \Sigma^*$  and  $\beta \in (\Gamma \uplus \{\mathbf{c}, \mathbb{S}, \uparrow\})^*$ , the following (a) and (b) are equivalent (see Appendix A for the proof):

(a)  $p = q'$ ,  $w = g((\gamma i)_{[m]})w'$ , and  $\beta = Z_0\gamma i\uparrow$ .

(b)  $(q, w, \#Z_0\gamma\uparrow\mathbb{S}) \vdash_{(3)} (W_{q'}, w, \#Z_0\gamma i\uparrow\mathbb{S}) \vdash \dots \vdash (p, w', \#\beta\mathbb{S})$ , where no ID with a state in  $Q_N$  appears in the calculation  $\dots$ .

**Proof of Theorem 13 (sketch).** For proving  $L(\alpha) \subseteq L(A_\alpha)$ , we take  $w \in L(\alpha)$  and  $v \in \mathcal{R}_k(\alpha)$  such that  $w = \mathcal{D}_k(v)$ . Decomposing  $v$  into  $v_0 n_1 v_1 \dots n_m v_m$  (where  $m = \text{cnt } v$ ), we obtain a transition sequence in the underlying NFA  $N$ , denoted by  $q_0 \xrightarrow{v_0}_N q_{(0)} \xrightarrow{n_1 v_1}_N q_{(1)} \xrightarrow{n_2 v_2}_N \dots \xrightarrow{n_m v_m}_N q_{(m)} \in F$ . We prove by induction on  $r = 0, \dots, m$  that  $A_\alpha$  can reach  $q_{(r)}$  while consuming  $z_r = g(v_0)g(v_{[1]})g(v_1) \dots g(v_{[r]})g(v_r)$  from the input and pushing  $y_r = v_0 n_1 v_1 \dots n_r v_r$  to the stack. Conversely, we suppose a calculation in  $A_\alpha$ , denoted by  $C_{(1)} = (q_0, w, \#Z_0\uparrow\mathbb{S}) \vdash \dots \vdash C_{(r)} \vdash \dots \vdash C_{(m)} = (p_m, \varepsilon, \#\beta_m\mathbb{S})$ , where  $p_m \in F$  and  $C_{(r)} = (p_r, w_r, \#\beta_r\mathbb{S})$  for each  $r \in \{1, \dots, m\}$ . By induction on  $r = 1, \dots, m$ , we extract an underlying transition  $q_0 \xrightarrow{\gamma_r}_N p_r$  step by step while maintaining the invariants  $\gamma_r \in (\Sigma \uplus B_k \uplus [k])^*$  and  $w = \mathcal{D}_k(\gamma_r)w_r$ , as long as  $p_r \in Q_N$  (the formal proof is available in the full version [13]). ◀

► **Corollary 16.** Every rew b describes an indexed language, but not vice versa.

**Proof.** The first half follows by Theorem 13 since 1N NSA and indexed grammars are equivalent [2]. The second half also follows since the class of CFLs is a subclass of indexed languages [1], and the class of rewbs and that of CFLs are incomparable [4]. ◀

In the case of a rew b  $\alpha$  without a captured reference (that is, one in which no reference  $\setminus i$  appears as a subexpression of an expression of the form  $(j \dots)_j$ ), we can transform  $A_\alpha$  into an NESAs  $A''_\alpha$  recognizing  $L(\alpha)$ , i.e., one that neither uses substacks nor pops its stack. First, we transform  $A_\alpha$  to an NSA without substacks (i.e., SA)  $A'_\alpha$ . Inspecting how substacks are used in  $A_\alpha$ , we can drop rules (12) and (16) in  $A'_\alpha$  because there is no captured reference in  $\alpha$ . We also remove the uses of substacks from rules (3) and (4), which correspond to calling, and rules (14), (15) and (17), which correspond to returning. Namely, while  $A_\alpha$ , upon a call, stores the substack  $eq'\mathbb{S}$  that consists of just the state  $q'$  where the control should return,  $A'_\alpha$  simply pushes  $q'$  to the stack top. That is, we remove (4), (15) and (17), and change (3) and (14) to the following (3') and (14'), respectively:

$$(3') \delta_N(q, i) \ni q' \implies \delta(q, c, Z\mathbb{S}) \ni (c_i, S, Zi q'\mathbb{S}), \quad (14') \delta(r_i, c, q\mathbb{S}) = \{(q, S, \mathbb{S})\}.$$

Furthermore, we transform  $A'_\alpha$  to an SA without stack popping (i.e., NESAs)  $A''_\alpha$ . Observe that  $A'_\alpha$  pops only when returning via (14') and popping a state that was pushed in a preceding call. Thus,  $A''_\alpha$ , rather than popping  $q'$ , leaves it on the stack, and has the modes  $c_i$ ,  $e_i$  and  $r_i$  skip all state symbols on the stack except the ones at the top. Here, we only need to modify  $e_i$  since  $A_\alpha$  already skips them at  $c_i$  and  $r_i$  (rules (6) and (13)). In short, we add the new rule (9\*) and change (14') to (14''), as follows:

$$(9^*) \delta(e_i, c, q) = \{(e_i, S, R)\}, \quad (14'') \delta(r_i, c, q\mathbb{S}) = \{(q, S, q\mathbb{S})\}.$$

This NESAs  $A''_\alpha$  whose transition function consists of the rules (1),(2),(3'),(5)–(9),(9\*), (10), (11), (13) and (14'') recognizes  $L(\alpha)$ . Therefore,

► **Corollary 17.** *Every rew without a captured reference describes a nonerasing stack language, but not vice versa.*<sup>6</sup>

Note that the converse of Corollary 17 fails to hold. In other words, there is a rew with a captured reference that describes a nonerasing stack language. The rew  $(1a)_1(2\backslash 1)_2\backslash 2$  is a simple counterexample. In addition, as shown later in Section 6, NESAs can recognize nontrivial language (hierarchy) with a captured reference such as Larsen's hierarchy [12].

## 5 A rew that describes a non-stack language

We just showed that every rew describes an indexed language and in particular every rew without a captured reference describes a nonerasing stack language. So, a natural question is whether every rew describes a (nonerasing) stack language. We show that the answer is *no*. That is, there is a rew that describes a non-stack language.

Ogden has proposed a pumping lemma for stack languages and shown that the language  $\{a^{n^3} \mid n \in \mathbb{N}\}$  is a non-stack language as an application (see [14], Theorem 2). A key point in the proof is that the exponential  $n^3$  of  $a$  is a cubic polynomial, and we can show that for every cubic polynomial  $f : \mathbb{N} \rightarrow \mathbb{N}$ , the language  $\{a^{f(n)} \mid n \in \mathbb{N}\}$  is also a non-stack language by the same proof. Thus, a rew that describes a language in this form is a counterexample. We borrow the technique in [6] (Example 1) which shows that the rew  $\alpha = ((1\backslash 2)_1(2\backslash 1a)_2)^*$  describes  $L(\alpha) = \{a^{n^2} \mid n \in \mathbb{N}\}$ . This follows since  $\mathcal{D}_k((\llbracket 12 \rrbracket_1 \llbracket 21a \rrbracket_2)^n) = a^{n^2}$  holds by recording the iteration count of the Kleene star,  $n$ , in the capture  $(2)_2$  as  $a^n$ , and extending the length by  $2n + 1$ , as shown below:

$$\begin{aligned} \mathcal{D}_k((\llbracket 12 \rrbracket_1 \llbracket 21a \rrbracket_2)^{n+1}) &= \mathcal{D}_k((\llbracket 12 \rrbracket_1 \llbracket 21a \rrbracket_2)^n \llbracket 12 \rrbracket_1 \llbracket 21a \rrbracket_2) = \mathcal{D}_k(\cdots \llbracket 2a^n \rrbracket_2 \llbracket 12 \rrbracket_1 \llbracket 21a \rrbracket_2) \\ &= \mathcal{D}_k(\cdots \llbracket 2a^n \rrbracket_2 \llbracket 1a^n \rrbracket_1 \llbracket 21a \rrbracket_2) = \mathcal{D}_k(\cdots \llbracket 2a^n \rrbracket_2 \llbracket 1a^n \rrbracket_1 \llbracket 2a^{n+1} \rrbracket_2) = \underline{\underline{a^{n^2}}} a^{2n+1} = a^{(n+1)^2}. \end{aligned}$$

The rew  $((1\backslash 4a)_1(2\backslash 3)_2(3\backslash 2a)_3(4\backslash 1\backslash 3)_4)^*$  describes  $\{a^{n(n+7)(2n+1)/6} \mid n \in \mathbb{N}\}$  and extends the length by a quadratic in  $n$  instead (see the full version [13] for the calculation). Thus,

► **Theorem 18.** *There exists a rew that describes a non-stack language.*

From this and Corollary 17, this rew needs a captured reference, in the sense that:

► **Corollary 19.** *There exists a rew that describes a language that no rew without a captured reference can describe.*

<sup>6</sup> For the latter part, we can take the language  $\{a^n b^n \mid n \in \mathbb{N}\}$  that can be described by an NESAs (see the full version [13]) but not by any rew [4].

**6 Larsen’s hierarchy is within the class of nonerasing stack language**

In this section, we construct an NESAs  $A_i$  that describes  $L(x_i)$ , where the rew  $x_i$  over the alphabet  $\Sigma = \{a_0^l, a_0^m, a_0^r, a_1^l, a_1^m, a_1^r, \dots\}$  is given by Larsen [12] and defined as follows:  $x_0 \triangleq (a_0^l a_0^m a_0^r)^*$ ,  $x_{i+1} \triangleq (a_{i+1}^l (x_i)_i a_{i+1}^m \setminus i a_{i+1}^r)^*$  ( $i \geq 0$ ). Our result implies that Larsen’s hierarchy is within the class of nonerasing stack languages. Since Larsen showed that no rew with its nested level less than  $i$  can describe  $L(x_i)$  [12], it also implies that for every  $i \in \mathbb{N}$ , there is a nonerasing stack language that needs a rew of nested level at least  $i$ .<sup>7</sup>

**Figure 1**  $A_0$  (upper left),  $A_1$  (upper right),  $A_2$  (lower).

The NESAs  $A_i$  has the start state  $q_0^i$  which is also its only final state. Figure 1 depicts  $A_0$ ,  $A_1$ , and  $A_2$ .  $A_0$  is easy.  $A_1$  is obtained by connecting the eight states to  $q_0^0$  and making  $q_0^1$  the start/final state, as shown in the figure. The five states on the right handle the dereference of  $\setminus 0$  in  $x_1$ . That is, at  $c_0^1$ ,  $A_1$  first seeks the left-nearest  $[0$ , passes the control to  $e_0^1$ , checks the input string against the stack at  $e_0^1$ , passes the control to  $r_0^1$ , and at  $r_0^1$ , finally goes back to the right-nearest  $0$  which must be written on the stack top. In much the same way,  $A_2$  is obtained from  $A_1$  but we must be sensitive to the handling of the dereference of  $\setminus 1$  because  $A_2$  must handle the dereference of not only  $\setminus 1$  but also  $\setminus 0$  that appears in a string captured by  $[1]_1$  whereas no backreference appears in a string captured by  $[0]_0$  in the case of  $A_1$ . To deal with this issue, we connect the three new states  $c_0^2$ ,  $e_0^2$  and  $r_0^2$  to  $e_1^2$ . At  $e_1^2$ , if  $A_2$  encounters  $0$  in a checking,  $A_2$  suspends the checking and first goes to  $c_0^2$  to seek  $[0$ , goes to  $e_0^2$  to check the input against the stack by reading out a  $]0$  (no number appears

<sup>7</sup> Technically, Larsen [12] adopts a syntax that excludes unbound references, and so this implied result applies only to rews with no unbound references.

in this checking), and finally goes to  $r_0^2$  to go back to 0 which passed the control to  $c_0^2$ . We repeat this modification until  $A_i$  is obtained. (Thus,  $A_i$  has such states  $c_j^i, e_j^i, r_j^i$  for each  $j \in \{0, \dots, i-1\}$ .) Therefore,

► **Theorem 20.** *There exists an NESAs  $A_i$  that recognizes  $L(x_i)$ .*

## 7 Conclusions

■ **Figure 2** The inclusion relations between the classes.

In this paper, we have shown the following five results: (1) that every rew b describes an indexed language (Corollary 16), (2) in particular that every rew b without a captured reference describes a nonerasing stack language (Corollary 17), (3) however that there exists a rew b that describes a non-stack language (Theorem 18), (4) therefore that there exists a rew b that needs a captured reference (Corollary 19), and (5) finally that Larsen’s hierarchy  $\{L(x_i) \mid i \in \mathbb{N}\}$  given in [12] is within the class of nonerasing stack languages (Theorem 20). We have obtained the results by using three automata models, namely NESAs, SAs, and NSAs, and using the semantics of rews b given in [15, 6] that treats a rew b as a regular expression allowing us to obtain the underlying NFA. Figure 2 depicts the inclusion relations between the classes mentioned in the paper. Here,  $A \rightarrow B$  stands for  $A \subseteq B$ ,  $A \twoheadrightarrow B$  for  $A \subsetneq B$ , and  $A \not\rightarrow B$  for  $A \not\subseteq B$ , respectively. A label on an arrow refers to the evidence. A red dashed arrow indicates a novel result proved in this paper, where for a strict inclusion, we show for the first time the inclusion itself in addition to the fact that it is strict.

As future work, we would like to investigate the use of the pumping lemma for rews b without a captured reference that can be derived from the contraposition of our Corollary 17 and a pumping lemma for NESAs [14]. We expect it to be a useful tool for discerning which rews b need captured references. Additionally, we suspect that our construction of NESAs in Theorem 20 is useful for not just  $x_i$  of [12] but also for more general rews b that have only one  $\setminus i$  for each  $(i)_i$ , and we would like to investigate further uses of the construction.

## A Proof of Lemma 15

First, we recall the notation  $v_{[r]}$  (cf. Section 3) and explain a new notation  $v^{(r)}$  informally (see the full version [13] for the formal definitions of  $v_{[r]}$  and  $v^{(r)}$ ). Let  $k$  be a positive integer and  $v = v_0 n_1 v_1 \dots n_m v_m$  ( $m = \text{cnt } v$ ) a matching string over  $\Sigma \uplus B_k \uplus [k]$ . For each  $r = 1, 2, \dots$ , the notation  $v_{[r]}$  denotes the string which  $\mathcal{D}_k$  scans at the  $r^{\text{th}}$  number  $n_r$  and  $v^{(r)}$  the string immediately after the  $r^{\text{th}}$  replacement (also we let  $v^{(0)} = v$ ). For example, in the case of  $v = [1a [2b]_2 2]_1 1$ ,  $\mathcal{D}_k$  processes  $v$  as follows, therefore  $v_{[1]} = b$  and  $v_{[2]} = a[2b]_2 b$ :  $v^{(0)} = [1a [2b]_2 2]_1 1 \rightarrow v^{(1)} = [1a [2b]_2 b]_1 1 \rightarrow v^{(2)} = [1a [2b]_2 b]_1 abb \rightarrow abbabb$ . We can easily prove the following claim (see also the full version [13]): For each  $r \in \{0, 1, \dots, m\}$ ,

$$v^{(r)} = v_0 g(v_{[1]}) v_1 \dots g(v_{[r]}) v_r n_{r+1} v_{r+1} \dots n_m v_m. \quad (*)$$

We prepare some more notations for the proof. Let  $\Sigma_{\perp}^* \triangleq \Sigma^* \uplus \{\perp\}$  and for every  $w \in \Sigma_{\perp}^*$  and  $s \in \Sigma^*$ , let  $w/s$  denote the string  $w$  but with the suffix  $s$  erased if  $w$  ends with  $s$ , and otherwise  $\perp$ . To use this notation, we expand the set of all IDs  $I = Q \times \Sigma^* \times \{\#\}$  ( $\Gamma \uplus \{\mathfrak{c}, \$, \uparrow\}^* \{\mathfrak{S}\}$ ) to  $I_{\perp} \triangleq Q \times \Sigma_{\perp}^* \times \{\#\}$  ( $\Gamma \uplus \{\mathfrak{c}, \$, \uparrow\}^* \{\mathfrak{S}\}$ ), and we let  $C(w)$  denote an ID  $C = (\cdot, w, \dots)$  and  $\vdash'_{(n)}$  denote the following binary relation over  $I_{\perp}$ :

$$\vdash'_{(n)} \triangleq \left\{ (C(w), C'(w/(a_i \dots a_{i+\bar{d}-1}))) \mid C(a_i \dots a_k) \vdash_{(n)} C'(a_{i+\bar{d}} \dots a_k), w \in \Sigma_{\perp}^* \right\}.$$

In addition, we define  $\vdash' \triangleq \bigcup_n \vdash'_{(n)}$ . Then,  $\vdash \subseteq \vdash'$  is immediate and we show that the converse partially holds, in the sense that:

► **Lemma 21.** *For every string  $w \in \Sigma^*$  and  $w' \in \Sigma^*$ ,  $C(w) \vdash' C'(w')$  implies  $C(w) \vdash C'(w')$ .*

**Proof.** By the definition of  $\vdash'$ , there is  $(C(a_i \dots a_k), C'(a_{i+\bar{d}} \dots a_k)) \in \vdash$  such that  $w' = w/(a_i \dots a_{i+\bar{d}-1})$ . By the definition of  $\vdash$ ,  $C(w) = C(a_i \dots a_{i+\bar{d}-1} w') \vdash C'(w')$  holds. ◀

► **Definition 22.** Given  $C, C' \in I_{\perp}$ , we write  $C \models_{(n)} C'$  if  $C \vdash'_{(n)} C'$  and  $\forall j, C'' . C \vdash'_{(j)} C'' \implies j = n \wedge C'' = C'$ . We often omit the subscript  $(n)$  and simply write  $C \models C'$ . Note that  $C \models C'$  implies not only  $C \vdash' C'$  but also determinism:  $\forall C'' \in I_{\perp} . C \vdash' C'' \implies C' = C''$ .

► **Lemma 23.** Suppose that  $\gamma \in (\Sigma \uplus B_k \uplus [k])^*$ ,  $i \in [k]$ ,  $w \in \Sigma^*$ ,  $\beta \in (\Gamma \uplus \{\mathfrak{c}, \$\})^*$  and  $p \in Q_N \uplus \{e_i \mid i \in [k]\}$ . Let  $m = \text{cnt}(\gamma i) (\geq 1)$ . If  $\gamma i$  is matching,

$$(c_i, w, \#Z_0 \gamma \text{cp} \uparrow \$i\beta\$) \models \dots \models (r_i, w/g((\gamma i)_{[m]}), \#Z_0 \gamma \text{cp} \uparrow \$i\beta\$)$$

holds, where no ID with a state in  $Q_N$  appears in the calculation  $\dots$ .

**Proof.** In this proof, we sometimes write the stack representation  $\# \dots Z \uparrow \dots \$$  as  $\# \dots \uparrow Z \dots \$$  with the head-reversed arrow  $\uparrow$ . First, if  $\gamma \not\# [i]$ , it holds that

$$\begin{aligned} (c_i, w, \#Z_0 \gamma \text{cp} \uparrow \$i\beta\$) &\models^* (c_i, w, \#Z_0 \uparrow \gamma \text{cp} \$i\beta\$) \\ &\models (r_i, w, \#Z_0 \uparrow \gamma \text{cp} \$i\beta\$) \models^* (r_i, w, \#Z_0 \gamma \text{cp} \uparrow \$i\beta\$), \end{aligned}$$

and by  $(\gamma i)_{[m]} = \varepsilon$ , we have  $w = w/g((\gamma i)_{[m]})$ , as required. Henceforth, we assume that  $\gamma \ni [i]$  and the decomposition  $\gamma = \gamma_0 [i \gamma_1]$  ( $\gamma_1 \not\# [i]$ ). Moreover, we can further decompose  $\gamma_1 = \gamma_2 [i \gamma_3]$  ( $\gamma_2 \not\# [i]$ ,  $\gamma_3 \not\# [i]$ ) because  $\gamma i$  is matching. We prove by induction on  $m$ .

Case  $m = 1$ : By  $\text{cnt} \gamma = 0$ ,  $\gamma_2 \in (\Sigma \uplus B_k)^*$  follows. Letting  $w' \triangleq w/g(\gamma_2)$ , we have

$$\begin{aligned} (c_i, w, \#Z_0 \gamma_0 [i \gamma_1 \text{cp} \uparrow \$i\beta\$) &\models^* (c_i, w, \#Z_0 \gamma_0 [i \uparrow \gamma_1 \text{cp} \$i\beta\$) \models (e_i, w, \#Z_0 \gamma_0 [i \uparrow \gamma_1 \text{cp} \$i\beta\$) \\ &\models^* (e_i, w', \#Z_0 \gamma_0 [i \gamma_2 [i \uparrow \gamma_3 \text{cp} \$i\beta\$) \models (r_i, w', \#Z_0 \gamma_0 [i \gamma_2 [i \uparrow \gamma_3 \text{cp} \$i\beta\$) \\ &\models^* (r_i, w', \#Z_0 \gamma_0 [i \gamma_2 [i \gamma_3 \text{cp} \uparrow \$i\beta\$). \end{aligned}$$

Therefore, the claim holds since no ID with a state in  $Q_N$  appears in this calculation and  $\gamma_2 = (\gamma i)_{[m]}$  follows from  $(\gamma i)^{(0)} = \gamma i = \gamma_0 [i \gamma_2 [i \gamma_3 i]$ ,  $\gamma_3 \not\# [i]$ .

Case  $\{1, \dots, m\} \implies m + 1$ : Let  $m_0 \triangleq \text{cnt} \gamma_0$  and  $l \triangleq \text{cnt} \gamma_2 (\geq 0)$ . Now,  $m_0 + l \leq m = \text{cnt} \gamma$  holds and we write  $\gamma_2 = \lambda_0 n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l$ . We also define  $\eta_r \triangleq \gamma_0 [\lambda_0 n_{m_0+1} \dots \lambda_{r-1} n_{m_0+r}]$  for each  $r \in \{1, \dots, l\}$ . By  $\eta_r$  being a prefix of  $\gamma i$  and Lemma 7,  $\eta_r$  is matching and  $(\eta_r)_{[m_0+r]} = (\gamma i)_{[m_0+r]}$ ,  $r \in \{1, \dots, l\}$  holds. In particular, it follows that  $n_{m_0+r} \neq i$  for every  $r$  (if there is  $r$  such that  $n_{m_0+r} = i$ ,  $\gamma_2 \supseteq \lambda_0 n_{m_0+1} \dots \lambda_{r-1} \ni [i]$  holds but this contradicts  $\gamma_2 \not\# [i]$ ). Thus, letting  $w_0 \triangleq w$ ,  $w'_r \triangleq w_{r-1}/g(\lambda_{r-1})$ ,  $w_r \triangleq w'_r/g((\eta_r)_{[m_0+r]})$  and  $w' = w_l/g(\lambda_l)$ , we have

$$\begin{aligned} &(c_i, w, \#Z_0 \gamma \text{cp} \uparrow \$i\beta\$) \\ &\models^* (c_i, w, \#Z_0 \gamma_0 [i \uparrow \lambda_0 n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models (e_i, w_0, \#Z_0 \gamma_0 [i \uparrow \lambda_0 n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models^* (e_i, w'_1, \#Z_0 \gamma_0 [i \lambda_0 n_{m_0+1} \uparrow \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models (c_{n_{m_0+1}}, w'_1, \#Z_0 \gamma_0 [i \lambda_0 \text{cr}_i \uparrow \$n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models^* (r_{n_{m_0+1}}, w_1, \#Z_0 \gamma_0 [i \lambda_0 \text{cr}_i \uparrow \$n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\quad \text{(by } \eta_1 \text{ being matching and induction hypothesis)} \\ &\models (E_{e_i, n_{m_0+1}}, w_1, \#Z_0 \gamma_0 [i \lambda_0 \mathfrak{c} \uparrow \$n_{m_0+1} \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models (L_{e_i, n_{m_0+1}}, w_1, \#Z_0 \gamma_0 [i \lambda_0 n_{m_0+1} \uparrow \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models (e_i, w_1, \#Z_0 \gamma_0 [i \lambda_0 n_{m_0+1} \uparrow \lambda_1 \dots n_{m_0+l} \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\models^* \dots \models^* (e_i, w_l, \#Z_0 \gamma_0 [i \lambda_0 n_{m_0+1} \lambda_1 \dots n_{m_0+l} \uparrow \lambda_l]_i \gamma_3 \text{cp} \$i\beta\$) \\ &\quad \text{(by similar calculation and induction hypothesis)} \end{aligned}$$

$$\begin{aligned}
& \models^* (e_i, w', \#Z_0\gamma_0[i\lambda_0n_{m_0+1}\lambda_1\cdots n_{m_0+l}\lambda_l]_i \uparrow \gamma_3 \mathit{cp} \$i\beta\$) \\
& \models (r_i, w', \#Z_0\gamma_0[i\lambda_0n_{m_0+1}\lambda_1\cdots n_{m_0+l}\lambda_l]_i \uparrow \gamma_3 \mathit{cp} \$i\beta\$) \\
& \models^* (r_i, w', \#Z_0\gamma_0[i\lambda_0n_{m_0+1}\lambda_1\cdots n_{m_0+l}\lambda_l]_i \gamma_3 \mathit{cp} \uparrow \$i\beta\$),
\end{aligned}$$

and

$$\begin{aligned}
w' &= w/g(\lambda_0) g((\eta_1)_{[m_0+1]}) g(\lambda_1) \cdots g((\eta_l)_{[m_0+l]}) g(\lambda_l) \\
&= w/g(\lambda_0) g((\gamma^i)_{[m_0+1]}) g(\lambda_1) \cdots g((\gamma^i)_{[m_0+l]}) g(\lambda_l),
\end{aligned}$$

where no ID with a state in  $Q_N$  appears in this calculation. Here, we write

$$\gamma = \gamma_0[i\lambda_0n_{m_0+1}\lambda_1\cdots n_{m_0+l}\lambda_l]_i \gamma_3 = v_0 n_1 v_1 \cdots n_m v_m$$

and decompose its substrings as

$$v_{m_0} = \chi_0[i\lambda_0, \quad v_{m_0+l} = \lambda_l]_i \chi_1, \text{ and } \gamma_3 = \chi_1 n_{m_0+l+1} v_{m_0+l+1} \cdots n_m v_m.$$

Then, by equation (\*), we can write  $(\gamma^i)^{(m)}$  as

$$v_0 \cdots \underbrace{\chi_0[i\lambda_0 g((\gamma^i)_{[m_0+1]}) v_{m_0+1} \cdots g((\gamma^i)_{[m_0+l]}) \lambda_l]_i}_{v_{m_0}} \underbrace{\chi_1 g((\gamma^i)_{[m_0+l+1]}) v_{m_0+l+1} \cdots g((\gamma^i)_{[m]}) v_m}_i.$$

That is, it holds that  $\gamma_3 \triangleq \chi_1 g((\gamma^i)_{[m_0+l+1]}) v_{m_0+l+1} \cdots g((\gamma^i)_{[m]}) v_m \not\equiv [i$  by  $\gamma_3 \not\equiv [i$ , and we obtain  $(\gamma^i)_{[m+1]} = \lambda_0 g((\gamma^i)_{[m_0+1]}) \lambda_1 \cdots g((\gamma^i)_{[m_0+l]}) \lambda_l$ , as shown above. Therefore, the claim holds for  $m+1$  since  $w' = w/g((\gamma^i)_{[m+1]})$ .  $\blacktriangleleft$

**Proof of Lemma 15.** For arbitrary  $w \in \Sigma^*$ , by Lemma 23,

$$\begin{aligned}
& (q, w, \#Z_0\gamma \uparrow \$) \vdash_{(3)} (W_{q'}, w, \#Z_0\gamma i \uparrow \$) \models_{(4)} (c_i, w, \#Z_0\gamma \mathit{cq}' \uparrow \$i\$) \\
& \models^* (r_i, w/g((\gamma^i)_{[m]}), \#Z_0\gamma \mathit{cq}' \uparrow \$i\$) \models_{(14)} (E_{q',i}, w/g((\gamma^i)_{[m]}), \#Z_0\gamma \mathit{c} \uparrow \$i\$) \\
& \models_{(15)} (L_{q',i}, w/g((\gamma^i)_{[m]}), \#Z_0\gamma i \uparrow \$) \models_{(17)} (q', w/g((\gamma^i)_{[m]}), \#Z_0\gamma i \uparrow \$) \quad (**)
\end{aligned}$$

holds. Assuming (a), we can replace  $\models$  in equation (\*\*) with  $\vdash$  by Lemma 21 because  $w/g((\gamma^i)_{[m]}) = w' \in \Sigma^*$  holds, and therefore, (b) follows. Supposing (b) conversely, we have  $(q, w, \#Z_0\gamma \uparrow \$) \vdash_{(3)} (W_{q'}, w, \#Z_0\gamma i \uparrow \$) \vdash' \cdots \vdash' (p, w', \#\beta\$)$ , where no ID with a state in  $Q_N$  appears in either this calculation or (\*\*) except in their leftmost and rightmost IDs. Therefore, their two calculations coincide by the determinism of  $\models$ . In particular, we obtain  $p = q'$ ,  $w' = w/g((\gamma^i)_{[m]})$  and  $\beta = Z_0\gamma i \uparrow$  by the equality of their rightmost IDs, and thus, (a) follows because  $w' \in \Sigma^*$ .  $\blacktriangleleft$

# OBDD(Join) Proofs Cannot Be Balanced

Sergei Ovcharov 

St. Petersburg State University, Russia

---

## Abstract

We study OBDD-based propositional proof systems introduced in 2004 by Atserias, Kolaitis, and Vardi that prove the unsatisfiability of a CNF formula by deduction of an identically false OBDD from OBDDs representing clauses of the initial formula. We consider a proof system  $\text{OBDD}(\wedge)$  that uses only the conjunction (join) rule and a proof system  $\text{OBDD}(\wedge, \text{reordering})$  (introduced in 2017 by Itsykson, Knop, Romashchenko, and Sokolov) that uses the conjunction (join) rule and the rule that allows changing the order of variables in OBDD.

We study whether these systems can be balanced i.e. every refutation of size  $S$  can be reassembled into a refutation of depth  $O(\log S)$  with at most a polynomial-size increase. We construct a family of unsatisfiable CNF formulas  $F_n$  such that  $F_n$  has a polynomial-size tree-like  $\text{OBDD}(\wedge)$  refutation of depth  $\text{poly}(n)$  and for arbitrary  $\text{OBDD}(\wedge, \text{reordering})$  refutation  $\Pi$  of  $F_n$  for every  $\alpha \in (0, 1)$  the following trade-off holds: either the size of  $\Pi$  is  $2^{\Omega(n^\alpha)}$  or the depth of  $\Pi$  is  $\Omega(n^{1-\alpha})$ . As a corollary of the trade-offs, we get that  $\text{OBDD}(\wedge)$  and  $\text{OBDD}(\wedge, \text{reordering})$  proofs cannot be balanced.

## 1 Introduction

The paper devotes to propositional proof complexity theory. Propositional proof systems are used for certifying that a given CNF formula is unsatisfiable. Investigation of propositional proof systems is highly connected with the construction of solvers for the Boolean satisfiability problem (SAT-solvers). The execution protocol of a SAT solver running on an unsatisfiable formula may be considered as a certificate of unsatisfiability. Every SAT solver is based on some proof system. For example, CDCL solvers are based on Resolution [3], Pseudo Boolean solvers are based on Cutting Planes [8], OBDD-solvers are based on OBDD-based proof systems [2].

The minimal refutation size of a formula is a natural lower bound on the running time of the corresponding SAT-Solvers. In this paper, we also study the depth of refutations, i.e. the length of the longest path from a clause of a refuted formula to a contradiction. The depth is a very natural but not a much-studied measure of the proofs. The minimal depth of a refutation is a lower bound on the parallel running time of the corresponding solver.

### Balancing proof systems

We consider only *refutational* proof systems. Each refutational proof system  $\Pi$  operates with *proof lines*, and each proof line is a Boolean predicate represented in some fixed way. Initially, all clauses of refuted formulas are represented by proof lines and new proof lines may be derived using a finite set of inference rules. The goal is to derive an identically false proof line. Every refutational proof system is defined by the type of predicates that may be

used as proof lines and by the list of inference rules. For example, in Resolution proof lines are clauses, in Cutting Planes [10] proof lines are linear inequalities with integer coefficients and Boolean variables, in Frege proof systems proof lines are propositional formulas, etc.

The *size* of a refutation is the total size of representations of all used proof lines.

Every refutation can be represented as a directed acyclic graph with one source corresponding to a contradiction and sinks corresponding to clauses of a refuted formula, and every proof line is obtained by the descendants using the inference rule. The *depth* of the refutation is the depth of the corresponding graph i.e. the length of the longest path from the source to a sink.

We say that proofs in some proof system can be balanced if it is always possible to reassemble each refutation in such a way that its depth becomes logarithmic in its size (perhaps with a polynomial-size increase).

The question of whether Resolution proofs can be balanced is trivial. Indeed, consider the formula  $(x_1 \vee \dots \vee x_n) \wedge (\neg x_1) \wedge \dots \wedge (\neg x_n)$ . It is easy to see that every refutation of this formula must have the depth at least  $n$ , therefore, Resolution refutations cannot be balanced in the general case. Urquhart [16] studied if refutations of  $O(1)$ -CNF formulas can be balanced for which the question is less trivial. It was proven that there exists a family of 3-CNF formulas  $F_{n_i}$  with  $n_i$  variables having a Resolution refutation of polynomial size but every its refutation must have depth  $\Omega(n_i / \log n_i)$ . Therefore Resolution refutations cannot be balanced even for  $O(1)$ -CNF formulas.

Atserias, Bonet, and Levy [1] proved that Cutting Planes proofs cannot be balanced either. However, it is known that refutations in Frege systems can be balanced (see, for instance, [15]).

### OBDD-based proof systems

In 1986 Bryant [6] proposed an important way to represent a Boolean function. Every such function can be represented as a branching program with two sinks so that variables on every path from the source to a sink appear in the same order  $\pi$ . Such representation is called *Ordered Binary Decision Diagram* (OBDD or  $\pi$ -OBDD if we need to specify that the variables are ordered according to  $\pi$ ). The restriction on a variables order allows us to perform many useful operations with OBDD efficiently e.g. check satisfiability, compute the conjunction of two OBDDs (given they use the same variable order), etc [13].

Atserias, Kolaitis, and Vardi [2] introduced an OBDD-based refutational proof system. Among them, we are most interested in  $\text{OBDD}(\wedge)$ .  $\text{OBDD}(\wedge)$  represents clauses of an unsatisfiable formula as  $\pi$ -OBDDs for some order  $\pi$  and the only refutation rule allows deriving the conjunction of two OBDDs which were derived earlier. The size of the refutation is the total size of the OBDDs in it.

Itsykson, Knop, Romashchenko, Sokolov [12] proposed the  $\text{OBDD}(\wedge, \text{reordering})$  proof system.  $\text{OBDD}(\wedge, \text{reordering})$  is obtained from  $\text{OBDD}(\wedge)$  by adding the reordering derivation rule that allows changing variables order of the derived OBDDs. While now OBDDs in the refutation may use different variable orders, the conjunction rule can be only applied to OBDDs that use the same variable order (otherwise it would be NP-hard to verify the correctness of such rule, see [14], Lemma 8.14).

Notice that the formula  $(x_1 \vee \dots \vee x_n) \wedge (\neg x_1) \wedge \dots \wedge (\neg x_n)$  that we considered above has a tree-like  $\text{OBDD}(\wedge)$  refutation of polynomial size and logarithmic depth.

For both the Resolution and the Cutting Planes proof systems there exist a family of formulas for which a refutation of small depth does not exist at all. We emphasize that it is not the case for OBDD-based proof systems. Indeed, every CNF formula with  $m$  clauses has

a tree-like OBDD( $\wedge$ ) refutation of the depth  $\log(m)$ ; the graph of this refutation is a full binary tree with  $m$  leaves. Note that the size of this proof can differ dramatically from the size of the minimum refutation. Hence in the notion of balancing we require that the size of the balanced proof should be bounded by a polynomial from the size of the initial proof.

### Our contribution

In Theorem 12 we construct a family of unsatisfiable formulas  $F_n$  having  $\text{poly}(n)$  size tree-like OBDD( $\wedge$ ) refutations such that the following size vs depth trade-offs holds. For every  $\alpha \in (0, 1)$ , any OBDD( $\wedge$ , reordering) refutation of  $F_n$  of depth  $O(n^{1-\alpha})$  requires size at least  $2^{\Omega(n^\alpha)}$ . Hence we prove that dag-like and tree-like OBDD( $\wedge$ ), OBDD( $\wedge$ , reordering) proofs cannot be balanced.

Formulas for which the trade-offs hold are the Pebbling formulas based on the grid graphs  $\text{Peb}(\text{Grid}_n)$ . Pebbling formulas are a well-studied family of formulas ([5], [16], [4]). Moreover, they were used for proving Resolution depth lower bounds in [16]. However, usually, they are used together with Pebbling games and Pebbling numbers of graphs. This is not the case for our result since we rely significantly on the structure of the grid graphs (including self-similarity and expansion) by themselves and do not use Pebbling games.

In Section 2 we define the main notions. In Subsection 3.1 we prove the OBDD size lower bounds for some set of *hard*  $\text{Peb}(\text{Grid}_n)$  subformulas. In Subsection 3.2 we prove the mentioned size vs depth trade-offs.

### Open question

It would be interesting to study the similar questions for OBDD( $\wedge$ , weakening) proof system which is obtained from OBDD( $\wedge$ ) by adding the *weakening* rule. The weakening rule allows deriving from an OBDD any its semantical implication represented by OBDD in the same order.

## 2 Preliminaries

► **Definition 1** (Branching Program). *Let  $X = \{x_1, \dots, x_n\}$  be a set of Boolean variables. A branching program is a directed acyclic graph with one node with indegree 0 (source) several inner nodes with outdegree 2 and two nodes with outdegree 0 (sinks). Every node except sinks is labeled with some variable from  $X$ , one of its outgoing edges is labeled with 0 and the other one is labeled with 1. One sink is labeled with 0 and the other one is labeled with 1.*

Every branching program represents some Boolean function of  $n$  variables. To compute a value of the function on input  $x_1 = a_1, \dots, x_i = a_i, \dots, x_n = a_n$  we start a path from the source, and for every vertex labeled with variable  $x_i$  we continue the path along the edge labeled with  $a_i$ , such a path reaches a sink and the label of this sink is the value of the function.

► **Definition 2** (Ordered Binary Decision Diagram(OBDD)). *A branching program is called OBDD if variables on every path from the source to sinks appear according to some fixed order of variables.*

*Sometimes we write  $\pi$ -OBDD instead of OBDD to emphasize that variables appear according to the order of variables  $\pi$ .*

## 72:4 OBDD(Join) Proofs Cannot Be Balanced

The order restriction in OBDDs allows to perform many useful operations on OBDDs efficiently e.g. minimize, check satisfiability, compute the conjunction of two OBDDs given they have a same order of variables, etc. [13].

Let us define a propositional proof system  $\text{OBDD}(\wedge, \text{reordering})$ .

► **Definition 3** ( $\text{OBDD}(\wedge, \text{reordering})$ ). *Let  $\varphi = \bigwedge_i C_i$  be an unsatisfiable CNF formula. A refutation of  $\varphi$  is a sequence of OBDDs  $D_1, D_2, \dots, D_t$  such that  $D_t$  is the constant false OBDD and for all  $1 \leq i \leq t$  the diagram  $D_i$  either represents a clause of  $\varphi$  or obtained from the previous  $D_j$ 's by one of the following derivation rules.*

- **Conjunction (or join)** rule allows deriving an  $\pi$ -OBDD for  $D_1 \wedge D_2$  from  $\pi$ -OBDDs  $D_1$  and  $D_2$ . We emphasize here that the conjunction rule can be only applied to OBDDs with the same order of variables.
- **Reordering** rule allows deriving an OBDD  $B$  from an equivalent OBDD  $A$  (note that  $A$  and  $B$  may use different variable orders).

*The size of a refutation is the sum of the sizes of the OBDDs from it.*

*Every  $\text{OBDD}(\wedge, \text{reordering})$  refutation can be represented as a directed acyclic graph (DAG) in which nodes are labeled with OBDDs from the refutation such that each sink is labeled with a OBDD for some clause of  $\varphi$ , the source is labeled with the constant false OBDD, and an OBDD in every inner node is the result of the application of some derivation rule to the OBDDs from the descendants.*

*A refutation is called tree-like if every node except the source has indegree one.*

*The depth of a refutation is the length of the longest path from the source to a sink.*

*We call a refutation a  $\pi$ -OBDD( $\wedge$ ) refutation if all OBDDs have the same order (i.e. no reordering rule was applied).*

Note, that in order to call  $\text{OBDD}(\wedge, \text{reordering})$  a proof system (in the sense of Cook-Reckhow [9]) we need to be able to efficiently check if some OBDD is the result of an application of the derivation rules to some others OBDDs. Fortunately, the restriction on a variable order allows us to do that, as we mentioned before (for the details see [12]).

► **Definition 4** (Pebbling formulas (see for instance [16])). *Let  $G = (E, V)$  be a directed acyclic graph. We associate with each node of  $G$  a distinct Boolean variable  $x$ ; we will identify nodes and the associated variables. The  $\text{Peb}(G)$  formula is the conjunction of the following clauses:*

- $(\neg u_1 \vee \dots \vee \neg u_n \vee v)$ , where  $v \in V$  and  $\{u_1, \dots, u_n\}$  is the set of all nodes such that edge  $(u_i, v) \in E$ . We denote this clause by  $(u_1, \dots, u_n \rightarrow v)$ . Note that if  $v$  is a source of the graph then  $n = 0$ . We call such clauses first type clauses.
- $(\neg v)$ , where  $v$  is a sink. We call such clauses second type clauses.

Note that for every directed acyclic graph  $G$  the formula  $\text{Peb}(G)$  is unsatisfiable.

Main goal of our work is to prove that  $\text{OBDD}(\wedge)$  and  $\text{OBDD}(\wedge, \text{reordering})$  refutations cannot be balanced. In order to do it we construct a family of CNF formulas such that the formulas have small  $\text{OBDD}(\wedge)$  refutations but they do not have refutations with small size and depth simultaneously.

► **Lemma 5** ([7]). *For every directed acyclic graph  $G$  and for every order of variables  $\pi$  formula  $\text{Peb}(G)$  has tree-like  $\pi$ -OBDD( $\wedge$ ) refutation of size  $O(|V|^2)$  and depth  $O(|V|)$ .*

**Proof.** See Appendix A. ◀

► **Definition 6** (Graph  $\text{Grid}_n$ ). Let  $\text{Grid}_n$  be a graph of the  $(n-1) \times (n-1)$  grid, with edges directed top to bottom and left to right.

In other words, the set of vertices is

$$V_n = \{(i, j), i, j \in [n]\}$$

and the set of edges is

$$E_n = \{((i, j), (i+1, j)) \mid i \in [n-1], j \in [n]\} \cup \{((i, j), (i, j+1)) \mid i \in [n], j \in [n-1]\}$$

► **Corollary 7.** Formula  $\text{Peb}(\text{Grid}_n)$  has  $\pi$ -OBDD( $\wedge$ ) refutation of the size  $O(n^4)$  and of the depth  $O(n^2)$  for every variable ordering  $\pi$ .

**Proof.** Follows from Lemma 5. ◀

Now, in order to prove that OBDD(join) proofs cannot be balanced, it is sufficient to prove size vs. depth trade-offs for refutations of  $\text{Peb}(\text{Grid}_n)$ . We prove such trade-offs in Theorem 12 but we still need several auxiliary lemmas.

► **Lemma 8** (Folklore). Let  $G$  be a directed acyclic graph with only one sink. Then  $\text{Peb}(G)$  minimal unsatisfiable i.e. a conjunction of every proper subset of its set of clauses is satisfiable.

**Proof.** See Appendix B. ◀

► **Notation 9.** For a graph  $G(V, E)$  (directed or undirected) and for two disjoint sets  $A, B \subset V$  denote by  $E(A, B)$  the set of edges with one end in  $A$  and the other one in  $B$ .

Note that for directed graphs we include in  $E(A, B)$  both the edges directed from  $A$  to  $B$  and the edges directed from  $B$  to  $A$ .

► **Definition 10** (Graph expansion [5]). Expansion of the graph  $G(V, E)$  is the minimum value of  $|E(U, V \setminus U)|$  among all subsets  $U \subset V$  such that  $\frac{|V|}{3} \leq |U| \leq \frac{2|V|}{3}$ .

► **Lemma 11** (Folklore).  $e(\text{Grid}_n) \geq \frac{1}{4}n$ .

**Proof.** Consider an arbitrary subset  $U \subset V$  such that  $\frac{1}{3}|V| \leq |U| \leq \frac{2}{3}|V|$ .

Assume that there are at least  $\frac{n}{4}$  columns of the grid containing nodes from both  $U$  and  $V \setminus U$ . Then there is at least one pair of incident nodes in every such column with one node in  $U$  and the other one in  $V \setminus U$ . Then the edges between the vertices from such pairs lie in  $E(U, V \setminus U)$ . Thus,  $|E(U, V \setminus U)| \geq \frac{n}{4}$ .

Now assume that there are at least  $\frac{3n}{4}$  columns lying completely in  $U$  or in  $V \setminus U$ . Since  $\frac{|V|}{3} \leq |U| \leq \frac{2|V|}{3}$ , there is at least one column completely lying in  $U$  and there is at least one column completely lying in  $V \setminus U$ . Therefore, in each row, there is at least one pair of incident nodes with one node in  $U$  and the other one in  $V \setminus U$ . In this case  $|E(U, V \setminus U)| \geq n$ . ◀

We want to point out that  $\text{Grid}_n$  graphs are not expanders in the conventional sense (see for example [11]) since  $\text{Grid}_n$  graph has  $n^2$  nodes but  $e(\text{Grid}_n) = \Theta(n)$  (Lemma 11 shows only that  $e(\text{Grid}_n) = \Omega(n)$  but upper bounds for  $e(\text{Grid}_n)$  are trivial).

### 3 Depth vs size trade-offs

In this section we prove our main result.

► **Theorem 12.** For every  $\alpha \in (0, 1)$  and for every OBDD( $\wedge$ , reordering) refutation of  $\text{Peb}(\text{Grid}_n)$  at least one of the following holds:

- the depth of the refutation is  $\Omega(n^\alpha)$ ;
- the size of the refutation is  $2^{\Omega(n^{1-\alpha})}$ .

■ **Figure 1** Possible partition for  $n = 15$ ,  $m = 13$ ,  $k = 5$ .

By a *configuration* we mean a conjunction of a subset of the set of  $\text{Peb}(\text{Grid}_n)$  clauses. In Subsection 3.1 we will show that some *hard* configurations cannot be represented by a small OBDD (see Lemma 13). Loosely speaking we are interested in configurations in which at least one clause from the top left part of the grid is missing and that contain many clauses from the bottom right part.

In Subsection 3.2 we finish the proof of Theorem 12 using Lemma 13. Namely, we show that either it is possible to find a hard configuration in the proof graph or the depth of the proof is large.

### 3.1 Configurations that are hard for OBDDs

Consider an arbitrary order  $\pi$  of variables of the formula  $\text{Peb}(\text{Grid}_n)$ .

Let  $\{x_0, y_0, x_1, y_1\} \subset [n]$ . We denote by  $[x_0, x_1] \times [y_0, y_1]$  the induced subgraph on the vertices set  $\{(x, y) \mid x_0 \leq x \leq x_1, y_0 \leq y \leq y_1\}$ .

Let  $m \in [n - 1]$ . We divide the nodes of the subgraph  $[1, m] \times [1, m]$  into the four parts:

- $[1, m - k] \times [1, m - k]$ ,
- $[m - k + 1, m] \times [m - k + 1, m]$ ,
- $[1, m - k] \times [m - k + 1, m]$ ,
- $[m - k + 1, m] \times [1, m - k]$ ,

where  $k \in [m]$  (see Fig. 1).

We divide variables associated with the vertices of  $[m - k + 1, m] \times [m - k + 1, m]$  into two equal (or differing by at most 1) parts in such a way that each variable from the first part appears in the order  $\pi$  before each variable of the second part. We denote the first part by  $A_\pi$  and the second by  $B_\pi$ . Recall that we identify each variable with the associated node and assume that  $A_\pi, B_\pi \subset V(\text{Grid}_n)$ .

Subgraph  $[m - k + 1, m] \times [m - k + 1, m]$  is isomorphic to the  $\text{Grid}_k$  and  $(|A_\pi| - |B_\pi|) \leq 1$ ,  $|A_\pi| + |B_\pi| = k^2$ , hence  $|E(A_\pi, B_\pi)| \geq \frac{k}{4}$  by Lemma 11.

Since the graph is directed, each edge in  $E(A_\pi, B_\pi)$  is directed from  $A_\pi$  to  $B_\pi$  or from  $B_\pi$  to  $A_\pi$ . Let us consider the direction with the majority of the edges. We denote the set of the corresponding edges by  $E_{0,\pi}$ ,  $|E_{0,\pi}| \geq |E(A_\pi, B_\pi)|/2 \geq \frac{k}{8}$ . All edges in  $E_{0,\pi}$  are directed from  $A_\pi$  to  $B_\pi$  or  $B_\pi$  to  $A_\pi$ . This gives us two cases that we consider later.

Using the following procedure we remove some of the edges from  $E_{0,\pi}$  to form a matching (that we will denote by  $E_{1,\pi}$ ).

While  $E_{0,\pi}$  is not empty:

- Choose an arbitrary edge  $e \in E_{0,\pi}$ , add it to  $E_{1,\pi}$ , remove it from  $E_{0,\pi}$ .
- If  $E_{0,\pi}$  still contains edges adjacent to  $e$  then we remove them. Since every node in  $\text{Grid}_n$  has degree at most 4 then we remove at most 6 edges per step.

We obtain matching  $E_{1,\pi} \subset E_{0,\pi}$  and  $|E_{1,\pi}| \geq \frac{|E_{0,\pi}|}{7} \geq \frac{k}{56}$ .

We call a node *special* if it is an head of some edge from  $E_{1,\pi}$ . There are  $|E_{1,\pi}|$  special nodes since  $E_{1,\pi}$  is a matching.

Using the following procedure we choose a subset  $W_\pi$  of the set of all special nodes such that the distance between any two nodes from  $W_\pi$  is at least 7.

While there are special nodes:

- Choose an arbitrary special node  $v$  that is not removed at the previous steps and add it to  $W_\pi$ .
- Remove all special nodes at the distance at most 6 from  $v$ . We removed at most  $(6 + 1 + 6)^2 = 169$  nodes, since all removed nodes are in the square of the size  $13 \times 13$  and with the center in  $v$ .

Since at each step we remove at most 169 special nodes and add one to  $W_\pi$ ,  $|W_\pi| \geq |E_{1,\pi}|/169 \geq k/9464$ .

For a node  $v = (i_0, j_0) \in V(\text{Grid}_n)$  we denote by  $B(v)$  the set  $\{(i, j) \in V(\text{Grid}_n) \mid |i - i_0| \leq 1, |j - j_0| \leq 1\}$  (i.e. the ball in the  $l_\infty$  metric). We refer to  $B(v)$  as a *ball* although it is not a ball in the graph distance sense.

For every node  $w \in W_\pi$  there is a unique edge in  $E_{1,\pi}$  with an endpoint  $w$ . Let us denote the set of start-points of such edges by  $U_\pi$ .

► **Lemma 13.** *Let  $\varphi$  be a conjunction of some subset of  $\text{Peb}(\text{Grid}_n)$  clauses. Suppose at least one clause of first type associated with a variable from the  $[1, m - k - 1] \times [1, m - k - 1]$  is not included in  $\varphi$ . Also, suppose that  $\varphi$  contains exactly  $d$  clauses associated with variables from  $W_\pi$ . Then the minimum size of an  $\pi$ -OBDD for  $\varphi$  is at least  $2^d$ .*

**Proof.** To prove that the size of any  $\pi$ -OBDD representation of  $\varphi$  is at least  $2^d$  it is sufficient to split  $\pi$  into two consequent parts and define  $2^d$  substitutions into the variables of the first part such that applications of them to  $\varphi$  lead to  $2^d$  different Boolean functions. To show that two substitutions  $\rho_0$  and  $\rho_1$  lead to two different functions we just define a substitution  $\rho$  into the second part of variables such that  $\varphi|_{\rho_0 \circ \rho} \neq \varphi|_{\rho_1 \circ \rho}$ .

We have already divided the variables of  $[m - k + 1, m] \times [m - k + 1, m]$  into two parts  $A_\pi$  and  $B_\pi$  according to  $\pi$ . Let us fix a partition of  $\pi$  into two parts such that  $A_\pi$  lies in the first and  $B_\pi$  in the second.

Let  $W'_\pi$  be the nodes from  $W_\pi$  whose associated clauses are in  $\varphi$ . Let  $U'_\pi$  be the nodes from  $U_\pi$  connected with  $W'_\pi$ . Let  $W'_\pi = \{w_1, \dots, w_d\}$  and  $U'_\pi = \{u_1, \dots, u_d\}$ .

Substitutions we are defining differ only on a small set of nodes. To every variable outside this set each substitution assigns a fixed value (values may differ for different variables); we now define these values. Let  $z = (x_0, y_0)$  be an arbitrary node from  $[1, m - k - 1] \times [1, m - k - 1]$  whose first type clause is missing from  $\varphi$  (see Fig. 2).

- **Assignment to the variables in  $[1, n] \times [1, n] \setminus [x_0, n] \times [y_0, n]$ :**

To the variables whose corresponding nodes are strictly to the left or strictly at the top from  $z$  all substitutions assign 1. Note that all first-type clauses corresponding to the nodes in which we substitute 1 are satisfied (follows trivially from the definition of the  $\text{Grid}_n$  clauses).

■ **Figure 2** Balls  $B(w_i)$  are shown with light blue; their centers lie in  $[m - k + 1, m] \times [m - k + 1, m]$  (blue rectangle). Black bold point is  $(x_0, y_0)$ , it lies in  $[1, m - k - 1] \times [1, m - k - 1]$  (pink rectangle).

■ **Assignment to the variables in  $[x_0, n] \times [y_0, n] \setminus \bigcup_i B(w_i)$ :**

Consider the rectangle  $[x_0, n] \times [y_0, n]$ . It contains square  $[m - k, n] \times [m - k, n]$  and, therefore, all balls  $B(w_i)$  for  $i \in [d]$  (their centers lie in  $[m - k + 1, m] \times [m - k + 1, m]$ ). Let  $L = [x_0, n] \times [y_0, n] \setminus \bigcup_i B(w_i)$ .

▷ **Claim 14.** For every node  $v \in L$  there exists a directed path from  $z$  to  $v$  that lies completely in  $L$ .

*Proof.* Let us first note that for every  $i \in [d]$  and for every  $(x, y) \in B(w_i)$  it holds that  $x > x_0, y > y_0$ . Indeed,  $w_i \in [m - k + 1, m] \times [m - k + 1, m]$  hence  $(x, y) \in [m - k, m] \times [m - k, m]$  but  $z = (x_0, y_0) \in [1, m - k - 1] \times [1, m - k - 1]$ .

It is sufficient to prove that for every  $x \in L \setminus \{z\}$  at least one of its immediate predecessors lies in  $L$ . If we prove it we can build a desired path by induction. Suppose that there is a node  $x \in L \setminus \{z\}$  such that its immediate predecessors lie outside of  $L$ . Hence each of them lies either in  $\bigcup_i B(w_i)$  or in  $V(\text{Grid}_n) \setminus [x_0, n] \times [y_0, n]$ .

Firstly, consider the case in which one of the predecessors lies outside the  $[x_0, n] \times [y_0, n]$ . Then coordinates of  $x$  look like  $(x_0, *)$  or  $(*, y_0)$ . Without loss of generality assume that  $x = (x_0, h)$  for some  $h \geq y_0$ . Then there is the following path:  $z = (x_0, y_0), (x_0, y_0 + 1), \dots, (x_0, h) = x$  between  $z$  and  $x$ . All its nodes lie in  $[x_0, n] \times [y_0, n]$  and none of them lie in  $\bigcup_i B(w_i)$  due to the restriction on the coordinates of vertices from the balls that we mentioned earlier. Hence, this case is impossible.

Therefore its predecessors lie in  $\bigcup_i B(w_i)$ . But one of its predecessors is above  $x$  and the other is to the left of  $x$ . Hence they lie in different balls (otherwise  $x$  would also lie in the ball, and this contradicts the assumption  $x \in L$ ). Hence the distance between the balls is at most 2 which contradicts the construction from the beginning of the subsection. This concludes the proof of the claim. ◁

All the substitutions assign 0 to the variables in  $L$ . Now we check that no first-type clause from  $\varphi$  is falsified after that. There is no  $z$ 's clause in  $\varphi$ . For every other node  $z' \in L$  there is a path from  $z$  to  $z'$  in  $L$ . We assign 0 to the nodes on the path hence we assign 0 to some immediate predecessor of  $z'$  hence its clause is satisfied (again, by the definition of the clause).

- We have already defined the substitutions into all variables except  $\bigcup_i B(w_i)$ . Fix  $j \in [d]$ . There are two nodes with edges going from them to  $w_j$ . One of them is  $u_j$ . We denote the other one by  $r_j$ . Note that  $\{u_j, r_j\} \subset B(w_j)$ . Every substitution will assign 1 to  $r_j$ . Hence its first-type clause is always satisfied. To the nodes  $B(w_j) \setminus \{u_j, w_j, r_j\}$  we always substitute 0. We need to check that it will not falsify their clauses. It is easy to see that each node from  $B(w_j) \setminus \{u_j, w_j, r_j\}$  has at least one immediate predecessor in  $L \setminus \{w_i, u_i, r_i \mid i \in [d]\}$  (see Fig. 3). But we assign zeros to the variables from this set. Hence clauses corresponding to the  $B(w_j) \setminus \{u_j, w_j, r_j\}$  are always satisfied (see Fig. 3).

Note that we substitute 0 to the sink. Indeed, if the sink does not lie in any ball, then it lies in  $L$ . Hence we substitute 0 to it. Otherwise, the sink lies in some ball; denote the center of this ball by  $(x_1, y_1)$ . Then  $x_1 \leq n - 1$  and  $y_1 \leq n - 1$ . But then the sink is the most right bottom variable of the ball, hence it is substituted with 0.

Therefore, the second-type clause corresponding to the sink is satisfied.

At this point, we have defined substitutions on the set where their values coincide. Now we define substitutions to the remaining nodes i.e.  $\{w_i, u_i \mid i \in [d]\}$ . We need to consider to cases: whether  $\{u_j \mid j \in [d]\}$  or  $\{w_j \mid j \in [d]\}$  lie in the first part of the variable order.

**Case 1:** Suppose that  $\{u_j \mid j \in [d]\}$  lies in the first part of the variable order. Consider all possible substitutions of zeros and ones into the  $\{u_j \mid j \in [d]\}$ . There are  $2^d$  such substitutions. Note that every node from  $\{u_j \mid j \in [d]\}$  has an immediate predecessor from  $L \setminus \{u_j, w_j, r_j \mid j \in [d]\}$  hence its clause is satisfied.

We show that we can separate any two such substitutions  $\rho_0 \neq \rho_1$  by some substitution  $\rho$  with support  $W'$ . There exists  $j_0 \in [d]$  such that  $\rho_0(u_{j_0}) \neq \rho_1(u_{j_0})$ . Without loss of generality suppose that  $\rho_0(u_{j_0}) = 0$  then  $\rho_1(u_{j_0}) = 1$ . We define a substitution  $\rho$  as follows:  $\rho(w_j) = \rho_0(u_j)$ .

- On the one hand substitution  $\rho_0 \circ \rho$  does not falsify  $\varphi$  since the only clauses that can be falsified are clauses associated with  $\{w_j \mid j \in [d]\}$  (we have already checked that the other clauses are satisfied). But the clause corresponding to the node  $w_j$  for  $\{j \in [d]\}$  is falsified iff 0 is substituted into  $w_j$  and 1 are substituted to all its immediate predecessors. But if  $\rho(w_j) = 0$  then  $\rho_0(u_j) = 0$ . Hence  $\varphi|_{\rho \circ \rho_0} = 1$ .
- On the other hand,  $\rho(w_{j_0}) = 0$ . The node  $w_{j_0}$  has two immediate predecessors: the node  $r_{j_0}$ , into which we always assign 1, and  $u_{j_0}$  such that  $\rho_1(u_{j_0}) = 1$ . Hence  $(u_{j_0}, r_{j_0} \rightarrow w_{j_0})|_{\rho \circ \rho_1} = 0$  and  $\varphi|_{\rho \circ \rho_1} = 0$ .

**Case 2:** Suppose that  $\{u_j \mid j \in [d]\}$  lies in the second part of the variable order.

Similarly to the Case 1, we define  $2^d$  substitutions into the variables  $\{w_j \mid j \in [d]\}$ . We need to show that substitutions  $\rho_0$  and  $\rho_1$  lead to different Boolean functions. Again we find  $j_0 \in [d]$  such that  $\rho_0(w_{j_0}) = 0$  and  $\rho_1(w_{j_0}) = 1$ . In this case we define  $\rho(u_j) = \rho_1(w_j)$ .

Similarly to the Case 1,  $\rho$  satisfies clauses for nodes from  $\{u_j \mid j \in [d]\}$ . Also  $\rho \circ \rho_1$  satisfy clauses for nodes from  $\{w_j \mid j \in [d]\}$  (we just copy  $\rho_1$  from  $\{w_j \mid j \in [d]\}$  to  $\{u_j \mid j \in [d]\}$ ). At the same time  $\rho(u_{j_0}) = 1$ ,  $r_{j_0}$  is always substituted with 1 and  $\rho_0(w_{j_0}) = 0$ . Hence  $(u_{j_0}, r_{j_0} \rightarrow w_{j_0})|_{\rho \circ \rho_0} = 0$  and  $\varphi|_{\rho \circ \rho_0} = 0$ . ◀

■ **Figure 3** An example of a substitution to a ball's variables.

### 3.2 Proof of Theorem 12

**Proof of Theorem 12.** Let us fix  $\alpha \in (0, 1)$ .

Now we show that for every OBDD( $\wedge$ , reordering) refutation of  $\text{Peb}(\text{Grid}_n)$  its depth is at least  $n^{1-\alpha}/2$  or its size is at least  $2^{n^\alpha/18928}$ .

Suppose there exists a refutation with depth less than  $n^{1-\alpha}/2$  and size less than  $2^{n^\alpha/18928}$ . Every refutation can be represented as directed acyclic graph such that:

- Each node is labeled with some OBDD from the refutation. Note that every such OBDD is equivalent to the conjunction of a subset of  $\text{Peb}(\text{Grid}_n)$  clauses. For every node, we add the conjunction to the label for clarity.
- Its only source is labeled with the constant false OBDD.
- Each sink is labeled with OBDD for some clause of  $\text{Peb}(\text{Grid}_n)$ .
- If an OBDD in a node is obtained by the conjunction rule then the node has outdegree 2 and the OBDD in the node is a conjunction of the OBDDs in the descendants.
- If an OBDD in a node is obtained by the reordering rule then the node has outdegree 1 and the OBDD in the node is the result of the reordering rule applied to the OBDD in the node's descendant.

Let us divide the subgrid  $[1, n-1] \times [1, n-1]$  into  $[1, n-n^\alpha] \times [1, n-n^\alpha]$ ,  $[n-n^\alpha+1, n-1] \times [n-n^\alpha+1, n-1]$ ,  $[n-n^\alpha+1, n-1] \times [1, n-n^\alpha]$ ,  $[1, n-n^\alpha] \times [n-n^\alpha+1, n-1]$  as in Subsection 3.1 (set  $m = n-1$  and  $k = n^\alpha$ ).

Let  $\varphi$  be a CNF formula and let  $S$  be a subset of its clauses. We denote  $\varphi_S = \bigwedge_{C \in S} C$ .

Consider an arbitrary OBDD( $\wedge$ , reordering) refutation of  $\text{Peb}(\text{Grid}_n)$ . Consider its source. Since by Lemma 8,  $\text{Peb}(\text{Grid}_n)$  is minimal unsatisfiable, the source is labeled with the conjunction of all clauses (i.e.  $\text{Peb}(\text{Grid}_n)$  itself). In particular, all clauses for vertices from  $[1, m] \times [1, m]$  lie there. We start a path at the source of the refutation. If the current node (initially the current node is the source) has only one immediate descendant then we move into the descendant until the current node has two of them. Assume that the current node is labeled with  $\pi$ -OBDD for some order of the variables  $\pi$ . By the definition of the conjunction rule the current node's descendants are also labeled with  $\pi$ -OBDDs. For this order  $\pi$  and parameters  $m$  and  $k$  find sets  $U_\pi, W_\pi$  as was described in Subsection 3.1. Suppose one of the descendants is labeled with formula  $\varphi_{S_1}$  and the other with  $\varphi_{S_2}$ . Then

$[1, m] \times [1, m] \subset S_1 \cup S_2$ . Hence  $|S_1 \cap W_\pi| \geq |W_\pi|/2$  or  $|S_2 \cap W_\pi| \geq |W_\pi|/2$ . Without loss of generality  $|S_1 \cap W_\pi| \geq |W_\pi|/2$ . Recall that  $|W_\pi| \geq k/9464$  so  $|S_1 \cap W_\pi| \geq k/18928$ . Consider two cases: whether  $[1, n - n^\alpha - 1] \times [1, n - n^\alpha - 1] \not\subset S_1$  or  $[1, n - n^\alpha - 1] \times [1, n - n^\alpha - 1] \subset S_1$ .

**Case 1:**  $[1, n - n^\alpha - 1] \times [1, n - n^\alpha - 1] \not\subset S_1$ . In this case we can apply Lemma 13 with  $d = |S_1 \cap W_\pi| \geq k/18928 = n^\alpha/18928$  and variable order  $\pi$ . Hence the size of  $\pi$ -OBDD for  $\varphi_{S_1}$  from the current node is at least  $2^{n^\alpha/18928}$ . Therefore the size of the refutation is at least  $2^{n^\alpha/18928}$ . Hence this case is impossible.

**Case 2:**  $[1, n - n^\alpha - 1] \times [1, n - n^\alpha - 1] \subset S_1$ . All clauses from  $[1, n - n^\alpha - 1] \times [1, n - n^\alpha - 1]$  are still in the conjunction.

We divide this square into 4 subsquares, same as we did with  $[1, n - 1] \times [1, n - 1]$ . Now we set  $m = n - n^\alpha - 1$ ,  $k = n^\alpha$  and repeat the actions for new values of  $m$  and  $k$ . Again we can move down at least one time in the refutation's graph so that at the current node there will be all clauses from the top left subsquare (this time it is  $[1, n - 2n^\alpha - 2] \times [1, n - 2n^\alpha - 2]$ ).

Again, we divide this subsquare into 4 subsubsquares ( $m = n - 2n^\alpha - 2$ ,  $k = n^\alpha$ ) and so on. Case 1 is always impossible since  $k$  is always equal to  $n^\alpha$  and we assumed that the size of the refutation is less than  $2^{n^\alpha/18928}$ . We can repeat the process  $\frac{n}{n^\alpha + 1} \geq n^{1-\alpha}/2$  times. Every time we move down in the refutation's graph at least once, therefore its depth is at least  $n^{1-\alpha}/2$ . ◀

► **Corollary 15.** *Dag-like and tree-like OBDD( $\wedge$ ) and OBDD( $\wedge$ , reordering) proofs cannot be balanced i.e. there is no polynomial  $p$  such that for every unsatisfiable formula  $\varphi$  and for every its refutation  $w$  (dag-like or tree-like) of the size  $S$ , there exists a refutation  $w'$  (dag-like or tree-like respectively) of the size  $p(S)$  and of the depth  $O(\log(S))$ .*

**Proof.** By Lemma 5 Formula  $\text{Peb}(\text{Grid}_n)$  has tree-like OBDD( $\wedge$ ) refutation of the size  $O(n^4)$ . But  $\text{Peb}(\text{Grid}_n)$  cannot have OBDD( $\wedge$ , reordering) a refutation of the size  $\text{poly}(n)$  and of the depth  $O(\log \text{poly}(n)) = O(\log n)$  due to Theorem 12. Hence the proof systems are not balanced. ◀

## A Proof of Lemma 5

► **Proposition 16.** *Let  $X = \{x_1, \dots, x_n\}$  be a set of Boolean variables and let  $Y \subset X$ . Let  $\varphi = \bigwedge_{y \in Y} y$ . Then there exists  $\pi$ -OBDD for  $\varphi$  of the size  $O(|Y|)$  for every order of variables  $\pi$ .*

**Proof.** We enumerate  $Y$  according to the order  $\pi$ :  $Y = \{y_1, \dots, y_{|Y|}\}$ . We define  $\pi$ -OBDD for  $\varphi$  as follows: there is the unique node  $y_i$  for every  $i \in [|Y|]$ . We identify node and its label. The node  $y_1$  is the source. For every  $i \in [|Y|]$ ,  $y_i$ 's outgoing edge labeled with 0 goes to the sink labeled with 0. If  $i < |Y|$  then  $y_i$ 's outgoing edge labeled with 1 goes to  $y_{i+1}$  otherwise it goes to the sink labeled with 1. It is easy to see that there is a unique path between the source and the sink, labeled with 1, and that all edges on the path are labeled with 1. Hence the  $\pi$ -OBDD we have defined represents  $\varphi$ . ◀

► **Lemma 5 ([7]).** *For every directed acyclic graph  $G$  and for every order of variables  $\pi$  formula  $\text{Peb}(G)$  has tree-like  $\pi$ -OBDD( $\wedge$ ) refutation of size  $O(|V|^2)$  and depth  $O(|V|)$ .*

**Proof.** Let  $\{A_1, \dots, A_{n_1}\}$  be the first-type clauses in topological sort order. Let  $B$  be an arbitrary second-type clause. Consider the following sequence of the CNF formulas:  $A_1, A_1 \wedge A_2, \dots, \bigwedge_{i=1}^{n_1} A_i, (\bigwedge_{i=1}^{n_1} A_i) \wedge B$ . Represent each of this formulas as  $\pi$ -OBDD. Then it is easy to see that the sequence of OBDDs is a tree-like  $\pi$ -OBDD( $\wedge$ ) refutation. We now prove that the refutation has the size  $O(|V|^2)$ . It consists of  $|V| + 1$  formulas. It is sufficient to prove that each formula has the size  $O(|V|)$ . We consider two cases:

**Case 1:** The formula is  $A_1 \wedge \dots \wedge A_i$  for some  $i \in [n_1]$ . We prove by the induction on  $i$  that  $A_1 \wedge \dots \wedge A_i \equiv v_1 \wedge \dots \wedge v_i$ , where  $\equiv$  stands for logical equivalence. **Base:**  $i = 1$  so  $v_1$  is a source and the corresponding clause is  $(v_1)$ . **Induction step:** Assume that  $A_1 \wedge \dots \wedge A_i \equiv v_1 \wedge \dots \wedge v_i$  then  $A_1 \wedge \dots \wedge A_i \wedge A_{i+1} \equiv v_1 \wedge \dots \wedge v_i \wedge A_{i+1}$ . Let  $A_{i+1} = (u_1, \dots, u_k \rightarrow v_{i+1})$  where  $u_1, \dots, u_k$  is the set of all immediate predecessors of  $v_{i+1}$ . Since the clauses  $\{A_i \mid i \in [n_1]\}$  appear in the topological sort order then the first-type clauses that correspond to the variables  $\{u_1, \dots, u_k\}$  lie in  $\{A_1, \dots, A_i\}$ . Then it is easy to see that  $v_1 \wedge \dots \wedge v_i \wedge (u_1, \dots, u_k \rightarrow v_{i+1}) \equiv v_1 \wedge \dots \wedge v_i \wedge v_{i+1}$ .

Proposition 16 implies that such formulas have OBDD representation of the size  $O(|V|)$ .

**Case 2:** The formula is  $(\bigwedge_{i=1}^{n_1} A_i) \wedge B$ . We already have proved that  $(\bigwedge_{i=1}^{n_1} A_i) \equiv \bigwedge_j v_j$  is the conjunction of the all nodes. This conjunction implies that the values of variables of all nodes equal 1. At the same time the clause  $B$  implies that the variable of the corresponding sink equals 0. Hence the formula is unsatisfiable and the corresponding OBDD is constant false. ◀

## B Proof of Lemma 8

► **Lemma 8 (Folklore).** *Let  $G$  be a directed acyclic graph with only one sink. Then  $\text{Peb}(G)$  minimal unsatisfiable i.e. a conjunction of every proper subset of its set of clauses is satisfiable.*

**Proof.** Fix some proper subset  $S$  of the set of all clauses of  $\text{Peb}(G)$ . We now prove that  $\bigwedge_{C \in S} C$  is satisfiable.

Consider two cases:

**Case 1:** There is no second type clause in  $S$ . Then each clause from  $S$  contains literal without negation. Then the assignment of all 1 is satisfiable.

**Case 2:** There is no first-type clause in  $S$ . Denote the corresponding variable by  $v$ . Denote by  $t$  the unique sink of the graph. Note that there is a path from  $v$  to  $t$  (otherwise there are at least two sinks in the graph). Then the assignment of 0 to the path's variables and 1 to the other variables is satisfiable. Indeed, the first-type clauses corresponding to the variables substituted with 1 are always satisfied. The second-type clause is satisfied since the sink is substituted with 0. The other variables substituted with 0 have at least one immediate predecessor substituted with 0, hence their first type clauses are also satisfied. ◀

# Lower Bounds for Choiceless Polynomial Time via Symmetric XOR-Circuits

Benedikt Pago  

Mathematical Foundations of Computer Science, RWTH Aachen University, Germany

---

## Abstract

Choiceless Polynomial Time (CPT) is one of the few remaining candidate logics for capturing PTIME. In this paper, we make progress towards separating CPT from polynomial time by firstly establishing a connection between the expressive power of CPT and the existence of certain symmetric circuit families, and secondly, proving lower bounds against these circuits. We focus on the isomorphism problem of unordered Cai-Fürer-Immerman-graphs (the CFI-query) as a potential candidate for separating CPT from PTIME. Results by Dawar, Richerby and Rossman, and subsequently by Pakusa, Schalhöfer and Selman show that the CFI-query is CPT-definable on linearly ordered and preordered base graphs with small colour classes. We define a class of CPT-algorithms, that we call “CFI-symmetric algorithms”, which generalises all the known ones, and show that such algorithms can only define the CFI-query on a given class of base graphs if there exists a family of symmetric XOR-circuits with certain properties. These properties include that the circuits have the same symmetries as the base graphs, are of polynomial size, and satisfy certain fan-in restrictions. Then we prove that such circuits with slightly strengthened requirements (i.e. stronger symmetry and fan-in and fan-out restrictions) do not exist for the  $n$ -dimensional hypercubes as base graphs. This almost separates the CFI-symmetric algorithms from PTIME – up to the gap that remains between the circuits whose existence we can currently disprove and the circuits whose existence is necessary for the definability of the CFI-query by a CFI-symmetric algorithm.

## 1 Introduction

A central open question in finite model theory is whether there exists a logic that captures the complexity class polynomial time. It was first raised by Chandra and Harel in 1980 [5] and later made precise by Gurevich [20]. According to his definition, the term “logic” refers to any computation model that operates on finite structures and is *isomorphism-invariant*, i.e. yields the same output on isomorphic input structures. The question for a logic for PTIME thus asks whether there exists some isomorphism-invariant computation model which can decide exactly the same classes of structures that can be decided by “classical” polynomial time algorithms (i.e. Turing machines). The latter are not isomorphism-invariant because every structure, for example a graph, has multiple different representations as a binary string (e.g. depending on the vertex order that is used for the adjacency list/matrix). The result of a classical computation depends on this string representation and not on the isomorphism-type of the graph, which is undesirable for a logic. Another way of phrasing the question is whether the time and space cost of ensuring symmetry-invariance in computations is necessarily super-polynomial or not. Gurevich himself conjectured that no logic for PTIME exists, and if we had a proof for this, it would immediately separate P and NP: It is long known by Fagin’s

theorem [14] that NP is captured by existential second order logic. In fact, many candidate logics that have been proposed in an attempt to capture PTIME have been proven to be only a strict fragment of it. For a survey on this topic (excluding the results from recent years), see [18].

One prominent logic for which research on lower bounds has not been so successful yet is *Choiceless Polynomial Time* (CPT). It was introduced in 1999 by Blass, Gurevich and Shelah [3] as a symmetry-invariant machine model. It has been open since then whether CPT (with counting) does capture PTIME or not. For more background information on CPT, see for example [17, 28, 32]. CPT can also be viewed as an extension of *fixed-point logic with counting* [6] with *hereditarily finite sets* as data structures. Other (perhaps less studied) candidates that have not been separated from PTIME so far are logics with witnessed choice constructs (a concept first introduced in [15]). These include fixed-point logic with witnessed symmetric choice and interpretations [23] and CPT extended with witnessed symmetric choice [24]. Prior to Lichter’s breakthrough [22], which separates *rank logic* from PTIME using a variation of the famous Cai-Fürer-Immerman (CFI) construction [4], logics with *linear-algebraic operators* [7] were also considered reasonable candidates. However, as outlined in [8], the results from [22] and [7] together imply that *no* set of isomorphism-invariant linear algebraic operators can be used to define a logic capturing PTIME. Thus, an important next step in this program would be to also rule out CPT as a logic for PTIME. In this article, we make progress towards this goal and propose an approach that allows to infer CPT lower bounds from lower bounds against certain symmetric Boolean circuit families. Thereby, the problem is narrowed down to the study of concrete combinatorial objects, for which we can present a first lower bound.

It should be remarked that the power of CPT is also of interest in another research context, namely with regards to the *graph isomorphism problem*: One can roughly divide the most important graph isomorphism algorithms into group-theoretic and combinatorial ones; the latter term refers to generalisations of the well-known *Weisfeiler-Leman* (WL) method, and these are choiceless. It is in a sense possible to characterise CPT as the class of all polynomial-time combinatorial graph isomorphism algorithms. A precise description of these has been given with the *Deep Weisfeiler-Leman* computation model [19], which was shown to be equivalent to CPT. Hence, lower bounds against CPT would also imply limitations for all combinatorial graph isomorphism algorithms.

Concerning CPT lower bounds, only relatively little is known. There is a non-definability result for a *functional* problem in PTIME, namely, it is impossible to define the dual of a given finite vector space in CPT [30]. What we would like to have is, however, the inexpressibility of a polynomial-time *decision problem*. We focus on a standard benchmark from finite model theory, namely the *CFI-query* [4]. Instances of this query are obtained by applying the so-called CFI construction to any connected undirected *base graph*, yielding either an “even” or an “odd” CFI-graph (see Section 3). The query asks to determine the parity of a given CFI-graph and it can be seen as a variant of the graph isomorphism problem or as the problem of solving a certain linear equation system over the finite field  $\mathbb{F}_2$ . Its descriptive complexity depends highly on the choice of base graphs and whether these come with a built-in linear order or not. The CFI-query is decidable in polynomial time but not in fixed-point logic with counting [4]. It is open whether it is CPT-definable on *unordered* base graphs, and our goal is to eventually answer this question in the negative. Our approach starts off from positive results: There do exist CPT-algorithms for linearly ordered and preordered versions of the CFI-query [9, 29] and also CFI-graphs over base graphs of linear degree [29]. In [26] it was shown that there exist unordered CFI-graphs (over  $n$ -dimensional hypercubes) whose degree is not linear and which cannot be preordered in CPT in such a way that the preorder-based algorithm from [29] (or the total-order-based one from [9]) could

be applied. This shows that these known choiceless algorithms for preordered versions of the CFI-query do not generalise to the unordered case because the necessary combinatorial objects (said preorders) are not symmetric enough. In the present paper, we define a general class of CPT-algorithms for the CFI-query, which encompasses all the known ones mentioned above, and show that their expressiveness depends on the existence of certain symmetric combinatorial objects, namely circuits with Boolean XOR-gates. We show that the CFI-query over a given class  $\mathcal{K}$  of base graphs is only definable by an algorithm from that class if there exists a family of polynomial-size symmetric XOR-circuits with the properties in Theorem 1. This means that the non-definability of the CFI-query over  $\mathcal{K}$  can be shown by proving the non-existence of such circuits. In Theorem 2, we almost achieve this goal: If we take as  $\mathcal{K}$  the family of  $n$ -dimensional hypercubes and make the circuit properties slightly more restrictive than required by our Theorem 1, then we succeed in showing that such circuits cannot exist. Thus, we come close to showing that the CFI-query over unordered hypercubes is undefinable by any CPT-algorithm from the class we are considering.

Following [9], we denote a CFI-graph over a base graph  $G$  or  $H$  as  $\mathfrak{G}^S$  or  $\mathfrak{H}^S$  (where  $S$  denotes the set of vertices whose CFI-gadget is odd). We consider circuits whose internal gates are XOR-gates and whose input gates are labelled with edges of the associated CFI base graph  $G$ . Therefore, the automorphism group of  $G$  has a natural action on the circuits as well. A circuit is said to be *sensitive* to a certain input bit if flipping just that bit changes the output. The other circuit properties will be explained in Section 5.

► **Theorem 1** (Main Theorem; see Theorem 31 in the full version for more details). *Let  $(G_n = (V_n, E_n))_{n \in \mathbb{N}}$  be a sequence of connected base graphs. Let  $\mathfrak{G}_n^S$  be a CFI-graph over  $G_n$ , and let  $\mathbf{tw}_n$  denote the treewidth of  $G_n$ . If there exists a CPT-program  $\Pi$  that is super-symmetric and CFI-symmetric and decides the CFI-query on all  $\mathfrak{G}_n^S$ , then there also exists a family  $(C_n)_{n \in \mathbb{N}}$  of XOR-circuits such that*

1. *The number of gates in  $C_n$  is polynomial in  $|\mathfrak{G}_n^S|$ .*
2. *The  $\mathbf{Aut}(G_n)$ -orbit of the circuit has size polynomial in  $|\mathfrak{G}_n^S|$ .*
3.  *$C_n$  is sensitive to  $\Omega(\mathbf{tw}_n)$  input bits.*
4. *The fan-in dimension of  $C_n$  is  $\mathcal{O}(\log |\mathfrak{G}_n^S|)$ .*

The terms *super-symmetric* and *CFI-symmetric* refer to the properties of a *hereditarily finite set* that is constructed by the program  $\Pi$  in order to decide the CFI-query. *Super-symmetry* is a property of h.f. sets that goes back to [9] (see Definition 5). *CFI-symmetry* is a concept that we define in this paper and which describes the internal structure and “local symmetries” of a h.f. set (see Section 4). The CFI-algorithms from [9] and [29] are based on super-symmetric and CFI-symmetric h.f. sets, and arguably, both these properties are crucial for the success of all these algorithms.

Our second main result shows that if we choose the  $n$ -dimensional hypercubes as the family of base graphs, and impose slightly stronger conditions on the circuits, then it is not possible to satisfy all of them together.

► **Theorem 2.** *Let  $(\mathcal{H}_n)_{n \in \mathbb{N}}$  be the family of  $n$ -dimensional hypercubes and let  $\mathbf{tw}_n$  denote the treewidth of  $\mathcal{H}_n$ . There exists no family of symmetric XOR-circuits  $(C_n)_{n \in \mathbb{N}}$  such that:*

1. *The number of gates in  $C_n$  is polynomial in  $|\mathfrak{H}_n^S|$ .*
2. *The  $\mathbf{Aut}(\mathcal{H}_n)$ -orbit of the circuit has size exactly one.*
3.  *$C_n$  is sensitive to  $\Omega(\mathbf{tw}_n)$  input bits.*
4. *For any two gates  $g, h$  in  $C_n$  such that  $h$  is a parent of  $g$ , it holds  $|\mathbf{Orbit}_{(h)}(g)| \in \mathcal{O}(\log |\mathfrak{H}_n^S|)$  and  $|\mathbf{Orbit}_{(g)}(h)| \in \mathcal{O}(\log |\mathfrak{H}_n^S|)$ .*

Here,  $\mathbf{Orbit}_{(h)}(g)$  denotes the orbit of the gate  $g$  with respect to the subgroup of  $\mathbf{Aut}(\mathcal{H}_n)$  that fixes the gate  $h$  (and vice versa for  $\mathbf{Orbit}_{(g)}(h)$ ).

If the four circuit properties were the same as in Theorem 1, then this would separate the class of super- and CFI-symmetric choiceless algorithms from PTIME. The difference between the two theorems is that here, the circuit has orbit size one, i.e. it is stabilised by the whole group  $\mathbf{Aut}(\mathcal{H}_n)$ , whereas in Theorem 1, the orbit of the circuit is only required to be polynomial. Moreover, here, we have a logarithmic bound on the parents and children (per orbit) of every gate, whereas in Theorem 1, the logarithmic bound is on the *fan-in dimension* of the gates. We define this notion in Section 5; we do not know if logarithmic fan-in dimension implies the orbit-wise logarithmic bound on the number of children (or vice versa), and probably, it does not imply the bound on the number of parents. So the gap between our two main results concerns how symmetric the circuits have to be and how restricted the connectivity between two consecutive circuit layers is. It remains a problem for future work to close this gap. This paper is thus a first step of a potentially longer programme towards showing  $\text{CPT} \neq \text{PTIME}$  via circuit lower bounds.

**Related work.** Lower bounds for symmetric circuits are studied in different contexts in the literature. For example, families of highly symmetric Boolean circuits with threshold gates characterise the power of fixed-point logic with counting [1], and certain more general circuits capture rank logic [11]. Our results are different in the sense that the XOR-circuits do not *characterise* CPT; they only represent the relevant structure of the h.f. sets that CPT uses to decide the CFI-query. Another line of research focuses on lower bounds for symmetric arithmetic circuits for the determinant and permanent polynomials, with the aim of making progress towards separating VP from VNP [10, 12]. Other examples of symmetric circuit lower bounds concern Boolean circuits for the parity function [31] and for computing products of permutation matrices [21]. The technical methods we employ in the proof of Theorem 2 might be applicable to the study of symmetric circuits in other contexts as well but we have not investigated this yet.

## 2 Choiceless Polynomial Time

**Hereditarily finite sets.** Let  $A$  be a finite set of atoms. The set of hereditarily finite objects over  $A$ ,  $\text{HF}(A)$ , is defined as  $\bigcup_{i \in \mathbb{N}} \text{HF}_i(A)$ , where  $\text{HF}_0(A) := A \cup \{\emptyset\}$ ,  $\text{HF}_{i+1}(A) := \text{HF}_i(A) \cup 2^{\text{HF}_i(A)}$ . The size of a h.f. set  $x \in \text{HF}(A)$  is measured in terms of its *transitive closure*  $\text{tc}(x)$ : The set  $\text{tc}(x)$  is the least transitive set such that  $x \in \text{tc}(x)$ . Transitivity means that for every  $a \in \text{tc}(x)$ ,  $a \subseteq \text{tc}(x)$ . Intuitively, one can view  $\text{tc}(x)$  as the set of all sets that appear as elements at some nesting depth within  $x$ .

**Choiceless Polynomial Time.** By CPT we always mean Choiceless Polynomial Time *with counting*. For details and various ways to define CPT formally, we refer to the literature: A concise survey can be found in [17]. The work by Blass, Gurevich and Shelah in which CPT was originally introduced as an abstract state machine model is [3]; later, more “logic-like” presentations of CPT were invented, such as Polynomial Interpretation Logic (see [16, 32]) and BGS-logic [30]. In short, CPT is like fixed-point logic with counting [6] plus a mechanism to construct isomorphism-invariant hereditarily finite sets of polynomial size. When a CPT-sentence (also called program)  $\Pi$  is evaluated in a finite structure  $\mathfrak{A}$ , then  $\Pi$  may augment  $\mathfrak{A}$  with hereditarily finite sets over its universe. The total number of distinct sets appearing in them (i.e. the sum over the sizes of the transitive closures of the h.f. sets) and the number of computation steps is bounded by  $p(|A|)$ , where  $p(n)$  is a polynomial that is explicitly part of the sentence  $\Pi$ . The run of  $\Pi$  on  $\mathfrak{A}$  is formally a sequence of computation stages, each of which is a h.f. set.

The h.f. sets that appear in the run of a program  $\Pi$  on a structure  $\mathfrak{A}$  are called the sets that are *activated* by  $\Pi$  on input  $\mathfrak{A}$ . Formally, the set of active objects is the union over the transitive closures of all the computation stages of the run of  $\Pi$  on  $\mathfrak{A}$ . The precise definition is not important for the purposes of this article and there exist multiple slightly varying definitions in the literature [9, 30, 32] which all essentially describe the same concept. The main limitation of CPT is that the set of objects activated by  $\Pi$  on  $\mathfrak{A}$  is closed under the automorphisms of  $\mathfrak{A}$  and at the same time of polynomial size in  $|A|$ . Thus, objects with super-polynomially large orbits cannot be activated by a CPT-program. It may be worth noting that while the whole set of activated objects has an orbit of size one, each activated object itself need not be fixed by *every* automorphism – as long as its orbit is only polynomial.

### 3 Unordered Cai-Fürer-Immerman graphs

Fix an undirected connected graph  $G = (V, E)$  as the *base graph* for the CFI-construction (whenever we speak of base graphs throughout the paper, we mean connected graphs). We turn  $G$  into a CFI-graph by replacing the edges with certain edge-gadgets and the vertices with vertex-gadgets. There are two types of vertex-gadgets, called odd and even. To construct a concrete CFI-graph over  $G$ , we have to fix a set  $S \subseteq V$  of vertices which are replaced by the *odd* gadget. The vertices in  $V \setminus S$  will be turned into the *even* gadget. We denote the resulting CFI-graph by  $\mathfrak{G}^S$ . The precise definition is as follows: Let  $\widehat{E} := \{e_0, e_1 \mid e \in E\}$ . These are the vertices that will form the edge-gadgets of  $\mathfrak{G}^S$ , so there are two vertices per edge-gadget. To define the vertices in vertex-gadgets, we let, for each  $v \in V$ ,  $v_S^* := \{v^X \mid X \subseteq E(v), |X| \text{ even}\}$  if  $v \notin S$ , and otherwise,  $v_S^* := \{v^X \mid X \subseteq E(v), |X| \text{ odd}\}$ . Here,  $E(v) \subseteq E$  are the edges incident to  $v$  in  $G$ . The vertices in  $v_S^*$  form the vertex-gadget of  $v$ . In total, we let  $\widehat{V}_S := \bigcup_{v \in V} v_S^*$ . Then the vertex-set of  $\mathfrak{G}^S$  is  $V(\mathfrak{G}^S) := \widehat{V}_S \cup \widehat{E}$ . The edges of the CFI-graph are given by

$$E(\mathfrak{G}^S) := \{\{v^X, e_i\} \mid v^X \in \widehat{V}_S, e_i \in \widehat{E}, |X \cap \{e\}| = i\} \cup \{\{e_0, e_1\} \mid e \in E\}.$$

In other words, for every  $v \in V$ , we connect each  $v^X \in v_S^*$  with the edge-gadgets of all edges  $e \in E(v)$  in such a way that  $v^X$  is connected with  $e_0$  if  $e \notin X$ , and otherwise with  $e_1$ . Also, we connect  $e_0$  and  $e_1$  to ensure that no automorphism of  $\mathfrak{G}^S$  can tear apart the edge-gadgets. Our CFI-graphs are unordered, so the only relation of the structure  $\mathfrak{G}^S$  is the edge relation  $E$ . The *CFI-query* asks for the parity of  $|S|$ , given a CFI-graph  $\mathfrak{G}^S$ . This is essentially the

■ **Figure 1** Gadgets  $v_S^*, w_S^*$  for  $v \notin S, w \in S$ , connected by the gadget for the edge  $e$ .

same question as the graph isomorphism problem for CFI-graphs:

► **Theorem 3** ([4, 9]). *For two given CFI-graphs over the same base graph, it holds  $\mathfrak{G}^S \cong \mathfrak{G}^R$  if and only if  $|S| \equiv |R| \pmod 2$ .*

Alternatively, deciding the parity of  $|S|$  can be phrased as a linear equation system over  $\mathbb{F}_2$  in the variables  $\widehat{E}$  [2]. Since the reduction to a linear equation system is easily computable from the given CFI-graph  $\mathfrak{G}^S$ , and linear equation systems can be efficiently solved using, for example, Gaussian elimination, the CFI-query is decidable in polynomial time.

For logics that lack the ability to create higher-order objects, such as bounded-variable counting logic  $\mathcal{C}^k$  (and hence fixed-point logic with counting), it is provably impossible to distinguish non-isomorphic CFI-graphs, provided that the treewidth of the base graphs is super-constant:

► **Theorem 4** ([4, 2]). *Let  $G = (V, E)$  be an undirected connected graph with treewidth  $t$ . Then for any two sets  $S, S' \subseteq V$ , it holds  $\mathfrak{G}^S \equiv_{\mathcal{C}^t} \mathfrak{G}^{S'}$ , even if  $\mathfrak{G}^S \not\cong \mathfrak{G}^{S'}$ .*

### 3.1 Automorphisms of unordered CFI-graphs

For a CFI-graph  $\mathfrak{G}^S$  over an *unordered* base graph  $G = (V, E)$ , two different kinds of automorphisms play a role: Firstly, there are what we call “CFI-automorphisms”. These are induced by swapping  $e_0$  and  $e_1$  in some edge-gadgets (this is called “flipping the edge”). Secondly, there are the automorphisms of the underlying graph  $G$  itself.

To speak about the CFI-automorphisms, we use the terminology from [9]: For a given base graph  $G$ , we consider not only a concrete CFI-instance with odd and even vertex gadgets, but we can also construct the “full” CFI-graph  $\mathfrak{G}$ , in which every vertex gadget is both even and odd. Formally, for  $v \in V$ , let  $v^* := v_0^* \cup v_{\{v\}}^* = \{v^X \mid X \subseteq E(v)\}$ , and  $\widehat{V} := \bigcup_{v \in V} v^*$ . The vertex-set of  $\mathfrak{G}$  is  $\widehat{V} \cup \widehat{E}$ , and the edge-set is

$$E(\mathfrak{G}) := \{\{v^X, e_i\} \mid v^X \in \widehat{V}, e_i \in \widehat{E}, |X \cap \{e\}| = i\} \cup \{\{e_0, e_1\} \mid e \in E\}.$$

Every CFI-instance  $\mathfrak{G}^S$  is an induced subgraph of  $\mathfrak{G}$ . Some of the CFI-automorphisms of  $\mathfrak{G}$  are also automorphisms of  $\mathfrak{G}^S$ , but not all of them are. The other automorphisms of  $\mathfrak{G}$  induce isomorphisms from  $\mathfrak{G}^S$  into another isomorphic CFI-graph. For each edge  $e = \{v, w\} \in E$ , let  $\rho_e$  denote the automorphism of  $\mathfrak{G}$  induced by flipping the edge  $e$ . Formally,  $\rho_e(e_0) = e_1, \rho_e(e_1) = e_0$ , and  $\rho_e(v^X) = v^{X \Delta \{e\}}, \rho_e(w^X) = w^{X \Delta \{e\}}$  for all  $v^X, w^X \in v^* \cup w^*$ . All other vertices in  $\widehat{V}$  are fixed by  $\rho_e$ . One can check that this is indeed an automorphism of  $\mathfrak{G}$ ; furthermore,  $\rho_e$  is an *isomorphism* from any CFI-instance  $\mathfrak{G}^S$  to  $\mathfrak{G}^{S \Delta \{v, w\}}$  (see also [9]). It is easy to see that these edge-flip automorphisms commute, so for  $F = \{e^1, \dots, e^m\} \subseteq E$  we may write  $\rho_F$  for  $\rho_{e^1} \circ \rho_{e^2} \circ \dots \circ \rho_{e^m}$ . So in total, for every  $F \subseteq E$ ,  $\rho_F$  is an automorphism of  $\mathfrak{G}$ . If every  $v \in V$  is incident to an even number of edges in  $F$ , then  $\rho_F$  is also an automorphism of  $\mathfrak{G}^S$ , not only of  $\mathfrak{G}$ . To sum up, we have the following groups of CFI-automorphisms of  $\mathfrak{G}$  and  $\mathfrak{G}^S$ :  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G}) := \{\rho_F \mid F \subseteq E\}$ . This group is isomorphic to the Boolean vector space  $\mathbb{F}_2^E$ : Each  $F \subseteq E$  is identified with its characteristic vector  $\chi(F) \in \mathbb{F}_2^E$ . It holds  $\rho_F \circ \rho_{F'} = \rho_{F \Delta F'}$ , and this corresponds to the vector  $\chi(F) + \chi(F') \in \mathbb{F}_2^E$ . As already said, for a CFI-instance  $\mathfrak{G}^S$ , i.e. an induced subgraph of  $\mathfrak{G}$ , we have that  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G}^S)$  is isomorphic to a subspace of  $\mathbb{F}_2^E$ . In addition to the CFI-automorphisms, we also have to consider  $\mathbf{Aut}(G) \leq \mathbf{Sym}(V)$ , i.e. the automorphism group of the unordered base graph. In total, the automorphism group of the full CFI-graph  $\mathfrak{G}$  is isomorphic to the following semi-direct product:  $\mathbf{Aut}(\mathfrak{G}) \cong \mathbf{Aut}_{\text{CFI}}(\mathfrak{G}) \rtimes \mathbf{Aut}(G) = \{(\rho_F, \pi) \mid \rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G}), \pi \in \mathbf{Aut}(G)\}$ . The automorphism group  $\mathbf{Aut}(\mathfrak{G}^S)$  of a concrete CFI-instance is  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G}^S) \rtimes \mathbf{Aut}(G) \leq \mathbf{Aut}(\mathfrak{G})$ .

Sets that are CPT-definable in  $\mathfrak{G}^S$  only have to be symmetric with respect to the latter, but nonetheless, we also consider the full group  $\mathbf{Aut}(\mathfrak{G})$  because it simplifies the analysis. The sets we call *super-symmetric* (see below) are also  $\mathbf{Aut}(\mathfrak{G})$ -symmetric.

### 3.2 Symmetries and supports of hereditarily finite sets over CFI-graphs

Let  $\mathfrak{G}^S$  be a CFI-graph over  $G = (V, E)$  and  $x \in \text{HF}(\widehat{E})$ . All the groups from the previous section act on  $\widehat{E}$  and therefore also on  $\text{HF}(\widehat{E})$ . The action of any permutation  $\pi$  on a set  $x \in \text{HF}(\widehat{E})$  is given by  $\pi(x) = \{\pi(y) \mid y \in x\}$ . If  $x$  is an atom  $e_i$ , with  $i \in \{0, 1\}$ ,

$e = \{u, v\} \in E$ , and  $\pi \in \mathbf{Aut}(G)$ , then  $\pi(x) = \pi(e)_i$ , where  $\pi(e) = \{\pi(u), \pi(v)\} \in E$ . If  $\pi = \rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ , then  $\pi(e_i) = e_j$ , where  $j = i + |F \cap \{e\}| \pmod{2}$ . A permutation  $\pi$  stabilises an object  $x \in \text{HF}(\widehat{E})$ , if  $\pi(x) = x$ . As already said,  $\mathbf{Aut}(\mathfrak{G}^S)$  is composed of edge flips and automorphisms of the base graph. We separate the effect of these two subgroups on the elements of  $\text{HF}(\widehat{E})$  and consider the following orbits and stabilisers for  $x \in \text{HF}(\widehat{E})$ . The different orbits we consider are  $\mathbf{Orb}_E(x) := \{\rho_F(x) \mid \rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})\}$ ,  $\mathbf{Orb}_G(x) := \{\pi(x) \mid \pi \in \mathbf{Aut}(G)\}$ , and the corresponding stabilisers are  $\mathbf{Stab}_E(x) = \{\chi(F) \mid \rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G}), \rho_F(x) = x\}$  and  $\mathbf{Stab}_G(x) = \{\pi \in \mathbf{Aut}(G) \mid \pi(x) = x\}$ . We always view  $\mathbf{Stab}_E(x)$  as a subspace of the Boolean vector space  $\mathbb{F}_2^E$ . Furthermore, let  $\mathbf{maxOrb}_E(x) := \max_{y \in \text{tc}(x)} |\mathbf{Orb}_E(y)|$ .

In [9], the term *super-symmetry* was introduced for h.f. sets which are fixed by *all* automorphisms in  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ . Here, we use a slightly relaxed notion:

► **Definition 5** (Super-symmetric objects). *Fix a family of CFI-graphs  $(\mathfrak{G}_n^S)_{n \in \mathbb{N}}$  and a  $\mu_n \in \text{HF}(\widehat{E}_n)$  for every  $n$ . The objects  $\mu_n$  are super-symmetric if there exists a polynomial  $p$  such that  $|\mathbf{Orb}_E(\mu_n)| \leq p(|\mathfrak{G}_n^S|)$ .*

### Supports for CFI-automorphisms

Generally, a *support* of a permutation group  $\Gamma \leq \mathbf{Sym}(A)$  is a subset  $S \subseteq A$  such that the pointwise stabiliser of  $S$  in  $\mathbf{Sym}(A)$  is a subgroup of  $\Gamma$ . A support of a h.f. set is a support of its stabiliser group. For subgroups of  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ , we will use a different notion, that we call *CFI-support*. The reason why we need a specific type of support for these groups is because otherwise, the group  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$  does not admit unique minimum supports.

► **Definition 6** (CFI-support). *A CFI-support of an object  $x \in \text{HF}(\widehat{E})$  is a subset  $S \subseteq E$  such that every  $\rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$  with  $F \cap S = \emptyset$  fixes  $x$ .*

For the proof of the next lemma, we refer to the long version; it is not very difficult and similar to the proof of Lemma 26 in [3]. The lemma entails that every  $x \in \text{HF}(\widehat{E})$  has a unique smallest CFI-support.

► **Lemma 7.** *Let  $x \in \text{HF}(\widehat{E})$ . Let  $A_1, A_2 \subseteq E$  be CFI-supports of  $x$ . Then  $A_1 \cap A_2$  is also a CFI-support of  $x$ .*

► **Definition 8** (Minimal CFI-support). *For  $x \in \text{HF}(\widehat{E})$ ,  $\text{sup}_{\text{CFI}}(x) \subseteq E$  denotes the unique minimal subset of  $E$  that is a CFI-support of  $x$ .*

## 4 CFI-symmetric hereditarily finite sets and algorithms

The CFI-query is definable in CPT on instances that arise from linearly ordered base graphs, base graphs that come with a preorder with colour classes of logarithmic size, and base graphs of linear degree [9, 29]. All these CPT-algorithms depend on the construction of a particular super-symmetric h.f. set  $\mu \in \text{HF}(\widehat{E})$  that encodes the parity of  $|S|$ , given an instance  $\mathfrak{G}^S$ . We isolate another property of these h.f. sets, besides super-symmetry, which is responsible for their small orbit size and suitability for encoding parities. We call this *CFI-symmetry*. Intuitively, a set  $\mu \in \text{HF}(\widehat{E})$  is CFI-symmetric if its “building blocks” behave similarly as CFI-gadgets in CFI-graphs, in the sense that they are “flipped” whenever an even number of “incident gadgets” is flipped. These building blocks are the *connected components* of sets. To define these, let a CFI-graph  $\mathfrak{G}^S$  and a set  $\mu \in \text{HF}(\widehat{E})$  be fixed, and let  $\sim_E$  be the following equivalence relation on the elements  $x \in \text{tc}(\mu)$ : For  $x, x' \in \text{tc}(\mu)$ , we write  $x \sim_E x'$

iff there exists an edge-flip  $\rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$  such that  $x' = \rho_F(x)$ . The  $\sim_E$ -equivalence class in  $\text{tc}(\mu)$  of an object  $x \in \text{tc}(\mu)$  is denoted  $[x]$ . The relation  $\sim_E$  induces a partition  $\mathcal{C}(x)$  on each  $x \in \text{tc}(\mu)$ , namely  $\mathcal{C}(x) := \{([y] \cap x) \mid y \in x\}$ . In [9], the elements of  $\mathcal{C}(x)$  are called the *connected components* of  $x$ . Now in a *CFI-symmetric* object, each connected component  $\gamma \in \mathcal{C}(x)$ , for each  $x \in \text{tc}(\mu)$ , behaves like a CFI-gadget. That is, the component has exactly two images under  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ , namely itself and its “flip”. Consider the following example of a small “parity-tracking” h.f. set that is constructed similarly as in the algorithms from [9] and [29].

► **Example 9.** Here is an example h.f. set  $\mu_{\{e,f,g\}} \in \text{HF}(\widehat{E})$  with  $E = \{e, f, g\}$ . It tracks the parity of edge-flips for the edges  $e, f, g$ . For better readability, the set is printed in a structured form, so the sets  $\mu_{\{f,g\}}$  and  $\tilde{\mu}_{\{f,g\}}$  are shown in the level below. Each of the

$$\mu_{\{e,f,g\}} = \left\{ \begin{array}{l} \{\mu_{\{f,g\}}, e_0\}, \{\tilde{\mu}_{\{f,g\}}, e_1\} \\ \{\{f_0, g_0\}, \{f_1, g_1\}\} \quad \{\{f_0, g_1\}, \{f_1, g_0\}\} \end{array} \right\}$$

$\mu$ -objects has only one connected component that consists of two sets which are related by  $\sim_E$ . For example, the set  $\mu_{\{e,f,g\}}$  is stabilised setwise whenever an even number of edges is flipped. The two elements of  $\mu_{\{e,f,g\}}$  themselves have two connected components: Clearly,  $e_0$  and  $\mu_{\{f,g\}}$  cannot be mapped to each other by any edge-flip. The same goes for example for  $f_0$  and  $g_0$ . They form distinct components of the set  $\{f_0, g_0\}$ , while  $\{\{f_0, g_0\}, \{f_1, g_1\}\}$  again only has one component that is stabilised if and only if an even number of edges in  $\{f, g\}$  is flipped. This pattern of alternation between sets with two components and sets with one component is typical of the super-symmetric objects constructed by the known CFI-algorithms.

► **Definition 10** (CFI-symmetric components and objects). *Let  $\mu \in \text{HF}(\widehat{E})$ ,  $x \in \text{tc}(\mu)$ , and  $\gamma \subseteq x$  be a connected component of  $x$ . Then we say that  $\gamma$  is CFI-symmetric if  $|\text{Orb}_E(\gamma)| = 2$ , and for each  $\rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ , it holds that  $\rho_F(\gamma) = \gamma$  iff for one/every  $y \in \gamma$ , the number of flipped components of  $y$ , that is  $|\{\gamma' \in \mathcal{C}(y) \mid \rho_F(\gamma') \neq \gamma'\}|$ , is even.*

*The set  $\mu$  is CFI-symmetric if the following two conditions are satisfied:*

1. *For each  $\rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ , it holds that  $\rho_F(\mu) = \mu$  iff the number of flipped components of  $\mu$ , that is,  $|\{\gamma \in \mathcal{C}(\mu) \mid \rho_F(\gamma) \neq \gamma\}|$ , is even.*
2. *For every  $x \in \text{tc}(\mu)$ , every connected component  $\gamma \in \mathcal{C}(x)$  is CFI-symmetric.*

In the full version, we show that the formulation “one/every” in the above definition is indeed justified. We call a CPT-program  $\Pi$  that decides the CFI-query on a class  $\mathcal{K}$  of base graphs *CFI-symmetric* if it activates a CFI-symmetric h.f. set  $\mu \in \text{HF}(\widehat{E})$  on every input  $\mathfrak{G}^S$  over every base graph  $G \in \mathcal{K}$ . To be precise,  $\mu$  must also have sufficient support size in order to enable the program to decide the CFI-query. This support lower bound is stated in Theorem 16. Similarly, we say that  $\Pi$  is *super-symmetric* if it activates a super-symmetric object of sufficient support.

## 5 Translating hereditarily finite sets to XOR-circuits

An XOR-circuit is a connected directed acyclic graph  $C = (V_C, E_C)$  with a unique designated root  $r$ . Its internal nodes are understood as XOR-gates and its leaves correspond to the input gates of the circuit. If  $(g, h) \in E_C$ , then the output of gate  $h$  is an input of gate  $g$ . Every XOR-circuit computes the Boolean XOR-function over a subset of its input bits.

We say that an XOR-circuit  $C$  is a circuit *over a graph*  $G = (V, E)$ , if the input gates of  $C$  are labelled with the edges in  $E$ . More precisely, let  $L \subseteq V_C$  be the leaves of  $C$ . There is an injective labelling function  $\ell : L \rightarrow E$  that relates the input gates with edges of  $G$ . To speak about the semantics of the circuit, we introduce a set of formal propositional variables  $\mathcal{V}(G) := \{X_e \mid e \in E\}$ . Every input gate  $g \in L$  is associated with the formal variable  $X_{\ell(g)}$ . Since every internal gate is an XOR-gate, the function computed by it is the XOR over a subset of  $\mathcal{V}(G)$ . For our purposes, this variable set (or actually the set of associated edges) is the main interesting property of a gate, and we call it  $\mathcal{X}(g)$ . Formally, if  $g \in L$ , then  $\mathcal{X}(g) := \{\ell(g)\} \subseteq E$ . If  $g$  is an internal gate, then  $\mathcal{X}(g) := \Delta_{h \in gE_C} \mathcal{X}(h)$ , that is, the symmetric difference over the  $\mathcal{X}(h)$  for all children of  $g$ . In other words,  $\mathcal{X}(g) \subseteq E$  is precisely the set of edges in  $E$  such that  $g$  computes the Boolean function  $\bigoplus_{e \in \mathcal{X}(g)} X_e$ . Thus, a gate  $g$  is *sensitive* to an input bit  $X_e$  if and only if  $e \in \mathcal{X}(g)$ . The function computed by the circuit  $C$  is the XOR over  $\mathcal{X}(r) \subseteq E$ , where  $r$  is the root of  $C$ .

## 5.1 Symmetries of circuits

A circuit  $C$  over a graph  $G$  is subject to the action of the automorphism group  $\mathbf{Aut}(G) \leq \mathbf{Sym}(V)$ . Any  $\pi \in \mathbf{Aut}(G)$  changes the labels of the input gates in  $L$ . So let  $g \in L$  with  $\ell(g) = e \in E$ . Then  $\pi(g)$  is an input gate with  $\ell(\pi(g)) = \pi(e)$ . The circuit  $\pi(C)$  is just  $C$  with the input labels modified accordingly. We say that  $\pi$  *extends to an automorphism* of  $C$  if there exists a bijection  $\sigma : V_C \rightarrow V_C$  that is an automorphism of the graph  $(V_C, E_C)$  and satisfies for each input gate  $g \in V_C$ :  $\ell(\sigma(g)) = \pi(\ell(g))$ . We write  $\mathbf{Stab}_G(C) = \{\pi \in \mathbf{Aut}(G) \mid \pi \text{ extends to an automorphism of } C\} \leq \mathbf{Aut}(G)$ , and  $\mathbf{Orb}_G(C) = \{\pi(C) \mid \pi \in \mathbf{Aut}(G)\}$ .

## 5.2 The parameter fan-in dimension

The XOR-circuits we will construct from CFI-symmetric h.f. sets will satisfy a certain fan-in bound on the gates. However, this bound will not be – as it is more common – on the number of incoming wires of a gate but rather, on the “linear algebraic complexity of incoming information”, so to say. The subsets of  $E$  form a Boolean vector space together with the symmetric difference operation. This space is isomorphic to  $\mathbb{F}_2^E$ .

For each gate  $g$  of an XOR-circuit  $C = (V_C, E_C)$ ,  $gE_C$  denotes the set of its children and  $E_C g$  the set of parents. With each internal gate  $g$  of an XOR-circuit  $C$  over a graph  $G = (V, E)$ , we can associate a Boolean matrix  $M(g) \in \mathbb{F}_2^{gE_C \times E}$ , that we call the *gate matrix*: The row at index  $h \in gE_C$  is defined as the characteristic vector of  $\mathcal{X}(h) \subseteq E$ , transposed, i.e.  $M(g)_{h-} = \chi(\mathcal{X}(h))^T$ . Here and in what follows, we write  $\chi$  for the bijection from  $\mathcal{P}(E)$  to  $\mathbb{F}_2^E$  that associates with each subset of  $E$  its characteristic Boolean vector. If  $g$  is an input gate, then we define  $M(g) \in \mathbb{F}_2^{[1] \times E}$  as the one-row matrix whose only row is  $\chi(\mathcal{X}(g))^T = \chi(\{\ell(g)\})^T$ .

The *fan-in dimension* of a gate  $g$  is the dimension of the row-space of  $M(g)$ ; this is the subspace of  $\mathbb{F}_2^E$  that is spanned by the characteristic vectors  $\chi(\mathcal{X}(h)) \in \mathbb{F}_2^E$ , for all children  $h$  of  $g$ . Equivalently, the fan-in dimension of  $g$  is  $\mathbf{rk}(M(g))$ . The *fan-in dimension* of the circuit  $C$  is the maximum fan-in dimension of any of its gates. The notion of fan-in dimension is unusual but as we will show, it nicely captures the orbit size of the original h.f. set with respect to the group of edge flips  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ . The  $\mathbf{Aut}(G)$ -symmetries of the h.f. set will be reflected in the symmetries of the circuit.

### 5.3 The circuit construction

► **Theorem 11.** Fix a family  $(G_n)_{n \in \mathbb{N}}$  of base graphs. For every  $n \in \mathbb{N}$ , let  $\mathfrak{G}_n^S$  be a CFI-graph over  $G_n = (V_n, E_n)$  and let  $\mu_n \in \text{HF}(\widehat{E}_n)$  be a CFI-symmetric h.f. set that is activated by a CPT-program on input  $\mathfrak{G}_n^S$  (by the same CPT-program for the whole family of graphs). Then for every  $n \in \mathbb{N}$ , there exists an XOR-circuit  $C(\mu_n) = (V_C, E_C)$  over the edges of  $G_n$  which satisfies:

1. The size of the circuit, i.e.  $|V_C|$ , is polynomial in  $|\mathfrak{G}_n^S|$ .
2. The orbit-size  $|\text{Orb}_G(C(\mu_n))|$  of the circuit is polynomial in  $|\mathfrak{G}_n^S|$ .
3.  $C(\mu_n)$  is sensitive to an edge  $e \in E_n$  if and only if  $e \in \text{sup}_{\text{CFI}}(\mu_n)$ .
4. The fan-in dimension of  $C(\mu)$  is  $\mathcal{O}(\log(\mathbf{maxOrb}_E(\mu)))$ . Recall that  $\mathbf{maxOrb}_E(\mu) = \max_{y \in \text{tc}(x)} |\text{Orb}_E(y)|$ .

For the proof, we fix  $\mu \in \text{HF}(\widehat{E})$  and denote by  $C(\mu) = (V_C, E_C)$  the corresponding XOR-circuit that we are going to define. The circuit is simply the factorised DAG-structure  $(\text{tc}(\mu), \in)_{/\sim_E}$ : The gates of the circuit are the  $\sim_E$ -equivalence classes (i.e.  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ -orbits) of the objects in  $\text{tc}(\mu)$ . Note that these orbits need not be subsets of  $\text{tc}(\mu)$ , so whenever we write  $[x]$ , we formally mean the orbit restricted to  $\text{tc}(\mu)$ :  $[x] = \{\rho_F(x) \mid \rho_F \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G}) \text{ such that } \rho_F(x) \in \text{tc}(\mu)\}$ . The circuit  $C(\mu)$  is defined as follows:

- $V_C := \text{tc}(\mu)_{/\sim_E} = \{[x] \mid x \in \text{tc}(\mu)\}$ .
- $E_C := \{([x], [y]) \mid \text{there exists } y' \in [y] \text{ such that } y' \in x\}$ .
- By definition, the leaves of  $C(\mu)$  correspond to  $\sim_E$ -classes of atoms in  $\text{tc}(\mu)$ . The set of atoms is  $\widehat{E}$ , so any leaf of  $C$  has the form  $[e_i]$ , for some  $e \in E, i \in \{0, 1\}$ . We let  $\ell([e_i]) := e$ .
- The root  $r$  of  $C(\mu)$  is  $[\mu]$ .

One can prove that the set of edges  $E_C$  can indeed be defined in this way: Whether or not there is an  $E_C$ -edge between  $[x]$  and  $[y]$  is independent of the choice of the representative of  $[x]$  in the definition. This is because all members of  $[x]$  are symmetric to each other in the DAG-structure  $(\text{tc}(\mu), \in)$ . Now we verify that the circuit has the desired properties. We start with the  $\mathbf{Aut}(G)$ -symmetry.

► **Lemma 12.** Every  $\pi \in \mathbf{Stab}_G(\mu) \leq \mathbf{Sym}(V)$  extends to an automorphism of the circuit  $C(\mu)$ , that is:  $\mathbf{Stab}_G(\mu) \leq \mathbf{Stab}_G(C(\mu))$ .

**Proof sketch.** Let  $\pi \in \mathbf{Stab}_G(\mu) \leq \mathbf{Aut}(G)$ . That is,  $\pi$  extends to an automorphism  $\sigma : \text{tc}(\mu) \rightarrow \text{tc}(\mu)$  of  $(\text{tc}(\mu), \in)$ . We define  $\sigma' : V_C \rightarrow V_C$  by letting  $\sigma'([x]) = [\sigma(x)]$ . This is well-defined because  $x \sim_E x'$  if and only if  $\sigma(x) \sim_E \sigma(x')$  ( $\sigma$  is an automorphism of  $\mu$ ). One can verify that  $\sigma'$  is an automorphism of  $C(\mu)$  that  $\pi$  extends to. ◀

► **Corollary 13.**  $|\text{Orb}_G(C(\mu))| \leq |\text{Orb}_G(\mu)|$ .

**Proof.** Follows from Lemma 12 together with the Orbit-Stabiliser Theorem, which says that  $|\text{Orb}_G(C(\mu))| = |\mathbf{Aut}(G)|/|\mathbf{Stab}_G(C(\mu))|$  and  $|\text{Orb}_G(\mu) = |\mathbf{Aut}(G)|/|\mathbf{Stab}_G(\mu)|$ . ◀

Next, we would like to analyse the fan-in dimension of  $C(\mu)$ , and the connection between  $C(\mu)$  and  $\text{sup}_{\text{CFI}}(\mu)$ . The key for this is to establish a connection between the stabilisers  $\mathbf{Stab}_E(x)$ , for all  $x \in \text{tc}(\mu)$ , and the kernels of the corresponding gate matrices. For the definition of these matrices, we refer back to Section 5.2.

► **Lemma 14.** For every gate  $[x] \in V_C$  and its gate matrix  $M[x] \in \mathbb{F}_2^{[x]E_C \times E}$ , it holds:  $\text{Ker}(M[x]) = \mathbf{Stab}_E(x) = \mathbf{Stab}_E(x')$  for every  $x' \in [x]$ . For every row  $M[x]_{[y]-}$ , for every  $[y] \in [x]E_C$ , it holds:

$$\text{Ker}(M[x]_{[y]-}) = \mathbf{Stab}_E([y] \cap x) \quad (\star)$$

**Proof.** It holds  $\mathbf{Stab}_E(x) = \mathbf{Stab}_E(x')$ , for every  $x' \in [x]$  and also  $\mathbf{Stab}_E([y] \cap x) = \mathbf{Stab}_E([y] \cap x')$ , for every  $x' \in [x]$  (because  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$  is Abelian). Therefore, equation  $(\star)$  does not depend on the choice of representatives. From  $(\star)$  it immediately follows that  $\mathbf{Ker}(M[x]) = \mathbf{Stab}_E(x)$ , because: The stabiliser of  $x$  is the intersection of the stabilisers of all connected components of  $x$ , and the kernel of  $M[x]$  is the intersection of the kernels of the individual rows of the matrix. We now prove  $(\star)$  via induction from the input gates to the root. If  $[x] = [e_0]$  is an input gate, then  $M[x]$  has just one row, which is  $\chi(e)^T$ . The kernel of  $\chi(e)^T$  is the set of all vectors in  $\mathbb{F}_2^E$  which are zero at index  $e$ . This is precisely  $\mathbf{Stab}_E(e_0) = \mathbf{Stab}_E(e_1)$ , as desired. Now suppose  $[x]$  is an internal gate, i.e.  $x$  is a non-atomic h.f. set in  $\text{tc}(\mu)$ . Each row of  $M[x] \in \mathbb{F}_2^{[x]E_C \times E}$  is the characteristic vector of  $\mathcal{X}[y] \subseteq E$ , for a  $[y] \in [x]E_C$ . Now fix such a child  $y$  of  $x$ . We have  $\mathcal{X}[y] = \Delta_{[w] \in [y]E_C} \mathcal{X}[w]$ . In matrix-vector notation, we can write this as:

$$M[x]_{[y]-} = \chi(\mathcal{X}([y]))^T = \sum_{[w] \in [y]E_C} (M[y]_{[w]-})^T = (1 \ 1 \ \dots \ 1) \cdot M[y].$$

Let  $\gamma \in \mathcal{C}(x)$  be the connected component such that  $\gamma = [y] \cap x$ . The equation above means that  $\mathbf{Ker}(M[x]_{[y]-}) = \mathcal{E}_y$ , where  $\mathcal{E}_y$  denotes the set of all vectors in  $\mathbb{F}_2^E$  whose image under  $M[y]$  has even Hamming weight. Thus we have to show that  $\mathcal{E}_y = \mathbf{Stab}_E(\gamma)$ . Each row  $M[y]_{[w]-}$  corresponds to a connected component  $\gamma' \in \mathcal{C}(y)$  with  $w \in \gamma'$ .

By the induction hypothesis, we have for each row  $M[y]_{[w]-}$  and each  $\mathbf{v} \in \mathbb{F}_2^E$  that  $M[y]_{[w]-} \cdot \mathbf{v} = 1$  iff  $\mathbf{v} \notin \mathbf{Stab}_E([w] \cap y)$ . So  $M[y] \cdot \mathbf{v}$  has even Hamming weight iff  $\rho_{\chi^{-1}(\mathbf{v})} \in \mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$  flips an even number of connected components of  $y$ . This is true iff  $\rho_{\chi^{-1}(\mathbf{v})}$  flips an even number of components in every  $y' \in \gamma$ . By definition of CFI-symmetry (Definition 10), this is the case iff  $\mathbf{v} \in \mathbf{Stab}_E(\gamma)$ , because  $\mu$  is CFI-symmetric, and thus,  $\gamma$  is a CFI-symmetric component. In total, we have shown that  $\mathbf{v} \in \mathcal{E}_y$  iff  $\mathbf{v} \in \mathbf{Stab}_E(\gamma)$ . This proves  $(\star)$  for every row of  $M[x]$ .  $\blacktriangleleft$

As a consequence of this correspondence between kernels and stabilisers, we can bound the fan-in dimension of  $C(\mu)$ . This proves **Property 4** from Theorem 11.

► **Lemma 15.** *The fan-in dimension of  $C(\mu)$  is  $\log(\mathbf{maxOrb}_E(\mu))$ .*

**Proof.** Let  $x \in \text{tc}(\mu)$ . From the Orbit-Stabiliser Theorem and the fact that  $|\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})| = 2^{|E|}$ , it follows that  $\mathbf{Orb}_E(x) = \frac{2^{|E|}}{|\mathbf{Stab}_E(x)|} \leq \mathbf{maxOrb}_E(\mu)$ . By Lemma 14,  $\mathbf{Stab}_E(x) = \mathbf{Ker}(M[x])$ . Applying the Rank Theorem to  $M[x]$ , we get:  $\mathbf{rk}(M[x]) = |E| - \dim \mathbf{Stab}_E(x) \leq \log(\mathbf{maxOrb}_E(\mu))$ . Since there is an object  $x \in \text{tc}(\mu)$  where  $\mathbf{maxOrb}_E(\mu)$  is attained,  $\mathbf{rk}(M[x]) = \log(\mathbf{maxOrb}_E(\mu))$  is indeed the maximum rank of any gate matrix of  $C(\mu)$ .  $\blacktriangleleft$

**Proof of Theorem 11.** First of all, since  $\mu$  is by assumption activated by a CPT-sentence in the structure  $\mathfrak{G}^S$ , the size  $|\text{tc}(\mu)|$  and the orbit  $|\mathbf{Orb}_{\mathbf{Aut}(\mathfrak{G}^S)}(\mu)|$  are polynomial in  $|\mathfrak{G}^S|$ . Therefore, **Property 1** from Theorem 11 clearly holds for  $C(\mu)$ , because  $|V_C| \leq |\text{tc}(\mu)|$ . **Property 2** follows from the bound on  $|\mathbf{Orb}_{\mathbf{Aut}(\mathfrak{G}^S)}(\mu)|$  together with Corollary 13, and the fact that  $|\mathbf{Orb}_G(\mu)| \leq |\mathbf{Orb}_{\mathbf{Aut}(\mathfrak{G}^S)}(\mu)|$ . **Property 4** is proven in Lemma 15. Finally, **Property 3** can be seen as follows: Suppose  $C(\mu)$  is sensitive to an edge  $e \in E$ . This means that  $e \in \mathcal{X}(r)$ , for the root  $r = [\mu]$  of  $C(\mu)$ . This is the case iff  $e \in \mathcal{X}[y]$  for an odd number of children  $[y] \in [\mu]E_C$ . This is the same as saying that the column  $M[\mu]_{-e}$  has odd Hamming weight. By equation  $(\star)$  from Lemma 14, this holds if and only if  $\chi(e) \notin \mathbf{Stab}_E([y] \cap x)$  for an odd number of children  $[y] \in [\mu]E_C$ . Since  $\mu$  is CFI-symmetric, by Definition 10 this is the case if and only if  $\rho_e(\mu) \neq \mu$ . And this holds iff  $e \in \text{sup}_{\text{CFI}}(\mu)$  (because  $\text{sup}_{\text{CFI}}(\mu)$  is the smallest possible CFI-support of  $\mu$ ).  $\blacktriangleleft$

## 5.4 Proving the main theorem

So far, we have a translation of CFI-symmetric h.f. sets in  $\text{HF}(\widehat{E})$  into XOR-circuits with the properties mentioned in Theorem 11. In order to conclude Theorem 1 from this, we additionally need the following: Any CPT-algorithm which is both super-symmetric and CFI-symmetric and decides the CFI-query must construct a h.f. set whose properties translate into the circuit properties from Theorem 1. Fortunately, a result to this effect exists already. The following support lower bound for general CPT-programs deciding the CFI-query is due to Dawar, Richerby, and Rossman [9].

► **Theorem 16** (implicit in the proof of Theorem 40 in [9]). *Let  $(G_n)_{n \in \mathbb{N}}$  be a family of base graphs and let  $\text{tw}_n$  denote the treewidth of  $G_n$ . Let  $\mathfrak{G}_n^0, \mathfrak{G}_n^1$  denote the even and odd CFI-structures over  $G_n$ . Assume that  $\mathfrak{G}_n^0$  and  $\mathfrak{G}_n^1$  are  $\mathcal{C}^{\text{tw}_n}$ -homogeneous. Then any CPT-program that distinguishes  $\mathfrak{G}_n^0$  and  $\mathfrak{G}_n^1$  for all  $n \in \mathbb{N}$  must activate on input  $\mathfrak{G}_n^i$  a h.f. set  $\mu_n$  whose smallest support has size at least  $\Omega(\text{tw}_n)$ .*

A structure  $\mathfrak{G}_n^S$  is  $\mathcal{C}^{f(n)}$ -homogeneous if whenever two tuples  $\bar{a}$  and  $\bar{b}$  satisfy exactly the same  $\mathcal{C}^{f(n)}$ -formulas in  $\mathfrak{G}_n^S$ , then there is an automorphism of  $\mathfrak{G}_n^S$  that maps  $\bar{a}$  to  $\bar{b}$ . In particular, this condition is satisfied by certain ordered CFI-graphs, as stated in [9], and one can also show that the unordered CFI-graphs over hypercubes, which we use for the lower bound in Theorem 2, satisfy it. There are other details which must be taken into account when connecting Theorem 16 with Theorem 11 in order to prove Theorem 1, e.g. one has to reconcile the different notions of support that these theorems talk about. We gloss over these things in this extended abstract and refer to Theorem 31 in the long version, which is the more precise formulation of Theorem 1. For our application to hypercube CFI-structures, it is shown in the long version that Theorem 1 really holds in this shortened formulation. The reason why Theorem 1 requires the object to be *super-symmetric* is that this allows us to infer that  $\mathcal{O}(\log \mathbf{maxOrb}_E(\mu)) \leq \mathcal{O}(\log |\mathfrak{G}_n^S|)$ . This is needed to translate Property 4 from Theorem 11 into Property 4 from Theorem 1. Super-symmetry together with the fact that  $|\text{tc}(\mu)|$  is polynomial guarantees that  $\mathbf{maxOrb}_E(\mu)$  is polynomially bounded in  $|\mathfrak{G}_n^S|$  (see Definition 5).

## 6 A lower bound for symmetric XOR-circuits

The detailed proof of Theorem 2 is too long for this extended abstract but here is an outline: The theorem states that no family of XOR-circuits exists which are stabilised by all automorphisms of the  $n$ -dimensional hypercube, are sensitive to sufficiently many input bits, of polynomial size, and satisfy certain logarithmic bounds on the orbit-wise number of parents and children of each gate. What the proof concretely shows is that the sensitivity requirement (condition 3 in Theorem 2) contradicts the other three conditions: Any sufficiently symmetric circuit  $C$  is so highly connected that most input bits cancel themselves out because the number of distinct (not necessarily vertex-disjoint) paths from the root  $r$  to the input is even, and every operation is XOR. To prove that this self-cancellation effect takes place for an input gate  $g$ , we partition the set of paths between  $g$  and  $r$  in  $C$  into their orbits. Then we show that each orbit contains an even number of paths. To achieve this, it suffices to look at one path  $P$  in each orbit and to show the existence of an edge  $(h', h)$  in this path such that  $\mathbf{Orbit}_{(h)}(h') := \{\pi(h') \mid \pi \in \mathbf{Stab}(h)\}$  has even size. Then we can conclude that  $P$  splits into an even number of “alternative routes” towards the root at gate  $h$ . Thus, the goal is to show that such an edge  $(h', h)$  exists on every path between  $r$  and  $g$ .

We do this by maintaining fine-grained information about the stabiliser groups  $\mathbf{Stab}(h_i)$  of the gates  $(h_1 = g, h_2, h_3, \dots, r)$  along a given path (the path here is presented in the reverse direction of the edges). The automorphism group of the  $n$ -dimensional hypercube contains as a subgroup the symmetric group  $\mathbf{Sym}_n$  acting on the  $n$  positions of the binary words  $\{0, 1\}^n$ , which form the vertex set of the hypercube. Thus, each  $\mathbf{Stab}(h_i)$  can be seen as a subgroup of  $\mathbf{Sym}_n$ . Such subgroups can be approximated by what we call their *coarsest alternating supporting partition*  $\mathbf{SP}_A(\mathbf{Stab}(h_i))$  (inspired by a similar concept used in [1]). This is the coarsest partition  $\mathcal{P}$  of  $[n]$  such that for each  $P \in \mathcal{P}$ , every even permutation of  $P$  is a member of  $\mathbf{Stab}(h_i)$ . We know what  $\mathbf{SP}_A(\mathbf{Stab}(g))$  looks like for every input gate  $g$ : This depends on the edge of the hypercube that  $g$  is labelled with. For a large proportion of the hypercube edges, this is a partition of  $[n]$  into two parts of size  $\Theta(n)$ . We also know for the root that  $\mathbf{SP}_A(\mathbf{Stab}(r)) = \{[n]\}$  because the circuit is stabilised by every permutation in  $\mathbf{Sym}_n$ . The bounds on the orbit-wise fan-in and fan-out degree that we assume in Theorem 2 allow us to prove that when we pass from any  $h_i$  to  $h_{i+1}$ , then  $\mathbf{SP}_A(\mathbf{Stab}(h_i)) \approx \mathbf{SP}_A(\mathbf{Stab}(h_{i+1}))$ , i.e. the supporting partitions hardly change (because if they did change more, then one would find that there must be more parent/child gates per orbit than allowed). Since  $\mathbf{SP}_A(\mathbf{Stab}(g))$  differs quite substantially from  $\mathbf{SP}_A(\mathbf{Stab}(r))$  but  $\mathbf{SP}_A(\mathbf{Stab}(h_i)) \approx \mathbf{SP}_A(\mathbf{Stab}(h_{i+1}))$  for every  $i$ , we can infer that all “intermediate partitions” between  $\mathbf{SP}_A(\mathbf{Stab}(g))$  and  $\mathbf{SP}_A(\mathbf{Stab}(r))$  appear for the gate stabilisers along the path. Then we show that one of these “intermediate partitions” which must appear as  $\mathbf{SP}_A(\mathbf{Stab}(h_i))$  for some  $i$  has properties which entail what we wanted, namely that  $\mathbf{Orbit}_{(h_i)}(h_{i+1})$  has even size. Thus, the edge  $(h_{i+1}, h_i)$  on the path satisfies what we were looking for. So in short, the proof works because: Firstly, in order to show that a path has an even number of automorphic images, it suffices to find one gate on the path where the number of symmetric predecessors is even. Secondly, whether or not this happens can be inferred from the supporting partition of the gate. Thirdly, the fan-in and fan-out bounds enable us to track very precisely how the supporting partitions along the path look like. With these arguments, we can show for a sufficient number of input gates  $g$ , that they do not contribute to the result of the XOR-computation because they have an even number of paths to  $r$  – thus, circuit property 3 in Theorem 2 is not satisfied when the other conditions are. Carrying out this proof sketch requires quite some work that we have swept under the carpet here; for example, one needs certain group-theoretic arguments similar to the proof of Theorem 5.2 B in [13] in order to be able to describe the stabiliser groups appropriately with alternating supporting partitions.

## 7 Conclusion and future research

We have shown that the definability of the CFI-query on a class  $\mathcal{K}$  of base graphs by means of a CFI-symmetric algorithm presupposes the existence of symmetric XOR-circuits with the properties from Theorem 1. We come close to proving the non-existence of these circuits for  $\mathcal{K}$  being the family of  $n$ -dimensional hypercubes. It remains as a problem for future research to improve this lower bound and close the gap between the circuit properties in Theorems 1 and 2 in order to separate the class of CFI-symmetric algorithms from PTIME. Once that is achieved, the next step would be to lift this circuit approach to *all* CPT-algorithms for the CFI-query, not just the CFI-symmetric ones. This is a potential route to eventually solve the extremely difficult problem of separating CPT from PTIME. In the full version of the paper, we also provide a generalised circuit construction which works for a larger class of h.f. sets than CFI-symmetric ones. These are sets whose  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ -symmetries and  $\mathbf{Aut}(G)$ -symmetries

go well together in the sense that the Boolean vector spaces describing the  $\mathbf{Aut}_{\text{CFI}}(\mathfrak{G})$ -stabilisers admit  $\mathbf{Aut}(G)$ -symmetric bases. However, one can prove that, unfortunately, the class of h.f. sets with this property is still not the full class of all CPT-definable sets.

A different approach towards CPT lower bounds could be to study the isomorphism problem of *multipedes* [25] instead of CFI-graphs. Such structures have been used to obtain lower bounds against individualization-refinement graph isomorphism algorithms. Multipedes differ from CFI-graphs in so far as they have no non-trivial automorphisms. Their inherent symmetries are rather given by counting-logic *types* (two tuples in a structure have the same *k-type* if they satisfy the same  $C^k$ -formulas). It could be that the circuit construction is adaptable to this kind of symmetry. This would be of particular interest in case that the (unordered) CFI-query turns out to be in fact CPT-definable; then, multipedes might still provide an example to separate CPT from PTIME.

# A Super-Polynomial Separation Between Resolution and Cut-Free Sequent Calculus

Theodoros Papamakarios ✉

Department of Computer Science, University of Chicago, IL, USA

---

## Abstract

We show a quadratic separation between resolution and cut-free sequent calculus width. We use this gap to get, for the first time, first, a super-polynomial separation between resolution and cut-free sequent calculus for refuting CNF formulas, and secondly, a quadratic separation between resolution width and monomial space in polynomial calculus with resolution. Our super-polynomial separation between resolution and cut-free sequent calculus only applies when clauses are seen as disjunctions of unbounded arity; our examples have linear size cut-free sequent calculus proofs writing, in a particular way, their clauses using binary disjunctions. Interestingly, this shows that the complexity of sequent calculus depends on how disjunctions are represented.

## 1 Introduction

Whether cut-free sequent calculus can polynomially simulate resolution for refuting CNF formulas is a question existing since the beginnings of proof complexity. It was first raised in [13] and iterated e.g. in [25]. Cook and Reckhow [13] show that in the tree-like case, there are examples where resolution can have exponentially smaller proofs. Arai, Pitassi and Urquhart [3] point out that the answer may heavily depend on how clauses are represented. A clause consisting of the literals, say  $\ell_1, \ell_2, \ell_3, \ell_4$ , can be seen as either a single disjunction of arity four, or as a series of applications of binary disjunctions, for example  $(\ell_1 \vee \ell_2) \vee (\ell_3 \vee \ell_4)$ , and this can have a profound impact on the complexity of sequent calculus proofs. The result of Cook and Reckhow above applies in the case where clauses are seen as single disjunctions of unbounded arity, or the case where the order in which the binary disjunctions are applied is fixed. If we are free to choose the order, then tree-like cut-free sequent calculus can quasi-polynomially simulate tree-like resolution, and this is optimal [3]. In the DAG-like case, and if we are free to choose the order in which binary disjunctions are applied, Reckhow [21] shows that cut-free sequent calculus can polynomially simulate regular resolution, and Arai [2] shows that it can polynomially simulate resolution for refuting  $k$ -CNF formulas  $F$ , where  $k$  grows at most logarithmically as a function of the size of the shortest resolution refutation of  $F$ . However, the general question has remained unresolved.

We define the width of a sequent calculus proof as the maximum number of formulas occurring in a sequent of the proof. This definition extends in a natural way the concept of the width of a resolution proof to stronger proof systems. Furthermore, it allows for a simple, abstract characterization of sequent calculus width generalizing the characterization of Atserias and Dalmau for resolution width [4]. Using this characterization, we show a quadratic gap between resolution width and cut-free sequent calculus width. Resolution is a

sequent calculus system that has only atomic cuts, so this says that including atomic cuts in cut-free sequent calculus can shorten the width of proofs. Utilizing then this gap, we show a super-polynomial separation between cut-free sequent calculus and resolution size. To put it in other words, atomic cuts can super-polynomially decrease the size of proofs. This result applies only when clauses are seen as disjunctions of unbounded arity. There is a way to write the clauses in our examples using binary disjunctions, so that the resulting formulas have linear size cut-free sequent calculus refutations. Thus, as it was already known for the tree-like case, the complexity of sequent calculus proofs can depend on how disjunctions are represented.

Several notions of width have been used to show space lower bounds in different proof systems, demonstrating a close relationship between the two measures [5, 14, 4, 11, 12, 10, 9, 17, 20]. We note that our characterization of cut-free sequent calculus width for refuting CNF formulas coincides with the concept of dynamic satisfiability, introduced by Esteban, Galesi and Messner [14] as a tool for proving space lower bounds in resolution and  $k$ -DNF resolution. It is easily seen that dynamic satisfiability is a weakened version of resolution width. How much weaker however is a question that has not been addressed. We show that it is strictly weaker, the quadratic gap between resolution and cut-free sequent calculus width being a quadratic gap between the two. Furthermore, our basic construction extends to stronger versions of dynamic satisfiability used to prove monomial space lower bounds in algebraic proof systems [11, 12], allowing us to make progress towards separating resolution width from monomial space.

To put things into perspective, Atserias and Dalmau [4] show that for a  $k$ -CNF formula  $F$ ,  $W(F \vdash \perp)$ , the minimum width, and  $\text{CSpace}(F \vdash \perp)$ , the minimum clause space needed to refute  $F$  in resolution satisfy

$$W(F \vdash \perp) \leq \text{CSpace}(F \vdash \perp) + k, \quad (1.1)$$

and Galesi, Kołodziejczyk and Thapen [17] show a similar relation between resolution width and the minimum monomial space needed to refute  $F$  in polynomial calculus with resolution:

$$W(F \vdash \perp) \leq O\left((\text{MSpace}(F \vdash \perp))^2\right) + k. \quad (1.2)$$

Ben-Sasson and Nordström [6, 7] give for every  $n$ , a formula  $F$  of size  $n$  such that  $W(F \vdash \perp) = O(1)$  and  $\text{CSpace}(F \vdash \perp) = \Omega(n/\log n)$ , rendering a relation between resolution width and clause space in the opposite direction impossible. Whether clause space can be meaningfully bounded in terms of monomial space is unknown, but the two measures are related in a more indirect way: they coincide up to polynomial and  $\log n$  factors once regularized, meaning that a super-polynomial separation of them would imply a strong trade-off between monomial space and size [20]. Despite however this close relationship, no separation between width and monomial space is currently known – the techniques of [6, 7] in particular fail to generalize to the case of monomial space. Our result shows a quadratic separation between the two.

## 2 Sequent calculus

The sequent calculus was introduced by Gentzen to formulate and prove his famous cut-elimination theorem. Many authors describe it as the most elegant proof system, and indeed, it illustrates the symmetries of logic at the level of syntax, like no other system.

Sequent calculus's version for classical logic is often denoted by LK. We shall use LK to denote its propositional part. LK operates with *sequents*. A sequent is a tuple of the form  $(\Gamma, \Delta)$ , where  $\Gamma$  and  $\Delta$  are finite sets of formulas. Traditionally, a sequent  $(\Gamma, \Delta)$  is written as  $\Gamma \rightarrow \Delta$ . This is to remind us its semantic interpretation:  $\Gamma \rightarrow \Delta$  is to be read as “if all formulas in  $\Gamma$  are true, then at least one formula in  $\Delta$  is true”.

Let us present the rules of the system. In what follows,  $A, B$  represent arbitrary formulas, and  $\Gamma, \Delta, \Gamma', \Delta'$  represent finite sets of formulas. Sets are written in a quite plain manner: We write  $\Gamma, A$  instead of  $\Gamma \cup \{A\}$ ,  $A$  instead of  $\{A\}$ ,  $A, B$  instead of  $\{A, B\}$  and so on. The *axioms* of LK are all sequents of the form  $A \rightarrow A$ . Of the inference rules, first we have a rule, which allows us to add formulas to the left or right part of a sequent. This rule is called the *thinning* or *weakening* rule and has the form

$$\frac{\Gamma \rightarrow \Delta}{\Gamma' \rightarrow \Delta'}$$

i.e., from  $\Gamma \rightarrow \Delta$  derive  $\Gamma' \rightarrow \Delta'$ , where  $\Gamma \subseteq \Gamma'$  and  $\Delta \subseteq \Delta'$ . Next, we have rules for each connective. These come in pairs; a connective is treated differently according to which side of its sequent it appears. The rules for the connectives  $\wedge$ ,  $\vee$  and  $\neg$  are shown in Table 1.

■ **Table 1** The analytic LK rules.

$$\begin{array}{l} \neg\text{L} : \frac{\Gamma, \neg A \rightarrow \Delta, A}{\Gamma, \neg A \rightarrow \Delta} \qquad \neg\text{R} : \frac{\Gamma, A \rightarrow \Delta, \neg A}{\Gamma \rightarrow \Delta, \neg A} \\ \wedge\text{L}_1 : \frac{\Gamma, A \wedge B, A \rightarrow \Delta}{\Gamma, A \wedge B \rightarrow \Delta} \qquad \wedge\text{R} : \frac{\Gamma \rightarrow \Delta, A \wedge B, A \quad \Gamma \rightarrow \Delta, A \wedge B, B}{\Gamma \rightarrow \Delta, A \wedge B} \\ \wedge\text{L}_2 : \frac{\Gamma, A \wedge B, B \rightarrow \Delta}{\Gamma, A \wedge B \rightarrow \Delta} \\ \vee\text{R}_1 : \frac{\Gamma \rightarrow \Delta, A \vee B, A}{\Gamma \rightarrow \Delta, A \vee B} \qquad \vee\text{L} : \frac{\Gamma, A \vee B, A \rightarrow \Delta \quad \Gamma, A \vee B, B \rightarrow \Delta}{\Gamma, A \vee B \rightarrow \Delta} \\ \vee\text{R}_2 : \frac{\Gamma \rightarrow \Delta, A \vee B, B}{\Gamma \rightarrow \Delta, A \vee B} \end{array}$$

These rules are called *analytic*, and they already form a complete proof system for proving tautologies; we shall call this system *cut-free* LK or  $\text{LK}^-$ . Finally, there is the *cut rule*:

$$\frac{\Gamma, A \rightarrow \Delta \quad \Gamma \rightarrow \Delta, A}{\Gamma \rightarrow \Delta}. \tag{2.1}$$

So, already having a proof of, say  $\rightarrow B$ , we may use it to prove  $\rightarrow A$ :  $\rightarrow A$  can be derived from  $B \rightarrow A$  and  $\rightarrow B$  via the cut rule, and now to prove  $\rightarrow A$ , we need to prove the weaker formula  $B \rightarrow A$ .  $B$  can be anything. It doesn't need to have any intuitive relation to  $A$ , but even as such, it might be the case that a proof of  $B \rightarrow A$  is much shorter than a proof of  $\rightarrow A$ . Gentzen's cut elimination theorem says that there is always an effective procedure of eliminating all applications of the cut rule from a proof, making it purely analytic. We refer to the formula  $A$  in applications of rule (2.1) as the formula being cut, or as the *cut formula*.

An LK proof of a sequent  $\sigma$  is a derivation of  $\sigma$  starting with the axioms and applying the rules of LK. We imagine starting with the axioms at the bottom, and going to the top by applying the LK rules. More formally, an LK proof of  $\sigma$  is a sequence consisting of sequents

that ends with  $\sigma$ , in which every sequent is either an axiom, or results from previous sequents by one of the LK rules. An  $LK^-$  proof is an LK proof that never uses the cut rule. We may view proofs as DAGs, by drawing edges from premises to conclusions in applications of the inference rules. If the DAG corresponding to a proof is a tree, we shall refer to the proof as being *tree-like*.

**3 Sequent calculus as a satisfiability algorithm**

It will be particularly convenient to consider the following view of LK. Following Smullyan [23], let us write a sequent  $A_1, \dots, A_k \rightarrow B_1, \dots, B_\ell$  as  $TA_1, \dots, TA_k, FB_1, \dots, FB_\ell$ . That is, we annotate the formulas appearing on the left side of a sequent by  $T$ , the formulas appearing on its right side by  $F$ , and conjoin the two sides to form a single set.  $T$  and  $F$  stand for true and false respectively –  $TA$  should be thought of as asserting that  $A$  is true and  $FA$  as asserting that  $A$  is false.

Annotated formulas that are not annotated variables are naturally divided into two groups: those of a conjunctive and those of a disjunctive type. Formulas of the form  $TA \wedge B$ ,  $FA \vee B$ ,  $T\neg A$  or  $F\neg A$  belong to the former group, and those of the form  $TA \vee B$  or  $FA \wedge B$  to the latter. We use the letter “ $\alpha$ ” to stand for an arbitrary annotated formula of conjunctive type, and the letter “ $\beta$ ” to stand for an arbitrary annotated formula of disjunctive type. We define the components  $\alpha_i$  of a formula  $\alpha$  and the components  $\beta_i$  of a formula  $\beta$  as shown in Table 2.

■ **Table 2** Smullyan’s notation.

$\alpha$	$\alpha_1$	$\alpha_2$	$\beta$	$\beta_1$	$\beta_2$
$TA \wedge B$	$TA$	$TB$	$FA \wedge B$	$FA$	$FB$
$FA \vee B$	$FA$	$FB$	$TA \vee B$	$TA$	$TB$
$T\neg A$	$FA$				
$F\neg A$	$TA$				

These provisions allow on the one hand for an extremely concise description of the rules of Table 1; they can be written as:

$$\frac{S, \alpha, \alpha_1}{S, \alpha}, \quad \frac{S, \alpha, \alpha_2}{S, \alpha}, \quad \frac{S, \beta, \beta_1 \quad S, \beta, \beta_2}{S, \beta}.$$

More importantly, they reveal an algorithmic interpretation of LK. An LK proof, seen from the top to the bottom, i.e. from the sequent  $\sigma := A_1, \dots, A_k \rightarrow B_1, \dots, B_\ell$  it is proving to the axioms, describes the execution of an algorithm that tries to find a truth assignment (or more generally a model) that falsifies  $\sigma$ . The algorithm begins with  $\sigma$  written as  $TA_1, \dots, TA_k, FB_1, \dots, FB_\ell$ , asserting that there is an assignment that makes all  $A_i$  true and all  $B_i$  false, or equivalently, an assignment that falsifies  $\sigma$ . Then it keeps expanding this set, by applying the LK rules in reverse, that is from the conclusion to the premises. This expansion takes the form of a tree (or a DAG if we identify nodes labelled by the same set). At any point, we may choose a leaf labelled by  $S, \alpha$  and add to it a single child labelled by  $S, \alpha, \alpha_i$ , as any assignment satisfying  $\alpha$  must also satisfy every  $\alpha_i$ . Or we may choose a leaf labelled by  $S, \beta$  and add to it two children, one labelled by  $S, \beta, \beta_1$  and the other by  $S, \beta, \beta_2$ , as any assignment satisfying  $\beta$  must either satisfy  $\beta_1$  or  $\beta_2$ . The thinning rule allows the algorithm to forget information: We may add to a leaf labelled by  $S$ , a child labelled by a subset of  $S$ . Finally, the cut rule allows us to add to a leaf labelled by  $S$ , two children,

one labelled by  $S, T A$  and the other by  $S, F A$  for any formula  $A$ , as every assignment must satisfy either  $A$  or  $\neg A$ . This may greatly facilitate the search procedure. If at any point a set of the form  $T A, F A$  is reached, then the search process may terminate at that particular branch, as no assignment can set  $A$  to both true and false. Notice that the contradiction  $T A, F A$  corresponds to the axiom  $A \rightarrow A$ . A tree (or DAG) constructed this way, every branch of which ends with a leaf labelled by a set of the form  $T A, F A$ , is an LK proof of  $\sigma$ .

A depth-first implementation of the algorithm described above is shown as Algorithm 1 below. Algorithm 1 is called on a sequent represented as a set of annotated formulas. It

■ **Algorithm 1** The LK algorithm.

---

```

procedure LK( $S$ )
  if  $S$  contains both  $T A$  and  $F A$  for some formula  $A$  then
    return false
  if for every  $\alpha \in S$ , all  $\alpha_i \in S$  and for every  $\beta \in S$ , there is a  $\beta_i \in S$  then
    return true
  go to either 1, 2 or 3
  1. select an  $S' \subseteq S$  and return LK( $S'$ )
  2. select an arbitrary formula  $A$  and return LK( $S, T A$ ) or LK( $S, F A$ )
  3. select an  $A \in S$ 
  if  $A = \alpha$  then
    select a component  $\alpha_i$  and return LK( $S, \alpha_i$ )
  if  $A = \beta$  then
    return LK( $S, \beta_1$ ) or LK( $S, \beta_k$ )

```

---

chooses at each recursive call non-deterministically what rule to apply and which formula to apply it to. If false is returned then there is an LK proof of our initial sequent; if no such proof exists, then there is an assignment that falsifies our initial sequent and Algorithm 1 is able to find it, returning true. As presented, line 1, corresponding to the thinning rule, is redundant. However, incorporating memoization, that is the ability to stop the search when a set  $S$  has already been encountered in a previous recursive call that has returned, effectively identifying nodes labelled by the same set, this line makes it possible to greatly prune the search for a falsifying assignment. In terms of proofs, DAG-like proofs may be shorter than tree-like proofs. The key point in analyzing the correctness of Algorithm 1 (or equivalently the completeness of LK), is that when at the base case true is returned, we can create an assignment consistent with  $S$  by setting for each formula  $A$ ,  $A$  to true if  $T A \in S$ , and false otherwise.

#### 4 The width of sequent calculus proofs

We define the *width* of a sequent as the number of formulas it contains, and the width of a sequent calculus proof as the maximum of the widths of the sequents it contains. It is not hard to see that for any provable sequent  $S_0$ , there is an LK proof of  $S_0$  of width a constant plus the width of  $S_0$ . The concept of the minimum width needed to prove a sequent becomes non-trivial only if we restrict the class of cut formulas we are allowed to use. We shall be mainly interested in the minimum width over all LK<sup>-</sup> proofs of  $S_0$ , which we denote by  $W_{\text{LK}^-}(\vdash S_0)$ .

We are going to give a characterization of  $W_{\text{LK}^-}(\vdash S_0)$  in terms of the definition below. In what follows, sequents are viewed as in the above section, viz. as sets of annotated formulas.

► **Definition 4.1.** Following the terminology of [23], let us call a sequent  $S_0$  *analytically  $k$ -consistent* if there is a set of sequents  $\mathcal{S}$  containing  $S_0$  and such that for each  $S \in \mathcal{S}$ :

1. for any formula  $A$ ,  $S$  does not contain both  $T A$  and  $F A$ ;
2.  $S' \subseteq S \implies S' \in \mathcal{S}$ ;
3.  $|S| < k$  &  $\alpha \in S \implies S, \alpha_i \in \mathcal{S}$  for every component  $\alpha_i$  of  $\alpha$ ;
4.  $|S| < k$  &  $\beta \in S \implies S, \beta_i \in \mathcal{S}$  for some component  $\beta_i$  of  $\beta$ .

If the following condition is also satisfied, then we call  $S_0$  *synthetically  $k$ -consistent* with respect to the set  $\mathcal{C}$ :

5.  $|S| < k \implies S, T A \in \mathcal{S}$  or  $S, F A \in \mathcal{S}$  for any formula  $A \in \mathcal{C}$ .

It is often helpful to see definitions such as the above, as describing a strategy for the adversary, in a game between a prover and an adversary played on a formula/sequent/set of formulas. In this case, the game is as follows: The configurations of the game are sequents. The initial configuration is  $S_0$ . In every round, the prover either deletes some formulas in the current sequent  $S$ , or selects an  $\alpha$ -formula in  $S$  and adds a component of it to  $S$ , or selects a  $\beta$  formula, in which case the adversary adds a component of it to  $S$ . Allowing condition 5, the prover may choose an arbitrary formula  $A \in \mathcal{C}$  and the adversary must respond by adding either  $T A$  or  $F A$  to  $S$ . The game ends with prover winning once  $S$  contains  $T A$  and  $F A$  for some formula  $A$ . The prover can always win provided that  $S_0$  is provable. The question is: given a bound  $k$ , can she win always maintaining that the width of  $S$  is at most  $k$ ? Definition 4.1 describes a strategy for the adversary, permitting the prover from winning when she maintains that bound.

► **Theorem 4.1.** *Suppose that  $|S_0| \leq k$ . Then  $S_0$  is analytically  $k$ -consistent if and only if  $W_{\text{LK}^-}(\vdash S_0) > k$ . It is synthetically  $k$ -consistent with respect to  $\mathcal{C}$  if and only if every LK proof of  $S_0$  in which every cut formula belongs to  $\mathcal{C}$  has width more than  $k$ .*

**Proof.** Let us only show the former sentence. Suppose first that  $S_0$  is analytically  $k$ -consistent, and let  $\mathcal{S}$  be the set of sequents witnessing this. We will show that in every tree-like LK<sup>-</sup> derivation (not necessarily beginning with axioms)  $\tau$  of  $S_0$ , of width at most  $k$ , there is an initial sequent (i.e. one appearing as a leaf) in  $\mathcal{S}$ . From the first condition of Definition 4.1 that sequent is not an axiom, thus  $\tau$  is not a proof. It is enough to show this for tree-like derivations, since a DAG-like derivation can be transformed into a tree-like one without increasing the width.

**Base case.** If  $\tau$  contains just  $S_0$ , then we are done since  $S_0 \in \mathcal{S}$ .

**Inductive step.** Take some initial sequents  $S_1, \dots, S_r$  from which a sequent  $S$  is derived via an inference rule  $\rho$ , and remove them to get the derivation  $\tau'$ . From the induction hypothesis, there is an initial sequent in  $\tau'$  that belongs to  $\mathcal{S}$ . If that sequent is not  $S$ , then it also appears in  $\tau$  and we are done. Otherwise, we have the following cases according to what rule  $\rho$  is:

**Case 1.** If it is the weakening rule, and thus  $r = 1$  and  $S_1 \subseteq S$ , then from the second condition of Definition 4.1,  $S_1 \in \mathcal{S}$ .

**Case 2.** If  $\rho$  is the  $\alpha$ -rule, and thus  $r = 1$ ,  $\alpha \in S$  and  $S_1 = S, \alpha_i$  for some  $\alpha_i$ , then since  $\tau$  has width at most  $k$ ,  $|S| < k$ , and hence from the third condition of Definition 4.1,  $S_1 \in \mathcal{S}$ .

**Case 3.** If  $\rho$  is the  $\beta$ -rule, and thus  $\beta \in S$  and each  $S_i$  is of the form  $S, \beta_i$ , then again  $|S| < k$ , and from the fourth condition of Definition 4.1, some  $S_i$  belongs to  $\mathcal{S}$ .

Now suppose that  $W_{\text{LK}^-}(\vdash S_0) > k$ . Set

$$\mathcal{S} := \{S \mid |S| \leq k \text{ \& } W_{\text{LK}^-}(\vdash S) > k\}.$$

Clearly  $S_0 \in \mathcal{S}$ . We will show that  $\mathcal{S}$  satisfies the conditions 1–4 of Definition 4.1. For each  $S \in \mathcal{S}$ , first  $S$  cannot contain  $T A$  and  $F A$  for some  $A$ . This is so, because such a sequent is a weakening of an axiom, and having size at most  $k$ , it has a proof of width at most  $k$ . For the closure under subsets, if  $S' \subseteq S$ , then  $W_{\text{LK}^-}(\vdash S') > k$ , for otherwise  $W_{\text{LK}^-}(\vdash S) \leq k$  since  $S$  follows from  $S'$  via the weakening rule. For the  $\alpha$  condition, if  $\alpha \in S$  and  $|S| < k$ , then for each  $\alpha_i$  it must be that  $S, \alpha_i \in \mathcal{S}$ , for otherwise  $W_{\text{LK}^-}(\vdash S) \leq k$  since  $S$  follows from  $S, \alpha_i$  via the  $\alpha$ -rule. Finally, if  $\beta \in S$  and  $|S| < k$ , then there must be a  $\beta_i$  such that  $S, \beta_i \in \mathcal{S}$ , otherwise  $W_{\text{LK}^-}(\vdash S) \leq k$ , since  $S$  follows from all  $S, \beta_i$  via the  $\beta$ -rule. ◀

## 5 LK<sup>-</sup> for refuting CNF formulas and resolution

A *literal* is a propositional variable  $x$ , or the negation of propositional variable  $\neg x$ . We let  $\bar{x} \stackrel{\text{def}}{=} \neg x$  and  $\overline{\neg x} \stackrel{\text{def}}{=} x$ . A *clause* is a disjunction (possibly empty) of literals, and a *CNF formula* is a conjunction of clauses. The ordering of literals in a clause does not matter, so that the clause  $x \vee y$  is considered to be the same as  $y \vee x$ . The *width*,  $W(F)$ , of a CNF formula  $F$  is the number of literals in the largest clause of  $F$ . A CNF formula of width at most  $k$  is called a  $k$ -CNF formula.

Refuting a CNF formula  $F = C_1 \wedge \dots \wedge C_m$  means proving that the clauses  $C_i$  cannot be simultaneously satisfied, that is, it means proving  $C_1, \dots, C_m \rightarrow$ . LK<sup>-</sup> for proving such sequents has the following form. Of the rules in Table 1, the only one that is relevant is  $\vee\text{L}$ , which now, seeing clauses as disjunctions of unbounded arity, has as many premises as the number of literals in the clause it is deriving. Moreover, there is no reason to always carry the clauses  $C_i$  in sequents. We may as well delete them from every sequent, but keep in our mind that they are implicitly there. What remains are sequents of the form  $\ell_1, \dots, \ell_r \rightarrow$ , where the  $\ell_i$ 's are literals, and such sequents are nothing other than clauses. To be explicit, the axioms of the resulting system are clauses of the form  $x \vee \neg x$ , and the inference rules are the weakening rule, from  $C$  infer  $C \vee D$ , and

$$\frac{C \vee \bar{\ell}_1 \quad \dots \quad C \vee \bar{\ell}_r}{C}, \quad (5.1)$$

where  $C$  and  $D$  are clauses and  $\ell_1 \vee \dots \vee \ell_r$  is a clause of the formula we are refuting. A proof of  $C_1, \dots, C_m \rightarrow$ , in other words a *refutation* of  $F = C_1 \wedge \dots \wedge C_m$ , in LK<sup>-</sup>, is a derivation of the empty clause using the above rules. The *size* of such a derivation is the number of clauses it contains, and its *width* is the size of the largest clause occurring in it. We shall denote by  $S_{\text{LK}^-}(F \vdash \perp)$  and  $W_{\text{LK}^-}(F \vdash \perp)$  and the minimum size and the minimum width respectively over all LK<sup>-</sup> refutations of  $F$ .

*Resolution* is the system we get by adding to the above system the cut rule (2.1), where the cut formula  $A$  is restricted to be a propositional variable:

$$\frac{C \vee x \quad C \vee \neg x}{C}. \quad (5.2)$$

We may make a proof in this system “cut-only”, by pushing all applications of the rule (5.1) at the bottom levels. Namely, we can simulate rule (5.1) by (5.2) as follows: Start with  $\ell_1 \vee \dots \vee \ell_r$ , derive from it and  $C \vee \bar{\ell}_1$ ,  $C \vee \ell_2 \vee \dots \vee \ell_r$ , then derive from  $C \vee \ell_2 \vee \dots \vee \ell_r$  and  $C \vee \bar{\ell}_2$ ,  $C \vee \ell_3 \vee \dots \vee \ell_r$ , and so on, until  $C$  is derived. Now the leaves containing clauses of  $F$  and these can be derived from axioms by (5.1). Deleting all axioms, and incorporating the weakening rule into (5.2), writing it as

$$\frac{C \vee x \quad D \vee \neg x}{C \vee D}, \quad (5.3)$$

we get the usual presentation of resolution, where, instead of deriving  $F \rightarrow$ , the empty clause is derived taking the clauses of  $F$  as axioms: A *resolution refutation* of a CNF formula  $F$  is a derivation of the empty clause from the clauses of  $F$ , using only the rule (5.3). We shall denote by  $W_R(F \vdash \perp)$  and  $S_R(F \vdash \perp)$  the minimum width and minimum size respectively, over all resolution refutations of  $F$ , and by  $S_{TR}(F \vdash \perp)$  the minimum size, over all tree-like resolution refutations of  $F$ .

## 6 Dynamic satisfiability

Adapting Definition 4.1 for resolution we get the characterization of [4] for resolution width. Adapting it for  $LK^-$  restricted to refuting CNF formulas, we get the definition of dynamic satisfiability from [14]. Namely, let us call sets of literals that do not contain contradictory literals *partial assignments*. We think of the assignment, say  $\{x, \neg y, z\}$ , as making  $x$  true,  $y$  false and  $z$  true. A partial assignment satisfies a clause  $C$ , if it contains a literal of  $C$ . It falsifies  $C$  if it contains  $\bar{\ell}$  for every  $\ell$  in  $C$ . We get:

► **Definition 6.1** [14]. Let  $F$  be a CNF formula, and let  $k$  be a natural number.  $F$  is said to be *k-dynamically satisfiable* if there is a non-empty set  $\mathcal{A}$  of partial assignments to its variables such that for every assignment  $\alpha \in \mathcal{A}$ ,

1. if  $\alpha' \subseteq \alpha$  then  $\alpha' \in \mathcal{A}$ ;
2. if  $|\alpha| < k$  and  $C$  is a clause of  $F$ , then there is an  $\alpha' \supseteq \alpha$  in  $\mathcal{A}$  that satisfies  $C$ .

Theorem 4.1 in particular, becomes:

► **Theorem 6.1.** A CNF  $F$  is *k-dynamically satisfiable* if and only if  $W_{LK^-}(F \vdash \perp) > k$ .

In the game corresponding to Definition 6.1, prover chooses in each round a clause of  $F$ , and the adversary responds by choosing a literal in that clause, which adds to the current assignment. Again, the closure under subsets condition corresponds to the ability of the prover to delete at any round literals from the current assignment. The prover wins once the current assignment falsifies a clause of  $F$ .

We get a characterization of resolution width by having the prover selecting variables instead of clauses, and the adversary responding by giving values to them. More specifically, in every round the prover selects a variable  $x$  of  $F$ . Then the adversary selects either  $x$  or  $\neg x$ , and the prover updates the current assignment  $\alpha$  by deleting (if she wants) literals and adding the choice of the adversary. Again the prover wins once  $\alpha$  falsifies a clause of  $F$ . She can win always maintaining  $|\alpha| < k$  if and only if  $W_R(F \vdash \perp) \leq k$  [4].

Notice that, if  $W(F)$  is small, the prover in the second game is more powerful. Namely, we have  $W_R(F \vdash \perp) \leq W_{LK^-}(F \vdash \perp) + W(F) - 1$ . We already saw this when we explained how the resolution rule can simulate (5.1). In terms of games, the argument goes as follows: When the prover in the first game selects a clause  $C$ , the prover in the second game can start selecting, one by one the variables of  $C$ . If the game does not end, then the current assignment satisfies  $C$ , and then the prover can delete literals to match the assignments in the two games.

Definition 6.1 was introduced in [14] as a tool for proving space lower bounds in resolution and  $k$ -DNF resolution. The following definition is from [15, 1]. A *memory configuration* in resolution, is a set of clauses. A resolution refutation of a CNF formula  $F$ , in configurational

form, is a sequence  $\mathcal{M}_1, \dots, \mathcal{M}_t$  of configurations where  $\mathcal{M}_1$  is empty,  $\mathcal{M}_t$  contains the empty clause and for  $i > 1$ ,  $\mathcal{M}_i$  is obtained from  $\mathcal{M}_{i-1}$  by one of the following rules:

**Axiom download:**  $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{C\}$ , where  $C$  is a clause of  $F$ .

**Inference:**  $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{C\}$ , where  $C$  is derived from clauses in  $\mathcal{M}_{i-1}$  by the resolution rule.

**Erasure:**  $\mathcal{M}_i \subseteq \mathcal{M}_{i-1}$ .

The clause space of such a refutation is  $\max_{1 \leq i \leq t} |\mathcal{M}_i|$ . The clause space of a CNF formula  $F$ , denoted by  $\text{CSpace}(F \vdash \perp)$ , is the minimum clause space, over all refutations, in configurational form, of  $F$ .

► **Theorem 6.2** [14]. *If  $F$  is  $k$ -dynamically satisfiable, then  $\text{CSpace}(F \vdash \perp) \geq k$ .*

We thus have

$$W_R(F \vdash \perp) - W(F) + 1 \leq W_{\text{LK}^-}(F \vdash \perp) \leq \text{CSpace}(F \vdash \perp). \quad (6.1)$$

It is shown in [6] that there are 6-CNF formulas  $F$  of size  $O(n)$  such that  $W_R(F \vdash \perp) = O(1)$  and  $\text{CSpace}(F \vdash \perp) = \Omega(n/\log n)$ . It is easy to show that  $W_{\text{LK}^-}(F \vdash \perp) = O(1)$ , thus these formulas in fact provide a gap between  $W_{\text{LK}^-}(F \vdash \perp)$  and  $\text{CSpace}(F \vdash \perp)$ . The question of whether there is a gap between  $W_R(F \vdash \perp)$  and  $W_{\text{LK}^-}(F \vdash \perp)$  has not been addressed, and it is what we will deal with next.

## 7 A quadratic gap between $\text{LK}^-$ and resolution width

Let  $F = \bigwedge_{i=1}^s C_i$  and  $G = \bigwedge_{i=1}^t D_i$  be unsatisfiable CNF formulas. We define

$$F \times G \stackrel{\text{def}}{=} \bigwedge_{i=1}^s \bigwedge_{j=1}^t (C_i \vee D_j).$$

$F \times G$  is the CNF expansion of the formula  $F \vee G$ , which is also unsatisfiable.

Remarkably,  $\text{LK}^-$  width and resolution width exhibit a different behavior with respect to this construction. This disparity ultimately relies on the fact that the cut rule gives us the ability to combine given proofs into a more complicated proof.

On one hand, we have:

► **Lemma 7.1.** *If  $F$  and  $G$  are over disjoint sets of variables, then*

$$W_{\text{LK}^-}(F \times G \vdash \perp) \geq W_{\text{LK}^-}(F \vdash \perp) + W_{\text{LK}^-}(G \vdash \perp) - 1.$$

**Proof.** Suppose that  $F$  is  $k$ -dynamically satisfiable,  $G$  is  $\ell$ -dynamically satisfiable, and let  $\mathcal{A}$  and  $\mathcal{B}$  respectively be sets witnessing this. We need to show that  $F \times G$  is  $(k+\ell)$ -dynamically satisfiable, that is we need to find a set satisfying the conditions of Definition 6.1 for the parameter  $k+\ell$ . We claim that

$$\mathcal{C} := \{\alpha \cup \beta \mid \alpha \in \mathcal{A} \ \& \ \beta \in \mathcal{B}\}$$

is such a set. Closure under subsets immediately follows from the fact that  $\mathcal{A}$  and  $\mathcal{B}$  are closed under subsets. For the second condition, suppose that  $\gamma \in \mathcal{C}$ ,  $|\gamma| < k+\ell$ , and let  $C_i \vee D_j$  be a clause of  $F \times G$ , where  $C_i$  is a clause of  $F$  and  $D_j$  is a clause of  $G$ . Since  $\gamma \in \mathcal{C}$ , there is an  $\alpha \in \mathcal{A}$  and a  $\beta \in \mathcal{B}$  such that  $\gamma = \alpha \cup \beta$ . Moreover, since  $|\gamma| < k$  and  $F$  and  $G$  do not share variables, either  $|\alpha| < k$  or  $|\beta| < \ell$ . In the first case there is an  $\alpha' \supseteq \alpha$  in  $\mathcal{A}$  satisfying  $C_i$ , and thus  $\alpha' \cup \beta$  is an assignment in  $\mathcal{C}$  satisfying  $C_i \vee D_j$ . In the second case there is a  $\beta' \supseteq \beta$  in  $\mathcal{B}$  satisfying  $D_j$ , and thus  $\alpha \cup \beta'$  is an assignment in  $\mathcal{C}$  satisfying  $C_i \vee D_j$ . ◀

For resolution on the other hand, we have:

► **Lemma 7.2.**  $W_R(F \times G \vdash \perp) \leq \max\{W_R(F \vdash \perp) + W(G), W_R(G \vdash \perp)\}$ .

**Proof.** Let  $\pi$  and  $\rho$  be resolution refutations of  $F$  and  $G$  respectively, both of minimum width. Replacing every clause  $C$  in  $\pi$  with  $C \vee D_i$  we get a resolution proof  $\pi_i$  of  $D_i$  from  $F \times G$ .  $\pi_i$  has width at most  $W_R(F \vdash \perp) + W(F)$ . Replacing then every clause  $D_i$  in  $\rho$  with  $\pi_i$  we get a resolution refutation of  $F \times G$  with the stated width. ◀

Choosing an appropriate seed and iterating, we get our result.

► **Theorem 7.1.** *There are CNF formulas  $G$  with  $n^2$  variables, size  $O(n)^n$ , and such that  $W_R(G \vdash \perp) = O(n)$  and  $W_{LK^-}(G \vdash \perp) = \Omega(n^2)$ .*

**Proof.** Let  $F$  be a CNF formula with  $n$  variables, width  $O(1)$ , size  $\Theta(n)$ , and such that  $W_R(F \vdash \perp) = \Theta(n)$ . Such formulas exist from e.g. [8]. Consider the formula  $F^n := F_1 \times \cdots \times F_n$ , where the  $F_i$ 's are copies of  $F$  over mutually disjoint sets of variables. From Lemma 7.2,  $W_R(F^n \vdash \perp) = O(n)$ . On the other hand  $W_{LK^-}(F \vdash \perp) = \Omega(n)$  from (6.1), and hence from Lemma 7.1,  $W_{LK^-}(F^n \vdash \perp) = \Omega(n^2)$ . ◀

## 8 Separating resolution width from monomial space

Monomial space is a generalized version of clause space. While configurations in the case of clause space are sets of clauses, for monomial space, arbitrary linear combinations, over a field  $\mathbb{F}$ , of clauses are allowed as the contents of a configuration, where such a linear combination  $P$  is interpreted as the asserting that  $P = 0$ . As a matter of fact, all known lower bounds for monomial space even hold in the case where arbitrary Boolean functions of clauses are allowed. The term monomial space comes from the fact that this concept captures space in proof systems employing algebraic reasoning.

Namely, seeing clauses as monomials – a clause  $\ell_1 \vee \cdots \vee \ell_r$  is seen as the monomial  $\overline{\ell_1} \dots \overline{\ell_r}$  – the question of whether a set of clauses over the variables  $x_1, \dots, x_n$  is unsatisfiable, becomes the question of whether the polynomial 1 belongs to the ideal generated by those clauses and the clauses  $x_i^2 - x_i$  and  $x_i + \overline{x_i} - 1$  in  $\mathbb{F}[x_1, \dots, x_n, \overline{x_1}, \dots, \overline{x_n}]$ . A systematic way of generating this ideal, in a space oriented model, is the following [1]. Configurations are sets of polynomials over  $\mathbb{F}[x_1, \dots, x_n, \overline{x_1}, \dots, \overline{x_n}]$ . A refutation of a CNF formula  $F$ , in configurational form, is a sequence  $\mathcal{M}_1, \dots, \mathcal{M}_t$  of configurations where  $\mathcal{M}_1$  is empty,  $\mathcal{M}_t$  contains the empty clause and for  $i > 1$ ,  $\mathcal{M}_i$  is obtained from  $\mathcal{M}_{i-1}$  by one of the following rules:

**Axiom download:**  $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{C\}$ , where  $C$  is either a clause of  $F$ ,  $x_i^2 - x_i$ , or  $x_i + \overline{x_i} - 1$ .

**Inference:**  $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{P\}$ , where  $P$  is either a linear combination of polynomials in  $\mathcal{M}_{i-1}$  or a literal multiplied by some polynomial in  $\mathcal{M}_{i-1}$ .

**Erasure:**  $\mathcal{M}_i \subseteq \mathcal{M}_{i-1}$ .

The monomial space of such a refutation is the maximum number of distinct monomials occurring in a configuration. The monomial space,  $\text{MSpace}(F \vdash \perp)$ , of  $F$ , is the minimum monomial space over all refutations of  $F$ .

The gap shown in the previous section can be extended to stronger versions of dynamic satisfiability that have been used to show monomial space lower bounds, thus showing a gap between resolution width and monomial space. The configurations in those are not assignments as in Definition 6.1, but sets of assignments. They will not be arbitrary sets however; they will have a certain structure. Namely, we call a set  $H$  of assignments *admissible*, if it is of the form

$$H = H_1 \times \cdots \times H_r \stackrel{\text{def}}{=} \{\alpha_1 \cup \cdots \cup \alpha_r \mid \alpha_i \in H_i\},$$

where each  $H_i$  is a non-empty set of non-empty assignments, for any two assignments  $\alpha_i \in H_i$  and  $\alpha_j \in H_j$  for  $i \neq j$ , the domains of  $\alpha_i$  and  $\alpha_j$  do not intersect, and moreover, if an assignment  $\alpha \in H_i$  gives the value  $\epsilon$  to a variable  $x$ , then there is also an assignment  $\alpha' \in H_i$  giving to  $x$  the value  $1 - \epsilon$ . The  $H_i$ 's are called the *factors* of  $H$ ; we write  $\|H\|$  for their number. We write  $H' \sqsubseteq H$  if every factor of  $H'$  is a factor of  $H$ .

► **Definition 8.1** [11, 12]. Let  $F$  be a CNF formula and let  $k$  be a natural number. We say that  $F$  is *k-extensible* if there is a non-empty set of admissible configurations  $\mathcal{H}$  such that for each  $H \in \mathcal{H}$ ,

1. if  $H' \sqsubseteq H$ , then  $H' \in \mathcal{H}$ ;
2. if  $\|H\| < k$  and  $C$  is a clause of  $F$ , then there is an  $H' \sqsupseteq H$  in  $\mathcal{H}$ , such that every  $\alpha \in H'$  satisfies  $C$ .

► **Theorem 8.1** [11, 12]. *If  $F$  is k-extensible, then  $\text{MSpace}(F \vdash \perp) \geq \lfloor k/4 \rfloor$ .*

Lemma 7.1 with the same proof applies here as well.

► **Lemma 8.1.** *Let  $F$  and  $G$  be CNF formulas over disjoint sets of variables. If  $F$  is k-extensible and  $G$  is  $\ell$ -extensible, then  $F \times G$  is  $(k + \ell)$ -extensible.*

**Proof.** Let  $\mathcal{H}$  and  $\mathcal{I}$  be sets of admissible configurations witnessing the  $k$  and  $\ell$ -extensibility of  $F$  and  $G$ . Since  $F$  and  $G$  are over disjoint sets of variables, we may assume that the domains for any of two assignments in  $\mathcal{H}$  and  $\mathcal{I}$  do not intersect. Set

$$\mathcal{J} := \{H \times I \mid H \in \mathcal{H} \ \& \ I \in \mathcal{I}\}.$$

Clearly,  $\mathcal{J}$  is a set of admissible configurations. We claim that it satisfies the conditions of Definition 8.1 for the parameter  $k + \ell$ . Closure under  $\sqsubseteq$  immediately follows from the fact that  $\mathcal{H}$  and  $\mathcal{I}$  are closed under  $\sqsubseteq$ . For the second condition, suppose that  $J = H \times I \in \mathcal{J}$ ,  $\|J\| < k + \ell$ , and let  $C_i \vee D_j$  be a clause of  $F \times G$ , where  $C_i$  is a clause of  $F$  and  $D_j$  is a clause of  $G$ . Since  $\|J\| < k + \ell$ , either  $\|H\| < k$  or  $\|I\| < \ell$ . In the first case, there is an  $H' \sqsupseteq H$  in  $\mathcal{H}$  such that all assignments in  $H'$  satisfy  $C_i$ . Then  $H' \times I$  is an admissible configuration in  $\mathcal{J}$  such that all assignments in it satisfy  $C_i \vee D_j$ . The second case is analogous. ◀

Therefore, we get:

► **Theorem 8.2.** *There are CNF formulas  $G$  with  $n^2$  variables, size  $O(n)^n$ , and such that  $W_R(G \vdash \perp) = O(n)$  and  $\text{MSpace}(G \vdash \perp) = \Omega(n^2)$ .*

**Proof.** Again, let  $F$  be a CNF formula with  $n$  variables, width  $O(1)$  and size  $\Theta(n)$ , that is  $\Omega(n)$ -extensible. Such formulas exist, see [11, 16, 12, 9]. The formulas  $F^n := F_1 \times \cdots \times F_n$ , where the  $F_i$ 's are copies of  $F$  over mutually disjoint sets of variables, have resolution width  $O(n)$ , and from Lemma 8.1 they are  $\Omega(n^2)$ -extensible, thus from Theorem 8.1 require  $\Omega(n^2)$  monomial space. ◀

## 9 A super-polynomial separation between resolution and $LK^-$ size

Many of the relations in resolution involving width, can be as well stated for  $LK^-$ . In fact, they seem to be better suited for  $LK^-$ ; there, the additive  $W(F)$  factor that naturally comes with resolution width disappears. We have already seen that  $W_{LK^-}(F \vdash \perp) \leq \text{CSpace}(F \vdash \perp)$ , refining the relation between clause space and width of [4]. But let us give an alternative, constructive proof, here. For sets  $S$  and  $T$  of formulas, we write  $S \models T$  if every total assignment satisfying every formula in  $S$ , also satisfies every formula in  $T$ .

► **Theorem 9.1.** *For any unsatisfiable CNF formula  $F$ ,  $W_{LK^-}(F \vdash \perp) \leq \text{CSpace}(F \vdash \perp)$ .*

**Proof.** Let  $\mathcal{M}_1, \dots, \mathcal{M}_t$  be a refutation of  $F$ , of clause space  $s$ . We shall construct a sequence  $\mathbf{T}_1, \dots, \mathbf{T}_t$  of trees, the vertices of which are labelled by sets of literals, such that for every set  $S$  labelling a leaf of  $\mathbf{T}_i$ ,  $S \models \mathcal{M}_i$  and  $|S| \leq |\mathcal{M}_i|$ .

We set  $\mathbf{T}_1$  to be a tree with one vertex labelled by the empty set. Now, suppose we have constructed  $\mathbf{T}_{i-1}$ . If  $\mathcal{M}_i$  results from  $\mathcal{M}_{i-1}$  via an inference step, we set  $\mathbf{T}_i := \mathbf{T}_{i-1}$ . If  $\mathcal{M}_i \subseteq \mathcal{M}_{i-1}$ , then we add to every leaf of  $\mathbf{T}_{i-1}$  labelled by a satisfiable set  $S$ , a child labelled by a subset  $S' \subseteq S$  such that  $|S'| \leq |\mathcal{M}_i|$  and  $S' \models \mathcal{M}_i$ . Finally, if  $\mathcal{M}_i = \mathcal{M}_{i-1} \cup \{C\}$ , for a clause  $C = \ell_1 \vee \dots \vee \ell_r$  of  $F$ , we add to every child of  $\mathbf{T}_i$  labelled by a satisfiable set  $S$ ,  $r$  children labelled by the sets  $S \cup \{\ell_j\}$ .

Replacing each set  $\{\ell_1, \dots, \ell_k\}$  occurring in  $\mathbf{T}_t$ , by the clause  $\bar{\ell}_1 \vee \dots \vee \bar{\ell}_k$ , we get an  $LK^-$  refutation of  $F$  of width at most  $s$ . It is clear from the construction of  $\mathbf{T}_t$  that every clause has width at most  $s$  and every clause not at a leaf, results from the clauses at its children via either the weakening or the  $\forall L$  rule. Moreover, since  $\mathcal{M}_t$  is unsatisfiable, no set labelling a leaf of  $\mathbf{T}_i$  is satisfiable, that is sets at the leaves become weakenings of axioms. ◀

Next, we have the size-width relations of [8]. Here the proofs are the same as those in [8].

► **Theorem 9.2.** *For any unsatisfiable CNF formula  $F$ ,  $W_{LK^-}(F \vdash \perp) \leq \log S_{\text{TR}}(F \vdash \perp) + 1$ .*

**Proof.** This is in fact a weakened version of Theorem 9.1, as  $\text{CSpace}(F \vdash \perp) \leq \log S_{\text{TR}}(F \vdash \perp) + 1$  [15]. But let us give a direct construction instead. We shall construct, by induction on  $s$ , for every tree-like resolution refutation  $\mathbf{T}$  of  $F$  of size  $s$ , an  $LK^-$  refutation of  $F$  of width at most  $\log s + 1$ .

If  $\mathbf{T}$  has size 1, then it has width 0; if it has size 3 then it has width 2. For the inductive step, suppose that  $\mathbf{T}$  has size  $s > 3$ . Let  $\mathbf{T}_1$  and  $\mathbf{T}_2$  be the subproofs of  $\mathbf{T}$ , deriving  $\neg x$  and  $x$  respectively, for some variable  $x$ . One of  $\mathbf{T}_1$  and  $\mathbf{T}_2$ , say  $\mathbf{T}_1$ , must have size at most  $s/2$ .  $\mathbf{T}_1|_x$  is a refutation of  $F|_x$  of size at most  $s/2$ , and  $\mathbf{T}_2|_{\bar{x}}$  is a refutation of  $F|_{\bar{x}}$  of size less than  $s$ . From the induction hypothesis, there are  $LK^-$  refutations  $\pi_1$  and  $\pi_2$  of  $F|_x$  and  $F|_{\bar{x}}$  of width  $\log s$  and  $\log s + 1$  respectively. Start with  $\pi_2$ . To every application of Rule (5.1), add the extra premise  $C \vee x$ . But  $x$  can be derived from  $\pi_1$ , and hence all those  $C \vee x$  can be derived via the weakening rule from  $x$ : We can do the same to  $\pi_1$ , now adding  $C \vee \bar{x}$  as the extra premise, and moreover add to every clause the variable  $x$ . The refutation obtained when we combine  $\pi_1$  and  $\pi_2$  is a valid  $LK^-$  refutation of  $F$  of width at most  $\log s + 1$ . ◀

► **Theorem 9.3.** *For any unsatisfiable CNF formula  $F$  over  $n$  variables,  $W_{LK^-}(F \vdash \perp) = O\left(\sqrt{n \log S_{LK^-}(F \vdash \perp)}\right)$ .*

**Proof.** The construction will be the same as that of Theorem 9.2. The problem here is that it is not clear what variable to choose to recurse on. The trick is to choose the variable that appears more often in the clauses of the proof.

For an  $\text{LK}^-$  refutation  $\pi$  of a CNF and a  $d \geq 0$ , let  $\pi^*$  be the set of clauses in  $\pi$  of width greater than  $d$ . We call the clauses in  $\pi^*$  the *fat* clauses of  $\pi$ . We show, by induction on  $n$ , that for any CNF  $F$  in  $n$  variables, any  $\text{LK}^-$  refutation  $\pi$  of  $F$  and any integers  $d, b \geq 0$ ,

$$|\pi^*| < a^b \implies W_{\text{LK}^-}(F \vdash \perp) \leq d + b,$$

where  $a = (1 - d/(2n))^{-1}$ . The theorem follows taking  $\pi$  to be of minimum size and  $d := \lceil \sqrt{n \log S(\pi)} \rceil$ .

If  $n = 1$ , then there is an  $\text{LK}^-$  refutation of  $F$  of width 2, and in the case that  $b + d < 2$  the implication becomes trivially true. For the inductive step, suppose that  $n > 1$ , let  $d, b \geq 0$ , and let  $\pi$  be an  $\text{LK}^-$  refutation of  $F$  with  $|\pi^*| < a^b$ . If  $b = 0$ , then  $\pi$  itself is a refutation of width at most  $d + b$ . Suppose  $b > 0$ . There are  $2n$  literals, so there must be some literal, say the variable  $x$ , appearing in at least  $d|\pi^*|/(2n)$  clauses in  $\pi^*$ .  $\pi|_x$  is an  $\text{LK}^-$  refutation of  $F|_x$  with at most  $|\pi^*|(1 - d/(2n)) < a^{b-1}$  fat clauses, so by the induction hypothesis (notice that  $a$  is a decreasing function of  $n$ ), there is an  $\text{LK}^-$  refutation  $\pi'$  of  $F|_x$  of width at most  $d + b - 1$ . Furthermore,  $\pi|_{\bar{x}}$  is an  $\text{LK}^-$  refutation of  $F|_{\bar{x}}$  with less than  $a^b$  clauses, so by the induction hypothesis, there is an  $\text{LK}^-$  refutation  $\pi''$  of  $F|_{\bar{x}}$  of width at most  $d + b$ . Combining  $\pi'$  and  $\pi''$  as in the proof of Theorem 9.2, we get an  $\text{LK}^-$  refutation of  $F$  of width at most  $d + b$ . ◀

Notice that in Theorem 9.2 and the relation  $W_{\text{LK}^-}(F \vdash \perp) \leq \text{CSpace}(F \vdash \perp)$ , we have  $\text{LK}^-$  in the left hand side and resolution in the right hand side. That is to say, cuts are eliminated when constructing the small width proofs. It is tempting to speculate on whether the same is also true for Theorem 9.3, that is whether we can replace  $S_{\text{LK}^-}(F \vdash \perp)$  with  $S_R(F \vdash \perp)$ . After all, the only place in the proof of Theorem 9.3 where we need  $\text{LK}^-$  in the right hand side is the case  $b = 0$ . Theorem 7.1 says that this cannot be true. In fact, the formulas of Theorem 7.1 give the main theorem of this section, which is:

► **Theorem 9.4.** *There is a CNF formula  $F$  with  $n^2$  variables and size  $O(n)^n$ , such that  $S_R(F \vdash \perp) = O(n)^n$  but  $S_{\text{LK}^-}(F \vdash \perp) \geq \exp(\Omega(n^2))$ .*

**Proof.** The formulas of Theorem 7.1 are such. The upper bound  $S_R(F \vdash \perp) = O(n)^n$  follows from the construction of Lemma 7.2. The lower bound follows from the fact that  $W_{\text{LK}^-}(F \vdash \perp) = \Omega(n^2)$  and Theorem 9.3. Namely, Theorem 9.3 gives

$$S_{\text{LK}^-}(F \vdash \perp) \geq \exp\left(\Omega\left(\frac{(W_{\text{LK}^-}(F \vdash \perp))^2}{n^2}\right)\right) = \exp(\Omega(n^2)). \quad \blacktriangleleft$$

It is important to note that the  $\exp(\Omega(n^2))$  lower bound in Theorem 9.4 holds for the version of  $\text{LK}^-$  operating on clauses, where the clauses of the CNF formula  $F$  to be refuted are viewed as disjunctions of unbounded arity. It does not hold when the clauses of  $F$  are made up from binary disjunctions and moreover we are free to choose the order in which they are applied. If  $\vee$  in the definition of  $F \times G$ , is seen as a binary disjunction, then having derived  $C_1, \dots, C_n \rightarrow$  and  $D_1, \dots, D_t \rightarrow$ , it is easy to see that we may derive from these sequents  $C_1 \vee D_1, \dots, C_1 \vee D_t, \dots, C_s \vee D_1, \dots, C_s \vee D_t \rightarrow$  in  $s \cdot t$  steps, and in this case  $F^n$  in Theorem 9.4 has an  $\text{LK}^-$  refutation of size  $n^{O(n)}$ . An analogous situation occurs between the tree-like versions of  $\text{LK}^-$  and resolution [3]. But let us notice, concluding, that with binary disjunctions,  $\text{LK}^-$  cannot be seen as a system operating on clauses, and it becomes rather unnatural to compare it with resolution – it is not even clear, in this case, whether resolution can polynomially simulate  $\text{LK}^-$ .  $\text{LK}^-$  for clauses consisting of binary disjunctions is closer to resolution with limited extension, in which case resolution does polynomially simulate it [24].

## 10 Conclusion

We showed a quadratic gap between resolution and cut-free sequent calculus width. In terms of the sequent calculus, this says that atomic cuts can shorten the width of proofs. It is well known that cuts can make proofs exponentially shorter. Allowing arbitrary cuts we get a system polynomially equivalent with any Frege system. These are very powerful; proving non-trivial lower bounds for them is completely out of reach of current methods. But even allowing cuts of depth  $d + 1$  in an LK system that has cuts of depth  $d$  for any constant  $d \geq 0$ , gives exponentially shorter proofs [19]. And this goes lower: For any constant  $k \geq 0$ , allowing as cut formulas conjunctions and disjunctions of arity  $k + 1$  in an LK system that has as cuts conjunctions and disjunctions of arity at most  $k$ , again gives exponentially shorter proofs [22]. We show in this paper that even allowing propositional variables as cuts, gives super-polynomially shorter proofs.

Cut-free sequent width for refuting CNF formulas naturally compares to well studied complexity measures related to resolution: it sits between resolution width and clause space. Our quadratic gap in particular, provides a separation between resolution width and clause space. Stronger such separations are known [6, 7]. Nonetheless, our basic construction extends to provide a quadratic gap between resolution width and monomial space. This is to be seen in conjunction with relation (1.2) showing that monomial space provides an upper bound to resolution width.

Several questions remain open:

1. Can cut-free sequent calculus width for refuting CNF formulas be bounded in terms of resolution width? Given the similarity between the two measures, the combination of Lemmas 7.1 and 7.2 giving a quadratic separation might come as a surprise. Can this separation be improved? A strong separation in particular, would give an exponential separation between resolution and cut-free sequent calculus.
2. Our super-polynomial separation of resolution and cut-free sequent calculus on the one hand applies only when clauses are seen as disjunctions of unbounded arity. On the other hand, it involves formulas whose size grows exponentially. Can there be a separation independent of the representation of clauses? Can there be a separation for formulas whose size grows polynomially?
3. Cut-free sequent calculus width is bounded by clause space. Can it be bounded in terms of monomial space in a relation similar to (1.2)? This is a good point to also mention that whether (1.2) can be improved to a linear inequality or there are examples where it is tight is unknown as well, and there do not seem to be strong indications for which case is true.
4. We show that resolution width and monomial space cannot coincide. Whether they coincide up to polynomial factors however remains open, although it is speculated (cf. [18]) that this is not the case, and moreover, as it is the case for resolution width and clause space [6, 7], there is an  $O(1)$  vs  $\Omega(n/\log n)$  separation.

---

## Abstract

Subshifts are sets of colourings – or tilings – of the plane, defined by local constraints. Historically introduced as discretizations of continuous dynamical systems, they are also heavily related to computability theory. In this article, we study a conjugacy invariant for subshifts, known as the projective fundamental group. It is defined via paths inside and between configurations. We show that any finitely presented group can be realized as a projective fundamental group of some SFT.

**2012 ACM Subject Classification** Theory of computation → Models of computation; Mathematics of computing → Discrete mathematics

## 1 Introduction

A  $d$ -dimensional subshift is a set of colourings of  $\mathbb{Z}^d$  by a finite number of colours which avoid some family of forbidden patterns. If the family is finite, it is called a subshift of finite type (SFT). Most problems concerning subshifts in dimension  $d \geq 2$  are undecidable [6, 20, 19], due to the fact that sets of Wang tilings are SFTs.

Together with the shift action  $\sigma$ , a subshift forms a dynamical system. Interesting dynamical aspects are usually invariant by conjugacy, which is the isomorphism notion for subshifts. Most conjugacy invariants of subshifts in dimensions  $d \geq 2$  are linked to computability theory or complexity theory. Historically, the first example was the characterization of the topological entropies of multi-dimensional SFTs as the upper semi-computable numbers [25]. Afterwards, many other computational characterizations of conjugacy invariants have been obtained: growth-type invariants [30], subactions [23, 4, 14] and so on.

Links between groups and subshifts have recently seen a surge in interest with several different approaches: subshifts can be defined on groups instead of  $\mathbb{Z}^d$  [1, 3] and some properties of the group are linked to decidability questions on the subshifts on it [26, 2, 15]. Analogies between groups and subshifts have allowed new characterizations to be proved for subshifts [27].

Another avenue is to associate a group to a subshift in order to construct conjugacy invariants in several ways [29, 22, 17]. The most well-known such group is the automorphism group, which is still not very well understood: for instance, while it is known that SFTs with positive entropy have very complex automorphism groups [24] or that SFTs whose

automorphism group has undecidable word problem can be constructed [18], it is still not known whether the automorphism groups of the full shifts on 2 and 3 symbols are the same. Apart from the low complexity setting [13, 12] not much is understood about it.

In this article, we study another group-related conjugacy invariant called the *projective fundamental group* introduced by Geller and Propp [17]. Fundamental groups are an object of interest in several fields of theoretical computer science, in particular graph reconfigurations [37], which bear links with a particular class of subshifts called *hom-shifts* [10] which are defined with a graph of allowed adjacency of colours. These are subshifts with a computable language that still exhibit interesting behavior [16]. An essential tool in their study is their *universal cover*, a graph which has strong ties to their projective fundamental group. Fundamental groups are also of interest when studying the “defects” in tilings [33, 5], or obstruction to the tileability of finite, untiled “holes” in tilings [11, 36]. In particular, provided that an SFT satisfies some mixing-like hypothesis, there is an explicit link between its fundamental cocycles [35, 34] and its projective fundamental group.

In the usual topological setting (see for example [21]), the fundamental group  $\pi_1(X)$  of a space  $X$  is a topological invariant which describes the number of holes and the general shape of  $X$ . It is defined as the group of equivalence classes of loops through continuous deformation, together with the composition operation. In this setting, the fundamental group is well-defined only when  $X$  is path-connected.

When viewed as subspaces of the Cantor space, subshifts are totally disconnected. Nevertheless, one can still define a notion of projective fundamental group using paths and deformations (see Subsection 3.1 for details). As in the classical setting, this notion is only well-defined in the case of *projectively connected subshifts*, the appropriate notion of path-connectedness. This property resembles mixing properties (see for instance [9] or [32]), but it is not known whether any of the mixing properties defined in [9] imply projective connectedness of an SFT, although some partial results exist [33, 35]. Projective connectedness is undecidable but we do not know how hard: it is open whether it belongs to the arithmetical hierarchy.

As a conjugacy invariant, the fundamental group allows one to distinguish between some subshifts which share the same entropy and periodicity data. It is also better understood than the automorphism group in the sense that the authors in [17] explicitly compute it for several well-known subshifts: the full shifts on any alphabet always have trivial fundamental group, the square-ice has  $\mathbb{Z}$  and  $k$ -to-1 factors of full shifts – *i.e.* in which every point has exactly  $k$  preimages by the factor map – always have a fundamental group with finite order  $k$ . They also prove that any group of finite order is realizable as a fundamental group of some SFT.

The main result of this article is that any finitely presented group can be the fundamental group of an SFT:

► **Theorem 1.** *Let  $G = \langle S \mid R \rangle$  be a finitely presented group. Then, there is a subshift of finite type  $X$  satisfying:*

- *$X$  is projectively connected,*
- *the projective fundamental group of  $X$  is isomorphic to  $G$ .*

We do not think that this constitutes a characterization of projective fundamental groups of SFTs, as we do not have a matching upper bound on the hardness its word problem. However, this theorem implies that the hardness of the word problem of the fundamental group – *i.e.* given a SFT, decide the word problem of its fundamental group – can be any recursively enumerable degree [8], and in particular that its upper bound is at least  $\Sigma_1^0$ -hard [31, 7]. It also implies that any undecidable property on finitely presented groups is undecidable for projective fundamental groups.

The main construction of the paper is quite different from other constructions used in undecidability results on tilings and subshifts: it does not use an aperiodic subshift.

The paper is organized as follows. After recalling the symbolic dynamics background in Section 2, we introduce the projective fundamental group in Subsection 3.1, some examples in Subsection 3.2 and finally in Section 4 we prove Theorem 1.

## 2 Definitions

A **d-dimensional full shift** on some finite alphabet  $\Sigma$  is the set  $\Sigma^{\mathbb{Z}^d}$ , together with the **shift-actions**  $\sigma_{\mathbf{u}}: \Sigma^{\mathbb{Z}^d} \rightarrow \Sigma^{\mathbb{Z}^d}$  defined for  $\mathbf{u} \in \mathbb{Z}^d$  by  $\sigma_{\mathbf{u}}(x)(\mathbf{v}) = x(\mathbf{u} + \mathbf{v}) = x_{\mathbf{u}+\mathbf{v}}$ . The underlying topology is the one induced by the **Cantor distance**, defined on  $\Sigma^{\mathbb{Z}^d}$  by

$$d(x, y) = 2^{-\min\{\|\mathbf{u}\|_{\infty} \mid x_{\mathbf{u}} \neq y_{\mathbf{u}}\}},$$

Two configurations are close in this topology if they agree on a large central square. A **subshift** is a closed, shift-invariant subset of some full shift. We call **configurations** of a subshift  $X$  the points of  $X$ .

Alternatively, subshifts can be defined using forbidden patterns. We call **pattern** any element  $P \in \Sigma^U$  where  $U \subset \mathbb{Z}^d$  is finite and is the **support** of  $P$ , denoted by  $\text{supp}(P)$ . For a configuration  $x$ , we say that  $P$  appears in  $x$  if there exists  $\mathbf{u} \in \mathbb{Z}^d$  such that  $\sigma_{\mathbf{u}}(x)|_U = P$ . Let  $\mathcal{F}$  be a collection (finite or not) of patterns. Then the set

$$X_{\mathcal{F}} = \left\{ x \in \Sigma^{\mathbb{Z}^d} \mid \forall P \in \mathcal{F}, P \text{ does not appear in } x \right\}$$

is a subshift. In fact, for any subshift  $X$ , there exists a family of patterns  $\mathcal{F}$  such that  $X = X_{\mathcal{F}}$ . A subshift  $X$  is a **subshift of finite type (SFT)** if there exists a finite  $\mathcal{F}$  such that  $X = X_{\mathcal{F}}$ .

For a given subshift  $X$  defined by a fixed family of forbidden patterns  $\mathcal{F}$ , a pattern  $P \in \Sigma^U$  is **locally admissible** if it contains no forbidden patterns  $F \in \mathcal{F}$ . It is **globally admissible** or **extensible** if it appears in some configuration  $x \in X$ .

## 3 Projective Fundamental Group

### 3.1 Intuitions and definitions

The Projective Fundamental Group, introduced by Geller and Propp [17], resembles the usual fundamental group construction in the topological setting: it is defined through paths, loops, and a homotopy notion. However, instead of directly considering paths between points of the subshift, they are defined between finite patterns with the same support. By doing so, one actually constructs a family of – potentially different – fundamental groups, for each finite support  $B \subset \mathbb{Z}^2$ . In order to obtain a single group, the projective fundamental group, one takes their inverse (also known as projective) limit. We will construct a subshift by defining a set  $\mathcal{T}$  of tiles. A configuration will then be a mapping  $x: \mathbb{Z}^2 \rightarrow \mathcal{T}$  associating a tile to each point of the plane and which verifies some adjacency rules depending on  $\mathcal{T}$ . Contrary to the usual convention, we will consider that when embedding such a configuration in the Euclidean plane  $\mathbb{R}^2$ , the tile in position  $(i, j)$  is a unit square whose bottom-left corner is placed on  $(i, j)$ , as opposed to its center. This is merely a discussion about conventions, but it will make some definitions substantially simpler.

Fix a support  $B \subset \mathbb{Z}^2$ . In what follows  $B$  will be called an **aperture window**. Most of the time, we will restrict ourselves to the windows  $B_n = \llbracket -n, n-1 \rrbracket^2$ . We choose this asymmetrical window to simplify some definitions, but also for consistency with the

aforementioned convention. In any configuration  $x$ , the tile  $x_{(0,0)}$  in position  $(0,0)$  will therefore be seen as the square whose bottom-left (resp. top-right) corner is  $(0,0)$  (resp.  $(1,1)$ ).

Consider  $P, P'$  two extensible patterns of support  $B$  and two points of the grid  $\mathbf{v}, \mathbf{v}' \in \mathbb{Z}^2$ . A **path** between  $(P, \mathbf{v})$  and  $(P', \mathbf{v}')$  is a sequence of pairs of patterns and of points of  $\mathbb{Z}^2$  (or equivalently, two sequences of the same length). The sequence of points represents an actual, “geometric” path, called its **trajectory**, that is to say a sequence of vertices of  $\mathbb{Z}^2$  starting at  $\mathbf{v}$  and ending at  $\mathbf{v}'$ , where consecutive vertices are at euclidean distance exactly 1. The sequence of patterns associates with each one of those vertices  $\mathbf{v}_t$  a pattern  $P_t$ , that needs to be coherent with the path: when moving to the next vertex  $\mathbf{v}_{t+1}$  on the trajectory, the next pattern  $P_{t+1}$  needs to be coherent with  $P_t$ , that is to say, they should be equal where their supports overlap (see Definition 2 for a precise statement). For example, in the full shift over two symbols  $\{0, 1\}$ , and for  $B = B_1$ , take the following patterns:

$$P_1 = \left( \begin{array}{|c|c|} \hline 0 & 0 \\ \hline 0 & 0 \\ \hline \end{array}, (0,0) \right), \quad P_2 = \left( \begin{array}{|c|c|} \hline 0 & 1 \\ \hline 0 & 1 \\ \hline \end{array}, (1,0) \right), \quad P_3 = \left( \begin{array}{|c|c|} \hline 1 & 1 \\ \hline 1 & 1 \\ \hline \end{array}, (1,0) \right)$$

The tile in position  $(0,0)$  is represented in red. The sequence  $(P_1, P_2)$  is a valid path, as the overlapping parts of the support are equal in both patterns, but  $(P_1, P_3)$  is not because the point  $(0,0)$  is tiled by 0 in the first pattern but by 1 in the second one. Moreover, the pattern obtained by “merging” two consecutive patterns also needs to be an extensible pattern.

**► Definition 2 (Path).** Let  $B \subset \mathbb{Z}^2$  be a finite set, a path of **aperture window**  $B$  is a finite sequence  $(P_t, \mathbf{v}_t)_{0 \leq t \leq N}$  such that for any  $t$  with  $0 \leq t \leq N$ :

- $P_t$  is an extensible pattern of  $X$  of support  $B + \mathbf{v}_t$ ,
- $\mathbf{v}_t$  is adjacent to  $\mathbf{v}_{t+1}$ , i.e.,  $\mathbf{d}_t = \mathbf{v}_{t+1} - \mathbf{v}_t$  has euclidean norm exactly 1,
- $P_t(u) = P_{t+1}(u)$  for any  $u \in B \cap \sigma_{\mathbf{d}_t}(B)$ , i.e., consecutive patterns overlap,
- the pattern  $P_t \cup P_{t+1}$  obtained by merging  $P_t$  and  $P_{t+1}$  is extensible in  $X$ .

The first and last element of the sequence are respectively called the **starting point** and the **ending point** of the path. If they are equal, the path is called a **loop**. The path  $(P_{N-t}, \mathbf{v}_{N-t})_{0 \leq t \leq N}$  is called its **inverse path**. If  $p$  is a path, its inverse will be denoted by  $p^{-1}$

The sequence  $(\mathbf{v}_t)_{0 \leq t \leq N}$  is called the **trajectory** of the path.

Two paths may be composed when the first one ends where the second one starts:

**► Definition 3 (Path composition).** Given  $p = (P_t, \mathbf{v}_t)_{0 \leq t \leq N}$  and  $p' = (P'_t, \mathbf{v}'_t)_{0 \leq t \leq N'}$  two paths such that  $(P_N, \mathbf{v}_N) = (P'_0, \mathbf{v}'_0)$  we denote by  $p * p'$  the path

$$p * p' = (P_0, \mathbf{v}_0) \dots (P_N, \mathbf{v}_N) (P'_1, \mathbf{v}'_1) \dots (P'_{N'}, \mathbf{v}'_{N'}).$$

**► Definition 4 (Coherent path).** A path  $p = (P_i, \mathbf{v}_i)_{i \leq N}$  is coherent if all its patterns are equal on the points where their supports overlap, and furthermore, the pattern obtained by merging all the  $P_i$  is globally admissible in  $X$ . In that case, for any  $x \in X$  containing  $\bigcup_{i \leq N} P_i$ , we say that  $p$  can be **traced** in  $x$ .

**► Definition 5 (Coherent path decomposition).** A **coherent decomposition** of a path  $p$  is a sequence  $p_1, \dots, p_L$  of coherent paths such that  $p = p_1 * p_2 \dots * p_L$ , and  $L$  is called the **length** of the decomposition.

One can now define a corresponding homotopy notion: let  $p = p_1 * p_2 * p_3$  be a path and suppose that  $p_2$  can be traced in a single configuration  $x \in X$ . Then, for any  $p'_2$  traced in  $x$  with the same starting and ending point as  $p_2$ , the path  $p_1 * p'_2 * p_3$  is called an **elementary deformation** of  $p$ . As paths might consist of a single point, they can be deformed by inserting or removing loops traced in a single configuration at any step.

► **Definition 6** (Homotopy). *Two paths  $p, p'$  are said to be **homotopic** if there exists a finite sequence of elementary deformations from  $p$  to  $p'$ . This defines an equivalence relation between paths, and we denote by  $[p]$  the equivalence class of  $p$ . If  $p$  and  $p'$  are paths with an aperture window  $B \subset \mathbb{Z}^2$ , we denote by  $p \sim_B p'$  the fact that they are homotopic.*

► **Remark 7.** When two paths are homotopic, they necessarily have the same starting and ending points. When  $B$  is clear from the context, we will simply write  $p \sim p'$ .

With this definition of a path and of homotopy, we can define a fundamental group for each possible aperture window  $B \subset \mathbb{Z}^2$ .

► **Definition 8** (Fundamental Group). *Let  $X$  be a SFT,  $B \subset \mathbb{Z}^2$  an aperture window,  $x_0 \in X$  and  $\mathbf{v} \in \mathbb{Z}^2$ . The **fundamental group** of  $X$  based at  $(x_0, \mathbf{v})$  for the aperture window  $B$ , denoted by  $\pi_1^B(X, (x_0, \mathbf{v}))$ , is the group of all the equivalence classes of loops starting and ending at  $(x_0|_B, \mathbf{v})$  for the homotopy equivalence relation, along with the  $*$  operation.*

Although our paths follow the  $\mathbb{Z}^2$  grid and seem to be discrete and combinatorial objects, it is legitimate to refer to those objects as *homotopy* and *deformations*, which usually suppose some kind of continuity. In fact, this simplification does not entail any loss of generality, compared to paths drawn in  $\mathbb{R}^2$ , and subshifts seen as  $\mathbb{Z}^2$ -invariants subsets of  $\Sigma^{\mathbb{R}^2}$  (see [17, Subshifts and albums] for more details). In order to obtain a single object associated with the subshift, we get rid of this reference to an aperture window by considering the projective limit of those groups to define the **Projective Fundamental Group** of the subshift.

► **Definition 9** (Restriction maps). *For any  $B' \subseteq B \subset \mathbb{Z}^2$ , the map*

$$\begin{aligned} \text{restr}_{B, B'} : \Sigma^B &\rightarrow \Sigma^{B'} \\ P &\mapsto (i \in B' \mapsto P(i)) \end{aligned}$$

*is called the **canonical restriction map** from  $B$  to  $B'$ . We can naturally extend it to  $\bigcup_{\mathbf{v} \in \mathbb{Z}^2} \Sigma^{B+\mathbf{v}}$  so that  $\text{supp}(P) = B + \mathbf{v} \implies \text{supp}(\text{restr}_{B, B'}(P)) = B' + \mathbf{v}$ .*

Intuitively, these maps simply “forget” some parts of the pattern. We also extend these maps to paths: if  $B' \subseteq B$ , the image of a path  $p$  with aperture window  $B$  is a path with the same trajectory with aperture window  $B'$ , obtained by mapping  $\text{restr}_{B, B'}$  element-wise on  $p$ .

► **Definition 10** (Projective path class). *Let  $x, x' \in X$  and  $\mathbf{v}, \mathbf{v}' \in \mathbb{Z}^2$ . A **projective path class** between  $(x, \mathbf{v})$  and  $(x', \mathbf{v}')$  is a sequence  $([p_n])_{n>0}$  along with the canonical restriction maps, such that  $p_n$  is a path of aperture window  $B_n$  between  $(x_{B_n}, \mathbf{v})$  and  $(x'_{B_n}, \mathbf{v}')$ , and for each  $n > n' > 0$ ,  $\text{restr}_{B_n, B_{n'}}(p_n) \sim_{B_{n'}} p_{n'}$ .*

*In the case where  $(x, \mathbf{v}) = (x', \mathbf{v}')$ , we instead say that  $([p_n])_{n>0}$  is a projective loop class based at  $(x, \mathbf{v})$ .*

► **Definition 11** (Projectively connected subshift). *A subshift  $X$  is **projectively connected** if for any two points  $x, x' \in X$ , there exists a projective path class between  $(x, (0, 0))$  and  $(x', (0, 0))$ .*

As before, projective loop classes based at the same  $(x, \mathbf{v})$  can be concatenated component-wise, to obtain another projective loop class.

► **Definition 12** (Projective Fundamental Group). *The **projective fundamental group** based at the point  $(x_0, \mathbf{v}) \in X \times \mathbb{Z}^2$  of a subshift  $X$  is the group of projective loop classes based at  $(x_0, \mathbf{v})$ , with the group operation being the component-wise concatenation of projective loop*

classes, and is denoted by  $\pi_1^{proj}(X, (x_0, \mathbf{v}))$ . If  $X$  is projectively connected, then its projective fundamental group does not depend on the chosen basepoint  $(x_0, \mathbf{v})$ , and we denote it by  $\pi_1^{proj}(X)$ .

This is a usual construction of what is called a projective (or inverse) limit in category theory. However, we do not use general properties of inverse limits in the rest of the article.

### 3.2 First example

We slightly modify an example of [17]. Consider the two-dimensional subshift  $X$  on the alphabet  $\{0, 1\}$  of all the configurations containing at most one 1. We show how some paths can be deformed to the trivial path. It is then easy to show that *all* paths are homotopic to the trivial path. Take an aperture window of size 1, *i.e.*, only one cell is visible at a time. Consider the following path  $p$ , starting at  $(0, (0, 0))$  (we see a 0 at the origin of the  $\mathbb{Z}^2$  plane). The path then moves in the  $\mathbb{Z}^2$  grid while only seeing 0's, and comes back to the origin where it now sees a 1. Then it moves away from the origin while only seeing 0's, and finally comes back to  $(0, 0)$  with a 0 in the window. For simplicity, we also suppose that the path does not pass through the origin at any other time. To sum up, the path is a loop, starting and ending at  $(0, (0, 0))$ , which only sees 0 along the way except at one time ( $t_2$  on the figure) where it sees a 1 at the origin. This is illustrated in Figure 1a.

(a) Example of a path that cannot be traced in a single configuration.

(b) A homotopic deformation to a path that can entirely be traced in the all-0 configuration.

**Figure 1** Example of a path and of a deformation of this path. Notice that the central 0 and 1 windows at  $t_0$  and  $t_2$  are actually located at the same point of the plane, although the figure depicts them on top of each other for the sake of clarity. Red wires can be traced in  $x_0$ , and blue wires in  $x_1$ . The wire of alternating colours can be traced within both, and so it is both homotopic to the initial path, and to the trivial path.

Let  $x_0, x_1$  respectively be the all-zero configuration, and the configuration containing a 1 at the origin. The path  $p$  can be homotopically deformed in the following way: between the times  $t_1$  and  $t_3$ , it can be considered to be entirely in  $x_1$ . It can thus be deformed in this configuration by completely avoiding the origin, and joining the same points, as in Figure 1b. By definition of  $x_1$ , this new path will now see only 0's. The resulting loop then also sees 0's at any point, and so it can be homotopically contracted to the trivial path in the configuration  $x_0$ . This proof can be extended to make any 1 on a path “disappear”, and so any path can be contracted. In this case, this shows that  $\pi_1^{proj}(X, (x_0, (0, 0))) = \{e\}$  is trivial, as the same argument works for arbitrary large  $B_n$ .

## 4 Realization of projective fundamental groups

We are now going to prove our main result: any finitely presented group is the fundamental projective group of some SFT.

► **Theorem 1.** *Let  $G = \langle S | R \rangle$  be a finitely presented group. Then, there is a subshift of finite type  $X$  satisfying:*

- $X$  is projectively connected,
- the projective fundamental group of  $X$  is isomorphic to  $G$ .

### 4.1 The construction

The subshift  $X$  that we construct will informally consist of oriented wires, drawn on an empty background, each wire corresponding to a generator  $s \in S$  of the group  $G = \langle S | R \rangle$ . We only authorize the wires to go up, perhaps in some kind of “zigzag” manner, but never down or horizontally. More precisely, we define the following tiles: first of all, a tile that we call **empty**, visually represented by  $\square$ , and we denote by  $\mathcal{T}_{\text{empty}}$  the singleton containing this tile. We denote by  $x_{\square} \in X$  the configuration which only contains empty tiles, and its patterns are called **empty patterns**. Then, for each element  $s \in \bar{S} = S \cup \{s^{-1} | s \in S\}$ , we also consider the set  $\mathcal{T}_s$  of the 5 following tiles:

If  $s \neq s'$ , then  $\mathcal{T}_s \cap \mathcal{T}_{s'} = \emptyset$ . Distinct  $\mathcal{T}_s$  will be represented by wires of different colours in the figures. These tiles will, intuitively, be used to represent generators of the group in valid configurations of  $X$ . Finally, we use some other tiles that will play the role of representing the group relations. We can always assume that  $R$  contains the trivial relators  $ss^{-1}$  and  $s^{-1}s$  for all  $s \in S$ . Now, for each relator  $r = r_1 r_2 \dots r_n \in R$ , we let  $\mathcal{T}_r$  be the tiles described by Figure 2.

■ **Figure 2** The relation tiles.

The wire exiting from the right side of the tile Figure 2a does *not* have the same colour as the one exiting from the top. The former colour is denoted by  $\bar{r}_1$ , to differentiate it from the actual  $r_1$  wires. In the other tiles,  $\bar{R}_i = \bar{r}_1 \bar{r}_2 \dots \bar{r}_i$ . Hence, for each relator  $r_1 \dots r_n$ , we have one tile of type Figure 2a and one of type Figure 2c, and  $n - 2$  tiles of type Figure 2b. Tiles belonging to some  $\mathcal{T}_r$  are called relation tiles. Note that if  $u \in R$  is such that it is the prefix of two different relators, *i.e.*, there exists  $v, v' \in \bar{S}^*$  such that  $uv \in R, uv' \in R$  then the colours  $\bar{u}$  are shared by the tiles used to represent those relators and so  $\mathcal{T}_{uv} \cap \mathcal{T}_{uv'} \neq \emptyset$ .  $X$  is the subshift generated by the tileset  $\mathcal{T} = \mathcal{T}_{\text{empty}} \cup \bigcup_{s \in \bar{S}} \mathcal{T}_s \cup \bigcup_{r \in R} \mathcal{T}_r$  along with the obvious adjacency rules: any wire must be extended, by a wire with the same orientation given by the arrows – *e.g.*,  $\begin{smallmatrix} \square \\ \uparrow \\ \square \end{smallmatrix}$  and  $\begin{smallmatrix} \square \\ \leftarrow \\ \square \end{smallmatrix}$  are forbidden patterns, but  $\begin{smallmatrix} \square \\ \uparrow \\ \square \\ \leftarrow \\ \square \end{smallmatrix}$  is allowed (assuming the two tiles contain a wire of the same colour).

We now formalize what we really mean by a wire.

► **Definition 13 (Wire).** A *wire* is a sequence  $\mathcal{U} = (T_t, \mathbf{v}_t)_{t \in I}, I \subseteq \mathbb{Z}$  a non-necessarily finite interval, of pairs of non-empty tiles and  $\mathbb{Z}^2$  points, such that

- $\|\mathbf{v}_{t+1} - \mathbf{v}_t\|_1 = 1$ ,
- The tile  $T_{t+1}$  in position  $\mathbf{v}_{t+1}$  extends the wire of tile  $T_t$  in position  $\mathbf{v}_t$ : placing a tile  $\begin{smallmatrix} \square \\ \uparrow \\ \square \end{smallmatrix}$  above or below another tile  $\begin{smallmatrix} \square \\ \uparrow \\ \square \end{smallmatrix}$  does extend it, while placing it on its right or left side does not, although they are valid patterns of  $X$ .
- $\mathcal{U}$  does not contain two consecutive relation tiles.

► **Remark 14.** We do not prevent a wire from moving back and forth: it is possible to have  $(T_t, \mathbf{v}_t) = (T_{t+2}, \mathbf{v}_{t+2})$ .

► **Definition 15** (Coherent wire). We say that a wire is *coherent* if there exists a configuration  $x \in X$  such that for any tile  $(T_i, \mathbf{v}_i)$  of the wire,  $x_{\mathbf{v}_i} = T_i$ .

► **Remark 16.** Valid configurations of  $X$  can contain non-intersecting infinite wires, and possibly some relation tiles with wires originating from them. Any relation tile belongs to one horizontal line of  $k$  relation tiles, corresponding to a valid relator  $r_1 \dots r_k$ .

One important concept associated to paths on this subshift is the idea that paths can cross wires. Informally, this is what happens when the window, and in particular, its center, moves from one side to the other of a given wire in a path.

► **Definition 17** (Crossing a wire tile). Let  $n > 0$ , and let  $\mathbf{v}, \mathbf{v}' \in \mathbb{Z}^2$  be two adjacent points, and  $P, P'$  two patterns of respective support  $\mathbf{v} + B_n, \mathbf{v}' + B_n$  such that  $(P, \mathbf{v}), (P', \mathbf{v}')$  is a valid path. For  $(i, j) \in B_n$ , let  $T_{(i,j)}$  be the tile whose bottom-left corner is on  $(i, j)$  in  $P$ . We say that this path crosses a wire tile if

■  $\mathbf{v}' - \mathbf{v} = e_0 = (1, 0)$  (resp.  $-e_0$ ) and the tile  $T_{\mathbf{v}}$  (resp.  $T_{\mathbf{v}-e_0}$ ) was of one of the following forms:

■  $\mathbf{v}' - \mathbf{v} = e_1 = (0, 1)$  (resp.  $-e_1$ ) at the next step  $t + 1$  and the tile  $T_{\mathbf{v}}$  (resp.  $T_{\mathbf{v}-e_1}$ ) was of one of the following form:

In the following, we let  $B_n = \{-n, \dots, n - 1\}^2$ . Unless stated otherwise, all the aperture windows considered will be of this form.

► **Definition 18** (Seeing a wire). A path  $p = (P_i, \mathbf{v}_i)_{i \leq N}$  sees a wire  $\mathcal{U}$  if there exists a timestep  $i \leq N$ , and  $(T_j, \mathbf{v}_j) \in \mathcal{U}$  such that the tile in position  $\mathbf{v}_j$  in  $P_i$  is  $T_j$ .

► **Definition 19** (Crossing a wire). A path crosses a wire if it crosses one of its tiles.

## 4.2 Only Crossed Wires Matter

Our final goal is to prove that the projective fundamental group of this subshift  $X$  is the group  $G = \langle S | R \rangle$ . To do so, the idea will be to associate an element of the group to each path, according to the wires that it crosses. The following lemmas can be seen as a procedure to put paths in some kind of normal form via homotopies, depending only the sequence of crossed wires, regardless of the underlying geometry of the path. All the lemmas consider paths that both start and end in empty patterns, but this is not really a restriction as we will later prove that the subshift  $X$  is projectively connected, and so we will only consider loops based at  $x_{\square}$ . Unless stated otherwise, all the considered paths are using some  $B_n$  as aperture window. We start with some easy statements about patterns of support  $B_n$ , and the wires they may contain.

► **Lemma 20** (Wire Order Lemma). Let  $x \in X$ , and let  $\mathcal{U}, \mathcal{V}$  be two infinite wires in  $x$ . Suppose that  $\mathcal{U}, \mathcal{V}$  do not contain relation tiles.

■ For all  $z \in \mathbb{Z}$ , there exists between one and two  $z_{\mathcal{U}}^0 \in \mathbb{Z}$  such that  $\mathcal{U}$  passes through the position  $(z_{\mathcal{U}}^0, z)$ . If there are two such  $z_{\mathcal{U}}^0$ , then they are necessarily adjacent, e.g.,  $\begin{bmatrix} \square & \square \\ \square & \square \end{bmatrix}$  side-by-side.

■ Let  $z \in \mathbb{Z}$ , and  $z_{\mathcal{U}}^0, z_{\mathcal{V}}^0 \in \mathbb{Z}$  as in the previous point respectively for  $\mathcal{U}$  and  $\mathcal{V}$ . If  $z_{\mathcal{U}}^0 < z_{\mathcal{V}}^0$ , then for all  $z_{\mathcal{U}}, z_{\mathcal{V}}, z \in \mathbb{Z}$  such that  $(z_{\mathcal{U}}, z) \in \mathcal{U}, (z_{\mathcal{V}}, z) \in \mathcal{V}$ , we have  $z_{\mathcal{U}} < z_{\mathcal{V}}$ . Intuitively, this means that wires can globally be ordered from left to right.

If  $\mathcal{U}$  or  $\mathcal{V}$  contains a relation tile, then the previous claims are true only for  $z$  large enough.

► **Remark 21.** Note that the previous lemma is true because we consider wires  $\mathcal{U}, \mathcal{V}$  belonging to some configuration. It is clearly false for arbitrary wires.

► **Lemma 22.** *Let  $P$  be a globally admissible pattern of support  $B_n$  for some  $n > 0$ . Let  $\mathcal{U}$  be a wire in  $P$  without relation tiles. Suppose that  $\mathcal{U}$  passes to the right (resp. left) of  $(0, 0)$  in  $P$ . Then,  $\mathcal{U}$  neither enters nor exits  $P$  on its left (resp. right) edge.*

**Proof.** This directly follows from the fact that no tile contains a horizontal wire, and that  $B_n$  is a square. ◀

► **Corollary 23.** *If  $P$  is a globally admissible pattern that sees a wire  $\mathcal{U}$  with no relation tiles, and  $x \in X$  is such that  $x|_{B_n} = P$ , then  $\sigma_{(0,1)}^{4n}(x)|_{B_n}$  and  $\sigma_{(0,1)}^{-4n}(x)|_{B_n}$  do not see  $\mathcal{U}$ .*

In order to show that the homotopy class of a path  $p$  is indeed only determined by the wires it crosses, we will need several lemmas in which the proof will always be similar: an induction on the length  $L$  of a Coherent path decomposition of  $p$ :

- for  $L = 1$  (i.e.  $p$  is coherent), we explicitly show how to deform  $p$  to obtain the required property.
- for  $L = 2$  we use the Path Co-extensibility Lemma to “normalize” both coherent subpaths of  $p$  using the base case  $L = 1$ .
- In general, if  $p = p_1 * \dots * p_N$ , we can deform both  $p_1$  and  $p_2$  so that  $p \sim p'_1 * p'_2 * \dots * p_N$ , in such a way that we can apply the base case to  $p'_1$ , and the induction case to  $p'_2 * \dots * p_N$ . The key step is therefore to properly show how to deal with the case  $L = 2$ ; this is the purpose of the Path Co-extensibility Lemma that we now show, after some preliminary results.

► **Lemma 24 (Finite Extension Lemma).** *Let  $P$  be an extensible finite pattern of  $X$ , there exists  $x \in X$  containing  $P$ , such that  $x$  contains a finite number of wires.*

► **Definition 25 (Cone).** *For  $n \in \mathbb{N}$ , we define the **cones***

$$C_n^- = \{(i, j) \mid j \leq 0, -|j| - n \leq i < |j| + n\} \quad C_n^+ = \{(i, j) \mid j \geq 0, -j - n \leq i < j + n\}$$

*We denote  $\partial C_n = C_n \cap ((\overline{C_n} + e_0) \cup (\overline{C_n} + e_1))$  the border of a cone.*

► **Lemma 26 (Extensibility Lemma).** *Let  $n > 0$ . There exists  $k > 0$  such that for any  $x \in X$ , there exists  $x' \in X$  with:*

- $x'|_{C_n^\pm} = x|_{C_n^\pm}$
- $x'|_{\sigma_{(0,k)}(C_n^\mp)} = x|_{\sigma_{(0,k)}(C_n^\mp)}$

**Proof.** We prove the case where  $x'$  is empty in a cone above the  $y = 0$  line, and equal to  $x$  below it, the other case being similar. Let  $r$  be the length of the longest relator in the finite presentation of  $G = \langle S|R \rangle$ . Let  $W \subset \mathbb{Z}^2$  be the set of positions of tiles that are part of a wire of  $x$  that:

- either passes by  $C_n^-$
- or originates from a relation tile which is itself part of a relator intersecting  $C_n^-$ .

Now, construct  $x'$  as follows:

- for  $(i, j) \in C_{n+r}^- \cap W$ , set  $x'_{(i,j)} = x_{(i,j)}$ . The other tiles of  $C_{n+r}^-$  are empty.
- for  $(i, j) \in \partial C_{n+r}^- \cap W$  and  $j < 0$ , extend the wire above  $(i, j)$  using only tiles  $\boxplus$  and  $\boxminus$  if  $i < 0$ , or  $\boxdot$  and  $\boxdash$  if  $i > 0$ .
- each wire of  $W$  passing by  $(i, 0)$  with  $|i| \leq n + r$  is extended by  $n - |i| + r$  tiles  $\boxplus$ , and then by tiles of the form  $\boxplus$  and  $\boxminus$  if  $i < 0$ , or  $\boxdot$  and  $\boxdash$  if  $i \geq 0$ .
- all the other tiles are empty.

## 75:10 Finitely Presented Groups as Fundamental Groups of Subshifts

Then,  $x'$  is a valid configuration of  $X$  and:

- By definition of  $W$ ,  $x', x$  coincide on  $C_n^-$ .
- $\partial C_{n+r}^-$  contains no relation tile, by definition of  $W$  and  $r$ .
- $(0, n+r+1) + C_n^+$  is empty. See for example Figure 3.

■ **Figure 3** Construction of  $x'$  (on the right) from  $x$  (on the left). In both figures, the central dot is the origin  $(0, 0)$ .

► **Corollary 27** (Path Co-extensibility Lemma). Let  $p = ((P_t, \mathbf{u}_t))_{t \leq N_p}$  and  $q = ((Q_t, \mathbf{v}_t))_{t \leq N_q}$  be two paths with the same aperture window  $B_n$ , satisfying:

- Both  $p$  and  $q$  are coherent paths
- $(P_{N_p}, \mathbf{u}_{N_p}) = (Q_0, \mathbf{v}_0)$  (equivalently,  $p * q$  is well-defined)
- $u_0^1 = v_{N_q}^1$  (i.e.  $q$  ends at the same height as  $p$  starts)

Then, there exists  $p', q', r$  paths such that:

- $r$  ends on an empty pattern
- $p' * r$  and  $r^{-1} * q'$  are well-defined and are both coherent paths.
- $p \sim p'$  and  $q \sim q'$

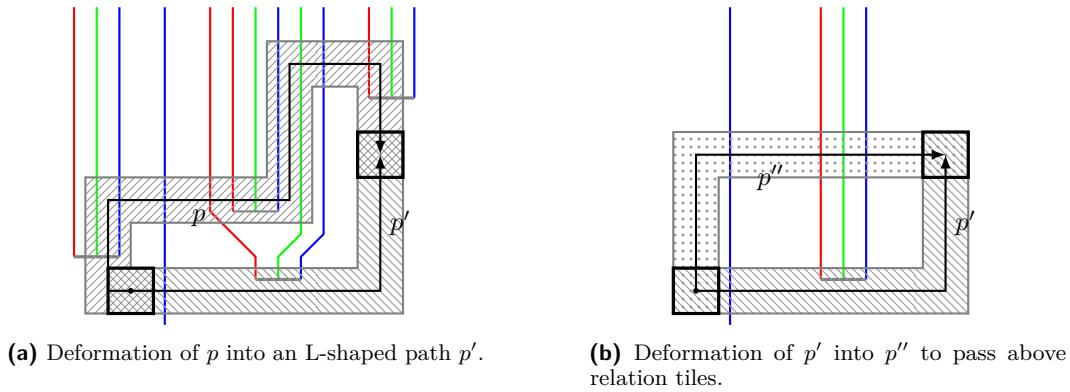

**Proof.** We may assume that  $u_0^1 \leq u_{N_p}^1$ , i.e. the ending point of  $p$  is higher than its starting point, the other case being similar. We can also assume that  $u_{N_p}^1$  is the highest point in the entire trajectory of both  $p$  and  $q$  (we can always homotopically deform  $p$  and  $q$  so that this is true), and up to some shift, we can assume that  $\mathbf{u}_{N_p} = (0, 0)$ . Consider now  $P \subset \mathbb{Z}^2$  so that  $P$  contains all the  $P_t$  and  $Q_t$ . Let  $x_p, x_q$  be configurations in which  $p, q$  can respectively be traced. Take  $N$  large enough so that  $P \subset C_N^-$ . Then, applying the Extensibility Lemma to  $x_p, N$  on one hand,  $x_q, N$  on the other hand, gives two configurations  $x'_p, x'_q \in X$ . Let  $r$  be the path obtained by moving up for  $2N + 1$  steps in either  $x'_p$  or  $x'_q$ , starting from the origin, which is the same path in both cases. Then  $r$  satisfies the conditions of Path Co-extensibility Lemma.

We are now ready to prove the main lemmas needed to show Theorem 1.

► **Lemma 28** (No Relation Tile Lemma). Let  $p$  be a path starting and ending on an empty pattern. Then there exists  $p' \sim p$  that does not contain any relation tile.

**Proof.** As explained above, the proof is by induction on the length of a coherent path decomposition of  $p$ . The base case when  $p$  is a coherent path is illustrated in Figure 4. See the appendix of the full version for the full proof.

► **Lemma 29** (Single Wire Lemma). Let  $p = (P_i, \mathbf{v}_i)_{0 \leq i \leq N}$  be a path starting and ending with empty patterns. There exists a path  $p'$ , homotopic to  $p$ , such that the union of any two consecutive patterns in  $p'$  contains at most a single wire.

■ **Figure 4** A coherent path deformed so as not to see relation tiles.

■ **Figure 5** Deformation of  $p$  into  $p'$  in a single configuration to see only one wire per pattern.

**Proof.** As for the No Relation Tile Lemma, we illustrate in Figure 5 the case where  $p$  is itself coherent. For the full proof, see the appendix of the full version. ◀

► **Lemma 30 (No Uncrossed Wire Lemma).** *Let  $p$  be a path starting and ending with empty patterns, and  $U$  some wire seen but not crossed by  $p$ . There exists a path  $p'$ , homotopic to  $p$ , which does not see  $U$ .*

**Proof.** The idea is that using the previous Single Wire Lemma, we can deal with each wire independently. In particular, the uncrossed wire  $U$  is the only wire seen by some subpath  $p'$  of  $p$ , and is not seen by  $p$  neither before nor after  $p'$ . Hence, it suffices to show the result for paths seeing a single wire overall. In that case, one observes that  $U$  has to stay in the same “side” of the aperture window along  $p'$ , that can therefore be deformed without crossing  $U$  by moving sufficiently far in the opposite direction. For more details, see the appendix of the full version. ◀

► **Lemma 31 (Cross Anywhere Lemma).** *Let  $p$  be a path starting and ending with empty patterns. If  $p$  sees no relation tiles, but sees and crosses a single wire  $U$  exactly once, then for all  $\mathbf{v} = (v^0, v^1) \in \mathbb{Z}^2$ ,  $p$  is homotopic to a path  $p'$  which crosses  $U$  exactly on  $\mathbf{v}$ .*

**Proof.** The idea is that if  $U$  exits the aperture window  $B_n$  of  $p$  in position  $(i, j) \in \mathbb{Z}^2$ , it can be extended using tiles  $\square$  and  $\square$ , or  $\square$  and  $\square$ , to pass anywhere inside  $(i, j) + C_n^-$  or  $(i, j) + C_n^+$ . The path  $p$  can then be deformed to cross it anywhere in those two cones. Using

several such deformations, we can deform  $p$  so that it crossed  $\mathcal{U}$  anywhere in the plane. Note that even if  $p$  is initially coherent, it might happen that  $p'$  is not, depending on  $\mathbf{v}$  and where  $p$  initially crossed  $\mathcal{U}$ . See the appendix of the full version for the complete proof. ◀

### 4.3 Projective connectedness

► **Lemma 32** (Projective connectedness).  *$X$  is projectively connected.*

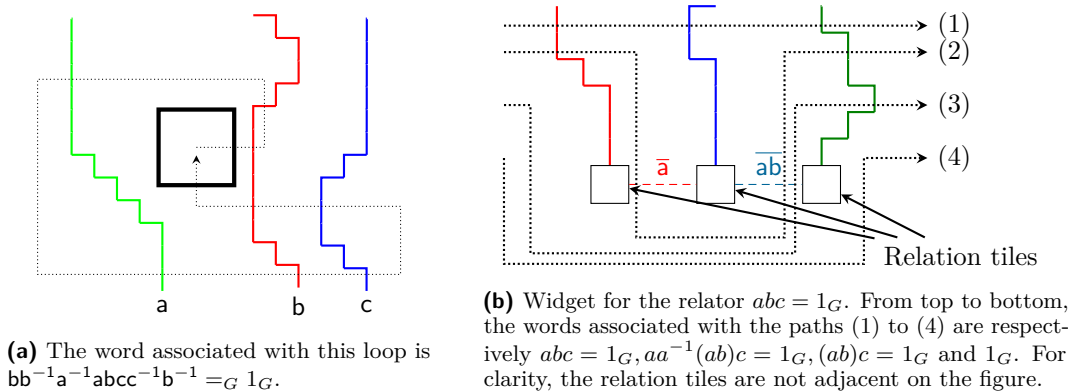

**Proof.** The proof relies on the Extensibility Lemma. The idea is that starting from any configuration  $x$ , there always exists a configuration  $x'$  containing a infinite cone (see Definition 25) of  $x_\square$ , and an infinite cone of  $x$ . We can then use this configuration to construct for  $n > 0$  a path  $p_n$  with aperture window  $B_n$  that first moves sufficiently far into the latter cone in  $x$ , then to the former cone in the configuration  $x'$ , and finally comes back to the origin in  $x_\square$ . See the appendix of the full version for the precise proof. ◀

### 4.4 Computing the projective fundamental group

We can now compute  $\pi_1^{proj}(X)$ , which is independent of the basepoint since  $X$  is projectively connected. Hence, unless stated otherwise, all the loops in this proof are based at  $(x_\square, (0, 0))$ . With any such loop  $p$ , we associate a word  $\llbracket p \rrbracket$  on the alphabet  $\bar{S}$  in the following way:

- If  $p$  does not cross any wire, we associate the empty word with it,  $\llbracket p \rrbracket = \varepsilon$ .
- If  $p$  crosses a single wire  $\mathcal{U}$ , then:
  - If  $\mathcal{U}$  is not a horizontal wire found on a relation tile, and  $s \in \bar{S}$  is the generator corresponding to  $\mathcal{U}$  (see Subsection 4.1)
    - \* if  $p$  crosses it from left to right, or from top to bottom on a tile shaped as  $\begin{smallmatrix} \square \\ \square \end{smallmatrix}$ , or from bottom to top on a tile  $\begin{smallmatrix} \square \\ \square \end{smallmatrix}$ , then  $\llbracket p \rrbracket = s \in \bar{S}$ .
    - \* if  $p$  crosses it in any other direction, we set  $\llbracket p \rrbracket = s^{-1} \in \bar{S}$
  - Otherwise,  $\mathcal{U}$  is a horizontal wire on a relation tile. Let  $\bar{R}_i = \bar{r}_0 \dots \bar{r}_i$  be its colour.
    - \* If it is crossed from top to bottom, then  $\llbracket p \rrbracket = \bar{r}_i^{-1} \dots \bar{r}_0^{-1} \in \bar{S}^*$
    - \* Otherwise,  $\llbracket p \rrbracket = R_i = r_0 \dots r_i$
- If  $p = p_1 * p_2$ , then  $\llbracket p \rrbracket = \llbracket p_1 \rrbracket \cdot \llbracket p_2 \rrbracket \in \bar{S}^*$  where  $\cdot$  represents the concatenation in  $\bar{S}^*$ .

Some examples are given in Figure 6a and Figure 6b.

■ **Figure 6** Some examples of words and group elements associated with coherent paths.

For any two words  $w, w'$  on  $\bar{S}$ , we write  $w \equiv w'$  if they are equal as words on this alphabet, and  $w =_G w'$  if they represent the same element of the group  $G$ . Let  $\leftrightarrow_R$  be the relation defined as the symmetric closure of  $\{(uvw, uv) \mid w \in R \text{ and } u, v \in (\bar{S})^*\}$ , corresponding to the operation of inserting and removing relators to words. We can always suppose that it is

reflexive by adding the empty word  $\varepsilon$  to the relators. We denote  $\leftrightarrow_R^*$  its transitive closure. By definition,  $w \leftrightarrow_R^* w' \iff w =_G w'$  (see e.g., [28, Theorem 1.1]). For example, if we take  $a \in S$ , we have  $aa^{-1} =_G 1_G$ , but  $aa^{-1} \neq \varepsilon$ .

In order to prove that the projective fundamental group of this subshift is  $G$ , we will prove that the operation  $\llbracket p \rrbracket$  entirely characterizes a loop up to homotopy, in the sense that loops associated with the same element of  $G$  are exactly a projective loop-class:

► **Lemma 33** (Homotopic Implies Equal). *For any window  $B_n$  and for any pair of loops  $p_n, p'_n$  starting at  $(x_{\square|B_n}, (0, 0))$ ,  $p_n \sim_{B_n} p'_n \implies \llbracket p_n \rrbracket =_G \llbracket p'_n \rrbracket$ .*

► **Lemma 34** (Equal Implies Homotopic). *For any window  $B_n$  and for any pair of loops  $p_n, p'_n$  starting at  $(x_{\square|B_n}, (0, 0))$ ,  $\llbracket p_n \rrbracket =_G \llbracket p'_n \rrbracket \implies p_n \sim_{B_n} p'_n$ .*

The full proofs can be found in the appendix of the full version.

► **Theorem 35.**  $\pi_1^{proj}(X) = G$

**Proof.** Let  $n > 0$  and let  $\Phi_n: p \in \pi_1^{B_n}(X, (x_{\square}, (0, 0))) \mapsto \llbracket p \rrbracket \in G$  be the function which associates with a loop-class with aperture window  $B_n$  the corresponding element of  $G$ . The Homotopic Implies Equal and Equal Implies Homotopic show that it is well-defined and injective. Let  $[p], [p']$  be two loop-classes based at  $(x_{\square|B_n}, (0, 0))$ . We have shown that  $[p] \sim_{B_n} [p'] \iff \Phi_n([p]) =_G \Phi_n([p'])$ . Now notice that  $\Phi_n([p * p']) =_G \Phi_n(p) \cdot_G \Phi_n(p')$ , i.e.,  $\Phi_n$  is a group morphism. To show that it is surjective, let  $g \in G$  any element, and  $u_1 \dots u_n \in \bar{S}^*$  such that  $u_1 \dots u_n =_G g$ . Let  $x^g$  the following configuration:

- For  $1 \leq i \leq \ell$  and  $j \in \mathbb{Z}$ ,  $x^g(i, j)$  is a tile of type  $\square$  and of colour  $u_i$
- Otherwise,  $x^g(i, j) = \square$

Now, consider the following loop: define  $p_n$  as the loop based at  $(x_{\square|B_n}, (0, 0))$ , which:

- moves left for  $n$  steps in  $x_{\square}$
- moves right for  $2n + \ell$  steps in  $x^g$  – at this point, it sees an empty pattern, after having crossed all the wires of  $x^g$
- comes back to  $(0, 0)$  in  $x_{\square}$ .

By definition,  $\llbracket p_n \rrbracket \equiv u_1 \dots u_n =_G g$ .

Furthermore, notice that for any loop-class  $[p_{n+1}]$  based at  $(x_{\square|B_{n+1}}, (0, 0))$ , if  $p_{n+1}$  projects down to  $p$  then  $\Phi_{n+1}([p_{n+1}]) =_G \Phi_n([p])$ . This shows that  $\pi_1^{proj}(X, (x_{\square}, (0, 0)))$  is isomorphic to  $G$ , and the final result follows from the fact that  $X$  is projectively connected. ◀

# Deciding Predicate Logical Theories Of Real-Valued Functions

Stefan Ratschan   

Institute of Computer Science of the Czech Academy of Sciences, Prague, Czech Republic

---

## Abstract

The notion of a real-valued function is central to mathematics, computer science, and many other scientific fields. Despite this importance, there are hardly any positive results on decision procedures for predicate logical theories that reason about real-valued functions. This paper defines a first-order predicate language for reasoning about multi-dimensional smooth real-valued functions and their derivatives, and demonstrates that – despite the obvious undecidability barriers – certain positive decidability results for such a language are indeed possible.

**2012 ACM Subject Classification** Mathematics of computing → Continuous functions; Theory of computation → Automated reasoning; Theory of computation → Logic and verification

**Keywords and phrases** decision procedures, first-order predicate logical theories, real numbers, real-valued functions

## 1 Introduction

Predicate logical decision procedures have become a major workhorse in computer science, for example, as the basic reasoning engines in SAT modulo theory (SMT) solvers [3]. Common decision procedures support theories such as uninterpreted function symbols, arrays, linear integer arithmetic, and real arithmetic. However, many areas of computer science (e.g., computer aided design, formal verification of physical systems, machine learning) use as their basic data structure not only real numbers but real-valued *functions*, for example, to represent solid objects [13], correctness certificates [30, 29] or neural networks [1]. Moreover, due to their fundamental role as a basic mathematical object, real-valued functions are used as a basic modeling tool throughout many further scientific areas. But unfortunately, real-valued functions have been left almost completely untouched by research on predicate logical decision procedures. The goal of this paper is to take a first step to fill this gap.

More concretely, the paper provides the following contributions:

- We formalize a first-order language of real-valued functions that allows reasoning about both real numbers and multi-dimensional real-valued smooth functions based on the usual arithmetical operations, function evaluation and differentiation.
- We prove that a quantifier-free fragment of the language that restricts arithmetic to addition and multiplication of real numbers, but still provides function evaluation and differentiation, is decidable.
- We prove that for a fragment of the language that keeps the restriction of arithmetic to addition and multiplication of real numbers but allows arbitrary quantification on real-valued variables (but not on function-valued variables), there is an algorithm that can detect satisfiability for all input formulas that are robustly satisfiable in the sense that there is a satisfying assignment that stays satisfying under small perturbations of the values of function-valued variables.

We neither claim theoretical nor practical efficiency of the resulting decision procedures. Instead, our goal is to overcome scientific fragmentation by developing a framework that can be instantiated to more efficient techniques for specific applications.

The paper has the following structure: In the next section, we discuss related work. In Section 3, we define the syntax and semantics of the mentioned predicate language for reasoning about smooth real-valued functions. In Section 4 we prove decidability of the quantifier-free case. In Section 5 we discuss decidability of the case with arbitrary quantification on real-valued variables. In Section 6 we conclude the paper.

## 2 Related Work

Reasoning about real-valued functions – that we also simply call *real functions* – will, of course, be usually based on reasoning about real numbers. This is facilitated by the fact that unlike the case of the integers, in the case of the real numbers, its non-linear theory (i.e., the theory of real closed fields) is decidable [38]. The decidability of the case with the exponential function is still unknown, but is decidable provided Schanuel’s conjecture holds [25]. Inclusion of the sine function makes the problem undecidable since – as a periodic function – it is able to encode the integers. This makes any theory that allows reasoning about systems of linear ordinary differential equations (ODEs) undecidable, since the sine function appears as the solution of the linear ODE  $\dot{x} = -y, \dot{y} = x$ .

In mathematical analysis, real functions are often abstracted to elements of abstract function spaces such as Banach spaces and Hilbert spaces [24]. However, with one notable exception [37] we are aware of, corresponding predicate logical decision problems have been largely ignored by computer science.

An important occurrence of real functions is in the role of solutions of ordinary differential equations (ODEs) and hybrid dynamical systems. Formal verification of such systems has been an active research topic over many years [10], with a plethora of decidability and undecidability results [16, 8, 23, 4, 5]. Deductive verification bases formal verification on automated reasoning frameworks such as hybrid dynamic logic [29], or proof assistants such as Isabelle/HOL [15]. Reasoning with functions as the solution of ODEs has been included into SAT solvers without formulation as a first-order decision problem [12, 18]. ODEs have also played a role as objects in constraint programming [21]. In contrast to the work mentioned in this paragraph, in this paper, we introduce a general logical language with variables and predicate and function symbols ranging over real-valued functions. Especially, we allow multi-dimensional functions and partial differentiation, whereas ODEs and hybrid systems are defined using one-dimensional functions, only (the single dimension being time).

Computation in function spaces plays a major role in numerical analysis, where it is mostly restricted to representing solutions to certain specific computation problems, especially, solving ordinary or partial differential equations. There are also some general approaches to computing with functions [11, 9]. However, the basic assumption in numerical analysis is that the solution to the given problem exists and is unique, and the goal is to compute an approximation of this solution, whereas in this paper we consider satisfiability questions, where a proof of existence is the goal, not an assumption.

Computer algebra [41] studies computation with symbolic objects, especially polynomials, that can be interpreted as representations of real functions. Unlike that, in this paper we are interested in solving problems of reasoning about functions that are independent from a certain representation.

The proof of decidability of the quantifier-free case will be based on abstracting function variables to uninterpreted function symbols. Abstraction to uninterpreted function symbols is a classical technique in formal verification [6] that has also been applied to real functions [7], but with the goal of modeling *specific* function symbols, while in this paper we are interested in general reasoning about smooth real functions and their derivatives.

For quite some time, robustness has been recognized as tool for characterizing solvable cases of undecidable decision problems. It was used for dynamical systems [16, 2] and for decision procedures for the real numbers [32, 17]. However, all of those results do not allow a general language for reasoning about real functions.

### 3 Formal Syntax and Semantics

In this section, we define the syntax and semantics of the first-order language for reasoning about real functions that we will want to decide. As a first example, consider the formula

$$\exists X \forall u, v . \text{app}(\partial_1 X, u, v) = 1 \wedge \text{app}(\partial_2 X, u, v) \leq u^2,$$

that asks the question whether there exists a smooth function in  $\mathbb{R}^2 \rightarrow \mathbb{R}$  whose partial derivative in its first argument is one everywhere, and whose partial derivative in its second argument is less or equal the square of its first argument. The reader will find more examples at the beginning of each of the two following sections.

The language will be sorted, allowing variables that range over real numbers and variables that range over real functions. We denote the sort ranging over real numbers, that we also call the *scalar sort*, by  $\mathcal{R}$ , and the sorts ranging over real-valued functions, that we also call the *function sorts*, by  $\mathcal{F}_n$ , where  $n \in \mathbb{N}$  refers to the number of arguments (i.e., dimension of the domain). We will also use the symbol  $\mathcal{F}$  to stand for any sort  $\mathcal{F}_i, i \in \mathbb{N}$ . For each of those sorts, we assume a corresponding set of variables  $\mathcal{V} = \mathcal{V}_{\mathcal{R}} \cup \mathcal{V}_{\mathcal{F}_1} \cup \mathcal{V}_{\mathcal{F}_2} \dots$ . We will write the elements of  $\mathcal{V}_{\mathcal{R}}$  using lower-case letters and the elements of  $\mathcal{V}_{\mathcal{F}_1} \cup \mathcal{V}_{\mathcal{F}_2} \dots$  using upper case letters. We will also use the symbol  $\mathcal{V}_{\mathcal{F}}$  to denote the set of all function variables  $\mathcal{V}_{\mathcal{F}_1} \cup \mathcal{V}_{\mathcal{F}_2} \dots$ .

We will build formulas based on the usual syntax of many-sorted first-order logic. Here, we allow rational constants, arithmetical function symbols such as  $+$ ,  $\times$ ,  $\exp$ ,  $\sin$ , and predicate symbols  $=, \leq, \geq, <, >$  that have the usual arity. For every  $n \in \mathbb{N}$ , we allow the function symbols  $\text{app} : \mathcal{F}_n \times \mathcal{R}^n \rightarrow \mathcal{R}$  and  $\partial_i : \mathcal{F}_n \rightarrow \mathcal{F}_n, i \in \{1, \dots, n\}$  that we call app-operator and differentiation operator, respectively. As usual, we will often write the differentiation operator without parenthesis, and for  $X \in \mathcal{F}_1$ , we also write  $\dot{X}$  instead of  $\partial_1 X$ . We will also call a term whose outermost symbol is the function symbol  $\text{app}$ , an *app-term*.

We will call formulas whose function symbols are restricted to  $\{+, \times, \text{app}\} \cup \{\partial_i \mid i \in \mathbb{N}\}$ , and hence avoiding transcendental function symbols, *function-algebraic*. As already mentioned in the introduction, in this paper, we concentrate on this case.

We define the semantics of formulas by defining a structure  $\mathfrak{A}$  giving the usual real-valued semantics to all function and predicate symbols. This allows us to avoid questions of axiomatization and, at the same time, ensures compatibility with the common intuition. Clearly, satisfiability of a formula based on classical mathematical semantics, implies its satisfiability wrt. an arbitrary axiomatization compatible with classical mathematics.

In more detail, the structure  $\mathfrak{A}$  will be many-sorted, where the sort  $\mathcal{R}$  ranges over the real numbers  $\mathbb{R}$  and the sorts  $\mathcal{F}_n, n \in \mathbb{N}$  range over the set of smooth (i.e., infinitely often differentiable) functions in  $\mathbb{R}^n \rightarrow \mathbb{R}$ . We will use the notation that for any smooth function  $F : \mathbb{R}^n \rightarrow \mathbb{R}$ , and tuple  $(\beta_1, \dots, \beta_n) \in \mathbb{N}_0^n$ ,  $D^{(\beta_1, \dots, \beta_n)} F$  denotes the function that is the result

of differentiating for every  $i \in \{1, \dots, n\}$  the function  $F$   $\beta_i$ -times wrt. its  $i$ -th component. The semantics of function and predicate symbols on the real numbers will be as usual. The app-operator and differentiation operator are defined as follows:

- For every  $n \in \mathbb{N}$ , for all  $X \in \mathcal{F}_n$ ,  $\mathfrak{A}(\text{app})(X, x_1, \dots, x_n) = X(x_1, \dots, x_n)$  (i.e., function application in its usual mathematical sense)
- For every  $n \in \mathbb{N}$ ,  $i \in \{1, \dots, n\}$ , for every  $X \in \mathcal{F}_n$ ,  $\mathfrak{A}(\partial_i)(X) = D^d X$ , where  $d \in \mathbb{N}_0^n$  with  $d(i) = 1$  and for every  $k \neq i$ ,  $d(k) = 0$  (i.e., the result of taking the derivative of  $X$  wrt. its  $i$ -th argument).

We will denote the set of variable assignments assigning to each variable an element of its respective domain, by  $\aleph$ . Given an assignment  $\alpha \in \aleph$  we can now assign semantics to formulas in the usual way, writing  $\alpha \models \phi$  iff the interpretation given by structure  $\mathfrak{A}$  and assignment  $\alpha$  satisfies  $\phi$ . We call a formula  $\phi$  *satisfiable* iff there is an assignment  $\alpha \in \aleph$  such that  $\alpha \models \phi$ . In such a case we will also say that  $\phi$  is  $\mathcal{F}$ -satisfiable. By abuse of notation, we will use the symbol  $\mathcal{F}$  to not only denote the function sorts, but also the *theory*  $\mathcal{F}$  of  $\mathcal{F}$ -satisfiable formulas.

#### 4 Quantifier-Free Case

In this section, we consider formulas that are quantifier-free and function-algebraic. Here are some examples:

- $\text{app}(X, t) \geq 1 \wedge \text{app}(X, t+1)^2 \leq 1$ : This formula restricts the value of the function  $X$  at two different points  $t$  and  $t+1$ . Since these points are different, for checking satisfiability of the formula, it suffices check satisfiability of the algebraic inequalities  $r \geq 1 \wedge s^2 \leq 1$ . Based on a satisfying assignment for this formula, we get a satisfying assignment for the original formula by assigning to  $X$  a function interpolating between the values for  $r$  and  $s$ .
- $\text{app}(X, 0) = 0 \wedge \text{app}(\dot{X}, 1) = \text{app}(X, 1)^2$ . This formula not only restricts values for the function  $X$ , but also states a relationship between the value of  $X$  and its derivative. The formula is satisfiable since the identity function satisfies the properties stated by the formula.
- $\text{app}(\partial_1 X, t) = 1 \wedge \text{app}(\partial_2 X, t) = 1$ . This formula states a relationship between two partial derivatives of  $X$  at the same value  $t$ . This holds, for example, for the function  $X$  with  $X(u, v) = u + v$ .

The basic idea for deciding such formulas is, that quantifier-free formulas constrain the values of function variables only at a finite (but not fixed) subset of their domain which will allow us to treat them as uninterpreted function symbols. To do so, we have to get rid of the app- and differentiation operators. For this, observe that the only syntactic elements that result in terms of function sort are function variables and differentiation operators. Hence, differentiation operators can only occur in the form of terms of the form  $\partial_{i_1} \partial_{i_2} \dots \partial_{i_n} V$ . So we let  $\tau_\partial(\phi)$  be the formula resulting from replacing every maximal term of this form (i.e., every term of this form that is not an argument of a differentiation operator) by a fresh function variable  $V_{i_1, \dots, i_n}$ . For example,

$$\tau_\partial(\text{app}(\partial_1 X, t) + \text{app}(\partial_2 X, t) = 1) \equiv \text{app}(X_1, t) + \text{app}(X_2, t) = 1.$$

The next step is to get rid of the app operator. For this, we denote, for every quantifier-free formula  $\phi$ , by  $\tau(\phi)$  the result of replacing every app-term  $\text{app}(X, t_1, \dots, t_k)$  of  $\tau_\partial(\phi)$  by  $X(t_1, \dots, t_k)$  where in the resulting formula, we now consider  $X$  a  $k$ -ary function symbol.

Continuing the example, we get

$$\tau(\text{app}(\partial_1 X, t) + \text{app}(\partial_2 X, t) = 1) \equiv X_1(t) + X_2(t) = 1.$$

The resulting formula is a formula in the language defined by the combination of the signature of the theory of real-closed fields and the signature of the theory of uninterpreted function symbols. The combination of these two theories, that we will denote by  $\mathcal{RU}$ , is decidable: The signatures of the theory of uninterpreted function symbols and the theory of real-closed fields only share equality, and both are stably infinite<sup>1</sup>, hence the decision procedures for the individual procedures can be combined to a decision procedure for the combined theory by the Nelson-Oppen theory combination procedure [27, 6]. As a consequence, we can algorithmically decide  $\mathcal{RU}$ -satisfiability of translated formulas  $\tau(\phi)$ . Moreover, the translation preserves satisfiability:

► **Theorem 1.** *A conjunctive formula  $\phi$  is  $\mathcal{F}$ -satisfiable if and only if  $\tau(\phi)$  is  $\mathcal{RU}$ -satisfiable.*

For proving this theorem, we have to bridge two differences between  $\mathcal{F}$ - and  $\mathcal{RU}$ -satisfiability: First, the semantics of  $\mathcal{F}$ -satisfiability restricts the domain of function variables to specific functions, more concretely, to smooth real function. And second, the theories of real closed fields and uninterpreted function symbols are defined using axioms, unlike our theory  $\mathcal{F}$  that we defined semantically, by fixing a certain structure. Before going into the details of the proof, we state a few lemmas. The first one extracts the non-algorithmic core of the Nelson-Oppen method [27, 39, 6]:

► **Lemma 2.** *Let  $T_1$  and  $T_2$  be two stably infinite theories of respective signatures  $\Sigma_1$  and  $\Sigma_2$ , having only equality in common. Let  $\phi_1$  be a conjunctive  $\Sigma_1$ -formula, and  $\phi_2$  a conjunctive  $\Sigma_2$ -formula. Then  $\phi_1 \wedge \phi_2$  is  $(T_1 \cup T_2)$ -satisfiable iff there is an equivalence relation  $E$  on the common variables  $V := \text{var}(\phi_1) \cap \text{var}(\phi_2)$  s.t.  $\phi_1 \wedge \rho(V, E)$  is  $T_1$ -satisfiable and  $\rho(V, E) \wedge \phi_2$  is  $T_2$ -satisfiable, where  $\rho(V, E)$  is the formula*

$$\bigwedge_{u,v \in V . uEv} u = v \wedge \bigwedge_{u,v \in V . \neg(uEv)} u \neq v.$$

Every  $(\Sigma_1 \cup \Sigma_2)$ -formula  $\phi$  can be brought into an equi-satisfiable formula of the form  $\phi_1 \wedge \phi_2$ , where  $\phi_1$  is a  $\Sigma_1$ -formula, and  $\phi_2$  is a  $\Sigma_2$ -formula using the so-called variable abstraction phase of the Nelson-Oppen method. In our case,  $T_1$  is the theory of real closed fields, and  $T_2$  the theory of uninterpreted function symbols. For the result

$$X(t) \geq 1 \wedge X(t+1)^2 \leq 1,$$

of translating the first example from the beginning of the section, the result of the variable abstraction phase is the equi-satisfiable formula

$$v_1 \geq 1 \wedge v_2 = t + 1 \wedge v_3^2 \leq 1 \wedge v_1 = X(t) \wedge v_3 = X(v_2).$$

The common variables are  $\{v_1, v_2, v_3, t\}$ , and the equivalence relation induced by the set of equivalence classes  $\{\{v_1, v_3\}, \{v_2\}, \{t\}\}$  illustrates Lemma 2, since

$$v_1 \geq 1 \wedge v_2 = t + 1 \wedge v_3^2 \leq 1 \wedge v_1 = v_3 \wedge v_1 \neq v_2 \wedge v_3 \neq v_2$$

<sup>1</sup> A theory  $T$  with signature  $\Sigma$  is called stably infinite iff for every quantifier-free  $\Sigma$ -formula  $\phi$ , if  $F$  is  $T$ -satisfiable, then there exists some  $T$ -interpretation that satisfies  $F$  and has a domain of infinite cardinality [27, 6].

is satisfiable in the theory of real-closed fields, and

$$v_1 = X(t) \wedge v_3 = X(v_2) \wedge v_1 = v_3 \wedge v_1 \neq v_2 \wedge v_3 \neq v_2$$

is satisfiable in the theory of uninterpreted function symbols.

The second lemma states a Hermite-like interpolation property whose proof follows from standard techniques in mathematical analysis.

► **Lemma 3.** *Let  $p$  be a function from a finite subset  $P$  of  $\mathbb{R}^n \times \mathbb{N}_0^n$  to  $\mathbb{R}$ . Then there exists a smooth function  $F : \mathbb{R}^n \rightarrow \mathbb{R}$  s.t. for every  $(x, d) \in P$ ,  $(D^d F)(x) = p(x, d)$ .*

**Proof.** Let  $X$  be the set  $\{x \mid (x, d) \in P\}$ . This set is finite, and hence the elements of  $X$  are isolated. For each  $c \in X$ , construct a smooth function  $f_c$  which for all  $d$  with  $(c, d) \in P$ ,  $(D^d f_c)(c) = p(c, d)$ . Let  $F : \mathbb{R}^n \rightarrow \mathbb{R}$  be such that for all  $x \in \mathbb{R}^n$ ,  $F(x) = \sum_{c \in X} B_c(f_c(x))$ , where  $B_c$  is a smooth function that is equal to the identity function in a sufficiently small neighborhood of  $c$ , and zero around all other elements of  $X$  (i.e., a so-called bump function). Then  $F$  satisfies the desired property. ◀

Now we return to the proof of Theorem 1:

**Proof.** To prove the  $\Rightarrow$  direction, we assume a variable assignment  $\alpha$  that  $\mathcal{F}$ -satisfies  $\phi$  and construct an interpretation that satisfies both the axioms of  $\mathcal{RU}$  and the formula  $\tau(\phi)$ . The interpretation is based on the structure of the real numbers, interprets the symbols  $\{0, 1, +, \times, \leq, <, \geq, >\}$  in the usual mathematical way, interprets the function symbols introduced by the translation  $\tau$  as the corresponding smooth real-valued functions given by  $\alpha$  and their respective derivatives, and assigns to the variables of  $\tau(\phi)$  the corresponding real values given by  $\alpha$ . The result satisfies the formula  $\phi$  by construction and satisfies the axioms of  $\mathcal{RU}$  since the real numbers are an instance of the theory of real closed fields,

We are left with proving the  $\Leftarrow$  direction. For this, we assume that  $\tau(\phi)$  is  $\mathcal{RU}$ -satisfiable, and build an assignment that satisfies  $\phi$ , assigning to each variable of  $\phi$  an element of the domain of its respective sort (i.e., either a real number and or a smooth real function).

Observe that both the theory of real closed fields and the theory of uninterpreted function symbols are stably infinite. Hence we can apply the Nelson-Oppen method. Let the formulas  $\pi_R$  and  $\pi_U$  be the result of applying the variable abstraction phase of the Nelson-Oppen method to  $\tau(\phi)$ . Hence,  $\pi_R$  is a formula in the language of real closed fields, and  $\pi_U$  a formula in the language of uninterpreted function symbols s.t.  $\pi_R \wedge \pi_U$  is  $\mathcal{RU}$ -equi-satisfiable with  $\tau(\phi)$ . Let  $V$  be the common variables of  $\pi_R$  and  $\pi_U$ , and let  $E$  be the equivalence relation on  $V$  ensured by Lemma 2. Then  $\pi_R \wedge \rho(V, E)$  is satisfiable in the theory of real closed fields and  $\rho(V, E) \wedge \pi_U$  in the theory of uninterpreted function symbols. Note that those theories are defined axiomatically, and hence satisfying interpretations do not necessarily have to be based on real numbers.

The theory of real closed fields is complete, and hence all its models are elementary equivalent. As a consequence, there is an interpretation  $I_R$  that satisfies  $\pi_R \wedge \rho(V, E)$  and assigns real numbers to all variables.

Also  $\rho(V, E) \wedge \pi_U$  has a satisfying interpretation. However, since the theory of uninterpreted symbols is not complete, we need a more involved construction to come up with an interpretation assigning real numbers and real-valued functions.

We observe that for a formula that is satisfiable in the theory of uninterpreted function symbols, the congruence closure algorithm [28] constructs a satisfying interpretation. Its domain is formed by equivalence classes  $T_\sim$  of the set of sub-terms  $T$  of the given formula. This domain is finite since the set  $T$  is finite. Moreover, each equivalence class contains only

finitely many terms. Let  $I_U$  be such an interpretation satisfying the formula  $\rho(V, E) \wedge \pi_U$ . Observe that the arrangement  $\rho(V, E)$  ensures that all variables shared by  $\pi_R$  and  $\pi_U$  and belonging to the same equivalence class, must have the same value in  $I_R$ .

We will combine the interpretations  $I_R$  and  $I_U$  into an interpretation  $I$  that satisfies  $\tau(\phi)$  and, in addition, uses the real numbers as its domain. Hence, we will translate the elements in the domain of  $I_U$  to real numbers, and extend them to real-valued functions corresponding to the uninterpreted function symbols.

We will now define a function  $r$  assigning to each equivalence class in  $T_{\sim}$  a distinct real number. Let this function  $r$  be such that it assigns to each equivalence class containing a variable shared by  $\pi_R$  and  $\pi_U$  the value of this variable in  $I_R$  (as we have observed, this is unique over all such variables belonging to the same equivalence class), and to all other equivalence classes a further, distinct real number. Let  $r' : T \rightarrow \mathbb{R}$  s.t. for every term  $t \in T$ ,  $r'(t)$  is the real number that  $r$  assigns to the equivalence class containing  $t$ .

Based on this, let  $I$  be the following interpretation which assigns real numbers to all variables in  $\tau(\phi)$  and partial real functions to the function symbols in  $\tau(\phi)$ :

- for every variable  $x$  occurring in  $\pi_R$ ,  $I(x) := I_R(x)$ ,
- for every variable  $x$  occurring in  $\pi_U$ ,  $I(x) := r'(x)$ ,
- for every function symbol  $X$  of arity  $k$ , let  $I(X)$  be the partial function such that for every term of the form  $X(t_1, \dots, t_k)$  in  $T$ ,  $I(X)(r'(t_1), \dots, r'(t_k)) := r'(X(t_1, \dots, t_k))$ , and  $I(X)$  is undefined for all other values.

The two following observations make this definition well-formed:

- The first two items overlap. This is no problem since for shared variables,  $I(x)$  and  $r'(x)$  coincide.
- The definition in the third item is unique since due to the congruence axioms of the theory of free function symbols, for all  $t_1, \dots, t_k, t'_1, \dots, t'_k \in T$ ,  $r'(t_1) = r'(t'_1), \dots, r'(t_k) = r'(t'_k)$  implies  $r'(X(t_1, \dots, t_k)) = r'(X(t'_1, \dots, t'_k))$ .

We will now build a variable assignment  $\alpha$  from  $I$  such that  $\alpha \models \phi$ . For every scalar variable  $x$ ,  $\alpha(x) := I(x)$ . For every function variable  $V$ ,  $\alpha(V)$  will be a smooth real-valued function whose values coincide with the values of the partial function  $I(V)$  on all points where this partial function has a defined value, and whose derivatives coincides with the values of the corresponding partial function  $I(V_{i_1, \dots, i_n})$  on all points where the latter has a defined value. Such a function exists due to Lemma 3, and it satisfies the formula  $\phi$ . ◀

To illustrate the theorem, we continue with the example from above. The real part of the formula is satisfiable, for example by  $\{v_1 \mapsto 1, v_2 \mapsto 7, v_3 \mapsto 1, t \mapsto 6\}$ . Applying the congruence closure algorithm to the part with uninterpreted function symbols, we work with the set of sub-terms  $T = \{v_1, v_2, v_3, t, X(t), X(v_2)\}$ . The result of the congruence closure algorithm is the equivalence relation  $\{\{v_1, v_3, X(v_2), X(t)\}, \{t\}, \{v_2\}\}$ . Hence  $r'$  is  $\{v_1 \mapsto 1, v_3 \mapsto 1, X(v_2) \mapsto 1, X(t) \mapsto 1, t \mapsto 6, v_2 \mapsto 7\}$ . Since every variable in  $\pi_U$  also occurs in  $\pi_R$ , the interpretation  $I$  can simply agree with  $r'$  on the scalar variables. Moreover, it assigns to the function variable  $X$  the partial function  $\{7 \mapsto 1, 6 \mapsto 1\}$ . The corresponding assignment  $\alpha$  assigns to the scalar variables the same real values as  $I$ , and assigns to  $X$  a smooth interpolation of the partial function  $\{7 \mapsto 1, 6 \mapsto 1\}$ . For example, this could be the constant function that has the value 1, everywhere.

Since a disjunction of formulas is satisfiable, if one of the constituting disjuncts is satisfiable, we get:

► **Corollary 4.** *The quantifier free, function-algebraic theory of real functions is decidable.*

The proof of Theorem 1 also shows how to compute satisfying assignments: After checking the satisfiability of  $\tau(\phi)$  using the congruence closure algorithm and the Nelson-Oppen combination procedure, construct the variable assignment  $\alpha$  defined in the proof.

Note that the concluding building block of the proof of Theorem 1 is Lemma 3. Any analogous lemma that ensures stronger properties of the constructed functions results in a corresponding strengthening of Theorem 1. For example, we could also be interested in constructing functions that generalize the constraints given by the input formula as much as possible, maximizing certain regularity properties [14].

## 5 Scalar Quantification

We will now allow arbitrary quantification on scalar variables. We will still require formulas to be function-algebraic and do not allow quantification on function variables. An example is

$$\forall t \in [0, 10] \exists t' \in [0, 10] . \text{app}(X, t, 2t)^2 + 1 \geq \text{app}(\partial_2 X, t', t'),$$

where  $X \in \mathcal{F}_2$  and the interval bounds on variables represent the obvious abbreviations. Many problems resulting from the synthesis of correctness certificates for continuous systems (e.g., Lyapunov function [22], barrier certificates [30] and their generalizations [29, 20]), belong to this class.

In Subsection 5.1, we will introduce a method for checking satisfiability under the condition that the functional variables are instantiated to fixed, user-provided polynomials. In Subsection 5.2, we will introduce a robustness property of formulas that will allow us to characterize solvability of formulas. In Subsection 5.3, we will introduce a systematic method for applying the satisfiability check from Subsection 5.1 and ensuring that it will succeed for all formulas satisfying the robustness property. In Subsection 5.4, we will discuss the relevance of the method for practical computation.

### 5.1 Check Satisfiability Under Polynomial Instantiations

The method for checking satisfiability of a formula that we introduce in this sub-section depends on an instantiation of its functional variables to polynomials with rational coefficients. This will allow us to rewrite the formula into a formula in the language of the theory of real-closed fields which is decidable. In this sub-section, we still assume these polynomials to be given (e.g., chosen by the user), and drop this assumption later.

► **Definition 5.** *We call a function  $\pi$  that assigns to every function variable of sort  $\mathcal{F}_n$  a polynomial with rational coefficients in the variables  $t_1, \dots, t_n$  a polynomial assignment. Moreover, we call a pair consisting of a formula and a polynomial assignment an instantiated formula.*

The intuition is that the polynomial assignment  $\pi$  in an instantiated formula  $(\phi, \pi)$  instantiates each function variable in  $\phi$  to the respective polynomial assigned by  $\pi$ . Let us define the following rules on instantiated formulas  $(\phi, \pi)$ :

- **varep:** Rename multiple occurrences of the same function variable in  $\phi$  by fresh function variables, and extend  $\pi$  to the new variables in such a way that it assigns the same polynomial to each new variable as to its original one.
- **$\partial$ -elim:** Replace a sub-term of  $\phi$  of the form  $\partial_i X$ , where  $X$  is a function variable, by  $X$  and  $\pi$  by  $\pi'$  that is identical to  $\pi$  except that it assigns the result of symbolic differentiation of the polynomial  $\pi(X)$  in its  $i$ -th argument to the function variable  $X$ .

■ **Table 1** Polynomial Instantiation.

rule	formula	polynomial assignment
	$\forall p \forall q . app(X, q) + p^2 app(\partial_1 X, r) app(Y, q) \geq 0$	$\{X \mapsto t^2 + 1, Y \mapsto t\}$
varsep	$\forall p \forall q . app(X, q) + p^2 app(\partial_1 X', r) app(Y, q) \geq 0$	$\{X \mapsto t^2 + 1, X' \mapsto t^2 + 1, Y \mapsto t\}$
$\partial$ -elim	$\forall p \forall q . app(X, q) + p^2 app(X', r) app(Y, q) \geq 0$	$\{X \mapsto t^2 + 1, X' \mapsto 2t, Y \mapsto t\}$
app-elim	$\forall p \forall q . q^2 + 1 + 2p^2 r q \geq 0$	$\{X \mapsto t^2 + 1, X' \mapsto 2t, Y \mapsto t\}$

- **app-elim:** Replace a sub-term of  $\phi$  of the form  $app(X, \hat{t}_1, \dots, \hat{t}_n)$ , where  $X$  is a function variable, and the terms  $\hat{t}_1, \dots, \hat{t}_n$  do not contain any app-operator, by the result of evaluating the polynomial  $\pi(X)$  using the values  $\hat{t}_1, \dots, \hat{t}_n$  for the respective variables  $t_1, \dots, t_n$ .

Now apply first the rule varsep, and then iterate applying the elimination rules until they cannot be applied any more. This process must terminate since every application of an elimination rule decreases the total number of  $\partial$ - and app-operators by one. Moreover, the result must be unique since the only possible alternative choices of the rules relate to independent sub-formulas. So denote by  $\Pi_\pi(\phi)$  the formula  $\phi'$  where  $(\phi', \pi')$  is the final result of the described rule-application process.

Table 1 shows the results of the individual steps of the process of forming  $\Pi_\pi(\phi)$  for an example of an instantiated formula with  $X, Y \in \mathcal{F}_1, p, q, r \in \mathcal{R}$ , where the result  $\Pi_\pi(\phi)$  can be seen at the bottom of the column “formula”.

Polynomial evaluation completely eliminates any function variables or operators:

- **Lemma 6.** *For every instantiated formula  $(\phi, \pi)$ ,  $\Pi_\pi(\phi)$  does not contain any function variable, and hence it also does not contain any app- or diff-operator.*

**Proof.** Function variables can only occur as arguments to diff and app operators. In such a situation, the rules  $\partial$ -elim and app-elim are applicable, and hence, such a formula cannot be the result of  $\Pi_\pi(\phi)$ . ◀

Therefore, if  $\phi$  is function-algebraic,  $\Pi_\pi(\phi)$  is a formula in the language of real-closed fields, which is decidable [38]. Moreover, instantiated formulas can be used for proving satisfiability:

- **Theorem 7.** *For every instantiated formula  $(\phi, \pi)$ ,  $\Pi_\pi(\phi)$  is satisfiable iff  $\pi \models \exists_{\mathcal{R}} \phi$ , where  $\exists_{\mathcal{R}}$  denotes the existential closure of the formula wrt. the scalar variables.*

**Proof.** For an instantiated formula  $(\phi, \pi)$ , let  $\rho(\phi, \pi)$  be the formula

$$\exists_{\mathcal{R}} \phi \wedge \bigwedge_{X \in \mathcal{V}_F} \forall t_1, \dots, t_n . app(X, t_1, \dots, t_n) = \pi(X).$$

Observe that  $\pi \models \exists_{\mathcal{R}} \phi$  iff  $\rho(\phi, \pi)$  is satisfiable. Moreover, every element of the sequence  $\rho(\phi_1, \pi_1), \dots, \rho(\phi_n, \pi_n)$  with  $(\phi_1, \pi_1) = (\phi, \pi)$ ,  $\phi_n = \Pi_\pi(\phi)$ , and each  $(\phi_i, \pi_i)$ ,  $i \in \{2, \dots, n\}$  being the result of the application of a rewrite rule to  $(\phi_{i-1}, \pi_{i-1})$ , is equi-satisfiable. Finally  $\rho(\phi_n, \pi_n)$  and  $\phi_n = \Pi_\pi(\phi)$  are equi-satisfiable since  $\Pi_\pi(\phi)$  does not contain any function variable. ◀

So we have reduced the satisfiability checking problem to the problem of finding a polynomial assignment  $\pi$  for which  $\Pi_\pi(\phi)$  is satisfiable. However, for some satisfiable formulas, the search for such a polynomial assignment is bound to fail. This can be easily seen on the simple initial value problem

$$\text{app}(X, 0) = 1 \wedge \forall t . t \geq 0 \Rightarrow \text{app}(\dot{X}, t) = \text{app}(X, t)$$

that is satisfiable, but not by any polynomial assignment (the only solution of the given initial value problem is the exponential function).

## 5.2 Robust Satisfiability

Even though differential equations such as  $\dot{x} = x$  (in our notation:  $\forall t . \text{app}(\dot{X}, t) = \text{app}(X, t)$ ) are ubiquitous in mathematics, they are highly idealized objects: In practice, no real physical system will satisfy such an equation precisely, and concrete differential equations can only be used in applications after introducing many simplifying assumptions that are part of the daily bread of practical engineering. However, this also makes it necessary for engineers to assess the consequences of such simplifications. Despite the existence of powerful deductive verification techniques [29, 15], in practice, differential equations are still solved by algorithms [19] that produce approximation errors both due to discretization and due to floating point computation. The reliability of the whole process depends essentially on the fact that the error made by the solver does not dominate the error made by simplifying assumptions. This is a major complication, that could be avoided if solvers could conservatively bound the produced errors. For the concrete example  $\dot{x} = x$ , it would be very useful, if a solver could – instead of solving the differential equation approximately – guarantee the solution of  $x - \epsilon \leq \dot{x} \leq x + \epsilon$  within a compact set, for a small constant  $\epsilon > 0$ . In this section, we will formally characterize such situations and show that in such cases, a formally correct satisfiability check is not only possible, but that we can even guarantee its success.

For being able to measure the distance between variable assignments, we will adjoin metrics to the set of variable assignments  $\aleph$ , making the pair  $(\aleph, d)$  a metric space. These metrics will be parametric in a family of compact sets  $K_n \subseteq \mathbb{R}^n, n \in \mathbb{N}$  which we will call *domain of interest*. We will denote this dependence on the domain of interest by an index, writing  $d_K$  for the metric associated to domain of interest  $K$ . We will call such a metric on  $\aleph$  a *variable assignment metric*.

► **Definition 8.** *A formula  $\phi$  is semantically robustly satisfiable wrt. a variable assignment metric  $d$  iff there is a variable assignment  $\alpha \in \aleph$  and an  $\epsilon > 0$  (that we call the robustness margin) such that for every  $\alpha'$  with  $d_K(\alpha, \alpha') < \epsilon$ ,  $\alpha' \models \phi$ .*

Note that unlike similar definitions [17, 33], this definition only depends on the semantics of a given formula, but not on its syntax, and hence is invariant wrt. equivalence transformations. We will later see that this is made possible by the fact that we restrict ourselves to operations on real numbers allowed by the decidable theory of real closed fields.

We will usually use metrics induced by some norm, and so we will call a formula robustly satisfiable wrt. a norm  $\|\cdot\|_K$  iff it is robustly satisfiable wrt. the metric  $d_K(x, x') = \|x - x'\|_K$ . Given metrics  $d^{\mathcal{T}}$  on  $\mathcal{T}$ , where  $\mathcal{T} \in \{\mathcal{R}, \mathcal{F}_1, \dots\}$ , we define their extension to variable assignments element-wise. So, for  $\alpha, \alpha' \in \aleph$ ,

$$d_K(\alpha, \alpha') := \max_{\mathcal{T} \in \{\mathcal{R}, \mathcal{F}_1, \dots\}} \max_{v \in \mathcal{V}_{\mathcal{T}}} d_K^{\mathcal{T}}(\alpha(v), \alpha'(v)).$$

Here, we will usually use a family of metrics on function variables of all dimensions. If  $d^{\mathcal{R}}$  is a metric on  $\mathbb{R}$  and  $d^{\mathcal{F}}$  such a family of metrics on smooth functions  $\mathbb{R}^i \rightarrow \mathbb{R}, i \in \mathbb{N}$ , then we will denote this extension to variable assignments by  $d^{\mathcal{R}} \times d^{\mathcal{F}}$ .

On real-numbers we will use the discrete metric  $d^{\mathcal{R}}(x, y) := \begin{cases} 1, & \text{if } x \neq y, \\ 0, & \text{if } x = y. \end{cases}$

The metric on functions will be based on a norm measuring the size of a given function and of its derivatives. For a function  $F : \mathbb{R}^n \rightarrow \mathbb{R}$ , at least  $k$ -times differentiable, let

$$\|F\|_K^k := \max_{|\beta| \leq k} \inf_{x \in K_n} |(D^\beta F)(x)|.$$

We denote the metric induced by this norm  $\|\cdot\|_K^k$  by  $d_K^k$ . Here are some examples:

- $\forall t \in [0, 1] . \text{app}(X, t) - 0.1 \leq \text{app}(\dot{X}, t) \wedge \text{app}(\dot{X}, t) \leq \text{app}(X, t) + 0.1$ , with  $x \in \mathcal{F}_1$  is *not* robustly satisfiable wrt. the norm  $\|\cdot\|_{[0,1]}^0$ , since that norm does not constrain any derivative of  $x$ . However, it is robustly satisfiable wrt.  $\|\cdot\|_{[0,1]}^1$  since, for example, every function with maximal distance 0.01 from the exponential function wrt.  $\|\cdot\|_{[0,1]}^1$  satisfies the formula.
- $\forall t \in [0, 1] . \text{app}(\dot{X}, t) = \text{app}(X, 0)$  is not robustly satisfiable wrt.  $\|\cdot\|_{[0,1]}^0$ , since for every function satisfying the formula adding the term  $\epsilon t$  to the function results in a function not satisfying it.
- The formula  $\forall t . \text{app}(X, t) \geq 0$ , while satisfiable, is not robustly satisfiable wrt. the norm  $\|\cdot\|_{[0,1]}^0$ , since this norm only restricts the value of functions in the domain of interest  $[0, 1]$ . Due to this, for every variable assignment  $\alpha$  satisfying the formula, there is an  $\alpha'$  with  $d(\alpha, \alpha') = 0$  that does not satisfy the formula: Simply choose an  $\alpha'$  that is identical to  $\alpha$  on  $[0, 1]$  but reaches a negative value outside of this interval. In contrast to that, the formula  $\forall t \in [0, 1] . \text{app}(X, t) \geq 0$ , is robustly satisfiable which explains the importance of bounds on quantified variables for ensuring robustness.

### 5.3 Robust Completeness

We will now introduce a systematic method that checks satisfiability using the test from Subsection 5.1 and that will succeed for all formulas satisfying the robustness property from Subsection 5.2. We will use the fact that one can approximate smooth functions on compact domains arbitrarily closely by polynomials. For this, recall that a subset  $X'$  of a metric space  $(X, d)$  is dense in  $(X, d)$  iff for every  $x \in X$  and  $\varepsilon > 0$  there is an  $x' \in X'$  with  $d(x, x') < \varepsilon$ .

► **Lemma 9.** *Let  $\phi$  be a formula,  $d$  a variable assignment metric and  $\aleph' \subseteq \aleph$  s.t.  $\aleph'$  is dense in  $(\aleph, d)$ . Then every formula that is semantically robustly satisfiable wrt. the metric  $d$  has a satisfying assignment from  $\aleph'$ .*

**Proof.** Assume that  $\phi$  is semantically robustly satisfiable wrt.  $d$ . Then there is a variable assignment  $\alpha \in \aleph$  and an  $\varepsilon > 0$  such that for every  $\alpha'$  with  $d(\alpha, \alpha') < \varepsilon$ ,  $\alpha' \models \phi$ . Since  $\aleph'$  is dense in  $(\aleph, d)$ , there is an  $\alpha' \in \aleph'$  with  $d(\alpha, \alpha') < \varepsilon$ . Hence  $\alpha'$  is within the robustness margin of  $\alpha$ , and hence  $\alpha' \models \phi$ . ◀

Now we observe:

► **Lemma 10.** *For every  $k \in \mathbb{N}_0$ , compact  $K \subseteq \mathbb{R}^n$ , the set of  $n$ -dimension polynomial functions with rational coefficients is dense in the set of  $n$ -dimensional polynomial functions with real coefficients wrt. the metric  $d_K^k$ .*

**Proof.** Let  $P$  be a polynomial function with real coefficients and  $\varepsilon > 0$ . We will prove that there is a polynomial  $P'$  with rational coefficients such that  $d_K^k(P, P') < \varepsilon$ , that is  $\max_{|\beta| \leq k} \inf_{x \in K} |(D^\beta P)(x) - (D^\beta P')(x)| < \varepsilon$ . During this, we will separate any given polynomial  $P$  into its vectors of coefficients  $C_P$  and monomials  $M_P$ . Hence  $P = C_P^T M_P$ .

## 76:12 Deciding Predicate Logical Theories of Real-Valued Functions

Let  $m = \max_{|\beta| \leq k} \inf_{x \in K} \|M_{D^\beta P}(x)\|$  with  $\|\cdot\|$  denoting the Euclidean metric. The value  $m$  is finite since  $K$  is compact. Let  $P'$  be a polynomial with rational coefficients s.t.  $M_P(x) = M_{P'}(x)$  and s.t.  $\max_{|\beta| \leq k} \|C_{D^\beta P} - C_{D^\beta P'}\| < \frac{\varepsilon}{m}$ . Now, due to Cauchy-Schwarz,

$$\begin{aligned} \max_{|\beta| \leq k} \inf_{x \in K} |(D^\beta P)(x) - (D^\beta P')(x)| &= \max_{|\beta| \leq k} \inf_{x \in K} |(C_{D^\beta P} - C_{D^\beta P'})^T M_{D^\beta P}(x)| \leq \\ &\max_{|\beta| \leq k} \inf_{x \in K} \|C_{D^\beta P} - C_{D^\beta P'}\| \|M_{D^\beta P}(x)\| < \frac{\varepsilon}{m} m = \varepsilon \quad \blacktriangleleft \end{aligned}$$

Moreover, the classical Stone-Weierstrass theorem generalizes to  $d_K^k$ , that is, the polynomials with real coefficients  $P(\mathbb{R})$  are dense in the set of  $C_k$ -real functions on any compact set  $K$  wrt.  $d_K^k$  [40, 26]. This allows us to conclude:

► **Lemma 11.** *For every  $k \in \mathbb{N}_0$  and compact  $K \subseteq \mathbb{R}^n$ , the set of  $n$ -dimensional polynomial functions with rational coefficients is dense in the metric space  $(\mathbb{N}, d_K^k)$ .*

Putting everything together, we get :

► **Theorem 12.** *For every  $k \in \mathbb{N}_0$  and and family of compact sets  $K_n \subseteq \mathbb{R}^n$ ,  $n \in \mathbb{N}$ , there is an algorithm for checking satisfiability of function-algebraic formulas that terminates for every input formula that is semantically robustly satisfiable wrt. the metric  $d^\# \times d_K^k$ .*

**Proof.** Assume a semantically robustly satisfiable function-algebraic formula  $\phi$ . Since by Lemma 11, the set of variable assignments assigning real values to scalar variables and polynomials with rational coefficients to function variables is dense in the metric space  $(\mathbb{N}, d^\# \times d_K^k)$ , by Lemma 9, there is an assignment  $\alpha \in \mathbb{N}$  that assigns polynomials with rational coefficients to function variables and that satisfies  $\phi$ . The restriction of  $\alpha$  to a polynomial assignment  $\alpha_\pi$  satisfies  $\exists_{\mathcal{R}} \phi$ .

Due to Theorem 7 we can algorithmically check whether for a given polynomial assignment  $\pi$ ,  $\pi \models \exists_{\mathcal{R}} \phi$ . Moreover, the set of polynomial assignments is recursively enumerable. Hence, an algorithm that enumerates its elements, checking for each element  $\pi$  whether  $\Pi_\pi(\phi)$  is satisfiable in the theory of real closed fields, will eventually find  $\alpha_\pi$ , and hence terminate proving that  $\phi$  is satisfiable. ◀

Note however, that we do not know how to check a given formula for robustness. Hence, for a given formula we do not know a-priori whether the enumeration algorithm from the proof of Theorem 12 will terminate. We just know that it will terminate *under the assumption* that the formula is robust.

### 5.4 Practical Computation – Templates

Of course, the algorithm from the proof of Theorem 12 is hopelessly inefficient in practice. Still, our approach may provide useful practical insight. In practice, problems of the kind studied here are solved in many, often distant areas [36, 31, 34, 35]. A common approach is to restrict the set of potential solutions to a fixed class of functions given by a parameterized expression (sometimes also called a *template*), and then searching for values for the parameters such that the result of instantiating the parameters by those values represents a solution to the problem.

There are two main classes of templates that are often used here. The first class are templates given by complex expressions, often called neural networks. The second class are polynomials whose coefficients are parameters which allows many methods to exploit the fact that polynomials are linear in their coefficients. If the given template polynomial

does not represent a solution, one can increase the degree of the polynomial. The resulting loop amounts to an enumeration of all polynomials with real coefficients. Our approach (1) formally justifies such algorithms showing that such a loop must terminate for all robust inputs, and (2) generalizes such algorithms to all formulas belonging to the language used in this paper.

## 6 Conclusion

We have developed a framework for decision procedures for a predicate logical theory formalizing a notion that is central to mathematics, computer science, and many other scientific fields – real-valued functions. Our long-term vision is to replace the need for research on application-specific automated reasoning techniques for smooth real-valued functions by a common framework that results in tools that can be used out-of-the-box in a similar way as decision procedure for common first-order theories in the frame of SMT solvers [3].

## Abstract

We study the partial search order problem (PSOP) proposed recently by Scheffler [WG 2022]. Given a graph  $G$  together with a partial order on the set of vertices of  $G$ , this problem determines if there is an  $\mathcal{S}$ -ordering that is consistent with the given partial order, where  $\mathcal{S}$  is a graph search paradigm like BFS, DFS, etc. This problem naturally generalizes the end-vertex problem which has received much attention over the past few years. It also generalizes the so-called  $\mathcal{F}$ -tree recognition problem which has just been studied in the literature recently. Our main contribution is a polynomial-time dynamic programming algorithm for the PSOP of the maximum cardinality search (MCS) restricted to chordal graphs. This resolves one of the most intriguing open questions left in the work of Scheffler [WG 2022]. To obtain our result, we propose the notion of layer structure and study numerous related structural properties which might be of independent interest.

## 1 Introduction

Graph search paradigms are pervasive in algorithms for innumerable graph problems. In addition to the most popular paradigms breadth-first search (BFS) and depth-first search (DFS), several other prevalent graph search paradigms – including, for instance, lexicographic breadth-first search (LBFS), lexicographic depth-first search (LDFS), maximum cardinality search (MCS), maximal neighborhood search (MNS) – have also been extensively studied in the literature [10, 25, 28, 29]. These graph search paradigms have proved to be exclusively useful in dealing with a variety of graph problems [6, 8, 9, 22]. For instance, MCS has been successfully used in the recognition of special graphs [29], the computation of minimal separators [22], the computation of minimal triangulation of graphs [3], determining lower bounds of treewidth [5, 21], etc. In several of these algorithmic applications, last vertices

visited in graphs are crucial for the correctness of the algorithms. Last visited vertices also exhibit some nice structural properties. For instance, for a cocomparability graph that is Hamiltonian, if a vertex is last visited by LDFS, then there is a Hamiltonian path starting from this vertex [1, 8]. For more concrete examples on this issue, we refer to [1, 11]. These specialities of last visited vertices inspired Corneil, Köhler, and Lanlignel [11] to put forward the end-vertex problem, in which we are given a graph and a particular vertex  $v$ , and are asked whether  $v$  can be the last visited one according to a certain graph search paradigm. Thenceforth, investigation on the end-vertex problem has flourished, resulting in the complexity of the problem for both general graphs and many special graphs such as chordal graphs, split graphs, interval graphs, bipartite graphs, etc., being substantially established [1, 24, 32]. For a comprehensive summary of the recent progress, we refer to [16].

A closely related problem is the search tree recognition problem which has a relatively longer history [17, 18, 20]. This problem determines if a given spanning tree of a graph can be obtained via a traversal of the graph by a certain search paradigm. This problem comes natural for some search paradigms like BFS and DFS, since they not only output an ordering but also generate a spanning tree during the search. However, it is ill-defined for some other search paradigms like MCS and MNS. Aiming at overcoming the plight, Beisegel et al. [2] introduced the notions of  $\mathcal{F}$ -tree and  $\mathcal{L}$ -tree ( $\mathcal{F}$  and  $\mathcal{L}$  respectively stand for “first” and “last”). Particularly, given an ordering  $\sigma$  of the vertices of a graph, the  $\mathcal{F}$ -tree (respectively,  $\mathcal{L}$ -tree) is a spanning tree of the graph so that every vertex  $v$  other than the first one in  $\sigma$  is adjacent to its first (respectively, last) neighbor appearing before  $v$  in  $\sigma$ . BFS-trees and DFS-trees are  $\mathcal{F}$ -trees and  $\mathcal{L}$ -trees of BFS and DFS, respectively. Having these notions, Beisegel et al. [2] studied the complexity of the  $\mathcal{F}$ -tree recognition problem and the  $\mathcal{L}$ -tree recognition problem of the above-mentioned search paradigms for both general graphs and many special graph classes. Very recently, Scheffler [27] complemented these results by showing that the  $\mathcal{L}$ -tree recognition problem of BFS restricted to bipartite graphs, and the  $\mathcal{F}$ -tree recognition problem of DFS restricted to chordal graphs and chordal bipartite graphs are NP-hard, standing in a strong contrast to the polynomial-time solvability of the  $\mathcal{F}$ -tree recognition problem of BFS and the  $\mathcal{L}$ -tree recognition problem of DFS in general [18, 20].

From the known results, Scheffler [26] discerned that the complexity of the end-vertex problem and the complexity of the  $\mathcal{F}$ -tree recognition problem seemed to be somewhat connected. For instance, for LBFS, MCS, and MNS, both problems are NP-hard on weakly chordal graphs and are linear-time solvable on split graphs. Additionally, for MNS and MCS, both problems are polynomial-time solvable when restricted to chordal graphs [2, 24]. Towards a comprehensive understanding of the connection, Scheffler [26] introduced the partial search order problem (PSOP) which generalizes both the end-vertex problem and the  $\mathcal{F}$ -tree recognition problem. Given a graph  $G$  and a partial order  $R$  on the set of vertices of  $G$ , the PSOP of a search paradigm  $\mathcal{S}$  determines if  $G$  admits an  $\mathcal{S}$ -ordering which linearly extends  $R$ . Scheffler [26] derived a polynomial-time algorithm for the PSOP of LBFS restricted to chordal bipartite graphs, and a polynomial-time algorithm for the PSOP of MCS restricted to split graphs. However, whether the PSOP of MCS restricted to chordal graphs, arguably the most intriguing case, is polynomial-time solvable is unknown prior to our current work. We resolve this open question in the affirmative. To this end, we propose the notion of layer structure and study a number of structural properties which might be of independent interest. At a high level, based on the properties studied, we iteratively decompose the clique graph of a given chordal graph into what we call layer structures, handle the components (which we call units) of each layer structure separately, and utilize dynamic programming techniques to merge local solutions into a whole one.

## 2 Preliminaries

For an integer  $i$ ,  $[i]$  denotes the set of positive integers no greater than  $i$ .

### 2.1 Graphs

We follow standard notions in graph theory. For notions used but not defined in the paper, we refer to [31]. The graphs we consider are finite, undirected, and simple. Let  $G$  be a graph. The *vertex set* and *edge set* of  $G$  are denoted by  $V(G)$  and  $E(G)$ , respectively. For a vertex  $v \in V(G)$ , its *neighborhood* in  $G$ , denoted  $N_G(v)$ , is the set of vertices adjacent to  $v$  in  $G$ . A *clique* of  $G$  is a subset of pairwise adjacent vertices in  $G$ . We call a clique of  $G$  containing a vertex  $v \in V(G)$  a *v-clique*. Analogously, a clique of  $G$  containing a subset  $X \subseteq V(G)$  is called an *X-clique*. The subgraph of  $G$  induced by  $X \subseteq V(G)$  is denoted by  $G[X]$ .

A *path*  $P$  of length  $t$  is a graph with a sequence of  $t + 1$  distinct vertices  $v_1, v_2, \dots, v_{t+1}$  and with the edge set  $\{v_i v_{i+1} \mid i \in [t]\}$ . We say that  $P$  is a path between  $v_1$  and  $v_t$ , or simply call it a  $v_1$ - $v_t$  *path*. Two vertices in  $G$  are *connected* if there is a path between them in  $G$ . For  $u, v \in V(G)$ , a *u-v separator* is a subset  $X \subseteq V(G)$  so that  $u$  and  $v$  are disconnected after deleting all vertices in  $X$  from  $G$ . A *u-v separator*  $X$  is *minimal* if there are no other *u-v separators*  $X'$  such that  $X' \subsetneq X$ . The *length* of a cycle is the number of edges it contains. A *hole* is an induced cycle of length greater than three. A graph is *chordal* if it does not contain any holes as induced subgraphs.

### 2.2 The Partial Search Order Problem

A *partial order* on a set  $X$  is a reflexive, antisymmetric, and transitive binary relation on  $X$ . For ease of exposition, for a partial order  $R$ , we sometimes use  $x <_R y$  to denote  $(x, y) \in R$ . A *linear order* is a partial order that is complete. We usually write a linear order  $R$  in the format of  $(x_1, x_2, \dots, x_m)$  which means that  $(x_i, x_j) \in R$  for all  $i, j \in [m]$  such that  $i < j$ . A linear order  $R$  *extends* a partial order  $R'$  if for every  $(x, y) \in R'$  it holds that  $(x, y) \in R$ . We also call  $R$  a (*linear*) *extension* of  $R'$ . For a binary relation  $R$  on a set  $X$ , and for  $X' \subseteq X$ , we use  $R|_{X'}$  to denote  $R$  restricted to  $X'$ . For a graph search paradigm  $\mathcal{S}$  and a graph  $G$ , an  $\mathcal{S}$ -*ordering* of  $G$  is an ordering of  $V(G)$  that can be generated from an  $\mathcal{S}$  search on  $G$ . The partial search order problem of  $\mathcal{S}$ , denoted PSOP- $\mathcal{S}$ , is defined as follows.

PSOP- $\mathcal{S}$	
<b>Given:</b>	A connected graph $G$ and a partial order $R$ on $V(G)$ .
<b>Question:</b>	Is there an $\mathcal{S}$ -ordering of $G$ that extends $R$ ?

This paper focuses on PSOP-MCS restricted to connected chordal graphs.

### 2.3 Clique Graphs

It has long been known that chordal graphs admit a characterization in terms of their clique trees. Precisely, a connected graph  $G$  is chordal if and only if there exists a tree  $T$  whose vertices one-to-one correspond to maximal cliques of  $G$  so that for every vertex  $v \in V(G)$  the vertices of  $T$  corresponding to all maximal  $v$ -cliques of  $G$  induce a subtree of  $T$  [4, 7, 15, 29]. Such a tree  $T$  is referred to as a *clique tree* of  $G$  [7, 15, 30]. It is a folklore that every chordal graph  $G$  has at most  $|V(G)|$  maximal cliques [13], and hence every clique tree of  $G$  contains at most  $|V(G)|$  vertices.

Another relevant notion is *clique graph*, first introduced by Galinier, Habib, and Paul [14]. Precisely, the clique graph of a connected chordal graph  $G$ , denoted  $C(G)$ , is the graph whose vertex set is exactly the set of all maximal cliques of  $G$ , and two vertices  $K$  and  $K'$  in

■ **Figure 1** A connected chordal graph (left) and its clique graph (right). In the clique graph, all omitted edge weights are 1.

the clique graph are adjacent if and only if  $K \cap K'$  is a minimal  $u$ - $v$  separator of  $G$  for all  $u \in K \setminus K'$  and all  $v \in K' \setminus K$ . Each edge  $KK'$  in the clique graph  $C(G)$  is associated with the label  $K \cap K'$  and with the weight  $|K \cap K'|$ .

For clarity, hereinafter we call vertices in a clique tree or a clique graph *nodes*.

► **Lemma 1** ([14]). *Let  $G$  be a connected chordal graph  $G$ , and let  $K$  and  $K'$  be two maximal cliques in  $G$ . Then,  $K$  and  $K'$  are adjacent in  $C(G)$  if and only if they are adjacent in some clique tree of  $G$ .*

In effect, Lemma 1 asserts that the clique graph of a connected chordal graph is the union of all clique trees of the same graph.

For a label  $S$  of some edge in  $C(G)$ , we use  $C(G) \ominus S$  to denote the graph obtained from  $C(G)$  by deleting all edges with the label  $S$ . For example, for the chordal graph  $G$  in Figure 1,  $C(G) \ominus \{f\}$  is the graph shown in Figure 2.

■ **Figure 2**  $C(G) \ominus \{f\}$  where  $G$  is the connected chordal graph in Figure 1.

► **Lemma 2** ([24]). *Let  $G$  be a connected chordal graph, and let  $S$  be the label of an edge in  $C(G)$  with the minimum weight. Then,*

- (i) *for every  $v \in V(G) \setminus S$ , all maximal  $v$ -cliques of  $G$  are in the same connected component of  $C(G) \ominus S$ ; and*
- (ii) *for every  $u, v \in V(G) \setminus S$ ,  $S$  is a  $u$ - $v$  separator in  $G$  if and only if any maximal  $u$ -clique and any maximal  $v$ -clique of  $G$  are in different connected components of  $C(G) \ominus S$ .*

## 2.4 Graph Search Paradigms

Now we give definitions of three graph search paradigms, namely, MCS, generic search, and Prim search. Each search paradigm regulates how the vertices of a graph are visited one after another without repeating. Our focus is PSOP-MCS, but our algorithm for PSOP-MCS resorts to Prim search of clique graphs and generic search of layer structures (defined in Section 3) of clique graphs.

Both MCS and generic search arbitrarily select one vertex to visit first. Then, MCS picks an unvisited vertex having the maximum number of visited neighbors as the next to visit [29], while the generic search picks an unvisited vertex having at least one visited neighbor as the next to visit [28].

Prim's algorithm is one of the most famous algorithms for finding minimum spanning trees [12, 19, 23]. In a nutshell, starting from a tree consisting of an edge with the minimum weight, the algorithm grows the tree by adding edges, one-by-one, of minimum possible weights without destroying the tree structure, until the tree becomes a spanning tree. By turning "minimum" to "maximum" in the algorithm, it instead returns a maximum spanning tree. Algorithm 1 delineates the Prim search modified from Prim's algorithm [24]. Generally speaking, starting from any arbitrary vertex, it picks as the next one to be visited a so far unvisited vertex incident to an edge with the maximum weight among all edges between visited vertices and unvisited vertices.

■ **Algorithm 1** Prim Search.

---

**Input:** A connected graph  $G$  of  $n$  vertices where every edge has a weight.  
**Output:** An ordering  $\pi$  of  $V(G)$ .

- 1:  $\pi(v) \leftarrow 1$ , where  $v$  is an arbitrary vertex of  $G$ ; /\* the first visited vertex \*/
- 2:  $S \leftarrow \{v\}$ ;
- 3: **for**  $i = 2, 3, \dots, n$  **do**
- 4:   let  $v$  be a vertex in  $V(G) \setminus S$  incident to an edge with the maximum weight among all edges between  $S$  and  $V(G) \setminus S$ ;
- 5:    $\pi(v) \leftarrow i$ ; /\* visit  $v$  \*/
- 6:    $S \leftarrow S \cup \{v\}$ ;
- 7: **return**  $\pi$ ;

---

Following [24], we call an ordering obtained from applying Algorithm 1 to a graph  $G$  a *Prim ordering* of  $G$ . Prim orderings of the clique graph of a chordal graph have an appealing property in respect of their clique graphs, as stated in the following lemma.

► **Lemma 3** ([24]). *Let  $G$  be a connected chordal graph, and let  $(K_1, K_2, \dots, K_t)$  be a Prim ordering of  $C(G)$ . For every  $i \in [t]$ , the subgraph of  $C(G)$  induced by  $\{K_1, K_2, \dots, K_i\}$  is the clique graph of the subgraph of  $G$  induced by  $\bigcup_{j \in [i]} K_j$ .*

Let  $\sigma$  be an ordering of  $V(G)$ , and let  $\pi$  be an ordering of the maximal cliques of  $G$ . For  $v \in V(G)$ , we use  $K_\pi^v$  to denote the first  $v$ -clique in  $\pi$ . We say that  $\sigma$  is a *generation* of  $\pi$  (or  $\pi$  *generates*  $\sigma$ ) if for all  $x, y \in V(G)$  it holds that  $K_\pi^x <_\pi K_\pi^y$  implies  $x <_\sigma y$ . Precisely, for an ordering  $\pi = (K_1, K_2, \dots, K_t)$  of maximal cliques of  $G$  and  $i \in [t-1]$ , let  $V(\pi, i) = \bigcup_{j \in [i]} K_j$  be the set of vertices of  $G$  contained in at least one of the first  $i$  cliques from  $\pi$ . For  $i \in [t] \setminus \{1\}$ , let  $K(\pi, i) = K_i \setminus V(\pi, i-1)$  be the set of vertices of  $G$  contained in  $K_i$  but not in any other cliques before  $K_i$  in  $\pi$ . Besides, let  $K(\pi, 1) = K_1$ . Then,  $\sigma$  is a generation of  $\pi$  if and only if it is of the form  $(\overrightarrow{K(\pi, 1)}, \overrightarrow{K(\pi, 2)}, \dots, \overrightarrow{K(\pi, t)})$ , where for a set  $X$ ,  $\overrightarrow{X}$  can be any ordering of  $X$ .

► **Lemma 4** ([24]). *Let  $G$  be a connected chordal graph. Then, an ordering of  $V(G)$  is an MCS ordering of  $G$  if and only if it is a generation of some Prim ordering of  $C(G)$ .*

### 3 Layer Structures of Clique Graphs

In this section, we introduce the notion of layer structure, and explore a number of structural properties pertinent to this notion. Throughout this section, let  $G$  be a connected chordal graph, and let  $K^*$  be a maximal clique of  $G$ .

Let  $\mathcal{U}$  be the set of connected components of  $C(G)$  after the deletion of all edges with the minimum weight. For the sake of readability, let us call each  $U \in \mathcal{U}$  a *unit*. If a maximal clique  $K$  of  $G$  is a node in a unit, we say that  $K$  is *contained* in this unit. We use  $U^K$  to

denote the unit containing  $K$ . Besides, we use  $\mathcal{K}(U)$  to denote the set of maximal cliques of  $G$  contained in a unit  $U$ , and use  $\mathcal{V}(U)$  to denote the set of vertices of  $G$  contained in nodes of  $U$ , i.e.,  $\mathcal{V}(U) = \bigcup_{K \in \mathcal{K}(U)} K$ . We say that an edge in  $C(G)$  *crosses* two units if the two endpoints of the edge are respectively from the two units.

The layer structure we shall study is a refinement of the clique graph  $C(G)$ . The following two lemmas pinpoint where the refinement lies.

► **Lemma 5.** *The weights of edges of  $C(G)$  whose both endpoints are contained in the same unit are greater than the minimum weight of edges of  $C(G)$ .*

**Proof.** Let  $KK'$  be an edge with the minimum weight in  $C(G)$ , and let  $S = K \cap K'$ . Therefore,  $S$  is a  $u$ - $v$  separator for all  $u \in K \setminus S$  and  $v \in K' \setminus S$ . Then, by Lemma 2 (ii),  $K$  and  $K'$  are in different connected components of  $C(G) \ominus S$ , implying that  $K$  and  $K'$  are contained in different units. ◀

Lemma 5 equivalently asserts that every unit  $U$  is exactly the subgraph of  $C(G)$  induced by  $\mathcal{K}(U)$ . To put it another way, an edge in  $C(G)$  crosses two units if and only if it has the minimum weight in  $C(G)$ .

► **Lemma 6.** *Let  $U$  and  $U'$  be two units from  $\mathcal{U}$  so that there are edges in  $C(G)$  crossing  $U$  and  $U'$ . Then, all edges in  $C(G)$  crossing  $U$  and  $U'$  have the same label.*

**Proof.** Towards a contradiction, assume that  $C(G)$  contains two distinct edges  $K_1K_2$  and  $K_3K_4$  crossing  $U$  and  $U'$  with different labels. Let  $S = K_1 \cap K_2$  and let  $S' = K_3 \cap K_4$ . So,  $S \neq S'$ . Obviously,  $U$  and  $U'$  both remain connected in  $C(G) \ominus S$ . Moreover, since the edge  $K_3K_4$  is present in  $C(G) \ominus S$ ,  $U$  and  $U'$  are in the same connected component of  $C(G) \ominus S$ . This means that  $K_1$  and  $K_2$  are in the same connected component of  $C(G) \ominus S$ . However, this contradicts Lemma 2 (ii). ◀

Now we are ready to define the layer structure.

► **Definition 7 (Layer Structure).** *The layer structure of  $C(G)$  rooted by  $K^*$  is a graph with the vertex set  $\mathcal{U}$  so that there is an edge between two units in  $\mathcal{U}$  if and only if there exists at least one edge in  $C(G)$  crossing the two units. The label and the weight of an edge  $UU'$  in the layer structure are respectively  $K \cap K'$  and  $|K \cap K'|$ , where  $KK'$  can be any edge in  $C(G)$  crossing  $U$  and  $U'$ . The unit  $U^{K^*}$  is called the root of the layer structure. A unit is in the  $i$ -th layer if it is at a distance  $i$  from the root, where the distance between two units is defined as the length of a shortest path between them in the layer structure.*

See Figure 3 for an illustration of Definition 7. By Lemma 6, the labels and the weights of edges in the layer structure are well-defined. Let  $\mathcal{L}_i$  be the set of all units in the  $i$ -th layer, and let  $\mathcal{L}_{\leq i} = \bigcup_{j \in [i] \cup \{0\}} \mathcal{L}_j$ . Obviously,  $\mathcal{L}_0 = \{U^{K^*}\}$ . In addition, if two units from respectively two layers  $\mathcal{L}_i$  and  $\mathcal{L}_j$  are adjacent, it holds that  $|i - j| \leq 1$ . Recall that  $G$  is connected. Hence,  $C(G)$  and the layer structure are connected too. As a result, every unit in  $\mathcal{U}$  is in some layer.

In the following, we explore numerous properties of the layer structure.

► **Property 1.** *Let  $UU'$  be an edge in the layer structure. Then, every path between  $U$  and  $U'$  in the layer structure contains an edge with the same label as  $UU'$ .*

**Proof.** Let  $KK'$  be an edge in  $C(G)$  crossing the two units  $U$  and  $U'$ . Let  $S = K \cap K'$ . It is clear that  $S$  is both the label of  $KK'$  and the label of  $UU'$ . By Lemma 2 (ii),  $K$  and  $K'$  are disconnected in  $C(G) \ominus S$ . It follows that every  $K$ - $K'$  path in  $C(G)$  contains at least one edge with the label  $S$ . Then, by Lemma 5, we know that every  $U$ - $U'$  path in the layer structure contains at least one edge with the label  $S$ . ◀

■ **Figure 3** The layer structure of the chordal graph in Figure 1 rooted by  $K_2$  (or  $K_5, K_6$ ).

► **Property 2.** Let  $U_1U_2$  and  $U_3U_4$  be two distinct edges of the layer structure with the same label  $S$ . Then, the units in the set  $\{U_1, U_2, U_3, U_4\}$  are pairwise adjacent in the layer structure, and all edges among them have the same label  $S$ .

**Proof.** Let  $K_1K_2$  and  $K_3K_4$  be two distinct edges of  $C(G)$  both with the label  $S$ , where  $K_i \in \mathcal{K}(U_i)$  for every  $i \in [4]$ . We first show that  $U_1, U_2, U_3$ , and  $U_4$  are pairwise adjacent in the layer structure. Assume, for the sake of contradiction, that one from  $\{U_1, U_2\}$  is not adjacent to one from  $\{U_3, U_4\}$ . By symmetry, suppose that  $U_1 \neq U_3$ , and  $U_1$  is not adjacent to  $U_3$  in the layer structure.

We claim that  $K_1$  and  $K_3$  are disconnected in  $C(G) \ominus S$ . Assume for contradiction that  $K_1$  and  $K_3$  are connected in  $C(G) \ominus S$ . Let  $C'$  be the connected component of  $C(G) \ominus S$  containing  $K_1$  and  $K_3$ , and let  $V'$  be the set of vertices of  $G$  contained in nodes of  $C'$ . By the minimality of  $|S|$ , there exists a Prim ordering of  $C(G)$  so that all maximal cliques of  $G$  contained in  $C'$  are visited before all the other maximal cliques of  $G$ . Additionally, in light of Lemma 2 (ii), the subgraph of  $C(G)$  induced by the nodes in  $C'$  does not contain any edge with the label  $S$ . Then, by Lemma 3,  $C'$  is the clique graph of  $G[V']$ . Obviously,  $S \subsetneq V'$ . By Lemma 1,  $C'$  contains all clique trees of  $G[V']$  as subgraphs. We fix a clique tree of  $G[V']$ . There is a unique  $K_1$ - $K_3$  path in the clique tree, and by the definition of clique trees, all nodes on this path are  $S$ -cliques. Obviously, this path is also present in  $C(G) \ominus S$ . The label of each edge on this path cannot be  $S$ , since such edges are absent in  $C(G) \ominus S$ . So, the labels of all edges on this path properly contain  $S$ . This indicates that  $K_1$  and  $K_3$  are contained in the same unit in the layer structure. However, this contradicts that  $U_1 \neq U_3$ .

So, it holds that  $K_1$  and  $K_3$  are disconnected in  $C(G) \ominus S$ . Then, according to Lemma 2 (ii),  $S$  is a  $u$ - $v$  separator for all  $u \in K_1 \setminus S$  and all  $v \in K_3 \setminus S$ . By the minimality of  $|S|$  and the definition of clique graphs,  $K_1K_3$  is an edge of  $C(G)$  with the label  $S$ . As a result,  $U_1U_3$  is an edge of the layer structure, contradicting that  $U_1$  and  $U_3$  are nonadjacent in the layer structure.

Now we can conclude that the units in  $\{U_1, U_2, U_3, U_4\}$  are pairwise adjacent in the layer structure. Then, from Property 1 and the fact that both  $U_1U_2$  and  $U_3U_4$  have the label  $S$ , it follows that the labels of the edges among  $U_1, U_2, U_3$ , and  $U_4$  are all  $S$ . ◀

Note that in Property 2 it may be that  $\{U_1, U_2\} \cap \{U_3, U_4\} \neq \emptyset$ .

► **Property 3.** Every unit  $U$  in the  $i$ -th layer  $\mathcal{L}_i$  where  $i \geq 1$  is adjacent to exactly one unit from the layer  $\mathcal{L}_{i-1}$ .

**Proof.** Let  $U$  be a unit from the  $i$ -th layer. The statement holds trivially for  $i = 1$ . Consider now the case where  $i \geq 2$ . Assume, for the sake of contradiction, that there are two distinct units  $U_1$  and  $U_2$  in the layer  $\mathcal{L}_{i-1}$  both adjacent to  $U$  in the layer structure. Let  $S_1$  and  $S_2$  be the labels of  $UU_1$  and  $UU_2$ , respectively. By Definition 7, there is a path from the root

to  $U_1$ , and a path from the root to  $U_2$  in the layer structure. Then, as  $i \geq 2$ , there exists a  $U_1$ - $U_2$  path  $P$  of length at least two in the layer structure such that all inner units of  $P$  are from  $\mathcal{L}_{\leq i-2}$ . Our proof proceeds by distinguishing between the following two cases.

**Case 1:**  $S_1 = S_2$ .

By Property 2,  $U_1U_2$  is an edge with the label  $S_1$  in the layer structure. By Property 1, there exists an edge in  $P$  with the label  $S_1$ . By Property 2,  $U$  is adjacent to the two endpoints of this edge, which is impossible since  $U$  is from the  $i$ -th layer but at least one of the two endpoints of the edge is from  $\mathcal{L}_{\leq i-2}$ .

**Case 2:**  $S_1 \neq S_2$ .

By Property 1, there exists an edge in  $E(P) \cup \{UU_2\}$  with the label  $S_1$ . As  $S_1 \neq S_2$ , this edge belongs to  $P$ . By Property 2,  $U$  is adjacent to the two endpoints of this edge. However, analogous to the discussion in Case 1, we know that this is impossible.

As both cases lead to some contradictions, we know that  $U$  is adjacent to exactly one unit from  $\mathcal{L}_{i-1}$ . ◀

Now for each unit  $U$  from a layer  $\mathcal{L}_i$  where  $i \geq 1$ , we call the only unit from the layer  $\mathcal{L}_{i-1}$  adjacent to  $U$  the *parent* of  $U$ , and use  $\text{parent}(U)$  to denote it. Correspondingly, we say that  $U$  is a *child* of  $\text{parent}(U)$ . Furthermore, for a unit  $U$  from a layer  $\mathcal{L}_i$  and a unit  $U'$  from a layer  $\mathcal{L}_j$  such that  $i < j$ , we say that  $U'$  is a *descendant* of  $U$  if there is a path from the root to  $U'$  through  $U$  (i.e.,  $U$  is also on the path) in the layer structure. For a unit  $U$ , let  $\text{dst}(U)$  be the set of all descendants of  $U$ , and let  $\text{dst}[U] = \text{dst}(U) \cup \{U\}$ .

► **Property 4.** Let  $U_1$  and  $U_2$  be two units in the same layer  $\mathcal{L}_i$  where  $i \geq 1$ . Then, the following statements are equivalent:

- (1)  $U_1$  and  $U_2$  are adjacent.
- (2)  $\text{parent}(U_1) = \text{parent}(U_2)$ , and the label of the edge between  $U_1$  and its parent equals that between  $U_2$  and its parent.

**Proof.** From Property 2, we know that Statement (2) implies Statement (1). In the following, we show that Statement (1) implies Statement (2).

Assume that  $U_1$  and  $U_2$  are adjacent, and let  $S$  be the label of the edge between them. Let  $U_3 = \text{parent}(U_1)$  and let  $U_4 = \text{parent}(U_2)$ . We first prove that  $U_1$  and  $U_2$  have the same parent, i.e.,  $U_3 = U_4$ . Assume, for contradiction, that  $U_3 \neq U_4$ . By Properties 2 and 3, this implies that neither the label of  $U_1U_3$  nor the label of  $U_2U_4$  is  $S$ . In addition, it also holds that  $i > 1$ , implying that there exists a  $U_3$ - $U_4$  path  $P$  of length at least two in the layer structure whose inner units are all from  $\mathcal{L}_{\leq i-2}$  (cf. the proof of Property 3). Then, by Property 1, there exists an edge in  $P$  with the label  $S$ . By Property 2, the two endpoints of this edge are adjacent to  $U_1$  in the layer structure. However, this is impossible since at least one endpoint of this edge is from  $\mathcal{L}_{\leq i-2}$  but  $U_1$  is from the layer  $\mathcal{L}_i$ . This completes the proof for that  $U_3 = U_4$ . Having  $U_3 = U_4$ , from Properties 1 and 2, it follows that the labels of  $U_1U_3$  and  $U_2U_4$  are both  $S$ . ◀

Property 4 implies that if a subset of units in the same layer  $\mathcal{L}_i$  are connected in the layer structure restricted to  $\mathcal{L}_i$ , then they are pairwise adjacent. For ease of exposition, we group units in the same layer into *bags* so that two units are in the same bag if they are adjacent. By Property 3, if we ignore edges inside all bags in the layer structure, we obtain a tree rooted at  $U^{K^*}$ . As an important consequence, every path connecting two units from the same layer  $\mathcal{L}_i$  is completely contained in  $\mathcal{L}_{\leq i}$ .

In addition, Property 3 indicates that every nonroot unit  $U$  in a layer  $\mathcal{L}_i$  is adjacent to exactly one unit in  $\mathcal{L}_{\leq i-1}$ , and this unit is its parent in  $\mathcal{L}_{i-1}$ . Property 4 further strengthens that  $\text{parent}(U)$  indeed separates all descendants of  $\text{parent}(U)$  from all the other units. In other

words,  $\{\text{parent}(U)\}$  is a  $U'$ - $U''$  separator in the layer structure for all  $U' \in \text{dst}(\text{parent}(U))$  and all  $U'' \in \mathcal{U} \setminus \text{dst}[\text{parent}(U)]$ . An important consequence is that every generic search ordering of the layer structure starting from the root visits every nonroot unit after (not necessarily consecutive) its parent.

The next property identifies labels of edges between adjacent units.

► **Property 5.** *The label of every edge  $UU'$  in the layer structure is  $\mathcal{V}(U) \cap \mathcal{V}(U')$ .*

**Proof.** Let  $U$  and  $U'$  be two adjacent units in the layer structure. Let  $S = \mathcal{V}(U) \cap \mathcal{V}(U')$ , and let  $S'$  be the label of the edge between  $U$  and  $U'$  in the layer structure. Clearly,  $S' \subseteq S$ . Therefore, to complete the proof, it needs only to show that every  $v \in S$  is contained in  $S'$ . In light of Properties 3 and 4, only the two cases described below may occur.

**Case 1:** one of  $U$  and  $U'$  is the parent of the other.

For the sake of contradiction, assume that there exists  $v \in S \setminus S'$ . By Lemma 6, all edges between  $\mathcal{K}(U)$  and  $\mathcal{K}(U')$  in  $C(G)$  have the same label  $S'$ . By the definition of the layer structure,  $|S'|$  is a minimum edge weight in  $C(G)$ . Then, by Properties 3 and 4,  $U$  and  $U'$  are disconnected in the layer structure after removing all edges with the label  $S'$ . This is equivalent to every  $K \in \mathcal{K}(U)$  and every  $K' \in \mathcal{K}(U')$  being disconnected in  $C(G) \ominus S'$ . However, as  $v \in \mathcal{V}(U) \cap \mathcal{V}(U')$ , this violates Lemma 2 (i).

**Case 2:**  $U$  and  $U'$  are in the same bag.

By Property 4,  $U$  and  $U'$  have the same parent, say  $\hat{U}$ , and the labels of edges among units in the same bag as  $U$  and their parent  $\hat{U}$  are  $S'$ . Then, similar to Case 1, it is easy to see that  $U$  and  $U'$  are disconnected in the layer structure after removing all edges with the label  $S'$ , which violates Lemma 2 (i) too.

As both cases violate Lemma 2, we know that Property 5 holds. ◀

► **Property 6.** *Let  $v$  be a vertex in  $G$ . Let  $i$  be the minimum integer such that  $\mathcal{L}_i$  contains a maximal  $v$ -clique. Then, all maximal  $v$ -cliques of  $G$  contained in  $\mathcal{L}_i$  are in one unit.*

**Proof.** Let  $v$  and  $i$  be as stipulated in the statement of Property 6. Assume for contradiction that there exist two maximal  $v$ -cliques  $K$  and  $K'$  respectively from two different units  $U$  and  $U'$  in the layer  $\mathcal{L}_i$ . Our proof is completed by considering the following two cases.

**Case 1:**  $U$  and  $U'$  are adjacent in the layer structure.

By Property 5,  $v$  is in the label of the edge  $UU'$ . By Property 4,  $U$  and  $U'$  have the same parent, say,  $\hat{U}$ . Moreover, by Properties 2 and 4, the edges  $U\hat{U}$  and  $U'\hat{U}$  have the same label as the edge  $UU'$ . It follows that  $\hat{U}$  contains some  $v$ -clique. However, this contradicts that  $i$  is the minimum integer with  $\mathcal{L}_i$  containing a maximal  $v$ -clique.

**Case 2:**  $U$  and  $U'$  are not adjacent in the layer structure.

Note that in this case  $i \geq 1$ . As the subgraph of  $C(G)$  induced by the set of maximal  $v$ -cliques is connected, there is a  $K$ - $K'$  path  $P$  in  $C(G)$  so that  $v$  is in the label of every edge on the path. By Properties 3 and 4, this path contains at least one maximal clique of  $G$  contained in  $\text{parent}(U)$ . However, similar to Case 1, this is in contradiction with the definition of  $i$ .

As each of the above two cases leads to a certain contradiction, Property 6 holds. ◀

Property 6 shows that for every vertex  $v$  in  $G$ , there is a unique unit that contains a maximal  $v$ -clique and is at the least distance to the root in the layer structure. Let  $U^v$  be such a unique unit for  $v$ .

► **Property 7.** *For each  $v \in V(G)$ , every unit containing a maximal  $v$ -clique of  $G$  is from  $\text{dst}[U^v]$ .*

## 77:10 Algorithm for MCS Partial Search on Chordal Graphs

**Proof.** Assume, for the sake of contradiction, there exists  $v \in V(G)$  and a unit  $U$  such that  $v \in \mathcal{V}(U)$  and  $U \notin \text{dst}[U^v]$ . By Property 6,  $U$  and  $U^v$  cannot be in the same layer. Then, as  $U \notin \text{dst}[U^v]$ , every  $U^v$ - $U$  path in the layer structure contains the parent of  $U^v$ . As all maximal  $v$ -cliques are connected in  $C(G)$ , and  $v \in \mathcal{V}(U) \cap \mathcal{V}(U^v)$ , we know that  $v \in \mathcal{V}(\text{parent}(U^v))$ . However, this contradicts the definition of  $U^v$ . ◀

► **Property 8.** *Let  $U$  and  $U'$  be two units from the same bag, and let  $\hat{U}$  be their parent. Then, for every edge  $KK'$  in  $C(G)$  so that  $K \in \mathcal{K}(U)$  and  $K' \in \mathcal{K}(U')$ , there exists  $\hat{K} \in \mathcal{K}(\hat{U})$  which is adjacent to both  $K$  and  $K'$  in  $C(G)$ .*

**Proof.** Let  $K \in \mathcal{K}(U)$  and  $K' \in \mathcal{K}(U')$  be as stipulated in Property 8. Let  $S = K \cap K'$ . As  $U$  and  $U'$  are in the same bag, they are adjacent in the layer structure. By Lemma 6 and Definition 7, the label of the edge  $UU'$  is  $S$ . This means that  $|S|$  is the minimum weight of edges in  $C(G)$ . By Properties 2 and 4, the labels of the edges  $U\hat{U}$  and  $U'\hat{U}$  are also  $S$ . As a result, there exists  $\hat{K} \in \mathcal{K}(\hat{U})$  so that  $S \subseteq \hat{K}$ . By Properties 3 and 4,  $\hat{K}$  is disconnected from  $K$  in  $C(G) \ominus S$ . Then, according to Lemma 2 (ii) and the minimality of  $|S|$ ,  $S$  is a minimal  $u$ - $v$  separator in  $G$  for all  $u \in K \setminus \hat{K}$  and all  $v \in \hat{K} \setminus K$ . Therefore,  $\hat{K}$  and  $K$  are adjacent in  $C(G)$ . Similarly,  $\hat{K}$  is also adjacent to  $K'$  in  $C(G)$ . ◀

Now we study two lemmas which provide insight into connections among MCS orderings of  $G$ , Prim orderings of  $C(G)$ , and generic search orderings of the layer structure. We say that a Prim ordering  $\pi$  of the clique graph  $C(G)$  *respects* a partial order  $R$  on  $V(G)$  if for every  $(x, y) \in R$  it holds that  $K_\pi^x <_\pi K_\pi^y$  or  $K_\pi^x = K_\pi^y$ . By saying that an ordering starts with elements in a subset, we mean the elements in the subset are before all the other elements in the ordering.

► **Lemma 8.** *Let  $R$  be a partial order on  $V(G)$ . There is an MCS ordering of  $G$  extending  $R$  if and only if there is a Prim ordering of  $C(G)$  respecting  $R$ . Moreover, given a Prim ordering of  $C(G)$  which starts with some node  $K$  and respects  $R$ , we can construct an MCS ordering of  $G$  starting with the vertices in  $K$  and extending  $R$  in polynomial time.*

**Proof.** We start the proof with the first statement. For the forward direction, let  $\sigma$  be an MCS ordering of  $G$  extending  $R$ . By Lemma 4, there exists a Prim ordering  $\pi$  of  $C(G)$  that generates  $\sigma$ . For every  $(x, y) \in R$ , since  $\sigma$  extends  $R$ , it holds that  $x <_\sigma y$ . As  $\pi$  generates  $\sigma$ , it holds that  $K_\pi^x <_\pi K_\pi^y$  or  $K_\pi^x = K_\pi^y$ . For the backward direction, let  $\pi = (K_1, K_2, \dots, K_t)$  be a Prim ordering of  $C(G)$  so that for all  $(x, y) \in R$  it holds that either  $K_\pi^x <_\pi K_\pi^y$  or  $K_\pi^x = K_\pi^y$ . Let  $\sigma$  be a generation of  $\pi$  so that for every  $i \in [t]$  it holds that  $\sigma$  restricted to  $K(\pi, i)$  extends  $R$  restricted to  $K(\pi, i)$ , i.e.,  $\sigma|_{K(\pi, i)}$  is a linear extension of  $R|_{K(\pi, i)}$ . As for every  $i, j \in [t]$  such that  $i \neq j$ ,  $K(\pi, i)$  and  $K(\pi, j)$  are disjoint,  $\sigma$  is well-defined. By Lemma 4,  $\sigma$  is an MCS ordering of  $G$ . To complete the proof for the first statement, it suffices to show that  $\sigma$  is a linear extension of  $R$ . Let  $(x, y) \in R$ . If  $K_\pi^x = K_\pi^y$ , i.e.,  $x$  and  $y$  are contained in some  $K(\pi, i)$  where  $i \in [t]$ , as  $\sigma|_{K(\pi, i)}$  extends  $R|_{K(\pi, i)}$ , it holds that  $x <_\sigma y$ . Otherwise,  $K_\pi^x <_\pi K_\pi^y$  holds. Then, as  $\sigma$  is a generation of  $\pi$ ,  $x <_\sigma y$  holds too. This completes the proof that  $\sigma$  extends  $R$ .

Concerning the second statement, observe that the above proof for the backward direction is constructive, and the polynomial-time solvability follows from the fact that computing a linear extension of a partial order can be done in polynomial time. ◀

By Property 6, each partial order  $R$  on  $V(G)$  specifies a partial order on the units:  $\mathcal{Q}^R = \{(U^x, U^y) \mid (x, y) \in R\}$ .

► **Lemma 9.** *Let  $R$  be a partial order on  $V(G)$ . Then, if there is an MCS ordering of  $G$  that starts with vertices from  $K^*$  and extends  $R$ , there is a generic search ordering of the layer structure rooted by  $K^*$  that starts with  $U^{K^*}$  and extends  $\mathcal{Q}^R$ .*

**Proof.** Let  $\sigma$  be an MCS ordering of  $G$  that starts with the vertices from  $K^*$  and extends  $R$ . By Lemma 4, there is a Prim ordering  $\pi$  of  $C(G)$  that generates  $\sigma$ . Obviously,  $K^*$  is the first node in  $\pi$ . Then, by Algorithm 1, Lemma 5, and Definition 7, we know that for every unit  $U$ , the nodes in  $U$  are consecutive in  $\pi$ . Moreover, in view of Properties 3 and 4, for every nonroot unit  $U$ , all nodes from  $\text{parent}(U)$  are before all nodes from  $U$  in  $\pi$ . Consequently, there is a linear order  $\pi' = (U_1, U_2, \dots, U_t)$  of the units in the layer structure so that

- (1)  $U_1 = U^{K^*}$ ;
- (2) for every nonroot unit  $U$ ,  $\text{parent}(U)$  is before  $U$  in  $\pi'$ ; and
- (3) for every  $i \in [t]$ , all nodes of  $U_i$  are consecutive in the Prim ordering  $\pi$ .

Conditions (1) and (2) mean that  $\pi'$  is a generic search ordering of the layer structure starting with the root. It remains to show that  $\pi'$  extends  $\mathcal{Q}^R$ . For this purpose, let  $(x, y) \in R$  such that  $U^x \neq U^y$ . As  $\sigma$  extends  $R$ ,  $x$  is before  $y$  in  $\sigma$ . As  $\pi$  generates  $\sigma$ , either  $K_\pi^x = K_\pi^y$  holds or  $K_\pi^x <_\pi K_\pi^y$  holds. Condition (2) given above and Property 7 imply that  $K_\pi^v$  is contained in  $U^v$  for all  $v \in V(G)$ . Then, as  $U^x \neq U^y$ , it must be that  $K_\pi^x <_\pi K_\pi^y$ . Finally, by Condition (3) given above, we know that  $U^x$  is before  $U^y$  in  $\pi'$ . This completes the proof that  $\pi'$  extends  $\mathcal{Q}^R$ . ◀

## 4 A Dynamic Programming Algorithm for PSOP

In this section, we present a polynomial-time dynamic programming algorithm for PSOP-MCS restricted to chordal graphs.

For an ordering  $\pi$  of units in a layer structure, and an ordering  $\sigma$  of nodes contained in a unit  $U$ , *realizing*  $\pi$  by  $\sigma$  is the operation of replacing  $U$  in  $\pi$  with  $\sigma$ . For instance, for  $\pi = (U_1, U_2, U_3, U_4)$  and  $\sigma = (K_1, K_2, K_3)$  where  $\{K_1, K_2, K_3\}$  is the set of nodes contained in  $U_2$ , realizing  $\pi$  by  $\sigma$  results in the linear order  $(U_1, K_1, K_2, K_3, U_3, U_4)$ .

► **Theorem 10.** *PSOP-MCS restricted to chordal graphs is polynomial-time solvable.*

**Proof.** Let  $I = (G, R)$  be an instance of PSOP-MCS where  $G$  is a connected chordal graph of  $n$  vertices. Our algorithm consists of the following steps.

**Step 1** We sort the weights of edges in the clique graph  $C(G)$  of  $G$  in increasing order. Let  $(w(1), w(2), \dots, w(t))$  be this order, where  $t$  is the number of different weights of edges in  $C(G)$ . Hence  $w(1) < w(2) < \dots < w(t)$  holds. Notice that  $t = O(n)$  since edges of  $C(G)$  may have at most  $n - 2$  different weights.

**Step 2** For each  $i \in [t]$ , let  $C^i(G)$  be the graph obtained from  $C(G)$  by removing edges whose weights are from  $\{w(1), w(2), \dots, w(i)\}$ . Let  $C^0(G) = C(G)$ . Clearly, every  $C^i(G)$ , where  $i \in [t]$ , is obtained from  $C^{i-1}(G)$  by deleting all edges with the minimum weight.

**Step 3** We maintain a binary dynamic programming table  $D(i, H, K)$ , where  $i \in [t] \cup \{0\}$ ,  $H$  is a connected component of  $C^i(G)$ , and  $K$  is a node in  $H$ . (Note that for  $i = 0$ , we have that  $H = C(G)$ .) As  $t = O(n)$ , every chordal graph of  $n$  vertices has at most  $n$  maximal cliques, and  $K$  is a node in  $H$ , the table has  $O(n^2)$  entries.

For each connected component  $H$  of some  $C^i(G)$ , let  $\mathcal{V}(H)$  be the subset of vertices of  $G$  contained in nodes of  $H$ . We define  $D(i, H, K)$  to be 1 if there is a Prim ordering of  $H$  which starts with  $K$  and respects  $R|_{\mathcal{V}(H)}$ , and define  $D(i, H, K)$  to be 0 otherwise. (We elaborate on how to compute the table later.)

## 77:12 Algorithm for MCS Partial Search on Chordal Graphs

**Step 4** After the table is computed, if  $D(0, C(G), K) = 0$  for all maximal cliques  $K$  of  $G$ , by the definition of the table there is no Prim ordering of  $C(G)$  respecting  $R$ , and by Lemma 8, the given instance  $I$  is a No-instance. Otherwise, there exists a maximal clique  $K$  of  $G$  such that  $D(0, C(G), K) = 1$ . By the definition of the table and by Lemma 8, there is an MCS ordering of  $G$  extending  $R$ . Therefore, in this case, we conclude that  $I$  is a Yes-instance.

Computing the table defined above lies at the core of the algorithm, which is the main focus of the remainder of the proof. To this end, we first show that each graph  $H$  used in Step 3 is a clique graph of a connected chordal graph.

▷ **Claim 11.** For every  $i \in [t] \cup \{0\}$ , every connected component  $H$  of  $C^i(G)$  is the clique graph of the subgraph of  $G$  induced by  $\mathcal{V}(H)$ .

Proof of Claim 11. We prove the claim by induction on  $i$ . The statement is clearly true for  $i = 0$ . Now let  $i \in [t]$ , and let  $H$  be a connected component of  $C^i(G)$ . Let  $H'$  be the connected component of  $C^{i-1}(G)$  containing  $H$ . By induction,  $H'$  is the clique graph of  $G[\mathcal{V}(H')]$  which is a connected chordal graph. Obviously,  $H$  is a connected component of  $H'$  after removing all edges with the minimum weight in  $H'$ . As a consequence, there is a Prim ordering of  $H'$  which starts with a node from  $H$  and consecutively visits nodes in  $H$ . Then, by Lemma 3,  $H$  is the clique graph of the subgraph of  $G[\mathcal{V}(H')]$  induced by  $\mathcal{V}(H)$  which is exactly  $G[\mathcal{V}(H)]$ . This completes the proof for the claim. ◁

By Claim 11, each  $H$  in Step 3 is the clique graph of a connected chordal graph. Therefore, all properties and lemmas studied in the previous section apply to  $H$  and each of its layer structures.

Now we show how to compute the table defined in Step 3. We fill the entries  $D(i, H, K)$  in a decreasing order of the values of  $i$ .

- filling the base entries

As  $C^t(G)$  consists of pairwise nonadjacent nodes corresponding to maximal cliques of  $G$ , by the definition of the table, we set  $D(t, H, K) = 1$  for all base entries.

- updating the table

Now we delineate how to update other entries  $D(i, H, K)$ , assuming all entries  $D(i + 1, H', K')$  have been computed. To compute the entry  $D(i, H, K)$ , we first compute the layer structure of  $H$  rooted by  $K$ . Let  $\mathcal{LS}$  be the layer structure. By Definition 7,  $\mathcal{LS}$  can be computed in polynomial time. Note that each unit in  $\mathcal{LS}$  is a connected component of  $C^{i+1}(G)$ . For each vertex  $x$  in  $\mathcal{V}(H)$ , let  $U^x$  be the unit in  $\mathcal{LS}$  which contains  $x$  and is at the least distance from the root of  $\mathcal{LS}$ . By Property 6, such a unit is unique. Besides, for each node  $K'$  of  $H$ , let  $U^{K'}$  be the unit in  $\mathcal{LS}$  containing  $K'$ . Let  $R' = R|_{\mathcal{V}(H)}$  be  $R$  restricted to  $\mathcal{V}(H)$ . Let  $\mathcal{Q}^{R'} = \{(U^x, U^y) \mid (x, y) \in R'\}$ . Now we determine if there is a generic search ordering of  $\mathcal{LS}$  which starts with the root and extends  $\mathcal{Q}^{R'}$ . This can be done in polynomial time [26, Theorem 6]<sup>1</sup>. If this is not the case, by Claim 11 and Lemma 9, there is no MCS ordering of  $G[\mathcal{V}(H)]$  that starts with vertices from  $K$  and extends  $R'$ , and by Claim 11 and Lemma 8 there is no Prim ordering of  $H$  which starts with  $K$  and respects  $R'$ . So in this case, we set  $D(i, H, K) = 0$ . Otherwise, let  $\pi = (U_0, U_1, \dots, U_p)$  be a generic search ordering of  $\mathcal{LS}$  extending  $\mathcal{Q}^{R'}$  so that  $U_0 = U^K$ . Then, we let  $D(i, H, K) = 1$  if and only if

<sup>1</sup> Scheffler [26] showed that the rooted version of the PSOP for the generic search can be solved in polynomial time. In this version, we are given a graph  $G$ , a partial order on  $V(G)$ , and a vertex  $v \in V(G)$ , and the question is whether  $G$  admits a generic search ordering which starts with  $v$  and extends the partial order.

- (1)  $D(i+1, U^K, K) = 1$ , and
- (2) for every  $U_j$ ,  $j \in [p]$ , there exists a node  $K_j$  contained in  $U_j$  such that in  $H$  the node  $K_j$  is adjacent to at least one node from the parent of  $U_j$  in  $\mathcal{LS}$  and, moreover,  $D(i+1, U_j, K_j) = 1$ .

We show the correctness of this step as follows. Observe that in every generic search ordering of  $\mathcal{LS}$  starting from the root, every unit is visited before all its children.

We first prove the “if” direction. Assuming Conditions (1) and (2), let  $\pi'$  be the ordering obtained from  $\pi$  by

- (a) realizing the first unit  $U^K$  by a Prim ordering of  $U^K$  which starts with  $K$  and respects  $R'$  restricted to  $U^K$  (guaranteed by  $D(i+1, U^K, K) = 1$ ), and
- (b) realizing every  $U_j$ , where  $j \in [p]$ , by a Prim ordering of  $U_j$  which starts with  $K_j$  and respects  $R'$  restricted to  $U_j$  (guaranteed by  $D(i+1, U_j, K_j) = 1$ ).

The remainder of the proof for the “if” direction comprises the two claims below.

▷ **Claim 12.**  $\pi'$  is a Prim ordering of  $H$  with the first node being  $K$ .

*Proof of Claim 12.* By Condition (1) and Operation (a), we know that the first node in  $\pi'$  is  $K$ . Besides, from Condition (2) and Operation (b), for every  $U_j$  where  $j \in [p]$  the first node of  $\pi'$  restricted to  $U_j$  is  $K_j$ . By the definition of Prim ordering (Algorithm 1) and the definition of  $\pi'$ , it suffices now to show that for every  $U_j$ ,  $j \in [p]$ , the following condition holds:  $K_j$  is adjacent to at least one node in  $H$  which is before  $K_j$  in  $\pi'$  and is from a different unit adjacent to  $U_j$ . This is the case as by Condition (2),  $K_j$  is adjacent to at least one node from the parent of  $U_j$  in  $\mathcal{LS}$ , and as  $\pi$  is a generic search ordering of  $\mathcal{LS}$  with the root being the first unit, by Properties 3 and 4, the parent of  $U_j$  is before  $U_j$  in  $\pi$ , implying that all nodes in the parent of  $U_j$  are before all nodes of  $U_j$  in  $\pi'$ . ◁

▷ **Claim 13.**  $\pi'$  respects  $R'$ .

*Proof of Claim 13.* To verify that  $\pi'$  respects  $R'$ , let  $(x, y) \in R'$ . Due to Properties 3, 4, 7, and that  $\pi$  is a generic search ordering of the layer structure starting with the root, we know that for every  $v \in V(G)$  the first node in  $\pi'$  containing  $v$  is from  $U^v$ , i.e.,  $K_{\pi'}^v \in \mathcal{K}(U^v)$ . Our proof proceeds by distinguishing between the following two cases. If  $U^x = U^y = U$ , then as  $\pi$  has been realized by a Prim ordering of  $U$  respecting  $R'$  restricted to  $U$  in  $\pi'$ , it holds that  $K_{\pi'}^x <_{\pi'} K_{\pi'}^y$ , or  $K_{\pi'}^x = K_{\pi'}^y$ . Otherwise, as  $\pi$  extends  $\mathcal{Q}^{R'}$ ,  $U^x$  is before  $U^y$  in  $\pi$ . By the definition of  $\pi'$ , maximal  $x$ -cliques in  $U^x$  are before maximal  $y$ -cliques in  $U^y$ . By Properties 3, 4, and 7, none of any units containing a maximal  $y$ -clique is before  $U^y$  in  $\pi$ . Then, from  $K_{\pi'}^x \in \mathcal{K}(U^x)$  and  $K_{\pi'}^y \in \mathcal{K}(U^y)$ , it follows  $K_{\pi'}^x <_{\pi'} K_{\pi'}^y$ . ◁

Now we give the proof for the “only if” direction. To this end, assume that  $D(i, H, K) = 1$ , i.e.,  $H$  admits at least one Prim ordering, say  $\pi'$ , which starts with  $K$  and respects  $R'$ . As  $\pi'$  respects  $R'$ , for each unit  $U$  in the layer structure,  $\pi'$  restricted to  $U$ , i.e.,  $\pi'|_U$ , is a Prim ordering of  $U$  respecting  $R'$  restricted to  $U$ . Consequently,  $D(i+1, U, K') = 1$  where  $K'$  is the first node in  $\pi'|_U$ . This immediately implies that Condition (1) holds. We show below that Condition (2) also holds. Let  $U_j$ ,  $j \in [p]$ , be a unit in  $\mathcal{LS}$ . Let  $K'$  be the first node in  $\pi'|_{U_j}$ . We claim that  $K'$  is adjacent in  $H$  to some node from the parent of  $U_j$  in  $\mathcal{LS}$ . As  $\pi'$  is a Prim ordering of  $H$  and  $K'$  is not the first node in  $\pi'$ ,  $K'$  is adjacent to at least one node, say  $\hat{K}$ , before  $K'$  in  $\pi'$  and, moreover, as  $K'$  is the first node in  $\pi'|_{U_j}$ ,  $\hat{K}$  is from a different unit, say  $\hat{U}$ . If  $\hat{U}$  is the parent of  $U_j$  in  $\mathcal{LS}$ , we are done. Otherwise, by Lemma 5

and Definition 7, we know that nodes in each unit are consecutive in  $\pi'$ . As  $K$  is the first node of  $\pi'$  and  $K$  is contained in the root of  $\mathcal{LS}$ , by Properties 3 and 4, none of the nodes contained in any descendant of  $U_j$  is visited before  $K'$  in  $\pi'$ . It follows that  $\hat{U}$  is in the same bag as  $U_j$ . Then, by Property 8, there is a node from the parent of  $U_j$  adjacent to  $K'$  in  $H$ .

The algorithm runs in polynomial time since the table has at most  $O(n^2)$  entries, and computing the value of each entry can be done in polynomial time as described above. ◀

## Abstract

A probabilistic variant of input-driven pushdown automata (IDPDA), also known as visibly pushdown automata, is introduced. It is proved that these automata can be determinized: an  $n$ -state probabilistic IDPDA that accepts each string with probability at least  $\lambda + \delta$  or at most  $\lambda - \delta$  is transformed to a deterministic IDPDA with at most  $(1 + \frac{1}{\delta})^{n^2 - n}$  states recognizing the same language. An asymptotically close lower bound is provided: for infinitely many  $n$ , there is a probabilistic IDPDA with  $4n + 1$  states and  $\delta = \frac{1}{270n}$ , such that every equivalent deterministic IDPDA needs at least  $7^{n^2/14}$  states. A few special cases of automata with reduced determinization complexity are identified.

## 1 Introduction

In probabilistic models of computation, there are several options for every step of the computation, each with a specified probability. Probabilistic finite automata (PFA) were introduced by Rabin [23] in 1963. Assuming the two-sided bounded-error condition, that is, that every string is accepted either with probability at most  $\lambda - \delta$ , or with probability at least  $\lambda + \delta$ , for some  $\lambda$  and  $\delta$  with  $0 < \lambda - \delta < \lambda + \delta < 1$ , Rabin proved that every such automaton with  $n$  states can be transformed to a deterministic automaton (DFA) with at most  $(1 + \frac{1}{\delta})^{n-1}$  states. The lower bound on the determinization complexity has been refined several times: in 1982, Freivalds [11] proved that in the worst case  $2^{\Omega(\sqrt{n})}$  states are necessary, in 1996, Ambainis [4] improved this lower bound to  $\Omega(2^{n \frac{\log \log n}{\log n}})$ . Finally, in 2008, Freivalds [12] established the first exponential lower bound of the order  $7^{n/14}$ , improved to  $2^{n/4}$  under Artin's conjecture from number theory.

A probabilistic version of pushdown automata (PDA) was studied by Freivalds [10], who proved that they can recognize a language not recognized by any nondeterministic PDA. Later, Hromkovič and Schnitger [13] showed that these two models are incomparable in power, whereas probabilistic PDA with one-sided error are weaker than both models, yet stronger than deterministic PDA.

The concept of *input-driven pushdown automata* (IDPDA) was introduced by Mehlhorn [16] in 1980. This is a special case of pushdown automata, in which the operations performed on the stack are determined by the input symbols. Nondeterministic IDPDA were first defined by von Braunmühl and Verbeek [25], who proved that they can be determinized, with an  $n$ -state nondeterministic automaton transformed to a deterministic one with  $2^{n^2}$  states and  $O(2^{n^2})$  stack symbols. In 2004, Alur and Madhusudan [2] have reintroduced the model under the name of *visibly pushdown automata*, and obtained some important new

results: in particular, they proved that determinization requires  $2^{\Omega(n^2)}$  states in the worst case, established the closure of the family under all basic language operations, and determined the computational complexity of the inclusion and universality problems for IDPDA. Their paper motivated further research in this area. In particular, several related models were investigated, such as alternating [7], unambiguous [21] and timed input-driven pushdown automata [24, 8, 19], input-driven pushdown automata on infinite strings [3, 15, 22]. This research has also inspired some further models, such as pushdown automata driven by finite transducers [14].

In this paper we introduce and study the probabilistic version of IDPDA, with two-sided bounded-error condition, similar to the classical PFA [23] and probabilistic PDA [10]. Even though input-driven pushdown automata with randomized transitions appeared in several papers on automata on infinite strings and their verification [5, 9, 26], the cited papers were not concerned with language recognition, making their models much different from what is studied in this paper.

The first result of this paper is that probabilistic IDPDA with bounded error define the same class of languages as deterministic IDPDA. To be precise, if a language is recognized by bounded-error  $n$ -state PIDPDA with  $\delta$ -cutpoint, then the same language is recognized by a DIDPDA with  $(1 + \frac{1}{\delta})^{n^2-n}$  states and  $\text{const} \cdot (1 + \frac{1}{\delta})^{n^2-n}$  stack symbols. This is done via considering transition matrices on well-nested strings, and proving that if two matrices are close enough with respect to a certain norm, then they are equivalent under an equivalence relation defined by Alur et al. [1]. This in turn implies that the language is recognizable by an IDPDA.

In Section 5 we also give a lower bound. To do so we essentially find a way to lift lower bounds for PFAs to lower bounds for PIDPDAs. Then we apply the best known lower bound for PFAs – the one due to Freivalds [12].

Finally, in Section 6 we study the special case of automata operating on strings nesting depth one. Three cases of automata with reduced determinization complexity are identified. First, there is an analog of *unary* languages, in which every substring enclosed in brackets is unary, for which determinization requires fewer states than in the general case: only  $O((1 + \frac{1}{\delta})^n)$ . We also prove that the same bound holds for automata with  $\Sigma_0 = \{a, b\}$  if the transitions by  $a$  and  $b$  commute. The latter condition means that the automaton “counts” the number of  $a$ s and  $b$ s. Lastly, we show that if the transitions by every symbol in  $\Sigma_0$  are *deterministic*, then the upper bound can also be significantly reduced to  $n^n$ , under no restrictions on the size of  $\Sigma_0$ .

## 2 Deterministic Input-driven Pushdown Automata

A *deterministic input-driven pushdown automaton* (DIDPDA) [3, 16] is a special case of a deterministic pushdown automaton, in which the input alphabet  $\Sigma$  is split into three disjoint sets of *left brackets*  $\Sigma_{+1}$ , *right brackets*  $\Sigma_{-1}$  and *neutral symbols*  $\Sigma_0$ . The type of the input symbol determines the type of the operation with the stack: on a left bracket from  $\Sigma_{+1}$ , then the automaton always pushes one symbol onto the stack; on a right bracket from  $\Sigma_{-1}$ , the automaton must pop one symbol; finally, on a neutral symbol in  $\Sigma_0$ , the automaton may not use the stack. In this paper, symbols from  $\Sigma_{+1}$  and  $\Sigma_{-1}$  are denoted by left and right angled brackets, respectively ( $<$ ,  $>$ ), whereas lower-case Latin letters from the beginning of the alphabet ( $a, b, c, \dots$ ) are used for symbols from  $\Sigma_0$ .

► **Definition 1.** A *deterministic input-driven pushdown automaton* (DIDPDA) is a 6-tuple  $A = (\Sigma, Q, \Gamma, q_0, [\delta_a]_{a \in \Sigma}, F)$ , where

■  $\Sigma = \Sigma_{+1} \cup \Sigma_0 \cup \Sigma_{-1}$  is an input alphabet split into three disjoint classes;

- $Q$  is a finite set of states of the automaton, with an initial state  $q_0 \in Q$  and with a subset of accepting states  $F \subseteq Q$ ;
- $\Gamma$  is a finite set of stack symbols,
- the transition function by each left bracket symbol  $< \in \Sigma_{+1}$  is a function  $\delta_{<}: Q \rightarrow Q \times \Gamma$ , which, for a given current state, provides the next state and the symbol to be pushed onto the stack;
- for every right bracket symbol  $> \in \Sigma_{-1}$ , a function  $\delta_{>}: Q \times \Gamma \rightarrow Q$  specifies the next state, assuming that the given symbol is popped from the stack;
- for a neutral symbol  $c \in \Sigma_0$ , a function  $\delta_c: Q \rightarrow Q$  provides the next state.

For a string  $w = a_1 \dots a_\ell$ , with  $a_1, \dots, a_\ell \in \Sigma$ , the computation on  $w$  starting in a state  $r_0$  with stack contents  $\gamma_0 \in \Gamma^*$  is the sequence  $\{(r_i, \gamma_i)\}_{i=0}^\ell \in Q \times \Gamma^*$ , defined as follows.

- If  $a_i \in \Sigma_{+1}$ , then  $\delta_{a_i}(r_{i-1}) = (r_i, s)$  and  $\gamma_i = \gamma_{i-1}s$ ,
- If  $a_i \in \Sigma_{-1}$ , then  $\gamma_{i-1} = \gamma_i s$ , for some  $s \in \Gamma$ , and  $r_i = \delta_{a_i}(r_{i-1}, s)$ .
- If  $a_i \in \Sigma_0$ , then  $\gamma_i = \gamma_{i-1}$  and  $r_i = \delta_{a_i}(r_{i-1})$ .

If  $w$  is well-nested, then this computation is always defined, and ends in the configuration  $(r_\ell, \gamma_\ell)$ , with  $\gamma_\ell = \gamma_0$ .

A well-nested string  $w$  is accepted if the computation on  $w$  starting in  $q_0$  with the empty stack ends in a configuration  $(q, \varepsilon)$  with  $q \in F$ . The set of all accepted strings is denoted by  $L(A)$ .

One can notice that each word  $w$  defines a function  $f^w: Q \rightarrow Q$ , such that if  $A$  is in state  $q$ , it will be in state  $f^w(q)$  after reading  $w$ . Then  $L(A) = \{w \mid w \text{ is well-nested and } f^w(q_0) \in F\}$ .

For every language  $L$ , we define the following equivalence relation on the set of all well-nested strings.

► **Definition 2.** Let  $L$  be a set of well-nested strings. Let  $w_1$  and  $w_2$  be well-nested. The relation  $\approx_L$  on the set of well-nested strings is defined by  $w_1 \approx_L w_2$  if, for every two strings  $u, v$  with  $uw$  well-nested, the string  $uw_1v$  is in  $L$  if and only if  $uw_2v$  is in  $L$ .

If the language  $L$  is understood from the context, the relation  $\approx_L$  is denoted by  $\approx$ .

► **Lemma 3** (Alur et al. [1]).  $L$  is recognized by an IDPDA if and only if there is only a finite number of the equivalence classes with respect to this equivalence relation.

Moreover, DIDPDA can be chosen such that it has  $m$  states and  $|\Sigma_{+1}| \cdot m$  stack symbols, where  $m$  is the number of the equivalence classes. Also, if  $L$  is recognized by an IDPDA with  $n$  states, then the number of equivalence classes is not more than  $n^n$ .

### 3 Probabilistic Input-driven Automata

Unlike DIDPDAs, probabilistic input-driven pushdown automata may have multiple available transitions, with a probability of making each of them. Nevertheless, whether the automaton pushes, pops or leaves the stack intact, is still determined by the current input symbol. In the end, the input string is accepted if and only if the probability of reaching an accepting state after reading the string is sufficiently large.

► **Definition 4.** Let  $S$  be a countable or a finite set. Let  $D(S)$  denote the set of probability distributions on  $S$ , that is,  $D(S) = \{p: S \rightarrow [0, 1] \mid \sum_{x \in S} p(x) = 1\}$ .

► **Definition 5.** A probabilistic input-driven pushdown automaton (PIDPDA) is a 6-tuple  $A = (\Sigma, Q, \Gamma, q_0, [\delta_a]_{a \in \Sigma}, F)$ , where

## 78:4 Probabilistic Input-Driven Pushdown Automata

- $\Sigma = \Sigma_{+1} \sqcup \Sigma_0 \sqcup \Sigma_{-1}$  is an input alphabet split into three disjoint classes;
- $Q$  is a finite set of states of the automaton, with an initial state  $q_0 \in D(Q)$  and with a subset of accepting states  $F \subseteq Q$ ;
- $\Gamma$  is a finite set of stack symbols,
- the transition function by each left bracket symbol  $< \in \Sigma_{+1}$  is a function  $\delta_{<}: Q \rightarrow D(Q \times \Gamma)$ , which, for a given current state  $p \in Q$ , assigns a probability to each pair  $(q, s)$ , that is, the probability of pushing  $s$  onto the stack and entering the state  $q$ ;
- for every right bracket symbol  $> \in \Sigma_{-1}$ , a function  $\delta_{>}: Q \times \Gamma \rightarrow D(Q)$  specifies the probabilities of entering each state, assuming that the given symbol is popped from the stack;
- for a neutral symbol  $c \in \Sigma_0$ , a function  $\delta_c: Q \rightarrow D(Q)$  provides the probabilities of the next state.

For a string  $w = a_1 \dots a_\ell$ , with  $a_1, \dots, a_\ell \in \Sigma$ , a computation sequence on  $w$  is a sequence  $\{(r_i, \gamma_i)\}_{i=0}^\ell \in Q \times \Gamma^*$ , which satisfies the following conditions.

- if  $a_i \in \Sigma_{+1}$ , then  $\gamma_i = \gamma_{i-1}s$ , for some  $s \in \Gamma$ , and the probability of this step is defined by  $p_i = \delta_{a_i}(r_{i-1})(r_i, s)$ ,
- if  $a_i \in \Sigma_{-1}$ , then  $\gamma_{i-1} = \gamma_i s$ , for some  $s \in \Gamma$ , and the probability of this step is  $p_i = \delta_{a_i}(r_{i-1}, s)(r_i)$ .
- if  $a_i \in \Sigma_0$ , then  $\gamma_i = \gamma_{i-1}$  and the probability is  $\delta_{a_i}(r_{i-1})(r_i)$ .

The probability of such a sequence is the product  $p_1 \cdot \dots \cdot p_\ell$  of probabilities of individual steps.

The probability of going from configuration  $(q, \gamma)$  to configuration  $(q', \gamma')$  by reading a string  $w$  is the sum of probabilities of all computation sequences on  $w$  that start with  $(q, \gamma)$  and end with  $(q', \gamma')$ .

The probability of accepting a well-nested string  $w$  is the probability of going from its initial configuration to any accepting configuration.

$$\Pr(A \text{ accepts } w) = \sum_{q \in F} \Pr(A \text{ goes from } (q_0, \varepsilon) \text{ to } (q, \varepsilon) \text{ by reading } w)$$

► **Definition 6.** A probabilistic input-driven pushdown automaton  $A$  is said to have a  $\delta$ -cut-point  $\lambda$ , with  $\delta > 0$  and  $\lambda \in [0, 1]$ , if, for every well-nested  $w$ , either  $\Pr(A \text{ accepts } w) \geq \lambda + \delta$  or  $\Pr(A \text{ accepts } w) \leq \lambda - \delta$ .

► **Definition 7.** The language  $L(A)$  recognized by an automaton  $A$  with a  $\delta$ -cut-point  $\lambda$  is the set of all well-nested strings  $w$  for which  $\Pr(A \text{ accepts } w) \geq \lambda + \delta$ .

Similarly to the deterministic case, each well-nested word  $w$  defines a stochastic matrix  $P^w$  of order  $|Q| \times |Q|$ , where  $P_{q,r}^w = \Pr(A \text{ goes into } q \text{ from } r \text{ after reading } w)$ . This is a generalization of functions  $f^w$  for deterministic IDPDAs.

### 4 Determinization and Upper Bound

► **Theorem 8.** Let  $A$  be a probabilistic IDPDA with a  $\delta$ -cut-point  $\lambda$  and  $n$  states. Then there exists a deterministic IDPDA that recognizes the same language and has at most  $(1 + \frac{1}{\delta})^{n^2-n}$  states and at most  $|\Sigma_{+1}| \cdot (1 + \frac{1}{\delta})^{n^2-n}$  stack symbols.

To compare, Rabin's [23] transformation of a PFA to a DFA uses only  $(1 + \frac{1}{\delta})^{n-1}$  states. Rabin's argument estimates the number of Myhill–Nerode equivalence classes, which is sufficient to describe the computation of a finite automaton. The computations of input-driven pushdown automata are harder to simulate, and require more involved equivalence classes of Alur et al. ( $\approx$ , see Definition 2).

The main idea of the proof is that if, for two well-nested strings,  $w$  and  $w'$ , the corresponding stochastic matrices  $P^w$  and  $P^{w'}$  are close under a certain metric, then they must be equivalent in the sense of Definition 2, that is, replacing any substring  $w$  with  $w'$  does not change the acceptance status of a string.

We shall use the following lemma which provides an upper bound on the maximum number of stochastic matrices at least  $2\delta$  apart in the metric given by the norm  $\|\xi\| = \max_{1 \leq k \leq n} \sum_{\ell=1}^n |\xi_{k\ell}|$ . The proof uses Rabin's idea involving volumes.

► **Lemma 9.** *Let  $\xi^{(1)}, \dots, \xi^{(m)}$  be stochastic matrices of order  $n$ , such that  $\|\xi^{(\ell)} - \xi^{(k)}\| \geq 2\delta$  for  $\ell \neq k$ . Then  $m \leq (1 + \frac{1}{\delta})^{n^2-n}$ .*

**Proof.** We view  $n \times n$  matrices as points in  $\mathbb{R}^{n^2}$ . Let  $M_n(\mathbb{R}_{\geq 0})$  denote the set of such matrices with non-negative elements. For  $r > 0$  let us define

$$S(r) = \left\{ t \in M_n(\mathbb{R}_{\geq 0}) \mid \sum_{1 \leq j \leq n} t_{ij} = r \text{ for } 1 \leq i \leq n \right\}$$

In particular, it follows from the definition that  $S(1)$  is the set of stochastic matrices.

▷ **Claim 10.** If  $r < \delta$ , then  $\xi^{(k)} + S(r)$  and  $\xi^{(\ell)} + S(r)$  are disjoint for  $k \neq \ell$ .

**Proof.** Suppose  $(\xi^{(k)} + S(r)) \cap (\xi^{(\ell)} + S(r)) \neq \emptyset$ . Then there exist  $x, y \in S(r)$  such that  $\xi^{(k)} + x = \xi^{(\ell)} + y$ . By definition, the norm of every element in  $S(r)$  is equal to  $r$ , therefore  $\|\xi^{(\ell)} - \xi^{(k)}\| = \|x - y\| \leq \|x\| + \|y\| = 2r < 2\delta$ , which contradicts the assumption that  $\|\xi^{(\ell)} - \xi^{(k)}\| \geq 2\delta$ . ◀

Clearly,  $\xi^{(1)}, \dots, \xi^{(m)} \in S(1)$  because they are stochastic. Thus,  $\xi^{(1)} + S(r), \dots, \xi^{(m)} + S(r) \subseteq S(1) + S(r) = S(1+r)$ , where the latter equality follows from the definition of  $S(r)$ . By the claim, the sets  $\xi^{(1)} + S(r), \dots, \xi^{(m)} + S(r)$  are pairwise disjoint, and all of them are contained in  $S(r+1)$ .

Now the plan is to use volumes of the sets  $\xi^{(k)} + S(r)$  to prove that only a limited number of such sets may fit into  $S(1+r)$ . Since the  $n^2$ -dimensional volume of  $S(r)$  is 0, the first step is determine the right dimension. Let  $d$  be the dimension of  $S(r)$ , which is the same as the dimension of  $S(1)$ , since these sets are the same up to scaling. It is claimed that  $d = n^2 - n$ . The set  $S(1)$  is contained in the  $(n^2 - n)$ -dimensional (affine) subspace  $H$  defined by the equations  $t_{i1} + \dots + t_{in} = 1, i = 1, \dots, n$ , so  $d \leq n^2 - n$ . On the other hand,  $S(1)$  contains a  $(n^2 - n)$ -dimensional ball of small radius, confirming that  $d = n^2 - n$ .

Let  $V_d$  denote the  $d$ -dimensional volume. The sum of the volumes of the disjoint sets  $\xi^{(k)} + S(r)$  does not exceed the volume of the set  $S(r+1)$  they are contained in.

$$V_d(S(r+1)) \geq V_d((\xi^{(1)} + S(r)) \cup \dots \cup (\xi^{(m)} + S(r))) = V_d(\xi^{(1)} + S(r)) + \dots + V_d(\xi^{(m)} + S(r))$$

Notice that  $V_d(\xi^{(1)} + S(r)) = V_d(S(r))$  because  $\xi^{(k)} + S(r)$  is a translation of  $S(r)$ . Hence, the last inequality yields  $mV_d(S(r)) \leq V_d(S(r+1))$ .

The linear transformation  $t \mapsto \frac{r+1}{r}t$  maps  $S(r)$  onto  $S(r+1)$  (because if  $\sum_{1 \leq j \leq n} t_{ij} = r$ , then  $\sum_{1 \leq j \leq n} \frac{r+1}{r}t_{ij} = \frac{r+1}{r}r = r+1$ ), therefore  $V_d(S(r+1)) = (\frac{r+1}{r})^d V_d(S(r))$ . But we have already established that  $V_d(S(r+1)) \geq mV_d(S(r))$ , thus  $(1 + \frac{1}{r})^d V_d(S(r)) \geq mV_d(S(r))$  and therefore  $m \leq (1 + \frac{1}{r})^d$  for  $0 < r < \delta$ . Passing to the limit as  $r$  tends to  $\delta$ , we obtain  $m \leq (1 + \frac{1}{\delta})^d = (1 + \frac{1}{\delta})^{n^2-n}$ . ◀

The next lemma provides a connection between the matrices  $P^w$  and the equivalence classes.

► **Lemma 11.** *If  $\|P^{w_1} - P^{w_2}\| < 2\delta$  then  $w_1 \approx w_2$ .*

**Proof.** Consider any well-nested strings  $w$  and  $uv$ . Note that because  $w$  is well-nested, after reading  $uw$  the stack will be exactly the same as after reading  $u$ . Let  $h$  be the nesting depth of  $u$ .

Then  $\Pr(A \text{ accepts } uv)$  is expressed as the following sum over all possible stack contents after reading  $u$  and states before and after reading  $w$ .

$$\sum_{\gamma \in \Gamma^h} \sum_{\substack{1 \leq i \leq n \\ 1 \leq j \leq n}} \Pr(A \text{ goes to } (i, \gamma) \text{ after reading } u) \cdot P_{ij}^w \cdot \Pr(A \text{ accepts from } (j, \gamma) \text{ after reading } v)$$

For brevity, denote the probabilities of parts of this computation by

$$\begin{aligned} q_i(\gamma) &:= \Pr(A \text{ goes into } (i, \gamma) \text{ after reading } u), \\ r_j(\gamma) &:= \Pr(A \text{ accepts from } (j, \gamma) \text{ after reading } v), \end{aligned}$$

so that the above probability is expressed as follows.

$$\Pr(A \text{ accepts } uv) = \sum_{\gamma \in \Gamma^h} \sum_{1 \leq i, j \leq n} q_i(\gamma) \cdot P_{ij}^w \cdot r_j(\gamma)$$

Then the probability  $q_i(\gamma)$  depends only on  $i$ ,  $\gamma$  and  $u$ ; the probability  $r_j(\gamma)$  depends only on  $j$ ,  $\gamma$  and  $v$ ; and  $\sum_{1 \leq i \leq n} \sum_{\gamma \in \Gamma^h} q_i(\gamma) = 1$ .

Therefore, the difference between the probabilities of accepting  $uw_1v$  and  $uw_2v$  is estimated as

$$\begin{aligned} |\Pr(A \text{ accepts } uw_1v) - \Pr(A \text{ accepts } uw_2v)| &= \left| \sum_{\gamma \in \Gamma^h} \sum_{1 \leq i, j \leq n} q_i(\gamma) (P_{ij}^{w_1} - P_{ij}^{w_2}) r_j(\gamma) \right| \leq \\ &\leq \sum_{\gamma \in \Gamma^h} \sum_{1 \leq i, j \leq n} q_i(\gamma) \cdot |P_{ij}^{w_1} - P_{ij}^{w_2}| \cdot r_j(\gamma) \leq \\ &\leq \sum_{\gamma \in \Gamma^h} \sum_{1 \leq i, j \leq n} q_i(\gamma) \cdot |P_{ij}^{w_1} - P_{ij}^{w_2}| = \\ &= \sum_{1 \leq i \leq n} \sum_{\gamma \in \Gamma^h} q_i(\gamma) \sum_{1 \leq j \leq n} |P_{ij}^{w_1} - P_{ij}^{w_2}| \leq \\ &\leq \left( \sum_{1 \leq i \leq n} \sum_{\gamma \in \Gamma^h} q_i(\gamma) \right) \cdot \max_{1 \leq i \leq n} \sum_{1 \leq j \leq n} |P_{ij}^{w_1} - P_{ij}^{w_2}| = \\ &= \max_{1 \leq i \leq n} \sum_{1 \leq j \leq n} |P_{ij}^{w_1} - P_{ij}^{w_2}| < 2\delta \end{aligned}$$

Since every well-nested string is accepted with the probability of either at least  $\lambda + \delta$  or at most  $\lambda - \delta$ ,  $w_1$  and  $w_2$  are accepted or rejected simultaneously, which proves the claim. ◀

Now we are ready to prove the theorem.

**Proof of Theorem 8.** The proof is by bounding the number of equivalence classes under  $\approx$ . Suppose there are at least  $m$  equivalence classes, then we can take  $w_1, \dots, w_m$  to be the representatives of these classes. This yields  $m$  points  $P^{w_1}, \dots, P^{w_m}$  in  $[0, 1]^{n^2}$ . Due to Lemma 11, for  $k \neq \ell$ , the inequality  $\|P_{ij}^{w_k} - P_{ij}^{w_\ell}\| \geq 2\delta$  holds because  $w_k \not\approx w_\ell$ . Then, Lemma 9 implies  $m \leq (1 + \frac{1}{\delta})^{n^2 - n}$ . By Lemma 3, there is a DIDPDA with  $m$  states and  $|\Sigma_{+1}| \cdot m$  stack symbols accepting the same language. ◀

## 5 Lower bounds

The first exponential lower bounds on the complexity of determinizing an  $n$ -state PFA were constructed by Freivalds [12]. His lower bound exists in two versions, both of the form  $c^n$ , but with different values of  $c$ : one bound holds unconditionally, whereas the other, with a greater base  $c$ , relies on Artin's conjecture from number theory. The second bound also uses PFAs with a smaller error probability.

► **Theorem 12** (Freivalds [12]). *For infinitely many numbers  $n$ , there exists a PFA with  $n$  states with a  $\delta_0$ -cutpoint  $\lambda_0 = \frac{1}{2}$ , such that any equivalent DFA needs at least  $c^n$  states, where  $c = 7^{\frac{1}{14}}$  and  $\delta_0 = \frac{1}{270}$ . If Artin's conjecture is true, then the estimate holds for  $c = 2^{\frac{1}{4}}$ ,  $\delta_0 = \frac{1}{36}$ .*

We will use this result to construct a lower bound in our setting.

► **Theorem 13.** *For infinitely many numbers  $n$ , there exists a PIDPDA with  $4n + 1$  states and a  $\delta_0$ -cutpoint  $\lambda(n) = \frac{1}{2n}$ , such that every equivalent DIDPDA needs at least  $c^{n^2}$  states, where  $c = 7^{\frac{1}{14}}$  and  $\delta_0 = \frac{1}{270}$ . If Artin's conjecture is true, then the estimate holds for  $c = 2^{\frac{1}{4}}$ ,  $\delta_0 = \frac{1}{36}$ .*

**Proof.** For infinitely many numbers  $n$ , Freivalds constructed a language  $K_n$  such that:

- it can be recognized by a PFA  $A$  with a  $\delta_0$ -cutpoint  $\lambda_0 = \frac{1}{2}$  and  $n$  states,
- any DFA recognizing  $K_n$  requires at least  $c^n$  states.

The latter means that there exists a set  $\{u_i \mid 1 \leq i \leq \lceil c^n \rceil\}$  of at least  $c^n$  strings such that for every two strings from this set,  $u_{i_1}$  and  $u_{i_2}$  with  $i_1 \neq i_2$ , there exists a separating string  $v$  with one of the concatenations  $u_{i_1}v$ ,  $u_{i_2}v$  in  $K_n$  and the other not in  $K_n$ . Let  $\{v_j \mid 1 \leq j \leq m\}$  be a finite set of such separating strings, so that for all  $i_1$  and  $i_2$  with  $i_1 \neq i_2$  there exists  $j \in \{1, \dots, m\}$  with  $u_{i_1}v_j \in K_n$  if and only if  $u_{i_2}v_j \notin K_n$ .

In the PFA defined by Freivalds, let  $Q$  be its set of states, and consider the probability distribution on the set of states after reading each string  $u_i$  from the initial state, as well as the probability of accepting each string  $v_j$  from each state, and denote them by the following vectors  $p_i \in \mathbb{R}^n$  and  $r_j \in \mathbb{R}^n$ .

$$(p_i)_q = \Pr(A \text{ goes into } q \text{ after reading } u_i)$$

$$(r_j)_q = \Pr(A \text{ accepts from } q \text{ after reading } v_j)$$

Then the probability of accepting each concatenation  $u_i v_j$  is a scalar product  $\langle p_i, r_j \rangle$ , and since this is a bounded-error PFA with  $\delta_0$ -cutpoint  $\lambda_0 = \frac{1}{2}$ , the following two properties must hold.

- (i) For every  $i, j$  either  $\langle p_i, r_j \rangle \geq \lambda_0 + \delta_0$  or  $\langle p_i, r_j \rangle \leq \lambda_0 - \delta_0$ .
- (ii) For every  $i_1 \neq i_2$  there exists  $j$  such that  $\langle p_{i_1}, r_j \rangle \geq \lambda_0 + \delta_0$  and  $\langle p_{i_2}, r_j \rangle \leq \lambda_0 - \delta_0$  (or  $\langle p_{i_2}, r_j \rangle \geq \lambda_0 + \delta_0$  and  $\langle p_{i_1}, r_j \rangle \leq \lambda_0 - \delta_0$ ).

Now these strings  $u_i$  and  $v_j$ , along with the PFA, are used to construct the desired probabilistic input-driven automaton. It is constructed over an alphabet with a single left bracket,

$$\Sigma_{+1} = \{<\},$$

with a large set of neutral symbols each encoding an  $n$ -tuple of strings  $u_i$ ,

$$\Sigma_0 = \{a_{i_1, \dots, i_n} \mid 1 \leq i_1, \dots, i_n \leq \lceil c^n \rceil\},$$

and with right brackets representing separating strings applied to one particular component of an  $n$ -tuple.

$$\Sigma_{-1} = \{ \rangle_{k,j} \mid k \in \{1, 2, \dots, n\}; 0 \leq j \leq m \}$$

Define the new language as  $L_n = \{ \langle a_{i_1, \dots, i_n} \rangle_{k,j} \mid u_{i_k} v_j \in K_n \}$ . Then, in order to test the membership of a concatenation  $u_{i_k} v_j$  in  $K_n$ , a deterministic IDPDA will have to remember the entire  $n$ -tuple of strings, whereas a probabilistic automaton can randomly choose  $k$  in the beginning, and then simulate Freivalds' automaton on the  $k$ -th component of the tuple.

▷ **Claim 14.** There exists a PIDPDA  $B$  with  $4n + 1$  states and a  $\delta(n)$ -cutpoint  $\lambda(n)$  recognizing  $L_n$ .

*Proof.* An  $n$ -state PIDPDA, which assumes three-symbol input strings of the form  $\langle a_{i_1, \dots, i_n} \rangle_{k,j}$ , is constructed first; later it will be extended to check the form of the string.

The automaton operating on well-formed strings uses the same set of states  $Q$  as Freivalds' automaton. Assume that the states are numbers:  $Q = \{1, \dots, n\}$ , and let  $n$  be the only accepting state. The same set  $Q$  is also used as the stack alphabet.

In the initial state, the automaton reads the left bracket  $\langle$  and equiprobably chooses the next state  $s$  and pushes  $s$  onto the stack. Next, it encounters a symbol  $a_{i_1, \dots, i_n}$  in the state  $s$ , and simply replicates the probability distribution of Freivalds' automaton on the string  $u_{i_s}$ .

$$\delta'_{a_{i_1, \dots, i_n}}(s)(t) = (p_{i_s})_t$$

Finally, upon reading a right bracket  $\rangle_{k,j}$  in a state  $t$ , the automaton should decide whether to enter the accepting state  $n$ . It pops the number  $s$  from the stack, and if it does not match  $k$ , the automaton rejects (by entering  $n$  with probability 0). If  $s$  equals  $k$ , then the automaton accepts with the same probability  $(r_j)_t$ , with which Freivalds' automaton accepts the string  $v_j$  from the state  $t$ .

$$\begin{aligned} \delta'_{\rangle_{k,j}}(t, s)(n) &= \begin{cases} 0, & \text{if } k \neq s \\ (r_j)_t, & \text{if } k = s \end{cases} \\ \delta'_{\rangle_{k,j}}(t, s)(1) &= 1 - \delta'_{\rangle_{k,j}}(t, s)(n) \\ \delta'_{\rangle_{k,j}}(t, s)(\ell) &= 0 \qquad \qquad \qquad (2 \leq \ell \leq n - 1) \end{aligned}$$

It is claimed that this automaton accepts a string  $\langle a_{i_1, \dots, i_n} \rangle_{k,j}$  with probability  $\frac{1}{n} \langle p_{i_k}, r_j \rangle$ . Indeed, the randomly chosen number  $s$  matches  $k$  with probability  $\frac{1}{n}$ , and, provided that it happened, the probability of acceptance is

$$\begin{aligned} &\sum_{q \in Q} \left( \Pr(B \text{ goes from } k \text{ to } q \text{ after reading } a_{i_1, \dots, i_n}) \cdot \right. \\ &\quad \left. \Pr(B \text{ accepts from } q \text{ upon reading } \rangle_{k,j} \text{ with } k \text{ in the stack}) \right) = \\ &\qquad \qquad \qquad = \sum_{q \in Q} (p_{i_k})_q \cdot (r_j)_q = \langle p_{i_k}, q_j \rangle \end{aligned}$$

By (ii), the scalar product  $\langle p_{i_k}, q_j \rangle$  is either at least  $\lambda_0 + \delta_0$  (if  $u_{i_k} v_j \in K_n$ ), or at most  $\lambda_0 - \delta_0$  (if  $u_{i_k} v_j \notin K_n$ ). Therefore, the overall probability is either at least  $\frac{\lambda_0}{n} + \frac{\delta_0}{n}$ , or at most  $\frac{\lambda_0}{n} - \frac{\delta_0}{n}$ .

The construction above works for words in  $\langle \Sigma_0 \Sigma_{-1}$ , other words may violate the  $\delta$ -cutpoint condition. To eliminate them we can take a 4-state partial DFA that verifies that the input string is indeed of the form  $\langle \Sigma_0 \Sigma_{-1}$ , and take the direct product of the automaton above and this DFA. One extra dead state is added for ill-formed strings. ◁

▷ **Claim 15.** Any DIDPDA recognizing  $L_n$  has at least  $|\Sigma_0| \geq c^{n^2}$  states.

*Proof.* Since all well-formed strings begin with the same left bracket  $\langle$ , a deterministic automaton cannot store any information on the stack: it always pushes the same stack symbol. Consider the state of the DIDPDA after reading  $\langle a_{i_1, \dots, i_n}$ . It is claimed that this state must be different for different symbols.

Suppose the contrary, that for some two symbols  $a_{i_1, \dots, i_n} \neq a_{i'_1, \dots, i'_n}$ , the state after reading them is the same state  $q$ . Let  $k$  be such that  $i_k \neq i'_k$ , and let  $v_j$  be the separating string for  $u_{i_k}$  and  $u_{i'_k}$  with respect to Freivalds' automaton, that is, exactly one of the strings  $u_{i_k} v_j$ ,  $u_{i'_k} v_j$  is in  $K_n$ . Then, by the definition of  $L_n$ , exactly one of the strings  $\langle a_{i_1, \dots, i_n} \rangle_{k,j}$  and  $\langle a_{i'_1, \dots, i'_n} \rangle_{k,j}$  is in  $L_n$ . However, since the IDPDA is in the same configuration before reading  $\rangle_{k,j}$  on either string, it either accepts both strings or rejects both of them. The contradiction obtained shows that the number of states in the DIDPDA is at least  $|\Sigma_0|$ . ◀

The theorem follows from the two claims. ◀

The upper bound on the size of the constructed automaton gives  $(1 + \frac{1}{\delta(n)})^{(4n+1)^2 - (4n+1)} = (1 + \frac{n}{\delta_0})^{16n^2 + 4n} \leq (\frac{n+1}{\delta_0})^{16n^2 + 4n} = c^{(16n^2 + 4n) \log_c \frac{n+1}{\delta_0}} = c^{(16n^2 + 4n)(\log_c(n+1) - \log_c \delta_0)} = c^{(16+o(1))n^2 \log_c n} = c^{(16 \log_c 2 + o(1))n^2 \log_2 n}$ . We see that the exponent differs from the one in the lower bound by an  $O(\log n)$  factor.

## 6 Sharper Upper Bounds in Special Cases

For probabilistic finite automata, the case of a unary alphabet is much different from the general case. The first lower bound on the determinization complexity in the unary case was given by Freivalds [11]. Milani and Pighizzini [18] proved that the worst-case determinization blowup in the unary case is of the order of Landau's function, that is,  $e^{(1+o(1))\sqrt{n} \ln n}$ . Later Mereghetti et al. [17] and Bianchi et al. [6] investigated more details of the complexity of unary PFAs.

For input-driven pushdown automata, there is no unary case in the strict sense: as long as there is a pair of matching brackets, one can use them to encode any alphabet. In order to obtain a variant of the unary case, the use of brackets should be somehow restricted. The following condition of *nesting depth one* still allows encoding a binary alphabet by abusing the brackets, but this can be done only outside the brackets; if  $|\Sigma_0| = 1$ , then inside the brackets the string is truly unary.

► **Definition 16.** A well-nested language  $L$  is called a *depth-one language* if for every  $w \in L$  the maximal nesting depth of  $w$  is one, i.e.,  $L \subseteq \Sigma_0^*(\Sigma_{+1}\Sigma_0^*\Sigma_{-1}\Sigma_0^*)^*$ .

For depth-one languages, it is natural to consider the classical Myhill–Nerode relation operating on the outer level of brackets and restricted to well-nested strings.

► **Definition 17.** For a language of well-nested strings  $L$ , define a relation  $\sim_L$  on the set of well-nested strings by  $u \sim_L u'$  if and only if, for every well-nested string  $v$ , the string  $uv$  is in  $L$  if and only if  $u'v$  is in  $L$ . When the language  $L$  is clear from the context, the relation  $\sim_L$  shall be denoted by  $\sim$ .

Denote by  $[u]$  the equivalence class of a string  $u$  under  $\sim$ .

Later it will be shown that if a depth-one language uses unary strings inside the brackets, then the determinization complexity is reduced. More generally, assume that the string inside each pair of brackets belongs to a regular set  $S \subseteq \Sigma_0^*$ .

► **Definition 18.** Let  $S \subseteq \Sigma_0^*$  be a regular prefix-closed language, that is, if  $w_1w_2 \in S$ , then  $w_1 \in S$ . A depth-one language  $L$  is called  $S$ -nice if, for every string  $x \in L$  and for every partition  $x = u\langle w \rangle v$ , with  $w \in \Sigma_0^*$ , the string  $w$  is in  $S$ .

For an  $S$ -nice language  $L$ , consider the equivalence relation from Definition 2, defined by  $w \approx w'$  if and only if, for all  $x, y$  with  $xy$  well-nested,  $xwy \in L$  if and only if  $xw'y \in L$ . The following notation is introduced for equivalence classes restricted to elements of  $S$ .

► **Definition 19.** For  $u \in S$ , let  $[[u]]_S \subseteq S$  be the set of all strings in  $S$  equivalent to  $u$  under the relation  $\approx$ .

For  $S$ -nice languages, there is an automaton of size proportional to the number of these equivalence classes (cf. Lemma 3 for the general case).

► **Lemma 20.** Let  $L$  be an  $S$ -nice language, and let  $n_1$  be the number of equivalence classes under  $\sim$ , and let  $n_2$  be the number of equivalence classes under  $\approx$  restricted to  $S$ . Then there exists a DIDPDA recognizing  $L$  with  $n_1 + O(n_2)$  states and  $n_1 \cdot |\Sigma_{+1}|$  stack symbols.

Equivalence classes under  $\sim$  become states used outside brackets. Whenever a bracket is encountered, these states are pushed onto the stack along with the bracket. Equivalence classes under  $\approx$  are used as states inside brackets. The details are omitted for brevity.

Thus, in order to obtain upper bounds on the size of DIDPDA recognizing various languages of restricted form, it is sufficient to estimate the number of equivalence classes under both relations  $\sim$  and  $\approx$ .

The first observation is that the number of Myhill–Nerode classes on the outer level of brackets can be estimated using Rabin’s [23] argument for finite automata.

► **Lemma 21.** Let a language  $L$  be recognized by a PIDPDA  $A$  with  $n$  states and a  $\delta$ -cutpoint  $\lambda$ . Then  $L$  has at most  $(1 + \frac{1}{\delta})^{n-1}$  equivalence classes under  $\sim$ .

**Sketch of a proof.** Rabin’s [23, Thm. 3] argument works, because it never refers to actual transitions of a probabilistic automaton, and uses only probabilities of computations over prefixes and suffixes. If these prefixes and suffixes contain any brackets, this does not affect the argument.

For well-nested  $u$  and  $v$  we introduce the vectors  $p(u), r(v) \in \mathbb{R}^n$  with

$$p(u)_i = \Pr(A \text{ goes into } q_i \text{ after reading } u),$$

$$r(v)_i = \Pr(A \text{ accepts from } q_i \text{ after reading } v).$$

Then the probability that  $A$  accepts  $uv$  is equal to

$$\sum_{i=1}^n \Pr(A \text{ goes into } q_i \text{ after reading } u) \cdot \Pr(A \text{ accepts from } q_i \text{ after reading } v) = \langle p(u), r(v) \rangle.$$

Again, for well-nested  $u$  and  $u'$  it turns out that  $\sum_{i=1}^n |p(u)_i - p(u')_i| < 2\delta$  implies  $u \sim u'$ , because for any well-nested  $v$  the following inequality holds.

$$\begin{aligned} |\Pr(A \text{ accepts } uv) - \Pr(A \text{ accepts } u'v)| &= |\langle p(u), r(v) \rangle - \langle p(u'), r(v) \rangle| = \\ &= |\langle p(u) - p(u'), r(v) \rangle| = \left| \sum_{i=1}^n (p(u)_i - p(u')_i) r(v)_i \right| \leq \\ &\leq \sum_{i=1}^n |p(u)_i - p(u')_i| \cdot r(v)_i \leq \sum_{i=1}^n |p(u)_i - p(u')_i| < 2\delta \end{aligned}$$

Therefore, pairwise inequivalent strings  $u_1, \dots, u_m$  yield vectors  $p(u_1), \dots, p(u_m)$  with  $\sum_{i=1}^n |p(u_k)_i - p(u_l)_i| > 2\delta$ , and, as Rabin showed, in this case  $m \leq (1 + \frac{1}{\delta})^n$ . ◀

In some special cases of languages, the number of equivalence classes under  $\approx$  restricted to  $S$  is fairly small, leading to upper bounds on the size of DIDPDA. The first such case is when the probabilistic automaton behaves deterministically inside the brackets.

► **Theorem 22.** *Let  $A$  be a PIDPDA with  $n$  states and a  $\delta$ -cutpoint  $\lambda$  that recognizes a depth-one language, and assume that all transitions by symbols in  $\Sigma_0$  are deterministic. Then there is an equivalent DIDPDA with  $O(n^n)$  states.*

**Proof.** By Lemma 21, the number of equivalence classes under  $\sim$  for  $L$  is at most  $(1 + \frac{1}{\delta})^{n-1}$ .

The language is  $S$ -nice with  $S = \Sigma_0^*$ . Recall that if  $P^{w_1} = P^{w_2}$ , the words  $w_1$  and  $w_2$  are equivalent under  $\approx$ . Since all matrices  $P^w$  for  $w \in S = \Sigma_0^*$  are deterministic, they correspond to functions from  $Q$  to  $Q$  and, hence, the number of such matrices is not greater than  $n^n$ . Thus, there are at most  $n^n$  equivalence classes under  $\approx$  restricted to  $S$ .

Finally, by Lemma 20, there is a DIDPDA with  $O((1 + \frac{1}{\delta})^{n-1} + n^n) = O(n^n)$  states. ◀

The theorem implies that it is impossible to achieve the  $\Omega(c^{n^2})$  lower bound with a depth-one language using probabilistic transitions only for the brackets.

The special case of automata in Theorem 22 had the transition matrices inside the brackets generate a finite set of size  $n^n$ . In other special cases of automata with reduced determinization complexity, defined below, transition matrices inside the brackets generate infinite subspaces, yet the *dimension* of those subspaces is bounded. The following lemma allows a small DIDPDA to be constructed in such cases.

► **Lemma 23.** *Let  $L$  be an  $S$ -nice language recognized by a PIDPDA with  $n$  states. Let  $W$  be the subspace of  $M_n(\mathbb{R})$  generated by  $\{P^w \mid w \in S\}$ . Then there is a DIDPDA with  $O((1 + \frac{1}{\delta})^{\max\{n-1, \dim W\}})$  states recognizing  $L$ .*

The proof of Lemma 23 relies on the following geometric property.

► **Lemma 24.** *Let  $\xi^{(1)}, \dots, \xi^{(m)}$  be stochastic matrices of order  $n$ , such that  $\|\xi^{(k)} - \xi^{(\ell)}\| \geq 2\delta$  for  $k \neq \ell$ . Assume that there exists a linear subspace  $W \leq M_n(\mathbb{R})$ , such that for every  $i$  the matrix  $\xi^{(i)}$  lies in  $W$ . Then  $m \leq (1 + \frac{1}{\delta})^{\min\{n^2 - n, \dim W\}}$ .*

Lemma 24 is proved generally similarly to Lemma 9, but requires a more careful choice of  $S(r)$ ; the proof is omitted due to space constraints.

**Proof of Lemma 23.** Indeed, the number of equivalence classes under  $\approx$  is bounded by  $(1 + \frac{1}{\delta})^{\max\{n-1, \dim W\}}$ : if we have  $m$  equivalence classes under  $\approx$ , then they yield  $m$  pairwise inequivalent strings  $w_1, \dots, w_m$ . That, in turn, by Lemma 11, gives rise to  $m$  matrices  $P^{w_1}, \dots, P^{w_m}$  with  $\|P^{w_k} - P^{w_\ell}\| \geq 2\delta$  for  $k \neq \ell$ . By Lemma 24,  $m \leq (1 + \frac{1}{\delta})^{\max\{n-1, \dim W\}}$ . Furthermore, the number of equivalence classes under  $\sim$  is bounded by  $(1 + \frac{1}{\delta})^{n-1}$  by Lemma 21. Combining these two observations and using Lemma 20, we obtain the desired result. ◀

The first class of languages with an improved bound on the dimension of the subspace generated by transition matrices inside the brackets is the following variant of unary languages.

► **Theorem 25.** *If  $L$  is an  $S$ -nice language, and  $S = a_1^* \cup \dots \cup a_k^*$  for some  $a_1, \dots, a_k \in \Sigma_0^*$ , then there is a DIDPDA recognizing  $L$  with  $O((1 + \frac{1}{\delta})^{kn})$  states.*

**Proof.** For every word  $w$  in  $S$  the matrix  $P^w$  is of the form  $(P^{a_i})^m$  for some  $m \in \mathbb{N}_0$  and  $1 \leq i \leq k$ . By Cayley–Hamilton theorem, for each  $a_i$  the space  $W_i$  generated by  $\{(P^{a_i})^m \mid m \geq 0\}$  has the dimension of at most  $n$ ; therefore, all such matrices lie in a vector space  $W = W_1 + \dots + W_n$  such that  $\dim W \leq \sum_{i=1}^n \dim W_i \leq kn$ . It remains to apply Lemma 23. ◀

► **Corollary 26.** *If  $S = a^*$ , then there is a DIDPDA recognizing  $L$  with  $O((1 + \frac{1}{\delta})^n)$  states.*

In particular, the theorem shows that we would not be able to prove the lower bound from Section 5 using a “unary” depth-one language. For instance, the determinization of the automaton that reads  $\langle a^n \rangle$  and verifies that  $n$  belongs to some fixed subset yields at most exponential growth in the number of states. This is somewhat similar to the case of probabilistic finite automata, where the state complexity of the determinization in the unary case is also reduced.

The last special case with improved determinization is the case of automata that use strings over an alphabet  $\{a, b\}$  inside the brackets, and the transitions by  $a$  commute with transitions by  $b$ , that is,  $P^a P^b = P^b P^a$ . In other words, such automata only count the number of  $as$  and  $bs$  inside the brackets. In this case, there is the following known result on the dimension of the subspace they generate.

► **Theorem 27** (Gerstenhaber, 1961). *Let  $A, B \in M_n(\mathbb{R})$  be a pair of commuting matrices. Then the dimension of the subalgebra generated by  $\{A, B\}$  is at most  $n$ .*

► **Theorem 28.** *If  $S = \{a, b\}^*$  and  $P^a$  and  $P^b$  commute, then there exists an equivalent DIDPDA with  $O((1 + \frac{1}{\delta})^n)$  states.*

**Proof.** If  $w \in S$ , then  $P^w = (P^a)^{|w|_a} (P^b)^{|w|_b}$  lies in the subalgebra generated by  $\{P^a, P^b\}$ , whose dimension is at most  $n$ . Now we can use Lemma 23 to get the desired upper bound. ◀

## 7 Conclusion

It would be interesting to refine the results on the complexity of determinization for the new model by proving a lower bound on both the number of states and the number of stack symbols. Such a lower bound is known for the determinization of nondeterministic input-driven pushdown automata [20] and of their event-clock real-time extension [19]. The method employed in these papers uses strings of arbitrarily large nesting depth, and the automaton makes non-deterministic choices at each nesting level; however, if the same approach were used in our case, then the probability of error would tend to 1 as the nesting depth goes to infinity. Apparently, a new method would be necessary to prove such a bound in the probabilistic case.

Another interesting direction to pursue is improving the bound with respect to  $\delta$ . Our current upper bound is polynomial in  $\frac{1}{\delta}$ . However, it seems possible that there is room for improvement: either a trade-off between the number of states and the probability of error, or perhaps an upper bound that does not depend on  $\delta$  at all.

---

## Abstract

We introduce the 2-sorted counting logic  $\text{GC}^k$  and its restriction  $\text{RGC}^k$  that express properties of hypergraphs. These logics have available  $k$  variables to address hyperedges, an unbounded number of variables to address vertices of a hypergraph, and atomic formulas  $E(e, v)$  to express that a vertex  $v$  is contained in a hyperedge  $e$ . We show that two hypergraphs  $H, H'$  satisfy the same sentences of the logic  $\text{RGC}^k$  if, and only if, they are homomorphism indistinguishable over the class of hypergraphs of generalised hypertree width at most  $k$ . Here,  $H, H'$  are called homomorphism indistinguishable over a class  $\mathcal{C}$  if for every hypergraph  $G \in \mathcal{C}$  the number of homomorphisms from  $G$  to  $H$  equals the number of homomorphisms from  $G$  to  $H'$ . This result can be viewed as a lifting (from graphs to hypergraphs) of a result by Dvořák (2010) stating that any two (undirected, simple, finite) graphs  $H, H'$  are indistinguishable by the  $k+1$ -variable counting logic  $C^{k+1}$  if, and only if, they are homomorphism indistinguishable over the class of graphs of tree-width at most  $k$ .

## 1 Introduction

Counting homomorphisms from a given class  $\mathcal{C}$  of graphs induces a similarity measure between graphs: Consider an arbitrary graph  $H$ . The results of the homomorphism counts for all  $G \in \mathcal{C}$  in  $H$  can be represented by a mapping (or, “vector”)  $\text{HOM}_{\mathcal{C}}(H)$  that associates with every  $G \in \mathcal{C}$  the number  $\text{hom}(G, H)$  of homomorphisms from  $G$  to  $H$ . A similarity measure for the mappings  $\text{HOM}_{\mathcal{C}}(H)$  and  $\text{HOM}_{\mathcal{C}}(H')$  can then be viewed as a similarity measure of two given graphs  $H, H'$ . An overview of this approach, its relations to *graph neural networks*, and its usability as a similarity measure of graphs can be found in Grohe’s survey [17].

Two graphs  $H, H'$  are viewed as “equivalent” (or, *indistinguishable*) over  $\mathcal{C}$  if  $\text{HOM}_{\mathcal{C}}(H) = \text{HOM}_{\mathcal{C}}(H')$ , i.e., for every graph  $G$  in  $\mathcal{C}$  the number of homomorphisms from  $G$  to  $H$  equals the number of homomorphisms from  $G$  to  $H'$ . A classical result by Lovász [19] shows that

two graphs  $H, H'$  are indistinguishable over the class of *all* graphs if, and only if, they are isomorphic. This inspired a lot of research in recent years, examining the notion of *homomorphism indistinguishability over a class  $\mathcal{C}$*  for various classes  $\mathcal{C}$  [11, 10, 6, 5, 7, 16, 21]. In particular, Grohe [16] proved that two graphs are homomorphism indistinguishable over the class of graphs of *tree-depth*  $\leq k$  if, and only if, they are indistinguishable by sentences of first-order counting logic  $C$  of quantifier-rank  $\leq k$  ( $C$  is the extension of first-order logic with counting quantifiers of the form  $\exists^{\geq n}x$  meaning “there exist at least  $n$  elements  $x$ ”). A decade earlier, Dvořák [11] proved that two graphs are homomorphism indistinguishable over the class of graphs of *tree-width*  $\leq k$  if, and only if, they are indistinguishable by sentences of the  $k+1$ -variable fragment  $C^{k+1}$  of  $C$ . From Cai, Fürer, Immerman [8] we know that this precisely coincides with indistinguishability by the  $k$ -dimensional Weisfeiler-Leman algorithm.

An obvious question is if and how these results can be lifted from graphs to hypergraphs. A first answer was given by Böker in [7]: He introduces a new version of a *color refinement* algorithm on hypergraphs and proves that two hypergraphs  $H, H'$  cannot be distinguished by this algorithm if, and only if, they are homomorphism indistinguishable over the class of *Berge-acyclic* hypergraphs. This is a lifting – from graphs to hypergraphs – of the result of [11, 8] for the case  $k = 1$  (i.e., trees) to “tree-like” hypergraphs. Note that there are different concepts of “tree-likeness” for hypergraphs. Berge-acyclicity is a rather restricted one; it is subsumed by the more general concept of  $\alpha$ -acyclic hypergraphs, which coincides with the hypergraphs of *generalised hypertree width 1* (cf., [13, 14, 12]).

This paper gives a further answer to the above question: For arbitrary  $k \geq 1$  let  $GHW_k$  be the class of hypergraphs of generalised hypertree width  $\leq k$ . Our main result provides a logical characterisation of homomorphism indistinguishability over the class  $GHW_k$ . We introduce a new logic called  $GC^k$  and a restriction  $RGC^k$  of  $GC^k$  and show that two hypergraphs are homomorphism indistinguishable over  $GHW_k$  if, and only if, they are indistinguishable by sentences of the logic  $RGC^k$ .

$GC^k$  is a 2-sorted counting logic for expressing properties of hypergraphs. It has available  $k$  “blue” variables to address edges, and an unbounded number of “red” variables to address vertices of a hypergraph, and atomic formulas  $E(e, v)$  to express that vertex  $v$  is contained in edge  $e$ , as well as atomic formulas  $e = e'$  and  $v = v'$  for expressing equality of edge or vertex variables. Counting quantifiers are of the form  $\exists^{\geq n}\bar{z}$  where  $\bar{z} = (z_1, \dots, z_\ell)$  is either a tuple of edge variables or a tuple of vertex variables; and their meaning is “there exist at least  $n$  tuples  $\bar{z}$ ”. In the logic  $GC^k$ , each vertex variable  $v$  has to be *guarded* by an edge variable  $e$  and an atomic statement  $E(e, v)$  (meaning that vertex  $v$  is included in edge  $e$ ); the use of quantifiers is restricted in a way to ensure that guards are always present. Our design of the logic  $GC^k$  is somewhat inspired by the *guarded fragment of first-order logic* (cf., [4, 15, 14]).  $RGC^k$  imposes certain restrictions on the way guards of red variables can change between quantifications in a formula.

Our main result can be viewed as a lifting – from graphs to hypergraphs – of Dvořák’s [11] result: Dvořák proves that two graphs are homomorphism indistinguishable over the class  $TW_k$  of graphs of *tree-width*  $\leq k$  iff they are indistinguishable by the logic  $C^{k+1}$ . We prove that two hypergraphs are homomorphism indistinguishable over the class  $GHW_k$  of hypergraphs of generalised hypertree width  $\leq k$  iff they are indistinguishable by the logic  $RGC^k$ . This is analogous (although not tightly related) to the following classical results: Kolaitis and Vardi [18] proved that the conjunctive queries of *tree-width*  $\leq k$  are precisely the queries expressible in the  $k+1$ -variable fragment of a certain subclass  $L$  of first-order logic. Gottlob et al. [14] proved that the conjunctive queries of *hypertree width*  $\leq k$  are precisely the ones expressible in the  $k$ -guarded fragment of  $L$ . This is somehow parallel to our result lifting Dvořák’s characterisation; it is what initially gave us the confidence to work on our hypothesis.

The proof of our theorem is at its core very similar to Dvořák’s proof – but it is far from straightforward. Before being able to follow along the lines of Dvořák’s proof, we first have to perform a number of reduction steps and build the necessary machinery. The first step is to move over from homomorphisms on hypergraphs to homomorphisms on incidence graphs. Fortunately, Böker [7] already implicitly achieved what is needed in our setting. The result is: Two hypergraphs  $H, H'$  are homomorphism indistinguishable over the class  $GHW_k$  iff their incidence graphs  $I, I'$  are homomorphism indistinguishable over the class  $IGHW_k$  of incidence graphs of generalised hypertree width  $\leq k$ ; see Section 3.

Next, for an inductive proof in the spirit of Dvořák, we would need an inductive characterisation of the class  $IGHW_k$  in the spirit of [9]. Unfortunately, generalised hypertree decompositions seem to be unsuitable for such a characterisation. That is why we work with severely restricted decompositions that we call *entangled hypertree decompositions* (ehds). In Section 4 we prove that homomorphism indistinguishability over the class  $IGHW_k$  coincides with homomorphism indistinguishability over the class  $IEHW_k$  of incidence graphs of *entangled hypertree width*  $\leq k$ . In our opinion this is interesting on its own, since the requirements of ehds are quite harsh and  $IEHW_k \subsetneq IGHW_k$  for arbitrarily large  $k$ .

In Section 6 we introduce the logic  $\text{GC}^k$  and its restriction  $\text{RGC}^k$ . The inductive characterisation of  $IEHW_k$  follows in Section 7, where we also provide the machinery of *quantum* incidence graphs as an analogue of the quantum graphs used in Dvořák’s proof, tailored towards our setting. In Section 8 we prove that two incidence graphs  $I, I'$  are indistinguishable by the logic  $\text{RGC}^k$  if, and only if, they are homomorphism indistinguishable over the class  $IEHW_k$ . This is achieved by two inductive proofs: We use the inductive characterisation of  $IEHW_k$  to show that for every incidence graph  $J$  in  $IEHW_k$  and every  $m \in \mathbb{N}$  there exists an  $\text{RGC}^k$ -sentence that is satisfied by an incidence graph  $I$  iff there are precisely  $m$  homomorphisms from  $J$  to  $I$ . For the opposite direction, we proceed by induction on the definition of  $\text{RGC}^k$  and construct for every sentence  $\chi$  in  $\text{RGC}^k$  and certain size parameters  $m, d \in \mathbb{N}$  a quantum incidence graph  $Q$  in  $IEHW_k$  satisfying the following: for all incidence graphs  $I$  that match the size parameters  $m, d$ , the number  $\text{hom}(Q, I)$  of homomorphisms from  $Q$  to  $I$  is either 0 or 1, and it is 1 if and only if  $I$  satisfies the sentence  $\chi$ . Both proofs are quite intricate, and the details of the syntax definition of  $\text{RGC}^k$  had to be tweaked right in order to enable proving *both* directions.

Plugging together the results achieved in the previous sections yields our main theorem, provided in Section 9: Two hypergraphs are homomorphism indistinguishable over the class  $GHW_k$  of hypergraphs of generalised hypertree width  $\leq k$  iff they are indistinguishable by the logic  $\text{RGC}^k$ .

Due to space limitations, many proof details had to be deferred to the paper’s extended version [22].

## 2 Preliminaries

This section provides basic notions concerning hypergraphs, incidence graphs, hypertree decompositions, and homomorphisms. We write  $\mathbb{R}$  for the set of reals,  $\mathbb{N}$  for the set of non-negative integers, and we let  $\mathbb{N}_{\geq 1} := \mathbb{N} \setminus \{0\}$  and  $[n] := \{1, \dots, n\}$  for all  $n \in \mathbb{N}_{\geq 1}$ .

**Hypergraphs.** The hypergraphs considered in this paper are generalisations of ordinary undirected graphs, where each edge can consist of an arbitrary number of vertices. For our proofs it will be necessary to deal with hypergraphs in which the same edge can have multiple occurrences. Furthermore, it will be convenient to assume that every vertex belongs to at least one edge. This is provided by the following definition that is basically taken from [7].

A *hypergraph*  $H := (V(H), E(H), f_H)$  consists of disjoint finite sets  $V(H)$  of *vertices* and  $E(H)$  of edges, and an *incidence function*  $f_H$  associating with every  $e \in E(H)$  the set  $f_H(e) \subseteq V(H)$  of vertices incident with edge  $e$ , such that  $V(H) = \bigcup_{e \in E(H)} f_H(e)$ . A *simple hypergraph* is a hypergraph  $H$  where the function  $f_H$  is injective. We can identify the edges of a hypergraph  $H$  with the multiset  $M_H := \{\{f_H(e) : e \in E(H)\}\}$ ; the number of occurrences of a set  $s \subseteq V(H)$  in this multiset then is the number of occurrences of “edge  $s$ ” in  $H$ . The *simple hypergraphs* are the hypergraphs in which every “edge  $s$ ” has only one occurrence.

Every hypergraph  $H = (V(H), E(H), f_H)$  can be represented by an ordinary, bipartite graph  $I_H$  in the following way: The vertices  $v \in V(H)$  occur as *red* nodes of  $I_H$ , i.e.,  $R(I_H) := V(H)$ . The edges  $e \in E(H)$  occur as *blue* nodes of  $I_H$ , i.e.,  $B(I_H) := E(H)$ . And there is an edge from each blue node  $e$  to all red nodes  $v \in f_H(e)$ . I.e.,  $E(I_H) := \{(e, v) \in B(I_H) \times R(I_H) : v \in f_H(e)\}$ . The condition  $V(H) = \bigcup_{e \in E(H)} f_H(e)$  implies that every red node is adjacent to at least one blue node. It is straightforward to see that the mapping  $H \mapsto I_H$  provides a bijection between the class of all hypergraphs and the class of all *incidence graphs*, where the notion of incidence graphs is as follows.

An *incidence graph*  $I = (R(I), B(I), E(I))$  consists of disjoint finite sets  $R(I)$  and  $B(I)$  of *red* nodes and *blue* nodes, resp., and a set of edges  $E(I) \subseteq B(I) \times R(I)$ , such that each red node is adjacent to at least one blue node. As usual for graphs, the *neighbourhood* of a node  $v$  is the set  $N_I(v)$  of all nodes adjacent to  $v$ . Thus, if  $I$  is the incidence graph  $I_H$  of a hypergraph  $H$ , the neighbourhood of every blue node  $e$  is  $N_I(e) = f_H(e)$ , i.e., the set of all vertices of  $H$  that are incident with edge  $e$ . The neighbourhood of every red node  $v$  is  $N_I(v) = \{e \in E(H) : v \in f_H(e)\}$ , i.e., the set of all edges of  $H$  that are incident with vertex  $v$ . Two incidence graphs  $I, I'$  are *isomorphic* ( $I \cong I'$ , for short) if there exists an *isomorphism*  $\pi = (\pi_R, \pi_B)$  from  $I$  to  $I'$ , i.e, bijections  $\pi_R : R(I) \rightarrow R(I')$  and  $\pi_B : B(I) \rightarrow B(I')$  such that for all  $(e, v) \in B(I) \times R(I)$  we have:  $(e, v) \in E(I) \iff (\pi_B(e), \pi_R(v)) \in E(I')$ . We sometimes drop the subscript and write  $\pi(e)$  and  $\pi(v)$  instead of  $\pi_B(e)$  and  $\pi_R(v)$ .

**Generalised Hypertree Decompositions.** We use the same notation as [12] for decompositions of hypergraphs, but we write  $bag(t)$  and  $cover(t)$  instead of  $\chi(t)$  and  $\lambda(t)$ , respectively, and we formalise them with respect to incidence graphs rather than hypergraphs.

► **Definition 2.1.** A *complete generalised hypertree decomposition* (*ghd*, for short) of an incidence graph  $I$  is a tuple  $D := (T, bag, cover)$ , where  $T := (V(T), E(T))$  is a finite undirected tree, and  $bag$  and  $cover$  are mappings that associate with every tree-node  $t \in V(T)$  a set  $bag(t) \subseteq R(I)$  of red nodes of  $I$  and a set  $cover(t) \subseteq B(I)$  of blue nodes of  $I$ , having the following properties:

1. *Completeness:* For each  $e \in B(I)$  there is a  $t \in V(T)$  with  $N_I(e) \subseteq bag(t)$  and  $e \in cover(t)$ .
2. *Connectedness for red nodes:* For every  $v \in R(I)$  the subgraph  $T_v$  of  $T$  induced on  $V_v := \{t \in V(T) : v \in bag(t)\}$  is a tree.
3. *Covering of Bags:* For every  $t \in V(T)$  we have  $bag(t) \subseteq \bigcup_{e \in cover(t)} N_I(e)$ .

It is straightforward to see that this notion of a *ghd* of an incidence graph  $I$  coincides with the classical notion (cf., [13, 12]) of a complete generalised hypertree decomposition of a hypergraph  $H$  where  $I_H = I$ . The *width*  $w(D)$  of a *ghd*  $D$  is defined as the maximum number of blue nodes in the cover of a tree-node, i.e.,  $w(D) := \max\{|cover(t)| : t \in V(T)\}$ . We write  $ghds(I)$  to denote the class of all *ghds* of an incidence graph  $I$ . The *generalised hypertree width* of an incidence graph  $I$  is  $ghw(I) := \min\{w(D) : D \in ghds(I)\}$ . By  $IGHW_k$  we denote the class of all incidence graphs of generalised hypertree width  $\leq k$ . It is straightforward to see that  $ghw(I_H)$  coincides with the classical notion (cf., [12]) of generalised hypertree width of a hypergraph  $H$ , and  $IGHW_k$  is the class of incidence graphs  $I_H$  of all hypergraphs  $H$  of generalised hypertree width  $\leq k$ .

For our proofs we need ghds with specific further properties, defined as follows; we are not aware of any related work that studies this particular kind of decompositions. Hypertree decompositions satisfying condition 4 (but not necessarily condition 5) of Definition 2.2 are known as *strong* decompositions [14].

► **Definition 2.2.** An *entangled hypertree decomposition* (ehd, for short) of an incidence graph  $I$  is a ghd  $D$  of  $I$  that additionally satisfies the following requirements:

4. *Precise coverage of bags:* For all tree-nodes  $t \in V(T)$  we have  $\bigcup_{e \in \text{cover}(t)} N_I(e) = \text{bag}(t)$ .
5. *Connectedness for blue nodes:* For every  $e \in B(I)$  the subgraph  $T_e$  of  $T$  induced on  $V_e := \{t \in V(T) : e \in \text{cover}(t)\}$  is a tree.

We write  $\text{ehds}(I)$  to denote the class of all ehds of an incidence graph  $I$ .

The *entangled hypertree width* of an incidence graph  $I$  is  $\text{ehw}(I) := \min\{w(D) : D \in \text{ehds}(I)\}$ . For a hypergraph  $H$  we let  $\text{ehw}(H) := \text{ehw}(I_H)$ . By  $\text{IEHW}_k$  we denote the class of all incidence graphs of entangled hypertree width  $\leq k$ .

Applying results from [2, 1, 3] shows that there exist arbitrarily large  $k$  such that  $\text{IEHW}_k$  is a strict subclass of  $\text{IGHW}_k$ . More precisely:

► **Theorem 2.3.**  $\text{IEHW}_k \subseteq \text{IGHW}_k$ , for every  $k \in \mathbb{N}_{\geq 1}$ . Furthermore,  $\text{IEHW}_1 = \text{IGHW}_1$ , but  $\text{IEHW}_k \subsetneq \text{IGHW}_k$  for each  $k \in \{2, 3\}$ . Moreover, for every  $n \in \mathbb{N}$  there exists a  $k \in \mathbb{N}_{\geq 1}$  such that  $\text{IGHW}_k \subsetneq \text{IEHW}_{k+n}$  (and hence,  $\text{IEHW}_{k+n} \subsetneq \text{IGHW}_{k+n}$ ).

**Proof.**  $\text{IEHW}_k \subseteq \text{IGHW}_k$  holds because every ehd also is a ghd.  $\text{IEHW}_1 = \text{IGHW}_1$  holds because ghds of width 1 are known to be equivalent to so-called *join trees*, and these can easily be translated into ehds of width 1. For the remaining statements, we use elaborate results from [2, 1, 3] that relate the *hypertree width*  $\text{hw}(H)$  (cf., [13, 14]) of a hypergraph to its *generalised hypertree width*  $\text{ghw}(H)$ :

From [2, Proposition 3.3.2] (cf. also [3, Example 3]) and [1, Claim 6.1] we obtain for each  $k \in \{2, 3\}$  a simple hypergraph  $H_k$  such that  $\text{ghw}(H_k) = k$  and  $\text{hw}(H_k) = k+1$ . Furthermore, [2, Fact 3.3.1] and [1, Theorem 4.1] provide for every  $n \in \mathbb{N}_{\geq 1}$  a simple hypergraph  $H^n$  such that  $\text{hw}(H^n) = \text{ghw}(H^n) + n$ .<sup>1</sup>

It is straightforward to verify that every ehd also is a complete *hypertree decomposition* in the sense of [13, 14]. Consequently, for every hypergraph  $H$  we have  $\text{hw}(H) \leq \text{ehw}(H)$ . Therefore, for each  $k \in \{2, 3\}$ , the incidence graph of  $H_k$  witnesses that  $\text{IEHW}_k \subsetneq \text{IGHW}_k$ .

To address the theorem's next statement, consider an arbitrary  $n \in \mathbb{N}$ . Let  $H := H^{n+1}$  and let  $k := \text{ghw}(H)$ . Then,  $\text{ehw}(H) \geq \text{hw}(H) = k+n+1$ . Thus, the incidence graph of  $H$  belongs to  $\text{IGHW}_k$  but not to  $\text{IEHW}_{k+n}$ . ◀

**Homomorphisms.** We use the classical notions for hypergraphs and incidence graphs:

A *homomorphism* from a hypergraph  $F$  to a hypergraph  $H$  is a pair  $(h_V, h_E)$  of mappings  $h_V : V(F) \rightarrow V(H)$  and  $h_E : E(F) \rightarrow E(H)$  such that for all  $e \in E(F)$  we have  $f_H(h_E(e)) = \{h_V(v) : v \in f_F(e)\}$ . We write  $\text{Hom}(F, H)$  for the set of all homomorphisms from  $F$  to  $H$ , and  $\text{hom}(F, H) := |\text{Hom}(F, H)|$  is the number of homomorphisms from  $F$  to  $H$ .

A *homomorphism* from an incidence graph  $J$  to an incidence graph  $I$  is a pair  $h = (h_R, h_B)$  of mappings  $h_R : R(J) \rightarrow R(I)$  and  $h_B : B(J) \rightarrow B(I)$  such that for all  $(e, v) \in E(J)$  we have  $(h_B(e), h_R(v)) \in E(I)$ . We sometimes drop the subscript and write  $h(e)$  and  $h(v)$  instead of  $h_B(e)$  and  $h_R(v)$ . By  $\text{Hom}(J, I)$  we denote the set of all homomorphisms from  $J$  to  $I$ , and we let  $\text{hom}(J, I) := |\text{Hom}(J, I)|$  be the number of homomorphisms from  $J$  to  $I$ .

<sup>1</sup> Note that the notions  $c_H\text{-hw}(H)$  and  $c_H\text{-ghw}(H)$  in [2] correspond to  $\text{hw}(H)$  and  $\text{ghw}(H)$  for all hypergraphs  $H$  according to [2, Example 2.1.10].

As pointed out in [7], every homomorphism from a hypergraph  $F$  to a hypergraph  $H$  also is a homomorphism from the incidence graph  $I_F$  to the incidence graph  $I_H$ ; but there exist homomorphisms from  $I_F$  to  $I_H$  that do not correspond to any homomorphism from  $F$  to  $H$ . In fact, every homomorphism  $(h_R, h_B)$  from  $I_F$  to  $I_H$  is a pair of mappings  $(h_V, h_E) := (h_R, h_B)$  with  $h_V : V(F) \rightarrow V(H)$  and  $h_E : E(F) \rightarrow E(H)$  such that for every  $e \in E(F)$  we have  $f_H(h_E(e)) \supseteq \{h_V(v) : v \in f_F(e)\}$  – i.e., the condition “=” of the definition of hypergraph-homomorphisms is relaxed into the condition “ $\supseteq$ ”.

### 3 Homomorphism Indistinguishability

Let  $(B, B', \mathcal{C})$  be either two incidence graphs and a class of incidence graphs or two hypergraphs and a class of hypergraphs. By  $\text{HOM}_{\mathcal{C}}(B)$  we denote the function  $\alpha : \mathcal{C} \rightarrow \mathbb{N}$  that associates with every  $A \in \mathcal{C}$  the number  $\text{hom}(A, B)$  of homomorphisms from  $A$  to  $B$ . We say that  $B$  and  $B'$  are *homomorphism indistinguishable over  $\mathcal{C}$*  if  $\text{HOM}_{\mathcal{C}}(B) = \text{HOM}_{\mathcal{C}}(B')$ . Note that  $\text{HOM}_{\mathcal{C}}(B) \neq \text{HOM}_{\mathcal{C}}(B')$  means that there exists an  $A \in \mathcal{C}$  that *distinguishes* between  $B$  and  $B'$  in the sense that  $\text{hom}(A, B) \neq \text{hom}(A, B')$ .

Recall from Section 2 that  $\text{IGHW}_k$  is the class of incidence graphs of generalised hypertree width  $\leq k$ . We write  $\text{GHW}_k$  for the class of all hypergraphs of generalised hypertree width  $\leq k$  (i.e., all hypergraphs  $H$  for which  $I_H \in \text{IGHW}_k$ ), and  $\text{sGHW}_k$  for the subclass consisting of all *simple* hypergraphs (i.e., hypergraphs where each edge has multiplicity 1) in  $\text{GHW}_k$ .

► **Theorem 3.1** (implicit in [7]). *Let  $H, H'$  be hypergraphs.*

(a) *If  $H$  and  $H'$  are simple hypergraphs, then*

$$\text{HOM}_{\text{GHW}_k}(H) = \text{HOM}_{\text{GHW}_k}(H') \iff \text{HOM}_{\text{sGHW}_k}(H) = \text{HOM}_{\text{sGHW}_k}(H').$$

(b)  $\text{HOM}_{\text{GHW}_k}(H) = \text{HOM}_{\text{GHW}_k}(H') \iff \text{HOM}_{\text{IGHW}_k}(I_H) = \text{HOM}_{\text{IGHW}_k}(I_{H'}).$

Böker [7] proved the analogous statement for  $BA, IBA$  instead of  $\text{GHW}_k, \text{IGHW}_k$ , where  $BA$  is the class of all Berge-acyclic hypergraphs and  $IBA$  is the class of all incidence graphs of hypergraphs in  $BA$ . Böker’s proof, however, works for all classes  $\mathcal{C}$  of hypergraphs and the associated class  $IC$  of all incidence graphs of hypergraphs in  $\mathcal{C}$ , provided that  $\mathcal{C}$  satisfies some mild closure properties, which  $\text{GHW}_k$  satisfies.

### 4 Relating $\text{IGHW}_k$ to $\text{IEHW}_k$

Recall from Section 2 that  $\text{IEHW}_k \subseteq \text{IGHW}_k$ , for the class  $\text{IEHW}_k$  of incidence graphs of entangled hypertree width  $\leq k$ . By Theorem 2.3 there exist arbitrarily large  $k$  such that  $\text{IEHW}_k$  is a strict subclass of  $\text{IGHW}_k$ . This section’s main result is that, nevertheless:

► **Theorem 4.1.** *For all incidence graphs  $I$  and  $I'$  we have*

$$\text{HOM}_{\text{IGHW}_k}(I) = \text{HOM}_{\text{IGHW}_k}(I') \iff \text{HOM}_{\text{IEHW}_k}(I) = \text{HOM}_{\text{IEHW}_k}(I').$$

**Proof sketch.** The proof heavily relies on our following technical main lemma, which uses the following notation: For an arbitrary incidence graph  $J$ , for  $s \subseteq R(J)$ , and for  $n \in \mathbb{N}$  we write  $J + n \cdot s$  to denote the incidence graph  $J'$  obtained from  $J$  by inserting  $n$  new blue nodes  $\hat{e}_1, \dots, \hat{e}_n$  and edges  $(\hat{e}_i, v)$  for all  $i \in [n]$  and all  $v \in s$  – i.e.,  $N_{J'}(\hat{e}_i) = s$ .

► **Lemma 4.2.** *Let  $J, I, I'$  be incidence graphs with  $\text{hom}(J, I) \neq \text{hom}(J, I')$ , let  $e \in B(J)$ , and let  $s \subseteq N_J(e)$ . For every  $m \in \mathbb{N}$  there exists an  $n \in \mathbb{N}$  with  $n \geq m$  such that  $J_n := J + n \cdot s$  satisfies  $\text{hom}(J_n, I) \neq \text{hom}(J_n, I')$ .*

The (combinatorially quite involved) proof of Lemma 4.2 can be found in the paper’s extended version [22].

The direction “ $\implies$ ” of Theorem 4.1 is trivial. For the direction “ $\impliedby$ ” it suffices to prove the following: If there is a  $J \in \text{IGHW}_k$  with  $\text{hom}(J, I) \neq \text{hom}(J, I')$ , then there also exists a  $J' \in \text{IEHW}_k$  with  $\text{hom}(J', I) \neq \text{hom}(J', I')$ . We construct such a  $J'$  in a 2-step process. We start with a ghd  $D = (T, \text{bag}, \text{cover})$  of  $J$  with  $w(D) \leq k$ . First, we transform  $D$  into a ghd  $D^1$  of an incidence graph  $J^1$  such that  $w(D^1) \leq w(D)$  and  $\text{hom}(J^1, I) \neq \text{hom}(J^1, I')$  and  $D^1$  satisfies condition 4 of Definition 2.2 (but condition 5 might still be violated). Afterwards, we transform  $D^1$  into a ghd  $D^2$  of an incidence graph  $J^2$  such that  $w(D^2) = w(D^1)$  and  $\text{hom}(J^2, I) \neq \text{hom}(J^2, I')$  and  $D^2$  satisfies conditions 4 and 5 of Definition 2.2 and hence is an ehd. Letting  $J' := J^2$  then completes the proof.

For the construction of  $D^1, J^1$  we consider all those  $t \in V(T)$  and  $e \in \text{cover}(t)$  where  $N_J(e) \not\subseteq \text{bag}(t)$  and let  $s := N_J(e) \cap \text{bag}(t)$ . We use Lemma 4.2 to choose a suitable number  $n_s \geq 1$  and replace  $J$  by  $J + n_s \cdot s$  (let us write  $e'_1, \dots, e'_{n_s}$  for the  $n_s$  newly inserted blue nodes). In  $D$  we replace  $e$  with  $e'_1$  in  $\text{cover}(t)$ , and we add new leaves  $t_j$  for  $j \in \{2, \dots, n_s\}$  adjacent to  $t$  with  $\text{cover}(t_j) = \{e'_j\}$  and  $\text{bag}(t_j) = s$ . After having done this for all combinations of  $t$  and  $e$ , we end up with the desired incidence graph  $J^1$  and ghd  $D^1 = (T^1, \text{bag}^1, \text{cover}^1)$ .

For the construction of  $D^2, J^2$ , for each  $e \in B(J^1)$  we let  $m_e$  be the number of connected components of the subgraph  $T_e^1$ , i.e., the subgraph of  $T^1$  induced on  $V_e := \{t \in V(T^1) : e \in \text{cover}^1(t)\}$ . Let  $V_{e,0}, \dots, V_{e,m_e-1}$  be the sets of tree-nodes (i.e., nodes in  $V(T^1)$ ) of these connected components. We consider all those  $e \in B(J^1)$  where  $m_e \geq 2$  and let  $s := N_{J^1}(e)$ . We use Lemma 4.2 to choose a suitable number  $n_e \geq m_e - 1$  and replace  $J$  with  $J + n_e \cdot s$  (let us write  $e'_1, \dots, e'_{n_e}$  for the  $n_e$  newly inserted blue nodes). In  $D^1$  we consider for every  $i \in \{1, \dots, m_e - 1\}$  all  $t \in V_{e,i}$  and replace  $e$  with  $e'_i$  in  $\text{cover}^1(t)$ . Furthermore, we pick an arbitrary  $t \in V_{e,0}$ , and for each  $i \in [n_e]$  with  $i \geq m_e$ , we insert into  $T^1$  a new leaf  $t_{e,i}$  adjacent to  $t$  and let  $\text{bag}^1(t_{e,i}) := s$  and  $\text{cover}^1(t_{e,i}) := \{e'_{e,i}\}$ . After having done this for all  $e \in B(J^1)$  with  $m_e \geq 2$ , we end up with the desired incidence graph  $J^2$  and ehd  $D^2$ . This completes the proof sketch of Theorem 4.1.  $\blacktriangleleft$

## 5 Notation for Partial Functions

We introduce some further notation that will be convenient for the remaining parts of the paper. We write  $f : A \rightarrow B$  to indicate that  $f$  is a partial function from  $A$  to  $B$ . By  $\text{dom}(f)$  we denote the domain of  $f$ , i.e., the set of all  $a \in A$  on which  $f(a)$  is defined. By  $\text{img}(f)$  we denote the image of  $f$ , i.e.,  $\text{img}(f) = \{f(a) : a \in \text{dom}(f)\}$ . Two partial functions  $f : A \rightarrow B$  and  $g : A \rightarrow B$  are called *compatible* if  $f(a) = g(a)$  holds for all  $a \in \text{dom}(f) \cap \text{dom}(g)$ .

We identify a partial function  $f$  with the set  $\{(a, f(a)) : a \in \text{dom}(f)\}$ . This allows us to compare and combine partial functions via standard notation from set theory. E.g.,  $f \subseteq g$  indicates that  $\text{dom}(f) \subseteq \text{dom}(g)$  and  $f(a) = g(a)$  for all  $a \in \text{dom}(f)$ . And  $f \cup g$  denotes the partial function  $h$  with  $\text{dom}(h) = \text{dom}(f) \cup \text{dom}(g)$  and  $h(a) = f(a)$  for all  $a \in \text{dom}(f)$  and  $h(a) = g(a)$  for all  $a \in \text{dom}(g) \setminus \text{dom}(f)$ ; note that  $f$  has precedence over  $g$  in case that  $f$  and  $g$  are not compatible. For a set  $S$  we write  $f - S$  to denote the partial function  $g$  with  $g \subseteq f$  and  $\text{dom}(g) = \text{dom}(f) \setminus S$ .

## 6 2-Sorted Counting Logic with Guards: $\text{GC}^k$ and $\text{RGC}^k$

This section provides the syntax and semantics of our 2-sorted logics  $\text{GC}^k$  and  $\text{RGC}^k$ . Formulas of these logics are evaluated on incidence graphs (cf. Section 2). We fix a  $k \in \mathbb{N}_{\geq 1}$ .

To address *blue* nodes (i.e., *edges* of a hypergraph), we have available  $k$  *blue variables*  $\mathbf{e}_1, \dots, \mathbf{e}_k$ . To address *red* nodes (i.e., *vertices* of a hypergraph), we have available countably many *red variables*  $\mathbf{v}_1, \mathbf{v}_2, \mathbf{v}_3, \dots$ . An atomic formula  $E(\mathbf{e}_j, \mathbf{v}_i)$  states that a hypergraph's

vertex  $v_i$  is included in the hypergraph's edge  $e_j$ . Let  $\text{Var}_B := \{e_1, \dots, e_k\}$ ,  $\text{Var}_R := \{v_i : i \in \mathbb{N}_{\geq 1}\}$ , and  $\text{Var} := \text{Var}_B \cup \text{Var}_R$ . An *interpretation*  $\mathcal{I} = (I, \beta)$  consists of an incidence graph  $I = (R(I), B(I), E(I))$  and an *assignment*  $\beta$  in  $I$ , i.e., a mapping  $\beta : \text{Var} \rightarrow R(I) \cup B(I)$  with  $\beta(e_j) \in B(I)$  for all  $e_j \in \text{Var}_B$  and  $\beta(v_i) \in R(I)$  for all  $v_i \in \text{Var}_R$ . In the formulas of our logics, red variables  $v_i$  have to be *guarded* by a blue variable  $e_j$  in the sense that  $E(e_j, v_i)$  holds. This is formalised by a *guard function*, i.e., a *partial function*  $g : \mathbb{N}_{\geq 1} \rightarrow [k]$  with *finite* domain  $\text{dom}(g)$ . Every guard function  $g$  corresponds to the formula  $\Delta_g := \bigwedge_{i \in \text{dom}(g)} E(e_{g(i)}, v_i)$ , and for the special case where  $\text{dom}(g) = \emptyset$  we let  $\Delta_g := \top$  where  $\top$  is a special atomic formula satisfied by *every* interpretation  $\mathcal{I}$ . We let  $\text{free}(\Delta_g)$  be the set of all (red or blue) variables that occur in  $\Delta_g$ . An interpretation  $\mathcal{I} = (I, \beta)$  *satisfies* a guard function  $g$  (in symbols:  $\mathcal{I} \models \Delta_g$ ) if for all  $i \in \text{dom}(g)$  we have:  $(\beta(e_{g(i)}), \beta(v_i)) \in E(I)$ . I.e., for every  $i \in \text{dom}(g)$ , the red variable  $v_i$  is guarded by the blue variable  $e_{g(i)}$  in the sense that it is connected to it by an edge of the incidence graph.

For any formula  $\chi$  we write  $\text{ifree}_B(\chi)$  for the set of all indices  $j \in [k]$  such that the blue variable  $e_j$  belongs to  $\text{free}(\chi)$ . Accordingly,  $\text{ifree}_R(\chi) := \{i \in \mathbb{N}_{\geq 1} : v_i \in \text{free}(\chi)\}$ . The definition of the syntax of  $\text{GC}^k$  is inductively given as follows.

**Base cases:** The atomic formulas in  $\text{GC}^k$  are of the form  $\top$ ,  $E(e_j, v_i)$ ,  $e_j = e_{j'}$ , and  $v_i = v_{i'}$  for  $j, j' \in [k]$  and  $i, i' \in \mathbb{N}_{\geq 1}$ .

**Inductive cases:**

1. If  $\psi \in \text{GC}^k$ , then  $\neg\psi \in \text{GC}^k$ .
2. If  $\psi_1, \psi_2 \in \text{GC}^k$ , then  $(\psi_1 \wedge \psi_2) \in \text{GC}^k$ .
3. If  $\psi \in \text{GC}^k$  and  $g$  is a guard function with  $\text{dom}(g) = \text{ifree}_R(\psi)$  and  $n, \ell \in \mathbb{N}_{\geq 1}$  and, for  $\chi := (\Delta_g \wedge \psi)$  and  $i_1 < \dots < i_\ell$  with
  - (a)  $i_1, \dots, i_\ell \in \text{ifree}_R(\chi)$ , then  $\varphi \in \text{GC}^k$  for  $\varphi := \exists^{\geq n}(v_{i_1}, \dots, v_{i_\ell}).(\Delta_g \wedge \psi)$ ;
  - (b)  $i_1, \dots, i_\ell \in \text{ifree}_B(\chi)$ , then  $\varphi \in \text{GC}^k$  for  $\varphi := \exists^{\geq n}(e_{i_1}, \dots, e_{i_\ell}).(\Delta_g \wedge \psi)$ .

The semantics are defined as expected. In particular, an interpretation  $\mathcal{I} = (I, \beta)$  satisfies the formula  $\varphi := \exists^{\geq n}(v_{i_1}, \dots, v_{i_\ell}).(\Delta_g \wedge \psi)$  iff there are at least  $n$  tuples  $(v_{i_1}, \dots, v_{i_\ell}) \in R(I)^\ell$  such that  $\mathcal{I}' = (I, \beta')$  satisfies  $(\Delta_g \wedge \psi)$ , where  $\beta'(v_{i_j}) = v_{i_j}$  for all  $j \in [\ell]$  and  $\beta'(\mathbf{x}) = \beta(\mathbf{x})$  for all  $\mathbf{x} \in \text{Var} \setminus \{v_{i_1}, \dots, v_{i_\ell}\}$ . Similarly,  $\mathcal{I} = (I, \beta)$  satisfies  $\varphi := \exists^{\geq n}(e_{i_1}, \dots, e_{i_\ell}).(\Delta_g \wedge \psi)$  iff there are at least  $n$  tuples  $(e_{i_1}, \dots, e_{i_\ell}) \in B(I)^\ell$  such that  $\mathcal{I}' = (I, \beta')$  satisfies  $(\Delta_g \wedge \psi)$ , where  $\beta'(e_{i_j}) = e_{i_j}$  for all  $j \in [\ell]$  and  $\beta'(\mathbf{x}) = \beta(\mathbf{x})$  for all  $\mathbf{x} \in \text{Var} \setminus \{e_{i_1}, \dots, e_{i_\ell}\}$ . Obviously we can emulate the  $\forall$ -quantifier (and disjunction) using  $\exists^{\geq 1}$  and  $\neg$  (and  $\wedge$  and  $\neg$ , respectively).

We write  $\mathcal{I} \models \chi$  to indicate that  $\mathcal{I}$  satisfies the formula  $\chi$ ; and  $\mathcal{I} \not\models \chi$  indicates that  $\mathcal{I}$  does not satisfy  $\chi$ . *Sentences* of  $\text{GC}^k$  are formulas  $\chi \in \text{GC}^k$  with  $\text{free}(\chi) = \emptyset$ . For an incidence graph  $I$  and a sentence  $\chi \in \text{GC}^k$  we write  $I \models \chi$  to indicate that  $\mathcal{I} \models \chi$  where  $\mathcal{I} = (I, \beta)$  for any assignment  $\beta$  in  $I$  (since  $\chi$  has no free variable, the assignment does not matter). For a hypergraph  $H$  and a sentence  $\chi \in \text{GC}^k$  we write  $H \models \chi$  to indicate that  $I_H \models \chi$ . For two incidence graphs  $I$  and  $I'$  we write  $I \equiv_{\text{GC}^k} I'$  and say that  $I$  and  $I'$  are *indistinguishable by the logic*  $\text{GC}^k$  if for all sentences  $\chi \in \text{GC}^k$  we have:  $I \models \chi \iff I' \models \chi$ .

Let us now introduce a restriction of  $\text{GC}^k$  that we call  $\text{RGC}^k$ . Every formula of  $\text{RGC}^k$  will be of the form  $(\Delta_g \wedge \psi)$ , where  $g$  is a guard function whose domain  $\text{dom}(g)$  consists of all indices  $i \in \mathbb{N}_{\geq 1}$  such that the red variable  $v_i$  is a free variable of  $\psi$ . We let  $\text{free}((\Delta_g \wedge \psi)) := \text{free}(\Delta_g) \cup \text{free}(\psi)$  denote the set of free variables of the formula. The definition of the syntax of  $\text{RGC}^k$  is inductively given as follows.

**Base cases:**  $(\Delta_g \wedge \psi) \in \text{RGC}^k$  for all  $\psi$  and all  $g : \mathbb{N}_{\geq 1} \rightarrow [k]$  matching one of the following:

1.  $\psi$  is  $E(e_j, v_i)$  and  $\text{dom}(g) = \{i\}$  and  $j \in [k]$  (note that  $g(i) \in [k]$  can be chosen arbitrarily);
2.  $\psi$  is  $e_j = e_{j'}$ , with  $\text{dom}(g) = \emptyset$  and  $j, j' \in [k]$ ;
3.  $\psi$  is  $v_i = v_{i'}$  with  $\text{dom}(g) = \{i, i'\}$ .

**Inductive cases:**

4. If  $(\Delta_g \wedge \psi) \in \text{RGC}^k$ , then  $(\Delta_g \wedge \neg\psi) \in \text{RGC}^k$ ;
5. If  $(\Delta_{g_i} \wedge \psi_i) \in \text{RGC}^k$  for  $i \in [2]$  and  $g_1$  and  $g_2$  are compatible (i.e., they agree on  $\text{dom}(g_1) \cap \text{dom}(g_2)$ ), then  $(\Delta_g \wedge \varphi) \in \text{RGC}^k$  for  $g := g_1 \cup g_2$  and  $\varphi := (\psi_1 \wedge \psi_2)$ ;
6. If  $(\Delta_g \wedge \psi) \in \text{RGC}^k$  and  $n, \ell \in \mathbb{N}_{\geq 1}$ , and  $i_1, \dots, i_\ell \in \text{dom}(g)$  with  $i_1 < \dots < i_\ell$ , then  $(\Delta_{\tilde{g}} \wedge \varphi) \in \text{RGC}^k$  for  $\varphi := \exists^{\geq n}(\mathbf{v}_{i_1}, \dots, \mathbf{v}_{i_\ell}).(\Delta_g \wedge \psi)$  and  $\tilde{g} := g - \{i_1, \dots, i_\ell\}$  (note that  $\text{free}(\varphi) = \text{free}((\Delta_g \wedge \psi)) \setminus \{\mathbf{v}_{i_1}, \dots, \mathbf{v}_{i_\ell}\}$ );
7. If  $(\Delta_g \wedge \psi) \in \text{RGC}^k$  and  $n, \ell \in \mathbb{N}_{\geq 1}$ , and  $S := \{i_1, \dots, i_\ell\} \subseteq \text{ifree}_B(\chi)$  for  $\chi := (\Delta_g \wedge \psi)$  with  $i_1 < \dots < i_\ell$ , and if  $\tilde{g} : \mathbb{N}_{\geq 1} \rightarrow [k]$  with  $\text{dom}(\tilde{g}) = \text{dom}(g)$  such that all  $i \in \text{dom}(g)$  satisfy

$$\tilde{g}(i) = g(i) \quad \text{or} \quad \tilde{g}(i) \in S \quad \text{or} \quad \tilde{g}(i) \notin \text{img}(g), \quad \text{then} \quad (1)$$

$$(\Delta_{\tilde{g}} \wedge \varphi) \in \text{RGC}^k \text{ for } \varphi := \exists^{\geq n}(\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_\ell}).(\Delta_g \wedge \psi) \text{ (here, } \text{free}(\varphi) = \text{free}(\chi) \setminus \{\mathbf{e}_{i_1}, \dots, \mathbf{e}_{i_\ell}\}).$$

Let us have a closer look at rule 7): The formula  $\varphi$  has exactly the same free red variables as the formula  $\chi$ . But the guard of red variable  $\mathbf{v}_i$  in  $\tilde{\chi} := (\Delta_{\tilde{g}} \wedge \varphi)$  is  $j' := \tilde{g}(i)$ , whereas in  $\chi$  it is  $j := g(i)$ . Condition (1) is equivalent to the following: the guard remains unchanged (i.e.,  $j' = j$ ), or the new guard  $j'$  has become “available” by the quantification (i.e.,  $j' \in S$ ) or it has not been used as a guard by  $g$  (i.e.,  $j' \notin \text{img}(g)$ ).

Note that  $\text{RGC}^k \subseteq \text{GC}^k$ . Furthermore, for all  $\chi := (\Delta_g \wedge \psi) \in \text{RGC}^k$  we have  $\text{dom}(g) = \{i \in \mathbb{N}_{\geq 1} : \mathbf{v}_i \in \text{free}(\chi)\}$ . Sentences of  $\text{RGC}^k$  are formulas  $\chi := (\Delta_g \wedge \psi)$  in  $\text{RGC}^k$  with  $\text{free}(\chi) = \emptyset$ . Since  $\text{dom}(g) = \{i \in \mathbb{N}_{\geq 1} : \mathbf{v}_i \in \text{free}(\chi)\}$ , this implies that  $\text{dom}(g) = \emptyset$ , i.e.,  $g = g_\emptyset$  where  $g_\emptyset$  is the uniquely defined partial mapping with empty domain; recall that  $\Delta_{g_\emptyset} = \top$ . For two incidence graphs  $I$  and  $I'$  we write  $I \equiv_{\text{RGC}^k} I'$  and say that  $I$  and  $I'$  are *indistinguishable by the logic  $\text{RGC}^k$*  if for all sentences  $\chi \in \text{RGC}^k$  we have:  $I \models \chi \iff I' \models \chi$ . The subsequent sections of this paper are devoted to proving the following theorem, stating that indistinguishability by the logic  $\text{RGC}^k$  coincides with homomorphism indistinguishability over the class  $\text{IEHW}_k$  of incidence graphs of entangled hypertree width at most  $k$ .

► **Theorem 6.1.** *For all incidence graphs  $I, I'$  and all  $k \in \mathbb{N}_{\geq 1}$  we have:*

$$I \equiv_{\text{RGC}^k} I' \iff \text{HOM}_{\text{IEHW}_k}(I) = \text{HOM}_{\text{IEHW}_k}(I').$$

This result can be viewed as a lifting of Dvořák’s theorem [11] stating that any two graphs  $G, G'$  are indistinguishable by the  $k+1$ -variable logic  $C^{k+1}$  if, and only if, they are homomorphism indistinguishable over the class  $\text{TW}_k$  of graphs of tree-width  $\leq k$ . Our proof of Theorem 6.1 is heavily inspired by Dvořák’s proof. But in order to proceed along a similar construction, we first have to provide a suitable inductive characterisation of the class  $\text{IEHW}_k$ . This is presented in Section 7, where we also provide the machinery of *quantum* incidence graphs as an analogue of the quantum graphs used in Dvořák’s proof. Section 8 is devoted to the proof of Theorem 6.1.

Before we close this section, let us have a look at some examples. Let  $k = 2$ . Consider the following formula  $\psi_1 \in \text{GC}^k$ :

$$\psi_1 := \exists^{\geq 1}(\mathbf{v}_1).(E(\mathbf{e}_1, \mathbf{v}_1) \wedge E(\mathbf{e}_2, \mathbf{v}_1)).$$

$\psi_1$  expresses that the hyperedges  $\mathbf{e}_1$  and  $\mathbf{e}_2$  share at least one vertex  $\mathbf{v}_1$ , i.e. they intersect. Since we quantify over  $\mathbf{v}_1$ , the definition of  $\text{GC}^k$  requires us to insert a guard ranging over the set of free red variables, i.e. over  $\{\mathbf{v}_1\}$ . We chose  $E(\mathbf{e}_1, \mathbf{v}_1)$  as the guard but note that  $E(\mathbf{e}_2, \mathbf{v}_1)$  would have been a valid choice as well. Next, consider the formula  $\psi_2 \in \text{GC}^k$ :

$$\psi_2 := \bigwedge_{j \in \{1,2\}} \exists^{\geq 3}(\mathbf{v}_1).(E(\mathbf{e}_j, \mathbf{v}_1) \wedge E(\mathbf{e}_j, \mathbf{v}_1)).$$

$\psi_2$  expresses that each of the hyperedges  $e_1, e_2$  contains at least three vertices. Again, we have to insert a guard after the quantifier, which is why  $E(e_j, v_1)$  appears twice in  $\psi_2$  – as a guard *and* as our “actual” subformula.

Finally, we use the formulas  $\psi_1, \psi_2$  to construct a sentence  $\varphi \in \text{GC}^k$ :

$$\varphi := \neg \exists^{\geq 1} (e_1, e_2). (\top \wedge ((\psi_1 \wedge \psi_2) \wedge \neg e_1 = e_2)).$$

$\varphi$  expresses that there is no pair of non-equal hyperedges  $(e_1, e_2)$  that intersect and that both contain at least 3 vertices. I.e.,  $\varphi$  expresses that all hyperedges that contain at least 3 vertices are pairwise disjoint. Once again, the quantification requires us to insert a guard; since there are no free red variables, we insert  $\top$  as the guard. Note that  $(\top \wedge \varphi) \in \text{RGC}^k$ . For more examples of formulas in  $\text{GC}^k$  and  $\text{RGC}^k$ , consult the paper’s extended version [22].

## 7 An Inductive Characterisation of $\text{IEHW}_k$

In this section we give an inductive definition of what we call *guarded  $k$ -labeled incidence graphs* ( $\text{GLI}_k$ ), and we show that these are equivalent to the incidence graphs in  $\text{IEHW}_k$ . Throughout this section, we fix an arbitrary number  $k \in \mathbb{N}_{\geq 1}$ .

**$k$ -Labeled Incidence Graphs and the Class  $\text{GLI}_k$ .** We enrich an incidence graph  $I$  by labeling some of its blue (red) nodes with labels in  $[k]$  (in  $\mathbb{N}_{\geq 1}$ ), and by providing, for every  $i \in \mathbb{N}_{\geq 1}$  that is used as a label for a red node, a “blue label”  $g(i) \in [k]$  that should be regarded as “the guard” of  $i$ . Each label can only be used once, not all labels have to be used, not all vertices have to be labeled, one vertex may have multiple labels, and “guards” can be chosen arbitrarily. This is formalised as follows: A  *$k$ -labeled incidence graph*  $L = (I, r, b, g)$  consists of an incidence graph  $I$  and partial mappings  $r : \mathbb{N}_{\geq 1} \rightarrow R(I)$ ,  $b : [k] \rightarrow B(I)$ , and  $g : \mathbb{N}_{\geq 1} \rightarrow [k]$  such that  $\text{dom}(g) = \text{dom}(r)$  is finite. We write  $I_L, r_L, b_L, g_L$  to address  $L$ ’s components  $I, r, b, g$ . Let  $L = (I, r, b, g)$  be a  $k$ -labeled incidence graph. If  $j \in \text{dom}(b)$ , the blue node  $b(j)$  of  $I$  is labeled with the number  $j$ . If  $i \in \text{dom}(r)$ , the red node  $r(i)$  of  $I$  is labeled with the number  $i$ , and  $g(i) = j$  indicates that the blue node labeled with the number  $j$  (if it exists) should be regarded as “the guard” of the red node labeled with the number  $i$ .

We say that  $L$  *has real guards* if for every  $i \in \text{dom}(r)$  the red node  $v$  labeled  $i$  is “guarded” by the blue node  $e$  labeled  $j := g(i)$  in the sense that  $I$  contains an edge from  $e$  to  $v$ . This is formalised as follows: A  $k$ -labeled incidence graph  $L = (I, r, b, g)$  is said to *have real guards w.r.t.  $f$*  for a partial function  $f : \mathbb{N}_{\geq 1} \rightarrow [k]$  if  $\text{dom}(f) \subseteq \text{dom}(r)$  and for all  $i \in \text{dom}(f)$  we have  $f(i) \in \text{dom}(b)$  and  $(b(f(i)), r(i)) \in E(I)$ . We say that  $L$  *has real guards* if it has real guards w.r.t.  $g$ . Particularly simple examples of  $k$ -labeled incidence graphs with real guards are provided by the following definition.

► **Definition 7.1.** Let  $f : \mathbb{N}_{\geq 1} \rightarrow [k]$  with finite  $\text{dom}(f) \neq \emptyset$ . The  $k$ -labeled incidence graph  $M_f$  defined by  $f$  is the  $k$ -labeled incidence graph  $L = (I, r, b, g)$  with  $g := f$ , where  $I$  consists of a red node  $v_i$  for every  $i \in \text{dom}(f)$ , a blue node  $e_j$  for every  $j \in \text{img}(f)$ , and an edge  $(e_{f(i)}, v_i)$  for every  $i \in \text{dom}(f)$ , and where  $\text{dom}(r) = \text{dom}(f)$  and  $r(i) = v_i$  for all  $i \in \text{dom}(r)$ , and  $\text{dom}(b) = \text{img}(f)$  and  $b(j) = e_j$  for all  $j \in \text{dom}(b)$ . Note that  $M_f$  has real guards.

We introduce a number of operations on  $k$ -labeled incidence graphs. The first kind of operations provides ways to modify the labels (the latter two of these do not necessarily preserve real guards). Let  $L = (I, r, b, g)$  be a  $k$ -labeled incidence graph. Let  $X_r \subseteq \mathbb{N}_{\geq 1}$  be finite, and let  $X_b \subseteq [k]$ .

1. Removing from the red nodes all the labels in  $X_r$  is achieved by the operation  $L[X_r \rightarrow \bullet] := (I, r', b, g')$  with  $r' := r - X_r$  and  $g' := g - X_r$ .
2. Removing from the blue nodes all the labels in  $X_b$  is achieved by the operation  $L\langle X_b \rightarrow \bullet \rangle := (I, r, b', g)$  with  $b' := b - X_b$ .
3. Let  $X_r = \{i_1, \dots, i_\ell\}$  for  $\ell := |X_r|$  and  $i_1 < \dots < i_\ell$ . For every  $\bar{v} = (v_1, \dots, v_\ell) \in R(I)^\ell$  we let  $L[X_r \rightarrow \bar{v}] := (I, r', b, g)$  with  $\text{dom}(r') = \text{dom}(r) \cup X_r$  and  $r'(i_j) = v_j$  for all  $j \in [\ell]$  and  $r'(i) = r(i)$  for all  $i \in \text{dom}(r) \setminus X_r$  (i.e., for each  $j \in [\ell]$ , the red label  $i_j$  is moved onto the red node  $v_j$ , and all other labels remain unchanged).
4. Let  $X_b = \{i_1, \dots, i_\ell\}$  for  $\ell := |X_b|$  and  $i_1 < \dots < i_\ell$ . For every  $\bar{e} = (e_1, \dots, e_\ell) \in B(I)^\ell$  we let  $L\langle X_b \rightarrow \bar{e} \rangle := (I, r, b', g)$  with  $\text{dom}(b') = \text{dom}(b) \cup X_b$  and  $b'(i_j) = e_j$  for all  $j \in [\ell]$  and  $b'(i) = b(i)$  for all  $i \in \text{dom}(b) \setminus X_b$  (i.e., for each  $j \in [\ell]$ , the blue label  $i_j$  is moved onto the blue node  $e_j$ , and all other labels remain unchanged).

The next operation enables us to *glue* two  $k$ -labeled incidence graphs  $L_1$  and  $L_2$ . This is achieved by first taking the disjoint union of  $L_1$  and  $L_2$  and then merging all red (blue) nodes that carry the same label into a single red (blue) node that inherits all neighbours of the merged nodes. We write  $(L_1 \cdot L_2)$  to denote the resulting  $k$ -labeled incidence graph. We need one further operation on  $k$ -labeled incidence graphs, namely, one that admits us to change its guard function:

- **Definition 7.2** (Applying a transition). Consider a partial function  $g : \mathbb{N}_{\geq 1} \rightarrow [k]$ .
- (a) A *transition for  $g$*  is a partial function  $f : \mathbb{N}_{\geq 1} \rightarrow [k]$  with  $\emptyset \neq \text{dom}(f) \subseteq \text{dom}(g)$  satisfying the following: for every  $i \in \text{dom}(g)$  with  $g(i) \in \text{img}(f)$  we have  $i \in \text{dom}(f)$ .
  - (b) Let  $L = (I, r, b, g)$  be a  $k$ -labeled incidence graph, and let  $f$  be a transition for  $g$ . *Applying* the transition  $f$  to  $L$  yields the  $k$ -labeled incidence graph  $L[\rightsquigarrow f] := (M_f \cdot L\langle X_b \rightarrow \bullet \rangle)$ , where  $X_b := \text{img}(g) \cap \text{img}(f) \cap \text{dom}(b)$ , and  $M_f$  is provided by Definition 7.1.

The idea of applying a transition  $f$  to a  $k$ -labeled incidence graph  $L = (I, r, b, g)$  is to assign new guards to a set of labeled red vertices (i.e. the domain of  $f$ ). These new guards should be newly inserted nodes, and they should be *real* guards. To this end, for every  $j \in \text{img}(f)$  we add a new blue node  $e'_j$  labeled  $j$ ; and in case that the label  $j$  had already been used by a blue node  $e$  of  $L$  (i.e.,  $j \in \text{dom}(b)$ ) and served as a guard according to  $g$  (i.e.,  $j \in \text{img}(g)$ ), we remove this label from  $e$ . For each  $i \in \text{dom}(f)$  with  $f(i) = j$  we add an edge from the red node of  $L$  labeled  $i$  to the new blue node  $e'_j$ .

The formal definition  $L[\rightsquigarrow f] := (M_f \cdot L\langle X_b \rightarrow \bullet \rangle)$  achieves this as follows: By  $L\langle X_b \rightarrow \bullet \rangle$  we release from  $L$  all blue labels  $j$  that are present in  $L$  and that we want to assign to newly created nodes. This is achieved by letting  $X_b = \text{img}(g) \cap \text{img}(f) \cap \text{dom}(b)$ . Afterwards, adding the edges from the nodes of  $L$  that carry a red label  $i \in \text{dom}(f)$  to the new blue node  $e'_{f(i)}$  is achieved by glueing  $M_f$  to  $L\langle X_b \rightarrow \bullet \rangle$ . Note that releasing from  $L$  all blue labels in  $X_b$  might be problematic: Consider a red node  $v$  labeled  $i$  that was originally guarded by the blue node  $e$  of  $L$  that carried the label  $j := g(i)$ . Releasing the label  $j$  from node  $e$  means that  $v$  loses its guard in case that  $i \notin \text{dom}(f)$ . Therefore, for  $f$  to be a transition for  $g$ , we require in Definition 7.2 that it assigns a new guard to all the affected labeled red vertices, i.e. we require  $i \in \text{dom}(f)$ , if  $g(i) \in \text{img}(f)$ . Finally, we are ready to define the class  $GLI_k$ :

- **Definition 7.3** ( $GLI_k$ ). The class  $GLI_k$  of *guarded  $k$ -labeled incidence graphs* is inductively defined as follows:

**Base case:** Any  $k$ -labeled incidence graph  $L = (I, r, b, g)$  with  $R(I) = \text{img}(r)$ ,  $B(I) = \text{img}(b)$ , and with real guards belongs to  $GLI_k$ .

**Inductive cases:** Let  $L = (I, r, b, g) \in GLL_k$ .

1.  $L[X_r \rightarrow \bullet] \in GLL_k$  for every  $X_r \subseteq \text{dom}(r)$ .
2.  $L\langle X_b \rightarrow \bullet \rangle \in GLL_k$  for every  $X_b \subseteq \text{dom}(b) \setminus \text{img}(g)$ .
3.  $L[\rightsquigarrow f] \in GLL_k$  for every transition  $f$  for  $g$ .
4.  $(L \cdot L') \in GLL_k$  for every  $L' = (I', r', b', g') \in GLL_k$  such that  $g$  and  $g'$  are compatible.

An easy inductive proof shows that every  $L \in GLL_k$  has real guards.

A  $k$ -labeled incidence graph  $L$  is called *label-free* if  $\text{dom}(r_L) = \text{dom}(b_L) = \text{dom}(g_L) = \emptyset$ . We are now ready for this section's technical main result, which states that, essentially,  $GLL_k$  provides an inductive characterisation of  $IEHW_k$ :

► **Theorem 7.4.**

- (a) *The incidence graph  $I_L$  of every  $L \in GLL_k$  is in  $IEHW_k$ .*
- (b) *For every  $I \in IEHW_k$  there exists a label-free  $L \in GLL_k$  such that  $I \cong I_L$ .*

The proof of (a) proceeds by induction on the definition of  $GLL_k$  and explicitly constructs an ehd of width  $\leq k$  for each  $L \in GLL_k$ ; for this it utilises that  $L$  has real guards. The proof of (b) starts with an ehd of  $I$  of width  $\leq k$ , chooses a suitable root node of the ehd's tree and performs a bottom-up traversal of this tree to associate each tree-node  $t$  with a corresponding  $k$ -labeled incidence graph  $L_t$ . This construction's details have to be carried out with care to ensure that  $L_t \in GLL_k$ .

**Homomorphisms on  $k$ -Labeled Incidence Graphs and their Quantum Analogues.**

We define the notion of *homomorphisms* of  $k$ -labeled incidence graphs in such a way that it respects labels, but ignores the guard function: Let  $L = (I, r, b, g)$  and  $L' = (I', r', b', g')$  be  $k$ -labeled incidence graphs. If  $\text{dom}(r) \not\subseteq \text{dom}(r')$  or  $\text{dom}(b) \not\subseteq \text{dom}(b')$ , then there exists no homomorphism from  $L$  to  $L'$ . Otherwise, a homomorphism from  $L$  to  $L'$  is a homomorphism  $h = (h_R, h_B)$  from  $I$  to  $I'$  satisfying the following condition:  $h(r(i)) = r'(i)$  for all  $i \in \text{dom}(r)$  and  $h(b(j)) = b'(j)$  for all  $j \in \text{dom}(b)$ . By  $\text{Hom}(L, L')$  we denote the set of all homomorphisms from  $L$  to  $L'$ , and we let  $\text{hom}(L, L') := |\text{Hom}(L, L')|$  be the number of homomorphisms from  $L$  to  $L'$ . In particular, if  $L$  is *label-free*, then  $\text{hom}(L, L') = \text{hom}(I_L, I_{L'})$ .

In order to enable us to “aggregate” homomorphism counts, we proceed in a similar way as Dvořák [11]: we use a variant of the *quantum graphs* of Lovász and Szegedy [20], tailored towards our setting. We say that  $k$ -labeled incidence graphs  $L_1, \dots, L_d$  are *compatible* if their labeling functions all have the same domain and they all have the same guard function, i.e.,  $\text{dom}(r_{L_1}) = \text{dom}(r_{L_i})$ ,  $\text{dom}(b_{L_1}) = \text{dom}(b_{L_i})$ , and  $g_{L_1} = g_{L_i}$  for all  $i \in [d]$ .

A  *$k$ -labeled quantum incidence graph*  $Q$  is a formal finite non-empty linear combination with real coefficients of compatible  $k$ -labeled incidence graphs. We represent a  $k$ -labeled quantum incidence graph  $Q$  as  $\sum_{i=1}^d \alpha_i L_i$ , where  $d \in \mathbb{N}_{\geq 1}$ ,  $\alpha_i \in \mathbb{R}$ , and  $L_i$  is a  $k$ -labeled incidence graph for  $i \in [d]$ . We let  $\text{dr}_Q := \text{dom}(r_{L_1}) = \dots = \text{dom}(r_{L_d})$ ,  $\text{db}_Q := \text{dom}(b_{L_1}) = \dots = \text{dom}(b_{L_d})$ , and  $g_Q := g_{L_1} = \dots = g_{L_d}$ . The  $\alpha_i$ 's and  $L_i$ 's are called the *coefficients* and *components*, respectively, and  $d$  is called the *degree* of  $Q$ . Note that a  $k$ -labeled incidence graph is a  $k$ -labeled quantum incidence graph with degree 1 and coefficient 1. For a  $k$ -labeled quantum incidence graph  $Q = \sum_{i=1}^d \alpha_i L_i$  and an arbitrary  $k$ -labeled incidence graph  $L'$  we let  $\text{hom}(Q, L') := \sum_{i=1}^d \alpha_i \cdot \text{hom}(L_i, L') \in \mathbb{R}$ .

We adapt the operations for  $k$ -labeled incidence graphs to their quantum equivalent in the expected way:  $Q[X_r \rightarrow \bullet] := \sum_{i=1}^d L_i[X_r \rightarrow \bullet]$ ,  $Q\langle X_b \rightarrow \bullet \rangle := \sum_{i=1}^d L_i\langle X_b \rightarrow \bullet \rangle$ ,  $Q[\rightsquigarrow f] := \sum_{i=1}^d \alpha_i L_i[\rightsquigarrow f]$ . Glueing two  $k$ -labeled quantum incidence graphs  $Q = \sum_{i=1}^d \alpha_i L_i$  and  $Q' = \sum_{j=1}^{d'} \alpha'_j L'_j$  is achieved by pairwise glueing of their components and multiplication of their respective coefficients, i.e.  $(Q \cdot Q') := \sum_{\substack{i \in [d] \\ j \in [d']}} (\alpha_i \cdot \alpha'_j) (L_i \cdot L'_j)$ .

The following can easily be proved for the case where  $Q, Q'$  have degree 1 and coefficient 1 (i.e.,  $Q, Q'$  are  $k$ -labeled incidence graphs), and then be generalised to quantum incidence graphs by simple linear arguments.

► **Lemma 7.5.** *For all  $k$ -labeled quantum incidence graphs  $Q, Q'$  and all  $k$ -labeled incidence graphs  $L$  we have:*

1.  $\text{hom}((Q \cdot Q'), L) = \text{hom}(Q, L) \cdot \text{hom}(Q', L)$ .
2.  $\text{hom}(Q[X_r \rightarrow \bullet], L) = \sum_{\bar{v} \in R(I_L)^\ell} \text{hom}(Q, L[X_r \rightarrow \bar{v}])$ , for all  $X_r \subseteq \text{dr}_Q$  and  $\ell := |X_r|$ .
3.  $\text{hom}(Q\langle X_b \rightarrow \bullet \rangle, L) = \sum_{\bar{e} \in B(I_L)^\ell} \text{hom}(Q, L\langle X_b \rightarrow \bar{e} \rangle)$ , for all  $X_b \subseteq \text{db}_Q$  and  $\ell := |X_b|$ .
4.  $\text{hom}(Q[\rightsquigarrow f], L) = \text{hom}(M_f, L) \cdot \sum_{\bar{e} \in B(I_L)^\ell} \text{hom}(Q, L\langle X_b \rightarrow \bar{e} \rangle)$ , for all transitions  $f$  for  $g_Q$ , for  $X_b := \text{db}_Q \cap \text{img}(f) \cap \text{img}(g)$  and  $\ell := |X_b|$ . Note that  $\text{hom}(M_f, L) \in \{0, 1\}$ .

The class  $QGLI_k$  of *guarded  $k$ -labeled quantum incidence graphs* consists of those  $k$ -labeled quantum incidence graphs where all components belong to  $GLI_k$ . The following lemma was provided for series-parallel quantum graphs by Lovász and Szegedy [20] and for labeled quantum graphs of tree-width  $\leq k$  by Dvořák [11]; their proof also works for  $QGLI_k$ .

► **Lemma 7.6.** *Let  $X, Y \subseteq \mathbb{N}$  be disjoint and finite, and let  $Q \in QGLI_k$ . There exists a  $Q[X, Y] \in QGLI_k$  with the same parameters  $\text{dr}_Q, \text{db}_Q, g_Q$  as  $Q$ , such that for all  $k$ -labeled incidence graphs  $L$  with real guards w.r.t.  $g_Q$  we have:*

1. If  $\text{hom}(Q, L) \in X$  then  $\text{hom}(Q[X, Y], L) = 0$ .
2. If  $\text{hom}(Q, L) \in Y$  then  $\text{hom}(Q[X, Y], L) = 1$ .

## 8 Proof of Theorem 6.1

Finally, we have available all the machinery so that, from a high-level point of view, our proof of Theorem 6.1 can follow a similar approach as Dvořák's proof in [11]. Analogously to the two main lemmas in [11], we provide a key lemma for each of the directions " $\Leftarrow$ " and " $\Rightarrow$ " of Theorem 6.1. These lemmas use the following notion: The *interpretation*  $\mathcal{I}_{L'}$  associated with a  $k$ -labeled incidence graph  $L'$  is an interpretation  $(I, \beta)$  with  $I := I_{L'}$  and  $\beta(\mathbf{v}_i) := r_{L'}(i)$  for all  $i \in \text{dom}(r_{L'})$  and  $\beta(\mathbf{e}_j) := b_{L'}(j)$  for all  $j \in \text{dom}(b_{L'})$ .

► **Lemma 8.1.** *Let  $L = (I, b, r, g) \in GLI_k$ . For every  $m \in \mathbb{N}$  there is a formula  $\varphi_{L,m}$  with  $(\Delta_g \wedge \varphi_{L,m}) \in \text{RG}C^k$  and  $\text{free}((\Delta_g \wedge \varphi_{L,m})) = \{\mathbf{v}_i : i \in \text{dom}(r)\} \cup \{\mathbf{e}_j : j \in \text{dom}(b)\}$  such that for every  $k$ -labeled incidence graph  $L' = (I', b', r', g')$  with  $\text{dom}(b_{L'}) \supseteq \text{dom}(b)$ ,  $\text{dom}(r_{L'}) \supseteq \text{dom}(r)$ , and with real guards w.r.t.  $g$  we have:  $\mathcal{I}_{L'} \models \Delta_g$ , and  $\text{hom}(L, L') = m \iff \mathcal{I}_{L'} \models \varphi_{L,m}$ .*

► **Lemma 8.2.** *Let  $\chi := (\Delta_g \wedge \psi) \in \text{RG}C^k$  and let  $m, d \in \mathbb{N}$  with  $m \geq 1$ . There exists a  $Q := Q_{\chi, m, d} \in QGLI_k$  with  $g_Q = g$ ,  $\text{db}_Q = \text{ifree}_B(\chi)$ ,  $\text{dr}_Q = \text{dom}(g) = \text{ifree}_R(\chi)$  such that for all  $k$ -labeled incidence graphs  $L' = (I', b', r', g')$  with  $|B(I')| = m$  and  $\max\{|N_{I'}(e)| : e \in B(I')\} \leq d$  and  $\text{dom}(b') \supseteq \text{db}_Q$ ,  $\text{dom}(r') \supseteq \text{dr}_Q$ ,  $g' \supseteq g$ , and with real guards w.r.t.  $g$  we have:  $\mathcal{I}_{L'} \models \Delta_g$ , and  $\text{hom}(Q, L') = 1$  if  $\mathcal{I}_{L'} \models \chi$ , and  $\text{hom}(Q, L') = 0$  if  $\mathcal{I}_{L'} \not\models \chi$ .*

The proofs of both lemmas are technically quite intricate because the concept of generalised hypertree width (as well as the classes  $IEHW_k$  and  $GLI_k$ ) is much more complicated than the concept of tree-width. For Lemma 8.1 we proceed by induction based on Definition 7.3; for Lemma 8.2 we proceed by induction on the construction of  $\chi$ . Finally, the proof of Theorem 6.1 can easily be achieved by using Theorem 7.4 and the Lemmas 8.1 (for direction " $\Leftarrow$ ") and 8.2 (for direction " $\Rightarrow$ ").

## 9 Conclusion

Combining the Theorems 3.1, 4.1, 6.1 yields:

► **Theorem 9.1** (Main Theorem). *Let  $H, H'$  be hypergraphs.*

(a)  $I_H \equiv_{\text{RGC}^k} I_{H'} \iff \text{HOM}_{\text{GHW}_k}(H) = \text{HOM}_{\text{GHW}_k}(H')$ .

(b) *If  $H$  and  $H'$  are simple, then:*  $I_H \equiv_{\text{RGC}^k} I_{H'} \iff \text{HOM}_{\text{sGHW}_k}(H) = \text{HOM}_{\text{sGHW}_k}(H')$ .

An obvious question is whether  $\text{RGC}^k$ -sentences have the same expressive power as  $\text{GC}^k$ -sentences. Since the submission of this paper, we were able to prove that this is indeed the case, i.e., any sentence of the logic  $\text{GC}^k$  can be transformed into an equivalent sentence in  $\text{RGC}^k$ . This implies that  $I_H \equiv_{\text{RGC}^k} I_{H'} \iff I_H \equiv_{\text{GC}^k} I_{H'}$ . Details are provided in the paper’s extended version [22].

For our proofs it was crucial to consider ehds instead of generalised hypertree decompositions. To the best of our knowledge, ehds have not been studied before. From Theorem 2.3 we know that there exist arbitrarily large  $k$  such that  $\text{IEHW}_k$  is a strict subclass of  $\text{IGHW}_k$ ; but nevertheless, according to Theorem 4.1 homomorphism indistinguishability coincides for both classes. Many other questions remain open, in particular: How hard is it, given a hypergraph  $H$  and a number  $k$ , to determine whether  $\text{ehw}(H) \leq k$ ? For  $\mathcal{C} := \text{IEHW}_k$ : how hard is it to compute the function (or, “vector”)  $\text{HOM}_{\mathcal{C}}(H)$  for a given hypergraph  $H$ ? Which properties does it have? What is the expressive power of the logic  $\text{GC}^k$ ? How does a suitable pebble game for  $\text{GC}^k$  look like? Our result lifts Dvořák’s result for tree-width  $\leq k$  [11] from graphs to hypergraphs. Does there also exist a lifting of Grohe’s result for *tree-depth*  $\leq k$  [16] from graphs to hypergraphs? Seeing that Dvořák’s result lifted nicely to hypergraphs, we believe that there should also be a lifting of Cai, Fürer and Immerman’s result [8], i.e., a hypergraph-variant of the Weisfeiler-Leman algorithm, whose distinguishing power matches precisely the logic  $\text{GC}^k$ . We plan to study this in future work.

---

## Abstract

---

The paper proposes dynamic parallel algorithms for connectivity and bipartiteness of undirected graphs that require constant time and  $\mathcal{O}(n^{1/2+\epsilon})$  work on the CRCW PRAM model. The work of these algorithms almost matches the work of the  $\mathcal{O}(\log n)$  time algorithm for connectivity by Kopelowitz et al. (2018) on the EREW PRAM model and the time of the sequential algorithm for bipartiteness by Eppstein et al. (1997). In particular, we show that the sparsification technique, which has been used in both mentioned papers, can in principle also be used for constant time algorithms in the CRCW PRAM model, despite the logarithmic depth of sparsification trees.

**2012 ACM Subject Classification** Theory of computation → Dynamic graph algorithms; Theory of computation → Parallel algorithms

## 1 Introduction

There has been a lot of research on dynamic algorithms for graph problems.<sup>1</sup> Usually, the setting is that graphs can be changed by edge insertions or deletions and that there are query operations that allow to check whether the graph has certain properties. Most of this research has been about sequential algorithms and the goal has been to find algorithms that are as fast as possible. Some algorithms use randomisation, others are deterministic, sometimes the time bounds are worst-case bounds per change or query operation and sometimes they are amortised bounds.

There has been also some research on dynamic *parallel* graph algorithms. Many of these algorithms use the EREW PRAM model<sup>2</sup> and try to achieve logarithmic or polylogarithmic running time, while being work-efficient or even work-optimal. That is, the overall work of all processors should be (almost) the same as for the best sequential algorithm.<sup>3</sup>

There is an entirely separate line of work that studied the maintenance of graph (and other) properties in a setting that was inspired by Database Theory. It is often called *Dynamic Complexity* in Database Theory. In the setting of Dynamic Complexity, dynamic algorithms are called *dynamic programs* and they are not specified in an “algorithmic fashion”

---

<sup>1</sup> Below we will give pointers to literature. For the beginning of the introduction, we try to keep the story simple.

<sup>2</sup> In an EREW PRAM, parallel processors can use shared memory, but at each moment, each memory cell can be accessed by only one processor. EREW stands for *exclusive-read/exclusive-write*.

<sup>3</sup> We note that in our context of constant-time parallel algorithms work is within a constant factor of the number of processors.

but rather by logical formulas. As a classical example from [13], to maintain reachability information between pairs of nodes in a directed acyclic graph, a dynamic program can use an auxiliary relation  $T$  that is intended to store the transitive closure of the graph. The program can then be specified by two formulas that specify how the new version  $T'$  of  $T$  is defined after the insertion or deletion of an edge  $(u, v)$ :

**Insertion:**  $T'(x, y) \stackrel{\text{def}}{=} T(x, y) \vee (T(x, u) \wedge T(v, y))$ . After inserting  $(u, v)$  there is a path from  $x$  to  $y$  if such a path already existed or if there was a path from  $x$  to  $u$  and from  $v$  to  $y$ .

**Deletion:**  $T'(x, y) \stackrel{\text{def}}{=} T(x, y) \wedge \left( E(x, y) \vee \neg T(x, u) \vee \neg T(v, y) \vee \exists u', v' \left( (u' \neq u \vee v' \neq v) \wedge T(x, u') \wedge E(u', v') \wedge T(v', y) \wedge T(u', u) \wedge \neg T(v', u) \right) \right)$ .

This formula is slightly more complicated. In the main case, the nodes  $u', v'$  are chosen such that neither the path from  $x$  to  $u'$  nor the path from  $v'$  to  $y$  relies on the edge  $(u, v)$ . In the former case this is thanks to  $T(u', u)$  (since if  $T(x, u')$  involved  $(u, v)$ , the graph were not be acyclic) and in the latter case it is thanks to  $\neg T(v', u)$ .

As in the example, the underlying logic is usually first-order logic, since it corresponds to the main (theoretical) query language for relational databases, the relational algebra, which in turn corresponds to the core of SQL. The class of problems or queries that can be maintained in this way is usually called DynFO.

Dynamic Complexity has existed quite separated from the world of dynamic algorithms, but there is a direct link that connects the two areas: it follows from a fundamental result<sup>4</sup> from Immerman [8, Theorem 1.1] that dynamic programs can be translated into parallel programs that run in *constant time* on suitable versions of CRCW PRAMs<sup>5</sup> with polynomially many processors. And vice versa.

Dynamic Complexity has focussed on the question whether a graph property can be maintained at all by first-order logic (or fragments thereof), but did not care about the work efficiency of the parallel algorithms that are obtained from translating the update formulas. It turns out that this automatic translation often does not yield very efficient parallel algorithms.

As an example, the parallel dynamic algorithm that is obtained by direct translation of the above formulas, has work  $\mathcal{O}(n^4)$  for deletions, since it would consist of two nested loops for  $x$  and  $y$  and two more for  $u$  and  $v$ . This is far from being work-efficient.<sup>6</sup> The translation of the dynamic program for Connectivity in undirected graphs from [13] even yields a work bound of  $\mathcal{O}(n^5)$ . We will show that this work bound can be improved considerably.

This paper is part of an effort to bridge the gap between Dynamic Complexity and (parallel) Dynamic Algorithms by developing algorithms that run in constant time on CRCW PRAMs and are as work efficient as possible. It presents constant-time dynamic parallel algorithms for Connectivity and Bipartiteness in undirected graphs. In the *arbitrary* CRCW model, the algorithms require work at most  $n^{\frac{1}{2}} \text{polylog}(n)$ . In the *common* CRCW model, the algorithms can be instantiated, for each constant  $\epsilon > 0$ , such that they obey a work bound of  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$ , where  $n$  is the number of nodes in the graph.

<sup>4</sup> Immerman's result is not about dynamic programs, but each formula of a dynamic program can be translated separately.

<sup>5</sup> In a CRCW PRAM more than one processor can read a memory cell, at the same time. Even more than one processor can write into the same cell, but there has to be a strategy that deals with conflicts. This will be explained later in the text.

<sup>6</sup> We have to admit that this paper does not present a better algorithm for directed reachability. We chose that problem only as an example, since its formulas are relatively easy to understand.

The algorithm for Connectivity follows the parallel EREW PRAM algorithm of Kopelowitz et al. [12], which in turn was based on a sequential algorithm by Fredrickson [5] and its sparsification by Eppstein et al. [4]. Thus, the work of our algorithm almost matches the work bound  $\mathcal{O}(n^{\frac{1}{2}})$  of the parallel algorithm of [12] and the worst-case runtime of [4]. However, it does not match the runtime of the recent breakthrough algorithm by Chuzhoy et al. [1].

The main technical challenge here is to make the sparsification and the tree-like data structure of [12] work in constant time, despite their use of trees of logarithmic depth. For sparsification, this means updating all logarithmically many nodes along the path from the changed leaf to the root of a tree of logarithmic height in parallel constant time although in classical sparsification the change in the leaf is propagated from one node to the other along the path. For handling the tree-like data structure of [12] in constant parallel time, data is stored differently by switching from lists to arrays and it is shown (in full version of this paper) that balanced search trees ( $(a, b)$ -trees to be precise) of logarithmic height are maintainable in constant parallel time. In the classical algorithm for, e.g., splitting an  $(a, b)$ -tree into two separate trees, the tree is first split into logarithmically many smaller trees and then the two new trees are built by merging logarithmically many of those smaller trees back together. Both steps are done sequentially in  $\mathcal{O}(\log n)$  time by splitting one of those smaller trees at a time and merging only two of the smaller trees at a time, but for our purpose have to be done in constant parallel time.

The algorithm for bipartiteness almost matches the runtime of the bipartiteness algorithm of Eppstein et al. [4]. It is based on the observation that a graph is bipartite if and only if its distance-2 graph has twice as many connected components as the graph itself. The algorithm therefore basically maintains two spanning trees, for the graph and its distance-2 graph. Here, the main technical challenge is to show that the same sparsification approach as for connectivity also works for bipartiteness.

**Structure of the paper.** We introduce some basic concepts about CRCW PRAMs in Section 2. The algorithm for connectivity is presented in Section 3. The algorithm for bipartiteness is given in Section 4.

**Related work.** Some related work has already been mentioned above. Dynamic Complexity has started by the work of Patnaik and Immerman [13] and Dong and Su [3]. For a recent survey on the dynamic complexity of Reachability in directed and undirected graphs, we refer to [14]. For a recent survey on dynamic graph algorithms, we refer to [6].

Of course, the PRAM model is not the only parallel computation model for parallel algorithms. Parallel dynamic algorithms for the MPC model can be found, e.g., in [9].

## 2 Preliminaries

For natural numbers  $i \leq j$ , we write  $[i, j]$  for the set  $\{i, \dots, j\}$ . We only deal with undirected graphs and denote an undirected edge between two vertices  $u$  and  $v$  by  $(u, v)$ .

**Dynamic algorithmic problems.** In this paper, we view a dynamic (algorithmic) problem basically as the interface of a data type: that is, there is a collection of operations by which some object can be initialised, changed, and queried. A *dynamic algorithm* is then a collection of algorithms, one for each operation. We consider two main dynamic problems in this paper, CONNECTIVITY and BIPARTITENESS.

The algorithmic problem CONNECTIVITY maintains an undirected graph  $G$  and has the following operations.

- `Init( $G, n$ )` yields an initial graph  $G$  with  $n$  nodes, that are initially deactivated but without edges;
- `ActivateNode( $G, v$ )` yields an identifier for a new node of  $G$ ;
- `DeactivateNode( $G, v$ )` deactivates the node  $v$  from  $G$ . The node  $u$  must be isolated;
- `InsertEdge( $G, u, v$ )` inserts edge  $(u, v)$  to  $G$ ;
- `DeleteEdge( $G, u, v$ )` deletes edge  $(u, v)$  from  $G$ ;
- `Connected( $G, u, v$ )` returns true if  $u$  and  $v$  are in the same connected component, otherwise false.
- `#Components( $G$ )` yields the number of connected components of  $G$  on the activated nodes.

BIPARTITENESS has almost the same operations, but instead of `Connected` and `#Components` it has a query operation `Bipartite( $G$ )` which yields true if the graph  $G$  is bipartite.

Throughout this paper we only consider the effort for change and query operations, but disregard the effort for the initialisation of a graph. We also note that the number  $n$  of nodes can not grow. The nodes are represented by numbers in  $\{1, \dots, n\}$ .

**Parallel Random Access Machines (PRAMs).** A *parallel random access machine* (PRAM) consists of a number of processors that work in parallel and use a shared memory.<sup>7</sup> The memory is comprised of memory cells which can be accessed by a processor in  $\mathcal{O}(1)$  time. Furthermore, we assume that simple arithmetic and bitwise operations, including addition, can be done in  $\mathcal{O}(1)$  time by a processor. The work of a PRAM computation is the sum of the number of all computation steps of all processors made during the computation. We define the space  $s$  required by a PRAM computation as the maximal index of any memory cell accessed during the computation.

We use the Concurrent-Read Concurrent-Write model (CRCW PRAM), i.e., processors are allowed to read and write concurrently from and to the same memory location. More precisely, we will consider two different versions of CRCW PRAMs.

- In the *arbitrary* model, if multiple processors concurrently write to the same memory location, one of them, “arbitrarily”, succeeds;
- In the slightly weaker *common* model, concurrent write into the same memory location, is only allowed if all processors write the same value.

The two models will yield slightly different work bounds for our dynamic algorithms for CONNECTIVITY and BIPARTITENESS: in the arbitrary model, the work will be at most  $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$ , whereas in the common model, we will have algorithms with work  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$ , for every  $\epsilon > 0$ . Here,  $\tilde{\mathcal{O}}(f(n))$  allows an additional polylogarithmic factor with  $f(n)$ .

We refer to [10] for more details on PRAMs and to [15, Section 2.2.3] for a discussion of alternative space measures.

For simplicity, we assume that even if the number  $n$  of nodes of the input graph grows, a number in the range  $[0, n]$  can still be stored in one memory cell. This assumption is justified, since addition of larger numbers  $N$  can still be done in constant time and polylogarithmic work on a CRCW PRAM.

The following lemma exhibits a simple CRCW PRAM algorithm in the common model that will be used as a sub-algorithm. It also illustrates the frequent use of arrays in PRAM algorithms. It will mainly be used as a tie-breaker, if one of several objects has to be chosen, and it will therefore not be needed in the context of the arbitrary model. The lemma was shown in a slightly more general form in [11, Proposition 5.4].

---

<sup>7</sup> Some content of this paragraph is copied from [11].

► **Lemma 2.1** ([11, Proposition 5.4]). *Let  $A$  be an array of size  $n$  over a finite alphabet  $\Sigma$ . The minimum/maximum value of  $A$  can be computed in constant parallel time on a common CRCW PRAM with work  $\mathcal{O}(n^{1+\epsilon})$  for any  $\epsilon > 0$ .*

**Proof sketch.** We only describe how the minimum can be computed, since finding the maximum value is completely analogous. A naïve approach is to assign one processor to each pair  $i, j$  of positions in the array. Whenever  $A[i] < A[j]$  or  $A[i] = A[j]$  and  $i < j$ , then a 1 is written into  $B[j]$ , where  $B$  is an auxiliary array of size  $n$ , in which all entries are initially set to zero. Afterwards, one processor is assigned to each cell of  $B$  and the processor assigned to the only cell  $B[i]$  with value 0 outputs  $A[i]$  as the minimum. However, this algorithm requires  $\mathcal{O}(n^2)$  work. The (standard) idea to reduce the work to  $\mathcal{O}(n^{1+\epsilon})$  is to first compute the minimum of subarrays of  $A$  of size  $n^\epsilon$ . This requires time  $\mathcal{O}(n^{2\epsilon})$ , for each of the  $n^{1-\epsilon}$  subarrays, resulting in work  $\mathcal{O}(n^{1+\epsilon})$ . The minimal values of the sub-arrays can then be stored in an array of size  $n^{1-\epsilon}$  whose minimum can be computed recursively. Since the number of recursion rounds is bounded by the constant  $\lceil \frac{1}{\epsilon} \rceil$ , the overall work is  $\mathcal{O}(n^{1+\epsilon})$ . ◀

### 3 Connectivity

In this section, we present the main result of this paper and (most of) its proof.

► **Theorem 3.1.** *There are dynamic parallel constant-time algorithms for CONNECTIVITY with the following work bounds per change or query operation.*

- $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$  work on the arbitrary CRCW PRAM model.
- $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$  work on the common CRCW PRAM model, for every  $\epsilon > 0$ .

As usual, the algorithm basically maintains a spanning forest and the graph  $G$  is connected if and only if  $\#\text{Components}(G)$  yields 1.

In fact, we will consider the data type SPANNINGFOREST as an extension of CONNECTIVITY with the following additional operation.

- $\text{TreeEdge}(G, u, v)$  returns true if  $(u, v)$  is a tree edge, otherwise false.

The proof is along the lines of [12] and is split into the same three main steps. For each step, we need to show that it can be done in constant parallel time on a CRCW PRAM, as opposed to  $\mathcal{O}(\log n)$  on an EREW PRAM. This strengthening comes with an additional work factor of  $\text{polylog}(m)$  or  $\text{polylog}(n)$  on an arbitrary CRCW PRAM and  $m^\epsilon$  or  $n^\epsilon$  on a common CRCW PRAM.

We first show that, for graphs of maximum degree 3, SPANNINGFOREST can be maintained with work  $\tilde{\mathcal{O}}(m^{\frac{1}{2}})$  and  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  per operation, depending on the PRAM model. Then we show that the case of graphs of unbounded degree can be reduced to the case of graphs with degree bound three. Finally, we show that, with the help of sparsification, both bounds from above are translatable to be in  $n$  instead of  $m$ .

More precisely, we show the following three results.

► **Proposition 3.2.** *There are dynamic parallel constant time algorithms for the special case of SPANNINGFOREST, where the maximum degree of the graph never exceeds 3 with the following work bounds per change or query operation.*

- $\tilde{\mathcal{O}}(m^{\frac{1}{2}})$  on the arbitrary CRCW PRAM model.
- $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  on the common CRCW PRAM model, for every  $\epsilon > 0$ .

► **Proposition 3.3.** *If SPANNINGFOREST can be maintained in parallel constant time on a CRCW PRAM with the work bounds of Proposition 3.2 per change or query operation, for any  $\epsilon > 0$ , for graphs with maximum degree 3, it can be maintained with the same bounds for general graphs with the provision that they never have more than  $cn$  edges, for some constant  $c$ .*

► **Proposition 3.4.** *If SPANNINGFOREST can be maintained in parallel constant time on a CRCW PRAM with the work bounds of Proposition 3.2 per change or query operation, then it can also be maintained with  $\tilde{O}(n^{\frac{1}{2}})$  work per change or query operation on the common CRCW model and with  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$  work per change or query operation on the arbitrary CRCW model.*

Proposition 3.2 will be shown in the next two subsections. Proposition 3.3 and Proposition 3.4 will be shown in Subsection 3.2.

### 3.1 Maintaining a spanning forest for bounded degree graphs

As mentioned before, our algorithm closely follows [12] and therefore uses a similar data structure. Some modifications are required though, to achieve constant parallel update and query time while keeping almost the same amount of work. The data structure maintains an Euler tour, for each spanning tree in a spanning forest of the graph. More precisely, it maintains, for each spanning tree, a cyclic list of tree edges that visits each tree edge once in either direction.

We first concentrate on the change operations `InsertEdge`( $G, u, v$ ) and `DeleteEdge`( $G, u, v$ ) and the query operations.

The algorithm does not need to change the Euler tour, if a new edge is inserted which connects two nodes of the same spanning tree or if a non-tree edge is deleted. If an edge  $e$  between two different spanning trees is inserted, the algorithm can just merge the two Euler tours. If an edge  $e$  of a spanning tree is deleted, the algorithm first splits the Euler tour at both occurrences of  $e$  and then tries to find a *replacement edge* that connects the two sub-trees resulting from the deletion. The search for a replacement edge is actually the most critical part of the algorithm, since trying out all edges of the graph would yield linear work.

Towards a more efficient algorithm, we follow the same two-tiered approach as [12]: each Euler tour is chopped into chunks of about  $\sqrt{m}$  edges, which are represented as *arrays of edges*. The underlying idea is that after a change operation the necessary updates can be divided into low-level manipulations inside only a few chunks and high-level manipulations on the level of sequences of chunks. Each kind of manipulation should cause not much more than  $\mathcal{O}(\sqrt{m})$  work.

Furthermore, it will maintain information about non-tree edges between different chunks, ultimately allowing to find a replacement edge with work close to  $\mathcal{O}(\sqrt{m})$ .

We fix a number  $K$  that will be roughly  $\sqrt{m}$  later on and enforce that chunks contain between  $\frac{K}{2}$  and  $K$  edges, with the exception of at most one chunk per spanning tree. We denote the number of chunks by  $J$  which is in  $\mathcal{O}(\frac{m}{K})$ .

For the lower tier, i.e., creating and removing chunks and changing their content and additional information, the edge arrays representing the chunks are stored together in one *master array*  $\mathcal{M}$  with  $\mathcal{O}(\sqrt{m})$  slots of sub-arrays of length  $K$ . The slots will contain some additional information to be specified later. The order of chunks in  $\mathcal{M}$  can be arbitrary and  $\mathcal{M}$  might contain empty slots from deleted chunks. By  $\mathcal{M}(i)$  we refer to the chunk that is stored in the  $i$ -th slot of the master array. Some entries in  $\mathcal{M}$  might be unused or deactivated. For a chunk  $C$ , we refer by  $C$  also to the entry in  $\mathcal{M}$  for this chunk.

We say that two chunks  $C$  and  $C'$  are *linked*, if there is a non-tree edge  $(u, v)$  in  $G$  such that  $u$  occurs in  $C$  and  $v$  in  $C'$ . With each chunk  $C$  of edges, we associate a *link vector*  $B_C$ , which is a bit array of length  $J$  that reflects which chunks are linked with  $C$ . More precisely,  $B_C(i) = 1$  if  $C$  and  $\mathcal{M}(i)$  are linked. Here all slots in  $\mathcal{M}$  are relevant, even the unused or deactivated ones (but they will inevitably yield the bit 0).

The higher tier, which is responsible for maintaining the order of the chunks and information about sequences of chunks, maintains, for each Euler tour a *chunk array*: this is an array of pointers to chunks such that the concatenation of all edge lists in the order induced by the array represents the Euler tour. Furthermore, it maintains information about links between sequences of chunks in a sufficiently work-efficient way.

The algorithm uses a data type `CHUNKARRAYS` whose operations can be split into two groups. The first group consists of the following operations, which only access chunks and their link arrays, but do not directly refer to chunk arrays. In both groups of operations,  $i, j$  and  $k$  are always indices,  $C, C_1$  and  $C_2$  are chunk (pointers),  $A, A_1$  and  $A_2$  are (pointers to) chunk arrays,  $B$  is a bit vector and  $E$  is an edge array.

- `SetChunk( $i, C, E$ )` activates a new chunk  $C$  in  $\mathcal{M}(i)$  and stores the edge array  $E$  in  $C$ ;
- `Deactivate( $C$ )` deactivates chunk  $C$  in  $\mathcal{M}$ ;
- `Link( $C_1, C_2$ )` and `Unlink( $C_1, C_2$ )` allow to mark chunks  $C_1$  and  $C_2$  as linked or unlinked;
- `BulkSetLinks( $C, B$ )` replaces the link vector of chunk  $C$  by the bit vector  $B$  and changes the bit that refers to  $C$  in all other chunks  $C'$  according to  $B$ . More precisely, if  $C = \mathcal{M}(i)$  then, for each  $j$ , the  $i$ -th bit in the link vector of  $\mathcal{M}(j)$  is set to  $B(j)$ .

We note that `SetChunk` and `Deactivate` do not automatically change any link vectors.

The operations of the other group are as follows. They explicitly refer to chunk arrays.

- `InsertChunk( $A, i, C$ )` inserts (a pointer to) chunk  $C$  at position  $i$  of chunk array  $A$ , moving each entry, from  $i$  on, by one to the right;
- `DeleteChunk( $A, i$ )` deletes the chunk pointer at position  $i$  of chunk array  $A$ , moving each entry, from  $i + 1$  on, one to the left;
- `Concatenate( $A_1, A_2$ )` concatenates the chunk array  $A_2$  to the end of  $A_1$ ;
- `Split( $A, i$ )` splits  $A$  into two arrays  $A_1$  and  $A_2$  getting intervals  $[1, i]$  and  $[i + 1, \max(A)]$  and yields (pointers to)  $A_1$  and  $A_2$ ;
- `Reorder( $A, i, j, k$ )` moves the chunks of positions  $j, \dots, k$  to position  $i < j$ . That is, the chunks are ordered as  $1, \dots, i - 1, j, \dots, k, i + 1, \dots, j - 1, k + 1, \dots, m$ , where  $m$  is the size of  $A$ ;
- `Query( $A, i, j, k, \ell$ )` yields an arbitrary pair  $(C, C')$  of linked chunks where  $C$  is from  $[i, j]$  and  $C'$  is from  $[k, \ell]$ .

The algorithm will maintain the invariant that each chunk that is present in  $\mathcal{M}$  occurs in at most one chunk array. Each chunk in the master array contains a back pointer to its chunk pointer in its chunk array, and these entries are maintained by the above operations.

The following lemma is shown in the full version of this paper.

► **Lemma 3.5.** *There is a dynamic parallel constant-time algorithm for `CHUNKARRAYS` on an arbitrary `CRCW PRAM` that supports all operations with  $\mathcal{O}(J \text{ polylog } J)$  work.*

*Furthermore, for each  $\epsilon > 0$ , there is a parallel constant-time dynamic algorithm for `CHUNKARRAYS` on a common `CRCW PRAM` that supports `Query` with  $\mathcal{O}(J^{1+\epsilon})$  work and all other operations with  $\mathcal{O}(J \text{ polylog } J)$  work.*

The implementation of `CHUNKARRAYS` uses  $(a, b)$ -trees [7], which are trees of logarithmic height in which inner nodes have between  $a$  and  $b$  children, and support insertion and deletion of leaves as well as split and join of trees. In the `CHUNKARRAYS` for each chunk array  $A$  one  $(2, 6)$ -tree is maintained, that has the link arrays of the chunks of  $A$  at its leaves, in the order of  $A$ . The inner vertices of the tree store link arrays that are the bitwise disjunction of the link arrays of the leaves below them.

Given Lemma 3.5, we can now show Proposition 3.2, stating that SPANNINGFOREST can be maintained in parallel constant time with  $\tilde{O}(m^{\frac{1}{2}})$  work per operation on an *arbitrary* CRCW PRAM and, for every  $\epsilon > 0$ , with work  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  work per operation, on a *common* CRCW PRAM, if the maximum degree of the graph never exceeds 3. The degree bound mainly helps by bounding the number of edges incident to one chunk by  $\mathcal{O}(K)$ .

**Proof (of Proposition 3.2).** We first describe the data structure and then how it is maintained for the different change operations.

The algorithm maintains a master array and a chunk array as described above. It uses them to maintain a spanning tree and a corresponding Euler tour for each connected component of the graph. It uses  $K = J = \sqrt{m}$ .

Furthermore, the algorithm maintains an array with all nodes of the graph, and three additional entries for the up to three neighbours of each node, representing the edges. Additionally, there are pointers to the at most six appearances of a node in edges of Euler tours in the master array. The algorithm thereby implicitly maintains pointers from each edge to its at most two appearances in the Euler tours. Finally, a counter for the number of connected components is maintained.

The two query operations `Connected` and `#Components` can be answered in constant sequential time using the pointers from each node to occurrences in an Euler tour or the maintained counter, respectively.

For the change operation `InsertEdge`( $u, v$ ), we consider two different cases: (1) the insertion of a new edge ( $u, v$ ) where  $u$  and  $v$  are in the same connected component and (2) the insertion of a new edge ( $u, v$ ) where  $u$  and  $v$  are in different connected components.

The algorithm first identifies through the master array two chunk arrays  $A_u$  and  $A_v$  in which  $u$  and  $v$  reside. If  $A_u = A_v$ , we are in case (1) and it suffices to mark  $C_u$  and  $C_v$  as linked by `Link`( $C_u, C_v$ ) for all  $C_u$  and  $C_v$  that contain  $u$  and  $v$  respectively. All those chunks can be found using the maintained pointers from nodes to their appearances in chunks.

If  $A_u$  and  $A_v$  are different, we are in case (2) and ( $u, v$ ) newly connects the two spanning trees  $T_u$  and  $T_v$ , yielding a new spanning tree  $T$ . To this end, the two Euler tours represented by  $A_u$  and  $A_v$  need to be joined. Let the tour of  $A_u$  consist of two paths  $P_1, P_2$ , where  $P_1$  ends in  $u$  and  $P_2$  starts in  $u$ . Note that the last node of  $P_2$  is the same as the first node of  $P_1$ . Let the two paths  $Q_1, Q_2$  be defined analogously for  $A_v$  and  $v$ . Then the combined Euler tour will be  $P_1, (u, v), Q_2, Q_1, (v, u), P_2$ .

The algorithm first joins the two chunk arrays by `Concatenate`( $A_u, A_v$ ). It splits the edge sequence of  $C_u$  into a sequence  $E_u^1$  that ends in  $u$  and the remaining sequence  $E_u^2$  that starts in  $u$ . The position where  $C_u$  needs to be split can be found using the maintained edge pointers.  $E_u^1$  remains in  $C_u$  and for  $E_u^2$  a new chunk  $C'_u$  is reserved in  $\mathcal{M}$  and inserted in  $A_u$ , next to  $C_u$ . Similarly, the content of  $C_v$  is split into  $C_v$  and a new chunk  $C'_v$ . Then ( $u, v$ ) is added to  $C_u$  and ( $v, u$ ) to  $C_v$ .

The algorithm then restructures  $A_u$  by copying the sub-arrays corresponding to  $Q_2$  and ( $Q_1, (v, u)$ ) to their correct places by two calls to `Reorder`. This also moves  $P_2$  to its right place. If any of the four modified chunks has fewer than  $\frac{K}{2}$  edges, it is combined with a neighbour chunk in  $A_u$ : if possible, the two chunks are joined or otherwise each gets at least  $\frac{K}{2}$  edges to fulfil the invariant. This completes the restructuring of  $A_u$ .

It remains to update the link information between chunks. To this end, the algorithm first computes the link vectors for  $C_u, C'_u, C_v$  and  $C'_v$ . This can be done by initializing the vector with  $\vec{0}$  and then scanning all at most  $3K$  edges of the respective chunk. The four resulting link vectors are then set by `BulkSetLinks`. The operation `BulkSetLinks` takes also care of the modifications in the link vectors of all other chunks. Finally, the connected component counter is decreased by 1.

For the change operation `DeleteEdge`( $u, v$ ), we consider again two different cases: (1) the deletion of an edge  $(u, v)$  that is not in any spanning tree and (2) the deletion of a spanning tree edge  $(u, v)$ . If there is no pointer from  $(u, v)$  to an occurrence in any Euler tour, we are in case (1) and  $(u, v)$  was not a spanning tree edge. The algorithm then checks whether the chunk pairs linked by  $(u, v)$  are still linked without  $(u, v)$  by scanning all, thanks to the degree bound at most  $3K$  many edges of one of the two chunks per pair. If not, it marks the two chunks as unlinked with `Unlink`.

If there are pointers from  $(u, v)$  to occurrences in an Euler tour, we are in case (2) and  $(u, v)$  was a spanning tree edge. Let  $P_1, (u, v), P_2, (v, u), P_3$  be the decomposition of the Euler tour of its tree  $T$ . By two applications of `Query` the algorithm checks whether there are any links between  $P_1$  and  $P_2$  or  $P_3$  and  $P_2$ , respectively.

If there are no such edges then it first reorders the chunk array, so that  $P_1$  and  $P_3$  are consecutive, moving  $P_2$  towards the end, and then splits it into the two parts  $P_1, P_3$  and  $P_2$ .

If there is such an edge, let us assume there are chunks  $C_1$  in  $P_1$  and  $C_2$  in  $P_2$  that are linked. The algorithm inspects all edges in  $C_1$  in parallel and tests, whether their partner edge is in  $C_2$ . It then either picks an arbitrary edge (if the PRAM model supports that) or computes the minimum edge with this property. Let the chosen replacement edge be  $(w_1, w_2)$ . Decomposing  $P_1$  into  $P'_1, P''_1$ , separated at  $w_1$ , and  $P_2$  into  $P'_2, P''_2$ , separated at  $w_2$ , the new Euler cycle is  $P'_1, (w_1, w_2), P'_2, P''_2, (w_2, w_1), P''_1, P_3$ . It can be constructed in  $T$  by splitting  $C_1$  and  $C_2$  into two chunks, with the help of two newly inserted chunks, reordering the array, and repairing small chunks, similarly to the above case of inserting a new tree edge.

The work of the algorithm is dominated by finding a replacement edge. It requires two initial calls to `Query` of the `CHUNKARRAYS` data type requiring  $\mathcal{O}(J \text{ polylog } J)$  or  $\mathcal{O}(J^{1+\epsilon})$  work, depending on the PRAM model. Then it requires work  $\mathcal{O}(K)$  to identify all at most  $3K$  possible replacement edges. In the arbitrary model the choice of the actual edge is immediate. In the common model, it might take work  $\mathcal{O}(K^{1+\epsilon})$ . Apart from that, the algorithm applies a constant number of calls to operations of `CHUNKARRAYS` that all require  $\mathcal{O}(J \text{ polylog } J)$  work. By Lemma 3.5 and the choice of  $J$  and  $K$  we get the desired work bounds.

The operations `ActivateNode` and `DeactivateNode` can be easily implemented in constant sequential time. ◀

### 3.2 From bounded to unbounded degree and from $m$ to $n$

We first show Proposition 3.3 which allows us to conclude that Proposition 3.2 can be lifted to graphs without a degree restriction.

**Proof sketch (of Proposition 3.3).** Like for [12] our algorithm uses the well known graph reduction already used by [5]. To maintain connectivity for an unrestricted graph  $G$ , the algorithm maintains a graph  $G'$  of degree at most 3, which is connected if and only if  $G$  is connected. The number of nodes of this graph is initialised as  $cn$ , where  $c$  is as in the statement of the proposition. The idea of the reduction is to replace each node  $v$  of  $G$  of degree  $d > 3$  in  $G'$  by a cycle of length  $d$  and to connect each node of the cycle to one node adjacent to  $v$ .

More formally,  $G'$  has two nodes, denoted as  $n(u, v)$  and  $n(v, u)$ , for each (undirected) edge  $(u, v)$  of  $G$  and one node, denoted  $v$ , for each isolated node  $v$  of  $G$ .

For each non-isolated node  $u$  of  $G$ , the nodes of the form  $n(u, v)$  are connected in some cyclic order. To this end, the algorithm maintains a doubly linked list of nodes of  $G'$ , for each node  $u$  of  $G$ .

An insertion of a new edge  $(u, v)$  into  $G$  translates into activating two new nodes  $n(u, v)$  and  $n(v, u)$  in  $G'$ , to connect them with each other and to insert them at an arbitrary position into the cycle of  $u$  and  $v$  respectively. Together, this yields 2 node additions, 2 edge deletions and 5 edge insertions.

A deletion of an edge  $(u, v)$  boils down to the reverse operations: 5 edge deletions, 2 edge insertions and 2 node deactivations.

And obviously, a connectivity query towards  $G$  can just be translated into a connectivity query towards  $G'$ .

Altogether, each operation for  $G$  can be translated into a constant number of operations for  $G'$ . The number of nodes of  $G'$  is linear in the number of edges plus the number of (isolated) nodes of  $G$ . Therefore, the work bounds  $\tilde{\mathcal{O}}(m^{\frac{1}{2}})$  and  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  for  $G'$  translates into a work bound  $\tilde{\mathcal{O}}(m^{\frac{1}{2}})$  and  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  for  $G$ . ◀

The final step towards Theorem 3.1 is to show that the work bounds  $\tilde{\mathcal{O}}(m^{\frac{1}{2}})$  and  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  for maintaining SPANNINGFOREST can be replaced by  $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$  and  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$ , thus showing Proposition 3.4. We use the sparsification technique of [4] which has also been used in [12] to maintain CONNECTIVITY in a parallel setting.

In a nutshell, the approach is to maintain a so-called *sparsification tree*  $\mathcal{S}$ , that is a rooted tree of logarithmic depth in  $n$ , each node  $u$  of which represents a certain subgraph  $G_u$  of  $G$  and carries additional structure. The root represents the whole graph, each leaf represents a subgraph consisting of (at most) one edge, and the graph of each inner node is basically the union of the edge sets of the graphs of its children. The crucial idea is that  $\mathcal{S}$  has an additional *base graph*  $B_u$ , for each tree node, which has a subset of the edges of  $G_u$  of linear size, and has the same connected components (viewed as sets of nodes) as  $G_u$ . Furthermore, the algorithm maintains a spanning forest  $F_u$  of  $B_u$  (and thus for  $G_u$ ), for each tree node  $u$ , using the algorithm with work bound  $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$  or  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  depending on the PRAM model. It has the invariant that, for each inner node  $u$ ,  $B_u$  consists of all edges of the spanning forests  $F_v$ , for all children  $v$  of  $u$ . As this number will be a constant (in fact: 4), the invariant guarantees the linear number of edges of  $B_u$ .

We will see that each change operation can be basically handled by triggering change operations along one path of the tree. Since the base graph of a node at level  $i$  has at most  $\frac{cn}{2^i}$  many edges, for some constant  $c$ , and, the overall work can be bounded by  $\tilde{\mathcal{O}}(n^{\frac{1}{2}} \log n) = \tilde{\mathcal{O}}(n^{\frac{1}{2}})$  and  $\mathcal{O}(n^{\frac{1}{2}+\epsilon'} \log n) = \mathcal{O}(n^{\frac{1}{2}+\epsilon})$ , if  $\epsilon'$  is chosen appropriately.<sup>8</sup>

We next describe the underlying tree structure of  $\mathcal{S}$  in more detail. It relies<sup>9</sup> on a *node partition tree*  $\mathcal{N}(G)$ : it is a binary tree, in which each node is a set  $U$  of nodes of  $G$ . The root is the set  $V$  of all nodes and, for each inner node  $U$  with children  $U_1, U_2$ ,  $U$  is the disjoint union of  $U_1$  and  $U_2$  and the sizes of  $U_1$  and  $U_2$  differ by at most 1. The leaves are the singleton sets. Clearly this tree has depth at most  $\log(n) + 1$ . We emphasise that the partitions are independent of the edge set of  $G$ , they do not need to partition the graph into meaningful clusters.

The edge set of  $G$  and  $\mathcal{N}(G)$  determine the structure of the sparsification tree  $\mathcal{S}$  and its graphs  $G_u$  as follows. For each level  $i$  of  $\mathcal{N}(G)$ ,  $\mathcal{S}$  has one node  $G_u$ , for each pair  $(V_1, V_2)$  of nodes of  $\mathcal{N}(G)$  of level  $i$ . Here,  $V_1 = V_2$  is allowed. The node set of  $G_u$  is  $V_1 \cup V_2$  and

<sup>8</sup> In fact, using the sizes of the base graphs along a path and the “well-behavedness” of  $n^{\frac{1}{2}+\epsilon}$ , one actually gets a  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$  bound, directly.

<sup>9</sup> We remark that for our algorithm it is actually not important how the (potential) edges of the graph  $G$  are exactly partitioned in the sparsification tree, as long as it has constant branching, logarithmic depth and the correspondence between edge sets of nodes and of their children. The definition with the help of the node partition tree is just one concrete way of doing it.

the edges are the edges of  $G$  that connect a node from  $V_1$  with a node from  $V_2$ . If  $V_1 = V_2$ , then  $G_u$  is thus just the subgraph of  $G$  induced by  $V_1$ . If  $U_1$  is the parent of  $V_1$  and  $U_2$  the parent of  $V_2$  in  $\mathcal{N}(G)$ , then the node corresponding to  $(U_1, U_2)$  is the parent of  $(V_1, V_2)$  in  $\mathcal{S}$ . For a leaf  $u$ ,  $G_u$  either has one edge or has no edges, if the edge for the pair  $(x, y)$  of nodes corresponding to  $u$  is not present in  $G$ .

The base graphs  $B_u$  and the spanning forests  $F_u$  can be chosen in any way that is consistent with the invariant that, for each inner node  $u$ ,  $B_u$  consists of all edges of the spanning forests  $F_v$ , for all children  $v$  of  $u$ .

Although our presentation slightly differs from [4, 12], the node partition tree and the sparsification tree are basically the same as there.

Before we present the proof of Proposition 3.4, we state some helpful observations about  $\mathcal{S}$ .

- (1) Each edge  $(x, y)$  of  $G$  occurs exactly in the graphs  $G_u$  along the paths from the leaf with  $(x, y)$  to the root.
- (2) If two nodes  $x, y$  are in the same connected component in  $G_u$ , this also holds in all  $G_v$ , where  $v$  is an ancestor of  $u$ .
- (3) If an edge  $(x, y)$  occurs in some spanning forest  $F_u$ , then it occurs in all spanning forests  $F_v$  on the path from  $u$  to the leaf containing  $(x, y)$ .

**Proof sketch (of Proposition 3.4).** The algorithm maintains a sparsification tree  $\mathcal{S}$  for the graph  $G$ . For each node  $u$  of  $\mathcal{S}$  it maintains a spanning forest  $F_u$  for  $B_u$  (and implicitly, for  $G_u$ ) with the help of the algorithm for SPANNINGFOREST from Proposition 3.3, with  $c = 4$ .

If an edge  $(x, y)$  is inserted to  $G$ , the algorithm checks, for each node  $u$  on the path  $\pi$  from the leaf for  $(x, y)$  to the root, whether  $x$  and  $y$  are in the same connected component of  $T_u$ . From Observation (2) it follows that the nodes  $u$ , for which this is *not* the case constitute some initial segment of  $\pi$ . For all these nodes  $u$ ,  $(x, y)$  is added to  $B_u$  and  $T_u$ . Furthermore, it is added to  $B_v$  of the parent  $v$  of the last node of  $\pi$ .

The deletion of an edge  $(x, y)$  is slightly more complicated. For all nodes  $u$  on the path from the leaf  $v$  with  $(x, y)$  to the root, the algorithm tests in parallel, whether  $(x, y)$  occurs in  $F_u$ . Thanks to Observation (3), the nodes  $v$ , for which this test is positive form an initial segment  $\pi'$  of  $\pi$  up to some node  $w$ . For each of these nodes, the algorithm computes a replacement edge for  $(x, y)$ , if such exists. Thanks to Observation (2), a replacement edge that works for some  $F_v$  is also a replacement edge for all nodes on  $\pi'$  above  $v$ . In particular, all edges  $v$ , for which  $F_v$  has a replacement edge form an upper segment of  $\pi'$  and the replacement edge for the lowest  $F_v$  can be used for all of them. Therefore, after doing the initial test and computing a replacement edge for each forest, constant time and work  $\mathcal{O}((\log n)^2)$  suffice to determine the lowest node  $w$  and its replacement edge  $e$ . Since  $(\log n)^2 = \mathcal{O}(\text{polylog } n)$  and  $(\log n)^\epsilon = \mathcal{O}(n^\epsilon)$ , for each  $\epsilon > 0$ , this work can be neglected. Afterwards, for each node  $u$  of  $\pi'$  above  $w$ ,  $(x, y)$  is deleted from  $B_u$  and  $F_u$  and instead  $e$  is added. In the base graph of the parent of  $w$ , edge  $(x, y)$  is deleted and  $e$  added.

As already explained above, the algorithm applies at most a logarithmic (in  $n$ ) number of times an operation of the algorithm underlying Proposition 3.3, for a base graph, i.e., a graph with  $\mathcal{O}(n)$  edges. The desired work bound  $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$  for arbitrary CRCW PRAMs is thus immediate and by choosing in Proposition 3.3, any  $\epsilon' < \epsilon$  instead of the given  $\epsilon$ , we can establish the desired work bound  $\mathcal{O}(n^{\frac{1}{2}+\epsilon'})$  for common CRCW PRAMs. ◀

## 4 Bipartiteness

In this section, we show that the work bound established for CONNECTIVITY in Section 3 also holds for BIPARTITENESS. In fact, the algorithm will rely on the algorithm of Proposition 3.3.

► **Theorem 4.1.** *There are dynamic parallel constant-time algorithms for BIPARTITENESS with the following work bounds per change or query operation.*

- $\tilde{O}(n^{\frac{1}{2}})$  work on the arbitrary CRCW PRAM model.
- $O(n^{\frac{1}{2}+\epsilon})$  work on the common CRCW PRAM model, for every  $\epsilon > 0$ .

The result follows from an analogous series of statements, as for CONNECTIVITY (or SPANNINGFOREST, for that matter).

► **Proposition 4.2.** *There are dynamic parallel constant time algorithms for the special case of BIPARTITENESS, where the maximum degree of the graph never exceeds 3 with the following work bounds per change or query operation.*

- $\tilde{O}(m^{\frac{1}{2}})$  on the arbitrary CRCW PRAM model.
- $O(m^{\frac{1}{2}+\epsilon})$  on the common CRCW PRAM model, for every  $\epsilon > 0$ .

► **Proposition 4.3.** *If BIPARTITENESS can be maintained in parallel constant time on a CRCW PRAM with the work bounds of Proposition 4.2 per change or query operation, for any  $\epsilon > 0$ , for graphs with maximum degree 3, it can be maintained with the same bounds for general graphs with the provision that they never have more than  $cn$  edges, for some constant  $c$ .*

► **Proposition 4.4.** *If BIPARTITENESS can be maintained in parallel constant time on a CRCW PRAM with the work bounds of Proposition 4.2 per change or query operation, then it can also be maintained with  $\tilde{O}(n^{\frac{1}{2}})$  work per change or query operation on the common CRCW model and with  $O(n^{\frac{1}{2}+\epsilon})$  work per change or query operation on the arbitrary CRCW model.*

For an undirected graph  $G = (V, E)$ , we write  $G^{(2)}$  for the graph<sup>10</sup>  $(V, E^{(2)})$ , where a pair  $(u, v)$  of nodes is in  $E^{(2)}$ , if they are connected by a path of length exactly 2 in  $G$ .

Bipartiteness of a graph  $G$  can be characterised in the following way by the numbers of connected components of  $G$  and  $G^{(2)}$ .

► **Lemma 4.5.** *An undirected graph  $G$  is bipartite, if and only if the number of connected components of  $G^{(2)}$  is twice the number of connected components of  $G$ .*

**Proof.** It suffices to show that a connected graph  $G$  is bipartite if and only if  $G^{(2)}$  has 2 connected components.

Let us assume first that  $G$  is bipartite and let the nodes of  $G$  be coloured with black or yellow such that no two nodes of the same color are connected by an edge. Clearly, each pair of nodes of the same color is connected by a path of even length in  $G$  and is therefore in the same connected component in  $G^{(2)}$ .

Towards a contradiction, let us assume that  $G^{(2)}$  is connected. Then there must be a yellow node  $u$  and a black node  $v$  that are connected by an edge in  $G^{(2)}$ . Therefore, there must be a node  $w$ , such that  $(u, w)$  and  $(w, v)$  are edges in  $G$ . But  $w$  can neither be black nor yellow, the desired contradiction.

Let us now assume that  $G$  is not bipartite and let  $C$  be a cycle of  $G$  of odd length. Then all pairs of nodes of  $C$  are connected by paths of even length and therefore all nodes of  $C$  are in the same connected component of  $G^{(2)}$ . But clearly, each other node of  $G$  is connected by a path of even length to *some* node of  $C$  and thus  $G^{(2)}$  is connected. ◀

<sup>10</sup>  $G^{(2)}$  should not be confused with the square  $G^2$  of  $G$ , where edges are induced by paths of length at most 2.

With the help of Lemma 4.5, it is now easy to find an algorithm for BIPARTITENESS for graphs of degree at most 3.

**Proof (of Proposition 4.2).** To maintain bipartiteness for a graph  $G$  of maximum degree 3, the algorithm maintains two instances of SPANNINGFOREST, one for  $G$ , and one for  $G^{(2)}$ . It answers that  $G$  is bipartite, whenever the number of connected components of  $G^{(2)}$  is twice the number of connected components of  $G$ .

An edge insertion in  $G$  results in at most 6 edge insertions in  $G^{(2)}$ , and likewise for edge deletions. Furthermore, the number of edges of  $G^{(2)}$  is at most  $3m$ , if  $m$  is the number of edges of  $G$ . Therefore, BIPARTITENESS can be maintained in parallel constant time with work  $\tilde{O}(m^{\frac{1}{2}})$  or rather  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$ , thanks to Proposition 3.3. ◀

Next we lift the bound to graphs of unbounded degree with the help of a bipartiteness preserving reduction.

**Proof (of Proposition 4.3).** To maintain bipartiteness of graph  $G$ , the algorithm again maintains bipartiteness for a graph  $G'$  of maximal degree 3, such that  $G$  is bipartite if and only if  $G'$  is bipartite. The graph  $G'$  results from  $G$  by applying the following replacement step, consecutively to all (original) nodes of  $G$ .

A node  $u$  of degree  $d > 1$  is replaced by a cycle  $u_1, u'_1, u_2, \dots, u'_d, u_1$  with  $2d$  nodes. Each node  $u_i$  is connected to a neighbour of  $u$  by an edge. It is easy to see that any path that connects two neighbours of  $u$  and uses intermediate nodes of the new cycle has even length. The construction therefore preserves bipartiteness. Furthermore, each node in  $G'$  has degree at most 3 and the number of edges of  $G'$  is at most 6 times the number of edges of  $G$ . Finally, each edge insertion or deletion in  $G$  triggers at most 5 edge insertions or deletions in  $G'$ . ◀

The final step from work  $\tilde{O}(m^{\frac{1}{2}})$  to  $\tilde{O}(n^{\frac{1}{2}})$  and work  $\mathcal{O}(m^{\frac{1}{2}+\epsilon})$  to  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$  again uses sparsification. In fact, it uses the same kind of sparsification tree as the proof of Proposition 3.4. The crucial observation is that if a graph  $G$  is not bipartite, it has a base graph in its sparsification tree that is not bipartite.

► **Lemma 4.6.** *Let  $G$  be an undirected graph and  $\mathcal{S}$  a sparsification tree for  $G$ . Then  $G$  is bipartite if and only if all base graphs in  $\mathcal{S}$  are bipartite.*

**Proof.** Since each base graph of  $\mathcal{S}$  is a subgraph of  $G$ , the “only if” implication is trivial.

To show the “if” implication, let  $G$  be a non-bipartite graph. Since the graph  $G_r$  for the root  $r$  of  $\mathcal{S}$  is non-bipartite, but all graphs  $G_v$  for leaves  $v$  of  $\mathcal{S}$  are bipartite, there must be a node  $u$ , such that  $G_u$  is non-bipartite, but all graphs  $G_w$ , for children  $w$  of  $u$ , are bipartite. We claim that the base graph  $B_u$  is non-bipartite.

Indeed, let  $C$  be some cycle of odd length in  $G_u$ . By construction of  $\mathcal{S}$ , each edge  $(x, y)$  of  $C$  occurs in some graph  $G_w$ , where  $w$  is a child of  $u$ . Therefore,  $x$  and  $y$  are in the same connected component of  $G_w$  and there must be a path between  $x$  and  $y$  in the spanning forest  $F_w$ . Since  $G_w$  is bipartite and there is an edge between  $x$  and  $y$ , the length of this path must be odd. By definition, all edges of this path are in  $B_u$ . Since this holds for every edge of  $C$ , there exists a closed path in  $B_u$ , consisting of an odd number of paths of odd length. This implies that  $B_u$  has a cycle of odd length and is therefore not bipartite. ◀

Now we are prepared to give the proof of Proposition 4.4 and thus complete the proof of Theorem 4.1.

**Proof (of Proposition 4.4).** Just like for Proposition 3.4, the algorithm maintains a sparsification tree  $\mathcal{S}$  for the graph  $G$ . For each node  $u$  of  $\mathcal{S}$  it maintains whether  $B_u$  is bipartite with the algorithm resulting from Proposition 4.2 and Proposition 4.3. This is possible with work bounds  $\tilde{\mathcal{O}}(n^{\frac{1}{2}})$  and  $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$  per change operation, just as for Proposition 3.4.

On top of that, the algorithm maintains, for each node  $u$  of  $\mathcal{S}$ , a flag, signalling whether all base graphs in the tree induced by  $u$  are bipartite. These flags can be maintained in a straightforward fashion with work  $\mathcal{O}(\log n)$ . The bipartiteness status of  $G$  can then be inferred from the flag of the root of  $\mathcal{S}$ , thanks to Lemma 4.6. ◀

## 5 Conclusion

This paper was motivated by the goal to find graph problems whose sublinear sequential dynamic complexity carries over to sublinear work of a dynamic parallel constant time algorithm. In future work it has to be seen whether the faster algorithm from [1] can be translated equally well. Another challenge is to find a dynamic parallel constant time algorithm for the reachability problem in directed graphs. The upper work bound of the algorithm stemming from [2] is roughly  $\mathcal{O}(n^{12})$ . Another interesting question is whether the algorithm for BIPARTITENESS can be adapted so that it also yields a 2-colouring of the graph.

## Abstract

---

Previous work on Dynamic Complexity has established that there exist dynamic constant-time parallel algorithms for regular tree languages and context-free languages under label or symbol changes. However, these algorithms were not developed with the goal to minimise work (or, equivalently, the number of processors). In fact, their inspection yields the work bounds  $\mathcal{O}(n^2)$  and  $\mathcal{O}(n^7)$  per change operation, respectively.

In this paper, dynamic algorithms for regular tree languages are proposed that generalise the previous algorithms in that they allow unbounded node rank and leaf insertions, while improving the work bound from  $\mathcal{O}(n^2)$  to  $\mathcal{O}(n^\epsilon)$ , for arbitrary  $\epsilon > 0$ .

For context-free languages, algorithms with better work bounds (compared with  $\mathcal{O}(n^7)$ ) for restricted classes are proposed: for every  $\epsilon > 0$  there are such algorithms for deterministic context-free languages with work bound  $\mathcal{O}(n^{3+\epsilon})$  and for visibly pushdown languages with work bound  $\mathcal{O}(n^{2+\epsilon})$ .

## 1 Introduction

It has been known for many years that regular and context-free string languages and regular tree languages are maintainable under symbol changes by means of dynamic algorithms that are specified by formulas of first-order logic, that is, in the dynamic class DynFO [10, 7]. It is also well-known that such specifications can be turned into parallel algorithms for the CRCW PRAM model that require only constant time [8] and polynomially many processors.

However, an “automatic” translation of a “dynamic program” of the DynFO setting usually yields a parallel algorithm with large work, i.e., overall number of operations performed by all processors.<sup>1</sup> In the case of regular languages, the dynamic program sketched in [10] has a polynomial work bound, in which the exponent of the polynomial depends on the number of states of a DFA for the language at hand. The dynamic program given in [7] has quadratic work.

---

<sup>1</sup> We note that in the context of constant-time parallel algorithms work is within a constant factor of the number of processors.

Only recently a line of research has started that tries to determine, how efficient such constant-time dynamic algorithms can be made with respect to their work. It turned out that regular languages can be maintained with work  $\mathcal{O}(n^\epsilon)$ , for every  $\epsilon > 0$  [11], even under polylogarithmic numbers of changes [12], and even with logarithmic work for star-free languages under single changes [11] and polylogarithmic work under polylogarithmic changes [12].

For context-free languages the situation is much less clear. The dynamic algorithms resulting from [7] have an  $\mathcal{O}(n^7)$  upper work bound. In [11] it was shown that the Dyck-1 language, i.e., the set of well-bracketed strings with one bracket type, can be maintained with work  $\mathcal{O}((\log n)^3)$  and that Dyck- $k$  languages can be maintained with work  $\mathcal{O}(n \log n)$ . Here, the factor  $n$  is due to the problem to test equality of two substrings of a string.

Most of these results also hold for the query that asks for membership of a substring in the given language. For Dyck languages the upper bounds for substring queries are worse than the bounds for membership queries: for every  $\epsilon > 0$  there exist algorithms for Dyck-1 and Dyck- $k$  languages with work bounds  $\mathcal{O}(n^\epsilon)$  and  $\mathcal{O}(n^{1+\epsilon})$ , respectively.

It was also shown in [11] that there is some context-free language that can be maintained in constant time with work  $\mathcal{O}(n^{\omega-1-\epsilon})$ , for any  $\epsilon > 0$ , only if the  $k$ -Clique conjecture [1] fails. Here,  $\omega$  is the matrix multiplication exponent, which is known to be smaller than 2.373 and conjectured by some to be exactly two according to [14].

In this paper, we pursue two natural research directions.

**Regular tree languages.** We first extend the results on regular string languages to regular tree languages. On one hand, this requires to adapt techniques from strings to trees. On the other hand, trees offer additional types of change operations beyond label changes that might change the structure of the tree. More concretely, besides label changes we study insertions of new leaves and show that the favourable bounds of [11] for regular string languages still hold. This is the main contribution of this paper. Our algorithms rely on a hierarchical partition of the tree of constant depth. The main technical challenge is to maintain such a partition hierarchy under insertion<sup>2</sup> of leaves.

**Subclasses of context-free languages.** We tried to improve on the  $\mathcal{O}(n^7)$  upper work bound for context-free languages, but did not succeed yet. The other goal of this paper is thus to find better bounds for important subclasses of the context-free languages: deterministic context-free languages and visibly pushdown languages. We show that, for each  $\epsilon > 0$ , there are constant-time dynamic algorithms with work  $\mathcal{O}(n^{3+\epsilon})$  for deterministic context-free languages and  $\mathcal{O}(n^{2+\epsilon})$  for visibly pushdown languages. Here, the main challenge is to carefully apply the technique from [11] that allows to store information for only  $\mathcal{O}(n^\epsilon)$  as opposed to  $n$  different values for some parameters. For more restricted change operations, the algorithm for regular tree languages yields an  $\mathcal{O}(n^\epsilon)$  work algorithm for visibly pushdown languages.

**Structure of the paper.** We explain the framework in Section 2, and present the results on regular tree languages and context-free string languages in Sections 3 and 4, respectively. Almost all proofs are delegated to the full version of this paper.

---

<sup>2</sup> For simplicity, we only consider insertions of leaves, but deletions can be handled in a straightforward manner, as discussed in Section 2.

**Related work.** In [12], parallel dynamic algorithms for regular string languages under bulk changes were studied. It was shown that membership in a regular language can be maintained, for every  $\epsilon > 0$ , in constant time with work  $\mathcal{O}(n^\epsilon)$ , even if a polylogarithmic number of changes can be applied in one change operation. If the language is star-free, polylogarithmic work suffices. The paper also shows that for regular languages that are not star-free, polylogarithmic work does *not* suffice.

Maintaining regular languages of trees under label changes has also been studied in the context of enumeration algorithms (for non-Boolean queries) [3]. The dynamic parallel algorithms of [11] partially rely on dynamic sequential algorithms, especially [6].

## 2 Preliminaries

**Trees and regular tree languages.** We consider ordered, unranked trees  $t$ , which we represent as tuples  $(V, r, c, \text{label})$ , where  $V$  is a finite set of nodes,  $r \in V$  is the root,  $c : V \times \mathbb{N} \rightarrow V$  is a function, such that  $c(u, i)$  yields the  $i$ -th child of  $u$ , and  $\text{label} : V \rightarrow \Sigma$  is a function that assigns a label to every node.

We denote the set of unranked trees over an alphabet  $\Sigma$  as  $T(\Sigma)$ . The terms *subtree*, *subforest*, *sibling*, *ancestor*, *descendant*, *depth* and *height* of nodes are defined as usual. A node that has no child is called a *leaf*. A *forest* is a sequence of trees.

Let  $\preceq$  denote the order on siblings, i.e.,  $u \prec v$  denotes that  $u$  is a sibling to the left of  $v$ . We write  $u \preceq v$  if  $u \prec v$  or  $u = v$  holds.

By  $t^v$  we denote the subtree of  $t$  induced by node  $v$ . For sibling nodes  $u \prec v$ , we write  ${}^u t^v$  for the subforest of the tree  $t$ , induced by the sequence  $u, \dots, v$ . If  $w$  is a node in  $t^v$ , then  $t_w^v$  denotes the subtree consisting of  $t^v$  without  $t^w$ . Analogously, for  ${}^u t_w^v$ .

Our definition of tree automata is inspired from hedge automata in the TaTa book [5], slightly adapted for our needs.

► **Definition 2.1.** A deterministic finite (bottom-up) tree automaton (DTA) over an alphabet  $\Sigma$  is a tuple  $\mathcal{B} = (Q_{\mathcal{B}}, \Sigma, Q_f, \delta, \mathcal{A})$  where  $Q_{\mathcal{B}}$  is a finite set of states,  $Q_f \subseteq Q_{\mathcal{B}}$  is a set of final states,  $\mathcal{A} = (Q_{\mathcal{A}}, Q_{\mathcal{B}}, \delta_{\mathcal{A}}, s)$  is a DFA over alphabet  $Q_{\mathcal{B}}$  (without final states) and  $\delta : Q_{\mathcal{A}} \times \Sigma \rightarrow Q_{\mathcal{B}}$  maps pairs  $(p, \sigma)$ , where  $p$  is a state of  $\mathcal{A}$  and  $\sigma \in \Sigma$ , to states of  $\mathcal{B}$ .

We refer to states from  $Q_{\mathcal{B}}$  as  $\mathcal{B}$ -states and typically denote them by the letter  $q$ . Likewise states from  $Q_{\mathcal{A}}$  are called  $\mathcal{A}$ -states and denoted by  $p$ . We note that we do not need a set of accepting states for  $\mathcal{A}$ , since its final states are fed into  $\delta$ .

The semantics of DTAs is defined as follows.

For each tree  $t \in T(\Sigma)$ , there is a unique *run* of  $\mathcal{B}$  on  $t$ , that is, a unary function  $\rho_t$  that assigns a  $\mathcal{B}$ -state to each node in  $V$ . It can be defined in a bottom-up fashion, as follows. For each node  $v \in V$  with label  $\sigma$  and children  $u_1, \dots, u_\ell$ ,  $\rho_t(v)$  is the  $\mathcal{B}$ -state  $\delta(\delta_{\mathcal{A}}^*(s, \rho_t(u_1) \cdots \rho_t(u_\ell)), \sigma)$ . That is, the state of a node  $v$  with label  $\sigma$  is determined by  $\delta(p, \sigma)$ , where  $p$  is the final  $\mathcal{A}$ -state that  $\mathcal{A}$  assumes when reading the sequence of states of  $v$ 's children, starting from the initial state  $s$ . In particular, if  $v$  is a leaf with label  $\sigma$ , its  $\mathcal{B}$ -state is  $\delta(s, \sigma)$ .

A tree  $t$  is accepted by the DTA  $\mathcal{B}$  if  $\rho_t(r) \in Q_f$  holds for the root  $r$  of  $t$ . We denote the language of all trees accepted by  $\mathcal{B}$  as  $L(\mathcal{B})$ . We call the languages decided by DTAs *regular*.

**Strings and context-free languages.** Strings  $w$  are finite sequences of symbols from an alphabet  $\Sigma$ . By  $w[i]$  we denote the  $i$ -th symbol of  $w$  and by  $w[i, j]$  we denote the substring from position  $i$  to  $j$ . We denote the empty string by  $\lambda$ , since  $\epsilon$  has a different purpose in this paper. We use standard notation for context-free languages and pushdown automata, to be found in the full version of this paper.

**Dynamic algorithmic problems.** In this paper, we view a dynamic (algorithmic) problem basically as the interface of a data type: that is, there is a collection of operations by which some object can be initialised, changed, and queried. A *dynamic algorithm* is then a collection of algorithms, one for each operation. We consider two main dynamic problems in this paper, for regular tree languages and context-free languages.

For each regular tree language  $L$ , the algorithmic problem  $\text{REGTREE}(L)$  maintains a labelled tree  $T$  and has the following operations.

- $\text{Init}(T, r, \sigma)$  yields an initial labelled tree object  $T$  and returns in  $r$  a node id for its root, which is labelled by  $\sigma$ ;
- $\text{Relabel}(T, u, \sigma)$  changes the label of node  $u$  in  $T$  into  $\sigma$ ;
- $\text{AddChild}(T, u, v, \sigma)$  adds a new child with label  $\sigma$  behind the last child of node  $u$  and returns its id in  $v$ ;
- $\text{Query}(T, v)$  returns true if and only if the subtree of  $T$  rooted at  $v$  is in  $L$ .

We refer to the restricted problem without the operation  $\text{AddChild}$  as  $\text{REGTREE}^-$ . For this data type, we assume that the computation starts from an initial non-trivial tree and that the auxiliary data for that tree is given initially.

For each context-free language  $L$ , the algorithmic problem  $\text{CFL}(L)$  maintains a string  $w$  and has the following operations.

- $\text{Init}(w)$  yields an initial string object  $w$  with an empty string;
- $\text{Relabel}(w, i, \sigma)$  changes the label at position  $i$  of  $w$  into  $\sigma$ ;
- $\text{InsertPositionBefore}(w, i, \sigma)$  and  $\text{InsertPositionAfter}(w, i, \sigma)$  insert a new position with symbol  $\sigma$  before or after the current position  $i$ , respectively;
- $\text{Query}(w, i, j)$  returns true if and only if the substring  $w[i, j]$  is in  $L$ .

Readers may wonder, why these dynamic problems do not have operations that delete nodes of a tree or positions in a string. This is partially to keep the setting simple and partially because node labels and symbols offer easy ways to simulate deletion by extending the alphabet with a symbol  $\sqcup$  that indicates an object that should be ignored. E.g., if  $\delta_A(p, \sqcup) = p$ , for every state  $p$  of the horizontal DFA of a DTA, then the label  $\sqcup$  at a node  $u$  effectively deletes the whole subtree induced by  $u$  for the purpose of membership in  $L(\mathcal{B})$ . Similarly, a CFL might have a neutral symbol or even a pair  $(\sqcup, )_{\sqcup}$  of “erasing” brackets that make the PDA ignore the substring between  $(\sqcup$  and  $)_{\sqcup}$ .

For  $\text{REGTREE}(L)$  and  $\text{CFL}(L)$ , the  $\text{Init}$  operation is possible in constant sequential time and will not be considered in detail.

Throughout this paper,  $n$  will denote an upper bound of the size of the structure at hand (number of nodes of a tree or positions of a string) that is linear in that size, but changes only infrequently. More precisely, the number of nodes of a tree or the length of the string will always be between  $\frac{1}{4}n$  and  $n$ . Whenever the size of the structure grows beyond  $\frac{1}{2}n$ , the data structure will be prepared for structures of size up to  $2n$  and, once this is done,  $n$  will be doubled. Since the size of the structure is always  $\theta(n)$  all bounds in  $n$  also hold with respect to the size of the structure.

**Parallel Random Access Machines (PRAMs).** A *parallel random access machine* (PRAM) consists of a number of processors that work in parallel and use a shared memory. The memory is comprised of memory cells which can be accessed by a processor in  $\mathcal{O}(1)$  time. Furthermore, we assume that simple arithmetic and bitwise operations, including addition, can be done in  $\mathcal{O}(1)$  time by a processor. We mostly use the Concurrent-Read Concurrent-Write model (CRCW PRAM), i.e. processors are allowed to read and write concurrently from and to the same memory location. More precisely, we assume the *common* PRAM model:

several processors can concurrently write into the same memory location, only if all of them write the same value. We also mention the Exclusive-Read Exclusive-Write model (EREW PRAM), where concurrent access is not allowed. The work of a PRAM computation is the sum of the number of all computation steps of all processors made during the computation. We define the space  $s$  required by a PRAM computation as the maximal index of any memory cell accessed during the computation. We refer to [9] for more details on PRAMs and to [13, Section 2.2.3] for a discussion of alternative space measures.

The main feature of the common CRCW model relevant for our algorithms that separates it from the EREW model is that it allows to compute the minimum or maximum value of an array of size  $n$  in constant time (with work  $\mathcal{O}(n^{1+\epsilon})$ ) which is shown in another paper at MFCS 2023.<sup>3</sup>

For simplicity, we assume that even if the size bound  $n$  grows, a number in the range  $[0, n]$  can still be stored in one memory cell. This assumption is justified, since addition of larger numbers  $N$  can still be done in constant time and polylogarithmic work on a CRCW PRAM. Additionally, we assume that the number of processors always depends on the current size bound  $n$ . Hence, the number of processors increases with growing  $n$  which allows us to use the PRAM model with growing structures.

We describe our PRAM algorithms on an abstract level and do not exactly specify how processors are assigned to data. Whenever an algorithm does something in parallel for a set of objects, these objects can be assigned to a bunch of processors with the help of some underlying array. This is relatively straightforward for strings and substrings and the data structures used in Section 4. In Section 3, it is usually based on zone records and their underlying partition records.

### 3 Maintaining regular tree languages

In this section, we present our results on maintaining regular tree languages under various change operations. We will first consider only operations that change node labels, but do not change the shape of the given tree. A very simple dynamic algorithm with work  $\mathcal{O}(n^2)$  is presented in the full version of this paper. We sketch its main idea and how it can be improved to  $\mathcal{O}(n^\epsilon)$  work per change operation by using a *partition hierarchy* in Subsection 3.1. These algorithms even work on the EREW PRAM model.

Afterwards, in Subsection 3.2, we also consider an operation that can change the tree structure: adding a leaf to the tree. Here, the challenge is to maintain the hierarchical structure that we used before to achieve work  $\mathcal{O}(n^\epsilon)$  per change operation. It turns out that maintaining this structure is possible without a significant increase of work, that is, maintaining membership under these additional operations is still possible with work  $\mathcal{O}(n^\epsilon)$  per change operation.

#### 3.1 Label changes: a work-efficient dynamic program

In this section, we describe how membership in a regular tree language can be maintained under label changes, in a work efficient way.

---

<sup>3</sup> Jonas Schmidt, Thomas Schwentick. Dynamic constant time parallel graph algorithms with sub-linear work.

► **Proposition 3.1.** *For each  $\epsilon > 0$  and each regular tree language  $L$ , there is a parallel constant time dynamic algorithm for  $\text{REGTREE}^-(L)$  with work  $\mathcal{O}(n^\epsilon)$  on an EREW PRAM. The Query operation can actually be answered with constant work.*

We start by briefly sketching the  $\mathcal{O}(n^2)$  work algorithm that is given in the full version of this paper. The algorithm basically combines the dynamic programs for regular string languages and binary regular tree languages from [7]. For regular string languages, the program from [7] stores the behaviour of a DFA for the input word  $w$  by maintaining information of the form “if the run of the DFA starts at position  $i$  of  $w$  and state  $p$ , then it reaches state  $q$  at position  $j$ ” for all states  $p, q$  and substrings  $w[i, j]$ . After a label change at a position  $\ell$ , this information can be constructed by combining the behaviour of the DFA on the intervals  $w[i, \ell - 1]$  and  $w[\ell + 1, j]$  with the transitions induced by the new label at position  $\ell$ .

The dynamic program for (binary) regular tree languages from [7] follows a similar idea and stores the behaviour of a (binary) bottom-up tree automaton by maintaining information of the form “if  $v$  gets assigned state  $q$ , then  $u$  gets assigned state  $p$  by the tree automaton” for all states  $p, q$  and all nodes  $v, u$ , where  $v$  is a descendant of  $u$ .

Both programs induce algorithms with  $\mathcal{O}(n^2)$  work bounds. Towards a  $\mathcal{O}(n^2)$  work algorithm for unranked tree languages, the two dynamic programs can be combined into an algorithm that mainly stores the following *automata functions* for a fixed DTA  $\mathcal{B} = (Q_{\mathcal{B}}, \Sigma, Q_f, \delta, \mathcal{A})$  for  $L$ , with DFA  $\mathcal{A} = (Q_{\mathcal{A}}, Q_{\mathcal{B}}, \delta_{\mathcal{A}}, s)$ :

- The ternary function  $\mathcal{B}_t : Q_{\mathcal{B}} \times V \times V \mapsto Q_{\mathcal{B}}$  maps each triple  $(q, u, v)$  of a state  $q \in Q_{\mathcal{B}}$  and nodes of  $t$ , where  $u$  is a proper ancestor of  $v$ , to the state that the run of  $\mathcal{B}$  on  $t_v^u$  takes at  $u$ , with the provision that the state at  $v$  is  $q$ .
- The ternary function  $\mathcal{A}_t : Q_{\mathcal{A}} \times V \times V \mapsto Q_{\mathcal{A}}$  maps each triple  $(p, u, v)$  of a state  $p \in Q_{\mathcal{A}}$  and nodes of  $t$ , where  $u \prec v$  are siblings, to the state that the run of  $\mathcal{A}$  on  $u, \dots, v$ , starting from state  $p$ , takes after  $v$ .

Every single function value can be updated in constant sequential time, as stated in the following lemma. This leads to a quadratic work bound since there are quadratically many tuples to be updated in parallel.

► **Lemma 3.2.** *After a Relabel operation, single values  $\mathcal{A}_t(p, u, x)$  and  $\mathcal{B}_t(q, u, x)$  can be updated by a sequential algorithm in constant time.*

Some information about the shape of the tree is required, which we refer to as *basic tree functions*. For more details we refer to the full version of this paper. However, as label changes cannot change the shape of the tree, this information does not need to be updated and can be assumed as precomputed.

To lower the work bound the basic idea now is to store the automata functions not for *all* possible arguments, but for a small subset of *special* arguments that allow the computation of function values for *arbitrary* arguments in constant time with constant work.

In [11], this idea was applied to the  $\mathcal{O}(n^2)$  work program for regular string languages. A constant-depth hierarchy of intervals was defined by repeatedly partitioning intervals into  $\mathcal{O}(n^\theta)$  subintervals, for some  $\theta > 0$ . This hierarchy allowed to define *special* intervals such that any update only affects  $\mathcal{O}(n^\epsilon)$  intervals and function values of arbitrary intervals can be computed in constant time with constant work.

We transfer this idea to the case of unranked tree languages by partitioning the tree into  $\mathcal{O}(n^\theta)$  *zones*, each of which is partitioned into further  $\mathcal{O}(n^\theta)$  zones and so on until, after a constant number of refinements, we arrive at zones of size  $\mathcal{O}(n^\theta)$ . Here,  $\theta > 0$  is a constant that will be chosen later. It will always be chosen such that  $h = \frac{1}{\theta}$  is an integer.

■ **Figure 1** Example of a  $(1, \frac{1}{3})$ -bounded partition hierarchy.

Before we define this partition hierarchy more precisely, we first define zones and show that they can always be partitioned in a way that guarantees certain number and size constraints.

- **Definition 3.3.** A *zone* is a set  $S$  of nodes with the following properties:
- $S$  is a proper subforest of  $t$ ,
  - for every  $v \in S$  it holds that either no or all children are in  $S$ , and
  - there exists at most one node  $v_S$  in  $S$ , whose children are not in  $S$ . The node  $v_S$  is called the *vertical connection node* of  $S$ .

We call a zone a *tree zone* if it consists of only one sub-tree of  $t$  and a *non-tree zone* otherwise. We call a zone *incomplete* if it has a vertical connection node and *complete*, otherwise. There are thus four different types of zones which can be written, with the notation introduced in Section 2, as follows: complete tree zones  $t^v$ , complete non-tree zones  ${}^u t^v$ , incomplete tree zones  $t_w^v$ , and incomplete non-tree zones  ${}^u t_w^v$ . Depending on the type, zones can therefore be represented by one to three “important nodes”. The overall tree can be seen as the zone  $t^r$ , where  $r$  is its root.

From now on, we always assume that  $n$  is as in Section 2, some  $\theta > 0$  is fixed, and that  $h = \frac{1}{\theta}$  is an integer.

We call a zone of  $t$  with at most  $n^{\theta \ell}$  nodes an  $\ell$ -zone. The tree  $t$  itself constitutes a  $h$ -zone, to which we will refer to as the *overall zone*.

We next define *partition hierarchies* formally. More precisely, for every  $\ell \geq 2$ , we define partition hierarchies of height  $\ell$  for  $\ell$ -zones as follows. If  $S$  is a 2-zone and  $S_1, \dots, S_k$  are 1-zones that constitute a partition of  $S$ , then  $(S, \{S_1, \dots, S_k\})$  is a partition hierarchy of height 2 for  $S$ . If  $S$  is an  $(\ell + 1)$ -zone,  $\{S_1, \dots, S_k\}$  is a partition of  $S$  into  $\ell$ -zones, and for each  $j$ ,  $H_j$  is a partition hierarchy of height  $i$  for  $S_j$ , then  $(S, \{H_1, \dots, H_k\})$  is a partition hierarchy of height  $\ell + 1$  for  $S$ . A partition hierarchy of height  $h$  of the zone consisting of  $t$  is called a partition hierarchy of  $t$ .

An example of a  $(1, \frac{1}{3})$ -bounded partition hierarchy is given in Figure 1.

We often call a zone  $S'$  that occurs at some level  $i < \ell$  within the partition hierarchy of a zone  $S$  of some level  $\ell$  a *component zone*. If  $S'$  has level  $\ell - 1$  we also call it a *sub-zone* of  $S$ .

We call a partition hierarchy  $H$   $(c, \theta)$ -bounded, constants  $c$  and  $\theta > 0$ , if each partition of a zone consists of at most  $cn^\theta$  nodes.

Our next aim is to prove that  $(10, \theta)$ -bounded partition hierarchies actually exist. To this end, we prove the following lemma. It is similar to [4, Lemma 3], but adapted to our context, which requires a hierarchy of constant depth and a certain homogeneity regarding children of vertical connection nodes.

► **Lemma 3.4.** *Let  $m \geq 2$  be a number and  $S$  a zone with more than  $m$  nodes. Then  $S$  can be partitioned into at most five zones, one of which has at least  $\frac{1}{2}m$  and at most  $m$  nodes.*

This lemma immediately yields the existence of  $(10, \theta)$ -bounded partition hierarchies.

► **Proposition 3.5.** *For each  $\theta > 0$ , each tree  $t$  has some  $(10, \theta)$ -bounded partition hierarchy.*

We now explain in more detail, which information about the behaviour of  $\mathcal{A}$  and  $\mathcal{B}$  is stored by the work-efficient algorithm.

Function values for the ternary functions are stored only for so-called special pairs of nodes, which we define next. Special pairs of nodes are always defined in the context of some zone  $S$  of a partition hierarchy. In the following, we denote, for a zone  $S$  of a level  $\ell \geq 2$  its set of sub-zones of level  $\ell - 1$  by  $T$ .

- Any pair of siblings  $u \prec v$  in a zone  $S$  of level 1 is a *special horizontal pair*. A pair of siblings  $u \prec v$  in a complete zone  $S$  of level  $\ell \geq 2$  is a *special horizontal pair*, if  $u$  is a left boundary of some zone in  $T$  and  $v$  is a right boundary of some zone in  $T$ . However, if  $S$  is incomplete and there is an ancestor  $w'$  of the lower boundary  $w$  with  $u \preceq w' \preceq v$ , then, instead of  $(u, v)$ , there are two special pairs:  $(u, \text{LEFT-SIBLING}(w'))$  and  $(\text{RIGHT-SIBLING}(w'), v)$ .
- Any pair of nodes  $u, v$  in some zone  $S$  of level 1 is a *special vertical pair*, if  $v$  is an ancestor of  $u$ . A pair of nodes  $u, v$  in some zone  $S$  of level  $\ell \geq 2$  is a *special vertical pair*, if  $v$  is an ancestor of  $u$ ,  $v$  is an upper or lower boundary of some zone in  $T$  and  $u$  is a lower boundary of some zone in  $T$ . However, if  $S$  is incomplete with lower boundary  $w$  and  $w' := \text{LCA}(w, u)$  is strictly above  $u$  and below or equal to  $v$ , then, instead of  $(u, v)$ , there are two special pairs:  $(u, \text{ANC-CHILD}(w', u))$  and  $(w', v)$ . Here LCA determines the least common ancestor and ANC-CHILD the child of  $w'$  that is an ancestor of  $u$ .

The algorithm stores  $\mathcal{A}_t(p, u, v)$  for each state  $p$  of  $\mathcal{A}$  and each special horizontal pair  $u, v$ . Furthermore, it stores  $\mathcal{B}_t(q, u, v)$ , for each state  $q$  of  $\mathcal{B}$  and each special vertical pair  $u, v$ .

We note, that in all cases  $\mathcal{A}_t(p, u, v)$  and  $\mathcal{B}_t(q, u, v)$  only depend on the labels of the nodes in the zone, for which  $(u, v)$  is special.

► **Lemma 3.6.** *From the stored values for functions  $\mathcal{A}_t$  and  $\mathcal{B}_t$  for special pairs, it is possible to compute  $\rho_t(v)$ , for arbitrary nodes  $v$ ,  $\mathcal{A}_t(p, u, u')$  for arbitrary pairs  $u \prec u'$  of siblings of  $t$  and  $\mathcal{B}_t(q, u, u')$  for arbitrary pairs  $u, u'$  of nodes, where  $u'$  is an ancestor of  $u$ , sequentially in constant time.*

This enables us to show the  $\mathcal{O}(n^\epsilon)$  work bound for label changes.

**Proof of Proposition 3.1.** To achieve the stated bound, we use the above algorithm with work parameter  $\theta = \frac{\epsilon}{2}$ . The algorithm uses a  $(\theta, 10)$ -bounded partition hierarchy, which exists thanks to Proposition 3.5.

As indicated before, the algorithm stores  $\mathcal{A}_t(\cdot, u, v)$  and  $\mathcal{B}_t(\cdot, u, v)$ , for all special pairs  $(u, v)$ . As already observed before, these values only depend on the labels of the nodes of the zone relative to which  $(u, v)$  is special. Therefore, if a node label is changed for some node  $x$ , values  $\mathcal{A}_t(\cdot, u, v)$  and  $\mathcal{B}_t(\cdot, u, v)$  need only be updated for special pairs of zones in

which  $x$  occurs. Since each node occurs in exactly  $h$  zones and each zone has  $\mathcal{O}(n^{2\theta}) = \mathcal{O}(n^\epsilon)$  special pairs,  $h \cdot \mathcal{O}(n^\epsilon)$  processors can be used, where every processor updates a single value in constant time and work, as is possible thanks to Lemma 3.2 and Lemma 3.6. Since the shape of the tree does not change we can assume a mapping from the updated node and the processor number to the special tuple that the respective processor recomputes. ◀

## 3.2 Structural Changes

In Proposition 3.1 only label changes were allowed, so the structure of the underlying tree did not change. In particular, there was no need to update any of the basic tree functions.

In this subsection, we consider structural changes of the tree. We show that the work bounds of Proposition 3.1 can still be met for the full data types  $\text{REGTREE}(L)$ .

► **Theorem 3.7.** *For each regular tree language  $L$  and each  $\epsilon > 0$ , there is a dynamic constant time parallel algorithm for  $\text{REGTREE}(L)$  that handles change operations with work  $\mathcal{O}(n^\epsilon)$  and answers query operations with constant work.*

In the next subsection, we describe the general strategy of the algorithm, define some notions that will be used and present its proof. Then, in a second subsection, we give some more detailed information about the data that is stored and how it can be maintained.

### 3.2.1 High-level description of the dynamic algorithm

Our approach generalises the algorithm of Subsection 3.1. It makes sure that, at any point in time, there is a valid partition hierarchy together with corresponding tree and automata functions. The general strategy of the dynamic algorithm is to add new leaves to their nearest zone. In principle, this is not hard to handle – unless it leads to a violation of a size constraint of some zone. As soon as zones exceed a certain size bound the affected parts of the hierarchy will thus be recomputed to ensure the size constraints.

For reasons that will become clearer below, we need to slightly modify the definition of partition hierarchies, basically by omitting the lowest two levels. To this end, we define 3-pruned partition hierarchies just like we defined partition hierarchies, but the lowest level is at height 3. More precisely, a *3-pruned partition hierarchy of height 3* is just a 3-zone, and *3-pruned partition hierarchies of height  $\ell > 3$*  are inductively defined just like partition hierarchies of height  $\ell$ . It is clear that a 3-pruned partition hierarchy exists for each tree by omitting the two lowest levels in the partition hierarchy computed in Proposition 3.5. Moreover, using a 3-pruned partition hierarchy as basis for our efficient label change approach still ensures the sequential constant time computation of arbitrary automaton function values from the stored values for special pairs. However, zones on the lowest level have size  $\mathcal{O}(n^{3\theta})$  leading to a work bound of  $\mathcal{O}(n^{6\theta})$  per change operation.

To ensure that at each point in time, a usable partition hierarchy is available, the general strategy is as follows: the algorithm starts from a *strong partition hierarchy* in which zones at level  $\ell$  have size at most  $\frac{1}{4}n^{\ell\theta}$ , well below the maximum allowed size of such a zone of  $n^{\ell\theta}$ . As soon as the size of a zone  $S$  at level  $\ell$  reaches its *warning limit*  $\frac{1}{2}n^{\ell\theta}$ , the algorithm starts to compute a new partition hierarchy for the parent zone  $S'$  of  $S$  at level  $\ell + 1$ . This computation is orchestrated in a way that makes sure that the new partition hierarchy for  $S'$  is ready (together with all required function values) before  $S$  reaches its size limit  $n^{\ell\theta}$ , at which point the old partition hierarchy for  $S'$  becomes useless.

Since a partition hierarchy of the whole tree together with the required function values has size  $\Omega(n)$ , its computation inherently requires that amount of work and it can probably not be done in constant time. Furthermore, since we aim at work  $\mathcal{O}(n^\epsilon)$  per operation, the

algorithm cannot afford to do the re-computation “as fast as possible” but rather needs to stretch over at least  $n^{1-\epsilon}$  steps. However, the fact that the tree can change during a re-computation poses a challenge: if many change operations happen with respect to a particular zone in a low level of the new partition hierarchy, this new zone might reach its warning limit and then its hard limit, before the overall re-computation of the hierarchy has finished. This challenge can be met by a careful orchestration of the re-computation.

We will next describe the data structure that the dynamic algorithm uses to orchestrate re-computations of partition hierarchies. As mentioned before, there will always be a valid partition hierarchy. However, for some zones, re-computations might be underway. The algorithm will always manage to complete the re-computation of a partition hierarchy for a zone of level  $\ell$ , before any of the subzones of level  $(\ell - 1)$  of the new partition reaches its warning limit. Therefore, for each zone within the data structure, there is always at most one partition hierarchy under construction, and therefore each zone has at any time at most two partition records. If a zone actually has two partition records, one of them contains a usable partition hierarchy. We formalise usability of a partition hierarchy by the term *operable* and tie the whole data structure together through the following notion of zone records. It is defined in an inductive fashion, together with the concept of partition records.

► **Definition 3.8.** A *zone record* of level 3 is a 3-zone. A *zone record* of level  $\ell > 3$  consists of an  $\ell$ -zone  $S$  and up to two partition records  $P_1, P_2$  of level  $\ell$  for  $S$ . If it has two partition records then  $P_1$  is complete and  $P_2$  is incomplete.

A *partition record*  $(Z, M)$  of level  $\ell > 3$  for an  $\ell$ -zone  $S$  consists of a set  $Z$  of zone records of level  $\ell - 1$  and a set  $M$  of zones, such that the zones from  $Z$  and the zones from  $M$  together constitute a partition of  $S$ . A partition record  $Z$  of level  $\ell$  is *valid*, if all zones of its zone records are actual  $(\ell - 1)$ -zones.

A zone record of level 3 is *operable*.

A partition record at level  $\ell > 3$  is *operable*, if it is valid and all its zone records are operable. A zone record of level  $\ell > 3$  is *operable*, if its first partition record is operable.

We refer to the hierarchical structure constituting the overall zone record as the *extended partition hierarchy*. Within the extended partition hierarchy, we are particularly interested in “operable substructures”. To this end, we associate with an operable zone record, the *primary partition hierarchy* that results from recursively picking the operable partition record from each zone record.

Altogether, the algorithm maintains an extended partition hierarchy for  $t$ .

Before we describe how the algorithm stores the extended partition hierarchy, we need two more concepts. For each zone record  $R$  of a level  $\ell$  there is a sequence  $R_h, \dots, R_\ell = R$  of zone records such that, for each  $i \geq \ell$ ,  $R_i$  is a zone record that occurs in a partition record of  $R_{i+1}$ . This sequence can be viewed as the *address* of  $R$  in the extended partition hierarchy. Furthermore, this address induces a *finger print* for  $R$ : the sequence  $\text{status}(R_h), \dots, \text{status}(R_\ell)$ , where  $\text{status}(R_i)$  is either *operable* or *in progress*. It is a simple but useful observation that if a tree node  $v$  occurs in two zones with zone records  $R \neq R'$  within the extended partition hierarchy, then the finger prints of  $R$  and  $R'$  are different. Consequently a tree node occurs in at most  $2^h$  and thus, a constant number of zones in the extended partition hierarchy.

Now we can describe, how the algorithm stores  $t$  and the extended partition hierarchy.

- A zone record of level 3 is represented as an array of  $\mathcal{O}(n^\theta)$  nodes.
- A zone record of a level  $\ell > 3$  consists of up to four boundary nodes and up to two pointers to partition records. The operable partition record is flagged.

- Each zone record of level  $\ell \geq 3$  with finger print  $pa$ , also stores a pointer to its zone on level  $\ell + 1$  with finger print  $p$ , and three pointers to the zone records of its parent, first child and right sibling zones.
- A partition record  $(Z, M)$  is represented as an array of zone records (some of which may be zones of  $M$ ). The zones records from  $Z$  are flagged.
- The nodes of  $t$  are stored in an array (in no particular order) together with pointers for the functions PARENT, LEFT-SIBLING, RIGHT-SIBLING, FIRST-CHILD, and LAST-CHILD.
- For each node  $v$ , and each possible finger print  $p$ , a pointer  $Z^p(v)$  to its zone with finger print  $p$ .

Now we are prepared to outline the proof of Theorem 3.7.

**Proof (of Theorem 3.7).** Let  $\mathcal{B}$  be a DTA for the regular tree language  $L$  and let  $\theta = \frac{\varepsilon}{7}$ . The dynamic algorithm stores  $t$  and an extended partition hierarchy as described above. It also stores some additional function values, including values for the automata functions, that will be specified in Subsubsection 3.2.2.

Some functions are independent from zones and are stored for all nodes. Some other functions are independent from zones but are only stored for particular node tuples that are induced from zones (like it was already the case for the automata functions in Subsection 3.1) and some functions are actually defined for (tuples of) zones.

After each change operation, the algorithm updates function values, pursues re-computations of hierarchies and computes function values that are needed for newly established zones. It starts a re-computation for a zone  $S$ , whenever one of its subzones reaches its warning limit. It starts a re-computation of the overall zone, whenever the number of nodes of  $t$  reaches  $\frac{1}{2}n$ .

The algorithm has one thread for each zone with an ongoing re-computation, that is, for each zone whose zone record is not yet operable.

A re-computation for a zone at level  $\ell$  requires the computation of  $\mathcal{O}(n^\theta)$  zones of level  $\ell - 1$ , each of which yields re-computations of  $\mathcal{O}(n^\theta)$  zones of level  $\ell - 2$  and so forth, down to level 3. It is easy to see that the overall number of zones that needs to be computed during a re-computation of a zone at level  $\ell$  is bounded by  $\mathcal{O}(n^{(\ell-3)\theta})$ . The re-computation of the overall zone requires the computation of at most  $\mathcal{O}(n^{1-3\theta})$  zones. We show in Lemma 3.9 that, in the presence of a primary partition hierarchy for the overall zone, the computation of a new zone is possible in constant time with work  $\mathcal{O}(n^{6\theta})$ .

The thread for the re-computation of a zone at level  $\ell$  thus (first) consists of  $\mathcal{O}(n^{(\ell-3)\theta})$  computations of component zones, each of which is carried out in constant time with work  $\mathcal{O}(n^{6\theta})$ . We refer to such a re-computation as a round. A thread thus consists of  $\mathcal{O}(n^{(\ell-3)\theta})$  rounds of zone computations. The thread follows a breadth-first strategy, that is, it first computes all zones of level  $\ell - 1$  then the sub-zones of those zones at level  $\ell - 2$  and so forth. Once the zone record of a zone  $S$  is operable, the thread computes in its second phase all function values associated to  $S$ . This can be done in constant time with work  $\mathcal{O}(n^{7\theta})$  per sub-zone of  $S$ , as is shown in the full version of this paper. That is, it requires at most  $\mathcal{O}(n^{(\ell-3)\theta})$  additional rounds.

We note that it does not matter if the primary partition hierarchy  $H$  required for Lemma 3.9 changes during the computation of a thread, since  $H$  is only used to make the identification of a new zone more efficient.

To address the above mentioned challenge, the algorithm starts a separate thread for each zone that is newly created during this process. That is, for each zone at level  $\ell - 1$ , an additional re-computation thread is started, as soon as the zone is created.

Now we can state the orchestration strategy for re-computations. This strategy is actually very simple:

**Re-computation strategy:** After each change operation affecting some node  $v$ , the algorithm performs one computation round, for all threads of zones  $S$ , at any level, with  $v \in S$ .

That is, thanks to the above observation, after a change operation, there are at most  $2^h$  threads for which one computation round is performed. Since  $2^h$  is a constant, these computations together require work at most  $\mathcal{O}(n^{7\theta})$ .

On the other hand, the whole re-computation for a zone  $S$  at level  $\ell$ , including the computation of the relevant function values, is finished after at most  $\mathcal{O}(n^{(\ell-3)\theta})$  change operations that affect  $S$ . Since  $\frac{1}{2}n^{(\ell-1)\theta}$  leaf additions are needed to let a sub-zone  $S'$  grow from the warning limit  $\frac{1}{2}n^{(\ell-1)\theta}$  to the hard limit  $n^{(\ell-1)\theta}$ , it is guaranteed that the re-computation thread for  $S$  is completed, before  $S'$  grows too large. In fact, this is exactly, why partition hierarchies are 3-pruned. When a re-computation of the overall zone was triggered by the size of  $t$ ,  $n$  is doubled as soon as this re-computation is completed.

Thanks to Lemma 3.11 the overall work to update the stored function values for all affected zones (in constant time) after a change operation is  $\mathcal{O}(n^{3\theta})$ .

Altogether, the statement of the theorem follows by choosing  $\theta = \frac{\epsilon}{7}$ . ◀

We state the lemma about the computation of new zones next. The partition hierarchy is used as a means to assign evenly distributed nodes to processors and to do parallel search for nodes with a particular property regarding the number of their descendants.

► **Lemma 3.9.** *Given a tree  $t$ , a 3-pruned partition hierarchy  $H$  of  $t$ , and a zone  $S$  with at least  $m$  nodes,  $S$  can be partitioned into at most five zones, one of which has at least  $\frac{1}{2}m$  and at most  $m$  nodes, in constant time with work  $\mathcal{O}(n^{6\theta})$ .*

### 3.2.2 Maintaining functions

In Subsection 3.1, the tree functions were static and given by the initialisation. Only the automata functions needed to be updated. However, if leaf insertions are allowed, the tree functions can change. To keep the algorithm efficient, the special pairs need to be adapted to the evolution of the partition hierarchy, and tree functions can no longer be stored for all possible arguments. Furthermore, additional tree functions and functions defined for zones will be used.

The stored information suffices to compute all required functions in constant time, and almost all of them with constant work.

► **Lemma 3.10.** *Given a tree  $t$ , a 3-pruned partition hierarchy  $H$  of  $t$ , and the stored information as described above, for each  $\theta > 0$ , the `CHILD` function can be evaluated in  $\mathcal{O}(1)$  time with work  $\mathcal{O}(n^\theta)$ . All other functions can be evaluated for all tuples with constant work.*

Furthermore, all stored information can be efficiently updated, with the help of and in accordance with the current primary partition hierarchy.

► **Lemma 3.11.** *Let  $\theta > 0$  and  $H$  be a 3-pruned partition hierarchy of  $t$  with automata and tree functions. The stored information described above can be maintained after each `Relabel` and `AddChild` operation in constant time with  $\mathcal{O}(n^{6\theta})$  work per operation.*

## 4 Maintaining context-free languages

As mentioned in the introduction, an analysis of the dynamic program that was used in [7] to show that context-free languages can be maintained in DynFO yields the following result.

► **Theorem 4.1** ([7, Proposition 5.3]). *For each context-free language  $L$ , there is a dynamic constant-time parallel algorithm on a CRCW PRAM for  $\text{CFL}(L)$  with  $\mathcal{O}(n^7)$  work.*

There is a huge gap between this upper bound and the conditional lower bound of  $\mathcal{O}(n^{\omega-1-\epsilon})$ , for any  $\epsilon > 0$ , derived from the  $k$ -Clique conjecture [1], where  $\omega < 2.373$  [11]. Our attempts to make this gap significantly smaller, have not been successful yet. However, for realtime deterministic context-free languages and visibly pushdown languages, more efficient dynamic algorithms are possible, as shown in the following two subsections.

### 4.1 Deterministic context-free languages

Realtime deterministic context-free languages are decided by deterministic PDAs without  $\lambda$ -transitions (RDPDAs).

► **Theorem 4.2.** *For each realtime deterministic context-free language  $L$  and each  $\epsilon > 0$ , there is a dynamic constant-time parallel algorithm on a CRCW PRAM for  $\text{CFL}(L)$  with  $\mathcal{O}(n^{3+\epsilon})$  work.*

Given an RDPDA  $\mathcal{A}$  for  $L$ , a configuration  $C = (p, u, s)$  consists of a state  $p$ , a string  $u$  that is supposed to be read by  $\mathcal{A}$  and a string  $s$ , the initial stack content. We use the following functions  $\delta_{\text{state}}$ ,  $\delta_{\text{stack}}$ , and  $\delta_{\text{empty}}$  to describe the behaviour of  $\mathcal{A}$  on configurations.

- $\delta_{\text{state}}(C)$  yields the last state of  $\text{run}(C)$ .
- $\delta_{\text{stack}}(C)$  yields the stack content at the end of  $\text{run}(C)$ .
- $\delta_{\text{empty}}(C)$  is the position in  $u$ , after which  $\text{run}(C)$  empties its stack. It is zero, if this does not happen at all.

The algorithm maintains the following information, for each simple configuration  $C = (p, u, \tau)$ , where  $u = w[i, j]$ , for some  $i \leq j$ , for each suffix  $v = w[m, n]$  of  $w$ , where  $j < m$ , each state  $q$ , and some  $k \leq n$ .

- $\hat{\delta}(C)$  defined as the tuple  $(\delta_{\text{state}}(C), |\delta_{\text{stack}}(C)|, \text{top}_1(\delta_{\text{stack}}(C)), \delta_{\text{empty}}(C))$ , consisting of the state, the height of the stack, the top symbol of the stack, at the end of the run on  $C$  and the position where the run ends. If the run empties the stack prematurely or at the end of  $u$ , then  $\text{top}_1(\delta_{\text{stack}}(C))$  is undefined;
- $\text{push-pos}(C, k)$ , defined as the length of the longest prefix  $x$  of  $u$ , such that  $|\delta_{\text{stack}}(p, x, \tau)| = k$ . Informally this is the position of  $u$  at which the  $k$ -th symbol of  $\delta_{\text{stack}}(C)$ , counted from the bottom, is written;
- $\text{pop-pos}(C, q, v, k)$ , defined as the pair  $(o, r)$ , where  $o$  is the length of the prefix  $v'$  of  $v$ , for which  $\text{run}(q, v, \text{top}_k(\delta_{\text{stack}}(C)))$  empties its stack at the last symbol of  $v'$ , and  $r$  is the state it enters.

However, tuples for push-pos and pop-pos are only stored for values  $k$  of the form  $an^{b\theta}$ , for integers  $b < \frac{1}{\theta}$  and  $a \leq n^\theta$ , for some fixed  $\theta > 0$ . A more detailed account is given in the full version of this paper.

### 4.2 Visibly pushdown languages

Visibly pushdown languages are a subclass of realtime deterministic CFLs. They use *pushdown alphabets* of the form  $\tilde{\Sigma} = (\Sigma_c, \Sigma_r, \Sigma_{\text{int}})$  and deterministic PDA that always push a symbol when reading a symbol from  $\Sigma_c$ , pop a symbol when reading a symbol from  $\Sigma_r$  and leave the stack unchanged otherwise. We refer to [2] for more information.

There is a correspondence between wellformed strings over a pushdown alphabet and labelled trees, where each matching pair  $(a, b)$  of a call symbol from  $\Sigma_c$  and a return symbol from  $\Sigma_r$  is represented by an inner node with label  $(a, b)$  and each other symbol by a leaf. From Theorem 3.7 and this correspondence the following can be concluded.

► **Proposition 4.3.** *For each visibly pushdown language  $L$  and each  $\epsilon > 0$ , there is a dynamic constant-time parallel algorithm on a CRCW PRAM for  $VPL^-(L)$  with  $\mathcal{O}(n^\epsilon)$  work.*

Here,  $VPL^-(L)$  only allows the following change operations:

- Replacement of a symbol by a symbol of the same type;
- Insertion of an internal symbol from  $\Sigma_{\text{int}}$  before a return symbol;
- Replacement of an internal symbol by two symbols  $ab$ , where  $a \in \Sigma_c$  and  $b \in \Sigma_r$ .

For arbitrary symbol replacements and insertions, there is a much less work-efficient algorithm which, however, is still considerably more efficient than the algorithm for DCFLs.

► **Theorem 4.4.** *For each visibly pushdown language  $L$  and each  $\epsilon > 0$ , there is a dynamic constant-time parallel algorithm on a CRCW PRAM for  $VPL(L)$  with  $\mathcal{O}(n^{2+\epsilon})$  work.*

The work improvement mainly relies on the fact that how the height of the stack evolves during a computation only depends on the types of symbols.

## 5 Conclusion

We have shown that the good work bounds for regular string languages from [11] carry over to regular tree languages, even under some structural changes of the tree. In turn they also hold for visibly pushdown languages under limited change operations. For realtime deterministic context-free languages and visibly pushdown languages under more general change operations better work bounds than for context-free languages could be shown.

There are plenty of questions for further research, including the following: are there other relevant change operations for trees that can be handled with work  $\mathcal{O}(n^\epsilon)$ ? What are good bounds for further operations? Can the bounds for context-free languages be improved? Can the  $\mathcal{O}(n^{3+\epsilon})$  be shown for arbitrary (not necessarily realtime) DCFLs? And the most challenging: are there further lower bound results that complement our upper bounds?

# Logical Equivalences, Homomorphism Indistinguishability, and Forbidden Minors

Tim Seppelt  

RWTH Aachen University, Germany

---

## Abstract

Two graphs  $G$  and  $H$  are *homomorphism indistinguishable* over a class of graphs  $\mathcal{F}$  if for all graphs  $F \in \mathcal{F}$  the number of homomorphisms from  $F$  to  $G$  is equal to the number of homomorphisms from  $F$  to  $H$ . Many natural equivalence relations comparing graphs such as (quantum) isomorphism, spectral, and logical equivalences can be characterised as homomorphism indistinguishability relations over certain graph classes.

Abstracting from the wealth of such instances, we show in this paper that equivalences w.r.t. any *self-complementarity* logic admitting a characterisation as homomorphism indistinguishability relation can be characterised by homomorphism indistinguishability over a minor-closed graph class. Self-complementarity is a mild property satisfied by most well-studied logics. This result follows from a correspondence between closure properties of a graph class and preservation properties of its homomorphism indistinguishability relation.

Furthermore, we classify all graph classes which are in a sense finite (*essentially profinite*) and satisfy the maximality condition of being *homomorphism distinguishing closed*, i.e. adding any graph to the class strictly refines its homomorphism indistinguishability relation. Thereby, we answer various questions raised by Roberson (2022) on general properties of the homomorphism distinguishing closure.

## 1 Introduction

In 1967, Lovász [23] proved that two graphs  $G$  and  $H$  are isomorphic if and only if they are *homomorphism indistinguishable* over all graphs, i.e. for every graph  $F$ , the number of homomorphisms from  $F$  to  $G$  is equal to the number of homomorphisms from  $F$  to  $H$ . Since then, homomorphism indistinguishability over restricted graph classes has emerged as a powerful framework for capturing a wide range of equivalence relations comparing graphs. For example, two graphs have cospectral adjacency matrices iff they are homomorphism indistinguishable over all cycles, cf. [13]. They are quantum isomorphic iff they are homomorphism indistinguishable over all planar graphs [25].

Most notably, equivalences with respect to many logic fragments can be characterised as homomorphism indistinguishability relations over certain graph classes [19, 12, 27, 31]. For example, two graphs satisfy the same sentences of  $k$ -variable counting logic iff they are homomorphism indistinguishable over graphs of treewidth less than  $k$  [14]. All graph classes

■ **Table 1** Overview of results on equivalent properties of a homomorphism distinguishing closed graph class  $\mathcal{F}$  and of its homomorphism indistinguishability relation  $\equiv_{\mathcal{F}}$ .

Closure property of $\mathcal{F}$	Preservation property of $\equiv_{\mathcal{F}}$	Theorem
taking minors	complements	Theorem 9
taking summands	disjoint unions	Theorem 5
taking subgraphs	full complements	Theorem 6
taking induced subgraphs	left lexicographic products	Theorem 12
contracting edges	right lexicographic products	Theorem 13

featured in such characterisations are minor-closed and hence of a particularly enjoyable structure. The main result of this paper asserts that this is not a mere coincidence: In fact, logical equivalences and homomorphism indistinguishability over minor-closed graph classes are intimately related.

To make this statement precise, the term “logic” has to be formalised. Following [15], a *logic on graphs* is a pair  $(\mathbb{L}, \models)$  of a class  $\mathbb{L}$  of *sentences* and an isomorphism-invariant<sup>1</sup> *model relation*  $\models$  between graphs and sentences. Two graphs  $G$  and  $H$  are  $\mathbb{L}$ -*equivalent* if  $G \models \varphi$  iff  $H \models \varphi$  for all  $\varphi \in \mathbb{L}$ . One may think of a logic on graphs as a collection of isomorphism-invariant graph properties. A logic is called *self-complementary* if for every  $\varphi \in \mathbb{L}$  there is an element  $\bar{\varphi} \in \mathbb{L}$  such that  $G \models \varphi$  if and only if  $\bar{G} \models \bar{\varphi}$ . Here,  $\bar{G}$  denotes the complement graph of  $G$ . Roughly speaking, a fragment/extension  $\mathbb{L}$  of first-order logic is self-complementary if expressions of the form  $Exy$  can be replaced by  $\neg Exy \wedge (x \neq y)$  in every formula while remaining in  $\mathbb{L}$ . This lax requirement is satisfied by many logics including first-order logic, counting logic, second-order logic, fixed-point logics, and bounded variable, quantifier depth, or quantifier prefix fragments of these. All these examples are subject to the following result:

► **Theorem 1.** *Let  $(\mathbb{L}, \models)$  be a self-complementary logic on graphs for which there exists a graph class  $\mathcal{F}$  such that two graphs  $G$  and  $H$  are homomorphism indistinguishable over  $\mathcal{F}$  if and only if they are  $\mathbb{L}$ -equivalent. Then there exists a minor-closed graph class  $\mathcal{F}'$  whose homomorphism indistinguishability relation coincides with  $\mathbb{L}$ -equivalence.*

Theorem 1 can be used to rule out that a given logic has a homomorphism indistinguishability characterisation (Corollary 17). Furthermore, it allows to use the deep results of graph minor theory to study the expressive power of logics on graphs (Theorem 22).

Theorem 1 is product of a more fundamental study of the properties of homomorphism indistinguishability relations. In several instances, it is shown that closure properties of a graph class  $\mathcal{F}$  correspond to preservation properties of its homomorphism indistinguishability relation  $\equiv_{\mathcal{F}}$ . These efforts yield answers to several open questions from [32]. A prototypical result is Theorem 2, from which Theorem 1 follows. For further results in the same vein concerning other closure properties, e.g. under taking subgraphs, see Table 1.

► **Theorem 2.** *Let  $\mathcal{F}$  be a homomorphism distinguishing closed graph class. Then  $\mathcal{F}$  is minor-closed if and only if  $\equiv_{\mathcal{F}}$  is preserved under taking complements, i.e. for all simple graphs  $G$  and  $H$  it holds that  $G \equiv_{\mathcal{F}} H$  if and only if  $\bar{G} \equiv_{\mathcal{F}} \bar{H}$ .*

Here, the graph class  $\mathcal{F}$  is *homomorphism distinguishing closed* [32] if for every  $K \notin \mathcal{F}$  there exist graphs  $G$  and  $H$  which are homomorphism indistinguishable over  $\mathcal{F}$  but differ in the number of homomorphisms from  $K$ . In other words, adding even a single graph to  $\mathcal{F}$  would change its homomorphism indistinguishability relation.

<sup>1</sup> For all  $\varphi \in \mathbb{L}$  and graphs  $G$  and  $H$  such that  $G \cong H$ , it holds that  $G \models \varphi$  iff  $H \models \varphi$ .

Proving that a graph class is homomorphism distinguishing closed is a pathway to separating equivalence relations comparing graphs [33]. However, establishing this property is a notoriously hard task. Thus, a general result establishing the homomorphism distinguishing closedness of a wide range of graph classes would be desirable. In [32], Roberson conjectured that *every graph class closed under taking minors and disjoint unions is homomorphism distinguishing closed*. At present, this conjecture has only been verified for few graph classes [32, 28].

Our final result confirms Roberson’s conjecture for all graph classes which are in a certain sense finite. The expressive power of homomorphism counts from finitely many graphs is of particular importance in practice. Applications include the design of graph kernels [21], motif counting [2, 26], or machine learning on graphs [6, 30, 20]. A theoretical interest stems for example from database theory where homomorphism counts correspond to results of queries under bag-semantics [8, 22], see also [9].

Since every homomorphism distinguishing closed graph class is closed under taking disjoint unions, infinite graph classes arise inevitably when studying homomorphism indistinguishability over finite graph classes. We introduce the notions of *essentially finite* and *essentially profinite* graph classes (Definition 23) in order to capture the nevertheless limited behaviour of graph classes arising from the finite. Examples for essentially profinite graph classes include the class of all minors of a fixed graph and the class of cluster graphs, i.e. disjoint unions of arbitrarily large cliques. In Theorem 24, the essentially profinite graph classes which are homomorphism distinguishing closed are fully classified. Thereby, the realm of available examples of homomorphism distinguishing closed graph classes is drastically enlarged. This classification has the following readily-stated corollary:

► **Theorem 3.** *Every essentially profinite union-closed graph class  $\mathcal{F}$  which is closed under taking summands<sup>2</sup> is homomorphism distinguishing closed. In particular, Roberson’s conjecture holds for all essentially profinite graph classes.*

## 2 Preliminaries

All graphs in this article are finite, undirected, and without multiple edges. A *simple graph* is a graph without loops. A *homomorphism* from a graph  $F$  to a graph  $G$  is a map  $h: V(F) \rightarrow V(G)$  such that  $h(u)h(v) \in E(G)$  whenever  $uv \in E(F)$  and vertices carrying loops are mapped to vertices carrying loops. Write  $\text{hom}(F, G)$  for the number of homomorphisms from  $F$  to  $G$ . For a class of graphs  $\mathcal{F}$  and graphs  $G$  and  $H$ , write  $G \equiv_{\mathcal{F}} H$  if  $\text{hom}(F, G) = \text{hom}(F, H)$  for all  $F \in \mathcal{F}$ , i.e.  $G$  and  $H$  are *homomorphism indistinguishable over  $\mathcal{F}$* . With the exception of Section 3.2, the graphs in  $\mathcal{F}$ ,  $G$  and  $H$  will be simple. Following [32], the *homomorphism distinguishing closure* of  $\mathcal{F}$  is

$$\text{cl}(\mathcal{F}) := \{K \text{ simple graph} \mid \forall \text{ simple graphs } G, H. \quad G \equiv_{\mathcal{F}} H \Rightarrow \text{hom}(K, G) = \text{hom}(K, H)\}.$$

Intuitively,  $\text{cl}(\mathcal{F})$  is the ‘largest’ graph class whose homomorphism indistinguishability relation coincides with the one of  $\mathcal{F}$ . A graph class  $\mathcal{F}$  is *homomorphism distinguishing closed* if  $\text{cl}(\mathcal{F}) = \mathcal{F}$ . Note that  $\text{cl}$  is a closure operator in the sense that  $\text{cl}(\mathcal{F}) \subseteq \text{cl}(\mathcal{F}')$  if  $\mathcal{F} \subseteq \mathcal{F}'$  and  $\text{cl}(\text{cl}(\mathcal{F})) = \text{cl}(\mathcal{F})$  for all graph classes  $\mathcal{F}$  and  $\mathcal{F}'$ .

For graphs  $G$  and  $H$ , write  $G + H$  for their *disjoint union* and  $G \times H$  for their *categorical product*, i.e.  $V(G \times H) := V(G) \times V(H)$  and  $gh$  and  $g'h'$  are adjacent in  $G \times H$  iff  $gg' \in E(G)$  and  $hh' \in E(H)$ . The *lexicographic product*  $G \cdot H$  is defined as the graph with vertex set

<sup>2</sup> A graph class  $\mathcal{F}$  is *closed under taking summands* if for all  $F \in \mathcal{F}$  which is the disjoint union of two graphs  $F_1 + F_2 = F$  also  $F_1, F_2 \in \mathcal{F}$ .

$V(G) \times V(H)$  and edges between  $gh$  and  $g'h'$  iff  $g = g'$  and  $hh' \in E(H)$  or  $gg' \in E(G)$ . It is well-known, cf. e.g. [24, (5.28)–(5.30)], that for all graphs  $F_1, F_2, G_1, G_2$ , and all connected graphs  $K$ ,

$$\text{hom}(F_1 + F_2, G) = \text{hom}(F_1, G) \text{hom}(F_2, G), \quad (1)$$

$$\text{hom}(F, G_1 \times G_2) = \text{hom}(F, G_1) \text{hom}(F, G_2), \text{ and} \quad (2)$$

$$\text{hom}(K, G_1 + G_2) = \text{hom}(K, G_1) + \text{hom}(K, G_2). \quad (3)$$

The *complement* of a simple graph  $F$  is the simple graph  $\bar{F}$  with  $V(\bar{F}) = V(F)$  and  $E(\bar{F}) = \binom{V(F)}{2} \setminus E(F)$ . Observe that  $\bar{\bar{F}} = F$  for all simple graphs  $F$ . The *full complement* of a graph  $G$  is the graph  $\widehat{G}$  obtained from  $G$  by replacing every edge with a non-edge and every loop with a non-loop, and vice-versa.

The *quotient*  $F/\mathcal{P}$  of a simple graph  $F$  by a partition  $\mathcal{P}$  of  $V(F)$  is the simple graph with vertex set  $\mathcal{P}$  and edges  $PQ$  for  $P \neq Q$  iff there exist vertices  $p \in P$  and  $q \in Q$  such that  $pq \in E(F)$ . For a set  $X$ , write  $\Pi(X)$  for the set of all partitions of  $X$ . We do not include loops in order to state Theorem 14 succinctly.

A graph  $F'$  can be obtained from a simple graph  $F$  by *contracting edges* if there is a partition  $\mathcal{P} \in \Pi(V(F))$  such that  $F[P]$  is connected for all  $P \in \mathcal{P}$  and  $F' \cong F/\mathcal{P}$ .

For a graph  $F$  and a set  $P \subseteq V(F)$ , write  $F[P]$  for the *subgraph induced by  $P$* , i.e. the graph with vertex set  $P$  and edges  $uv$  if  $u, v \in P$  and  $uv \in E(F)$ . A graph  $F'$  is a *subgraph* of  $F$ , in symbols  $F' \subseteq F$  if  $V(F') \subseteq V(F)$  and  $E(F') \subseteq E(F)$ . A *minor* of a simple graph  $F$  is a subgraph of a graph which can be obtained from  $F$  by contracting edges.

### 3 Closure Properties Correspond to Preservation Properties

This section is concerned with the interplay of closure properties of a graph class  $\mathcal{F}$  and preservation properties of its homomorphism indistinguishability relation  $\equiv_{\mathcal{F}}$ . The central results of this section are Theorem 2 and the other results listed in Table 1.

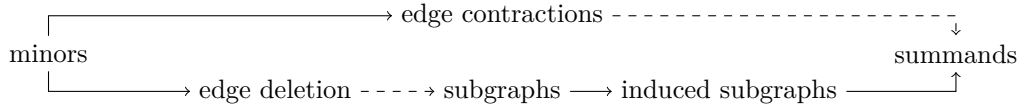

The relevance of the results is twofold: On the one hand, they yield that if a graph class  $\mathcal{F}$  has a certain closure property then so does  $\text{cl}(\mathcal{F})$ . In the case of minor-closed graph families, this provides evidence for Robertson's conjecture [32]. On the other hand, they establish that equivalence relations comparing graphs which are preserved under certain operations coincide with the homomorphism indistinguishability relation over a graph class with a certain closure property, if they are homomorphism indistinguishability relations at all. Further consequences are discussed in Sections 3.5 and 4. Essential to all proofs is the following lemma:

► **Lemma 4.** *Let  $\mathcal{F}$  and  $\mathcal{L}$  be classes of simple graphs. Suppose  $\mathcal{L}$  is finite and that its elements are pairwise non-isomorphic. Let  $\alpha: \mathcal{L} \rightarrow \mathbb{R} \setminus \{0\}$ . If for all simple graphs  $G$  and  $H$*

$$G \equiv_{\mathcal{F}} H \implies \sum_{L \in \mathcal{L}} \alpha_L \text{hom}(L, G) = \sum_{L \in \mathcal{L}} \alpha_L \text{hom}(L, H)$$

*then  $\mathcal{L} \subseteq \text{cl}(\mathcal{F})$ .*

**Proof.** The following argument is due to [11, Lemma 3.6]. Let  $n$  be an upper bound on the number of vertices of graphs in  $\mathcal{L}$  and let  $\mathcal{L}'$  denote the class of all graphs on at most  $n$  vertices. By classical arguments [23], the matrix  $M := (\text{hom}(K, L))_{K, L \in \mathcal{L}'}$  is invertible. Extend  $\alpha$  to a function  $\alpha': \mathcal{L}' \rightarrow \mathbb{R}$  by setting  $\alpha'(L) := \alpha(L)$  for all  $L \in \mathcal{L}$  and  $\alpha'(L') := 0$  for all  $L' \in \mathcal{L}' \setminus \mathcal{L}$ . If  $G \equiv_{\mathcal{F}} H$  then  $G \times K \equiv_{\mathcal{F}} H \times K$  for all graphs  $K$ . Hence, by Equation (2),

■ **Figure 1** Relationship between closure properties of homomorphism distinguishing closed graph classes. The non-obvious implications (dashed) are proven in Lemmas 8 and 16.

$$\sum_{L \in \mathcal{L}'} \text{hom}(L, K) \alpha_L \text{hom}(L, G) = \sum_{L \in \mathcal{L}'} \text{hom}(L, K) \alpha_L \text{hom}(L, H).$$

Both sides can be read as the product of the matrix  $M^T$  with a vector of the form  $(\alpha_L \text{hom}(L, -))_{L \in \mathcal{L}'}$ . By multiplying from the left with the inverse of  $M^T$ , it follows that  $\alpha_L \text{hom}(L, G) = \alpha_L \text{hom}(L, H)$  for all  $L \in \mathcal{L}'$  which in turn implies that  $\text{hom}(L, G) = \text{hom}(L, H)$  for all  $L \in \mathcal{L}$ . Thus,  $\mathcal{L} \subseteq \text{cl}(\mathcal{F})$ . ◀

In the setting of Lemma 4, we say that the relation  $\equiv_{\mathcal{F}}$  determines the linear combination  $\sum_{L \in \mathcal{L}} \alpha_L \text{hom}(L, -)$ . Note that it is essential for the argument to carry through that the elements of  $\mathcal{L}$  are pairwise non-isomorphic and that  $\alpha_L \neq 0$  for all  $L$ . Efforts will be undertaken to establish this property for certain linear combinations in the subsequent sections.

### 3.1 Taking Summands and Preservation under Disjoint Unions

In this section, the strategy yielding the results in Table 1 is presented for the rather simple case of Theorem 5. This theorem relates the property of a graph class  $\mathcal{F}$  to be closed under taking summands to the property of  $\equiv_{\mathcal{F}}$  to be preserved under disjoint unions. This closure property is often assumed in the context of homomorphism indistinguishability [1, 32] and fairly mild. It is the most general property among those studied here, cf. Figure 1. Theorem 5 answers a question from [32, p. 7] affirmatively: Is it true that if  $\equiv_{\mathcal{F}}$  is preserved under disjoint unions then  $\text{cl}(\mathcal{F})$  is closed under taking summands?

► **Theorem 5.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under taking summands, i.e. if  $F_1 + F_2 \in \mathcal{F}$  then  $F_1, F_2 \in \mathcal{F}$ ,
- (ii)  $\equiv_{\mathcal{F}}$  is preserved under disjoint unions, i.e. for all simple graphs  $G, G', H,$  and  $H'$ , if  $G \equiv_{\mathcal{F}} G'$  and  $H \equiv_{\mathcal{F}} H'$  then  $G + H \equiv_{\mathcal{F}} G' + H'$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is closed under taking summands.

*the implications  $i \Rightarrow ii \Leftrightarrow iii$  hold.*

**Proof.** The central idea is to write, given graphs  $F, G,$  and  $H,$  the quantity  $\text{hom}(F, G + H)$  as expression in  $\text{hom}(F', G)$  and  $\text{hom}(F', H)$  where the  $F'$  range over summands of  $F$ . To this end, write  $F = C_1 + \dots + C_r$  as disjoint union of its connected components. Then,

$$\begin{aligned} \text{hom}(F, G + H) &\stackrel{(1)}{=} \prod_{i=1}^r \text{hom}(C_i, G + H) \stackrel{(3)}{=} \prod_{i=1}^r (\text{hom}(C_i, G) + \text{hom}(C_i, H)) \\ &\stackrel{(1)}{=} \sum_{I \subseteq [r]} \text{hom}\left(\sum_{i \in I} C_i, G\right) \text{hom}\left(\sum_{i \in [r] \setminus I} C_i, H\right). \end{aligned} \tag{4}$$

In particular, if  $\mathcal{F}$  is closed under taking summands then  $\sum_{i \in I} C_i \in \mathcal{F}$  for all  $I \subseteq [r]$ . Thus, i implies ii.

Assume ii and let  $F \in \text{cl}(\mathcal{F})$ . Write as above  $F = C_1 + \cdots + C_r$  as disjoint union of its connected components. By the assumption that  $\equiv_{\mathcal{F}}$  is preserved under disjoint unions, for all graphs  $G$  and  $G'$ , if  $G \equiv_{\mathcal{F}} G'$  then  $G + F \equiv_{\mathcal{F}} G' + F$  and hence  $\text{hom}(F, G + F) = \text{hom}(F, G' + F)$ . By Equation (4) with  $H = F$ , the relation  $\equiv_{\mathcal{F}}$  determines the linear combination  $\sum_{I \subseteq [r]} \text{hom}(\sum_{i \in I} C_i, -) \text{hom}(\sum_{i \in [r] \setminus I} C_i, F)$ . Note that it might be the case that  $\sum_{i \in I} C_i \cong \sum_{j \in J} C_j$  for some  $I \neq J$ . Grouping such summands together and adding their coefficients yields a linear combination satisfying the assumptions of Lemma 4 since  $\text{hom}(C_i, F) > 0$  for all  $i \in [r]$ . Hence,  $\sum_{i \in I} C_i \in \text{cl}(\mathcal{F})$  for all  $I \subseteq [r]$  and iii follows.

The implication iii  $\Rightarrow$  ii follows from i  $\Rightarrow$  ii for  $\text{cl}(\mathcal{F})$  since  $\equiv_{\mathcal{F}}$  and  $\equiv_{\text{cl}(\mathcal{F})}$  coincide.  $\blacktriangleleft$

The proofs of the other results in Table 1 are conceptually similar to the just completed proof. The general idea can be briefly described as follows:

1. Derive a linear expression similar to Equation (4) for the number of homomorphisms from  $F$  into the graph constructed using the assumed preservation property of  $\equiv_{\mathcal{F}}$ , e.g. the graph  $G + H$  in the case of Theorem 5. These linear combinations typically involve sums over subsets  $U$  of vertices or edges of  $F$ , each contributing a summand of the form  $\alpha_U \text{hom}(F_U, -)$  where  $\alpha_U$  is some coefficient and  $F_U$  is a graph constructed from  $F$  using  $U$ . Hence, if  $\mathcal{F}$  is closed under the construction transforming  $F$  to  $F_U$  then  $\equiv_{\mathcal{F}}$  has the desired preservation property.
2. In general, it can be that  $F_U$  and  $F_{U'}$  are isomorphic even though  $U \neq U'$ , e.g. in Equation (4) if  $F$  contains two isomorphic connected components. In order to apply Lemma 4, one must group the summands  $\alpha_U \text{hom}(F_U, -)$  by the isomorphism type  $F'$  of the  $F_U$ . The coefficient of  $\text{hom}(F', -)$  in the new linear combination ranging over pairwise non-isomorphic graphs is the sum of  $\alpha_U$  over all  $U$  such that  $F_U \cong F'$ . Once it is established that this coefficient is non-zero, it follows that if  $\equiv_{\mathcal{F}}$  has the preservation property then  $\text{cl}(\mathcal{F})$  has the desired closure property.

### 3.2 Taking Subgraphs and Preservation under Full Complements

The strategy which yielded Theorem 5 can be extended to obtain the following Theorem 6 relating the property of a graph class  $\mathcal{F}$  to be closed under taking subgraphs to the property of  $\equiv_{\mathcal{F}}$  to be preserved under taking full complements.

Since our definition of the homomorphism distinguishing closure involves only simple graph in order to be aligned with [32], Theorem 6 deviates slightly from the other results in Table 1. This is because the relations  $\equiv_{\mathcal{F}}$  and  $\equiv_{\text{cl}(\mathcal{F})}$  a priori coincide only on simple graphs and not necessarily on all graphs, a crucial point raised by a reviewer.

► **Theorem 6.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under deleting edges,
- (ii)  $\equiv_{\mathcal{F}}$  is preserved under taking full complements, i.e. for all simple graphs  $G$  and  $H$  it holds that  $G \equiv_{\mathcal{F}} H$  if and only if  $\widehat{G} \equiv_{\mathcal{F}} \widehat{H}$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is closed under deleting edges,
- (iv)  $\text{cl}(\mathcal{F})$  is closed under taking subgraphs, i.e. it is closed under deleting edges and vertices,
- (v)  $\equiv_{\text{cl}(\mathcal{F})}$  is preserved under taking full complements,

the implications  $i \Rightarrow ii \Rightarrow iii \Leftrightarrow iv \Leftrightarrow v$  hold.

The linear expression required by Lemma 4 is provided by the following Lemma 7 based on the Inclusion–Exclusion principle. That iii implies iv follows from the Lemma 8. The proofs are deferred to the full version [35].

► **Lemma 7** ([24, Equation (5.23)]). *For every simple graph  $F$  and graph  $G$ ,*

$$\text{hom}(F, \widehat{G}) = \sum_{F' \subseteq F \text{ s.t. } V(F')=V(F)} (-1)^{|E(F')|} \text{hom}(F', G).$$

► **Lemma 8.** *If a homomorphism distinguishing closed graph class  $\mathcal{F}$  is closed under deleting edges then it is closed under taking subgraphs.*

### 3.3 Taking Minors and Preservation under Complements

The insights gained in the previous sections are now orchestrated to prove Theorem 9, which implies Theorem 2. This answers a question of Robertson [32, Question 8] affirmatively: Is it true that if  $\mathcal{F}$  is such that  $\equiv_{\mathcal{F}}$  is preserved under taking complements then there exist a minor-closed  $\mathcal{F}'$  such that  $\equiv_{\mathcal{F}}$  and  $\equiv_{\mathcal{F}'}$  coincide.

Theorem 9 is among the first results substantiating Robertson's conjecture not only for example classes but in full generality. In particular, as noted in [32, p. 2], there was little reason to believe that minor-closed graph families should play a distinct role in the theory of homomorphism indistinguishability. Theorem 9 indicates that this might be the case. Indeed, while Robertson's conjecture asserts that  $\text{cl}(\mathcal{F})$  coincides with  $\mathcal{F}$  for a minor-closed and union-closed graph class  $\mathcal{F}$ , Theorem 9 yields unconditionally that  $\text{cl}(\mathcal{F})$  is a minor-closed graph class itself.

► **Theorem 9.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under edge contraction and deletion,
- (ii)  $\equiv_{\mathcal{F}}$  is preserved under taking complements, i.e. for all simple graphs  $G$  and  $H$  it holds that  $G \equiv_{\mathcal{F}} H$  if and only if  $\widehat{G} \equiv_{\mathcal{F}} \widehat{H}$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is minor-closed,

*the implications  $i \Rightarrow ii \Leftrightarrow iii$  hold.*

Again, the strategy is to write  $\text{hom}(F, \widehat{G})$  as a linear combination of  $\text{hom}(F', G)$  for minors  $F'$  of  $F$ . For a simple graph  $G$ , write  $G^\circ$  for the graph obtained from  $G$  by adding a loop to every vertex. In light of Lemma 7, which concerns  $\text{hom}(F, \widehat{G})$ , noting that  $\widehat{G^\circ} \cong \widehat{G}$  for every simple graph  $G$ , it suffices to write  $\text{hom}(F, G^\circ)$  as a linear combination of  $\text{hom}(F', G)$  for minors  $F'$  of  $F$ . To that end, we consider a particular type of quotient graphs.

For a simple graph  $F$  and a set of edges  $L \subseteq E(F)$ , define the *contraction relation*  $\sim_L$  on  $V(F)$  by declaring  $v \sim_L w$  if  $v$  and  $w$  lie in the same connected component of the subgraph of  $F$  with vertex set  $V(F)$  and edge set  $L$ . Write  $[v]_L$  for the classes of  $v \in V(F)$  under the equivalence relation  $\sim_L$ .

The *contraction quotient*  $F \circledast L$  is the graph whose vertex set is the set of equivalence classes under  $\sim_L$  and with an edge between  $[v]_L$  and  $[w]_L$  if and only if there is an edge  $xy \in E(F) \setminus L$  such that  $x \sim_L v$  and  $y \sim_L w$ . In general,  $F \circledast L$  may contain loops, cf. Example 11. However, if it is simple then it is equal to  $F/\mathcal{P}$  where  $\mathcal{P}$  is the partition of  $V(F)$  into equivalence classes under  $\sim_L$ , i.e.  $\mathcal{P} := \{[v]_L \mid v \in V(F)\}$ . In this case,  $F \circledast L$  is a graph obtained from  $F$  by edge contractions.

With this notation, the quantity  $\text{hom}(F, G^\circ)$  can be succinctly written as linear combination. Using Proposition 10 and Lemma 7, Theorem 9 can be proven by the strategy described in Section 3.1. The proofs are deferred to [35].

► **Proposition 10.** *Let  $F$  and  $G$  be simple graphs. Then*

$$\text{hom}(F, G^\circ) = \sum_{L \subseteq E(F)} \text{hom}(F \circledast L, G).$$

► **Example 11.** Let  $K_3$  denote the clique with vertex set  $\{1, 2, 3\}$ . Then  $K_3 \circledast \emptyset \cong K_3$ ,  $K_3 \circledast \{12\} \cong K_2$ ,  $K_3 \circledast \{12, 23\} \cong K_1$ , and  $K_3 \circledast \{12, 23, 13\} \cong K_1$ . For every simple graph  $G$ ,  $\text{hom}(K_3, G^\circ) = \text{hom}(K_3, G) + 3 \text{hom}(K_2, G) + \text{hom}(K_1, G)$  since  $\text{hom}(K_1, G) = 0$ .

### 3.4 Taking Induced Subgraphs, Contracting Edges, and Lexicographic Products

In this section, it is shown that a homomorphism distinguishing closed graph class is closed under taking induced subgraphs (contracting edges) if and only if its homomorphism indistinguishability relation is preserved under lexicographic products with a fixed graph from the left (from the right).

Examples for equivalence relations preserved under lexicographic products related to chromatic graph parameters are listed in Corollary 18. Further examples are of model-theoretic nature and stem from winning strategies of the Duplicator player in bijective pebble games [35].

► **Theorem 12.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under taking induced subgraphs,
- (ii)  $\equiv_{\mathcal{F}}$  is such that for all simple graphs  $G, H, H'$ , if  $H \equiv_{\mathcal{F}} H'$  then  $G \cdot H \equiv_{\mathcal{F}} G \cdot H'$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is closed under taking induced subgraphs.

*the implications  $i \Rightarrow ii \Leftrightarrow iii$  hold.*

An example for a lexicographic product from the right is the  $n$ -blow-up  $G \cdot \overline{K_n}$  of a graph  $G$ . It can be seen [24] that every homomorphism indistinguishability relation is preserved under blow-ups. Preservation under arbitrary lexicographic products from the right, however, is a non-trivial property corresponding to the associated graph class being closed under edge contractions:

► **Theorem 13.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under edge contractions,
- (ii)  $\equiv_{\mathcal{F}}$  is such that for all simple graphs  $G, G', H$ , if  $G \equiv_{\mathcal{F}} G'$  then  $G \cdot H \equiv_{\mathcal{F}} G' \cdot H$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is closed under edge contractions.

*the implications  $i \Rightarrow ii \Leftrightarrow iii$  hold.*

For the proofs, homomorphism counts  $\text{hom}(F, G \cdot H)$  are written as linear combinations of homomorphism counts  $\text{hom}(F', H)$  where  $F'$  ranges over induced subgraphs of  $F$  in the case of Theorem 12 and over graphs obtained from  $F'$  by contracting edges in the case of Theorem 13. The following succinct formula for counts of homomorphisms into a lexicographic product is derived in the full version [35]. It may be of independent interest.

► **Theorem 14.** *Let  $F, G$ , and  $H$  be simple graphs. Then*

$$\text{hom}(F, G \cdot H) = \sum_{\mathcal{R}} \text{hom}(F/\mathcal{R}, G) \text{hom}\left(\sum_{R \in \mathcal{R}} F[R], H\right)$$

*where the outer sum ranges over all  $\mathcal{R} \in \Pi(V(F))$  such that  $F[R]$  is connected for all  $R \in \mathcal{R}$ .*

Theorem 14 yields Theorems 12 and 13, which in turn imply together the following Corollary 15. The proofs are deferred to the full version [35].

► **Corollary 15.** *For a graph class  $\mathcal{F}$  and the assertions*

- (i)  $\mathcal{F}$  is closed under taking induced subgraphs and edge contractions,
- (ii)  $\equiv_{\mathcal{F}}$  is such that for all simple graphs  $G, G', H$ , and  $H'$ , if  $G \equiv_{\mathcal{F}} G'$  and  $H \equiv_{\mathcal{F}} H'$  then  $G \cdot H \equiv_{\mathcal{F}} G' \cdot H'$ ,
- (iii)  $\text{cl}(\mathcal{F})$  is closed under taking induced subgraphs and edge contractions.

*the implications  $i \Rightarrow ii \Leftrightarrow iii$  hold.*

As a final observation, the following Lemma 16 relates the property of being closed under edge contractions to the other closure properties in Table 1.

► **Lemma 16.** *If a homomorphism distinguishing closed graph class  $\mathcal{F}$  is closed under contracting edges then it is closed under taking summands.*

### 3.5 Applications

As applications of Theorems 6, 9, 12, and 13, we conclude, in the spirit of [3], that certain equivalence relations on graphs cannot be homomorphism distinguishing relations.

► **Corollary 17.** *Let  $\mathcal{F}$  be a non-empty graph class such that one of the following holds:*

- $\equiv_{\mathcal{F}}$  is preserved under complements, cf. Theorem 9,
- $\equiv_{\mathcal{F}}$  is preserved under full complements, cf. Theorem 6,
- $\equiv_{\mathcal{F}}$  is preserved under left lexicographic products, cf. Theorem 12, or
- $\equiv_{\mathcal{F}}$  is preserved under right lexicographic products, cf. Theorem 13.

*Then  $G \equiv_{\mathcal{F}} H$  implies that  $|V(G)| = |V(H)|$  for all graphs  $G$  and  $H$ .*

**Proof.** By Theorems 6, 9, 12, and 13,  $\mathcal{F}$  can be chosen to be closed under taking minors, subgraphs, induced subgraphs, or contracting edges. In any case,  $K_1 \in \mathcal{F}$  as  $\mathcal{F}$  is non-empty and hence  $|V(G)| = \text{hom}(K_1, G) = \text{hom}(K_1, H) = |V(H)|$ . ◀

As concrete examples, consider the following relations.

► **Corollary 18.** *There is no graph class  $\mathcal{F}$  satisfying any of the following assertions for all graphs  $G$  and  $H$ :*

- (i)  $G \equiv_{\mathcal{F}} H$  iff  $a(G) = a(H)$  where  $a$  denotes the order of the automorphism group,
- (ii)  $G \equiv_{\mathcal{F}} H$  iff  $\alpha(G) = \alpha(H)$  where  $\alpha$  denotes the size of the largest independent set,
- (iii)  $G \equiv_{\mathcal{F}} H$  iff  $\omega(G) = \omega(H)$  where  $\omega$  denotes the size of the largest clique,
- (iv)  $G \equiv_{\mathcal{F}} H$  iff  $\chi(G) = \chi(H)$  where  $\chi$  denotes the chromatic number.

**Proof.** The relation in Item i is preserved under taking complements. By [17, Theorem 1, Corollary p. 90], the relations in Items ii and iv are preserved under left lexicographic products. For Item iii, the same follows from [17, Theorem 1] observing that  $\overline{G} \cdot \overline{H} = \overline{G \cdot H}$  and  $\omega(G) = \alpha(\overline{G})$ . In each case, it is easy to exhibit a pair of graphs  $G$  and  $H$  in the same equivalence class with different number of vertices. By Corollary 17, none of the equivalence relations is a homomorphism indistinguishability relation. ◀

## 4 Equivalences over Self-Complementary Logics

In this section, Theorem 1 is derived from Theorem 9. The theorem applies to self-complementary logics, of which examples are given subsequently. Finally, a result from graph minor theory is used to relate logics on graphs to quantum isomorphism.

► **Theorem 1.** *Let  $(\mathbb{L}, \models)$  be a self-complementary logic on graphs for which there exists a graph class  $\mathcal{F}$  such that two graphs  $G$  and  $H$  are homomorphism indistinguishable over  $\mathcal{F}$  if and only if they are  $\mathbb{L}$ -equivalent. Then there exists a minor-closed graph class  $\mathcal{F}'$  whose homomorphism indistinguishability relation coincides with  $\mathbb{L}$ -equivalence.*

## 82:10 Logical Equivalences, Homomorphism Indistinguishability, and Forbidden Minors

**Proof.** It is shown that  $\equiv_{\mathcal{F}}$  is preserved under taking complements in the sense of Theorem 9. Suppose  $G \equiv_{\mathcal{F}} H$ . By assumption, for all  $\varphi \in \mathbf{L}$  it holds that  $G \models \varphi$  iff  $H \models \varphi$  and hence, by self-complementarity,

$$\overline{G} \models \varphi \iff G \models \overline{\varphi} \iff H \models \overline{\varphi} \iff \overline{H} \models \overline{\overline{\varphi}} \iff \overline{H} \models \varphi.$$

Here, the penultimate equivalence holds since  $H \models \varphi$  if and only if  $H \models \overline{\overline{\varphi}}$  for all  $\varphi$  and  $H$  by the definition of self-complementarity observing that  $\overline{\overline{H}} \cong H$ . Thus,  $\overline{G} \equiv_{\mathcal{F}} \overline{H}$ . By Theorem 9,  $\mathcal{F}' := \text{cl}(\mathcal{F})$  is minor-closed.  $\blacktriangleleft$

In particular, by Corollary 17, all  $\mathbf{L}$ -equivalent graphs  $G$  and  $H$  must have the same number of vertices unless  $\mathbf{L}$  is trivial in the sense that all graphs  $G$  and  $H$  are  $\mathbf{L}$ -equivalent.

A first example of a self-complementarity logic is first-order logic  $\text{FO}$  over the signature of graphs  $\{E\}$ . In order to establish this property, a formula  $\overline{\varphi} \in \text{FO}$  has to be constructed for every  $\varphi \in \text{FO}$  such that  $G \models \varphi$  iff  $\overline{G} \models \overline{\varphi}$  for all graphs  $G$ . Only subformulae  $Exy$  require non-trivial treatment:

► **Definition 19.** For every  $\varphi \in \text{FO}$ , define  $\overline{\varphi} \in \text{FO}$  inductively as follows:

1. if  $\varphi = Exy$  then  $\overline{\varphi} := \neg Exy \wedge (x \neq y)$ ,
2. if  $\varphi = \perp$  or  $\varphi = \top$  then  $\overline{\varphi} := \varphi$ , if  $\varphi = (x = y)$  then  $\overline{\varphi} := \varphi$ , if  $\varphi = \neg\psi$  then  $\overline{\varphi} := \neg\overline{\psi}$ , if  $\varphi = \psi \wedge \chi$  then  $\overline{\varphi} := \overline{\psi} \wedge \overline{\chi}$ , if  $\varphi = \psi \vee \chi$  then  $\overline{\varphi} := \overline{\psi} \vee \overline{\chi}$ , if  $\varphi = \exists x. \psi$  then  $\overline{\varphi} := \exists x. \overline{\psi}$ , and if  $\varphi = \forall x. \psi$  then  $\overline{\varphi} := \forall x. \overline{\psi}$ .

► **Lemma 20.** Let  $\varphi \in \text{FO}$  be a formula with  $k \geq 0$  free variables. Then for all simple graphs  $G$  with  $\mathbf{v} \in V(G)^k$  it holds that

$$G, \mathbf{v} \models \varphi \iff \overline{G}, \mathbf{v} \models \overline{\varphi}.$$

In particular,  $\text{FO}$  is self-complementary.

**Proof.** The proof is by induction on the structure of  $\varphi$ . If  $\varphi$  is  $Exy$ , observe that  $v_1 v_2 \in E(G)$  if and only if  $v_1 v_2 \notin E(\overline{G})$  and  $v_1 \neq v_2$ . In all other cases, the claim is purely syntactical.  $\blacktriangleleft$

Lemma 20 gives a purely syntactical criterion for a fragment  $\mathbf{L} \subseteq \text{FO}$  to be self-complementary. Indeed, if  $\overline{\varphi} \in \mathbf{L}$  as defined in Definition 19 for all  $\varphi \in \mathbf{L}$  then  $\mathbf{L}$  is self-complementary. Note that the operation in Definition 19 increases neither the number of variables nor affects the quantifiers in the formula. Thus, Lemma 20 automatically extends to fragments of  $\text{FO}$  defined by restricting the number of variables, order or number of quantifiers. For extensions of  $\text{FO}$ , Definition 19 can be easily extended, cf. [35]. This yields a rich realm of self-complementary logics, of which the following Example 21 lists only a selection.

- **Example 21.** The following logics on graphs are self-complementary. For every  $k, d \geq 0$ ,
- the  $k$ -variable and quantifier-depth- $d$  fragments  $\text{FO}^k$  and  $\text{FO}_d$  of  $\text{FO}$ ,
  - first-order logic with counting quantifiers  $\mathbf{C}$  and its  $k$ -variable and quantifier-depth- $d$  fragments  $\mathbf{C}^k$  and  $\mathbf{C}_d$ ,
  - inflationary fixed-point logic  $\text{IFP}$ , cf. [18],
  - second-order logic  $\text{SO}$  and its fragments monadic second-order logic  $\text{MSO}_1$ , existential second-order logic  $\text{ESO}$ , cf. [10, 16].

Corollary 17 readily gives an alternative proof of [3, Propositions 1 and 2], which assert that neither  $\text{FO}^k$ -equivalence nor  $\text{FO}_d$ -equivalence are characterised by homomorphism indistinguishability relations. The logic fragments  $\mathbf{C}^k$  and  $\mathbf{C}_d$  are however characterised by homomorphism indistinguishability relations [14, 19].

The final result of this section demonstrates how graph minor theory can yield insights into the expressive power of logics via Theorem 1. Subject to it are self-complementary logics which have a homomorphism indistinguishability characterisation and are stronger than  $C^k$  for every  $k$ , e.g. they are capable of distinguishing CFI-graphs [7]. It is shown that equivalence w.r.t. any such logic is a sufficient condition for quantum isomorphism, an undecidable equivalence comparing graphs [4].

► **Theorem 22.** *Let  $(L, \equiv)$  be a self-complementary logic on graphs for which there exists a graph class  $\mathcal{F}$  such that two graphs  $G$  and  $H$  are homomorphism indistinguishable over  $\mathcal{F}$  if and only if they are  $L$ -equivalent. Suppose that for all  $k \in \mathbb{N}$  there exist graphs  $G$  and  $H$  such that  $G \equiv_{C^k} H$  and  $G \not\equiv_L H$ . Then all  $L$ -equivalent graphs are quantum isomorphic.*

**Proof.** Contrapositively, it is shown that if there exist non-quantum-isomorphic  $L$ -equivalent graphs then there exists a  $k \in \mathbb{N}$  such that  $G \equiv_{C^k} H \implies G \equiv_L H$  for all  $G$  and  $H$ . By [25, 14], this statement can be rephrased in the language of homomorphism indistinguishability as  $\mathcal{P} \not\subseteq \text{cl}(\mathcal{F}) \implies \exists k \in \mathbb{N}. \mathcal{F} \subseteq \text{cl}(\mathcal{TW}_k)$  where  $\mathcal{P}$  denotes the class of all planar graphs and  $\mathcal{TW}_k$  the class of all graphs of treewidth at most  $k$ . By Theorem 9,  $\text{cl}(\mathcal{F})$  is a minor-closed graph class. By [34, (2.1)], cf. [29, Theorem 3.8], if  $\text{cl}(\mathcal{F})$  does not contain all planar graphs then it is of bounded treewidth. Hence, there exists a  $k \in \mathbb{N}$  such that  $\mathcal{F} \subseteq \text{cl}(\mathcal{F}) \subseteq \mathcal{TW}_k \subseteq \text{cl}(\mathcal{TW}_k)$ . ◀

## 5 Classification of Homomorphism Distinguishing Closed Essentially Profinite Graph Classes

The central result of this section is a classification of the homomorphism distinguishing closed graph classes which are in a sense finite. Since every homomorphism distinguishing closed graph class is closed under disjoint unions, infinite graph classes arise naturally when studying the semantic properties of the homomorphism indistinguishability relations of finite graph classes. Nevertheless, the infinite graph classes arising in this way are *essentially finite*, i.e. they exhibit only finitely many distinct connected components. One may generalise this definition slightly by observing that all graphs  $F$  admitting a homomorphism into some fixed graph  $G$  have chromatic number bounded by the chromatic number of  $G$ . Thus, in order to make a graph class  $\mathcal{F}$  behave much like an essentially finite class, it suffices to impose a finiteness condition, for every graph  $K$ , on the subfamily of all  $K$ -colourable graphs in  $\mathcal{F}$ .

Formally, for a graph  $F$ , write  $\Gamma(F)$  for the set of connected components of  $F$ . For a graph class  $\mathcal{F}$ , define  $\Gamma(\mathcal{F})$  as the union of the  $\Gamma(F)$  where  $F \in \mathcal{F}$ . For a graph class  $\mathcal{F}$  and a graph  $K$ , define  $\mathcal{F}_K := \{F \in \mathcal{F} \mid \text{hom}(F, K) > 0\}$ , the set of  $K$ -colourable graphs in  $\mathcal{F}$ .

► **Definition 23.** *A graph class  $\mathcal{F}$  is essentially finite if  $\Gamma(\mathcal{F})$  is finite. It is essentially profinite if  $\mathcal{F}_K$  is essentially finite for all graphs  $K$ .*

Clearly, every finite graph class is essentially finite and hence essentially profinite. Other examples for essentially profinite classes are the class of all cliques. They represent a special case of the following construction from [32, Theorem 6.16]: For every  $S \subseteq \mathbb{N}$ , the family

$$K^S := \{K_{n_1} + \dots + K_{n_r} \mid r \in \mathbb{N}, \{n_1, \dots, n_r\} \subseteq S\} \quad (5)$$

is essentially profinite. In particular, there are uncountably many such families of graphs. Note that one may replace the sequence of cliques  $(K_n)_{n \in \mathbb{N}}$  in Equation (5) by any other sequence of connected graphs  $(F_n)_{n \in \mathbb{N}}$  such that the sequence of chromatic numbers  $(\chi(F_n))_{n \in \mathbb{N}}$  takes every value only finitely often.

Every graph  $F$  of an essentially finite family  $\mathcal{F}$  can be represented uniquely as vector  $\vec{F} \in \mathbb{R}^{\Gamma(\mathcal{F})}$  whose  $C$ -th entry for  $C \in \Gamma(\mathcal{F})$  is the number of times the graph  $C$  appears as a connected component in  $F$ . The classification of the homomorphism distinguishing closed essentially profinite graph classes can now be stated as follows. The proof, deferred to the full version [35], is based on a generalisation of a result by Kwiecień, Marcinkowski, and Ostropowski-Nalewaja [22].

► **Theorem 24.** *For an essentially profinite graph class  $\mathcal{F}$ , the following are equivalent:*

- (i)  $\mathcal{F}$  is homomorphism distinguishing closed,
- (ii) For every graph  $K$ , if  $\vec{K} \in \text{span}\{\vec{F} \in \mathbb{R}^{\Gamma(\mathcal{F}_K \cup \{K\})} \mid F \in \mathcal{F}_K\}$  then  $K \in \mathcal{F}$ ,
- (iii)  $\mathcal{F}_K$  is homomorphism distinguishing closed for every graph  $K$ .

Theorem 24 directly implies Theorem 3. Indeed, if  $\mathcal{F}$  is union-closed and closed under summands then  $\Gamma(\mathcal{F}) \subseteq \mathcal{F}$  and every graph  $K$  such that  $\Gamma(K) \subseteq \Gamma(\mathcal{F})$  is itself in  $\mathcal{F}$ . In particular, Theorem 24 implies that all essentially profinite union-closed minor-closed graph classes are homomorphism distinguishing closed. For example, for every graph  $G$ , the union-closure of the class of minors of  $G$  is homomorphism distinguishing closed.

To demonstrate the inner workings of condition ii in Theorem 24, we consider the following examples. The first example shows that not even the weakest closure property from Figure 1 is shared by all homomorphism distinguishing closed families. The second example answers a question from [32, p. 29] negatively: Is the disjoint union closure of the union of homomorphism distinguishing closed families homomorphism distinguishing closed?

► **Example 25.** Let  $F_1, F_2$  be connected non-isomorphic graphs such that  $\text{hom}(F_1, F_2) > 0$ .

1. The class  $\mathcal{F}_1 := \{n(F_1 + F_2) \mid n \geq 1\}$  is homomorphism distinguishing closed and not closed under taking summands.
2. For the homomorphism distinguishing closed  $\mathcal{F}_2 := \{nF_1 \mid n \geq 1\}$ , the disjoint union closure of  $\mathcal{F}_1 \cup \mathcal{F}_2$  is not homomorphism distinguishing closed.

Some further enjoyable properties of essentially (pro)finite graph classes merit being commented on. Statements and proofs are deferred to the full version [35]. Firstly, the homomorphism indistinguishability relation of no essentially profinite graph class is as fine as the isomorphism relation  $\cong$ . This is because the homomorphism distinguishing closure of an essentially profinite graph class is essentially profinite. Secondly, the complexity-theoretic landscape of the problem  $\text{HOMIND}(\mathcal{F})$  of deciding whether two graphs  $G$  and  $H$  are homomorphism indistinguishable over an essentially profinite class  $\mathcal{F}$  is rather diverse. For essentially finite  $\mathcal{F}$ ,  $\text{HOMIND}(\mathcal{F})$  is in polynomial time. For essentially profinite  $\mathcal{F}$ , the problem can be arbitrarily hard.

## 6 Conclusion

The main technical contribution of this work is a characterisation of closure properties of graph classes  $\mathcal{F}$  in terms of preservation properties of their homomorphism indistinguishability relations  $\equiv_{\mathcal{F}}$ , cf. Table 1. In consequence, a surprising connection between logical equivalences and homomorphism indistinguishability over minor-closed graph classes is established. In this way, results from graph minor theory are made available to the study of the expressive power of logics on graphs. Finally, a full classification of the homomorphism distinguishing closed graph classes which are essentially profinite is given. Various open questions of [32] are answered by results clarifying the properties of homomorphism indistinguishability relations and of the homomorphism distinguishing closure.

It is tempting to view the results in Table 1 as instances of a potentially richer connection between graph-theoretic properties of  $\mathcal{F}$  and *polymorphisms* of  $\equiv_{\mathcal{F}}$ , i.e. isomorphism-invariant maps  $f$  sending tuples of graphs to graphs such that  $f(G_1, \dots, G_k) \equiv_{\mathcal{F}} f(H_1, \dots, H_k)$  whenever  $G_i \equiv_{\mathcal{F}} H_i$  for all  $i \in [k]$ . Recalling the algebraic approach to CSPs, cf. [5], one may ask what structural insights into  $\mathcal{F}$  can be gained by considering polymorphisms of  $\equiv_{\mathcal{F}}$ . More concretely, can bounded treewidth or closure under topological minors be characterised in terms of some polymorphism?

# Decomposing Finite Languages

Daniel Alexander Spenner  

Technische Universität Dortmund, Germany

---

## Abstract

The paper completely characterizes the primality of acyclic DFAs, where a DFA  $\mathcal{A}$  is *prime* if there do not exist DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  with  $\mathcal{L}(\mathcal{A}) = \bigcap_{i=1}^t \mathcal{L}(\mathcal{A}_i)$  such that each  $\mathcal{A}_i$  has strictly less states than the minimal DFA recognizing the same language as  $\mathcal{A}$ . A regular language is prime if its minimal DFA is prime. Thus, this result also characterizes the primality of finite languages.

Further, the NL-completeness of the corresponding decision problem  $\text{PRIME-DFA}_{\text{fin}}$  is proven. The paper also characterizes the primality of acyclic DFAs under two different notions of compositionality, union and union-intersection compositionality.

Additionally, the paper introduces the notion of *S-primality*, where a DFA  $\mathcal{A}$  is S-prime if there do not exist DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  with  $\mathcal{L}(\mathcal{A}) = \bigcap_{i=1}^t \mathcal{L}(\mathcal{A}_i)$  such that each  $\mathcal{A}_i$  has strictly less states than  $\mathcal{A}$  itself. It is proven that the problem of deciding S-primality for a given DFA is NL-hard. To do so, the NL-completeness of  $2\text{MINIMAL-DFA}$ , the basic problem of deciding minimality for a DFA with at most two letters, is proven.

## 1 Introduction

Under intersection compositionality a deterministic finite automaton (DFA)  $\mathcal{A}$  is *composite* if there exist DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  with  $\mathcal{L}(\mathcal{A}) = \bigcap_{i=1}^t \mathcal{L}(\mathcal{A}_i)$  such that the size of each  $\mathcal{A}_i$  is smaller than the index of  $\mathcal{A}$ . Otherwise,  $\mathcal{A}$  is *prime* [10]. The index of  $\mathcal{A}$  is the size of the minimal DFA recognizing the same language as  $\mathcal{A}$ .  $\text{PRIME-DFA}$  denotes the problem of deciding primality for a given DFA.  $\text{PRIME-DFA}_{\text{fin}}$  denotes the restriction of  $\text{PRIME-DFA}$  to DFAs recognizing a finite language.

Compositionality in general is a key concept in both practical and theoretical computer science [3, 16]. The intersection decomposition of finite automata can be motivated by LTL model checking as well as automaton identification. Both will be briefly discussed below.

The notion of intersection compositionality of finite automata was introduced in [10], while a limitation of this notion was already studied in [5]. Surprisingly, [10] found even the complexity of the basic problem  $\text{PRIME-DFA}$  to be open. They proved that  $\text{PRIME-DFA}$  is in  $\text{EXPSPACE}$  and is NL-hard. So far, this doubly exponential gap has not been closed.

Given the difficulties in tackling the general problem, it has proven fruitful to characterize the intersection compositionality of fragments of the regular languages [10, 8, 9]. Our study joins this line of research by completely characterizing the intersection compositionality of acyclic DFAs (ADFA) and thereby of finite languages. Further, we prove the NL-completeness of  $\text{PRIME-DFA}_{\text{fin}}$  and characterize the compositionality of finite languages under two different notions of compositionality suggested in [10], union and union-intersection compositionality.

Additionally, we present a proof of the NL-completeness of the basic problem 2MINIMAL-DFA, the problem of deciding minimality for a DFA with at most two letters. For arbitrary alphabets, the NL-hardness is a folklore result that seemingly has not been explicitly published but follows from the constructions in [2], while the NL-hardness of 2MINIMAL-DFA appears to be new [4]. We use this result to establish complexity boundaries for S-PRIME-DFA, a modification of PRIME-DFA using the size of the given DFA, not its index.

**Related Work.** The notion of intersection compositionality was introduced in [10], where the aforementioned complexity boundaries were established. They already considered language fragments, analyzing safety DFAs and permutation DFAs. This line of research was followed up in [8, 9], which focused on unary DFAs and permutation DFAs, respectively.

The intersection decomposition of automata can be motivated by LTL model checking, where the validity of a specification, given as an LTL formula, is checked for a system. The automata-based approach entails translating the specification into a finite automaton [17]. Since the LTL model checking problem is PSPACE-complete in the size of the LTL formula [1], it is desirable to decompose the formula into a conjunction of subformulas. This can also be understood as decomposing the finite automaton corresponding to the formula.

Another application of intersection decomposition arises in the field of automaton identification. The basic task here is, given a set of labeled words, to construct a finite automaton conforming to this set [6]. An interesting approach is to construct multiple automata instead of one, which can lead to smaller and more intuitive solutions [11].

An alternative notion of compositionality uses concatenation. Here, a language  $L$  is composite if there exist two non-trivial languages  $L_1, L_2$  with  $L = L_1L_2$ . The concatenation primality problem for regular languages is PSPACE-complete [12]. The restriction to finite languages is known to be NP-hard [15], while the conjectured NP-completeness of this restriction remains open [14, 13, 18].

**Contributions.** In Section 3 we completely characterize the intersection compositionality of ADFAs and thereby of finite languages. We expand on this by proving the NL-completeness of PRIME-DFA<sub>fin</sub> in Section 4, thus showing that finite languages are significantly easier to handle under intersection compositionality than under concatenation compositionality. We characterize the union and union-intersection compositionality of finite languages in Section 5, where we also prove the existence of languages that are union-intersection composite but both union prime and intersection prime.

In Section 6 we introduce the problem S-PRIME-DFA, which is analogous to PRIME-DFA but uses the size for the definition of compositionality, not the index. We prove that S-PRIME-DFA is in EXPSpace and is NL-hard. We also prove these boundaries for 2PRIME-DFA and 2S-PRIME-DFA, the restrictions of the respective problems to DFAs with at most two letters. To establish these boundaries we prove the NL-completeness of 2MINIMAL-DFA.

Detailed proofs of these results are provided in the appendix.

## 2 Preliminaries

A *deterministic finite automaton* (DFA) is a 5-tuple  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$ , where  $Q$  is a finite set of states,  $\Sigma$  is a finite non-empty alphabet,  $q_I \in Q$  is an initial state,  $\delta : Q \times \Sigma \rightarrow Q$  is a transition function, and  $F \subseteq Q$  is a set of accepting states. As usual, we extend  $\delta$  to words:  $\delta : Q \times \Sigma^* \rightarrow Q$  with  $\delta(q, \varepsilon) = q$  and  $\delta(q, \sigma_1 \dots \sigma_n) = \delta(\delta(q, \sigma_1 \dots \sigma_{n-1}), \sigma_n)$ . For  $q \in Q$ , the DFA  $\mathcal{A}^q$  is constructed out of  $\mathcal{A}$  by setting  $q$  as the initial state, thus  $\mathcal{A}^q = (Q, \Sigma, q, \delta, F)$ .

The *run* of  $\mathcal{A}$  on a word  $w = \sigma_1 \dots \sigma_n$  starting in state  $q$  is the sequence  $q_0, \sigma_1, q_1, \dots, \sigma_n, q_n$  with  $q_0 = q$  and  $q_i = \delta(q_{i-1}, \sigma_i)$  for each  $i \in \{1, \dots, n\}$ . The *initial run* of  $\mathcal{A}$  on  $w$  is the run of  $\mathcal{A}$  on  $w$  starting in  $q_I$ . The run of  $\mathcal{A}$  on  $w$  starting in  $q$

is *accepting* if  $q_n \in F$ , otherwise it is *rejecting*. The DFA  $\mathcal{A}$  *accepts*  $w$  if the initial run of  $\mathcal{A}$  on  $w$  is accepting. Otherwise, it *rejects*  $w$ . The *language*  $\mathcal{L}(\mathcal{A})$  of  $\mathcal{A}$  is the set of words accepted by  $\mathcal{A}$ . We say that  $\mathcal{A}$  *recognizes*  $\mathcal{L}(\mathcal{A})$ . A language is *regular* if there exists a DFA recognizing it. Since we only consider regular languages, we use the terms language and regular language interchangeably.

The *size*  $|\mathcal{A}|$  of  $\mathcal{A}$  is the number of states in  $Q$ . The DFA  $\mathcal{A}$  is *minimal* if  $\mathcal{L}(\mathcal{A}) \neq \mathcal{L}(\mathcal{B})$  holds for every DFA  $\mathcal{B}$  with  $|\mathcal{B}| < |\mathcal{A}|$ . It is well known that for every regular language  $L$  there exists a canonical minimal DFA recognizing  $L$ . The *index*  $\text{ind}(L)$  of  $L$  is the size of this canonical minimal DFA. The index of  $\mathcal{A}$  is the index of the language recognized by  $\mathcal{A}$ , thus  $\text{ind}(\mathcal{A}) = \text{ind}(\mathcal{L}(\mathcal{A}))$ . Note that  $\mathcal{A}$  is minimal iff  $|\mathcal{A}| = \text{ind}(\mathcal{A})$ .

We borrow a few terms from graph theory. Let  $q_0, \sigma_1, q_1, \dots, \sigma_n, q_n$  be the run of  $\mathcal{A}$  on  $w = \sigma_1 \dots \sigma_n$  starting in  $q_0$ . Then  $q_0, \dots, q_n$  is a *path* in  $\mathcal{A}$  from  $q_0$  to  $q_n$ . The *length* of this path is  $n$ . Thus, for two states  $q, q'$  there exists a path from  $q$  to  $q'$  in  $\mathcal{A}$  of length  $n$  iff there exists a  $w \in \Sigma^n$  with  $\delta(q, w) = q'$ . The state  $q'$  is *reachable from*  $q$  if there exists a path from  $q$  to  $q'$ . Otherwise,  $q'$  is *unreachable from*  $q$ . Obviously, if  $q'$  is reachable from  $q$  then there exists a path from  $q$  to  $q'$  of a length strictly smaller than  $|\mathcal{A}|$ . We say that  $q'$  is *reachable* if it is reachable from  $q_I$ . Otherwise, it is *unreachable*. A *cycle* in  $\mathcal{A}$  is a path  $q_0, \dots, q_n$  in  $\mathcal{A}$  where  $q_0 = q_n$  and  $n \in \mathbb{N}_{\geq 1}$ . The DFA  $\mathcal{A}$  is *acyclic* (ADFA) if every cycle in  $\mathcal{A}$  begins in a rejecting sink. Clearly, a DFA recognizes a finite language iff its minimal DFA is acyclic.

We call a DFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  *linear* if for every  $q, q' \in Q$  with  $q \neq q'$  either  $q'$  is reachable from  $q$  or  $q$  is reachable from  $q'$ , but not both. Thus, in a linear DFA reachability induces a linear order over the states. Obviously, every linear DFA has exactly one sink. Furthermore, a minimal ADFA  $\mathcal{A}$  is linear iff  $|\mathcal{A}| = n + 2$ , where  $n$  is the length of the longest word in  $\mathcal{L}(\mathcal{A})$ .

Consider a word  $w = \sigma_1 \dots \sigma_n \in \Sigma^n$ . A word  $wv$  with  $v \in \Sigma^+$  is an *extension* of  $w$ . A word  $\sigma_1 \dots \sigma_i \sigma_{i+l} \dots \sigma_n$  with  $i \in \{0, \dots, n-2\}, l \in \{2, \dots, n-i\}$  is a *compression* of  $w$ . An ADFA  $\mathcal{A}$  has the *compression-extension-property* (CEP) if for every  $w \in \mathcal{L}(\mathcal{A})$  with  $|w| = n$ , where  $n$  is the length of the longest word in  $\mathcal{L}(\mathcal{A})$ , there exists a compression  $w'$  of  $w$  such that every extension of  $w'$  is rejected by  $\mathcal{A}$ .

We introduce a type of DFA already inspected in [10]. A regular language  $L \subseteq \Sigma^*$  is a *safety language* if  $w \notin L$  implies  $wy \notin L$  for every  $y \in \Sigma^*$ . A DFA  $\mathcal{A}$  is a *safety DFA* if  $\mathcal{L}(\mathcal{A})$  is a safety language. A regular language  $L \subseteq \Sigma^*$  is a *co-safety language* if the complement language  $\bar{L}$  of  $L$  is a safety language. A DFA  $\mathcal{A}$  is a *co-safety DFA* if  $\mathcal{L}(\mathcal{A})$  is a co-safety language. Clearly, every non-trivial minimal safety DFA has exactly one rejecting state, and this state is a sink. Conversely, every non-trivial minimal co-safety DFA has exactly one accepting state, and this state is a sink.

We introduce the notions of intersection compositionality and primality of DFAs and languages, following the definitions in [10]:

► **Definition 2.1.** For  $k \in \mathbb{N}_{\geq 1}$ , a DFA  $\mathcal{A}$  is *k-decomposable* if there exist DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  with  $\mathcal{L}(\mathcal{A}) = \bigcap_{i=1}^t \mathcal{L}(\mathcal{A}_i)$  and  $|\mathcal{A}_i| \leq k$  for each  $i \in \{1, \dots, t\}$ , where  $t \in \mathbb{N}_{\geq 1}$ . We call such DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  a *k-decomposition* of  $\mathcal{A}$ . We call  $\mathcal{A}$  *composite* if  $\mathcal{A}$  is *k-decomposable* for a  $k < \text{ind}(\mathcal{A})$ , that is, if it is  $(\text{ind}(\mathcal{A}) - 1)$ -decomposable. Otherwise, we call  $\mathcal{A}$  *prime*. ◻

We use compositionality or  $\cap$ -compositionality when referring to intersection compositionality.

When analyzing the compositionality of a given DFA  $\mathcal{A}$ , it is sufficient to consider minimal DFAs  $\mathcal{B}$  strictly smaller than the minimal DFA of  $\mathcal{A}$  with  $\mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}(\mathcal{B})$ . Thus, we define  $\alpha(\mathcal{A}) = \{\mathcal{B} \mid \mathcal{B} \text{ is a minimal DFA with } \text{ind}(\mathcal{B}) < \text{ind}(\mathcal{A}) \text{ and } \mathcal{L}(\mathcal{A}) \subseteq \mathcal{L}(\mathcal{B})\}$ . Obviously, the DFA  $\mathcal{A}$  is composite iff  $\mathcal{L}(\mathcal{A}) = \bigcap_{\mathcal{B} \in \alpha(\mathcal{A})} \mathcal{L}(\mathcal{B})$ . We call a word  $w \in (\bigcap_{\mathcal{B} \in \alpha(\mathcal{A})} \mathcal{L}(\mathcal{B})) \setminus \mathcal{L}(\mathcal{A})$  a *primality witness* of  $\mathcal{A}$ . Clearly, the DFA  $\mathcal{A}$  is composite iff  $\mathcal{A}$  has no primality witness.

We extend the notions of  $k$ -decompositions, compositionality, primality and primality witnesses to regular languages by identifying a regular language with its minimal DFA.

We denote the problem of deciding primality for a given DFA with PRIME-DFA. We denote the restriction of PRIME-DFA to DFAs recognizing finite languages with PRIME-DFA<sub>fin</sub>. PRIME-DFA is in EXPSPACE and is NL-hard [10].

We denote the connectivity problem in directed graphs, which is NL-complete [7], with STCON. We denote the restriction of STCON to graphs with a maximum outdegree of two with 2STCON. Clearly, 2STCON is NL-complete as well. We denote the problem of deciding minimality for a given DFA with MINIMAL-DFA. For  $k \in \mathbb{N}_{\geq 2}$ , the problem  $k$ MINIMAL-DFA is the restriction of MINIMAL-DFA to DFAs with at most  $k$  letters. As mentioned in Section 1, the NL-completeness of  $k$ MINIMAL-DFA for  $k \in \mathbb{N}_{\geq 3}$  is folklore, while the NL-hardness of 2MINIMAL-DFA appears to be open.

### 3 Compositionality of Finite Languages

We characterize the compositionality of ADFAs and thereby of finite languages by proving:

► **Theorem 3.1.** *Consider a minimal ADFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  recognizing a non-empty language. Then  $\mathcal{A}$  is prime iff  $\mathcal{A}$  is linear and:*

- (i)  $\sigma^n \in \mathcal{L}(\mathcal{A})$  for some  $\sigma \in \Sigma$ , where  $n \in \mathbb{N}$  is the length of the longest word in  $\mathcal{L}(\mathcal{A})$ , or
- (ii)  $\mathcal{A}$  is a safety DFA and  $\mathcal{A}$  does not have the CEP. ┘

To prove Theorem 3.1 we will consider five cases in turn.

First, if the ADFA  $\mathcal{A}$  is not linear we essentially have a surplus of states, allowing us to construct one DFA rejecting overlong words and one specific DFA for each of the remaining words also rejected by  $\mathcal{A}$ . This approach fails with linear ADFAs. Nevertheless, we will come back to the idea of excluding words longer than a threshold value and tailoring a DFA for each word shorter than the threshold value which has to be rejected as well.

Second, if  $\mathcal{A}$  is linear and  $\sigma^n \in \mathcal{L}(\mathcal{A})$  holds the DFAs in  $\alpha(\mathcal{A})$  do not possess enough states to differentiate the words  $\sigma^0, \dots, \sigma^n$  but have to accept  $\sigma^n$ , which implies cyclic behavior on the words in  $\{\sigma\}^*$  from which primality follows.

Third, if there is no  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  and  $\mathcal{A}$  is not a safety DFA we can return to the idea of excluding words longer than a threshold value. For each of the words left to reject, it is possible to construct a DFA similar to  $\mathcal{A}$  but without the rejecting sink, which circles back to the rejecting non-sink.

Fourth, if there is no  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  and  $\mathcal{A}$  has the CEP we can utilize DFAs similar to  $\mathcal{A}$  possessing a rejecting sink, since the CEP allows us to skip over one state.

Fifth and finally, if  $\mathcal{A}$  is linear and  $\mathcal{A}$  is a safety DFA and does not have the CEP both of the above approaches fail. There is no state to circle back to, and for the word breaching the CEP skipping over states is not possible either, which implies primality.

Formalizing these five cases, we get:

▷ **Claim 3.2.** Consider a minimal ADFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  recognizing a non-empty language. Let  $n \in \mathbb{N}$  be the length of the longest word in  $\mathcal{L}(\mathcal{A})$ . The following assertions hold:

- (a)  $\mathcal{A}$  is composite if  $\mathcal{A}$  is not linear.
- (b)  $\mathcal{A}$  is prime if  $\mathcal{A}$  is linear and  $\sigma^n \in \mathcal{L}(\mathcal{A})$  holds for some  $\sigma \in \Sigma$ .
- (c)  $\mathcal{A}$  is composite if there is no  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  and  $\mathcal{A}$  is not a safety DFA.
- (d)  $\mathcal{A}$  is composite if there is no  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  and  $\mathcal{A}$  has the CEP.
- (e)  $\mathcal{A}$  is prime if  $\mathcal{A}$  is linear and  $\mathcal{A}$  is a safety DFA and  $\mathcal{A}$  does not have the CEP. ┘

Formalizing the intuition given above for (a) and (b) is not too complex. Assertions (c)–(e) prove to be much harder. Thus, we commence by discussing (c) in Section 3.1 and (d) and (e) in Section 3.2. Henceforth, we consider a minimal ADFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  recognizing the non-empty language  $L$  with  $\sigma^n \notin L$  for each  $\sigma \in \Sigma$ , where  $n \in \mathbb{N}$  is the length of the longest word in  $L$ . W.l.o.g. we assume  $Q = \{q_0, \dots, q_{n+1}\}$  with  $q_j$  being reachable from  $q_i$  for all  $i < j$ , which implies  $q_I = q_0$  and  $q_n \in F$  with  $q_{n+1}$  being the rejecting sink. Finally, we define  $\Sigma_{i,j} = \{\sigma \in \Sigma \mid \delta(q_i, \sigma) = q_j\}$ .

### 3.1 Linear non-safety ADFAs

We consider Claim 3.2 (c). Therefore, we assume that  $\mathcal{A}$  is not a safety DFA, which implies  $\{q_n\} \subseteq F \subset Q \setminus \{q_{n+1}\}$ . Let  $d \in \{0, \dots, n-1\}$  with  $q_d \notin F$ .

We show the compositionality of  $\mathcal{A}$  by specifying an  $(n+1)$ -decomposition of  $\mathcal{A}$ . First, we construct DFAs rejecting words not in  $L$  that are not extensions of words  $u \in L, |u| = n$ . Afterwards, we turn to such extensions, whose handling poses the main difficulty. Here, we first construct DFAs rejecting such extensions that are longer than a certain threshold value. For the remaining extensions we employ the idea of circling back to  $q_d$ .

We begin by considering words not in  $L$  which are not extensions of words  $u \in L, |u| = n$ . We introduce three DFA types handling these words.

First, let  $\mathcal{A}_0$  be the DFA constructed out of  $\mathcal{A}$  by removing  $q_n$ , redirecting every transition  $q \rightarrow q_n$  to  $q_0$ , and including  $q_0$  into the acceptance set. Clearly,  $\mathcal{A}_0 \in \alpha(\mathcal{A})$  and  $\mathcal{A}_0$  rejects every  $w \notin L$  on which  $\mathcal{A}$  enters the rejecting sink prematurely, that is, without entering  $q_n$ .

Second, let  $\hat{\mathcal{A}}_d$  be the DFA constructed out of  $\mathcal{A}$  by removing  $q_{n+1}$ , redirecting every transition  $q_i \rightarrow q_{n+1}$  with  $i < n$  to  $q_n$  and every transition  $q_n \rightarrow q_{n+1}$  to  $q_d$ . Clearly,  $\hat{\mathcal{A}}_d \in \alpha(\mathcal{A})$  and  $\hat{\mathcal{A}}_d$  rejects every  $w \notin L$  on which  $\mathcal{A}$  does not enter the rejecting sink.

Third, we construct DFAs rejecting extensions of words  $w \in L, |w| < n$  with  $\delta(q_0, w) = q_n$ . Let  $I = \{0, \dots, n\}$ . For each  $m \in \{1, \dots, n-1\}$  let  $I_m = \{(i_0, \dots, i_m) \in I^{m+1} \mid 0 = i_0 < \dots < i_m = n\}$ . For each  $\underline{i} \in I_m$  define  $\mathcal{A}_{\underline{i}}$  as in Figures 1a and 1b. It is easy to confirm that each  $\mathcal{A}_{\underline{i}}$  is in  $\alpha(\mathcal{A})$  and rejects extensions of words on which  $\mathcal{A}$  visits the states  $q_{i_0}, \dots, q_{i_m}$ .

Lemma 3.3 formalizes the results concerning  $\mathcal{A}_0, \hat{\mathcal{A}}_d$  and  $\mathcal{A}_{\underline{i}}$ :

► **Lemma 3.3.** *The following assertions hold:*

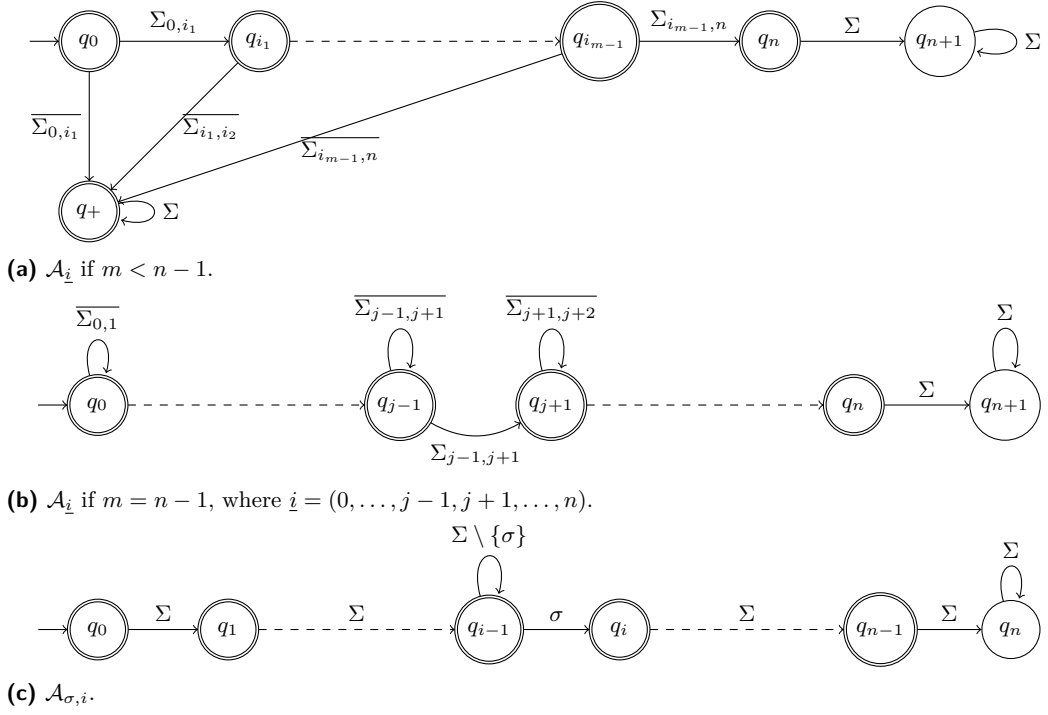

- (i)  $\mathcal{A}_0, \hat{\mathcal{A}}_d, \mathcal{A}_{\underline{i}} \in \alpha(\mathcal{A})$ , where  $\underline{i} \in \bigcup_{m=1}^{n-1} I_m$ .
- (ii) Consider a word  $w \notin L$ , where  $w$  is not an extension of a word  $u \in L, |u| = n$ . Then  $w \notin \mathcal{L}(\mathcal{A}_0) \cap \mathcal{L}(\hat{\mathcal{A}}_d) \cap \bigcap_{m=1}^{n-1} \bigcap_{\underline{i} \in I_m} \mathcal{L}(\mathcal{A}_{\underline{i}})$  holds. ◻

Next, we turn to the extensions of words  $u \in L, |u| = n$ . We begin by constructing DFAs that taken together reject every word strictly longer than  $n + (n-2)$ . Then we turn to the remaining extensions one by one, of which only a finite number are left to reject.

Let  $\sigma \in \Sigma$ . Since  $\sigma^n \notin L$ , there exists a value  $i \in \{1, \dots, n\}$  with  $\sigma \notin \Sigma_{i-1,i}$ . Define  $\mathcal{A}_{\sigma,i}$  as in Figure 1c. First, note that  $\mathcal{A}_{\sigma,i} \in \alpha(\mathcal{A})$  because a word rejected by  $\mathcal{A}_{\sigma,i}$  is strictly longer than  $n$  or is of length  $n$  with letter  $\sigma$  at position  $i$ . Next, consider a word  $w = \sigma_1 \dots \sigma_m \in \Sigma^m$  such that  $\sigma_j = \sigma$  for a  $j \in \{1, \dots, m\}$  with  $j \geq i$  and  $m \geq j + (n-i)$ . After reading the prefix  $\sigma_1 \dots \sigma_{j-1}$  the DFA  $\mathcal{A}_{\sigma,i}$  is at least in state  $q_{i-1}$ . Thus, after reading  $\sigma_1 \dots \sigma_j$  it is at least in state  $q_i$  and will reject after reading  $n-i$  more letters. Since  $m \geq j + (n-i)$ , we have  $w \notin \mathcal{L}(\mathcal{A}_{\sigma,i})$ . Lemma 3.4 formalizes this result:

► **Lemma 3.4.** *Let  $\sigma \in \Sigma$  and  $i \in \{1, \dots, n\}$  with  $\sigma \notin \Sigma_{i-1,i}$ . The following assertions hold:*

- (i)  $\mathcal{A}_{\sigma,i} \in \alpha(\mathcal{A})$ .
- (ii) Let  $m \in \mathbb{N}$ . Let  $w \in \sigma_1 \dots \sigma_m \in \Sigma^m$  such that  $\sigma_j = \sigma$  for a  $j \in \{1, \dots, m\}$  with  $j \geq i$  and  $m \geq j + (n-i)$ . Then  $w$  is rejected by  $\mathcal{A}_{\sigma,i}$ . ◻

■ **Figure 1** DFA  $\mathcal{A}_{\underline{i}}$  for  $\underline{i} \in I_m$  with  $m \in \{1, \dots, n - 1\}$  and DFA  $\mathcal{A}_{\sigma, i}$  for  $\sigma \in \Sigma, i \in \{1, \dots, n\}$ .

Now consider a word  $w = \sigma_1 \dots \sigma_m \in \Sigma^m$  with  $m \geq n + (n - 1)$  and  $\sigma_1 \dots \sigma_n \in L$ . Note that Lemma 3.4 implies  $w \notin \mathcal{L}(\mathcal{A}_{\sigma_n, i})$  where  $i \in \{1, \dots, n\}$  with  $\sigma_n \notin \Sigma_{i-1, i}$ . With this limitation of length, we only need DFAs to reject the extensions of words  $u \in L, |u| = n$  with a maximum length of  $n + (n - 2)$ . Consider such an extension  $w = \sigma_1 \dots \sigma_m \in \Sigma^m$ . That is,  $n + 1 \leq m \leq n + (n - 2)$  and  $\sigma_1 \dots \sigma_n \in L$ . This implies  $\sigma_i \in \Sigma_{i-1, i}$  for each  $i \in \{1, \dots, n\}$  but provides no information about the  $\sigma_i$  with  $i \in \{n + 1, \dots, m\}$ . Therefore, we construct DFAs rejecting every such extension not confirming to a certain structure. This structure will be key to the further DFA constructions.

For a word  $w \in \Sigma^*$ , let  $\mathcal{A}_w^!$  be the DFA rejecting exactly the words containing  $w$  as a subsequence. Clearly, the following holds:

► **Lemma 3.5.** *Let  $w \notin L, |w| = n$ . Then  $\mathcal{A}_w^! \in \alpha(\mathcal{A})$  holds.* ◻

With the DFAs  $\mathcal{A}_w^!$  for every  $w \notin L, |w| = n$  in hand, we only have to consider extensions of words  $u \in L, |u| = n$  with a maximum length of  $n + (n - 2)$  for which every subsequence of length  $n$  is in  $L$ .

Let  $w = \sigma_1 \dots \sigma_m$  be an extension satisfying these conditions. We construct a DFA  $\tilde{\mathcal{A}}_w \in \alpha(\mathcal{A})$  rejecting  $w$ . We utilize the rejecting state  $q_d$  and define  $\tilde{\mathcal{A}}_w = (\tilde{Q}_w, \Sigma, q_0, \tilde{\delta}_w, \tilde{F}_w)$  with  $\tilde{Q}_w = \{q_0, \dots, q_n\}$ ,  $\tilde{F}_w = \tilde{Q}_w \setminus \{q_d\}$  and  $\tilde{\delta}_w(q_0, w) = q_d$ . Further, we have  $\tilde{\delta}_w(q_0, v) = q_d$  for a  $v \in \Sigma^*$  only if  $\delta(q_0, v) \in \{q_d, q_{n+1}\}$ , ensuring  $\tilde{\mathcal{A}}_w \in \alpha(\mathcal{A})$ . In order to utilize  $q_d$  in this manner, the DFA  $\tilde{\mathcal{A}}_w$  simulates the behavior of  $\mathcal{A}$  for the states  $q_0, \dots, q_{d-1}$ . The task then is to select the transitions of states  $q_d, \dots, q_n$ .

If  $|\sigma_{d+1} \dots \sigma_m|_{\sigma_m} \leq n - d$  the DFA  $\tilde{\mathcal{A}}_w$  can simply advance for occurrences of  $\sigma_m$  and the first  $n - d - |\sigma_{d+1} \dots \sigma_{m-1}|_{\sigma_m}$  occurrences of letters unequal to  $\sigma_m$ . Thus, we only have to consider the case  $|\sigma_{d+1} \dots \sigma_m|_{\sigma_m} > n - d$ .

If  $\sigma_{n+1} \neq \sigma_m$  the DFA  $\tilde{\mathcal{A}}_w$  can advance for each letter in  $\Sigma$ , ensuring  $\tilde{\delta}_w(q_d, \sigma_{d+1} \dots \sigma_n) = q_n$ . Further, we can define  $\tilde{\delta}_w(q_n, \sigma_{n+1}) = q_{n-[(m-1)-(n+2)+1]}$  and  $\tilde{\delta}_w(q_n, \sigma_m) = q_d$ . Note that  $|\sigma_{n+2} \dots \sigma_{m-1}| = (m-1) - (n+2) + 1$ . Since every subsequence of  $w$  of length  $n$  is in  $L$ , we have  $\tilde{\delta}_w(q_{n-[(m-1)-(n+2)+1]}, \sigma_{n+2} \dots \sigma_{m-1}) = q_n$ .

The case  $\sigma_{n+1} = \sigma_m$  is more complex and needs a further case distinction, but the idea used above of circling back after reading an appropriate prefix can be employed again.

Lemma 3.6 summarizes these ideas:

► **Lemma 3.6.** *Let  $w \in \Sigma^*$  with  $|w| > n$  such that  $w \in \mathcal{L}(\mathcal{A}_v^!)$  for each  $v \notin L$ ,  $|v| = n$  and  $w \in \bigcap_{\sigma \in \Sigma} \mathcal{L}(\mathcal{A}_{\sigma, i_\sigma})$ , where for each  $\sigma \in \Sigma$  it is  $i_\sigma = \max(\{i \in \{1, \dots, n\} \mid \sigma \notin \Sigma_{i-1, i}\})$ . Then there exists a DFA  $\tilde{\mathcal{A}}_w \in \alpha(\mathcal{A})$  rejecting  $w$ .  $\lrcorner$*

Lemmas 3.3–3.6 imply Claim 3.2 (c). To be more precise, we have  $\mathcal{L}(\mathcal{A}) = \mathcal{L}(\mathcal{A}_0) \cap \mathcal{L}(\tilde{\mathcal{A}}_d) \cap \bigcap_{m=1}^{n-1} \bigcap_{i \in I_m} \mathcal{L}(\mathcal{A}_i) \cap \bigcap_{\sigma \in \Sigma} \mathcal{L}(\mathcal{A}_{\sigma, i_\sigma}) \cap \bigcap_{w \in X^!} \mathcal{L}(\mathcal{A}_w^!) \cap \bigcap_{w \in \tilde{X}} \mathcal{L}(\tilde{\mathcal{A}}_w)$ , where  $X^! = \{w \in \Sigma^n \mid w \notin L\}$  and  $\tilde{X}$  is the set of all extensions  $w$  of words  $u \in L$ ,  $|u| = n$  with  $|w| \leq n + (n-2)$  for which every subsequence of length  $n$  is in  $L$ . This proves the compositionality of  $\mathcal{A}$  and thereby Claim 3.2 (c).

### 3.2 Linear safety ADFAs

Next, we consider Claim 3.2 (d) and (e). For (d) we argue that  $\mathcal{A}$  is composite if it has the CEP, even if  $\mathcal{A}$  is a safety DFA, which makes circling back impossible. For (e) we argue that  $\mathcal{A}$  is prime if it is a safety DFA and it does not have the CEP.

First, we consider (d). We assume that  $\mathcal{A}$  has the CEP and argue that this implies compositionality. Note that we can reuse the DFAs  $\mathcal{A}_0$  and  $\mathcal{A}_i$ , while  $\tilde{\mathcal{A}}_d$  is not needed. This again leaves the task of rejecting the extensions of words  $w \in L$ ,  $|w| = n$ . But, since for every such word  $w = \sigma_1 \dots \sigma_n$  there now exist  $i \in \{0, \dots, n-2\}$ ,  $l \in \{2, \dots, n-i\}$  such that  $\delta(q_0, \sigma_1 \dots \sigma_i \sigma_{i+l} \dots \sigma_n) \in \{q_n, q_{n+1}\}$ , we can construct a DFA  $\mathcal{A}_{i,l} \in \alpha(\mathcal{A})$  rejecting every extension of  $w$ .

The DFA  $\mathcal{A}_{i,l}$  possesses states  $q_0, \dots, q_{i+l-2}, q_{i+l}, \dots, q_{n+1}$ . It simulates the behavior of  $\mathcal{A}$  for states  $q_0, \dots, q_{i-1}$ , redirecting transitions  $q_j \rightarrow q_{i+l-1}$  to  $q_i$ . From  $q_i$  it directly advances to  $q_{i+l}$  if a letter in  $\bigcup_{j=i+l}^{n+1} \Sigma_{i,j}$  is read, otherwise it advances to  $q_{i+1}$ . The states  $q_i, \dots, q_{i+l-2}$  form a loop. For states  $q_{i+l}, \dots, q_n$ , every transition leads to the direct successor state. The state  $q_{n+1}$  is a rejecting sink.

It is shown in the appendix that every extension of  $w$  is rejected by  $\mathcal{A}_{i,l}$ , where  $i$  is the largest possible value belonging to  $w$ , and that  $\mathcal{A}_{i,l} \in \alpha(\mathcal{A})$ . Thus,  $\mathcal{L}(\mathcal{A}) = \mathcal{L}(\mathcal{A}_0) \cap \bigcap_{m=1}^{n-1} \bigcap_{i \in I_m} \mathcal{L}(\mathcal{A}_i) \cap \bigcap_{i=0}^{n-2} \bigcap_{l=2}^{n-i} \mathcal{A}_{i,l}$  holds, proving the compositionality of  $\mathcal{A}$  and thus (d).

Next, we consider (e) and assume that  $\mathcal{A}$  is a safety DFA and does not have the CEP. Thus, there is a  $w = \sigma_1 \dots \sigma_n$  such that  $\delta(q_0, \sigma_1 \dots \sigma_i \sigma_{i+l} \dots \sigma_n) \notin \{q_n, q_{n+1}\}$  holds for every  $i \in \{0, \dots, n-2\}$ ,  $l \in \{2, \dots, n-i\}$ . This implies the existence of a letter  $\sigma \in \Sigma_{n-1, n}$  with  $\sigma \notin \Sigma_{j, n+1}$  for every  $j \in \{0, \dots, n-1\}$ . We show in the appendix that  $w\sigma$  is a primality witness of  $\mathcal{A}$ , thus proving the primality of  $\mathcal{A}$  and thereby (e).

This completes our discussion of Claim 3.2 (a)–(e). Since they imply Theorem 3.1, we have characterized the compositionality of ADFAs and thereby of finite languages.

## 4 Complexity of Prime-DFA<sub>fin</sub>

After characterizing the compositionality of ADFAs and thereby of finite languages in Section 3, we now analyze the complexity of PRIME-DFA<sub>fin</sub>. We argue:

► **Theorem 4.1.** *The problem PRIME-DFA<sub>fin</sub> is NL-complete. The NL-completeness holds true even when restricting PRIME-DFA<sub>fin</sub> to DFAs with at most two letters.  $\lrcorner$*

■ **Algorithm 1** NL-algorithm for PRIME-DFA<sub>fin</sub>.

---

**Require:** DFA  $\mathcal{A} = (Q, \Sigma, q_0, \delta, F)$  with  $Q = \{q_0, \dots, q_m\}$  recognizing a finite language  $L$ .  
**Ensure:** The DFA  $\mathcal{A}$  is prime.

- 1: Accept if  $L = \emptyset$ .
- 2:  $c \leftarrow 0$
- 3: **for all**  $i \in \{0, \dots, m\}$  **do**
- 4:   **if**  $q_i$  is unreachable **then**

---

We begin by arguing that PRIME-DFA<sub>fin</sub> is in NL, providing an NL-algorithm for PRIME-DFA<sub>fin</sub> with Algorithm 1. The algorithm accepts in line 1 if the given DFA  $\mathcal{A}$  recognizes the empty language. Then lines 2-18 ensure that the minimal DFA belonging to  $\mathcal{A}$  is linear. Lines 19-22 ensure that  $\mathcal{A}$  is accepted if a letter  $\sigma \in \Sigma$  with  $\sigma^n \in L$  exists or else that  $\mathcal{A}$  is rejected if it is not a safety DFA. Finally, in lines 23-29 the CEP is checked for  $\mathcal{A}$ .

The NL-hardness of PRIME-DFA<sub>fin</sub> can be proven by L-reducing STCONDAG to PRIME-DFA<sub>fin</sub>, where STCONDAG is the restriction of STCON to acyclic graphs. The L-reduction is similar to the L-reduction of STCON to the emptiness problem for DFAs.

## 5 Finite Languages under Different Notions of Compositionality

So far, we have only considered  $\cap$ -compositionality. Now we will define two further notions of compositionality and characterize the compositionality of finite languages for these notions.

► **Definition 5.1.** For  $k \in \mathbb{N}_{\geq 1}$ , a DFA  $\mathcal{A}$  is  $k$ - $\cup$ -decomposable ( $k$ -DNF-decomposable) if there exist DFAs  $\mathcal{A}_1, \dots, \mathcal{A}_t$  ( $\mathcal{A}_{1,1}, \dots, \mathcal{A}_{1,t_1}, \dots, \mathcal{A}_{s,1}, \dots, \mathcal{A}_{s,t_s}$ ) with  $\mathcal{L}(\mathcal{A}) = \bigcup_{i=1}^t \mathcal{L}(\mathcal{A}_i)$  ( $\mathcal{L}(\mathcal{A}) = \bigcup_{i=1}^s \bigcap_{j=1}^{t_i} \mathcal{L}(\mathcal{A}_{i,j})$ ) and  $|\mathcal{A}_i| < k$  for every  $i$  ( $|\mathcal{A}_{i,j}| < k$  for every pair  $i, j$ ). The further concepts introduced in Definition 2.1 are defined analogously. ◻

In [10], it is correctly remarked that many results for  $\cap$ -compositionality can be trivially transferred to  $\cup$ -compositionality. For example, the complexity boundaries for PRIME-DFA established in [10] also hold for  $\cup$ -compositionality. This does not hold true for results concerning language fragments that are not closed under complement. In particular, the complement language of a finite language is not finite, but co-finite. Thus, characterizing the  $\cup$ -compositionality of finite languages is equivalent to characterizing  $\cap$ -compositionality of co-finite languages.

Also in [10], the notion of compositionality allowing both union and intersection is suggested. Note that DNF-compositionality enforces a structure similar to a disjunctive normal form, but is as strong as unrestricted union-intersection compositionality. It is correctly remarked in [10] that union-intersection compositionality - and thus, DNF-compositionality - is strictly stronger than  $\cap$ -compositionality. Obviously, it is also strictly stronger than  $\cup$ -compositionality. It is less obvious whether languages exist that are DNF-composite, but are neither  $\cap$ - nor  $\cup$ -composite. We will see that there are finite languages witnessing this.

The following result characterizes the  $\cup$ - and DNF-compositionality of finite languages:

► **Theorem 5.2.** Consider a minimal A DFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  recognizing a non-empty language. Let  $n \in \mathbb{N}$  be the length of the longest word in  $\mathcal{L}(\mathcal{A})$ . The following assertions hold:

- (i)  $\mathcal{A}$  is  $\cup$ -prime iff  $\mathcal{A}$  is linear.
- (ii)  $\mathcal{A}$  is DNF-prime iff  $\mathcal{A}$  is linear and there exists a  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$ . ◻

These conditions are similar to the conditions in Theorem 3.1, but much simpler. Let  $\mathcal{A}$  and  $n$  be as required. It is easy to show  $\cup$ - and DNF-compositionality if  $\mathcal{A}$  is not linear.

The proof of  $\cup$ -primality if  $\mathcal{A}$  is linear relies on the observation that every minimal DFA  $\mathcal{B}$  with  $\mathcal{L}(\mathcal{B}) \subseteq \mathcal{L}(\mathcal{A})$  and  $\text{ind}(\mathcal{B}) < \text{ind}(\mathcal{A})$  has to have a rejecting sink. From this follows that no such DFA  $\mathcal{B}$  can accept a word  $w \in \mathcal{L}(\mathcal{A})$ ,  $|w| = n$ . Thus,  $\mathcal{A}$  is  $\cup$ -prime.

If  $\mathcal{A}$  is linear and there exists no  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  the DNF-compositionality of  $\mathcal{A}$  follows from [10, Example 3.2]. On the other hand, if  $\mathcal{A}$  is linear and there exists a  $\sigma \in \Sigma$  with  $\sigma^n \in \mathcal{L}(\mathcal{A})$  DNF-primality can be shown by adapting the proof of Claim 3.2 (b).

As mentioned, Theorems 3.1 and 5.2 immediately imply:

► **Theorem 5.3.** There exists a finite language that is DNF-composite but  $\cap$ - and  $\cup$ -prime. ◻

To summarize, Theorems 3.1 and 5.2 characterize the  $\cap$ -,  $\cup$ - and DNF-compositionality of ADFAs and thus of finite languages. Obviously, this characterizes the  $\cap$ -,  $\cup$ - and DNF-compositionality of co-finite languages as well. The results further imply the existence of languages that are DNF-composite but  $\cap$ - and  $\cup$ -prime.

## 6 2Minimal-DFA and S-Prime-DFA

We defined compositionality using the index of the given DFA. Thus, the compositionality of a DFA  $\mathcal{A}$  is a characteristic of  $\mathcal{L}(\mathcal{A})$ . Slightly changing the definition, using the size instead of the index, turns compositionality of  $\mathcal{A}$  into a characteristic of  $\mathcal{A}$  itself. It is interesting to analyze the effects of this change, which results in the notion of S-compositionality.

Many results known for compositionality hold for S-compositionality as well. The characterization of finite languages in Section 3 and other results concerning language fragments [10, 8, 9] are valid with only minor technical modifications. In fact, [8, 9]

already implicitly used S-compositionality instead of compositionality without discussing the differences. The upper complexity boundary of PRIME-DFA holds for S-PRIME-DFA as well. But the known lower boundary, the NL-hardness of PRIME-DFA, cannot simply be adapted for S-PRIME-DFA. The lower boundary for S-PRIME-DFA is connected to MINIMAL-DFA, since non-minimal DFAs are trivially S-composite. Note that PRIME-DFA is connected to the emptiness problem for DFAs in a similar manner [10].

We begin by discussing MINIMAL-DFA, proving the NL-hardness of 2MINIMAL-DFA. Then we formally introduce S-compositionality and prove the NL-hardness of the restriction 2S-PRIME-DFA and thereby of S-PRIME-DFA as well. We also prove the NL-hardness of the restriction 2PRIME-DFA, so far only known for the unrestricted problem PRIME-DFA.

## 6.1 NL-hardness of 2Minimal-DFA

As mentioned, the NL-hardness and thus NL-completeness of  $k$ MINIMAL-DFA for  $k \in \mathbb{N}_{\geq 3}$  is folklore, while the NL-hardness of 2MINIMAL-DFA appears to be open. We prove:

► **Theorem 6.1.** *The problem 2MINIMAL-DFA is NL-hard and thus NL-complete.* ◻

The NL-hardness of 3MINIMAL-DFA can be proven by L-reducing 2STCON to 3MINIMAL-DFA. This known reduction uses an additional letter and cannot be used to prove the NL-hardness of 2MINIMAL-DFA. We give an L-reduction of 2STCON not using an additional letter, proving the NL-hardness and thus the NL-completeness of 2MINIMAL-DFA.

Let  $(G, s, t)$  be an input for 2STCON. That is,  $G = (V, E)$  is a graph with a maximum outdegree of two and  $s, t \in V$  are nodes of  $G$ . We construct a DFA  $\mathcal{A} = (Q, \Sigma, q_I, \delta, F)$  with  $\Sigma = \{0, 1\}$ , which is minimal iff there exists a path in  $G$  from  $s$  to  $t$ . If  $s = t$  such a path exists trivially and we can construct the minimal DFA for the empty language. Thus, we only have to consider the case  $s \neq t$ . W.l.o.g. we assume  $V = \{0, \dots, n-1\}$  and  $s = 0, t = n-1$ .

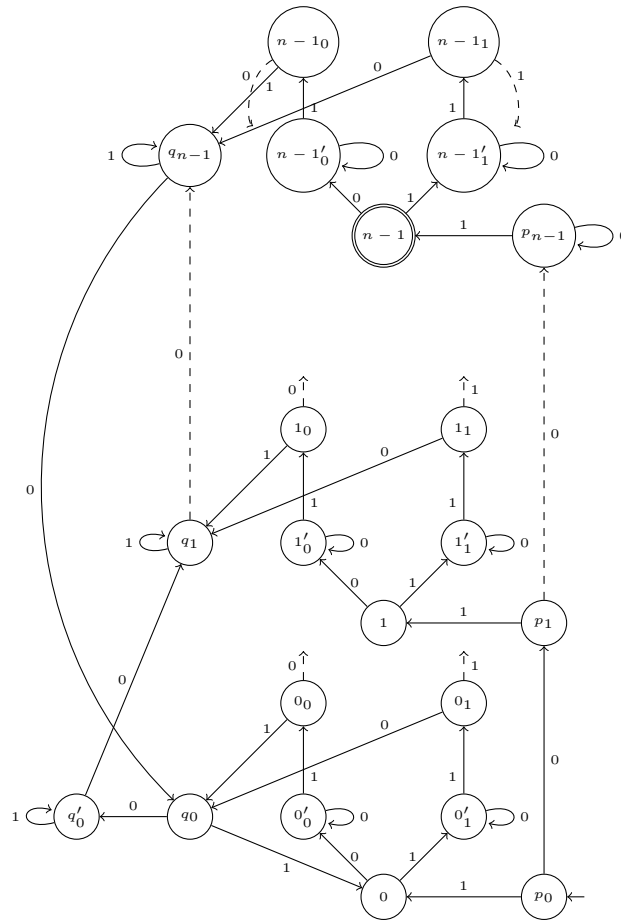

Let  $\mathcal{A}' = (Q', \Sigma, 0, \delta', F')$  be the DFA constructed out of  $G$  in the usual manner, that is, by turning nodes into states, edges into transitions, setting the state 0 as the initial state and  $n-1$  as the only accepting state. For  $\mathcal{A}$ , we introduce the new states  $p_0, \dots, p_{n-1}$ , called  $p$ -states, the new states  $q_0, \dots, q_{n-1}$  and  $q'_0$ , called  $q$ -states, and for each  $i \in Q'$  the states  $i'_0, i'_1, i_0, i_1$ . We call the states  $i, i'_0, i'_1, i_0, i_1$  for  $i \in Q'$   $v$ -states. We say that states  $p_i, q_i, i, i'_0, i'_1, i_0, i_1$  for an  $i \in Q'$  are located on the same layer. Figure 2 specifies the DFA  $\mathcal{A}$  constructed for the L-reduction. We now discuss the key ideas of this construction.

First, note that the idea of the  $p$ - and  $q$ -states is similar to the known L-reduction of 2STCON to 3MINIMAL-DFA. The  $p$ -states are used to access every state in  $Q$ , thus avoiding unreachable states. The  $q$ -states are used to allow the return to 0 from every state.

Second, we cannot use an additional letter to switch from  $p_i$  to  $i$  to  $q_i$ . Thus, letter 1 is used to leave the  $p$ -states and to exit  $q_0$  to state 0. Letter 0 is used to advance to the next layer in both the  $p$ - and  $q$ -states. To allow switching from the  $v$ -states to the  $q$ -states, we introduce for each  $i \in Q'$  a component consisting of  $i$  and the two branches  $i'_0, i_0$  and  $i'_1, i_1$ . The states  $i'_0, i'_1$  are waiting states used to prove the non-equivalence of  $q$ - and  $v$ -states. The states  $i_0, i_1$  implement on the one hand the original transitions in  $\mathcal{A}'$ , that is,  $\delta(i_j, j) = \delta'(i, j)$ , and on the other hand the transitions into the  $q$ -states, that is,  $\delta(i_j, 1-j) = q_i$ .

Third, an extra  $q$ -state  $q'_0$  is introduced, which is only directly accessible from  $q_0$ . Without  $q'_0$  the situation  $\delta(1_1, 1) = 0 = \delta(q_0, 1)$  and  $\delta(1_1, 0) = q_1 = \delta(q_0, 0)$  would be possible, immediately implying the non-minimality of  $\mathcal{A}$ . The introduction of  $q'_0$  solves this problem.

Note that there is a path from 0 to  $n-1$  in  $\mathcal{A}$  iff there is such a path in  $G$ . Using this it follows that  $\mathcal{A}$  is minimal iff there exists a path from 0 to  $n-1$  in  $G$ . Since  $\mathcal{A}$  can obviously be constructed in logarithmic space, the given construction is indeed an L-reduction of 2STCON to 2MINIMAL-DFA. Consequently, 2MINIMAL-DFA is NL-hard.

■ **Figure 2** DFA  $\mathcal{A}$  constructed for the L-reduction of 2STCON to 2MINIMAL-DFA. The  $j$ -transitions exiting states of the form  $i_j$  are only indicated.

## 6.2 Complexity of S-Prime-DFA

We end our discussion by using the construction presented in Section 6.1 to establish complexity boundaries for S-PRIME-DFA. First, we define the notion of S-compositionality.

► **Definition 6.2.** A DFA  $\mathcal{A}$  is *S-composite* if there is a  $k \in \mathbb{N}_{\geq 1}, k < |\mathcal{A}|$  such that  $\mathcal{A}$  is  $k$ -decomposable. Otherwise,  $\mathcal{A}$  is *S-prime*. ◻

We denote the problem of deciding S-primality for a given DFA with S-PRIME-DFA and the restriction of S-PRIME-DFA to DFAs with at most  $k \in \mathbb{N}_{\geq 2}$  letters with  $k$ S-PRIME-DFA.

Note that the proof used in [10] to show that PRIME-DFA is in EXPSPACE is applicable for S-PRIME-DFA with only slight modifications. Next, note that the L-reduction of the emptiness problem for DFAs to PRIME-DFA used in [10] to prove the NL-hardness of PRIME-DFA relies on the fact that every DFA recognizing the empty language is prime. Thus, it is not easily adaptable for S-PRIME-DFA. Instead, the NL-hardness of 2S-PRIME-DFA is shown by using a reduction from 2STCON, which adapts the construction outlined in Section 6.1. We get:

► **Theorem 6.3.** *The problems S-PRIME-DFA and kS-PRIME-DFA for  $k \in \mathbb{N}_{\geq 2}$  are in EXPSPACE and they are NL-hard.* ◻

Further, we denote with  $k\text{PRIME-DFA}$  the restriction of  $\text{PRIME-DFA}$  to DFAs with at most  $k \in \mathbb{N}_{\geq 2}$  letters and remark that the results presented in [10] can be expanded to:

► **Theorem 6.4.** *The problems  $\text{PRIME-DFA}$  and  $k\text{PRIME-DFA}$  for  $k \in \mathbb{N}_{\geq 2}$  are in  $\text{EXPSPACE}$  and they are  $\text{NL-hard}$ . ┘*

This ends our discussion of the complexity of  $\text{S-PRIME-DFA}$  and its restrictions, in which we have applied the construction outlined in Section 6.1 to prove  $\text{NL-hardness}$ .

## 7 Discussion

We studied the intersection compositionality, also denoted with  $\cap$ -compositionality, of regular languages. We added to the existing line of research focusing on fragments of the regular languages by analyzing the  $\cap$ -compositionality of ADFAs and thereby of finite languages. This research was in part motivated by existing results concerning the concatenation compositionality of finite languages.

We completely characterized the  $\cap$ -compositionality of ADFAs and thus finite languages. Using this characterization we proved the  $\text{NL-completeness}$  of  $\text{PRIME-DFA}_{\text{fin}}$ . Thus, finite languages are significantly easier to handle under  $\cap$ -compositionality than under concatenation compositionality, where the respective primality problem for finite languages is  $\text{NP-hard}$  [15].

With notions of compositionality using union and both union and intersection already suggested in [10], we formally introduced the notions of  $\cup$ - and  $\text{DNF-compositionality}$ . We characterized the  $\cup$ - and  $\text{DNF-compositionality}$  of finite languages, which proved to be far simpler than the characterization of  $\cap$ -compositionality. These results also imply the characterization of the  $\cap$ -,  $\cup$ - and  $\text{DNF-compositionality}$  of co-finite languages.

This suggests that the key feature of finite languages regarding compositionality is not the finiteness of the languages per se, but rather the existence of only finitely many meaningfully different runs of the respective DFAs, a feature finite languages have in common not only with co-finite languages, but also with languages whose minimal DFAs allow for cycles in both accepting and rejecting sinks. A logical next step would therefore be the characterization of the compositionality of these DFAs.

We also note that in our proofs we employed  $\cap$ -compositionality results concerning a different language fragment, namely co-safety DFAs, studied in [10]. This suggests the possibility of employing the results concerning finite languages in future analyses and stresses the usefulness of working with language fragments. We provided one application of the results concerning finite languages by using them to prove the existence of a language that is  $\text{DNF-composite}$  but  $\cap$ - and  $\cup$ -prime.

Furthermore, we presented a proof of the  $\text{NL-hardness}$  and thereby  $\text{NL-completeness}$  of the basic problem  $2\text{MINIMAL-DFA}$ . While the  $\text{NL-hardness}$  of  $k\text{MINIMAL-DFA}$  for  $k \in \mathbb{N}_{\geq 3}$  is folklore, this result appears to be new.

We utilized this result to establish the known complexity boundaries of  $\text{PRIME-DFA}$  for the here newly introduced problem  $\text{S-PRIME-DFA}$ . We extended these results to the restrictions  $k\text{PRIME-DFA}$  and  $k\text{S-PRIME-DFA}$  for  $k \in \mathbb{N}_{\geq 2}$ .

While it is interesting that a slight variation in the definition of  $\cap$ -compositionality, which does not touch the validity of most results, requires a whole new approach to establish the known lower complexity boundary, the big task of closing the doubly exponential complexity gap for  $\text{PRIME-DFA}$  still remains. And now, this gap exists for  $\text{S-PRIME-DFA}$  as well.

Therefore, with the analysis of language fragments, further notions of compositionality, and the complexity gaps for  $\text{PRIME-DFA}$  and  $\text{S-PRIME-DFA}$ , there is still need for further research.

## Abstract

Specialized hereditary systems, e.g., matroids, are known to have many applications in algorithm design. We define a new notion called  *$d$ -polynomoid* as a hereditary system  $(E, \mathcal{F} \subseteq 2^E)$  so that every two maximal sets in  $\mathcal{F}$  have less than  $d$  elements in common. We study the problem that, given a  $d$ -polynomoid  $(E, \mathcal{F})$ , asks if the ground set  $E$  contains  $\ell$  disjoint  $k$ -subsets that are not in  $\mathcal{F}$ , and obtain a complexity trichotomy result for all pairs of  $k \geq 1$  and  $d \geq 0$ . Our algorithmic result yields a sufficient and necessary condition that decides whether each hypergraph in some classes of  $r$ -uniform hypergraphs has a perfect matching, which has a number of algorithmic applications.

## 1 Introduction

Finding the conditions that decide whether an  $r$ -uniform hypergraph  $H$  contains a perfect matching has received much attention. Some conditions are based on the minimum degree of a vertex in  $H$  [14, 34, 35], and some are based on the minimum degree of a set of  $r - 1$  vertices in  $H$  [38]. More conditions are known for bipartite hypergraphs, such as Hall's [24], Aharoni's [1, 3], and Haxell's [27], and multipartite hypergraphs [11, 2]. Because finding a maximum matching for  $r$ -uniform hypergraphs with  $r \geq 3$  is APX-complete [32, 29], any computationally efficient conditions to decide whether an  $r$ -uniform hypergraph with  $r \geq 3$  contains a perfect matching cannot be both sufficient and necessary unless  $P = NP$ . Indeed, all the conditions above except Hall's are sufficient but not necessary. In the literature, a number of polynomial-time algorithms to compute perfect matchings for dense  $r$ -uniform hypergraphs are known [33, 26, 25].

In this paper, we give a sufficient and necessary condition that, for any pair of integers  $k > d \geq 0$ , the  $k$ -uniform hypergraph

$$H = \left( V, E = \left\{ e \in \binom{V}{k} : e \not\subseteq S_i \text{ for all } i \in [m] \right\} \right)$$

has a perfect matching, where  $\binom{V}{k}$  denotes the collection of all  $k$ -subsets of  $V$  and  $S_1, S_2, \dots, S_m$  are subsets of  $V$  with  $|S_i \cap S_j| < d$  for all  $i \neq j \in [m] := \{1, 2, \dots, m\}$ . We prove also the hardness of finding a maximum matching for such hypergraphs when  $k \leq d$ . Combining the above, we obtain a complexity trichotomy for our problem for all pairs of  $k$  and  $d$ , detailed in Theorem 2.

To better understand the structure of the hypergraphs defined above and compare our results with related work, we restate finding a maximum matching for such hypergraphs as the dependent  $k$ -set packing on a kind of hereditary systems that we call **polynomoids**, defined in Definition 1. Our notation for hereditary systems follows West [42].

► **Definition 1** ( $d$ -Polynomoid). *Let  $d \geq 0$  be an integer. Let  $(E, \mathcal{F})$  be a tuple where  $E$  is a finite set and  $\mathcal{F} \subseteq 2^E$  is a non-empty collection of some subsets of  $E$ . The sets in  $\mathcal{F}$  are called **independent sets**, and the other subsets of  $E$  are **dependent sets**. We say that  $P = (E, \mathcal{F})$  is a  **$d$ -polynomoid** if  $P$  satisfies the following two properties:*

- *Hereditary Property: For every  $B \in \mathcal{F}$ , if  $A \subseteq B$  then  $A \in \mathcal{F}$ .*
- *Join Property: For every  $A, B \in \mathcal{F}$ , if  $|A \cap B| \geq d$  then  $A \cup B \in \mathcal{F}$ .*

If the join property is removed, then  $P = (E, \mathcal{F})$  is a hereditary system [42]; if the join property is replaced with the exchange property, then  $P$  is a matroid [37].

Given a  $d$ -polynomoid  $P = (E, \mathcal{F})$  and integers  $k \geq 1, \ell \geq 0$ , the **dependent  $k$ -set packing** for  $P$  asks if there exist  $\ell$  pairwise disjoint  **$k$ -sets** not in  $\mathcal{F}$ , where a set is called  $k$ -set if it consists of  $k$  elements. If the  $\ell$  disjoint  $k$ -sets exist, then output them. Our main result is a complexity trichotomy for the dependent  $k$ -set packing problem on polynomoids, stated formally in Theorem 2. An illustration is depicted in Figure 1.

► **Theorem 2.** *The time complexities of the dependent  $k$ -set packing on  $d$ -polynomoids for all pairs of integers  $k \geq 1, d \geq 0$  can be classified into the following three categories:*

1. *If  $k \leq d$  and  $k \geq 3$ , there exists a  $d$ -polynomoid  $P$  so that the dependent  $k$ -set packing for  $P$  is APX-complete.*
2. *If  $k \leq d$  and  $k \leq 2$ , then:*
  - *for  $k = 2$ , there exists a  $d$ -polynomoid  $P$  so that the dependent  $k$ -set packing for  $P$  is as hard as the matching problem on ordinary graphs (i.e. 2-uniform hypergraphs);*
  - *for  $k = 1$ , this is a degenerate case solvable in  $O(|E|q(1))$  time, where  $q$  is a function defined below.*
3. *Otherwise  $k > d$ , for any  $d$ -polynomoid  $P = (E, \mathcal{F})$ ,*

$$E \text{ contains } \lfloor |E|/k \rfloor \text{ disjoint dependent } k\text{-sets if and only if } r(E) \leq (1 - 1/k)|E|,$$

where  $r(E)$  is the size of a maximum independent subset of  $E$ . The dependent  $k$ -set packing can be found in  $O(k|E|q(2k))$  time, where  $q(t)$ <sup>1</sup> denotes a monotone function that upper-bounds the running time to test whether a  $t$ -subset of  $E$  is independent.

It may be worth noting that for some polynomoids computing  $r(E)$  requires quadratic time unless the 3SUM conjecture fails, as shown in Section 2.2. To obtain Theorem 2, it suffices to test  $r(E) \leq (1 - 1/k)|E|$  without computing the exact value of  $r(E)$ , which can be tested in deterministic linear time (Section 4.1). In addition, greedily grouping the elements in a largest independent set with those from other independent sets in general cannot work correctly because the condition  $r(E) \leq (1 - 1/k)|E|$  may be violated in the residual polynomoid obtained from the initial polynomoid with a greedy removal of the elements in a largest independent set and the corresponding grouped elements from other independent sets.

In addition to the complexity trichotomy result, Theorem 2 can also be used to yield a sufficient and necessary condition for each polynomoid when a perfect packing exists, such as Corollary 3 (also follows from [14]), Corollary 4, Corollary 22, and Corollary 24 (also proven in [7]).

<sup>1</sup> Indeed, it has to be written as  $q_P(t)$  because it varies among different polynomoids. We suppress the subscript  $P$  when the context is clear.

Figure 1 A complexity trichotomy for the dependent  $k$ -set packing.

► **Corollary 3.** *Let  $G$  be a 3-uniform hypergraph with at least four vertices. If the number of vertices in  $G$  is a multiple of 3 and every two hyperedges in  $G$  have at most one vertex in common, then the complement of  $G$  has a perfect matching.*

**Proof.** Let  $P = (E, \mathcal{F})$  where  $E$  is the set of vertices in  $G$  and  $\mathcal{F}$  is the set of hyperedges in  $G$ . By definition,  $P$  is a 2-polynomoid. By setting  $(k, d) = (3, 2)$  and applying Theorem 2 on  $P$ , we are done. ◀

We remark that a number of related works discuss the independent set partition for hereditary systems [20, 43], and the minimal dependent set packing [39] and partition [17, 41, 31, 13, 21] for matroids. Note that partition problems can be reduced to packing problems.

### 1.1 Example Polynomoids

There are a number of structures that satisfy the requirements of polynomoids. We list three of them below, and more can be found in Appendix B.

- Let  $E$  be a finite set of points in  $\mathbb{R}^2$  and

$$\mathcal{F} = \{E' \subseteq E : \text{all points in } E' \text{ are colinear}\}.$$

$P = (E, \mathcal{F})$  is a 2-polynomoid because:

- Hereditary Property: Let  $S$  be a point set in  $\mathbb{R}^2$ . If all points in  $S$  are colinear, then all points in any subset of  $S$  also are colinear.
- Join Property: Let  $S_1, S_2$  be two point sets in  $\mathbb{R}^2$ . If all points in each of  $S_1$  and  $S_2$  are colinear and  $|S_1 \cap S_2| \geq 2$ , then all points in  $S_1 \cup S_2$  are colinear.

The dependent  $k$ -set packing problem for  $P$  asks if  $E$  contains  $\ell$  disjoint  $k$ -sets so that the points in each  $k$ -set are not colinear. In particular, for  $k = 3$ , the points in each  $k$ -set are on a circle with a finite radius, as depicted in Figure 2a. By Theorem 2, this problem can be solved in  $O(|E|)$  time as  $k, q(2k) = O(1)$ .

► **Remark.** More generally, the above example can be generalized to any set of degree- $d$  univariate polynomials for any  $d \geq 1$ . Let  $E$  denote a finite set of distinct points in  $\mathbb{R}^2$ . We may need a rotation of axes to ensure that no two points in  $E$  have the same  $x$ -coordinate. Let  $\mathcal{L}$  denote a collection of polynomials with degree  $d$ . Let  $\mathcal{F}$  denote the collection of all the subsets  $E'$  of  $E$  that some polynomial in  $\mathcal{L}$  passes through all points in  $E'$ . It is not hard to check that such an  $(E, \mathcal{F})$  is a  $d$ -polynomoid. This motivates us to call the hereditary systems defined in Definition 1 *polynomoids*.

2. Let  $G = (V, E)$  be an undirected simple graph and

$$\mathcal{F} = \{E' \subseteq E : \text{all edges in } E' \text{ have a vertex in common}\}.$$

Hence, for any  $A \in \mathcal{F}$ , the subgraph of  $G$  induced by the edges in  $A$  is a star graph.  $P = (E, \mathcal{F})$  is a 2-polynomoid because:

- Hereditary Property: Any subgraph of a star graph also is a star.
- Join Property: If two star subgraphs have at least two edges in common, then their union also is a star.

The dependent  $k$ -set packing problem for  $P$  asks if  $E$  contains  $\ell$  disjoint  $k$ -sets so that the edges in each  $k$ -set do not form a star graph. In particular, for  $k = 3$ , the edges in each  $k$ -set edge-induce a triangle or a *linear forest*, i.e. each component in the forest is a path, as depicted in Figure 2b. Because the union of the edges in a triangle and those in any 3-edge non-star graph can be partitioned into two 3-edge linear forests (Lemma 25), the problem of partitioning the edges in a graph into 3-edge linear forests is linear-time reducible to the dependent  $k$ -set packing for  $P$ . By Theorem 2, both problems can be solved in  $O(|E|)$  time as  $k, q(2k) = O(1)$ .

► **Remark.** It is shown in [9, 6, 4] that an  $m$ -edge undirected simple graphs with maximum degree  $\Delta$ , except for a finite number of exceptions, can be edge-partitioned into  $3P_2$ s, i.e., three vertex-disjoint edges if and only if  $m$  is a multiple of 3 and  $\Delta \leq m/3$ . By Theorem 2 and the above discussion, we obtain an analogous result that:

► **Corollary 4.** *An  $m$ -edge undirected simple graph with maximum degree  $\Delta$  can be edge-partitioned into 3-edge linear forests if and only if  $m$  is a multiple of 3 and  $\Delta \leq 2m/3$ .*

Let  $\{H_1, H_2, \dots, H_t\}$ -decomposition be the problem that, given an undirected simple graph  $G = (V, E)$ , decide whether  $E$  can be partitioned into subsets so that each subset edge-induces a subgraph isomorphic to  $H_i$  for some  $i \in [t]$ . It is conjectured in [40] that  $\{H_1, H_2, \dots, H_t\}$ -decomposition is NP-complete if and only if  $\{H_i\}$ -decomposition is NP-complete for all  $i \in [t]$ . Let  $P_\ell$  be a path of  $\ell$  nodes. Let  $P_i \cup P_j$  be the union of vertex-disjoint  $P_i$  and  $P_j$  and let  $kP_i$  be the union of  $k$  vertex-disjoint  $P_i$ s. By the above conjecture and the fact that  $P_4$ -decomposition is NP-complete [28, 15] but  $P_3 \cup P_2$ -decomposition [18, 10] and  $3P_2$ -decomposition [9, 6, 4] are polynomial-time solvable, partitioning the edge set of an undirected simple graph into 3-edge linear forests shall (assuming the conjecture holds) be solvable in polynomial time. Our above linear-time algorithm gives an example that supports the conjecture.

3. Let  $G = (V, A)$  be an edge-weighted directed graph and

$$\mathcal{F}_\Delta = \{V' \subseteq V : \text{a minimum } st\text{-cut in } G \text{ has weight at least } \Delta \text{ for every } s \neq t \in V'\},$$

where an  $st$ -cut is a partition of  $V$  into two disjoint sets  $S$  and  $T$  with  $s \in S, t \in T$  and the weight of an  $st$ -cut is defined to be the sum of weights on the directed edges from  $S$  to  $T$ . Note that by definition  $\mathcal{F}_\Delta$  contains  $\emptyset$  and all singleton sets.  $P = (V, \mathcal{F}_\Delta)$  is a 1-polynomoid because:

- Hereditary Property: If a minimum  $st$ -cut in  $G$  has weight at least  $\Delta$  for all pairs of  $s \neq t \in V'$ , then it also applies for all pairs of vertices in a subset of  $V'$ .
- Join Property: Let  $A, B \in \mathcal{F}_\Delta$  and  $z$  be a vertex that  $A, B$  have in common. For any pair of  $s \in A, t \in B$ , a minimum  $st$ -cut  $(S, T)$  that separates  $s, t$  has either  $z \in S$  or  $z \in T$ . We assume w.l.o.g. that  $z \in S$ . Since a minimum  $tz$ -cut and a minimum  $zt$ -cut both have weights at least  $\Delta$ , the  $(S, T)$ -cut also has weight at least  $\Delta$ .

The dependent  $k$ -set packing problem for  $P$  asks if  $V$  contains  $\ell$  disjoint  $k$ -sets so that for each  $k$ -set there is a cut in  $G$  of weight less than  $\Delta$  that separates the vertices in it, as depicted in Figure 2c. By Theorem 2, this problem can be solved in  $O(k|V|k^2f(G))$  time as  $q(2k) = O(k^2f(G))$  where  $f(G)$  denotes the running time of exact maxflow computation between two distinct nodes  $s$  and  $t$  on  $G$ .

► Remark. A naive approach for this problem needs to compute the minimum  $st$ -cuts for all pairs of  $s, t \in V$ , but ours needs only  $O(k^3V) = O(V)$  pairs. For undirected graphs, by Gomory-Hu trees [23] the number of the minimum  $st$ -cuts that are needed to compute is also  $O(V)$ . For unweighted directed graphs, the running time also can be reduced by the approach in [12]. For weighted directed graphs, to the best of our knowledge, our algorithm is the first one with running time matching the current best algorithm for weighted undirected graphs.

■ **Figure 2** (a) The figure to the left: a partition of the given points into 3-sets so that the points in each 3-set are on a circle with a finite radius. (b) The figure in the middle: a partition of the edges into 3-sets so that the edges in each 3-set induces a linear forest. (c) The figure to the right: a partition of the vertices into 2-sets so that for each 2-set there is a cut in  $G$  has weight less than 7 that separates vertices in it.

## 1.2 Sharpness of Our Result

The two properties of polymoids are essential to make the dependent  $k$ -set packing for polymoids solvable in linear time for  $k > d$ .

- Case I: if the hereditary property is removed from the Definition 1, then we have an example problem for  $k > d$  that cannot be solved in polynomial time unless  $P = NP$ . Let  $G$  be an undirected graph. Let  $(E, \mathcal{F})$  be a set system where  $E$  denotes the vertex set of  $G$  and  $\mathcal{F}$  consists of all the subsets  $E'$  of  $E$  so that the subgraph of  $G$  induced by the vertices in  $E'$  are connected. Note that, for any  $E_1, E_2 \in \mathcal{F}$ , if  $|E_1 \cap E_2| \geq 1$ , then  $E_1 \cup E_2 \in \mathcal{F}$ . Thus, this set system corresponds to the case  $d = 1$ .

Set  $k = 3$ , so  $k > d$ . To find a dependent  $k$ -set packing for  $(E, \mathcal{F})$ , it is equivalent to asking whether  $E$  contains  $\ell$  disjoint  $k$ -sets so that the subgraph in  $G$  induced by the vertices in each  $k$ -subset is disconnected. For  $k = 3$ , this problem is equivalent to asking whether  $E$  contains  $\ell$  disjoint  $k$ -sets so that the subgraph in  $\bar{G}$  (the complement graph of  $G$ ) induced by the vertices in each  $k$ -set is connected, which is known to be NP-complete [16].

- Case II: if the join property is removed from the Definition 1, then the parameter  $d$  is removed. So the complexity trichotomy in Figure 1 collapses. For  $k \geq 3$ , then it is APX-complete; for  $k = 2$ , then it is as hard as matching [36]. It is not known how to solve either case in linear time.

### 1.3 Paper Organization

In Section 2, we devise a polynomial-time algorithm to find a maximum independent set for any polymoid  $P$ , assuming that the independence oracle can be queried in polynomial time, and prove that no algorithms can solve this problem in truly subquadratic time unless the 3SUM conjecture fails. Then, in Section 3, we relate the problem of finding a maximum independent set and that of finding a largest dependent  $k$ -set packing for any  $d$ -polymoids with  $k > d$ . Because finding a maximum independent set for polymoids is 3SUM-hard in general, we devise a deterministic linear-time algorithm without involving the exact computation of the maximum independent sets in Section 4. We prove the hardness for the case of  $k \leq d$  in Appendix A. Finally, we present more applications of our results in Appendix B and place omitted proofs in Appendix C.

## 2 Maximum Independent Sets

For any matroid, finding a maximum independent set can be done greedily because all maximal independent sets have equal size. Since maximal independent sets of a polymoid may have different sizes, the greedy approach for matroids cannot be applied to polymoids. In what follows, we devise a polynomial-time algorithm to find a maximum independent set for any polymoid, assuming that testing whether a set is independent can be done in polynomial time. In addition, we prove that this problem cannot be solved by any truly subquadratic-time algorithm even if the independence oracle can be decided in time linear in the input size unless the 3SUM conjecture fails.

### 2.1 A Polynomial-Time Algorithm

Our polynomial-time algorithm for finding a maximum independent set is mainly based on the following key lemma.

► **Lemma 5.** *Let  $P = (E, \mathcal{F})$  be a  $d$ -polymoid for some  $d \geq 0$ . For any  $d$ -subset  $C$  of  $E$ , precisely one of the following two statements holds:*

- *No maximal independent sets in  $P$  contain  $C$ .*
- *Exactly one maximal independent set in  $P$  contains  $C$ .*

**Proof.** If  $C$  is dependent, then no independent set contains  $C$  due to the hereditary property of  $P$ . If  $C$  is independent and there exist two distinct maximal independent sets  $M_1, M_2$  of  $P$  that contain  $C$  as a subset, then

$$|M_1 \cap M_2| \geq |C| = d.$$

By the join property of  $P$ ,  $M_1 \cup M_2$  is independent. Since  $M_1 \neq M_2$  and they are maximal, we have

$$|M_1 \cup M_2| \geq \max\{|M_1|, |M_2|\} + 1,$$

contradicting the maximality of  $M_1$  and  $M_2$ . Therefore, precisely one maximal independent set contains  $C$ . Each of the above two cases corresponds to one of the claimed statements. ◀

Lemma 5 yields an efficient algorithm that, for any independent set  $C$  of a  $d$ -polymoid with size at least  $d$ , finds “the” maximal independent set containing  $C$  as a subset. Formally, we state it in Corollary 6.

► **Corollary 6.** *Let  $P = (E, \mathcal{F})$  be a  $d$ -polymoid for some  $d \geq 0$ . For any  $C \in \mathcal{F}$  with size at least  $d$ , finding the maximal independent set  $M_C$  that contains  $C$  as a subset can be done in  $O(|E|q(d+1))$  time.*

**Proof.** By Lemma 5, there is a unique independent set  $M_C$  that contains any  $d$ -subset  $C_d$  of  $C$  as a subset. Hence, for any  $x \in E$ , if  $C_d \cup \{x\} \in \mathcal{F}$ , then  $x \in M_C$ . Testing whether  $C_d \cup \{x\} \in \mathcal{F}$  for all  $x \in E$  can be realized by invoking the independence oracle of  $P$  on  $(d+1)$ -subsets of  $E$   $O(|E|)$  times. Thus, the total running time is  $O(|E|q(d+1))$ . ◀

Lemma 5 and Corollary 6 imply that for any polymoid  $P = (E, \mathcal{F})$  finding a maximum independent set can be done in  $O(|E|^{d+1}q(d+1))$  time. This can be seen from the following two cases.

1. If the size  $s$  of maximum independent sets in  $P$  is at most  $d$ , then they can be found by invoking the independence oracle once for each subset of  $E$  that has size  $\leq d$ . Hence, the running time is

$$\sum_{i=0}^d \binom{|E|}{i} q(i) = O(|E|^d q(d)) \text{ for } |E| \geq 2 \text{ or } O(q(1)) \text{ for } |E| \leq 1.$$

2. Otherwise, there is a maximum independent set  $M$  that has size  $> d$ . Because  $|M| > d$  and the hereditary property of  $P$ ,  $M$  contains a subset  $M_d$  of size  $d$  in  $\mathcal{F}$ . By Lemma 5, exactly one maximal independent set  $W$  contains  $M_d$ , so  $W = M$ . By Corollary 6,  $W = M_d \cup \{e \in E : M_d \cup \{e\} \in \mathcal{F}\}$ , which can be found in  $O(|E|q(d+1))$  time. Hence, the total running time is at most

$$|E|q(d+1) \cdot \binom{|E|}{d} = O(|E|^{d+1}q(d+1)).$$

The implementations of the above two cases can be unified as in the following pseudocode.

■ **Algorithm 1** Finding a maximum independent set for polymoids.

---

**input** : a  $d$ -polymoid  $P = (E, \mathcal{F})$   
**output** : a maximum independent set of  $P$   
 $A \leftarrow \emptyset$ ;  
**foreach**  $S \in \{E' \subseteq E : |E'| \leq d\}$  **do**  
    **if**  $S \in \mathcal{F}$  **then**  
         $M \leftarrow$  a maximal independent set in  $\mathcal{F}$  that contains  $S$ ;  
        **if**  $|M| > |A|$  **then**  
             $A \leftarrow M$ ;  
**return**  $A$ ;

---

As a consequence, we have:

► **Theorem 7.** *For any  $d$ -polymoid  $P = (E, \mathcal{F})$ , given an independence oracle  $\mathcal{O}_{ind} : 2^E \rightarrow \{0, 1\}$  that tests whether a  $t$ -subset of  $E$  is contained in  $\mathcal{F}$  in  $q(t)$  time where  $q$  is a monotone function, then finding an independent set in  $\mathcal{F}$  that has the largest cardinality can be done in  $O(|E|^{d+1}q(d+1))$  time.*

## 2.2 3SUM-Hardness

We show in Theorem 8 that, unless the 3SUM conjecture fails, there exists some polymoid  $P = (E, \mathcal{F})$  so that any algorithm that finds a maximum independent set for  $P$  requires  $\Omega(|E|^{2-\varepsilon})$  time for any constant  $\varepsilon > 0$ .

► **Theorem 8.** *There exists some polynomoid  $P$  whose independence oracle can be decided in time linear in the input size so that finding a maximum independent set of  $P$  is 3SUM-hard.*

**Proof.** Let  $P = (E, \mathcal{F})$  be a polynomoid where  $E$  is a finite set of distinct points in  $\mathbb{R}^2$  and  $\mathcal{F} = \{E_j \subseteq E \mid \text{all points in } E_j \text{ are colinear}\}$ . It is clear that  $P$  is a 2-polynomoid. A maximum independent set of  $P$  corresponds to a line in  $\mathbb{R}^2$  that passes through the most number of points in  $E$ . Hence, it suffices to answer whether there exist three points in  $E$  that are colinear, which is known to be 3SUM-hard [19]. ◀

### 3 Dependent $k$ -Set Packing

In this section, we will present a reduction from the dependent  $k$ -set packing to the maximum independent set.

For each polynomoid  $P = (E, \mathcal{F})$ , we define a *rank* function  $r : 2^E \rightarrow \{0, 1, \dots, |E|\}$  so that  $r(S)$  denotes the cardinality of a largest subset of  $S$  that is contained in  $\mathcal{F}$ . In particular,  $r(E)$  equals the size of a maximum independent set of  $P$ , which can be computed in polynomial time by Theorem 7. More generally, for every  $S \subseteq E$ ,  $r(S)$  equals the size of a maximum independent set of the polynomoid  $Q = (S, 2^S \cap \mathcal{F})$ . Hence, the rank function  $r$  for any subset of  $E$  is computable in polynomial time, assuming that the independence oracle of  $P$  can be decided in polynomial time. Let  $\rho_k(E)$  denote the maximum number of disjoint dependent  $k$ -subsets that  $E$  contains. We claim that  $r(E)$  and  $\rho_k(E)$  can be related as follows, so  $\rho_k(E)$  can be computed no slower than finding  $r(E)$ .

► **Theorem 9.** *Let  $k, d$  be two integers with  $k > d \geq 0$ . For any  $d$ -polynomoid  $P = (E, \mathcal{F})$ ,*

$$\rho_k(E) = \begin{cases} |E| - r(E) & \text{if } r(E) > (1 - 1/k)|E| \\ \lfloor |E|/k \rfloor & \text{otherwise} \end{cases}$$

It suffices to prove Theorem 9 for  $k = d + 1$  because of the observation that a  $d$ -polynomoid is also a  $t$ -polynomoid for every  $t > d$ .

#### 3.1 Case I: $r(E) > (1 - 1/k)|E|$

We prove the first case of Theorem 9 by the following lemma.

► **Lemma 10.** *Let  $d \geq 0$  and  $k = d + 1$  be two integers. For any  $d$ -polynomoid  $P = (E, \mathcal{F})$ , if  $r(E) > (1 - 1/k)|E|$ , then  $\rho_k(E) = |E| - r(E)$ .*

**Proof.** The proof for  $d = 0$  is clear because any 0-polynomoid has  $\mathcal{F} = 2^S$  for some  $S \subseteq E$ . Hence we assume that  $d \geq 1$ , so  $k \geq 2$ . Let  $M$  be a maximum independent set of  $P$ . By definition,  $|M| = r(E)$ . For each element  $x$  in  $E \setminus M$ , we remove  $k - 1$  distinct elements from  $M$  and let  $A_x$  be the set containing  $x$  and the  $k - 1$  removed elements.

▷ **Claim 11.**  $A_x$  is dependent.

**Proof.** Suppose for contradiction that  $A_x \in \mathcal{F}$ , the intersection of  $A_x$  and  $M$  is  $k - 1 = d$ , so  $A_x \cup M \in \mathcal{F}$  by the join property of  $P$ . This violates the maximality of  $M$ . Hence,  $A_x$  is dependent. ◀

Since  $r(E) > (1 - 1/k)|E|$ , we have  $r(E) > (k - 1)(|E| - r(E))$ . So the above grouping procedure can iterate until  $E \setminus M$  is exhausted. Hence, we obtain a collection of  $|E| - r(E)$  dependent  $k$ -sets (not necessarily the largest one), so  $\rho_k(E) \geq |E| - r(E)$ . Note that, if  $\rho_k(E) > |E| - r(E)$ , by the pigeonhole principle, at least one of the  $\rho_k(E)$   $k$ -sets contains elements only from  $M$ . By the hereditary property of  $P$ , such a  $k$ -set must be independent because it is a subset of  $M$ , a contradiction. As a result,  $\rho_k(E) = |E| - r(E)$ . ◀

### 3.2 Case II: $r(E) \leq (1 - 1/k)|E|$

We prove the second case of Theorem 9 by the following lemmas. We will show that, if  $r(E) \leq (1 - 1/k)|E|$ , let  $Z_1, Z_2, \dots, Z_\ell$  be  $k$ -sets of  $E$  and  $W = E \setminus \bigcup_{i \in [\ell]} Z_i$  with  $|W| < k$ , then either  $Z_i$ s are all dependent, or there exist two sets in  $\{Z_i : i \in [\ell]\} \cup W$  whose elements can be exchanged so as to increase the number of dependent sets in  $\{Z_i : i \in [\ell]\}$ .

We begin with a helper lemma.

► **Lemma 12.** *Let  $d \geq 0$  and  $k = d + 1$  be two integers. Let  $P = (E, \mathcal{F})$  be a  $d$ -polynomoid. For any two disjoint  $k$ -subsets  $X, Y \subseteq E$ , if  $r(X \cup Y) \leq 2d$ , then  $X \cup Y$  can be partitioned into two disjoint dependent  $k$ -subsets of  $E$ . This partition can be done in  $O(d^2q(d + 1))$  time.*

**Proof.** We begin with the proofs of the following claims.

▷ **Claim 13.** If  $X$  has a subset  $Z \in \mathcal{F}$  with  $|Z| \geq d$ , then  $Z \cup \{y\} \notin \mathcal{F}$  for some  $y \in Y$ .

**Proof.** If such a  $y$  does not exist, then  $Z \cup \{y\} \in \mathcal{F}$  for every  $y \in Y$ . By Lemma 5, there is exactly one maximal independent set that contains  $Z$ . The above two facts imply that  $Z \cup Y \in \mathcal{F}$ . This yields  $r(Z \cup Y) \geq 2d + 1 > r(X \cup Y)$ , a contradiction. ◁

▷ **Claim 14.** If  $X \in \mathcal{F}$ , there exists  $y \in Y$ , for every  $d$ -subset  $Z$  of  $X$ ,  $Z \cup \{y\} \notin \mathcal{F}$ .

**Proof.** By Claim 13,  $X \cup \{y\} \notin \mathcal{F}$  for some  $y \in Y$ . If  $X$  has a  $d$ -subset  $Z$  with  $Z \cup \{y\} \in \mathcal{F}$ , since  $X \cap (Z \cup \{y\}) = Z$ , by the join property of  $P$  we have  $X \cup (Z \cup \{y\}) = X \cup \{y\} \in \mathcal{F}$ , a contradiction. ◁

We are ready to give a proof. If both  $X$  and  $Y$  are dependent, then we are done. Otherwise, we assume w.l.o.g. that  $X \in \mathcal{F}$ . By Claim 14, there exists an  $y^* \in Y$ , for every  $x \in X$ ,  $X \setminus \{x\} \cup \{y^*\} \notin \mathcal{F}$ . If  $Y \setminus \{y^*\} \in \mathcal{F}$ , then by Claim 13 there exists some  $x^* \in X$  so that  $Y \setminus \{y^*\} \cup \{x^*\} \notin \mathcal{F}$ . Otherwise  $Y \setminus \{y^*\} \notin \mathcal{F}$ , then for any  $x \in X$  we have  $Y \setminus \{y^*\} \cup \{x\} \notin \mathcal{F}$ . As a result,  $X \setminus \{x^*\} \cup \{y^*\}$  and  $Y \setminus \{y^*\} \cup \{x^*\}$  both are not in  $\mathcal{F}$  and together partition  $X \cup Y$ . By enumerating all possible  $x^*, y^*$ , it yields the time bound. ◀

We are ready to prove that the swapping procedure can iterate until no sets in  $\{Z_i : i \in [\ell]\}$  are independent.

► **Lemma 15.** *Let  $d \geq 0$ ,  $k = d + 1$ , and  $\ell \geq 1$  be integers. Let  $P = (E, \mathcal{F})$  be a  $d$ -polynomoid. For any subset  $S$  of  $E$ , if  $|S| = \ell k + t$  and  $r(S) \leq \ell d + t$  for some  $t \geq 0$ , then  $S$  contains  $\ell$  disjoint dependent  $k$ -subsets of  $E$ .*

**Proof.** Initially, we partition  $S$  arbitrarily into  $\ell$   $k$ -sets  $Z_1, Z_2, \dots, Z_\ell$  and one  $t$ -set  $W$ . If none of  $Z_i$  for  $i \in [\ell]$  is independent, then we are done. Otherwise,  $Z_i \in \mathcal{F}$  for some  $i \in [\ell]$ . Since  $Z_i \in \mathcal{F}$  and  $|Z_i| = k \geq d$ , by Lemma 5 there is exactly one maximal independent set  $M(Z_i)$  that contains  $Z_i$ . Hence, there are at least  $|S| - |M(Z_i)|$  elements  $x \in S$  so that  $Z_i \cup \{x\} \notin \mathcal{F}$ . We color these elements blue. By the maximality of  $r(S)$ ,  $|M(Z_i)| \leq r(S) \leq \ell d + t$ . Hence,  $|S| - |M(Z_i)| \geq \ell k + t - \ell d - t = \ell$ . There are two cases to discuss.

1.  $W$  contains a blue element  $b$ . By the definition of blue elements,  $Z_i \cup \{b\} \notin \mathcal{F}$ . Let  $y$  be an arbitrary element in  $Z_i$ . Then,  $(Z_i \setminus \{y\}) \cup \{b\} \notin \mathcal{F}$ ; otherwise, by the join property of  $P$

$$\{y\} \cup (Z_i \setminus \{y\}) \in \mathcal{F} \text{ and } (Z_i \setminus \{y\}) \cup \{b\} \in \mathcal{F} \text{ together imply } Z_i \cup \{b\} \in \mathcal{F},$$

a contradiction. If we set  $(Z_i, W) \rightarrow (Z_i \setminus \{y\} \cup \{b\}, W \setminus \{b\} \cup \{y\})$ , then the number of independent sets in  $\{Z_1, Z_2, \dots, Z_\ell\}$  is reduced by one.

2.  $W$  contains no blue elements. Because  $Z_i$  also contains no blue elements, the  $\geq \ell$  blue elements are distributed among  $\{Z_1, Z_2, \dots, Z_\ell\} \setminus \{Z_i\}$ . By the pigeonhole principle, some  $Z_j$  contains at least 2 blue elements. We claim that  $r(Z_i \cup Z_j) \leq 2d$ . Thus, by Lemma 12 we can partition  $Z_i \cup Z_j$  into two dependent  $k$ -sets. Hence, the number of independent sets in  $\{Z_1, Z_2, \dots, Z_\ell\}$  is reduced by at least one.

We prove the claim as follows. Suppose for contradiction that  $r(Z_i \cup Z_j) \geq 2d+1$ . Because  $|Z_i| + |Z_j| = 2(d+1)$ , there exists one element  $x$  so that  $Z_i \cup Z_j \setminus \{x\} \in \mathcal{F}$ . Because there are two blue elements  $b_1, b_2 \in Z_j$  and any independent superset of  $Z_i$  contains no blue elements,  $x \notin Z_j$  and thus  $x \in Z_i$ . By the hereditary property of  $P$ ,  $Z_i \setminus \{x\} \cup \{b_1\} \in \mathcal{F}$ . By the join property of  $P$ ,  $\{x\} \cup (Z_i \setminus \{x\}) \in \mathcal{F}$  and  $(Z_i \setminus \{x\}) \cup \{b_1\} \in \mathcal{F}$  imply that  $Z_i \cup \{b_1\} \in \mathcal{F}$ , a contradiction.

For each case, we can reduce the number of independent sets in  $\{Z_1, Z_2, \dots, Z_\ell\}$  by at least one. Since  $\ell$  is finite, one can always obtain a feasible packing. ◀

Let  $|E| = \ell k + t$  for some  $t \in [0, k)$ . Thus  $\lfloor |E|/k \rfloor = \ell$ . Since  $r(E) \leq (1 - 1/k)(\ell k + t) \leq \ell d + t$ , by Lemma 15 we complete the proof of the second case.

#### 4 Finding a Largest Dependent $k$ -Set Packing in Deterministic Linear Time

In Theorem 8, we have shown that computing  $r(E)$  in general requires  $\Omega(|E|^{2-\varepsilon})$  time for any constant  $\varepsilon > 0$  unless the 3SUM conjecture fails. Hence, to compute the  $k$ -set packing in  $O(E)$  time, one cannot directly compute  $r(E)$  to distinguish which case in Theorem 9 applies.

##### 4.1 The Deterministic Linear-Time Algorithm

In this section, we devise a deterministic linear-time algorithm for finding a largest dependent set packing for any  $d$ -polymoid  $P = (E, \mathcal{F})$ . Let  $d, k$  be two integers with  $k = d + 1$ . Recall that we have to consider only the case of  $k = d + 1$ . Let  $|E| = \ell k + t$  for some  $t \in [0, k)$ . Initially, we partition  $E$  arbitrarily into  $Z_1, Z_2, \dots, Z_\ell$  and  $W$  so that  $|Z_i| = k$  for  $i \in [\ell]$  and  $|W| = t$ . Then we apply the following five steps to find a largest dependent  $k$ -set packing  $\mathcal{D}$ .

1. Set  $\mathcal{A} = \{Z_1, Z_2, \dots, Z_\ell\}$ . Set  $\mathcal{D} = \emptyset$ .
2. If some  $Z_i \in \mathcal{A}$  is dependent, remove  $Z_i$  from  $\mathcal{A}$  and set  $\mathcal{D} = \mathcal{D} \cup \{Z_i\}$ . Otherwise, proceed to the next step.
  - ▶ Remark. This step takes  $O(q(k)|E|/k)$  time.
3. If there exist  $Z_i, Z_j \in \mathcal{A}$  that  $Z_i \cup Z_j$  is dependent, remove  $Z_i$  and  $Z_j$  from  $\mathcal{A}$  and set  $\mathcal{D} = \mathcal{D} \cup \{Z'_i, Z'_j\}$  where  $Z'_i$  and  $Z'_j$  are dependent  $k$ -sets and they partition  $Z_i \cup Z_j$ . Otherwise, proceed to the next step.
  - ▶ Remark. The existence of  $Z'_i$  and  $Z'_j$  is shown in Section 4.2. Because  $|Z_i| \geq d$  and  $|Z_j| \geq d$ ,  $Z_i \cup Z_j$  is independent iff  $Z_i$  and  $Z_j$  belong to the same maximal set. So if  $Z_i \cup Z_j \in \mathcal{F}$  but  $Z_i \cup Z_k \notin \mathcal{F}$ , then  $Z_j \cup Z_k \notin \mathcal{F}$ . Hence, we can keep a list of  $Z$ s so that their pairwise unions are independent sets. For each unpaired  $Y$  outside the pool, pick any  $Z$  in the pool, if  $Z \cup Y \in \mathcal{F}$ , then  $Z' \cup Y \in \mathcal{F}$  for any  $Z'$  in the pool, so expand the pool by adding  $Y$ ; otherwise, pair  $Y, Z$  and throw out  $Y, Z$ . Indeed, this is a generalization of the majority voting [8]. This step takes  $O((q(2k) + k^2q(k))|E|/k)$  time.
4. If  $\mathcal{A} = \emptyset$ , return  $\mathcal{D}$  and stop. Otherwise, find a maximal independent set  $M_{\mathcal{A}}$  of  $P$  that contains all elements in  $\mathcal{A}$  as subsets.

► Remark. If  $\mathcal{A} = \emptyset$ , then  $\mathcal{D}$  is largest possible, so it is a largest dependent  $k$ -set packing. The existence of  $M_{\mathcal{A}}$  is shown in Section 4.2. To find  $M_{\mathcal{A}}$ , let  $Z$  be some element in  $\mathcal{A}$  and find the maximal independent set that contains  $Z$  as a subset in  $O(|E|q(k))$  time by Corollary 6. Since  $|Z| = k \geq d$  and  $Z \in \mathcal{F}$ , we know that  $M_{\mathcal{A}} = M_Z$  by Lemma 5.

5. This final step is reached only if  $|\mathcal{A}| \geq 1$ .

- Case 1:  $r(E) > (1 - 1/k)|E|$ . By Lemma 18,  $M_{\mathcal{A}}$  is a maximum independent set of  $P$ . Since  $M_{\mathcal{A}}$  is given, one can simulate Lemma 10 in  $O(|E|)$  time.
- Case 2:  $r(E) \leq (1 - 1/k)|E|$ . By Lemma 17,  $M_{\mathcal{A}}$  contains all elements in  $\mathcal{A}$ . One can simulate Lemma 15 efficiently as follows.

For each  $Z \in \mathcal{A}$ , to implement Lemma 15, we need to find a set  $Z' \in \{Z_i : i \in [\ell]\} \cup \{W\}$  that contains a sufficient number of elements in  $E \setminus M_{\mathcal{A}}$  (aka “blue elements” in the proof of Lemma 15). Given  $M_{\mathcal{A}}$ , we compute  $E \setminus M_{\mathcal{A}}$  in  $O(|E|)$  time and maintain the locations of these “blue elements” so that for each  $Z \in \mathcal{A}$  we can find the  $Z'$  in  $O(1)$  time.

Hence, the number of swapping steps is  $O(|E|/k)$  and each takes  $O(k^2q(k))$  time (Lemma 12). So this step needs  $O(k|E|q(k))$  time.

As a consequence, the total running time of all steps is bounded by  $O(k|E|q(2k))$ . This completes the proof of Theorem 2 for  $k > d$ .

## 4.2 The Existence Proofs

We will prove the existence proofs required by the algorithm in Section 4.1. In Step 3,  $Z_i, Z_j \in \mathcal{F}$  and  $Z_i \cup Z_j \notin \mathcal{F}$ , so  $r(Z_i \cup Z_j) \leq 2d$  by Lemma 16. Hence, by Lemma 12,  $Z_i \cup Z_j$  can be partitioned into two disjoint dependent sets of size  $k$ . The existence of  $M_{\mathcal{A}}$  required by Step 4 is shown in Lemma 17. Finally, we prove in Lemma 18 that  $M_{\mathcal{A}}$  is a maximum independent set of  $P$  if  $r(E) \geq (1 - 1/k)|E|$  and  $|\mathcal{A}| \geq 1$ .

► **Lemma 16.** *For any  $k$ -subsets  $X, Y$  of  $E$ , if  $X, Y \in \mathcal{F}$  but  $X \cup Y \notin \mathcal{F}$ , then  $r(X \cup Y) \leq 2d$ .*

**Proof.** Let  $S$  be any subset of  $X \cup Y$  with  $|S| = r(X \cup Y)$ . If  $|S| > 2d$ , then there exists  $z \in X \cup Y$  so that  $(X \cup Y) \setminus \{z\} \in \mathcal{F}$ . We assume w.l.o.g. that  $z \in X$  and  $Y \subseteq S$ . Let  $M$  be a maximal independent set of  $P$  that contains  $S$  as a subset. Because  $|M \cap X| \geq |S \cap X| \geq d$ , by the join property of  $P$  we have  $M \cup X \in \mathcal{F}$ . By the maximality of  $M$ ,  $X \subseteq M$ , so  $X \cup Y \subseteq M$ . By the hereditary property of  $P$ ,  $M \in \mathcal{F}$  implies  $X \cup Y \in \mathcal{F}$ . This violates the setting. Therefore,  $r(X \cup Y) \leq 2d$ . ◀

► **Lemma 17.** *In Step 4, such a maximal independent set  $M_{\mathcal{A}}$  of  $P$  always exists.*

**Proof.** The construction of  $\mathcal{A}$  yields that, for any  $X, Y \in \mathcal{A}$ ,  $X \cup Y \in \mathcal{F}$ . By Lemma 5, there is a unique maximal independent set  $M_X$  (resp.  $M_{X \cup Y}$ ) that contains  $X$  (resp.  $X \cup Y$ ) as a subset. The uniqueness of  $M_X$  and  $M_{X \cup Y}$  implies that  $M_X = M_{X \cup Y}$ . Similarly,  $M_Y = M_{X \cup Y}$ . Hence,  $M_X = M_Y$ . Because this fact applies to every pair of elements in  $\mathcal{A}$ , there is a maximal independent set  $M_{\mathcal{A}}$  that contains every element in  $\mathcal{A}$  as a subset. ◀

► **Lemma 18.** *In Step 4, if  $r(E) > (1 - 1/k)|E|$  and  $|\mathcal{A}| \geq 1$ , then  $M_{\mathcal{A}}$  is a maximum independent set of  $P$ .*

**Proof.** We begin with the proofs that, for any maximal independent set  $M$  of  $P$ , each removed  $Z_i$  in Steps 2 and 3 contains at least one element outside  $M$  on average.

## 84:12 Dependent $k$ -Set Packing on Polymoids

▷ **Claim 19.** Let  $M$  be any maximal independent set of  $P$ . In Step 2, for each removed  $Z_i$ ,  $Z_i$  contains at least one element in  $E \setminus M$ .

*Proof.* Because  $Z_i \notin \mathcal{F}$  and  $M \in \mathcal{F}$ , by the hereditary property of  $P$ ,  $Z_i$  is not a subset of  $M$ . Hence,  $Z_i$  contains at least one element outside  $E \setminus M$ . ◁

▷ **Claim 20.** Let  $M$  be any maximal independent set of  $P$ . In Step 3, for each pair of removed  $Z_i$  and  $Z_j$ ,  $Z_i \cup Z_j$  contains at least two elements in  $E \setminus M$ .

*Proof.* By Lemma 16, we know that  $r(Z_i \cup Z_j) \leq 2d$ . If  $M \cap (Z_i \cup Z_j) > 2d$ , then  $r(Z_i \cup Z_j) > 2d$ , a contradiction. Hence,  $M \cap (Z_i \cup Z_j) \leq 2d$ , as desired. ◁

We are ready to give a proof. Let  $S$  be a subset of  $E$  with  $|S| = r(E)$ , and let

$$U_{\mathcal{A}} = W \cup \bigcup_{Z \in \mathcal{A}} Z \text{ and } U_B = E \setminus U_{\mathcal{A}}.$$

By Claims 19 and 20, we have

$$\frac{|S \cap U_B|}{|U_B|} \leq \frac{k-1}{k}. \quad (1)$$

By restating  $r(E) > (1 - 1/k)|E|$ , we get

$$\frac{|S \cap E|}{|E|} > \frac{k-1}{k}. \quad (2)$$

Combining (1), (2), and the average argument, it yields that

$$\frac{|S \cap U_{\mathcal{A}}|}{|U_{\mathcal{A}}|} > \frac{k-1}{k}. \quad (3)$$

To satisfy the inequality (3), if  $|\mathcal{A}| \geq 1$ , either  $S$  contains  $U_{\mathcal{A}} \setminus W$  as a subset or  $S$  does not contain  $U_{\mathcal{A}} \setminus W$  as a subset. The former implies that  $S = M_{\mathcal{A}}$  due to the uniqueness of  $M_{\mathcal{A}}$  (Lemma 5), as desired. Note that  $|S \cap (U_{\mathcal{A}} \setminus W)| \leq k-2$ ; otherwise,  $S \cup M_{\mathcal{A}} \in \mathcal{F}$  due to the join property of  $P$  and thus  $S = M_{\mathcal{A}}$  by the maximality of  $S$  and  $M_{\mathcal{A}}$ . The latter cannot hold because  $|S \cap (U_{\mathcal{A}} \setminus W)| \leq k-2$  and  $0 \leq |W| \leq k-1$  implies that

$$\frac{k-1}{k} < \frac{|S \cap U_{\mathcal{A}}|}{|U_{\mathcal{A}}|} = \frac{|S \cap W| + |S \cap (U_{\mathcal{A}} \setminus W)|}{|W| + |U_{\mathcal{A}} \setminus W|} \leq \frac{|W| + k-2}{|W| + k|\mathcal{A}|} \leq \frac{2k-3}{2k-1},$$

which cannot hold for positive  $k$ . ◀

## 5 Conclusion

We obtain a complexity trichotomy result for the dependent  $k$ -set packing problem on  $d$ -polymoids. For each of the three categories, our algorithm is optimal. It may worth noting that the running time of the algorithm for the case of  $k > d$  can be reduced by a factor of  $k$  by group testing [30, 22], which will be introduced in the full version of this manuscript. Though this yields a constant-factor improvement, it may affect the performance of real applications.

## **A** Hardness Reduction

In this section, we prove that the dependent  $k$ -set packing for  $d$ -polynomoids with  $d \geq k$  is as hard as hypergraph matchings in general. We reduce the matching problem for  $k$ -uniform hypergraphs to the dependent  $k$ -set packing problem on  $d$ -polynomoids with  $d \geq k$  in Theorem 21. The other direction is clear because the latter problem is a special case of the former one. This completes the proof of Theorem 2 for  $k \leq d$ .

► **Theorem 21.** *For any integers  $d \geq k \geq 1$ , there exists a  $d$ -polynomoid  $P = (E, \mathcal{F})$  so that dependent  $k$ -set packing on  $P$  is as hard as matchings on  $k$ -uniform hypergraphs.*

**Proof.** We prove this lemma by showing a reduction from the perfect matching for  $k$ -uniform graphs to the dependent  $k$ -set packing for  $P$ . Let  $G = (V, \mathcal{E})$  be a  $k$ -uniform hypergraph. Let  $P = (V, \mathcal{F})$  be a  $d$ -polynomoid where  $\mathcal{F} = \{\text{all subsets of } V \text{ with size at most } k\} \setminus \mathcal{E}$ . We now show that  $P$  is a  $d$ -polynomoid. Note that each set in  $\mathcal{F}$  has size at most  $k$ . By the definition of  $\mathcal{F}$ , all subsets of  $V$  with size at most  $k - 1$  are in  $\mathcal{F}$  so  $P$  satisfies the hereditary property. When  $k = d$ , two sets  $A, B$  in  $\mathcal{F}$  have  $|A \cap B| \geq d$  if and only if  $A = B$ . When  $k < d$ , two sets  $A, B$  in  $\mathcal{F}$  have  $|A \cap B| \geq d$  cannot happen. Hence,  $P$  satisfies the join property. Observe that a hyperedge is in  $G$  if and only if it is a dependent set of  $P$ . Hence, finding a dependent  $k$ -set packing for  $P$  is equivalent to finding a matching for  $G$ . ◀

## B More Applications

In this section, we present more applications of our results that are not covered in Section 1.1.

1. Let  $G = (V, E)$  be an  $m$ -edge undirected simple graph. Let  $P = (E, \mathcal{F})$  so that  $\mathcal{F} = \{A \subseteq E : \text{there exists a triangle in } G \text{ that contains all edges in } A\}$ . One may verify that  $P$  is a 2-polymoid. By Theorem 2, we obtain a deterministic linear-time algorithm for the dependent  $k$ -set packing for  $P$ , which is equivalent to partitioning the edge set of  $G$  into subsets, each of which edge-induces a 3-edge forest. In addition, we obtain the following sufficient and necessary condition:

► **Corollary 22.** *An  $m$ -edge undirected simple graph  $G$  can be edge-partitioned into 3-edge forests if and only if  $m$  is a multiple of 3 and  $G$  is not a triangle.*

In [5], they give a sufficient and necessary condition to partition the edge set of the given graph into a designated four-edge tree for highly-edge-connected graphs.

2. Let  $G = (V, E)$  be a complete multipartite graph. Let  $P = (V, \mathcal{F})$  so that  $\mathcal{F} = \{A \subseteq V : \text{all vertices in } A \text{ are from the same partite set}\}$ . One may verify that  $P$  is a 1-polymoid. By Theorem 2, we obtain the following sufficient and necessary condition:

► **Corollary 23.** *An  $n$ -vertex undirected simple complete multipartite graph  $G$  has a perfect matching if and only if  $n$  is a multiple of 2 and the number of vertices in a largest partite set is at most  $n/2$ .*

By an argument in [7], Corollary 23 suffices to prove:

► **Corollary 24.** *Given a set of points in  $\mathcal{R}^2$  in general position where each point has a color in  $[c]$ , one can group the points into pairs so that the line segment joining the points in a pair does not cross that of another pair and the points in each pair have different colors if and only if  $n$  is a multiple of 2 and for each color  $i \in [c]$  the number of points of color  $i$  is at most  $n/2$ .*

## C Omitted Proofs

► **Lemma 25.** *Let  $G = (V, E)$  be an undirected simple graph consisting of six edges. If  $E$  can be partitioned into  $E_1, E_2$  so that  $E_1$  edge-induces a triangle and  $E_2$  edge-induces a non-star graph, then  $E$  can also be partitioned into two subsets so that each subset edge-induces a 3-edge linear forest.*

**Proof.** By definition,  $E_2$  edge-induces either a triangle or a 3-edge linear forest. Suppose that  $E_2$  edge-induces a triangle. For any  $E' \subseteq E$ , let  $V(E')$  denote the set of the end-vertices of edges in  $E'$ . Since  $G$  is simple,  $V(E_1)$  and  $V(E_2)$  have at most one vertex in common. Hence, there exist  $e_1 \in E_1, e_2 \in E_2$  so that  $V(\{e_1\}) \cap V(E_2) = \emptyset$  and  $V(\{e_2\}) \cap V(E_1) = \emptyset$ . This yields that  $E_1 \cup \{e_2\} \setminus \{e_1\}$  and  $E_2 \cup \{e_1\} \setminus \{e_2\}$  both edge-induce  $P_3 \cup P_2$ , i.e., two vertex-disjoint paths of 3 vertices and 2 vertices.

Suppose that  $E_2$  edge-induces a 3-edge linear forest. Let  $e_2$  be an edge in  $E_2$  so that  $E_2 \setminus \{e_2\} = 2P_2$ , i.e., two edges with no end-vertices in common. Since  $G$  is simple and  $E_1$  edge-induces a complete graph,  $|V(\{e_2\}) \cap V(E_1)| \leq 1$ . Hence,  $E_1 \cup \{e_2\}$  has at most one vertex of degree  $\geq 3$  and  $e_2$  is not an edge in any cycle of  $E_1 \cup \{e_2\}$ . Let  $e_1$  be any edge in  $E_1$  incident with the maximum degree vertex in  $E_1 \cup \{e_2\}$ . Thus,  $E_1 \cup \{e_2\} \setminus \{e_1\}$  has max degree  $\leq 2$  and contains no cycle, i.e., a linear forest. On the other hand, because the union of  $2P_2$  and any other edge also has max degree  $\leq 2$  and contains no cycle,  $E_2 \cup \{e_1\} \setminus \{e_2\}$  also is a linear forest. ◀

# Exponential Lower Bounds for Threshold Circuits of Sub-Linear Depth and Energy

## Abstract

---

In this paper, we investigate computational power of threshold circuits and other theoretical models of neural networks in terms of the following four complexity measures: size (the number of gates), depth, weight and energy. Here, the energy of a circuit measures sparsity of their computation, and is defined as the maximum number of gates outputting non-zero values taken over all the input assignments.

As our main result, we prove that any threshold circuit  $C$  of size  $s$ , depth  $d$ , energy  $e$  and weight  $w$  satisfies  $\log(\text{rk}(M_C)) \leq ed(\log s + \log w + \log n)$ , where  $\text{rk}(M_C)$  is the rank of the communication matrix  $M_C$  of a  $2n$ -variable Boolean function that  $C$  computes. Thus, such a threshold circuit  $C$  is able to compute only a Boolean function of which communication matrix has rank bounded by a product of logarithmic factors of  $s, w$  and linear factors of  $d, e$ . This implies an exponential lower bound on the size of even sublinear-depth and sublinear-energy threshold circuit. For example, we can obtain an exponential lower bound  $s = 2^{\Omega(n^{1/3})}$  for threshold circuits of depth  $n^{1/3}$ , energy  $n^{1/3}$  and weight  $2^{o(n^{1/3})}$ . We also show that the inequality is tight up to a constant factor when the depth  $d$  and energy  $e$  satisfies  $ed = o(n/\log n)$ .

For other models of neural networks such as a discretized ReLU circuits and discretized sigmoid circuits, we define energy as the maximum number of gates outputting non-zero values. We then prove that a similar inequality also holds for a discretized circuit  $C$ :  $\text{rk}(M_C) = O(ed(\log s + \log w + \log n)^3)$ . Thus, if we consider the number gates outputting non-zero values as a measure for sparse activity of a neural network, our results suggest that larger depth linearly helps neural networks to acquire sparse activity.

## 1 Introduction

**Background.** DiCarlo and Cox argued that constructing good internal representations is crucial to perform visual information processing, such as object recognition, for neural networks in the brain [5]. Here, an internal representation is described by a vector in a very high dimensional space, where each axis is one neuron's activity and the dimensionality equals to the number (e.g.,  $\sim 1$  million) of neurons in a feedforward neural network. They call a representation good if, for a given pair of two images that are hard to distinguish at the input space, there exist representations for them that are easy to separate by simple

classifiers such as a linear classifier. While such internal representations are likely to play fundamental role in information processing in the brain, it is also known that a neuron needs relatively high energy to be active [18, 27], and hence neural networks are forced to acquire representations supported by only a small number of active neurons [7]. These observations pose a question: for what information processing can neural networks construct good internal representations?

In the paper [42], Uchizawa *et al.* address the question from the viewpoint of circuit complexity. More formally, they employed threshold circuits as a model of neural networks [23, 24, 28, 31, 34, 35, 36], and introduced a complexity measure, called energy complexity, for sparsity of their internal representations. A threshold circuit is a feedforward logic circuit whose basic computational element computes a linear threshold function, and energy of a circuit is defined as the maximum number of internal gates outputting ones over all the input assignments. (See also [6, 16, 33, 37, 45] for studies on energy complexity of other types of logic circuits). Uchizawa *et al.* then show that the energy complexity is closely related to the rank of linear decision trees. In particular, they prove that any linear decision tree of  $l$  leaves can be simulated by a threshold circuit of size  $O(l)$  and energy  $O(\log l)$ . Thus, even logarithmic-energy threshold circuits have certain computational power: any linear decision tree of polynomial number of leaves can be simulated by a polynomial-size and logarithmic-energy threshold circuit.

Following the paper [42], a sequence of papers show relations among other major complexity measures such as size (the number of gates), depth, weight and fan-in [22, 38, 39, 43, 41, 40, 44]. In particular, Uchizawa and Takimoto [43] showed that any threshold circuit  $C$  of depth  $d$  and energy  $e$  requires size  $s = 2^{\Omega(n/e^d)}$  if  $C$  computes a high bounded-error communication complexity function such as Inner-Product function. Even for low communication complexity functions, an exponential lower bound on the size is known for constant-depth threshold circuits: any threshold circuit  $C$  of depth  $d$  and energy  $e$  requires size  $s = 2^{\Omega(n/e^{2^{e+d}} \log^e n)}$  if  $C$  computes the parity function [41]. These results provide exponential lower bounds if the depth is constant and energy is sub-linear [43] or sub-logarithmic [41], while both Inner-Product function and Parity function are computable by linear-size, constant-depth, and linear-energy threshold circuits. Thus these results imply that the energy complexity strongly related to representational power of threshold circuits. However these lower bounds break down when we consider threshold circuits of larger depth and energy, say, non-constant depth and sub-linear energy.

**Our Results for Threshold Circuits.** In this paper, we prove that simple Boolean functions are hard even for sub-linear depth and sub-linear energy threshold circuits. Let  $C$  be a threshold circuit with Boolean input variables  $\mathbf{x} = (x_1, x_2, \dots, x_n)$  and  $\mathbf{y} = (y_1, y_2, \dots, y_n)$ . A communication matrix  $M_C$  of  $C$  is a  $2^n \times 2^n$  matrix where each row (resp., each column) is indexed by an assignment  $\mathbf{a} \in \{0, 1\}^n$  to  $\mathbf{x}$  (resp.,  $\mathbf{b} \in \{0, 1\}^n$  to  $\mathbf{y}$ ), and the value  $M_C[\mathbf{a}, \mathbf{b}]$  is defined to be the output of  $C$  given  $\mathbf{a}$  and  $\mathbf{b}$ . We denote by  $rk(M_C)$  the rank of  $M_C$  over  $\mathbb{F}_2$ . Our main result is the following relation among size, depth energy and weight.

► **Theorem 1.** *Let  $s, d, e$  and  $w$  be integers satisfying  $2 \leq s, d$ ,  $10 \leq e$ ,  $1 \leq w$ . If a threshold circuit  $C$  computes a Boolean function of  $2n$  variables, and has size  $s$ , depth  $d$ , energy  $e$  and weight  $w$ , then it holds that*

$$\log(rk(M_C)) \leq ed(\log s + \log w + \log n). \quad (1)$$

The theorem implies exponential lower bounds for sub-linear depth and sub-linear energy threshold circuits. As an example, let us consider a Boolean function  $CD_n$  defined as follows: For a  $2n$  input variables  $x_1, \dots, x_n$  and  $y_1, \dots, y_n$ ,

$$CD_n(\mathbf{x}, \mathbf{y}) = \bigvee_{i=1}^n x_i \wedge y_i.$$

We note that  $CD_n$  is a biologically motivated Boolean function: Maass [21] defined  $CD_n$  to model coincidence detection or a pattern matching, and Lynch and Musco [19] introduced a related problem, called Filter problem, for studying theoretical aspect of spiking neural networks. Since  $CD_n$  is the complement of the disjointness function and has rank  $2^n$ , the theorem implies that

$$n \leq ed(\log s + \log w + \log n) \quad (2)$$

holds if a threshold circuit  $C$  computes  $CD_n$ . Arranging Eq. (2), we can obtain a lower bound  $2^{n/(ed)}/(wn) \leq s$  which is exponential in  $n$  if both  $d$  and  $e$  are sub-linear and  $w$  is sub-exponential. For example, we can obtain an exponential lower bound  $s = 2^{\Omega(n^{1/3})}$  even for threshold circuits of depth  $n^{1/3}$ , energy  $n^{1/3}$  and weight  $2^{o(n^{1/3})}$ . We can obtain similar lower bounds for the Inner-Product function and the equality function, since they have linear rank.

Comparing the lower bound  $s = 2^{\Omega(n/e^d)}$  given in [43] to ours, our lower bound is meaningful only for sub-exponential weight, but improves on it in two-fold: the lower bound is exponential even if  $d$  is sub-linear, and provide a nontrivial lower bound for Boolean functions with much weaker condition: Threshold circuits need exponential size even for Boolean functions of the standard rank  $\Omega(n)$ .

Threshold circuits have received considerable attention in circuit complexity, and a number of lower bound arguments have developed for threshold circuits under some restrictions on computational resources including size, depth, energy and weight [1, 2, 3, 9, 10, 13, 15, 22, 26, 30, 32, 41, 43, 44]. However, the arguments for lower bounds are designated for constant-depth threshold circuits, and hence cannot provide meaningful ones when the depth is not constant. In particular,  $CD_n$  is computable by a depth-2 and linear-size threshold circuit. Thus, directly applying known techniques are unlikely to yield an exponential lower bound for  $CD_n$ .

To complement Theorem 1, we also show that the lower bound is tight up to a constant factor if the product of  $e$  and  $d$  are small:

► **Theorem 2.** *For any integers  $e$  and  $d$  such that  $2 \leq e$  and  $2 \leq d$ ,  $CD_n$  is computable by a threshold circuit of size*

$$s \leq (e-1)(d-1) \cdot 2^{\frac{n}{(e-1)(d-1)}}.$$

*depth  $d$ , energy  $e$  and weight*

$$w \leq \left( \frac{n}{(e-1)(d-1)} \right)^2.$$

Substituting  $s, d, e$  and  $w$  of a threshold circuit given in Theorem 2 to the right hand side of Eq. (2), we have

$$\begin{aligned} & ed(\log s + \log w + \log n) \\ & \leq ed \left( \frac{n}{(e-1)(d-1)} + \log(e-1)(d-1) + \log \left( \frac{n}{(e-1)(d-1)} \right)^2 + \log n \right) \\ & \leq 4n + O(ed \log n), \end{aligned}$$

which almost matches the left hand side of Eq. (2) if  $ed = o(n/\log n)$ . Thus, Theorem 1 neatly captures the computational aspect of threshold circuits computing  $CD_n$ . Recall that any linear decision tree of polynomial number of leaves can be simulated by a polynomial-size and logarithmic-energy threshold circuit [42]. Also, it is known that any Boolean function is computable by a threshold circuit of depth two and energy one if an exponential size is allowed [22]. Thus, we believe that the situation  $ed = o(n/\log n)$  is not too restrictive. We also show that the lower bound is also tight for the equality function.

**Our Result for Discretized Circuits.** Besides threshold circuits, we consider other well-studied models of neural network, where an activation function and weights of a computational element are discretized (such as, discretized sigmoid or ReLU circuits). The size, depth, energy and weight are important parameters also for artificial neural networks. The size and depth are major topics on success of deep learning. The energy is related to important techniques for deep learning method such as regularization, sparse coding, or sparse autoencoder [11, 17, 25]. The weight resolution is closely related to chip resources in neuromorphic hardware systems [29], and quantization schemes received attention [4, 12].

We define energy for a discretized circuit as the maximum number of gates outputting non-zero values, and show that any discretized circuit can be simulated by a threshold circuit with a moderate increase in size, depth, energy, and weight. Consequently, combining with Theorem 1, we can show that its rank is bounded by a product of the polylogarithmic factors of  $s, w$  and linear factors of  $d, e$  for discretized circuits. For example, we can obtain the following proposition for discretized sigmoid circuits:

► **Theorem 3.** *If a discretized sigmoid circuit  $C$  of size  $s$ , depth  $d$ , energy  $e$ , and weight  $w$  computes a Boolean function  $f$ , then it holds that*

$$\log(\text{rk}(M_C)) = O(ed(\log s + \log w + \log n)^3).$$

Maass, Schnitger and Sontag [20] showed that a sigmoid circuit could be simulated by a threshold circuit, but their simulation was optimized to be depth-efficient and did not consider energy. Thus, their result does not fit into our purpose.

Theorems 1 and 3 imply that a threshold circuit or discretized circuit are able to compute a Boolean function of bounded rank. Thus, we can consider these theorems as bounds on corresponding concept classes. According to the bound,  $c$  times larger depth is comparable to  $2^c$  times larger size. Thus, large depth could enormously help neural networks to increase its expressive power. Also, the bound suggests that increasing depth could also help a neural network to acquire sparse activity when we have hardware constraints on both the number of neurons and the weight resolution. These observations may shed some light on the reason for the success of deep learning.

**Organization.** The rest of the paper is organized as follows. In Section 2, we define terms needed for analysis. In Section 3, we present our main lower bound result. In Section 4, we show the tightness of the lower bound. In Section 5, we show a bound for discretized circuits. In Section 6, we conclude with some remarks.

## 2 Preliminaries

For an integer  $n$ , we denote by  $[n]$  a set  $\{1, 2, \dots, n\}$ . The base of the logarithm is two unless stated otherwise. In Section 2.1, we define terms on threshold circuits and discretized circuits. In Section 2.2, we define communication matrix, and give some known facts.

## 2.1 Circuit Model

In Sections 2.1.1 and 2.1.2, we give definitions of threshold and discretized circuits, respectively.

### 2.1.1 Threshold Circuits

Let  $k$  be a positive integer. A *threshold gate*  $g$  with  $k$  input variables  $\xi_1, \xi_2, \dots, \xi_k$  has weights  $w_1, w_2, \dots, w_k$ , and a threshold  $t$ . We define the output  $g(\xi_1, \xi_2, \dots, \xi_k)$  of  $g$  as

$$g(\xi_1, \xi_2, \dots, \xi_k) = \text{sign} \left( \sum_{i=1}^k w_i \xi_i - t \right) = \begin{cases} 1 & \text{if } t \leq \sum_{i=1}^k w_i \xi_i; \\ 0 & \text{otherwise} \end{cases}$$

To evaluate the weight resolution, we assume single synaptic weight to be discrete, and that  $w_1, w_2, \dots, w_n$  are integers. The *weight*  $w_g$  of  $g$  is defined as the maximum of the absolute values of  $w_1, w_2, \dots, w_k$ . In other words, we assume that  $w_1, w_2, \dots, w_k$  are  $O(\log w_g)$ -bit coded discrete values. Throughout the paper, we allow a gate to have both positive and negative weights, although biological neurons are either excitatory (all the weights are positive) or inhibitory (all the weights are negative). As mentioned in [21], this relaxation has basically no impact on circuit complexity investigations, unless one cares about constant blowup in computational resources.

A *threshold circuit*  $C$  is a combinatorial circuit consisting of threshold gates, and is expressed by a directed acyclic graph. The nodes of in-degree 0 correspond to input variables, and the other nodes correspond to gates. Let  $G$  be a set of the gates in  $C$ . For each gate  $g \in G$ , the *level* of  $g$ , denoted by  $\text{lev}(g)$ , is defined as the length of a longest path from an input variable to  $g$  on the underlying graph of  $C$ . For each  $l \in [d]$ , we define  $G_l$  as a set of gates in the  $l$ th level:  $G_l = \{g \in G \mid \text{lev}(g) = l\}$ .

In this paper, we consider a threshold circuit  $C$  for a Boolean function  $f : \{0, 1\}^{2n} \rightarrow \{0, 1\}$ . Thus,  $C$  has  $2n$  Boolean input variables  $\mathbf{x} = (x_1, x_2, \dots, x_n)$  and  $\mathbf{y} = (y_1, y_2, \dots, y_n)$ , and a unique output gate, denoted by  $g^{\text{clf}}$ , which is a linear classifier separating internal representations given by the gates in the lower levels (possibly together with input variables). Consider a gate  $g$  in  $C$ . Let  $w_1^x, w_2^x, \dots, w_n^x$  (resp.,  $w_1^y, w_2^y, \dots, w_n^y$ ) be the weights for  $x_1, x_2, \dots, x_n$  (resp.,  $y_1, y_2, \dots, y_n$ ), and  $t_g$  be threshold of  $g$ . For each gate  $h$  directed to  $g$ , let  $w_{h,g}$  be a weight of  $g$  for the output of  $h$ . Then the output  $g(\mathbf{x}, \mathbf{y})$  of  $g$  is defined as

$$g(\mathbf{x}, \mathbf{y}) = \text{sign}(p_g(\mathbf{x}, \mathbf{y}) - t_g)$$

where  $p_g(\mathbf{x}, \mathbf{y})$  denotes a potentials of  $g$  invoked by the input variables and gates:

$$p(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^n w_i^x x_i + \sum_{i=1}^n w_i^y y_i + \sum_{l=1}^{\text{lev}(g)-1} \sum_{h \in G_l} w_{h,g} h(\mathbf{x}, \mathbf{y}).$$

We sometimes write  $p_g^x(\mathbf{x})$  (resp.,  $p_g^y(\mathbf{y})$ ) for the potential invoked by  $\mathbf{x}$  (resp.,  $\mathbf{y}$ ):

$$p_g^x(\mathbf{x}) = \sum_{i=1}^n w_i^x x_i \quad \text{and} \quad p_g^y(\mathbf{y}) = \sum_{i=1}^n w_i^y y_i.$$

Although the inputs to  $g$  are not only  $\mathbf{x}$  and  $\mathbf{y}$  but the outputs of gates in the lower levels, we write  $g(\mathbf{x}, \mathbf{y})$  for the output of  $g$ , because  $\mathbf{x}$  and  $\mathbf{y}$  inductively decide the output of  $g$ . We say that  $C$  *computes* a Boolean function  $f : \{0, 1\}^{2n} \rightarrow \{0, 1\}$  if  $g^{\text{clf}}(\mathbf{a}, \mathbf{b}) = f(\mathbf{a}, \mathbf{b})$  for every  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ .

Let  $C$  be a threshold circuit. We define *size*  $s$  of  $C$  as the number of the gates in  $C$ , and *depth*  $d$  of  $C$  as the level of  $g^{\text{clf}}$ . We define the *energy*  $e$  of  $C$  as

$$e = \max_{(\mathbf{a}, \mathbf{b}) \in \{0,1\}^{2n}} \sum_{g \in G} g(\mathbf{a}, \mathbf{b}).$$

We define *weight*  $w$  of  $C$  as the maximum of the weights of the gates in  $C$ :  $w = \max_{g \in G} w_g$ .

### 2.1.2 Discretized Circuits

Let  $\varphi$  be an activation function. Let  $\delta$  be a discretizer that maps a real number to a number representable by a bitwidth  $b$ . We define a discretized activation function  $\delta \circ \varphi$  as a composition of  $\varphi$  and  $\delta$ , that is,  $\delta \circ \varphi(x) = \delta(\varphi(x))$  for any number  $x$ . We say that  $\delta \circ \varphi$  has *silent range for an interval*  $I$  if  $\delta \circ \varphi(x) = 0$  if  $x \in I$ , and  $\delta \circ \varphi(x) \neq 0$ , otherwise. For example, if we use the ReLU function as the activation function  $\varphi$ , then  $\delta \circ \varphi$  has silent range for  $I = (-\infty, 0]$  for any discretizer  $\delta$ . If we use the sigmoid function as the activation function  $\varphi$  and linear partition as discretizer  $\delta$ , then  $\delta \circ \varphi$  has silent range for  $I = (-\infty, t_{\max}]$  where  $t_{\max} = \ln(1/(2^b - 1))$  where  $\ln$  is the natural logarithm.

Let  $\delta \circ \varphi$  be a discretized activation function with silent range. A  $(\delta \circ \varphi)$ -gate  $g$  with  $k$  input variables  $\xi_1, \xi_2, \dots, \xi_k$  has weights  $w_1, w_2, \dots, w_k$  and a threshold  $t$ , where each of the weights and threshold are discretized by  $\delta$ . The output  $g(\xi_1, \xi_2, \dots, \xi_k)$  of  $g$  is then defined as

$$g(\xi_1, \xi_2, \dots, \xi_k) = \delta \circ \varphi \left( \sum_{i=1}^k w_i \xi_i - t \right).$$

A  $(\delta \circ \varphi)$ -circuit is a combinatorial circuit consisting of  $(\delta \circ \varphi)$ -gates except that the top gate  $g^{\text{clf}}$  is a threshold gate, that is, a linear classifier. We define size and depth of a  $(\delta \circ \varphi)$ -circuit same as the ones for a threshold circuit. We define energy  $e$  of a  $(\delta \circ \varphi)$ -circuit as the maximum number of gates outputting non-zero values in the circuit:

$$e = \max_{(\mathbf{a}, \mathbf{b}) \in \{0,1\}^{2n}} \sum_{g \in G} \llbracket g(\mathbf{a}, \mathbf{b}) \neq 0 \rrbracket$$

where  $\llbracket P \rrbracket$  for a statement  $P$  denote a notation of the function which outputs one if  $P$  is true, and zero otherwise. We define *weight*  $w$  of  $C$  as  $w = 2^{2b}$ , where  $2b$  is the bitwidth possibly needed to represent a potential value invoked by a single input of a gate in  $C$ .

## 2.2 Communication Matrix and its Rank

Let  $Z \subseteq \{0,1\}^n$ . For a Boolean function  $f : Z \times Z \rightarrow \{0,1\}$ , we define a communication matrix  $M_f$  over  $Z$  as a  $|Z| \times |Z|$  matrix where each row and column are indexed by  $\mathbf{a} \in Z$  and  $\mathbf{b} \in Z$ , respectively, and each entry is defined as  $M_f(\mathbf{a}, \mathbf{b}) = f(\mathbf{a}, \mathbf{b})$ . We denote by  $rk(M_f)$  the rank of  $M_f$  over  $\mathbb{F}_2$ . If a circuit  $C$  computes  $f$ , we may write  $M_C$  instead of  $M_f$ . If a Boolean function  $f$  does not have an obvious separation of the input variables to  $\mathbf{x}$  and  $\mathbf{y}$ , we may assume a separation so that  $rk(M_f)$  is maximized.

Let  $k$  and  $n$  be natural numbers such that  $k \leq n$ . Let

$$Z_k = \{\mathbf{a} \in \{0,1\}^n \mid \text{The number of ones in } \mathbf{a} \text{ is at most } k\}.$$

A  $k$ -disjointness function  $\text{DISJ}_{n,k}$  over  $Z_k$  is defines as follows:

$$\text{DISJ}_{n,k}(\mathbf{x}, \mathbf{y}) = \bigwedge_{i=1}^n \overline{x_i} \vee \overline{y_i}$$

where the input assignments are chosen from  $Z_k$ . The book [14] contains a simple proof showing that  $\text{DISJ}_{n,k}$  has full rank [14].

► **Theorem 4.**  $rk(M_{\text{DISJ}_{n,k}}) = \sum_{i=0}^k \binom{n}{i}$ . In particular,  $rk(M_{\text{DISJ}_{n,n}}) = 2^n$ .

$\text{CD}_n$  is the complement of  $\text{DISJ}_{n,n}$ . We can obtain the same bound for  $\text{CD}_n$ , as follows:

► **Corollary 5.**  $rk(M_{\text{CD}_n}) = 2^n$ .

We also use well-known facts on the rank. Let  $A$  and  $B$  be two matrices of same dimensions. We denote by  $A + B$  the summation of  $A$  and  $B$ , and by  $A \circ B$  the Hadamard product of  $A$  and  $B$ .

► **Fact 1.** For two matrices  $A$  and  $B$  of same dimensions, we have

(i)  $rk(A + B) \leq rk(A) + rk(B)$ ;

(ii)  $rk(A \circ B) \leq rk(A) \cdot rk(B)$ .

### 3 Lower Bound for Threshold Circuits

In this section, we give the inequality relating the rank of the communication matrix to the size, depth, energy and weight.

► **Theorem 6** (Theorem 1 restated). Let  $s, d, e$  and  $w$  be integers satisfying  $2 \leq s, d, 10 \leq e, 1 \leq w$ . Suppose a threshold circuit  $C$  computes a Boolean function of  $2n$  variables, and has size  $s$ , depth  $d$ , energy  $e$ , and weight  $w$ . Then it holds that

$$\log(rk(M_C)) \leq ed(\log s + \log w + \log n).$$

We prove the theorem by showing that  $M_C$  is a sum of matrices each of which corresponds to an internal representation that arises in  $C$ . Since  $C$  has bounded energy, the number of internal representations is also bounded. We then show by the inclusion-exclusion principle that each matrix corresponding to an internal representation has bounded rank. Thus, Fact 1 implies the theorem.

**Proof.** Let  $C$  be a threshold circuit that computes a Boolean function of  $2n$  variables, and has size  $s$ , depth  $d$ , energy  $e$  and weight  $w$ . Let  $G$  be a set of the gates in  $C$ . For  $l \in [d]$ , let  $G_l$  be a set of the gates in  $l$ -th level of  $C$ . Without loss of generality, we assume that  $G_d = \{g^{\text{clf}}\}$ . We evaluate the rank of  $M_C$ , and prove that

$$rk(M_C) \leq \left(\frac{c \cdot s}{e-1}\right)^{e-1} \cdot \left(\left(\frac{c \cdot s}{e-1}\right)^{e-1} \cdot (2nw+1)^{e-1}\right)^{d-1} \cdot (2nw+1) \quad (3)$$

where  $c < 3$ . Equation (3) implies that

$$rk(M_C) \leq \left(\frac{c \cdot s}{e-1} \cdot (2nw+1)\right)^{(e-1)d} \leq (snw)^{ed},$$

where the last inequality holds if  $e \geq 10$ . Taking the logarithm of the inequality, we obtain the theorem.

Below we verify that Eq. (3) holds. Let  $\mathbf{P} = (P_1, P_2, \dots, P_d)$ , where  $P_l$  is a subset of  $G_l$  for each  $l \in [d]$ . Given an input  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ , we say that an *internal representation*  $\mathbf{P}$  arises for  $(\mathbf{a}, \mathbf{b})$  if, for every  $l \in [d]$ ,  $g(\mathbf{a}, \mathbf{b}) = 1$  for every  $g \in P_l$ , and  $g(\mathbf{a}, \mathbf{b}) = 0$  for every  $g \notin P_l$ . We denote by  $\mathbf{P}^*(\mathbf{a}, \mathbf{b})$  the internal representation that arises for  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ . We then define  $\mathcal{P}_1$  as a set of the internal representations that arise for  $(\mathbf{a}, \mathbf{b})$  such that  $g^{\text{clf}}(\mathbf{a}, \mathbf{b}) = 1$ :

$$\mathcal{P}_1 = \{\mathbf{P}^*(\mathbf{a}, \mathbf{b}) \mid g^{\text{clf}}(\mathbf{a}, \mathbf{b}) = 1\}.$$

**85:8 Exponential Lower Bounds for Threshold Circuits of Sub-Linear Depth and Energy**

Note that, for any  $\mathbf{P} = (P_1, P_2, \dots, P_d) \in \mathcal{P}_1$ , we have  $|P_1| + |P_2| + \dots + |P_{d-1}| \leq e - 1$  and  $|P_d| = 1$ . Thus a standard upper bound on a sum of binomial coefficients implies that

$$|\mathcal{P}_1| \leq \sum_{k=0}^{e-1} \binom{s}{k} \leq \left( \frac{c \cdot s}{e-1} \right)^{e-1}. \quad (4)$$

For each  $\mathbf{P} \in \mathcal{P}_1$ , let  $M_{\mathbf{P}}$  be a  $2^n \times 2^n$  matrix such that, for every  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ ,

$$M_{\mathbf{P}}(\mathbf{a}, \mathbf{b}) = \begin{cases} 1 & \text{if } \mathbf{P} = \mathbf{P}^*(\mathbf{a}, \mathbf{b}); \\ 0 & \text{if } \mathbf{P} \neq \mathbf{P}^*(\mathbf{a}, \mathbf{b}). \end{cases}$$

By the definitions of  $\mathcal{P}_1$  and  $M_{\mathbf{P}}$ , we have

$$M_C = \sum_{\mathbf{P} \in \mathcal{P}_1} M_{\mathbf{P}},$$

and hence Fact 1(i) implies that

$$rk(M_C) \leq \sum_{\mathbf{P} \in \mathcal{P}_1} rk(M_{\mathbf{P}}).$$

Thus Eq. (4) implies that

$$rk(M_C) \leq \left( \frac{c \cdot s}{e-1} \right)^{e-1} \cdot \max_{\mathbf{P} \in \mathcal{P}_1} rk(M_{\mathbf{P}}).$$

We complete the proof by showing that, for any  $\mathbf{P} \in \mathcal{P}_1(C)$ , it holds that

$$rk(M_{\mathbf{P}}) \leq \left( \left( \frac{c \cdot s}{e-1} \right)^{e-1} \cdot (2nw + 1)^{e-1} \right)^{d-1} \cdot (2nw + 1).$$

In the following argument, we consider an arbitrary fixed internal representation  $\mathbf{P} = (P_1, P_2, \dots, P_d)$  in  $\mathcal{P}_1$ . We call a gate a *threshold function* if the inputs of the gate consists of only  $\mathbf{x}$  and  $\mathbf{y}$ . For each  $g \in G$ , we denote by  $\tau[g, \mathbf{P}]$  a threshold function defined as

$$\tau[g, \mathbf{P}](\mathbf{x}, \mathbf{y}) = \text{sign} (p_g^x(\mathbf{x}) + p_g^y(\mathbf{y}) + t_g[\mathbf{P}]).$$

where  $t_g[\mathbf{P}]$  is a threshold of  $g$ , being assumed that the internal representation  $\mathbf{P}$  arises:

$$t_g[\mathbf{P}] = \sum_{l=1}^{\text{lev}(g)-1} \sum_{h \in P_l} w_{h,g} - t_g.$$

For each  $l \in [d]$ , we define a set  $T_l$  of threshold functions as  $T_l = \{\tau[g, \mathbf{P}] \mid g \in G_l\}$ . Since every gate in  $G_1$  is a threshold function,  $T_1$  is identical to  $G_1$ .

For any set  $T$  of threshold functions, we denote by  $M[T]$  a  $2^n \times 2^n$  matrix such that, for every  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ ,

$$M[T](\mathbf{a}, \mathbf{b}) = \begin{cases} 1 & \text{if } \forall \tau \in T, \tau(\mathbf{a}, \mathbf{b}) = 1; \\ 0 & \text{if } \exists \tau \in T, \tau(\mathbf{a}, \mathbf{b}) = 0. \end{cases}$$

It is well-known that the rank of  $M[T]$  is bounded [8, 9], as follows. We give a proof for completeness.

▷ **Claim 7.**  $rk(M[T]) \leq (2nw + 1)^{|T|}$ .

Proof. Let  $z = |T|$ , and  $\tau_1, \tau_2, \dots, \tau_z$  be an arbitrary order of threshold functions in  $T$ . For each  $k \in [z]$ , we define

$$R_k = \{p_{\tau_k}^x(\mathbf{a}) \mid \mathbf{a} \in \{0, 1\}^n\}.$$

Since a threshold function receives a value between  $-w$  and  $w$  from a single input, we have  $|R_k| \leq 2nw + 1$ . For  $\mathbf{r} = (r_1, r_2, \dots, r_z) \in R_1 \times R_2 \times \dots \times R_z$ , we define  $R(\mathbf{r}) = X(\mathbf{r}) \times Y(\mathbf{r})$  as a combinatorial rectangle where

$$X(\mathbf{r}) = \{\mathbf{x} \mid \forall k \in [z], p_{\tau_k}(\mathbf{x}) = r_k\}$$

and

$$Y(\mathbf{r}) = \{\mathbf{y} \mid \forall k \in [z], t_{\tau_k} \leq r_k + p_{\tau_k}^y(\mathbf{y})\}.$$

Clearly, all the rectangles are disjoint, and hence  $M[T]$  can be expressed as a sum of rank-1 matrices given by  $R(\mathbf{r})$ 's taken over all the  $\mathbf{r}$ 's. Thus Fact 1(i) implies that its rank is at most  $|R_1 \times R_2 \times \dots \times R_z| \leq (2nw + 1)^z$ .  $\triangleleft$

For each  $l \in [d]$ , based on  $P_l$  in  $\mathbf{P}$ , we define a set  $Q_l$  of threshold functions as

$$Q_l = \{\tau[g, \mathbf{P}] \mid g \in P_l\} \subseteq T_l$$

and a family  $\mathcal{T}(Q_l)$  of sets  $T$  of threshold functions as

$$\mathcal{T}(Q_l) = \{T \subseteq T_l \mid Q_l \subseteq T \text{ and } |T| \leq e - 1\}.$$

Following the inclusion-exclusion principle, we define a  $2^n \times 2^n$  matrix

$$H[Q_l] = \sum_{T \in \mathcal{T}(Q_l)} (-1)^{|T| - |Q_l|} M[T].$$

We can show that  $M_{\mathbf{P}}$  is expressed as the Hadamard product of  $H[Q_1], H[Q_2], \dots, H[Q_d]$ :

$\triangleright$  Claim 8.  $M_{\mathbf{P}} = H[Q_1] \circ H[Q_2] \circ \dots \circ H[Q_d]$ .

Proof. Consider an arbitrary fixed assignment  $(\mathbf{a}, \mathbf{b}) \in \{0, 1\}^{2n}$ . We show that

$$H[Q_1](\mathbf{a}, \mathbf{b}) \circ H[Q_2](\mathbf{a}, \mathbf{b}) \circ \dots \circ H[Q_d](\mathbf{a}, \mathbf{b}) = 0,$$

if  $M_{\mathbf{P}}(\mathbf{a}, \mathbf{b}) = 0$ , and

$$H[Q_1](\mathbf{a}, \mathbf{b}) \circ H[Q_2](\mathbf{a}, \mathbf{b}) \circ \dots \circ H[Q_d](\mathbf{a}, \mathbf{b}) = 1,$$

if  $M_{\mathbf{P}}(\mathbf{a}, \mathbf{b}) = 1$ . We write  $\mathbf{P}^* = (P_1^*, P_2^*, \dots, P_d^*)$  to denote  $\mathbf{P}^*(\mathbf{a}, \mathbf{b})$  for a simpler notation.

Suppose  $M_{\mathbf{P}}(\mathbf{a}, \mathbf{b}) = 0$ . In this case, we have  $\mathbf{P} \neq \mathbf{P}^*$ , and hence there exists a level  $l \in [d]$  such that  $P_l \neq P_l^*$  while  $P_{l'} = P_{l'}^*$  for every  $l' \in [l - 1]$ . For such  $l$ , it holds that

$$\tau[g, \mathbf{P}^*](\mathbf{a}, \mathbf{b}) = \tau[g, \mathbf{P}](\mathbf{a}, \mathbf{b}) \tag{5}$$

for every  $g \in G_l$ . We show that  $H[Q_l](\mathbf{a}, \mathbf{b}) = 0$  by considering two cases:  $P_l \setminus P_l^* \neq \emptyset$  and  $P_l \subset P_l^*$ .

Consider the case where  $P_l \setminus P_l^* \neq \emptyset$ , then there exists  $g \in P_l \setminus P_l^*$ . Since  $g \notin P_l^*$ , we have  $\tau[g, \mathbf{P}^*](\mathbf{a}, \mathbf{b}) = 0$ . Thus, Eq. (5) implies that  $\tau[g, \mathbf{P}](\mathbf{a}, \mathbf{b}) = 0$ , and hence  $M[T](\mathbf{a}, \mathbf{b}) = 0$  for every  $T$  such that  $Q_l \subseteq T$ . Therefore, for every  $T \in \mathcal{T}(Q_l)$ , we have  $M[T](\mathbf{a}, \mathbf{b}) = 0$ , and hence

$$H[Q_l](\mathbf{a}, \mathbf{b}) = \sum_{T \in \mathcal{T}(Q_l)} M[T](\mathbf{a}, \mathbf{b}) = 0.$$

## 85:10 Exponential Lower Bounds for Threshold Circuits of Sub-Linear Depth and Energy

Consider the other case where  $P_l \subset P_l^*$ . Let  $Q_l^* = \{\tau[g, \mathbf{P}^*] \mid g \in P_l^*\}$ . Equation (5) implies that  $M[T](\mathbf{a}, \mathbf{b}) = 1$  if  $T$  satisfies  $Q_l \subseteq T \subseteq Q_l^*$ , and  $M[T](\mathbf{a}, \mathbf{b}) = 0$ , otherwise. Thus,

$$H[Q_l](\mathbf{a}, \mathbf{b}) = \sum_{T \in \mathcal{T}(Q_l)} (-1)^{|T| - |Q_l|} M[T] = \sum_{Q_l \subseteq T \subseteq Q_l^*} (-1)^{|T| - |Q_l|}$$

Therefore, by the binomial theorem,

$$H[Q_l](\mathbf{a}, \mathbf{b}) = \sum_{k=0}^{|Q_l^*| - |Q_l|} \binom{|Q_l^*| - |Q_l|}{k} (-1)^k = (1 - 1)^{|Q_l^*| - |Q_l|} = 0.$$

Suppose  $M_{\mathbf{P}}(\mathbf{a}, \mathbf{b}) = 1$ . In this case, we have  $\mathbf{P} = \mathbf{P}^*$ . Thus, for every  $l \in [d]$ , Eq. (5) implies that  $M[T](\mathbf{a}, \mathbf{b}) = 1$  if  $T = Q_l$ , and  $M[T](\mathbf{a}, \mathbf{b}) = 0$ , otherwise. Therefore,

$$H[Q_l](\mathbf{a}, \mathbf{b}) = \sum_{T \in \mathcal{T}(Q_l)} (-1)^{|T| - |Q_l|} M[T](\mathbf{a}, \mathbf{b}) = (-1)^{|Q_l| - |Q_l|} = 1.$$

Consequently,  $H[Q_1](\mathbf{a}, \mathbf{b}) \circ H[Q_2](\mathbf{a}, \mathbf{b}) \circ \cdots \circ H[Q_d](\mathbf{a}, \mathbf{b}) = 1$ , as desired.  $\triangleleft$

We finally evaluate  $rk(M_{\mathbf{P}})$ . Claim 8 and Fact 1(ii) imply that

$$rk(M_{\mathbf{P}}) = rk(H[Q_1] \circ H[Q_2] \circ \cdots \circ H[Q_d]) \leq \prod_{l=1}^d rk(H[Q_l]). \quad (6)$$

Since

$$|\mathcal{T}(Q_l)| \leq \left( \frac{c \cdot s}{e - 1} \right)^{e-1}$$

Fact 1(i) and Claim 7 imply that

$$\begin{aligned} rk(H[Q_l]) &\leq \sum_{T \in \mathcal{T}(Q_l)} rk(M[T]) \\ &\leq \left( \frac{c \cdot s}{e - 1} \right)^{e-1} \cdot (2nw + 1)^{e-1} \end{aligned} \quad (7)$$

for every  $l \in [d - 1]$ , and

$$rk(H[Q_d]) \leq 2nw + 1. \quad (8)$$

Equations (6)-(8) imply that

$$rk(M_{\mathbf{P}}) \leq \left( \left( \frac{c \cdot s}{e - 1} \right)^{e-1} \cdot (2nw + 1)^{e-1} \right)^{d-1} \cdot (2nw + 1)$$

as desired. We thus have verified Eq. (3).  $\blacktriangleleft$

Combining Corollary 5 and Theorem 6, we obtain the following corollary:

**► Corollary 9.** *Let  $s, d, e$  and  $w$  be integers satisfying  $2 \leq s, d, 10 \leq e, 1 \leq w$ . Suppose a threshold circuit  $C$  of size  $s$ , depth  $d$ , energy  $e$ , and weight  $w$  computes  $CD_n$ . Then it holds that*

$$n \leq ed(\log s + \log w + \log n).$$

*Equivalently, we have  $2^{n/(ed)}/(nw) \leq s$ .*

Theorem 6 implies lower bounds for other Boolean functions with linear rank. For example, consider another Boolean function  $\text{EQ}_n$  asking if  $\mathbf{x} = \mathbf{y}$ :

$$\text{EQ}_n(\mathbf{x}, \mathbf{y}) = \bigwedge_{i=1}^n \overline{x_i \oplus y_i}$$

Since  $M_{\text{EQ}_n}$  is the identity matrix with full rank, we have the same lower bound.

► **Corollary 10.** *Let  $s, d, e$  and  $w$  be integers satisfying  $2 \leq s, d$ ,  $10 \leq e$ ,  $1 \leq w$ . Suppose a threshold circuit  $C$  of size  $s$ , depth  $d$ , energy  $e$ , and weight  $w$  computes  $\text{EQ}_n$ . Then it holds that*

$$n \leq ed(\log s + \log w + \log n).$$

Equivalently, we have  $2^{n/(ed)}/(nw) \leq s$ .

## 4 Tightness of the Lower Bound

In this section, we show that the lower bound given in Theorem 6 is tight if the depth and energy are small.

### 4.1 Definitions

Let  $z$  be a positive integer, and  $f$  be a Boolean function of  $2n$  variables. We say that  $f$  is  $z$ -piecewise with  $f_1, f_2, \dots, f_z$  if the following conditions are satisfied: Let

$$B_j = \{i \in [n] \mid x_i \text{ or } y_i \text{ are fed into } f_j\},$$

then

- (i)  $B_1, B_2, \dots, B_z$  compose a partition of  $[n]$ ;
- (ii)  $|B_j| \leq \lceil n/z \rceil$  for every  $j \in [z]$ ;
- (iii)

$$f(\mathbf{x}, \mathbf{y}) = \bigvee_{j=1}^z f_j(\mathbf{x}, \mathbf{y}) \quad \text{or} \quad f(\mathbf{x}, \mathbf{y}) = \overline{\bigvee_{j=1}^z f_j(\mathbf{x}, \mathbf{y})}.$$

We say that a set of threshold gates sharing input variables is a neural set, and a neural set is selective if at most one of the gates in the set outputs one for any input assignment. A selective neural set  $S$  computes a Boolean function  $f$  if for every assignment in  $f^{-1}(0)$ , no gates in  $S$  outputs one, while for every assignment in  $f^{-1}(1)$ , exactly one gate in  $S$  outputs one. We define the size and weight of  $S$  as  $|S|$  and  $\max_{g \in S} w_g$ , respectively.

By a DNF-like construction, we can obtain a selective neural set of exponential size that computes  $f$  for any Boolean function  $f$ .

► **Theorem 11.** *For any Boolean function  $f$  of  $n$  variables, there exists a selective neural set of size  $2^n$  and weight one that computes  $f$ .*

### 4.2 Upper Bounds

The following proposition shows that we can construct threshold circuits of small energy for piecewise functions.

## 85:12 Exponential Lower Bounds for Threshold Circuits of Sub-Linear Depth and Energy

► **Lemma 12.** *Let  $e$  and  $d$  be integers satisfying  $2 \leq e$  and  $2 \leq d$ , and  $z$  be an integer. Suppose  $f : \{0, 1\}^{2n} \rightarrow \{0, 1\}$  is a  $z$ -piecewise function with  $f_1, f_2, \dots, f_z$ . If  $f_j$  is computable by a selective neural set of size at most  $s'$  and weight  $w'$  for every  $j \in [z]$ ,  $f$  is computable by a threshold circuit of size*

$$s \leq z \cdot s' + 1,$$

*depth  $d$ , energy  $e$  and weight*

$$w \leq \frac{2n}{z} \cdot w'.$$

Clearly,  $\text{CD}_n$  is a piecewise function, and so the lemma gives our upper bound for  $\text{CD}_n$ .

► **Theorem 13** (Theorem 2 restated). *For any integers  $e$  and  $d$  such that  $2 \leq e$  and  $2 \leq d$ ,  $\text{CD}_n$  is computable by a threshold circuit of size*

$$s \leq (e-1)(d-1) \cdot 2^{\frac{n}{(e-1)(d-1)}}.$$

*depth  $d$ , energy  $e$  and weight*

$$w \leq \left( \frac{n}{(e-1)(d-1)} \right)^2.$$

We can also obtain a similar proposition for  $\text{EQ}_n$ .

► **Theorem 14.** *For any integers  $e$  and  $d$  such that  $2 \leq e$  and  $2 \leq d$ ,  $\text{EQ}_n$  is computable by a threshold circuit of size*

$$s \leq (e-1)(d-1) \cdot 2^{\frac{2n}{(e-1)(d-1)}}.$$

*depth  $d$ , energy  $e$  and weight*

$$w \leq \frac{n}{(e-1)(d-1)}.$$

### 5 Simulating Discretized Circuits

In this section, we show that any discretized circuit can be simulated using a threshold circuit with a moderate increase in size, depth, energy, and weight. Thus, a similar inequality holds for discretized circuits, as follows.

► **Theorem 15.** *Let  $\delta$  be a discretizer and  $\varphi$  be an activation function such that  $\delta \circ \varphi$  has a silent range. If a  $(\delta \circ \varphi)$ -circuit  $C$  of size  $s$ , depth  $d$ , energy  $e$ , and weight  $w$  computes a Boolean function  $f$ , then it holds that*

$$\log(\text{rk}(M_C)) = O(ed(\log s + \log w + \log n)^3).$$

We prove the theorem by showing that, given a  $(\delta \circ \varphi)$ -circuit  $C$ , we can safely replace any  $(\delta \circ \varphi)$ -gate  $g$  in  $C$  by a set of threshold gates that simulate  $g$ . Our simulation is based on a binary search of the potentials of a discretized gate, and employ a conversion technique from a linear decision tree to a threshold circuit given in [42]. We omit our proof of the theorem due to the page limitation.

## 6 Conclusions

In this paper, we prove that a threshold circuit is able to compute only a Boolean function of which communication matrix has rank bounded by a product of logarithmic factors of size and weight, and linear factors of depth and energy. This bound implies that any threshold circuit of sub-linear depth, sub-linear energy and sub-exponential weight needs exponential size to compute  $CD_n$ ,  $EQ_n$ , and the Inner-Product function. We show that the bounds are tight up to a constant factor. We also prove that a similar bound holds for discretized circuits. Thus, increasing depth could help a neural network to acquire sparse activity. This observation may shed some light on the reason for the success of deep learning.

## Abstract

We study routing problems of a convoy in a graph, generalizing the shortest path problem (SPP), the travelling salesperson problem (TSP), and the Chinese postman problem (CPP) which are all well-studied in the classical (non-convoy) setting. We assume that each edge in the graph has a length and a speed at which it can be traversed and that our convoy has a given length. While the convoy moves through the graph, parts of it can be located on different edges. For safety requirements, at all time the whole convoy needs to travel at the same speed which is dictated by the slowest edge on which currently a part of the convoy is located. For Convoy-SPP, we give a strongly polynomial time exact algorithm. For Convoy-TSP, we provide an  $O(\log n)$ -approximation algorithm and an  $O(1)$ -approximation algorithm for trees. Both results carry over to Convoy-CPP which – maybe surprisingly – we prove to be NP-hard in the convoy setting. This contrasts the non-convoy setting in which the problem is polynomial time solvable.

## 1 Introduction

A fundamental setting within combinatorial optimization is to compute a route within a given graph, e.g., for a car in a street network. Well-studied problems in this area include the shortest path problem (SPP), the traveling salesperson problem (TSP), and the Chinese postman problem (CPP). For a single car, they model very well the problems of finding a route from one point to another, finding a tour that visits all given cities, or finding a tour that traverses all given edges, respectively.

However, this changes when instead we have a convoy that consists of several vehicles. Different streets in a network may allow different speeds. Because of safety considerations, the vehicles in the convoy need to adhere a constant inter-vehicle distance. Therefore, all the vehicles in the convoy need to travel at the same speed at any point in time. Hence, the *whole* convoy must move at the speed of the vehicle that is currently on the *slowest* edge (among all vehicles), see Figure 1. Thus, the classical algorithms for shortest path, TSP, and CPP cannot be used to find the fastest route for a convoy for these respective settings and they do not even yield approximation algorithms with any non-trivial approximation guarantee. Even more, shortest path and CPP are solvable in polynomial time in the usual setting, but it is not clear whether this is also the case for a convoy. Therefore, in this paper we investigate shortest path, TSP, and CPP in the convoy setting, present the first algorithms for these problems, and settle their complexity.

■ **Figure 1** Five snapshots of a convoy moving along a path. The numbers along the edges denote the corresponding speeds. In the first snapshot, the convoy is entirely on an edge with speed 80, so it will move at speed 80. In the second snapshot, the front of the convoy is on an edge with speed 40, so the entire convoy will move at speed 40. In the third snapshot, the convoy still moves at speed 40. Note that in this example the convoy will never move at speed 100. In the fourth snapshot, the back of the convoy is on an edge with speed 60, so the convoy will move at speed 60. Finally, in the last snapshot, the convoy moves at speed 80.

Formally, we assume that we are given a directed graph  $G = (V, E)$ , where each edge  $e \in E$  has a length  $\ell(e) \geq 0$  and a speed  $q(e) > 0$ , and a length of the convoy  $L \geq 0$ . In Convoy-SPP we are given additionally two special vertices  $s, t \in V$  and the goal is to find a path from  $s$  to  $t$  that minimizes the time between the moment that the head of the convoy leaves  $s$  until the moment that the tail arrives in  $t$ . Figuratively, we assume that at the beginning all vehicles of the convoy are located in  $s$ . Therefore, when the head of the convoy leaves  $s$ , we assume that the parts of the convoy not having left  $s$  do not restrict the speed of the convoy. We make a symmetric assumption when the convoy enters  $t$ . In Convoy-TSP we are given a special vertex  $r \in V$  in which the convoy needs to start and end and we seek a tour for the convoy that visits every vertex  $v \in V$  at least once, minimizing the time between the moment that the head of the convoy leaves  $r$  until the moment that the tail arrives in  $r$  again (making the same assumptions when leaving and entering  $r$  as above for  $s$  and  $t$ ). Note that both problems can also be defined for undirected graphs, by simply replacing every undirected edge by two directed edges for both directions, with the same length and speed. Finally, in Convoy-CPP we assume that our graph  $G$  is undirected (as it is common when studying the Chinese postman problem in the classical setting, e.g., [3]) but again each edge  $e \in E$  has a length  $\ell(e) \geq 0$  and a speed  $q(e) > 0$ . Also, like in Convoy-TSP we are given a special vertex  $r \in V$  in which the convoy starts and ends. The goal is to find a tour that traverses every edge at least once, minimizing the time between the moment that the head of the convoy leaves  $r$  until the moment that the tail arrives in  $r$  again. In all problems, we assume without loss of generality that  $\min_{e \in E} q(e) = 1$ .

Convoy-SPP is the most basic routing problem for a convoy and it is motivated by any movement of a convoy from one point to another in a street network. The problem was introduced in [8] where the authors give an exponential time exact algorithm and argue that this “hints” that the problem is NP-hard. The Convoy-TSP problem arises for example when relief supplies need to be delivered to several locations, e.g., to several villages or cities, after a natural disaster or in unsecure territory. In these cases, moving in a convoy may be necessary so that the vehicles can support each other when roads are interrupted, or for protection. Similarly, Convoy-CPP arises when instead the convoy needs to visit all edges, e.g., because several villages are located on roads connecting the major cities. We are not aware of prior results for Convoy-TSP or Convoy-CPP. The setting of a convoy moving through a network can be considered as a variant of dynamic flows or flows over time, see [12].

## 1.1 Our contributions

We give an exact algorithm for Convoy-SPP that runs in strongly polynomial time. Note that this contrasts the argumentation mentioned above in [8]. A natural approach for Convoy-SPP would be to generalize algorithms for the usual shortest path problem, like Dijkstra's algorithm or Bellman-Ford. However, it is not clear how to do this. In both algorithms, we compute a value for each vertex  $v$  that indicates the distance of a shortest path from  $s$  to  $v$  (in the case of Bellman-Ford, we have one such value for each possible number of edges on this path). However, for continuing this path from  $v$  to  $t$ , it is crucial to know the speeds of the edges in which the convoy is located when reaching  $v$ . For example, there can be a long path from  $s$  to  $v$  such that the whole convoy is located on very fast edges when reaching  $v$ , and a short path such that the whole convoy is located on very slow edges when reaching  $v$ , and many other Pareto-optimal possibilities in between. We cannot afford to compute each of these possibilities. Instead, we use a very different approach. We guess the slowest edge  $(u, v)$  on the optimal path from  $s$  to  $t$ . The remaining problem splits into two independent subproblems: finding the optimal path from  $s$  to  $u$  and finding the optimal path from  $v$  to  $t$ . For each of these subproblems, we can assume that no edge slower than  $(u, v)$  is used. This leads to a polynomial number of possible subproblems which we solve via dynamic programming. Here, let  $n$  and  $m$  denote the number of vertices and edges in the graph, respectively.

► **Theorem 1.** *There is an algorithm for the Convoy-SPP with a running time of  $O(nm^2)$ .*

For usual TSP and asymmetric TSP there are polynomial time approximation algorithms known, e.g., [6, 14, 15]. However, it is not clear how to generalize them to Convoy-TSP, even if the graph were undirected. A natural attempt would be to define the cost of an edge  $e$  to be  $\ell(e)/q(e)$ , i.e., the time that it takes for an infinitesimally small convoy to traverse only this edge. However, the actual convoy of length  $L$  might be much slower than this on  $e$  if a part of it is located on a slower edge. In particular, even one single edge  $e$  can slow down the convoy for  $L/q(e)$  time units which might be much larger than  $\ell(e)/q(e)$ . On the other hand, we cannot add this value  $L/q(e)$  as a penalty to the cost of  $e$ , since if the convoy traverses many edges of speed  $q(e)$ , this penalty would overcount the slowdown by an arbitrarily large amount. Also, it is not obvious how to compute good lower bounds on the optimal solution: the strongest lower bound used in the known results for (asymmetric) TSP is the Held-Karp LP-relaxation [5] which does not take the convoy feature into account. It is not clear how to add this aspect to the LP.

Instead, we use a reduction to group-TSP (in the usual setting, not in the convoy setting). The intuition is the following. Suppose that  $v_1, v_2, \dots, v_n$  is the order in which the vertices are visited for the first time in the optimal solution. We identify that a key question is to determine for each vertex  $v_j$  the minimum speed at which the convoy travels while going from  $v_{j-1}$  to  $v_j$ . Therefore, in our reduction to group-TSP we introduce a copy of  $v_j$  for each possible speed and assign all these copies into the same group, i.e., only one of these copies needs to be visited. We introduce edges between these copies, corresponding to paths that use only edges with the respective minimum speeds, using our algorithm for Convoy-SPP as a subroutine. We show that our reduction loses only a constant factor in the approximation guarantee. By scaling the speeds to powers of 2, we ensure that there are intuitively only  $O(\log n)$  different speeds, and thus each group for some vertex  $v_j$  has at most  $O(\log n)$  copies of  $v_j$ . For such instances of group-TSP there is an  $O(\log n)$ -approximation [13] which we invoke as a subroutine.

We give a simple reduction from Convoy-CPP to Convoy-TSP which yields an  $O(\log n)$ -approximation algorithm for Convoy-CPP as well.

► **Theorem 2.** *There is a polynomial time  $O(\log n)$ -approximation algorithm for Convoy-TSP.*

► **Theorem 3.** *There is a polynomial time  $O(\log n)$ -approximation algorithm for Convoy-CPP.*

Maybe surprisingly, we prove that Convoy-CPP is NP-hard, which contrasts the fact that the usual Chinese postman problem is solvable in polynomial time [3].

► **Theorem 4.** *The Convoy-CPP is NP-hard, both for directed and undirected graphs, even when all edge lengths are equal to 1 and  $L = 2$ .*

Finally, we give an  $O(1)$ -approximation algorithm for Convoy-TSP in undirected trees. While for normal TSP in trees, a simple depth-first-search (DFS) is optimal, this is *not* the case for Convoy-TSP. In fact, DFS can yield a very bad solution, already on stars in which the edges have all length 1 and only two different speeds: assume that  $r$  is the center of the star, then the optimal solution visits first all slow edges and then all fast edges (or vice versa) while in a DFS solution this order can be arbitrary and the convoy could travel all the time with the low speed, which can be much slower than the optimal solution. While this particular example has an obvious optimal solution, it is not clear how to generalize it to arbitrary trees. Instead, we use a recursive approach. It is useful to imagine that our goal is to solve Convoy-CPP, which is equivalent to Convoy-TSP on trees, and hence we want to compute a tour that traverses all edges. We round the speeds to powers of 2 and form clusters of the edges with the lowest speed such that, intuitively, the edges in each cluster are close together and any two different clusters are far apart (at least  $L$  units). For each cluster we compute a DFS tour and argue that the optimal solution cannot be much faster when it traverses the edges of the cluster. Then, we remove all edges of the lowest speed and recurse on each connected component.

► **Theorem 5.** *There is a polynomial time  $O(1)$ -approximation algorithm for Convoy-TSP and Convoy-CPP on undirected trees.*

We defer the proof of this theorem to the full version of the paper. Our  $O(1)$ -approximation for trees is non-trivial and, although the analysis leaves room for a modest improvement of the constant 13, getting a ratio close to 1 needs a substantially different approach. In fact, an exact algorithm may still be possible. Also, it remains an open problem whether an  $O(1)$ -approximation for Convoy-TSP in arbitrary graphs exists.

## 1.2 Related work

The authors of [8] actually refer to our Convoy-SPP as the convoy quickest path problem. This is because there are some similarities between Convoy-SPP and the quickest path problem (QPP) [7]. In the QPP, we are given a directed graph  $G = (V, E)$ , where each edge  $e \in E$  has a time value  $d(e) \geq 0$ , and a capacity  $c(e) \geq 0$ . The capacity is an upper bound on the number of units per time unit that can pass through an edge. Here, we are also given two special vertices  $s, t \in V$ , and a length of a transmission  $\sigma \geq 0$ . The goal in QPP is to find a path from  $s$  to  $t$  minimizing the total time spent on the path plus the delay caused by the edge capacities. Note that this is different from our model in which the edges have speeds. Several polynomial time exact algorithms have been developed for QPP, we refer to [10] for a survey.

Another related problem is the convoy movement problem as studied in [1]. It is concerned with routing *multiple* convoys simultaneously such that there is no moment in time in which two convoys cross paths. Also in the variable speed convoy movement problem, studied in [11], the goal is to route several convoys to their respective destinations such that their paths do not cross.

### 1.3 Outline

The rest of the paper is organized as follows. In Section 2 we will present a dynamic programming algorithm that solves Convoy-SPP to optimality in polynomial time. Then in Section 3 we consider Convoy-TSP on arbitrary directed graphs, and we give an  $O(\log n)$ -approximation, where  $n$  is the number of vertices. In Section 4, we will show that Convoy-CPP is NP-hard, and show how the results for Convoy-TSP can be used to obtain similar results for Convoy-CPP.

## 2 Convoy-Shortest Path Problem

In this section we present an algorithm for Convoy-SPP with a running time of  $O(nm^2)$ , i.e., we prove Theorem 1. Without loss of generality we assume that the edges are indexed in non-increasing order of their speed, i.e., such that  $q(e_1) \geq q(e_2) \geq \dots \geq q(e_m) = 1$ . First, we show that we can restrict ourselves to instances of the form described in the statement of the following lemma. This will simplify our algorithm since it eliminates certain special cases, e.g., when the distance between  $s$  and  $t$  is shorter than  $L$ .

► **Lemma 6.** *Without loss of generality we can assume that  $s$  has exactly one outgoing edge  $e$  with  $q(e) = 1$  and  $\ell(e) = L$ , and  $t$  has exactly one incoming edge  $e'$  with  $q(e') = 1$  and  $\ell(e') = L$ .*

**Proof.** Consider an instance  $I$  of the convoy-shortest path problem on a graph  $G = (V, E)$  with speeds  $q(e_1) \geq \dots \geq q(e_m) = 1$ . Create an instance  $I'$  on the graph  $G' = (V', E')$  with  $V' = V \cup \{s', s'', t', t''\}$ , where  $E'$  includes all edges of  $E$ , but all edges connected to  $s$  and  $t$  are now connected to  $s''$  and  $t''$  respectively. We also add the new edges  $(s, s')$ ,  $(s', s'')$ ,  $(t'', t')$  and  $(t', t)$  to  $E'$  with speeds  $q((s, s')) = q((t', t)) = 1$  and  $q((s', s'')) = q((t'', t')) = q(e_1)$ , all of length  $L$ .

Any path in  $I$  can be transformed into a corresponding path in  $I'$  in which the convoy first traverses the edges  $(s, s')$  and  $(s', s'')$ , then takes the corresponding edge from  $s''$  followed by the same edges as in  $I$ , and finishes its path with the corresponding edge to  $t''$  and finally edges  $(t'', t')$  and  $(t', t)$ . The time of the path in  $I'$  is exactly  $4L$  longer than the time of the path in  $I$ . We can transform any path in  $I'$  similarly into a corresponding path in  $I$  that is  $4L$  shorter.

Since the solution values in  $I$  and  $I'$  differ only by a global constant that is independent of the respective solution, we can make this transformation for any instance  $I$  without loss of generality, solve the solution on the modified instance  $I'$ , and transform its solution back to a solution for  $I$ . ◀

From now on we denote with  $I'$  a given instance that satisfies the properties of Lemma 6. Our algorithm is a dynamic program (DP) that uses a divide and conquer strategy. Intuitively, we first guess the edge  $e_i = (v, w)$  with the largest index  $i$  on the path of the optimal solution; hence, no edge is slower on this path. This splits this path into three parts: a path from  $s$  to  $v$ , the edge  $(v, w)$ , and a path from  $w$  to  $t$ . Note that the first and the last part use only edges that have a smaller index than  $i$ , i.e., that are at least as fast as  $(v, w)$ . We recurse in order to find these two subpaths, i.e., we will ensure that there is a DP-cell for each of these subproblems. These two subproblems are independent, since while a part of the convoy is located on the edge  $(v, w)$ , that edge defines the speed of the convoy.

Formally, our DP-table has a cell  $CSP(u, (v, w))$  for combinations of a vertex  $u \in V$  and an edge  $e_i = (v, w) \in E$ . This cell encodes the following subproblem. First, place the convoy in the graph such that its tail is located on  $u$ , in any way you like. Then, we need to find a

path such that beginning with this starting position, the head of the convoy reaches  $v$  as fast as possible, while we are only allowed to use edges in the set  $E_{(v,w)} = \{e_1, \dots, e_{i-1}\}$  (i.e., edges with index lower than the index of  $(v, w)$  and which are hence at least as fast as  $(v, w)$ ). In this cell  $CSP(u, (v, w))$  we store the time the convoy needs to traverse this path; we also store the path itself in order to determine later the optimal path and not only its time. Note that the edges on which we place the convoy in the first step are part of the computed path but there is no cost involved in this placement. Also note that it is sufficient that the head of the convoy reaches  $v$  but it does not need to traverse the edge  $(v, w)$ . We include  $(v, w)$  in the description of the cell  $CSP(u, (v, w))$  because it determines  $E_{(v,w)}$ , the subset of the edges that the convoy is allowed to use in its path. We introduce a cell  $CSP(u, (v, w))$  for each combination of a vertex  $u \in V$  and an edge  $e_i = (v, w) \in E$  such that the shortest path from  $u$  to  $v$  using only edges in  $E_{(v,w)}$  has a length of more than  $L$ . We will see later that if the shortest path from  $u$  to  $v$  has length at most  $L$ , then we do not need to recurse on that subproblem but we can simply take the shortest path from  $u$  to  $v$  in  $E_{(v,w)}$ .

Suppose that we are given a  $CSP(u, (v, w))$ . Let  $e_{i'} = (v', w') \in E_{(v,w)}$  be the edge with largest index  $i'$  in the path  $P^*$  of the optimal solution corresponding to the cell  $CSP(u, (v, w))$ . Suppose that the part of  $P^*$  between  $u$  and  $v'$  has a length of at least  $L$  and that the same holds for the part of  $P^*$  between  $w'$  and  $v$ . Then the former part is the optimal solution to the DP-cell  $CSP(u, (v', w'))$  and after that the convoy needs  $(\ell(e_{i'}) + L)/q(e_{i'})$  time units for traversing  $e_{i'}$ . The last part of  $P^*$  would be the optimal solution to the DP-cell  $CSP(v, (w', v'))$  if the edges of  $G$  were all reversed, so if each edge  $(\hat{u}, \hat{v})$  were replaced by the edge  $(\hat{v}, \hat{u})$  with the same length and speed as  $(\hat{u}, \hat{v})$ . Therefore, we define a “reversed” auxiliary graph  $G^R = (V, E^R)$  with  $E^R = \{(v, u) \mid (u, v) \in E\}$  where every reversed edge  $e^R \in E^R$  has the same speed and length as its original  $e \in E$ . Also, we define the same DP-cells as above for the same subproblems for  $G^R$ , i.e., we define a cell  $CSP^R(\hat{u}, (\hat{w}, \hat{v}))$  for each combination of a vertex  $\hat{u} \in V$  and an edge  $(\hat{w}, \hat{v}) \in E^R$  (so  $(\hat{v}, \hat{w}) \in E$ ) such that the shortest path from  $\hat{u}$  to  $\hat{w}$  in  $G^R$  has a length of more than  $L$ . Thus, we can split  $P^*$  into the optimal solution for  $CSP(u, (v', w'))$ , the edge  $(v', w')$ , and the optimal solution to  $CSP^R(v, (w', v'))$ , and it takes the convoy a total time of  $CSP(u, (v', w')) + (\ell(e_{i'}) + L)/q(e_{i'}) + CSP^R(v, (w', v'))$  to traverse  $P^*$ .

If the part of  $P^*$  from  $u$  to  $v'$  has length at most  $L$ , then one can show that it coincides simply with the shortest path from  $u$  to  $v'$  using only edges in  $E_{(v',w')}$  (since the edge  $(v', w')$  determines the speed of the convoy anyway), and a similar statement holds for the part of  $P^*$  from  $w'$  to  $v$ . Thus, when we want to compute the entry of the cell  $CSP(u, (v, w))$ , we guess the edge  $e_{i'} = (v', w')$ , i.e., we try each edge in  $E_{(v,w)}$ , we compute the lengths of the shortest paths from  $u$  to  $v'$  and from  $w'$  to  $v$  using only edges in  $E_{(v',w')}$ , and depending on their lengths look up the DP-cells  $CSP(u, (v', w'))$  and  $CSP^R(v, (w', v'))$  or take these shortest paths directly.

This yields the following recursive formula, where for each combination of a vertex  $u$  and an edge  $(v, w) \in E$  we denote by  $SP(u, (v, w))$  the shortest path in  $G$  from  $u$  to  $v$  that uses only edges in  $E_{(v,w)}$ ; we define  $SP^R(u, (v, w))$  similarly for  $G^R$ .

$$CSP(u, (v, w)) = \min \left\{ \begin{array}{l} \min_{\substack{e \in E_{(v,w)}: \\ SP(u,e) > L, \\ SP^R(v,e^R) > L}} \left\{ CSP(u, e) + \frac{\ell(e) + L}{q(e)} + CSP^R(v, e^R) \right\}, \\ \min_{\substack{e \in E_{(v,w)}: \\ SP(u,e) \leq L, \\ SP^R(v,e^R) > L}} \left\{ \frac{SP(u, e) + \ell(e)}{q(e)} + CSP^R(v, e^R) \right\}, \end{array} \right. \quad (1)$$

$$\min_{\substack{e \in E(v,w): \\ SP(u,e) > L, \\ SP^R(v,e^R) \leq L}} \left\{ CSP(u,e) + \frac{\ell(e) + SP^R(v,e^R)}{q(e)} \right\},$$

$$\min_{\substack{e \in E(v,w): \\ SP(u,e) \leq L, \\ SP^R(v,e^R) \leq L}} \left\{ \frac{SP(u,e) + \ell(e) + SP^R(v,e^R) - L}{q(e)} \right\}.$$

Note that we need not define base cases for this dynamic program. All cells where both subpaths are shorter than  $L$  are computed using  $SP$ . In the first cell where we recurse on a previously computed cell  $C$  of the DP, the length of the path corresponding to  $C$  is larger than  $L$ , but cell  $C$  has already been computed at that point because its value will be attained because of the fourth term of the recursion using  $SP$ .

We could compute all shortest paths in the graph restricted to  $E_{(v,w)}$  for each  $(v,w) \in E$  with any shortest path algorithm, e.g., with Dijkstra's algorithm. However, in order to improve the running time slightly, we use another DP which is analogous to the DP above. We initialize  $SP(v,(v,w)) = 0$  for all  $(v,w) \in E$ ,  $SP^R(v,(v,w)) = 0$  for all  $(v,w) \in E^R$ , and we use the recurrence

$$SP(u,(v,w)) = \min_{e \in E(v,w)} \{ SP(u,e) + \ell(e) + SP^R(v,e^R) \},$$

for each cell  $SP(u,(v,w))$  with  $u \neq v$  and a symmetric recurrence for each entry  $SP^R(u,(v,w))$  for which  $u \neq v$ .

Finally, we output the path stored in  $CSP(s,(t',t))$ . Note that the time stored in that cell corresponds to the time that the convoy, starting with its tail in  $s$ , needs such that its head reaches  $t'$ . The convoy needs an additional  $L$  time units in order to leave  $s$ , an additional  $L$  time units to reach  $t$ , and an additional  $L$  time units to enter  $t$  completely. This yields our solution to the transformed instance  $I'$ , which we can transform back to a solution to the original instance  $I$  using Lemma 6.

► **Theorem 1.** *There is an algorithm for the Convoy-SPP with a running time of  $O(nm^2)$ .*

**Proof.** First we prove correctness and then we prove the running time.

Consider a cell  $CSP(u,(v,w))$  for which we want to compute the optimal solution, which is a path  $P$  from  $u$  to  $v$  that minimizes the convoy travel time. We guess the slowest edge in  $P$ , let this be  $e^* = (u^*,v^*)$ . Let  $P_1$  and  $P_2$  be the subpaths of  $P$  before and after  $e^*$  respectively (both excluding  $e^*$ ).

First consider the case where both  $P_1$  and  $P_2$  are strictly larger than  $L$ . Then we can subdivide the problem encoded in this cell of the DP by using edge  $e^*$ . The total time it takes for the convoy to travel along  $P$  is the time to travel along  $P_1$  plus the time to travel along  $e^*$  plus the time to travel along  $P_2$ . Since both  $P_1$  and  $P_2$  are larger than  $L$  and they do not contain this new bottleneck edge  $e^*$ , their travel time is equal to  $CSP(u,e^*)$  and  $CSP^R(v,e^*)$  respectively. Note that these terms indeed do not contain the travel time along  $e^*$ , as the first term is the travel time until the head of the convoy reaches  $e^*$  and the second term is the travel time from the point in time onward when the tail leaves  $e^*$ . Finally, the travel time along  $e^*$  that is missing is the time it takes for the convoy to completely traverse the edge  $e^*$  from head to tail. This equals  $(\ell(e^*) + L)/q(e^*)$ , since this bottleneck edge determines the speed of the convoy for all these time units. Together, this gives us the first term of Equation (1).

Now observe that if  $SP(u, e^*) \leq L$ , there exists a path from  $u$  to  $u^*$  such that the tail of the convoy has just left  $u$  and some part of the convoy has reached  $u^*$ . Thus, edge  $e^*$  is the edge that determines the speed of the convoy while it is moving along  $P_1$  and along  $e^*$ . Since it travels a distance of  $SP(u, e^*) + \ell(e^*)$  there at speed  $q(e^*)$ , this takes  $(SP(u, e^*) + \ell(e^*)) / q(e^*)$  time units. Then, if the second part of the path is longer than  $L$  (i.e., if  $SP^R(v, e^*) > L$ ),  $P_2$  is the path corresponding to the solution  $CSP^R(v, e^*)$  and we retrieve the second term of Equation (1).

Similarly, if  $SP^R(v, e^*) \leq L$ , then  $P_2 = SP^R(v, e^*)$ , and by the same arguments as above we see that the third term of Equation (1) is correct.

Finally, if both  $SP(u, e^*) \leq L$  and  $SP^R(v, e^*) \leq L$ , then this total path is traversed at speed  $e^*$ . The total length of the path that the convoy needs to cover between  $u$  and  $v$  is therefore  $SP(u, e^*) + \ell(e^*) + SP^R(v, e^*)$ . Since we measure the time it takes for the tail to leave  $u$  and the head to reach  $v$ , we need to subtract  $L$  from this distance to get the distance that the convoy traverses. Note that the distance  $SP(u, e^*) + \ell(e^*) + SP^R(v, e^*) - L$  must be positive because we only introduce this cell whenever  $SP(u, (v, w)) > L$ . Dividing by the speed  $q(e^*)$  at which the convoy traverses this distance, we obtain the last term of Equation (1). This finishes the proof of correctness of the algorithm.

Using these observations, the entry of the cell  $CSP(u, (v, w))$  can be computed using only previously computed entries of cells of shorter paths. There are  $O(nm)$  cells in each of the dynamic programs. In each computation there are  $O(m)$  terms that need to be compared for the minimum value, since we recurse on one of the edges of the path. Therefore, the total running time of each of the dynamic programs is bounded by  $O(nm^2)$ . ◀

### 3 Convoy-TSP in general graphs

In this section we present our  $O(\log n)$ -approximation algorithm for Convoy-TSP in general graphs. First, we do some guesses and preprocessing in order to simplify our problem, while losing only a constant factor in our approximation guarantee.

► **Lemma 7.** *By losing a factor of 2 in the approximation ratio, we can assume that  $\ell(e) \geq L/nm$  for each edge  $e$ .*

**Proof.** Let  $\epsilon = L/nm$ . First, increase the length of any edge with length smaller than  $\epsilon$  to  $\epsilon$ . It follows that the optimal value of the modified instance cannot be smaller than the optimal value of the original instance. Now, consider the optimal solution of the original instance. Let  $e^*$  be the slowest edge with length less than  $\epsilon$  that is traversed by the optimal solution. We know that the optimal value of the original instance is at least  $L/q(e^*)$ . If we follow the same tour in the modified instance, we have to spend at most  $\epsilon/q(e^*)$  time additionally for each modified edge. This is true since staying longer on an edge will not decrease the speed of the convoy. In total, we spend at most  $nm\epsilon/q(e^*) = L/q(e^*)$  time units extra, so we lose at most a factor 2. ◀

From now on we assume that all edges have length at least  $L/nm$ . We say that an edge  $e$  is *short* if  $\ell(e) \leq 2L$  and *long* otherwise. Intuitively, the long edges are easy to deal with: if the convoy traverses a long edge  $e$ , then the whole convoy will be on  $e$  while traversing a distance of at least  $L$ , which takes at least  $L/q(e)$  time. Potentially, for some time only a part of the convoy is on  $e$  and then  $e$  slows the convoy down. However, this time is at most  $2L/q(e)$  which can be charged to the previous time of  $L/q(e)$ . In particular, if we had only long edges then we could reduce the problem to (normal) TSP by losing only a factor  $O(1)$  by simply giving each (long) edge length  $(\ell(e) + L)/q(e)$ .

■ **Figure 2** Illustration of constructed instance of group-TSP. Note that there is an edge between any pair of the form  $u(v, i)$  and  $u(v, j)$ . From the set of vertices enclosed by both the blue and red rectangle, at least one vertex has to be visited.

Thus, the core difficulty of the problem stems from the short edges. We want to modify the instance such that the short edges have only  $O(\log n)$  different speeds.

► **Lemma 8.** *By losing a factor of 6 in the approximation ratio, we will assume that the short edges have only  $O(\log n)$  different speeds and that they are all powers of 2.*

**Proof.** We guess the short edge with the lowest speed that is used in OPT. Let  $e^*$  be this edge. First, we remove each short edge that is slower than  $e^*$ . Then, if a short edge  $e$  is faster than  $n^2 m^2 \cdot q(e^*)$ , we round its speed down to  $n^2 m^2 \cdot q(e^*)$ . Since these edges are short, and any tour uses at most  $nm$  edges, this rounding will incur at most an additional

$$nm \cdot \frac{2L}{n^2 m^2 q(e^*)} = \frac{2L}{nmq(e^*)} \leq \frac{2\ell(e^*)}{q(e^*)} \leq 2\text{OPT}$$

time units, where the first inequality follows from Lemma 7. Hence, we lose at most a factor 3 in the approximation ratio. Finally, we round all speeds of the short edges down to powers of 2, which loses us another factor 2, to obtain  $O(\log n^2 m^2) = O(\log n)$  different speeds for the short edges. ◀

Let  $\bar{q}^{(1)} < \bar{q}^{(2)} < \dots < \bar{q}^{(K)}$  denote the different speeds of the short edges, and by Lemma 8 we have that  $K = O(\log n)$ . We guess the speed of the slowest short edge used in OPT and remove all slower short edges. Hence, we assume w.l.o.g. that OPT uses a short edge of speed  $\bar{q}^{(1)}$ .

We define now an instance of asymmetric group-TSP to which we reduce our given instance of Convoy-TSP. In group-TSP, the input consists of a directed graph  $G' = (V', E')$ , a weight  $w(e)$  for each  $e \in E'$  and a set of groups  $\mathcal{V}'_1, \dots, \mathcal{V}'_s \subseteq V'$ . Intuitively, the edge weights denote the lengths of the edges  $E'$ , but we call them weights here in order to distinguish them better from the lengths  $\ell(e)$  of the edges  $e \in E$ . The goal is to compute a minimum weight tour that visits at least one vertex from each group  $\mathcal{V}'_i$ .

For each input vertex  $v \in V$  we define a group of  $K + 1$  vertices  $\{u(v, 1), \dots, u(v, K + 1)\}$  (see Figure 2), i.e., the tour needs to visit at least one of these vertices. Intuitively, for each  $i \in \{1, \dots, K\}$  the vertex  $u(v, i)$  corresponds to arriving at the vertex  $v$  at speed  $\bar{q}^{(i)}$ , while the vertex  $u(v, K + 1)$  corresponds to arriving at  $v$  after traversing a long edge  $e$  (and then

the speed does not matter much since any slowdown due to  $e$  can be charged to the time the convoy spends on  $e$ ). For any pair of vertices  $v, v' \in V$  and each  $i \in \{1, \dots, K+1\}$  we introduce a directed edge  $e = (u(v, i), u(v', i))$  and we define the weight  $w(e)$  to be the time of the quickest path from  $v$  to  $v'$  such that

- at the beginning the head of the convoy is on  $v$  and the convoy travels at speed at most  $\bar{q}^{(i)}$  until the tail of the convoy has left  $v$ ,
- at the end the head of the convoy is at  $v'$ ,
- the convoy is allowed to use only short edges of speed at least  $\bar{q}^{(i)}$  and long edges (of any speed); if  $i = K+1$  it is only allowed to use long edges.

We denote by  $\overline{SP}(v, v', i)$  the corresponding path. We can compute  $\overline{SP}(v, v', i)$  with our algorithm from Section 2.

► **Lemma 9.** *For each  $v, v' \in V$  and each  $i \in \{1, \dots, K+1\}$  we can compute  $\overline{SP}(v, v', i)$  in time  $O(nm^2)$ .*

**Proof.** From graph  $G$ , create an auxiliary graph  $\bar{G}$  with a new vertex  $\bar{v}$  and an edge  $\bar{e} = (\bar{v}, v)$  with speed  $\bar{q}^{(i)}$  and length  $L$ . Moreover, delete all short edges from  $E'$  with a speed slower than  $\bar{q}^{(i)}$ . Indeed, the solution to that instance gives us exactly  $\overline{SP}(v, v', i)$  as requested, which can be solved using the algorithm from Theorem 1. ◀

Also, for each vertex  $v$  and any  $i, i' \in \{1, \dots, K+1\}$  we introduce the edge  $e = (u(v, i), u(v, i'))$ , and define its weight  $w(e) := L / \min\{\bar{q}^{(i)}, \bar{q}^{(i')}\}$ . Intuitively, this models that if the convoy traverses some edge of speed  $\bar{q}^{(i)}$  and after that edges of a higher speed  $\bar{q}^{(i')}$ , then the edge of speed  $\bar{q}^{(i)}$  slows down the convoy for  $L/\bar{q}^{(i)}$  more time units. To streamline our argumentation, we introduce this edge with this cost also if  $\bar{q}^{(i')} < \bar{q}^{(i)}$ .

We solve our instance of group-TSP with an adaptation of the algorithm in [13] which yields an  $O(K)$ -approximate tour  $T'$ . We translate  $T'$  to a tour  $T$  of our given instance of Convoy-TSP as follows. We define  $T$  by adding to it step by step the edges that the convoy needs to traverse. We know that  $T'$  must visit at least one vertex  $u(r, i)$  of the group corresponding to the initial vertex  $r \in V$  of the convoy. Starting in  $u(r, i)$ , we follow  $T'$ . Whenever  $T'$  uses an edge  $e = (u(v, i), u(v', i))$  for two vertices  $v, v'$  and an  $i \in \{1, \dots, K+1\}$  then we add to  $T$  the edges in  $\overline{SP}(v, v', i)$ . When the convoy travels along an edge  $e = (u(v, i), u(v, i'))$  for a vertex  $v$  and  $i, i' \in \{1, \dots, K+1\}$  we do not add edges to  $T$  (such an edge  $e$  ensures only that the time of our convoy in tour  $T$  is comparable to  $w(T')$ ).

► **Lemma 10.** *The convoy needs time  $O(w(T'))$  to traverse the tour  $T$ .*

**Proof.** Suppose that when the convoy traverses  $T$  it does this during the time interval  $I$ . Let  $I_1$  denote the union of all subintervals of  $I$  during which the speed of the convoy is determined by a long edge  $e$ . Consider one such edge  $e$ . Then there are two vertices  $v, v'$  and an  $i \in \{1, \dots, K+1\}$  such that  $(u(v, i), u(v', i)) \in T'$  and  $e \in \overline{SP}(v, v', i)$ . Thus, the time during  $I$  in which  $e$  determines the speed of the convoy is at most  $\frac{L+\ell(e)}{q(e)}$ , while  $e$  contributes at least  $\frac{\ell(e)}{q(e)} = \Omega\left(\frac{L+\ell(e)}{q(e)}\right)$  to  $w((u(v, i), u(v', i)))$ . Therefore,  $|I_1| \in O(w(T'))$ .

Let  $I_2 := I \setminus I_1$ , i.e., the union of the time intervals in  $I$  during which the speed of the convoy is determined by a short edge. We want to bound  $|I_2|$ . To this end, take  $T'$  and consider all connected components of edges of the form  $e = (u(v, i), u(v', i))$  for two vertices  $v, v'$  and an  $i \in \{1, \dots, K+1\}$ . Let  $C = \{e_1, e_2, \dots\}$  be such a component. Then there exists an  $i \in \{1, \dots, K+1\}$  such that for each edge  $e_j \in C$  there are two vertices  $v_j, v'_j \in V$  such that  $e_j = (u(v_j, i), u(v'_j, i))$  and the convoy traverses the path  $\overline{SP}(v_j, v'_j, i)$ . The total time that the convoy traverses the paths  $\{\overline{SP}(v_j, v'_j, i)\}_{j:e_j \in C}$  such that the speed of the convoy

is determined by a short edge of speed *at least*  $\bar{q}^{(i)}$  is bounded by  $\sum_{j:e_j \in C} w(e_j)$  (note that  $w(e_j)$  might over-estimate the time needed by the convoy to traverse the edges of  $\overline{SP}(v_j, v'_j, i)$  since we assume that the convoy travels at speed at most  $\bar{q}^{(i)}$  when leaving  $v_j$ ). It remains to bound the time that the convoy traverses the paths  $\{\overline{SP}(v_j, v'_j, i)\}_{j:e_j \in C}$  such that the speed of the convoy is determined by a short edge of some speed that is strictly *slower* than  $\bar{q}^{(i)}$ ; we denote by  $\hat{t}$  this amount of time. Let  $\bar{q}^{(i^*)}$  be the smallest such speed. In particular, this implies that  $\hat{t} \leq L/\bar{q}^{(i^*)}$ .

Let  $C'$  denote the connected component of the edges of the form  $e = (u(v, i), u(v, i'))$  for a vertex  $v \in V$  and  $i, i' \in \{1, \dots, K+1\}$  that is traversed in  $T'$  right before  $C$ . If  $\hat{t} > 0$ , then  $C'$  must contain an edge  $e^* = (u(v, i^*), u(v, \hat{i}))$  with  $\bar{q}^{(i^*)} < \bar{q}^{(\hat{i})}$  and thus  $w(e^*) = L/\bar{q}^{(i^*)} \geq \hat{t}$ . Hence, the total time that the convoy traverses  $C$  is bounded by  $w(e^*) + \sum_{j:e_j \in C} w(e_j)$ . Applying this argumentation to all components  $C$  yields that  $|I_2| \in O(w(T'))$  and thus  $|I| = |I_1| + |I_2| \in O(w(T'))$ .  $\blacktriangleleft$

Abusing notation, we denote by  $\text{OPT}$  the time that it takes to traverse  $\text{OPT}$ . It remains to show that  $w(T') = O(\log n \cdot \text{OPT})$ . To this end, we show that we can construct a tour  $T^*$  for our instance of group-TSP for which  $w(T^*) = O(\text{OPT})$  holds. This implies that  $w(T') = O(K \cdot w(T^*)) = O(\log n \cdot \text{OPT})$ . Note that hence our reduction to group-TSP loses only a factor  $O(1)$  (and we lose the factor  $O(\log n)$  because we can solve the instance of group-TSP only approximately).

Based on  $\text{OPT}$ , we describe now how we construct  $T^*$  such that  $w(T^*) = O(\text{OPT})$ . Assume w.l.o.g. that  $V = \{v_1, \dots, v_n\}$  such that  $v_1 = r$  (i.e., the initial vertex) and for each  $j \in \{1, \dots, n-1\}$  we have that  $v_j$  is visited in  $\text{OPT}$  for the first time before  $v_{j+1}$  is visited in  $\text{OPT}$  for the first time (note that  $\text{OPT}$  might visit a vertex several times). For convenience, we define that  $v_{n+1} = v_1$ . For each  $j \in \{1, \dots, n\}$  we do the following: let  $P_j$  denote the path that the convoy takes between visiting  $v_j$  and  $v_{j+1}$  for the first time. If  $P_j$  contains a short edge, we add  $(u(v_j, i), u(v_{j+1}, i))$  to  $T$  where  $\bar{q}^{(i)}$  is the minimum speed at which the convoy travels in  $\text{OPT}$  while the head of the convoy is on an edge in  $P_j$ . If  $P_j$  does not contain a short edge, then we add  $(u(v_j, K+1), u(v_{j+1}, K+1))$  to  $T$ .

It can happen that for some vertex  $v_j$  we added two edges  $(u(v_{j-1}, i), u(v_j, i))$ ,  $(u(v_j, i'), u(v_{j+1}, i'))$  with  $i \neq i'$ . In this case we add the edge  $(u(v_j, i), u(v_j, i'))$ . Let  $T^*$  be the resulting tour.

**► Lemma 11.** *The group-TSP solution  $T^*$  has total weight  $w(T^*) = O(\text{OPT})$ .*

**Proof.** Suppose that we change  $\text{OPT}$  to a new tour  $\text{OPT}'$  by slowing down the convoy even though it would not be necessary. We do this such that  $\text{OPT}'$  can be traversed in at most time  $O(\text{OPT})$ . Let  $\ell(\text{OPT})$  denote the total length that the head of the convoy travels in  $\text{OPT}$ . Here, we assume w.l.o.g. that the head keeps traveling after reaching  $r$  for a distance of  $L$  using edges of unbounded speed. Now, consider the interval  $I = [0, \ell(\text{OPT})]$ . For each point  $d \in I$  denote by  $q_{\text{OPT}}(d)$  the speed that the convoy travels in  $\text{OPT}$  when the head of the convoy has already traveled a distance of  $d$ . Let  $I' = [a, b] \subseteq I$  denote a maximally large subinterval of  $I$  such that  $q_{\text{OPT}}(d) = \bar{q}^{(1)}$  for each  $d \in I'$ . Let  $a'$  denote the largest value  $x \leq a$  such that after travelling a distance of  $x$  in  $\text{OPT}$  the head of the convoy visits a vertex  $v \in V$  for the first time. We define a new speed function  $q'$  for the head of the convoy for which we define for each  $d \in [a', \min\{a' + L, b\}]$  that  $q'(d) := \bar{q}^{(1)}$ .

Similarly, let  $b'$  denote the smallest value  $y \geq b$  such that after travelling a distance of  $y$  in  $\text{OPT}$  the head of the convoy visits a vertex  $v \in V$  for the first time. We define  $q'$  such that for each  $d \in [\max\{b' - L, a\}, b']$  we define the speed  $q'(d) := \bar{q}^{(1)}$  for the head of the convoy. We define that the interval  $[a', b']$  is *clean*. We do this operation for each interval

$I' \subseteq I$  such that  $q_{\text{OPT}}(d) = \bar{q}^{(1)}$  for each  $d \in I'$ . Let  $I_2$  denote the union of subintervals of  $I$  that we obtain if we remove from  $I$  each clean interval  $I' = [a', b']$ . Inductively, we do the same transformation for each maximally large interval  $I'$  of  $I_2$  such that  $q_{\text{OPT}}(d) = \bar{q}^{(2)}$  for each  $d \in I'$ , obtaining a set  $I_3$ . We continue for each  $k' \in \{3, 4, \dots, K\}$ .

If for a value  $d \in [0, \ell(\text{OPT}))$  we did not define a value  $q'(d)$ , then we define  $q'(d) := q_{\text{OPT}}(d)$ . Let  $\text{OPT}'$  denote a tour in which we traverse the edges of  $\text{OPT}$  at the speeds given by  $q'$ . Observe that  $q'(d) \leq q_{\text{OPT}}(d)$  for each  $d \in [0, \ell(\text{OPT}))$ . Using that the speeds are powers of 2 and geometric sum arguments, one can show that  $\text{OPT}' \in O(\text{OPT})$ , see Lemma 13 in the appendix.

We want to argue that  $w(T^*) \in O(\text{OPT}')$ . Consider first the edges  $e \in T^*$  of the form  $e = (u(v, i), u(v', i))$  for two vertices  $v, v'$  and an  $i \in \{1, \dots, K+1\}$ . Let  $T_1^*$  denote the set of all these edges and let  $T_2^* := T^* \setminus T_1^*$ . We first want to show that  $w(T_1^*) \in O(\text{OPT}')$ . Let  $C = \{e_1, e_2, \dots\}$  be a connected component of  $T_1^*$ . Then there exists an  $i \in \{1, \dots, K+1\}$  such that for each edge  $e_j \in C$  there are two vertices  $v_j, v'_j \in V$  such that  $e_j = (u(v_j, i), u(v'_j, i))$ . By definition of  $\text{OPT}'$  and  $w(e_j)$ , we have that  $w(e_j)$  is at most the time that in  $\text{OPT}'$  the head of the convoy needs to move from  $v_j$  to  $v'_j$ . Repeating this argumentation for each edge  $e_j \in T_1^*$ , this implies that  $w(T_1^*) \in O(\text{OPT}')$ .

It remains to argue that  $w(T_2^*) \in O(\text{OPT}')$ . Assume that  $V = \{v_1, \dots, v_n\}$ . For each vertex  $v_j \in V$ , denote by  $d_j$  the distance traveled by the head of the convoy when it reaches  $v_j$  for the first time. Assume w.l.o.g. that the vertices are ordered such that  $d_j < d_{j'}$  for each  $j, j'$  with  $j < j'$ . This partitions the  $[0, \ell(\text{OPT}'))$  into intervals of the form  $[d_j, d_{j+1})$  with  $j \in \{1, \dots, n\}$ , where for convenience we define  $d_{n+1} := \ell(\text{OPT}')$ . Consider an edge  $e \in T_2^*$ . By definition of  $T^*$ , there are vertices  $v_j, v_{j+1}, v_{j+2}$  and speeds  $\bar{q}^{(i)}, \bar{q}^{(i')}$  such that  $e = (u(v_{j+1}, i), u(v_{j+1}, i'))$  and at some point during the interval  $[d_j, d_{j+1})$  or at some point during the interval  $[d_{j+1}, d_{j+2})$  (measured in the total distance that the head of the convoy has traveled) the convoy travels at speed  $\min\{\bar{q}^{(i)}, \bar{q}^{(i')}\}$  due to some edge  $e'$ . We charge  $w(e) = L / \min\{\bar{q}^{(i)}, \bar{q}^{(i')}\}$  to the slow-down of the convoy due to  $e'$ . The remainder of the argumentation follows via geometric sum arguments, addressing the case when we charge two edges of different speeds that are traversed (partially) at the same time by the convoy in  $\text{OPT}'$ .

To this end, for each speed  $\bar{q}^{(i)}$  we define  $\mathcal{I}^{(i)}$  to be the family of maximal intervals  $I$  of interval  $[0, \ell(\text{OPT}'))$  during which the convoy travels at speed  $\bar{q}^{(i)}$  or slower (again, measured in the total distance that the head of the convoy has traveled). For each speed  $\bar{q}^{(i)}$  we define  $|\mathcal{I}^{(i)}|$  to be the total length of the intervals in  $\mathcal{I}^{(i)}$  and we observe that  $|\mathcal{I}^{(i)}|/\bar{q}^{(i)} \leq \text{OPT}'$ . Since the speeds are powers of 2, via a geometric sum argument we also obtain that  $\sum_i |\mathcal{I}^{(i)}|/\bar{q}^{(i)} \leq O(\text{OPT}')$ . We argue now how to charge  $w(T_2^*)$  to  $\sum_i |\mathcal{I}^{(i)}|/\bar{q}^{(i)}$ . Consider an edge  $e = (u(v_{j+1}, i), u(v_{j+1}, i')) \in T_2^*$  as defined above and corresponding speeds  $\bar{q}^{(i)}, \bar{q}^{(i')}$ . Let  $i^*$  be such that  $\bar{q}^{(i^*)} = \min\{\bar{q}^{(i)}, \bar{q}^{(i')}\}$ . Then there is an interval  $I = [a, b) \in \mathcal{I}^{(i^*)}$  such that  $a \in [d_j, d_{j+2})$  or  $b \in [d_j, d_{j+2})$ . We have that  $w(e) \leq (b-a)/\bar{q}^{(i^*)}$ . Thus, we charge  $w(e)$  to  $I$ . In this way, each interval  $I$  in each set  $\mathcal{I}^{(i)}$  is charged at most twice, and we obtain that hence the total charge of all edges in  $T_2^*$  amounts to  $w(T_2^*) = \sum_{e \in T_2^*} w(e) \leq 2 \sum_i |\mathcal{I}^{(i)}|/\bar{q}^{(i)} \leq O(\text{OPT}')$ . Thus,  $w(T^*) = w(T_1^*) + w(T_2^*) \in O(\text{OPT}')$ . ◀

We conclude that the time the convoy needs to traverse our computed tour  $T$  is bounded by  $O(w(T')) = O(K \cdot w(T^*)) = O(\log n \cdot \text{OPT})$ . This yields our  $O(\log n)$ -approximation algorithm for the Convoy-TSP problem.

► **Theorem 2.** *There is a polynomial time  $O(\log n)$ -approximation algorithm for Convoy-TSP.*

## 4 Convoy-Chinese Postman Problem

In this section we discuss Convoy-CPP, which is defined on undirected graphs. First we show that Convoy-CPP is NP-hard, also for directed graphs. Note that CPP can be solved to optimality in polynomial time for both undirected [2] and directed graphs [3]. For mixed graphs, CPP is already NP-hard [9].

► **Theorem 4.** *The Convoy-CPP is NP-hard, both for directed and undirected graphs, even when all edge lengths are equal to 1 and  $L = 2$ .*

**Proof.** To show NP-hardness for undirected graphs we use a reduction from the Hamiltonian path problem [4]. In this problem we are given a graph  $G = (V, E)$  and the question is whether there exists a Hamiltonian path, i.e., a path visiting all vertices exactly once, in  $G$ .

Let  $I$  be an instance of the Hamiltonian path problem. We create graph  $G'$  by copying the graph  $G$  of  $I$ . Each edge in  $G'$  has a length of 1 and a speed of  $M = 4m + 1$ , where  $m$  is the number of edges in  $G$ . We also pick an arbitrary vertex from this graph as the special vertex  $r$ . Now we create a new vertex in  $G'$  for every vertex in  $G$ , and connect it to its corresponding vertex. Each new edge has length 1 and speed 1. Further, we set  $L$  equal to 2. We will show that there is a solution in which the convoy needs less than  $3n + 2$  time units to traverse all edges if and only if the original graph has a Hamiltonian path.

Suppose that  $G$  contains a Hamiltonian path. The convoy can first visit all edges with speed  $M$  spending at most  $2m/M$  time units. It can then move to one of the endpoints of the Hamiltonian path, spending at most  $m/M$  time units. The convoy can now follow the Hamiltonian path, where it visits the edges with speed 1 upon arrival at a vertex. Since this will decrease the speed to 1, the head of the convoy will arrive at the other endpoint of the Hamiltonian path after  $3n - 1$  more time units. While the head of the convoy heads back to  $r$ , the convoy will travel at speed 1 for  $L = 2$  more time units. After that, the tail of the convoy still needs to travel a distance of at most  $m$ , while the convoy is at speed  $M$ . In total, the time spent by the convoy is at most

$$\frac{2m}{M} + \frac{m}{M} + 3n - 1 + L + \frac{m}{M} = \frac{4m}{M} + 3n - 1 + L < 3n + 2.$$

On the other hand, suppose that  $G$  does not contain a Hamiltonian path. In any solution, traversing the edges of speed 1 takes  $2n$  time units. After the last visit to an edge with speed 1, the convoy moves at speed 1 for another  $L = 2$  time units. The convoy also travels at speed 1 for at least one time unit between consecutive visits of speed 1 edges, since none of these edges are adjacent. Moreover, since  $G$  does not contain a Hamiltonian path, there needs to be at least one pair of speed 1 edges that are visited consecutively for which the convoy travels at speed 1 for at least two time units. In total, the time spent in any solution is at least  $2n + n + L = 3n + 2$ . To show NP-hardness for directed graphs we reduce from the directed Hamiltonian path problem [4] and perform a similar reduction. ◀

Next, we will relate the approximability of Convoy-CPP and Convoy-TSP. As a corollary, we also obtain an  $O(\log n)$ -approximation for Convoy-CPP on general graphs.

► **Lemma 12.** *For a given instance of Convoy-CPP whose optimal solution has value  $\alpha$ , we can construct in polynomial time an instance of Convoy-TSP whose optimal solution has value  $\beta$  such that  $\beta \leq \alpha \leq 2\beta$ .*

**Proof.** First, replace each edge  $(u, v) \in E$  with edges  $(u, w)$ ,  $(w, u)$ ,  $(w, v)$ , and  $(v, w)$ , where each of these edges gets length  $\ell((u, v))/2$ , and speed  $q((u, v))$ . The optimal solution to the given instance of Convoy-CPP is also feasible for the constructed instance of Convoy-TSP,

and thus  $\beta \leq \alpha$ . On the other hand, consider an optimal solution for the created Convoy-TSP instance with value  $\beta$ . If the resulting tour turns at  $w$  for some edge  $(u, v)$ , we can adjust this tour to one that visits the original edge  $(u, v)$  fully at once, by moving back and forth between  $u$  and  $v$  when we visit  $w$ . Since this will not slow down the convoy, and the distance traveled along  $(u, v)$  is doubled, the total time spent will increase with at most a factor 2. This implies that  $\alpha \leq 2\beta$ . ◀

Together with our algorithm from Section 3, this yields our  $O(\log n)$ -approximation algorithm for Convoy-CPP.

► **Theorem 3.** *There is a polynomial time  $O(\log n)$ -approximation algorithm for Convoy-CPP.*

We remark that with similar arguments one can obtain an  $O(\log n)$ -approximation algorithm for Convoy-CPP on directed or on mixed graphs.

## A

 Details for the proof of Lemma 11

► **Lemma 13.** *We have that  $\text{OPT}' \in O(\text{OPT})$ .*

**Proof.** Let  $I' = [a, b] \subseteq I$  denote a maximally large subinterval of  $I$  such that  $q_{\text{OPT}}(d) = \bar{q}^{(1)}$  for each  $d \in I'$ . We have that  $|I'| \geq L$  since  $\bar{q}^{(1)}$  is the lowest speed. Due to  $I'$  we defined for each  $d \in [a', \min\{a' + L, b\})$  and for each  $d \in [\max\{b' - L, a\}, b')$  that  $q'(d) := \bar{q}^{(1)}$ . We charge the time traveled with speed  $\bar{q}^{(1)}$  on  $[a', \min\{a' + L, b\}) \cup [\max\{b' - L, a\}, b')$  to  $I'$ . For our charging scheme, we say that the clean interval  $[a', b')$  gives  $4L/\bar{q}^{(1)}$  credits to each adjacent maximally large non-clean interval, and we charge this to  $[a', b')$ . We do the same argumentation and charging for each interval that became clean in this iteration.

Suppose by induction that we have given as input a maximally large non-clean interval  $\tilde{I}$  such that, for some  $k$ ,  $q_{\text{OPT}}(d) \geq \bar{q}^{(k)}$  for each  $d \in \tilde{I}$  that received  $4L/\bar{q}^{(k-1)}$  credits from the previous iterations. Let  $I' = [a, b] \subseteq \tilde{I}$  denote a maximally large subinterval of  $\tilde{I}$  such that  $q_{\text{OPT}}(d) = \bar{q}^{(k)}$  for each  $d \in I'$ . Suppose that due to  $I'$  we define for each  $d \in [a', \min\{a' + L, b\})$  and for each  $d \in [\max\{b' - L, a\}, b')$  that  $q'(d) := \bar{q}^{(k)}$ .

First, if  $|I'| \geq L$  then we charge the times traveled with speed  $\bar{q}^{(k)}$  on  $[a', \min\{a' + L, b\}) \cup [\max\{b' - L, a\}, b')$  to  $I'$ . Also, we charge  $I'$  in order to give  $4L/\bar{q}^{(k)}$  credits to each adjacent maximally large non-clean interval that is adjacent to  $[a', b')$ .

Second, if  $|I'| < L$  then  $I'$  must be at the left or the right end of  $\tilde{I}$ . In that case we charge those times to  $2L/\bar{q}^{(k-1)}$  of the  $4L/\bar{q}^{(k-1)}$  credits that we received from the previous iteration. We use the remaining  $2L/\bar{q}^{(k-1)} = 4L/\bar{q}^{(k)}$  credits to give  $4L/\bar{q}^{(k)}$  credits to each maximally large non-clean interval that is adjacent to  $[a', b')$ . Together, this implies the lemma. ◀

# Ordinal Measures of the Set of Finite Multisets

Isa Vialard 

Université Paris-Saclay, CNRS, ENS Paris-Saclay, Laboratoire Méthodes Formelles, 91190, Gif-sur-Yvette, France

## Abstract

Well-partial orders, and the ordinal invariants used to measure them, are relevant in set theory, program verification, proof theory and many other areas of computer science and mathematics. In this article we focus on a common data structure in programming, finite multisets of some well partial order. There are two natural orders one can define on the set of finite multisets of a partial order: the multiset embedding and the multiset ordering. Though the maximal order type of these orders is already known, other ordinal invariants remain mostly unknown. Our main contributions are expressions to compute compositionally the width of the multiset embedding and the height of the multiset ordering. Furthermore, we provide a new ordinal invariant useful for characterizing the width of the multiset ordering.

## Introduction

**Measuring partial orders** is useful in many domains, from set theory to proof theory, including infinitary combinatorics, program verification, rewriting theory, proof automation and many more.

There are intuitive notions of measure for a partial order when it is finite: its cardinal obviously, but also its height (the length of a maximal chain) or its width (the length of a maximal antichain). Similar notions exist for infinite partial orders, as long as they are *well partial orders* (**wpo**), i.e., well-founded partial orders with no infinite antichains [10, 12]. Two such notions are the *ordinal height*, which is the order type of a maximal chain, and the *maximal order type* (**mot**), which is the order type of a maximal linearisation, a notion introduced by De Jongh and Parikh in order to measure hierarchies of functions [6]. These are transfinite measures, hence we call them *ordinal invariants*. Kříž and Thomas introduced alternative characterizations for **mot** and ordinal height, which naturally led to the definition of a third ordinal invariant, *ordinal width* [11]. Less studied than its counterparts, the width of a **wpo** relates to its antichains, even though it cannot be defined as the order type of a maximal antichain. While exploring techniques for program termination, Blass and Gurevich rediscovered these characterizations with a game-theoretical point of view [4].

Ordinal invariants of **wpos** have also been used to prove complexity bounds. In the last decade there has been a flurry of complexity results for the verification of well-structured transition systems (**wsts**), i.e., transition systems whose set of configurations is a **wpo** and whose transitions respect this ordering [5]. When a **wsts** is based on a **wpo**  $X$  of maximal order type  $\omega^\alpha$ , one can expect the complexity of coverability to be in  $H_{\omega^\alpha}$  in the Hardy hierarchy, or in  $F_\alpha$  in the fast-growing hierarchy [9]. This bound can be refined by looking at controlled antichains instead of controlled bad sequences [14], thus bounding complexity with width instead of maximal order type.

**Computing ordinal invariants compositionally.** Many wpos underlying wsts are built from classical operations on simpler wpos whose invariants are known. This has spurred new interest in measuring the ordinal invariants of various well-ordered data structures: De Jongh and Parikh computed the *mot* of the disjoint sum and the Cartesian product of wpos [6]. Schmidt then computed the *mot* of word embedding and homeomorphic tree embedding on a wpo [13]. Abraham and Bonnet pursued this line of study by computing the height of Cartesian product, but also the width of disjoint sum and lexicographic product [1]. For a complete survey of these results see [8], where Džamonja et al. computed the ordinal invariants of the lexicographic product, but also the height of the multiset word and tree embeddings.

**Finite multisets.** In this article, we study the ordinal invariants of the set of finite multisets. Multisets, also called “bags”, a common data structure in computer science. Informally, a finite multiset over a set  $X$  is a finite subset of  $X$  where an element can appear finitely many times. For instance,  $\langle a, a, b \rangle$  denote the multiset where  $a$  appears twice and  $b$  once. One can see the set of finite multisets on a wpo as the set of finite words quotiented by the equivalence relation “equality up to some permutation”. It comes down to describing a multiset as a word where the order of terms is irrelevant. A finite multiset can be represented by a function from  $X$  to  $\mathbb{N}$  with finite support, which associates its multiplicity with each element.

Two orderings are classically defined on the finite multisets of any ordered set. The first one is the *multiset ordering*, which often appears in rewriting theory and automation of termination proofs [7]. The other, less-known, ordering is the *multiset embedding*, or term ordering as it is called in [15]. It was presented by Aschenbrenner and Pong as a natural extension of the embedding order over finite words [3].

Some invariants of these two orderings have already been measured: Van der Meeren, Rathjen, and Weiermann [15] built on [17] to compute the *mot* of the set of finite multisets on a wpo  $X$  ordered with the multiset ordering, and provided a new proof for the expression of the *mot* of the multiset embedding computed in [18]. Džamonja et al. [8] proved that the height of the multiset embedding is equal to the height of the set of finite words ordered with word embedding. It is noteworthy that these three results give expressions that are functional in (i.e., can be expressed as a function of) the *mot* and height of  $X$ . However, the height of the multiset ordering still needs to be determined, and the width remains unstudied for both orderings.

**Our contributions.** In this article, we provide functional expressions for the width of the multiset embedding (Theorem 2.1) and the height of the multiset ordering (Theorem 3.1).

We further show that the width of the multiset ordering cannot be expressed as a function of the three ordinal invariants (Example 3.2). Nonetheless, we get around this issue by introducing a fourth ordinal invariant, the *friendly order type* (Definition 3.3), in which the width of the multiset ordering is functional (Theorem 3.4). We then proceed to investigate and compute this new ordinal invariant.

## 1 Definitions and state of the art

### 1.1 Width, height and maximal order type

A sequence  $x_1, \dots, x_n, \dots$  on a partial order  $(X, \leq_X)$  is *good* when there exist  $i < j$  such that  $x_i \leq_X x_j$ , otherwise it is a *bad* sequence. An *antichain* is a sequence whose elements are pairwise incomparable.

A *well partial order* (**wpo**) is a partial order that has no infinite bad sequences. Equivalently, a **wpo** is a partial order that is both well-founded (i.e. no infinite strictly decreasing sequences) and has no infinite antichains.

Let  $(X, \leq_X)$  be a **wpo**. We often write just  $X$  when  $\leq_X$  is understood. The trees  $Bad(X)$ ,  $Dec(X)$  and  $Ant(X)$  are defined as the sets of bad sequences, strictly decreasing sequences, and antichains of  $X$ , respectively, ordered by inverse prefix order (a sequence is smaller than its prefixes) ([11, 8]). The finiteness of bad sequences, strictly decreasing sequences and antichains in a **wpo** implies that these trees are well-founded. Therefore, one can define a notion of rank on these trees: a sequence has rank 0 when it cannot be extended; otherwise its rank is the smallest ordinal strictly larger than the ranks of its extensions. The rank of a tree is the rank of the empty sequence (which is the root of the tree).

The *maximal order type* (or **mot**) of  $X$ , denoted by  $\mathbf{o}(X)$ , is defined as the rank of  $Bad(X)$ . Similarly, the *height*  $\mathbf{h}(X)$  and the *width*  $\mathbf{w}(X)$  of  $X$  are defined as the ranks of  $Dec(X)$  and  $Ant(X)$ , respectively. Together,  $\mathbf{o}(X)$ ,  $\mathbf{h}(X)$  and  $\mathbf{w}(X)$  are called the *ordinal invariants* of  $X$ .

For any **wpo**  $X$ ,  $Dec(X)$  and  $Ant(X)$  are subtrees of  $Bad(X)$ . Thus  $\mathbf{h}(X) \leq \mathbf{o}(X)$  and  $\mathbf{w}(X) \leq \mathbf{o}(X)$ .

Let  $x \perp y$  denote that  $x$  and  $y$  are incomparable. For a relation  $*$  among  $\{ \not\leq, <, \perp \}$ , we define the residual  $X_{*x}$  as  $\{ y \in X : y * x \}$ . This definition can be extended to subsets  $S \subseteq X$ :  $X_{*S} \stackrel{\text{def}}{=} \{ y \in X : \forall x \in S, y * x \}$ .

► **Example 1.1.** In Figure 1, you can see the residuals at  $x = (4, 6)$  of  $\mathbb{N} \times \mathbb{N}$  ordered component-wise.

■ **Figure 1** Residuals of  $\mathbb{N}^2$  at  $(4, 6)$ .

Since the rank of the empty sequence is the smallest ordinal strictly larger than the ranks of the sequences of length 1, the definitions of **mot**, height and width can be reformulated inductively through the following *residual equations*:

$$\mathbf{o}(X) = \sup_{x \in X} (\mathbf{o}(X_{\not\leq x}) + 1) \tag{Res-o}$$

$$\mathbf{h}(X) = \sup_{x \in X} (\mathbf{h}(X_{< x}) + 1) \tag{Res-h}$$

$$\mathbf{w}(X) = \sup_{x \in X} (\mathbf{w}(X_{\perp x}) + 1) \tag{Res-w}$$

With these equations we can compute easily the ordinal invariants of  $\mathbb{N}^2$ . For instance, observe that  $(\mathbb{N}^2_{< x})$  is finite for any  $x \in \mathbb{N}^2$ , so its height is finite but can be arbitrarily big. Hence  $\mathbf{h}(\mathbb{N}^2) = \omega$ .

### 1.2 Ordinal arithmetic

We suppose well-known the notions of sum, product, subtraction, natural sum, natural product on ordinals, denoted with  $+$ ,  $\cdot$ ,  $-$ ,  $\oplus$ ,  $\otimes$  [2]. However, let us recall some definitions and notations that might be less familiar to the reader.

An ordinal  $\alpha$  is *indecomposable* iff for any  $\delta, \gamma < \alpha$ , we have  $\delta \oplus \gamma < \alpha$ . Equivalently,  $\alpha$  is indecomposable when there is an ordinal  $\beta$  such that  $\alpha = \omega^\beta$ .  $\alpha$  is an  $\epsilon$ -number when  $\alpha = \omega^\alpha$ .

The *Hessenberg-based product*  $\alpha \odot \beta$  is defined inductively as follows [1]:

$$\alpha \odot 0 = 0, \quad \alpha \odot (\beta + 1) = (\alpha \odot \beta) \oplus \alpha, \quad \alpha \odot \beta = \sup\{\alpha \odot \gamma : \gamma < \beta\} \text{ for limit } \beta.$$

This definition ensures that  $\alpha \cdot \beta \leq \alpha \odot \beta \leq \alpha \otimes \beta$ .

For any ordinal  $\alpha = \omega^{\alpha_1} + \dots + \omega^{\alpha_n}$ , let  $\hat{\alpha} \stackrel{\text{def}}{=} \omega^{\alpha'_1} + \dots + \omega^{\alpha'_n}$ , where  $\alpha'_i$  is  $\alpha_i + 1$  when  $\alpha_i$  is the sum of an  $\epsilon$ -number and a finite ordinal, otherwise  $\alpha'_i = \alpha_i$ .

For any ordinals  $\alpha, \beta$ , let  $\alpha \hat{\oplus} \beta \stackrel{\text{def}}{=} \sup\{\alpha' \oplus \beta' : \alpha' < \alpha, \beta' < \beta\}$ .

### 1.3 Ordinal invariants of basic data structures

For any wpos  $P, Q$ , the *disjoint sum*  $P \sqcup Q$  is the disjoint union of  $P$  and  $Q$  ordered such that elements of  $P$  and  $Q$  cannot be compared together, whereas the *direct sum*  $P + Q$  is the disjoint union of  $P$  and  $Q$  ordered such that for all  $p \in P, q \in Q, p \leq q$ . For a family of wpos  $(A_i)_{i < \alpha}$ , let  $\Sigma_{i < \alpha} A_i$  denote the direct sum of the  $A_i$ s along the ordinal  $\alpha$ .

The *Cartesian product*  $P \times Q$  is the set of pairs  $(p, q) \in P \times Q$  where elements are compared component-wise. The *lexicographic product* of  $P$  along  $Q$ , written  $P \cdot Q$ , has the same support as  $P \times Q$ , with a different ordering:  $(p, q) \leq_{P \cdot Q} (p', q')$  iff  $q <_Q q'$ , or  $q = q'$  and  $p \leq_P p'$ .

Sums and products are the most basic operations on wpos one can find. Their ordinal invariants are easy to compute compositionally (see Table 1), with the notable exception of the width of the Cartesian product which cannot be expressed as a function of the ordinal invariants its factors [16].

■ **Table 1** How to compute ordinal invariants compositionally, [8]. See Section 1.2 for definitions of  $\hat{\oplus}$  and  $\odot$ .

Space $X$	M.O.T. $\mathfrak{o}(X)$	Height $\mathfrak{h}(X)$	Width $\mathfrak{w}(X)$
$A \sqcup B$	$\mathfrak{o}(A) \oplus \mathfrak{o}(B)$	$\max(\mathfrak{h}(A), \mathfrak{h}(B))$	$\mathfrak{w}(A) \oplus \mathfrak{w}(B)$
$A + B$	$\mathfrak{o}(A) + \mathfrak{o}(B)$	$\mathfrak{h}(A) + \mathfrak{h}(B)$	$\max(\mathfrak{w}(A), \mathfrak{w}(B))$
$A \times B$	$\mathfrak{o}(A) \otimes \mathfrak{o}(B)$	$\mathfrak{h}(A) \hat{\oplus} \mathfrak{h}(B)$	(Not functional)
$A \cdot B$	$\mathfrak{o}(A) \cdot \mathfrak{o}(B)$	$\mathfrak{h}(A) \cdot \mathfrak{h}(B)$	$\mathfrak{w}(A) \odot \mathfrak{w}(B)$

### 1.4 Comparing wpos

A widely-used and intuitive relation between wpos is the *reflection* relation. A mapping between wpos  $f: (A, \leq_A) \rightarrow (B, \leq_B)$  is a *reflection* if  $f(x) \leq_B f(y)$  implies  $x \leq_A y$ , i.e. it is a morphism from  $(A, \not\leq_A)$  to  $(B, \not\leq_B)$ . Let  $A \leftrightarrow B$  denote that there is a reflection from  $A$  to  $B$ .

However, in this article, we prefer to use the stronger notions of augmentations and substructures.

► **Definition 1.2** (Substructure, augmentation). *A wpo  $(A, \leq_A)$  is a substructure of a wpo  $(B, \leq_B)$  whenever  $A \subseteq B$  and  $\leq_A$  is the restriction of  $\leq_B$  to  $A$ . This relation is written  $A \leq_{st} B$ . Similarly  $(A, \leq_A)$  is an augmentation of  $(B, \leq_B)$  whenever  $A = B$  and  $\leq_B \subseteq \leq_A$ . We write this relation  $A \geq_{aug} B$ .*

Obviously,  $A \leq_{st} B$  or  $A \geq_{aug} B$  imply  $A \leftrightarrow B$ .

We often abuse these notations and write  $A \leq_{st} B$  (resp.  $B \leq_{aug} A$ ) to mean that  $A$  is isomorphic to a substructure (resp. an augmentation) of  $B$ .

We denote by  $A \equiv B$  that  $(A, \leq_A)$  is isomorphic to  $(B, \leq_B)$ .

In this article, when we consider a subset  $Y$  of a wpo  $X$ , it is understood that  $Y \leq_{st} X$ , i.e.  $Y$  is ordered with  $\leq_X$  restricted to the subset.

These notions of augmentations and substructures allow us to compare the ordinal invariants of wpos.

► **Lemma 1.3.** *Let  $A$  and  $B$  be wpos.*

*If  $A \leq_{st} B$  then  $\mathbf{i}(A) \leq \mathbf{i}(B)$  for  $\mathbf{i} \in \{ \mathbf{o}, \mathbf{h}, \mathbf{w} \}$ .*

*If  $A \geq_{aug} B$  then  $\mathbf{o}(A) \leq \mathbf{o}(B)$  and  $\mathbf{w}(A) \leq \mathbf{w}(B)$ . However  $\mathbf{h}(A) \geq \mathbf{h}(B)$ .*

The substructure and augmentation relations are monotonous through most operations on wpos. For instance, if  $A \leq_{st} A'$ , then  $A \times B \leq_{st} A' \times B$ .

An ordinal, as defined by Von Neumann, is the linear wpo that contains all smaller ordinals. Thus augmentations and substructures relations can also be used to compare directly ordinals to wpos. The following result is well-known:

► **Proposition 1.4.** *For any wpo  $X$ ,  $\mathbf{h}(X)$  and  $\mathbf{o}(X)$  are the largest ordinals such that  $\mathbf{h}(X) \leq_{st} X$  and  $\mathbf{o}(X) \geq_{aug} X$ .*

## 1.5 Orderings on the set of finite multisets

We assume familiarity with finite multisets and the associated operations as used in [17]: union, intersection and subtraction, denoted by  $\cup, \cap$  and  $\setminus$ , respectively. Let  $\langle x_1, \dots, x_n \rangle$  denote the finite multiset that contains the elements  $x_1, \dots, x_n$  (they do not have to be distinct). For any  $k \in \mathbb{N}$ ,  $m \times k$  means the union of  $k$  copies of  $m$ . Let  $|m|$  denote the number of elements of a multiset  $m$ .

There are two main orderings classically defined on the set of finite multisets  $M(X)$  of a partial order  $X$ :

► **Definition 1.5** (Multiset embedding [18]). *The multiset embedding on  $M(X)$ , also known as the term ordering, is defined as:*

$m \leq_{\diamond} m'$  iff there exists  $f : m \rightarrow m'$  injective such that for any  $x \in m$ ,  $x \leq f(x)$ .

► **Definition 1.6** (Multiset ordering [17]). *The multiset ordering on  $M(X)$  is defined as:*

$m \leq_r m' \iff m = m' \text{ or } \forall x \in m \setminus (m \cap m'), \exists y \in m' \setminus (m \cap m'), x < y$ .

We write  $M^{\diamond}(X)$  for  $(M(X), \leq_{\diamond})$  and  $M^r(X)$  for  $(M(X), \leq_r)$ .

The multiset ordering and the multiset embedding are both augmentations of the word embedding on  $X^*$  the set of finite words on  $X$ . Therefore, according to Higman's lemma [10],  $M^{\diamond}(X)$  and  $M^r(X)$  are wpos when  $X$  is. Moreover  $M^{\diamond}(X) \leq_{aug} M^r(X)$ , as was observed by Aschenbrenner and Pong [3].

Observe that if  $X$  is a linear ordering, then  $M^r(X)$  is linear, while  $M^\diamond(X)$  is not as long as  $X$  has more than two elements.

► **Proposition 1.7** (Transformation equations). *For any wpos  $A$  and  $B$ ,*

$$M^*(A \sqcup B) \equiv M^*(A) \times M^*(B) \text{ for } * \in \{\diamond, r\}, \quad (\text{Trans-1})$$

$$M^r(A + B) \equiv M^r(A) \cdot M^r(B), \quad (\text{Trans-2})$$

$$M^\diamond(A + B) \leq_{\text{aug}} M^\diamond(A) \cdot M^\diamond(B). \quad (\text{Trans-3})$$

► **Lemma 1.8** (Width of  $M(X)$  on  $\Gamma_k$ ). *For any  $k < \omega$ , we denote by  $\Gamma_k$  the wpo that contains  $k$  incomparable elements. Then  $\mathbf{w}(M^\diamond(\Gamma_k)) = \mathbf{w}(M^r(\Gamma_k)) = \omega^{k-1}$ .*

**Proof.** Since  $M^\diamond(\Gamma_1) \equiv M^r(\Gamma_1) \equiv \omega$ , Equation (Trans-1) tells us that  $M^\diamond(\Gamma_k)$  and  $M^r(\Gamma_k)$  are both isomorphic to the  $k$ -fold Cartesian product  $\omega \times \cdots \times \omega$ . This special case of the width of a Cartesian product is known [16]:  $\mathbf{w}(\omega \times \cdots \times \omega) = \omega^{k-1}$ . ◀

The augmentation and substructure relations are monotone with respect to the multiset ordering and multiset embedding:

► **Proposition 1.9.** *Let  $A, B$  be two wpos. Then  $A \leq_{\text{st}} B$  implies  $M^\diamond(A) \leq_{\text{st}} M^\diamond(B)$  and  $M^r(A) \leq_{\text{st}} M^r(B)$ . Moreover,  $A \geq_{\text{aug}} B$  implies that  $M^\diamond(A) \geq_{\text{aug}} M^\diamond(B)$  and  $M^r(A) \geq_{\text{aug}} M^r(B)$ .*

### Ordinal invariants of the set of finite multisets

Van der Meeren, Rathjen and Weiermann computed the mot of  $M^\diamond(X)$  and  $M^r(X)$ .

► **Theorem 1.10** (Mot of multiset embedding [15, 18]). *For any wpo  $X$ ,  $\mathbf{o}(M^\diamond(X)) = \omega^{\widehat{\mathbf{o}(X)}}$ .*

► **Theorem 1.11** (Mot of multiset ordering [15, 17]). *For any wpo  $X$ ,  $\mathbf{o}(M^r(X)) = \omega^{\mathbf{o}(X)}$ .*

Observe that  $\omega^{\mathbf{o}(X)} \leq \omega^{\widehat{\mathbf{o}(X)}}$ , as one would expect since  $M^r(X) \geq_{\text{aug}} M^\diamond(X)$ . Furthermore, we expect that  $\mathbf{w}(M^r(X)) \leq \mathbf{w}(M^\diamond(X))$ , while  $\mathbf{h}(M^r(X)) \geq \mathbf{h}(M^\diamond(X))$ .

► **Theorem 1.12** (Height of the multiset embedding [8]). *Let  $X$  be a wpo. Then  $\mathbf{h}(M^\diamond(X)) = \mathbf{h}^*(X)$ , where*

$$\mathbf{h}^*(X) \stackrel{\text{def}}{=} \begin{cases} \mathbf{h}(X) & \text{if } \mathbf{h}(X) \text{ is infinite and indecomposable,} \\ \mathbf{h}(X) \cdot \omega & \text{otherwise.} \end{cases}$$

## 1.6 A tool to compute the width: Quasi-incomparable subsets

Of all three ordinal invariants, the width is the less studied, since it has been introduced more recently, and also the hardest invariant to study for lack of tools.

A powerful tool to analyse the width of a wpo is the notion of *quasi-incomparable* subsets of a wpo, which was first introduced in [16] for the Cartesian product of several ordinals.

For any subsets  $Y, Z$  of  $X$ , let  $Y \perp Z$  denote that for every  $y \in Y, z \in Z, y \perp z$ .

► **Definition 1.13.** *Let  $A$  be a wpo, and  $A_1, \dots, A_n$  be  $n$  subsets of  $A$ . Then  $(A_i)_{1 \leq i \leq n}$  is a quasi-incomparable family of subsets of  $A$  iff for any  $i < n$ , for any finite  $Y \subseteq A_1 \cup \cdots \cup A_i$ , there exists  $A'_{i+1} \subseteq A_{i+1}$  such that  $A'_{i+1} \perp Y$  and  $A'_{i+1} \equiv A_{i+1}$ .*

This definition is slightly more restrictive than the one in [16], which only required that  $w(A'_{i+1}) = w(A_{i+1})$ .

The idea behind these quasi-incomparable subsets is that sometimes one can slice a wpo  $A$  into simpler subsets  $A_1, \dots, A_n$  whose width is known, such that  $Ant(A_n) + \dots + Ant(A_1)$  is embedded in  $Ant(A)$ . Intuitively, it means that one can combine antichains of  $A_1, \dots, A_n$  into one antichain of  $A$ .

This entails a practical relation between the widths of  $A$  and its subsets:

► **Lemma 1.14** ([16]). *Let  $(A_i)_{i \leq n}$  be a quasi-incomparable family of subsets of  $A$ . Then  $w(A) \geq w(A_n) + \dots + w(A_1)$ .*

## 2 Ordinal width of the multiset embedding

In this section we compute the width of  $M^\diamond(X)$  for any wpo  $X$ , which happens to be functional in the width of  $X$ :

► **Theorem 2.1** (Width of the multiset embedding). *For any wpo  $X$ ,  $w(M^\diamond(X)) = \omega^{\widehat{o(X)}-1}$ . (See Section 1.2 for the definition of  $\widehat{\alpha}$ .)*

It is already known that, in some cases, the width of the multiset embedding reaches its mot.

► **Lemma 2.2** ([8]). *If  $o(X)$  is infinite and indecomposable,  $w(M^\diamond(X)) = o(M^\diamond(X))$ .*

We focus for now on the set of finite multisets on a linear wpo, i.e., an ordinal. Let us treat first the case of successor ordinals.

► **Lemma 2.3.** *For any successor ordinal  $\alpha = \beta + 1$ ,  $w(M^\diamond(\alpha)) \geq w(M^\diamond(\beta)) \cdot \omega$ .*

**Proof.** We denote with  $M_{>k}^\diamond(X)$  the subset  $\{ m \in M^\diamond(X) : |m| > k \}$  for any  $k \in \mathbb{N}$  of  $M^\diamond(X)$  for any wpo  $X$ , for any  $k < \omega$ .

Let  $m_n \stackrel{\text{def}}{=} \langle \beta \rangle \times n$  for any  $n \in \mathbb{N}$ . According to Equation (Res-w),

$$\begin{aligned} w(M^\diamond(\alpha)) &= \sup\{ w(M^\diamond(\alpha)_{\perp m}) + 1 : m \in M^\diamond(\alpha) \} \\ &\geq \sup\{ w(M^\diamond(\alpha)_{\perp m_n}) + 1 : n \in \mathbb{N} \}. \end{aligned}$$

Let  $M_k \stackrel{\text{def}}{=} \{ \langle \beta \rangle \times (n - k) \cup m : m \in M_{>k}^\diamond(\beta) \}$  for  $k \in [1, n]$ . These subsets of  $M^\diamond(\alpha)$  are actually subsets of  $M^\diamond(\alpha)_{\perp m_n}$ : for all  $m \in M_k$ ,  $m \perp m_n$  since  $|m| > |m_n|$ . Observe also that for any  $k \in [1, n]$ ,  $M_k \equiv M^\diamond(\beta)$ .

Moreover,  $(M_k)_{k \in [1, n]}$  is a quasi-incomparable family of subsets of  $M^\diamond(\alpha)_{\perp m_n}$ : for any  $i < n$ , for any finite  $Y \subset M_1 \cup \dots \cup M_i$ , let  $s(Y) = \max\{|m|, m \in Y\}$ . Observe that  $M_{i+1}$  contains  $M_{i+1} \cap M_{>s(Y)}^\diamond(\beta)$  which is incomparable to  $Y$ , and isomorphic to  $M_{i+1}$ .

Therefore,  $w(M^\diamond(\alpha)_{\perp m_n}) \geq w(M_n) + \dots + w(M_1) = w(M^\diamond(\beta)) \cdot n$  according to Lemma 1.14. Thus  $w(M^\diamond(\alpha)) \geq \sup\{ w(M^\diamond(\beta)) \cdot n + 1 : n \in \mathbb{N} \} = w(M^\diamond(\beta)) \cdot \omega$ . ◀

► **Lemma 2.4.** *For any infinite ordinal  $\alpha$ ,  $w(M^\diamond(\alpha)) = o(M^\diamond(\alpha))$ .*

**Proof.** We already know that  $w(M^\diamond(\alpha)) \leq o(M^\diamond(\alpha))$ . We prove the lower bound by induction on  $\alpha$ :

■ If  $\alpha$  is indecomposable, see Lemma 2.2.

- If  $\alpha = \beta + 1$ , then according to Lemma 2.3,

$$\begin{aligned} \mathbf{w}(M^\circ(\alpha)) &\geq \mathbf{w}(M^\circ(\beta)) \cdot \omega \\ &= \mathbf{o}(M^\circ(\beta)) \cdot \omega && \text{by induction hypothesis,} \\ &= \omega^{\widehat{\beta+1}} = \omega^{\widehat{\beta+1}} = \mathbf{o}(M^\circ(\alpha)) && \text{according to Theorem 1.10.} \end{aligned}$$

- If  $\alpha = \beta + \omega^\rho$  with  $\beta, \omega^\rho < \alpha$  and  $\rho > 0$ , then according to the transformation equation Trans-3,  $M^\circ(\alpha) \leq_{\text{aug}} M^\circ(\beta) \cdot M^\circ(\omega^\rho)$ . Hence according to Lemma 1.3 and Table 1,

$$\begin{aligned} \mathbf{w}(M^\circ(\alpha)) &\geq \mathbf{w}(M^\circ(\beta)) \odot \mathbf{w}(M^\circ(\omega^\rho)) \\ &= \mathbf{o}(M^\circ(\beta)) \odot \mathbf{o}(M^\circ(\omega^\rho)) && \text{by induction hypothesis,} \\ &= \omega^{\widehat{\beta}} \odot \omega^{\widehat{\omega^\rho}} = \omega^{\widehat{\alpha}} \\ &= \mathbf{o}(M^\circ(\alpha)) && \text{according to Theorem 1.10.} \quad \blacktriangleleft \end{aligned}$$

We can now prove that Lemma 2.4 generalizes to non-linear wpos.

- **Lemma 2.5.** *If  $\mathbf{o}(X)$  is infinite then  $\mathbf{w}(M^\circ(X)) = \mathbf{o}(M^\circ(X))$ .*

**Proof.** Let  $\alpha = \mathbf{o}(X)$ . Then  $X \leq_{\text{aug}} \alpha$  from Proposition 1.4, hence  $M^\circ(X) \leq_{\text{aug}} M^\circ(\alpha)$  according to Lemma 1.3 and Proposition 1.9. Thus

$$\mathbf{w}(M^\circ(\alpha)) \leq \mathbf{w}(M^\circ(X)) \leq \mathbf{o}(M^\circ(X)).$$

Now  $\mathbf{o}(M^\circ(X)) = \omega^{\widehat{\alpha}} = \mathbf{o}(M^\circ(\alpha))$  according to Theorem 1.10. Now with Lemma 2.4  $\mathbf{w}(M^\circ(\alpha)) = \mathbf{o}(M^\circ(\alpha))$ , hence  $\mathbf{w}(M^\circ(X)) = \mathbf{o}(M^\circ(X))$ .  $\blacktriangleleft$

We can also compute the width of  $M^\circ(X)$  when  $X$  is a finite wpo:

- **Lemma 2.6.** *If  $\mathbf{o}(X)$  is finite, then  $\mathbf{w}(M^\circ(X)) = \omega^{\mathbf{o}(X)-1}$ .*

**Proof.** Let  $k = \mathbf{o}(X)$ . Then  $\Gamma_k \leq_{\text{aug}} X \leq_{\text{aug}} k$ , hence  $\mathbf{w}(M^\circ(\Gamma_k)) \geq \mathbf{w}(M^\circ(X)) \geq \mathbf{w}(M^\circ(k))$  thanks to Lemma 1.3. According to Lemma 1.8,  $\mathbf{w}(M^\circ(\Gamma_k)) = \omega^{k-1}$ , and according to Lemma 2.3 applied  $(k-1)$  times,  $\mathbf{w}(M^\circ(k)) \geq \mathbf{w}(M^\circ(1)) \cdot \omega^{k-1} = \omega^{k-1}$ . Therefore  $\mathbf{w}(M^\circ(X)) = \omega^{k-1} = \omega^{\mathbf{o}(X)-1}$ .  $\blacktriangleleft$

This section's main result follows directly from Lemmas 2.5 and 2.6.

**Proof of Theorem 2.1.** If  $\mathbf{o}(X)$  is finite, then  $\widehat{\mathbf{o}(X)} - 1 = \mathbf{o}(X) - 1$ . On the other hand, if  $\mathbf{o}(X)$  is infinite, then  $\widehat{\mathbf{o}(X)} - 1 = \widehat{\mathbf{o}(X)}$ .  $\blacktriangleleft$

### 3 Ordinal height and width of the multiset ordering

For the height of  $M^r(X)$ , we obtain a result similar to Theorem 1.11.

- **Theorem 3.1** (Height of the multiset ordering). *Let  $X$  be a wpo. Then  $\mathbf{h}(M^r(X)) = \omega^{\mathbf{h}(X)}$ .*

**Proof.** Observe that the multiset ordering of any linear ordering is also linear. Thus, for any ordinal  $\alpha$ ,  $M^r(\alpha)$  is isomorphic to  $\omega^\alpha$  (the function  $\langle x_1, \dots, x_n \rangle \mapsto \omega^{x_1} \oplus \dots \oplus \omega^{x_n}$  is an isomorphism).

According to Proposition 1.4,  $X \geq_{\text{st}} \mathbf{h}(X)$ , and thus  $M^r(X) \geq_{\text{st}} M^r(\mathbf{h}(X)) \equiv \omega^{\mathbf{h}(X)}$  (Proposition 1.9). Therefore  $\mathbf{h}(M^r(X)) \geq \omega^{\mathbf{h}(X)}$  according to Lemma 1.3. See the proof of the upper bound in Appendix A.  $\blacktriangleleft$

The width of the multiset ordering is harder to compute, as  $\mathbf{w}(M^r(X))$  is not functional in the ordinal invariants of  $X$ . The following example exhibits two wpos  $X_1$  and  $X_2$ , with identical ordinal invariants, such that  $\mathbf{w}(M^r(X_1)) \neq \mathbf{w}(M^r(X_2))$ .

► **Example 3.2.** Let  $H \stackrel{\text{def}}{=} \Sigma_{n < \omega} \Gamma_n$ . An interesting property of  $H$  is that  $\mathbf{w}(H) = \mathbf{h}(H) = \mathbf{o}(H) = \omega$ . Since  $M^r(H) \geq_{\text{st}} M^r(\Gamma_n)$ , then  $\omega^{n-1} \leq \mathbf{w}(M^r(H)) \leq \mathbf{o}(M^r(H)) = \omega^\omega$  for all  $n < \omega$  according to Lemma 1.8 and Theorem 1.11. Hence  $\mathbf{w}(M^r(H)) = \omega^\omega$ .

Consider  $X_1 = H + H$  and  $X_2 = H + \omega$ , two wpos with the same ordinal invariants:  $\mathbf{o}(X_i) = \mathbf{h}(X_i) = \omega \cdot 2$  and  $\mathbf{w}(X_i) = \omega$  for  $i \in \{1, 2\}$ . According to Equation (Trans-2) and Table 1,  $\mathbf{w}(M^r(X_1)) = \mathbf{w}(M^r(H)) \odot \mathbf{w}(M^r(H)) = \omega^\omega \odot \omega^\omega = \omega^{\omega \cdot 2}$  and  $\mathbf{w}(M^r(X_2)) = \mathbf{w}(M^r(H)) \odot \mathbf{w}(M^r(\omega)) = \omega^\omega \odot 1 = \omega^\omega$ .

Fortunately, we uncovered a new ordinal invariant, defined similarly to the usual invariants, in which the width of the multiset ordering is functional.

► **Definition 3.3** (Friendly order type). *A bad sequence is open-ended if it is empty or of the form  $sx$  where  $s$  is an open-ended sequence and  $x$  has a “friend”<sup>1</sup> in the residual  $X_{\not\geq s}$ , i.e., an element incomparable to  $x$ . For any wpo  $X$ , let  $\text{Bad}_\perp(X)$  be the subtree of  $\text{Bad}(X)$  which contains all open-ended bad sequences. As  $\text{Bad}_\perp(X)$  is a substructure of  $\text{Bad}(X)$ , it has a rank that we denote by  $\mathbf{o}_\perp(X)$  the friendly order type of  $X$  (or fot).*

*This definition can be expressed as the following residual equation:*

$$\mathbf{o}_\perp(X) = \sup_{x \in X, X_{\perp x} \neq \emptyset} (\mathbf{o}_\perp(X_{\not\geq x}) + 1) \quad (\text{Res-f})$$

► **Theorem 3.4.** *For any wpo  $X$ ,  $\mathbf{w}(M^r(X)) = \omega^{\mathbf{o}_\perp(X)}$*

**Proof.** See Appendix B. The proof of Theorem 3.4 is quite technical, and relies on the notion of quasi-incomparable subsets. ◀

## 4 Computing the friendly order type

Like the usual ordinal invariants, the fot can be computed compositionally for some basic operations on wpos:

► **Proposition 4.1.** *For any non empty wpo  $A, B$ ,*

1.  $\mathbf{o}_\perp(A + B) = \mathbf{o}_\perp(A) + \mathbf{o}_\perp(B)$ ,
2.  $\mathbf{o}_\perp(A \sqcup B) = 1 + (\mathbf{o}(A) - 1) \oplus (\mathbf{o}(B) - 1)$ ,

**Proof.**

1. For any sequences  $s_A, s_B$  in  $\text{Bad}_\perp(A), \text{Bad}_\perp(B)$ , the concatenation  $s_B s_A$  is a sequence of  $\text{Bad}_\perp(A + B)$ . Furthermore, any sequence of  $\text{Bad}_\perp(A + B)$  is of this form.
2. For any two sequences  $s_1, s_2$ , let  $s_1 \sqcup s_2$  denote the set of sequences obtained through shuffling  $s_1, s_2$  together (e.g.  $abcad \in aba \sqcup cd$ ). Let  $x_A, x_B$  be two minimal elements of  $A$  and  $B$ . For any sequences  $s_A, s_B$  in  $\text{Bad}(A \setminus \{x_A\}), \text{Bad}(B \setminus \{x_B\})$ , for any  $s \in s_A \sqcup s_B$ , we know that  $s$  and  $s x_A$  and  $s x_B$  are in  $\text{Bad}_\perp(A \sqcup B)$ . Reciprocally, from any  $s \in \text{Bad}_\perp(A \sqcup B)$ , there is a partition  $s_A \in \text{Bad}(A), s_B \in \text{Bad}(B)$  such that  $s \in s_A \sqcup s_B$ . Furthermore, the natural sum of the ranks of  $s_A$  in  $\text{Bad}(A)$  and  $s_B$  in  $\text{Bad}(B)$  is strictly positive.

<sup>1</sup> Can one be friend with one’s superior or inferior? No. Your true friends are those you cannot (and do not have to) compare yourselves with.

## 87:10 Ordinal Measures of the Set of Finite Multisets

Suppose for contradiction sake that  $s_A$  and  $s_B$  have rank 0 in  $Bad(A)$  and  $Bad(B)$ . Let  $s = s'x$ . Then  $(A \sqcup B)_{\succeq s} = \emptyset$  and in particular  $x$  has no friend in  $(A \sqcup B)_{\succeq s'}$ . Thus  $s \notin Bad_{\perp}(A \sqcup B)$ , contradiction.  $\blacktriangleleft$

Observe how friendly order type behaves similarly to  $\text{mot}$ . It is not unusual to have  $\text{fot}$  coincides with  $\text{mot}$ , for instance  $\mathbf{o}_{\perp}(\omega \sqcup \omega) = \mathbf{o}(\omega \sqcup \omega)$  (Proposition 4.1).

To bring this new ordinal invariant closer to familiar grounds, we bound the  $\text{fot}$  of a wpo  $X$  with the  $\text{mot}$  of a special subset of  $X$ , the *stripped* subset.

► **Definition 4.2** (Stripped subset). *The stripped subset of a wpo  $X$ , denoted by  $\text{str}(X)$ , is  $X$  without its friendless elements:*

$$\text{str}(X) \stackrel{\text{def}}{=} \{ x \in X : X_{\perp x} \neq \emptyset \}.$$

Since  $Bad_{\perp}(X)$  is a subtree of  $Bad(\text{str}(X))$ , we know that  $\mathbf{o}_{\perp}(X) \leq \mathbf{o}(\text{str}(X))$ . Here is an example where this inequality is strict:

► **Example 4.3.** Let  $X = \omega \sqcup \{\clubsuit\}$ . Here  $\text{str}(X) = X$ , so  $\mathbf{o}(\text{str}(X)) = \omega + 1$ . However, in  $Bad_{\perp}(X)$ , the singleton  $\clubsuit$  has rank 0, and the singleton  $n$  for any  $n \in \omega$  has rank  $n$ . Therefore  $\mathbf{o}_{\perp}(X) = \omega < \mathbf{o}(\text{str}(X))$ .

Let us show that  $\mathbf{o}(\text{str}(X))$  also appears in a lower bound on  $\mathbf{o}_{\perp}(X)$ , by introducing an alternative characterisation of  $\text{fot}$  as the  $\text{mot}$  of a specific subset.

A *maximal linearisation* is a monotonic function from a wpo  $X$  onto  $\mathbf{o}(X)$ .

► **Definition 4.4** (Friendly subset). *A subset  $X'$  of  $X$  is friendly if there exist a maximal linearisation  $\ell : X' \rightarrow \mathbf{o}(X')$  such that for any bad sequence  $s = x_1, \dots, x_n$  in  $X'$  verifying  $\ell(x_1) > \dots > \ell(x_n)$ ,  $s$  is open-ended. We say that  $\ell$  witnesses the friendly condition.*

Observe that every friendly subset of  $X$  is a substructure of  $\text{str}(X)$ .

For any ordinal  $\alpha$ , let

$$\delta(\alpha) \stackrel{\text{def}}{=} \begin{cases} \alpha & \text{if } \alpha \text{ is limit,} \\ \gamma + \lfloor n/2 \rfloor & \text{if } \alpha = \gamma + n \text{ with } \gamma \text{ limit and } n < \omega. \end{cases}$$

► **Theorem 4.5** (Alternative characterisation of  $\mathbf{o}_{\perp}(X)$ ). *Let  $X$  be a wpo. There exists a friendly subset  $X'$  of  $X$  which maximizes  $\mathbf{o}(X')$ , and  $\mathbf{o}_{\perp}(X) = \mathbf{o}(X')$ . Furthermore,  $\delta(\mathbf{o}(\text{str}(X))) \leq \mathbf{o}_{\perp}(X) \leq \mathbf{o}(\text{str}(X))$ .*

**Proof.** See proof in Appendix C.  $\blacktriangleleft$

► **Example 4.6** (Following on Example 3.2). Remember that  $H \stackrel{\text{def}}{=} \sum_{n < \omega} \Gamma_n$ . Thus  $\text{str}(H) = \sum_{2 \leq n < \omega} \Gamma_n$ , and  $\mathbf{o}(\text{str}(H)) = \mathbf{o}(H) = \omega$ . Consider  $X_1 = H + H$  and  $X_2 = H + \omega$ . Observe that  $\text{str}(X_1) = \text{str}(H) + \text{str}(H)$  whereas  $\text{str}(X_2) = \text{str}(H)$ . Therefore, according to Theorem 4.5,  $\mathbf{o}_{\perp}(X_1) = \omega \cdot 2$  and  $\mathbf{o}_{\perp}(X_2) = \omega$ .

► **Corollary 4.7.** *For any wpo  $X$ , if  $\mathbf{o}(X)$  is limit and  $\mathbf{o}(\text{str}(X)) = \mathbf{o}(X)$ , then  $\mathbf{o}_{\perp}(X) = \mathbf{o}(X)$ .*

The conditions in Corollary 4.7 are often satisfied:

► **Proposition 4.8.** *For any wpo non-empty  $X$ ,  $\mathbf{o}_{\perp}(M^{\circ}(X)) = \mathbf{o}(M^{\circ}(X))$ .*

**Proof.** Observe that  $M^{\circ}(X) = M^{\circ}(X) \setminus \{\emptyset\}$ . Thus  $\mathbf{o}(\text{str}(M^{\circ}(X))) = \mathbf{o}(M^{\circ}(X)) - 1 = \mathbf{o}(M^{\circ}(X))$  (Theorem 1.10). We conclude with Corollary 4.7.  $\blacktriangleleft$

## Conclusion

Table 2 sums up this article’s contributions (in the gray cases) amidst the former state of the art.

■ **Table 2** Ordinal invariants of the set of finite multisets.

Invariants	Multiset embedding of $X$	Multiset ordering of $X$
Mot $\mathbf{o}$	$\omega^{\widehat{\mathbf{o}(X)}}$	$\omega^{\mathbf{o}(X)}$
Height $\mathbf{h}$	$\mathbf{h}^*(X)$	$\omega^{\mathbf{h}(X)}$
Width $\mathbf{w}$	$\omega^{\widehat{\mathbf{o}(X)}-1}$	$\omega^{\mathbf{o}_\perp(X)}$

These results are part of a more general research program (see [8, 16]) aimed at measuring more precisely and more effectively the complexity of wpos used in well-structured systems, termination proofs, and other algorithmic applications.

Investigating the friendly order type is a subject for further research: How does it relate to other concepts? Can it be computed compositionally for more operations? Can we define a class of wpos where friendly order type always coincides with mot?

---

### A Proof of Theorem 3.1

We write  $m \overset{\curvearrowright}{\leq}_r m'$  (resp.  $m \overset{\curvearrowright}{<} m'$ ,  $m \overset{\curvearrowright}{\perp} m'$ ) when  $m \cap m' \neq \emptyset$  and  $m \leq_r m'$  (resp  $m < m'$ ,  $m \perp m'$ ). With these new notations, the multiset ordering can be reformulated as follows

► **Definition A.1** (Multiset ordering (reformulated)).  $M^r(X) = (M(X), \leq_r)$  is ordered with the multiset ordering:  $m \leq_r m'$  iff there exists  $m_1, m'_1, m_2$  such that  $m = m_1 \cup m_2$ ,  $m' = m'_1 \cup m_2$ , and  $m_1 \overset{\curvearrowright}{<} m'_1$ .

► **Lemma A.2.** Let  $A = \cup_{i \leq n} A_i$  a set partitioned in  $n$  subsets, for some  $n \in \mathbb{N}$ . Let  $\leq_A$  a well-partial ordering on  $A$ , and  $\leq_{A_i}$  the same ordering restricted to the subset  $A_i$  for  $i \leq n$ . Then

$$\mathbf{h}(A, \leq_A) \leq \bigoplus_{i \leq n} \mathbf{h}(A_i, \leq_{A_i}).$$

**Proof.** From any decreasing sequence  $s$  on  $A$ , one can extract a decreasing sequence  $s_i$  by restricting  $s$  to  $A_i$  for any  $i \leq n$ . By induction on the rank of  $s$  in  $\text{Dec}(A)$ , one shows that  $\text{rk}(s) \leq \bigoplus_{i \leq n} \text{rk}(s_i)$ . ◀

**Proof of Theorem 3.1.** We prove the upper bound by induction on  $\mathbf{h}(X)$ .

If  $\mathbf{h}(X) = 0$  then  $X = \emptyset$  and  $\mathbf{h}(M^r(\emptyset)) = 1 = \omega^0$ .

Suppose that  $X$  is not empty. For any non-empty multiset  $m \in M^r(X)$ , the residual  $M^r(X)_{< m}$  can be partitioned as follows:

$$M^r(X)_{< m} = \bigcup_{m_1 + m_2 = m, m_1 \neq \emptyset} \{ m' + m_2 : m' \overset{\curvearrowright}{<} m_1 \}.$$

Note that this union is a partition of the support of  $M^r(X)_{< m}$ , it does not say anything on the order between the elements of the subsets in the union.

For any non-empty multiset  $m$ , we define  $S_m \stackrel{\text{def}}{=} (\cap_{x \in m} X_{\not\leq x}) \cap (\cup_{x \in m} X_{< x})$  a subset of  $X$ . Thus for any multiset  $m'$  in  $M^r(X)$ ,  $m' \stackrel{\not\leq}{<} m$  iff  $m' \in M^r(S_m)$ . Therefore:

$$M^r(X)_{< m} = \bigcup_{m_1+m_2=m, m_1 \neq \emptyset} \{ m' + m_2 : m' \in M^r(S_{m_1}) \}.$$

Observe that  $\mathbf{h}(S_{m_1}) < \mathbf{h}(X)$  by definition of  $S_{m_1}$ . Hence by induction hypothesis  $\mathbf{h}(M^r(S_{m_1})) \leq \omega^{\mathbf{h}(S_{m_1})} < \omega^{\mathbf{h}(X)}$ . Moreover,  $\omega^{\mathbf{h}(X)}$  is indecomposable. Hence according to Lemma A.2:

$$\mathbf{h}(M^r(X)_{< m}) \leq \bigoplus_{m_1+m_2=m, m_1 \neq \emptyset} \mathbf{h}(M^r(\cup_{x \in m_1} X_{< x})) < \omega^{\mathbf{h}(X)}.$$

Therefore  $\mathbf{h}(M^r(X)) \leq \omega^{\mathbf{h}(X)}$  according to Equation (Res-h). ◀

## B Proof of Theorem 3.4

First we prove intermediary lower and upper bounds on the width of the multiset ordering.

► **Lemma B.1.** *Let  $X$  be a wpo. Then*

$$\mathbf{w}(M^r(X)) \geq \sup_{x \in X, n < \omega} \mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \cdot n + 1$$

**Proof.** This proof follows the same structure as the proof of Lemma 2.3: We study the residual of  $M^r(X)$  which contains every element incomparable to some multiset of the form  $\langle x \rangle \times n$ , and slice this residual into a family of quasi-incomparable subsets.

According to Equation (Res-w),

$$\begin{aligned} \mathbf{w}(M^r(X)) &= \sup_{m \in M^r(X)} \mathbf{w}(M^r(X)_{\perp m}) + 1 \\ &\geq \sup_{x \in X, n < \omega} \mathbf{w}(M^r(X)_{\perp \langle x \rangle \times n}) + 1. \end{aligned}$$

For all  $k \in [1, n]$ , let  $M_k = \{ \langle x \rangle \times (n - k) \cup m : m \in M^r(X)_{\perp \langle x \rangle} \}$ . Observe that  $M_k \equiv M^r(X)_{\perp \langle x \rangle}$  for any  $k \in [1, n]$ , and for all  $m \in M_k$ ,  $m \perp \langle x \rangle \times n$ . We claim that  $(M_k)_{k \in [1, n]}$  is a quasi-incomparable family of subsets of  $M^r(X)_{\perp \langle x \rangle \times n}$ : Let  $i < n$  and  $Y$  a finite subset of  $M_1 \cup \dots \cup M_i$ . We define  $m_Y$  and  $M'_{i+1}$  as

$$\begin{aligned} m_Y &\stackrel{\text{def}}{=} \bigcup_{j \leq i} \bigcup_{m \in (M_j \cap Y)} (m \setminus (\langle x \rangle \times (n - j))), \\ M'_{i+1} &\stackrel{\text{def}}{=} \{ \langle x \rangle \times (n - i - 1) \cup m_Y \cup m : m \in M^r(X)_{\perp \langle x \rangle} \}. \end{aligned}$$

Observe that  $M'_{i+1}$  is an isomorphic subset of  $M_{i+1}$ , and  $Y \perp M'_{i+1}$ .

Therefore according to Lemma 1.14,  $\mathbf{w}(M^r(X)_{\perp \langle x \rangle \times n}) \geq \mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \cdot n$ . ◀

► **Lemma B.2.** *Let  $X$  be a wpo. Then*

$$\mathbf{w}(M^r(X)) \leq \sup_{x \in X, n < \omega} \mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \otimes n + 1$$

## 87:14 Ordinal Measures of the Set of Finite Multisets

**Proof.** By definition, for any multisets  $m, m' \in M^r(X)$ ,  $m \perp m'$  means that  $m \neq m'$  and there exists  $m_1, m'_1, m_2$  such that  $m = m_1 \cup m_2$ ,  $m' = m'_1 \cup m_2$  and  $m_1 \overset{\uparrow}{\perp} m'_1$ .

Therefore, the residual  $M^r(X)_{\perp m}$  can be partitioned as an augmentation of a disjoint union:

$$M^r(X)_{\perp m} \geq_{\text{aug}} \bigsqcup_{m_1+m_2=m, m_1 \neq \emptyset} \{ m'_1 + m_2 : m' \in M^r(X), m'_1 \overset{\uparrow}{\perp} m_1 \},$$

which can be reformulated into

$$M^r(X)_{\perp m} \geq_{\text{aug}} \bigsqcup_{m_1 \subseteq m, m_1 \neq \emptyset} M^r(X)_{\overset{\uparrow}{\perp} m_1}$$

where  $M^r(X)_{\overset{\uparrow}{\perp} m_1}$  is the residual  $\{ m' \in M^r(X) : m' \overset{\uparrow}{\perp} m_1 \}$ .

Let us observe this residual:  $m' \overset{\uparrow}{\perp} m_1$  means that  $m'$  and  $m_1$  are disjoint and there exists  $x \in m_1$  such that for all  $y' \in m'$ ,  $x \not\leq y'$ , and there exists  $x' \in m'$  such that for all  $y \in m_1$ ,  $x' \not\leq y$ . In particular  $x' \not\leq x$ . Hence  $m' \overset{\uparrow}{\perp} m_1$  implies there exists  $x \in m_1$  such that  $\langle x \rangle \overset{\uparrow}{\perp} m'$ , which is equivalent to  $\langle x \rangle \perp m'$ . Therefore the support of  $M^r(X)_{\overset{\uparrow}{\perp} m_1}$  is included in a union on  $x \in m_1$  of residuals  $M^r(X)_{\perp \langle x \rangle}$ . With an augmentation we get a disjoint union:

$$M^r(X)_{\overset{\uparrow}{\perp} m_1} \leq_{\text{st}} \geq_{\text{aug}} \bigsqcup_{x \in m_1} M^r(X)_{\perp \langle x \rangle}.$$

Hence according to Table 1,  $M^r(X)_{\perp m} \leq \bigoplus_{m_1 \subseteq m, m_1 \neq \emptyset} \bigoplus_{x \in m_1} \mathbf{w}(M^r(X)_{\perp \langle x \rangle})$ .

Let  $x \in m$  such that  $\mathbf{w}(M^r(X)_{\perp \langle x \rangle})$  is maximal. Then  $\mathbf{w}(M^r(X)_{\perp m}) \leq \mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \otimes n$  for some  $n < \omega$ . Hence according to Equation (Res-w),

$$\mathbf{w}(M^r(X)) = \sup_{m \in M^r(X)} \mathbf{w}(M^r(X)_{\perp m}) + 1 \leq \sup_{x \in X, n < \omega} \mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \otimes n + 1. \quad \blacktriangleleft$$

The bounds provided in Lemmas B.1 and B.2 actually match. Furthermore, they can be reformulated in such a way that the residual on  $M^r(X)$  boils down to a residual on  $X$ :

► **Lemma B.3.** For any non-linear wpo  $X$ ,

$$\mathbf{w}(M^r(X)) = \sup\{ \mathbf{w}(M^r(X_{\not\leq x})) \cdot \omega : x \in X, X_{\perp x} \neq \emptyset \}. \quad (\text{W})$$

**Proof.** For any ordinal  $\alpha$ ,  $\sup_{n < \omega} (\alpha \cdot n + 1) = \sup_{n < \omega} (\alpha \otimes n + 1) = \alpha \cdot \omega$ . Hence according to Lemmas B.1 and B.2,  $\mathbf{w}(M^r(X)) = \sup_{x \in X} (\mathbf{w}(M^r(X)_{\perp \langle x \rangle}) \cdot \omega)$ .

Let  $x \in X$ . If  $X_{\perp x} = \emptyset$ , then  $M^r(X)_{\perp \langle x \rangle} = \emptyset$ . Otherwise let  $y \in X_{\perp x}$ . Observe that, for any  $m \in M^r(X_{\not\leq x})$ ,  $m \cup \langle y \rangle \perp \langle x \rangle$ . Hence

$$\{ \langle y \rangle \cup m : m \in M^r(X_{\not\leq x}) \} \leq_{\text{st}} M^r(X)_{\perp \langle x \rangle} \leq_{\text{st}} M^r(X_{\not\leq x}).$$

Therefore  $\mathbf{w}(M^r(X)_{\perp \langle x \rangle}) = \mathbf{w}(M^r(X_{\not\leq x}))$  if  $X_{\perp x} \neq \emptyset$ , otherwise  $\mathbf{w}(M^r(X)_{\perp \langle x \rangle}) = 0$ . ◀

**Proof of Theorem 3.4.** If  $X$  is linear,  $\text{Bad}_{\perp}(X)$  only contains the empty sequence, hence  $\mathbf{o}_{\perp}(X) = 0$  and  $\mathbf{w}(\text{Mulr}(X)) = 1$ . Otherwise, observe that Equation (W) is quite similar to Equation (Res-f) in its structure. Thus  $\mathbf{w}(M^r(X)) = \omega^{\mathbf{o}_{\perp}(X)}$  follows directly from Equation (W). ◀

### C Proof of Theorem 4.5

► **Lemma C.1.** *For any wpo  $X$ , for any maximal linearisation  $\ell : \text{str}(X) \rightarrow \mathbf{o}(\text{str}(X))$ , there exists a friendly subset  $X'$  such that  $\ell$  restricted to  $X'$  verifies the friendly condition, and  $\mathbf{o}(X') \geq \delta(\mathbf{o}(\text{str}(X)))$ .*

**Proof.** We claim that for any  $\beta \leq \mathbf{o}(\text{str}(X))$ , there exists  $X_\beta \subseteq \ell^{-1}(\{\gamma : \gamma < \beta\})$  a friendly subset of  $X$  where  $\ell$  restricted to  $X_\beta$  verifies the friendly condition, such that  $\mathbf{o}(X_\beta) \geq \delta(\beta)$ . In this proof, when we say that a subset is friendly, it is always implied that  $\ell$  restricted to this subset witnesses the friendly condition.

We build the subsets  $(X_\beta)_{\beta \leq \mathbf{o}(\text{str}(X))}$  as follows:

- $X_0 = \emptyset$ ,
- For  $\gamma$  limit,  $X_\gamma = \bigcup_{\beta < \gamma} X_\beta$ ,
- For any  $\beta$ ,  $X_{\beta+1} = X_\beta \cup \ell^{-1}(\beta)$  if friendly, otherwise  $X_{\beta+1} = X_\beta$ .

First observe that  $X_\beta$  is friendly for any  $\beta \leq \mathbf{o}(\text{str}(X))$ . Indeed,  $X_0$  is friendly, and since for any  $\beta < \beta'$ ,  $X_\beta \subseteq X_{\beta'}$ , then the union  $\bigcup_{\beta < \gamma} X_\beta$  for  $\gamma$  limit is friendly by induction.

Let us prove the claim  $\mathbf{o}(X_\beta) \geq \delta(\beta)$ , by showing that for any  $\beta + 2 \leq \mathbf{o}(\text{str}(X))$ , we have  $\mathbf{o}(X_{\beta+2}) > \mathbf{o}(X_\beta)$ . Let  $x = \ell^{-1}(\beta')$  and  $x' = \ell^{-1}(\beta' + 1)$ . Assume for the sake of contradiction that  $X_{\beta+2} = X_\beta$ . This means that neither  $X_\beta \cup \{x\}$  nor  $X_\beta \cup \{x'\}$  are friendly. Hence there exists  $y, y' \in X_\beta$  such that for any  $z \in X$ , we have  $z \perp y \implies z \geq x$  and  $z \perp y' \implies z \geq x'$ . Now because of  $\ell$  we know that  $x \not\geq x'$  and  $y, y' \not\geq x, x'$ . Since  $y, y' \in \text{str}(X)$ , then  $X_{\perp y}$  and  $X_{\perp y'}$  are both non-empty, so actually  $x \perp y$  and  $x' \perp y'$ . And since  $x \not\geq x'$ , we know  $y' < x$ . Therefore  $x \perp x'$ , hence  $y < x'$ . Which leads to a contradiction on the relationship between  $y$  and  $y'$ . ◀

For any friendly subset  $X'$ ,  $\mathbf{o}(X') \leq \mathbf{o}(\text{str}(X))$ , and there exist  $X'$  such that  $\mathbf{o}(X') \geq \delta(\mathbf{o}(\text{str}(X)))$ . Therefore there exists a friendly subset  $X'$  which maximizes  $\mathbf{o}(X')$ .

**Proof of Theorem 4.5.** We say that a bad sequence  $x_1, \dots, x_n$  respects a maximal linearisation  $\ell$  when  $\ell(x_1) > \dots > \ell(x_n)$ . Let  $X'$  be a friendly subset of  $X$  and  $\ell$  a maximal linearisation of  $X'$  that verifies the friendly condition. Observe that  $\text{Bad}(X')$  restricted to sequences that respect  $\ell$  has for rank  $\mathbf{o}(X')$ , and is embedded in  $\text{Bad}_\perp(X)$ . Hence  $\mathbf{o}_\perp(X) \geq \mathbf{o}(X')$ .

We prove the upper bound by induction on  $\mathbf{o}_\perp(X)$ . If  $\mathbf{o}_\perp(X) = 0$  then the only friendly subset of  $X$  is the empty set. Now suppose that  $\mathbf{o}_\perp(X) > 0$ . For any  $x \in \text{str}(X)$ , by induction hypothesis on  $X_{\not\geq x}$ , there exists a friendly subset  $X'$  of  $X_{\not\geq x}$ , with a maximal linearisation  $\ell$  which verifies the friendly condition, such that  $\mathbf{o}(X') \geq \mathbf{o}_\perp(X_{\not\geq x})$ . We extend  $\ell$  to the subset  $X' \cup \{x\}$  of  $X$ , such that  $\ell(x) = \mathbf{o}(X')$ . Now  $\ell$  is a maximal linearisation of  $X' \cup \{x\}$  which verifies the friendly condition, therefore  $\mathbf{o}(X' \cup \{x\})$  is a friendly subset of  $X$  and  $\mathbf{o}(X' \cup \{x\}) > \mathbf{o}_\perp(X_{\not\geq x})$ . Let  $X'$  be a friendly subset of  $X$  which maximizes  $\mathbf{o}(X')$ . Then for any  $x \in \text{str}(X)$ ,  $\mathbf{o}_\perp(X_{\not\geq x}) < \mathbf{o}(X')$ . Therefore  $\mathbf{o}_\perp(X) \leq \mathbf{o}(X')$  according to Equation (Res-f). ◀

# Checking Presence Reachability Properties on Parameterized Shared-Memory Systems

Nicolas Waldburger

---

## Abstract

We consider the verification of distributed systems composed of an arbitrary number of asynchronous processes. Processes are identical finite-state machines that communicate by reading from and writing to a shared memory. Beyond the standard model with finitely many registers, we tackle round-based shared-memory systems with fresh registers at each round. In the latter model, both the number of processes and the number of registers are unbounded, making verification particularly challenging. The properties studied are generic presence reachability objectives, which subsume classical questions such as safety or synchronization by expressing the presence or absence of processes in some states. In the more general round-based setting, we establish that the parameterized verification of presence reachability properties is PSPACE-complete. Moreover, for the roundless model with finitely many registers, we prove that the complexity drops down to NP-complete and we provide several natural restrictions that make the problem solvable in polynomial time.

## 1 Introduction

**Parameterized verification.** Distributed systems consist of multiple processes running in parallel. Verification of such systems is a major topic of modern verification, because of how common these systems are and how difficult their verification has proven to be. Indeed, when multiple processes run asynchronously, the number of relevant interleavings to consider quickly becomes large. An intuitive approach for their verification is to fix the number of processes involved and try to apply classical verification techniques. Another approach is that of parameterized verification, where one aims to prove the more general statement that the property of interest holds for any number of participants. The interest of this approach is threefold. First, it allows to prove that the system is correct regardless of the number of processes. Second, the efficiency of parameterized techniques does not depend on the number of participants, which makes them more suitable for large systems for which classical techniques scale poorly. Third, parameterized verification often yields decidability or better computational complexity for problems that are hard to solve with classical techniques; see for example [14] for a problem that becomes decidable in the parameterized case. In their seminal work [13], German and Sistla consider systems consisting of a leader and arbitrarily many contributors, all of which are finite-state machines communicating via *rendez-vous*. In this setting, the safety verification problem is EXPSpace-complete and the complexity drops down to polynomial time when the leader is removed. Since then, many similar models have been studied, with variations on the expressiveness of the processes and the means of communication in order to capture the large variety of existing distributed algorithms [10, 7].

**Contributions.** We study parameterized verification of systems where all processes are identical and anonymous finite-state machines that communicate via reading from and writing to a shared memory. The read and write actions are performed non-atomically, meaning that no process may perform a read-write combination while preventing all other processes from acting. Our registers are *initialized* with a special symbol; this assumption is common in parameterized verification of shared-memory systems [8, 1], since some algorithms require initialized registers, *e.g.* [2]. First, we study a model with finitely many registers. This model is inspired by [11] where registers were uninitialized and the verification is restricted to safety properties. In contrast, we study the more general *presence reachability problems*, in which one asks whether one may reach a configuration that satisfies a property. This property takes the form of a Boolean combination of constraints expressing whether there is at least one process in a given state of the finite-state machine. We prove that this problem is NP-complete and we provide several natural restrictions on the process description and on the property that make the problem solvable in polynomial time. We then work on the more general setting of *round-based* shared-memory systems [6], which are designed to model round-based shared-memory algorithms present in the literature, see *e.g.* [2, 15]. In this model, the processes proceed in asynchronous rounds, each round having its own fresh set of registers. The source of infinity is twofold, as the number of processes and the number of registers are both unbounded, making round-based systems particularly challenging to verify. The safety problem was proved to be PSPACE-complete in round-based shared-memory systems [6]. In this article, we go beyond safety by considering a round-based, richer version of the presence reachability problem where the property may quantify existentially and universally over the rounds. Nonetheless, we establish that the round-based presence reachability problem is PSPACE-complete.

**Related work.** Similar models and problems have been studied in the literature. In the shared-memory model (without rounds and without register initialization), the safety problem has been studied extensively with variations on the expressiveness given to the leader and the contributors [11]; in particular, when processes are finite-state machines, the safety problem is shown to be coNP-complete and to decrease to PTIME when the leader is removed. However, this result does not hold when registers are initialized or when the property is more general than safety. A model that has perhaps been more studied is that of *reconfigurable broadcast networks* (RBN), where processes communicate via broadcasting messages that can be received by any of the other processes. This model has similarities with shared-memory systems, although broadcast tends to be simpler (messages disappear after being sent, while written values remain in the registers). A source of inspiration for the first part of our article is the study of reachability problems in RBN [9], where it is shown that the cardinality reachability problem, where one wants to reach a configuration that satisfies cardinality constraints, is PSPACE-complete. When the constraints cannot count processes, this problem is analogous to our presence reachability problem; for RBN, it is shown to be NP-complete, a complexity that we also obtain in our setting. Finally, this complexity drops down to PTIME in RBN when considering the special case of safety. This tractability result no longer holds in the shared-memory world unless we make further assumptions about the number of registers or their initialization. The cube reachability problem is a generalization of the cardinality constraint problem where the initial configuration is also subject to cardinality constraints; this problem is PSPACE-complete both in RBN and in (roundless) asynchronous shared-memory systems [9, 5, 4], although it is unknown whether this remains true when allowing the  $\text{Pre}^*$  and  $\text{Post}^*$  operators in the description of the cubes [4, 3]. While it is

interesting to compare results on RBN with our results on shared-memory systems without rounds, such a comparison is not possible with the more expressive model of round-based shared-memory systems, in particular because the unboundedness in the number of registers has no equivalent in broadcast networks.

Due to space constraints, some details are omitted. These details can be found in the full version of this paper.

## 2 Roundless Register Protocols

In this section, we introduce *register protocols*, a model inspired by [11]. We call these systems *roundless* to distinguish them from *round-based* systems introduced later in this article.

### 2.1 Definitions

► **Definition 1** (Roundless register protocols). *A roundless register protocol is a tuple  $\mathcal{P} = \langle Q, Q_0, \text{dim}, D, \mathbf{d}_0, \Delta \rangle$  where*

- $Q$  is a finite set of states with a distinguished subset of initial states  $Q_0 \subseteq Q$ ;
- $\text{dim} \in \mathbb{N}$  is the number of shared registers;
- $D$  is a finite data alphabet containing the initial symbol  $\mathbf{d}_0$ ;
- $\Delta \subseteq Q \times \mathcal{A} \times Q$  is the set of transitions, where  $\mathcal{A} := \{\text{read}_\alpha(\mathbf{d}) \mid \alpha \in [1, \text{dim}], \mathbf{d} \in D\} \cup \{\text{write}_\alpha(\mathbf{d}) \mid \alpha \in [1, \text{dim}], \mathbf{d} \in D \setminus \{\mathbf{d}_0\}\}$  is the set of actions.

Roundless register protocols are executed on multiple processes that behave asynchronously and can only communicate via reading from and writing to the shared registers. The behavior of a process is described by a finite-state machine. The possible actions of the transitions are reading a symbol from and writing a symbol to one of the  $\text{dim}$  shared registers;  $\mathbf{d} \in D$  denotes the symbol and  $\alpha$  indicates the register on which the action is performed. Each register stores one *symbol* from the finite set  $D$  at a time. Read-write combinations are performed non-atomically, i.e., no process can perform a read-write combination while excluding all other processes. The *size* of the protocol  $\mathcal{P}$  is defined as  $|\mathcal{P}| := |Q| + |D| + |\Delta| + \text{dim}$ . For all  $\alpha \in [1, \text{dim}]$ , we write  $\text{rg}[\alpha]$  for the register of index  $\alpha$ . We also write  $\text{Reg}$  for the set  $\{\text{rg}[\alpha] \mid \alpha \in [1, \text{dim}]\}$  of all registers.

Processes are assumed to have no identifiers so they are identical anonymous agents. Therefore, a *configuration* is a pair  $\gamma = \langle \mu, \vec{d} \rangle \in \mathbb{N}^Q \times D^{\text{Reg}}$  such that  $0 < \sum_{q \in Q} \mu(q) < \infty$ . Let  $\text{st}(\gamma) := \mu$  which indicates the number of processes in each state, and  $\text{data}(\gamma) := \vec{d}$  mapping to each register its symbol: for all  $r \in \text{Reg}$ ,  $\text{data}(\gamma)(r)$  is the symbol contained in register  $r$  in  $\gamma$ . Let  $\Gamma := \mathbb{N}^Q \times D^{\text{Reg}}$  denote the set of all configurations. Let  $\text{supp}(\gamma) := \{q \in Q \mid \text{st}(\gamma)(q) > 0\}$  denote the support of the multiset  $\text{st}(\gamma)$ . We write  $\oplus$  and  $\ominus$  the operations on multisets that add and remove elements, respectively. A configuration is *initial* if all processes are in states from  $Q_0$  while all registers have value  $\mathbf{d}_0$ . We denote by  $\text{Init}_c$  the set of initial configurations (the letter  $c$  stands for “concrete” as opposed to “abstract” configurations defined later). Formally,  $\text{Init}_c := \{\gamma \mid \text{st}(\gamma) \subseteq Q_0, \text{data}(\gamma) = \mathbf{d}_0^{\text{Reg}}\}$ .

Given  $\gamma, \gamma' \in \Gamma$ ,  $\gamma'$  is a *successor* of  $\gamma$  when there exists  $\delta = (q, a, q') \in \Delta$  such that  $\text{st}(\gamma)(q) > 0$ ,  $\text{st}(\gamma') = (\text{st}(\gamma) \ominus \{q\}) \oplus \{q'\}$  and:

- if  $a = \text{read}_\alpha(\mathbf{d})$  then  $\text{data}(\gamma)(\text{rg}[\alpha]) = \mathbf{d}$  and  $\text{data}(\gamma') = \text{data}(\gamma)$ ,
- if  $a = \text{write}_\alpha(\mathbf{d})$  then  $\text{data}(\gamma')(\text{rg}[\alpha]) = \mathbf{d}$  and  $\forall \alpha' \neq \alpha, \text{data}(\gamma')(\text{rg}[\alpha']) = \text{data}(\gamma)(\text{rg}[\alpha'])$ .

In that case, we write  $\gamma \xrightarrow{\delta} \gamma'$  or simply  $\gamma \rightarrow \gamma'$ , which is called a *step*. A *concrete execution* is a sequence  $\pi = \gamma_0, \delta_1, \gamma_1, \dots, \gamma_{l-1}, \delta_l, \gamma_l$  such that for all  $i$ ,  $\gamma_i \xrightarrow{\delta_{i+1}} \gamma_{i+1}$ . We write  $\gamma_0 \xrightarrow{*} \gamma_l$

■ **Figure 1** An example of a protocol.

for the existence of such an execution.  $\gamma'$  is *reachable from*  $\gamma$  when  $\gamma \xrightarrow{*} \gamma'$ . Given a set  $C$  of configurations, we write  $\text{Reach}_c(C) := \{\gamma' \mid \exists \gamma \in C, \gamma \xrightarrow{*} \gamma'\}$ . A configuration is *reachable* when it is in  $\text{Reach}_c(\text{Init}_c)$ .

► **Example 2.** Figure 1 provides an example of a roundless register protocol  $\mathcal{P}$  with  $D = \{d_0, a, b, c\}$ ,  $Q_0 = \{q_0\}$  and  $\dim = 1$ , hence read and write actions are implicitly on register  $\alpha = 1$ . The red and blue labels are to be ignored for now.

The set of initial configurations is  $\text{Init}_c := \{\langle q_0^n, d_0 \rangle \mid n \geq 1\}$ . The following execution with two processes witnesses that  $\langle q_f \oplus C, a \rangle \in \text{Reach}_c(\text{Init}_c)$ :

$$\begin{aligned} \langle q_0^2, d_0 \rangle &\xrightarrow{(q_0, \text{read}(d_0), B)} \langle q_0 \oplus B, d_0 \rangle \xrightarrow{(B, \text{read}(d_0), C)} \langle q_0 \oplus C, d_0 \rangle \xrightarrow{(q_0, \text{write}(c), A)} \\ \langle A \oplus C, c \rangle &\xrightarrow{(C, \text{write}(a), C)} \langle A \oplus C, a \rangle \xrightarrow{(A, \text{read}(a), q_f)} \langle q_f \oplus C, a \rangle. \end{aligned} \quad \lrcorner$$

## 2.2 Reachability Problems

Our first problem of interest is the *coverability problem* (COVER):

COVER FOR ROUNDLESS REGISTER PROTOCOLS

**Input:** A roundless register protocol  $\mathcal{P}$ ,  $q_f \in Q$

**Question:** Does there exist  $\gamma \in \text{Reach}_c(\text{Init}_c)$  such that  $\text{st}(\gamma)(q_f) > 0$ ?

Note that, because the model is parameterized, a witness execution of COVER may have an arbitrarily large number of processes. The dual is the *safety problem*, the answer to which is yes when an error state cannot be covered regardless of the number of processes. A similar problem is the *target problem* (TARGET) where processes must synchronize at  $q_f$ :

TARGET FOR ROUNDLESS REGISTER PROTOCOLS

**Input:** A roundless register protocol  $\mathcal{P}$ ,  $q_f \in Q$

**Question:** Does there exist  $\gamma \in \text{Reach}_c(\text{Init}_c)$  s.t. for all  $q \neq q_f$ ,  $\text{st}(\gamma)(q) = 0$ ?

► **Remark 3.** TARGET is harder than COVER: consider the reduction in which one adds a loop on  $q_f$  writing a joker symbol which, from any state, may be read to reach  $q_f$ .

*Presence constraints* are Boolean combinations (with  $\wedge$ ,  $\vee$  and  $\neg$ ) of atomic propositions of the form “ $q$  populated” with  $q \in Q$ , or of the form “ $r$  contains  $d$ ” with  $r \in \text{Reg}$  and  $d \in D$ . A presence constraint is interpreted over a configuration  $\gamma$  by interpreting “ $q$  populated” as true if and only if  $\text{st}(\gamma)(q) > 0$  and “ $r$  contains  $d$ ” as true if and only if  $\text{data}(\gamma)(r) = d$ . Note that presence constraints cannot refer to how many processes are on a given state. We write  $\gamma \models \phi$  when configuration  $\gamma$  satisfies presence constraint  $\phi$ .

► **Example 4.** If  $Q = \{q_1, q_2, q_3\}$ ,  $\dim = 2$ ,  $D = \{d_0, a, b\}$  and  $\phi := (q_1 \text{ populated}) \vee ((q_2 \text{ populated}) \wedge (\text{rg}[1] \text{ contains } a))$  then  $\langle q_1 \oplus q_3, d_0^2 \rangle \models \phi$ ,  $\langle q_2^2, (a, b) \rangle \models \phi$  but  $\langle q_2^2, b^2 \rangle \not\models \phi$ .  $\lrcorner$

The *Presence Reachability Problem* (PRP) generalizes both COVER and TARGET. It corresponds to the cardinality reachability problem for cardinality constraints restricted to  $CC[\geq 1, = 0]$  studied for broadcast protocols [9].

PRP FOR ROUNDLESS REGISTER PROTOCOLS

**Input:** A roundless register protocol  $\mathcal{P}$ , a presence constraint  $\phi$

**Question:** Does there exist  $\gamma \in \text{Reach}_c(\text{Init}_c)$  such that  $\gamma \models \phi$ ?

The formula  $\phi$  automatically makes PRP NP-hard, since one can encode the SAT problem. Therefore, we also consider the *DNF Presence Reachability Problem* (DNF-PRP), in which  $\phi$  is in *disjunctive normal form*. COVER and TARGET are special cases of DNF-PRP, with  $\phi = (q_f \text{ populated})$  for COVER and  $\phi = \bigwedge_{q \neq q_f} \neg(q \text{ populated})$  for TARGET.

► **Example 5.** Consider again the protocol  $\mathcal{P}$  defined in Figure 1.  $(\mathcal{P}, q_f)$  is a positive instance of COVER, as proved in Example 2. Let  $\mathcal{P}_{\text{blue}}$  be the protocol obtained from  $\mathcal{P}$  by changing to  $\text{read}(c)$  the label of the transition from  $q_0$  to  $B$  (in blue in Figure 1).  $(\mathcal{P}_{\text{blue}}, q_f)$  is a negative instance of COVER. In fact, a process can only get to  $B$  if  $c$  has been written to the register, and then  $d_0$  can no longer be read so no process may go to state  $C$ ,  $a$  cannot be written and no process may go from  $A$  to  $q_f$ .

$(\mathcal{P}, q_f)$  is a negative instance of TARGET: to leave  $A$ , one needs to read  $a$ , hence must have a process on state  $C$ , and to leave  $C$ , one must read  $b$  which would force us to send a process to  $A$ . Let  $\mathcal{P}_{\text{red}}$  be the protocol obtained from  $\mathcal{P}$  by changing to  $\text{write}(a)$  the label of the transition from  $C$  to  $A$  (in red in Figure 1).  $(\mathcal{P}_{\text{red}}, q_f)$  is a positive instance of TARGET:

$$\langle q_0^2, d_0 \rangle \xrightarrow{(q_0, \text{read}(d_0), B)} \langle q_0 \oplus B, d_0 \rangle \xrightarrow{(B, \text{read}(d_0), C)} \langle q_0 \oplus C, d_0 \rangle \xrightarrow{(q_0, \text{write}(c), A)} \langle A \oplus C, c \rangle \xrightarrow{(C, \text{write}(a), A)} \langle A^2, a \rangle \xrightarrow{(A, \text{read}(a), q_f)} \langle A \oplus q_f, a \rangle \xrightarrow{(A, \text{read}(a), q_f)} \langle q_f^2, a \rangle.$$

Let  $\phi := \neg(C \text{ populated}) \wedge ((\text{rg contains } a) \vee [(\text{rg contains } b) \wedge \neg(A \text{ populated})])$ .  $\phi$  is a presence constraint and  $(\mathcal{P}, \phi)$  is a negative instance of PRP. Indeed, if  $a$  is in the register, then  $C$  must be populated and if  $b$  is in the register, then  $A$  must be populated. ◻

## 2.3 Abstract Semantics

In this subsection, we define an abstraction of the semantics that is sound and complete with respect to PRP. The intuition of this abstraction is that the exact number of processes in a given state is not relevant. Indeed, register protocols, thanks to non-atomicity, enjoy a classical monotonicity property named copycat property.

► **Lemma 6** (Copycat). *Consider  $\gamma_1, \gamma_2, q_2$  such that  $\gamma_1 \xrightarrow{*} \gamma_2, q_2 \in \text{supp}(\gamma_2)$ . There exists  $q_1 \in \text{supp}(\gamma_1)$  s.t.  $\langle \text{st}(\gamma_1) \oplus q_1, \text{data}(\gamma_1) \rangle \xrightarrow{*} \langle \text{st}(\gamma_2) \oplus q_2, \text{data}(\gamma_2) \rangle$ .*

An *abstract configuration* is a pair  $\sigma = \langle \text{st}(\sigma), \text{data}(\sigma) \rangle \in 2^Q \times D^{\text{Reg}}$  such that  $\text{st}(\sigma) \neq \emptyset$ . The set of *initial configurations* is  $\text{Init}_a := \{\langle S, d_0^{\dim} \rangle \mid S \subseteq Q_0\}$ . Given a concrete configuration  $\gamma$ , the projection  $\text{abst}(\gamma)$  is the abstract configuration  $\langle \text{supp}(\gamma), \text{data}(\gamma) \rangle$ . Let  $\Sigma := 2^Q \times D^{\text{Reg}}$  denote the set of abstract configurations. For  $\sigma, \sigma' \in \Sigma$ ,  $\sigma'$  is the *successor* of  $\sigma$  when there exists  $\delta = (q, a, q') \in \Delta$  such that  $q \in \text{st}(\sigma)$ , either  $\text{st}(\sigma') = \text{st}(\sigma) \cup \{q'\}$  or  $\text{st}(\sigma') = (\text{st}(\sigma) \setminus \{q\}) \cup \{q'\}$ , and: if  $a = \text{read}_\alpha(d)$  then  $\text{data}(\sigma)(\text{rg}[\alpha]) = d$  and  $\text{data}(\sigma) = \text{data}(\sigma')$ , and if  $a = \text{write}_\alpha(d)$  then  $\text{data}(\sigma')(\text{rg}[\alpha]) = d$  and for all  $\alpha' \neq \alpha$ ,  $\text{data}(\sigma')(\text{rg}[\alpha']) = \text{data}(\sigma)(\text{rg}[\alpha'])$ . Again, we denote such a step by  $\sigma \xrightarrow{\delta} \sigma'$  or  $\sigma \rightarrow \sigma'$ . Note that one could equivalently define  $\sigma \xrightarrow{\delta} \sigma'$  by:  $\sigma \xrightarrow{\delta} \sigma' \iff \exists \gamma, \gamma' \in \Gamma, \gamma \xrightarrow{\delta} \gamma'$  and  $\text{abst}(\gamma) = \sigma, \text{abst}(\gamma') = \sigma'$ . This notion of abstraction is classical in parameterized verification of systems with identical anonymous agents that enjoy monotonicity properties. Note, however, that this semantics is

non-deterministic: one could have  $\sigma'' \neq \sigma'$  such that  $\sigma \xrightarrow{\delta} \sigma'$  and  $\sigma \xrightarrow{\delta} \sigma''$ . This alternative corresponds to whether all processes in  $q$  take the transition ( $\text{st}(\gamma') = (\text{st}(\gamma) \setminus \{q\}) \cup \{q'\}$ ) or only some ( $\text{st}(\gamma') = \text{st}(\gamma) \cup \{q'\}$ ). We define *abstract executions* similarly to concrete ones, and denote them using  $\rho$ . We also define the *reachability set*  $\text{Reach}_a(A)$  and the notion of *coverability* as in the concrete case. This abstraction is sound and complete for PRP:

► **Proposition 7** (Soundness and completeness of the abstraction). *For all  $S \subseteq Q$ ,  $\vec{d} \in D^{\text{Reg}}$ :*

$$(\exists \gamma \in \text{Reach}_c(\text{Init}_c) : \text{supp}(\gamma)=S, \text{data}(\gamma)=\vec{d}) \iff (\exists \sigma \in \text{Reach}_a(\text{Init}_a) : \text{st}(\sigma)=S, \text{data}(\sigma)=\vec{d}).$$

The intuition of the proof is the following: any concrete configuration can easily be lifted into an abstract one. Conversely, any abstract execution may be simulated in the concrete semantics for a sufficiently large number of processes by using the copycat property.

Given a presence constraint  $\phi$  and  $\sigma \in \Sigma$ , we define whether  $\sigma$  satisfies  $\phi$ , written  $\sigma \models \phi$ , in a natural way. Given a concrete configuration  $\gamma$ , one has  $\gamma \models \phi$  if and only if  $\text{abst}(\gamma) \models \phi$ . Indeed,  $\gamma$  and  $\text{abst}(\gamma)$  have the same populated states and register values. Therefore, there exists  $\gamma \in \text{Reach}_c(\text{Init}_c)$  such that  $\gamma \models \phi$  if and only if there exists  $\sigma \in \text{Reach}_a(\text{Init}_a)$  such that  $\sigma \models \phi$ : one can consider PRP directly in the abstract semantics.

### 3 Complexity Results for Roundless Register Protocols

In this section, we provide complexity results for the presence reachability problems defined above in the general case and in some restricted cases. Throughout the rest of the section, all configurations and executions are implicitly abstract.

#### 3.1 NP-Completeness of the General Case

First, all problems defined in the previous section are NP-complete.

► **Proposition 8.** *COVER, TARGET, DNF-PRP and PRP for roundless register protocols are all NP-complete.*

**Proof.** First, we prove that all four problems are in NP. It suffices to prove it for PRP, as the three other problems reduce to it.

Let  $\rho : \sigma_0 \xrightarrow{*} \sigma$  an abstract execution, we simply prove the existence of  $\rho' : \sigma_0 \xrightarrow{*} \sigma$  of length at most  $4|Q|$ . To obtain  $\rho'$  from  $\rho$ , we iteratively:

- remove any read step that is non-deserting and does not cover a new location,
- remove any write step that is non-deserting, does not populate a new state and whose written symbol is never read,
- make non-deserting any deserting step whose source state is populated again later in  $\rho$ .

In  $\rho'$ , at most  $|Q|$  steps populate a new state and at most  $|Q|$  steps are deserting. This implies that there are at most  $2|Q|$  read steps, therefore, at most  $2|Q|$  write steps whose written value is actually read. In total, this bounds the number of steps by  $4|Q|$ . In particular, for PRP, we can look for an execution of length less than  $4|Q|$  which can be guessed in polynomial time.

We prove NP-hardness of COVER, as it reduces to the three other problems.

The proof is by a reduction from 3-SAT. Consider a 3-CNF formula  $\phi = \bigwedge_{i=1}^m l_{i,1} \vee l_{i,2} \vee l_{i,3}$  over  $n$  variables  $x_1, \dots, x_n$  where, for all  $i \in [1, m]$ , for all  $k \in [1, 3]$ ,  $l_{i,k} \in \{x_j, \neg x_j \mid j \in [1, n]\}$ . We define a roundless register protocol  $\mathcal{P}_{\text{SAT}}(\phi)$  with a distinguished state  $q_f$  which is coverable if and only if  $\phi$  is satisfiable. In  $\mathcal{P}_{\text{SAT}}(\phi)$ , one has  $D = \{\mathbf{d}_0, \mathbf{T}\}$  and  $\dim = 2n$ , there are two registers for each variable  $x_i$ ,  $\text{rg}(x_i)$  and  $\text{rg}(\neg x_i)$ . The protocol is represented on Figure 2.

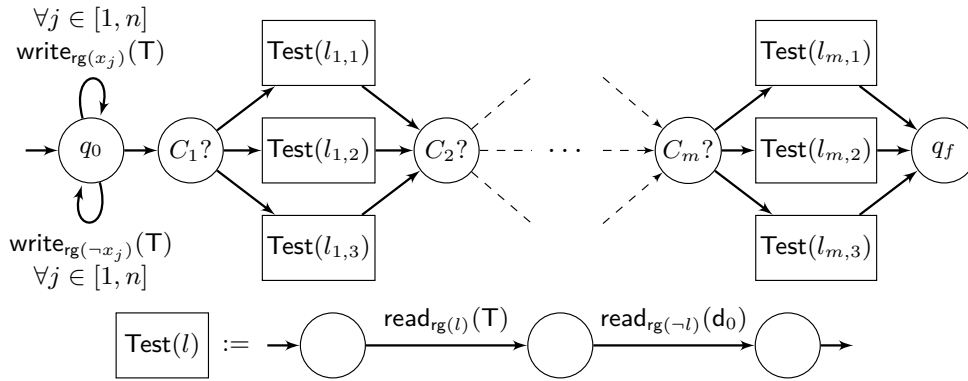

Figure 2 The protocol  $\mathcal{P}_{\text{SAT}}(\phi)$  for NP-hardness of COVER.

While any register may be set to  $\top$  thanks to the loops on  $q_0$ , a register set to  $\top$  can never be set back to  $d_0$ .  $l$  is considered true if  $\text{rg}(l)$  is set to  $\top$  while  $\text{rg}(\neg l)$  still has value  $d_0$ . Suppose that the instance of 3-SAT is positive, *i.e.*,  $\phi$  is satisfiable by some assignment  $\nu$ . Consider an execution that writes  $\top$  exactly to all  $\text{rg}(l)$  with  $l$  true in  $\nu$ . For each clause, one of the three literals is true in  $\nu$ . Therefore the execution may cover  $C_i?$  for all  $i$  so it may cover  $q_f$  and the instance of COVER is positive. Conversely, if the instance COVER is positive, there exists an execution  $\rho : \sigma_0 \xrightarrow{*} \sigma$  with  $\sigma_0 \in \text{Init}_a$  and  $q_f \in \text{st}(\sigma)$ . Consider  $\nu$  that assigns to each variable  $x$  value true if  $\text{rg}(x)$  is written before  $\text{rg}(\neg x)$  in  $\rho$  and false otherwise. Given a literal  $l$ ,  $\rho$  may only go through  $\text{Test}(l)$  if  $\nu(l)$  is true; because  $\rho$  covers  $q_f$ , this proves that  $\nu \models \phi$ . ◀

► Remark 9. In [11], the authors prove NP-completeness of COVER in a similar model, but with a leader: in the NP-hardness reduction, the leader make non-deterministic decisions about the values of the variable. This argument does not hold in the leaderless case.

### 3.2 Interesting Restrictions

Although all the problems defined above are NP-complete, they are sometimes tractable under appropriate restrictions on the protocols. We will consider two restrictions on the protocols. The first one is having  $\text{dim} = 1$ , *i.e.*, a single register. The second restriction is the *uninitialized case* where processes are not allowed to read the initial value  $d_0$  from the registers. Formally, a protocol  $\mathcal{P}$  is *uninitialized* if its set of transitions  $\Delta$  does not contain an action reading symbol  $d_0$ : in uninitialized protocols, it is structurally impossible to read from an unwritten register. One might object that forbidding transitions that read  $d_0$  contradicts the intuition that, when a process reads from a register, it does not know whether the value is initial or not; one could settle the issue by considering that reading  $d_0$  sends processes to a sink state. The uninitialized setting tends to yield better complexity than the general, initialized case, see for example [1, Section 7].

Of course, for PRP, the formula itself always makes the problem NP-hard.

► Proposition 10. PRP for roundless register protocols is NP-hard even with  $\text{dim} = 1$  and the register uninitialized.

### 3.3 Tractability of COVER and DNF-PRP under Restrictions

In this subsection, we prove that COVER is solvable in PTIME when the protocol is uninitialized or when  $\text{dim}$  is fixed and that DNF-PRP is solvable in PTIME when  $\text{dim} = 1$ .

In [11, Theorem 9.2], uninitialized COVER is proved to be PTIME-complete; their approach, based on languages, is quite different from the one presented here. Our approach, similar to the one presented in [9, Algorithm 1] in the setting of reconfigurable broadcast networks, is to compute the set of coverable states using a simple *saturation* technique, a fixed-point computation over the set of states.

When registers are initialized, the saturation technique breaks down as it may be that some states are coverable but not in the same execution, as they require registers to lose their initial value in different orders (see the notion of first-write order developed in [6] for more development on this in a round-based setting). However, in the initialized case with a fixed number of registers, one can iterate over every such order and COVER is tractable as well.

► **Proposition 11.** *COVER for roundless register protocols is PTIME-complete either when the registers are uninitialized or when  $\text{dim}$  is fixed.*

For DNF-PRP, we provide a PTIME algorithm in the more restrictive case of  $\text{dim} = 1$ .

► **Proposition 12.** *DNF-PRP for roundless register protocols with  $\text{dim} = 1$  is in PTIME.*

**Proof sketch.** We give here the proof for TARGET. Our algorithm shares similarities with [12, page 41] for broadcast protocols, although it is more complex because of the persistence of symbols in the register.

First, we have a polynomial reduction from initialized TARGET with  $\text{dim} = 1$  to uninitialized TARGET with  $\text{dim} = 1$ . It proceeds as follows. Consider the graph  $G = (Q, E)$  when  $(q_1, q_2) \in E$  when there exists  $(q_1, \text{read}(\mathbf{d}_0), q_2) \in \Delta$ . Let  $I \subseteq Q$  the set of states that are reachable in  $G$  from  $Q_0$ . The reduction simply replaces  $Q_0$  by  $I$  as set of initial states.

Any (abstract) execution  $\rho : \sigma_0 \xrightarrow{*} \langle q_f, \mathbf{d}_f \rangle$ , called *synchronizing execution*, can be rearranged into  $\rho_+ : \sigma_0 \xrightarrow{*} \langle S, \mathbf{d} \rangle$  and  $\rho_- : \langle S, \mathbf{d} \rangle \xrightarrow{*} \langle q_f, \mathbf{d}_f \rangle$  where  $S$  contains all states that appear in  $\rho$ . Additionally, we can make  $\rho_-$  start with a write action (there is a transition in  $\rho$  that writes  $\mathbf{d}$ ). To obtain the decomposition,  $\rho_+$  mimics  $\rho$  but does not empty any state, and  $\rho_-$  mimics  $\rho$  but from a configuration with more states. We compute the maximum such set  $S$  by iteratively deleting states that cannot appear in any synchronizing execution. Let

$$\mathcal{C}(\mathcal{P}) := \max\{S \subseteq Q \mid \exists \mathbf{d} \in \mathbf{D}, \exists \sigma_0 \in \text{Init}_a, \sigma_0 \xrightarrow{*} \langle S, \mathbf{d} \rangle\}$$

$$\mathcal{BC}(\mathcal{P}) := \max\{S \subseteq Q \mid \forall \mathbf{d} \in \mathbf{D}, \exists \mathbf{d}' \in \mathbf{D}, \langle S, \mathbf{d}' \rangle \xrightarrow{*} \langle q_f, \mathbf{d}_f \rangle\}$$

Both maxima exist as the sets are non-empty ( $Q_0$  is included in the first set and  $q_f$  is in the second set) and they are stable by union (concatenate the corresponding executions). Intuitively,  $\mathcal{C}(\mathcal{P})$  corresponds to the set of coverable sets, and  $\mathcal{BC}(\mathcal{P})$  to the set of backward coverable states. In the decomposition  $\rho_+ : \sigma_0 \xrightarrow{*} \langle S, \mathbf{d} \rangle$ ,  $\rho_- : \langle S, \mathbf{d} \rangle \xrightarrow{*} \langle q_f, \mathbf{d}_f \rangle$ ,  $\rho_+$  is a witness that  $S \subseteq \mathcal{C}(\mathcal{P})$  and  $\rho_-$  that  $S \subseteq \mathcal{BC}(\mathcal{P})$  (because  $\rho_-$  starts with a write action, for every  $\mathbf{d}' \in \mathbf{D}$  one has  $\langle S, \mathbf{d}' \rangle \xrightarrow{*} \langle q_f, \mathbf{d}_f \rangle$ ).

$\mathcal{C}(\mathcal{P})$  and  $\mathcal{BC}(\mathcal{P})$  can be computed in polynomial time. For  $\mathcal{C}(\mathcal{P})$ , we use a saturation technique. For  $\mathcal{BC}(\mathcal{P})$ , we work backwards: a symbol is read before it is written. We start with  $S := \{q_f\}$ . Until a fixpoint for  $S$  is reached, we do the following. We iterate on  $\mathbf{D}$ , trying to pick the symbol that was in the register before  $S$  could be reached. For each  $\mathbf{d} \in \mathbf{D}$ , we saturate  $S$  with backward transitions reading  $\mathbf{d}$ , then check if  $\mathbf{d}$  can be written by a transition ending in  $S$ . If not, we backtrack by removing states that were just added.

The algorithm iteratively removes from  $\mathcal{P}$  states that are not in  $\mathcal{C}(\mathcal{P}) \cap \mathcal{BC}(\mathcal{P})$ . Indeed, states that are not in  $\mathcal{C}(\mathcal{P}) \cap \mathcal{BC}(\mathcal{P})$  cannot appear in any synchronizing execution. If it ends up with  $Q(\mathcal{P}) = \emptyset$ , then there is no synchronizing execution and the algorithm rejects. If it ends up with  $\mathcal{C}(\mathcal{P}) = \mathcal{BC}(\mathcal{P}) = Q(\mathcal{P}) \neq \emptyset$ , then applying the definitions of  $\mathcal{C}(\mathcal{P})$  and  $\mathcal{BC}(\mathcal{P})$  gives a synchronizing execution, and the algorithm accepts.  $\blacktriangleleft$

It is unknown whether the previous result still holds when  $\text{dim}$  is fixed to a value greater than 1. The case  $\text{dim} = 1$  is particularly easy because writing to the register completely erases its content.

Unlike COVER, TARGET and therefore DNF-PRP are not tractable under the uninitialized hypothesis. For TARGET, one cannot add fresh processes at no cost, since the fresh processes would eventually have to get to  $q_f$ . For example, if a register  $r$  can only be written from a given state  $q$ , the last process to leave  $q$  will fix the value in register  $r$ .

► **Proposition 13.** *TARGET for uninitialized roundless register protocols is NP-hard.*

	COVER	TARGET	DNF-PRP	PRP
General case	NP-complete (Prop. 8)	NP-complete (Prop. 8)	NP-complete (Prop. 8)	NP-complete (Prop. 8)
Uninitialized	PTIME-complete (Prop. 11)	NP-complete (Prop. 8 & 13)	NP-complete (Prop. 8 & 13)	NP-complete (Prop. 8 & 10)
$\text{dim} = 1$ (one register)	PTIME-complete (Prop. 11)	PTIME-complete (Prop. 12 & 11)	PTIME-complete (Prop. 12 & 11)	NP-complete (Prop. 8 & 10)

■ **Figure 3** Summary of complexity results for roundless register protocols.

## 4 Round-based Register Protocols

We now extend the previous model to a round-based setting. The model and semantics are the same as in [6], however we consider a more general problem than COVER. Thus, the abstract semantics developed here differs from [6].

### 4.1 Definitions

In round-based settings, there is a fresh set of  $\text{dim}$  registers at each round, and each process has its own private round value that starts at 0 and never decreases. Processes may only read from and write to registers of nearby rounds.

► **Definition 14** (Round-based register protocols). *A round-based register protocol is a tuple  $\mathcal{P} = \langle Q, Q_0, \text{dim}, D, d_0, v, \Delta \rangle$  where*

- $Q$  is a finite set of states with a distinguished subset of initial states  $Q_0 \subseteq Q$ ;
- $\text{dim} \in \mathbb{N}$  is the number of shared registers per round;
- $D$  is a finite data alphabet with an initial symbol  $d_0$ ;
- $v$  is the visibility range;
- $\Delta \subseteq Q \times \mathcal{A} \times Q$  is the set of transitions, where  $\mathcal{A} = \{\text{read}_\alpha^{-i}(d) \mid i \in [0, v], \alpha \in [1, \text{dim}], d \in D\} \cup \{\text{write}_\alpha(d) \mid \alpha \in [1, \text{dim}], d \in D \setminus \{d_0\}\} \cup \{\text{Inc}\}$  is the set of actions.

Read actions specify the round of the register:  $\text{read}_\alpha^{-i}(d)$  means, for a process at round  $k$ , “read  $d$  from register  $\alpha$  of round  $k-i$ ”. A process at round  $k$  may only write to the registers of round  $k$ . The Inc action increments the round of a process.

■ **Figure 4** An example of round-based register protocol.

Let  $\text{rg}_k[\alpha]$  denote the register  $\alpha$  of round  $k$ . The set of registers of round  $k$  is written  $\text{Reg}_k$ , and we let  $\text{Reg} = \bigcup_{k \in \mathbb{N}} \text{Reg}_k$ . The size of a protocol is  $|\mathcal{P}| = |Q| + |D| + |\Delta| + \nu + \dim$ . A given process is described by its state and round, formalized by a pair  $(q, k) \in Q \times \mathbb{N}$  called *location*. Let  $\text{Loc} := Q \times \mathbb{N}$  denote the set of locations. A *concrete configuration* describes the number of processes in each location along with the value of each register. Formally, a *concrete configuration* is a pair  $\langle \mu, \vec{d} \rangle$  with  $\mu \in \mathbb{N}^{\text{Loc}}$  such that  $0 < \sum_{(q,k) \in \text{Loc}} \mu(q,k) < \infty$  and  $\vec{d} \in D^{\text{Reg}}$ . For  $\gamma = \langle \mu, \vec{d} \rangle$ , we write  $\text{loc}(\gamma) := \mu$  and  $\text{data}(\gamma) := \vec{d}$ . Again, we write  $\Gamma$  for the set of concrete configurations. The set of initial configurations is  $\text{Init}_c := \{\gamma \in \Gamma \mid \text{data}(\gamma) = \vec{d}_0^{\text{Reg}} \text{ and } \forall (q,k) \notin Q_0 \times \{0\}, \text{loc}(\gamma)(q,k) = 0\}$ .

A *move* is a pair  $\theta \in \Delta \times \mathbb{N}$ :  $\text{move}(\delta, k)$  expresses that transition  $\delta$  is taken by a process at round  $k$ ; we write  $\text{Moves} := \Delta \times \mathbb{N}$  for the set of all moves. A move  $\theta$  has *effect* on round  $k$  when  $\theta$  is at round  $k$  or  $\theta$  is an increment at round  $k-1$ . We define a step as follows: for  $\theta = ((q, a, q'), k) \in \text{Moves}$ ,  $\gamma \xrightarrow{\theta} \gamma'$  when  $(q, k) \in \text{loc}(\gamma)$  and:

- if  $a = \text{read}_{\alpha}^{-i}(d)$ ,  $\text{loc}(\gamma') = (\text{loc}(\gamma) \ominus \{(q, k)\}) \oplus \{(q', k)\}$ ,  $\text{data}(\gamma)(\text{rg}_{k-i}[\alpha]) = d$  and  $\text{data}(\gamma') = \text{data}(\gamma)$ ;
- if  $a = \text{write}_{\alpha}(d)$ ,  $\text{loc}(\gamma') = (\text{loc}(\gamma) \ominus \{(q, k)\}) \oplus \{(q', k)\}$ ,  $\text{data}(\gamma')(\text{rg}_k[\alpha]) = d$  and for all  $r \neq \text{rg}_k[\alpha]$ ,  $\text{data}(\gamma')(r) = \text{data}(\gamma)(r)$ ;
- if  $a = \text{Inc}$ ,  $\text{loc}(\gamma') = (\text{loc}(\gamma) \ominus \{(q, k)\}) \oplus \{(q', k+1)\}$  and  $\text{data}(\gamma') = \text{data}(\gamma)$ .

A step is *at round  $k$*  when the corresponding move is of the form  $(\delta, k)$ . Note that action  $\text{read}_{\alpha}^{-i}(d)$  is only possible for processes at rounds  $k \geq i$ . The notions of execution, of reachability and of coverability are defined as in the roundless case.

► **Example 15.** Consider the round-based protocol  $\mathcal{P}$  from Figure 4, with  $\dim = 1$ ,  $\nu = 1$ ,  $Q_0 = \{q_0\}$  and  $D = \{d_0, a, b\}$ . In this protocol, state  $q_f$  cannot be covered. By contradiction, consider an execution  $\pi : \gamma_0 \xrightarrow{*} \gamma$  with  $\gamma_0 \in \text{Init}_c$  and  $\text{loc}(\gamma)(q_f, k) > 0$  for some  $k \in \mathbb{N}$ . We have that, at some point in  $\pi$ ,  $(E, k)$  is populated and  $b$  is in  $\text{rg}[k]$ . Therefore, some process went from  $(A, k)$  to  $(B, k)$ , which implies that  $\text{rg}[k]$  lost value  $d_0$  before  $\text{rg}[k-1]$ ; this in turn implies that  $\pi$  does not send any process to  $(E, k)$  which is a contradiction.  $\lrcorner$

Since round-based register protocols enjoy the same monotonicity properties as roundless register protocols, we define the same non-counting abstraction. Note that this abstraction differs from the one in [6] which was designed specifically for COVER. The set of *abstract configurations* is  $\Sigma := 2^{\text{Loc}} \times D^{\text{Reg}}$ ; the abstract semantics are defined as in Subsection 2.3. Again,  $\sigma \xrightarrow{\delta} \sigma'$  if and only if there exist  $\gamma, \gamma' \in \Gamma$ ,  $\gamma \xrightarrow{\delta} \gamma'$  and  $\text{abst}(\gamma) = \sigma$ ,  $\text{abst}(\gamma') = \sigma'$ . All the properties of Subsection 2.3 apply to round-based abstract semantics. In particular, we have the soundness and completeness of the abstraction:

► **Proposition 16** (Soundness and completeness of the abstraction). *For all  $L \subseteq \text{Loc}$ ,  $\vec{d} \in D^{\text{Reg}}$ :*

$$(\exists \gamma \in \text{Reach}_c(\text{Init}_c) : \text{supp}(\gamma) = L, \text{data}(\gamma) = \vec{d}) \iff (\exists \sigma \in \text{Reach}_a(\text{Init}_a) : \text{loc}(\sigma) = L, \text{data}(\sigma) = \vec{d}).$$

## 4.2 Presence Reachability Problem

COVER is extended to round-based protocols by asking whether some reachable configuration has a process on  $q_f$  on some round  $k$ , and TARGET by asking whether some reachable configuration has no process on states  $q \neq q_f$  on any round  $k$ . Formally, one asks whether there exists  $\gamma \in \text{Reach}_c(\text{Init}_c)$  such that  $\gamma \models \psi$  where  $\psi = “\exists k \in \mathbb{N}, (q, k) \in \text{loc}(\gamma)”$  for COVER and  $\psi = “\forall k \in \mathbb{N}, \forall q \neq q_f, (q, k) \notin \text{loc}(\gamma)”$  for TARGET. We will now extend roundless PRP to round-based PRP, where the formula is allowed to have non-nested quantification over rounds.

Presence constraints are first-order formulas (quantifying over the rounds) without any nested quantifiers. Formally:

- a *term* is of the form  $m$  or  $k+m$  with  $m \in \mathbb{N}$  and  $k$  a free variable;
- an *atomic proposition* is either of the form “ $(q, t)$  populated” with  $t$  a term and  $q \in Q$  or of the form “ $\text{rg}_t[\alpha]$  contains  $d$ ” with  $t$  a term,  $\alpha \in [1, \text{dim}]$  and  $d \in D$ ;
- a *literal* is either an atomic proposition or the negation of an atomic proposition;
- a *proposition* is a Boolean combination of atomic propositions that has at most one free variable;
- an *atomic presence constraint* is either a *closed* proposition (no free variables), or of the form “ $\exists k \phi$ ” or “ $\forall k \phi$ ” where  $\phi$  is a proposition with  $k$  as a free variable.

Finally, a *presence constraint* is a Boolean combination of atomic presence constraints.

► **Example 17.** “ $(\exists k (q_2, k)$  populated)  $\vee$  ( $\forall k ((q_0, k+2)$  populated)  $\wedge$   $\text{rg}_1[1]$  contains a)” is an example of presence constraint.

Let  $\gamma := ((q_0, 0) \oplus (q_1, 1), d_0^{\text{Reg}})$  with  $q_0 \neq q_1$ ,  $\text{dim} = 1$ . One has  $\gamma \models (\text{rg}_0[1]$  contains  $d_0) \wedge (\exists k (q_1, k+1)$  populated) but  $\gamma \not\models \forall k (((q_0, k)$  populated)  $\vee$   $\neg((q_1, k)$  populated)). ◻

We define the *round-based presence reachability problem* (round-based PRP):

ROUND-BASED PRP

**Input:** A round-based register protocol  $\mathcal{P}$ , a presence constraint  $\psi$

**Question:** Does there exist  $\gamma \in \text{Reach}_c(\text{Init}_c)$  such that  $\gamma \models \psi$ ?

► **Example 18.** Consider  $\mathcal{P}$  from Example 15. If  $\psi := \exists k, (q_f, k)$  populated, then  $(\mathcal{P}, \psi)$  is a negative instance of round-based PRP. If  $\psi' := \exists k, ((E, k)$  populated)  $\wedge$   $((E, k+1)$  populated), then  $(\mathcal{P}, \psi')$  is also negative. However, if  $\psi'' := ((E, 2)$  populated)  $\wedge$   $[\forall k, (\text{rg}[k+1]$  contains  $b) \vee (\text{rg}[k+1]$  contains  $d_0)]$ , then  $(\mathcal{P}, \psi'')$  is positive: a witness execution sends a process to  $(B, 1)$ , writes  $a$  to  $\text{rg}[0]$  then  $b$  to  $\text{rg}[1]$  and finally sends a process from  $(q_0, 2)$  to  $(E, 2)$ . ◻

COVER and TARGET for round-based register protocols are special cases of PRP. The following lower bound hence applies to all these problems:

► **Proposition 19** ([6, Theorem 23]). *COVER for round-based register protocols is PSPACE-hard, even in the uninitialized case with  $v = 0$  and  $\text{dim} = 1$ .*

Note that, in the round-based setting,  $\text{dim} = 1$  means one register *per round*, therefore still an unbounded number of registers.  $v = 0$  means that a process can only interact with registers of its current round. The previous proposition implies that all problems considered in Figure 3 are PSPACE-hard when working with round-based protocols. In [6], COVER for round-based register protocols is shown to be PSPACE-complete. In the rest of this paper, we establish that the more general round-based PRP lies in the same complexity class:

► **Theorem 20.** *Round-based PRP is PSPACE-complete.*

## 5 A Polynomial-Space Algorithm for Round-Based PRP

In this section, we provide a polynomial-space algorithm for round-based PRP. Thanks to Savitch's theorem, it suffices to find a non-deterministic polynomial-space algorithm. To do so, one wants to guess an execution that reaches a configuration satisfying the presence constraint. However, as shown in [6, Proposition 13], one may need, at a given point along such an execution, the number of active rounds to be exponential (an active round being informally a round on which something has already happened and something else is yet to happen). Thus, storing the execution step by step in polynomial space seems hard; instead, our algorithm will guess the execution round by round. To do this, we define the notion of footprint, which represents the projection of an execution onto a narrow window of rounds.

Thanks to Proposition 7, round-based PRP can be studied directly in the abstraction. In the rest of the paper, all configurations and executions are implicitly abstract.

### 5.1 Footprints

Let  $j \leq k$ . We write  $\text{Loc}[j, k]$  for the set of locations at rounds  $\max(j, 0)$  to  $k$ ; similarly, we write  $\text{Reg}[j, k]$  for the set of registers of rounds  $\max(j, 0)$  to  $k$ . A *local configuration* on (rounds)  $[j, k]$  is an element of  $2^{\text{Loc}[j, k]} \times \text{D}^{\text{Reg}[j, k]}$ . The set of local configurations on  $[j, k]$  is written  $\Sigma[j, k]$ . Given  $\sigma \in \Sigma$ , the local configuration  $\text{local}[j, k](\sigma)$  is obtained by removing from  $\sigma$  all information that is not about rounds  $j$  to  $k$ . Note that local configurations are local with respect to the rounds, and not with respect to processes.

Given  $\lambda, \lambda' \in \Sigma[j, k]$  and a move  $\theta$ , we write  $\lambda \xrightarrow{\theta} \lambda'$  when there exist two configurations  $\sigma$  and  $\sigma'$  such that  $\sigma \xrightarrow{\theta} \sigma'$ ,  $\text{local}[j, k](\sigma) = \lambda$  and  $\text{local}[j, k](\sigma') = \lambda'$ . In practice:

- if  $\theta$  is a move with no effect on rounds  $j$  to  $k$ , then  $\lambda \xrightarrow{\theta} \lambda'$  if  $\lambda = \lambda'$ ;
- if  $\theta = ((q, \text{Inc}, q'), j-1)$  then  $\lambda \xrightarrow{\theta} \lambda'$  holds with no condition that  $(q, j-1)$  is populated in  $\lambda$ , since  $j-1$  is outside of  $[j, k]$ ;
- if  $\theta = ((q, \text{read}_\alpha^{-b}(\text{d})), l)$  with  $l-b < j$  (read from register of round  $< j$ ), there is no condition on the content of the register.

A *footprint* on (rounds)  $[j, k]$  corresponds to the projection of an execution on rounds  $[j, k]$ . Formally, it is an alternating sequence  $\lambda_0, \theta_0, \lambda_1, \dots, \theta_{m-1}, \lambda_m$  where for all  $i \in [0, m]$ ,  $\lambda_i \in \Sigma[j, k]$  and for all  $i \leq m-1$ ,  $\lambda_i \xrightarrow{\theta_i} \lambda_{i+1}$  and  $\lambda_i \neq \lambda_{i+1}$ .

Let  $\rho = \sigma_0, \theta_0, \sigma_1, \dots, \theta_{m-1}, \sigma_m$  be an execution. The *footprint of  $\rho$  on (rounds)  $[j, k]$* , written  $\text{footprint}[j, k](\rho)$ , is the footprint on  $[j, k]$  obtained from  $\rho$  by replacing  $\sigma_i$  by  $\lambda_i = \text{local}[j, k](\sigma_i)$  and then removing all useless steps  $\lambda_i \xrightarrow{\theta} \lambda_{i+1}$  with  $\lambda_i = \lambda_{i+1}$  (by merging  $\lambda_i$  and  $\lambda_{i+1}$ , so  $\text{footprint}[j, k](\rho)$  can be shorter than  $\rho$ ). Similarly, for  $[j', k'] \supseteq [j, k]$  and  $\tau$  a footprint on  $[j', k']$ , define the *projection footprint  $[j, k](\tau)$*  by the footprint obtained by replacing each local configuration in  $\tau$  by its projection on  $[j, k]$  and removing useless steps.

The following result provides a sufficient condition for a sequence of footprints to be seen as projections of a single common execution.

► **Lemma 21.** *Let  $K \in \mathbb{N}$ ,  $(\tau_k)_{k \leq K}$  and  $(T_k)_{k \leq K-1}$  such that:*

- *for all  $k \leq K$ ,  $\tau_k$  is a footprint on  $[k-v+1, k]$ ,*
- *for all  $k \leq K-1$ ,  $T_k$  is a footprint on  $[k-v+1, k+1]$ ,*
- *for all  $k \leq K-1$ ,  $\text{footprint}[k-v+1, k](T_k) = \tau_k$ ,*
- *for all  $k \leq K-1$ ,  $\text{footprint}[k-v+2, k+1](T_k) = \tau_{k+1}$ .*

*There exists an execution  $\rho$  such that, for all  $k \leq K$ ,  $\text{footprint}[k-v+1, k](\rho) = \tau_k$ .*

## 5.2 A Polynomial-Space Algorithm for Round-Based PRP

The algorithm guesses the witness execution footprint by footprint, and stops when the presence constraint is satisfied. Algorithm 1 provides the skeleton of this procedure. For the sake of simplicity, we suppose that  $v \geq 1$ . If  $v = 0$ , we artificially increase  $v$  to 1.

■ **Algorithm 1** Non-deterministic algorithm for round-based PRP.

---

```

1 Input: A PRP instance  $(\mathcal{P}, \psi)$ 
2  $E, U, C \leftarrow \emptyset$  ;
3  $\tau \leftarrow \epsilon$  ; // dummy footprint on rounds  $[-v, -1]$ 
4 Guess the initial set  $I \subseteq Q_0$  of populated states at round 0 ;
5  $\text{NDInit}(E, U, C)$  ;
6 for  $k$  from 0 to  $+\infty$  do
7   Guess  $T$  a footprint on  $[k-v, k]$  such that  $\text{footprint}[k-v, k-1](T) = \tau$  ;
8   Check that  $T$  is consistent with the initial configuration ;
9    $\lambda \leftarrow$  last configuration in  $T$  ;
10   $\text{NDComputeIteration}(E, U, C, \lambda)$  ;
11  if  $\text{TestPresenceConstraint}(E, U, C, \lambda)$  then Accept ;
12   $\tau \leftarrow \text{footprint}[k-v+1, k](T)$  ;

```

---

For all  $k \in \mathbb{N}$ , let  $\tau_k$  be the value of  $\tau$  at the end of iteration  $k$  and  $T_k$  the value of  $T$  guessed at iteration  $k+1$ . Thanks to Lemma 21, if the algorithm reaches the end of iteration  $K$  then there exists an execution  $\rho$  whose projection on  $[k-v, k-1]$  is  $\tau_k$  for every  $k \leq K$ .

Handling the round-based presence constraint is technical, so we hide it in functions  $\text{NDInit}$ ,  $\text{NDComputeIteration}$  and  $\text{TestPresenceConstraint}$ , whose pseudocode can be found in Algorithm 2. We guess why  $\psi$  is true by guessing satisfied *atomic propositions* of three types: existentially quantified on the round (*i.e.*, of the form “ $\exists k \phi$ ” where  $\phi$  has no quantifiers and only  $k$  as free variable) which we put in  $E$ ; universally quantified on the round (*i.e.*, of the form “ $\forall k \phi$ ” where  $\phi$  has no quantifiers and only  $k$  as free variable) which we put in  $U$ ; with no quantifier (*i.e.*, of the form “ $\phi$ ” where  $\phi$  has no quantifiers and no free variables) which we put in  $C$ . Formulas in  $C$  refer to constant rounds and are checked at these rounds only. Formulas in  $U$  are checked at every round. For formulas in  $E$ , the algorithm guesses at which round the formula is true. See Appendix B.3 of the full version for more detailed explanations. Our algorithm is correct with respect to round-based PRP:

► **Proposition 22.**  $(\mathcal{P}, \psi)$  is a positive instance of round-based PRP if and only if there exists an accepting computation of Algorithm 1 on  $(\mathcal{P}, \psi)$ .

The integer constants in the presence constraint  $\psi$  are encoded in unary, like the visibility range  $v$ . These two hypotheses are reasonable since practical examples typically use constants of small value (*e.g.*, 1). Under these hypotheses, we obtain a polynomial spatial bound on the size of footprints of a well-chosen witness execution, which in turn gives a polynomial spatial bound for the algorithm:

► **Proposition 23.** Algorithm 1 works in space  $O(|\psi|^3 + |Q|^2 (v+1)^2 \log(\dim |D|))$ .

Finally, we need to discuss the termination of the algorithm. According to the pigeonhole principle, after an exponential number of iterations, the elements stored in memory repeat from a previous iteration and we can stop the computation. One can thus use a counter, encoded in polynomial space, to count iterations and return a decision when the counter

reaches its largest value. Thanks to the space bounds from Proposition 23, correctness from Proposition 22 and the stopping criterion, our algorithm decides round-based PRP in non-deterministic polynomial space, proving Theorem 20.

■ **Algorithm 2** The functions at **Line 5**, **Line 10** and **Line 11** of Algorithm 1.

---

```

1 Function NDInit( $E, U, C$ ) :
  /* Sets containing what needs to be checked:  $U$  and  $E$  contain
   respectively universally and existentially quantified atomic
   presence constraints,  $C$  contains closed literals */
2 Guess  $X \subseteq \text{PosOrNeg}(\text{APC}(\psi))$  s.t.  $\psi$  is true when all APCs in  $X$  are true ;
3 for  $P$  in  $X$  do
4   for  $\phi$  closed atomic proposition in  $P$  do
5     /*  $\phi$  refers to constant rounds only */
6     if  $\phi$  guessed to be true then Add  $\phi$  to  $C$  ; Replace  $\phi$  by true in  $P$  ;
7     else Add  $\neg\phi$  to  $C$  ; Replace  $\phi$  by false in  $P$  ;
8     if  $P$  is a closed proposition then
9       Check that  $P$  is true with guessed values of atomic propositions ;
10      if  $P$  universal then Add  $P$  to  $U$  ;
11      if  $P$  existential then Add  $P$  to  $E$  ;
12 Function NDComputeIteration( $E, U, C, \lambda$ ) :
13 for " $\forall l \phi$ " in  $U$  do
14   Guess  $\mathcal{L} \subseteq \text{PosOrNeg}(\text{AP}(\phi[l \leftarrow k]))$  s.t.  $\phi[l \leftarrow k]$  is true when all literals in  $\mathcal{L}$ 
15   are true ;
16   Add all literals in  $\mathcal{L}$  to  $C$  ;
17 for " $\exists l \phi$ " in  $E$  do
18   if  $\phi[l \leftarrow k]$  guessed to be true then
19     Guess  $\mathcal{L} \subseteq \text{PosOrNeg}(\text{AP}(\phi[l \rightarrow k]))$  s.t.  $\phi[l \leftarrow k]$  is true when all literals in
20      $\mathcal{L}$  are true ;
21     Add all literals in  $\mathcal{L}$  to  $C$  ; Remove " $\exists l \phi$ " from  $E$  ;
22 for  $\phi$  in  $C$  about round  $k$  do
23   //  $\phi$  is of the form (negation of) " $(q, k)$  populated", or (negation
24   of) " $\text{rg}_k[\alpha]$  contains  $d$ "
25   Check that  $\phi$  is satisfied in  $\lambda$  ; Remove  $\phi$  from  $C$  ;
26 Function TestPresenceConstraint( $E, U, C, \lambda$ ) :
27 if  $E \neq \emptyset$  then return false ;
28 for  $\phi \in C$  or " $\forall l \phi$ " in  $U$  do
29   if  $\langle \emptyset, d_0^{\text{Reg}} \rangle \not\models \phi$  then
30     return false ; // Execution cannot stop at round  $k$ 
31 return true ;

```
