# Preface

This volume contains the extended abstracts selected for presentation at ESA 2023, the 31st European Symposium on Algorithms. The event was organized by Centrum Wiskunde & Informatica (CWI), Amsterdam, the Netherlands, as a part of ALGO 2023, on September 4–6, 2023.

The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions that also address real- world applications, engineering, and experimental analysis of algorithms. In 2022, a new track – Track S – was added, inviting contributions that *simplify* algorithmic results. We find that simpler algorithms are easier to implement, bridging the gap between theory and practice, and we find that new simple or elegant proofs are easier to understand and to teach, and may contain interesting new insights whose relevance only the future will reveal.

In response to the call for papers for ESA 2023, 370 papers were submitted, 267 for Track A, 61 for Track B, and 42 for Track S. Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews. The program committees selected 103 papers for inclusion in the program: 79 from Track A, 15 from Track B, and 9 for Track S, yielding an overall acceptance rate of about 28%. The presentations of the accepted papers, together with two invited talks by Martin Dietzfelbinger (TU Ilmenau) and Rotem Oshman (Tel Aviv University) promise to make up an exciting program.

The European Association for Theoretical Computer Science (EATCS) sponsored best paper and best student paper awards. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission. For Track A, the best paper award was given to Ursula Hebert-Johnson, Daniel Lokshtanov and Eric Vigoda for the paper "Counting and Sampling Labeled Chordal Graphs in Polynomial Time". For Track B, the best paper award was given to Xiangyun Ding, Xiaojun Dong, Yan Gu, Youzhe Liu and Yihan Sun for the paper "Efficient Parallel Output-Sensitive Edit Distance". The best paper award for Track S was given to Oleg Verbitsky and Maksim Zhukovskii for the paper "Canonization of a Random Graph by Two Matrix-Vector Multiplications". The best student paper award was given to Joakim Blikstad and Peter Kiss for the paper "Incremental (1-$\epsilon$)-Approximate Dynamic Matching in O(poly(1/$\epsilon$)) Update Time".

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and the over 500 external reviewers who assisted the program committees in the evaluation process. Special thanks go to the organizing committee, who helped us with the organization of the conference.

Information on past ESA symposia, including locations and proceedings, is maintained at `http://esa-symposium.org`.

# Program Committees

## Track A (Design and Analysis) Program Committee

- Marek Adamczyk, Wroclaw University
- Soheil Behnezhad, Northeastern University
- Mark Bun, Boston University
- Sergio Cabello, University of Ljubljana
- Bhaskar Ray Chaudhury, University of Illinois at Urbana
- Alex Conway, VMWare Research
- Christian Coester, St. Anne's College
- Rathish Das, University of Liverpool
- Anne Driemel, University of Bonn
- Hendrik Fichtenberger, Google Research Zürich
- Moses Ganardi, Max Planck Institute for Software Systems
- Naveen Garg, IIT Delhi
- Cyril Gavoille, LaBRI, University of Bordeaux
- Paweł Gawrychowski, Wroclaw University
- Shay Golan, Reichman and Haifa University
- Inge Li Gørtz, Technical University of Denmark (Chair)
- Carla Groenland, Utrecht University
- Maximilian Probst Gutenberg, ETH Zürich
- Danny Hermelin, Ben-Gurion University
- Giuseppe Italiano, Luiss University
- Lars Jaffke, University of Bergen
- Haim Kaplan, Tel Aviv University
- William Kuszmaul, MIT
- Frédéric Magniez, CNRS, IRIF
- Miguel Mosteiro, Pace University
- Yasamin Nazari, University of Salzburg and VU Amsterdam
- Eunjin Oh, Pohang University of Science and Technology
- Merav Parter, Weizmann Institute of Science
- Adam Polak, Max Planck Institute for Informatics
- Kent Quanrud, Purdue University
- Nicola Prezza, Ca' Foscari University of Venice
- Jakub Radoszewski, University of Warsaw and Samsung R&D Warsaw
- Malin Rau, Hamburg University
- Liam Roditty, Bar-Ilan
- Marc Roth, University of Oxford
- Saeed Seddighin, Toyota Technological Institute at Chicago
- Francesco Silvestri, University of Padova
- Christian Sohler, University of Cologne
- Tatiana Starikovskaya, École Normale Supérieure Paris
- Jukka Suomela, Aalto University
- Alexandru Tomescu, University of Helsinki
- Meng-Tsung Tsai, Academia Sinica
- Ivor Djinn Van Der Hoog, Technical University of Denmark

- Nicole Wein, DIMACS
- Karol Węgrzycki, Max Planck Institute for Informatics
- Anna Zych-Pawlewicz, University of Warsaw

## Track B (Engineering and Applications) Program Committee

- Jarno Alanko, University of Helsinki
- Giulia Bernardini, University of Trieste
- Vincenzo Bonifaci, University of Rome Tre
- Katrin Casel, Humboldt University of Berlin
- David Coudert, INRIA Sophia Antipolis
- Donatella Firmani, University of Rome, La Sapienza
- Klaus Jansen, Christian-Albrechts University of Kiel
- Quanquan C. Liu, Northwestern University
- Tamara Mchedlidze, University of Utrecht
- Prashant Pandey, University of Utah
- Giulio Piribi, Ca' Foscari University of Venice
- Simon J. Puglisi, University of Helsinki (Chair)
- Christian Schulz, University of Heidelberg
- Sabine Storandt, University of Konstanz
- David Tench, Rutgers University
- Helen Xu, Lawrence Berkeley National Lab

## Track S (Simplicity) Program Committee

- Sepehr Assadi, Rutgers University and University of Waterloo
- Deeparnab Chakrabarty, Dartmouth College
- Graham Cormode, University of Warwick
- Leah Epstein, University of Haifa
- Martin Farach-Colton, Rutgers University (Chair)
- Magnus M. Halldorsson, Reykjavik University
- John Iacono, Université libre de Bruxelles
- Dominik Kempa, Stony Brook University
- John Lapinskas, University of Bristol
- Kasper Green Larsen, Aarhus University
- Michał Pilipczuk, University of Warsaw
- Aditya Potukuchi, York University
- Ronitt Rubinfeld, MIT and Tel-Aviv University
- Chris Schwiegelshohn, Aarhus University
- Vera Traub, University of Bonn
- Przemek Uznanski, University of Wroclaw
- Oren Weimann, University of Haifa
- Omri Weinstein, Hebrew University

# On Hashing by (Random) Equations

**Martin Dietzfelbinger**
Technische Universität Ilmenau, Germany

## Abstract

The talk will consider aspects of the following setup: Assume for each (key) $x$ from a set $\mathcal{U}$ (the universe) a vector $a_x = (a_{x,0}, \ldots, a_{x,m-1})$ has been chosen. Given a list $Z = (z_i)_{i\in[m]}$ of vectors in $\{0,1\}^r$ we obtain a mapping

$$\varphi_Z : \mathcal{U} \to \{0,1\}^r, x \mapsto \langle a_x, Z\rangle := \bigoplus_{i\in[m]} a_{x,i} \cdot z_i,$$

where $\bigoplus$ is bitwise XOR. The simplest way for creating a data structure for calculating $\varphi_Z$ is to store $Z$ in an array $Z[0..m-1]$ and answer a query for $x$ by returning $\langle a_x, Z\rangle$. The length $m$ of the array should be $(1+\varepsilon)n$ for some small $\varepsilon$, and calculating this inner product should be fast. In the focus of the talk is the case where for all or for most of the sets $S \subseteq \mathcal{U}$ of a certain size $n$ the vectors $a_x, x \in S$, are linearly independent. Choosing $Z$ at random will lead to hash families of various degrees of independence. We will be mostly interested in the case where $a_x, x \in \mathcal{U}$ are chosen independently at random from $\{0,1\}^m$, according to some distribution $\mathcal{D}$. We wish to construct (static) *retrieval data structures*, which means that $S \subset \mathcal{U}$ and some mapping $f : S \to \{0,1\}^r$ are given, and the task is to find $Z$ such that the restriction of $\varphi_Z$ to $S$ is $f$. For creating such a data structure it is necessary to solve the linear system

$$(a_x)_{x\in S} \cdot Z = (f(x))_{x\in S}$$

for $Z$. Two problems are central: Under what conditions on $m$ and $\mathcal{D}$ can we expect the vectors $a_x, x \in S$ to be linearly independent, and how can we arrange things so that in this case the system can be solved fast, in particular in time close to linear (in $n$, assuming a reasonable machine model)? Solutions to these problems, some classical and others that have emerged only in recent years, will be discussed.

## Abstract

Computing the diameter of a graph, i.e. the largest distance, is a fundamental problem that is central in fine-grained complexity. In undirected graphs, the Strong Exponential Time Hypothesis (SETH) yields a lower bound on the time vs. approximation trade-off that is quite close to the upper bounds.

In *directed* graphs, however, where only some of the upper bounds apply, much larger gaps remain. Since $d(u, v)$ may not be the same as $d(v, u)$, there are multiple ways to define the problem, the two most natural being the *(one-way) diameter* ($\max_{(u,v)} d(u, v)$) and the *roundtrip diameter* ($\max_{u,v} d(u, v) + d(v, u)$). In this paper we make progress on the outstanding open question for each of them.

- We design the first algorithm for diameter in sparse directed graphs to achieve $n^{1.5-\varepsilon}$ time with an approximation factor better than 2. The new upper bound trade-off makes the directed case appear more similar to the undirected case. Notably, this is the first algorithm for diameter in sparse graphs that benefits from fast matrix multiplication.
- We design new hardness reductions separating roundtrip diameter from directed and undirected diameter. In particular, a 1.5-approximation in subquadratic time would refute the All-Nodes $k$-Cycle hypothesis, and any $(2 - \varepsilon)$-approximation would imply a breakthrough algorithm for approximate $\ell_\infty$-Closest-Pair. Notably, these are the first conditional lower bounds for diameter that are not based on SETH.

**2012 ACM Subject Classification** Theory of computation → Problems, reductions and completeness; Theory of computation → Graph algorithms analysis

# 1 Introduction

The diameter of the graph is the largest shortest paths distance. A very well-studied parameter with many practical applications (e.g. [23, 36, 45, 15]), its computation and approximation are also among the most interesting problems in Fine-Grained Complexity (FGC). Much effort has gone into understanding the approximation vs. running time tradeoff for this problem (see the survey [43] and the progress after it [14, 13, 34, 35, 28, 25]).

Throughout this introduction we will consider $n$-vertex and $m$-edge graphs that, for simplicity, are *unweighted* and *sparse* with $m = n^{1+o(1)}$ edges[1]. The diameter is easily computable in $\tilde{O}(mn) = n^{2+o(1)}$ time[2] by computing All-Pairs Shortest Paths (APSP). One of the first and simplest results in FGC [41, 46] is that any $O(n^{2-\varepsilon})$ time algorithm for $\varepsilon > 0$ for the exact computation of the diameter would refute the well-established Strong Exponential Time Hypothesis (SETH) [30, 18]. Substantial progress has been achieved in the last several years [41, 19, 14, 13, 34, 35, 28, 25], culminating in an approximation/running time lower bound tradeoff based on SETH, showing that even for undirected sparse graphs, for every $k \geq 2$, there is no $2 - 1/k - \delta$-approximation algorithm running in $\tilde{O}(n^{1+1/(k-1)-\varepsilon})$ time for some $\delta, \varepsilon > 0$.

In terms of upper bounds, the following three algorithms work for both undirected and directed graphs:

1. compute APSP and take the maximum distance, giving an exact answer in $\tilde{O}(n^2)$ time,
2. compute single-source shortest paths from/to an arbitrary node and return the largest distance found, giving a 2-approximation in $\tilde{O}(n)$ time, and
3. an algorithm by [41, 19] giving a 3/2-approximation in $\tilde{O}(n^{1.5})$ time.

For undirected graphs, there are some additional algorithms, given by Cairo, Grossi and Rizzi [17] that qualitatively (but not quantitatively) match the tradeoff suggested by the lower bounds: for every $k \geq 1$ they obtain an $\tilde{O}(n^{1+1/(k+1)})$ time, almost-$(2 - 1/2^k)$ approximation algorithm, meaning that there is also a small constant additive error.

The upper and lower bound tradeoffs for undirected graphs are depicted in Figure 1 ; a gap remains (depicted as white space) because the two trade-offs have different rates. In directed graphs, however, the gap is significantly larger because an upper bound trade-off is missing (the lower bound tradeoff follows immediately because it is a harder problem). One could envision for instance, that the conditional lower bounds for directed diameter could be strengthened to show that if one wants a $(2 - \varepsilon)$-approximation algorithm, then it must take at least $n^{1.5-o(1)}$ time. Since the work of [17], the main open question (also asked by [43]) for diameter algorithms in directed graphs has been:

*Why are there only three approximation algorithms for directed diameter, but undirected diameter has an infinite approximation scheme? Is directed diameter truly harder, or can one devise further approximation algorithms for it?*

[1] Notably, however, our algorithmic results hold for general graphs, and our hardness results hold even for very sparse graphs.

[2] The notation $\tilde{O}(f(n))$ denotes $O(f(n) \operatorname{poly} \log(f(n)))$.

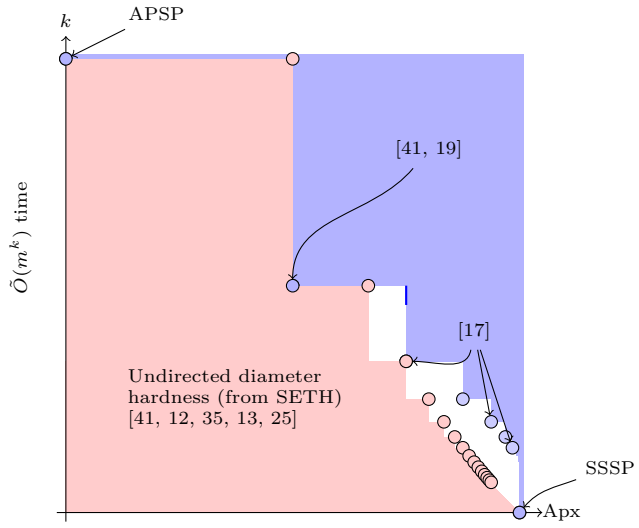

**Figure 1** Undirected diameter algorithms and hardness.

## Directed is Closer to Undirected

Our first result is that one *can* devise algorithms for directed diameter with truly faster running times than $n^{1.5}$, and approximation ratios between 3/2 and 2. It turns out that the directed case has an upper bound tradeoff as well, albeit with a worse rate than in the undirected case. Conceptually, this brings undirected and directed diameter closer together. See Figure 2 for our new algorithms.

▶ **Theorem 1.** *Let $k = 2^{t+2}$ for a nonnegative integer $t \geq 0$. For every $\varepsilon > 0$ (possibly depending on $m$), there exists a randomized $2-\frac{1}{k}+\varepsilon$-approximation algorithm for the diameter of a directed weighted graphs in time $\tilde{O}(m^{1+\alpha}/\varepsilon)$, for*

$$\alpha = \frac{2(\frac{2}{\omega-1})^t - \frac{(\omega-1)^2}{2}}{(\frac{2}{\omega-1})^t(7-\omega) - \frac{\omega^2-1}{2}}.$$

The constant $2 \leq \omega < 2.37286$ in the theorem refers to the fast matrix multiplication exponent [6]. A surprising feature of our algorithms is that we utilize fast matrix multiplication techniques to obtain faster algorithms for a problem in sparse graphs. Prior work on shortest paths has often used fast matrix multiplication to speed-up computations, but to our knowledge, all of this work is for dense graphs (e.g. [7, 44, 47, 24]). Breaking the $n^{1.5}$ bound with a combinatorial algorithm is left as an open problem.

## Roundtrip is Harder

One unsatisfactory property of the shortest paths distance measure in directed graphs is that it is not symmetric ($d(u,v) \neq d(v,u)$) and is hence not a metric. Another popular distance measure used in directed graphs that is a metric is the roundtrip measure. Here the *roundtrip distance* $\tilde{d}(u,v)$ between vertices $u, v$ is $d(u,v) + d(v,u)$.

Roundtrip distances were first studied in the distributed computing community in the 1990s [22]. In recent years, powerful techniques were developed to handle the fast computation of sparse roundtrip spanners, and approximations of the *minimum* roundtrip distance, i.e.

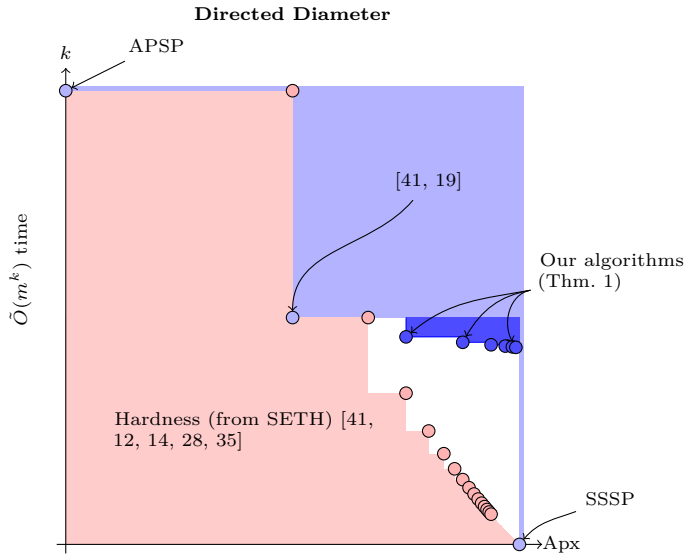

**Figure 2** Directed diameter algorithms and hardness. All tradeoffs hold for both weighted and unweighted graphs (though citations may differ for weighted vs. unweighted).

the shortest cycle length, the girth, of a directed graph [38, 21, 26, 20]. These techniques give hope for new algorithms for the *maximum* roundtrip distance, the roundtrip diameter of a directed graph.

Only the first *two* algorithms in the list in the beginning of the introduction work for roundtrip diameter: compute an exact answer by computing APSP, and a linear time 2-approximation that runs SSSP from/to an arbitrary node. These two algorithms work for any distance *metric*, and surprisingly there have been no other algorithms developed for roundtrip diameter. The only fine-grained lower bounds for the problem are the ones that follow from the known lower bounds for diameter in undirected graphs, and these cannot explain why there are no known subquadratic time algorithms that achieve a better than 2-approximation.

*Are there $O(n^{2-\varepsilon})$ time algorithms for roundtrip diameter in sparse graphs that achieve a $2-\delta$-approximation for constants $\varepsilon, \delta > 0$?*

This question was considered e.g. by [4] who were able to obtain a hardness result for the related roundtrip radius problem, showing that under a popular hypothesis, such an algorithm for roundtrip radius does not exist. One of the main questions studied at the "Fine-Grained Approximation Algorithms and Complexity Workshop" at Bertinoro in 2019 was to obtain new algorithms or hardness results for roundtrip diameter. Unfortunately, however, no significant progress was made, on either front.

The main approach to obtaining hardness for roundtrip diameter, was to start from the Orthogonal Vectors (OV) problem and reduce it to a gap version of roundtrip diameter, similar to all known reductions to (other kinds of) diameter approximation hardness. Unfortunately, it has been difficult to obtain a reduction from OV to roundtrip diameter that has a larger gap than that for undirected diameter; in Section 4.1 we give some intuition for why this is the case.

In this paper we circumvent the difficulty by giving stronger hardness results for roundtrip diameter starting from *different* problems and hardness hypotheses. We find this intriguing because all previous conditional lower bounds for (all variants of) the diameter problem were

based on SETH. In particular, it gives a new approach for resolving the remaining gaps in the undirected case, where higher SETH-based lower bounds are provably impossible (under the so-called NSETH) [35].

Our first negative result conditionally proves that any $5/3-\varepsilon$ approximation for roundtrip requires $n^{2-o(1)}$ time; separating it from the undirected and the directed one-way cases where a 1.5-approximation in $\tilde{O}(n^{1.5})$ time is possible. This result is based on a reduction from the so-called All-Nodes $k$-Cycle problem.

▶ **Definition 2** (All-Nodes $k$-Cycle in Directed Graphs). *Given a $k$ partite directed graph $G=(V,E), V=V_1\cup\cdots\cup V_k$, whose edges go only between "adjacent" parts $E\subseteq\bigcup_{i=1}^{k} V_i\times V_{i+1 \mod k}$, decide if all nodes $v\in V_1$ are contained in a $k$-cycle in $G$.*

This problem can be solved for all $k$ in time $O(nm)$, e.g. by running an APSP algorithm, and in subquadratic $O(m^{2-1/k})$ for any fixed $k$ [8]. Breaking the quadratic barrier for super-constant $k$ has been a longstanding open question; we hypothesize that it is impossible.

▶ **Hypothesis 3.** *No algorithm can solve the All-Nodes $k$-Cycle problem in sparse directed graphs for all $k\geq 3$ in $O(n^{2-\delta})$ time, with $\delta>0$.*

Similar hypotheses have been used in recent works [5, 37, 10, 40]. The main difference is that we require all nodes in $V_1$ to be in cycles; such variants of hardness assumptions that are obtained by changing a quantifier in the definition of the problem are popular, see e.g. [4, 16, 1].

▶ **Theorem 4.** *Under Hypothesis 3, for all $\varepsilon,\delta>0$, no algorithm can $5/3-\varepsilon$ approximate the roundtrip diameter of a sparse directed unweighted graph in $O(n^{2-\delta})$ time.*

We are thus left with a gap between the linear time factor-2 upper bound and the subquadratic factor-5/3 lower bound. A related problem with a similar situation is the problem of computing the eccentricity of all nodes in an undirected graph [4]; there, 5/3 is the right number because one can indeed compute a 5/3-approximation in subquadratic time [19]. Could it be the same here?

Alas, our final result is a reduction from the following classical problem in geometry to roundtrip diameter, establishing a barrier for any better-than-2 approximation in subquadratic time.

▶ **Definition 5** (Approximate $\ell_\infty$ Closest-Pair). *Let $\alpha>1$. The $\alpha$-approximate $\ell_\infty$ Closest-Pair (CP) problem is, given $n$ vectors $v_1,\ldots,v_n$ of some dimension $d$ in $\mathbb{R}^n$, determine if there exists $v_i$ and $v_j$ with $\|v_i-v_j\|_\infty\leq 1$, or if for all $v_i$ and $v_j$, $\|v_i-v_j\|_\infty\geq\alpha$.*

Closest-pair problems are well-studied in various metrics; the main question being whether the naive $n^2$ bound can be broken (when $d$ is assumed to be $n^{o(1)}$). For $\ell_\infty$ specifically, a simple reduction from OV proves a quadratic lower bound for $(2-\varepsilon)$-approximations [31]; but going beyond this factor with current reduction techniques runs into a well-known "triangle-inequality" barrier (see [42, 33]). This leaves a huge gap from the upper bounds that can only achieve $O(\log\log n)$ approximations in subquadratic time [31]. Cell-probe lower bounds for the related nearest-neighbors problem suggest that this log-log bound may be optimal [11]; if indeed constant approximations are impossible in subquadratic time then the following theorem implies a tight lower bound for roundtrip diameter.

▶ **Theorem 6.** *If for some $\alpha\geq 2,\varepsilon>0$ there is a $2-\frac{1}{\alpha}-\varepsilon$ approximation algorithm in time $O(m^{2-\varepsilon})$ for roundtrip diameter in unweighted graphs, then for some $\delta>0$ there is an $\alpha$-approximation for $\ell_\infty$-Closest-Pair with vectors of dimension $d\leq n^{1-\delta}$ in time $\tilde{O}(n^{2-\delta})$.*

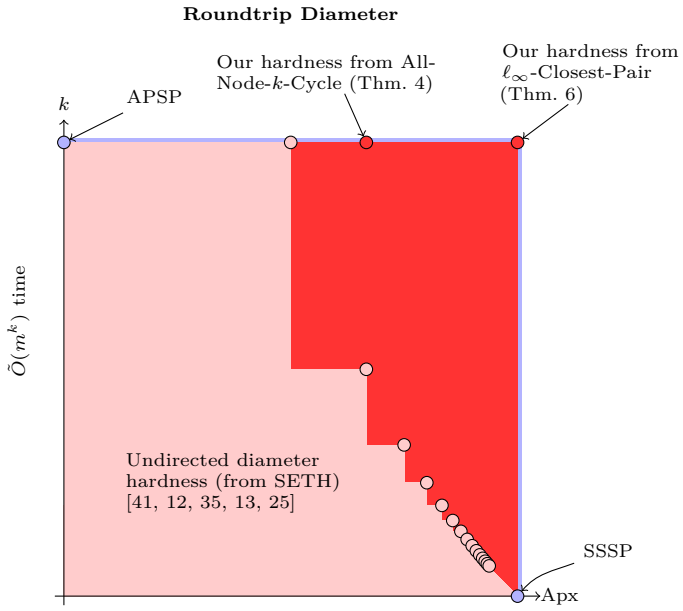

**Figure 3** Roundtrip Diameter algorithms and hardness. All tradeoffs hold for both weighted and unweighted graphs (though citations may differ for weighted vs. unweighted). The previously best hardness results were those inherited from undirected diameter.

In particular, a $2-\varepsilon$ approximation for roundtrip diameter in subquadratic time implies an $\alpha$-approximation for the $\ell_\infty$-Closest-Pair problem in subquadratic time, for some $\alpha = O(1/\varepsilon)$. Thus, any further progress on the roundtrip diameter problem requires a breakthrough on one of the most basic algorithmic questions regarding the $\ell_\infty$ metric (see Figure 3).

## 1.1 Related Work

Besides the diameter and the roundtrip diameter, there is another natural version of the diameter problem in directed graphs called Min-Diameter [4, 27, 24]. The distance between $u, v$ is defined as the $\min(d(u,v), d(v,u))$.[3] This problem seems to be even harder than roundtrip because even a 2-approximation in subquadratic time is not known.

The fine-grained complexity results on diameter (in the sequential setting) have had interesting consequences for computing the diameter in distributed settings (specifically in the CONGEST model). Techniques from both the approximation algorithms and from the hardness reductions have been utilized, see e.g. [39, 2, 9]. It would be interesting to explore the consequences of our techniques on the intriguing gaps in that context [29].

## 1.2 Organization

In this extended abstract, we highlight the key ideas in some of our main results (Theorem 1 and Theorem 6) by proving an "easy version" of each theorem. The full proofs of all the results are in the full version of our paper. First, we establish some preliminaries in Section 2. In Section 3, we prove the special case of Theorem 1 when $t = 0$, giving a 7/4-approximation

[3] Note that the Max-Diameter version where we take the max rather than the min is equal to the one-way version.

of the diameter in directed unweighted graphs in time $O(m^{1.458})$. In Section 4.1 we give an overview of the hardness reductions. In Section 4.2, we prove a weakening of Theorem 6 that only holds for weighted graphs.

## 2 Preliminaries

All logs are base $e$ unless otherwise specified. For reals $a \geq 0$, let $[\pm a]$ denote the real interval $[-a, a]$. For a boolean statement $\varphi$, let $\mathbf{1}[\varphi]$ be 1 if $\varphi$ is true and 0 otherwise.

For a vertex $v$ in a graph, let $\deg(v)$ denote its degree. For $r \geq 0$, let $B_r^{in}(v) = \{u : d(u, v) \leq r\}$ be the in-ball of radius $r$ around $v$, and let $B_r^{out}(v) = \{u : d(v, u) \leq r\}$ be the out-ball of radius $r$ around $v$. For $r \geq 0$, let $B_r^{in+}(v)$ be $B_r^{in}(v)$ and their in-neighbors, and let $B_r^{out+}(v)$ be $B_r^{out}(v)$ and their out-neighbors.

Throughout, let $\omega \leq 2.3728596$ denote the matrix multiplication constant. We use the following lemma which says that we can multiply sparse matrices quickly.

▶ **Lemma 7** (see e.g. Theorem 2.5 of [32]). *We can multiply a $a \times b$ and a $b \times a$ matrix, each with at most $ac$ nonzero entries, in time $O(ac \cdot a^{\frac{\omega-1}{2}})$.*[4]

We repeatedly use the following standard fact.

▶ **Lemma 8.** *Given two sets $B \subset V$ with $B$ of size $k$ and $V$ of size $2m$, a set of $4(m/k)\log m$ uniformly random elements of $V$ contains an element of $B$ with probability at least $1 - \frac{1}{m^2}$.*

**Proof.** The probability that $B$ is not hit is $(1 - \frac{k}{2m})^{4m/k \log m} \leq e^{-2\log m} = \frac{1}{m^2}$. ◀

## 3 7/4-approximation of directed (one-way) diameter

In this section, we prove Theorem 1 in the special case of $t = 0$ and unweighted graphs. That is, we give a 7/4-approximation of the (one-way) diameter of a directed unweighted graph in $O(m^{1.4575})$ time. For the rest of this section, let $\alpha = \frac{\omega+1}{\omega+5} \leq 0.4575$.

Before stating the algorithm and proof, we highlight how our algorithm differs from the undirected algorithm of [17]. At a very high level, all known diameter approximation algorithms compute some pairs of distances, and use the triangle inequality to infer other distances, saving runtime. Approximating diameter in directed graphs is harder than in undirected graphs because distances are not symmetric, so we can only use the triangle inequality "one way." For example, we always have $d(x, y) + d(y, z) \geq d(x, z)$, but not necessarily $d(x, y) + d(z, y) \geq d(x, z)$. The undirected algorithm [17] crucially uses the triangle inequality "both ways," so it was not clear whether their algorithm could be adapted to the directed case. We get around this barrier using matrix multiplication together with the triangle inequality to infer distances quickly. We consider the use of matrix multiplication particularly interesting because, previously, matrix multiplication had only been used for diameter in dense graphs, but we leverage it in sparse graphs.

▶ **Theorem 9.** *Let $\alpha = \frac{\omega+1}{\omega+5}$. There exists a randomized 7/4-approximation algorithm for the diameter of an unweighted directed graph running in $\tilde{O}(m^{1+\alpha})$ time.*

[4] In [32], this runtime of $O(ac \cdot a^{\frac{\omega-1}{2}})$ is stated only for the case $ac > a^{(\omega+1)/2}$. However, the runtime bound for this case works for other cases as well so the lemma is correct for all matrices.

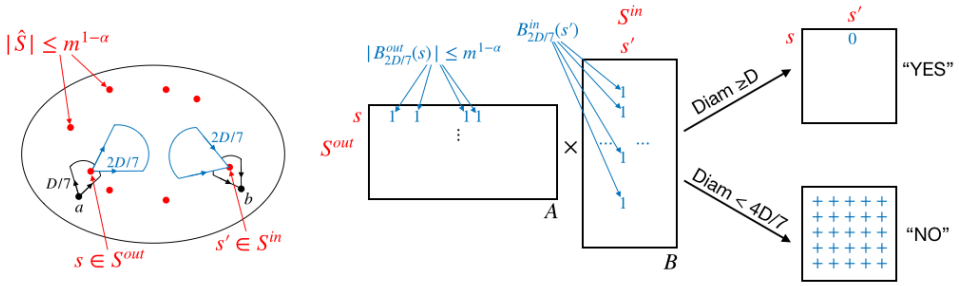

**Figure 4** Steps 5 and 6. If $d(a,b) \ge D$ and Steps 2, 3, and 4 do not accept, with high probability, set $\hat{S}$ hits the $D/7$ out- and in- neighborhoods of $a$ and $b$ at vertices $s$ and $s'$, respectively, that must have distance at least $5D/7$ by the triangle inequality. Thus, checking all pairs of distances in $S^{out} \times S^{in}$, which can be done quickly with sparse matrix multiplication, distinguishes at Step 6 whether the diameter is at least $D$ or less than $4D/7$.

**Proof.** It suffices to show that, for any positive integer $D > 0$, there exists an algorithm $\mathcal{A}_D$ running in time $\tilde{O}(m^{1+\alpha})$ that takes as input any graph and accepts if the diameter is at least $D$, rejects if the diameter is less than $4D/7$, and returns arbitrarily otherwise. Then, we can find the diameter up to a factor of $7/4$ by running binary search with $\mathcal{A}_D$,[5] which at most adds a factor of $O(\log n)$.

We now describe the algorithm $\mathcal{A}_D$. The last two steps, illustrated in Figure 4 contain the key new ideas.

1. First, we apply a standard trick that replaces the input graph on $n$ vertices and $m$ edges with an $2m$-vertex graph of max-degree-3 that preserves the diameter: replace each vertex $v$ with a $\deg(v)$-vertex cycle of weight-0 edges and where the edges to $v$ now connect to distinct vertices of the cycle. From now on, we work with this max-degree-3 graph on $2m$ vertices.
2. Sample $4m^{\alpha} \log m$ uniformly random vertices and compute each vertex's in- and out-eccentricity. If any such vertex has (in- or out-) eccentricity at least $4D/7$ Accept.
3. For every vertex $v$, determine if $|B^{out}_{D/7}(v)| \le m^{\alpha}$. If such a vertex $v$ exists, determine if any vertex in $B^{out+}_{D/7}(v)$ has eccentricity at least $4D/7$, and Accept if so.
4. For every vertex $v$, determine if $|B^{in}_{D/7}(v)| \le m^{\alpha}$. If such a vertex $v$ exists, determine if any vertex in $B^{in+}_{D/7}(v)$ has eccentricity at least $4D/7$, and Accept if so.
5. Sample $4m^{1-\alpha} \log m$ uniformly random vertices $\hat{S}$. Let $S^{out} = \{s \in \hat{S} : |B^{out}_{2D/7}(s)| \le m^{1-\alpha}\}$ and $S^{in} = \{s \in \hat{S} : |B^{in}_{2D/7}(s)| \le m^{1-\alpha}\}$. Compute $B^{out}_{2D/7}(s)$ and $B^{out+}_{2D/7}(s)$ for $s \in S^{out}$, and $B^{in}_{2D/7}(s)$ and $B^{in+}_{2D/7}(s)$ for $s \in S^{in}$.
6. Let $A^{out} \in \mathbb{R}^{S^{out} \times V}$ be the $|S^{out}| \times n$ matrix where $A_{s,v} = \mathbf{1}[v \in B^{out}_{2D/7}(s)]$. Let $A^{in} \in \mathbb{R}^{V \times S^{in}}$ be the $n \times |S^{in}|$ matrix where $A^{in}_{v,s} = \mathbf{1}[v \in B^{in}_{2D/7}(s)]$ if $\lfloor 4D/7 \rfloor = 2\lfloor 2D/7 \rfloor$ and $A^{in}_{v,s} = \mathbf{1}[v \in B^{in+}_{2D/7}(s)]$ otherwise. Compute $A^{out} \cdot A^{in} \in \mathbb{R}^{S^{out} \times S^{in}}$ using sparse matrix multiplication. If the product has any zero entries, Accept, otherwise Reject.

[5] We have to be careful not to lose a small additive factor. Here are the details: Let $D^*$ be the true diameter. Initialize $hi = n, lo = 0$. Repeat until $hi - lo = 1$: let $mid = \lfloor (hi + lo)/2 \rfloor$, run $\mathcal{A}_{mid}$, if accept, set $lo = mid$, else $hi = mid$. One can check that $hi \ge D^* + 1$ and $lo \le 7D^*/4$ always hold. If we return $lo$ after the loop breaks, the output is always in $[D^*, 7D^*/4]$.

**Runtime.** Computing a single eccentricity takes time $O(m)$, so Step 2 takes time $\tilde{O}(m^{1+\alpha})$. For Step 3 checking if $|B^{out}_{D/7}(v)| \leq m^\alpha$ takes $O(m^\alpha)$ time for each $v$ via a partial Breadth-First-Search (BFS). Here we use that the max-degree is 3. If $|B^{out}_{D/7}(v)| \leq m^\alpha$, there are at most $3m^\alpha$ eccentricity computations which takes time $O(m^{1+\alpha})$. Step 4 takes time $O(m^{1+\alpha})$ for the same reason. Similarly, we can complete Step 5 by running partial BFS for each $s \in \hat{S}$ until $m^{1-\alpha}$ vertices are visited. This gives $S^{out}$ and $S^{in}$ and also gives $B^{out}_{2D/7}(s)$ and $B^{out+}_{2D/7}(s)$ for $s \in S^{out}$ and $B^{in}_{2D/7}(s)$ and $B^{in+}_{2D/7}(s)$ for $s \in S^{in}$. For Step 6, the runtime is the time to multiplying sparse matrices. Matrix $A^{out}$ has at most $|\hat{S}| \leq 4m^{1-\alpha}\log m$ rows each with at most $\max_{s\in S^{out}} |B^{out}_{2D/7}(s)| \leq m^{1-\alpha}$ entries, and similarly $A^{in}$ has at most $4m^{1-\alpha}\log m$ columns each with at most $\max_{s\in S^{in}} |B^{in+}_{2D/7}(s)| \leq 3m^{1-\alpha}$ entries. The sparse matrix multiplication takes time $\tilde{O}(m^{(2-2\alpha)} \cdot m^{(1-\alpha)\frac{\omega-1}{2}}) = \tilde{O}(m^{1+\alpha})$ by Lemma 7 with $a = m^{1-\alpha}, b = n, c = m^{1-\alpha}$.

**If the Diameter is less than $4D/7$, we always reject.** Clearly every vertex has eccentricity less than $4D/7$, so we indeed do not accept at Steps 2, 3, and 4. In Step 5, we claim for every $s \in S^{out}, s' \in S^{in}$ there exists $v$ such that $A^{out}_{s,v} = A^{in}_{v,s'} = 1$, so that $(A^{out} \cdot A^{in})_{s,s'} \geq 1$ for all $s \in S^{out}$ and $s' \in S^{in}$ and thus we reject. Fix $s \in S^{out}$ and $s' \in S^{in}$. By the diameter bound, $d(s, s') \leq \lfloor 4D/7 \rfloor$. Let $v$ be the last vertex on the $s$-to-$s'$ shortest path such that $d(s, v) \leq \lfloor 2D/7 \rfloor$, and, if it exists, let $v'$ be the vertex after $v$. Clearly $A^{out}_{s,v} = 1$. We show $A^{in}_{v,s'} = 1$ as well. If $v = s'$, then clearly $v \in B^{in}_{2D/7}(s')$ so $A^{in}_{v,s'} = 1$ as desired. Otherwise $d(s, v) = \lfloor 2D/7 \rfloor$. If $\lfloor 4D/7 \rfloor = 2\lfloor 2D/7 \rfloor$, then $d(v, s') \leq d(s, s') - d(s, v) \leq \lfloor 4D/7 \rfloor - \lfloor 2D/7 \rfloor = \lfloor 2D/7 \rfloor$, so $v \in B^{in}_{2D/7}(s')$ and $A^{in}_{v,s'} = 1$, so again $A^{in}_{v,s'} = 1$. If $\lfloor 4D/7 \rfloor = 2\lfloor 2D/7 \rfloor + 1$, then $d(v', s') \leq d(s, s') - d(s, v') \leq \lfloor 4D/7 \rfloor - (\lfloor 2D/7 \rfloor + 1) = \lfloor 2D/7 \rfloor$, so $v' \in B^{in}_{2D/7}(s')$ and thus $v \in B^{in+}_{2D/7}(s')$ and $A^{in}_{v,s'} = 1$, as desired. This covers all cases, so we've shown we reject.

**If the Diameter is at least $D$, we accept with high probability.** Let $a$ and $b$ be vertices with $d(a, b) \geq D$.

If $|B^{out}_{3D/7}(a)| > m^{1-\alpha}$, Step 2 computes the eccentricity of some $v \in B^{out}_{3D/7}(a)$ with high probability (by Lemma 8), which is at least $d(v, b) \geq d(a, b) - d(a, v) \geq 4D/7$ by the triangle inequality, so we accept. Similarly, we accept with high probability if $|B^{in}_{3D/7}(b)| > m^{1-\alpha}$. Thus we may assume that $|B^{out}_{3D/7}(a)|, |B^{in}_{3D/7}(b)| \leq m^{1-\alpha}$ for the rest of the proof.

If $|B^{out}_{D/7}(v)| \leq m^\alpha$ for any vertex $v$, then either (i) $d(v, b) \geq 4D/7$, in which case $v$ has eccentricity at least $4D/7$ and we accept at Step 3, or (ii) $d(v, b) \leq 4D/7$, in which case there is a vertex $u \in B^{out+}_{D/7}(v)$ on the $v$-to-$b$ path with $d(u, b) \leq 3D/7$ (take the $u \in B^{out+}_{D/7}(v)$ closest to $b$ on the path). Then $d(a, u) \geq 4D/7$ by the triangle inequality and we accept in Step 3 as we perform a BFS from $u$. Thus we may assume $|B^{out}_{D/7}(v)| > m^\alpha$ for all vertices $v$. Similarly, because of Step 4, we may assume $|B^{in}_{D/7}(v)| > m^\alpha$ for all vertices $v$.

In particular, we may assume $|B^{out}_{D/7}(a)| > m^\alpha$ and $|B^{in}_{D/7}(b)| > m^\alpha$. Figure 4 illustrates this last step. Then $\hat{S}$ hits $B^{out}_{D/7}(a)$ with high probability (by Lemma 8), so $B^{out}_{D/7}(a)$ has some $s \in \hat{S}$ with high probability, and similarly $B^{in}_{D/7}(b)$ has some $s' \in \hat{S}$ with high probability. The triangle inequality implies that $B^{out}_{2D/7}(s) \subset B^{out}_{3D/7}(a)$, so $|B^{out}_{2D/7}(s)| \leq |B^{out}_{3D/7}(a)| \leq m^{1-\alpha}$ and thus $s \in S^{out}$. Similarly $s' \in S^{in}$. By the triangle inequality, we have $d(s, s') \geq d(a, b) - d(a, s) - d(s', b) \geq D - D/7 - D/7 = 5D/7$. Then we must have $(A \cdot B)_{s,s'} = 0$, as otherwise there is a $v$ such that $d(s, v) \leq \lfloor 2D/7 \rfloor$ and $d(v, s') \leq 4D/7 - \lfloor 2D/7 \rfloor$, contradicting $d(s, s') \geq 5D/7$. Hence, we accept at step 5, as desired. ◀

# 4 Hardness Reductions for Roundtrip

## 4.1 Overview

In this paper we prove hardness results for roundtrip diameter that go beyond the 2 vs. 3 barrier. Before presenting the proofs, let us begin with an abstract discussion on why this barrier arises and (at a high level) how we overcome it.

All previous hardness results for diameter are by reductions from OV (or its generalization to multiple sets). In OV, one is given two sets of vectors of size $n$ and dimension $d = \text{poly} \log n$, $A$ and $B$, and one needs to determine whether there are $a \in A, b \in B$ that are orthogonal. SETH implies that OV requires $n^{2-o(1)}$ time [46]. In a reduction from OV to a problem like diameter, one typically has nodes representing the vectors in $A$ and $B$, as well as nodes $C$ representing the coordinates, and if there is an orthogonal vector pair $a, b$, then the corresponding nodes in the diameter graph are far (distance $\geq 3$), and otherwise *all* pairs of nodes are close (distance $\leq 2$). Going beyond the 2 vs. 3 gap is difficult because each node $a \in A$ must have distance $\leq 2$ to each coordinate node in $C$, regardless of the existence of an orthogonal pair, and then it is automatically at distance $2 + 1$ from any node $b \in B$ because each $b$ has at least one neighbor in $C$. So even if $a, b$ are orthogonal, the distance will not be more than 3.

The key trick for proving a higher lower bound (say 3 vs. 5) for roundtrip is to have two sets of coordinate nodes, a $C^{fwd}$ set that can be used to go *forward* from $A$ to $B$, and a $C^{bwd}$ set that can be used to go back. The default roundtrip paths from $A/B$ to each of these two sets will have different forms, and this asymmetry will allow us to overcome the above issue. This is inspired by the difficulty that one faces when trying to make the subquadratic 3/2-approximation algorithms for undirected and directed diameter work for roundtrip.

Unfortunately, there is another (related) issue when reducing from OV. First notice that all nodes within $A$ and within $B$ must always have small distance (or else the diameter would be large). This can be accomplished simply by adding direct edges of weight 1.5 between all pairs (within $A$ and within $B$); but this creates a dense graph and makes the quadratic lower bound uninteresting. Instead, such reductions typically add auxiliary nodes to simulate the $n^2$ edges more cheaply, e.g. a star node $o$ that is connected to all of $A$. But then the node $o$ must have small distance to $B$, decreasing all distances between $A$ and $B$.

Overcoming this issue by a similar trick seems impossible. Instead, our two hardness results bypass it in different ways.

The reduction from $\ell_\infty$-Closest-Pair starts from a problem that is defined over *one set of vectors* $A$ (not two) which means that the coordinates are "in charge" of connecting all pairs within $A$. We remark that while OV can also be defined over one set (monochromatic) instead of two (bichromatic) and that it remains SETH hard; that would prevent us from applying the above trick of having a forward and a backward sets of coordinate nodes. Our reduction in Section 4.2 is able to utilize the structure of the metric in order to make both ideas work simultaneously.

The reduction from All-Node $k$-Cycle relies on a different idea: it uses a construction where only a small set of $n$ pairs $a_i \in A, b_i \in B$ are "interesting" in the sense that we do not care about the distances for other pairs (in order to solve the starting problem). Then the goal becomes to connect all pairs within $A$ and within $B$ by short paths, without decreasing the distance for the $(a_i, b_i)$ pairs. A trick similar to the *bit-gadget* [3, 2] does the job. For the complete reduction see the full version of the paper.

## 4.2 Weighted Roundtrip $2-\varepsilon$ hardness from $\ell_\infty$-CP

In this section, we highlight the key ideas in Theorem 6 by proving a weaker version, showing the lower bound for weighted graphs. See the full version of the paper for the extension to unweighted graphs.

The main technical lemma is showing that to $\alpha$-approximate $\ell_\infty$-Closest-Pair, it suffices to do so on instances where all vector coordinates are in $[\pm(0.5+\varepsilon)\alpha]$. Towards this goal, we make the following definition.

▶ **Definition 10.** *The $\alpha$-approximate $\beta$-*bounded *$\ell_\infty$-Closest-Pair problem is, given $n$ vectors $v_1,\ldots,v_n$ of dimension $d$ in $[-\beta,\beta]^d$ determine if there exists $v_i$ and $v_j$ with $\|v_i-v_j\|_\infty\le 1$, or if for all $v_i$ and $v_j$, $\|v_i-v_j\|_\infty\ge\alpha$.*

We now prove the main technical lemma.

▶ **Lemma 11.** *Let $\varepsilon\in(0,1/2)$ and $\alpha>1$. If one can solve $\alpha$-approximate $(0.5+\varepsilon)\alpha$-bounded $\ell_\infty$-CP on dimension $O(d\varepsilon^{-1}\log n)$ in time $T$, then one can solve $\alpha$-approximate $\ell_\infty$-CP on dimension $d$ in time $T+O_\varepsilon(dn\log n)$, where in $O_\varepsilon(\cdot)$ we neglect dependencies on $\varepsilon$.*

**Proof.** Start with an $\ell_\infty$ instance $\Phi=(v_1,\ldots,v_n)$. We show how to construct a bounded $\ell_\infty$ instance $\Phi'$ such that $\Phi$ has two vectors with $\ell_\infty$ distance $\le 1$ if and only if $\Phi'$ has two vectors with $\ell_\infty$ distance $\le 1$.

First we show we may assume that $v_1,\ldots,v_n$ are on domain $[0,\alpha n]$. Suppose that $x\in[d]$. Reindex $v_1,\ldots,v_n$ in increasing order of $v_i[x]$ (by sorting). Let $v_1',\ldots,v_n'$ be vectors identical to $v_1,\ldots,v_n$ except in coordinate $x$, where instead

$$v_i'[x]=\sum_{j=0}^{i-1}\min(\alpha,v_{j+1}[x]-v_j[x])$$

for $i=1,\ldots,n$, where the empty sum is 0. We have that $v_i'[x]\le\alpha n$ for all $i$, and furthermore $|v_i'[x]-v_j'[x]|\ge\alpha$ if and only if $|v_i[x]-v_j[x]|\ge\alpha$ and also $|v_i'[x]-v_j'[x]|\le 1$ if and only if $|v_i[x]-v_j[x]|\le 1$. Hence, the instance given by $v_1',\ldots,v_n'$ is a YES instance if and only if the instance $\Phi$ is a YES instance, and is a NO instance if and only if the instance $\Phi$ is a NO instance. Repeating this with all other coordinates $x$ gives an instance $\Phi'$ such that $\Phi'$ is a YES instance if and only if $\Phi$ is a YES instance, and $\Phi'$ is a NO instance if and only if $\Phi'$ is a NO instance, and furthermore $\Phi'$ has vectors on $[0,\alpha n]$.

Now we show how to construct an $\ell_\infty$-CP instance in dimension $O_\varepsilon(d\log n)$ vectors with coordinates in $[\pm(0.5+\varepsilon)\alpha]$.

▶ **Lemma 12.** *Let $\varepsilon\in(0,0.5)$ and $\alpha>1$. For any real number $M$, there exists two maps $g:[0,M]\to[-(0.5+\varepsilon)\alpha,(0.5+\varepsilon)\alpha]^{2\lceil\varepsilon^{-1}\rceil+1}$ and $h:[0,M]\to[0,M/2]$ such that for all $a,b\in[0,M]$, we have $\min(|a-b|,\alpha)=\min(\|(g(a),h(a))-(g(b),h(b))\|_\infty,\alpha)$. (here, $(g(\cdot),h(\cdot))$ is a length $2\lceil\varepsilon^{-1}\rceil+2$ vector.) Furthermore, $g$ and $h$ can be computed in $O_\varepsilon(1)$ time.*

**Proof.** It suffices to consider when $\varepsilon^{-1}$ is an integer. Let $f_z:\mathbb{R}\to[-(0.5+\varepsilon)\alpha,(0.5+\varepsilon)\alpha]$ be the piecewise function

$$f_z(x)=\begin{cases}-(0.5+\varepsilon)\alpha & \text{if } x\le z-(0.5+\varepsilon)\alpha\\ (0.5+\varepsilon)\alpha & \text{if } x\ge z+(0.5+\varepsilon)\alpha\\ x-z & \text{otherwise.}\end{cases}$$

For $a \in [M]$, define $g(a) \in \mathbb{R}^{2\varepsilon^{-1}+1}$ and $h(a) \in \mathbb{R}$ as follows, where we index coordinates by $-\varepsilon^{-1}, \dots, -1, 0, 1, \varepsilon^{-1}$ for convenience

$$g(a)_i = f_{M/2+0.5i\varepsilon\alpha}(a) \text{ for } -\varepsilon^{-1} \le i \le \varepsilon^{-1}$$
$$h(a) = |a - M/2|.$$

Clearly $g$ and $h$ have the correct codomain, and they can be computed in $O_\varepsilon(1)$ time. Additionally, note that $f_z(x)$ and $|x - M/2|$ are 1-Lipschitz functions of $x$ for all $z$, so $g$ is a Lipschitz function and thus $\|g(a) - g(b)\|_\infty \le |a - b|$.

Now, it suffices to show that $\min(\|(g(a), h(a)) - (g(b), h(b))\|_\infty, \alpha) \ge \min(|a - b|, \alpha)$. If $a$ and $b$ are on the same side of $M/2$, then $\|h(a) - h(b)\|_\infty \ge ||a - M/2| - |b - M/2|| = |a - b|$, as desired. Now suppose $a$ and $b$ are on opposite sides of $M/2$, and without loss of generality $a < M/2 < b$. Let $0 \le i \le \varepsilon^{-1}$ be the largest integer such that $a \le M/2 - i\varepsilon\alpha$ ($i = 0$ works so $i$ always exists). If $i = \varepsilon^{-1}$, then $a < M/2 - \alpha$ and

$$\|g(a) - g(b)\|_\infty \ge f_{M/2-0.5\alpha}(b) - f_{M/2-0.5\alpha}(a) \ge 0.5\alpha - (-0.5\alpha) = \alpha \ge \min(|a - b|, \alpha),$$

as desired. Now assume $i < \varepsilon^{-1}$. Let $z = M/2 + (0.5 - i\varepsilon)\alpha$. By maximality of $i$, we have $a - z \in [-(0.5+\varepsilon)\alpha, -0.5\alpha]$. We have $g(\cdot)_{\varepsilon^{-1}-2i} = f_z(\cdot)$ by definition of $g$. By the definition of $f_z(\cdot)$, since $a \in [z-(0.5+\varepsilon)\alpha, z-0.5\alpha]$ and $b \ge a$, we have $\min(f_z(b)-f_z(a), \alpha) = \min(b-a, \alpha)$. Thus,

$$\begin{aligned}\min(\|g(a) - g(b)\|_\infty, \alpha) &\ge \min\left(g(b)_{\varepsilon^{-1}-2i} - g(a)_{\varepsilon^{-1}-2i}, \alpha\right) \\ &= \min(f_z(b) - f_z(a), \alpha) = \min(b - a, \alpha),\end{aligned}$$

as desired. In either case, we have $\min(\|g(a) - g(b)\|_\infty, \alpha) \ge \min(|a - b|, \alpha)$, so we conclude that $\min(\|g(a) - g(b)\|_\infty, \alpha) = \min(|a - b|, \alpha)$. ◀

Iterating Lemma 12 gives the following.

▶ **Lemma 13.** *Let $\varepsilon \in (0, 1/2)$. There exists a map $g : [0, \alpha n] \to [\pm(0.5+\varepsilon)\alpha]^{4\lceil\varepsilon^{-1}\rceil \log n}$ such that for all $a, b \in [0, \alpha n]$, we have $\min(|a - b|, \alpha) = \min(\|g(a) - g(b)\|_\infty, \alpha)$. Furthermore, $g$ can be computed in $O_\varepsilon(\log n)$ time.*

**Proof.** For $\ell = 1, \dots,$ let $M_\ell = \alpha n/2^{\ell-1}$, and let $g^*_\ell : [M_\ell] \to [\pm(0.5 + \varepsilon)\alpha]^{2\lceil\varepsilon^{-1}\rceil+1}$ and $h^*_\ell : [M_\ell] \to [M_{\ell+1}]$ be the functions given by Lemma 12. For $\ell = 0, 1, \dots,$ let $g_\ell : [0, \alpha n] \to [-(0.5 + \varepsilon)\alpha, (0.5 + \varepsilon)\alpha]^{\ell(2\lceil\varepsilon^{-1}\rceil+1)}$ and $h_\ell : [0, \alpha n] \to [0, \alpha n/2^\ell]$ be such that $g_0(x) = ()$ is an empty vector, $h_0(x) = x$ is the identity, and for $\ell \ge 1$, $g_\ell(x) = (g_{\ell-1}(x), g^*_\ell(h_{\ell-1}(x)))$ and $h_\ell(x) = h^*_\ell(h_{\ell-1}(x))$. By Lemma 12, we have that

$$\begin{aligned}&\min\left(\|(g_{\ell-1}(a), h_{\ell-1}(a)) - (g_{\ell-1}(b), h_{\ell-1}(b))\|_\infty, \alpha\right) \\ &= \min\left(\|\big(g_{\ell-1}(a), g^*_\ell(h_{\ell-1}(a)), h^*_\ell(h_{\ell-1}(a))\big) - \big(g_\ell(b), g^*_\ell(h_{\ell-1}(b)), h^*_\ell(h_{\ell-1}(b))\big)\|_\infty, \alpha\right) \\ &= \min\left(\|\big(g_\ell(a), h_\ell(a)\big) - \big(g_\ell(b), h_\ell(b)\big)\|_\infty, \alpha\right)\end{aligned}$$

for all $\ell$. For $\ell = \lceil \log n \rceil$, the vector $g(a) \stackrel{\text{def}}{=} (g_\ell(a), h_\ell(a) - 0.5\alpha)$ has every coordinate in $[\pm(0.5 + \varepsilon)\alpha]$, and by (4.2), we have

$$\begin{aligned}\min(|a - b|, \alpha) &= \min(|g_0(a) - g_0(b)|, \alpha) \\ &= \min(|g_\ell(a) - g_\ell(b)|, \alpha) = \min(|g(a) - g(b)|_\infty, \alpha),\end{aligned}$$

as desired. The length of this vector is at most $\lceil \log n \rceil (2\lceil\varepsilon^{-1}\rceil + 1) + 1$, which we bound by $4\lceil\varepsilon^{-1}\rceil \log n$ for simplicity (and pad the corresponding vectors with zeros). ◀

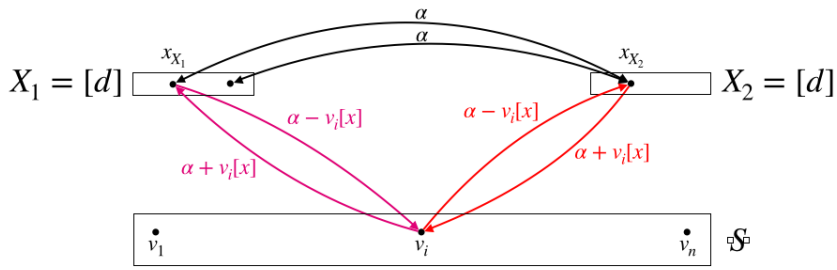

**Figure 5** The roundtrip diameter instance $G$ for $\ell_\infty$-CP hardness.

To finish, let $g : [0, \alpha n] \to [\pm(0.5+\varepsilon)\alpha]$ be given by Lemma 13, and let the original $\ell_\infty$ instance be $v_1, \ldots, v_n$. Let the new $(0.5+\varepsilon)\alpha$-bounded $\ell_\infty$ instance be $w_i = (g(v_i[x]))_{x\in[d]}$ of length $4d\lceil\varepsilon^{-1}\rceil \log n$. ◀

We now prove our goal for this section, Theorem 6 for weighted graphs.

▶ **Theorem 14.** *If for some $\alpha \geq 2, \varepsilon > 0$ there is a $2 - \frac{1}{\alpha} - \varepsilon$ approximation algorithm in time $O(m^{2-\varepsilon})$ for roundtrip diameter in* weighted *graphs, then for some $\delta > 0$ there is an $\alpha$-approximation for $\ell_\infty$-Closest-Pair with vectors of dimension $d \leq n^{1-\delta}$ in time $\tilde{O}(n^{2-\delta})$.*

**Proof.** By Lemma 11 it suffices to prove that there exists an $O(n^{2-\delta})$ time algorithm for $\alpha$-approximate $(0.5+\varepsilon)\alpha$-bounded $\ell_\infty$-CP for $\varepsilon = (4\alpha)^{-1}$.

Let $\Phi$ be the bounded-domain $\ell_\infty$-CP instance with vectors $v_1, \ldots, v_n \in [\pm(0.5+\varepsilon)\alpha]^n$. Then construct a graph $G$ (see Figure 5) with vertex set $S \cup X_1 \cup X_2$ where $X_1 = X_2 = [d]$ and $S = [n]$. We identify vertices with the notations $i_S, x_{X_1}$, and $x_{X_2}$, for $i \in [n]$ and $x \in [d]$. Draw directed edges

1. from $i_S$ to $x_{X_1}$, of weight $\alpha + v_i[x]$,
2. from $x_{X_1}$ to $i_S$, of weight $\alpha - v_i[x]$,
3. from $i_S$ to $x_{X_2}$, of weight $\alpha - v_i[x]$,
4. from $x_{X_2}$ to $i_S$, of weight $\alpha + v_i[x]$, and
5. between any two vertices in $X_1 \cup X_2$, of weight $\alpha$.

Note that all edge weights are nonnegative, and any two vertices in $X_1 \cup X_2$ are roundtrip distance $2\alpha$, and any $s \in S$ and $x \in X_1 \cup X_2$ are distance $2\alpha$. Suppose $\Phi$ has no solution, so that every pair has $\ell_\infty$ distance $\alpha$. Then for vertices $i_S, j_S$, there exists a coordinate $x$ such that $v_i[x] - v_j[x]$ is either $\geq \alpha$ or $\leq -\alpha$. Without loss of generality, we are in the case $v_i[x] - v_j[x] \geq \alpha$. Then the path $i_S \to x_{X_2} \to j_S \to x_{X_1} \to i_S$ is a roundtrip path of length

$$(\alpha - v_i[x]) + (\alpha + v_j[x]) + (\alpha + v_j[x]) + (\alpha - v_i[x]) = 4\alpha - 2(v_i[x] - v_j[x]) \leq 2\alpha.$$

So when $\Phi$ has no solution, the roundrip diameter is at most $2\alpha$.

On the other hand, suppose $\Phi$ has a solution $i, j$ such that for all $x$, $|v_i[x] - v_j[x]| \leq 1$. Then, as every edge has weight at least $(0.5-\varepsilon)\alpha$,

$$\begin{aligned} d(i_S, j_S) &\geq \min\left(\min_{x\in[d]} \left(d(i_S, x_{X_1}) + d(x_{X_1}, j_S), d(i_S, x_{X_2}) + d(x_{X_2}, j_S)\right), 4(0.5-\varepsilon)\alpha\right) \\ &\geq \min\left(\min_{x\in[d]} (\alpha + v_i[x] + \alpha - v_j[x], \alpha + v_j[x] + \alpha - v_i[x]), 2\alpha - 4\varepsilon\alpha\right) \\ &\geq \min(2\alpha - 1, 2\alpha - 4\alpha\varepsilon) \;=\; 2\alpha - 1. \end{aligned}$$

Similarly, we have

$$d(j_S, i_S) \geq 2\alpha - 1,$$

so we have

$$d_{RT}(j_S, i_S) \geq 4\alpha - 2.$$

so in this case the RT-diameter is at least $4\alpha - 2$. A $2 - \alpha^{-1} - \varepsilon$ approximation for RT diameter can distinguish between RT diameter $4\alpha - 2$ and RT-diameter $2\alpha$. Thus, a $2 - \alpha - \varepsilon$ approximation for RT diameter solves $\alpha$-approximate $\ell_\infty$-CP. ◀

## Abstract

We study the fundamental problem of finding the best string to represent a given set, in the form of the *Closest String* problem: Given a set $X \subseteq \Sigma^d$ of $n$ strings, find the string $x^*$ minimizing the radius of the smallest Hamming ball around $x^*$ that encloses all the strings in $X$. In this paper, we investigate whether the Closest String problem admits algorithms that are faster than the trivial exhaustive search algorithm. We obtain the following results for the two natural versions of the problem:

- In the *continuous* Closest String problem, the goal is to find the solution string $x^*$ anywhere in $\Sigma^d$. For binary strings, the exhaustive search algorithm runs in time $O(2^d \operatorname{poly}(nd))$ and we prove that it cannot be improved to time $O(2^{(1-\epsilon)d} \operatorname{poly}(nd))$, for any $\epsilon > 0$, unless the Strong Exponential Time Hypothesis fails.
- In the *discrete* Closest String problem, $x^*$ is required to be in the input set $X$. While this problem is clearly in polynomial time, its fine-grained complexity has been pinpointed to be quadratic time $n^{2\pm o(1)}$ whenever the dimension is $\omega(\log n) < d < n^{o(1)}$. We complement this known hardness result with new algorithms, proving essentially that whenever $d$ falls out of this hard range, the discrete Closest String problem can be solved faster than exhaustive search. In the small-$d$ regime, our algorithm is based on a novel application of the inclusion-exclusion principle.

Interestingly, all of our results apply (and some are even stronger) to the natural dual of the Closest String problem, called the *Remotest String* problem, where the task is to find a string maximizing the Hamming distance to all the strings in $X$.

# 1 Introduction

The challenge of characterizing a set of strings by a single *representative* string is a fundamental problem all across computer science, arising in essentially all contexts where strings are involved. The basic task is to find a string $x^*$ which minimizes the maximum number of mismatches to all strings in a given set $X$. Equivalently, the goal is to find the center $x^*$ of a smallest ball enclosing all strings in $X$ in the Hamming (or $\ell_0$) metric. This problem has been studied under various names, including *Closest String*, *1-Center in the Hamming metric* and *Chebyshev Radius*, and constitutes the perhaps most elementary clustering task for strings.

In the literature, the Closest String problem has received a lot of attention [11, 12, 23, 14, 22, 26, 9, 25, 20, 27, 1], and it is not surprising that besides the strong theoretical interest, it finds wide-reaching applications in various domains including machine learning, bioinformatics, coding theory and cryptography. One such application in machine learning is for clustering *categorical* data. Typical clustering objectives involve finding good center points to characterize a set of feature vectors. For numerical data (such as a number of publications) this task translates to a center (or median) problem over, say, the $\ell_1$ metric which can be solved using geometry tools. For categorical data, on the other hand, the points have non-numerical features (such as blood type or nationality) and the task becomes finding a good center string over the Hamming metric.

Another important application, in the context of computational biology, is the computer-aided design of PCR primers [25, 24, 10, 29, 13, 32]. On a high level, in the PCR method the goal is to find and amplify (i.e., copy millions of times) a certain fragment of some sample DNA. To this end, short DNA fragments (typically 18 to 25 nucleotides) called *primers* are used to identify the start and end of the region to be copied. These fragments should match as closely as possible the target regions in the sample DNA. Designing such primers is a computational task that reduces exactly to finding a closest string in a given set of genomes.

The Closest String problem comes in two different flavors: In the *continuous* Closest String problem the goal is to select an *arbitrary* center string $x^* \in \Sigma^d$ (here, $\Sigma$ is the underlying alphabet) that minimizes the maximum Hamming distance to the $n$ strings in $X$. This leads to a baseline algorithm running in exponential time $O(|\Sigma|^d \operatorname{poly}(nd))$. In the *discrete* Closest String problem, in contrast, the task is to select the best center $x^*$ in the given set of strings $X$; this problem therefore admits a baseline algorithm in time $O(n^2 d)$. Despite the remarkable attention that both variants have received so far, the most basic questions about the continuous and discrete Closest String problems have not been fully resolved yet:

*Can the $O(|\Sigma|^d \operatorname{poly}(nd))$-time algorithm for continuous Closest String be improved?*
*Can the $O(n^2 d)$-time algorithm for discrete Closest String be improved?*

In this paper, we make considerable progress towards resolving both driving questions, by respectively providing tight conditional lower bounds and new algorithms. In the upcoming Sections 1.1 and 1.2 we will address these questions in depth and state our results.

Interestingly, in both cases our results also extend, at times even in a stronger sense, to a natural dual of the Closest String problem called the *Remotest String* problem. Here, the task is to find a string $x^*$ that maximizes the minimum Hamming distance from $x^*$ to a given set of strings $X$. This problem has also been studied in computational biology [22, 21] and more prominently in the context of coding theory: The remotest string distance is a fundamental parameter of any code which is also called the *covering radius* [8], and under this

name the Remotest String problem has been studied in previous works [28, 15, 6, 17] mostly for specific sets $X$ such as linear codes or lattices. See Alon, Panigrahy and Yekhanin [6] for further connections to matrix rigidity.

## 1.1 Continuous Closest/Remotest String

Let us start with the more classical *continuous* Closest String problem. It is well-known that the problem is NP-complete [11, 22], and up to date the best algorithm remains the naive one: Exhaustively search through all possible strings in time $O(|\Sigma|^d \operatorname{poly}(nd))$. This has motivated the study of approximation algorithms leading to various approximation schemes [12, 23, 25, 27], and also the study through the lens of parameterized algorithms [14]. In this work, we insist on exact algorithms and raise again the question: *Can you solve the continuous Closest String problem faster than exhaustive search?*

For starters, focus on the Closest String problem for *binary* alphabets (i.e., for $|\Sigma| = 2$) which is of particular importance in the context of coding theory [20]. From the known NP-hardness reduction which is based on the 3-SAT problem [11], it is not hard to derive a $2^{d/2}$ lower bound under the Strong Exponential Time Hypothesis (SETH) [18, 19]. This bound clearly does not match the upper bound and possibly leaves hope for a meet-in-the-middle-type algorithm. In our first contribution we shatter all such hopes by strengthening the lower bound, with considerably more effort, to match the time complexity of exhaustive search:

▶ **Theorem 1** (Continuous Closest String is SETH-Hard). *The continuous Closest String problem cannot be solved in time $O(2^{(1-\epsilon)d} \operatorname{poly}(n))$, for any $\epsilon > 0$, unless SETH fails.*

Interestingly, we obtain this lower bound as a corollary of the analogous lower bound for the continuous Remotest String problem (see the following Theorem 2). This is because both problems are equivalent over the binary alphabet. However, even for larger sized alphabet sets $\Sigma$, we obtain a matching lower bound against the Remotest String problem:

▶ **Theorem 2** (Continuous Remotest String is SETH-Hard). *The continuous Remotest String problem cannot be solved in time $O(|\Sigma|^{(1-\epsilon)d} \operatorname{poly}(n))$, for any $\epsilon > 0$ and $|\Sigma| = o(d)$, unless SETH fails.*

Theorem 2 gives a *tight* lower bound for the continuous Remotest String problem in all regimes where we can expect lower bounds, and we therefore close the exact study of the continuous Remotest String problem. Indeed, in the regime where the alphabet size $|\Sigma|$ exceeds the dimension $d$, the Closest and Remotest String problems *can* be solved faster in time $O(d^d \operatorname{poly}(n, d))$ (and even faster parameterized in terms of the target distance [14]).

The intuition behind Theorem 2 is simple: We encode a $k$-SAT instance as a Remotest String problem by viewing strings as *assignments* and by searching for a string which is remote from all *falsifying* assignments. The previously known encoding [11] was inefficient (encoding a single variable $X_i$ accounted for *two* letters in the Remotest String instance: one for encoding the truth value and another one as a "don't care" value for clauses not containing $X_i$), and our contribution is that we make the encoding lossless. While superficially simple, this baseline idea requires a lot of technical effort.

## 1.2 Discrete Closest/Remotest String

Recall that in the *discrete* Closest String problem (in contrast to the continuous one) the solution string $x^*$ must be part of the input set $X$. For applications in the context of data compression and summarization, the discrete problem is often the better choice: Selecting the representative string from a set of, say, grammatically or semantically meaningful strings is typically more informative than selecting an arbitrary representative string.

The problem can be naively solved in time $O(n^2 d)$ by exhaustive search: Compute the Hamming distance between all $\binom{n}{2}$ pairs of strings in $X$ in time $O(d)$ each. In terms of exact algorithms, this running time is the fastest known. Toward our second driving question, we investigate whether this algorithm can be improved, at least for some settings of $n$ and $d$. In previous work, Abboud, Bateni, Cohen-Addad, Karthik, and Seddighin [1] have established a conditional lower bound under the Hitting Set Conjecture [3], stating that the problem requires quadratic time in $n$ whenever $d = \omega(\log n)$:

▶ **Theorem 3** (Discrete Closest String for Super-Logarithmic Dimensions [1]). *The discrete Closest String problem in dimension $d = \omega(\log n)$ cannot be solved in time $O(n^{2-\epsilon})$, for any $\epsilon > 0$, unless the Hitting Set Conjecture fails.*

This hardness result implies that there is likely no polynomially faster algorithm for Closest String whenever the dimension $d$ falls in the range $\omega(\log n) < d < n^{o(1)}$. But this leaves open the important question of whether the exhaustive search algorithm can be improved outside this region, if $d$ is very small (say, $o(\log n)$) or very large (i.e., polynomial in $n$). In this paper, we provide answers for both regimes.

**Small Dimension.** Let us start with the small-dimension regime, $d = o(\log n)$. The outcome of the question whether better algorithms are possible is a priori not clear. Many related center problems (for which the goal is to select a center point $x^*$ that is closest not necessarily in the Hamming metric but in some other metric space) differ substantially in this regard: On the one hand, in the Euclidian metric, even for $d = 2^{O(\log^* n)}$, the center problem requires quadratic time under the Hitting Set Conjecture [1].[1] On the other hand, in stark contrast, the center problem for the $\ell_1$ and $\ell_\infty$ metrics can be solved in almost-linear time $n^{1+o(1)}$ whenever the dimension is $d = o(\log n)$. This dichotomy phenomenon extends to even more general problems including nearest and furthest neighbor questions for various metrics and the maximum inner product problem [33, 7].

In view of this, we obtain the perhaps surprising result that whenever $d = o(\log n)$ the discrete Closest String problem can indeed be solved in subquadratic – even almost-linear – time. More generally, we obtain the following algorithm:

▶ **Theorem 4** (Discrete Closest String for Small Dimensions). *The discrete Closest String problem can be solved in time $O(n \cdot 2^d)$.*

Note that this result is trivial for binary alphabets, and our contribution lies in finding an algorithm in time $O(n \cdot 2^d)$ for alphabets of *arbitrary* size.

We believe that this result is interesting also from a technical perspective, as it crucially relies on the *inclusion-exclusion* principle. While this technique is part of the everyday tool-set for exponential-time and parameterized algorithms, it is uncommon to find applications for polynomial-time problems and our algorithm yields the first such application to a center-type

[1] Technically, the problem is only known to be hard in the *listing* version where we require to list *all* feasible centers [1].

problem, to the best of our knowledge. We believe that our characterization of the Hamming distance in terms of an inclusion-exclusion-type formula (see Lemma 23) is very natural and likely to find applications in different contexts.

**Large Dimension.** In the large-dimension regime, where $d$ is polynomial in $n$, it is folklore that fast matrix multiplication should be of use. Specifically, over a binary alphabet we can solve the Closest String problem in time $O(\mathrm{MM}(n,d,n))$ (where $\mathrm{MM}(n,d,n)$ is the time to multiply an $n \times d$ by a $d \times n$ matrix) by using fast matrix multiplication to compute the Hamming distances between all pairs of vectors, rather than by brute-force. For arbitrary alphabet sizes this idea leads to a running time of $O(\mathrm{MM}(n,d|\Sigma|,n))$ which is of little use as $|\Sigma|$ can be as large as $n$ and in this case the running time becomes $\Omega(n^2 d)$.

We prove that nevertheless, the $O(n^2 d)$-time baseline algorithm can be improved using fast matrix multiplication – in fact, using ideas from *sparse* matrix multiplication such as Yuster and Zwick's heavy-light idea [34].

▶ **Theorem 5** (Discrete Closest String for Large Dimensions). *For all $\delta > 0$, there is some $\epsilon > 0$ such that the discrete Closest String problem with dimension $d = n^\delta$ can be solved in time $O(n^{2+\delta-\epsilon})$.*

**Remotest String.** Finally, we turn our attention to the discrete Remotest String problem. In light of the previously outlined equivalence in the continuous setting, we would expect that also in the discrete setting, the Closest and Remotest String problem are tightly connected. We confirm this suspicion and establish a strong equivalence for binary alphabets:

▶ **Theorem 6** (Equivalence of Discrete Closest and Remotest String). *If the discrete Closest String over a binary alphabet is in time $T(n,d)$, then the discrete Remotest String over a binary alphabet is in time $T(O(n), O(d+\log n)) + \widetilde{O}(nd)$. Conversely, if the discrete Remotest String over a binary alphabet is in time $T'(n,d)$, then the discrete Closest String over a binary alphabet is in time $T'(O(n), O(d+\log n)) + \widetilde{O}(nd)$.*

In combination with Theorem 3, this equivalence entails that also Remotest String requires quadratic time in the regime $\omega(\log n) < d < n^{o(1)}$. Let us remark that, while the analogous equivalence is trivial in the continuous regime, proving Theorem 6 is not trivial and involves the construction of a suitable gadget that capitalizes on explicit constant-weight codes.

The similarity between discrete Closest and Remotest String continues also on the positive side: All of our algorithms extend naturally to Remotest String, not only for binary alphabets (see the full version for more details).

## 1.3 Open Problems

Our work inspires some interesting open problems. The most pressing question from our perspective is whether there also is a $|\Sigma|^{(1-o(1))d}$ lower-bound for continuous Closest String (for alphabets of size bigger than 2).

▶ **Open Question 7** (Continuous Closest String for Large Alphabets). *For $|\Sigma| > 2$, can the continuous Closest String problem be solved in time $O(|\Sigma|^{(1-\epsilon)d}\,\mathrm{poly}(n))$, for some $\epsilon > 0$?*

We believe that our approach (proving hardness under SETH) hits a natural barrier for the Closest String problem. In some sense, the $k$-SAT problem behaves very similarly to Remotest String (with the goal to be remote from all falsifying assignments), and over binary alphabets remoteness and closeness can be exchanged. For larger alphabets this trivial equivalence simply does not hold. It would be exciting if this insight could fuel a faster *algorithm* for Closest String, and we leave this question for future work.

On the other hand, consider again the discrete Closest and Remotest String problems. While we close *almost all* regimes of parameters, there is one regime which we did not address in this paper:

▶ **Open Question 8** (Discrete Closest/Remotest String for Logarithmic Dimension). *Let $c$ be a constant. Can the discrete Closest and Remotest String problems with dimension $d = c \log n$ be solved in time $O(n^{2-\epsilon})$, for some $\epsilon = \epsilon(c) > 0$?*

In the regime $d = \Theta(\log n)$, we typically expect only very sophisticated algorithms, say using the polynomial method in algorithm design [2], to beat exhaustive search. And indeed, using the polynomial method it is possible to solve also discrete Closest and Remotest String in subquadratic time for binary (or more generally, constant-size) alphabets [5, 4, Theorem 1.4]. The question remains whether subquadratic time complexity is also possible for unrestricted alphabet sizes.

## 1.4 Outline of the Paper

We organize this paper as follows. In Section 2 we give some preliminaries and state the formal definitions of the continuous/discrete Closest/Remotest String problems. In Section 3 we prove our conditional hardness results for the continuous problems. In Section 4 we treat in detail the discrete problems. Throughout, due to space constraints, we defer several proofs to the full version of this paper.

# 2 Preliminaries

We set $[n] = \{1, \ldots, n\}$ and write $\widetilde{O}(T) = T(\log T)^{O(1)}$ and $\mathrm{poly}(n) = n^{o(1)}$. We occasionally write $\mathbf{1}(P) \in \{0, 1\}$ to express the truth value of the proposition $P$.

**Strings.** Let $\Sigma$ be a finite alphabet of size at least 2. For a string $x \in \Sigma^d$ of length (or dimension) $d$, we write $x[i]$ for the $i$-th character in $x$. For a subset $I \subseteq [d]$, we write $x[I] \in \Sigma^I$ for the subsequence obtained from $x$ by restricting to the characters in $I$. The *Hamming distance* between two equal-length strings $x, y \in \Sigma^d$ is defined as $\mathrm{HD}(x, y) = |\{i \in [d] : x[i] \neq y[i]\}|$. Let $X$ be a set of length-$d$ strings and let $x^*$ be a length-$d$ string. Then we set

$$r(x^*, X) = \max_{y \in X} \mathrm{HD}(x^*, y) \quad \text{(the } \textit{radius} \text{ of } X \text{ around } x^*\text{)},$$
$$d(x^*, X) = \min_{y \in X} \mathrm{HD}(x^*, y) \quad \text{(the } \textit{distance} \text{ from } x^* \text{ to } X\text{)}.$$

Let us formally repeat the definitions of the four problems studied in this paper:

▶ **Definition 9** (Continuous Closest String). *Given a set of $n$ strings $X \subseteq \Sigma^d$, find a string $x^* \in \Sigma^d$ which minimizes the radius $r(x^*, X)$.*

▶ **Definition 10** (Continuous Remotest String). *Given a set of $n$ strings $X \subseteq \Sigma^d$, find a string $x^* \in \Sigma^d$ which maximizes the distance $d(x^*, X)$.*

▶ **Definition 11** (Discrete Closest String). *Given a set of $n$ strings $X \subseteq \Sigma^d$, find a string $x^* \in X$ which minimizes the radius $r(x^*, X)$.*

▶ **Definition 12** (Discrete Remotest String). *Given a set of $n$ strings $X \subseteq \Sigma^d$, find a string $x^* \in X$ which maximizes the distance $d(x^*, X \setminus \{x^*\})$.*

**Hardness Assumptions.** In this paper, our lower bounds are conditioned on the following two plausible hypotheses from fine-grained complexity.

▶ **Definition 13** (Strong Exponential Time Hypothesis, SETH [18, 19]). *For all $\epsilon > 0$, there is some $k \geq 1$ such that $k$-CNF SAT cannot be solved in time $O(2^{(1-\epsilon)n})$.*

▶ **Definition 14** (Hitting Set Conjecture [3]). *For all $\epsilon > 0$, there is some $c \geq 1$ such that no algorithm can decide in $O(n^{2-\epsilon})$ time, whether in two given lists $A, B$ of $n$ subsets of a universe of size $c \log n$, there is a set in the first list that intersects every set in the second list (i.e. a "hitting set").*

## 3 Continuous Closest String is SETH-Hard

In this section we present our fine-grained lower bounds for the continuous Closest and Remotest String problems. We start with a high-level overview of our proof, and then provide the technical details in Sections 3.1–3.4.

Let us first recall that over *binary* alphabets, the continuous Closest and Remotest String problems are trivially equivalent. The insight is that for any two strings $x, y \in \{0,1\}^d$ we have that $\mathrm{HD}(x, y) = d - \mathrm{HD}(\overline{x}, y)$ where $\overline{x}$ is the *complement* of $x$ obtained by flipping each bit. From this it easily follows that

$$\min_{x^* \in \{0,1\}^d} \max_{y \in X} \mathrm{HD}(x^*, y) = d - \max_{x^* \in \{0,1\}^d} \min_{y \in X} \mathrm{HD}(x^*, y).$$

Note that finding a string $x^*$ optimizing the left-hand side is exactly the Closest String problem, whereas finding a string $x^*$ optimizing the right-hand side is exactly the Remotest String problem, and thus both problems are one and the same. For this reason, let us focus our attention for the rest of this section only on the Remotest String problem.

**Tight Lower Bound for Remotest String.** Our goal is to establish a lower bound under the Strong Exponential Time Hypothesis. To this end, we reduce a $k$-SAT instance with $N$ variables to an instance of the Remotest String problem with dimension $d = (1 + o(1))N$. In Sections 3.1–3.4 we will actually reduce from a $q$-ary analogue of the $k$-SAT in order to get a tight lower bound for all alphabet sizes $|\Sigma|$. However, for the sake of simplicity we stick to binary strings and the usual $k$-SAT problem in this overview. Our reduction runs in two steps.

**Step 1: Massaging the SAT Formula.** In the first step, we bring the given SAT formula into a suitable shape for the reduction to the Remotest String problem. Throughout, we partition the variables $[N]$ into *groups* $P_1, \ldots, P_{\frac{N}{s}}$ of size exactly $s$ (where $s$ is a parameter to be determined later). We assert the following properties:

- *Regularity:* All clauses contain exactly $k$ literals, and all clauses contain literals from the same number of groups (say $r$). This property can be easily be guaranteed by adding a few fresh variables to the formula, all of which must be set to 0 in a satisfying assignment, and by adding these variables to all clauses which do not satisfy the regularity constraint yet.
- *Balancedness:* Let us call an assignment $\alpha \in \{0,1\}^N$ *balanced* if in every group it assigns exactly half the variables to 0 and half the variables to 1. We say that a formula is *balanced* if it is either unsatisfiable or if it is satisfiable by a balanced assignment. To make sure that a given formula is balanced, we can for instance flip each variable in the

formula with probability $\frac{1}{2}$. In this way we balance each group with probability $\approx \frac{1}{\sqrt{s}}$, and so all $\frac{N}{s}$ groups are balanced with probability at least $s^{-\frac{N}{2s}}$. By choosing $s = \omega(1)$, this random experiment yields a balanced formula after a negligible number of repetitions. In Lemma 19 we present a deterministic implementation of this idea.

**Step 2: Reduction to Remotest String.** The next step is to reduce a regular and balanced $k$-CNF formula to an instance of the Remotest String problem. The idea is to encode all *falsifying* assignments of the formula as strings – a sufficiently remote point should in spirit be remote from falsifying and thus satisfying. To implement this idea, take any clause $C$ from the instance. Exploiting the natural correspondence between strings and assignments, we add all strings $\alpha \in \{0,1\}^n$ that satisfy the following two constraints to the Remotest String instance:

1. The assignment $\alpha$ falsifies the clause $C$.
2. For any group $P_i$ that does *not* contain a variable from $C$, we have that $\alpha[P_i] = 0^s$ or $\alpha[P_i] = 1^s$.

We start with the intuition behind the second constraint: For any *balanced* assignment $\alpha$ and any group $P_i$ that does not contain a variable from $C$, we have that $\mathrm{HD}(\alpha^*[P_i], \alpha[P_i]) = \frac{s}{2}$ (the string $\alpha^*[P_i]$ contains half zeros and half ones, whereas $\alpha[P_i]$ is either all-zeros or all-ones). There are exactly $\frac{N}{s} - r$ such groups (by the regularity), leading to Hamming distance $\frac{s}{2}(\frac{N}{s} - r)$.

It follows that the only groups that actually matter for the distance between $\alpha^*$ and $\alpha$ are the groups which do contain a variable from $C$. Here comes the first constraint into play: If $\alpha^*$ is a satisfying assignment, then $\alpha^*$ and $\alpha$ must differ in at least one of these groups and therefore have total distance at least $\frac{s}{2}(\frac{N}{s} - r) + 1$. Conversely, for any falsifying assignment $\alpha^*$ there is some string $\alpha$ in the instance with distance at most $\frac{s}{2}(\frac{N}{s} - r)$. Therefore, to decide whether the SAT formula is satisfiable it suffices to compute whether there is a Remotest String with distance at least $\frac{s}{2}(\frac{N}{s} - r) + 1$. Finally, it can be checked that the number of strings $\alpha$ added to the instance is manageable.

This completes the outline of our hardness proof, and we continue with the details. In Section 3.1 we introduce the $(q,k)$-SAT problem which we will use to give a clean reduction also for alphabet larger than size 2. In Section 3.2 we formally prove how to guarantee that a given $(q,k)$-SAT formula is regular and balanced, and in Section 3.3 we give the details about the reduction to the Remotest String problem. We put these pieces together in Section 3.4 and formally prove Theorem 2.

## 3.1 $q$-ary SAT

To obtain our full hardness result, we base our reduction on the hardness of *$q$-ary* analogue of the classical $k$-SAT problem. We start with an elaborate definition of this problem. Let $X_1, \ldots, X_N$ denote some $q$-ary variables (i.e., variables taking values in the domain $[q]$). A *literal* is a Boolean predicate of the form $X_i \neq a$, where $x_i$ is one of the variables and $a \in [q]$. A *clause* is a disjunction of several literals; we say the clause has *width* $k$ if it contains exactly $k$ literals. A *$(q,k)$-CNF formula* is a disjunction of clauses of width at most $k$. Finally, in the $(q,k)$-SAT problem, we are given a $(q,k)$-CNF formula over $M$ clauses and $N$ $q$-ary variables, and the task is to check whether there exists an assignment $\alpha \in [q]^N$ which satisfies all clauses. This problem has already been addressed in previous works [31, 30], and it is known that $q$-ary SAT cannot be solved faster than exhaustive search unless SETH fails:

▶ **Lemma 15** ($q$-ary SAT is SETH-Hard [30, Theorem 3.3]). *For any $\epsilon > 0$, there is some $k \geq 3$ such that for all $q = q(N) \geq 2$, $(q,k)$-SAT cannot be solved in time $O(q^{(1-\epsilon)N}\operatorname{poly}(M))$, unless SETH fails.*

While $k$ is always constant, note that this hardness result applies even when $q$ grows with $N$. We will later exploit this by proving hardness for Remotest String even for alphabets of super-constant size.

## 3.2 Regularizing and Balancing

Before we get to the core of our hardness result, we need some preliminary lemmas on the structure of $(q,k)$-CNF formulas. Throughout, let $N$ be the number of variables and let $\mathcal{P}$ be a partition of $N$ into *groups* of size exactly $s$. (Note that the existence of $P$ implies that $N$ is divisible by $s$.) In two steps we will now formally introduce the definitions of regular and balanced formulas and show how to convert unconstrained formulas into regular and balanced ones. We defer the proofs of the upcoming lemmas to the full version of this paper.

▶ **Definition 16** (Regular Formulas). *Let $\phi$ be a $(q,k)$-CNF formula over $N$ variables, and let $\mathcal{P}$ be a partition of $[N]$. We say that $\phi$ is* $r$-regular *(with respect to $\mathcal{P}$) if every clause contains exactly $k$ literals from exactly $r$ distinct groups in $\mathcal{P}$.*

▶ **Lemma 17** (Regularizing). *Let $\phi$ be a $(q,k)$-CNF formula, and let $2k \leq s \leq N$. In time $\operatorname{poly}(NM)$ we can construct a $(q,2k)$-CNF formula $\phi'$ satisfying the following properties:*

- *$\phi'$ is satisfiable if and only if $\phi$ is satisfiable.*
- *$\phi'$ has at most $N + O(s)$ variables and at most $M + O(s\operatorname{poly}(q))$ clauses.*
- *$\phi'$ is $(k+1)$-regular with respect to some partition $\mathcal{P}$ into groups of size exactly $s$.*

▶ **Definition 18** (Balanced Formulas). *Let $\mathcal{P}$ be a partition of $[N]$ into groups of size $s$. We say that an assignment $\alpha \in [q]^N$ is* balanced *(with respect to $\mathcal{P}$) if in every group of $\mathcal{P}$, $\alpha$ assigns each symbol in $[q]$ exactly $\frac{s}{q}$ times. We say that a $(q,k)$-CNF formula $\phi$ is* balanced *(with respect to $\mathcal{P}$) if either $\phi$ is unsatisfiable, or $\phi$ is satisfiable by a balanced assignment $\alpha$.*

▶ **Lemma 19** (Balancing). *Let $\phi$ be a $(q,k)$-CNF formula over $N$ variables, let $\mathcal{P}$ be a partition of $[N]$ into groups of size $s$, and assume that $q$ divides $s$. We can construct $(q,k)$-CNF formulas $\phi_1, \ldots, \phi_t$ over the same number of variables and clauses as $\phi$ such that:*

- *For all $i \in [t]$, $\phi_i$ is satisfiable if and only if $\phi$ is satisfiable.*
- *There is some $i \in [t]$ such that $\phi_i$ is balanced (with respect to $\mathcal{P}$).*
- *$t = ((s+1)(q-1))^{(q-1)\frac{N}{s}}$, and we can construct each formula in time $\operatorname{poly}(NMt)$.*

## 3.3 Reduction to Remotest String

Having in mind that for our reduction we can assume the SAT formula to be regular and balanced, the following lemma constitutes the core of our reduction:

▶ **Lemma 20** (Reduction from Regular Balanced SAT to Remotest String). *Suppose there is an algorithm for the continuous Remotest String problem, running in time $O(|\Sigma|^{(1-\epsilon)d}\operatorname{poly}(n))$, for some $\epsilon > 0$. Then there is an algorithm that decides whether a given $s$-partitioned $r$-regular $(q,k)$-SAT formula is satisfiable, and runs in time $O(q^{(1-\epsilon)N + O(s+\frac{N}{s})}\operatorname{poly}(M))$.*

**Proof.** We start with some notation: For a clause $C$, we write $\mathcal{P}(C) \subseteq \mathcal{P}$ to address all groups containing a literal from $C$. We start with the construction of the Remotest String instance with alphabet $\Sigma = [q]$ and dimension $d = N$. Here, we make use of the natural

correspondence between strings $\alpha \in \Sigma^d$ and assignments $\alpha \in [q]^N$. In the instance, we add the following strings: For each clause $C$, add all assignments $\alpha \in [q]^N$ to the instance which satisfy the following two constraints:

1. The assignment $\alpha$ falsifies the clause $C$.
2. For each group $P \in \mathcal{P} \setminus \mathcal{P}(C)$, the subsequence $\alpha[P]$ contains only one symbol. (That is, $\alpha[P] = a^s$ for some $a \in [q]$.)

We prove that this instance is complete and sound.

▷ Claim 21 (Completeness). If $\phi$ is satisfiable, then there is some $\alpha^* \in [q]^d$ with $d(\alpha^*, X) > \frac{(q-1)(N-rs)}{q}$.

Proof. Since we assume that the formula $\phi$ is satisfiable and balanced, there is a satisfying and balanced assignment $\alpha^*$. To prove that $d(\alpha^*, X) > \frac{(q-1)(N-rs)}{q}$, we prove that for each string $\alpha$ added to the Remotest String instance, we have $\mathrm{HD}(\alpha^*, \alpha) > \frac{(q-1)(N-rs)}{q}$ . Let $C$ be the clause associated to $\alpha$. From the two conditions on $\alpha$, we get the following two bounds.

By the first condition, $\alpha$ is a falsifying assignment of $C$. In particular, the subsequence $\alpha[\bigcup_{P\in\mathcal{P}(C)} P]$ falsifies $C$ (which is guaranteed to contain all variables visible to $C$) falsifies $C$. Since $\alpha^*$ is a satisfying assignment to the whole formula, and in particular to $C$, we must have that $\alpha^*[\bigcup_{P\in\mathcal{P}(C)} P] \neq \alpha[\bigcup_{P\in\mathcal{P}(C)} P]$, and thus $\sum_{P\in\mathcal{P}(C)} \mathrm{HD}(\alpha^*[P], \alpha[P]) \geq 1$.

By the second condition, for any group $P \in \mathcal{P} \setminus \mathcal{P}(C)$, the subsequence $\alpha[P]$ contains only one symbol. Since $\alpha^*$ is balanced, $\alpha^*[P]$ contains that symbol exactly in a $1/q$-fraction of the positions and differs in the remaining ones from $\alpha[P]$. It follows that $\mathrm{HD}(\alpha^*[P], \alpha[P]) = s - \frac{s}{q} = \frac{(q-1)s}{q}$.

Combining both bounds, we have that

$$\begin{aligned}\mathrm{HD}(\alpha^*, \alpha) &= \sum_{P\in\mathcal{P}(C)} \mathrm{HD}(\alpha^*, \alpha[P]) + \sum_{P\in\mathcal{P}\setminus\mathcal{P}(C)} \mathrm{HD}(\alpha^*, \alpha[P]) \\ &\geq 1 + \left(\frac{N}{s} - r\right) \cdot \frac{(q-1)s}{q} = \frac{(q-1)(N-rs)}{q} + 1,\end{aligned}$$

and the claim follows. ◁

▷ Claim 22 (Soundness). If $\phi$ is not satisfiable, then for all $\alpha^* \in [q]^d$ we have $d(\alpha^*, X) \leq \frac{(q-1)(N-rs)}{q}$.

Proof. Take any $\alpha^* \in [q]^d$. Since $\phi$ is not satisfiable, $\alpha^*$ is a falsifying assignment of $\phi$ and thus there is some clause $C$ that is falsified by $\alpha^*$. Our strategy is to find some string $\alpha \in [q]^d$ in the constructed instance with $\mathrm{HD}(\alpha^*, \alpha) \leq \frac{(q-1)(N-rs)}{q}$.

We define that string $\alpha$ group-wise: In the groups $\mathcal{P}(C)$ touching $C$, we define $\alpha$ to be exactly as $\alpha^*$, that is, $\alpha[\bigcup_{P\in\mathcal{P}(C)}] := \alpha^*[\bigcup_{P\in\mathcal{P}(C)}]$. For each group $P \in \mathcal{P} \setminus \mathcal{P}(C)$ not touching $C$, let $a \in [q]$ be an arbitrary symbol occurring at least $\frac{s}{q}$ times in $\alpha^*[P]$ and assign $\alpha[P] := a^s$. By this construction we immediately have $\mathrm{HD}(\alpha[P], \alpha^*[P]) \leq s - \frac{s}{q} = \frac{(q-1)s}{q}$, and in total

$$\begin{aligned}\mathrm{HD}(\alpha^*, \alpha) &= \sum_{P\in\mathcal{P}(C)} \mathrm{HD}(\alpha^*, \alpha[P]) + \sum_{P\in\mathcal{P}\setminus\mathcal{P}(C)} \mathrm{HD}(\alpha^*, \alpha[P]) \\ &\leq 0 + \left(\frac{N}{s} - r\right) \cdot \frac{(q-1)s}{q} = \frac{(q-1)(N-rs)}{q},\end{aligned}$$

as claimed. ◁

In combination, Claims 21 and 22 show that the constructed instance of the Remotest String problem is indeed equivalent to the given $(q,k)$-SAT instance $\phi$ in the sense that $\phi$ is satisfiable if and only if there is a remote string with distance more than $\frac{(q-1)(N-rs)}{q}$.

It remains to analyze the running time. Let $n$ denote the number of strings in the constructed instance. As a first step, we prove that $n \leq q^{O(s)+\frac{N}{s}} \cdot M$ and that we can construct the instance in time $\text{poly}(n)$. Indeed, focus on any clause $C$. The strings $\alpha$ in the instance are unconstrained in all groups touching $C$ (up to the condition that $\alpha$ must falsify $C$) which accounts for $r \cdot s$ positions and thus $q^{rs} = q^{O(s)}$ options. For each group not touching $C$ we can choose between $q$ possible values, and therefore the total number of options is $q^{\frac{N}{s}-r} \leq q^{\frac{N}{s}}$. Therefore, the total number of strings is indeed $n \leq M \cdot q^{O(s)} \cdot q^{\frac{N}{s}}$. Moreover, it is easy to see that the instance can be constructed in time $\text{poly}(n)$.

As the time to construct the instance is negligible, the total running time is dominated by solving the Remotest String instance. Assuming an algorithm in time $O(|\Sigma|^{(1-\epsilon)d}\,\text{poly}(n))$, this takes time $O(q^{(1-\epsilon)N+O(s+\frac{N}{s})}\,\text{poly}(M))$ as claimed. ◀

## 3.4 Putting the Pieces Together

We are finally ready to prove Theorems 1 and 2.

▶ **Theorem 2** (Continuous Remotest String is SETH-Hard). *The continuous Remotest String problem cannot be solved in time $O(|\Sigma|^{(1-\epsilon)d}\,\text{poly}(n))$, for any $\epsilon > 0$ and $|\Sigma| = o(d)$, unless SETH fails.*

**Proof.** Suppose that the continuous Remotest String problem is in time $O(|\Sigma|^{(1-\epsilon)d}\,\text{poly}(n))$ for some $\epsilon > 0$ and for $|\Sigma| = o(d)$. With this in mind, we design a better-than-brute-force $(q,k)$-SAT algorithm for $q = |\Sigma|$ by combining the previous three Lemmas 17, 19, and 20. Let $\phi$ be the input formula, and let $\mathcal{P}$ denote a partition of the variables into groups of size $s$ (which is yet to be determined) as before.

1. Using Lemma 17, construct a *regular* $(q,2k)$-formula $\phi'$ which is equivalent to $\phi$.
2. Using Lemma 19, construct regular $(q,2k)$-formulas $\phi'_1,\ldots,\phi'_t$ all of which are equivalent to $\phi$. At least one of these formulas is *balanced*.
3. By means of the reduction in Lemma 20, solve all $t$ formulas $\phi'_1,\ldots,\phi'_t$. If a formula is reported to be satisfiable, check whether the answer is truthful (e.g., using the standard decision-to-reporting reduction) and if so report that the formula is satisfiable. We need the additional test since, strictly speaking, we have not verified in Lemma 20 that the algorithm is correct for non-balanced inputs.

The correctness is obvious. Let us analyze the running time. Constructing the formula $\phi'$ takes polynomial time and can be neglected. By Lemma 17, $\phi'$ has $N' = N + O(s)$ variables and $M' = M + O(s\,\text{poly}(q))$ clauses. The construction of the formulas $\phi'_1,\ldots,\phi'_t$ also runs in polynomial time $\text{poly}(N'M't)$ and can be neglected; this time we do not increase the number of variables and clauses. Moreover, Lemma 19 guarantees that

$$t = ((s+1)(q-1))^{(q-1)\frac{N'}{s}} \leq (sq)^{O(\frac{qN}{s})},$$

By picking $s = cq$ (for some parameter $c$ to be determined), this becomes

$$t \leq (cq^2)^{O(\frac{N}{c})} = q^{O(\frac{N}{c}\log_q(cq^2))} = q^{N\cdot O(\frac{\log c}{c})}.$$

Finally, by Lemma 20 solving each formula $\phi'_i$ takes time

$$q^{(1-\epsilon)N'+O(s+\frac{N'}{s})}\,\text{poly}(M') = q^{(1-\epsilon)N+O(s+\frac{N}{s})}\,\text{poly}(M) = q^{(1-\epsilon)N+o(cN)+O(\frac{N}{c})}\,\text{poly}(M),$$

(using that $s = cq = o(cN)$), and thus the total running time is bounded by

$$q^{N \cdot O(\frac{\log c}{c})} \cdot q^{(1-\epsilon)N + o(cN) + O(\frac{N}{c})} \operatorname{poly}(M) = q^{(1-\epsilon+o(c)+O(\frac{\log c}{c}))N} \operatorname{poly}(M).$$

Note that by picking $c$ to be a sufficiently large constant (depending on $\epsilon$), the exponent becomes $(1 - \frac{\epsilon}{2})N$, say. We have therefore obtained an algorithm for the $(q, k)$-SAT problem in time $O(q^{(1-\epsilon/2)N} \operatorname{poly}(M))$, which contradicts SETH by Lemma 15. ◀

## 4 Discrete Closest String via Inclusion-Exclusion

In this section, we present an algorithm for the discrete Closest String problem with *subquadratic* running time whenever the dimension is small, i.e. $d = o(\log n)$. Our algorithm relies on the inclusion-exclusion principle, and is, to the best of our knowledge, the first application of this technique to the Closest and Remotest String problems. Specifically, we obtain the following result:

▶ **Theorem 4** (Discrete Closest String for Small Dimensions). *The discrete Closest String problem can be solved in time $O(n \cdot 2^d)$.*

We structure this section as follows: First, we present a high-level overview of the main ideas behind the algorithm; for the sake of presentation, we focus only on the Closest String problem. We start developing a combinatorial toolkit to tackle the Closest String problem (with all proofs deferred to the full version of this paper). Then, in Section 4.1 we provide the actual algorithm and prove Theorem 4.

Before we describe our algorithm, we provide some intuition about the general connection between the inclusion-exclusion principle and the Hamming distance between a pair of strings. Our key insight is that the inclusion-exclusion principle allows us to express whether two strings have Hamming distance bounded by, say $k$. The following lemma makes this idea precise:

▶ **Lemma 23** (Hamming Distance by Inclusion-Exclusion). *Let $x$ and $y$ be two strings of length $d$ over some alphabet $\Sigma$, and let $0 \leq k < d$. Then:*

$$\mathbf{1}(\mathrm{HD}(x, y) \leq k) = \sum_{\substack{I \subseteq [d] \\ |I| \geq d-k}} (-1)^{|I|-d+k} \cdot \binom{|I|-1}{d-k-1} \cdot \mathbf{1}(x[I] = y[I]).$$

Recall that we write $x[I] = y[I]$ to express that the strings $x$ and $y$ are equally restricted to the indices in $I$. The precise inclusion-exclusion-type formula does not matter too much here, but we provide some intuition for Lemma 23 by considering the special cases where $\mathrm{HD}(x, y) = k$ and $\mathrm{HD}(x, y) = k - 1$. If $\mathrm{HD}(x, y) = k$, then there is a unique set $I$ of size $d - k$ for which $x[I] = y[I]$. If instead $\mathrm{HD}(x, y) = k - 1$, then there is a unique such set of size $d - k + 1$, and additionally there are $d - k + 1$ such sets of size $d - k$. The scalars $(-1)^{|I|-d+k}\binom{|I|-1}{d-k-1}$ are chosen in such a way that in any case, all these contributions sum up to exactly 1.

The takeaway from the above lemma is that we can express the proposition that two strings satisfy $\mathrm{HD}(x, y) \leq k$ by a linear combination of $2^d$ indicators of the form $\mathbf{1}(x[I] = y[I])$. It is easy to extend this idea further to the following lemma, which is the core of our combinatorial approach:

▶ **Lemma 24** (Radius by Inclusion-Exclusion). *Let $x$ be a string of length $d$ over some alphabet $\Sigma$, let $X$ be a set of strings each of length $d$ over $\Sigma$, and let $0 \leq k < d$. Then $r(x, X) \leq k$ if and only if*

$$|X| = \sum_{\substack{I \subseteq [d] \\ |I| \geq d-k}} (-1)^{|I|-d+k} \cdot \binom{|I|-1}{d-k-1} \cdot |\{y \in X : x[I] = y[I]\}|.$$

Given this lemma, our algorithm for the Closest String problem is easy to state. Informally, we proceed in the following two steps:

**Step 1: Partition.** Precompute, for all $x \in X$ and for all $I \subseteq [d]$, the value $|\{y \in X : x[I] = y[I]\}|$. This can be implemented in time $O(n \cdot 2^d \cdot \text{poly}(d))$ by partitioning the input strings $X$ depending on their characters in the range $I$. After computing this partition, we can read the value $|\{y \in X : x[I] = y[I]\}|$ as the number of strings in the same part as $x$.

**Step 2: Inclusion-Exclusion.** We test for each $0 \leq k \leq d$ and $x \in X$, whether $r(x, X) \leq k$ and finally return the best answer. By Lemma 24 we can equivalently express the event $r(x, X) \leq k$ via

$$|X| = \sum_{\substack{I \subseteq [d] \\ |I| \geq d-k}} (-1)^{|I|-d+k} \cdot \binom{|I|-1}{d-k-1} \cdot |\{y \in X : x[I] = y[I]\}|.$$

By observing that the sum contains only $2^d$ terms and noting that we have precomputed the values $|\{y \in X : x[I] = y[I]\}|$, we can evaluate the sum, for a fixed $x$, in time $O(2^d \cdot \text{poly}(d))$. In total, across all strings $x \in X$, the running time becomes $O(n \cdot 2^d \cdot \text{poly}(d))$.

Finally, let us briefly comment on the $\text{poly}(d)$ term in the running time. When evaluating the above sum naively, we naturally incur a running time overhead of $\text{poly}(d)$ since the numbers in the sum need $\Omega(d + \log n)$ bits to be represented. However, this overhead can be circumvented by evaluating the expression in a smarter way. We provide more details in Section 4.1.

## 4.1 The Algorithm in Detail

In this subsection, we provide our algorithms for the discrete Closest String problem. Let us first demonstrate how to precompute $|\{y \in X : x[I] = y[I]\}|$ for all strings $x \in X$ efficiently.

▶ **Lemma 25.** *We can compute $|\{y \in X : x[I] = y[I]\}|$ for all strings $x \in X$ in time $O(n \cdot 2^d)$.*

**Proof.** Our strategy is to compute, for each $I \subseteq [d]$, a partition $\mathcal{P}_I$ of the set of all strings $X$ such that two strings $y_1, y_2 \in X$ are in the same part in $\mathcal{P}_I$ if and only if $y_1[I] = y_2[I]$. This is our goal since, for all strings $x \in X$, the value we are interested in $|\{y \in X : x[I] = y[I]\}|$ is exactly the size of the part $P$ in $\mathcal{P}_I$ that contains $x$. Thus, if we can efficiently compute, for all $I \subseteq [d]$ and all $x \in X$, the partition $\mathcal{P}_I$ and the part $P \in \mathcal{P}_I$ such that $x \in P$ then we have the desired algorithm.

Computing the partition $\mathcal{P}_I$ for each subset of $I \subseteq [d]$ when $|I| \leq 1$ is simple: The partition $\mathcal{P}_\emptyset$ contains just one part which is the entire input set. We also know that $\mathcal{P}_{\{i\}} = \{\{x \in X : x[i] = \sigma\} : \sigma \in \Sigma\}$ for every $0 \leq i \leq d-1$. Thus, we can compute the partitions $\mathcal{P}_\emptyset$ and $\mathcal{P}_{\{i\}}$ for every $0 \leq i \leq d-1$ in time $O(n \cdot d)$. The remaining question is how to efficiently compute the partitions $\mathcal{P}_I$ for each subset of $I \subseteq [d]$ where $|I| \geq 2$.

The idea is to use dynamic programming in combination with a *partition refinement* data structure. Let us start with some notation: For a partition $\mathcal{P}$ and a set $S$, we define the *refinement* of $\mathcal{P}$ by $S$ as the partition $\{P \cap S, P \setminus S : P \in \mathcal{P}\}$. For two partitions $\mathcal{P}$ and $\mathcal{P}'$, we define the refinement of $\mathcal{P}$ by $\mathcal{P}'$ by the iterative refinement of all sets $S \in \mathcal{P}'$. In previous work, Habib, Paul, and Viennot [16] have established a data structure to maintain partitions $\mathcal{P}$ of some universe $[n]$ that efficiently supports the following two operations:

- *Refinement:* We can refine a partition $\mathcal{P}$ by another partition $\mathcal{P}'$ in time $O(n)$.
- *Query:* Given a partition $\mathcal{P}$ and an element $i \in [d]$, we can find the part $i \in P \in \mathcal{P}$ in time $O(1)$.

Given this data structure, our algorithm is simple: Enumerate all sets $I$ in nondecreasing order with respect to their sizes $|I|$. Writing $I = I' \cup \{i\}$ (for some $i \in [d]$), we compute $\mathcal{P}_I$ as the refinement of the previously computed partitions $\mathcal{P}_{I'}$ and $\mathcal{P}_{\{i\}}$. It is straightforward to verify that this algorithm is correct. The running time of each refinement step is $O(n)$ and so the total running time is $O(n \cdot 2^d)$ as claimed. ◀

We are finally ready to state our algorithm and prove its correctness using Lemmas 24 and 25.

**Proof of Theorem 4.** First, it is clear that if we test for each $0 \leq k \leq d$ and $x \in X$ whether $r(x, X) \leq k$ then we can find the solution to the discrete Closest String problem. From Lemma 24 we know that $r(x, X) \leq k$ if and only if:

$$|X| = \sum_{\substack{I \subseteq [d] \\ |I| \geq d-k}} (-1)^{|I|-d+k} \cdot \binom{|I|-1}{d-k-1} \cdot |\{y \in X : x[I] = y[I]\}|.$$

Thus, if we efficiently compute $|\{y \in X : x[I] = y[I]\}|$ for all strings $x \in X$ and efficiently compute the right-hand side of the equation we will have an efficient algorithm for the discrete Closest String problem. We know from Lemma 25 that we can precompute $|\{y \in X : x[I] = y[I]\}|$ for all strings $x \in X$ in time $O(n \cdot 2^d)$. Therefore, the only missing part of the algorithm is computing the inclusion-exclusion step in $O(n \cdot 2^d)$ time.

If we naively evaluate the inclusion-exclusion formula the running time becomes $\Omega(n \cdot 2^d \cdot d)$ as the intermediate values need $\Omega(d)$ bits to be represented in memory. However, we observe that inclusion-exclusion formula can indeed be evaluated more efficiently by rewriting it as follows:

$$\sum_{\substack{I \subseteq [d] \\ |I| \geq d-k}} (-1)^{|I|-d+k} \cdot \binom{|I|-1}{d-k-1} \cdot |\{y \in X : x[I] = y[I]\}|$$

$$= \sum_{\ell=d-k}^{d} (-1)^{\ell} \cdot \binom{\ell-1}{d-k-1} \cdot \sum_{\substack{I \subseteq [d] \\ |I| = \ell}} |\{y \in X : x[I] = y[I]\}|.$$

We can precompute $S[x, \ell] := \sum_{I \subseteq [d], |I| = \ell} |\{y \in X : x[I] = y[I]\}|$ for all strings $x \in X$ and all values $1 \leq \ell \leq d$ before we compute the inclusion exclusion step. Since there are $2^d$ different subsets of $[d]$ and since we already have access to the values $|\{y \in X : x[I] = y[I]\}|$, for all strings $x \in X$, computing $S[x, \ell]$ amounts to time $O(n \cdot 2^d)$. Afterwards, computing

$$\sum_{\ell=d-k}^{d} (-1)^{\ell} \cdot \binom{\ell-1}{d-k-1} \cdot S[x, \ell]$$

for all strings $x \in X$ and for all $0 \leq k \leq d-1$ only takes time $O(n \cdot d^3)$. Hence, the total running time of the algorithm is $O(n \cdot 2^d)$. ◀

**Algorithm 1** An algorithm for the discrete Closest String problem in the small-distance regime. See Theorem 4.

*(Step 1: Precompute $T[x, I] = |\{y \in X : x[I] = y[I]\}|$)*
$\mathcal{P}_\emptyset \leftarrow X$
$\mathcal{P}_{\{i\}} \leftarrow \{\{x \in X : x[i] = \sigma\} : \sigma \in \Sigma\} \ \forall i \in [0, \ldots, d-1]$
**for** $I = I' \cup \{i\}$ **do**
    $\mathcal{P}_I \leftarrow$ refinement of $\mathcal{P}_{I'}, \mathcal{P}_{\{i\}}$
**for** $x \in X, I \subseteq [d]$ **do**
    $T[x, I] \leftarrow |P|$ where $x \in P \in \mathcal{P}_I$

*(Step 2: Inclusion-Exclusion)*
**for** $x \in X, I \subseteq [d]$ **do**
    $S[x, |I|] \leftarrow S[x, |I|] + T[x, I]$
**for** $k \leftarrow 0, \ldots, d-1$ **do**
    **for** $x \in X$ **do**
        **if** $|X| = \sum_{\ell=d-k}^{d} (-1)^\ell \cdot \binom{\ell-1}{d-k-1} \cdot S[x, \ell]$ **then**
            return $x$
return an arbitrary $x \in X$

We summarize the pseudocode of the algorithm outlined in the proof of Theorem 4 in Algorithm 1.

## Abstract

The Voronoi diagrams technique, introduced by Cabello [SODA'17] to compute the diameter of planar graphs in subquadratic time, has revolutionized the field of distance computations in planar graphs. We present novel applications of this technique in static, fault-tolerant, and partially-dynamic undirected unweighted planar graphs, as well as some new limitations.

- In the static case, we give $n^{3+o(1)}/D^2$ and $\tilde{O}(n \cdot D^2)$ time algorithms for computing the diameter of a planar graph $G$ with diameter $D$. These are faster than the state of the art $\tilde{O}(n^{5/3})$ [SODA'18] when $D < n^{1/3}$ or $D > n^{2/3}$.
- In the fault-tolerant setting, we give an $n^{7/3+o(1)}$ time algorithm for computing the diameter of $G \setminus \{e\}$ for every edge $e$ in $G$ (the replacement diameter problem). This should be compared with the naive $\tilde{O}(n^{8/3})$ time algorithm that runs the static algorithm for every edge.
- In the incremental setting, where we wish to maintain the diameter while adding edges, we present an algorithm with total running time $n^{7/3+o(1)}$. This should be compared with the naive $\tilde{O}(n^{8/3})$ time algorithm that runs the static algorithm after every update.
- We give a lower bound (conditioned on the SETH) ruling out an amortized $O(n^{1-\varepsilon})$ update time for maintaining the diameter in *weighted* planar graph. The lower bound holds even for incremental or decremental updates.

Our upper bounds are obtained by novel uses and manipulations of Voronoi diagrams. These include maintaining the Voronoi diagram when edges of the graph are deleted, allowing the sites of the Voronoi diagram to lie on a BFS tree level (rather than on boundaries of $r$-division), and a new reduction from incremental diameter to incremental *distance oracles* that could be of interest beyond planar graphs. Our lower bound is the first lower bound for a dynamic planar graph problem that is conditioned on the SETH.

## 1 Introduction

The DIAMETER problem asks to compute the largest distance in the graph. It is one of the most basic and extensively studied problems in the graph algorithms literature, and moreover, it is prominent in Fine-grained Complexity where it has driven the development

of innovative hardness reductions [1,4,5,9,11,17,29,36,67]. Assuming the strong exponential time hypothesis (SETH), there is also no truly subquadratic algorithm for DIAMETER [5,67] in undirected, unweighted graphs with treewidth $\Omega(\log n)$. For graphs of bounded treewidth, the diameter can be computed in near-linear time [5] (see also [41,50] for algorithms with time bounds that depend on $D$). Near-linear time algorithms were developed for many other restricted graph families, see e.g. [8,14,31–34,40,43,49,66].

One of the outstanding questions that has remained open despite a decade of major developments in algorithms and conditional lower bounds for graph problems is whether DIAMETER can be solved in near-linear time in *planar graphs*. Until 2017, only logarithmic improvements over the natural $O(n^2)$ bound (of computing all-pairs shortest-path, APSP) had been known [23,72]. The consensus was that truly subquadratic time is impossible and the focus of the community was on proving a hardness result, e.g. under SETH. But then, in a celebrated paper, Cabello [22] gave a subquadratic $\tilde{O}(n^{11/6})$ time algorithm, that was later improved to the current-best $\tilde{O}(n^{5/3})$ bound [45].

The breakthrough in Cabello's work [22] is his novel use of *Voronoi Diagrams* (VDs) in planar graph algorithms. This new machinery has revolutionized the field of distance computation problems in planar graphs and has lead to several breakthroughs [26,28,35,47,63] including a surprising and almost-optimal *distance oracle* - a problem that had hitherto seen many gradual improvements using different techniques both in the exact [10,21,26,30,35,39, 42,47,56,63–65,73] and the approximate [24,48,54,55,58,69,74] settings. Consequently, the main meta question occupying the minds of researchers in planar graph algorithms is: *what else can Voronoi diagrams do for us?*

## 1.1 Dynamic Planar Diameter

It is natural to expect VDs to produce breakthroughs in the domain of *dynamic* planar graphs. Dynamic data structures that support updates and queries to a graph have remarkable applications in theory (as a subroutine in static algorithms) and practice (for changing inputs). Many ingenious algorithms for basic problems in dynamic planar graphs have been developed in the last few decades, including connectivity, distances, and cuts [6,18,19,25, 28,37,42,51–53,55,56,59,62,68,69], but large (polynomial) gaps remain compared to the lower bounds [3]. Only few of these works [27,28] use VDs and only in a limited way (they recompute the VD from scratch after every update). It is clear that major advancements await if one is able to maintain the VD machinery *dynamically* in a meaningful way. In this paper, we investigate this possibility by focusing on the DIAMETER problem.

The state-of-the-art algorithm recomputes the diameter from scratch after every update in time $\tilde{O}(n^{5/3})$. This is not surprising since the only useful technique against DIAMETER (in static graphs) is based on VDs, and we do not know how to make VDs dynamic.

The first question that comes to mind is: Suppose, optimistically, we could make VDs as dynamic as possible; *what time bound would we hope to get?* Clearly, we cannot get $O(n^{2/3-\varepsilon})$ time per update until we break the $\tilde{O}(n^{5/3})$ bound for static graphs. Moreover, a conditional $n^{2/3-o(1)}$ lower bound (under the APSP or Online Matrix Vector Conjectures) follows from the reductions of Abboud and Dahlgaard [3]. So perhaps dynamic VDs would lead to a matching $O(n^{2/3})$ upper bound? Our first result rules out this possibility with an $n^{1-o(1)}$ lower bound under SETH.

▶ **Theorem 1** (Lower Bound on Dynamic Diameter)**.** *If the diameter of a dynamic undirected planar graph on $n$ nodes can be maintained with $O(n^{1-\varepsilon})$ amortized time per weight-change, then SETH is false. This holds even if the dynamic algorithm is allowed to preprocess the initial graph in poly$(n)$ time, and even in the partially-dynamic setting where weights only increase or only decrease.*

Notably, this is the first lower bound for a dynamic planar graph problem that is based on the SETH (as opposed to other conjectures) and only the second example of such a result if we consider *static* planar graph problems as well [2, 46].

**Towards Dynamic Voronoi Diagrams.** A large gap of $n^{2/3}$ remains despite our lower bound and it is likely that it can be closed if we can indeed make VDs dynamic.[1]

In this paper, we take a small (but arguably the first) step towards this goal: we give an efficient algorithm for updating the VD after the deletion of one edge in the graph, much faster than recomputing it from scratch. (We refer to Section 5 for an overview and all the details.) This small step already has interesting applications. While it applies for general (weighted) planar graphs, the applications we have found only gain an advantage in unweighted planar graphs.

A concrete application is a faster algorithm for the REPLACEMENT DIAMETER: given a graph $G$ return the diameter of $G \setminus \{e\}$, the graph obtained by removing the edge $e$, for all edges $e$. The trivial algorithm for this problem makes $O(n)$ calls to a static diameter algorithm, one for each edge, and achieves $\tilde{O}(n^{8/3})$ running time. We improve this upper bound by an $n^{1/3}$ factor to $n^{7/3+o(1)}$ by utilizing our efficient updates to VDs, along with other tricks that are also based on VDs (but not in a dynamic way).

▶ **Theorem 2** (Replacement Diameter). *Given an unweighted undirected planar graph $G = (V, E)$, there is an $n^{7/3+o(1)}$ time algorithm that for every edge $e \in E$ outputs the diameter of $G^e = (V, E \setminus \{e\})$.*

An additional new result is a faster algorithm for DIAMETER in the *incremental* setting where we start from an empty graph and need to maintain the diameter while $O(n)$ edges are being added (without violating the planarity). The trivial algorithm recomputes the diameter after every update in a total of $\tilde{O}(n^{8/3})$ time, and we improve it to $n^{7/3+o(1)}$.

▶ **Theorem 3** (Incremental Diameter). *There is an algorithm that maintains the diameter of an unweighted undirected planar graph undergoing edge insertions in a total of $n^{7/3+o(1)}$ time.*

This result is based on an elegant reduction from incremental DIAMETER to incremental *distance oracles* that could be of interest beyond planar graphs. Its analysis relies on recent works on the *bipartite independent set* queries introduced by Beame et al. [13].

## 1.2 Static Planar Diameter

Back to DIAMETER in static graphs, what else can we hope to get from VDs? Of course, the biggest open question is whether the $n^{5/3}$ bound can be improved to $n^{1+o(1)}$, or whether one can prove a super-linear lower bound. Toward this question, we would like to understand the hard/easy cases, and a natural parameter to consider is $D$ – the diameter itself.

One of the main algorithmic contributions of this paper, that is crucial to the aforementioned upper bounds, is an algorithm beating $n^{5/3}$ when $D$ is large (in the range $[n^{2/3+\varepsilon}, n]$). Notably, it implies that anyone seeking a tight conditional lower bound cannot use constructions with very large diameter.

[1] It is tempting to think that Theorem 6 implies a dynamic diameter algorithm with update time $\tilde{O}(n^{1.6})$; Use an $r$-division and maintain for each piece the DDG and bisectors. Upon an update of an edge in a piece $P$, recompute the DDG of $P$ (using MSSP) and the bisectors of $P$ (using Theorem 6). For each vertex in the graph, recompute all additive weights using FR-Dijkstra, and compute the furthest vertex in each piece using Theorem 6. The caveat is that this approach does not handle properly the case where both endpoints of the diameter path belong to the same piece (not necessarily $P$). The reason is that the VD mechanism only handles paths that visit at least one boundary node.

▶ **Theorem 4** (Static Large Diameter). *The diameter can be computed in $n^{3+o(1)}/D^2$ time on an unweighted undirected planar graph with diameter $D$.*

Our new algorithm applies VDs in a novel way, where the VD sites lie on a BFS tree level, as opposed to lying on the boundary of pieces in an $r$-divisions.

While our result is the first to address the large $D$ case, the other extreme of small $D$ has already been studied. Eppstein [41] gave the first near-linear time algorithm for constant $D$, with an exponential dependence on $D$. This dependency was later improved as a byproduct of new $(1+\varepsilon)$-approximation algorithms for DIAMETER [15, 24, 41, 70]. The state of the art is $\tilde{O}(n \cdot D^5)$ using the $(1+\varepsilon)$-approximation $\tilde{O}(n \cdot (1/\varepsilon)^5)$-time algorithm of Chan and Skrepetos [24] with $\varepsilon = 1/D$. The final result of this paper is an improved bound of $\tilde{O}(nD^2)$ which increases the range in which the $n^{5/3}$ bound can be beaten from $D < n^{2/15-\varepsilon}$ to $D < n^{1/3-\varepsilon}$.

▶ **Theorem 5** (Static Small Diameter). *The diameter can be computed in $\tilde{O}(n \cdot D^2)$ time on an unweighted undirected planar graph with diameter $D$.*

Our algorithm exploits VDs in a more natural way than that of Chan and Skrepetos [24], if our goal is solve the small $D$ case exactly (recall that their focus is on approximations). It remains an interesting open question whether the $\tilde{O}(n \cdot (1/\varepsilon)^5)$ time approximation algorithm can be improved. This is related to another challenge of computing *approximate VDs* faster than exact, which we do not address in this paper.

## 2 Preliminaries

A recursive decomposition tree $\mathcal{T}$ of a planar graph $G$ is the tree obtained (in linear time) by recursively separating $G$ with a separator of size $\sqrt{|G|}$. $\mathcal{T}$ is a binary tree whose nodes correspond to subgraphs of $G$ (called *pieces*), with the root being all of $G$ and the leaves being pieces of constant size. We identify each piece $P$ with the node representing it in $\mathcal{T}$ (we can thus abuse notation and write $P \in \mathcal{T}$), and with its boundary $\partial P$ (i.e. vertices that belong to some separator along the recursive decomposition used to obtain $P$). An important property for us (see e.g. [47, Lemma 3.1]) is that the sum of $|P| \cdot |\partial P'|$ over all pairs of siblings $P, P'$ in $\mathcal{T}$ is $\tilde{O}(n^{1.5})$.

An *$r$-division* [44] of a planar graph $G$ is a decomposition of $G$ into $\Theta(n/r)$ pieces, each of them with $O(r)$ vertices and $O(\sqrt{r})$ boundary vertices (vertices shared with other pieces). It is possible to compute an $r$-division in $O(n)$ time [57] with the useful property that the boundary vertices of each piece lie on a constant number of faces of the piece (called *holes*).

The *dense distance graph* (DDG) of a piece $P$ is the complete graph over the boundary vertices of $P$. The length of edge $uv$ in the DDG of $P$ equals to the $u$-to-$v$ distance inside $P$. Note that the DDG of $P$ is non-planar. The DDG of an $r$-division is the union of DDGs of all pieces of the $r$-division. Thus, the total number of vertices in the DDG is $O(n/\sqrt{r})$, and the total number of edges is $O(n)$. The DDG of an $r$-division can be computed in $\tilde{O}(n)$ time using the MSSP algorithm [56]. Fakcharoenphol and Rao [42] described an $\tilde{O}(n/\sqrt{r})$ time implementation of Dijkstra's algorithm (nicknamed FR-Dijkstra) on the DDG.

The difficult case for computing the diameter is when the furthest pair of vertices lie in different pieces. Consider some source vertex $s$ outside of some piece $P$. For every boundary vertex $u$ of $P$, let $d(u)$ denote the $s$-to-$u$ distance in $G$. The *additively weighted Voronoi diagram* of $P$ with respect to $d(\cdot)$ is a partition of the vertices of $P$ into pairwise disjoint sets (Voronoi cells), each associated with a unique boundary vertex (site) $u$. The vertices in the cell $\mathrm{Vor}(u)$ are all the vertices $v$ of $P$ such that $u$ is the last boundary vertex of $P$ on the shortest $s$-to-$v$ path. In other words, every site $u$ of $P$ has *additive weight* $d(u)$, the

*additive distance* from a site $u$ to a vertex $v$ of $P$ is defined as $d(u)$ plus the length of the shortest $u$-to-$v$ path inside $P$, and the cell $\mathrm{Vor}(u)$ contains all vertices $v$ of $P$ that are closer (w.r.t. additive distances) to $u$ than to any other site in $S$. The *boundary* $\partial\mathrm{Vor}(u)$ of a cell $\mathrm{Vor}(u)$ consists of all edges of $P$ that have exactly one endpoint in $\mathrm{Vor}(u)$. For example, in a Voronoi diagram of just two sites $u$ and $v$, the boundary of the cell $\mathrm{Vor}(u)$ is a $uv$-cut and is therefore a cycle in the dual graph. This cycle is called the *uv-bisector*. The complexity $|\partial\mathrm{Vor}(u)|$ of a Voronoi cell $\mathrm{Vor}(u)$ is the number of faces of $P$ that contain vertices of $\mathrm{Vor}(u)$ and of at least two more Voronoi cells. For every source $s$, computing the furthest vertex from $s$ in $P$ thus boils down to computing, for each site $u$, the furthest vertex (w.r.t. additive distance) from $u$ in $\mathrm{Vor}(u)$, and then returning the maximum value among all sites $u$.

▶ **Theorem 6** ([45]). *Let $P$ be an edge-weighted planar graph with $r$ vertices. Let $S$ be a set of $b$ sites that lie on the boundaries of $\tilde{O}(1)$ faces[2] of $P$. The uv-bisectors of all pairs $u, v \in S$ and all possible additive weights $d(u), d(v)$ can be computed and represented in $\tilde{O}(rb^2)$ time and space. Then, given any additive weights $d(\cdot)$ to $S$, a representation of the Voronoi diagram w.r.t these weights can be constructed in $\tilde{O}(|S|)$ time. With this representation, for any site $u \in S$ we can query the maximum distance from $u$ to a vertex in $\mathrm{Vor}(u)$ in $\tilde{O}(|\partial\mathrm{Vor}(u)|)$ time.*

# 3 Static Diameter

## 3.1 An $n^{3+o(1)}/D^2$ Algorithm

In this subsection we prove Theorem 4, stating that the diameter can be computed in $n^{3+o(1)}/D^2$ time on an unweighted undirected planar graph with diameter $D$. We first present a randomized $\tilde{O}(n^4/D^3)$ time algorithm, and then show how to improve it to $n^{3+o(1)}/D^2$. We then show how to derandomize both algorithms. We begin with two simple observations about the BFS levels when the diameter is $\geq D$.

▶ **Observation 7.** *Let $s$ be any node in a graph of diameter $\geq D$. Then at least one out of the $D/2$ middle levels of the BFS tree rooted at $s$ has size $O(n/D)$.*

▶ **Observation 8.** *Let $s$ be any node in $G$ and let $L_i$ be the set of nodes at level $i$ in the BFS tree rooted at $s$. Let $G_i$ be the subgraph of $G$ that is induced by $\bigcup_{j\geq i} L_j$. Then for each connected component $C$ of $G_i$ the nodes in $L_i \cap C$ lie on a single face.*

**Proof.** To see that the vertices of $L_i \cap C$ all lie on the same face in $G_i$, consider the embedding of the component $C$ of $G_i$ inherited from the embedding of $G$. Viewing $C$ as a graph obtained from $G$ by deleting edges and vertices, one can start from any vertex of $L_i$ and follow a curve in the plane that only goes through deleted edges and vertices until reaching the root $s$ of the BFS tree. Hence all vertices of $L_i$ lie on a single face of $C$, and hence also of $G_i$. ◀

**A randomized algorithm.** We first compute in $O(n)$ time a 2-approximation (lower bound) $\tilde{D}$ of $D$ by computing a BFS tree and choosing $\tilde{D}$ to be the furthest root-to-leaf distance. Then, we repeat the following procedure $\theta(n \log n/\tilde{D})$ times, and return the largest distance found:

[2] Theorem 1.1 in [45] is phrased for a constant number of faced (called holes). However, as pointed in footnote 8 in [45], the dependency of the running time on the number of holes is polynomial, so the theorem applies also to the case of a polylogarithmic number of holes.

1. Randomly sample a source $s$, compute its BFS tree. Let $D'$ be the depth of this tree. Note that $D \geq D' \geq D/2$. Let $S = L_i$ be the set of nodes at level $i$ satisfying both $D'/4 < i < 3D'/4$ and $|S| = O(n/D') = O(n/D)$. By Observation 7, such a set exists. Let $G_i$ be the subgraph of $G$ induced by $\bigcup_{j \geq i} L_j$.
2. Compute $d(v, b)$ for all $v \in G$ and all $b \in S$.
3. For each connected component $C$ of $G_i$:
   a. Compute all bisectors in $C$ of sites $C \cap S$ (that lie on a single face by Observation 8).
   b. For each node $v$ in $G \setminus G_i$, compute the VD of $C$ w.r.t the additive weights $d(v, b)$, and compute the distance from $v$ to its furthest vertex in every Voronoi cell of the VD.

**Running time.** The first step takes $O(n)$ time by computing and traversing the BFS tree of $s$. The second step takes $O(n^2/D)$ time by doing a BFS from each vertex of $S$ in $O(n)$ time. The most expensive step is 3a. By Theorem 6, all bisectors of a connected component $C$ can be computed in $\tilde{O}(|C| \cdot |C \cap S|^2)$ time. Over all connected components, this sums up to $\tilde{O}(n \cdot (n/D)^2)$ (since the $C$'s are disjoint and sum up to $n$, and the $C \cap S$ are disjoint and sum up to $O(n/D)$). Finally, in step 3b, for each vertex $v$, computing $v$'s VD and furthest vertex in every cell takes $\tilde{O}(|C \cap S|)$ time by Theorem 6. Over all connected components, this sums up to $\tilde{O}(n/D)$, and thus over all vertices $v$ to $\tilde{O}(n^2/D)$. The total running time of the entire procedure is thus $\tilde{O}(n \cdot (n/D)^2)$, and since we repeat the procedure $\tilde{O}(n/D)$ times we get $\tilde{O}(n^4/D^3)$.

**Correctness.** It remains to prove that the distance we return is indeed the diameter with high probability. Let $x, y$ be the two endpoints of the diameter (i.e. $D = d(x, y)$). Then, the probability that a random source $s$ satisfies $d(s, x) \leq D'/4$ and $d(s, y) \geq 3D'/4$ is at least $D'/4n$ (because this happens if $s$ is one of the first $D'/4$ nodes on the path from $x$ to $y$). Therefore, this happens with high probability for at least one of the sources $s$ that we choose. For this $s$, we will have that $x \in G \setminus G_i$ while $y \in G_i$ (it is impossible that $y \in G \setminus G_i$ because then an $x$-to-$y$ path through $s$ would be shorter than $D$), and then the largest distance that we find is guaranteed to be $d(x, y)$.

**Derandomization.** Observe that to derandomize the algorithm, it suffices to replace the sampling of sources with a (deterministic) selection of a set of sources $\mathcal{S}$ of size $O(n/D)$ such that a diameter endpoint $x$ is at distance $\leq D'/4$ from at least one source $s \in \mathcal{S}$.

To construct $\mathcal{S}$, pick an arbitrary source $s$ and compute it's BFS tree $T$ of depth $D' \leq D$. Find a level $L_i$ that has only $O(n/D') = O(n/D)$ nodes and $0.4D' \leq i \leq 0.5D'$. Similarly, find a level $L_j$ that has only $O(n/D)$ nodes and $0.8D' \leq j \leq 0.9D'$. The set of sources is then $\mathcal{S} = \{s\} \cup L_i \cup L_j$. It is easy to verify that every vertex $v$ in the graph has an ancestor or a descendant in $T$ that belongs to $\mathcal{S}$ and is at distance at most $D'/4 \leq D/4$ from $v$.

**A faster algorithm.** Next, we improve the running time to $n^{3+o(1)}/D^2$. Again, we will start with a randomized algorithm and then derandomize. Let $B_\rho(v)$ denote the ball with radius $\rho$ around vertex $v$. Recall that our goal is to sample w.h.p. a vertex $s$ in $B_{\tilde{D}/4}(x)$ (without knowing $x$), where $x$ is a diameter endpoint.

Let $\rho = \tilde{D}/4$. In order to sample a vertex $s$ in $B_\rho(x)$ w.h.p., it suffices to randomly sample a set of $\tilde{O}(n/|B_\rho(x)|)$ vertices (rather than sampling $\tilde{O}(n/\rho)$ vertices as in the approach above). Then, for each sampled vertex $s$, we can find a level $L_i$ in the BFS tree of $s$ with $\rho < i \leq 2\rho$ s.t. $|L_i| < |B_{2\rho}(s)|/\rho$ (rather than $n/\rho$ as in the approach above). Then, executing the approach above (i.e., executing steps 2–3 of the $\tilde{O}(n^4/D^3)$ algorithm above) for a specific

$s$ would take time $\tilde{O}(n(|B_{2\rho}(s)|/\rho)^2)$ to compute all bisectors, $\tilde{O}(n|B_{2\rho}(s)|/\rho)$ to compute all additive weights, and $\tilde{O}(|B_{2\rho}(s)|^2/\rho)$ to construct the Voronoi diagrams for all vertices above level $i$. We see that if $|B_\rho(x)|$ is large then we gain because we have to sample fewer vertices, and if $|B_{2\rho}(s)|$ is small then we gain because the amount of work for each sampled vertex decreases.

For this approach to work, we need to (1) estimate $|B_\rho(x)|$, and (2) relate $|B_\rho(x)|$ and $|B_{2\rho}(s)|$. To address (1), we simply estimate $|B_\rho(x)|$ by enumerating all powers of two $2^k$ for $0 \le k \le \log n$. To address (2), note that $|B_\rho(x)| < |B_{2\rho}(s)| < |B_{3\rho}(x)|$, and that there must exist a $j \in \{1, 2, \ldots, \sqrt{\log_3 n}\}$ s.t. $|B_{3\rho 3^{-j}}(x)|/|B_{\rho 3^{-j}}(x)| < 3^{\sqrt{\log_3 n}} = n^{o(1)}$ (if not, $|B_\rho(x)| > n$, a contradiction).

The algorithm is therefore: For each $1 \le j \le \sqrt{\log_3 n}$, let $\rho_j = 3^{-j}\rho$. For each $0 \le k < \log n$ we sample $(n \log n)/2^k$ vertices $s$ (reflecting our assumption that $B_{\rho_j}(x) \le 2^k$). For each sampled vertex $s$, if $|B_{2\rho_j}(s)| > 2^k 3^{\sqrt{\log_3 n}}$, then, since $|B_\rho(x)| < |B_{2\rho}(s)| < |B_{3\rho}(x)|$, it must be that $s \notin B_{\rho_j}(x)$ or $|B_{\rho_j}(x)| > 2^k$ or $|B_{\rho_{j-1}}(x)|/|B_{\rho_j}(x)| > 3^{\sqrt{\log_3 n}}$ (the disjunction is not exclusive). Hence, in this case we discard $s$ and move on to the next sampled vertex. Otherwise, $|B_{2\rho_j}(s)| \le 2^k 3^{\sqrt{\log_3 n}}$, and we can find a level $L_i$ with $\rho_j < i < 2\rho_j$ in the BFS tree rooted at $s$ s.t. $|L_i| < 2^k 3^{\sqrt{\log_3 n}}/\rho_j$, and continue as in steps 2–3 from the previous algorithm. The overall running time is

$$\sum_{j=0}^{\sqrt{\log_3 n}} \sum_{k=0}^{\log n} \tilde{O}\left(\frac{n}{2^k}\left(n(2^k 3^{\sqrt{\log_3 n}}/\rho_j)^2 + n2^k 3^{\sqrt{\log_3 n}}/\rho_j + (2^k 3^{\sqrt{\log_3 n}})^2/\rho_j\right)\right) = n^{3+o(1)}/D^2.$$

To argue correctness, note that for $j$ such that $|B_{\rho_{j-1}}(x)|/|B_{\rho_j}(x)| \le 3^{\sqrt{\log_3 n}}$ and $k$ such that $2^{k-1} \le |B_{\rho_j}(x)| \le 2^k$, sampling $(n \log n)/2^k$ vertices will yield with high probability a vertex $s \in B_{\rho_j}(x)$, and this $s$ will not be discarded. This $s$ satisfies $d(s,x) \le \rho_j$ and $d(s,y) \ge 2\rho_j$, so the largest distance found for this $s$ is guaranteed to be $d(x,y)$ by the same argument as in the correctness of the slower algorithm.

**Derandomization.** We use sparse neighborhood covers of Busch, Lafortune and Tirthapura [20] to derandomize the algorithm. A $\rho$-neighborhood cover $Z$ of a graph $G$ is a set of connected subgraphs called clusters, such that the union of all clusters is the vertex set of $G$ and such that for each node $v \in G$, there is some cluster $C \in Z$ that contains $B_\rho(v)$. The radius of a cover $Z$ is the maximum radius of a cluster in $Z$. The degree of a cover $Z$ is the maximum number of clusters that a node in $G$ is a part of. Busch et al. gave a deterministic $O(n \log n)$-time algorithm for computing, for any $\rho > 0$ and any connected planar graph, a $\rho$-neighborhood cover of any connected planar graph with radius $16\rho$ and degree 18. See also [60] for an $O(n)$ time algorithm.

To adjust the arguments we redefine $\rho_j = \rho 33^{-j}$ for $j = 1, \ldots, \sqrt{\log_{33}(n)}$, and use the fact that for some $j$, $|B_{\rho_{j-1}}|/|B_{\rho_j}| < 33^{\sqrt{\log_{33} n}}$. To avoid sampling in our algorithm, for each choice of $j, k$, we compute a $\rho_j$-neighborhood cover $Z$. We pick an arbitrary vertex $s$ from each cluster $C$ of $Z$ such that $|C| > 2^k$. Since the degree of $Z$ is 18, the number vertices $s$ we choose is at most $18n/2^k$.

If $2^k < |B_{\rho_j}(x)| > 2^{k+1}$ then the cluster $C$ containing $B_{\rho_j}(x)$ will have $|C| > 2^k$ vertices, and we will choose a vertex $s \in C$. Since the radius of $Z$ is $16\rho_j$, $d(s,x) \le 16\rho_j$. If $|B_{17\rho_j}(s)| > 2^{k+1} 33^{\sqrt{\log_{33} n}}$, we discard $s$. Since $B_{17\rho_j}(s)$ is contained in $B_{33\rho_j}(x) = B_{\rho_{j-1}(x)}$, we are guaranteed that some $s$ will not be discarded. For such $s$ we find a level $L_i$ with $16\rho_j < i < 17\rho_j$ in the BFS tree rooted at $s$ s.t. $|L_i| < 2^{k+1} 33^{\sqrt{\log_{33} n}}/\rho_j$. The level of $x$ in

the BFS tree is at most $16\rho_j$, and since $\rho_j < \rho < D/4$, the vertex $y$ such that $d(x,y) = D$ is at level greater than $i$ in the BFS tree. Hence, executing lines 2–3 of the procedure for the algorithm in section 5 will report the distance $D$. The running time analysis is identical to that of the randomized version since we made sure that the number of vertices we choose in the derandomiztion is at most some fixed constant times the number of sampled vertices in the randomized algorithm.

## 3.2 An $\tilde{O}(n \cdot D^2)$ Algorithm

In this subsection we prove Theorem 5, stating that the diameter can be computed in $\tilde{O}(n \cdot D^2)$ time on an unweighted planar graph with diameter $D$. We begin with some preliminaries on a recursive decomposition using shortest path separators.

**Preliminaries.** A *shortest path separator* of a planar graph $G$ is an undirected cycle $C(G)$ consisting of a shortest $s$-to-$u$ path, a shortest $s$-to-$v$ path, and a single edge $uv$, such that both the interior and exterior of the cycle consist of at most 2/3 of the total number of the faces of $G$. Such a separator can be found in $O(n)$ time [61]. By recursively separating $G$ with shortest path separators (halting the recursion when we reach subgraphs of size $\leq D$), we obtain the *decomposition tree* $\mathcal{T}$. The root of $\mathcal{T}$ corresponds to the entire graph $G$. A node corresponding to subgraph $P$ (we interchangeably refer to it as node $P$) has two children, whose subgraphs correspond to the interior and exterior of the separator $C(P)$.

Observe that for every node $P \in \mathcal{T}$ the size of the shortest path separator $C(P)$ is $O(D)$. This is because $C(P)$ consists of two shortest paths, each of length at most $D$. Moreover, the boundary of $P$ (vertices of $P$ that have incident edges to vertices not in $P$) is included in the union of all $C(P')$ where $P'$ is an ancestor of $P$, and is therefore of size $O(D \log n)$ and lies on $O(\log n)$ faces of $P$. We compute the DDGs of every node (subgraph) $P \in \mathcal{T}$ (i.e. copmute a data structure that can report in $\tilde{O}(1)$ time the distances in the graph $P$ between and pair of boundary vertices of $P$) using $O(\log n)$ executions of MSSP on $P$. This takes total $\tilde{O}(n)$ time over the entire $\mathcal{T}$. Now, given any vertex $v$ in the subgraph $P$, we can compute the distances in $G$ from $v$ to all boundary vertices of $P$ in $\tilde{O}(D)$ time using FR-Dijkstra. Namely, we initialize the $\tilde{O}(D)$ boundary vertices of $P$ to their distances from $v$ in the graph $P$ (via MSSP queries), and we run FR-Dijkstra on the union of the DDG of $P$ and the DDGs of all $P'$ where $P'$ is a sibling of some ancestor of $P$.

**The algorithm.** For every non-leaf node $P \in \mathcal{T}$, we compute the furthest pair of vertices $u, v \in P$ where $u$ is internal to $C(P)$ and $v$ is external to $C(P)$. Observe that distances must be taken in the entire graph $G$ since the shortest $u$-to-$v$ path may venture out of $P$. To this end, we precompute all bisectors of every graph $P \in \mathcal{T}$, with the sites being the $\tilde{O}(D)$ boundary vertices of $P$. Using Theorem 6, this takes $\tilde{O}(|P| \cdot D^2)$ time (where $|P|$ denotes the size of the subgraph $P$), so over all $\mathcal{T}$ this takes $\tilde{O}(n \cdot D^2)$ time. (Observe that here we have used Theorem 6 with the sites lying on $O(\log n)$ faces. As far as we know, in all prior uses of Theorem 6 the sites lie on $O(1)$ faces). Then, for every vertex $v \in P$, we compute the distances in $G$ from $v$ to all boundary vertices of $P$ using FR-Dijkstra in $\tilde{O}(D)$ time as explained above. We then use these distances as additive weights and apply Theorem 6 to find the furthest vertex from $v$ in $P$. This also takes $\tilde{O}(D)$ time, so overall $\tilde{O}(n \cdot D)$.

We handle the leaf nodes $P \in \mathcal{T}$ explicitly (recall that $|P| \leq D$). For each leaf node $P$ we compute the all-pairs shortest-paths (APSP) in $G$ between any two vertices $u, v \in P$. This is done by running Dijkstra's standard algorithm from every $v \in P$ on the graph $P$ where the boundary vertices of $P$ are initialized to their distances from $v$ in $G$ (that we have already computed as $v$'s additive weights). This takes $\tilde{O}(D)$ time per $v$, so $\tilde{O}(D^2)$ time per $P$, and $\tilde{O}(D^2 \cdot n/D) = \tilde{O}(nD)$ over all leaves $P$.

## 4 A Lower Bound on Dynamic Diameter

In this section we prove Theorem 1. Namely, we give a conditional lower bound ruling out an amortized $O(n^{1-\varepsilon})$ update time for maintaining the diameter of *weighted* planar graphs that undergo a sequence of edge-weight updates.

The proof is inspired by [3], however, there are quite a few changes since the reduction in [3] is from APSP (not SETH), to dynamic distance oracles (not dynamic diameter), and rules out $O(n^{0.5-\varepsilon})$ update time (not $O(n^{1-\varepsilon})$). Our reduction is from the following problem, which is simply a recasting of the Orthogonal Vectors problem in the language of graphs.

▶ **Definition 9** (Graph OV). *Given an undirected tripartite graph $G$ with parts $A, C, B$ where $|A| = |B| = n$ and the middle level has size $|C| = O(\log n)$, where all edges are in $A \times C$ and $C \times B$ decide if there exists a pair $a_i \in A, b_j \in B$ such that $d_G(a_i, b_j) > 2$.*

It is known that solving this Graph OV problem in $O(n^{2-\varepsilon})$ time refutes SETH [67, 71]. Moreover, in the unbalanced version where $|A| = n^\alpha$ and $|B| = n^\beta$ for arbitrary constants $\alpha, \beta > 0$ we know that an $O(n^{\alpha+\beta-\varepsilon})$ time algorithm refutes SETH.

**The structure of the reduction.** Given an instance $G$ of the Graph OV problem, we construct a dynamic planar graph $H$. The graph $H$ is composed of two grids, a left grid and a right grid, each of dimension $|C| = O(\log n)$ by $|A| = n$. The columns of both grids are indexed by the nodes of $A$, such that the top node of the $i^{th}$ column in the left (resp. right) grid is called $a_i$ (resp. $a'_i$). The rows of the grids correspond to the nodes in $C$ such that the rightmost (resp. leftmost) node in the $k^{th}$ row of the left (resp. right) grid is called $c_k$ (resp. $c'_k$). In both grids, all horizontal edges have weight $2|C|$. In the left grid, the vertical edges in column $i$ have weight $2i$ and in the right grid the vertical edges of column $i$ have weight $2(n-i)$. In the left grid, for every $i$ and $k$, if the edge $(a_i, c_k)$ exists in $G$, then we add a diagonal edge $e_k$ from vertex $(k-1, i)$ to vertex $(k, i+1)$ whose weight is $2i + 2|C| - 1$. We call such $e_k$ a *shortcut* edge (as it is shorter by 1 compared to the alternative path composed of a vertical edge followed by a horizontal edge). The two grids are connected by $|C|$ edges: for each $k$ we have an edge from $c_k$ to $c'_k$ of weight $2n|C| - 2nk$. These $|C|$ edges are the only edges in $H$ whose weights will change throughout the reduction - all others will remain fixed. We add a single node $x$ that is connected to all nodes in the top row of the left grid and all nodes of the top row in the right grid. We set the weight of every edge $(a_i, x)$ to be $i \cdot 4|C|$ and the weight of every edge $(x, a'_j)$ to be $(n-j) \cdot 4|C|$.

**The dynamic updates.** After constructing the initial graph $H$ as above, for every $j = 1, \ldots, n$ we obtain a graph $H_j$ by applying the following updates to $H$: for every $k = 1, \ldots, |C|$ if the edge $(c_k, b_j)$ exists in $G$ then decrease by 1 the weight of the edge $(c_k, c'_k)$ in $H$ (we refer to such edge $(c_k, c'_k)$ as a *decreased* edge). The following main lemma shows that the diameter of $H_j$ reveals whether or not there exists an $a_i \in A$ such that $d_G(a_i, b_j) > 2$. Note, crucially, that we can generate all graphs $H_1, \ldots, H_n$ in sequence using only $O(n \log n)$ updates since $H_i$ differ from $H_{i-1}$ by only $O(\log n)$ edge weights. Under SETH, we cannot maintain the diameter throughout this sequence in $O(n^{2-\varepsilon})$ time. Therefore, each update cannot be done in $O(n^{1-\varepsilon})$ amortized time, thus proving Theorem 1 for the fully-dynamic case. To get a proof for the incremental case where edge weights only decrease we can do the following (the decremental case is symmetric). Redefine the weight of the $O(\log n)$ edges so that they only decrease during the sequence: add $2(n-i)$ to their weight in $H_i$ so that their weight is the largest in $H_1$ and smallest in $H_n$. Then, the sequence of graphs can be generated by only

$O(n \log n)$ decrease-weight updates. The diameter of $H_i$ increases by exactly $2(n-i)$ so the same analysis goes through. For simplicity, we continue the proof in this section with the construction in the fully-dynamic case.

▶ **Lemma 10.** *For any $j$, the diameter of $H_j$ is larger than $4n|C|-2$ iff there exists $a_i \in A$ such that $d_G(a_i, b_j) > 2$.*

In the remainder of this section we prove the above lemma. First observe that by our choice of edge-weights the diameter of $H_j$ correspond to some shortest $a_i$-to-$a'_\ell$ path. The following claim shows that in fact it is an $a_i$-to-$a'_i$ path.

▷ Claim 11. For all $i \neq \ell$, $d_{H_j}(a_i, a'_\ell) < 4n|C|-2$.

Proof. If $\ell > i$, then the path $a_i - x - a'_\ell$ consisting of two edges costs $(n-(\ell-i)) \cdot 4|C| < 4n|C|-2$. Otherwise $\ell < i$, then the $a_i$-to-$a'_\ell$ path that only uses horizontal edges costs $2|C|(n-i+\ell) + 2|C| = 2n < 4n|C|-2$. ◁

The following claim concludes the proof.

▷ Claim 12. For any $i$, $d_{H_j}(a_i, a'_i) > 4n|C|-2$ iff $d_G(a_i, b_j) > 2$.

Proof. Observe that the path $a_i - x - a'_i$ consisting of two edges costs $4n|C|$. There may however be a shorter $a_i$-to-$a'_i$ path that passes through the grids. By our choice of edge weights (similarly to [3]) such shortest path must start with an $a_i$-to-$c_k$ prefix (for some $k \leq |C|$) in the left grid, then use the $(c_k, c'_k)$ edge, then in the right grid do $i$ horizontal steps followed by $k$ vertical steps. Moreover, the $a_i$-to-$c_k$ prefix starts with $k-1$ vertical steps, then uses a shortcut edge $e_k$ if it exists (otherwise it does a horizontal step followed by a vertical step), and then it does $n-i-1$ horizontal steps until reaching $c_k$.

Suppose first that there were no shortcut edges and no decreased edges at all. The length of such $a_i$-to-$a'_i$ path would then be

$$d_H(a_i, a'_i) = k \cdot 2i + (n-i) \cdot 2|C| + (2n|C| - 2nk) + i \cdot 2|C| + k \cdot 2(n-i) = 4n|C|.$$

Note that this length ($4n|C|$) is the same independent of $k$ and of $i$. Hence, the only way an $a_i$-to-$a'_i$ path can be shorter than $4n|C|$ is by using shortcut edges and decreased edges. However, it can use at most one shortcut edge $e_k$ and one decreased edge $(c_k, c'_k)$. So its length is $4n|C|-2$ iff there exists a $k$ such that the shortcut $e_k$ exists (i.e., $(a_i, c_k) \in E(G)$) and the edge $(c_k, c'_k)$ is decreased (i.e., $(c_k, b_j) \in E(G)$), and this is iff $d_G(a_i, b_j) \leq 2$. ◁

▶ Remark 13. By subdividing all edges, the above reduction implies that $O(n^{1/2-\varepsilon})$ update time is impossible for maintaining the diameter of *unweighted* planar graphs.

## 5 Decremental Voronoi diagrams and Replacement Diameter

**Overview: A Step Toward Dynamic Voronoi Diagrams.** The usefulness of Voronoi diagrams for diameter and distance reporting in static planar graphs make it natural to ask whether one can efficiently maintain some useful representation of Voronoi diagrams in the dynamic setting. This seems challenging because a change in a single edge or in a single additive weight can cause the entire Voronoi diagram to completely change. For example, decreasing the weight of a single edge in the Voronoi cell $\mathrm{Vor}(b)$ of some site $b$ may cause an expansion of $\mathrm{Vor}(b)$ on the expense of every other Voronoi cell, even cells that were not neighbors of $\mathrm{Vor}(b)$ before the change. The same is true for decreasing the additive weight of $b$. Indeed, the few attempts to use Voronoi diagrams in dynamic planar graphs that we are aware of [27, 28], all recompute the Voronoi diagrams from scratch upon every update.

We make a small step towards dynamic Voronoi diagrams by developing a mechanism for updating Voronoi diagrams in the decremental setting. In our opinion, this is the most novel technical contribution of our work. The deletion of an edge in some part of the graph only causes an increase in the additive weights of certain sites. When the additive weight of site $b$ increases, its Voronoi cell shrinks. Namely, some vertices that were in $\mathrm{Vor}(b)$ before the increase will belong to Voronoi cells of other sites after the increase. The crucial observation is that the only relevant sites in this process are $b$ and the sites of the neighboring cells to $\mathrm{Vor}(b)$ in the original Voronoi diagram. The time for the resulting update procedure is therefore proportional to the cell-degree of $b$, rather than to the total number of sites in the Voronoi diagram. Unfortunately, the cell-degree of $b$ may, in general, be as large as the number of sites. Nonetheless, this procedure turns out to be useful for the replacement diameter problem, where we can bound the number of times each site is affected by some edge deletion.

**Representing Voronoi diagrams.** Let $P$ be a planar graph with real edge-lengths. Let $S$ be the set of vertices (*sites*) that lie on $\tilde{O}(1)$ faces, called holes. Recall that every site $s \in S$ has an associated additive weight $d(s)$.

Consider the Voronoi diagram of $P$ with sites $S$ and additive weights $d(s)$. Let $P^*$ be the planar dual of $P$. Let $\mathrm{VD}_0$ be the subgraph of $P^*$ consisting of the duals of edges $(u, v)$ of $P$ such that $u$ and $v$ are in different Voronoi cells. Let VD be the graph obtained from $\mathrm{VD}_0$ after eliminating all degree-2 vertices by repeatedly contracting any one of their incident edges. The vertices of VD are called *Voronoi vertices* and the edges of VD are called *Voronoi edges*. Observe that every Voronoi edge corresponds to a consecutive segment of some bisector between two sites. Note that VD may be disconnected, i.e., a planar map, and that the boundaries of faces of this planar map may be disconnected. Each face of VD corresponds to a cell $\mathrm{Vor}(s)$ of some site $s \in S$. Hence there are at most $|S|$ faces in VD. It is shown in [45] that the total number of edges, vertices, and faces of VD is $O(|S|)$. In what follows, when we say we compute a Voronoi diagram VD, we mean we use the algorithm in Theorem 6, which computes a representation of the planar map VD defined above. Each Voronoi edge of VD corresponds to a segment of a bisector.

## 5.1 Maintaining Voronoi diagrams while additive weights increase

Consider an increase in the additive weight of a set $B \subseteq S$ of sites. Such an increase can only change the shortest path (w.r.t. additive weights) of vertices $v$ in the Voronoi cells of sites in $B$. Either the shortest path to such $v$ remains the same but its length increases by the change in the additive weight of the site, or $v$ becomes part of a Voronoi cell of a different site. In the latter case, since each shortest path is entirely contained in a single Voronoi cell, planarity dictates that the new site must be a neighbor of a site in $B$. We define the set $N(B)$ of neighbors of the sites in $B$ as the set of sites that are either in $B$ or sites whose Voronoi cells are adjacent to the Voronoi cells of sites in $B$. Note that $|N(B)| = O(\sum_{b \in B} \text{cell-degree}(b))$. It follows from the discussion above that the only sites whose Voronoi cells might change as a result of such an increase are those in $N(B)$.

To compute the new Voronoi diagram we first compute the Voronoi diagram of $P$ with just the sites $N(B)$. By Theorem 6, this takes $O(\sum_{b \in B} \text{cell-degree}(b))$ time. Let $\mathrm{VD}'$ denote this Voronoi diagram, and let VD denote the Voronoi diagram of $P$ before the change. We stress that the additive weights of $\mathrm{VD}'$ are the ones after the increase, and the additive weights of VD are the ones before the increase. To obtain the Voronoi diagram of $P$ after the change, we "glue" together parts of $\mathrm{VD}'$ and VD as follows. See Figure 1 for an illustration.

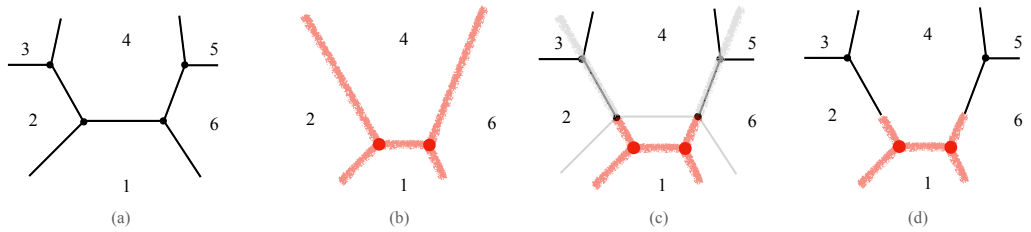

**Figure 1** An illustration of the process of computing the Voronoi diagram of a piece with 6 sites when the additive weight of site 1 is increased. (a) VD, the Voronoi diagram of all 6 sites before the weight increase. (b) VD$'$, the Voronoi diagram of just the increased site (1) and its neighbors (2, 4, 6), after the increase. (c) VD and VD$'$ superimposed, with the edges deleted from VD, and from VD$'$ in grey. Observe that all segments of bisectors between cells of the neighbors (2,4,6) that appear in VD also appear in VD$'$. (d) The glued Voronoi diagram.

Recall that VD is a (possibly disconnected) planar map whose edges correspond to segments of bisectors of pairs of sites of VD. The endpoints of these segments are Voronoi vertices of VD. We start by deleting from VD all the Voronoi edges corresponding to bisectors involving at least one site of $B$. For every Voronoi vertex $v$ incident to a Voronoi cell of a site in $B$, if all the Voronoi edges incident to $v$ were deleted, then we delete $v$ as well. Let $\mathcal{E}$ denote the set of Voronoi edges $e$ of VD such that $e$ is incident to some Voronoi vertex $v$, $e$ was not deleted, but the preceding or following Voronoi edge of $e$ in the cyclic order of edges around $v$ was deleted. Every Voronoi edge $e \in \mathcal{E}$ corresponds to a segment $\beta$ of a bisector between two sites $s_1, s_2 \in N(B) \setminus B$. Since the additive weights of these sites are unchanged, the segment $\beta$ must be represented by a Voronoi edge $e'$ of VD$'$. Note that $\beta$ may be a sub-segment of the bisector segment $\beta'$ corresponding to $e'$. Also note that it is easy to identify $e'$ with $e$ during the computation of VD$'$ with no asymptotic time overhead.[3] For each Voronoi edge $e \in \mathcal{E}$ (of VD), we split its corresponding Voronoi edge $e'$ (of VD$'$) into two edges $e'_1, e'_2$ by breaking $\beta'$ into two sub-segments at $v$. Suppose $e'_2$ is the one whose corresponding bisector segment contains $\beta$. Note that if $v$ is an endpoint of $e'$ (i.e., if $v$ is a Voronoi vertex of VD$'$ as well), then $e'_1$ is a trivial empty segment of the $s_1$-$s_2$ bisector. We delete $e'_2$ from VD$'$, and merge the Voronoi edges $e$ of VD and $e'_1$ of VD$'$ into a single Voronoi edge whose corresponding segment is the concatenation of the segment $\beta$ of $e$ and the segment of $e'_1$.

Doing so for the edges $e \in \mathcal{E}$ effectively "glues" the relevant portion of VD$'$ into VD, replacing the portion of VD that we had deleted. The algorithm of [45] for constructing Voronoi diagrams from precomputed bisectors performs similar stitching and glueing operations, and the data structures used to represent Voronoi diagrams and bisectors support all the necessary operations in $\tilde{O}(1)$ time per operation. Hence, the time complexity of this entire procedure is proportional (up to logarithmic factors) to the number of Voronoi vertices of the Voronoi cells of the sites in $B$, which is $O(\sum_{b \in B} \text{cell-degree}(b))$.

[3] This can be done, for example, by augmenting the binary search tree representation of segments of bisectors used in the construction algorithm (cf. [45]) with a boolean flag marking edges in $\mathcal{E}$. Then we can go over all Voronoi edges of VD$'$ and list for each one the corresponding marked edge $e \in \mathcal{E}$, if such an edge exists in the segment of the bisector corresponding to that Voronoi edge.

## 5.2 Replacement Diameter

We now describe how to use the new algorithm for maintaining Voronoi diagrams under additive weight decreases to get a faster algorithm for replacement diameter. The algorithm starts by computing a complete recursive decomposition tree $\mathcal{T}$ of the graph $G$. For every node (piece) in $\mathcal{T}$ (corresponding to a subgraph of $G$) we compute all its bisectors. This takes $\tilde{O}(n^2)$ time over all $\mathcal{T}$ using Theorem 6. Then, for every vertex $s \in V$ we compute the BFS tree $T_s$ of $s$ in $G$ and compute the *fault-tolerant single source distance oracle* of Baswana et. al. [12] for $s$ in $G$. This oracle is constructed in $\tilde{O}(n)$ time from $G$, and can report in $\tilde{O}(1)$ time the $s$-to-$t$ distance in the graph $G^e = (V, E \setminus \{e\})$ for any $s, t \in V$ and any $e \in E$. Overall, this also takes $\tilde{O}(n^2)$ time. For each piece $P \in \mathcal{T}$, for each boundary vertex $b \in \partial P$ we create the *induced tree* $T_b^P$ from $T_b$ by marking all vertices of $P$ and all their lowest common ancestors, and contracting any edge whose endpoints are not marked. The resulting $T_b^P$ has size $O(|P|)$. For each edge $e$ of $G$ that was contracted in the process we store the edge of $T_b^P$ into which $e$ was contracted. Since the total number of boundary nodes and piece sizes over all pieces of $\mathcal{T}$ is $\tilde{O}(n)$, the total time to construct all these induced trees is $\tilde{O}(n^2)$. For each piece $P \in \mathcal{T}$, let $P'$ be the sibling of $P$ in $\mathcal{T}$. Let $b_1, b_2, \ldots$ be the vertices of $\partial P'$ in some arbitrary order. For each vertex $s \in P$ we compute the additivley weighted Voronoi diagram of $s$ w.r.t $P'$ with sites $\{b_i\}$ and additive weights $d(s, b_i)$. We also store for $s$ a binary search tree (BST) over $b_1, b_2, \ldots$, where the node $i$ in the tree stores the distance from $s$ to the furthest vertex in $\mathrm{Vor}(b_i)$. This takes total $\tilde{O}(n\sqrt{n})$ time over all $P \in \mathcal{T}$ and all $s \in P$. For each piece $P$ with vertices $v_1, v_2, \ldots$ in arbitrary order, we store a BST over $\{v_i\}$, where node $i$ stores the furthest vertex from $v_i$ in $P'$. This vertex can be found in $\tilde{O}(1)$ time for each $v_i$ by querying the maximum distance stored in the BST of $v_i$.

For every edge $e \in E$, we need to compute the furthest pair of vertices in the graph $G^e = (V, E \setminus \{e\})$. For an edge $e \in E$ and two vertices $u, v \in G$, we say that the pair $u, v$ is *affected* in $G^e$ if $e$ lies on the root-to-$v$ path in $T_u$. The main idea is to use the fact that a specific pair $u, v$ is affected in at most $D$ (rather than $n$) graphs $G^e$ (since the shortest $u$-to-$v$ path in $G$ has at most $D$ edges).

For every affected pair $(u, v)$ there is some pair of sibling pieces $(P, P')$ s.t. $u \in P$ and $v \in P'$. Our strategy is to go over pairs of sibling pieces $(P, P')$ in $\mathcal{T}$, and handle all affected pairs for each $(P, P')$ together as follows. Assume w.l.o.g. that $e \notin P'$. For each $b \in \partial P'$, we enumerate in $T_b^P$ all the decendant vertices of the edge of $T_b^P$ into which $e$ was contracted (this may be an empty set if $e \notin T_b$). This way we identify all the affected pairs of the form $(u, b)$, where $u \in P$ and $b \in \partial P'$. We query the Baswana et al. oracle for the $u$-to-$b$ distance in $G^e$ for each such affected pair. For each $u \in P$, let $B$ be the set of boundary vertices $b$ such that $(u, b)$ is an affected pair. For each vertex $u \in P$ with $|B| \geq 1$, we update the Voronoi diagram of $u$ w.r.t. $P'$ using the procedure Decremental-VD, which is described in subsection 5.1. This procedure updates the VD (and the furthest vertex from each site) w.r.t the new additive weights in time $\sum_{b \in B} \text{cell-degree}(b)$ where cell-degree is the number of Voronoi cells that are adjacent[4] to the cell $\mathrm{Vor}(b)$ in the original VD (i.e. before the deletion of $e$). Using the updated VD, we update the node corresponding to every $b \in B$ in the BST of $u$ with the new furthest vertex in $\mathrm{Vor}(b)$. Let $d$ be the maximum distance stored in the entire BST of $u$. We update the node corresponding to $u$ in the BST of $P$ with the value $d$. After handling all $u \in P$ with $|B| \geq 1$ in this way, the maximum value stored in the entire BST of $P$ is the maximum distance in $G^e$ between any pair of vertices $(u, v)$ with $u \in P$ and $v \in P'$. Taking the maximum over all pairs of siblings $(P, P') \in \mathcal{T}$ gives the diameter of $G^e$.

[4] Two cells are adjacent if there exists an edge $e$ of $G$ with one endpoint in each cell.

The total running time for computing the furthest pair for the siblings $(P, P')$ is analyzed as follows. The bottleneck is the time to update the VDs. Every time a pair $u, b$ (where $u \in P$ and $b \in \partial P'$) is affected we spend $\tilde{O}(\text{cell-degree}(b))$ time updating the VD of $u$. Since each pair is affected by the deletion of at most $D$ edges, the total time invested in updating VDs for $(P, P')$ is bounded by $\sum_{u \in P, b \in \partial P'} D \cdot \text{cell-degree}(b) = |P|D \sum_b \text{cell-degree}(b)$, which is $\tilde{O}(|P|D \cdot |\partial P'|)$, since the sum of cell-degrees of the cells in a VD is order of the number of sites of the VD. Summing over all pairs of sibling pieces we get that the total time is $\sum_{(P,P') \in \mathcal{T}} \tilde{O}(|P|D \cdot |\partial P'|) = \tilde{O}(n^{1.5}D)$. Hence, including the preprocessing, the total time for the entire replacement diameter algorithm is $\tilde{O}(n^2 + n^{1.5}D)$.

We note that when $D \geq n^{5/6}$, it is better to naively use the static $n^{3+o(1)}/D^2$-time algorithm from section 3.1 for each edge failure. Hence, replacement diameter can be solved in $\min(n^{3+o(1)}/D^2, \tilde{O}(n^2 + n^{1.5}D)) = n^{7/3+o(1)}$ time.

## 6 Incremental Diameter

In this section we prove Theorem 3. Namely, we present a general reduction showing how to solve the diameter problem efficiently in *incremental* graphs given two components: (1) a distance oracle for incremental graphs, and (2) a diameter algorithm for static graphs that is relatively fast when the diameter is large. Plugging in the incremental distance oracle of Das et al. [37] and the static algorithm of Section 3.1 we obtain an algorithm with total time $n^{7/3+o(1)}$ which improves over the naive bound of $\tilde{O}(n^{8/3})$. The new algorithm of this section comes closer to the $n^{2-o(1)}$ lower bound of Section 4 for weighted graphs (the best lower bound for unweighted graphs is $n^{1.5-o(1)}$).

The rest of this section is dedicated to proving this theorem. We begin by presenting the general reduction (that does not assume planarity nor unweighted edges) and then explain how it can be combined with existing algorithms for planar graphs to obtain the theorem.

**A reduction from diameter to $s, t$-shortest path.** In an incremental graph, the diameter decreases with time, starting from some $D \leq n$ (otherwise the graph is not connected and it is easy to check this efficiently) and ending at some $D \geq 1$. The idea for the reduction is simple: we would like to recompute the diameter only when it decreases, and not after each of the $n$ updates. While it is true that the diameter could decrease $\Omega(n)$ times, from $n$ to 1, the point is that re-computation is efficient when the diameter is large (due to the $n^{3+o(1)}/D^2$ algorithm of Section 3.1) and then only $O(D)$ of the re-computations will happen when the diameter is smaller than $D$.

Our incremental algorithm works as follows:

- **Step 1 - sample a new diameter pair:** Let $P = \{(s,t) \mid d(s,t) = \Delta(G)\}$ be the set of pairs that realize the current diameter $\Delta(G)$. Sample a pair $(s', t')$ from $P$ uniformly at random (or from some distribution in which every pair is sampled with probability at most $O(1/|P|)$).
- **Step 2 - monitor the distance of the sampled pair:** Using an incremental distance oracle, monitor the distance between $s'$ and $t'$ throughout the sequence of edge insertions. Do nothing (except querying the oracle) as long as $d(s', t')$ does not decrease; in which case it is still the correct diameter of the graph and can be output whenever there is a query. If a new edge causes $d(s', t')$ to decrease, go back to Step 1.

Each of the two steps involves one of the two ingredients in our reduction. Step 2 utilizes an incremental distance oracle, while Step 1 uses a static diameter algorithm *that can also sample a diameter pair*. At the end of this section we give a general reduction from the

latter approximate sampling problem to the problem of finding the largest distance from each node in the graph (i.e. computing all eccentricities). Alternatively, one could notice that the diameter algorithms we will employ in Step 1 (and many other natural diameter algorithms) can be modified to also sample a diameter pair uniformly at random.

**Running time.** Let us first bound the number of times we go to Step 1, which is the most costly step since it involves a static diameter computation. Step 2 is actually very cheap since we only perform one update and one query to an incremental distance oracle.

▷ Claim 14. For any (non adaptive) sequence of edge insertions that does not decrease the diameter of the graph, the expected number of times our algorithm samples a diameter pair (i.e. goes to Step 1) is $O(\log n)$.

Proof. Let us first analyze the idealistic case in which we manage to sample truly uniformly in Step 1, and then point out that the same analysis essentially goes through when we sample almost uniformly.

Each new edge $e$ decreases the distance for a subset of pairs $X_e \subseteq P$. Since the special pair $(s', t')$ is completely unknown to the adversary who is choosing the sequence of edge insertions, the probability that $e$ causes the algorithm to go to Step 1 is exactly $|X_e|/|P|$ and in that case the new set of "diameter pairs" becomes $P \setminus X_e$. Therefore, the expected number of times we sample can be upper bounded by: $f(|P|) \leq \max_{0 \leq x \leq |P|} x/|P| + f(|P| - x) = O(\log |P|)$.

If the sampling in Step 1 is only approximately uniform, but still satisfies that a pair is chosen with probability at most $O(1/|P|)$ then the same analysis above goes through, up to an additional $O(1)$ factor. ◁

Let $T^{Diam}(n, D)$ denote the running time of a static diameter algorithm that samples a diameter pair as in Step 1, when the diameter of the graph is $D$. Over all the $O(n)$ edge insertions, the total expected running time of Step 1 is therefore at most $\sum_{D=1}^{n} \log n \cdot T^{Diam}(n, D)$.

To obtain our claimed upper bound of $n^{7/3+o(1)}$ we will use two diameter algorithms inside this reduction: the $T^{Diam}(n, D) = n^{3+o(1)}/D^2$ algorithm from Section 3.1 (for large $D$) and the $T^{Diam}(n, D) = \tilde{O}(n^{5/3})$ algorithm [45] (for small $D$). (By the reduction in Section 6.1, these algorithms can also sample an approximately uniform pair as required by Step 1). The total expected time becomes:

$$\sum_{D=1}^{n} \log n \cdot T^{Diam}(n, D) = \tilde{O}\left(\sum_{D=1}^{n^{2/3}} n^{5/3} + \sum_{D=n^{2/3}}^{n} n^{3+o(1)}/D^2\right) = n^{7/3+o(1)},$$

because $\sum_{D=n^{2/3}}^{n} n^{3+o(1)}/D^2 \leq \sum_{i=\log_2 n^{2/3}}^{\log_2 n} 2^{i+1} \cdot n^{3+o(1)}/(2^i)^2 \leq \frac{n^{3+o(1)}}{n^{2/3}} \cdot 2 \log n$. The additional time of Step 2 is at most $n \cdot \sqrt{n}$ using the incremental distance oracle of Das et al. [37] that has $O(\sqrt{n})$ time per update and query.

## 6.1 Sampling a Diameter Pair

In this section we show the final piece of the incremental diameter algorithm. Namely, a way to adapt the aforementioned static diameter algorithms so that they sample a diameter pair approximately uniformly.

A first attempt, that does not quite work, is to add a random "perturbation" $p_e \in (0, \varepsilon)$ to the weight of each edge $e$, where $\varepsilon < 1/D$, and then argue that the (probably unique) pair realizing the diameter in the new graph is a uniformly random pair in $P = \{(s, t) \mid d(s, t) =$

$\Delta(G)\}$. Note that the perturbations increase the distance between all pairs by $< 1$ and therefore non-diameter-pairs cannot become diameter pairs. One issue, however, is that pairs with many paths of length $\Delta(G)$ between them are more likely to be chosen than pairs with few such paths. A second attempt that resolves this issue is to add a perturbation to the nodes (e.g. by appending a private leaf to each node with a random weight on the new edge). This idea is closer to the actual solution but it still has an issue of correlations: a node that participates in many pairs might be sampled less frequently than a node that participates in few pairs. Therefore, we must take this difference into account when assigning the weights.

Making these ideas go through is a bit complicated. Fortunately, there is an elegant reduction from our setting to the *bipartite independet set* query model introduced by Beame et al. [13] and then use existing results on this model [7, 16, 38] in a black-box way.

▶ **Theorem 15.** *There is an algorithm that samples a pair in* $P = \{(s,t) \mid d(s,t) = \Delta(G)\}$ *where each pair is sampled with probability at most* $O(1/|P|)$ *and runs in time* $(\min(\tilde{O}(n^{5/3}), n^{3+o(1)}/D^2))$ *on unweighted planar graphs of diameter* $D$*.*

The main lemma towards proving the theorem is the following.

▶ **Lemma 16.** *By making* $\log^{O(1)} n$ *calls to an algorithm that returns all eccentricities we can sample a pair in* $P = \{(s,t) \mid d(s,t) = \Delta(G)\}$ *where each pair is sampled with probability at most* $O(1/|P|)$

**Proof.** Consider an implicit graph $H$ in which there is an edge between two nodes $s, t$ iff they are a diameter pair in $G$ (i.e., $(s,t) \in P$). Our goal is to sample an edge from $H$ approximately uniformly. This can be achieved [7, 16, 38] by making a polylogarithmic number of queries to an oracle that, given two subsets $L, R \subseteq V(H)$, decides whether there is any edge in $L \times R \cap E(H)$. This is called a bipartite independent set oracle in the literature, following Beame et al. [13]. Thus, all we have to do is show that such a query can be supported in the time of a call to an algorithm that computes all eccentricities in the graph.

First, we precompute the diameter $\Delta(G)$ of $G$. Then, given a query $L, R \subseteq V$ we construct a graph $G'$ from $G$ as follows. For each node $v \in R$ we add a new "leaf" node $l_v$ and connect it with an edge (of weight 1) to $v$. Next, we compute the eccentricity of all nodes in $G'$. Finally, the answer to the query is yes if and only if there is a $u \in L$ such that the eccentricity of $u$ in $G'$ is $\Delta(G) + 1$; this can be checked in $O(n)$ time.

The correctness of the answer follows from the observation that the eccentricity of any node $u$ in $G'$ is $\Delta(G) + 1$ if and only if there is a node $v$ in $G$ such that (1) $d_G(u,v) = \Delta(G)$ and (2) a new leaf node $l_v$ was appended to $v$. This implies that (1) $(u,v) \in P$ is a diameter pair in $G$, meaning that $(u,v) \in E(H)$, and that (2) $v \in L$. Since we only check for $u \in R$ our answer that $L \times R \cap E(H)$ is non-empty is correct. ◀

To conclude the proof of Theorem 15 we simply point out that both of the relevant diameter algorithms already compute the eccentricity of all nodes.

## Abstract

Traditional problems in computational geometry involve aspects that are both discrete and continuous. One such example is nearest-neighbor searching, where the input is discrete, but the result depends on distances, which vary continuously. In many real-world applications of geometric data structures, it is assumed that query results are continuous, free of jump discontinuities. This is at odds with many modern data structures in computational geometry, which employ approximations to achieve efficiency, but these approximations often suffer from discontinuities.

In this paper, we present a general method for transforming an approximate but discontinuous data structure into one that produces a smooth approximation, while matching the asymptotic space efficiencies of the original. We achieve this by adapting an approach called the partition-of-unity method, which smoothly blends multiple local approximations into a single smooth global approximation.

We illustrate the use of this technique in a specific application of approximating the distance to the boundary of a convex polytope in $\mathbb{R}^d$ from any point in its interior. We begin by developing a novel data structure that efficiently computes an absolute $\varepsilon$-approximation to this query in time $O(\log(1/\varepsilon))$ using $O(1/\varepsilon^{d/2})$ storage space. Then, we proceed to apply the proposed partition-of-unity blending to guarantee the smoothness of the approximate distance field, establishing optimal asymptotic bounds on the norms of its gradient and Hessian.

## 1 Introduction

The field of computational geometry has largely focused on computational problems with discrete inputs and outputs. Discrete structures are often used to represent geometric objects that are naturally continuous. Examples include using triangulated meshes to represent smooth surfaces, Voronoi diagrams to represent distance maps, and various spatial partitions for answering ray-shooting queries. Due to the high computational complexities involved, researchers often turn to approximation algorithms. Unfortunately, in retrieval problems, efficient approximation is often achieved at the expense of continuity.

To make this more precise, consider the common example of distance functions. For a given set $S \subseteq \mathbb{R}^d$ (which may be discrete or continuous), a natural *distance map* over $\mathbb{R}^d$ arises as:

$$d_S : x \mapsto \inf_{p \in S} \|x - p\|,$$

where $\|\cdot\|$ denotes the Euclidean norm. In turn, the distance map gives rise to the following query problem. Given a query point $x \in \mathbb{R}^d$, the objective is to compute $d_S(x)$ efficiently from a data structure of low storage.

It is well known that answering the distance query can be reduced to computing the Voronoi diagram of $S$. Unfortunately, beyond special low-dimensional cases, the combinatorial complexity of the Voronoi diagram grows too fast for practical use. For this reason, much work has focused on data structures for approximate nearest neighbor (ANN) searching [7, 9, 21, 23, 24]. Given any $\varepsilon > 0$, an $\varepsilon$-ANN data structure returns a point that is within a factor of $1 + \varepsilon$ of the true closest distance.

While approximate nearest-neighbor searching is clearly related to approximating the distance map, there are fundamental differences between the two problems. The distance map induced by any set is clearly continuous (and indeed it is 1-Lipschitz continuous [12]). As two query points converge on a common location, their respective distances to $S$ must also converge. The same cannot be said for any of the existing approaches based on approximate nearest neighbor searching. The ANN distances reported for two query points can differ by an amount that is arbitrarily larger than the distance between the two query points. In Section 1.1, we will show that this is not merely an artifact of the design of these data structures; it is unavoidable.

Answering distance queries efficiently is key to many applications including motion planning [45], surface reconstruction [3, 26], physical modeling [36], and data analysis [10, 18]. Discontinuities can result in various sorts of aberrant behaviors. This is because queries are generated adaptively in a feedback loop, where answers to earlier queries are used to determine subsequent queries. Consider, for example, a navigation system that is trying to precisely dock two crafts moving in space. Discontinuities in the distance map can alter the behavior of the feedback process, resulting in jittering, oscillations, and even infinite looping (see examples in Section 1.1).

This motivates the main question considered in this paper: Does there exist a data structure that answers distance queries approximately so that the induced distance function is continuous? Ideally, the distance function should also be smooth, characterized by bounds on the norm of its gradient and Hessian. Note that this is quite different from approximate nearest-neighbor searching, where the objective is to find a point that approximates the closest distance. Here, the objective is approximate the distance itself.

Applications of distance queries include collision detection [14], penetration depth [47], robot navigation [31, 42], shape matching [2], and density estimation [32]. Often, the set $S$ arises as a discrete point set obtained by sampling an underlying surface. Implicit representations of surfaces [13], based on approximating the induced distance map, have recently witnessed significant developments based on deep neural networks [16, 22, 37], where the properties of learned distance fields are yet to be fully understood [30, 38].

In this paper we present a general approach for smooth approximation from traditional non-continuous data structures. This is achieved through a process called *blending*, where discrete local approximations are combined to form a smooth function. Our method is loosely based on the *partition-of-unity method* (see, e.g., Melenk and Babuška [34]). The approach involves constructing an open cover of the domain by overlapping patches, computing a local approximation within each patch, and then blending these approximations together by associating a smooth weighting function with each patch (see Section 2 for details).

Unfortunately, a direct adaptation of these methods does not yield an efficient solution. To the best of our knowledge, existing work on partition-of-unity methods for distance approximation have not considered the asymptotic efficiency of the resulting access structures. These works have typically involved blending over relatively simple spatial decompositions, such as grids [40] and balanced quadtrees [35]. The covering elements employed in the blending were naturally fat, that is, *isotropic*. These subdivisions are particularly suitable for blending,

but they lack the flexibility needed to achieve the highest levels of efficiency. Moreover, we are not aware of prior results on the asymptotic interplay between approximation and smoothness. (We refer the interested reader to recent works in the finite element literature on anisotropic [46] and high-dimensional [27] refinements.) In this paper, we adopt the partition-of-unity approach to perform smooth blending for distance maps while achieving asymptotic complexity bounds that match the best existing approximation algorithms. Our results will be presented in Section 1.2.

## 1.1 On Discontinuities and Witnesses

To better understand how discontinuities arise, it is useful to understand the general structure of most data structures for answering distance queries. Space is subdivided into regions, or *cells*. This is either done explicitly by defining the subdivision over the query range or implicitly by viewing the data structure abstractly as a decision tree and associating each leaf of the tree with the subset of query points that land in this leaf due to the search process. Queries are answered by determining the cell (or cells) that are relevant to the answer, and accessing distance information for each cell. When the query point moves from one cell to another, even infinitesimally, different distance information is accessed, and the computed distance may change discontinuously.

For example, consider four point sites $P = \{p_1, p_2, p_3, p_4\}$ in $\mathbb{R}^2$. Suppose that we construct an $\varepsilon$-ANN data structure based on a subdivision into rectangular cells (see Figure 1(a)). We assume that each cell stores a single site of $P$, called a *representative*, that serves as an $\varepsilon$-ANN for every query point lying in this cell, and assume further that the representatives have been chosen as shown in the figure, with $q_i$'s representative being $p_i$. Suppose that a gradient descent algorithm is run using this structure. Starting from an initial position (e.g., $q_i$), the descent takes a step towards the cell's representative ($p_i$). If the representatives and step sizes are chosen as in the figure, the descent could loop infinitely.

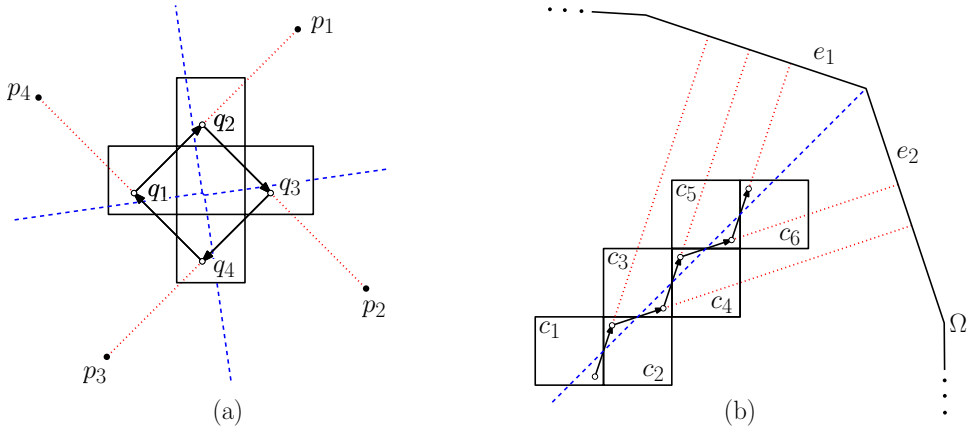

**Figure 1** Problems with witness-based distance approximation: (a) infinite loops and (b) jittering. (The dashed blue lines bound the Voronoi cells of the sites, and the dotted red lines indicate the direction to the closest site.)

In Figure 1(b), we consider another distance function computed with respect to the boundary of a convex object $\Omega$. Cells $c_1$, $c_3$, and $c_5$ are assigned edge $e_1$ as representative, and cells $c_2$, $c_4$, and $c_6$ are assigned $e_2$. If at each point we walk towards the closest edge to the cell's centroid, the path oscillates or "jitters" between the two contenders.

In both of these examples, we assume a standard model in which each cell stores a *witness* to an approximate nearest neighbor, and the distance function returns the distance from the query point to this witness. Let $\mathcal{Q}$ be a function that maps query points to witnesses (presumably based on the cell containing the query point), and let $\widetilde{d}_{\mathcal{Q}}$ denote the induced distance function $\widetilde{d}_{\mathcal{Q}}(x) = \|x - \mathcal{Q}(x)\|$. Such an approach is said to be *witness-based*. The following lemma shows that any witness-based method that fails to be exact cannot be both continuous and accurate with respect to relative errors.

▶ **Lemma 1.** *If a witness-based distance function $\widetilde{d}_{\mathcal{Q}}$ for a finite point set $P \subset \mathbb{R}^d$ is inexact at even one point, it cannot be both continuous and provide a finite bound on relative errors.*

**Proof.** Suppose towards a contradiction that $\widetilde{d}_{\mathcal{Q}}$ is continuous, guarantees a relative error of at most $c$ for some $c > 0$, but there exists a point $x \in \mathbb{R}^d$ such that $\widetilde{d}_{\mathcal{Q}}(x) > d_P(x)$. In particular, we may select an arbitrarily small $\delta > 0$ such that $\widetilde{d}_{\mathcal{Q}}(x) > d_P(x) + \delta$. Let $p \in P$ denote a nearest neighbor of $x$ and consider how the value $\widetilde{d}_{\mathcal{Q}}$ varies as we walk from $x$ to $p$ along the line segment $\overline{xp}$. More precisely, letting $u$ be a unit vector directed from $x$ to $p$, define $x(t) = x + t \cdot u$, and $\widetilde{d}_{\mathcal{Q}}(t) = \widetilde{d}_{\mathcal{Q}}(x(t))$. Except at a finite number of transition points where the witness changes, the derivative of $\widetilde{d}_{\mathcal{Q}}(t)$ with respect to $t$ cannot be smaller than $-1$. (A derivative of $-1$ occurs when we are walking straight towards the current witness, and otherwise it is strictly larger.) Since the function is continuous, its value does not change at transition points. It follows that as we travel a distance of $t \leq d_P(x)$ from $x$ to $p$, the value returned by $\widetilde{d}_{\mathcal{Q}}$ cannot decrease by an amount more than $t$. Setting $t = d_P(x) - \delta/c$, we conclude that

$$\widetilde{d}_{\mathcal{Q}}(x(t)) \;\geq\; \widetilde{d}_{\mathcal{Q}}(x) - t \;>\; (d_P(x) + \delta) - \left(d_P(x) - \frac{\delta}{c}\right) \;=\; \frac{(1+c)\delta}{c}.$$

But, $d_P(x(t)) = d_P(x) - t = \delta/c$, implying that the relative error is

$$\frac{\widetilde{d}_{\mathcal{Q}}(x(t)) - d_P(x(t))}{d_P(x(t))} \;=\; \frac{\widetilde{d}_{\mathcal{Q}}(x(t))}{d_P(x(t))} - 1 \;>\; \frac{(1+c)\delta}{c} \cdot \frac{c}{\delta} - 1 \;=\; (c+1) - 1 \;=\; c,$$

a contradiction. ◀

## 1.2 Main Result

For the sake of concreteness, we will illustrate our approach to producing smooth approximate distance functions in a specific application which is fairly simple, but still new. Let $\Omega$ denote a convex polytope in $\mathbb{R}^d$, and let $\mathrm{diam}(\Omega)$ denote its diameter and $\partial\Omega$ its boundary. We further assume that $\Omega$ is represented as the intersection of $n$ halfspaces. Given a point $x \in \Omega$, we define the *boundary distance function* $d_{\partial\Omega}(x)$ as the Euclidean distance to $x$'s closest point on $\partial\Omega$. To simplify notation, we will refer to this as $d_\Omega(x)$ (see Figure 2(a)). Our objective is to efficiently evaluate an $\varepsilon$-approximation $\widetilde{d}_\Omega$ for any given query $x \in \Omega$, while guaranteeing smoothness (i.e., continuity and norm bounds on the gradient and Hessian).

By convexity, if $x$ lies in $\Omega$'s interior, $\mathrm{int}(\Omega)$, its closest point on the boundary lies on one of $\Omega$'s facets, that is, its faces of dimension $d-1$. Thus, in the exact setting, the distance map is determined by the Voronoi diagram of $\Omega$'s facets. The skeleton of this Voronoi diagram is known as the *medial axis* or *medial diagram* of $\Omega$ [17, 19, 41]. While the combinatorial complexity of the medial axis is $O(n)$ in $\mathbb{R}^2$, it grows much faster in higher dimensions. It is not hard to show that medial axis corresponds to the lower-envelope of $n$ hyperplanes in $\mathbb{R}^{d+1}$, with a combinatorial complexity of $\Theta(n^{\lceil d/2 \rceil})$ in the worst case [33].

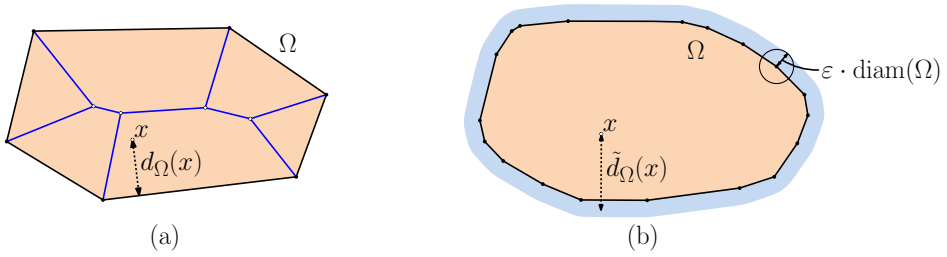

**Figure 2** (a) The medial axis of $\Omega$ and the boundary distance function $d_\Omega$ and (b) approximating the boundary distance in terms of absolute errors with parameter $\varepsilon > 0$.

The obvious discrete analog to our problem is approximate polytope membership, where the data structure merely indicates whether the query point lies inside or outside the polytope, up to a Hausdorff error of $\varepsilon \cdot \mathrm{diam}(\Omega)$ (see Figure 2(b)). In recent work, it was shown that this problem can be solved in query time $O(\log(1/\varepsilon))$ from a data structure using $O(1/\varepsilon^{(d-1)/2})$ of space [1, 5].

In this paper, we show how to apply the partition-of-unity method to evaluate an absolute $\varepsilon$-approximate boundary distance function $\widetilde{d}_\Omega$ for a convex polytope $\Omega$ in a manner that guarantees smoothness while nearly matching the query times achieved in approximate membership queries. Specifically, we require that $|\widetilde{d}_\Omega(x) - d_\Omega(x)| \leq \varepsilon \cdot \mathrm{diam}(\Omega)$, for all $x \in \mathrm{int}(\Omega)$. Throughout we treat $\varepsilon$ as an asymptotic quantity, and assume the dimension $d$ is a constant. Our main result is:

▶ **Theorem 2.** *Given a convex polytope $\Omega$ and an approximation parameter $\varepsilon > 0$, there exists a smooth function $\widetilde{d}_\Omega$ satisfying $d_\Omega(x) \leq \widetilde{d}_\Omega(x) \leq d_\Omega(x) + \varepsilon \cdot \mathrm{diam}(\Omega)$ for all $x \in \Omega$, which can be evaluated along with its gradient from a data structure with*

$$\textit{Query time} \;=\; O(\log(1/\varepsilon)) \qquad \textit{and} \qquad \textit{Storage} \;=\; O(1/\varepsilon^{d/2}).$$

*Further, the norms of the gradient and Hessian of $\widetilde{d}_\Omega$ satisfy*

$$\left\|\nabla \widetilde{d}_\Omega(x)\right\| \;=\; O(1) \qquad \textit{and} \qquad \left\|\nabla^2 \widetilde{d}_\Omega(x)\right\| \;=\; O\left(\frac{1}{\varepsilon}\right).$$

Observe that this is almost as good as the best query and space times for approximate polytope membership [1, 5], suffering just an additional factor $1/\sqrt{\varepsilon}$ in the space bound. Our data structure can be viewed as incorporating blending into the data structure of [1]. While we assume that the query point lies within $\Omega$, if this is not the case and $x$ is at distance at least $\varepsilon \cdot \mathrm{diam}(\Omega)$ outside, the data structure will report this. If $x$ is external to $\Omega$ but is closer than this to the boundary, it may erroneously report an answer to the query. Our focus is on the existence of the data structure, but through the use of known constructions, it can be built in time $O(n/\varepsilon^{O(d)})$, where $n$ denotes the number of facets of the polytope.

Let us remark on the bounds on the norms of the gradient and Hessian. Clearly, in any Euclidean distance field the directional derivative of the distance field is as high as 1 (when moving directly towards or away from the nearest point) and is never greater, that is, $\|\nabla d_\Omega(x)\| \leq 1$. Therefore, it is reasonable that the norm of our approximate function, $\|\nabla \widetilde{d}_\Omega(x)\|$, is $O(1)$. The following lemma shows that the $O(1/\varepsilon)$ upper bound on the norm of the Hessian is a necessity, up to constant factors. It establishes a lower bound in the context of a relative errors for approximating the distance to a discrete point set, but the result can be adapted to our context as well.

▶ **Lemma 3.** *Fix a set of points $P \subset \mathbb{R}^d$, and let $\mathcal{Q}$ be a smooth $\varepsilon$-approximate distance query structure over $P$ with the associated distance $\widetilde{d}_{\mathcal{Q}}$, for any $\varepsilon > 0$ bounding the relative error. If $|P| > 1$, then there exists a point $x \in \mathbb{R}^d$ such that $\left\|\nabla^2 \widetilde{d}_{\mathcal{Q}}(x)\right\| \geq 1/\varepsilon$.*

**Proof.** Given a function $f : \mathbb{R}^d \to \mathbb{R}$ and $\gamma \geq 0$, the assertion $\|\nabla f(a) - \nabla f(b)\| \leq \gamma$ is equivalent to saying that $\nabla f$ is $\gamma$-Lipschitz, that is, $\|\nabla f(a) - \nabla f(b)\| \leq \gamma \cdot \|a - b\|$, for all $a, b \in \mathbb{R}^d$. Letting $f := \nabla \widetilde{d}_{\mathcal{Q}}$, we will show that $f$ is $\gamma$-Lipschitz with $\gamma \geq 1/\varepsilon$.

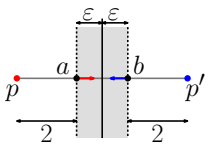

**Figure 3** Proof of Lemma 3.

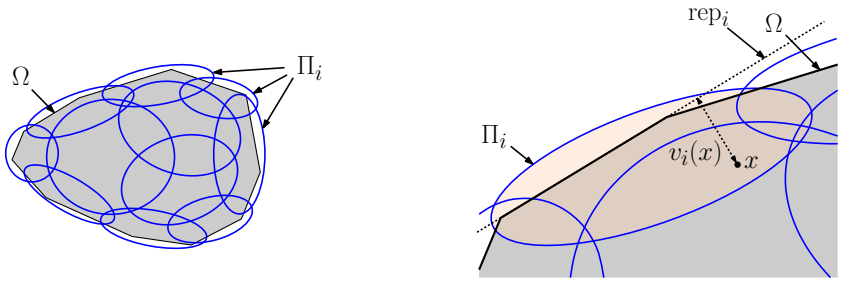
Consider two sites $p$ and $p'$ such that $\|pp'\| = 2(2 + \varepsilon)$ (see Figure 3). Select points $a$ and $b$ along the segment $pp'$ on opposite sides and at distance $\varepsilon$ from the perpendicular bisector. Observe that a query point placed at any point on the open segment $pa$ must return $p$ as the answer, since otherwise the relative error would exceed $((2 + 2\varepsilon) - 2)/2 = \varepsilon$. This holds symmetrically for $p'b$. It follows that $\nabla f(a)$ and $\nabla f(b)$ are unit vectors pointing to the right and left, respectively. Hence, $\|\nabla f(a) - \nabla f(b)\|/\|a - b\| = 2/2\varepsilon = 1/\varepsilon$, as desired. ◀

The remainder of the paper is organized as follows. In the next section we present an overview of the partition-of-unity approach. In Section 3 we present an efficient data structure for answering approximate distance queries for a convex polytope $\Omega$, but without continuity. Finally, in Section 4, we combine these to obtain the desired smooth approximation.

## 2 Blending and Partition of Unity

The partition of unity is a standard mathematical tool for integrating local constructions into global ones [29, 40]. It is widely used and has applications in various disciplines [34, 35]. The approach involves a collection of *patches* $\Pi = \{\Pi_i\}$ forming a locally-finite open cover of a given domain $\Omega \subseteq \mathbb{R}^d$. The partition of unity is a set of non-negative smooth *partition functions* $\{\phi_i\}$ such that the support of $\phi_i$, denoted $\mathrm{supp}(\phi_i)$, is a subset of $\Pi_i$ (see Figure 4(a)). The name derives from the requirement that for all $x \in \Omega$, $\sum_i \phi_i(x) = 1$.



(a) (b)

**Figure 4** Patches, representatives, and the partition of unity.

In the context of distance approximation, let us assume that each patch is associated with a *local distance function* $v_i$, such that the restriction of $v_i$ to $\Pi_i$ is an $\varepsilon$-approximation to the true distance function $d_\Omega$. Concretely, each patch is associated with a *representative*,

denoted $\text{rep}_i$. For example, when approximating the distance to a discrete point set $P$, $\text{rep}_i$ may be a point $p \in P$. In our case, where $\Omega$ is a convex polytope, $\text{rep}_i$ will be chosen to be a supporting hyperplane of a facet of $\Omega$ (see Figure 4(b)). Then, $v_i(x)$ can be defined to be distance from $x$ to the associated representative,

$$v_i(x) \;=\; \text{dist}(x, \text{rep}_i). \tag{1}$$

The final approximate distance map results by taking the sum of these local distance functions over all patches weighted by the associated partition functions.

$$\widetilde{d}_\Omega(x) \;=\; \sum_i \phi_i(x) \cdot v_i(x). \tag{2}$$

Recall that the support of $\phi_i$ is limited to $\Pi_i$, so we need only compute the sum over patches containing $x$. Define the *depth* of $x$ with respect to $\Pi$, denoted $\Delta_\Pi(x)$, to be the number of patches of $\Pi$ containing $x$, and define $\Delta_\Pi = \max_x \Delta_\Pi(x)$. As in standard applications of the partition-of-unity method, we will design our patches so that $\Delta_\Pi$ is $O(1)$.

In order to enforce the condition that the functions $\phi_i$ sum to unity at any point in the domain, we will define a set of smooth, non-negative *weight functions* $\{\psi_i\}$, and then define

$$\phi_i(x) \;=\; \frac{\psi_i(x)}{\Psi(x)}, \text{ where } \Psi(x) = \sum_i \psi_i(x). \tag{3}$$

Observe that since $\widetilde{d}_\Omega(x)$ is a convex linear combination of functions, each of which is locally an $\varepsilon$-approximate distance map for $\Omega$, it follows that $\widetilde{d}_\Omega(x)$ is itself an $\varepsilon$-approximate distance map. Our construction will guarantee that there exists a positive constant $\Psi_{\min}$, such that $\Psi(x) > \Psi_{\min}$, for all $x \in \Omega$. It follows that $\phi_i(x)$ can be made as smooth as desired, being the quotient of two positive continuous functions. Assuming that the local distance approximations $\{v_i\}$ are smooth, it follows that $\widetilde{d}_\Omega$ is itself smooth, being a sum of products of pairs of continuous functions. As a 1-dimensional example, see Figure 5.

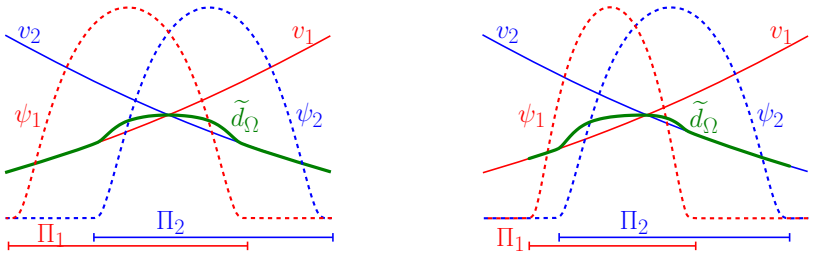


**Figure 5** Blending two distance functions $\{v_i\}$ using two overlapping intervals $\{\Pi_i\}$ with associated weight functions $\{\psi_i\}$, yielding a smooth approximation $\widetilde{d}_\Omega$ using (a) symmetric covers and (b) non-symmetric covers.

It remains to define the weight function $\psi_i$ associated with each patch. These functions depend on the patch's shape. For our application, patches will be ellipsoids, but for this introduction, let us consider the simple case of a Euclidean ball with center point $c_i$ and radius $r_i$. First, for $x \in \mathbb{R}^d$, define

$$f_i(x) \;=\; \frac{1}{r_i^2}\|x - c_i\|^2.$$

Observe that $f$ achieves its minimum value of 0 at the ball's center and grows to 1 at its boundary. To obtain a compactly-supported weight function, we use the standard technique of composing $f$ with a bump function, also known as the *standard mollifier* [39]

$$\mu(\sigma) \;=\; \begin{cases} \exp\left(-\dfrac{1}{1-\sigma^2}\right) & \text{if } |\sigma| < 1, \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

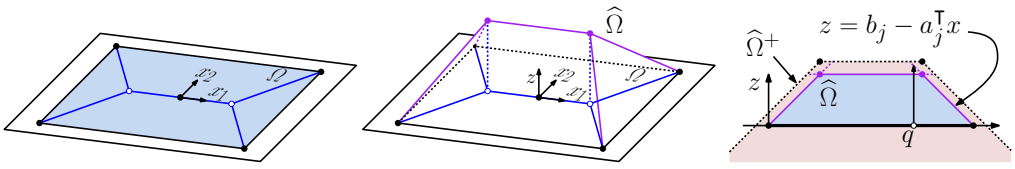
Since $\mu(0) = e^{-1}$ and $\mu(1) = 0$, we see that the weight is highest near the middle of the shape, where $f = 0$, and decays gracefully towards the boundary, where $f = 1$. It is well-known that $\mu \in C_c^\infty(\mathbb{R})$ and is non-analytic with vanishing derivatives for $|\sigma| = 1$ [39]. Therefore, we may define $\psi_i(x) = \mu(f_i(x))$.

In summary, given any query point $x$, we first determine the patches that contain it. (The number of which, $\Delta_\Pi(x)$, will be bounded by a constant.) Given the shape functions $f_i$ for each of these patches, we compute the weight functions $\psi_i$'s by applying the mollifier of Eq. (4). We then apply Eq. (3) to obtain the partition-of-unity blending functions. Finally, we apply Eqs. (1) and (2) to obtain the final smooth distance approximation. The overall space and query time are dominated by the total number of patches and the time needed to determine which patches contain the query point, respectively.

## 3 Approximating the Boundary Distance Function

The process described in the previous section is generic and can be applied in settings where the answer to the query can be expressed in terms of a covering of space by regions of low combinatorial complexity. For the sake of illustration, let us now explore how this works in the specific application of computing a smooth absolute $\varepsilon$-approximation to the boundary distance in a convex polytope $\Omega$ in $\mathbb{R}^d$. Let us assume that $\Omega$ has been scaled uniformly to unit diameter, so the absolute approximation error is $\varepsilon$.

We will employ a standard method for reducing distance approximation to a covering problem. First, let's consider the *graph* of the boundary distance function $d_\Omega$, that is, the manifold $(x, d_\Omega(x))$ in $\mathbb{R}^{d+1}$. We will use $z$ to denote coordinate values along the $(d+1)$st coordinate axis, which we will take to be directed vertically upwards in our drawings (see Figure 6(b) and (c)).



(a) (b) (c)

**Figure 6** Lifting the polytope $\Omega \subseteq \mathbb{R}^d$ to the lifted body $\widehat{\Omega} \subseteq \mathbb{R}^{d+1}$.

Assuming that the polytope $\Omega$ contains the origin in its interior, it can be represented as the intersection of a set of $n$ halfspaces in $\mathbb{R}^d$, $\Omega = \bigcap_{j=1}^n H_j$, with each $H_j$ taking the form

$$H_j \;=\; \{x \in \mathbb{R}^d \,:\, a_j^\intercal x \leq b_j\},$$

where $a_j \in \mathbb{R}^d$ is an outward-pointing unit normal vector orthogonal to $H_j$'s bounding hyperplane and $b_j \in \mathbb{R}^+$ is the distance of the bounding hyperplane from the origin. The distance of a point $x \in \Omega$ to the bounding hyperplane is the non-negative scalar $z$ such that

$x + za_j$ lies on the bounding hyperplane, that is $z = b_j - a_j^\intercal x$. The set of points lying below this surface (that is, the hypograph of the distance function) is the halfspace in $\mathbb{R}^{d+1}$ given by the linear inequality $z \leq b_j - a_j^\intercal x$. The boundary distance function is just the lower envelope (or minimization diagram [25]) of this set of halfspaces. To turn this into a bounded convex polytope, we add a horizontal ground-surface halfspace $\widehat{H}_0 = \{(x; z) : z \geq 0\}$. Define the *lifted body* $\widehat{\Omega} \subset \mathbb{R}^{d+1}$ to be

$$\widehat{\Omega} \;=\; \widehat{H}_0 \cap \bigcap_{j=1}^{n} \widehat{H}_j, \quad \text{where } \widehat{H}_j = \{(x; z) \in \mathbb{R}^{d+1} \,:\, z \leq b_j - a_j^\intercal x\} \text{ for } j \in [n].$$

Since the sides have a slope of $+1$, the diameter of $\widehat{\Omega}$ is $O(1)$.

To achieve an absolute approximation error of at most $\varepsilon$, we lift each of the upper halfspaces of $\widehat{\Omega}$ by a vertical distance of $+\varepsilon$ to obtain the resulting expanded object $\widehat{\Omega}^+$. That is, we define $\widehat{H}_j^\delta = \{(x; z) \in \mathbb{R}^{d+1} \,:\, z \leq b_j - a_j^\intercal x + \delta\}$ and $\widehat{\Omega}^+ = \bigcap_{j=1}^n \widehat{H}_j^\varepsilon$ (see Figure 6(c)). Note that the ground-surface halfspace ($\widehat{H}_0$) is not needed for $\widehat{\Omega}^+$, and hence it is unbounded. The essential features of lifting and expansion are summarized in the following lemma.

▶ **Lemma 4.** *Given a convex polytope $\Omega$ of unit diameter and any $x \in \Omega$, if a vertical ray is shot upwards from $x$ (viewed as a point in $\mathbb{R}^{d+1}$) hits a bounding hyperplane of $\widehat{\Omega}$ within $\widehat{\Omega}^+$, then the associated facet of $\Omega$ is an absolute $\varepsilon$-approximate nearest neighbor of $x$.*

The upshot is that we can base the local distance functions $v_i(x)$ (recall Eq. (1)) on the distance to the bounding hyperplane of $\Omega$ corresponding to the bounding hyperplane in the lifted body $\widehat{\Omega}$ that is hit by the vertical ray shot upwards from the query point $x$. An important feature of $\widehat{\Omega}^+$, which will be of later use (in Lemma 8), is that the distance between its boundary and that of $\widehat{\Omega}$ is at least $c\varepsilon \cdot \mathrm{diam}(\widehat{\Omega})$, for some constant $c$.

## 3.1 Macbeath Regions and Ellipsoids

Our approach to approximating $\widehat{\Omega}$ for the purpose of answering distance map queries will be based on generating a net-like covering of $\widehat{\Omega}$ based on objects called *Macbeath regions*. Macbeath regions and their variants have been widely used in convex approximation (see, e.g., [1, 4, 6–8]). In contrast to traditional covers based on subdivisions by fat objects, e.g., hypercubes, Macbeath regions naturally adapt to the shape of the object being covered. In this section we present a brief review of the salient features of Macbeath regions.

Given a convex body $\Omega$ and any point $x \in \Omega$, the *Macbeath region* at $x$ is the largest centrally-symmetric body centered at $x$ and contained within $\Omega$. It is common to apply a constant scaling factor. Formally, for $\lambda \in \mathbb{R}^+$, the *$\lambda$-scaled Macbeath region* at $x$ is

$$M_\Omega^\lambda(x) \;=\; x + \lambda((\Omega - x) \cap (x - \Omega))$$

(see Figure 7(a)). When $\Omega$ is clear from context, we will often omit the subscript. We refer to $x$ and $\lambda$ as the *center* and *scaling factor* of $M^\lambda(x)$, respectively. When $\lambda < 1$, we say $M^\lambda(x)$ is *shrunken*.

It is useful to have a low-complexity, smooth proxy for a Macbeath region. Given a Macbeath region, define its associated *Macbeath ellipsoid* $E_\Omega^\lambda(x)$ to be the maximum-volume ellipsoid contained within $M_\Omega^\lambda(x)$ (see Figure 7(b)). Clearly, this ellipsoid is centered at $x$, and $E_\Omega^\lambda(x)$ is a $\lambda$-factor scaling of $E_\Omega^1(x)$ about $x$. By John's Theorem [11]

$$E_\Omega^\lambda(x) \;\subseteq\; M_\Omega^\lambda(x) \;\subseteq\; E_\Omega^{\lambda\sqrt{d}}(x).$$

Chazelle and Matoušek showed that this ellipsoid can be computed for a convex polytope $\Omega$ in time linear in the number of its bounding halfspaces [15].

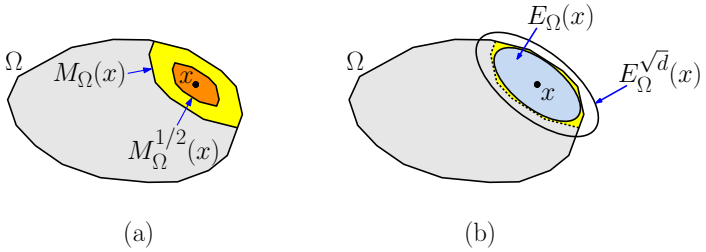


**Figure 7** (a) Macbeath regions and (b) Macbeath ellipsoids.

A fundamental property of Macbeath regions, called *expansion-containment*, states that if two shrunken Macbeath regions (or ellipsoids) overlap, then a constant-factor expansion of one contains the other. There are many formulations. The following can be found in [1].

▶ **Lemma 5** (Expansion-Containment). *Given a convex body* $\Omega \in \mathbb{R}^d$, $0 < \lambda < 1$, *let* $\beta = (3+\lambda)/(1-\lambda)$. *Then for any* $x, y \in \Omega$*:*
*(i)* $M^\lambda(x) \cap M^\lambda(y) \neq \emptyset \implies M^\lambda(y) \subseteq M^{\beta\lambda}(x)$,
*(ii)* $E^\lambda(x) \cap E^\lambda(y) \neq \emptyset \implies E^\lambda(y) \subseteq E^{\beta\lambda\sqrt{d}}(x)$.

## 3.2 Approximation through Covering

Our approach to computing an $\varepsilon$-approximation to the boundary distance function within a convex polytope $\Omega$ in $\mathbb{R}^d$ utilizes Macbeath regions to cover the lifted body $\widehat{\Omega}$ in $\mathbb{R}^{d+1}$. Recall our assumption that $\Omega$ has been scaled to unit diameter, and hence the lifted body $\widehat{\Omega}$ also has unit diameter. Given this scaling, our objective is to answer vertical ray-shooting queries up to an absolute error of at most $\varepsilon$, (see Lemma 4).

Before presenting our solution, let us recall some known results for convex approximation. Given a convex body $\Omega$ of unit diameter and $\varepsilon > 0$, an *$\varepsilon$-approximate polytope membership query* is given a query point $q$ and returns positive answer if $q$ lies within $\Omega$, a negative answer if $q$ lies at distance more than $\varepsilon$ from $\Omega$, and otherwise, it may give either answer. Arya *et al.* presented an efficient data structure for answering approximate membership queries [7]. Later, Abdelkader and Mount [1] presented a simpler approach with the same space and query times, as described in the following lemma. We will employ a variant of the latter data structure.

▶ **Lemma 6.** *Given a convex polytope* $\Omega \in \mathbb{R}^d$, *there exists a data structure that can answer absolute* $\varepsilon$*-approximate polytope membership queries for* $\Omega$ *in time* $O(\log(1/\varepsilon))$ *and storage* $O(1/\varepsilon^{(d-1)/2})$.

In order to apply this data structure for our purposes, we will need to delve a bit deeper into how it works. Our application of this structure will be in the lifted space $\mathbb{R}^{d+1}$, but let us describe it now for an arbitrary convex body $\Omega$ in $\mathbb{R}^d$. Given a non-negative parameter $\delta$, define the *expanded body* $\Omega_\delta$ to be a convex set such that $\Omega \subseteq \Omega_\delta$, and the minimum distance between their boundaries of is at least $\delta$.

Next, we define the notion of a *Macbeath-based Delone set* of $\Omega$ relative to $\Omega_\delta$. This structure is parameterized by two constants $0 < \lambda_p < \lambda_c < 1$, called the *packing* and *covering* constants, respectively (which may depend on the dimension $d$). Given any point $x \in \Omega$, define the *covering ellipsoid* $E'_\delta(x) = E^{\lambda_c}_{\Omega_\delta}(x)$, that is, a Macbeath ellipsoid centered at $x$ with scaling factor $\lambda_c$ defined with respect to the outer body $\Omega_\delta$. Define the *packing ellipsoid* $E''_\delta(x)$ analogously, but with a scaling factor of $\lambda_p$. A *Macbeath-based Delone set* for $\Omega$

relative to $\Omega_\delta$ is any maximal set of points $X \subset \Omega$, such that the packing ellipsoids $E''_\delta(x)$ centered at these points are pairwise disjoint. Abdelkader and Mount [1] showed that, by standard properties of Macbeath regions, constants $\lambda_p$ and $\lambda_c$ can be chosen such that $X$ has the following properties:

**(i)** The union of the covering ellipsoids $E'_\delta(x)$ over all $x \in X$ covers the original body, $\Omega$,
**(ii)** For each $x \in X$, $E'_\delta(x)$ is contained within the expanded body, $\Omega_\delta$,
**(iii)** The number of ellipsoids $E'_\delta$ that contain any point $x$ is $O(1)$,
**(iv)** $|X| = O(1/\delta^{(d-1)/2})$.

Note that the constant factors hidden in the $O$-notation depend on the dimension $d$.

To turn this into an approximate search structure, a layered DAG is constructed as follows. For $i \geq 0$, let $\delta_i = 2^i\delta$. Construct a series of such Delone sets, $X_0, X_1, \ldots, X_m$ where $X_i$ is any Macbeath-based Delone set of $\Omega$ with respect to $\Omega_{\delta_i}$. As $i$ increases, the expanded body grows larger, and hence the Macbeath ellipsoids also grow larger. But since they need only cover the original body $\Omega$, their size, $|X_i|$, decreases with $i$. The final layer $\ell_m$ is defined to be the smallest integer such that $|X_{\ell_m}| = 1$. (It can be shown that $\ell_m = O(\text{diam}(\Omega)) = O(1)$, which implies that $m = O(\log(1/\delta))$.) The leaves of the DAG correspond to the covering ellipsoids $E'_{\delta_0}$ centered at the points of $X_0$. The root is corresponds to the covering ellipsoid $E'_{\delta_{\ell_m}}$ associated with the single point of $X_{\ell_m}$ (see Figure 8). Finally, the nodes of level $i$ are connected to nodes at level $i-1$ whenever their associated $E'$ ellipsoids overlap. Abdelkader and Mount [1] showed the following:

- The DAG has $O(\log(1/\varepsilon))$ layers.
- The out-degree of any node in the DAG is $O(1)$.
- The total number of nodes in the DAG is $O(1/\delta^{(d-1)/2})$.

Lemma 6 follows by applying a natural search process which simply descends from the root to any leaf in the DAG, always visiting a node whose $E'$ ellipsoid contains the query point. If a query point $x \in \Omega$, the search will succeed in finding a leaf-level ellipsoid $E'$ that contains this point.

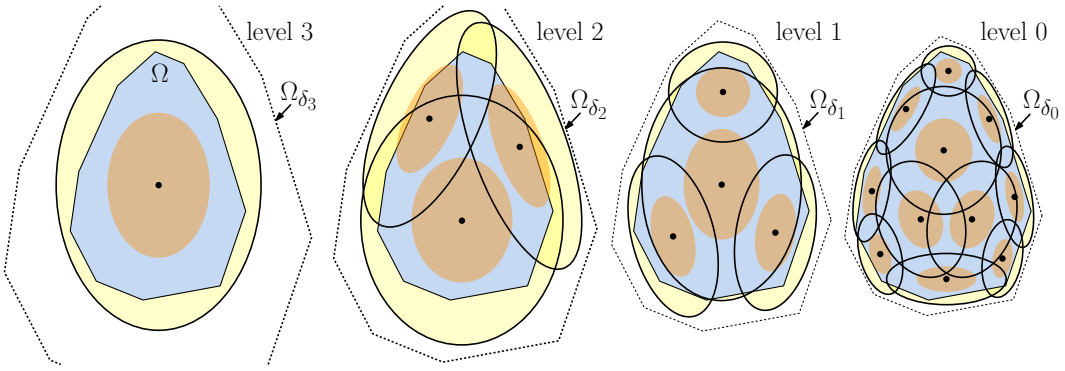

**Figure 8** Layers of the Macbeath-based Delone set data structure.

## 3.3 Approximation through Vertical Ray Shooting

We can now explain how to construct the smooth boundary distance approximation for $\Omega$. First, we construct the lifted body $\widehat{\Omega}$, as described in Section 3. Given a query point $x \in \Omega$, its distance to the boundary is determined by the height of the point on $\partial\widehat{\Omega}$ hit by an upward-directed vertical ray shot from $x$ in $\mathbb{R}^{d+1}$. To apply the hierarchical search, let $\delta = \varepsilon$,

and for any $\ell \geq 0$, define $\widehat{\Omega}_{\delta_\ell}$ to be the unbounded convex set that results by translating all the upper halfspaces bounding $\widehat{\Omega}$ up by distance $\delta_\ell = 2^\ell \varepsilon$. That is, $\widehat{\Omega}_{\delta_\ell} = \bigcap_{j=1}^{n} \widehat{H}_j^{\delta_\ell}$. Observe that $\widehat{\Omega}_{\delta_0} = \widehat{\Omega}^+$, the $\varepsilon$-expanded body.

We can apply the data structure described in Lemma 6 to these bodies in $\mathbb{R}^{d+1}$. For any level of the structure, we say that a covering ellipsoid is a *top ellipsoid* if there exists $x \in \Omega$, such that this ellipsoid has the highest intersection point with the vertical ray directed up from $x$ among all the ellipsoids in the cover. Because the covering ellipsoids cover $\widehat{\Omega}$ it follows that the union of the top ellipsoids, when projected vertically onto $\mathbb{R}^d$, covers the original body $\Omega$.

To answer vertical ray-shooting queries using our hierarchy, we traverse the hierarchy of ellipsoids, but whenever we descend a level in the DAG structure, among all the nodes whose covering ellipsoid $E'$ intersects the vertical line segment passing through $x$, we visit the one having the highest point of intersection with the ray (see Figure 9). It was shown in [1] that the number of ellipsoids that need to be considered is $O(1)$. Therefore, in time proportional to the number of levels, which is $O(\log(1/\varepsilon))$, we can find the top ellipsoid at the leaf level traversed by the vertical ray.

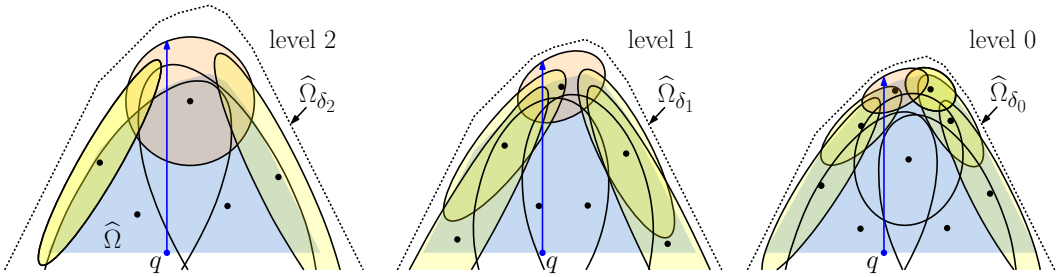

**Figure 9** Vertical ray-shooting in the hierarchical structure.

Furthermore, because all these ellipsoids lie within $\widehat{\Omega}_{\delta_0}$, the terminus of the vertical ray lies within the vertical gap of length $\varepsilon$ between $\widehat{\Omega}$ and $\widehat{\Omega}^+$, as required in Lemma 4. Finally, through an appropriate adjustment of the scaling factors $\lambda_p$ and $\lambda_c$, we can apply the same analysis as in Arya *et al.* [4, Lemma 3.5] to find a witness hyperplane that serves as the representative for all vertical rays passing through this ellipsoid. Since the construction is performed in $\mathbb{R}^{d+1}$, the space required is $O(1/\varepsilon^{d/2})$. This implies that, even ignoring continuity, we can answer $\varepsilon$-approximate boundary distance queries efficiently.

▶ **Theorem 7.** *Given a convex polytope $\Omega \in \mathbb{R}^d$, there exists a data structure that can answer absolute $\varepsilon$-approximate boundary distance queries (without continuity guarantees) for $\Omega$ in time $O(\log(1/\varepsilon))$ and storage $O(1/\varepsilon^{d/2})$.*

There are a couple of additional properties, which will be useful for the task of computing smooth distance approximations. First, because the boundaries of $\widehat{\Omega}$ and $\widehat{\Omega}^+$ are separated by a vertical distance of $\varepsilon$, we can infer that the Macbeath ellipsoids cannot be too skinny.

▶ **Lemma 8.** *Each of the covering Macbeath ellipsoids in the data structure of Theorem 7 contains a Euclidean ball at its center of radius at least $c\varepsilon$, for some constant $c$ (depending on $\lambda_c$ and $d$).*

**Proof.** The centers lie within $\widehat{\Omega}$, and Macbeath regions are defined with respect to $\widehat{\Omega}^+$ whose boundary has a vertical separation of $\varepsilon$. Because the distance function is 1-Lipschitz continuous, the sides of both of these bodies have a slope (with respect to vertical) of at

most 1. Hence, the distance from any point in $\widehat{\Omega}$ to the boundary of $\widehat{\Omega}^+$ is at least $\varepsilon/\sqrt{d}$. Therefore, the scale-1 Macbeath region contains a ball of this radius at its center. The covering Macbeath region has a ball of radius $\varepsilon(\lambda_c/\sqrt{d})$. The John ellipsoid contains a ball of radius $\varepsilon(\lambda_c/\sqrt{d})/\sqrt{d} = \varepsilon(\lambda_c/d)$. Setting $c = \lambda_c/d$, completes the proof. ◀

Second, from the properties of the Macbeath-based Delone set, each point of $\widehat{\Omega}$ is covered by only a constant number of the covering ellipsoids at the leaf level. While this does not necessarily hold for the vertical projections of these ellipsoids, it does hold when we restrict attention to the top ellipsoids. Let $\Delta_\Pi$ denote maximum number of ellipsoids that may contain any given point $x \in \Omega$.

▶ **Lemma 9.** *The blending patches* $\Pi$ *resulting from the vertical projections of the top covering ellipsoids have constant depth, that is,* $\Delta_\Pi = O(1)$.

Before giving the proof, we establish a useful technical lemma. Let us begin with some notation. Given a concave function $f : \mathbb{R}^d \to \mathbb{R}$, its *hypograph*, denoted $f^-$, is the set of points in $\mathbb{R}^{d+1}$ lying on or below the function. Clearly, $f^-$ is a convex set. For any point $x \in f^-$, define the *ray distance* of $x$ with respect to $f^-$, denoted $\text{ray}_{f^-}(x)$ to be the length of a ray shot upwards from $x$ to the boundary of $f^-$. For any $x \in f^-$ and $\lambda \geq 0$, define $M^\lambda_{f^-}(x)$ as the $\lambda$-scaled Macbeath region relative to $f^-$. We omit explicit references to $f^-$ in subscripts when it is clear from context.

▶ **Lemma 10.** *Given concave* $f : \mathbb{R}^d \to \mathbb{R}$, $x \in f^-$ *and* $\lambda \geq 0$, *for all* $y \in M^\lambda_{f^-}(x)$,

$$(1-\lambda)\cdot \text{ray}_{f^-}(x) \;\leq\; \text{ray}_{f^-}(y) \;\leq\; (1+\lambda)\cdot \text{ray}_{f^-}(x).$$

**Proof.** To simplify notation, let $r_x = \text{ray}_{f^-}(x)$ and $r_y = \text{ray}_{f^-}(y)$. To prove the upper bound, let $x'$ denote the intersection of the vertical ray through $x$ with the boundary of $f^-$ (see Figure 10(a)). Consider a supporting hyperplane $h_0$ for $f^-$ passing through $x'$. Let $h_1$ be the parallel supporting hyperplane passing through $x$, and let $h_2$ be the parallel supporting hyperplane along the lower side of $M^\lambda(x)$. Clearly, the vertical distance between $h_0$ and $h_1$ is $r_x$, and the vertical distance between $h_1$ and $h_2$ is $\lambda r_x$. Since $M^\lambda(x)$ lies entirely above $h_2$, it follows that the vertical segment defining $r_y$ lies entirely below $h_0$ and above $h_2$, which implies that $r_y \leq r_x + \lambda r_x = (1+\lambda)r_x$, as desired.

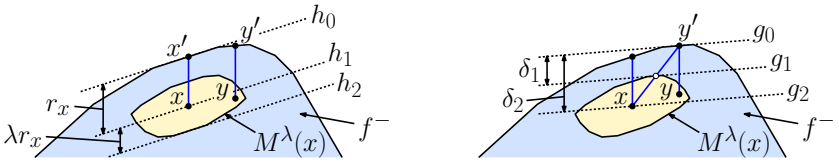

**Figure 10** Proof of Lemma 10.

To prove the lower bound, let $y'$ denote the point where the vertical ray through $y$ intersects the boundary of $f^-$ (see Figure 10(b)). Let $g_0$ denote a supporting hyperplane for $f^-$ passing through $y'$. Let $g_1$ be the upper parallel supporting hyperplane for $M^\lambda(x)$, and let $g_2$ be the parallel hyperplane passing through $x$. Let $\delta_1$ denote the vertical distance between $g_0$ and $g_1$, and let $\delta_2$ denote the vertical distance between $g_0$ and $g_2$. By definition of the Macbeath region, we have $\delta_2 - \delta_1 = \lambda\delta_2$, or equivalently $\delta_1 = (1-\lambda)\delta_2$. Clearly, $y$ lies below $g_1$, and so $r_y \geq \delta_1$. Since all of $f^-$ (including $x'$) lies below $g_0$, we have $r_x \leq \delta_2$. Therefore, $r_y \geq \delta_1 = (1-\lambda)\delta_2 \geq (1-\lambda)r_x$, as desired. ◀

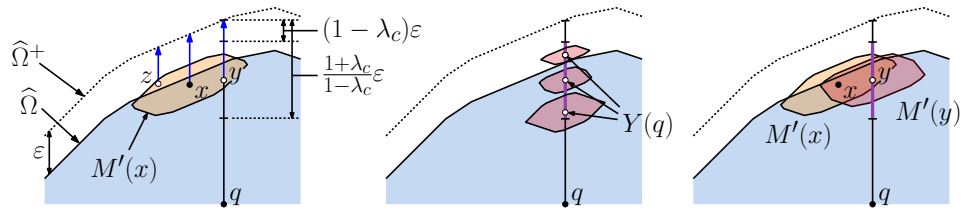
**Proof of Lemma 9.** Recall that constants $\lambda_c$ and $\lambda_p$ are the so called *covering* and *packing* scale factors used in our construction. Given a point $x \in \Omega^+$, let $M'(x)$ and $M''(x)$ denote respectively the covering ($\lambda_c$-scaled) and packing ($\lambda_p$-scaled) Macbeath regions centered at $x$ with respect to the expanded body $\widehat{\Omega}^+$. Define $E'(x)$ and $E''(x)$ analogously for Macbeath ellipsoids.

Recall that our construction is based on a maximal point set $X \subset \widehat{\Omega}$ such that the packing ellipsoids $E''(x)$ are disjoint for $x \in X$ and $E'(x)$ cover $\widehat{\Omega}$. Given any $q \in \Omega$, let $X(q) \subseteq X$ denote the set of top covering ellipsoids $E'(x)$ whose vertical projection contains $q$. Equivalently, $x \in X(q)$ if the vertical ray passing through $q$ intersects $E'(x)$. It suffices to show that for any $q \in \Omega$, $|X(q)| = O(1)$.

For any $x \in \widehat{\Omega}^+$, define $\mathrm{ray}(x)$ to be the length of a vertical ray shot from $x$ up to the boundary of $\widehat{\Omega}^+$. By definition of a top ellipsoid, for any $x \in X(q)$, there exists a point $z \in E'(x)$ such that $\mathrm{ray}(z) \leq \varepsilon$. Since $E'(x) \subseteq M'(x)$, we have $z \in M'(x)$ (see Figure 11(a)). Thus, by Lemma 10 with $\widehat{\Omega}^+$ playing the role of $f^-$ and $z$ playing the role of $y$, it follows that $\mathrm{ray}(x) \leq \mathrm{ray}(z)/(1-\lambda_c) \leq \varepsilon/(1-\lambda_c)$. Applying the lemma again, it follows that for any other point $y \in E'(x)$, we have

$$\mathrm{ray}(y) \;\leq\; (1+\lambda_c)\cdot \mathrm{ray}(x) \;\leq\; \frac{1+\lambda_c}{1-\lambda_c}\varepsilon.$$

Also, because $x \in \widehat{\Omega}$, we have $\mathrm{ray}(x) \geq \varepsilon$, implying again by Lemma 10 that $\mathrm{ray}(y) \geq (1-\lambda_c)\varepsilon$. In summary, for each $x \in X(q)$, there exists a point $y$ along the vertical ray shot up from $q$ such that $(1-\lambda_c)\varepsilon \leq \mathrm{ray}(y) \leq \frac{1+\lambda_c}{1-\lambda_c}\varepsilon$.



(a) (b) (c)

**Figure 11** Proof of Lemma 9.

Let $Y(q)$ be any maximal set of points along the vertical line through $q$ that have ray distances in the interval $\left[(1-\lambda_c), \frac{1+\lambda_c}{1-\lambda_c}\right]\varepsilon$ and whose packing Macbeath regions are pairwise disjoint (see Figure 11(b)). Each such Macbeath region covers an interval of length at least $\lambda_p(1-\lambda_c)\varepsilon$. By a standard packing argument, there are at most a constant $c'$ (depending on $\lambda_p$ and $\lambda_c$) of such Macbeath regions, and their covering Macbeath regions cover this subsegment of the vertical line.

Now, associate each point $x \in X(q)$ with any one of the points of $y \in Y(q)$, such that $M'(x) \cap M'(y) \neq \emptyset$ (see Figure 11(c)). By the prior observations, such a point of $y$ exists for each $x$. By expansion containment (Lemma 5), a constant factor expansion of $M'(y)$ contains $M'(x)$ and vice versa. Therefore, the volumes of these bodies are equal up to constant factors (depending on $\lambda_c$ and the dimension $d$). Because $\lambda_p$ and $\lambda_c$ are both constants, the volumes of $M''(x)$ and $M''(y)$ are related by constant factors. Thus, by a straightforward packing argument, the disjointness of the $M''(x)$ Macbeath regions implies that the number of $x \in X(q)$ that are associated with any $y \in Y(q)$ is bounded above by some constant $c''$. Thus, we have $|X(q)| \leq c'c'' = O(1)$, as desired. ◀

## 4 Putting it Together

We can now explain how to combine the results of the previous section with the partition-of-unity method from Section 2, to obtain the final smooth distance approximation.

The set of patches $\Pi = \{\Pi_i\}$ used in blending consist of the vertical projections of all the top ellipsoids from level-0 of the vertical ray-shooting data structure. Each ellipsoidal patch $\Pi_i$ is represented by its center $c_i \in \mathbb{R}^d$ and a positive-definite matrix $M_i$ such that

$$\Pi_i \;=\; \{x \in \mathbb{R}^d : f_i(x) \le 1\}, \qquad \text{where } f_i(x) \;=\; (x - c_i)^\intercal M_i (x - c_i). \tag{5}$$

Recalling the definition of the standard mollifier $\mu$ from Eq. (4), we define

$$\psi_i(x) \;=\; \mu(f_i(x)). \tag{6}$$

Given these weight functions, we apply Eq. (3) to obtain the blending function $\phi_i(x)$ for each patch. Recall that each of the top ellipsoids $\Pi_i$ is associated with a representative of the upper envelope of $\widehat{\Omega}$ in the form of a halfspace $H_i = \{x \in \mathbb{R}^d : a_i^\intercal x \le b_i\}$. As mentioned in Section 3, the associated local distance function is $v_i(x) = b_i - a_i^\intercal x$ (Eq. (1)).

Given a query point $x$, we use the vertical ray-shooting data structure to determine the patches $\Pi_i$ containing it. By Lemma 9, there are a constant number of them. We apply Eq. (2) to blend together the local distance functions to obtain the final distance approximation, $\widetilde{d}_\Omega(x)$. The space and query time are dominated by the complexity bounds for the ray-shooting data structure, given in Lemma 7. This establishes the correctness and complexity bounds of Theorem 2. The bounds on the norms of the gradient and Hessian are rather technical and will appear in the full version.

## 5 Concluding Remarks

In this paper, we have taken first steps towards designing data structures for approximately answering geometric distance queries approximately, while more faithfully preserving properties of the underlying distance functions. Existing data structures based on computing approximate nearest neighbors suffer from discontinuities in the resulting distance field, which is undesirable in many applications. We have presented a general method for achieving smoothness by combining a traditional (discontinuous) method with blending, and we have illustrated the technique in the concrete application of approximating (in terms of absolute errors) the distance field to the boundary, induced within a convex polytope $\Omega$ in $\mathbb{R}^d$. Our data structure is efficient in the sense that it nearly matches the best asymptotic space and time bounds for the simpler problem of approximately determining membership within the polytope (being suboptimal by a factor of $1/\sqrt{\varepsilon}$ in the space). We have also presented bounds on the norms of the gradient (first derivative) and Hessian (second derivative) of the approximation.

There are a number of interesting open problems that remain. The first is applying this method to more approximate nearest neighbor search applications. We have done this for a discrete set of points in $\mathbb{R}^d$, which we plan to publish in a future paper. While our results nearly matching the best known complexity bounds for $\varepsilon$-approximate nearest neighbor searching, the technical issues are quite involved. The method can be applied to other query problems where the answer is naturally associated with a continuous field. Examples include penetration depth in collision detection [47], distance oracles in robotics and autonomous navigation [44], and novel-view synthesis using parametric radiance fields [20].

While our approach produces a smooth approximation, there are other properties of distance fields that would be useful to preserve. One shortcoming of our method is that it can produce spurious local minima in the approximate distance field. An interesting question is whether our approach can be modified to eliminate these minima. We anticipate interesting connections to the literature on vector field design [43] and mode finding [28].

## Abstract

Motivated by the problem of redistricting, we study area-preserving reconfigurations of connected subdivisions of a simple polygon. A connected subdivision of a polygon $\mathcal{R}$, called a *district map*, is a set of interior disjoint connected polygons called *districts* whose union equals $\mathcal{R}$. We consider the *recombination* as the reconfiguration move which takes a subdivision and produces another by merging two adjacent districts, and by splitting them into two connected polygons of the same area as the original districts. The *complexity* of a map is the number of vertices in the boundaries of its districts. Given two maps with $k$ districts, with complexity $O(n)$, and a perfect matching between districts of the same area in the two maps, we show constructively that $(\log n)^{O(\log k)}$ recombination moves are sufficient to reconfigure one into the other. We also show that $\Omega(\log n)$ recombination moves are sometimes necessary even when $k = 3$, thus providing a tight bound when $k = 3$.

## 1 Introduction

We consider the problem of *redistricting* – the partition of a geographic domain into disjoint districts. In particular, we consider the case when these districts are required to be connected and of roughly equal population. These criteria are typically enforced in political redistricting, wherein each district elects one or more representatives to serve on a governing body, a canonical example being Congressional districts in the United States. Even under these restrictions, the space of possible redistricting plans for a typical domain is intractably vast, making it difficult to sample from this space. Recently, algorithms for generating large samples of plans have made it possible to find the neutral baseline for a particular state, which in turn can be used to detect and describe gerrymanders (i.e., unfair maps) [9, 8, 10, 13, 14, 17, 18].

The most common and successful sampling algorithms for redistricting are Markov chains that perform a sequence of reconfiguration moves on an initial map. The most prominent reconfiguration move is the *recombination* or *ReCom* move (see Figure 1), which is a move that modifies two adjacent districts while maintaining population balance and connectivity [13, 14]. In order to properly sample from the space of redistricting plans, we should require that any feasible redistricting plan can be reached from the initial map by a finite sequence of ReCom moves. That is, we want to positively answer the *reachability* question for this reconfiguration move; in the language of Markov chains this would be to prove that any chain built on the ReCom move is *irreducibile*.

Historically, most redistricting algorithms have operated on a discretized version of the geographic domain. In this framework, a district map is modeled as a vertex partition of an adjacency graph [14, 24]. This is natural since population data is only available at the level of fixed geographic units, such as Census blocks in the case of the United States. The ReCom algorithm fits within this framework, and current versions all use a spanning tree method on the adjacency graph to perform the ReCom move. Unfortunately, it is easy to construct small pathological examples of graphs for which ReCom reachability fails. Moreover, even determining whether two plans can be connected via a sequence of ReCom moves is PSPACE-complete [3] for general (planar) graphs.

A reasonable but unproven hypothesis is that for real-world adjacency graphs representing sufficiently fine discretizations of the geographic domain, we will indeed have reachability. A general theorem covering all adjacency graphs of interest seems beyond reach, which has led to a search for intermediate results. One direction of investigation is to allow a large class of graphs but relax the population balance constraint considerably; in such cases theoretical results are possible [2, 3] (see Related Work below). Reachability on grid graphs or triangular lattices is an active area of research but as of yet without concrete results.

In this paper, we return to the original hypothesis – that sufficient discretization leads to reachability – to motivate our result. Instead of modeling redistricting plans as graph partitions, we adopt a continuous model where the districts are connected polygons of equal population which partition a polygonal domain. Note that sampling algorithms based on this model do exist in the literature, most notably the power diagram method in [11], but these algorithms are not Markov chains and require an extra refinement step to go from polygonal partitions to partitions that respect the geographic units.

In our continuous model, we are able to establish reachability for the ReCom move – that is, any two polygonal partitions can be connected by finitely many ReCom steps that merge and resplit adjacent polygonal districts. The implication is that given two real-world redistricting plans, a sufficiently fine discretization of the geographic domain allows a finite sequence of ReCom moves (on the adjacency graph) to connect them. In practice this could mean that a particular map is not reachable from the initial map when considering voting precincts as geographic units, but could become reachable when working with Census blocks.

**Related Work.** In the discrete setting, the context for the reachability problem consists of a graph $G$ with $n$ nodes, a number of districts $k$ and a *slack* $\varepsilon \geq 0$. Valid partitions are defined as partitions of $V(G)$ into $k$ non-empty subsets (called *districts*) that each induce connected subgraphs such that the number of vertices in each district lies in the interval $[(1-\varepsilon)\frac{n}{k}, (1+\varepsilon)\frac{n}{k}]$. Two common reconfiguration moves on the space of valid partitions are the switch move and ReCom move. A *switch move* [15, 21] consists of reassigning a single node to a new district. Using the switch move allows one to construct a Markov chain on the space of valid partitions with easily computable transition probabilities. A

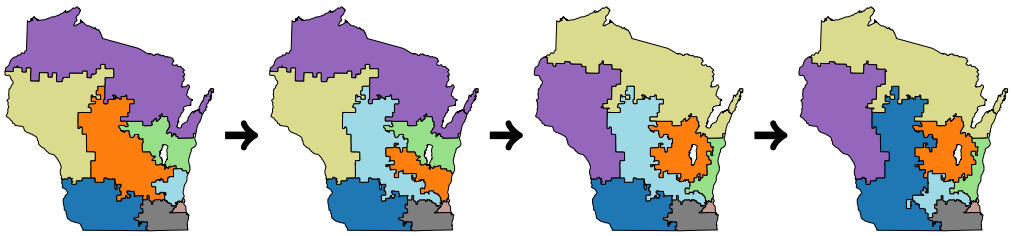

**Figure 1** A sequence of three recombination moves on the state of Wisconsin. At each step, two districts are merged and split again. The reachability problem is to determine whether any map can be reached from any other by a finite sequence of such steps.

Metropolis-Hastings weighting can then be used to ensure that the chain samples (in the limit) from any desired distribution on the space of valid partitions. Crucially, however, this relies on the assumption that the state space is connected, i.e., that any two partitions can be connected by switch moves. It is not hard to design concrete examples of graphs for which this is not true with $\varepsilon = 0$. It is known that for $\varepsilon = \infty$, the state space is connected under the switch move when $G$ is biconnected; furthermore, that deciding whether two partitions can be connected by switch moves is PSPACE-complete even when $G$ is planar [2].

The usefulness of the switch move is hampered by the fact that Markov chains built on it tend to mix slowly [23]. As a result, larger reconfiguration moves, that are often more effective on real-world instances, were introduced. The *ReCom move* [13, 14] consists of merging and resplitting two adjacent districts (note that the switch move is a special case of a ReCom move). When designing a Markov chain based on this move, the most common method for resplitting is to draw a random spanning tree of the merged districts and cut an edge such that the resulting connected components form a valid partition. The disadvantage to such a process is that the transition probabilities between partitions appear to be intractable, so that the resulting Markov chain has an unknown stationary distribution. Recently, modifications of the original ReCom Markov chain have been proposed which have computable transition probabilities [4, 6]; however, an accurate description of the stationary distribution still requires the state space to be connected. It is easy to construct a graph $G$ for which the space of valid partitions is not ReCom-connected for $\varepsilon = 0$ (even for a $6\times6$ grid graph [6]). It is known [3] that the state space is connected whenever $G$ is connected and $\varepsilon = \infty$, and also when $G$ is Hamiltonian and $\varepsilon \geq 2$; deciding whether two partitions can be connected by ReCom moves is PSPACE-complete even when $G$ is a triangulation.

**Contributions.** In this paper, we introduce a continuous model for redistricting and ReCom moves, where the districts can be arbitrary connected polygons (with real coordinates) in a polygonal domain (Section 2). While the configuration space in this setting contains infinitely many maps, we prove that it is always connected under ReCom moves. Our proof is constructive, and provides an upper bound on the minimum number of ReCom moves between any two maps in terms of the number of districts $k$ and the complexity of the district maps $n$ (i.e., the number of vertices of all polygons in the initial and target maps). We start with the first nontrivial case, $k = 3$ districts in a unit square domain, and show that between any two maps of complexity $O(n)$, there is a reconfiguration path consisting of $O(\log n)$ ReCom moves (Theorem 9 in Section 3). Importantly, the complexity of the map remains $O(n)$ in all intermediate steps. Our reconfiguration algorithm generalizes to $k$ districts in an arbitrary polygonal domain, using a recursion of depth $O(\log k)$. It yields an $\exp(O(\log k \log\log n))$

bound on the number of ReCom moves between two maps; however, for the complexity of intermediate maps we obtain only a weaker bound of $n^{k^{O(1)}}$ (Theorem 10 in Section 4). On the other hand, we show that (even for $k = 3$) the diameter of the configuration space is infinite by constructing pairs of maps which require arbitrarily large numbers of ReCom moves to connect (Theorem 12 in Section 5). The number of moves for these examples grows logarithmically with the complexity of the maps, thereby providing a lower bound which perfectly matches our upper bound.

## 2 Preliminaries

A *region* is a connected set in $\mathbb{R}^2$ bounded by one or more pairwise disjoint Jordan curves. A *$k$-district map* $M(\mathcal{R}) = \{D_1, \dots, D_k\}$ is a decomposition of a region $\mathcal{R}$ into $k$ interior-disjoint regions (that is, $\mathcal{R} = \bigcup_{i=1}^{k} D_i$ and $\operatorname{int}(D_i) \cap \operatorname{int}(D_j) = \emptyset$ for $i \neq j$), where $\mathcal{R}$ is the *domain*, and $D_1, \dots, D_k$ are the *districts* of the map. We may refer to $M(\mathcal{R})$ simply as $M$ if $\mathcal{R}$ is clear from the context. A *recombination* move (for short, *ReCom*) takes a map $M(\mathcal{R})$ and two districts $D_i, D_j \in M(\mathcal{R})$ and returns a new district map of the same domain $M'(\mathcal{R}) = M(\mathcal{R}) \setminus \{D_i, D_j\} \cup \{D'_i, D'_j\}$. A recombination is *area-preserving* if $\operatorname{area}(D_i) = \operatorname{area}(D'_i)$ and $\operatorname{area}(D_j) = \operatorname{area}(D'_j)$. Two $k$-district maps, $M(\mathcal{R}) = \{D_1, \dots, D_k\}$ and $M'(\mathcal{R}) = \{D'_1, \dots, D'_k\}$, on a domain $\mathcal{R}$ are *area-compatible* if there is a permutation $\pi : \{1, \dots, k\} \to \{1, \dots, k\}$ such that $\operatorname{area}(D_i) = \operatorname{area}(D'_{\pi(i)})$ for all $i = 1, \dots, k$.

We assume that the domain $\mathcal{R}$ is a simple polygon, and each district is a connected polygon (possibly with holes). The *configuration space* of a map $M(\mathcal{R})$ is the set of all polygonal district maps on $\mathcal{R}$ that are area-compatible with $M(\mathcal{R})$. We define the *complexity* of a map $M$ as the total number of vertices on the boundaries of all districts in $M(\mathcal{R})$. We show (in Section 4) that w.l.o.g. we may assume a unit square domain $\mathcal{R} = [0, 1]^2$. The *area* of a polygon $P$, denoted $\operatorname{area}(P)$, is either the Euclidean area of $P$ or the integral $\int_P \delta$ of some nonnegative integrable density function $\delta : \mathcal{R} \to \mathbb{R}_{\geq 0}$. We show (Theorem 10) that between any pair of area-compatible district maps there is a sequence of area-preserving recombinations (i.e., the configuration space of area-compatible district maps is connected).

**Weak Representation.** In intermediate maps of a ReCom sequence, we use infinitesimally narrow *corridors* to keep the districts connected. In order to handle narrow corridors efficiently, we rely on a compressed representation of district maps using *weak embeddings* (defined below), where each corridor is represented by a polygonal path; see Fig. 2. The compressed representation has two key advantages: (1) We may assume that corridors have zero area; and (2) we may reduce the total number of vertices by representing several parallel corridors by overlapping polygonal paths (with shared vertices). In Sections 3–4, we construct a sequence of ReCom moves on compressed maps. We show (in Proposition 1 below) that the polygonal paths can be thickened into narrow corridors in each stage of the ReCom sequence to produce a ReCom sequence in which the districts are simple polygons.

An *embedding* of a planar graph $G$ is an injective function from $G$ (seen as a 1-dimensional topological space) to $\mathbb{R}^2$; intuitively it is a drawing of $G$ in which edges can intersect only at common endpoints. A *weak embedding* of $G$ is a continuous function from $G$ to $\mathbb{R}^2$ such that, for every $\varepsilon > 0$, each vertex can be moved by at most $\varepsilon$ and each edge can be replaced by a curve within Fréchet distance $\varepsilon$ to form an embedding of $G$ (i.e., an *$\varepsilon$-perturbation* of a weak embedding is an embedding). In particular, a *simple polygon* is a piecewise linear embedding of a cycle and the region bound by it; and a *weakly simple polygon* is a piecewise linear weak

embedding of a cycle and the region bounded by it. A *polygon* (with possible holes) is a simple polygon with pairwise disjoint simple polygons (holes) removed. Similarly, a *weak polygon* is a weakly simple polygon with pairwise disjoint weakly simple polygons removed.

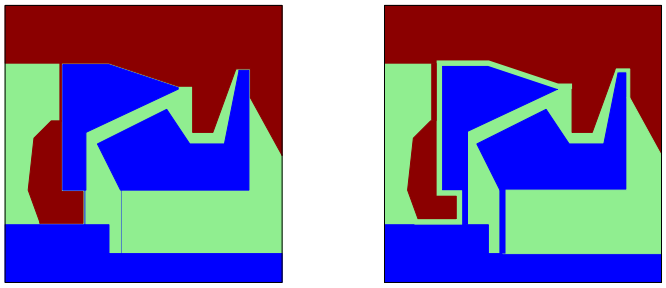

**Figure 2** An example of a weak embedding of a map. Left: multiple corridors connect disconnected regions. Right: the corridors are thickened to create three simple polygons.

For a district map $M$, the boundaries of the districts jointly form a straight-line embedding of some abstract graph $G$. By identifying edges on opposite sides of narrow corridors, we obtain a weak embedding of $G$. In a weak embedding, two or more corridors may overlap, and we maintain a linear order among all overlapping corridors.

We use the machinery introduced by Akitaya et al. [1] (based on earlier work [12, 7]); see also [5, 16]. A weak embedding of $G$ is a piecewise linear map of $\varphi : G \to \mathbb{R}^2$. The *image graph* $H$ is a planar straight-line graph formed by the image $\varphi(G)$, where overlapping vertices (edges) of $G$ are mapped to the same vertex (edge). A *weak representation* of $G$ comprises of a weak embedding $\varphi$ and a linear order of overlapping edges of $\varphi(G)$ along each edge of $H$. We define an *$\varepsilon$-thickening* of $H$ so that $G$ admits an embedding $\psi$ into the $\varepsilon$-thickening of $H$ so that the Fréchet distance between $\varphi$ and $\psi$ is at most $\varepsilon$. We call $\psi$ an *$\varepsilon$-perturbation* of the weak representation if the order of the edges of $G$ in the neighborhood of an edge of $H$ agrees with the given linear order. It is known that if $G$ has $n$ vertices, then an $\varepsilon$-perturbation $\psi(G)$ with $O(n)$ vertices can be computed in $O(n \log n)$ time [1].

**Weak Representation for ReCom Sequences.** We construct a ReCom sequence in two passes: The first pass operates on a generic $\varepsilon$-perturbation, where the *area* of each district is given by the weak representation (hence the corridors have zero area). The second pass then expands the weak representations into an $\varepsilon$-perturbation, using Proposition 1 below (see the full version of the paper for omitted proofs), where each district is a simple polygon with the desired area. Note that the number of moves is determined in the first pass.

▶ **Proposition 1.** *Given two area-compatible $k$-district maps and a sequence of area-preserving ReCom moves where districts in intermediate maps are weak polygons with $O(n)$ vertices, we can compute a sequence of area-preserving ReCom moves of the same length where the districts in intermediate maps are all polygons with $O(n)$ vertices.*

We define the *compressed complexity* of a district map as the number of vertices in the image graph $H$ of the weak representation (that is, repeated vertices are counted only once). The number of ReCom moves produced by our algorithm in Sections 3–4 depends on the compressed complexity. Using $\varepsilon$-perturbations would increase the complexity of maps. For this reason, it is also useful in our analysis to convert an $\varepsilon$-perturbations to a weak embedding which we do by applying the inverse of the operations described here. Throughout this paper we use set operations on weak polygons such as $D_1 \cup D_2$ where $D_1$ and $D_2$ are weak polygons. Let $D_1'$ and $D_2'$ be the polygons obtained by the $\varepsilon$-perturbation defined in Proposition 1. We define $D_1 \cup D_2$ to be the weak polygon obtained from $D_1' \cup D_2'$.

# 3 Reconfiguration for Three Districts

In this section, we consider maps with three districts with a total of $n$ vertices in a unit square domain $\mathcal{R} = [0,1]^2$. We show that any 3-district map $M(\mathcal{R}) = \{D_1, D_2, D_3\}$ can be transformed by a finite sequence of ReCom moves into an area-compatible *canonical map* in which the districts are axis-aligned rectangles, $Q_1$, $Q_2$ and $Q_3$, of unit width such that $\text{area}(Q_i) = \text{area}(D_i)$ for $i = 1, 2, 3$.

## 3.1 Overview of the Algorithm

Our algorithm for transforming a map into the canonical map consists of three stages, each containing multiple ReCom moves:

- *Preprocessing* (Section 3.2). In this stage, we ensure that our three districts are ordered top to bottom in a well-defined way, and the middle district has the largest area. Moves needed: $O(1)$.
- *Gravity moves* (Section 3.3). We perform three ReCom moves to place the districts into their final positions, with the possible exception of corridors. Moves needed: 3.
- *Exchange sequences* (Section 3.5). Corridors maintaining connectivity are carefully removed, using a tree representation to determine a move that simultaneously removes a constant fraction of corridors. Moves needed: $O(\log n)$.

## 3.2 Preprocessing: Ordering Property

First we transform the three given districts into simple polygons if necessary. While there is a district $D_i$ that is a polygon with holes, there is an adjacent district $D_j$ contained within a hole. Recombine $D_i$ and $D_j$ to create a single-edge corridor between $D_j$ and the outer boundary of $D_i$. Next, we create corridors, if necessary, such that each district touches both the left and right sides of $\mathcal{R}$. While there is a district that is not adjacent to the left (resp., right) side $s$ of the $\mathcal{R}$, let $D_i$ be such a district closest to $s$ and let $D_j$ be an adjacent district that already touches $s$; then we recombine $D_i$ and $D_j$ and append to $D_i$ a shortest path to $s$ along the boundary of $D_j$. Thus, both districts remain simply connected. As all corridors run along existing vertices of the three districts, the complexity of the map does not increase. This stage takes $O(1)$ ReCom moves.

After preprocessing, the intersection of each district with the left (resp., right) side of the square domain is connected; and the order of these intersections is the same on both sides, or else two districts would cross. Therefore, the districts can be ordered from top to bottom.

We also need to establish the property that the middle district has the largest area. This can be done trivially with a single ReCom move between the middle district and the largest district of the three. We call these properties combined the *ordering property*:

▶ **Definition 2.** *A three district map $M(\mathcal{R}) = \{D_1, \ldots, D_k\}$ satisfies the* ***ordering property*** *if the intersection of each district with the left (resp., right) side of the square domain is connected, and the middle district, as defined by the resulting order from top to bottom, has area greater than or equal to each other district.*

We assume that the districts are simple polygons in the unit square with a total of $n$ vertices and describe the details of the recombination moves as we use them in the algorithm. To reconfigure the districts into their canonical positions, apart from possible corridors, we perform three gravity moves.

## 3.3 Gravity Move

Assume that $M$ is a 3-district map satisfying the ordering property, with districts labeled $D_1$ (red), $D_2$ (green), and $D_3$ (blue) from top to bottom. We describe the move $\textsc{Gravity}(D_1, D_2)$, which recombines the red and green districts; refer to Figures 3–4. Let $P = D_1 \cup D_2$, which is a weakly simple polygon by the ordering property. By continuity, there exists a horizontal line $\ell$ (that we call the *waterline*) that partitions the plane into upper and lower halfplanes $\ell^+$ and $\ell^-$, resp., such that $\text{area}(P \cap \ell^+) = \text{area}(D_1)$ and $\text{area}(P \cap \ell^-) = \text{area}(D_2)$. We shall define new districts $D_1'$ and $D_2'$, resp., that contain $P \cap \ell^+$ and $P \cap \ell^-$.

Note, however, that $P \cap \ell^+$ and $P \cap \ell^-$ may be disconnected. We then reconnect disjoint components of each district by corridors along the boundary of $P$; see Fig. 4. Note that, by the ordering property, there is a path $\pi$ on the boundary of $D_3$ (blue) between the left and right side of the domain $\mathcal{R}$. If there are two or more components of $P \cap \ell^+$, they are separated by blue and, therefore they all touch the path $\pi$. Therefore $(P \cap \ell^+) \cup \pi$ is a connected region. Similarly, $(P \cap \ell^-) \cup \pi$ is also connected.

We define a *red graph* as follows: the vertices are the connected components of $P \cap \ell^+$ and edges are minimal arcs along $\pi \cap \ell^-$ that connect two distinct components of $P \cap \ell^+$. Since $(P \cap \ell^+) \cup \pi$ is connected, then the red graph is connected. Consider an arbitrary spanning tree of the red graph, and add its edges (as corridors) to the red district along the boundary of $P$. This completes the definition of $D_1'$.

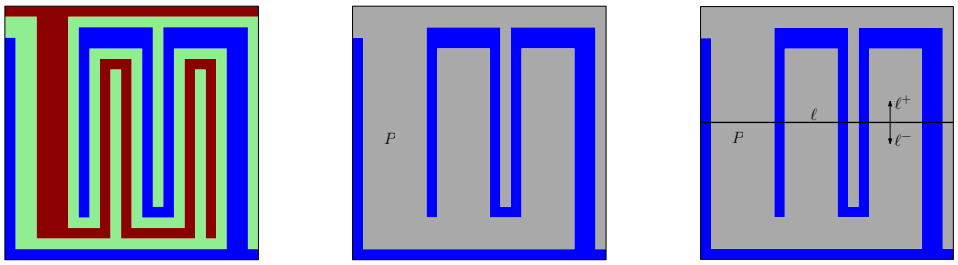

**Figure 3** The setup for a gravity move between the red district $D_1$ and green district $D_2$. Left: a district map satisfying the ordering property. Middle: the union $P = D_1 \cup D_2$ is shown in gray. Right: the horizontal line $\ell$ equipartitions the gray polygon $P$.

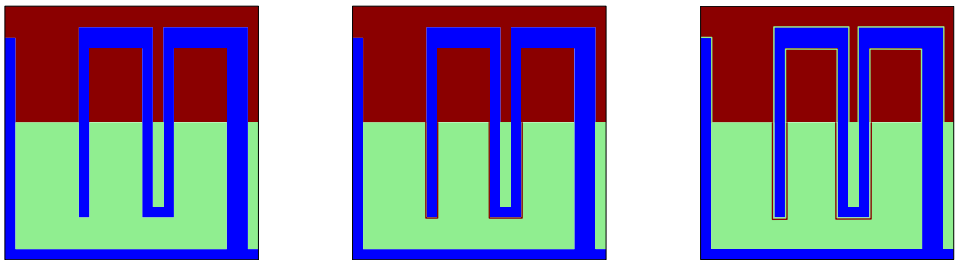

**Figure 4** Constructing the result of a gravity move between red and green on the map in Figure 3. Left: the red region $P \cap \ell^+$ and the green region $P \cap \ell^-$ are each disconnected. Middle: red corridors create a connected red district $D_1'$. Right: green corridors create a connected green district $D_2'$ and restore the ordering property.

Since the blue district is simply connected, each component of $P \cap \ell^-$ also intersects $\ell$ and therefore is adjacent to the red district $D_1'$. Intuitively, we add corridors along $\pi$ "coating" the blue district with green and thus restoring the ordering property. Note that $\pi$ may pass along the boundary of $D_1'$, including all red corridors, and the boundaries of the components

of $P \cap \ell^-$. Formally, we add green corridors at the intersection of $\pi$ and $\partial D_1'$, if such a corridor is parallel to a red corridor, it runs between the blue district and the red corridor. That defines $D_2'$ and concludes the description of the gravity move.

▶ **Lemma 3.** *Assume $D_1$ and $D_2$ are the top two districts on a map satisfying the ordering property. Then* Gravity$(D_1, D_2)$ *is an area-preserving ReCom move that maintains the ordering property.*

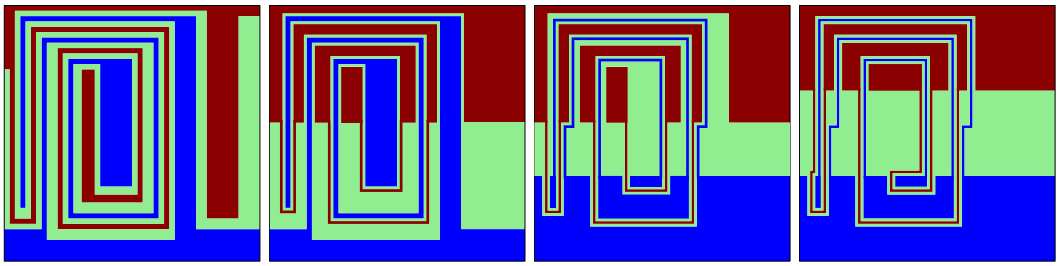
Since each waterline intersects an edge of a district at most once we have:

▶ **Lemma 4.** *Assume $D_1$, $D_2$ and $D_3$ each have at most $m$ vertices. Then* Gravity$(D_1,D_2)$ *produces districts $D_1'$ and $D_2'$, each with at most $O(m)$ vertices.*

The move Gravity$(D_3, D_2)$ is defined analogously: a reflection in a horizontal line that reverses the order of the three districts, such that $D_1' = D_3$ becomes the top district and $D_2' = D_2$ is the middle district, then apply Gravity$(D_1', D_2')$, followed by another reflection.

▶ **Lemma 5.** *Let $M$ be a map satisfying the ordering property, with districts $D_1$, $D_2$ and $D_3$ from top to bottom. Then* Gravity$(D_1, D_2)$ *returns a map that satisfies the ordering property and $D_1'$ is disjoint from $Q_3$ with the possible exception of corridors, where $Q_3$ is the axis-aligned rectangle of the blue district in the canonical map.*

**Proof.** It suffices to show that the horizontal line $\ell$ is above $Q_3$. Lemma 3 yields the rest. By definition, the area below $\ell$ is at least area$(D_2) \geq$ area$(Q_3)$, since $D_2$ has the maximum area of the three districts. Thus, the line $\ell$ is above $Q_3$. ◀



(a) (b) (c) (d)

**Figure 5** An example of a sequence of three gravity moves. (a) A starting configuration; (b) the result of Gravity$(D_1, D_2)$; (c): the result of Gravity$(D_3, D_2)$; (d) the result of the third gravity move Gravity$(D_1, D_2)$.

After three gravity moves each district has positive area only in the regions in their corresponding districts in the canonical configuration (see Figure 5 for an example).

▶ **Lemma 6.** *Let $M$ be a map satisfying the ordering property, with districts $D_1$, $D_2$ and $D_3$ from top to bottom. Then the sequence of three moves* Gravity$(D_1, D_2)$, Gravity$(D_2, D_3)$, *and* Gravity$(D_1, D_2)$ *return a map $M'$ where $D_1$, $D_2$, and $D_3$ are each contained in their canonical rectangles, with the possible exception of some corridors.*

## 3.4 Tree Representation of a Region

After prepocessing and the three gravity moves in Lemma 6, we want to eliminate corridors. We encode the topology of the region $P = D_1 \cup D_2$ in a graph that we use for the Exchange sequence, described below.

We define the *corridor graph* $T(R)$ of a weakly simple polygon $R \subset \mathcal{R}$. A weakly simple polygon has a natural decomposition into pairwise disjoint simple polygons and corridors (polygonal paths). The nodes of $T(R)$ are simple polygons in the decomposition of $R$, and the edges represent corridors between two polygons in $R$. Denote the set of edges by $E(T(R))$. At each node, the rotation of the incident edges represents the counterclockwise order of corridors along the corresponding polygon in $R$. The weight of each node is the area of the corresponding polygon. As corridors have zero thickness, the total weight of the nodes is $W = \text{area}(R)$.

In particular, we want to consider the corridor graph of $P = D_1 \cup D_2$. Assume that $M$ is a 3-district map returned by the three gravity moves in Lemma 6. By the ordering property, we know that the intersection of $D_1$ and $D_2$ is a simple path - either from one side of the square to another or, if $D_1$ is contained in $D_2$, then it is a closed curve. Thus, $P$ is a weakly simple polygon. Let $Q_{12}$ be the union of the two axis-aligned rectangles that contain $D_1$ and $D_2$ in the canonical configuration. Then, the nodes of $T(P)$ are simple polygons in $P \cap Q_{12}$ (regions bounded by corridors of $D_3$) and the edges are corridors in $R \setminus Q_{12}$ that connect two such polygons (corridors of $D_1$ and $D_2$ running through $Q_3$). Note, however, that a corridor in $P$ may be the union of three parallel corridors in $D_2$, $D_1$, and $D_2$, resp.; see Fig. 6. Since $P$ is a weakly simple polygon, $T(P)$ is a tree; see Fig. 6. Note that the number of vertices in $T(P)$ is bounded above by the compressed complexity of the map and that many different maps can have the same corridor graph.

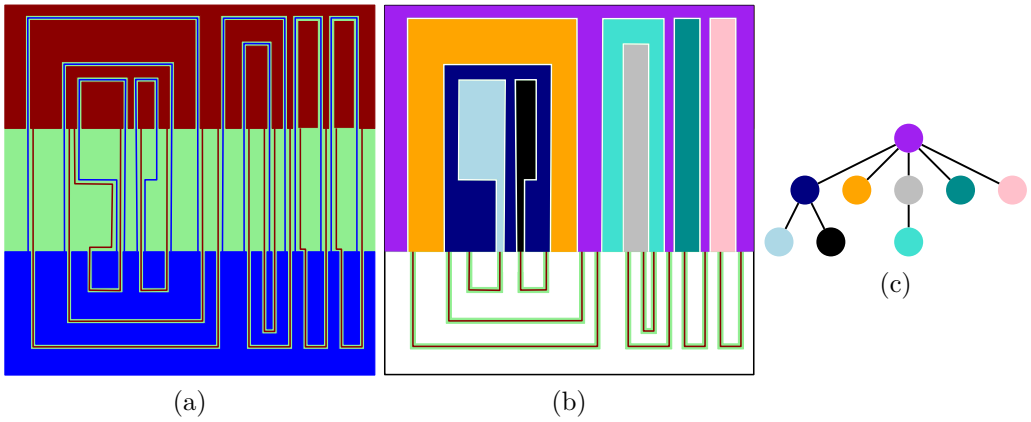


**Figure 6** (a) A map $M$ after 3 Gravity moves. (b) The nodes of the corridor graph $T(P)$ correspond to connected components of $P \cap Q_{12}$, indicated by distinct colors. (c) The corridor graph $T(P)$ encodes the topology of $P$.

We use the corridor graph $T(P)$ to eliminate corridors. Consider what happens if the tree has a leaf that is entirely part of the green district (see Fig. 7). This means that by doing a gravity move between green and blue we can eliminate the green and blue corridors adjacent to this leaf, removing the leaf from the tree altogether. Our goal is therefore to create a part of the tree which is entirely green.

The *centroid* of a vertex-weighted tree of total weight $W$ is a vertex whose removal partitions the tree into subtrees of weight at most $\frac{W}{2}$ each. Jordan [19] proved that every tree (with unit weights) has a centroid; this was perhaps the oldest separator theorem [20, 22]. The result extends to weighted trees: a greedy algorithm finds the centroid in linear time.

Let $c$ be a centroid of $T(P)$, and assume that $T(P)$ is rooted at $c$. A subtree of $T(P)$ is *contiguous* if it consists of the centroid $c$, some children of $c$ that are consecutive in the rotation order of $c$, and all their descendants in $T(P)$.

▶ **Lemma 7.** *There exists a contiguous subtree $T^*$ of $T(P)$ such that:* (i) *$T^*$ contains at least $\frac{1}{3}$ of the vertices of $T(P)$, and* (ii) *the weight of $T^*$ is at most $\frac{W}{2} + w(c)$, where $w(c)$ is the weight of the centroid $c$.*

**Proof.** By the definition of the centroid $c$, the removal of $c$ produces a forest $T(P) - c$, where the weight of each component (tree) is at most $\frac{W}{2}$. Partition these $\deg(c)$ trees into up to three forests of consecutive subtrees such that each forest has weight at most $\frac{W}{2}$ as follows. Begin with a partition into $\deg(c)$ forests, each containing a single tree, and maintain their cyclic order around $c$. While there are two consecutive forests whose combined weight is at most $\frac{W}{2}$, merge them into a single forest. The while loop terminates with three or fewer forests: Indeed, for four or more forests, the combined weight of at least one of the consecutive pairs would be at most $\frac{W}{2}$ by the pigeonhole principle. Since we partition $T(P) - c$ into three forests, one of them contains at least $\frac{1}{3}$ of the vertices $T(P) - c$. Adding $c$ to this forest, we obtain a contiguous subtree of $T(P)$ containing at least $\frac{1}{3}$ of the vertices of $T(P)$. ◀

## 3.5 Exchange Sequence

We now describe the *exchange sequence*, a sequence of three ReCom moves, which eliminates a fraction of the corridors and reduces the (compressed) complexity of the map. Assume we are given a 3-district map $M$ satisfying the ordering property. As before, label its districts red, green, and blue from top to bottom. We further require that there exist two horizontal lines $\ell_1$ and $\ell_2$ such that red has positive area only above $\ell_2$, blue has positive area only below $\ell_1$, and green has positive area only between $\ell_1$ and $\ell_2$ (cf. Lemma 6). See Figure 7 for an example.

Let $c$ be a centroid of $T(P)$, where $P = D_1 \cup D_2$ and let $T^*$ be a contiguous subtree of $T(P)$ rooted at the centroid, as in Lemma 7. The exchange sequence consists of the following three ReCom moves:

1. ReCom green and red: Let $Q$ denote the regions of $T^*$ except for the region corresponding to node $c$. First make $Q$ green. Then partition the remaining region $P \setminus Q$ with a gravity-like move as follows. Apply a GRAVITY move w.r.t. $P \setminus Q$ to subdivide it into two weak polygons of areas $\text{area}(D_1)$ for red and $\text{area}(D_2) - \text{area}(Q)$ for green; see Fig. 7. After this ReCom move, $D_1$ is weakly simple and $D_2$ is a weak polygon (in which $D_1$ is a hole if $Q$ is a weak polygon with a hole).
2. ReCom green and blue removing unnecessary green and blue corridors simultaneously as follows. Remove any green and blue monochromatic corridors corresponding to all edges of $T^*$. Note that this merges some nodes of $T(D_3)$ (see Fig. 7), and creates cycles in $T(D_3)$. While there is a cycle in $T(D_3)$ remove a blue corridor in an edge of $T(D_3)$ in a cycle. As this process modifies only green and red, it requires a single ReCom move. After this ReCom move, $D_3$ is a weakly simple polygon and $D_2$ is a weakly simple or weak polygon.
3. ReCom green and red with a GRAVITY move, restoring the ordering property.

▶ **Lemma 8.** *Let $M = \{D_1, D_2, D_3\}$ be a 3-district map with the ordering property, and $M' = \{D_1', D_2', D_3'\}$ the map returned by an EXCHANGE sequence on $M$. Let $P = D_1 \cup D_2$ and $P' = D_1' \cup D_2'$. Then, $M'$ satisfies the ordering property, and $|E(T(P'))| \leq \frac{2}{3}|E(T(P))|$.*

## 3.6 Full Reconfiguration Algorithm

Overall, the algorithm for a 3-district map $M([0,1]^2) = \{D_1, D_2, D_3\}$ works as follows: after a preprocessing phase of $O(1)$ ReCom moves, apply the sequence of three moves GRAVITY$(D_1, D_2)$, GRAVITY$(D_2, D_3)$, and GRAVITY$(D_1, D_2)$; compute the corridor graph

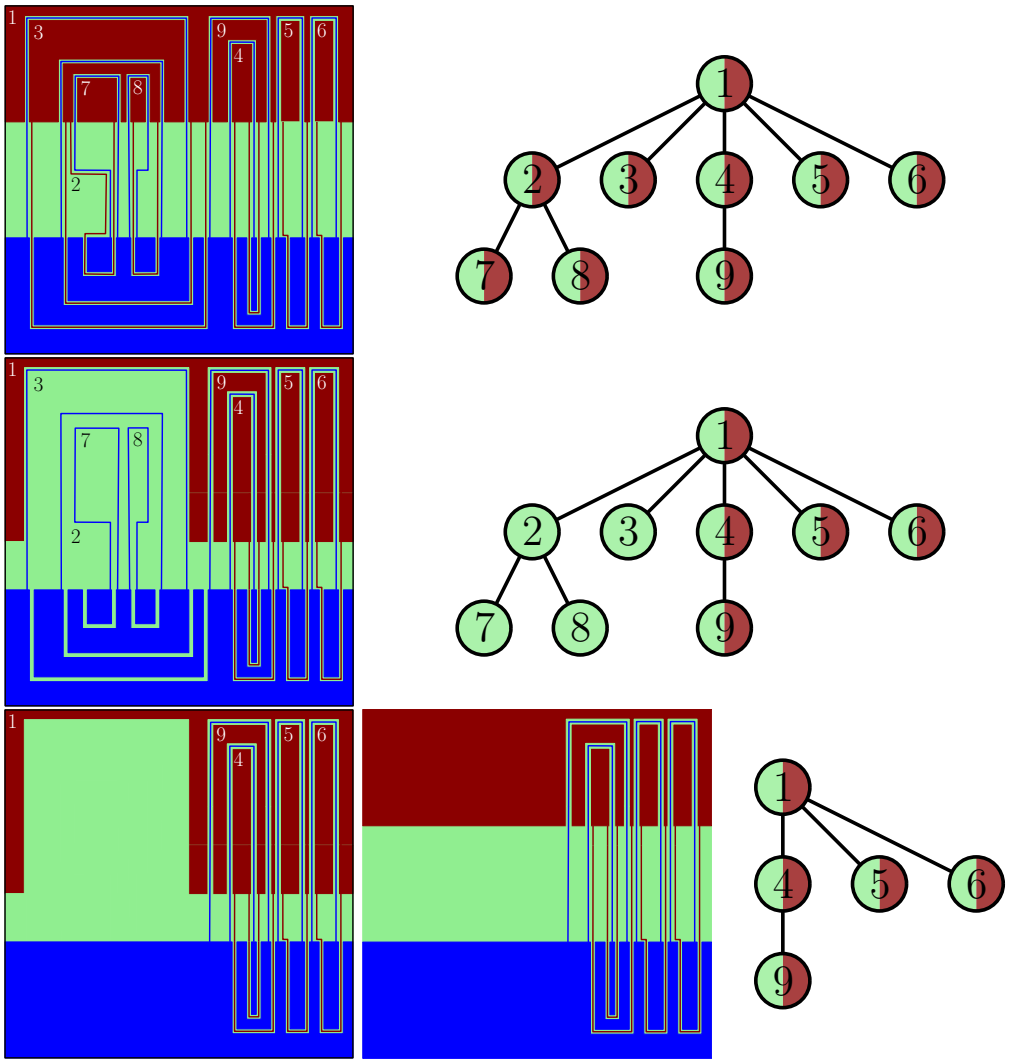

**Figure 7** An exchange sequence, shown with maps (left) and corresponding tree representations (right). Top: a map returned by a sequence of three gravity moves. Middle: using node 1 as the centroid $c$ and filling the subtree containing nodes 2, 3, 7 and 8 with green. Bottom: removing unnecessary corridors and performing a gravity move.

$T(P)$ for $P = D_1 \cup D_2$; while $T(P)$ has two or more nodes, apply an exchange sequence. Once $T(P)$ has one node, $\textsc{Gravity}(D_1, D_2)$ yields the canonical configuration.

▶ **Theorem 9.** *Given a 3-district map $M([0,1]^2) = \{D_1, D_2, D_3\}$ of complexity $n$, there is a sequence of $O(\log n)$ ReCom moves that transforms it into a canonical map. Furthermore, the districts in each intermediate map are polygons with $O(n)$ vertices and at most one hole.*

**Proof.** After preprocessing, three Gravity moves bring the districts into canonical form with the possible exception of corridors. Each exchange sequence eliminates a constant fraction of corridors by Lemma 8. After $O(\log n)$ ReCom moves we then obtain the canonical configuration.

The algorithm described above produces a sequence of ReCom moves, where the districts in intermediate maps are weak polygons. By Proposition 1, these maps can successively be perturbed into polygons. This completes the proof of the first claim.

It remains to show that the districts in each intermediate map are polygons with $O(n)$ vertices and at most one hole. By construction, the only possible hole appears in the green district after the first step of the EXCHANGE sequence. Each of the $O(1)$ ReCom moves in preprocessing adds a corridor with $O(n)$ vertices, and so each district has $O(n)$ vertices at the end of preprocessing. By Lemma 4, each gravity move increases the number of vertices by a constant factor. After three gravity moves, each district still has $O(n)$ vertices.

The algorithm applies $O(\log n)$ exchange sequences. At the end of every exchange sequence, the districts are in canonical form with the exception of corridors. Each exchange sequence removes some of the corridors, and does not create new corridors. It should be clear that the complexity of the blue district only decreases since corridors are only eliminated and never created. Note that intermediate ReCom moves within an EXCHANGE sequence (step 1) may add $O(n)$ new vertices to the red district. In an exchange sequence, the 1st ReCom move is a GRAVITY move w.r.t. a sub-polygon, and creates only $O(n)$ new vertices by Lemma 4. The 2nd ReCom move eliminates corridors (and the corresponding vertices); and the 3rd ReCom move eliminates any other vertices created in the 1st move of the sequence. Thus, the complexities of the red and green districts decrease after one EXCHANGE sequence.

Finally, when we perturb all weak polygons into polygons in the entire ReCom sequence, the number of vertices remains $O(n)$ for each district by Proposition 1. ◀

## 4 Reconfiguration for $k$ Districts

We generalize our algorithm to an arbitrary number of districts, using recursion. For any $3 \le k \le n$, an *instance* $I = (M(\mathcal{R}), M'(\mathcal{R}), \delta)$ of the problem consists of two area-compatible $k$-district maps $M(\mathcal{R}) = \{D_1, \ldots, D_k\}$ and $M'(\mathcal{R}) = \{D'_1, \ldots, D'_k\}$, where $\mathcal{R}$ is a weak polygon with at most one hole, and $\delta$ is a density function. We define the complexity of $I$ (denoted $|I|$) as the pair $(k, n)$, where $n$ is the maximum over the compressed complexities of $M$ and $M'$, and the complexities of all districts $D_i$ and $D'_i$ ($i \in \{1, \ldots, k\}$). The overall recursive strategy goes as follows (see the full paper for the details): First construct a piecewise linear retraction from a (possibly punctured) unit square $\mathcal{S}$ to $\mathcal{R}$, and extend $M$ and $M'$ to two maps on $\mathcal{S}$. If $k \ge 4$, then group the $k$ districts into three *superdistricts*, each containing $\lfloor k/3 \rfloor$ or $\lceil k/3 \rceil$ districts; and run the algorithm in Section 3 on the superdistricts. Note that each ReCom move on a pair of superdistricts is an instance of our problem with fewer districts, which can be solved recursively. The retraction then transforms the ReCom sequence on $\mathcal{S}$ to a ReCom sequence on $\mathcal{R}$. We analyze the recursion to give a bound on the number of ReCom moves.

▶ **Theorem 10.** *Given any two area-compatible polygonal $k$-district maps of complexity at most $n$ in a simply connected domain,* $\exp(O(\log k \log\log n)) = (\log n)^{O(\log k)} = k^{O(\log\log n)}$ *ReCom moves are sufficient to transform one into the other. Furthermore, the complexity of each map in intermediate steps is* $n^{k^{O(1)}}$.

**Proof.** For $3 \le k \le n$, let $T(k, n)$ denote the minimum number of ReCom moves that can transform any polygonal $k$-district map to any other with compatible areas, and the domain as well as each district is a polygon with at most $n$ vertices. From an instance $I(k, n)$, our algorithm makes $O(\log n)$ recursive calls of the form $I(\frac{2k}{3}, c \cdot n)$, where $c$ is a constant. Then,

$$T(k, n) \le O\left(T\left(\frac{2k}{3}, c \cdot n\right) \cdot \log n\right) + O(k).$$

The height of the recursion tree is $O(\log k)$ and the maximum branching factor is $O(\log(n \cdot c^{\log k})) = O(\log n + \log k) = O(\log n)$ since $k < n$. Then $T(k, n)$ solves to $\exp(O(\log k \log\log n)) = (\log n)^{O(\log k)} = k^{O(\log\log n)}$. By Proposition 1, we can convert the ReCom sequence on weak representation to a ReCom sequence of the same length in which all districts are simple polygons.

The analysis above prioritized the number of ReCom moves, rather than the complexity of the map at intermediate steps. For instance, consider the recursion that simulates a ReCom move of superdistricts transforming a $k$-district map $M(\mathcal{R})$ into $M'(\mathcal{R})$. Our algorithm recurses on a $\frac{2k}{3}$-district map of complexity $c \cdot n$ on a punctured square $\mathcal{S}$, which yields a sequence of $O(\log n)$ ReCom moves. However, to convert this into a sequence of ReCom moves on $k$-district maps, one must apply a retraction $\mathcal{H}^*$ (in the full paper) to every intermediate map, retracting a weakly simple polygon $H$ to its boundary $\partial H$. Since the complexity of $H$ could be $\Omega(n)$, $H$ might cross the same district $\Omega(n)$ times, which causes $\mathcal{H}^*$ to push the district into $\Omega(n)$ narrow corridors along the boundary of $H$. This might cause the complexity of the district to increase to $\Omega(n^2)$ in intermediate steps. The retraction $\mathcal{H}^*$, described in the full paper, ensures that the complexity goes up from $n$ to at most $O(n^2)$ after applying $\mathcal{H}^*$ in each recursive step. Since the depth of the recursion tree is $O(\log k)$, the maximum complexity of all intermediate maps is $n^{2^{O(\log k)}} = n^{k^{O(1)}}$. Note that this does not increase the number of ReCom moves since $M$ and $M'$ are determined in the parent level, and $\mathcal{H}^*$ is only applied to recover intermediate steps between $M$ and $M'$, which are obtained from lower complexity maps in the children level. ◀

## 5 Lower Bound Construction

This section shows that $\Omega(\log n)$ ReCom moves are sometimes necessary to transform a given map of complexity $n$ into canonical form, even for three districts of equal areas in $[0, 1]^2$.

**Overview.** We describe an initial map with 3 districts in a unit square, and show that after $k$ ReCom moves, each district contains an arc of a specific combinatorial pattern (defined below). These arcs are defined recursively, each iteration roughly tripling the complexity of the arcs. Thus the total complexity of the arcs in iteration $\ell$ is $O(3^\ell)$. The initial district map is a thickening of one of these arcs after $m \geq 6$ iterations. We show that if each district contains an arc from iteration $\ell$, then after a recombination they each contain an arc of iteration $\ell - 4$. In the canonical configuration, each district can only contain arcs of iteration 1. Then, the number of recombinations from the initial district map to the canonical configuration is at least linear in the number of iterations.

**Construction.** We first describe the family of simple arcs $F_\ell$, for all $\ell \in \mathbb{N}_0$, mentioned in the overview. All arcs in $F_\ell$ will start at the $\varepsilon$-neighborhood of the left side of the square and end at the $\varepsilon$-neighborhood of the right side, crossing the middle section $3^\ell$ times. Each family $F_\ell$ can be described with a combinatorial pattern, namely, the order in which the arcs traverse the $3^\ell$ segments in the middle section of the square. In the base case, $F_0$ is the set of arcs that cross the middle section only once. Given an arc $\gamma_\ell \in F_\ell$, we describe an arc $\gamma_{\ell+1} \in F_{\ell+1}$. We construct two arcs, $\gamma_\ell^+, \gamma_\ell^- \in F_\ell$, that closely follow $\gamma_\ell$ on the left and on the right, respectively, and are mutually noncrossing. Then $\gamma_{\ell+1}$ is the concatenation of $\gamma_\ell$, the reverse of $\gamma_\ell^-$, and $\gamma_\ell^+$, where two consecutive arcs are connected by short arcs in the left and right $\varepsilon$-neighborhoods of the square; see Fig 8. Let $F_{\ell+1}$ be the family of all arcs with the same combinatorial pattern as $\gamma_{\ell+1}$. The following observation follows by construction.

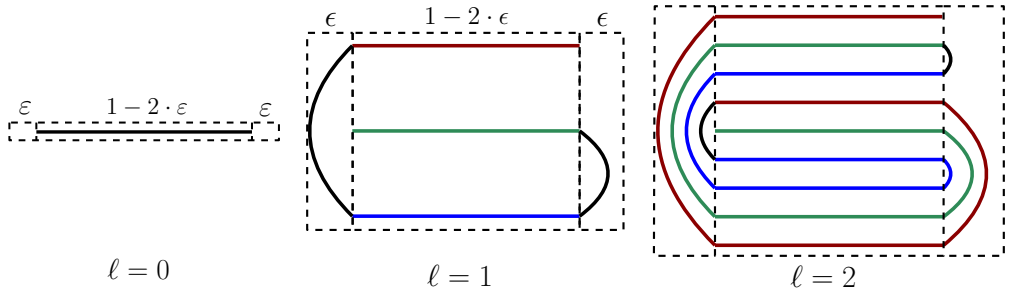

**Figure 8** The first three levels of the recursive construction for arcs in $F_\ell$, for $\ell \in \{0,1,2\}$. Note that the blue, green, and red arcs for $\ell = 2$ each resemble a copy of the entire stage for $\ell = 1$.

▶ **Observation 11.** *For $0 \le j \le \ell$, we can partition every arc $\gamma_\ell \in F_\ell$ into $3^j$ arcs in $F_{\ell-j}$.*

**Initial Map.** The initial map is drawn relative to an arc $\gamma_m \in F_m$ whose middle segments are equally spaced horizontal line segments in the unit square. The map is a "thickening" of $\gamma_m$ where the middle section is partitioned into $3^m$ rectangles of equal area. Each of the three districts is created based on one of three rough copies of $\gamma_{m-1}$, i.e., the $(m-1)$-anchors of $\gamma_m$. We use the portions of the anchors of $\gamma_m$ in the $\varepsilon$-neighborhoods of the vertical sides of the unit square to construct corridors that make each district connected.

In the full paper, we show that any ReCom move can only make constant progress (in the number of iterations) towards the canonical map.

▶ **Theorem 12.** *There exist two area-compatible 3-district maps, $M$ and $M'$, both with complexity $O(n)$, such that $\Omega(\log n)$ ReCom moves are necessary to reconfigure $M$ into $M'$, even when the districts in both maps are axis-aligned orthogonal polygons with vertices on an integer grid of size $O(n) \times O(n)$.*

## 6 Conclusions

We have shown that (in our continuous setting) any pair of area-compatible district maps can be reconfigured into each other by a sequence of area-preserving recombination moves. Though the discrete version of this result remains unsolved (see Related Work), our result suggests that for any two maps, with a discretization of the geographic domain which is granular enough, we can connect them by ReCom moves. However, establishing quantitative bounds on the necessary granularity is left for future work.

Between 3-district maps, the number of recombination moves is $O(\log n)$, where $n$ is the combinatorial complexity of the maps, matching our worst-case lower bound of $\Omega(\log n)$. Between $k$-district maps, for $k \ge 4$, we construct a sequence of $\exp(O(\log k \log\log n)) = (\log n)^{O(\log k)}$ ReCom moves. It remains an open problem whether the number of moves can be reduced to be polynomial in both $k$ and $n$. For $k \ge 4$ districts, our algorithm uses a recursion of depth $O(\log k)$. However, this approach increases the complexity of intermediate maps to $n^{k^{O(1)}}$. It is also an open problem whether there exists a sequence of ReCom moves where the complexity of intermediate maps remains polynomial in both $k$ and $n$.

## Abstract

The $k$-Detour problem is a basic path-finding problem: given a graph $G$ on $n$ vertices, with specified nodes $s$ and $t$, and a positive integer $k$, the goal is to determine if $G$ has an $st$-path of length exactly $\mathsf{dist}(s,t)+k$, where $\mathsf{dist}(s,t)$ is the length of a shortest path from $s$ to $t$. The $k$-Detour problem is NP-hard when $k$ is part of the input, so researchers have sought efficient parameterized algorithms for this task, running in $f(k)\,\mathrm{poly}(n)$ time, for $f(\cdot)$ as slow-growing as possible.

We present faster algorithms for $k$-Detour in undirected graphs, running in $1.853^k\,\mathrm{poly}(n)$ randomized and $4.082^k\,\mathrm{poly}(n)$ deterministic time. The previous fastest algorithms for this problem took $2.746^k\,\mathrm{poly}(n)$ randomized and $6.523^k\,\mathrm{poly}(n)$ deterministic time [Bezáková-Curticapean-Dell-Fomin, ICALP 2017]. Our algorithms use the fact that detecting a path of a given length in an undirected graph is easier if we are promised that the path belongs to what we call a "bipartitioned" subgraph, where the nodes are split into two parts and the path must satisfy constraints on those parts. Previously, this idea was used to obtain the fastest known algorithm for finding paths of length $k$ in undirected graphs [Björklund-Husfeldt-Kaski-Koivisto, JCSS 2017], intuitively by looking for paths of length $k$ in randomly bipartitioned subgraphs. Our algorithms for $k$-Detour stem from a new application of this idea, which does not involve choosing the bipartitioned subgraphs randomly.

Our work has direct implications for the $k$-Longest Detour problem, another related path-finding problem. In this problem, we are given the same input as in $k$-Detour, but are now tasked with determining if $G$ has an $st$-path of length *at least* $\mathsf{dist}(s,t)+k$. Our results for $k$-Detour imply that we can solve $k$-Longest Detour in $3.432^k\,\mathrm{poly}(n)$ randomized and $16.661^k\,\mathrm{poly}(n)$ deterministic time. The previous fastest algorithms for this problem took $7.539^k\,\mathrm{poly}(n)$ randomized and $42.549^k\,\mathrm{poly}(n)$ deterministic time [Fomin et al., STACS 2022].

## 1 Introduction

The $k$-Path problem is a well-studied task in computer science:

> $k$-Path
> **Given:** $k \in \mathbb{N}^+$, a graph $G$, nodes $s$ and $t$.
> **Determine:** Does $G$ contain a simple path of length $k$ from $s$ to $t$?

For graphs $G$ with $n$ nodes, this problem can be easily solved in $O(kn^k)$ time by enumerating all sequences of $k$ vertices. In the 1980s, Monien [13] showed that the $k$-Path problem is actually fixed-parameter tractable (FPT) in $k$, presenting a $k!\,\mathrm{poly}(n)$ time algorithm solving $k$-Path. Since then, significant research has gone into obtaining faster algorithms for $k$-Path, with better dependence on $k$ (see [3, Table 1] for an overview of the many results in this line of work). This research culminated in the work of Koutis and Williams [11, 16, 12], who showed that $k$-Path can be solved in $2^k\,\mathrm{poly}(n)$ (randomized) time, and Björklund, Husfeldt, Kaski, and Koivisto [3, Section 2], who proved that in undirected graphs, $k$-Path can be solved even faster in $1.657^k\,\mathrm{poly}(n)$ (randomized) time. *Throughout this paper, we assume that algorithms are randomized (and return correct answers with high probability in the stated time bounds), unless otherwise specified.*

The $k$-Path problem is a parameterized version of the NP-complete Longest Path problem, but it is not the only natural parameterization. Various other parameterizations of $k$-Path have been proposed and studied, which we consider in the present paper.

1. **Finding a path of length at least $k$.** Instead of looking for a path of length *exactly* $k$ from $s$ to $t$, one can try to determine the existence of an $st$-path of length *at least* $k$:

   > $k$-Longest Path
   > **Given:** $k \in \mathbb{N}^+$, a graph $G$, nodes $s$ and $t$.
   > **Determine:** Does $G$ contain a simple path of length ***at least*** $k$ from $s$ to $t$?

   Observe that in the $k$-Longest Path problem, the length of a solution path is not necessarily bounded as a function of $k$. However, it is known that $k$-Longest Path is also FPT: work of Zehavi [17] and Fomin, Lokshtanov, Panolan, and Saurabh [9] implies that $k$-Longest Path can be solved in $4^k\,\mathrm{poly}(n)$ time. More recently, Eiben, Koana, and Wahlström [7, Section 6.3] proved that over undirected graphs, $k$-Longest Path can be solved in $1.657^k\,\mathrm{poly}(n)$ time, matching the fastest known runtime for $k$-Path.

2. **Finding an $st$-path longer than a polynomial-time guarantee.** Another parameterization for $k$-Path is motivated by the fact that one can find a *shortest path* from $s$ to $t$ in polynomial time. If the shortest path distance $\mathsf{dist}(s,t)$ happens to already be long, then it is actually "easy" to find a long path from $s$ to $t$. Therefore, it is natural to consider the parameterized complexity of searching for an $st$-path that is $k$ edges *longer* than the shortest path length from $s$ to $t$. Our work focuses on these so-called "detour" variants of the path detection problems discussed above.

   > $k$-Detour (a.k.a. $k$-Exact Detour)
   > **Given:** $k \in \mathbb{N}^+$, a graph $G$, nodes $s$ and $t$.
   > **Determine:** Does $G$ contain a simple path of length $\mathsf{dist}(s,t)+k$ from $s$ to $t$?

Since $k$-Path efficiently reduces to solving a single instance of $(k-1)$-Detour,[1] the $k$-Detour problem is at least as hard as the classical $k$-Path problem.
The $k$-Detour problem was introduced by Bezáková, Curticapean, Dell, and Fomin [2], who showed that it can be solved by calling polynomially many instances of $\ell$-Path, for path lengths $\ell \leq 2k+1$. Employing the fastest known $k$-Path algorithms, this implies that $k$-Detour can be solved in $2^{2k}\operatorname{poly}(n) = 4^k \operatorname{poly}(n)$ time in general, and even faster over undirected graphs in $1.657^{2k}\operatorname{poly}(n) \leq 2.746^k \operatorname{poly}(n)$ time.

The two parameterizations above can be combined to produce the following problem:

$k$-Longest Detour
**Given:** $k \in \mathbb{N}^+$, a graph $G$, nodes $s$ and $t$.
**Determine:** Does $G$ contain a simple path of length ***at least*** $\mathsf{dist}(s,t)+k$ from $s$ to $t$?

Observe that $k$-Longest Detour is at least as hard as $k$-Longest Path. Unlike the problems discussed above, $k$-Longest Detour over directed graphs is not known to be FPT: in fact, it remains open whether $k$-Longest Detour is in P even for the special case of $k = 1$! However, in undirected graphs, Fomin, Golovach, Lochet, Sagunov, Simonov, and Saurabh [8] showed that $k$-Longest Detour can be reduced to solving $p$-Detour for $p \leq 2k$, and then solving polynomially many instances of $\ell$-Longest Path, for $\ell \leq 3k/2$. Employing the fastest known algorithms for $k$-Detour and $k$-Longest Path as subroutines, this implies that $k$-Longest Detour can be solved over undirected graphs in $7.539^k \operatorname{poly}(n)$ time.

The algorithms for $k$-Detour and $k$-Longest Detour discussed above are significantly slower than the fastest known algorithms for the analogous $k$-Path and $k$-Longest Path problems. This motivates the questions: can $k$-Detour be solved as quickly as $k$-Path, and can $k$-Longest Detour be solved as quickly as $k$-Longest Path? Given the extensive and influential line of work that has gone into finding faster algorithms for $k$-Path and $k$-Longest Path, obtaining faster algorithms for these detour problems as well is an interesting open problem in parameterized complexity and exact algorithms.

## Our Results

The main result of our work is a faster algorithm for $k$-Detour on undirected graphs.

▶ **Theorem 1.** *In undirected graphs, $k$-Detour can be solved in $1.853^k \operatorname{poly}(n)$ time.*

This marks a significant improvement over the previous fastest $2.746^k \operatorname{poly}(n)$ time algorithm for $k$-Detour (and shows, for example, that this problem can be solved in faster than $2^k \operatorname{poly}(n)$ time, which is often a barrier for parameterized problems). Since the fastest known algorithms for $k$-Longest Detour over undirected graphs have a bottleneck of solving $2k$-Detour, Theorem 1 implies the following result.

▶ **Theorem 2.** *In undirected graphs, $k$-Longest Detour can be solved in $3.432^k \operatorname{poly}(n)$ time.*

Again, this is a significant improvement over the previous fastest algorithm for $k$-Longest Detour on undirected graphs, which ran in $7.539^k \operatorname{poly}(n)$ time.

Our algorithm for Theorem 1 applies the fact that $k$-Path is easier to solve on undirected graphs which have a prescribed vertex partition into two sets, where we constrain the path to contain a particular number of nodes from one set, and a particular number of edges

[1] Given an instance of $k$-Path, add an edge from $s$ to $t$. Then a solution to $(k-1)$-Detour in this new graph corresponds to a solution to $k$-Path in the original graph.

whose vertices are in the other set. Formally, we consider the $(\ell, k_1, \ell_2)$-Bipartitioned Path problem: given a graph $G$ on $n$ nodes, whose vertices are partitioned into parts $V_1$ and $V_2$, with distinguished vertices $s$ and $t$, the goal is to determine if $G$ contains a simple path from $s$ to $t$ of length $\ell$, which uses exactly $k_1$ vertices from $V_1$, and exactly $\ell_2$ edges whose endpoints are both in $V_2$. A careful application of the following result from [3] is the main source of the speed-up in our algorithm for $k$-Detour.

▶ **Lemma 3** ([3, Section 2]). *Let $\ell, k_1, \ell_2$ be nonnegative integers satisfying the inequality $\ell + 1 \geq k_1 + 2\ell_2$. Then over undirected graphs, the $(\ell, k_1, \ell_2)$-Bipartitioned Path problem can be solved in $2^{k_1+\ell_2}\,\mathrm{poly}(n)$ time.*

Although this "Bipartitioned Path" problem may appear esoteric at first, Lemma 3 plays a crucial role in obtaining the fastest known algorithm for $k$-Path in undirected graphs [3], and an analogue of Lemma 3 for paths of length at least $k$ is the basis for the fastest known algorithm for $k$-Longest Path in undirected graphs [7]. Proofs of Lemma 3 can be found in [3, Section 2], [5, Section 10.4], and in the full version of this paper in [1, Appendix B].

In Section 3, we provide an intuitive overview of how Lemma 3 helps us obtain our algorithm for $k$-Detour.

The fastest known algorithms for the path and detour problems discussed above all use randomness. Researchers are also interested in obtaining fast *deterministic* algorithms for these problems. We note that a simplified version of our algorithm for $k$-Detour implies faster deterministic algorithms for these detour problems over undirected graphs.

▶ **Theorem 4.** *The $k$-Detour problem can be solved over undirected graphs by a deterministic algorithm in $4.082^k\,\mathrm{poly}(n)$ time.*

Prior to this work, the fastest known deterministic algorithm for $k$-Detour on undirected graphs ran in $6.523^k\,\mathrm{poly}(n)$ time [2].

▶ **Theorem 5.** *The $k$-Longest Detour problem can be solved over undirected graphs by a deterministic algorithm in $16.661^k\,\mathrm{poly}(n)$ time.*

Prior to this work, the fastest known deterministic algorithm for $k$-Longest Detour on undirected graphs ran in $42.549^k\,\mathrm{poly}(n)$ time [8].

In summary, we obtain new randomized and deterministic algorithms for $k$-Detour and $k$-Longest Detour over undirected graphs, whose runtimes present significant advances over what was previously known for these problems.

## Organization

The remainder of this paper presents our new algorithms $k$-Detour. A thorough discussion of additional related work can is included in the full version of this paper in [1, Appendix A].

In Section 2, we introduce relevant notation, assumptions, and definitions concerning graphs. In Section 3, we provide an overview of our algorithm for $k$-Detour. In Section 4, we present the details of our algorithm, and prove its correctness. The runtime analysis for our algorithm (and thus the formal proofs of Theorems 1, 2, 4, and 5, given correctness of our algorithm) are presented in Section 5. In Section 6, we highlight some open problems.

## 2 Preliminaries

Given positive integers $a$ and $b$, we let $[a] = \{1, 2, \ldots, a\}$, and $[a, b] = \{a, a+1, \ldots, b\}$. Given an integer $a$ and a set of integers $S$, we define $a + S = \{a + s \mid s \in S\}$.

Throughout, we let $G$ denote the input graph. We assume that $G$ is undirected, has vertex set $V$ with $|V| = n$, and, without loss of generality, is connected.[2] Throughout, we let $s$ and $t$ denote the two distinguished vertices that come as part of the input to the $k$-Detour problem. Given a vertex $u$, we let $d(u) = \mathsf{dist}(s, u)$ denote its distance from $s$. This distance is well-defined, since $G$ is connected. Given a path $P$ containing vertices $u$ and $v$, we let $P[u, v]$ denote the subpath from $u$ to $v$ on $P$.

Given an edge $e = (u, v)$ from $u$ to $v$, we say $e$ is ***forward*** if $d(v) = d(u) + 1$, ***backwards*** if $d(v) = d(u) - 1$, and ***stable*** if $d(v) = d(u)$. In an undirected graph, by triangle inequality and symmetry of distance, adjacent vertices $u$ and $v$ have $|d(u) - d(v)| \leq 1$, so every edge in a path falls into one of these three categories.

Given two vertices $u, v \in V$, let $G_{(u,v]}$ denote the induced subgraph of $G$ on the set $\{u\} \cup \{w \in V \mid d(u) < d(w) \leq d(v)\}$. Let $G_{(u,\infty)}$ denote the induced subgraph of $G$ on the set $\{u\} \cup \{w \in V \mid d(u) < d(w)\}$. Note that for every $u$ and $v$, the subgraphs $G_{(u,v]}$ and $G_{(v,\infty)}$ overlap at vertex $v$, but are disjoint otherwise.

# 3 Technical Overview

In this section, we provide an overview of how our $k$-Detour algorithm works. Our starting point is the algorithm for this problem presented in [2, Section 4], which we review in Section 3.1. Then in Section 3.2 we review how the algorithm from Lemma 3 for $(\ell, k_1, \ell_2)$-Bipartitioned Path has previously been used to obtain the fastest known algorithm for $k$-Path in undirected graphs. With this context established, in Section 3.3 we outline how we combine the techniques from Sections 3.1 and 3.2 with new ideas to prove Theorem 1.

## 3.1 Previous Detour Algorithm

The previous algorithm for $k$-Detour from [2, Section 4] performs dynamic programming over nodes in the graph, starting from $t$ and moving to vertices closer to $s$. In the dynamic program, for each vertex $x$ with $d(x) \leq d(t)$, we compute all offsets $r \leq k$ such that there is a path of length $d(t) - d(x) + r$ from $x$ to $t$ in the subgraph $G_{(x,\infty)}$. Determining this set of offsets for $x = s$ solves the $k$-Detour problem, since $G_{(s,\infty)} = G$.

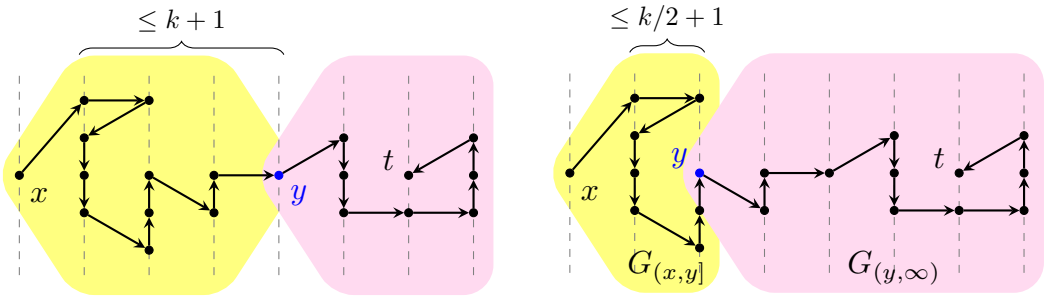
If $d(t) - d(x) \leq k$, we can find all such offsets just by solving $\ell$-Path for $\ell \leq 2k$.

So, suppose we are given a vertex $x$ with $d(t) - d(x) \geq k + 1$ and an offset $r \leq k$, and wish to determine if there is a path of length $d(t) - d(x) + r$ from $x$ to $t$ in $G_{(x,\infty)}$. If there is such a path $P$, then [2] argues that $P$ can always be split in as depicted in Figure 1a: for some vertex $y$ with $d(y) > d(x)$, we can decompose $P$ into two subpaths:

1. a subpath $A$ from $x$ to $y$ of length at most $2k + 1$, such that all internal vertices $v$ in $A$ satisfy $d(x) < d(v) < d(y)$, and
2. a subpath $B$ from $y$ to $t$ in $G_{(y,\infty)}$ of length at most $d(t) - d(y) + k$.

We can always split a path $P$ in this manner because $P$ has length at most $d(t) - d(x) + k$, so at most $k$ edges in $P$ are not forward edges. Intuitively, as we follow the vertices along the path $P$, the distance of the current vertex from $s$ can decrease or stay the same at most $k$ times, and so $P$ cannot contain too many vertices which are the same distance from $s$. This allows one to argue that there is a vertex $y$ with $d(y) \leq d(x) + k + 1$ such that all internal vertices $v$ of the subpath $P[x, y]$ have $d(x) < d(v) < d(y)$. Since $d(y) \leq d(x) + k + 1$ and $P$ has length at most $d(t) - d(x) + k$, it turns out that $P[x, y]$ has length at most $2k + 1$.

[2] If $G$ were not connected, we could replace it with the connected component containing $s$, and solve the detour problems on this smaller graph instead.



**(a) Previous Algorithms**: A subpath $P$ from $x$ to $t$ in $G_{(x,\infty)}$ of a solution path can always be split at a vertex $y$ with $d(y) \leq d(x) + k + 1$, such that $d(u) \neq d(y)$ for all vertices $u \neq y$ in $P$.

**(b) Our Algorithm**: In undirected graphs, a subpath $P$ from $x$ to $t$ in $G_{(x,\infty)}$ of a solution path can be split at a vertex $y$ with $d(y) \leq d(x)+k/2+1$, such that $P[x, y]$ is in $G_{(x,y]}$ and $P[y, t]$ is in $G_{(y,\infty)}$.

**Figure 1** To solve $k$-Detour, we split subpaths $P$ of candidate solutions at a vertex $y$ satisfying certain nice properties. We obtain a speed-up by getting better upper bounds on $d(y)$ in Figure 1b than previous work did in Figure 1a, by allowing $P[x, y]$ to have internal vertices $u$ with $d(u) = d(y)$.

Note that since $G_{(y,\infty)}$ only contains vertices $v$ with $d(v) \geq y$, the paths $A$ and $B$ must be disjoint. We can find the length of $A$ using an algorithm for $(2k+1)$-Path, and the length of $B$ will have already been computed in our dynamic program (since $y$ is further from $s$ than $x$). So, by trying out all possible $y$, finding the possible lengths for subpaths $A$ and $B$, and then adding up these lengths, we can get all possible lengths for $P$ in the dynamic program, and solve $k$-Detour.

## 3.2 Previous Path Algorithm

The fastest known algorithm for $k$-Path in undirected graphs goes through the $(k, k_1, \ell_2)$-Bipartitioned Path problem. Recall that in this problem, we are given a bipartition $V_1 \sqcup V_2$ of the vertices in the graph, and want to find a path of length $k$ from $s$ to $t$, which uses $k_1$ vertices in $V_1$ and $\ell_2$ edges with both endpoints in $V_2$. The authors of [3] showed that $(k, k_1, \ell_2)$-Bipartitioned Path can be solved in $2^{k_1+\ell_2}\,\mathrm{poly}(n)$ time over undirected graphs.

Why does this imply a faster algorithm for $k$-Path in undirected graphs? Well, suppose the input graph contains a path $P$ of length $k$ from $s$ to $t$. Consider a uniform random bipartition of the vertices of the graph into parts $V_1$ and $V_2$. We expect $(k+1)/2$ vertices of $P$ to be in $V_1$, and $k/4$ edges of $P$ to have both endpoints in $V_2$. In fact, this holds with constant probability, so we can solve $k$-Path by solving $(k, (k+1)/2, k/4)$-Bipartitioned Path in the randomly partitioned graph. By Lemma 3 this yields a $2^{3k/4}\,\mathrm{poly}(n) \approx 1.682^k\,\mathrm{poly}(n)$ time algorithm for $k$-Path. We can obtain a faster algorithm using the following modification: take several uniform random bipartitions of the graph, and solve $(k, k_1, \ell_2)$-Bipartitioned Path separately for each bipartition, for $k_1 + \ell_2 \leq 3(1-\varepsilon)k/4$, where $\varepsilon > 0$ is some constant. The number of bipartitions used is some function of $k$ and $\varepsilon$, set so that with high probability at least one of the partitions $V_1 \sqcup V_2$ has the property that the total number of vertices of $P$ in $V_1$ and number of edges of $P$ with both endpoints in $V_2$ is at most $3(1-\varepsilon)k/4$. Setting the parameter $\varepsilon$ optimally yields a $1.657^k\,\mathrm{poly}(n)$ time algorithm for $k$-Path [3].

## 3.3 Our Improvement

As in the previous approach outlined in Section 3.1, our algorithm for $k$-Detour performs dynamic programming over vertices in the graph, starting at $t$, and then moving to vertices closer to $s$. For each vertex $x$ with $d(x) \leq d(t)$, we compute all offsets $r \leq k$ such that there is a path of length $d(t) - d(x) + r$ from $x$ to $t$ in the subgraph $G_{(x,\infty)}$. Obtaining this information for $x = s$ and $r = k$ solves the $k$-Detour problem.

Given a vertex $x$ and offset $r \leq k$, we wish to determine if $G$ contains a path of length $d(t) - d(x) + r$ from $x$ to $t$ in $G_{(x,\infty)}$. Suppose there is such a path $P$. If $d(t) - d(x)$ is small enough, it turns out we can find $P$ by solving $p$-Path for small values of $p$. So, for the purpose of this overview, suppose that $d(t) - d(x)$ is sufficiently large. In this case, as outlined in Section 3.1, previous work showed that $P$ can be split into two subpaths $A$ and $B$ contained in disjoint subgraphs, such that $A$ has length at most $2k + 1$. This splitting argument holds even for directed graphs. Our first improvement comes from the observation that in undirected graphs, we can decompose the path $P$ with a smaller prefix: as depicted in Figure 1b, there must exist a vertex $y$ with $d(y) > d(x)$, such that $P$ splits into a subpath $A$ from $x$ to $y$ in $G_{(x,y]}$ of length at most $3k/2+1$, and a path $B$ from $y$ to $t$ in $G_{(y,\infty)}$ of length at most $d(t) - d(y) + k$. We can find the length of $A$ by solving $(3k/2 + 1)$-Path, and the length of $B$ will already have been computed by dynamic programming, since $d(y) > d(x)$.

This split is possible because any consecutive vertices $u$ and $v$ in $P$ have $|d(u) - d(v)| \leq 1$ (this is true for undirected graphs, but is not true in general for directed graphs). Since $P$ has length at most $d(t) - d(x) + k$, it turns out that $P$ has at most $k/2$ backwards edges. This lets us argue that there exists a vertex $y$ with $d(y) \leq d(x) + k/2 + 1$ such that $P[x, y]$ is contained in $G_{(x,y]}$ and $P[y, t]$ is contained in $G_{(y,\infty)}$. Finally, $A = P[x, y]$ should have length at most $k$ more than $d(y) - d(x)$, which means it has length at most $3k/2 + 1$.

This simple modification already yields a faster algorithm[3] for $k$-Detour. We get further improvements by performing casework on the number of stable edges in $P$ (recall that an edge $(u, v)$ is stable if both its endpoints have the same distance $d(u) = d(v)$ from $s$).

First, suppose $P$ has at least $m$ stable edges, for some parameter $m$. Since $P$ has length at most $d(t) - d(x) + k$, we can argue that $P$ has at most $(k - m)/2$ backwards edges. With this better upper bound on the number of backwards edges, we can improve the splitting argument and show that $P$ decomposes into subpaths $A$ and $B$, such that the length of $A$ is at most $(3k - m)/2$, and the length of $B$ was already computed by our dynamic program. It then suffices to solve $(3k - m)/2$-Path, which yields a speed-up whenever $m \geq \Omega(k)$.

Otherwise, $P$ has at most $m$ stable edges. In this case, we consider the bipartition $V_1 \sqcup V_2$ of the vertex set, where $V_1$ has all vertices at an odd distance from $s$, and $V_2$ has all vertices with even distance from $s$. Since $G$ is undirected, consecutive vertices on the path $P$ differ in their distance from $s$ by at most one. In particular, all forward and backward edges in $P$ cross between the parts $V_1$ and $V_2$. Only the stable edges can contribute to edges with both endpoints in $V_2$. Since we assumed that the number of stable edges is small, it turns out we can find the length of the subpath $A$ of $P$ by solving $(\ell, k_1, \ell_2)$-Bipartitioned Path with respect to the given bipartition, for some $\ell_2$ which is very small. In particular, this approach computes the length of $A$ faster than naively solving $(3k - m)/2$-Path. By setting an appropriate threshold for $m$, we can minimize the runtimes of the algorithm in both of the above cases, and establish Theorem 1.

So in summary, our faster algorithms come from two main sources of improvement: using the structure of shortest paths in undirected graphs to get a better "path-splitting" argument in the dynamic program from $k$-Detour, and cleverly applying the fast algorithm from Lemma 3 for $(\ell, k_1, \ell_2)$-Bipartitioned Path with carefully chosen bipartitions.

We note that our application of $(\ell, k_1, \ell_2)$-Bipartitioned Path is qualitatively different from its uses in previous work. As discussed in Section 3.1, previous algorithms for $k$-Detour work by solving instances of $k$-Path, and as described in Section 3.2, the fastest algorithms for $k$-Path on undirected graphs work by reduction to various instances of $(\ell, k_1, \ell_2)$-Bipartitioned Path. Thus, previous algorithms for $k$-Detour on undirected graphs *implicitly* rely on the

[3] In fact, this observation already yields the fast deterministic algorithms for Theorems 4 and 5.

fast algorithm for $(\ell, k_1, \ell_2)$-Bipartitioned Path, applied to random bipartitions of the input graph. We obtain a faster algorithm for $k$-Detour arguing that in certain cases, we can "beat randomness," by constructing bipartitions which leverage structural information about the graph (namely, whether the shortest path distance from $s$ to a given vertex is even or odd).

## 4 Detour Algorithm

In this section, we present Algorithm 1, our new algorithm for the $k$-Detour problem. As mentioned in the previous section, our algorithm behaves differently depending on the number of stable edges that a potential solution path contains. In particular, the algorithm depends on a parameter $\alpha \in (0, 1)$, which determines the threshold for what counts as "many" stable edges. Later, we will set $\alpha$ to optimize the runtime of Algorithm 1. Certain lines of Algorithm 1 have comments indicating case numbers, which are explained in Section 4.1.

Our algorithm computes a set $L(x)$ for each vertex $x$ in the graph, corresponding to the possible lengths of potential subpaths from $x$ to $t$ of a solution path from $s$ to $t$.

In step 3 of Algorithm 1, we compute $L(x)$ for all $x$ that are "far" from $s$, by solving instances of $\ell$-Path for $\ell \leq (3-\alpha)k/2$. Starting in step 4, we compute $L(x)$ for vertices $x$ closer to $s$, in terms of the previously computed sets $L(y)$ for vertices $y$ further from $s$. In steps 5 through 7, we compute some lengths in $L(x)$ by solving instances of $(a, k_1, \ell_2)$-Bipartitioned Path for appropriate $a, k_1, \ell_2$ values, and in 8 and 9 we compute the remaining lengths in $L(x)$ by solving $a$-Path for $a \leq (3 - \alpha)k/2 + 1$.

### 4.1 Correctness

In this section, we show that Algorithm 1 correctly solves the $k$-Detour problem for any choice of $\alpha \in (0, 1)$. The main technical part of the proof lies in inductively showing that every possible solution path from $s$ to $t$ will be considered by the algorithm and its length will be included in the set $L(s)$. In Algorithm 1, we try out values of the variable $m$ from 0 to $k$, and execute differently depending on how $m$ compares to $\alpha k$. This is interpreted as follows: suppose there is a solution path $P$ from $x$ to $t$, then $m$ corresponds to a guess of the number of stable edges in $P$.

In **Case 1**, we guess that $P$ has few stable edges $m < \alpha k$ which corresponds to steps 5 to 7. Under **Case 1**, there are two possible structures a potential solution path might take on depending on how $d(x)$ compares to $d(t)$. We refer to the case where $d(x) - d(t)$ is small as **Case 1(a)** considered by step 6, and the case where $d(x) - d(t)$ is large as **Case 1(b)** considered by step 7. In **Case 2**, we guess that $m \geq \alpha k$, so $P$ has many stable edges, which corresponds to steps 8 to 9. These cases are also formally defined in our proof of correctness.

▶ **Theorem 6.** *For any fixed $\alpha \in (0, 1)$, Algorithm 1 correctly solves the $k$-Detour problem.*

**Proof.** We prove that upon halting, each set $L(x)$ computed by Algorithm 1 has the property that for all integers $\ell \in [d(t) - d(x), d(t) - d(x) + k]$, we have

$$\ell \in L(x) \text{ if and only if there is a path of length } \ell \text{ from } x \text{ to } t \text{ in } G_{(x,\infty)}. \tag{1}$$

If this property holds, then step 10 of Algorithm 1 returns the correct answer to the $k$-Detour problem, since $\mathsf{dist}(s, t) + k$ is in $L(s)$ if and only if there is a path from $s$ to $t$ of length $\mathsf{dist}(s, t) + k$ in $G_{(s,\infty)} = G$.

So, it suffices to show that Equation (1) holds for all vertices $x$. We prove this result by induction on the distance of $x$ from $s$ in the graph.

**Algorithm 1** Our algorithm for solving $k$-Detour in undirected graphs.

**Input:** An undirected graph $G$ with distinguished vertices $s$ and $t$, and a parameter $\alpha \in (0,1)$.

1: Initialize $V_1 \leftarrow \{x \in V \mid d(x) \equiv 1 \mod 2\}$, $V_2 \leftarrow \{x \in V \mid d(x) \equiv 0 \mod 2\}$.
2: For each vertex $x$ in the graph with $d(x) \leq d(t)$, initialize $L(x) \leftarrow \emptyset$.
▷ *$L(x)$ will be the set of lengths $\ell \in [d(t)-d(x), d(t)-d(x)+k]$ such that there is a path of length $\ell$ from $x$ to $t$ in $G_{(x,\infty)}$.*

3: For each vertex $x$ with $d(x) \in [d(t)-(1-\alpha)k/2, d(t)]$, set $L(x)$ to be the set of all positive integers $\ell \leq (3-\alpha)k/2$ such that there is a path of length $\ell$ from $x$ to $t$ in $G_{(x,\infty)}$.
▷ *Base case: we compute $L(x)$ for the vertices $x$ which are furthest from $s$.*

4: For each $d$ from $d(t)-(1-\alpha)k/2-1$ down to 0, for each vertex $x$ with $d(x)=d$, complete steps 5 through 9.
▷ *Inductive Case: compute $L(x)$ layer by layer towards $s$.*

5: For each integer $m$ with $0 \leq m < \alpha k$, and for each choice of integers $k_1, \ell_2 \geq 0$ satisfying $k_1 + \ell_2 \leq (3k+m+2)/4$, complete steps 6 and 7.
▷ *This step handles **Case 1:** the solution path has few stable edges.*

6: If there is a path of length $\ell \leq 2k_1 + \ell_2$ from $x$ to $t$ in $G_{(x,\infty)}$, update $L(x) \leftarrow L(x) \cup \{\ell\}$.
▷ *This step handles **Case 1(a):** $d(t)-d(x) \leq (k-m)/2$.*

7: Try out all vertices $y$ with $d(y) \in [d(x)+1, \min(d(t), d(x)+(3k-m)/2+1)]$. If for some such $y$, there is a path from $x$ to $y$ in $G_{(x,y]}$ of length $a \leq 2k_1+\ell_2$ with exactly $k_1$ vertices in $V_1$, and $\ell_2$ edges with both endpoints in $V_2$, update $L(x) \leftarrow L(x) \cup (a + L(y))$.
▷ *This step handles **Case 1(b):** $d(t)-d(x) > (k-m)/2$.*

8: For each integer $m$ with $\alpha k < m \leq k$, complete step 9.
▷ *This step handles **Case 2:** the solution path has many stable edges.*

9: Try out all vertices $y$ with $d(y) \in [d(x)+1, d(x)+(1-\alpha)k/2+1]$. If for some such $y$, there is a path from $x$ to $y$ in $G_{(x,y]}$ of length $a \leq (3-\alpha)k/2+1$, update $L(x) \leftarrow L(x) \cup (a + L(y))$

10: Return **yes** if and only if $(\mathsf{dist}(s,t)+k) \in L(s)$.

**Base Case.** For the base case, suppose $x$ is a vertex with

$$d(x) \in [d(t)-(1-\alpha)k/2, d(t)]. \tag{2}$$

Then $L(x)$ is computed in step 3 of Algorithm 1. We now verify that Equation (1) holds.
First, suppose $\ell \in L(x)$.
Then, $\ell$ must be the length of some path from $x$ to $t$ in $G_{(x,\infty)}$ by design.
Conversely, suppose we have a path $P$ from $x$ to $t$ in $G_{(x,\infty)}$ of some length

$$\ell \leq d(t)-d(x)+k.$$

Then by the assumption on $x$ from Equation (2) in this case, we have

$$\ell \leq d(t) - d(x) + k \leq (1-\alpha)k/2 + k = (3-\alpha)k/2$$

so step 3 of Algorithm 1 correctly includes $\ell$ in $L(x)$.

Thus Equation (1) holds for all vertices $x$ satisfying Equation (2).

**Inductive Case.** For the inductive step, suppose $x$ is a vertex with

$$d(x) \leq d(t) - (1-\alpha)k/2 - 1. \tag{3}$$

We may inductively assume that we have computed sets $L(y)$ satisfying Equation (1), for all vertices $y$ with $d(y) > d(x)$.

Suppose $\ell \in L(x)$ at the end of Algorithm 1. Then either $\ell$ was added to $L(x)$ in step 6, or $\ell$ was added to $L(x)$ in steps 7 or 9 of Algorithm 1. In the former case, $\ell$ is the length of a path from $x$ to $t$ in $G_{(x,\infty)}$ by design. In the latter cases, we have $\ell = a + b$, where $a$ is the length of some path from $x$ to $y$ (for some vertex $y$ with $d(y) > d(x)$) in $G_{(x,y]}$, and (by the inductive hypothesis) $b$ is the length of some path from $y$ to $t$ in $G_{(y,\infty)}$. Since $G_{(x,y]}$ and $G_{(y,\infty)}$ intersect only at $y$, the union of these paths is a path from $x$ to $t$ in $G_{(t,\infty)}$. So, every integer in $L(x)$ is a valid length of a path from $x$ to $t$ in $G_{(x,\infty)}$ as desired.

Conversely, suppose there is a path $P$ from $x$ to $t$ in $G_{(x,\infty)}$ of length

$$\ell \in [d(t) - d(x), d(t) - d(x) + k]. \tag{4}$$

We prove that $\ell$ appears in $L(x)$.

To do this, we will analyze the number of forward, backward, and stable edges appearing in $P$. Note that $P$ has at least $d(t) - d(x)$ forward edges, since $P$ begins at a vertex at distance $d(x)$ from $s$, ends at a vertex at distance $d(t)$ from $s$, and only the forward edges allow us to move to vertices further from $s$.

Let $m$ denote the number of stable edges in $P$. We have $m \leq k$, since the length of $P$ is at most $d(t) - d(x) + k$, and $P$ has at least $d(t) - d(x)$ forward edges.

▷ Claim 7. Suppose $d(x) \leq d(t) - (k-m)/2 - 1$. Then $P$ contains a vertex $y$ such that

1. $d(y) \in [d(x) + 1, d(x) + (k-m)/2 + 1]$,
2. every vertex $u \in P[y,t]$ with $u \neq y$ has $d(u) > d(y)$, and
3. every vertex $v \in P[x,y]$ has $d(v) \leq d(y)$.

Proof. For each $i \in [(k-m)/2 + 1]$, let $z_i$ denote the last vertex on $P$ satisfying

$$d(z_i) = d(x) + i.$$

These vertices exist because we are assuming that $d(x) \leq d(t) - (k-m)/2 - 1$, and $P$ must contain vertices $v$ with $d(v) = d$ for every $d \in [d(x), d(t)]$.

By definition, each $z_i$ satisfies conditions **1** and **2** from the claim. If some $z_i$ satisfies condition **3** as well, then the claim is true.

So, suppose that none of the $z_i$ satisfy condition **3**. This means that for each index $i$, the subpath $P[x, z_i]$ contains a vertex $u$ with $d(u) > d(z_i)$. Consecutive vertices in $P$ differ in their distance from $s$ by at most one, so $P[x, z_i]$ must contain an edge $e = (v, w)$ such that $d(v) = d(w) + 1$ and $d(w) = d(z_i) = d(x) + i$. That is, $P$ contains a backwards edge from a vertex at distance $i + 1$ from $s$ to a vertex at distance $i$ from $s$, as depicted in Figure 2.

Note that $z_1, z_2, \ldots, z_{(k-m)/2+1}$ occur on $P$ in the listed order. This is because

$$d(z_1) < d(z_2) < \cdots < d(z_{(k-m)/2+1})$$

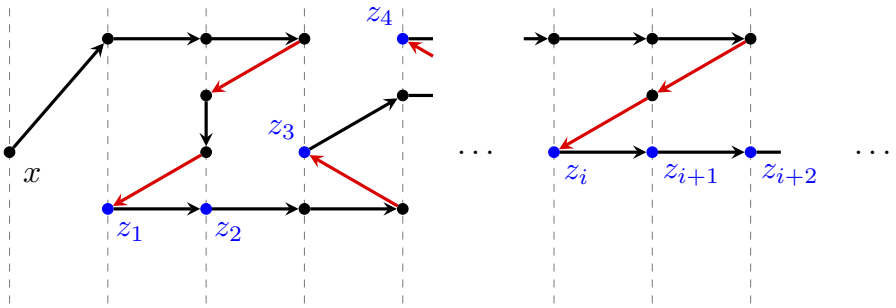


**Figure 2** If node $z_i$ does not satisfy condition **3** of Claim 7, it means that before hitting $z_i$, the path visited a node further from $s$ than $z_i$. Thus, we can associate $z_i$ with some backwards edge. The presence of too many of these backwards edges would violate the length condition on $P$, so it turns out that one such node (in the figure, $z_{i+2}$) does have to satisfy condition **3**.

and each $z_i$ satisfies condition **1** from the claim. Combined with the discussion from the previous paragraph, this means that $P$ contains at least $(k-m)/2+1$ backwards edges. We now argue that this violates the assumption on the length of $P$.

Let $f$ and $b$ denote the number of forward and backwards edges in $P$ respectively.

Since $P$ starts at $x$ and ends at $t$, we have $f - b = d(t) - d(x)$, which implies that

$$f = d(t) - d(x) + b. \tag{5}$$

Then the total length of $P$ is $f + b + m = d(t) - d(x) + m + 2b$ by Equation (5). However, since $P$ has at least $(k-m)/2+1$ backwards edges, this length satisfies

$$d(t) - d(x) + m + 2b \geq d(t) - d(x) + m + 2\left((k-m)/2 + 1\right) > d(t) - d(x) + k$$

which contradicts the fact that the length $\ell$ of $P$ satisfies Equation (4). Thus our assumption was incorrect, and one of the $z_i$ satisfies all three conditions from the claim, as desired. ◁

We now perform casework on the number of stable edges $m$ in $P$. We start with **Case 2** from step 8 of Algorithm 1, since this is the easiest case to analyze.

**Case 2: Many Stable Edges ($m \geq \alpha k$).** Suppose $m \geq \alpha k$. In this case, by Equation (3) we have

$$d(x) \leq d(t) - (1-\alpha)k/2 - 1 \leq d(t) - (k-m)/2 - 1$$

So, by Claim 7, there exists a vertex $y$ in $P$ satisfying the three conditions of Claim 7.

By condition **3** from Claim 7, the subpath $A = P[x, y]$ is contained in $G_{(x,y]}$. By condition **2** from Claim 7, the subpath $B = P[y, t]$ is contained in $G_{(y,\infty)}$.

Let $a$ denote the length of $A$, and $b$ denote the length of $B$.

Since $A$ has length at least $d(y) - d(x)$, and $P$ has length at most $d(t) - d(x) + k$ by Equation (4), we know that the length $B$ satisfies

$$b \leq d(t) - d(y) + k. \tag{6}$$

By the inductive hypothesis, $L(y)$ satisfies Equation (1), so $b \in L(y)$.

Similar to the reasoning that established Equation (6), we can prove that

$$a \leq d(y) - d(x) + k. \tag{7}$$

By condition **1** of Claim 7, we know that $d(y) \leq d(x) + (k-m)/2 + 1$. Since $m \geq \alpha k$, this implies that $d(y) \leq d(x) + (1-\alpha)k/2 + 1$.

Substituting this into Equation (7) yields

$$a \leq (1-\alpha)k/2 + 1 + k = (3-\alpha)k/2 + 1.$$

Thus, the length $a$ of $A$ will be found in step 9 of Algorithm 1. As mentioned before, $b \in L(y)$. Thus, $\ell = a + b \in (a + L(y))$ is correctly added to the set $L(x)$ in step 9 of Algorithm 1, which proves the desired result in this case.

**Case 1: Few Stable Edges ($m < \alpha k$).** If we do not fall into **Case 2**, we must have $m < \alpha k$. Recall that in step 1 of Algorithm 1, we defined $V_1 = \{u \mid d(u) \text{ is odd}\}$ and $V_2 = \{u \mid d(u) \text{ is even}\}$.

We want to argue that most edges in path $P$ cross the bipartition $V_1 \sqcup V_2$. To that end, the following claim will be helpful.

▷ Claim 8. Let $Q$ be a path of length $q$, with at most $m$ stable edges. Let $k_1$ denote the number of vertices of $Q$ in $V_1$, and let $\ell_2$ denote the number of edges in $Q$ with both endpoints in $V_2$. Then we have

$$k_1 + \ell_2 \leq (q + m + 1)/2.$$

Proof. Let $k_2$ denote the number of vertices of $Q$ in $V_2$.

Consider the cycle $C$ formed by taking $Q$ together with an additional edge between its endpoints (this new edge is imagined for the purpose of argument, and does not change the definition of $V_1$ and $V_2$).

Let $q_1$, $q_2$, and $q_{\text{cross}}$ denote the number of edges of $C$ with both endpoints in $V_1$, both endpoints in $V_2$, and endpoints in both $V_1$ and $V_2$ respectively. We have

$$2k_1 = 2q_1 + q_{\text{cross}} \tag{8}$$

because both sides of the above equation count the number of pairs $(u, e)$ such that $u$ is a vertex in $C \cap V_1$, and $e$ is an edge in $C$ incident to $u$. A symmetric argument implies that

$$2q_2 + q_{\text{cross}} = 2k_2. \tag{9}$$

Adding Equation (8) and Equation (9) together and simplifying yields

$$k_1 + q_2 = k_2 + q_1.$$

This implies that

$$k_1 + q_2 = (k_1 + k_2 + q_1 + q_2)/2.$$

Since $C$ is $Q$ with one additional edge, we have $\ell_2 \leq q_2$. So the above equation implies that

$$k_1 + \ell_2 \leq (k_1 + k_2 + q_1 + q_2)/2. \tag{10}$$

We have

$$k_1 + k_2 = q + 1 \tag{11}$$

since the total number of vertices in $Q$ must be one more than its length. By assumption on the number of stable edges in $Q$, we have

$$q_1 + q_2 \leq m. \tag{12}$$

Substituting Equation (11) and Equation (12) into the right hand side of Equation (10) yields

$$k_1 + \ell_2 \leq (q + m + 1)/2$$

which proves the desired result. ◁

With Claim 8 established, we are now ready to analyze the two subcases under **Case 1**, based on the relative distances of $x$ and $t$ from $s$.

**Case 1(a): $d(t) - d(x)$ is small.** Suppose that $d(x) \in [d(t) - (k - m)/2, d(t)]$.

In this case, Equation (4) implies that $P$ has length

$$\ell \leq d(t) - d(x) + k \leq (3k - m)/2.$$

Let $k_1$ denote the number of vertices of $P$ in $V_1$, and $k_2$ denote the number of edges in $P$ with both endpoints in $V_2$. Then by setting $Q = P$ and $q = \ell$ in Claim 8, we have

$$k_1 + \ell_2 \leq (\ell + m + 1)/2 \leq (3k + m + 2)/4. \tag{13}$$

Also, note that $P$ has length $\ell \leq 2k_1 + \ell_2$, since $2k_1$ is greater than or equal to the number of edges in $P$ incident to a vertex in $V_1$. This observation, together with Equation (13), shows that in this case, the length $\ell$ is correctly included in $L(x)$ in step 6 of Algorithm 1.

**Case 1(b): $d(t) - d(x)$ is large.** If we do not fall into **Case 1(a)**, it means that

$$d(x) \leq d(t) - (k - m)/2 - 1. \tag{14}$$

Thus, by Claim 7, there exists a vertex $y$ in $P$ satisfying the three conditions of Claim 7. The proof that $\ell \in L(x)$ in this case is essentially a combination of the proofs from **Case 2** and **Case 1(a)**.

As in **Case 2**, by condition **3** from Claim 7, the subpath $A = P[x, y]$ is contained in $G_{(x,y]}$. By condition **2** from Claim 7, the subpath $B = P[y, t]$ is contained in $G_{(y,\infty)}$.

Let $a$ and $b$ denote the lengths of paths $A$ and $B$ respectively. Reasoning identical to the arguments which established Equations (6) and (7) prove that in this case we also have

$$b \leq d(t) - d(y) + k \tag{15}$$

and

$$a \leq d(y) - d(x) + k. \tag{16}$$

Condition **1** of Claim 7 implies that $d(y) \leq d(x) + (k - m)/2 + 1$. Substituting this into Equation (16) implies that

$$a \leq (3k - m)/2 + 1.$$

Let $k_1$ denote the number of vertices of $A$ in $V_1$, and let $\ell_2$ denote the number of edges in $A$ with both endpoints in $V_2$. Then by setting $Q = A$ and $q = a$ in Claim 8, we have

$$k_1 + \ell_2 \leq (a + m + 1)/2 \leq (3k + m + 2)/4. \tag{17}$$

Also, we know that $a \leq 2k_1 + \ell_2$, because $2k_1$ is greater than or equal to the number of edges in $A$ incident to a vertex in $V_1$. Combining this observation with Equation (17), we see that the length $a$ is indeed computed in step 7 of Algorithm 1.

By the inductive hypothesis (Equation (1)) and Equation (15), we know that $b \in L(y)$. Thus we have $\ell = a + b \in (a + L(y))$, so in this case, $\ell$ is correctly included in $L(x)$ in step 7 of Algorithm 1.

This completes the induction, and proves that Equation (1) holds for all vertices $x$ in the graph. In particular, Equation (1) holds for $x$ equal to $s$. This implies that step 10 of Algorithm 1 returns the correct answer to the $k$-Detour algorithm. ◀

## 5 Applications

In this section, we present consequences of our new algorithm for $k$-Detour from Section 4.

▶ **Theorem 1.** *In undirected graphs, $k$-Detour can be solved in $1.853^k \operatorname{poly}(n)$ time.*

**Proof.** By Theorem 6, Algorithm 1 correctly solves $k$-Detour, for any value $\alpha \in (0, 1)$,

What is the runtime of Algorithm 1? Well, steps 3 and 9 of Algorithm 1 involve solving polynomially many instances of $\ell$-Path, for $\ell \leq (3 - \alpha)k/2 + 1$. Using the fastest known algorithm for $k$-Path in undirected graphs [3], these steps take

$$1.657^{(3-\alpha)k/2} \operatorname{poly}(n)$$

time. The remaining computationally intensive steps of Algorithm 1 occur in steps 6 and 7, which can be implemented by solving $\operatorname{poly}(n)$ instances of $(\ell, k_1, \ell_2)$-Bipartitioned Path, for $k_1 + \ell_2 < (3k + \alpha k + 2)/4$. By Lemma 3, these steps then take

$$2^{(3+\alpha)k/4} \operatorname{poly}(n)$$

time overall. Then by setting $\alpha = 0.55814$ to balance the above runtimes, we see that we can solve $k$-Detour over undirected graphs in

$$\left(1.657^{(3-\alpha)k/2} + 2^{(3+\alpha)k/4}\right) \operatorname{poly}(n) \leq 1.8526^k \operatorname{poly}(n)$$

time, as desired. ◀

▶ **Theorem 2.** *In undirected graphs, $k$-Longest Detour can be solved in $3.432^k \operatorname{poly}(n)$ time.*

**Proof.** The proof of [8, Corollary 2] shows that $k$-Longest Detour in undirected graphs reduces, in polynomial time, to solving $p$-Detour for all $p \leq 2k$ and $\operatorname{poly}(n)$ instances of $(3k/2)$-Longest Path on graphs with at most $n$ nodes.

The proof of Theorem 1 implies that $k$-Detour can be solved over undirected graphs in $1.8526^k \operatorname{poly}(n)$ time. Previous work in [7, Section 6.3] shows that $k$-Longest Path can be solved over undirected graphs in $1.657^k \operatorname{poly}(n)$ time. Combining these results together with the above discussion shows that $k$-Longest Detour can be solved over undirected graphs in

$$\left(1.8526^{2k} + 1.657^{3k/2}\right) \operatorname{poly}(n) \leq 3.432^k \operatorname{poly}(n)$$

time, as desired. ◀

▶ **Theorem 4.** *The $k$-Detour problem can be solved over undirected graphs by a deterministic algorithm in $4.082^k \operatorname{poly}(n)$ time.*

**Proof.** By Theorem 6, we can solve $k$-Detour over an undirected graph by running Algorithm 1 with parameter $\alpha = 0$. When $\alpha = 0$ in Algorithm 1, steps 5, 6, 7 never occur. In this case, the algorithm only needs to solve $\text{poly}(n)$ instances of $\ell$-Path, for $\ell \leq 3k/2 + 1$, in steps 3 and 9. Since $k$-Path can be solved deterministically in $2.554^k \text{poly}(n)$ time [15], this means that we can solve $k$-Detour deterministically in

$$2.554^{3k/2} \text{poly}(n) \leq 4.0817^k \text{poly}(n)$$

time, as desired. ◀

▶ **Theorem 5.** *The $k$-Longest Detour problem can be solved over undirected graphs by a deterministic algorithm in $16.661^k \text{poly}(n)$ time.*

**Proof.** The proof of [8, Corollary 2] shows that $k$-Longest Detour in undirected graphs reduces, in deterministic polynomial time, to solving $p$-Detour for $p \leq 2k$, and $\text{poly}(n)$ instances of $(3k/2)$-Longest Path on graphs with at most $n$ nodes.

The proof of Theorem 4 implies that $k$-Detour can be solved over undirected graphs deterministically in $4.0817^k \text{poly}(n)$ time. Previous work [9] shows that $k$-Longest Path can be solved deterministically in $4.884^k \text{poly}(n)$ time. Combining these results together with the above discussion shows that $k$-Longest Detour can be solved over undirected graphs deterministically in

$$\left(4.0817^{2k} + 4.884^{3k/2}\right) \text{poly}(n) \leq 16.661^k \text{poly}(n)$$

time, as desired. ◀

## 6 Conclusion

In this paper, we obtained faster algorithms for $k$-Detour and $k$-Longest Detour over undirected graphs. However, many mysteries remain surrounding the true time complexity of these problems. We highlight some open problems of interest, relevant to our work.

1. The most pertinent question: what is the true parameterized time complexity of $k$-Detour and $k$-Longest Detour? In particular, could it be the case that $k$-Detour can be solved as quickly as $k$-Path, and $k$-Longest Detour can be solved as quickly as $k$-Longest Path? No known conditional lower bounds rule out these possibilities.
2. The current fastest algorithm for $k$-Longest Path in directed graphs has a bottleneck of solving $2k$-Path. The current fastest algorithm for $k$-Detour in directed graphs has a bottleneck of solving $2k$-Path. Similarly, the fastest known algorithm[4] for $k$-Longest Detour in undirected graphs requires first solving $2k$-Detour. Is this parameter blow-up necessary? Could it be possible to solve these harder problems with parameter $k$ faster than solving these easier problems with parameter $2k$?
3. The speed-up in our results crucially uses a fast algorithm for the $(\ell, k_1, \ell_2)$-Bipartitioned Path problem in undirected graphs. In directed graphs no $(2-\varepsilon)^\ell \text{poly}(n)$ time algorithm appears to be known for this problem, for any constant $\varepsilon > 0$ and interesting range of parameters $k_1$ and $\ell_2$. Such improvements could yield faster algorithms for $k$-Detour in directed graphs. Can we get such an improvement? Also of interest: can we get a faster deterministic algorithm for $(\ell, k_1, \ell_2)$-Bipartitioned Path?

[4] In fact, even the recent alternate algorithm of [10] for $k$-Longest Detour requires solving $2k$-Detour first.

4. An easier version of the previous question, also raised in [7, Section 9.1]: can we solve $k$-Path in directed bipartite graphs in $(2-\varepsilon)^k \operatorname{poly}(n)$ time, for some constant $\varepsilon > 0$? In the unparameterized setting, the Hamiltonian Path ($k$-Path for $k = n$) problem admits several distinct algorithms running in $(2-\varepsilon)^n \operatorname{poly}(n)$ time in directed bipartite graphs. Specifically, [6] shows Hamiltonian Path in directed bipartite graphs can be solved in $1.888^n \operatorname{poly}(n)$ time, and [4] uses very different methods to solve this problem even faster in $3^{n/2} \operatorname{poly}(n)$ time.[5] We conjecture that the same speed-up is possible for $k$-Path, so that this problem can be solved over directed bipartite graphs in $3^{k/2} \operatorname{poly}(n)$ time.

# A Local-To-Global Theorem for Congested Shortest Paths

**Shyan Akmal**

## Abstract

Amiri and Wargalla proved the following local-to-global theorem about shortest paths in directed acyclic graphs (DAGs): if $G$ is a weighted DAG with the property that for each subset $S$ of 3 nodes there is a shortest path containing every node in $S$, then there exists a pair $(s, t)$ of nodes such that there is a shortest $st$-path containing every node in $G$. We extend this theorem to general graphs. For undirected graphs, we prove that the same theorem holds (up to a difference in the constant 3). For directed graphs, we provide a counterexample to the theorem (for any constant). However, we prove a *roundtrip* analogue of the theorem which guarantees there exists a pair $(s, t)$ of nodes such that every node in $G$ is contained in the union of a shortest $st$-path and a shortest $ts$-path.

The original local-to-global theorem for DAGs has an application to the $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC) problem. In this problem, we are given a weighted graph $G$, together with $k$ node pairs $(s_1, t_1), \ldots, (s_k, t_k)$, and a positive integer $c \leq k$, and tasked with finding a collection of paths $P_1, \ldots, P_k$ such that each $P_i$ is a shortest path from $s_i$ to $t_i$, and every node in the graph is on at most $c$ paths $P_i$, or reporting that no such collection of paths exists. When $c = k$, there are no congestion constraints, and the problem can be solved easily by running a shortest path algorithm for each pair $(s_i, t_i)$ independently. At the other extreme, when $c = 1$, the $(k, c)$-SPC problem is equivalent to the $k$-Disjoint Shortest Paths ($k$-DSP) problem, where the collection of shortest paths must be node-disjoint. For fixed $k$, $k$-DSP is polynomial-time solvable on DAGs and undirected graphs. Amiri and Wargalla interpolated between these two extreme values of $c$, to obtain an algorithm for $(k, c)$-SPC on DAGs that runs in polynomial time when $k - c$ is constant.

In the same way, we prove that $(k, c)$-SPC can be solved in polynomial time on undirected graphs whenever $k - c$ is constant. For directed graphs, because of our counterexample to the original theorem statement, our roundtrip local-to-global result does not imply such an algorithm $(k, c)$-SPC. Even without an algorithmic application, our proof for directed graphs may be of broader interest because it characterizes intriguing structural properties of shortest paths in directed graphs.

## 1 Introduction

An intriguing question in graph theory and algorithms is: "can we understand the structure of shortest paths in (directed and undirected) graphs?" More specifically: "can we understand the structure of the *interactions* between shortest paths in graphs?" This question has been approached from various angles in the literature. For instance, Bodwin [12] characterizes which sets of nodes can be realized as *unique* shortest paths in weighted graphs, and Cizma

and Linial investigate the properties of graphs whose shortest paths satisfy or violate certain geometric properties [19, 20]. Additionally, there is a large body of work on distance preservers, where the goal is to construct a subgraph that preserves distances in the original graph (see [11] and the references therein). There are also numerous computational tasks in which structural results about shortest paths inform the creation and analysis of algorithms, including distance oracle construction [15], the $k$-disjoint shortest paths problem, [8], and the next-to-shortest path problem [35] (the cited papers are the most recent publications in their respective topics).

The angle of our work is inspired by the following local-to-global theorem[1] of Amiri and Wargalla [3] concerning the structure of shortest paths in directed acyclic graphs (DAGs):

▶ **Theorem 1** ([3]). *Let $G$ be a weighted DAG with the property that, for each set $S$ of 3 nodes, there is a shortest path containing every node in $S$. Then, there exists a pair $(s, t)$ of nodes such that there is a shortest $st$-path containing every node in $G$.*

Note that in the statement of Theorem 1, the condition that "for each set $S$ of 3 nodes, there is a shortest path containing every node in $S$" is equivalent to the condition that one of the 3 nodes is on a shortest path between the other two.

Theorem 1 is "local-to-global" in the sense that from a highly congested local structure (every small subset of nodes is contained in a shortest path) we deduce a global structure (all nodes in the graph live on a single shortest path).

At first glance, Theorem 1 may appear rather specialized, since the existence of shortest paths through *all* triples of nodes is a rather strong condition. However, Amiri and Wargalla [3] show that Theorem 1 has applications to the $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC) on problem on DAGs: in this problem we are given a DAG, and are tasked with finding a collection of shortest paths between $k$ given source/sink pairs, such that each node in the graph is on at most $c$ of the paths. We discuss this application in detail in Section 1.2.

Amiri and Wargalla [3] raised the question of whether their results can be extended to general graphs, both undirected and directed. Our work answers this question.

## 1.1 Structural Results

We ask the following question:

*Is Theorem 1 true for general (undirected and directed) graphs?*

Our first result answers this question affirmatively for undirected graphs (with constant 4 instead of 3).

▶ **Theorem 2** (Undirected graphs). *Let $G$ be a weighted undirected graph with the property that, for each set $S$ of 4 nodes, there is a shortest path containing every node in $S$. Then, there exists a pair $(s, t)$ of nodes such that some shortest $st$-path contains every node in $G$.*

The constant 4 in the statement of Theorem 2 cannot be replaced with 3, as seen by considering an undirected cycle on four vertices.

Theorem 2 implies a faster algorithm for $(k, c)$-SPC on *undirected* graphs, answering an open question raised in [3, Section 4]. We discuss the background of this problem and our improvement in Section 1.2.

[1] This is slightly different from the statement of the theorem in [3], where the authors write present their result in the context of the Shortest Paths with Congestion problem, which we discuss in detail later.

Our second result is for directed graphs. First, we observe that there is actually a *counterexample* to Theorem 1 for general directed graphs: let $a$ be the constant for which we desire a counterexample (i.e., the constant that is 3 in Theorem 1, and 4 in Theorem 2). Let $G$ be a cycle with bidirectional edges, where all clockwise-pointing edges have weight 1 and all counterclockwise-pointing edges have weight $a$. One can verify that the precondition of the theorem holds: for each set $S$ of $a$ nodes there is a shortest path containing every node in $S$, just by taking the shortest clockwise path through all nodes in $S$. However, no single shortest path contains every node in $G$, so the theorem does not hold.

Even though a direct attempt at generalizing Theorem 1 to all directed graphs fails, one might hope for some analogue of Theorem 1 that does hold. One interpretation of the above counterexample is that the exact statement of Theorem 1 is not the "right" framework for getting a local-to-global shortest path phenomenon in general directed graphs. To that end, we consider the *roundtrip* analogue of Theorem 1, where the final path through every node is a shortest roundtrip path, i.e., the union of a shortest $st$-path and a shortest $ts$-path (roundtrip distances are a common object of study in directed graphs, with there being much research, for example, in roundtrip routing [21], roundtrip spanners [33], and roundtrip diameter computation [1]). Note that the above counterexample does not apply to the roundtrip analogue of Theorem 1 since there exists a pair $(s, t)$ of nodes such that the union of a shortest $st$-path and a shortest $ts$-path are both in the clockwise direction and thus contain all nodes in the graph.

For our second result, we present a roundtrip analogue of Theorem 1 which holds true for general directed graphs (with the constant 11 instead of 3):

▶ **Theorem 3** (Directed graphs). *Let $G$ be a weighted directed graph with the property that, for each set $S$ of 11 nodes, there is a shortest path containing every node in $S$. Then, there exists a pair $(s, t)$ of nodes such that the union of a shortest $st$-path and a shortest $ts$-path contains every node in $G$.*

Proving Theorem 3 requires overcoming a number of technical challenges involving the c omplex structure of shortest paths in directed graphs. Due to its roundtrip nature, unlike Theorem 2, Theorem 3 does not appear to have any immediate algorithmic applications.

## 1.2 Disjoint and Congested Shortest Path Problems

In this section we introduce the $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC) problem and state the implications of our work for this problem.

### 1.2.1 Background

We begin by discussing the related $k$-Disjoint Shortest Paths ($k$-DSP) problem. For more related work on disjoint path problems in general, see the full version.

#### Disjoint Shortest Paths

Formally, the $k$-Disjoint Shortest Paths ($k$-DSP) problem is defined as follows:

> $k$-Disjoint Shortest Paths ($k$-DSP): Given a graph $G$ and $k$ node pairs $(s_1, t_1), \ldots, (s_k, t_k)$, find a collection of node-disjoint paths $P_1, \ldots, P_k$ such that each $P_i$ is a shortest path from $s_i$ to $t_i$, or report that no such collection of paths exists.

The $k$-DSP problem was introduced in the 90s by Eilam-Tzoreff [22], who gave a polynomial-time algorithm for undirected graphs when $k = 2$, and conjectured that there is a polynomial-time algorithm for any fixed $k$ in both undirected and directed graphs. Recently, Lochet [30] proved Eilam-Tzoreff's conjecture for undirected graphs by showing that $k$-DSP can be solved in polynomial time for any fixed $k$. Subsequently, the dependence on $k$ in the running time was improved by Bentert, Nichterlein, Renken, and Zschoche [8]. It is known that $k$-DSP on undirected graphs is W[1]-hard [8, Proposition 36], so this problem is unlikely to be fixed-parameter tractable.

For directed graphs, Bérczi and Kobayashi [9] showed that 2-DSP can be solved in polynomial time. For $k \geq 3$ however, determining the complexity of $k$-DSP on directed graphs remains a major open problem. This problem is only known to be polynomial-time solvable for special classes of directed graphs, such as DAGs and planar graphs [9].

### Shortest Paths with Congestion

The $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC) problem is the variant of $k$-DSP where some amount of *congestion* (paths overlapping at nodes) is allowed. In general, problems of finding paths with limited congestion are well-studied studied in both theory and practice. For instance, there is much work on the problem in undirected graphs where the goal is to find a maximum cardinality subset of node pairs $(s_i, t_i)$ that admit (not necessarily shortest) paths with congestion at most $c$ [32, 28, 7, 6, 5, 17, 4, 26, 16, 18]. As another example, [27] provides, for fixed $k$, a polynomial-time algorithm for the problem on directed graphs of determining that either there is no set of disjoint paths between the node pairs $(s_i, t_i)$, or finding a set of such paths with congestion at most 4. Another example for directed graphs is the problem of finding paths between the node pairs $(s_i, t_i)$ where only some nodes in the graph have a congestion constraint [31].

Formally, the $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC) problem is defined as follows:

> $k$-Shortest Paths with Congestion $c$ ($(k, c)$-SPC): Given a graph $G$, along with $k$ node pairs $(s_1, t_1), \ldots, (s_k, t_k)$, and a positive integer $c \leq k$, find a collection of paths $P_1, \ldots, P_k$ such that each $P_i$ is a shortest path from $s_i$ to $t_i$, and every node in $V(G)$ is on at most $c$ paths $P_i$, or report that no such collection of paths exists.

The $(k, c)$-SPC problem was introduced by Amiri and Wargalla [3]. Before that, the version of $(k, c)$-SPC where the paths are not restricted to be shortest paths was studied by Amiri, Kreutzer, Marx, and Rabinovich [2].

When $c = 1$, the $(k, c)$-SPC problem is equivalent to the $k$-DSP problem. At the other extreme, when $c = k$, there are no congestion constraints, so the problem can be easily solved in polynomial time by simply finding a shortest path for each pair $(s_i, t_i)$ independently. Amiri and Wargalla [3] asked the following question: *can we interpolate between these two extremes?* In particular, can we get algorithms for $(k, c)$-SPC where the exponential dependence on $k$ for $k$-DSP can be replaced with some dependence on $O(k - c)$ instead?

Amiri and Wargalla [3] achieved this goal for DAGs. In particular, they gave a reduction from $(k, c)$-SPC on DAGs to $k$-DSP on DAGs of the following form: letting $d = k - c$, if $k$-DSP on DAGs can be solved in time $f(n, k)$, then $(k, c)$-SPC on DAGs can be solved in time $O\left(\binom{k}{3d} \cdot f(2dn, 3d)\right)$. The essential aspect of this running time is that the second input to the function $f$ is not $k$ but rather an $O(d)$ term. A key tool in their reduction is Theorem 1 (stated in a different way).

Since $k$-DSP can be solved in $n^{O(k)}$ time on DAGs [9], the above result implies that $(k, c)$-SPC can be solved in $\binom{k}{3d} \cdot (2dn)^{O(d)}$ time on DAGs. That is, $(k, c)$-SPC on DAGs is polynomial-time solvable for arbitrary $k$ whenever $d$ is constant. We note that for for every $c$, the $(k, c)$-SPC problem on DAGs is W[1]-hard with respect to $d$, so the problem is unlikely to be fixed-parameter tractable with respect to $d$ [3, Proof of Theorem 3].

### 1.2.2 Algorithmic Results

Similarly to Amiri and Wargalla's result for DAGs, our result for undirected graphs, Theorem 2, implies a reduction from $(k, c)$-SPC to $k$-DSP on undirected graphs.

▶ **Lemma 4.** *If $k$-DSP can be solved in $f(n, k)$ time on undirected graphs, then $(k, c)$-SPC can be solved in $O\left(\binom{k}{4d} \cdot f(3dn, 4d)\right)$ time on undirected graphs.*

Lemma 4 follows from Theorem 2 using an argument nearly identical to the one presented for DAGs in [3] (up to a difference in constants). For completeness, we include a full proof of this result in the full version.

Since it is known that $k$-DSP can be solved in undirected graphs in time $n^{O(k \cdot k!)}$ [8], applying Theorem 2 together with Lemma 4, we deduce the following result.

▶ **Corollary 5.** *$(k, c)$-SPC on undirected graphs can be solved in $\binom{k}{4d} \cdot (3dn)^{O(d \cdot (4d)!)}$ time.*

Thus $(k, c)$-SPC on undirected graphs is in polynomial time whenever $d = k - c$ is constant; that is, it is in the complexity class XP with respect to the parameter $d$. Prior to our work, no polynomial-time algorithm for this problem appears to have been known in this regime, even for simple cases such as $(k, k-1)$-SPC on undirected graphs.

In contrast, our structural result for directed graphs, Theorem 3, does not imply a faster algorithm for $(k, c)$-SPC in directed graphs. This is because Theorem 3 does not appear to imply a reduction from $(k, c)$-SPC to $k$-DSP in the manner of Lemma 4. Moreover, even if such a reduction did exist, this would not imply an algorithm for directed graphs analogous to Corollary 5. This is because while $k$-DSP is polynomial-time solvable for constant $k$ in undirected graphs, it remains open whether even 3-DSP over directed graphs can be solved in polynomial time.

## 1.3 The Structure of Shortest Paths in Directed Graphs

Although our result for directed graphs, Theorem 3, does not appear to have immediate algorithmic applications, we believe it is still interesting from a graph theoretic perspective, especially in light of the current scarcity of results for shortest disjoint path problems in directed graphs. In this section, we expand upon this idea with some remarks, and then state a lemma from our proof concerning the structure of shortest paths in directed graphs.

We currently have a poor understanding of the complexity of the $k$-DSP problem in directed graphs: for fixed $k \geq 3$, it is still not known if this problem is either polynomial-time solvable or NP-hard. In fact, even the complexity of the seemingly easier $(3, 2)$-SPC problem on directed graphs is open. In this context, Theorem 3 is compelling because it presents an example of interesting behavior which holds for collections of shortest paths in DAGs, and then continues to hold, under suitable generalization, for systems of shortest paths in general directed graphs. This sort of characterization appears to be rare in the literature.

More generally, the methods we use to establish Theorem 3 involve combinatorial observations about the structure of shortest paths in directed graphs, and the interactions between them. We believe our analysis could offer more insight into resolving other problems that

concern systems of shortest paths in directed graphs. There are many such problems, where the undirected case is well-understood, but in the directed case not much is known. This barrier is in-part due to the relatively complex patterns of shortest paths which can appear in directed graphs. We hope that our analysis of directed shortest paths may shed light on problems for which the structural complexity of directed shortest paths is the bottleneck towards progress.

One example of a problem where the undirected case is well-understood while the directed case remains poorly understood is, as discussed previously, the $k$-DSP problem. Another curious example is the Not-Shortest Path problem, where the goal is to find an $st$-path that is not a shortest path. Although Not-Shortest Path can be solved over undirected graphs in polynomial time [29], no polynomial time algorithm is known for this problem in directed graphs. A third example is the problem of approximating the diameter of a graph. For undirected graphs there is an infinite hierarchy of algorithms that trade off between time and accuracy [14], while only two points on the hierarchy are known for directed graphs. Additionally, the roundtrip variant of diameter is the least understood of any studied variant of the diameter problem [34]. Another example is the construction of approximate hopsets: for directed graphs there is there a polynomial gap between upper and lower bounds [25, 10, 13], while for undirected graphs the gap is subpolynomial [23, 24]. The preponderance of such examples motivates proving results like Theorem 3, which characterize interesting behavior of shortest paths in directed graphs.

### Structural Lemma for Directed Shortest Paths

One of the lemmas we establish on the way to proving Theorem 3 is a general statement about the structure of shortest paths in directed graphs. It can be stated independently of the context of the proof of Theorem 3 and we highlight it here.

We categorize any shortest path $P$ into one of two main types, based on the ways that other shortest paths intersect with it. The following simple definition will be useful for defining our path types.

▶ **Definition 6.** *For any nonnegative integer $\ell$ and set of $\ell$ nodes, $v_1, v_2, \ldots, v_\ell$, we say that the order $v_1 \to v_2 \to \cdots \to v_\ell$ is a* shortest-path ordering *if there is a shortest path containing all of the nodes $v_1, v_2, \ldots, v_\ell$ in that order.*

In addition to our two main path types, there is a third path type which we call a *trivial path* because it is easy to handle:

▶ **Definition 7** (Trivial Path)**.** *Given a directed graph, nodes $a$ and $b$, and a shortest path $P$ from $a$ to $b$, we say $P$ is a* trivial path *if $P$ contains at least one node $w$ such that $a \to w \to b$ is the* only *shortest-path ordering of $a, w, b$.*

Now we are ready to state our two main types of shortest paths. The first type is a *reversing path*:

▶ **Definition 8** (Reversing path)**.** *Given a directed graph, nodes $a$ and $b$, and a non-trivial shortest path $P$ from $a$ to $b$, $P$ is* reversing *if $P$ contains at least one node $w$ such that $w$ falls on some shortest path from $b$ to $a$. A* non-reversing path *is a non-trivial path that is not reversing.*

We prove a lemma that characterizes the structure of reversing and non-reversing paths in terms of the possible shortest-path orderings of each node on the path and the endpoints of the path. See Figures 1a and 1b for a depiction of the structure enforced by the lemma.

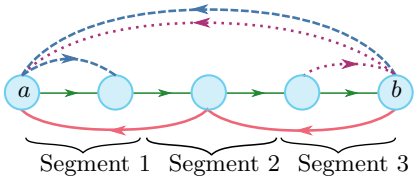
▶ **Lemma 9** (Reversing/Non-Reversing Lemma). *Let $P$ be a non-trivial shortest path and let $a$ and $b$ be the first and last nodes of $P$ respectively. Then $P$ can be partitioned into three contiguous ordered segments with the following properties (where $a$ is defined to be in Segment 1, $b$ is defined to be in Segment 3, and Segment 2 could be empty).*

*Segment 1 consists of nodes $w$ such that the shortest-path orderings of $a, w, b$ are precisely $a \to w \to b$, and $b \to a \to w$.*

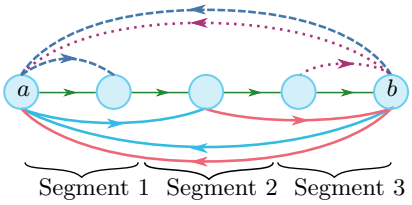
*Segment 2 consists of nodes $w$ such that the shortest-path orderings of $a, w, b$ are precisely*

$$\begin{cases} a \to w \to b, \text{ and } b \to w \to a & \text{if } P \text{ is a reversing path} \\ a \to w \to b, \text{ and } b \to a \to w, \text{ and } w \to b \to a & \text{if } P \text{ is a non-reversing path.} \end{cases}$$

*Segment 3 consists nodes $w$ such that the shortest-path orderings of $a, w, b$ are precisely $a \to w \to b$, and $w \to b \to a$.*



**(a) Reversing Path.** The structure of a reversing path, as given by Lemma 9. The blue dashed path, pink solid path, and purple dotted path are examples of the allowed orderings for nodes in segments 1, 2, and 3 respectively.



**(b) Non-Reversing Path.** The structure of a non-reversing path, as given by Lemma 9. The possible shortest-path orderings for nodes in segment 2 are represented by pink and light blue solid paths, while the orderings allowed for nodes in segments 1 and 3 are represented by blue dashed and purple dotted segments respectively.

**Figure 1** Possible orderings of vertices on shortest paths in the reversing and non-reversing cases. The blue circles are representative examples of the types of nodes on the path from $a$ to $b$ (in general this path will contain more than just five nodes).

In the proof of Theorem 3 we employ the strategy of categorizing shortest paths as reversing or non-reversing (or trivial), and applying Lemma 9 to glean some structure. We note, however, that Lemma 9 itself is not the main technical piece of the proof.

## 2 Preliminaries

All graphs are assumed to have positive edge weights. Graphs are either undirected or directed, depending on the section. For any pair of nodes $(u, v)$, we use $\mathsf{dist}(u, v)$ to denote the shortest path distance from $u$ to $v$. Given a path $P$ and two nodes $u$ and $v$ occurring on $P$ in that order, we let $P[u, v]$ denote the subpath of $P$ with $u$ and $v$ as endpoints.

For the $(k, c)$-SPC problem, we always let $d$ denote the difference $d = k - c$. When considering a particular solution to a $(k, c)$-SPC instance, we refer to the paths $P_1, \ldots, P_k$ between $(s_1, t_1), \ldots, (s_k, t_k)$ respectively as *solution paths*. Any node in the graph which lies in $c$ of the solution paths is referred to as a *max-congestion* node.

## 2.1 Subpath Swapping

In our proofs, we will frequently modify collections of shortest paths by "swapping subpaths" between intersecting paths. This procedure is depicted in Figure 2, and we formally describe it below.

▶ **Definition 10** (Subpath Swap). *Let $\mathcal{R}$ be a collection of shortest paths in a directed graph. Let $P$ and $Q$ be two paths in $\mathcal{R}$. Let $a, b \in P \cap Q$ be nodes in these paths, such that $a$ appears before $b$ in both $P$ and $Q$. We define* swapping *the subpaths of $P$ and $Q$ between $a$ and $b$ to be updating the set of paths $\mathcal{R}$ by simultaneously replacing $P$ with $(P \setminus P[a,b]) \cup Q[a,b]$ and $Q$ with $(Q \setminus Q[a,b]) \cup P[a,b]$. We often refer to this process simply as "swapping $P[a,b]$ and $Q[a,b]$."*

**Figure 2** A simple subpath swap, where the subpaths from $a$ to $b$ of the green path (from $s_i$ to $t_i$) and pink path (from $s_j$ to $t_j$) are switched.

▶ **Observation 11** (Subpath Swap). *Let $\mathcal{R}$ be the solution to some $(k,c)$-SPC problem. Then swapping subpaths in $\mathcal{R}$ produces a new solution to the same $(k,c)$-SPC instance with the same set of max-congestion nodes.*

**Proof.** This observation holds because swapping subpaths does not change the number of solution paths any given node is contained in, does not change the endpoints of any solution path, and all solution paths remain shortest paths. ◀

## 2.2 Correspondence Between Our Results and $(k, c)$-SPC

In this section we detail some nuances regarding the correspondence between the statement of our results and the $(k,c)$-SPC problem. For the sake of generality and simplicity, we stated Theorems 1-3 independently of the $(k,c)$-SPC problem. In contrast, the original result of Amiri and Wargalla, corresponding to Theorem 1, was stated as follows:

▶ **Lemma 12** ([3]). *If $k > 3d$, then any instance of $(k,c)$-SPC on DAGs either has no solution, or has a solution where some solution path $P_i$ passes through all max-congestion nodes.*

Although the statement of Lemma 12 may initially seem unrelated to the statement of Theorem 1, their correspondence becomes clearer with the following observation, which is a simple generalization of an observation from [3]:

▶ **Observation 13.** *Let $N$ be a positive integer. Suppose $k > Nd$, and let $\mathcal{R}$ be a solution to an arbitrary $(k,c)$-SPC instance. Then for any set $S$ of $N$ max-congestion nodes in $\mathcal{R}$, there exists some solution path in $\mathcal{R}$ which contains every node in $S$.*

We defer the proof of Observation 13 to the appendix.

To prove our results for the $(k,c)$-SPC problem in undirected graphs (Lemma 4 and Corollary 5), we need to prove a lemma analogous to Lemma 12 but for undirected graphs:

▶ **Lemma 14.** *If $k > 4d$, then any instance of $(k, c)$-SPC either has no solution, or has a solution where some solution path $P_i$ passes through all max-congestion nodes.*

The following generalizes Theorem 2 and Lemma 14.

▶ **Lemma 15** (General Undirected Result)**.** *Given an undirected graph and subset $W$ of nodes, let $\mathcal{R}$ be a collection of shortest paths with the following property:*

$$\text{for every set } S \subseteq W \text{ of 4 nodes, some path in } \mathcal{R} \text{ contains every node in } S. \qquad (\star)$$

*Further suppose that applying any sequence of $O(n^3)$ subpath swaps to $\mathcal{R}$ yields a collection of shortest paths that still has property $(\star)$. Then starting from $\mathcal{R}$, there exists a sequence of subpath swaps that results in a collection of shortest paths in which some path $P$ passes through all nodes in $W$.*

We note that the quantity $O(n^3)$ is an unimportant technicality used in the proof of the following observation, and is chosen as a loose upper bound on the number of subpath swaps we will perform.

▶ **Observation 16.** *Lemma 15 generalizes both Theorem 2 and Lemma 14.*

We defer the proof of Observation 16 to the appendix.

We also prove an analogue of Lemma 12 and Lemma 15 for directed graphs:

▶ **Lemma 17** (General Directed Result)**.** *Given a directed graph and subset $W$ of nodes, let $\mathcal{R}$ be a collection of shortest paths with the following property:*

$$\text{for every set } S \subseteq W \text{ of 11 nodes, some path in } \mathcal{R} \text{ contains every node in } S. \qquad (\dagger)$$

*Further suppose that applying any sequence of $O(n^3)$ subpath swaps to $\mathcal{R}$ yields a collection of paths that still has property $(\dagger)$. Then starting from $\mathcal{R}$, there exists a sequence of subpath swaps that results in a collection of shortest paths in which either:*

1. *some path $P$ passes through all nodes in $W$, or*
2. *the union of two paths $P, P'$ contain all nodes in $W$, and the first and last nodes on $P$ from $W$ are the same as the last and first nodes on $P'$ from $W$, respectively.*

Lemma 17 generalizes Theorem 3, in exactly the same way as Lemma 15 generalizes Theorem 2 for undirected graphs. In the same way that Lemma 15 generalizes Lemma 14 for undirected graphs, Lemma 17 implies the following lemma:

▶ **Lemma 18.** *If $k > 11d$, then any instance of $(k, c)$-SPC on directed graphs either has no solution, or has a solution where the union of some two solution paths $P_i$ and $P_j$ contains all max-congestion nodes.*

Although Lemma 18 does not immediately lead to an algorithm for $(k, c)$-SPC on directed graphs, it specifies some structure which may be useful for future work on $(k, c)$-SPC and related problems.

One might wonder whether Lemma 18 can be modified to have only one solution path $P_i$ that contains all max-congestion nodes, like for DAGs (Lemma 12) and undirected graphs (Lemma 14), since this would imply interesting algorithms for $(k, c)$-SPC on directed graphs. Unfortunately, the answer to this question turns out to be no. Similar to the counterexample against extending Theorem 2 to directed graphs, we present a counterexample in the full version which rules out replacing two solution paths with a single solution path in Lemma 18.

# 3 Technical Overview

## 3.1 Prior Work on DAGs

As a starting point for our proofs for general graphs, we use Amiri and Wargalla's proof of Theorem 1 for DAGs [3]. We describe their proof differently than they do for the sake of comparison to our work. We actually describe their proof of the following lemma (which they do not explicitly state), which is analogous to the statements of our general results (Lemmas 15 and 17).

▶ **Lemma 19** ([3]). *Given a DAG and subset $W$ of nodes, let $\mathcal{R}$ be a collection of shortest paths with the following property:*

$$\text{for every set } S \subseteq W \text{ of 3 nodes, some path in } \mathcal{R} \text{ contains every node in } S. \qquad (*)$$

*Further suppose that applying any sequence of $O(n^3)$ subpath swaps to $\mathcal{R}$ yields a collection of paths that still has property $(*)$. Then starting from $\mathcal{R}$, there exists a sequence of subpath swaps that results in a collection of shortest paths in which some path $P$ passes through all nodes in $W$.*

The proof of Lemma 19 is as follows. Let $a$ and $b$ be the first and last nodes in $W$ (respectively) in a topological ordering of the DAG. Let $v_1, \dots v_{|W|-2}$ be the remaining nodes in $W$ in order topologically. For ease of notation, we consider $\mathcal{R}$ to be changing over time via subpath swaps, and we will let $\mathcal{R}$ denote the current value of $\mathcal{R}$.

The argument is inductive. For the base case, by property $(*)$ there is a path in $\mathcal{R}$ that contains $a$ and $b$. Suppose inductively that a path $P \in \mathcal{R}$ currently contains $a$, $b$, and $v_1, \dots, v_\ell$ for some $\ell$. We would like to perform a subpath swap to augment $P$ by adding $v_{\ell+1}$ to $P$. To do so, we consider a path $P' \in \mathcal{R}$ that contains $v_\ell$, $v_{\ell+1}$, and $b$, where such a path exists by property $(*)$. Importantly, because the graph is a DAG, $v_\ell$, $v_{\ell+1}$, and $b$ appear in that order on both $P$ and $P'$. Thus, according to the definition of a subpath swap (Definition 10) we can swap $P[v_\ell, b]$ with $P'[v_\ell, b]$, as shown in Figure 3. As a result of this subpath swap, $P$ now contains $v_{\ell+1}$ in addition to all of the nodes in $W$ that $P$ originally contained. By induction, this completes the proof.

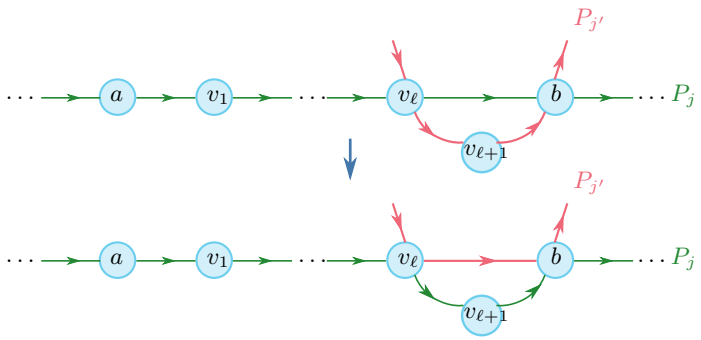


**Figure 3** In a DAG, the topological ordering of the nodes allows us to perform a sequence of subpath swaps, each adding the next node in $W$ in order to a path $P$.

## 3.2 Undirected Graphs

Recall that our goal for undirected graphs is to prove the following theorem:

▶ **Lemma 15** (General Undirected Result). *Given an undirected graph and subset $W$ of nodes, let $\mathcal{R}$ be a collection of shortest paths with the following property:*

$$\text{for every set } S \subseteq W \text{ of 4 nodes, some path in } \mathcal{R} \text{ contains every node in } S. \qquad (\star)$$

*Further suppose that applying any sequence of $O(n^3)$ subpath swaps to $\mathcal{R}$ yields a collection of shortest paths that still has property $(\star)$. Then starting from $\mathcal{R}$, there exists a sequence of subpath swaps that results in a collection of shortest paths in which some path $P$ passes through all nodes in $W$.*

The essential property that enables the subpath swapping in the above argument for DAGs is the fact that for any triple of nodes in a DAG, there is *only one* possible order this triple can appear on any path. This property is not exactly true for general undirected graphs, but we observe that a similar "consistent ordering" property is true: if there is a *shortest* path containing nodes $u, v, w$ in that order, then any shortest path containing these nodes, has them in that order (or in the reverse order $w, v, u$, but since the graph is undirected we can without loss of generality assume they are in the order $u, v, w$). This property is true simply because $\mathsf{dist}(u, w)$ is larger than both $\mathsf{dist}(u, v)$ and $\mathsf{dist}(v, w)$, so $v$ must appear between $u$ and $w$ on any shortest path.

To perform subpath swapping on undirected graphs, we need an initial pair of nodes in $W$ such that the rest of the nodes in $W$ will be inserted between this initial pair (in the DAG algorithm, this initial pair $a, b$ was the first and last nodes in $W$ in the topological order). For undirected graphs, our initial pair is the pair $a, b$ of nodes in $W$ whose distance is maximum. We order the rest of the nodes in $W$ by their distance from $a$, to form $v_1, \ldots, v_{|W|-2}$.

Now, our consistent ordering property from above implies the following: for any shortest path $P$ containing $a$, all nodes in $W \cap P$ are ordered as a subsequence of $a, v_1, v_2, \ldots, v_m, b$ on $P$. As a result, we can perform the same type of iterative subpath swapping argument as the DAG algorithm.

## 3.3 Roundtrip Paths in Directed Graphs

The situation for directed graphs is significantly more involved than the previous cases. There are several challenges that are present for directed graphs that were not present for either undirected graphs or DAGs. These difficulties stem from the fact that the *interactions* between shortest paths is much more complicated in directed graphs than in DAGs or undirected graphs.

We first outline these challenges, and then provide an overview of how we address them. Our techniques for addressing these issues exemplify that despite the possibly complex arrangement of shortest paths in directed graphs, there still exists an underlying structure to extract. We hope that our methods might illuminate some structural properties of shortest paths in directed graphs in a way that could apply to other directed-shortest-path problems.

Recall that our goal is to prove the following theorem:

▶ **Lemma 17** (General Directed Result). *Given a directed graph and subset $W$ of nodes, let $\mathcal{R}$ be a collection of shortest paths with the following property:*

$$\text{for every set } S \subseteq W \text{ of 11 nodes, some path in } \mathcal{R} \text{ contains every node in } S. \qquad (\dagger)$$

*Further suppose that applying any sequence of $O(n^3)$ subpath swaps to $\mathcal{R}$ yields a collection of paths that still has property (†). Then starting from $\mathcal{R}$, there exists a sequence of subpath swaps that results in a collection of shortest paths in which either:*

1. *some path $P$ passes through all nodes in $W$, or*
2. *the union of two paths $P, P'$ contain all nodes in $W$, and the first and last nodes on $P$ from $W$ are the same as the last and first nodes on $P'$ from $W$, respectively.*

## Challenges for directed graphs

### Challenge 1: No "extremal" nodes

In the proofs for DAGs and undirected graphs, to begin building the path $P$ containing all nodes in $W$, we chose two initial extremal nodes $a, b \in W$ and added the rest of the nodes of $W$ between $a$ and $b$. These nodes $a, b$ were straightforward to choose because there was only one pair of nodes in $W$ that could possibly appear first and last on a path containing all nodes in $W$ (for DAGs $a$ and $b$ were the first and last nodes in a topological ordering of $W$, and for undirected graphs $a$ and $b$ were the pair of nodes in $W$ with largest distance).

For directed graphs however, it is entirely unclear how to pick these two initial extremal nodes. For instance, choosing the pair of nodes $a, b \in W$ with largest directed distance $\mathsf{dist}(a, b)$ does not work because there could be a shortest path $Q$ containing $a$ and $b$, where $a$ and $b$ are not the first and last nodes in $W$ on $Q$ (in particular, if $b$ appears before $a$ on the shortest path).

To circumvent this issue for directed graphs, we avoid selecting a pair of initial nodes at all. Without initial nodes as an anchor, we cannot build our path $P$ in order from beginning to end as we did for DAGs and undirected graphs. Instead, our goal is to ensure the following weaker property: as we iteratively transform the overall collection of shortest paths $\mathcal{R}$, the set of nodes in $W$ on the path in $\mathcal{R}$ containing the most nodes in $W$ grows over time. That is, the path of $\mathcal{R}$ containing the most nodes in $W$ might currently be $P$, but at the previous iteration, the path of $\mathcal{R}$ with the most nodes in $W$ might have been a different path $P'$. In this case, our weaker property ensures that $P$ currently contains a *superset* of the nodes in $W$ that $P'$ contained at the previous iteration.

To perform a single iteration with this guarantee, we may need to significantly reconfigure *many* different paths of $\mathcal{R}$ via many subpath swaps. As a result, our path building procedure is much more intricate than the procedures employed for DAGs and undirected graphs.

### Challenge 2: No consistent ordering of nodes on shortest paths

In the proof for DAGs and undirected graphs, we were able to perform subpath swaps due to the following crucial property: consider an arbitrary set of nodes $v_1, \ldots, v_\ell$ (for any $\ell$) in a DAG or an undirected graph. If there is a shortest path containing the nodes $v_1, \ldots, v_\ell$ in that order, then *every* shortest path containing these nodes has them in that same order.

For directed graphs, however, this property is not even close to being true. In fact, given that the nodes $v_1, \ldots, v_\ell$ appear in that order on some shortest path, there are *exponentially many* other possible orderings of these nodes on other shortest paths. For instance, when $\ell = 4$, given that the nodes $v_1, v_2, v_3, v_4$ appear in that order on some shortest path, there are eight possible orderings of these nodes on shortest paths, as depicted in Figure 4 (note that despite the large number of possible orderings, not all orderings are possible; for instance the ordering $v_1, v_2, v_4, v_3$ is not possible, as this would imply that $\mathsf{dist}(v_1, v_4) < \mathsf{dist}(v_1, v_3)$, which contradicts our assumption that some shortest path contains $v_1, v_2, v_3, v_4$ in that order).

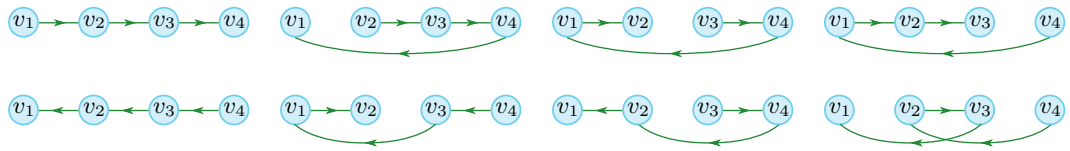

**Figure 4** If nodes $v_1, v_2, v_3, v_4$ appear in that order on some shortest path, they can still appear on different shortest paths in up to seven other distinct possible orders.

Because directed graphs have no consistent ordering of nodes on shortest paths, it becomes much more difficult to perform subpath swaps like those in the algorithms for DAGs and undirected graphs.

To address this challenge, we provide a structural analysis of the ways in which shortest paths in directed graphs can interact with each other. First, as introduced in Section 1.3, we categorize shortest paths into two main types, *reversing* paths and *non-reversing* paths, and we prove the Reversing/Non-Reversing Path Lemma (Lemma 9). Roughly speaking, this lemma is useful because it helps us construct sets of nodes that exhibit some sort of consistent ordering property. This, in turn, enables us to perform sequences of subpath swaps. Defining these consistently ordered sets of nodes and the corresponding subpath swaps is the most involved part of the proof, and works differently for each of the two path types.

## Proof structure

Our proof is structured as follows. Initially, we define $P$ to be the path in $\mathcal{R}$ that contains the most nodes in $W$ (breaking ties arbitrarily). Then we proceed with the following two cases:

- (Case 1) We first check whether, roughly speaking, $P$ is contained in a *cycle* that contains *all* nodes in $W$. In this case, we can use a sequence of subpath swaps to build a second path $P'$ so that the union of $P$ and $P'$ contains all nodes in $W$ and have the "roundtrip" structure specified in the theorem statement, in which case we are done.
- (Case 2) If we are not in Case 1, our goal is to augment some path in $\mathcal{R}$ so that the set of nodes of $W$ on the path in $\mathcal{R}$ with the most nodes in $W$ grows (the goal introduced in the discussion of Challenge 1).

After going through these cases, if we are not done we redefine $P$ as the path in $\mathcal{R}$ containing the most nodes in $W$ and repeatedly apply the appropriate case, until we are done. Most technical details of our proof are in the path augmentation procedure of Case 2. We elaborate on the main ideas for this procedure next.

## Handling Case 2: Path Augmentation

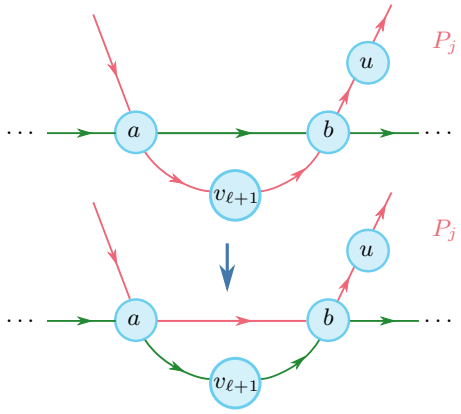
Recall that our goal is the following: Let $P$ be the path in $\mathcal{R}$ containing the most nodes in $W$, and let $W' = W \cap P$. Fix a node $u \in W \setminus W'$. We wish to perform subpath swaps to yield a path $P'$ that contains every node in $W' \cup \{u\}$.

We begin with a few warm-up cases to motivate our general approach.

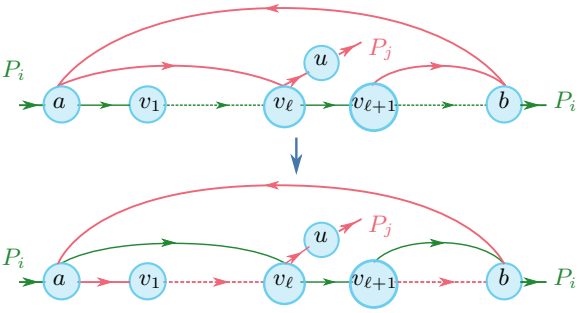
### Warm-up cases

Let $a$ and $b$ be the first and last nodes on $P$ that are in $W$, respectively. By property (†) there exists a path in $\mathcal{R}$ containing $a$, $b$, and $u$. We will suppose in all of the subsequent examples, that for *all* paths in $\mathcal{R}$ containing the nodes $a$, $b$, and $u$, the node $u$ is always the last node in $W$ on the path; this is not a conceptually important assumption and it makes the description simpler.

We claim that if there is a path $P' \in \mathcal{R}$ containing $a$, $b$, and $u$, such that $a$ appears before $b$, then we are done. Indeed, as depicted in Figure 5a, in this case we can simply swap the subpath $P[a, b]$ with $P'[a, b]$, to form a new solution where $P'$ contains $W' \cup \{u\}$.



**(a)** If $a$ appears before $b$ on $P'$, a subpath swap lets $P'$ pass through $u$ together with all of the nodes in $W'$.



**(b)** More generally, when $P'$ passes through $v_{\ell+1}, b, a, v_\ell$ in that order, we can perform two subpath swaps to get $P'$ to pass through the rest of $W'$. Here, the dotted segments indicate portions of the paths which pass through the nodes of $W'$ that are not labeled in the figure.

**Figure 5** The two warm-up cases.

Now we will slightly generalize this warm-up case. Let $a, v_1, v_2, \ldots, b$ be the nodes in $W'$ in the order they appear on $P$. Consider $v_\ell$ and $v_{\ell+1}$ for any $\ell$. By property (†) there exists a path in $\mathcal{R}$ containing $a$, $b$, $u$, $v_\ell$, and $v_{\ell+1}$. We know from the previous warm-up case that if there is a pathin $\mathcal{R}$ containing these nodes such that $a$ appears before $b$, then we are done. We also claim that if there exists a path $P' \in \mathcal{R}$ containing these nodes such that $v_{\ell+1}, b, a, v_\ell$ appear in that order, then we are done. This is because as depicted in Figure 5b, we can swap the subpath $P[a, v_\ell]$ with $P'[a, v_\ell]$, and swap the subpath $P[v_{\ell+1}, b]$ with $P'[v_{\ell+1}, b]$. Now, $P'$ contains $W' \cup \{u\}$.

### General Approach: "Critical nodes"

We will motivate our general approach in the context of the above warm-up cases. In the second warm-up case, we considered 5 nodes ($a$, $b$, $u$, $v_\ell$, and $v_{\ell+1}$) in $W'$, and argued that if there is a path $P' \in \mathcal{R}$ containing these 5 nodes in one of several "good" orders, then we are done because we can perform subpath swaps to reroute $P'$ through all of $W' \cup \{u\}$. Thus, our goal is to choose these 5 (or in general, at most 11) nodes carefully, to guarantee that they indeed fall into a "good" order on some path in $\mathcal{R}$. We refer to these at most 11 nodes as *critical nodes*:

▶ **Definition 20** (Critical Nodes (Informal)). *Given a path $P \in \mathcal{R}$, a set of nodes $T \subseteq W$ of size $|T| \leq 11$ are* critical nodes of $P$ *if there exists a path $P' \in \mathcal{R}$ containing the nodes of $T$ in an order that allows us to perform subpath swaps to reroute some path in $\mathcal{R}$ through all of $W' \cup \{u\}$ (where $W' = W \cap P$).*

*Our general approach is to show that any path $P \in \mathcal{R}$ contains a set of at most 11 critical nodes.* We remind the reader that this section only concerns Case 2, so our goal is to show that $P$ contains a set of critical nodes only if $P$ does not already fall into Case 1. After showing that $P$ contains a set of critical nodes, we are done, because performing subpath swaps to yield a path containing $W' \cup \{u\}$ was our stated goal.

It is not at all clear a priori that any $P$ should contain a set of critical nodes. Indeed, the critical nodes need to be chosen very carefully. Specifically, they need to be chosen based on the structure of the path $P$.

This is where the definitions from Section 1.3 come into play. We categorize $P$ based on whether it is *reversing* or *non-reversing*, (or trivial). Then we construct the critical nodes of $P$ using a different procedure specialized for which type of path $P$ is.

If $P$ is a reversing path, then we argue that a valid choice of critical nodes are $a$, $b$, and $u$, along with the two nodes at the two boundaries between the segments defined in Lemma 9 (and a few other nodes for technical reasons). To make this argument, which we will not detail here, we construct an involved series of subpath swaps to reroute some path through all of $W' \cup \{u\}$.

On the other hand, if $P$ is a non-reversing path, the critical nodes are less straightforward to define than if $P$ is a reversing path. Indeed, defining the critical nodes for non-reversing paths is the most conceptually difficult part of our proof. The high-level reason for this difficulty is the fact that the nodes of Segment 2 of a non-reversing path are quite unconstrained because they admit 3 possible shortest-path orderings instead of only 2.

To be more concrete, suppose every node on $P$ falls into Segment 2. For simplicity, suppose we were to choose critical nodes $a, b, w$, where $a$ and $b$ are the endpoints of $P$ and also happen to be in $W'$, and $w$ is any other node in $W'$. Consider the path $P' \in \mathcal{R}$ containing $a$, $b$, and $w$, which exists by property (†). By the definition of Segment 2, there are 3 possible orderings of $a, b, w$ on $P'$ ($a \to w \to b$, or $b \to a \to w$, or $w \to b \to a$). Note that these 3 orderings are cyclic shifts of one another. Suppose, as an illustrative example, that $P'$ has the ordering $b \to a \to w$. We would like to reroute $P'$ through all of $W' \cup \{u\}$, but we have a problem. For any node $s \in W'$ that appears between $a$ and $w$ on $P$, we can reroute $P'$ through $s$ by swapping the subpath $P[a, w]$ with $P'[a, w]$; however, for a node $s \in W'$ that appears between $w$ and $b$ on $P$, we cannot do this because there is no path segment from $w$ to $b$ on $P'$, since $b$ appears before $w$ on $P'$. Thus, we cannot reroute $P'$ through $s$. That is, no matter how we choose the critical nodes, if we do not impose extra structural constraints, we can always identify a segment of the path that we cannot reroute $P'$ through. Overcoming this issue is our main technical challenge, and we defer it to the full proof.

## Abstract

A RAC graph is one admitting a RAC drawing, that is, a polyline drawing in which each crossing occurs at a right angle. Originally motivated by psychological studies on readability of graph layouts, RAC graphs form one of the most prominent graph classes in beyond planarity.

In this work, we study a subclass of RAC graphs, called axis-parallel RAC (or apRAC, for short), that restricts the crossings to pairs of axis-parallel edge-segments. apRAC drawings combine the readability of planar drawings with the clarity of (non-planar) orthogonal drawings. We consider these graphs both with and without bends. Our contribution is as follows: (i) We study inclusion relationships between apRAC and traditional RAC graphs. (ii) We establish bounds on the edge density of apRAC graphs. (iii) We show that every graph with maximum degree 8 is 2-bend apRAC and give a linear time drawing algorithm. Some of our results on apRAC graphs also improve the state of the art for general RAC graphs. We conclude our work with a list of open questions and a discussion of a natural generalization of the apRAC model.

## 1 Introduction

Planar graphs form a fundamental graph class in algorithms and graph theory. This is due to the fact that planar graphs have many useful properties, e.g., they are closed under minors and have a linear number of edges. Several decision problems, which are NP-complete for general graphs, become polynomial-time tractable, when restricted to planar inputs, e.g. [28]. As a result, the corresponding literature is tremendously large.

A recent attempt to extend this wide knowledge from planar to non-planar graphs was made in the context of *beyond-planarity*, informally defined as a generalization of planarity encompassing several graph-families that are close-to-planar in some sense (e.g., by imposing structural restrictions on corresponding drawings). Notable examples are the classes of

(i) $k$-planar graphs [31], in which each edge cannot be crossed more than $k$ times, (ii) $k$-quasi-planar graphs [1], which disallow $k$ pairwise crossing edges, and (iii) $k$-gap planar graphs [9], in which each crossing is assigned to one of the two involved edges such that each edge is assigned at most $k$ of its crossings. For an overview refer to the recent textbook [29].

While all of the aforementioned graph-classes are topological, meaning that the actual geometry of the graph's elements is not important, there is a single class proposed in the literature that is purely geometric. The motivation for its study primarily stems from cognitive experiments indicating that the negative effect of edge crossings in a graph drawing tends to be eliminated when the angles formed at the edge crossings are large [30]. In that aspect, the class of *right-angle-crossing* (RAC) graphs forms the optimal case in this scenario, where all crossing angles occur at 90°. Formally, it was introduced by Didimo, Eades and Liotta [22] a decade ago, and since then it has been a fruitful subject of intense research [5, 17, 19, 23, 25].

Generally speaking, the research on RAC graphs has focused on two main research directions depending on whether bends are allowed along the edges or not. Formally, in a $k$-bend RAC drawing of a graph each edge is a polyline with at most $k$ bends and the angle between any two crossing edge-segments is 90°. Accordingly, a $k$-bend RAC graph is one admitting such a drawing. A 0-bend RAC graph (or simply RAC graph) with $n$ vertices has at most $4n - 10$ edges [22], that is, at most $n - 4$ edges more than those of a corresponding maximal planar graph. The edge-density bounds for 1- and 2-bend RAC graphs are $5.5n - 10$ [2] and $74.2n$ [8], respectively, while for $k \geq 3$ it is known that every graph is $k$-bend RAC [25]. The research on RAC graphs, however, is not limited to edge-density bounds. Several algorithmic and combinatorial results [5, 7, 6, 18, 21, 25], as well as relationships with other graph classes [10, 13, 15, 16, 23, 14] are known; see [20] for a survey.

In this work, we continue the study of RAC graphs along a new and intriguing research line. Inspired by several well-established models for representing graphs (including the widely-used orthogonal model [12, 26, 27]), we introduce and study a natural subfamily of $k$-bend RAC graphs, which restricts all edge segments involved in crossings to be axis-parallel. We call this class $k$-bend apRAC. We expect that this restriction will further enhance the readability of the obtained drawings, as these combine the simple nature of the planar drawings with the clarity of the (non-planar) orthogonal drawings by allowing non axis-parallel edge segments, only when those are crossing-free. We further expect that our restriction will lead to new results of algorithmic nature. As a matter of fact, almost all algorithms that have been already proposed in the literature about $k$-bend RAC graphs in fact yield $k$-bend apRAC drawings [11, 22, 25]; e.g., every Hamiltonian degree-3 graph is 0-bend apRAC [6], while degree-4 and degree-6 graphs are 1- and 2-bend apRAC, respectively [3, 5].

Our contribution is as follows:

- In Section 2 we study preliminary properties of 0-bend apRAC graphs in order to prove that recognizing 0-bend apRAC graphs is NP-hard (see Theorem 3).
- We study whether $k$-bend apRAC graphs form a proper subclass of $k$-bend RAC graphs: For $k = 0$, we establish a strict inclusion relationship with $K_6$ minus one edge being the smallest graph separating the two classes. Further, our edge-density result for 1-bend apRAC graphs establishes a strict inclusion relationship for $k = 1$, see Corollary 5. The case $k = 2$ is more challenging (due to the degrees of freedom introduced by bends) and we leave it as an open problem. For $k \geq 3$, the two classes coincide, as the construction establishing that every graph is 3-bend RAC [22] can be converted to 3-bend apRAC by a rotation of 45°.

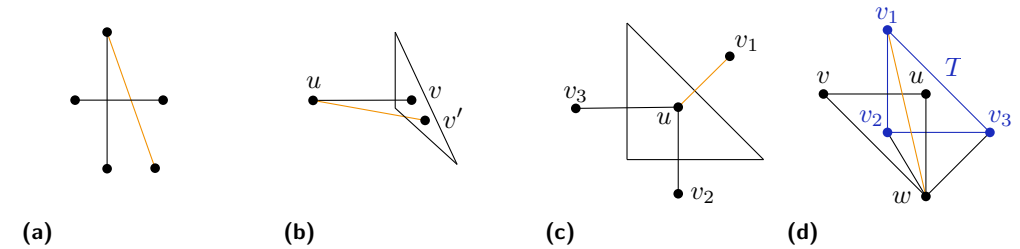

**Figure 1** Forbidden configurations by Properties 1–4.

- We establish bounds on the edge density of $n$-vertex $k$-bend apRAC graphs: For $k = 0$, we prove an upper bound of $4n - \sqrt{n} - 6$ and give a corresponding lower bound construction with $4n - 2\lfloor\sqrt{n}\rfloor - 7$ edges (see Theorem 1). For $k \in \{1, 2\}$, we give linear upper bounds that are tight up to small additive constants (see Theorems 4 and 6). Notably, for $k = 2$ our lower-bound construction is a graph with $n$ vertices and $10n - \mathcal{O}(1)$ edges. This bound extends to general 2-bend RAC graphs and improves the previous best one of $7.83n - \mathcal{O}(\sqrt{n})$ [8], answering an open question in [2].
- We show that every graph with maximum degree 8 is 2-bend apRAC and give a linear time drawing algorithm (see Theorem 8) improving the previous best known result stating that 7-edge colorable degree-7 graphs are 2-bend (ap)RAC [3].
- Inspired by the slope-number of graphs, in Section 7 we discuss a natural generalization of apRAC drawings where each edge segment involved in a crossing is parallel or perpendicular to a line having one out of $s$ different slopes.

## 2 Preliminaries

Throughout this paper, basic graph drawing concepts are used as found in [29, 32]. Let $G$ be a graph and $\Gamma$ be a polyline drawing of $G$ and let $e = (u, v)$ be an edge of $G$. We say that $e$ uses a horizontal (vertical) port at $u$ if the edge-segment of $e$ that is incident to $u$ is parallel to the $x$-axis (to the $y$-axis) in $\Gamma$. If $e$ uses neither a vertical nor a horizontal port at $u$, then it uses an *oblique* port at $u$. In particular, we denote the four orthogonal ports (i.e., the vertical and the horizontal ports) as $\{N, E, S, W\}$-ports according to compass directions. In a polyline drawing, vertices and bends are placed on grid-points, whereby the area of the drawing is determined by the smallest rectangular bounding box that contains the drawing. In the following, we recall two properties that hold for 0-bend RAC drawings.

▶ **Property 1** (Didimo, Eades and Liotta [22]). *In a 0-bend RAC drawing no edge is crossed by two adjacent edges (see Fig. 1a).*

▶ **Property 2** (Didimo, Eades and Liotta [22]). *A 0-bend RAC drawing does not contain a triangle $T$ formed by edges of the graph and two edges $(u, v)$ and $(u, v')$, such that $u$ lies outside $T$ while both $v$ and $v'$ lie inside $T$ (see Fig. 1b).*

Next, we establish two properties limited to 0-bend apRAC drawings.

▶ **Property 3.** *A 0-bend apRAC drawing does not contain a triangle $T$ formed by edges of the graph and three vertices $v_1, v_2, v_3$ adjacent to a vertex $u$, such that $v_1, v_2, v_3$ lie outside $T$ and $u$ lies inside $T$ (see Fig. 1c).*

**Proof.** Assuming the contrary, Property 1 implies that no two edges adjacent to $u$ cross the same boundary edge of $T$. Hence, $T$ consists of three axis-parallel edges; a contradiction. ◀

▶ **Property 4.** *Let $\Gamma$ be a 0-bend apRAC drawing containing a triangle $T$ formed by edges of the graph and two adjacent vertices $u$ and $v$ such that $u$ is contained inside $T$ while $v$ is outside $T$. Then, $\Gamma$ does not contain a vertex $w$ adjacent to $u$, $v$ and all vertices of $T$ (see Fig. 1d).*

**Proof.** For the sake of contradiction, assume there is a vertex $w$ adjacent to $u$, $v$ and all vertices of $T$. If $w$ is inside $T$ in $\Gamma$, then $(v, u)$ and $(v, w)$ violate Property 2; a contradiction. Otherwise, since $(u, v)$ and $(u, w)$ cross $T$, by Property 1, it follows that $T$ is a right-angled triangle whose legs are axis parallel. W.l.o.g., let $(v_1, v_2)$ and $(v_2, v_3)$ be the legs of $T$ crossed by $(u, v)$ and $(u, w)$, respectively, such that $(v_1, v_2)$ is horizontal and $(v_2, v_3)$ is vertical. It follows that the edge $(v_2, v_3)$ of $T$ is crossed by $(u, w)$ and $(w, v_1)$ violating Property 1; a contradiction. ◀

In Theorem 3 we leverage the following property shown in [7] of the so-called *augmented square antiprism graph*. The gadget used in the NP-hardness proof of Theorem 3 is depicted in Fig. 2a, while the vertex-colored subgraph in Fig. 2a corresponds to the augmented square antiprism graph.

▶ **Property 5** (Argyriou, Bekos, Symvonis [7])**.** *Any straight-line RAC drawing of the augmented square antiprism graph has two combinatorial embeddings.*

## 3 0-bend apRAC graphs

In this section, we focus on properties of 0-bend apRAC graphs. We start with an almost tight bound on the edge-density of 0-bend apRAC graphs - for comparison, recall that $n$-vertex 0-bend RAC graphs have at most $4n - 10$ edges [22].

▶ **Theorem 1.** *A 0-bend apRAC graph with $n$ vertices has at most $4n - \sqrt{n} - 6$ edges. Also, there is an infinite family of graphs with $4n - 2\lfloor\sqrt{n}\rfloor - 7$ edges that admit 0-bend apRAC drawings.*

**Proof.** For the upper bound consider any 0-bend apRAC drawing $\Gamma$ of a graph $G$ with $n$ vertices. As a $(k \times k)$-grid has only $k^2$ grid points, we may assume without loss of generality that the vertices of $G$ use at least $\sqrt{n}$ different $y$-coordinates in $\Gamma$. It follows that the subgraph $G_h$ of $G$ defined by the set $E_h$ of all horizontal edges of $\Gamma$ is a forest of paths with at least $\sqrt{n}$ components; at least one for each used $y$-coordinate. Thus $|E_h| \leq n - \sqrt{n}$. As $G - E_h$ is crossing-free in $\Gamma$, it has at most $3n - 6$ edges, giving the desired upper bound of $4n - \sqrt{n} - 6$ edges for $G$.

For the lower bound, consider the construction shown in Fig. 2b. For any even $k > 0$, construct a $k \times k$ grid graph $H_k$ which contains a pair of crossing edges in every quadrangular face. Let $G_k$ be the graph obtained from $H_k$ by adding two extremal adjacent vertices $N$ and $S$ connected to $2k - 1$ consecutive boundary vertices of $H_k$ each (refer to the blue edges in Fig. 2b and observe that the edge between $N$ and $S$ can be added by moving $N$ upwards and to the right and $S$ downwards and to the right of $H_k$). If we denote by $n$ the number of vertices of $G_k$, then $n = k^2 + 2$, $k = \sqrt{n-2}$ and thus $m = 4n - 2\lfloor\sqrt{n}\rfloor - 7$. ◀

Since there exist $n$-vertex 0-bend RAC graphs with $4n - 10$ edges, Corollary 2 follows from Theorem 1. In [4], we show that $K_6$ minus one edge is the smallest graph that is 0-bend RAC but not 0-bend apRAC.

▶ **Corollary 2.** *The class of 0-bend apRAC graphs is properly contained in the class of 0-bend RAC graphs.*

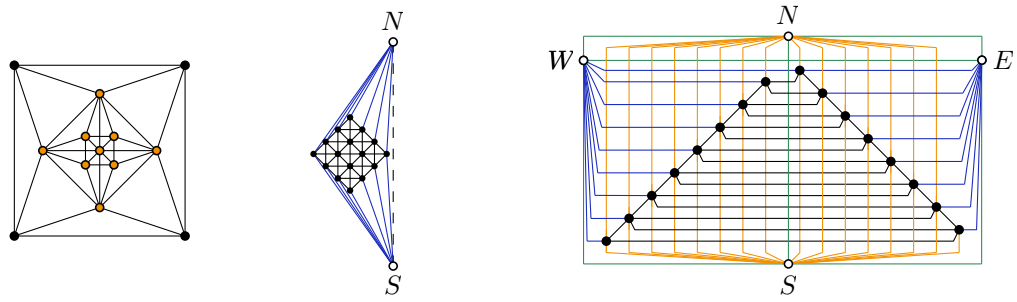

**Figure 2** (a) Graph used in Theorem 3. (b) Lower bound construction for 0-bend apRAC. (c) Lower bound construction for 1-bend apRAC.

We conclude this section by studying the recognition problem of whether a graph is 0-bend apRAC. Due to space reasons, we only sketch the idea of the proof; the complete proof can be found in [4].

▶ **Theorem 3.** *It is NP-hard to decide whether a given graph is* 0*-bend apRAC.*

**Sketch.** We adjust the NP-hardness reduction (from 3-SAT) for the general case of RAC graphs introduced in [7], whose main gadgets use a building block $\mathcal{H}$. We determine a 0-bend apRAC graph $H$ as a substitute for this building block which has the same properties as $\mathcal{H}$: $(i)$ $H$ has a unique embedding, $(ii)$ there are four vertices properly contained in its interior, which can be connected to vertices in its exterior by crossing a single boundary edge, $(iii)$ no edge can (completely) pass through $H$ without forming a fan crossing, and $(iv)$ $H$ can be extended horizontally or vertically maintaining properties $(i) - (iii)$. The graph shown in Fig. 2a satisfies all these criteria and can therefore be used for the reduction. ◀

## 4 1-bend apRAC graphs

In this section, we will establish an upper bound and an almost matching lower bound for the class of 1-bend apRAC graphs. Recall that $n$-vertex 1-bend RAC graphs have at most $5.5n - 10$ edges [2].

▶ **Theorem 4.** *A* 1*-bend apRAC graph with $n$ vertices has at most $5n - 8$ edges. Also, there is an infinite family of graphs with $5n - 16$ edges that admit* 1*-bend apRAC drawings.*

**Proof.** For the upper bound, consider a 1-bend apRAC drawing $\Gamma$ of an $n$-vertex graph $G$. Each edge segment in $\Gamma$ is either horizontal (h), vertical (v) or oblique (o). For $x, y \in \{h, v, o\}$, let $E_{xy}$ be the edges of $G$ with two edge segments of type $x$ and $y$. Then, $E_{hv}$, $E_{ho}$, $E_{vo}$ and $E_{oo}$ form a partition of the edge-set of $G$, assuming that edges that consist of only one $h$-, $v$- or $o$-segment are counted towards $E_{ho}$, $E_{vo}$ and $E_{oo}$, respectively. By construction, any crossing involves exactly one vertical and one horizontal segment. Hence, the subgraph of $G$ induced by $E_{ho} \cup E_{oo}$ is planar and contains at most $3n - 6$ edges. Further, as every segment is incident to a vertex and since any vertex is incident to at most two vertical segments, we have $|E_{vo} \cup E_{hv}| \leq 2n$. We can assume that the topmost vertex $v_t$ is incident to at most one vertical edge-segment, since the edge segment incident to $v_t$ that points upwards cannot be involved in a crossing with a horizontal edge-segment. Otherwise, the endpoint incident to this edge segment would contradict the fact that $v_t$ is topmost in $\Gamma$. Hence, it can be replaced by a steep oblique edge-segment without introducing new crossings. Analogous observations can be made for the bottommost vertex in $\Gamma$, which implies that $|E_{vo} \cup E_{hv}| \leq 2n - 2$. Thus, $|E| = |E_{ho}| + |E_{vo}| + |E_{hv}| + |E_{oo}| \leq 5n - 8$.

Our lower bound construction is as follows; see Fig. 2c. For $n \geq 7$, we arrange $n-4$ vertices forming a cycle along the two legs of an isosceles triangle with a horizontal base (outer black edges), such that the left leg has $\lfloor \frac{n-4}{2} \rfloor$ vertices while the right one has $\lceil \frac{n-4}{2} \rceil$. These $n-4$ vertices are further joined by a $y$-monotone path of $n-7$ edges (inner black edges). Two extremal vertices $N$ and $S$ above and below the triangle are connected to all $n-4$ vertices (orange edges). Similarly, two extremal vertices $W$ and $E$ to the left and right of the triangle are connected to all vertices of the left and right legs of the triangle respectively (blue edges); the topmost vertex of the right leg is also connected to $W$. Finally, we add six edges between the extremal vertices, which gives $n-4+n-6+3(n-4)+6 = 5n-16$ edges. ◀

Since there exists 1-bend RAC graphs with $5.5n-72$ edges [2], the following corollary is immediate.

▶ **Corollary 5.** *The class of* 1*-bend apRAC graphs is a proper subclass of the one of* 1*-bend RAC graphs.*

## 5 2-bend apRAC graphs

In Theorem 6, we provide an upper-bound for the edge density of 2-bend apRAC graphs together with a lower-bound construction which is tight up to an additive constant. Our result provides a stark contrast to the one for 2-bend RAC graphs, where the current best upper-bound on the number of edges of $n$-vertex graphs is $74.2n$ [8], while the previous best lower bound-construction contained only $7.83n - \mathcal{O}(\sqrt{n})$ [8] edges.

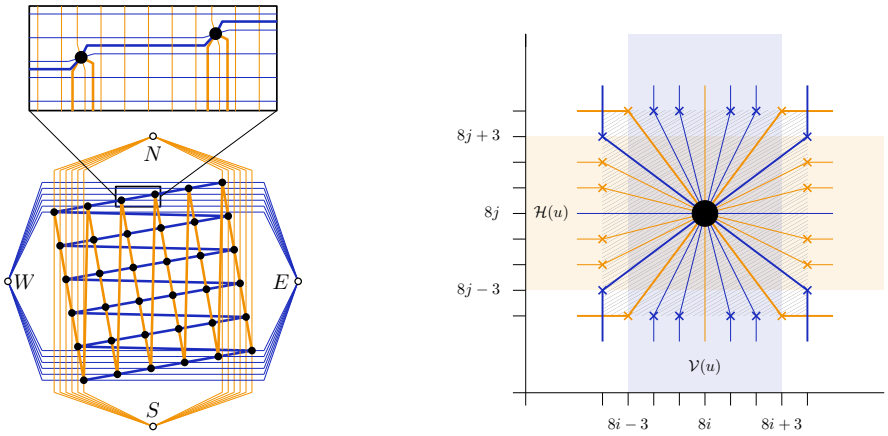
▶ **Theorem 6.** *A* 2*-bend apRAC graph with $n$ vertices has at most $10n-12$ edges. Also, there is an infinite family of graphs with $10n-46$ edges that admit* 2*-bend apRAC drawings.*

**Proof.** Consider a 2-bend apRAC drawing $\Gamma$ of an $n$-vertex graph $G$. Each edge segment in $\Gamma$ is either horizontal (h), vertical (v) or oblique (o). Denote by $S$ the set of edges that contain at least one segment in $\{h, v\}$ incident to a vertex. Since any vertex is incident to at most two vertical and at most two horizontal segments, it follows that $|S| \leq 4n$. Let $E_h$, $E_v$ and $E_o$ be the set of edges of $E \setminus S$ whose middle part is $h$, $v$ and $o$, respectively. Assuming that an edge of $E \setminus S$ consisting of less than three segments belongs to $E_o$, it follows that $E_h$, $E_v$ and $E_o$ form a partition of $E \setminus S$. Observe that the edges of $E_o$ cannot be involved in any crossing in $\Gamma$, as all of its segments are oblique. Further, no two edges of $E_h$ or of $E_v$ can cross. Hence, the subgraphs induced by $E_h \cup E_o$ and $E_v \cup E_o$ are planar and contain at most $3n-6$ edges each. Recall that $|S| \leq 4n$ and thus $|E| \leq |S| + |E_h| + |E_v| + 2|E_o| \leq 4n + 3n - 6 + 3n - 6 = 10n - 12$.

Refer to Fig. 3a for a schematization of the upcoming lower-bound construction and to Fig. 4 for a concrete example. Fix an integer $k \geq 6$ and consider a set $P$ of $k^2$ points of a $k \times k$ square grid in the plane but rotated very slightly, say counterclockwise, so that the points in each column have consecutive $x$-coordinates (consequently the points in each row have consecutive $y$-coordinates). For two points $p, q \in P$ let their *$x$-distance* $\mathrm{dist}_x(p, q)$ be the number of points in $P$ having their $x$-coordinate between $p$ and $q$. Similarly define the $y$-distance $\mathrm{dist}_y(p, q)$. The crucial property of point set $P$ is the following.

$$\text{For any } p \neq q \in P \text{ we have } \mathrm{dist}_x(p, q) + \mathrm{dist}_y(p, q) \geq k - 1 \geq 5. \tag{1}$$

Between any pair $p, q \in P$ with consecutive $x$-coordinates, i.e., $\mathrm{dist}_x(p, q) = 0$, we add a 2-bend edge with vertical middle segment by starting and ending with a very short oblique segment at $p$ respectively $q$. Similarly, we add a 2-bend edge with horizontal middle segment when $\mathrm{dist}_y(p, q) = 0$. Note that these are in total $2k^2 - 2$ edges, no two of which connect the same pair of points, due to (1).



(a) (b)

**Figure 3** (a) Illustration of the construction in Theorem 6 with $k = 6$. Edges with two oblique segments are indicated in orange for vertical middle segments and in blue for horizontal middle segments. Edges using the horizontal or vertical ports are omitted for readability. (b) Edge routing in the $8 \times 8$ box $B(u)$ of a vertex $u$. Blue ports are exclusively used by edges of $F_1$ and $F_3$ and orange ports by $F_2$ and $F_4$. Note that the ports illustrated by bold lines are reserved for oblique-2 edges. Bends on the border of the box are emphasized by a cross.

Next we add four additional points $N, E, S, W$ to the top, right, bottom, and left of all points in $P$, respectively. For every point $p$ we add a 2-bend edge with vertical middle segment between $p$ and $N$ starting with a very short oblique segment at $p$ and ending with an almost horizontal (but still oblique) segment at $N$. Similarly, we add a 2-bend edge with vertical middle segment between $p$ and $S$, as well as one with horizontal middle segment to each of $E, W$. Note that these are in total $4k^2$ edges, and that all oblique segments can be chosen such that all crossings involve middle segments only.

Next we add for (almost) each point $p \in P$ four more 2-bend edges. First, consider for $p$ the point $q \in P$ to the right of $p$ with $\text{dist}_x(p, q) = 1$, unless $p$ is one of the two rightmost points in $P$. We draw a 2-bend edge from $p$ to $q$ by starting with a horizontal segment at $p$ to almost the $x$-coordinate of $q$, continuing with a vertical segment to almost the $y$-coordinate of $q$, and ending with a very short oblique segment at $q$. Similarly, we use the left horizontal port at $p$ for an edge to the point $q$ left of $p$ with $\text{dist}_x(p, q) = 2$. (We take $x$-distance 2 instead of 1 to avoid introducing a parallel edge.) Symmetrically, we draw two edges using the vertical ports at $p$. Note that these are in total $4k^2 - 10$ edges, and that all crossings involve horizontal and vertical segments only.

Finally, we add easily add six edges to create a $K_4$ on vertices $N, E, S, W$. To conclude, we have constructed a 2-bend apRAC graph with $n = k^2 + 4$ vertices and $(2k^2 - 2) + 4k^2 + (4k^2 - 10) + 6 = 10k^2 - 6 = 10n - 46$ edges. ◀

## 6 Every graph with maximum degree 8 is 2-bend apRAC

In the following, we prove that graphs with maximum degree 8 admit 2-bend apRAC drawings of quadratic area which can be computed in linear time. We leverage the following result in order to decompose the input graph.

▶ **Lemma 7** (Eades, Symvonis, Whitesides [24]). *Let $G = (V, E)$ be an $n$-vertex undirected graph of degree $\Delta$ and let $d = \lceil \Delta/2 \rceil$. Then, there exists a directed multigraph $G' = (V, E')$ with the following properties:*

1. *each vertex of $G'$ has indegree $d$ and outdegree $d$;*
2. *$G$ is a subgraph of the underlying undirected graph of $G'$; and*
3. *the edges of $G'$ can be partitioned into $d$ edge-disjoint directed 2-factors (where a 2-factor is a spanning subgraph of $G'$ consisting of vertex disjoint cycles, called cycle cover in [24]).*

*The directed graph $G'$ and the $d$ 2-factors can be computed in $\mathcal{O}(\Delta^2 n)$ time.*

Now, we are ready to state the main result.

▶ **Theorem 8.** *Given a graph $G$ with maximum degree 8 and $n$ vertices, it is possible to compute in $\mathcal{O}(n)$ time a 2-bend apRAC drawing of $G$ with $\mathcal{O}(n^2)$ area.*

**Proof.** Let $G$ be a simple graph with maximum degree 8 and $n$ vertices. We apply Lemma 7 to augment $G$ to a **directed** 8-regular multigraph having four edge-disjoint 2-factors $F_1$, $F_2$, $F_3$ and $F_4$. Before we present our algorithm in full detail, we sketch an outline of the necessary steps. We want to stress that in the following, the direction of an edge $(u, v)$ plays an important role and hence we consider it as a directed edge with source $u$ and target $v$.

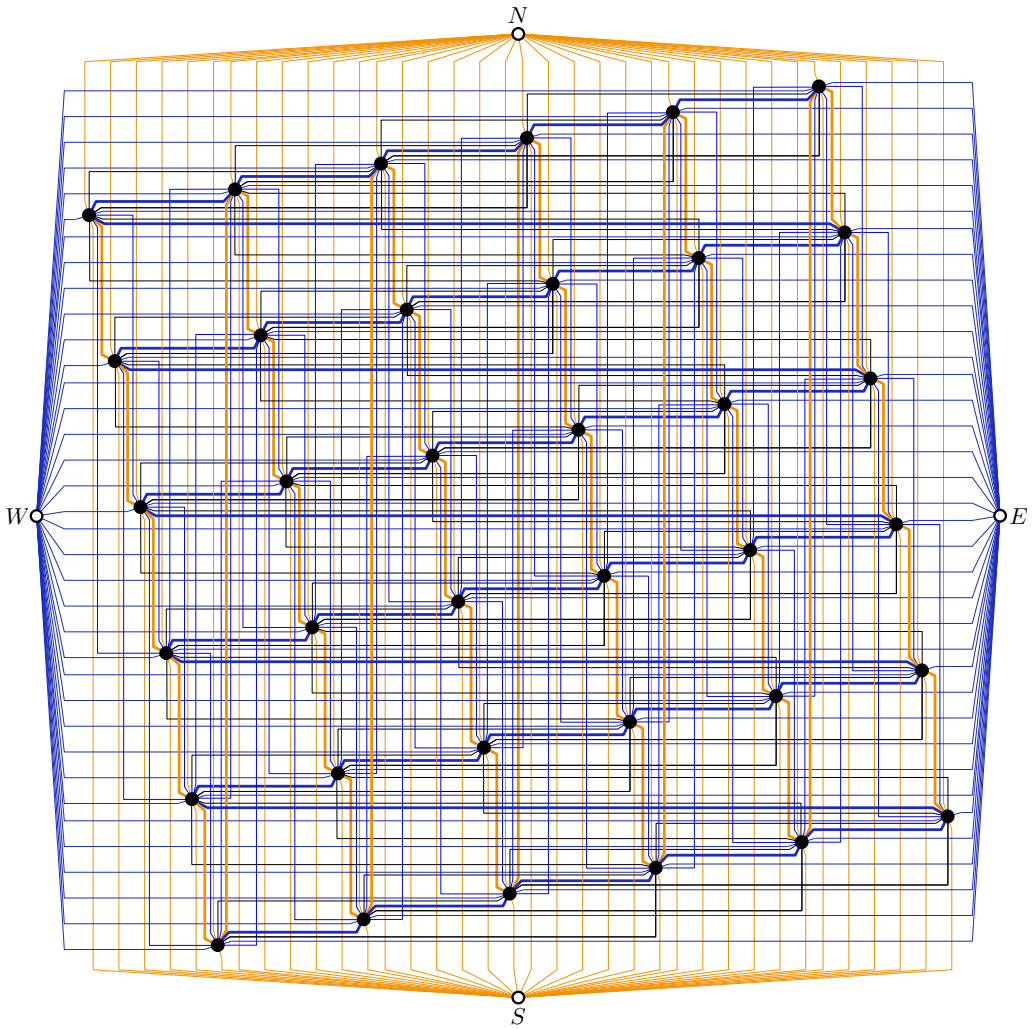


**Figure 4** Illustration of the construction in Theorem 6 with $k = 6$. The $K_4$ on the vertices $N, E, S, W$ is omitted due to space reasons.

## 6.1 Outline of the algorithm

In the first step, we will construct two total orders $\prec_x$ and $\prec_y$ of the vertices of $G$ which will determine the $x$- and $y$-coordinates of the vertices in the final drawing. In particular, if vertex $u$ of $G$ has the $i$-th position in $\prec_x$ and the $j$-th position in $\prec_y$, then $u$ will be placed at point $(8i, 8j)$ in the final drawing. We will construct these two orders independently such that $\prec_x$ is defined by $F_1 \cup F_3$ and $\prec_y$ is defined by $F_2 \cup F_4$. After the computation of $\prec_x$ and $\prec_y$, which finalizes the position of the vertices in our resulting drawing $\Gamma$, it remains to draw the edges which are fully characterized by the placement of the respective bend-points. Every edge will be drawn with exactly three segments, which are either horizontal, vertical or oblique. To ensure that all crossings in $\Gamma$ occur between horizontal and vertical segments, we will restrict oblique segments to be "short" (a precise definition follows below) and require that they are incident to a vertex. To this end, we will define, for each vertex $u$ of $G$, a closed box $B(u)$ centered at $u$ of size $8 \times 8$, such that the oblique segments incident to $u$ are fully contained inside $B(u)$. Note that by construction, the interior of two boxes do not overlap (they may touch at a corner). Since the $x$-coordinate of two consecutive vertices $u$ and $v$ of $\prec_x$ differs by exactly 8, there is a vertical line that is (partially) contained inside both $B(u)$ and $B(v)$ (analogous for a horizontal line and consecutive vertices in $\prec_y$). This allows us to join $u$ and $v$ by an edge that consists of two oblique segments, which is called an *oblique*-2 edge. If the unique orthogonal segment of an oblique-2 edge is vertical (horizontal), we will refer to it as a vertical (horizontal) oblique-2 edge. An edge that contains exactly one oblique segment will analogously be called an *oblique*-1 edge.

In the second step, we will classify every edge of $G$ as either an oblique-1 or an oblique-2 edge - again this classification is done independently for $F_1 \cup F_3$ and $F_2 \cup F_4$; we focus on the description of $F_1 \cup F_3$, the other one is symmetric. Let $e = (u, v)$ be an edge of $F_1 \cup F_3$. If $u$ and $v$ are consecutive in $\prec_x$, then $e$ is classified as a vertical oblique-2 edge. Otherwise, $e$ is classified as an oblique-1 edge such that the (unique) oblique segment is incident to the target $v$, while the orthogonal segment at $u$ uses the $E$-port at $u$ if $u \prec_x v$, otherwise it uses the $W$-port.

In the final step, we will specify the exact coordinates of the bend-points. At a high level, oblique segments (which are by construction all incident to vertices) will end at the boundary of the corresponding box, see Fig. 3b. The bend-points between vertical and horizontal segments are then naturally defined by the intersections of their corresponding lines.

The final drawing $\Gamma$ will then satisfy the following two properties.

- **(i)** No bend-point of an edge lies on another edge and
- **(ii)** the edges are drawn with two bends each so that only the edge segments that are incident to $u$ are contained in the interior of $B(u)$, while all the other edge segments are either vertical or horizontal.

This will guarantee that the resulting drawing is 2-bend RAC; for an example see Fig. 5. Note that (i) guarantees that no two segments have a non-degenerate overlap.

## 6.2 Computing $\prec_x$ and $\prec_y$

We will now describe how to construct $\prec_x$ and $\prec_y$ explicitly. We focus on the construction of $\prec_x$ which is based on $F_1$ and $F_3$, the order $\prec_y$ can be constructed analogously. Let $C_1, C_2, \ldots, C_k$ be an arbitrary ordering of the components of $F_1$. Recall that by definition, each such $C_i$ is a directed cycle. Let $S$ be a set of vertices that contains exactly one arbitrary vertex from each cycle in $F_1$ and let $P_1, P_2, \ldots, P_k$ be the resulting directed paths obtained by restricting the cycles to $V \setminus S$. Note that this may yield paths that are empty, i.e., when the

corresponding cycle consists of a single vertex. We construct $\prec_x$ (limited to $V \setminus S$) such that the vertices of each path appear consecutively defined by the unique directed walk from one endpoint of the path to the other. The relative order between paths is $P_1 \prec_x P_2 \prec_x \cdots \prec_x P_k$. Hence it remains to insert the vertices of $S$ into $\prec_x$. Throughout the algorithm, we will maintain the following invariant which will ensure the correctness of our approach.

**I.1** Let $u \in S$ be a vertex of cycle $C_i$. If $|C_i| > 1$, then $u$ is placed next to at least one vertex of $P_i$. Otherwise, $u$ is placed directly after the last vertex of $C_{i-1}$ (or as first vertex if $i = 1$) in $\prec_x$.

If I.1 is maintained, we can guarantee the following observation.

▶ **Observation 1.** *Let $u \in C_i$ and $v \in C_j$ be two vertices of $G$ with $i \neq j$. Then, the relative order of $u$ and $v$ in $\prec_x$ is known.*

Assume that each vertex in $S$ that belongs to $C_1, \ldots, C_{i-1}$ has been inserted in $\prec_x$. Let $u \in S$ be the vertex that belongs to $C_i \setminus P_i$. If $|C_i| \leq 2$, then we place $u$ immediately after the last vertex of $C_{i-1}$ in $\prec_x$ if $i > 1$, otherwise $u$ is the first vertex of $\prec_x$ which maintains I.1. Hence, in the remainder we can assume that $C_i$ consists of at least three vertices. Let $a$, $b$ and $c$ be the vertices of $G$ such that $(u, a)$, $(b, u) \in F_1$ and $(u, c) \in F_3$. Even though $G$ is a multigraph, we have that $a \neq b$ since $C_i$ contains at least three vertices. Hence, by construction we have $a \prec_x b$ - in particular, $a$ is the first vertex of $P_i$ in $\prec_x$, while $b$ is the last one. Let $C_j$ (possibly $j = i$) be the cycle that contains $c$. Note that it is possible that $c \in S$, i.e., $c$ is not part of $\prec_x$ initially. However, as this can only happen if $i \neq j$, we know the relative position of $u$ and $c$ by Observation 1. We distinguish between the following cases based on the relative order of cycle $C_i$ (which contains $u$) and cycle $C_j$ (which contains $c$) in $\prec_x$.

1. $j < i$. We insert $u$ immediately before $a$ in $\prec_x$ such that it is the first vertex of $C_i$, see Fig. 6a. Clearly, this maintains I.1.
2. $i < j$. This case is symmetric to the previous one - we insert $u$ immediately after $b$ in $\prec_x$ such that it is the last vertex of $C_i$, see Fig. 6b, which again maintains I.1.
3. $i = j$. In this case, we have that $c$ also belongs to $C_i$ (in particular, $c$ belongs to $P_i$ and thus is already part of $\prec_x$). If $c = a$ or $c = b$, we simply omit the edge $(u, c)$ and proceed as in the first case, i.e., we place $u$ as the first vertex of $C_i$. Otherwise, we insert $u$ directly before or directly after $c$ in $\prec_x$ based on the edge $(c, d) \in F_3$. The relative order of $c$ and $d$ in $\prec_x$ is known by Observation 1 unless $d \in C_i$. If $d \in P_i$, the relative order between $c$ and $d$ is also known (as both are already present in $\prec_x$). If $d \notin P_i$, then $d = u$ and we can omit the edge $(u, c) \in F_3$ (because it is a copy of $(c, d) \in F_3$), in which case we can again proceed as in the first case. Hence, $d \neq u$ holds. If $c \prec_x d$, we insert $u$ directly before $c$ in $\prec_x$, see see Fig. 6c, otherwise we insert $u$ directly after $c$ in $\prec_x$. In both cases, we maintain I.1.

This concludes our construction of $\prec_x$.

## 6.3 Classification of the edges and port assignment

We focus on the classification of the edges of $F_1 \cup F_3$ and their port assignment, the classification of the edges of $F_2 \cup F_4$ is analogous. Our classification will maintain the following invariants.

**I.2** The endpoints of each vertical oblique-2 edge are consecutive in $\prec_x$.

**I.3** Each oblique-1 edge $(u, v) \in F_1 \cup F_3$ is assigned the $W$-port at its source vertex $u$, if $v \prec_x u$; otherwise, if $u \prec_x v$, it is assigned the $E$-port at $u$.

**I.4** Every horizontal port is assigned at most once.

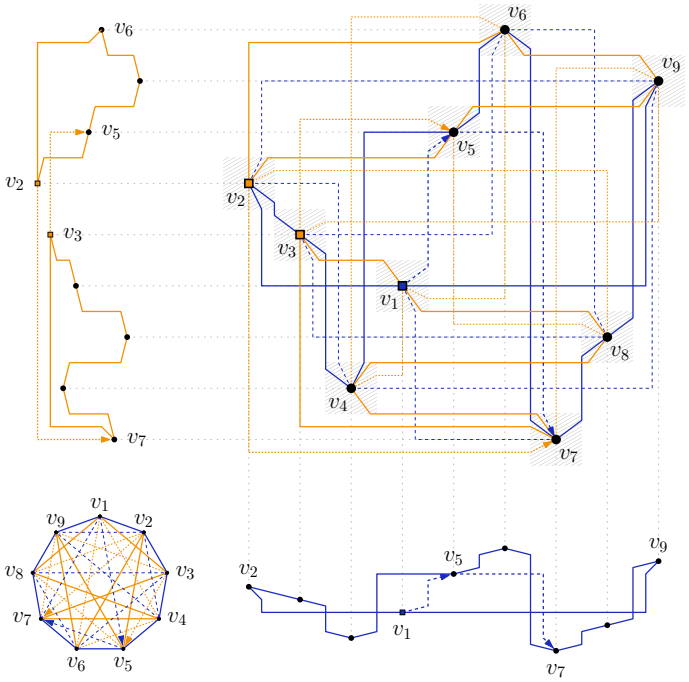

**Figure 5** A 2-bend apRAC drawing of $K_9$; $F_1$ and $F_3$ are blue; $F_2$ and $F_4$ are orange. Below the drawing of $K_9$ there is a illustration of the cycles in $F_1$ and the relevant edges in $F_3$ for positioning $v_1 \in S$ according to Case 3 in the construction of $\prec_x$. Similarly, a visualization of the cycles in $F_2$ and the relevant edges in $F_4$ is displayed to the left.

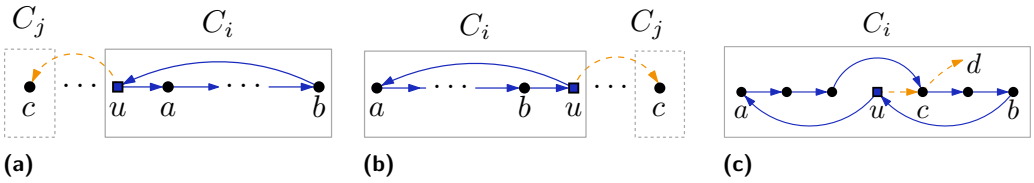

**Figure 6** Illustration of the construction of $\prec_x$, Case 1 is shown in (a), Case 2 in (b) and Case 3 in (c). Blue edges belong to $F_1$, while dashed orange edges belong to $F_3$.

Let us consider an edge $e \in F_1 \cup F_3$ between vertices $u$ and $v$. If $u$ and $v$ are consecutive in $\prec_x$, then we classify $e$ as a vertical oblique-2 edge. If $u$ and $v$ are not consecutive in $\prec_x$, we will classify $e$ as an oblique-1 edge, which therefore guarantees I.2. For any oblique-1 edge, we will, in an initial phase, assign the ports precisely as stated in I.3. In a subsequent step, we will create a unique assignment of the horizontal ports by reorienting some edges of $F_1 \cup F_3$ in order to guarantee I.4. Suppose that after the initial assignment, there exists a vertex $u$ such that one of its orthogonal ports is assigned to two oblique-1 edges. Assume first the $W$-port of $u$ is assigned to edges $(u, a)$ and $(u, b)$. By construction, $u$ has exactly one outgoing edge in $F_1$, say $(u, a)$, and exactly one outgoing edge in $F_3$, say $(u, b)$. Let $C_i$ be the cycle of $F_1$ that contains both $u$ and $a$ (which implies that $|C_i| > 1$, as we omit self-loops) and let $C_j$ be the cycle that contains $b$ (possibly $i = j$). Recall that by construction, the vertices of $P_i$ appear consecutively in $\prec_x$ before the insertion of the vertex $v \in C_i \setminus P_i$. Since $(u, a)$ is an oblique-1 edge, we have that $u$ and $a$ are not consecutive in $\prec_x$. If $|C_i| = 2$, one of $u$ or $a$ coincides with $v$, but then $u$ and $a$ are consecutive in $\prec_x$ and thus the edge $(u, a)$ is

an oblique-2 edge. Hence, $|C_i| > 2$ holds and we either have $u = v$, $a = v$ or $v$ was inserted directly in between $a$ and $u$. In the following, we will refer to Cases 1 - 3 of Section 6.2, where we computed the total order $\prec_x$.

1. $u = v$. Assume first that $C_i \neq C_j$. Then, since $(u, b)$ is assigned the $W$-port at $u$, we have $b \prec_x u$ by I.3 which implies $j < i$ and hence we placed $u$ according to Case 1, i.e., as the first vertex of $C_i$ in $\prec_x$. But since $a \in C_i$, we then have $u \prec_x a$ and thus $(u, a)$ would use the $E$-port at $u$, a contradiction.
   Hence assume that $C_i = C_j$, i.e., $b \in C_i$. Then we are in Case 3. In particular, we placed $u$ such that $u$ and $b$ are consecutive, thus $(u, b)$ is classified as an oblique-2 edge, again we obtain a contradiction.
2. $a = v$. Since $(u, a)$ uses the $W$-port at $u$ by assumption, we have that $a \prec_x u$ by I.3 and thus $a$ cannot be the last vertex of $C_i$ in $\prec_x$, and so we are in Case 1 or 3. In Case 1, $a$ is placed as the first vertex of $C_i$ since there exists a vertex $a'$ with $a' \prec_x a$ such that $(a, a') \in F_3$. Further, $a$ is placed next to vertex $v'$ (i.e., the first vertex of $P_i$ in $\prec_x$) with $(a, v') \in F_1$ by construction. Then, we can redirect the edge $(u, a) \in F_1$ such that we can assign $(a, u)$ the $E$-port at $a$ which solves the conflict at $u$ and does not introduce a conflict at $a$ which guarantees I.4. In Case 3, $a$ was placed consecutive to vertex $a' \in P_i$ with $(a, a') \in F_3$. As $(u, a)$ uses the $W$-port at $u$, $u$ is necessarily the last vertex of $C_i$ in $\prec_x$. Since the other neighbor of $a$ in $F_1$ different from $u$ is the first vertex of $C_i$ in $\prec_x$, i.e., it precedes $a$ in $\prec_x$, we can again reorient the edge $(u, a)$ and assign the edge $(a, u)$ to the free $E$-port of $a$, solving the conflict at $u$ which guarantees I.4.
3. $v$ was inserted directly in between $a$ and $u$. In this case, we have that both $a$ and $u$ belong to $P_i$. Since we assume that $(u, a)$ uses the $W$-port at $u$, it follows that $a \prec_x u$ holds. But then by construction, the edge of $F_1$ that joins $a$ und $u$ is directed from $a$ to $u$ and we obtain a contradiction.

The case where the $E$-port of $u$ is assigned to two edges can be solved in a similar way; refer to [4] for details.
Observe that if an edge $(u, v)$ was redirected, then both $u$ and $v$ belong to the same cycle $C_i$ of $F_1$ and since this operation has to be performed at most once per cycle, it follows that they can be considered independently. So far, we have computed $\prec_x$ and classified every edge of $F_1 \cup F_3$ guaranteeing Invariants 1-I.4. Symmetrically, we can compute $\prec_y$ and classify every edge of $F_2 \cup F_4$ guaranteeing corresponding versions of Invariants 1-I.4; see [4] for details.

## 6.4 Bend placement

We begin by describing how to place the bends of the edges on each side of the box $B(u)$ of an arbitrary vertex $u$ based on the type of the edge that is incident to $u$, refer to Fig. 3b. Let $(x_u, y_u)$ be the coordinates of $u$ in $\Gamma$ that are defined by $\prec_x$ and $\prec_y$. Recall that the box $B(u)$ has size $8 \times 8$. Let $e$ be an edge incident to $u$. We focus on the case in which $e \in F_1 \cup F_3$, the other case in which $e$ belongs to $F_2 \cup F_4$ is handled symmetrically by simply exchanging $x$ with $y$, "top/bottom" with "right/left" and "vertical" with "horizontal" from the following description. By definition, $e$ is either an oblique-1 edge or a vertical oblique-2 edge. Suppose first that $e$ is an oblique-1 edge. If $e = (u, v)$, i.e., $e$ is an outgoing edge of $u$ in $F_1 \cup F_3$, then by Invariant I.3 edge $e$ uses either the $W$- or $E$-port at $u$. In the former case, the segment of $e$ incident to $u$ passes through point $(y_u, y_u - 4)$, while in the latter case it passes through point $(y_u, y_u + 4)$. For an example, refer to the outgoing edge $(v_3, v_6)$ of $v_3$ in Fig. 5. If $e = (v, u)$, i.e., $e$ is an incoming edge of $u$ in $F_1 \cup F_3$, then by Invariant I.3 $e$ uses a horizontal port at $v$ and by the fact that every edge consists of exactly three segments, the

vertical segment of $e$ ends at the top or the bottom side of $B(u)$. Since any vertex has at most three incoming edges in $F_1 \cup F_3$ by construction, we can place the respective bends at $x$-coordinate $x_u + i$ with $i \in \{-2, -1, 1, 2\}$ and $y$-coordinate $y_u + 4$ ($y_u - 4$) for the top (bottom) side such that the assigned $i$-value is unique, refer to the incoming edge $(v_4, v_9)$ of $v_9$ in Fig. 5, where $i = -1$. Finally, the other bend-point of $e$ is uniquely defined as $(x_u + i, y_v)$, since it connects a vertical with a horizontal segment by construction.

Suppose now that $e$ is a vertical oblique-2 edge. By I.2, $u$ and $v$ are consecutive in $\prec_x$. If $v \prec_x u$ the $x$-coordinate of the bend point is $x_u - 4$, otherwise it is $x_u + 4$; e.g., refer to the edges $(v_2, v_3)$ and $(v_3, v_4)$ of $v_3$ in Fig. 5, respectively. In order to define the $y$-coordinate of the bend point, we have to consider the relative position of $u$ and $v$ in $\prec_y$. If $v \prec_y u$ the $y$-coordinate of the bend point of $e$ is $y_u - 3$ and otherwise it is $y_u + 3$. I.2 implies that any vertex has at most two vertical oblique-2 edges since no vertex has more than two direct neighbors in $\prec_x$. From the description of the bend-points, the observation follows:

▶ **Observation 2.** *Let $b$ be a bend-point that delimits an oblique segment $s$ which belongs to an edge $e$. If $s$ is incident to $u$, then $b$ does not lie on any other edge incident to $u$.*

## 6.5 Proof of correctness

The fact that the obtained drawing is 2-bend apRAC is proved in [4]. To complete the proof of Theorem 8, we discuss the time complexity and the required area. We apply Lemma 7 to $G$ to obtain $F_1$, $F_2$, $F_3$ and $F_4$ in $\mathcal{O}(n)$ time. For each cycle of $F_1$ and $F_2$, an appropriate ordering of its internal vertices, the classification of the incident edges and the assignment of the orthogonal ports can be computed in time linear in the size of the cycle. Clearly, computing the bend-points can be done in linear time as well. Hence we can conclude that the drawing can be computed in $\mathcal{O}(n)$ time. For the area, we can observe that the size of the grid defined by the boxes is $8n \times 8n$ and by construction, any vertex and any bend point is placed on a distinct point on the grid. ◀

# 7 Conclusion and Open Problems

In this paper, we introduced the class of $k$-bend apRAC graphs, gave edge-density bounds, studied inclusion relationships with the general $k$-bend RAC graphs, and concluded with an algorithmic result for graphs with maximum degree 8. A natural extension is to allow drawings where each crossing edge-segment is parallel or perpendicular to a line having one out of $s$ different slopes. We denote the class of graphs which admit such a drawing as $k$-bend $s$-apRAC, and w.l.o.g. we assume that the horizontal slope is among the $s$ ones. Observe that for $s = 1$, the derived class coincides with the class of $k$-bend apRAC graphs. By joining several copies of the graph supporting Property 5 that all share a common vertex, we show that 0-bend $s$-apRAC graphs form a proper subclass of 0-bend RAC graphs for any $s \in o(n)$; see [4] for details. We also adjust the proof of Theorem 6 to derive an upper bound on the edge density of 2-bend $s$-apRAC graphs, which is better than the one of [8] that holds for general 2-bend RAC graphs for values of $s$ up to 17. We conclude with the following open problems.

- Are there 2-bend RAC graphs that are not 2-bend apRAC?
- For $k \in \{1, 2\}$, our edge-density bounds do not relate to the simplicity of the drawings. Are bounds different for simple drawings, as in the general 1-bend RAC case [2]?
- For $k \in \{1, 2\}$, does the class of $k$-bend $s$-apRAC graphs on $n$ vertices coincide with the corresponding class of $k$-bend RAC graphs, when $s \in o(n)$?

- Based on our exploration of 2-bend apRAC graphs, we conjecture that the edge density of general 2-bend RAC graphs on $n$ vertices is $10n - \mathcal{O}(1)$.
- Another important open problem in the field is to settle the complexity of the recognition of general 1-bend RAC graphs. What if we restrict ourselves to the axis-parallel setting?
- From a practical perspective, can an advantage in the readability of $k$-bend apRAC drawings over $k$-bend RAC drawings be demonstrated in user studies?

## Abstract

Undirected *st*-connectivity is important both for its applications in network problems, and for its theoretical connections with logspace complexity. Classically, a long line of work led to a time-space tradeoff of $T = \widetilde{O}(n^2/S)$ for any $S$ such that $S = \Omega(\log(n))$ and $S = O(n^2/m)$. Surprisingly, we show that quantumly there is no nontrivial time-space tradeoff: there is a quantum algorithm that achieves both optimal time $\widetilde{O}(n)$ and space $O(\log(n))$ simultaneously. This improves on previous results, which required either $O(\log(n))$ space and $\widetilde{O}(n^{1.5})$ time, or $\widetilde{O}(n)$ space and time. To complement this, we show that there is a nontrivial time-space tradeoff when given a lower bound on the spectral gap of a corresponding random walk.

## 1 Introduction

For an undirected graph $G = (X, E)$ on $n = |X|$ vertices and $m = |E|$ edges, with $s, t \in X$, *st*-connectivity or USTCON is the problem of deciding whether $s$ and $t$ are in the same component. This problem has applications in many other graph and network problems, and is of theoretical importance for its connection with space complexity (see e.g. [23]). In particular, USTCON is complete for the class *symmetric logspace*, SL, which was shown to be equal to *logspace*, L, by exhibiting a classical deterministic logspace algorithm for USTCON [22]. In this paper, we consider quantum algorithms for this problem.

There are different versions of the problem USTCON depending on how $G$ is accessed. If $G$ is given as an adjacency matrix, we denote the problem $\text{USTCON}_{\text{mat}}$. If $G$ is given as an array of arrays, one for each vertex, enumerating the neighbours, we denote the problem $\text{USTCON}_{\text{arr}}$. [1] If one only cares about space complexity, these problems are equivalent, but the same is not true of time complexity: adjacency queries can simulate an array query, and vice versa, in logspace, but there is a non-negligible time overhead.

A classical deterministic algorithm based on breadth-first search or depth-first search can solve $\text{USTCON}_{\text{arr}}$ in $\widetilde{O}(m)$ time, using $\widetilde{O}(n)$ space. Using a random walk, the space complexity can be improved to $O(\log(n))$, at the expense of $\widetilde{O}(nm)$ time complexity [2]. A series of works [11, 7, 14, 5, 16] culminated in a space-time tradeoff for $\text{USTCON}_{\text{arr}}$ of $T = \widetilde{O}(n^2/S)$ queries for any space bound $S = \Omega(\log(n))$ and $S = O(n^2/m)$, due to Kosowski [19]. While there is no matching time-space lower bound, it is unlikely that this tradeoff can be significantly improved (see [19, Section 5.1 of arXiv v2] for a discussion). Kosowski's algorithm is based on using Metropolis-Hastings random walks to find connections between $S$ sampled vertices and $s, t$ until it is becomes possible to conclude that $s$ and $t$ are connected. For comparison, in the adjacency matrix model, the randomized query complexity of $\text{USTCON}_{\text{mat}}$ is $\widetilde{\Theta}(n^2)$ and there is no space-time tradeoff.

A quantum algorithm of Dürr, Heiligman, Høyer and Mhalla [13] for CONNECTIVITY can be adapted to solve $\text{USTCON}_{\text{mat}}$ in $\widetilde{O}(n^{1.5})$ time and $\text{USTCON}_{\text{arr}}$ in $\widetilde{O}(n)$ time, both of which are optimal up to polylog factors. Both of these algorithms use $\widetilde{O}(n)$ space, of which all but $O(\log(n))$ can be classical space (assuming quantum RAM access). A subsequent quantum algorithm for $\text{USTCON}_{\text{mat}}$ due to Belovs and Reichardt uses $\widetilde{O}(n^{1.5})$ time, but only $O(\log(n))$ space [9], which is optimal in terms of both space and time. It is also possible to solve $\text{USTCON}_{\text{arr}}$ in $O(\log(n))$ space and $\widetilde{O}(\sqrt{nm})$ time, using a quantum walk (see for example [8]). This quantum walk algorithm requires a quantum version of array access to the input graph, which we refer to as $\text{USTCON}_{\text{qw}}$ in the next section.

## 1.1 Summary of results

We describe new quantum walk algorithms for $\text{USTCON}_{\text{arr}}$. These algorithms consider a quantum walk version of the adjacency array model, in which the input graph is accessed by a quantum analogue of classical random walk steps. Recall that in the adjacency array model, we assume that for any vertex $u$, we can query, for any $i \in [d_u]$, the $i$-th neighbour of $u$, $v_i(u)$. Then a random walk step can be performed from state $u$ by sampling a uniform $i \in [d_u]$, and then computing $v_i(u)$, which becomes the current state. In the *quantum walk access model*, we assume that for any vertex $u$, we can prepare a uniform superposition over the neighbours of $u$. While these models are not identical, they are very similar, and in Section 3, we formally define the models, and show that quantum walk access can be simulated in the array model with polylogarithmic overhead under reasonable additional assumptions.

Letting $\text{USTCON}_{\text{qw}}$ denote the *st*-connectivity problem in the quantum walk access model, we present a one-sided error quantum algorithm that solves $\text{USTCON}_{\text{qw}}$ in time $\widetilde{O}(n)$ and space $O(\log(n))$. Perhaps surprisingly, this means that $\text{USTCON}_{\text{qw}}$ admits *no* nontrivial tradeoff between space and time in the quantum setting – a single algorithm can solve this problem optimally in terms of both time and space (see Theorem 15 for the formal result).

[1] There are variations on the details of this model. For now, we allow $\text{USTCON}_{\text{arr}}$ to stand in for multiple variations of the array access model, but precise details of the variations can be found in Section 3.

**Table 1** A summary of classical (randomized) and quantum time and space complexities for USTCON in the adjacency matrix and adjacency array models. The classical results for $\text{USTCON}_{\text{mat}}$ follow from (1) the $\log(n)$-space result for $\text{USTCON}_{\text{arr}}$ with an $n/d$ overhead for finding neighbours of the current vertex in a $d$-regular graph; and (2) BFS.

| $\text{USTCON}_{\text{mat}}$ | | |
|---|---|---|
| | Time | TS-tradeoffs |
| Classical | $\widetilde{\Theta}(n^2)$ | $S = O(\log(n))$, $T = \widetilde{O}(n^3/d)$<br>$S = \widetilde{O}(n)$, $T = \widetilde{O}(n^2)$ |
| Quantum | $\widetilde{\Theta}(n^{1.5})$ | $S = O(\log(n))$, $T = \widetilde{O}(n^{1.5})$ [9] |
| $\text{USTCON}_{\text{arr}}$ | | |
| | Time | TS-tradeoffs |
| Classical | $\widetilde{\Theta}(m)$ | $T = \widetilde{O}(\max\{n^2/S, m\})$ |
| Quantum | $\widetilde{\Theta}(n)$ | $S = O(\log(n))$, $T = \widetilde{O}(n^{1.5})$<br>$S = T = \widetilde{O}(n)$ [13] |
| | | **This work:** $S = O(\log(n))$, $T = \widetilde{O}(n)$ |

▶ **Theorem 1** (Informal). *There is a $O(\log(n))$-space quantum algorithm that decides $\text{USTCON}_{\text{qw}}$ with one-sided error in $\widetilde{O}(n)$ time.*

In this paper, when we say *time*, we are counting: (1) quantum gates (unitaries that act on at most a constant number of qubits); (2) quantum walk queries to $G$; and (3) (quantum) random access (QCRAM) operations (QCRAM is used in our second algorithm only, see below). Inspired by [19], our algorithm is based on a quantum walk search for $t$ starting from $s$ using a random walk that can be interpreted as a Metropolis-Hastings random walk.

Because of the close relationship between USTCON and classical logspace, we can consider what this means for logspace problems in general. It does not mean that more space does not reduce the quantum time complexity of *any* problem, but it is interesting to consider: in what settings do we get a non-trivial time-space tradeoff? We consider one such setting: when we are given a promise on the spectral gap or mixing time of the random walk on $G$ (see Section 2.2). In that case, we prove the following theorem (see Theorem 17 for the formal result).

▶ **Theorem 2** (Informal). *Suppose whenever $s$ and $t$ are connected, the random walk spectral gap is at least $\delta > 0$. For any $S \in \Omega(\log(n))$, there is a quantum algorithm that decides $\text{USTCON}_{\text{qw}}$ with bounded error in $O(S)$ space and $T = \widetilde{O}\left(\frac{S}{\delta} + \sqrt{\frac{n}{\delta S}}\right)$ time.*

The time bound decreases monotonically for $S \in \Omega(\log n)$ until $S \in O((n\delta)^{1/3})$, at which point it reaches time complexity $T = \widetilde{O}(n^{1/3}/\delta^{2/3})$. We leave it as an open problem to prove a matching lower bound (at least for some values of $\delta$), which would prove that in certain regimes, it is not possible to achieve optimal time and space simultaneously.

Our algorithm takes inspiration from [3]. In fact, with some imagination, one can derive a similar (but incomparable) time-space tradeoff for $\text{USTCON}_{\text{qw}}$ from that work: for $1 \leq S \leq m$, the algorithm in [3] can be adapted to use space $\widetilde{O}(S)$ and time $T \in \widetilde{O}(S + \sqrt{m/(\delta S)})$, with $\delta$ the random walk spectral gap.

In the space bound $S$ of both algorithms in Theorems 1 and 2, only $O(\log(n))$ memory needs to be actual quantum workspace (i.e., qubits). The remaining $O(S)$ memory can be classical RAM in the first algorithm and QCRAM in the second algorithm, that is, classical RAM that is queryable at a quantum superposition of addresses. We discuss the latter in Section 2.4.

We summarize our results in Figure 1. For $S = \log(n)$, the algorithm of Theorem 2 has a worse time complexity than the algorithm of Theorem 1, whenever $\delta < \frac{1}{n}$. We leave it as an open problem to give a single algorithm that is optimal for all $\delta$.

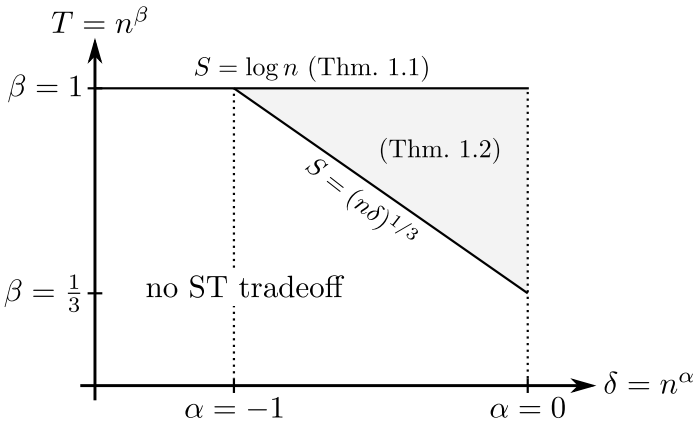

**Figure 1** Quantum space-time tradeoffs for USTCON, with axes representing the time complexity and spectral gap promise (up to polylog-factors). The grey area represents the regime in which a non-trivial tradeoff is achieved. Theorem 1 (upper line) corresponds to the regime with space $S = O(\log n)$ and time $T = \widetilde{O}(n)$. Theorem 2 (grey area) corresponds to the regime with a promise on $\delta$, and interpolates between $S = O(\log n)$ and $T = \widetilde{O}(n)$, and $S = O((n\delta)^{1/3})$ and $T = \widetilde{O}(n^{1/3}/\delta^{2/3})$.

### Organization

The remainder of this paper is organized as follows. We describe preliminaries in Section 2 and Section 3. In Section 4, we prove Theorem 1 by exhibiting a quantum algorithm for $\text{USTCON}_{\text{qw}}$ that is optimal in both time and space. For completeness, we also include a proof of a corresponding lower bound in Section 4.1. In Section 5, we prove Theorem 2 exhibiting a quantum time-space tradeoff when given a promise on the spectral gap.

## 2 Preliminaries

We first give some general notation. For a positive integer $k$, we let $[k] = \{1, \ldots, k\}$. Throughout this work, $n$ denotes the number of vertices and $m$ the number of edges of the input graph. For any function $f$, we let $\widetilde{O}(f(n)) = f(n) \cdot \text{polylog}(n)$.

### 2.1 Probability theory

A *(probability) distribution* on a finite set $X$ is a non-negative function $\sigma\colon X \to \mathbb{R}_{\geq 0}$ such that $\sum_{v \in X} \sigma(v) = 1$. Its *support* is defined as $\text{supp}(\sigma) := \{v \in X : \sigma(v) > 0\}$. We will implicitly identify such $\sigma$ with *row* vectors, as is customary in the random walk literature. To any distribution $\sigma$, we also associate a quantum state $|\sigma\rangle := \sum_{v \in X} \sqrt{\sigma(v)}\,|v\rangle$. Measuring $|\sigma\rangle$ in the standard basis returns a sample from $\sigma$.

For any distribution $\sigma$ on $X$, and any subset $M \subseteq X$, we will let $\sigma(M) = \sum_{u \in M} \sigma(u)$. We let $\sigma_M$ denote the *normalized restriction* of $\sigma$ to $M$, defined by $\sigma_M(u) = \sigma(u)/\sigma(M)$ for all $u \in M$ and $\sigma_M(u) = 0$ elsewhere.

Finally, the *total variation distance* between two distributions $\sigma$ and $\tau$ on $X$ is defined as

$$\|\sigma - \tau\|_{\mathrm{TV}} := \frac{1}{2} \sum_{u \in X} |\sigma(u) - \tau(u)| = \max_{A \subseteq X} |\sigma(A) - \tau(A)|.$$

## 2.2 Random walks

Fix an undirected graph $G = (X, E)$ with $n = |X|$ vertices and $m = |E|$ edges. We take $E \subseteq \binom{X}{2}$, that is, edges $e \in E$ are subsets $e = \{u, v\} = \{v, u\}$ of pairs of vertices. We will let

$$N(u) := \{v \in X : \{u, v\} \in E\}$$

denote the neighbourhood of $u \in X$, and $d_u = |N(u)|$ the degree of $u$. For convenience we assume that all vertices have positive degree.

Fix edge weights given by a symmetric matrix $W \in \mathbb{R}_{\geq 0}^{X \times X}$ such that $W_{u,v} = W_{v,u}$ for all $u, v \in X$, and $W_{u,v} > 0$ if and only if $\{u, v\} \in E$. Then $G = (X, E, W)$ defines a *weighted graph*. When no $W$ is given, the graph is *unweighted* and we let $W_{u,v} = 1$ for all $\{u, v\} \in E$. For $u \in X$, define $w_u = \sum_{v \in X} W_{u,v}$. The corresponding *(weighted) random walk* is the reversible Markov chain on $X$ with *transition matrix* $P \in \mathbb{R}_{\geq 0}^{X \times X}$ given by

$$P_{u,v} = \begin{cases} \frac{W_{u,v}}{w_u} & \text{if } \{u, v\} \in E \\ 0 & \text{otherwise} \end{cases} \qquad \forall u, v \in X. \tag{1}$$

This means that the probability of moving from the vertex $u$ along an edge to a neighbouring vertex $v$ is proportional to the edge's weight. In the unweighted case, this is called the *simple random walk*; in each step it simply moves to a neighbouring vertex chosen uniformly at random.

Let $\pi \in \mathbb{R}_{>0}^{X}$ be the distribution defined by

$$\pi(u) = \frac{w_u}{\mathcal{W}(G)} \qquad \forall u \in X,$$

where $\mathcal{W}(G) = \sum_{u \in X} w_u = \sum_{u,v \in X} W_{u,v}$. In the unweighted case, $\pi$ is proportional to the degree. The distribution $\pi$ is a *stationary* distribution of the random walk, i.e., $\pi P = \pi$ (it is a left eigenvector of $P$ with eigenvalue 1).

In fact, when the graph $G$ is connected, $\pi$ is also the *unique* stationary distribution of $P$. If in addition the graph is not bipartite, then all other eigenvalues have absolute value strictly less than one. That is, if $1 = \lambda_1 \geq \cdots \geq \lambda_n \geq -1$ are the eigenvalues of $P$ then the *(absolute) spectral gap* $\gamma_\star = \gamma_\star(G) := \min\{1 - |\lambda_j| : j = 2, \ldots, n\} = \min\{1 - \lambda_2, 1 + \lambda_n\}$ is strictly positive. Importantly, the inverse of the spectral gap bounds the random walk's *mixing time*, that is, the time required for convergence to the stationary distribution:

▶ **Theorem 3** ([21, Thm. 12.4]). *Assume $G$ is connected and not bipartite. Let $\varepsilon > 0$ and*

$$t \geq \frac{1}{\gamma_\star} \log\left(\frac{1}{\varepsilon \pi_{\min}}\right),$$

*where $\pi_{\min} = \min_{u \in X} \pi(x)$. Then $\|\sigma P^t - \pi\|_{\mathrm{TV}} \leq \varepsilon$ for any distribution $\sigma$ on $X$.*

Conversely, it is known that $t \geq (\frac{1}{\gamma_\star} - 1)\log\left(\frac{1}{2\varepsilon}\right)$ is necessary to ensure mixing from an arbitrary initial distribution [21, Thm. 12.5]. In the unweighted case, we have $\pi_{\min} \geq \frac{d_{\min}}{n\, d_{\max}} \geq \frac{1}{n^2}$, so the former shows that Theorem 3 is tight up to $\log(n)$ factors in that case.

Finally, for any $s, t \in X$ we let $\mathcal{H}_{s,t}$ denote the *hitting time* from $s$ to $t$, which is the expected number of steps needed to reach $t$ in a random walk starting from $s$. We let $\mathcal{C}_{s,t} = \mathcal{H}_{s,t} + \mathcal{H}_{t,s}$ denote the *commute time* between $s$ and $t$ – the expected number of steps needed to reach $t$ and then return to $s$ in a random walk starting from $s$. These quantities are finite if and only if $s$ and $t$ are in the same component of $G$. More generally, the commute time $\mathcal{C}_{s,M}$ from $s$ to a subset $M \subseteq X$ is the expected number of steps needed to reach any vertex in $M$ and then return to $s$ in a random walk starting from $s$.

## 2.3 Quantum walk search algorithms

Quantum walk search refers to the use of quantum walks to find certain "marked" elements on a graph. We will use quantum walk search to search for a vertex connected to $t$ in the connected component of $S$. Specifically, we will use the following special case of [4, Thm. 13].[2]

▶ **Theorem 4.** *Let $P$ be a random walk on a weighted graph with vertex set $X$, $M \subseteq X$ a subset of "marked" vertices, and $s \in X$. Let $\mathsf{C}$ be the (quantum) time complexity to check for a given $u \in X$ whether $u \in M$, let $\mathsf{U}$ be the time complexity of implementing the weighted quantum walk oracle*

$$|u\rangle|0\rangle \mapsto \sum_{v \in N(u)} \sqrt{P_{u,v}}\,|u\rangle|v\rangle\,.$$

*in space $O(\log(n))$. Let $\mathcal{C}$ be a known upper bound on the commute time $\mathcal{C}_{s,M}$ in the case where $s$ and $M$ are connected (and in particular $M \neq \emptyset$). Then there is a quantum algorithm that, if $M \neq \emptyset$ and $s$ is connected to $M$, finds an element of $M$ with probability at least $2/3$. If $M = \emptyset$ or $s$ is not connected to $M$, then the algorithm outputs a vertex not in $M$. The algorithm has time complexity $O(\sqrt{\log(\mathcal{C})}\log(n) + \sqrt{\mathcal{C}\log(\mathcal{C})\log(\log(\mathcal{C}))}(\mathsf{C}+\mathsf{U}))$ and space complexity $O(\log(n))$.*

## 2.4 Quantum RAM

Our algorithm will exploit the given space by saving sets of vertices which will be either connected to $s$ or to $t$. For our quantum algorithm to access this space, we assume access to a so-called quantum-classical random access memory or *QCRAM*. This refers to a memory that only stores classical information, but can be queried at a superposition of addresses. More specifically, an $R$-bit QCRAM stores a string of bits $q \in \{0,1\}^R$ so that the following operations are supported in time $\mathrm{polylog}(R)$:

1. *UPDATE(i, x):* store $x \in \{0,1\}$ in the $i$-th bit (i.e., set $q_i = x$).
2. *QUERY:* for any superposition $\sum_i \alpha_i |i\rangle|s_i\rangle$, it maps

$$\sum_i \alpha_i |i\rangle|s_i\rangle \mapsto \sum_i \alpha_i |i\rangle|s_i \oplus q_i\rangle\,.$$

As was first described by Kerenidis and Prakash [18], using such a QCRAM we can set up a data structure to generate quantum superpositions over elements in the QCRAM. We will use the following formulation based on [3].

[2] To see that this follows from [4, Thm. 13], note that when $|\sigma\rangle = |s\rangle$, the cost to set up $|\sigma\rangle$ is $\log(n)$ and the value $C_{\sigma,M}$ from [4] is exactly the commute time from $s$ to $M$ [4, Thm. 4].

▶ **Lemma 5.** *Fix integer parameters $\ell$ and $k$. Using an $O(k\ell\log(\ell))$-bit QCRAM, there is a data structure, $D$, that stores up to $\ell$ elements $x \in \{0,1\}^k$ with associated integer weights, $c_x$, of bounded absolute value for some poly($\ell$) bound, and supports the following operations in time $O(k \cdot \mathrm{polylog}(k\ell))$ per operation:*

1. *insertion or deletion of a pair $(x, c_x)$,*
2. *quantum queries of the form "Is $x \in D$?",*
3. *preparation of the quantum state $\frac{1}{\sqrt{\sum_{x\in D} c_x}} \sum_{x\in D} \sqrt{c_x}\,|x\rangle$.*

## 3 USTCON and the Quantum Walk model

In this section we define the undirected *st*-connectivity problem (USTCON). The input to this problem is an undirected graph $G = (X, E)$. Classically, there are various ways this input may be given, which may change the complexity of the problem. For example, in the *adjacency array model* (defined below), it is possible to randomly sample a neighbour of any vertex $u$ in $O(1)$ queries to $G$ (assuming access to the vertex degrees), facilitating a random walk on $G$, whereas if $G$ is given as an *adjacency matrix*, a random walk step is not so simple.

We will work in a quantum walk analogue of the adjacency array model. We assume that $G$ can be accessed via the *quantum walk oracle* that for every $u \in X$ outputs a uniform superposition over its neighbours:[3]

$$\mathcal{O}_W : |u\rangle\,|0\rangle \mapsto \frac{1}{\sqrt{d_u}} \sum_{v\in N(u)} |u\rangle\,|v\rangle\,. \tag{2}$$

Formally, we describe $\mathrm{USTCON}_{\mathrm{qw}}$ in terms of the input and output.

▶ **Problem 6** ($\mathrm{USTCON}_{\mathsf{qw}}$). *Given access to an undirected graph $G = (X, E)$ via the quantum walk oracle $\mathcal{O}_W$, and two vertices $s, t \in X$, decide whether $s$ and $t$ are in the same connected component of $G$.*

To compare our work with classical results on $\mathrm{USTCON}_{\mathrm{arr}}$, we describe an implementation of the quantum walk oracle defined above based on adjacency array access to a graph. Let $u \in X$ and $i \in [d_u]$. We assume that for each vertex $u$ there is a fixed numbering of its neighbours from 1 to $d_u$. In the *adjacency array model*, two types of queries are allowed:

- Degree query $\mathcal{O}_D : |0\rangle\,|u\rangle \mapsto |d_u\rangle\,|u\rangle$
- Neighbour query $\mathcal{O}_N : |u\rangle\,|i\rangle\,|0\rangle \mapsto |u\rangle\,|i\rangle\,|v_i(u)\rangle$

In the *sorted adjacency array model* we additionally assume that for every vertex $u \in X$ its neighbours are sorted: for any $i, j \in [d_u]$, if $i < j$ then $v_i(u) < v_j(u)$. In particular, this allows us to check with $O(\log(n))$ queries whether a given pair of vertices $u, v$ are adjacent. We define the USTCON-problem in this model as follows.

▶ **Problem 7** ($\mathrm{USTCON}_{\mathsf{s\text{-}arr}}$). *Given access to an undirected graph $G = (X, E)$ via the sorted adjacency array model and two vertices $s, t \in X$, decide whether $s$ and $t$ are in the same connected component of $G$.*

The question that we consider is how many sorted adjacency array queries to the graph it takes to implement the quantum walk oracle $\mathcal{O}_W$.

[3] Note that this is exactly the quantum walk oracle defined in Theorem 4, specialized to unweighted graphs.

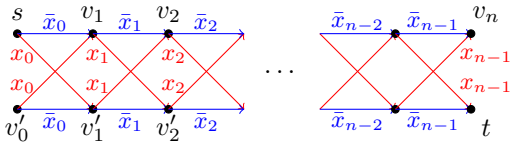

**Figure 2** The parity graph. We include an edge labelled by "$x_i$" (in red) if and only if $x_i = 1$, and an edge labelled "$\bar{x}_i$" (in blue) if and only if $x_i = 0$, meaning that for each vertex we include exactly one of the two incoming edges, and exactly one of the two outgoing edges. The resulting graph has $s$ and $t$ connected if and only if $\text{PARITY}(x) = 1$.

▶ **Lemma 8.** *The quantum walk oracle $\mathcal{O}_W$ for an unweighted graph $G$ (Equation (2)) with maximum degree $d_{\max}$ can be implemented with $O(\log(d_{\max}))$ queries in the sorted adjacency array model, and $\widetilde{O}(1)$ other elementary operations and space.*

The proof of this lemma is deferred to the appendix.

It follows that any quantum algorithm solving $\text{USTCON}_{\text{qw}}$ in $T$ time and $S = \Omega(\log(n))$ space can solve $\text{USTCON}_{\text{s-arr}}$ in $\widetilde{O}(T)$ time and $O(S)$ space.

## 4 Time- and space-optimal quantum algorithm

In Section 4.2 and Section 4.3, we give an algorithm for $\text{USTCON}_{\text{qw}}$ that is optimal in both time and space. For completeness, we first give a time lower bound in Section 4.1.

### 4.1 Lower bound

The proof of the following lower bound follows the lines of the proof of an analogous lower bound for the strong connectivity problem described in [13]. The proof is via a reduction from PARITY.

▶ **Problem 9** (PARITY). *Given oracle access to a string $x \in \{0,1\}^n$ via $\mathcal{O}_x : |i\rangle|b\rangle \mapsto |i\rangle|b \oplus x_i\rangle$, return $\bigoplus_{i=0}^{n-1} x_i$.*

▶ **Lemma 10** ([6, 15]). *The bounded error quantum query complexity of PARITY is $\Omega(n)$.*

We use Lemma 10 and a reduction from parity, using the parity graph illustrated in Figure 2, to show the following result. The detailed proof can be found in the appendix.

▶ **Theorem 11.** *The bounded error quantum query complexity of $\text{USTCON}_{\text{s-arr}}$ and $\text{USTCON}_{\text{qw}}$ is $\Omega(n)$.*

### 4.2 Metropolis-Hastings walk

In this section, we consider an unweighted simple graph $G$. The algorithm that we propose involves a quantum walk on a modified weighted version of $G$ that we call $G' = (X', E', W)$. We start by describing the construction of $G'$ that was introduced in [19, arXiv v2].

▶ **Definition 12** (Metropolis-Hastings walk). *For any graph $G = (X, E)$, the corresponding* Metropolis-Hastings walk *is the random walk on the weighted graph $G' = (X', E', W)$ defined as follows. For every $u \in X$, we include a corresponding vertex $x_u$ in $X'$. In addition, for every edge $\{u, v\} \in E$, we add a new vertex $x_{u,v}$ that splits the edge into two new edges. Formally:*

$$X' = \{x_u : u \in X\} \cup \{x_{u,v} : \{u,v\} \in E, u < v\}$$
$$E' = \{\{x_u, x_{u,v}\} : \{u,v\} \in E\}.$$

*For every edge $\{x_u, x_{u,v}\} \in E'$, we define the edge weight $W_{x_u,x_{u,v}} = \frac{1}{d_u}$. These weights define transition probabilities for the random walk on $G'$.*

The above has been called the *cautious walk* in [19, arXiv v2], while *Metropolis-Hastings-type* walks are walks in which neighbours are sampled and accepted with some probability. Our terminology is motivated by the following observation. If we start with a vertex $u \in X$ and take two steps of the walk of Definition 12, then we arrive at another vertex $v \in X$, which is either the same or a neighbour of $u$ in $G$. The walk on $G$ defined this way has the following alternative description: sample a uniformly random neighbour and accept it with probability $\frac{1/d_v}{1/d_u+1/d_v} = \frac{1}{1+d_v/d_u}$. This is precisely a random walk that falls into the Metropolis-Hastings framework, justifying our terminology. The precise choice of acceptance probabilities is sometimes called the *Glauber choice* in the literature (e.g., [20]). We note that a later version of [19] uses another choice of Metropolis-Hastings walk, but of our purposes we find it convenient to stick to the walk as defined above.

While the hitting time of a random walk between two vertices in $G$ may be as high as $O(n^3)$, in $G'$ it is at most $O(n^2)$ [19, Lemma 2 of arXiv v2]:

▶ **Lemma 13** ([19]). *Let $G = (X, E)$ be any unweighted graph, and $G'$ the corresponding (weighted) Metropolis-Hastings graph as in Definition 12. For any $u, v \in X$ connected by a path, $\mathcal{H}_{u,v}(G') \leq 18n^2$.*

In order to apply Theorem 4 to $G'$, we need to upper bound $\mathsf{U}$, the cost of implementing the weighted quantum walk oracle. For $u \in X'$ the oracle is defined as

$$U : |x\rangle |0\rangle \mapsto \sum_{y \in N(x)} \sqrt{P'_{xy}} |x\rangle |y\rangle , \quad \forall x \in X'$$

where $P'_{xy}$ is the probability of walking from $x$ to $y$ defined by the edge weights.

▶ **Lemma 14.** *The weighted quantum walk oracle $U$ for the Metropolis-Hastings walk $G'$ can be implemented with $\widetilde{O}(1)$ degree queries $\mathcal{O}_D$, $\widetilde{O}(1)$ applications of the quantum walk operator $\mathcal{O}_W$ on the graph $G$, and $\widetilde{O}(1)$ additional gates.*

*Therefore, $U$ can be implemented with $\widetilde{O}(1)$ queries to $G$ in the sorted adjacency array model, and $\widetilde{O}(1)$ additional gates.*

**Proof.** Note that the first statement implies the second one due to Lemma 8. Therefore, we will only prove the first statement. Consider the following encoding of the vertices of $G'$.

$$X' = \{(u,0) : u \in X\} \cup \{(u,v) : \{u,v\} \in E, u < v\} \subseteq X \times \big(X \cup \{0\}\big),$$

where 0 is a null symbol not contained in $X$. The first set of this union corresponds to original vertices of $G$ and the second one corresponds to the added ones.

To implement $U$ on $|x\rangle |0\rangle$, we first compute a bit in an ancilla register $A$ that is $|0\rangle_A$ if $x = (u,0)$ for some $u$, and $|1\rangle_A$ otherwise. We will condition on this value.

First, conditioned on $|0\rangle_A$, our implementation proceeds as follows, for $u \in X$:

$$|x_u\rangle |0\rangle = |u,0\rangle |0\rangle \overset{J\mathcal{O}_W}{\mapsto} \frac{1}{\sqrt{d_u}} \sum_{v \in N(u)} |u\rangle |v\rangle |u,v\rangle$$
$$\overset{J'}{\mapsto} \frac{1}{\sqrt{d_u}} \sum_{v \in N(u)} |u,0\rangle |u,v\rangle = \frac{1}{\sqrt{d_u}} \sum_{v \in N(u)} |x_u\rangle |x_{u,v}\rangle = U |x_u\rangle |0\rangle$$

where $J$ is a unitary that acts as $|u,v\rangle|0\rangle \mapsto |u,v\rangle|u,v\rangle$, and $J'$ as $|u,v\rangle|u,v\rangle \mapsto |u,0\rangle|u,v\rangle$, each of which can be implemented with $O(\log(n))$ controlled-NOT gates (since every vertex is described by $O(\log(n))$ bits).

Next, conditioned on $|1\rangle_A$, our implementation proceeds as follows, for $\{u,v\} \in E$ with $u < v$, and $|0\rangle_{A'}$ a fresh ancilla:

$$
\begin{aligned}
|0\rangle_{A'}|x_{u,v}\rangle|0\rangle &= |0\rangle_{A'}|u,v\rangle|0\rangle \\
&\overset{1}{\mapsto} \left(\sqrt{\frac{1/d_u}{1/d_u+1/d_v}}|0\rangle + \sqrt{\frac{1/d_v}{1/d_u+1/d_v}}|1\rangle\right)_{A'}|u,v\rangle|0\rangle \\
&\overset{2}{\mapsto} \sqrt{\frac{1/d_u}{1/d_u+1/d_v}}|0\rangle_{A'}|u,v\rangle|u\rangle + \sqrt{\frac{1/d_v}{1/d_u+1/d_v}}|1\rangle_{A'}|u,v\rangle|v\rangle \\
&\overset{3}{\mapsto} |0\rangle_{A'}\left(\sqrt{\frac{1/d_u}{1/d_u+1/d_v}}|u,v\rangle|u\rangle + \sqrt{\frac{1/d_v}{1/d_u+1/d_v}}|u,v\rangle|v\rangle\right) \\
&= |0\rangle_{A'}\left(\sqrt{\frac{W_{x_{u,v},x_u}}{w(x_{u,v})}}|x_{u,v}\rangle|x_u\rangle + \sqrt{\frac{W_{x_{u,v},x_v}}{w(x_{u,v})}}|x_{u,v}\rangle|x_v\rangle\right) \\
&= |0\rangle_{A'}U|x_{u,v}\rangle|0\rangle,
\end{aligned}
$$

where we use the following mappings:

**1:** Query degrees for $u$ and $v$ into a new ancilla register, perform the rotation controlled on the degrees (cf. [17]), and then uncompute the degrees ($O(1)$ degree queries to $G$).

**2:** Controlled on the first register, select one of the two vertices to copy into the last register ($O(\log(n))$ Toffoli gates).

**3:** Flip the bit in $A'$ if the second vertex of $|u,v\rangle$ is the same as the one written in the third register ($O(\log(n))$ elementary gates).

To complete the proof, note that we can uncompute the bit in ancilla $A$, because the register containing $|x\rangle$ has not been changed. ◀

## 4.3 The algorithm

We can solve $\text{USTCON}_{\text{qw}}(G)$ using Algorithm 1. This leads to our main theorem of this section.

**Algorithm 1** Quantum algorithm for $\text{USTCON}_{\text{qw}}$ with optimal time and space.

> Apply the algorithm from Theorem 4 to the Metropolis-Hastings walk $P'$ with $M = \{t\}$, using Lemma 14 to implement the quantum walk oracle for $G'$. If the algorithm returns $t$, output "connected", and otherwise output "disconnected".

▶ **Theorem 15.** *There exists a $O(\log(n))$-space quantum algorithm that decides $\text{USTCON}_{\text{qw}}$ and $\text{USTCON}_{\text{s-arr}}$ with bounded one-sided error in $\widetilde{O}(n)$ gates and queries.*

**Proof.** Let $X_s \subseteq X$ denote the connected component of $s$. If $t \in X_s$, the algorithm will output $t$ with probability at least $2/3$, in which case our algorithm will output the correct answer, "connected". If $t \notin X_s$, then the algorithm will output an element of $X_s$ with probability 1, in which case, our algorithm will output the correct answer "disconnected". This establishes correctness of Algorithm 1 with one-sided error.

To analyze the complexity, note that by Lemma 14 we have $\mathsf{U} = \widetilde{O}(1)$. For any $u \in X_s$, we can check if $u \in M$ by checking if $u = t$ in complexity $\mathsf{C} = O(\log(n)) = \widetilde{O}(1)$. To complete the analysis, we need only upper bound the commute time between $s$ and $t$ when $t \in X_s$. Since $\mathcal{C}_{s,t} = \mathcal{H}_{s,t} + \mathcal{H}_{t,s}$, by Lemma 13, we have $\mathcal{C}_{s,t} \leq 36n^2 =: \mathcal{C}$. Thus, referring to Theorem 4, the complexity of our algorithm is:

$$\widetilde{O}\left(\sqrt{\mathcal{C}\log(\mathcal{C})\log(\log(\mathcal{C}))}(\mathsf{C}+\mathsf{U})\right) = \widetilde{O}(n). \qquad \blacktriangleleft$$

## 5 Time-space tradeoff for bounded spectral gap

In this section we revisit the problem of undirected *st*-connectivity in the setting where one is given a lower bound on the spectral gap of the random walk. As discussed in Section 2.2, such a bound is tightly related to the mixing time of the walk. We will give a quantum algorithm that exhibits a nontrivial time-space tradeoff in this setting.

Our discussion will be general and apply to random walks on weighted graphs as defined in Equation (1). This is useful since the spectral gaps and mixing times of random walks on $G$ with different edge weights are in general *not* comparable. E.g., on the lollipop graph (an $n$-vertex clique connected to an $O(n)$-vertex path) the mixing time of the unweighted random walk is $\Theta(n^3)$ [10], while it is $O(n^2)$ for the Metropolis-Hastings walk.[4] On the other hand, on an $n$-vertex star graph the unweighted random walk has mixing time $O(1)$ while the Metropolis-Hastings walk has mixing time $\Theta(n)$. Thus, while the specific edge weights do not affect whether $s$ and $t$ are connected, they do impact the algorithm. Throughout this section, we assume some fixed edge weights are given, and we do not try to optimize for "good" edge weights. More specifically, we assume access to a *weighted quantum walk oracle* that for every vertex outputs a superposition of its neighbours, with squared amplitudes proportional to the edge weights:

$$\mathcal{O}_W : |u\rangle|0\rangle \mapsto \sum_{v\in N(u)} \sqrt{\frac{W_{u,v}}{w_u}}|u\rangle|v\rangle = \sum_{v\in N(u)} \sqrt{P_{u,v}}|u\rangle|v\rangle \qquad \forall u \in X$$

Moreover, we assume access to the weighted vertex degrees $w_u$ and that these degrees are of bounded absolute value for some $\mathrm{poly}(n)$ bound. This will allow us to generate the state $|\pi_{X'}\rangle$ for any subset $X' \subseteq X$ stored in QCRAM.

▶ **Problem 16** ($\textsc{ustcon}_{\mathsf{qw},\delta}$). *Given access to an undirected weighted graph via the quantum walk oracle $\mathcal{O}_W$, two vertices $s, t \in X$, and the promise that either $s$ and $t$ are disconnected or the spectral gap of the transition matrix of the walk is at least some $\delta > 0$, decide which is the case.*

Our main result of this section is the following:

▶ **Theorem 17.** *Fix $\delta \geq 0$. Let $\mathcal{G}_n$ be a family of undirected weighted graphs $G = (X, E, W)$ with $n = |X|$, such that $\gamma_\star(G) \geq \delta$ whenever $s$ and $t$ are connected. Then for any $S = \Omega(\log(n))$, there is a quantum algorithm that decides $\textsc{ustcon}_{\mathrm{qw},\delta}$ on $\mathcal{G}_n$ with bounded error in $O(S)$ space – of which $O(\log(n/\delta))$ is quantum memory, and the remainder is QCRAM – and $T = \widetilde{O}(\frac{S}{\delta}\log\left(\frac{1}{\pi_{\min}}\right) + \sqrt{\frac{n}{\delta S}})$ queries to $\mathcal{O}_W$, elementary gates, and QCRAM queries.*

[4] This follows from the $O(n^2)$ upper bound on the maximum hitting time of the Metropolis-Hastings walk (Lemma 13), and the fact that the maximum hitting time upper bounds the mixing time [21, Lemma 10.2].

Note that we can assume $\delta \geq 1/n$. If $\delta < 1/n$ then $T \approx S/\delta$. There is no time-space tradeoff, and it is always faster to run the Metropolis-Hastings algorithm (Algorithm 1).

The algorithm is stated below as Algorithm 2. It consists of three stages. We fix some parameter $p$, which denotes the number of "pebbles", or vertices the algorithm will keep track of (so $S = O(p \log(n))$). First, we run $O(p)$ classical random walks starting from $s$, each of length $\ell = O\left(\frac{1}{\delta} \log\left(\frac{n}{p\pi_{\min}}\right)\right)$. This allows us to sample a set $L$ of $O(p)$ points from $X_s$, the connected component of $s$ (the big-O notation suppresses a universal constant that is given in the proof). Since $\ell$ is at least the mixing time of $G$ (see Theorem 3), assuming $s$ and $t$ are connected, each point is sampled (approximately) from $\pi$. We do the same from $t$ to get a random subset $M \subseteq X_t$ connected to $t$.

Next, we use $L$ and $M$ to prepare (up to some error) the states $|\pi_{X_s}\rangle$ and $|\pi_{X_t}\rangle$, using *inverse quantum walk search*, which we describe in more detail in Section 5.2. If $s$ and $t$ are in the same connected component, then $|\pi_{X_s}\rangle = |\pi_{X_t}\rangle$, and otherwise, the states are orthogonal. The final step is to distinguish these two cases using a SWAP test [1, Claim 1]. This roughly follows an earlier approach in [3], the main difference being that we sample the sets $L$ and $M$ using a random walk (which allows us to exploit the gap promise), while in [3] the sets are constructed using a breadth-first search.

**Algorithm 2** Quantum algorithm for $\text{USTCON}_{\text{qw}}$ with a tradeoff.

`Seed set:` Run $O(p)$ classical random walks from $s$ and $O(p)$ classical random walks from $t$, each for $O(\frac{1}{\delta} \log\left(\frac{n}{p\pi_{\min}}\right))$ steps. Let $L$ and $M$ denote the respective sets of endpoints, without duplicates. If $L \cap M \neq \emptyset$, return "connected".[5]

`State preparation:` Run inverse quantum walk search from $|\pi_L\rangle$ and $|\pi_M\rangle$ for time $\widetilde{O}\left(\sqrt{\frac{n}{\delta p}}\right)$ to prepare $|\pi_{X_s}\rangle$ and $|\pi_{X_t}\rangle$, respectively, to precision $1/8$.

`SWAP test:` Do a SWAP test on the resulting states. If the test returns "0", return "connected", otherwise return "disconnected".

If we specialize Theorem 17 to the unweighted graph case, we get the following corollary.

▶ **Corollary 18.** *For any $S > 0$, there is a quantum algorithm that solves $\text{USTCON}_{\text{s-arr}}$ with a promise $\delta > 0$ on the random walk spectral gap using space $S$ and time $T \in \widetilde{O}(S/\delta + \sqrt{n/(\delta S)})$.*

An analogous result holds for the Metropolis-Hastings walk described in Section 4.2 given a promise on its spectral gap, since we showed that the corresponding quantum walk oracle can also be efficiently implemented.

In the remainder of this section we will analyze each stage of Algorithm 2.

## 5.1 Analysis of step 1: Seed set

Recall that the first stage results in random sets $L = \{x_1, \ldots, x_{cp}\}$ and $M = \{y_1, \ldots, y_{cp}\}$, where $x_1, \ldots, y_{cp}$ are the endpoints of independent random walks starting at $s$ or $t$, respectively, and $c > 0$ is some universal constant that we will choose later. Since we run those random walks for $O(\frac{1}{\delta} \log\left(\frac{n}{p\pi_{\min}}\right))$ steps, by Theorem 3 it follows that the $x_j$ are independent

[5] We use the following strategy to check whether $L \cap M \neq \emptyset$: Sort $L$ and $M$ and check for every element of $L$ if it is present in $M$. This takes $\widetilde{O}(p)$ time and space.

samples drawn from a distribution $\tilde{\pi}$ such that

$$\|\tilde{\pi} - \pi\|_{\mathrm{TV}} \leq \frac{p}{8n},$$

where $\pi$ is the stationary distribution on $X_s$. If $s$ and $t$ are connected then $X_s = X_t$ and the samples $y_j$ are similarly drawn from a distribution that is $p/(8n)$-close to $\pi$. Here we prove that this implies lower bounds on the stationary measure of the sets $L$ and $M$.

▶ **Proposition 19.** *There exists a universal constant $c > 0$ such that the following holds. Let $p \in [n]$ and assume $L \subseteq X$ is a random set obtained by sampling $cp$ independent elements from a distribution $\tilde{\pi}$ such that $\|\tilde{\pi} - \pi\|_{\mathrm{TV}} \leq \frac{p}{8n}$ (and removing duplicates). Then, $\mathbf{Pr}(\pi(L) \geq \frac{p}{8n}) \geq \frac{9}{10}$.*

The proof of the proposition uses the following lemma, which formalizes the intuition that adding a random element to a low-probability subset should increase the probability.

▶ **Lemma 20.** *Let $X$ be a set of cardinality $n$, $A \subseteq X$ an arbitrary fixed subset, and let $b$ be drawn at random from an arbitrary distribution $\sigma$ on $X$. Then:*

$$\mathbf{Pr}\left(\sigma(A \cup \{b\}) > \sigma(A) + \frac{1 - \sigma(A)}{2n}\right) \geq \frac{1 - \sigma(A)}{2}.$$

**Proof.** Say $b$ is *bad* if $b \in A$ or $\sigma(b) \leq \frac{1-\sigma(A)}{2n}$, and *good* otherwise. Then

$$\mathbf{Pr}\left(\sigma(A \cup \{b\}) > \sigma(A) + \frac{1 - \sigma(A)}{2n}\right) = \mathbf{Pr}(b \text{ is good}) = 1 - \mathbf{Pr}(b \text{ is bad}).$$

We can compute:

$$\begin{aligned}\mathbf{Pr}(b \text{ is bad}) &= \sigma\left(A \cup \left\{x \in X : \sigma(x) \leq \frac{1 - \sigma(A)}{2n}\right\}\right) \\ &\leq \sigma(A) + n \cdot \frac{1 - \sigma(A)}{2n} = \frac{1 + \sigma(A)}{2},\end{aligned}$$

from which the claim follows. ◀

**Proof of Proposition 19.** Let $x_1, x_2, \ldots$ denote samples drawn independently at random from $\tilde{\pi}$. For any integer $T \geq 1$, define $L_T := \{x_1, \ldots, x_T\}$ as the set consisting of the first $T$ samples (with duplicates removed), as well as $L_0 := \emptyset$. We say that the $T$-th sample is a *success* if

$$\tilde{\pi}(L_{T-1}) \geq \frac{1}{2} \quad \text{or} \quad \tilde{\pi}(L_T) \geq \tilde{\pi}(L_{T-1}) + \frac{1}{4n},$$

and a *failure* otherwise. Let $T_j$ denote the index of the $j$-th success, with $T_0 := 0$. Then, clearly,

$$\tilde{\pi}(L_{T_p}) \geq \min\left\{\frac{1}{2}, \frac{p}{4n}\right\} = \frac{p}{4n} \quad \text{and hence} \quad \pi(L_{T_p}) \geq \tilde{\pi}(L_{T_p}) - \frac{p}{8n} \geq \frac{p}{8n}.$$

On the other hand, note that by Lemma 20, the $T$-th sample is a success with probability at least $\frac{1}{4}$, even if we condition on all prior samples. In particular, the probability that there are $k$ failures in a row is at most $(\frac{3}{4})^k$. Therefore,

$$\mathbf{E}[T_j - T_{j-1}] = \sum_{k=1}^{\infty} k \,\mathbf{Pr}(T_j = T_{j-1} + k) \leq \sum_{k=1}^{\infty} k \left(\frac{3}{4}\right)^k = 12$$

and hence, by Markov's inequality,

$$\mathbf{Pr}(T_p > cp) \leq \frac{1}{cp}\,\mathbf{E}[T_p] = \frac{1}{cp}\sum_{j=1}^{p}\mathbf{E}[T_j - T_{j-1}] \leq \frac{12p}{cp} = \frac{1}{10}$$

provided we choose $c := 120$. Since the random set $L$ in the statement of the lemma is defined by taking $cp$ many samples, we obtain that

$$\mathbf{Pr}\Big(\pi(L) \geq \frac{p}{8n}\Big) \geq \mathbf{Pr}(T_p \leq cp) \geq 1 - \frac{1}{10} = \frac{9}{10}.$$ ◀

## 5.2 Analysis of step 2: State preparation

Now we turn to the analysis of the quantum walk search routine in step 2 of the algorithm. We rely on the following proposition from [3], which formalizes the idea of "inverse quantum walk search".[6]

▶ **Proposition 21** ([3, Proposition 1]). *Consider a subset $A \subseteq X$ of a (connected) graph $G$, and let $\delta$ be a lower bound on the spectral gap of a random walk $P$ on $G$ with stationary distribution $\pi$. From $|\pi_A\rangle$, we can generate a state $|\tilde{\pi}\rangle = |\pi\rangle + |\Gamma\rangle$ with $\| |\Gamma\rangle \|_2 \leq \epsilon$ using an expected number of calls to the weighted quantum walk oracle*

$$O\left(\frac{1}{\sqrt{\pi(A)\delta}}\log\left(\frac{1}{\pi(A)\epsilon}\right)\right),$$

*and $O(1/\sqrt{\pi(A)\delta})$ reflections around $|\pi_A\rangle$. The algorithm uses space logarithmic in $n$, $1/\delta$, $1/\pi(A)$ and $1/\epsilon$.*

The proposition implies the following.

▷ Claim 22. Step 2 of Algorithm 2 prepares 1/8-approximations of $|\pi_{X_s}\rangle$ and $|\pi_{X_t}\rangle$ with probability at least 9/10 in time complexity $O\left(\sqrt{\frac{n}{p\delta}}\log\left(\frac{n}{p}\right)\right)$.

## 5.3 Analysis of step 3: SWAP test

In the last step of our algorithm, we wish to decide whether $|\pi_{X_s}\rangle = |\pi_{X_t}\rangle$ or whether they are orthogonal. For this we use the SWAP test.

▷ Claim 23. Step 3 of Algorithm 2 decides whether $|\pi_{X_s}\rangle = |\pi_{X_t}\rangle$ or whether they are orthogonal with constant probability in time $\widetilde{O}(1)$.

Proof. Using a single copy of two states $|\psi\rangle$ and $|\psi'\rangle$, and $O(\log(n))$ additional gates, the SWAP test returns "0" with probability $(1 + |\langle\psi|\psi'\rangle|^2)/2$ and "1" with probability $(1 - |\langle\psi|\psi'\rangle|^2)/2$ [1, Claim 1].

By Claim 22, in step 2 we prepared states $|\tilde{\pi}_{X_s}\rangle = |\pi_{X_s}\rangle + |\Gamma_L\rangle$ and $|\tilde{\pi}_{X_t}\rangle = |\pi_{X_t}\rangle + |\Gamma_M\rangle$ such that $\| |\Gamma_L\rangle \|_2, \| |\Gamma_M\rangle \|_2 \leq 1/8$ with probability 9/10. By a triangle inequality, this implies that

$$\Big|\,|\langle\tilde{\pi}_{X_s}|\tilde{\pi}_{X_t}\rangle| - |\langle\pi_{X_s}|\pi_{X_t}\rangle|\,\Big| < 1/3,$$

and so $|\langle\tilde{\pi}_{X_s}|\tilde{\pi}_{X_t}\rangle| > 2/3$ if $s$ and $t$ are connected, but $|\langle\tilde{\pi}_{X_s}|\tilde{\pi}_{X_t}\rangle| < 1/3$ otherwise. The SWAP test distinguishes these cases with constant probability. ◁

[6] [3, Proposition 1] only proves the proposition for simple random walks, however it trivially extends to random walks on weighted graphs.

## 5.4 Proof of Theorem 17

In this section, we prove Theorem 17, which we restate here for convenience.

▶ **Theorem 17.** *Fix $\delta \geq 0$. Let $\mathcal{G}_n$ be a family of undirected weighted graphs $G = (X, E, W)$ with $n = |X|$, such that $\gamma_\star(G) \geq \delta$ whenever $s$ and $t$ are connected. Then for any $S = \Omega(\log(n))$, there is a quantum algorithm that decides $\text{USTCON}_{\text{qw},\delta}$ on $\mathcal{G}_n$ with bounded error in $O(S)$ space – of which $O(\log(n/\delta))$ is quantum memory, and the remainder is QCRAM – and $T = \widetilde{O}(\frac{S}{\delta}\log\left(\frac{1}{\pi_{\min}}\right) + \sqrt{\frac{n}{\delta S}})$ queries to $\mathcal{O}_W$, elementary gates, and QCRAM queries.*

**Proof.** We first analyze the space complexity of Algorithm 2. Step 1 is purely classical, and uses $O(p\log(n))$ space to store the $O(p)$ vertices in $L$ and $M$, with each random walk using $O(\log(n))$ space. We can implement step 2 using the algorithm referred to in Proposition 21 using $O(\log(n))$ qubits of space, but this requires that the $O(p\log(n))$ classical space used to store $L$ and $M$ in step 1 is QCRAM. Finally, step 3 just uses $O(\log(n))$ quantum space. Thus, the claimed space complexity follows if we set $S = p\log(n)$.

Next, we analyze the time complexity. Every random walk of step 1 adds $O\left(\frac{1}{\delta}\log\left(\frac{n}{p\pi_{\min}}\right)\right)$ to the time complexity. The total number of walks is $O(p)$. Checking whether $L \cap M = \emptyset$ is $O(p)$ as this is the total number of samples. Hence, the overall complexity of the first step is $\widetilde{O}\left(\frac{p}{\delta}\log\left(\frac{1}{\pi_{\min}}\right)\right)$. By Claim 22, the complexity of step 2 is $O\left(\sqrt{\frac{n}{p\delta}}\log\left(\frac{n}{p}\right)\right)$. Finally, the SWAP test in step 3 uses only $O(\log(n))$ gates, since the states being compared are $O(\log(n))$-qubit states. Hence, the total time complexity of Algorithm 2 is

$$T = \widetilde{O}\left(\frac{p}{\delta}\log\left(\frac{1}{\pi_{\min}}\right) + \sqrt{\frac{n}{\delta p}}\right) = \widetilde{O}\left(\frac{S}{\delta}\log\left(\frac{1}{\pi_{\min}}\right) + \sqrt{\frac{n}{\delta S}}\right),$$

since $S = \widetilde{O}(p)$.

Finally, for the correctness of the algorithm, by Claim 23, Algorithm 2 distinguishes between the case where $|\pi_{X_s}\rangle$ and $|\pi_{X_t}\rangle$ are equal and the case where they are orthogonal with bounded error. If $X_s = X_t$ (i.e. $s$ and $t$ are connected) then the states are equal, and if $X_s \cap X_t = \emptyset$ (i.e. $s$ and $t$ are not connected) then they are orthogonal. ◀

# A Appendix

**Proof of Lemma 8.** Assume first that there is an additional type of query allowed, namely:

$$\text{Index query: } \mathcal{O}_I : |u\rangle |v\rangle |0\rangle \mapsto |u\rangle |v\rangle |i\rangle \tag{3}$$

for $u, v \in X$ and $i \in [d_u]$ such that $v_i(u) = v$. Then $\mathcal{O}_W$ can be implemented using $\mathcal{O}_I$, $\mathcal{O}_D$, and $\mathcal{O}_N$ as follows. Let $F_d$ denote the Fourier transform over $\mathbb{Z}_d$, and let $F = \sum_{d=1}^{n} |d\rangle \langle d| \otimes F_d$, which can be implemented (to any inverse polynomial precision) in $O(\log(n))$ gates [12]. Then for any $u \in X$, we implement:

$$|0\rangle|u\rangle|0\rangle|0\rangle \overset{\mathcal{O}_D}{\mapsto} |d_u\rangle|u\rangle|0\rangle|0\rangle \overset{F}{\mapsto} \frac{1}{\sqrt{d_u}}|d_u\rangle\sum_{i=1}^{d_u}|u\rangle|i\rangle|0\rangle$$
$$\overset{\mathcal{O}_N}{\mapsto} \frac{1}{\sqrt{d_u}}|d_u\rangle\sum_{i=1}^{d_u}|u\rangle|i\rangle|v_i(u)\rangle \overset{\mathcal{O}_I^\dagger\mathcal{O}_D^\dagger}{\mapsto} \frac{1}{\sqrt{d_u}}\sum_{i=1}^{d_u}|u\rangle|v_i(u)\rangle = \mathcal{O}_W|u\rangle|0\rangle.$$

To complete the proof, note that the index query operator $\mathcal{O}_I$ only requires $O(\log(d_u))$ sorted adjacency array queries, since the neighbours are sorted and this makes it possible to perform binary search for $i$ such that $v_i(u) = v$. ◀

**Proof of Theorem 11.** We will reduce the PARITY problem to $\text{USTCON}_{\text{s-arr}}$. Since PARITY requires $\Omega(n)$ queries by Lemma 10, and the quantum walk oracle $\mathcal{O}_W$ can be implemented using $\widetilde{O}(1)$ sorted array queries by Lemma 8, this reduction will prove the statement of the theorem.

Let $x \in \{0,1\}^n$ be an input of PARITY. The corresponding output would be $\bigoplus_{i=0}^{n-1} x_i$. Given this, we need to build a $\text{USTCON}_{\text{s-arr}}$ input that can be queried with a constant number of queries to $x$. Consider an undirected graph $G = (X, E)$ defined as follows (see also Figure 2):

$$X = \{s = v_0, v_0', v_1, v_1', \ldots, v_{n-1}, v_{n-1}', v_n, t = v_n'\}$$
$$E = \{\{v_i, v_{i+1}'\}, \{v_i', v_{i+1}\} : i \in \{0,\ldots,n-1\}, x_i = 1\}$$
$$\cup \{\{v_i, v_{i+1}\}, \{v_i', v_{i+1}'\} : i \in \{0,\ldots,n-1\}, x_i = 0\}.$$

In this setting, $\bigoplus_{i=0}^{n-1} x_i = 1$ if and only if $s$ and $t$ are connected in the graph $G$.

Next, we describe how to implement queries $\mathcal{O}_D$ and $\mathcal{O}_N$ to $G$ as required by the $\text{USTCON}_{\text{s-arr}}$ problem, using queries to $\mathcal{O}_x$. Consider the following encoding of vertices of $G$. For $i \in \{0,\ldots,n\}$, we let $v_i = (i, 0)$, and $v_i' = (i, 1)$. That is, for a vertex $(i, b)$, $i \in \{0,\ldots,n\}$ encodes the "column" and $b \in \{0, 1\}$ encodes the "row". Assume that the vertices are ordered lexicographically, i.e.

$$(i, b_i) < (j, b_j) \iff i < j \text{ or } i = j, b_i < b_j.$$

Queries to $G$ are described according to this ordering.

1. Degree queries, $\mathcal{O}_D$, are trivial in this case as $d_{v_0} = d_{v_0'} = d_{v_n} = d_{v_n'} = 1$, and all other degrees are 2.
2. Since every vertex has degree at most 2, we explicitly describe neighbour queries, $\mathcal{O}_N$ for indices 1 and 2 such that the ordering assumption holds:
   - $\mathcal{O}_N : |i\rangle|b\rangle|1\rangle|0\rangle|0\rangle \mapsto |i\rangle|b\rangle|1\rangle|i-1\rangle|b\rangle \overset{\mathcal{O}_x}{\mapsto} |i\rangle|b\rangle|1\rangle|i-1\rangle|b \oplus x_{i-1}\rangle,\ \forall\, 0 < i \le n,$
   - $\mathcal{O}_N : |i\rangle|b\rangle|2\rangle|0\rangle|0\rangle \mapsto |i\rangle|b\rangle|2\rangle|i+1\rangle|b\rangle \overset{\mathcal{O}_x}{\mapsto} |i\rangle|b\rangle|2\rangle|i+1\rangle|b \oplus x_i\rangle,\ \forall\, 0 \le i < n.$

It can be seen from the formulas that queries to $G$ can be implemented with a constant number of queries to the parity input $x$. This implies the $\Omega(n)$ lower bound in $\text{USTCON}_{\text{s-arr}}$.

For $\text{USTCON}_{\text{qw}}$, note that the graph has bounded degree, and so by Lemma 8 we can simulate a query in this model using $O(1)$ queries in the sorted adjacency array model. This implies a similar $\Omega(n)$ lower bound for this model. ◀

## Abstract

We study the online graph exploration problem proposed by Kalyanasundaram and Pruhs (1994) and prove a constant competitive ratio on minor-free graphs. This result encompasses and significantly extends the graph classes that were previously known to admit a constant competitive ratio. The main ingredient of our proof is that we find a connection between the performance of the particular exploration algorithm Blocking and the existence of light spanners. Conversely, we exploit this connection to construct light spanners of bounded genus graphs. In particular, we achieve a lightness that improves on the best known upper bound for genus $g \geq 1$ and recovers the known tight bound for the planar case ($g = 0$).

## 1 Introduction

We study a classic online graph exploration problem that was first proposed by Kalyanasundaram and Pruhs in 1994 [29]. In this setting, a single agent needs to systematically traverse an initially unknown, undirected, connected graph with non-negative edge weights. Upon visiting a new vertex, the agent learns the unique identifiers of all adjacent vertices and the weights of the corresponding edges. The cost incurred when traversing an edge is simply its weight. The objective in online graph exploration is to visit all vertices of the graph and return to the starting vertex while minimizing the total cost.

The performance of a (deterministic) online algorithm Alg is measured in terms of competitive analysis. That is, given a graph $G$ and starting vertex $v$ of $G$, we compare the cost $\textsc{Alg}(G, v)$ of the traversal it produces to the cost of an offline optimum traversal $\textsc{Opt}(G)$. Note that the optimum cost corresponds to the length of a shortest TSP tour of $G$ and does not depend on $v$. We say that Alg is *(strictly) $\rho$-competitive* for a class of graphs if $\textsc{Alg}(G, v) \leq \rho \cdot \textsc{Opt}(G)$ for every graph $G$ in the class and every vertex $v$ of $G$. The *(strict) competitive ratio* of an algorithm Alg is given by $\inf\{\rho : \textsc{Alg} \text{ is } \rho\text{-competitive}\}$.

Kalyanasundaram and Pruhs [29] posed the following question: *Is there a deterministic algorithm for online graph exploration with a constant competitive ratio?* Several algorithms were proposed with a competitive ratio of $\mathcal{O}(\log(n))$ [31, 36], where $n$ is the number of vertices, but better competitive ratios are only known for restricted classes of graphs [29, 31, 33]. The best known lower bound on the competitive ratio is 10/3 [5]. In particular, the original question of Kalyanasundaram and Pruhs remains open.

We formalize a connection between the performance of the particular exploration algorithm Blocking and the existence of light spanners. Spanners were introduced in 1989 by Peleg and Schäffer [35] and have been instrumental in the development of approximation algorithms, particularly for TSP [3, 8, 9]. Here, a subgraph $H = (V, E_H)$ of a connected, undirected graph $G = (V, E)$ with edge weights $w\colon E \to \mathbb{R}_{\geq 0}$ is called a $(1+\varepsilon)$-*spanner* of $G$ if $d_H(u,v) \leq (1+\varepsilon)\, d_G(u,v)$ for all $u, v \in V$, where $d_H$ and $d_G$ denote the shortest-path distance in $H$ and $G$, respectively. Then, $H$ has *stretch* at most $(1+\varepsilon)$ and its *lightness* is $w(H)/w(\text{MST})$, where $w(H) := \sum_{e \in E_H} w(e)$ and MST denotes a minimum spanning tree of $G$.

We show that the online graph exploration algorithm Blocking has a constant competitive ratio on every class of graphs that admits spanners of constant lightness for a fixed stretch. Prominent graph classes with this property are the classes with a forbidden minor [9]. We thus, in particular, obtain a constant competitive ratio for online graph exploration on all graph classes excluding a minor. They encompass many other important classes, such as graphs of bounded genus or bounded treewidth. Overall, this result subsumes and significantly extends all previously known graph classes for which a competitive ratio of $o(\log(n))$ was known.

Regarding research for graph spanners, results typically revolve around the existence of good, in particular light, spanners. For example, the Erdős girth conjecture [19] is equivalent to a lower bound of $\Omega(n^{1/k})$ on the best lightness of a $(2k-1)$-spanner in unweighted graphs. While this conjecture remains unresolved, a nearly matching upper bound was proven by Chechik and Wulff-Nilsen [11]. Various constant upper bounds on the lightness are known for restricted classes of graphs [2, 9, 12, 24]. Our newly discovered connection to graph exploration also allows us to contribute an improved upper bound for graphs of bounded genus using the ideas given in [31].

**Our results.** We significantly expand the class of graphs on which the exploration problem admits a constant-competitive algorithm.

▶ **Theorem 1.** *For every graph $H$ and constant $\delta > 0$, there is a constant $c$ (depending on $H$ and $\delta$) such that Blocking$_\delta$ is $c$-competitive on $H$-minor-free graphs.*

The technical contribution of this work is a new-found connection between graph spanners and the performance of the exploration algorithm Blocking$_\delta$ (see Section 2.1) introduced by Megow et al. [31] based on an algorithm of Kalyanasundaram and Pruhs [29]. This connection will allow us to prove Theorem 1.

Prior to our work, the largest class of graphs which was known to admit a constant-competitive algorithm was the class of bounded genus graphs [31]. As an aside, we obtain a slightly stronger bound also for bounded genus graphs (cf. Corollary 13).

So far, Blocking$_\delta$ was only studied for constant choices of the parameter $\delta$, i.e., independent of the number of vertices $n$. It is known that its competitive ratio is at least $\Omega(n^{1/(4+\delta)})$ if $\delta$ is a constant [31]. This naturally raises the question of whether improvement is possible if $\delta$ may depend on $n$. We obtain the following results.

▶ **Theorem 2.** *Blocking$_{\log(n)}$ is $O(\log(n))$-competitive.*

This shows that Blocking$_{\log(n)}$ achieves the best previously known competitiveness. We complement this with the following lower bounds.

▶ **Theorem 3.** *The competitive ratio of Blocking$_\delta$, where $\delta = \delta(n) > 0$, is at least*

**a)** $\Omega(\log(n)/\log(\log(n)))$,

**b)** $\Omega(\log(n))$ *for* $\delta \in o(\log(n)/\log\log(n))$ *as well as for* $\delta \in \Omega(\log(n))$.

In particular, this shows that there is no $\delta$ such that BLOCKING$_\delta$ is constant-competitive, but it remains open, whether there is a choice of $\delta$ for which the algorithm is $o(\log(n))$-competitive.

Next, we exploit the connection between spanners and exploration in reverse to derive the existence of good spanners in bounded genus graphs.

▶ **Theorem 4.** *For every $\varepsilon > 0$, the greedy $(1+\varepsilon)$-spanner of a graph of genus $g$ has lightness at most $\left(1+\frac{2}{\varepsilon}\right)\left(1+\frac{2g}{1+\varepsilon}\right)$.*

Prior to our work, the best known bound was due to Grigni [24] who showed that every graph of genus $g \geq 1$ contains a $(1+\varepsilon)$-spanner of lightness $1+\frac{12g-4}{\varepsilon}$. Moreover, it is already known that planar graphs, i.e., graphs of genus 0, contain $(1+\varepsilon)$-spanners of lightness $1+\frac{2}{\varepsilon}$ and that this is best possible [2]. This means that Theorem 4 gives a tight bound in the case $g = 0$ and extrapolates this bound to graphs of larger genus.

**Related work.** Kalyanasundaram and Pruhs [29] introduced the online graph exploration problem and gave a constant-competitive algorithm for planar graphs. Megow, Mehlhorn and Schweitzer [31] revisited the algorithm, addressed some technical intricacies, and proposed their reinterpretation BLOCKING$_\delta$, which we also consider in this paper. They expanded the result by Kalyanasundaram and Pruhs and showed that the algorithm is constant-competitive on bounded genus graphs. Moreover, they suggested a new algorithm hDFS and showed that it is constant-competitive on graphs with a bounded number of different weights and $O(\log(n))$-competitive on general graphs.

Another very natural approach for exploration is the *Nearest Neighbor* algorithm, which, in each step, explores the unvisited vertex nearest to the current location. This algorithm has been studied extensively as a TSP heuristic. Rosenkrantz, Stearns and Lewis were able to show that its competitive ratio is $\Theta(\log(n))$ [36]. It turned out that the lower bound of $\Omega(\log(n))$ is already achieved on unweighted planar graphs [28] and on trees [23]. Eberle et al. [18] revisited the algorithm with learning augmentation.

In addition to planar and bounded genus graphs, the exploration problem has been studied on many more graph classes. For example, Miyazaki, Morimoto and Okabe were able to show that the competitive ratio of the exploration problem is $(1+\sqrt{3})/2$ on cycles and 2 on unweighted graphs. Other examples of such graph classes are tadpole graphs [10], unicyclic graphs [23], and cactus graphs [23].

Currently, the best known lower bound for the graph exploration problem is 10/3 which was shown by Birx, Disser, Hopp, and Karousatou [5]. Their construction builds on a previously known lower bound of 2.5 shown by Dobrev, Královič, and Markou [17]. Since the construction by Birx et al. is planar, the lower bound of 10/3 even holds when the problem is restricted to planar graphs.

Several other settings of the exploration problem have been studied, such as exploration on directed graphs [1, 13, 22, 21] or exploration with a team of agents [14, 15, 16]. Another problem which is closely related to graph exploration is online TSP, where a single agent has to serve requests appearing over time in a known graph [6, 7].

Through the connection with spanners, we are concerned with the existence of light spanners for a given stretch. Examples of graph classes where the worst-case lightness does not depend on the number of vertices include planar graphs [2], bounded genus graphs [24], apex graphs [26], bounded pathwidth graphs [25], bounded treewidth graphs [12], and minor-free graphs [9]. Our results rely on the existence of light spanners for minor-free graphs [9] and improve on the lightness for bounded genus graphs. In particular, we study the lightness of the so-called greedy spanner [2] for graphs of bounded genus. It was shown by Filtser and

Solomon [20] that this spanner construction is existentially optimal for every class of graphs closed under taking subgraphs, which means that the optimal lightness guarantee on any such class is achieved by the greedy spanner.

Light and sparse spanners have applications in various fields. Most importantly, spanners were used to give polynomial-time approximation schemes (PTAS) for the travelling salesperson problem for various graph classes [3, 8, 9]. Note that the difference between approximations for TSP and online exploration is that, in our setting, the tour is computed on-the-fly. Indeed, in comparison to our online setting, we desire a constant approximation for an arbitrary constant, which in the TSP setting is easily obtained by traversing a minimum spanning tree twice. On the other hand, in the online setting, we are not concerned with efficiency of the algorithms which is crucial in the TSP setting. Other fields of application of spanners include distributed systems [4], routing [38], or computational biology [37].

## 2 The online graph exploration problem on minor-free graphs

In this section, we prove new upper bounds for $\textsc{Blocking}_\delta$ on $H$-minor-free graphs (Theorem 1) and for general graphs (Theorem 2). To this end, we begin by introducing the algorithm $\textsc{Blocking}_\delta$ proposed by Megow et al. [31] based on the work of Kalyanasundaram and Pruhs [29].

### 2.1 The algorithm Blocking

During the execution of an online graph exploration algorithm, a vertex is *explored* if it has been visited by the agent. A neighbor of an explored vertex is a *learned* vertex. An edge is a *boundary edge* if exactly one of its endpoints is explored. By convention, we denote boundary edges $e = (u, v)$ such that $u$ is explored and $v$ is unexplored. A path is *internally explored* if each of its internal vertices is explored. Given two learned vertices $x$ and $y$, we set the distance $d(x, y)$ to be the length of a shortest internally explored path linking $x$ with $y$. In particular, the distance may decrease during execution.

▶ **Definition 5** (Kalyanasundaram and Pruhs [29]). *Given some $\delta > 0$, we say that a boundary edge $e = (u, v)$ is* $\delta$-blocked *if there is another boundary edge $e' = (u', v')$ such that $w(e') < w(e)$ and $d(u, v') \leq (1 + \delta)w(e)$.*

The rough idea of Blocking is to perform a depth-first-traversal while ignoring all blocked edges. Whenever a previously blocked edge turns unblocked, the agent moves to and explores one such edge, and initiates a DFS-traversal from its new position. Blocking is formally specified in Algorithm 1. It is executed on an undirected, weighted, connected, and initially unexplored graph $G = (V, E, w)$ and takes as input a vertex $v$ of $G$, denoting the current position of the agent. The algorithm follows a recursive DFS-like structure and the input of the initial invocation is the start vertex.

**Algorithm 1** $\textsc{Blocking}_\delta(v)$ [29, 31].

```
1 while there is a boundary edge e = (y, x) that is not δ-blocked and such that y = v
    or e was previously blocked by some edge (u, v) do
2     traverse a shortest internally explored path from v to y
3     traverse e
4     Blocking_δ(x)
5     traverse a shortest internally explored path from x to v
```

Observe that the algorithm is correct, i.e., every vertex is explored: Assume, for the sake of contradiction, that some vertex remains unexplored when the algorithm terminates, i.e., there are still boundary edges. Let $e = (u, v)$ be a boundary edge of minimum weight. Then, $e$ is not $\delta$-blocked. Therefore, either the exploration of $u$ should have triggered the exploration of $v$, or $v$ should have been explored at the last point in time the edge turned unblocked.

## 2.2 Key properties of Blocking

Throughout the remainder of Section 2, let $G = (V, E, w)$ be a graph, $n = |V|$ be its number of vertices, $v$ the given start vertex of $G$, and $\delta = \delta(n) > 0$. We analyze the performance of $\textsc{Blocking}_\delta$ on $G$, i.e., we estimate its total cost $W_{\textsc{Blocking}}(G, v, \delta)$. For this, let $B$ be the set of boundary edges taken by $\textsc{Blocking}_\delta$, i.e., the edges traversed during the execution of line 3.

Note that the total cost of the offline optimum is bounded from below by the weight of a minimum spanning tree $w(\text{MST})$ and from above by $2w(\text{MST})$. That is, to show that $\textsc{Blocking}_\delta$ is $\rho$-competitive, it suffices to show $W_{\textsc{Blocking}}(G, v, \delta) \leq \rho \cdot w(\text{MST})$.

▶ **Observation 6** (Megow et al. [31]). *We have* $W_{\textsc{Blocking}}(G, v, \delta) \leq 2(\delta + 2)w(B)$.

**Proof.** We charge all cost incurred in lines 2,3, and 5 to the corresponding boundary edge $e \in B$. Note that the cost in line 2 is at most $(1 + \delta)w(e)$, because either we have $y = v$ such that $d_G(v, y) = 0$, or $e$ was blocked by an edge $(u, v)$, which implies $d_G(y, v) \leq (1+\delta)w(e)$. The cost in line 3 is $w(e)$ and the cost in line 5 is at most the sum of the cost in lines 2 and 3. Therefore, each edge $e$ in $B$ is charged at most $2(\delta + 2)w(e)$. ◀

In our subsequent analysis, we will frequently use a minimum spanning tree with a particular property. For this, in what follows, let $\text{MST}_B$ be a minimum spanning tree of $G$ that maximizes the number of edges in $\text{MST}_B \cap B$. As pointed out in [31], cycles in $B \cup \text{MST}_B$ are long relative to the weight of the edges they contain. Specifically, the following holds.[1]

▶ **Lemma 7.** *Let $C$ be a cycle in $B \cup \text{MST}_B$ and $e$ be an edge of $C$. Then,*

$$w(C \setminus \{e\}) > (1 + \delta)w(e).$$

**Proof.** It suffices to show the assertion for an edge of maximum weight in $C$. We first show that this edge must be in $B$, i.e., $\operatorname{argmax}\{w(e) \colon e \in C\} \subseteq B$:

Assume otherwise and let $e = (u, v) \in \operatorname{argmax}\{w(e) \colon e \in C\} \cap (\text{MST}_B \setminus B)$. Removing $e$ from $\text{MST}_B$ separates $\text{MST}_B$ into two connected components. In particular, $u$ and $v$ are in different components. Start walking in $C \setminus \{e\}$ from $u$ to $v$ and let $e'$ be the first edge that leads from $u$'s connected component in $\text{MST}_B \setminus \{e\}$ to $v$'s connected component. Then, $e' \in B \setminus \text{MST}_B$ and by maximality of $e$, we have $w(e') \leq w(e)$. Therefore, replacing $e$ by $e'$ in $\text{MST}_B$ gives another spanning tree of weight at most $w(\text{MST}_B)$. This new spanning tree has one more edge in common with $B$ than $\text{MST}_B$. This contradicts the choice of $\text{MST}_B$, so that we can assume from now on $\operatorname{argmax}\{w(e) \colon e \in C\} \subseteq B$, i.e., every edge in $\operatorname{argmax}\{w(e) \colon e \in C\}$ is *charged*, i.e., the edge is traversed in some exectution of line 3 of the algorithm.

[1] The assertion of Lemma 7 implies Claim 1 in [31], which only concerns edges not in the minimum spanning tree. However, there is a subtle flaw in the proof of Claim 1 in [31]. In fact, in that proof, it is not clear that when we replace the edge $e'$ with an edge of the fixed MST, we again obtain a minimum spanning tree. In any case, the argument above rectifies this.

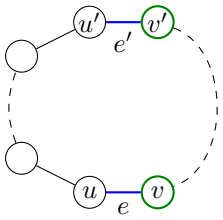

**Figure 1** Illustration of Lemma 7: The black vertices are explored and the green vertices ($v$ and $v'$) are unexplored. The blue edges ($e$ and $e'$) are boundary edges.

Let $e = (u, v)$ be the edge in $\operatorname{argmax}\{w(e) \colon e \in C\}$ that is charged last. At the time $e$ is traversed, it is a boundary edge, so that $u$ is explored but $v$ is not yet explored. Start walking in $C \setminus \{e\}$ from $u$ to $v$ and let $e' = (u', v')$ be the first edge leading from an explored vertex $u'$ to an unexplored vertex $v'$, i.e., $e'$ is another boundary edge in $C$ (cf. Figure 1).

Next, we show that $w(e') < w(e)$: Assume otherwise. By maximality of $e$, this means $w(e') = w(e)$ so that $e' \in \operatorname{argmax}\{w(e) \colon e \in C\}$. But then, we also have $e' \in B$. This contradicts the fact that $e$ is the edge in $\operatorname{argmax}\{w(e) \colon e \in C\}$ that is charged last.

Summing up, we have shown the following facts: Upon exploration of $e = (u, v)$, there is another boundary edge $e' = (u', v')$ in $C$ with $w(e') < w(e)$. Since $e$ is not blocked, this implies

$$w(C \setminus \{e\}) \geq d(u, v') > (1 + \delta)w(e). \qquad \blacktriangleleft$$

## 2.3 Connection to spanners

Next, we investigate how the performance of $\textsc{Blocking}_\delta$ is related to graph spanners. For this, note that Lemma 7 can be reformulated as follows.

▶ **Lemma 8.** *No proper subgraph of $B \cup \mathrm{MST}_B$ is a $(1 + \delta)$-spanner of $B \cup \mathrm{MST}_B$.*

The lemma relates spanners to the behavior of $\textsc{Blocking}_\delta$. However, we need to take note that the lemma applies to $B \cup \mathrm{MST}_B$ rather than the original graph $G$. A *monotone graph class* is a class of graphs $\mathcal{G}$ closed under taking subgraphs, i.e., if $G \in \mathcal{G}$ and $H$ is a subgraph of $G$, then also $H \in \mathcal{G}$. Given a graph $G$, we define $\textsc{OptSpan}_\delta(G)$ as the minimum lightness of a $(1 + \delta)$-spanner of $G$. Moreover, we set $\textsc{OptSpan}_\delta(\mathcal{G}) := \sup\{\textsc{OptSpan}_\delta(G) : G \in \mathcal{G}\}$ to be the supremum over all graphs in $\mathcal{G}$.

▶ **Theorem 9.** *For every monotone graph class $\mathcal{G}$ and every $\delta = \delta(n) > 0$, the algorithm $\textsc{Blocking}_\delta$ is $(2(\delta + 2) \cdot \textsc{OptSpan}_\delta(\mathcal{G}))$-competitive on $\mathcal{G}$.*

**Proof.** Let $G \in \mathcal{G}$. We have

$$W_{\textsc{Blocking}}(G, v, \delta) \overset{\text{Obs 6}}{\leq} 2(\delta + 2)w(B) \leq 2(\delta + 2)w(B \cup \mathrm{MST}_B). \tag{1}$$

Since $B \cup \mathrm{MST}_B$ is a subgraph of $G$, we have $B \cup \mathrm{MST}_B \in \mathcal{G}$. By Lemma 8, the only $(1 + \delta)$-spanner of $B \cup \mathrm{MST}_B$ is $B \cup \mathrm{MST}_B$ itself. Therefore,

$$w(B \cup \mathrm{MST}_B) \leq \textsc{OptSpan}_\delta(B \cup \mathrm{MST}_B) \cdot w(\mathrm{MST}_B) \leq \textsc{OptSpan}_\delta(\mathcal{G}) \cdot w(\mathrm{MST}_B). \tag{2}$$

Combined, we obtain

$$W_{\textsc{Blocking}}(G, v, \delta) \overset{(1)}{\leq} 2(\delta + 2)w(B \cup \mathrm{MST}_B) \overset{(2)}{\leq} 2(\delta + 2) \cdot \textsc{OptSpan}_\delta(\mathcal{G}) \cdot w(\mathrm{MST}_B). \qquad \blacktriangleleft$$

The theorem puts us in a position to leverage results on the lightness of spanners in order to draw conclusions regarding the competitive ratio of Blocking$_\delta$. For example, it has been shown that every planar graph contains a $(1+\delta)$-spanner of lightness at most $1+\frac{2}{\delta}$ [2]. Feeding this into Theorem 9, we conclude that Blocking$_\delta$ is $2(\delta+2)(1+2/\delta)$-competitive on planar graphs. This agrees with the bound proven in [29]. However, more generally, bounded genus graphs have light spanners. In fact, in Section 3.3, we show that every graph of genus at most $g$ contains a $(1+\delta)$-spanner of lightness at most $\left(1+\frac{2}{\delta}\right)\left(1+\frac{2g}{1+\delta}\right)$ (Theorem 4). From this, we obtain the following.

▶ **Corollary 10.** *Blocking$_\delta$ is $2(\delta+2)\left(1+\frac{2}{\delta}\right)\left(1+\frac{2g}{1+\delta}\right)$-competitive on graphs of genus at most $g$.*

Even more generally, it is known that $H$-minor-free graphs have light spanners [9]. Specifically, every $H$-minor-free graph contains a $(1+\delta)$-spanner of lightness $O\left(\frac{\sigma_H}{\delta^3}\log\left(\frac{1}{\delta}\right)\right)$ where $\sigma_H = |V(H)|\sqrt{\log|V(H)|}$. This yields a constant competitive ratio for Blocking$_\delta$ on $H$-minor-free graphs as follows.

▶ **Corollary 11.** *Blocking$_\delta$ is $2(\delta+2)\cdot O\left(\frac{\sigma_H}{\delta^3}\log\left(\frac{1}{\delta}\right)\right)$-competitive on $H$-minor-free graphs where $\sigma_H = |V(H)|\sqrt{\log|V(H)|}$.*

There are also strong bounds for general graphs. Given a graph $G$ with $n$ vertices and an integer $k \geq 1$ and $\varepsilon \in (0,1)$, $G$ contains a $(2k-1)(1+\varepsilon)$-spanner of lightness $O_\varepsilon\left(n^{1/k}\right)$ [11], where the notation $O_\varepsilon$ indicates that the constant factor hidden in the $O$-notation depends on $\varepsilon$. This gives us the following.

▶ **Corollary 12.** *Given an integer $k = k(n) \geq 1$ and $\varepsilon \in (0,1)$, Blocking$_{(2k-1)(1+\varepsilon)}$ is $2((2k-1)(1+\varepsilon)+2)\cdot O_\varepsilon\left(n^{1/k}\right)$-competitive on every graph.*

In particular, by suitably choosing $\delta$, we obtain the following.[2]

▶ **Corollary 13.**

**a)** *Blocking$_2$ is $16(1+\frac{2}{3}g)$-competitive on graphs of genus at most $g$.*

**b)** *For every constant $\delta > 0$ and every graph $H$, Blocking$_\delta$ is constant-competitive on $H$-minor-free graphs.*

**c)** *Blocking$_{\log(n)}$ is $O(\log(n))$-competitive on every graph.*

For the case of planar graphs, part a) matches the best known bounds on planar graphs [29, 31]. For general surfaces, it slightly improves on the best known bound of $16(1+2g)$ on bounded genus graphs [31]. Part b) is the first constant bound on minor-free graphs, and part c) is the first $O(\log(n))$ bound for Blocking.

## 2.4 Lower bounds for Blocking

Next, we investigate lower bounds for Blocking when $\delta$ is allowed to depend on the input size. In [31], it was shown that the competitive ratio of Blocking$_\delta$ on general graphs is at least $\Omega(n^{1/(\delta+4)})$ when $\delta$ is a constant. We begin by observing that this can be generalized to non-constant $\delta$ that are not too large.

▶ **Observation 14.** *Suppose $\delta = \delta(n) > 0$ such that $\delta^{2\delta+8} = o(n)$. Then, the competitive ratio of Blocking$_\delta$ is at least $\Omega(\delta \cdot n^{1/(\delta+4)})$.*

[2] All missing proofs are deferred to the full version.

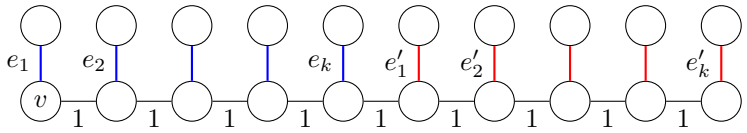

**Figure 2** Illustration of the lower bound construction for BLOCKING$_\delta$ (Lemma 15). The light edges (depicted in blue) are of weight 1 and the heavy edges (depicted in red) are of weight $\frac{k+1}{\delta+1}$.

Note that $2\delta + 8 \leq \log(n)/\log(\log(n))$ implies that

$$\delta^{2\delta+8} \leq \left(\frac{\log(n)}{\log(\log(n))}\right)^{\frac{\log(n)}{\log(\log(n))}} = \left(\frac{1}{\log(\log(n))}\right)^{\frac{\log(n)}{\log(\log(n))}} \cdot e^{\log(\log(n))\frac{\log(n)}{\log(\log(n))}}$$
$$= \left(\frac{1}{\log(\log(n))}\right)^{\frac{\log(n)}{\log(\log(n))}} \cdot n = o(n),$$

i.e., the prerequisites of Observation 14 are fulfilled. Moreover, $\Omega(\delta n^{1/(\delta+4)}) \geq \Omega(\log(n))$ for every $\delta = \delta(n)$. Therefore, Observation 14 shows that BLOCKING$_\delta$ has competitive ratio in $\Omega(\log(n))$ whenever $\delta = o(\log(n)/\log\log(n))$. In particular, this shows the first part of Theorem 3b.

Next, we give another lower bound which shows that the parameter $\delta$ cannot be chosen too large either (the second part of Theorem 3b).

▶ **Lemma 15.** *Suppose $\delta = \delta(n) \in (0, \frac{n-4}{4})$. The competitive ratio of* BLOCKING$_\delta$ *is at least $\Omega(\delta)$, even on trees.*

**Proof sketch.** It is not difficult to check that, on the graph illustrated in Figure 2, the cost of BLOCKING is asymptotically $\delta$ times the cost of the offline optimum. A complete proof can be found in the full version. ◀

To conclude our lower bound arguments for BLOCKING$_\delta$, observe that, for $\delta \geq \frac{n-4}{4}$, the behavior of BLOCKING$_\delta$ closely resembles the behavior of the algorithm hDFS [31]. In fact, it is not difficult to check that, on the lower bound construction for hDFS given in [31, Theorem 5], after proceeding to edges of weight more than 16, BLOCKING$_\delta$ takes the exact same route as hDFS, if $\delta \geq \frac{n-4}{4}$. Therefore, we obtain the following.

▶ **Observation 16.** *For $\delta \geq \frac{n-4}{4}$, the competitive ratio of* BLOCKING$_\delta$ *is at least $\Omega(\log(n))$.*

We can now combine the lower bound constructions from this section to prove Theorem 3.

**Proof of Theorem 3.** We begin with proving part b). In Observation 14, we have seen that the competitive ratio of BLOCKING$_\delta$ is at least $\Omega(\log(n))$ if $\delta \in o(\log(n)/\log\log(n))$. By Lemma 15, we obtain the same lower bound for every $\delta$ in the range from $\Omega(\log(n))$ to $(n-4)/4$, and by Observation 16, we obtain the lower bound for $\delta$ at least $(n-4)/4$. Therefore, this proves the assertion of Theorem 3b. For part a), note that part b) implies that a competitive ratio of $o(\log(n))$ is only possible for $\delta$ in the range from $\Omega(\log(n)/\log\log(n))$ to $o(\log(n))$. Using Observation 14 in this range implies the assertion of Theorem 3a. ◀

## 3 Graph spanners in bounded genus graphs

In this section, we prove Theorem 4 about the existence of light spanners in bounded genus graphs. For this, we begin by introducing the greedy spanner.

## 3.1 The greedy spanner

The *greedy* $(1+\varepsilon)$*-spanner* was suggested by Althöfer et al. [2] and is formally defined as the output of Algorithm 2. After ordering the edges by weight, it iteratively adds edges if they are short in comparison to the distance of their endpoints in the graph constructed so far.

**Algorithm 2** GreedySpanner$(G=(V,E,w),\varepsilon)$.

```
sort E = {e_1, ..., e_m} such that w(e_1) ≤ w(e_2) ≤ ··· ≤ w(e_m)
H ← (V, ∅)
for i ← 1, ..., m do
    if d_H(u_i, v_i) > (1+ε)w(e_i), where e_i = (u_i, v_i) then
        H ← H ∪ {e_i}
return H
```

Note that the resulting graph $H$ is indeed a $(1+\varepsilon)$-spanner of $G$. The output of the algorithm actually depends on the chosen order of the edges. In particular, when edge weights appear multiple times, there may be several possible outputs. However, this will not be important in our context. When we refer to *the* greedy spanner, we mean that we arbitrarily fix some output of the algorithm.

The greedy spanner fulfills the following two key properties: First, the algorithm implicitly executes Kruskal's algorithm for finding a minimum spanning tree, i.e., it adds all edges to $H$ that Kruskal's algorithm adds. With this, we obtain the following.

▶ **Observation 17.** *The greedy spanner contains all edges of some minimum spanning tree of the input graph.*

The second key property, in fact, resembles the property of Blocking$_\delta$ in Lemma 7.

▶ **Observation 18** (Althöfer et al. [2])**.** *For every cycle $C$ in the greedy spanner $H$ and every edge $e$ of $C$, we have $w(C\setminus\{e\})>(1+\varepsilon)w(e)$. In other words, no proper subgraph of $H$ is a $(1+\varepsilon)$-spanner of $H$.*

**Proof.** Let $C$ be a cycle in the greedy spanner. Let $e=(u,v)$ be the edge in $C$ that is added last. At the time it is added, we have $(1+\varepsilon)w(e)<d_H(u,v)\le w(C\setminus\{e\})$ by definition of the algorithm. Since all other edges in $C$ have lower or equal weight than $e$, the property is fulfilled for them as well. ◀

## 3.2 Spanners in planar graphs

Before investigating spanners in bounded genus graphs, we illustrate the technique for the special case of planar graphs, giving an alternate proof of the following result.

▶ **Theorem 19** (Althöfer et al. [2])**.** *For every planar graph $G$ and $\varepsilon>0$, the greedy $(1+\varepsilon)$-spanner of $G$ has lightness at most $1+\frac{2}{\varepsilon}$.*

Our proof uses similar ideas as in [31, Theorem 1] and is based on the following main idea: Fix an embedding of the greedy spanner in the plane and, in a suitable way, partition the greedy spanner into facial cycles, i.e., cycles that form the boundary of a face. Then use the fact that none of these cycles are short (cf. Observation 18).

▶ **Lemma 20.** *Let $G$ be a planar graph, $H$ be the greedy $(1+\varepsilon)$-spanner of $G$ and* MST *be a minimum spanning tree of $H$. Fix an embedding of $H$ in the plane. Then, we can associate with every edge $e \in H \setminus \text{MST}$ a facial cycle $C_e$ containing $e$, so that $C_e \neq C_{e'}$ for $e \neq e'$.*

Next, we illustrate how this can be combined with the fact that the greedy spanner does not contain short cycles (cf. Observation 18).

▶ **Lemma 21.** *Let $G$ be a graph and $H$ be the greedy $(1+\varepsilon)$-spanner of $G$. Let $D$ be a subgraph of $G$ such that we can associate with every edge $e \in H \setminus D$ a cycle $C_e$ of $H$ containing $e$, with the property that $\sum_{e \in H \setminus D} w(C_e) \leq 2w(H)$. Then, $w(H) \leq \left(1 + \frac{2}{\varepsilon}\right) w(D)$.*

Next, we show how this implies Theorem 19.

**Proof of Theorem 19.** Let $G$ be a planar graph, let $H$ be the greedy $(1+\varepsilon)$-spanner of $G$, and let MST denote a minimum spanning tree of $H$. By Observation 17, MST is also a minimum spanning tree of $G$, so that it suffices to show $w(H) \leq \left(1 + \frac{2}{\varepsilon}\right) w(\text{MST})$. Since $G$ is planar, its subgraph $H$ is planar as well. Let us fix an embedding of $H$ on the plane such that no two edges cross. By Lemma 20, there is a facial cycle $C_e$ for every edge $e \in H \setminus \text{MST}$ such that $C_e \neq C_{e'}$ for $e \neq e'$. As every edge of $H$ is contained in at most two facial cycles, we have $\sum_{e \in H \setminus \text{MST}} w(C_e) \leq 2w(H)$. Therefore, we can apply Lemma 21 with $D = \text{MST}$ and obtain $w(H) \leq \left(1 + \frac{2}{\varepsilon}\right) w(\text{MST})$. ◀

## 3.3 Generalization to bounded genus graphs

The *genus* of a graph $G$ is the smallest integer $g$ such that $G$ can be embedded on an orientable surface of genus $g$. In this subsection, we study light spanners for the class of bounded genus graphs and prove Theorem 4. We begin by recalling the theorem.

▶ **Theorem 4** (restated). *For every $\varepsilon > 0$, the greedy $(1+\varepsilon)$-spanner of a graph of genus $g$ has lightness at most $\left(1 + \frac{2}{\varepsilon}\right)\left(1 + \frac{2g}{1+\varepsilon}\right)$.*

Our proof is based on similar arguments as in [31, Theorem 2] and the main idea is roughly as follows: Given an embedding of the greedy spanner on a surface of genus $g$, first cut the surface along several edges such that we obtain a disk. Then, we can proceed along similar lines as for Theorem 19. In this work, we estimate more carefully the weight of the edges along which we cut so that we obtain a slightly improved bound than in [31]. We will use the following topological lemma for the first step.

▶ **Lemma 22.** *Let $G$ be an unweighted connected graph of genus (exactly) $g \geq 1$. Fix an embedding of $G$ on an orientable surface of genus $g$ and let $T$ be a spanning tree of $G$. Then, there is a subgraph $D$ of $G$ with $T \subseteq D$ and $|E(D) \setminus E(T)| \leq 2g$ such that, in the inherited embedding of $D$, there is only a single face and the edges in $D$ bound a topological disk.*[3]

**Proof.** It is a standard fact from topology that, on a surface of genus $g$, one can embed precisely $2g$ closed curves that are non-separating, i.e., it is possible to draw $2g$ cycles on the surface such that cutting along all of them does not disconnect the surface. Every collection of $2g$ curves that are non-separating bounds a topological disk (see Figure 3).[4]

[3] A topological disk is a surface homeomorphic to a 2-dimensional disk. Intuitively, a topological disk is a continuous deformation of a 2-dimensional disk.

[4] This can be proven as follows: The Euler characteristic of a surface of genus $g$ is $2 - 2g$ [27, Section 2.2] and cutting along a non-separating closed curve increases the Euler characteristic by 1.

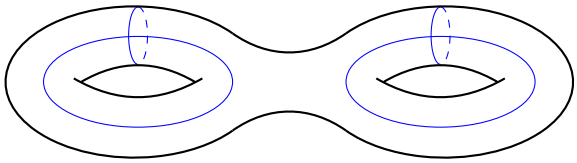

**Figure 3** surface of genus 2 with 4 non-separating cycles bounding a topological disk.

We construct the set $D$ greedily as follows (see Figure 4): Initially, let $D := T$. Ignoring all edges in $G \setminus D$, we have only a single face. Note that every edge in $G \setminus D$ closes a cycle with $D$. If we find an edge which only closes non-separating cycles, i.e, does not separate the surface into two faces, we add it to $D$. After this, the edges of $D$ still only bound a single face. We repeat this step until we cannot find further edges whose addition would separate the surface into multiple faces.

Since there are at most $2g$ cycles on a surface of genus $g$ that are non-separating, we have $|E(D) \setminus E(T)| \leq 2g$. It is left to show that $D$ bounds a disk. By maximality of $D$, every edge $e \in G \setminus D$ is separating when added to $D$, i.e., in the inherited embedding of $D \cup \{e\}$, the edge $e$ is incident to two faces. In particular, $e$ is incident to two faces in the inherited embedding of every supergraph of $D$.

Consider again the embedding of the entire graph $G$. It is known from topological graph theory that a minimal genus embedding of a connected graph is cellular, i.e., every face of the embedding of $G$ is a topological disk [39] (see [34, Proposition 3.4.1]). Since every edge $e \in G \setminus D$ is incident to two distinct faces, its removal merges the two corresponding disks along a connected part of their common boundary, which yields another disk. Iteratively removing all edges in $G \setminus D$ in this way, we thus obtain a cellular embedding of $D$. Since, by construction, $D$ induces only a single face, we obtain that $D$ bounds a topological disk.

For an illustration of the construction, consider Figure 4. In the example in the left column, the two green edges enclose non-separating cycles, whereas all blue edges close separating cycles. In the example in the right column, the half-dotted green edge in $D$ could be replaced by the blue edge between $u$ and $v$. ◀

Now, we have all the prerequisites in place to prove Theorem 4. The main idea is to give a similar construction as in Lemma 20 to partition the greedy spanner into facial cycles. Before delving into the proof, let us briefly comment on why Lemma 22 is not a reduction to the planar case, i.e., we cannot use the same construction as in Lemma 20.

Recall that the key ingredient of Lemma 20 was to define a partial order in which an edge $e'$ precedes another edge $e$ if $e'$ is embedded on the inside of the cycle that $e$ closes with MST. In the bounded genus case, if the cycle closed by $e$ is non-separating, there is no such thing as "the inside" of the cycle. For example, consider the edge $(u, v)$ in the right column of Figure 4 and the cycle it closes with MST. This cycle does not have an "inside" and cannot be decomposed into multiple faces. In particular, the cycle disappears after cutting the surface along $D$. However, it separates the disk bounded by $D$ into two parts. Therefore, we have to consider cycles that include edges of $D \setminus \text{MST}$.

**Proof of Theorem 4.** Let $G$ be some graph of genus $g$. Let $H$ be the greedy $(1 + \varepsilon)$-spanner of $G$ and let MST denote a minimum spanning tree of $H$. By Observation 17, we know that MST is also a minimum spanning tree of $G$, so that it suffices to show $w(H) \leq \left(1 + \frac{2}{\varepsilon}\right)\left(1 + \frac{2g}{1+\varepsilon}\right) w(\text{MST})$.

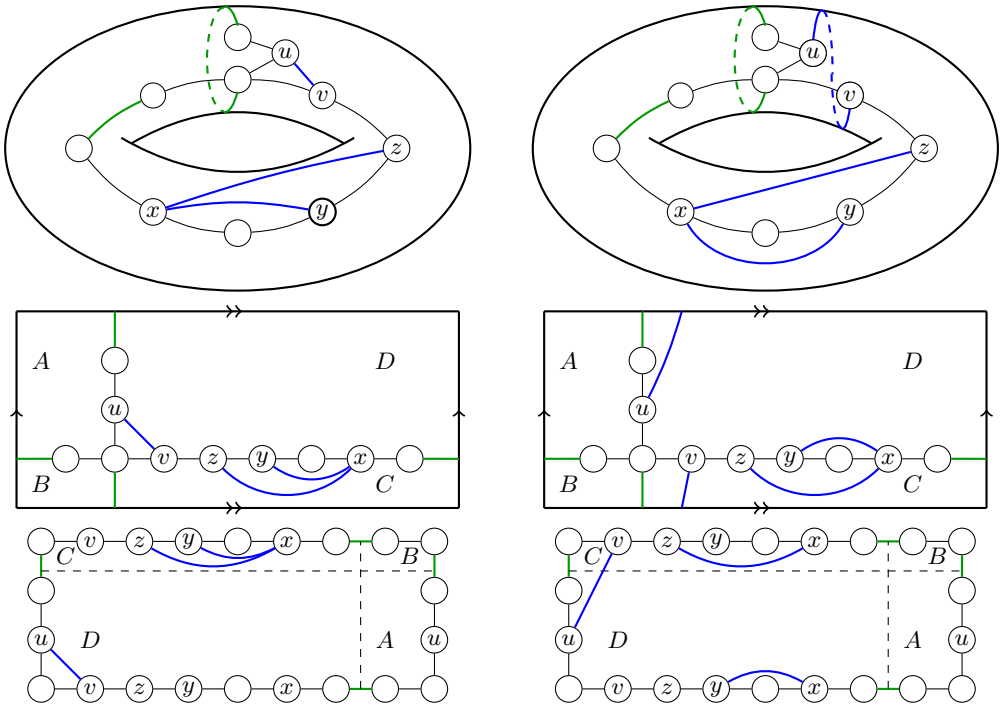

**Figure 4** The two columns show the construction of $D$ for the same graph with two different embeddings. The black edges belong to $T$, the green edges to $D \setminus T$, and the blue edges to $G \setminus D$. In each column, the first subfigure shows the embedding on the torus. The second subfigure shows a different representation: The torus is obtained by gluing together the opposite sides of the rectangle. The last subfigure shows the disk obtained by cutting the surface along $D$. Note that it contains every edge of $D$ twice and therefore, every vertex up to 4 times. However, note that the embedding specifies between which copies of the vertices the blue edges have to be drawn. The capital letters $A, B, C, D$ denote areas of the torus and are included for better orientation: Leaving area $A$ to the left leads to area $D$, leaving $A$ to the top leads to $B$ and so on.

Let $g'$ be the genus of $H$. If $g' = 0$, the assertion follows directly by Theorem 19. Therefore, we assume from now on $g' \geq 1$. Note that $g' \leq g$ because $H$ is a subgraph of $G$. Fix an embedding of $H$ on an orientable closed surface of genus $g'$ such that no two edges cross. By Lemma 22, there is a subgraph $D$ of $H$ with MST $\subseteq D$ such that

$$|E(D) \setminus E(\text{MST})| \leq 2g' \leq 2g \tag{3}$$

and such that the edges of $D$ induce only one face and bound a topological disk. Next, observe that, for every edge $e$ in $H \setminus \text{MST}$, we have $w(e) \leq w(\text{MST})/(1+\varepsilon)$: Every edge $e$ in $H \setminus \text{MST}$ closes a cycle $C$ together with the edges of MST. Using Observation 18, we obtain

$$w(e) < \frac{w(C \setminus \{e\})}{1+\varepsilon} \leq \frac{w(\text{MST})}{1+\varepsilon}.$$

In particular, this is fulfilled for edges in $D \setminus \text{MST}$. Combining this with (3), we obtain

$$w(D) \leq \left(1 + \frac{2g}{1+\varepsilon}\right) w(\text{MST}). \tag{4}$$

The next step is to bound the weight of $H$ by $(1 + 2/\varepsilon)w(D)$. For this, we use a similar construction as in Lemma 20 and show that it is possible to iteratively choose an edge $e$ in $H \setminus D$ which, together with the edges of $D$ and the edges chosen in previous iterations, closes a facial cycle $C_e$ in the embedding of $H$.

In each iteration, we find a suitable edge as follows: Pick an arbitrary edge $e$ of $H \setminus D$. If it defines a facial cycle together with $D$ and edges chosen in previous iterations, we can simply choose $e$. Assume this is not the case. Note that $e$ cuts the disk bounded by $D$ in two parts and both contain edges in $H \setminus D$ to which no cycles have been assigned yet (otherwise $e$ would close a suitable facial cycle). Pick the part whose boundary with $D$ contains fewer edges (breaking ties arbitrarily) and pick a new edge $e'$ in $H \setminus D$ which lies inside this half and has not yet been chosen in a previous iteration. Note that $e'$ again cuts the disk in two parts and the boundary of the smaller part contains fewer edges of $D$ than in the step before. Therefore, by repeating the steps above, we will end up with a suitable edge after finitely many steps. For example, on the left side of Figure 4, if we pick $e = (x, z)$, we will set $e' = (x, y)$ and this edge is suitable. After this, we can assign a facial cycle to $(x, z)$ and then to $(u, v)$. In the instance on the right, we can assign the cycles to the blue edges in any order.

Note that, in this construction, no two edges are assigned the same facial cycle. As every edge is contained in at most two facial cycles, we have

$$\sum_{e \in H \setminus D} w(C_e) \leq 2w(H). \tag{5}$$

Therefore, we can now apply Lemma 21 and obtain

$$w(H) \overset{\text{Lem 21}}{\leq} \left(1 + \frac{2}{\varepsilon}\right) w(D) \overset{(4)}{\leq} \left(1 + \frac{2}{\varepsilon}\right)\left(1 + \frac{2g}{1+\varepsilon}\right) w(\text{MST}). \qquad \blacktriangleleft$$

Recall that Grigni showed that every graph of genus $g \geq 1$ contains a $(1+\varepsilon)$-spanner of lightness at most $1 + (12g - 4)/\varepsilon$ [24]. Let us briefly comment on how our bound compares to Grigni's bound. For this, note that, for $g \geq 1$,

$$\left(1 + \frac{2}{\varepsilon}\right)\left(1 + \frac{2g}{1+\varepsilon}\right) = 1 + \frac{2}{\varepsilon} + \frac{2g}{1+\varepsilon} + \frac{4g}{\varepsilon(1+\varepsilon)} < 1 + \frac{2g}{\varepsilon} + \frac{2g}{\varepsilon} + \frac{4g}{\varepsilon} = 1 + \frac{8g}{\varepsilon}.$$

Therefore, our bound is stronger than Grigni's bound for every $g \geq 1$. Moreover, in the planar case (i.e., $g = 0$), we obtain a lightness of $1 + \frac{2}{\varepsilon}$. It was shown by Althöfer et al. [2, Theorem 5] that this is best possible, i.e., our bound is tight for planar graphs. Note that the worst-case lightness for spanners of graphs of genus $g$ has to increase in $g$, since not every graph admits a light spanner. For example, for every $k \geq 3$ and almost all $n$, there is a graph on $n$ vertices with girth at least $k$ and at least $\frac{1}{4}n^{1+\frac{1}{k}}$ edges [32, Theorem 6.6].

## 4 Open problems

The key question in online graph exploration is whether the problem admits a constant-competitive algorithm [29]. While this problem remains open, our results suggest steps that might be needed towards a resolution of this question. Firstly, we have shown that the online graph exploration problem allows for a constant-competitive algorithm on graphs admitting a light spanner, in particular, minor-free graphs. This suggests that, for proving a non-constant general lower bound on the competitive ratio, one might require dense high-girth graphs or expanders [30]. Not even a competitive ratio of $o(\log(n))$ has yet been attained, and our results eliminate $\textsc{Blocking}_\delta$, for most values of $\delta$, as a candidate for achieving this. It remains to close the gap between $\delta \in o(\log(n)/\log\log(n))$ and $\delta \in \Omega(\log(n))$.

Regarding spanners, we gave an improved upper bound on the lightness of spanners in bounded genus graphs. It is a natural question whether our bound is already tight for $g \geq 1$ or can further be improved. In particular, it is unclear whether the worst-case lightness for a fixed stretch must depend linearly on $g$.

## Abstract

We study the Online Traveling Salesperson Problem (OLTSP) with predictions. In OLTSP, a sequence of initially unknown requests arrive over time at points (locations) of a metric space. The goal is, starting from a particular point of the metric space (the origin), to serve all these requests while minimizing the total time spent. The server moves with unit speed or is "waiting" (zero speed) at some location. We consider two variants: in the open variant, the goal is achieved when the last request is served. In the closed one, the server additionally has to return to the origin. We adopt a prediction model, introduced for OLTSP on the line [24], in which the predictions correspond to the locations of the requests and extend it to more general metric spaces.

We first propose an oracle-based algorithmic framework, inspired by previous work [14]. This framework allows us to design online algorithms for general metric spaces that provide competitive ratio guarantees which, given perfect predictions, beat the best possible classical guarantee (*consistency*). Moreover, they degrade gracefully along with the increase in error (*smoothness*), but always within a constant factor of the best known competitive ratio in the classical case (*robustness*).

Having reduced the problem to designing suitable efficient oracles, we describe how to achieve this for general metric spaces as well as specific metric spaces (rings, trees and flowers), the resulting algorithms being tractable in the latter case. The consistency guarantees of our algorithms are tight in almost all cases, and their smoothness guarantees only suffer a linear dependency on the error, which we show is necessary. Finally, we provide robustness guarantees improving previous results.

## 1 Introduction

In the classical Traveling Salesperson Problem (TSP), we are given a set of locations as well as the pairwise distances between them and the objective is to find a shortest tour visiting all the locations. TSP is one of the most fundamental and well studied problems in Computer Science [31]. We focus on the online version of the problem in a metric space, the Online Traveling Salesperson Problem (OLTSP), introduced in the seminal paper of Ausiello et al. [10]. In OLTSP, the input arrives over time, i.e., new requests (locations) that have to be visited by the traveler (or server) will appear during the travel. The time in which a request is communicated to the traveler is called its release time (or release date). The objective is the minimization of the total traveled time assuming that at any time the traveler either moves at unit speed or is "waiting" (zero speed) at some location[1]. We study both the *closed* variant, where the server is required to return to the origin after serving all requests, and the *open* variant, where the server does not have to return to the origin after serving all the requests. A series of papers considered many variations of OLTSP in different metric spaces (general metric space [10, 14], the line [10, 18, 24], the semi-line [9, 14, 19], the ring [14, 28] and the star [14]).

The motivation of studying OLTSP and its variations comes from applications in many different domains, such as e.g. logistics and robotics [8, 38]. In the framework of competitive analysis, the performance of an online algorithm is usually evaluated using the competitive ratio which is defined as the maximum ratio between the cost of the online algorithm and the cost of an optimal offline algorithm, which by definition has knowledge of the entire input in advance, over all input instances. However, it is admitted that the competitive analysis approach can be overly pessimistic as it is calculated considering worst-case instances, giving a lot of power to the adversary. Hence, many papers try to limit the power of the adversary [19], or give extra knowledge and hence more power to the online algorithm [1, 14, 27].

More recently, the framework of *Learning-Augmented (LA) algorithms* has emerged due to the vibrant successes of Machine Learning methods and Artificial Intelligence in predicting and learning the unknown (i.e., future inputs in the case of online algorithms) based on data [33]. In this line of research, the goal is to utilize predictions of the future input that have potentially been acquired using a learning algorithm, in order to have provably improved competitive ratio in the case that the predictions are accurate enough, while maintaining worst-case guarantees even if the prediction error is arbitrarily large. In particular, a (possibly erroneous) prediction of the input is given to the algorithm and the goal is to design algorithms with a good performance guarantee when the prediction is accurate (consistency), a not too bad (and bounded) performance when the prediction is wrong (robustness) and a gradual deterioration of the competitive ratio with respect to the prediction error (smoothness). We give more precise definitions in Section 2.

[1] Note that this choice of possible speeds is w.l.o.g., as any setting where the maximum speed is bounded can be reduced to this setting. Specifically, if the maximum speed is some $S > 0$, we can normalize the maximum speed to be 1 and multiply all distances by $S$. Also, our setting can simulate any other setting where the algorithm is free to chose either the unit speed of some other speed $0 < s < 1$. Moving at speed $s$ is equivalent to dividing the time into intervals of length $dt \to 0$ and moving at unit speed only for time $s \cdot dt$ within each interval.

Recent works have proposed a variety of approaches to tackle OLTSP with predictions (LA-OLTSP). In [24], Gouleakis et al. studied a learning-augmented framework for OLTSP on the line. They introduced a prediction model in which the predictions correspond to the locations of the requests. They proposed LA algorithms for both the closed and the open variants that are consistent, smooth and robust. Bampis et al., in [14], considered the case of perfect predictions of the locations and studied different metric spaces (general metric space, semi-line, ring, and star) and proposed competitive online algorithms and lower bounds. In [26], Hu et al. proposed three different prediction models for OLTSP. In two of their models, each request is associated to a prediction for both its release time and its location while in the third one the prediction is just the release time of the last request. In [17], Bernardini et al. studied OLTSP with predictions of both the release time and the location of each request. They introduced a new error measure, the cover error, and they also considered other online graph problems. More recently, Chawla and Christou [20] studied the Online Time-Windows TSP with predictions of release time and location of the requests.

In this work, we adopt the prediction model of [24]. We propose a general oracle-based framework that allows us to design consistent, smooth and robust LA algorithms for both the closed and open variants of the problem for different metric spaces. We also provide some interesting lower bounds.

## 1.1 Our contributions and techniques

In this paper, we propose a novel approach to improve the competitive ratio of OLTSP using predictions concerning the locations of requests in general metric spaces. Our algorithms provide tight competitive ratio guarantees in most cases. Moreover, we show how to get polynomial-time/FPT algorithms in specific metrics, namely rings, trees and flowers.

Bampis et al. [14] gave an algorithm for general metrics with a competitive ratio of 3/2 for the case of perfect predictions (known locations), which is tight. First, in Section 3, we modify this algorithm (still under the assumption of perfect predictions) and introduce our main oracle-based 3/2-competitive framework, which we call *Strategically Wait And Go* (`SWAG`, for pseudocode see Algorithm 1). The main idea is to consider a suitable subset of permutations of the requests, referred to as *Dominating permutations*, given by a so-called *Domination oracle* instead of all the permutations. This allows for a reduction of the running time, since the bottleneck is located in the cardinality of the set of considered permutations. This restriction of the permutation set preserves the consistency of 3/2.

Then, we introduce our main algorithm, *Learning-Augmented Strategically Wait And Go* (`LA-SWAG`, for pseudocode see Algorithm 2), which does not assume perfect predictions. `LA-SWAG` is consistent, smooth, and robust. More formally, in Section 4 we show the following.

▶ **Theorem 1** (Consistency and Smoothness). *`LA-SWAG` has a competitive ratio of at most* $3/2 + 5\eta$ *for both closed and open LA-OLTSP.*

Here, $\eta$ is the error of the prediction (defined formally later) that captures the normalized sum of distances between predicted and actual locations of the requests. Note that for $\eta = 0$, we get a consistency of 3/2, which is tight for all cases except the open variant on trees.

Additionally, we show a smoothness lower bound of $3/2 + \eta/2$ for the open variant with $\eta \in [0, 1/3]$ (Proposition 14), implying that a linear dependency on $\eta$ is required.

Regarding robustness, the algorithm in [24] achieves 3-robustness on the line. `LA-SWAG` improves this bound for general metrics and further so in specific metrics.

▶ **Theorem 2** (Robustness-Closed). *`LA-SWAG` is* 2.75*-robust for closed LA-OLTSP in general metric spaces, and* 2.5*-robust in Euclidean spaces and in trees.*

▶ **Theorem 3** (Robustness-Open). *LA-SWAG is* $(3 - 1/6)$*-robust for open LA-OLTSP in general metric spaces, and* $(3 - 1/3)$*-robust in trees.*

Our analysis for 2.5-robustness and $(3 - 1/3)$-robustness is tight even on the line. Moreover, we show a negative result concerning the consistency/robustness trade-off of any algorithm for the open variant (Lemma 15).

The main technical contribution of our work is the implementation of the domination oracles we have referred to. On a high level, we say that a permutation $\pi_{dom}$ dominates another permutation $\pi$ at time $t$, if the following conditions hold. Assuming $q$ is the first unreleased request in $\pi$ at time $t$, the distance traveled up to $q$ is not longer in $\pi_{dom}$, and also a superset of the requests preceding $q$ in $\pi$ is visited before $q$. Moreover, $\pi_{dom}$ induces a not longer path than $\pi$. These two key facts allow us to preserve 3/2-consistency.

For general metrics, we achieve this domination using a very similar idea as the one employed in the definition of the $O(n^2 2^n)$ dynamic programming solution of the classical TSP [16, 25]. That is, for any possible subset of released requests that might have been served by $\pi$ before $q$, we simply build two optimal paths for the parts before and after $q$ (without release times) and then we concatenate them to get a dominating permutation. We call the resulting sets *general dominating sets*. Any permutation is dominated by the one corresponding to the correct guess of requests served up to $q$. This yields a single-exponential time algorithm overall.

▶ **Theorem 4** (General Metrics). *LA-SWAG with an oracle* $\mathcal{D}$ *which uses the general dominating sets runs in single-exponential time and is* $\min\{3/2 + 5\eta, 2.75\}$*-competitive for the closed variant and* $\min\{3/2 + 5\eta, 3 - 1/6\}$*-competitive for the open variant of LA-OLTSP.*

The overarching insight behind how we reduce the runtime in specific metrics is the fact that we do not really need to try all possible subsets of requests served before $q$. For example, in trees, we first show a structural result about the optimal solutions (with release times). Specifically, we prove that the requests placed along a path from a leaf to the origin (considered the root) can be assumed to be served in a very specific order. This is the order in which the requests are encountered as one traverses the path from the leaf to the origin. This fact allows us to design a domination oracle which, roughly, provides a single permutation for any subset of *leaves* visited before $q$. Hence, we get an FPT algorithm parameterized by the number $l$ of leaves of the tree.

▶ **Theorem 5** (Trees). *There exists a Domination oracle for LA-SWAG in trees which yields a time complexity of* $O(2^l \cdot n^3)$ *for the closed variant and* $O(2^l \cdot n^4)$ *for the open variant, where* $l$ *is the number of leaves of the input tree.*

As a first step towards more general graphs, we deal with the concept of cycles by considering the ring. While we cannot retrieve the exact same structural result about online optimal solutions, we show something quite similar. Namely, we prove that the cyclic nature of the ring may be utilized only once by an optimal solution. After such a cyclic traversal, we can assume that the ring is split in half, yielding a tree which we know how to deal with.

▶ **Theorem 6** (Ring). *There exists a Domination oracle for LA-SWAG in the ring which yields a time complexity of* $O(n^3)$ *for the closed variant and* $O(n^5)$ *for the open variant.*

Finally, we combine the two previous sets of ideas to tackle flowers. Flowers are essentially comprised of a bunch of rings (petals) and a semi-line (stem), all of which are attached to the origin. It is still true that each single ring may be assumed to be traversed with a loop only once in this case. It turns out that we can consider at most 6 options for every petal.

▶ **Theorem 7** (Flowers). *There exists a Domination oracle for* `LA-SWAG` *in flowers which yields a time complexity of* $O(6^p \cdot n^3)$ *for the closed variant and* $O(6^p \cdot n^5)$ *for the open variant, where* $p$ *is the number of petals of the input flower.*

We summarize our results in Tables 1 and 2. In the closed variant, there is a lower bound of 3/2 even in the case of a line [24]. In the open one, we show a lower bound of $\approx 1.468$ even in the case of a line and there is a lower bound of 3/2 even in the case of a ring [14]. A full version of the paper including all proofs can be found in [13].

**Table 1** Consistency, smoothness, robustness and runtime guarantees of `LA-SWAG` for different metrics and variants.

| | Smoothness (Consistency for $\eta = 0$) | Robustness | | Runtime | |
|---|---|---|---|---|---|
| | Closed/Open | Closed | Open | Closed | Open |
| Tree | $3/2 + 5\eta$ | 2.5 | $3 - 1/3$ | $O(2^l \cdot n^3)$ | $O(2^l \cdot n^4)$ |
| Ring | | 2.75 | $3 - 1/6$ | $O(n^3)$ | $O(n^5)$ |
| Flower | | 2.75 | $3 - 1/6$ | $O(6^p \cdot n^3)$ | $O(6^p \cdot n^5)$ |
| Euclidean | | 2.5 | $3 - 1/6$ | $O(n^2 \cdot 2^n)$ | $O(n^2 \cdot 2^n)$ |
| General | | 2.75 | $3 - 1/6$ | $O(n^2 \cdot 2^n)$ | $O(n^2 \cdot 2^n)$ |

**Table 2** Consistency of `LA-SWAG` and other tractable algorithms. The upper bounds with * are given by an FPT algorithm and a polytime algorithm otherwise. Tight bounds are denoted in bold.

| | Consistency | | | |

## 1.2 Further related works

The offline version of the problem, in which the locations and release times are known in advance, has been studied in [18, 38] for both closed and open variants. For OLTSP, a 2-competitive algorithm for the closed variant and a 2.5-competitive algorithm for the open variant have been proposed in general metric spaces by [10]. Specifically on the line, there exist lower bounds of 1.64 [10] and 2.04 [18] for the closed and open variants, respectively.

In addition to online TSP, there are several works that have explored learning augmented settings. The online caching problem with predictions was investigated by [33], and the initial results were improved by [3, 40, 42]. Adopting the LA approach, algorithms were developed for the ski-rental problem [2, 23, 39, 41] as well as for scheduling problems [4, 11, 35, 37]. There is also literature on learning augmented algorithms for classical data structures [30], bloom filters [34], routing problems [15, 22, 29], online selection and matching problems [5, 21] and a more general framework of online primal-dual algorithms [12]. There is a survey [36] and an updated list of papers [32] in this area.

## 2 Preliminaries

### Online TSP (OLTSP)

The input of OLTSP consists of a metric space $M$ with a distinguished point $\mathcal{O}$ (the origin), and a set $Q = \{q_1, ..., q_n\}$ of $n$ requests. Every request $q_i$ is a pair $(x_i, t_i)$, where $x_i$ is a point of $M$ and $t_i \geq 0$ is a real number. We use $t$ to quantify time. The number $t_i$ represents the moment after which the request $q_i$ can be served (release time). A server located at the origin at time $t = 0$, which can move with unit speed, must serve all the requests after their release times with the goal of minimizing the total completion time (makespan).

We consider a wide class of continuous metric spaces $M$ whose corresponding distance metric $d(x, y)$ is defined as the shortest path from $x \in M$ to $y \in M$ and is continuous in $M$, as in [10]. We call this class general metric spaces (or general metrics). The release times for continuous metric spaces can be any non-negative real number.

For the rest of the paper, we denote the total completion time of an online algorithm ALG by $|\,\mathrm{ALG}\,|$ and that of an optimal (offline) solution OPT by $|\,\mathrm{OPT}\,|$. We recall that an algorithm ALG is $\rho$-competitive if on all instances we have $|\,\mathrm{ALG}\,| \leq \rho \cdot |\,\mathrm{OPT}\,|$.

### Learning-augmented algorithms

In order to measure the quality of the predictions, we will define a prediction error $\eta$. LA algorithms have three main properties. We use the formal definitions in [24] here. We say that an algorithm is

- $\alpha$-*consistent*, if it is $\alpha$-*competitive* when $\eta = 0$,
- $\beta$-*robust*, if it is always $\beta$-*competitive* regardless of $\eta$, and
- $\gamma$-*smooth* for a continuous function $\gamma(\eta)$, if it is $\gamma(\eta)$-*competitive*.

In general, if $c$ is the best competitive ratio achievable without predictions, it is desirable to have $\alpha < c$, $\beta \leq k \cdot c$ for some constant $k$ and also the function $\gamma$ should increase from $\alpha$ to $\beta$ along with the error $\eta$.

### Our prediction setting

Let $Q = \{q_1, \ldots, q_n\}$ be the set of requests. As we mentioned, each request $q_i$ has a corresponding release time $t_i$ and a location $x_i$. We have a set of predictions $P = \{p_1, \ldots, p_n\}$ in which $p_i$ predicts $x_i$, the location of request $q_i$. The algorithm gets these predictions as well as the number of requests $n$ as an offline input. The actual values of $x_i$ and $t_i$ only become known at time-point $t_i$.

The predictions' quality can vary and is unknown to the algorithm. We can evaluate the quality by defining a measure $\eta$. Essentially, $\eta$ measures the sum of all the distance between the predicted location and the actual ones normalized by the length of a shortest path serving all the requests.

▶ **Definition 8** (Prediction Error). *The prediction error of an instance is defined by* $\eta = \frac{\sum_{i=1}^{n} d(x_i, p_i)}{F}$*, where* $F$ *is the length of a shortest path serving all the requests (and returning to the origin in the closed case).*

Note that the prediction error is scale invariant (i.e., it will not change if all the distances are multiplied by a constant factor), and $F$ acts as the normalization factor.

## 3 Oracle-based framework: the SWAG algorithm

In this section, we define an oracle-based algorithm, SWAG, designed for the case of perfect predictions. The oracle provides the algorithm with a set of permutations of the requests. We show that if the oracle satisfies some conditions, then SWAG has a competitive ratio of 3/2.

SWAG is actually a (slightly) modified version of the general algorithm in [14]. The principle of this latter algorithm is the following:

- First, to wait at $\mathcal{O}$ until a chosen time $T$. This time $T$ depends both on the requests' locations and on their release times.
- Then, to choose a route of serving requests that minimizes some criterion involving the length of the corresponding route and the fraction of it which is released at time $T$, and to follow this route, waiting at unreleased requests.

The calculation of the chosen time $T$ on the first step is done by computing some values on *all* the $n!$ permutations of the requests. The improvement we show here is that we can get the same competitive ratio (i.e., 3/2) while considering not the whole set of permutations, but some well chosen (and ideally small) subset that satisfies a certain property. This subset of permutations is given to the algorithm by the oracle.

Then, based on this framework, to derive an efficient 3/2-competitive algorithm, one only has to build an efficient oracle. We will show for example in Section 5.2 that for lines or rings, we can devise a polytime oracle building a polysize subset of permutations, leading to a polytime 3/2-competitive algorithm for these metrics.

More formally, we consider SWAG, which uses the following notation. For a given order $\sigma$ on the requests (where $\sigma[i]$ denotes the $i$-th request in the order), we denote:

- by $\ell_\sigma$ the length of the route associated to $\sigma$ (starting at $\mathcal{O}$), i.e., $\ell_\sigma = d(\mathcal{O}, \sigma[1]) + \sum_{j=1}^{n-1} d(\sigma[j], \sigma[j+1])$ in the open case, $\ell_\sigma = d(O, \sigma[1]) + \sum_{j=1}^{n-1} d(\sigma[j], \sigma[j+1]) + d(\sigma[n], \mathcal{O})$ in the closed case;
- by $\alpha_\sigma(t)$ the fraction of the length of the largest fully released prefix of the route associated to $\sigma$ at time $t$ over $\ell_\sigma$. More formally, if all $n$ requests are released, then $\alpha_\sigma(t) = 1$ for all $\sigma$, otherwise, if requests $\sigma[1], \ldots, \sigma[k-1]$ are released at $t$ but $\sigma[k]$ is not, then the route is fully released up to $\sigma[k]$, and

$$\alpha_\sigma(t) = \big(d(\mathcal{O}, \sigma[1]) + \sum_{j=1}^{k-1} d(\sigma[j], \sigma[j+1])\big)/\ell_\sigma \ .$$

  Note that this requires $\ell_\sigma > 0$. If $\ell_\sigma = 0$, i.e., all requests are at $\mathcal{O}$, we set $\alpha_\sigma = 1$.

The key idea behind these subsets is the following. To achieve the same competitive ratio, it is sufficient that for any possible permutation $\sigma$, the set $S$ contains a permutation $\sigma'$ that induces a tour/path that is not longer than that of $\sigma$, and its unreleased portion of the tour at time $t$ is not larger than that of $\sigma$. We will say that $\sigma'$ dominates $\sigma$ and define this notion formally below. Furthermore, since the released parts only change when a new request is released, it is sufficient to only update the subset then.

▶ **Definition 9** (Dominating Permutation). *Let $\sigma$ be a permutation of the $n$ requests and $t$ a given time. We define $Dom(\sigma, t)$ to be the set of permutations that dominate permutation $\sigma$ at time $t$. A permutation $\sigma' \in Dom(\sigma, t)$ if and only if:*

$$\ell_{\sigma'} \leq \ell_\sigma \quad \text{and} \quad (1 - \alpha_{\sigma'}(t))\ell_{\sigma'} \leq (1 - \alpha_\sigma(t))\ell_\sigma \ .$$

*We also say that $\sigma'$ is a corresponding dominating permutation of $\sigma$ (at time $t$).*

**Algorithm 1** Strategically Wait And Go (SWAG).

**Input:** Offline: request locations $x_1, \ldots, x_n$
Online: release times $t_1, \ldots, t_n$
Parameter: an oracle $\mathcal{D}$ which outputs a set of permutations on requests

Call the oracle $\mathcal{D}$ to get an initial set $S(0)$ of permutations at $t = 0$. Set $S = S(0)$.
**while** *true* **do**
  At each release time $t_i$, request a new set $S(t_i)$ of permutations and update $S = S(t_i)$. For every $\sigma \in S$, compute $\ell_\sigma$ and $\alpha_\sigma(t_i)$.
  If $\exists\, \sigma_0 \in S$ s.t. (1) $t \geq \ell_{\sigma_0}/2$ and (2) $\alpha_{\sigma_0}(t) \geq 1/2$, set $T = t$ and **break**.
**end**
At time $T$:
- Compute an order $\sigma_1$ which minimizes, over all orders $\sigma' \in S$, $(1 - \beta_{\sigma'})\ell_{\sigma'}$, where $\beta_{\sigma'} = \min\{\alpha_{\sigma'}(T), 1/2\}$.
- Follow the tour/path associated to $\sigma_1$. Serve the requests in this order, waiting at a request location if this request is not released.

We show that SWAG with an oracle $\mathcal{D}$ is 3/2-consistent if $\mathcal{D}$ is a *domination oracle*.

▶ **Definition 10** (Domination Oracle). *An oracle $\mathcal{D}$ which outputs at time $t$ a set $S(t)$ of permutations is a domination oracle if*

1. *$S(t) \subseteq S(t')$ for every $t \leq t'$, and*
2. *for all $t$ there exists a permutation $\sigma' \in S(t)$ such that $\sigma' \in Dom(\sigma_{\mathrm{OPT}}, t)$. Here, $\sigma_{\mathrm{OPT}}$ is the permutation corresponding to the serving order of requests in an optimal solution.*

▶ **Lemma 11.** *SWAG is 3/2-consistent for both closed and open variants of OLTSP with perfect predictions if it uses a domination oracle.*

Note that this matches the lower bounds in [24, 14], making the result tight in almost all cases. Regarding the computational complexity of SWAG, we have the following lemma.

▶ **Lemma 12.** *If $N$ is the maximum number of permutations which the oracle $\mathcal{D}$ outputs at each time $t$ and $T_{\mathcal{D}}$ is the total time required (by the oracle) to compute all permutations, then the running time of SWAG is $O(\max\{n^2 \cdot N, T_{\mathcal{D}}\})$.*

## 4 Performance guarantees for LA-OLTSP: the LA-SWAG algorithm

In this section, we deal with imperfect predictions; more specifically, we show how to adapt SWAG to also get smoothness and robustness upper bounds.

We note that if the predictions are perfect, then LA-SWAG is at least as good as SWAG (it works the same, the only difference being that it optimally serves the remaining unserved requests when everything is released). So in particular it is 3/2-consistent as well, provided that the oracle satisfies the conditions of Lemma 11, which is tight in almost all cases.

We also note that the algorithm could serve the requests in a more clever way: instead of going first to the predicted location of a request and then to its true location, the algorithm could go to the true location directly if it is released (or as soon as it is). However, no gain can be obtained; the tightness of analysis given in the full version of the paper would still hold.

Regarding the running time of LA-SWAG, it can be shown that if $T_{TSP}$ is the time required for the computation of an optimal path serving a subset of the requests, then from Lemma 12 we get the following corollary. Note that, for the cases we consider, we achieve suitable upper bounds on $T_{TSP}$. We describe how this is done in the full version of the paper.

**Algorithm 2** Learning-Augmented Strategically Wait And Go (LA-SWAG).

**Input:** Offline: predicted request locations $p_1, \ldots, p_n$
Online: release times $t_1, \ldots, t_n$, true request locations $x_1, \ldots, x_n$
Parameter: an oracle $\mathcal{D}$ which outputs a set of permutations on requests

(Breaking rule) At any time $t$: if all requests are released, follow an optimal path serving all unserved requests (returning to $\mathcal{O}$ if in the closed variant) and **break**.

Run SWAG until the starting time $T$ of the server, and the computation of $\sigma_1$.

At time $T$, follow the tour/path $\sigma_1$, serving the requests in the following order:
**for** $i = 1, \ldots, n$ **do**
- first go to $p_{\sigma_1[i]}$; if $q_{\sigma_1[i]}$ is not released, wait there until it is released;
- then, go to $x_{\sigma_1[i]}$ and serve the request.

**end**
In the closed version, go back to $\mathcal{O}$.

▶ **Corollary 13.** *If $N$ is the maximum number of permutations which the oracle $\mathcal{D}$ outputs at each time $t$, $T_{\mathcal{D}}$ is the total time required (by the oracle) to compute all permutations and $T_{TSP}$ is the time for the computation of an optimal path that serves a subset of the requests, then the running time of LA-SWAG is $O(\max\{n^2 \cdot N, T_{\mathcal{D}}, T_{TSP}\})$.*

## 4.1 Smoothness

In this subsection, we show that LA-SWAG is smooth with respect to the measure of error $\eta$. To show the main result, we relate the performance of LA-SWAG on a hypothetical instance using the predictions as requests. As noted above, LA-SWAG inherits its 3/2-consistency from SWAG. Leveraging triangle inequality, we further get upper and lower bounds on the performance of LA-SWAG in terms of the performance of LA-SWAG and OPT on the actual instance, respectively. This allows us to determine their maximum ratio.

▶ **Theorem 1** (Consistency and Smoothness). *LA-SWAG has a competitive ratio of at most $3/2 + 5\eta$ for both closed and open LA-OLTSP.*

Giving a simple example with 2 requests, we further show that a linear dependency on $\eta$ is necessary for the open variant for any algorithm.

▶ **Proposition 14** (Smoothness Lower Bound). *No algorithm can have a better competitive ratio than $\left(\frac{3}{2} + \frac{\eta}{2}\right)$ for the open variant on an instance with prediction error $\eta \in [0, 1/3]$.*

The example is built symmetrically, such that the adversary will be able to react to any choice made by an algorithm, thereby forcing it to take a detour. At the same time, OPT is able to quickly finish its route without having to wait or turn back.

## 4.2 Robustness

LA-SWAG can easily be shown to be 3-robust, as it can always go back to the origin when all requests are released and then follow an optimal tour. Since the distance to the origin is at most $|\,\mathrm{OPT}\,|$ when all requests are released, $3|\,\mathrm{OPT}\,|$ is an immediate upper bound. We first show improved upper bounds on the robustness of LA-SWAG, and then complement this analysis with some lower bounds.

The first step in the analysis is to assume LA-SWAG waits for some portion of $|\,\mathrm{OPT}\,|$ in the origin, say $c$. Then, a $(3-c)$ robustness follows. Otherwise, by construction of LA-SWAG, we get a suitable bound on the distances of predictions from the origin, depending on $c$.

For the following, we focus on the case where LA-SWAG leaves early. In the closed variant, we observe that the furthest away from the origin LA-SWAG can be when the last request is released is $3/4|\,\mathrm{OPT}\,|$, thereby improving the robustness bound to 2.75. This stems from the fact that the furthest prediction and the furthest request each cannot have a distance more than $1/2|\,\mathrm{OPT}\,|$ (corresponding to $c = 1/4$) from the origin as we consider the closed version, but LA-SWAG could be in between the two locations.

For trees or in a Euclidean space, the same argument can be used, but here it holds that any point in between the two locations cannot be further away from the origin than either of the two locations, which gives us overall a 2.5-robustness in these cases.

▶ **Theorem 2** (Robustness-Closed). *LA-SWAG is 2.75-robust for closed LA-OLTSP in general metric spaces, and 2.5-robust in Euclidean spaces and in trees.*

In the open variant, we can use a similar approach. While going back to the origin and following OPT is always a viable option when everything is released, we can also go the the final request OPT visited and then take OPT backwards to serve all requests. It turns out that these two choices are sufficient to improve the robustness below 3. We again consider general metrics first and show an improvement to $3 - 1/6$, before we again study the case of trees to show that a bigger improvement to $3 - 1/3$ is possible in this scenario.

▶ **Theorem 3** (Robustness-Open). *LA-SWAG is $(3 - 1/6)$-robust for open LA-OLTSP in general metric spaces, and $(3 - 1/3)$-robust in trees.*

We show in the full version that the analyses for 2.5-robustness in the closed variant and $(3 - 1/3)$-robustness in the open variant are tight. Moreover, we show the following consistency-robustness tradeoff for any algorithm in the open variant. For a good consistency result, the algorithm has to trust the predictions more, which will lead to a bad robustness.

▶ **Proposition 15.** *Let* ALG *be an algorithm for the open variant with consistency guarantee $2 - \lambda$, where $\lambda \in [0, 1]$. Then,* ALG *cannot be $(2 + \lambda - \epsilon)$-robust, for any $\epsilon > 0$.*

## 5 Domination oracles

In this section, we implement a domination oracle for general metrics using a Dynamic Programming inspired technique and then we exploit structural insights about specific metrics to obtain more efficient oracles. We focus on the closed variant; we explain in the full version how to deal with the open variant. In the following, $R(t)$ and $U(t)$ will refer to the released and unreleased requests at time $t$. We may drop the dependency on $t$.

### 5.1 General metrics

In the case of perfect predictions, using SWAG and Lemma 11 we can reduce the factorial running time of the algorithm in [14] for general metrics. We will show that an exponential number of permutations suffices to have a domination oracle. After that, using the scheme of LA-SWAG and the theorems proved in the previous section we will get an exponential-time algorithm that is 3/2-consistent, smooth and robust.

Consider an arbitrary permutation $\sigma$ of the $n$ requests at time $t$. A corresponding dominating tour for this permutation can be constructed in the following way; find the first unreleased request $u \in U(t)$ in the permutation $\sigma$. The released requests before $u$ in

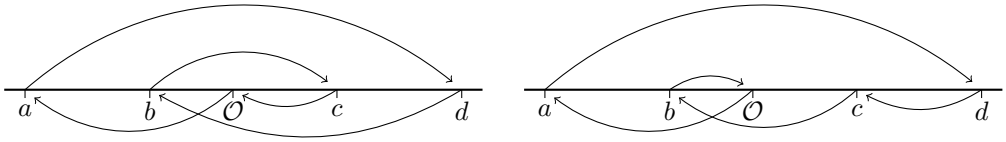

**Figure 1** Two permutations illustrating the notion of domination as in Example 16. Left side: OPT, right side: $\sigma'$.

the permutation form a subset $R'(t) \subseteq R(t)$ of released requests. Then, a corresponding general dominating tour would be the optimal TSP path that starts from the origin, serves all requests in $R'(t)$ and ends at request $u$ plus the optimal TSP path that starts from $u$, serves all requests in $\big(R(t) \setminus R'(t)\big) \cup \big(U(t) \setminus \{u\}\big)$ and returns to the origin. We will call these tours (corresponding) *general dominating tours*. It can be shown that at time $t$ a corresponding general dominating tour $\sigma'$ of a permutation $\sigma$ dominates $\sigma$. In Example 16, we illustrate the notion of a dominating tour.

▶ **Example 16.** Consider the following example on the line in the closed variant. There are 4 requests $a, b, c, d$, located at $-10, -4, 5, 11$, respectively. Assume the release times to be $t_a = 10, t_b = 46, t_c = 55, t_d = 31$. The optimal tour OPT is $\mathcal{O} \to a \to d \to b \to c \to \mathcal{O}$ with $|\operatorname{OPT}| = 60$, never having to wait and reaching requests just as they are released. Thus, we also have $\ell_{\operatorname{OPT}} = 60$.

Let us focus on the setting in which only the first request has been released, i.e., for $t \in [10, 31)$. At this time, we have $R(t) = \{a\}$ and $U(t) = \{b, c, d\}$. We can see that $d$ is the first unreleased request in permutation OPT at this time, so $u = d$, and $R' = R$. The first part of the general dominating permutation $\sigma'$ of OPT is thus $\mathcal{O} \to a \to d$, and the second part $d \to c \to b \to \mathcal{O}$. This means that $\ell_{\sigma'} = 50 < 60 = \ell_\sigma$. An illustration of OPT and $\sigma'$ is given in Figure 1.

When we run SWAG, we can see why this notion of domination makes sense: Clearly, the released lengths of OPT and $\sigma'$ are 31 for $t \in [10, 31)$ (for both permutations, the server can already serve $a$ and continue to $d$ without having to wait anywhere – but $d$ itself cannot yet be served). This also means that $\alpha_{\operatorname{OPT}} \geq 1/2$ and $\alpha_{\sigma'} \geq 1/2$. Thus, both of the permutations would start the second part of the algorithm when $t$ would be large enough. Since $\ell_{\sigma'} \leq \ell_\sigma$, it suffices to consider the permutation $\sigma'$ instead of $\sigma$, as regardless of the release time of $a$, no earlier starting time could be computed when using OPT than when using $\sigma'$. Additionally, $\beta_{\sigma'}(t) = \beta_{\operatorname{OPT}}(t) = 1/2$ and thus OPT would not be chosen as permutation to follow in the second part of the algorithm.

Note that, if $a, b$, and $d$ are released but $c$ is not at some time $t'$, then OPT would not be dominated at $t'$ by $\sigma'$. This is because the unreleased part of $\sigma'$ would be greater than that of OPT. Clearly, OPT would be dominated at time $t'$ by another permutation, e.g., $\mathcal{O} \to a \to b \to d \to c \to \mathcal{O}$. ◀

If we assume that $t_1 \leq t_2 \leq \cdots \leq t_n$ are the release times of the requests, $t_0 = 0$ and $t_{n+1} = \infty$, then at time $t_i$, with $i \leq n$, we compute the set of general dominating permutations $D_i$ given the sets $R(t_i)$ and $U(t_i)$. Together with the previously computed sets, it is then provided to SWAG as set $S(t_i) = \bigcup_{j=0}^{i} D_j$. It is easy to show that an oracle $\mathcal{D}$ which outputs at any time $t \in [t_i, t_{i+1})$ the general dominating sets $S(t) = \bigcup_{j=0}^{i} D_j$ for each $i \in \{0, 1, 2, \ldots, n\}$, is a domination oracle and SWAG is 3/2-consistent (Lemma 11). Condition 1 of the domination oracle is satisfied as $S(t) \subseteq S(t')$ for every $t \leq t'$. Condition 2 is also satisfied since for each time $t$ we have a corresponding dominating permutation for every possible subset of $R(t)$ and choice of $u$, and thus for every permutation $\sigma$.

Concerning the running time of the algorithm, we begin by bounding the number of general dominating permutations which are contained in the set $\bigcup_{j=0}^{i} D_j$ for all $i \leq n$. Formally, we prove the following lemma.

▶ **Lemma 17.** *There always exists a set $\bigcup_{j=0}^{i} D_j$ which consists of at most $2^n$ distinct general dominating permutations, for all $i \in \{0, 1, \ldots, n\}$.*

In order to get an LA algorithm, we run `LA-SWAG` with the oracle of general dominating permutations. Since all possible general dominating permutations can be precomputed at $t = 0$ using the dynamic programming algorithm for classical TSP in time $O(n^2 \cdot 2^n)$, we use Corollary 13 and Lemma 17 to show the following result for the running time of `LA-SWAG`.

▶ **Lemma 18.** *`LA-SWAG` that uses the general dominating sets runs in $O(n^2 \cdot 2^n)$ time complexity for both closed and open variants of OLTSP.*

Using theorems 1, 2, and 3 we show that `LA-SWAG` with the general dominating permutations is a single-exponential time algorithm with the following performance guarantees.

▶ **Theorem 4** (General Metrics). *`LA-SWAG` with an oracle $\mathcal{D}$ which uses the general dominating sets runs in single-exponential time and is $\min\{3/2 + 5\eta, 2.75\}$-competitive for the closed variant and $\min\{3/2 + 5\eta, 3 - 1/6\}$-competitive for the open variant of LA-OLTSP.*

## 5.2 Specific metrics

In the following we explain how to implement domination oracles for trees, rings, and flowers. These will dominate a so-called *sensible* set of permutations, which we define later.

We also need to implement the "cleanup" step of `LA-SWAG`, where a computation of an optimal classical (offline, without release times) TSP path/tour is required. In fact, these subroutines are also employed within the domination oracles themselves. We describe how this is done efficiently (in $O(n)$ time) in the full version of the paper.

▶ **Definition 19** (Safe Set). *Let $X$ be a set of request locations. A set of permutations $\Pi$ is safe for $X$ if for any assignment $f$ of release times to each location in $X$, there exists a permutation $\pi \in \Pi$ which is optimal for the resulting input $Q = \{(x, f(x)) \mid x \in X\}$.*

Note that the set of all permutations is safe. However, we can define *sensible* sets of permutations that follow some desirable structure but are still safe. The guarantees of `LA-SWAG` follow even when dominating a sensible set.

In general, the idea is to ensure domination as follows. Let $Q_1$ be the requests served by a permutation $\pi$ before its current request $q$. We construct a permutation $\pi_{dom}$, which serves a superset of $Q_1$ before $q$ and is not longer than $\pi$ on both parts, before and after $q$.

### Trees

We consider metric spaces that are shaped like a tree. By that we mean continuous spaces that can be embedded into trees with edges weighted by their lengths. The requests may appear on nodes of the tree or at some point along the edges.

Suppose that an algorithm serves a request $q$ at time $t$. There is only one path $\mathcal{P}_q$ from $q$ to $\mathcal{O}$, and it must be traversed after $t$. Hence, any request $q'$ on $\mathcal{P}_q$ will be visited at some point after $t$ anyway, rendering the earlier serving of such requests useless. From this, it follows that any sequence of requests $S_q$ encountered along a path $\mathcal{P}_q$ towards the origin may be safely assumed to be a subsequence of the optimal permutation.

▶ **Definition 20** (Sensible Set for Trees). *Let $\mathcal{T}$ be a tree rooted at the origin $\mathcal{O}$ and $X$ a set of request locations on $\mathcal{T}$. The set $\Pi_s(\mathcal{T}, X)$ of sensible permutations consists of all permutations $\pi$ where the following holds. Let $\pi = x_{\pi(1)}, x_{\pi(2)}, \ldots, x_{\pi(n)}$. For any $x_{\pi(i)}$ and any $x_{\pi(j)}$ on the path $\mathcal{P}_{x_{\pi(i)}}$ from $x_{\pi(i)}$ to the origin, we have $j > i$.*

▷ Claim 21. For any tree $\mathcal{T}$ and any set of request locations $X$, the set $\Pi_s(\mathcal{T}, X)$ is safe.

### Dominating set

For the above sensible set, we will define a dominating set whose cardinality is of order $O(2^l \cdot n)$, where $l$ is the number of leaves of the underlying tree. The idea is to look at subsets of paths of leaves to the origin. That is, for each such subset and each selection of intermediate request $q$, we consider the permutation which first optimally visits the selected leaves finishing at $q$ and then "cleans up" the rest of the requests starting from $q$ and ending at the origin. The set of these permutations for all different choices of leaf subsets and current request is called $Dom^{\curlyvee}(R, U, \mathcal{T}, L)$, where $\mathcal{T}$ is the input tree and $L$ is its set of leaves.

▶ **Lemma 22** (Tree Domination). *Let $\pi$ be a sensible permutation for a tree $\mathcal{T}$ and $L$ be its set of leaves. Then, $\exists\, \pi_{dom} \in Dom^{\curlyvee}(R, U, \mathcal{T}, L)$ dominating $\pi$.*

Using the above lemma, we obtain our main theorem for trees.

▶ **Theorem 5** (Trees). *There exists a Domination oracle for* `LA-SWAG` *in trees which yields a time complexity of $O(2^l \cdot n^3)$ for the closed variant and $O(2^l \cdot n^4)$ for the open variant, where $l$ is the number of leaves of the input tree.*

## Ring

If a permutation makes more than one "full" loops around the ring, it may as well keep only the last. Moreover, no serving needs to be done before the loop. After such a loop, we can assume that the permutation moves along the ring as if it were a line, i.e., it never crosses the antipodal point of the origin. Hence, we can define the sensible permutations by branching on whether a loop is performed and then reduce to the tree case.

▶ **Definition 23** (Sensible Set for the Ring). *Let $X$ be a set of request locations on the ring. The sensible set of permutations $\Pi_s^{\circ}(X)$ consists of all permutations $\pi$ resulting from the concatenation of $\pi_{loop}$ and $\pi_{line}$ where $\pi_{loop}$ is a subpermutation covering $X' \subseteq X$ in a cyclic fashion and $\pi_{line} \in \Pi_s(T, X \setminus X')$, where $T$ is the tree resulting from splitting the ring at the midpoint across from the origin.*

▷ Claim 24. For any set of request locations $X$, the set $\Pi_s^{\circ}(X)$ is safe.

### Dominating set

It suffices to define the dominators under the assumption that $\pi$ does indeed have a loop in the beginning, since we can take the union with the tree dominators.

A crucial distinction is whether the current request $q$ of $\pi$ is part of the loop or not. In the first case, $\pi$ has only traveled a portion of the loop so far and in the second case it has traveled a full loop and serves as if on a tree afterwards. For every choice of $q$, we define two permutations, one pertaining to the first case and another to the second one.

The first permutation serves all released requests within $\pi$'s traveled portion of the loop and then moves to $q$. The second permutation serves all released requests with a full loop and then moves to $q$. Both finish by cleaning up the rest of the requests. We call the resulting set of permutations $Dom^{\circ}(R, U)$.

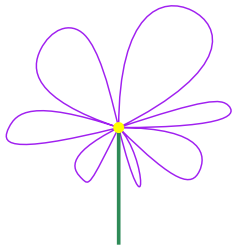

**Figure 2** A flower with 7 petals (purple), connected with the stem (green) at the origin (yellow).

▶ **Lemma 25** (Ring Domination). *Let $\pi$ be a sensible permutation whose tour contains a full loop in the beginning. $Dom^{\circ}(R, U)$ contains a permutation $\pi_{dom}$ which dominates $\pi$.*

Thus, our main theorem for the ring follows.

▶ **Theorem 6** (Ring). *There exists a Domination oracle for* `LA-SWAG` *in the ring which yields a time complexity of $O(n^3)$ for the closed variant and $O(n^5)$ for the open variant.*

## Flowers

We extend the reasoning used for the ring and trees to the so-called flowers. A flower consists of a number of rings (petals), all of which are attached to the origin point (receptacle). For reasons of artistic completion, a semi-line (stem) disjoint from the petals is also attached to the origin point. An illustration is given in Figure 2.

### Sensible set

We can assume that any sensible permutation traverses a petal of the flower in a cyclic fashion at most once, for the same reason that this is true for the ring. Thus, the sensible set here is defined to include the permutations which have at most one loop for each petal, such loops are the first visit on the corresponding petal and the restrictions of the sensible set on trees also apply to every petal after such a loop is carried out.

### Dominating set

First, choose the current request $q$ of the permutation $\pi$ to be dominated. Then, we guess the subset $\mathcal{P}$ of petals "looped" by $\pi$. We also guess the petals $\mathcal{P}_{done} \subseteq \mathcal{P}$ already looped before $q$. For a set of such choices, we traverse all petals in $\mathcal{P}_{done}$ in an arbitrary order. Next, we "snip" every petal except the ones in $\mathcal{P}$, yielding a tree $\mathcal{T}$ (actually, a star) and the petals in $\mathcal{P}$.

Now, we also guess the subset $L'$ of the leaves $L$ of $\mathcal{T}$ to be visited before $q$. Having fixed that, we append to our permutation the optimal path from $\mathcal{O}$ to $q$ that visits every leaf in $L'$ and the possible arc of $\pi$ to $q$. Finally, we append the optimal path from $q$ that "cleans up" the remaining unserved requests. The resulting set is called $Dom^{✿}(R, U)$.

▶ **Lemma 26** (Flower Domination). *Let $\pi$ be a sensible permutation for the flower. The set $Dom^{✿}(R, U)$ contains a permutation $\pi_{dom}$ which dominates $\pi$.*

Note that to make all these different guesses, one has at most 6 choices for every petal. So, if the graph has $p$ petals, the cardinality of the dominators is $O(6^p \cdot n) = O(2^{2.59p} \cdot n)$. The below complexity comes from the term related to the cardinality of the dominating set.

▶ **Theorem 7** (Flowers). *There exists a Domination oracle for* `LA-SWAG` *in flowers which yields a time complexity of* $O(6^p \cdot n^3)$ *for the closed variant and* $O(6^p \cdot n^5)$ *for the open variant, where* $p$ *is the number of petals of the input flower.*

## 6 Conclusion

We studied Online TSP augmented with predictions regarding the locations of the requests. Our algorithm, `LA-SWAG`, achieves a competitive ratio of 3/2 under the assumption of perfect predictions, which is tight in most cases we considered. Additionally, it is smooth and provides robustness guarantees below 3, improving over previous work. The runtime of `LA-SWAG` is single-exponential; however, we show how to remove the exponential dependency on the number of requests for specific metric spaces.

We believe that our techniques can be generalized to obtain FPT algorithms for other classes of graphs also; cactus graphs, graphs of bounded treewidth in general, as well as planar graphs are interesting options. Additionally, extending the algorithm to the Dial-A-Ride Problem seems like a reasonable direction to follow.

Another interesting direction is to leverage the ideas behind the PTAS for classical TSP on the Euclidean plane [6, 7] (or any other space which admits an approximation scheme for that matter) to obtain consistency guarantees which approach 3/2 arbitrarily close as the computational time is allowed to increase. Note that, since our smoothness proof follows from consistency itself and robustness from solving a classical TSP instance, these results would automatically extend, modulo some worsening of the bounds as a function of the approximation quality. For this, one possible approach is to extend the notion of a sensible set to that of $\epsilon$-sensible, meaning that a $(1+\epsilon)$-approximation of the optimal Online TSP solution is guaranteed to exist within the set. A similar relaxation would also make sense for the idea of dominating sets.

## Abstract

In the Vertex Connectivity Survivable Network Design (VC-SNDP) problem, the input is a graph $G$ and a function $d : V(G) \times V(G) \to \mathbb{N}$ that encodes the vertex-connectivity demands between pairs of vertices. The objective is to find the smallest subgraph $H$ of $G$ that satisfies all these demands. It is a well-studied NP-complete problem that generalizes several network design problems. We consider the case of *uniform demands*, where for every vertex pair $(u, v)$ the connectivity demand $d(u, v)$ is a fixed integer $\kappa$. It is an important problem with wide applications.

We study this problem in the realm of Parameterized Complexity. In this setting, in addition to $G$ and $d$ we are given an integer $\ell$ as the *parameter* and the objective is to determine if we can remove at least $\ell$ edges from $G$ without violating any connectivity constraints. This was posed as an open problem by Bang-Jansen et.al. [SODA 2018], who studied the edge-connectivity variant of the problem under the same settings. Using a powerful classification result of Lokshtanov et al. [ICALP 2018], Gutin et al. [JCSS 2019] recently showed that this problem admits a (non-uniform) FPT algorithm where the running time was unspecified. Further they also gave an (uniform) FPT algorithm for the case of $\kappa = 2$. In this paper we present a (uniform) FPT algorithm any $\kappa$ that runs in time $2^{O(\kappa^2 \ell^4 \log \ell)} \cdot |V(G)|^{O(1)}$.

Our algorithm is built upon new insights on vertex connectivity in graphs. Our main conceptual contribution is a novel graph decomposition called the *Wheel decomposition*. Informally, it is a partition of the edge set of a graph $G$, $E(G) = X_1 \cup X_2 \ldots \cup X_r$, with the parts arranged in a cyclic order, such that each vertex $v \in V(G)$ either has edges in at most two consecutive parts, or has edges in every part of this partition. The first kind of vertices can be thought of as the rim of the wheel, while the second kind form the hub. Additionally, the vertex cuts induced by these edge-sets in $G$ have highly symmetric properties. Our main technical result, informally speaking, establishes that "nearly edge-minimal" $\kappa$-vertex connected graphs admit a wheel decomposition – a fact that can be exploited for designing algorithms. We believe that this decomposition is of independent interest and it could be a useful tool in resolving other open problems.

## 1 Introduction

One of the most important challenges in designing real world networks is to ensure their reliability in the face of damages and equipment failures. A natural solution is to build additional redundancy in the network, at lowest possible costs, to guarantee connectivity up to a certain number of failures. This motivates the study of *network design problems*, and they are well studied in combinatorial optimization and algorithm design. The problem is abstractly described using graphs, where vertices naturally represent the nodes of the network, the edges represent the connections between the nodes and each edge has an associated cost. In many applications, the objective is to find a minimum cost subgraph that connects all the nodes and is also able to withstand a certain number of failures of vertices or edges. We refer to the surveys [14, 19, 22] for details.

Formally, in the case of vertex failures this problem is called Minimum $\kappa$-Vertex Connected Spanning Subgraph ($\kappa$-VCSS); the input is a graph $G$ on $n$ vertices with edge costs $w : E(G) \to \mathbb{R}^+$, and the objective is to find a spanning subgraph $H$ of minimum total cost such that it remains connected even when $\kappa - 1$ vertices are deleted, for some fixed integer $\kappa$. And in the case of edge-failures, we get Minimum $\lambda$-Edge Connected Spanning Subgraph ($\lambda$-ECSS) where we must ensure network connectivity even after $\lambda - 1$ edges fail, for some fixed integer $\lambda$. Both these problems are very well studied, and have wide applications. Unfortunately they are NP-hard, even in the unweighted setting. Therefore they have been extensively studied in Approximation algorithms [14, 19, 22], and more recently in Parameterized algorithms.

If a pair of vertices $u, v \in V(G)$ remain connected even after $\kappa - 1$ vertex failures, then by the Menger's Theorem [3, Theorem 7.3.1], there must be $\kappa$ internally disjoint paths from $u$ to $v$ in $G$. In other words, the *vertex-connectivity between $u$ and $v$* is at least $\kappa$ in $G$. Since every pair of vertices in $G$ must have this property, the graph $G$ must be $\kappa$-vertex connected. Similarly, in the case of edge-connectivity, the graph $G$ must be $\lambda$-edge connected. Interpreting $\kappa$-VCSS / $\lambda$-ECSS in terms of connectivity leads to the Survivable Network Design Problem (SNDP), where we may have different connectivity demands between different vertex pairs. SNDP captures a number of network design problems such as Steiner Tree, Minimum Equivalent Digraph, Hamiltonian Cycle etc. We can classify many network design problems by the nature of their connectivity constraints into variants of Edge Connectivity SNDP (EC-SNDP) and Vertex Connectivity SNDP (VC-SNDP). Observe that $\kappa$-VCSS and $\lambda$-ECSS correspond to the uniform connectivity demands case of these problems, respectively. Hence they are also called VC-SNDP / EC-SNDP with Uniform Demands. There has been a vast amount on research network design problems, especially in Approximation algorithms [14, 19, 22], which has led to the development of a number of new algorithmic techniques; e.g. the 2-approximation algorithm of Jain for EC-SNDP [13] which introduced iterative LP-rounding.

Typically, vertex connectivity problems are often significantly more difficult than the corresponding edge-connectivity problems. In contrast to the 2-approximation for EC-SNDP, VC-SNDP has an approximation lower bound of $2^{\log^{1-\epsilon} n}$ [18], and $\kappa^\epsilon$ for every $\kappa > \kappa_0$ where $\epsilon > 0$ and $\kappa_0 > 1$ are constants [6]. Even in the case of uniform requirements, i.e. $\kappa$-VCSS, the best known approximation algorithm for $\kappa$-VCSS has an approximation factor $\mathcal{O}(\log \kappa \cdot \log \frac{n}{n-\kappa})$[23], although it is improved to 6 assuming that $n \geq \kappa^3(\kappa - 1) + \kappa$ [7]. Another example is the Unrestricted Vertex Connectivity Augmentation (UVCA), where the objective is to augment a $\kappa$-vertex connected graph to a $\kappa + t$-vertex connected

graph by adding new edges.[1] While Unrestricted Edge Connectivity Augmentation (UECA), that is similarly defined, is known to be in polynomial time from many decades ago[11], the complexity of UVCA still remains open. Currently, a polynomial time algorithm is only known for $t = 1$ [26].

Recently, there has been a lot of interest in the study of the Parameterized algorithms [8][2] for network design problems [2, 21, 4, 1, 12, 15, 16, 17, 10, 9]. The separation between vertex-connectivity problems and edge-connectivity problems also persists in this setting; nearly all of the currently known results are for edge-connectivity problems. Bang-Jensen et al. [1] gave an FPT algorithm for the parameterized version of $\lambda$-ECSS[3] in this setting. This naturally raises the question for $\kappa$-VCSS, denoted by p-$\kappa$-VCSS[4], which they pose as an open problem. This is the problem we study here. Gutin et.al. [12] gave a *non-uniform FPT algorithm*[5] for p-$\kappa$-VCSS using a powerful classification result of Lokshtanov et al. [20]. The running time of this algorithm is unspecified. They also gave an (uniform) FPT algorithm for p-$\kappa$-VCSS when $\kappa = 2$ (Biconnectivity Deletion) [12].

| p-$\kappa$-VCSS | **Parameter:** $\ell$ |
|---|---|
| **Input:** A $\kappa$-connected graph $G = (V, E)$ and an integer $\ell$. | |
| **Question:** Does there exist a set of edges $F \subseteq E$ such that $\lvert F\rvert \geq \ell$ and $G' = (V, E \setminus F)$ is $\kappa$-connected? | |

**Our contribution.** In this work we give an (uniform) FPT algorithm for p-$\kappa$-VCSS for any constant $\kappa$; indeed our result is stronger and the algorithm is FPT in both $\ell$ and $\kappa$. We build upon the broad approach of Bang-Jensen et al. [1], but develop new insights into vertex connectivity that are of independent interest.

▶ **Theorem 1.** p-$\kappa$-*VCSS admits an FPT algorithm running in time* $2^{\mathcal{O}(\kappa^2\ell^4 \log \ell)} \cdot |G|^{\mathcal{O}(1)}$.

Our algorithm follows the general scheme laid down by Bang-Jensen et al. [1] for p-$\lambda$-ECSS. We consider the set of all *deletable edges*, i.e. all those edges $e \in G(G)$ such that $G - e$ is $\kappa$-vertex connected. Our goal is to identify an *irrelevant edge*[6] among these edges and shrink the pool of *relevant* deletable edges until the instance can be more easily solved. Bang-Jensen et al. [1] show that, for p-$\lambda$-ECSS, if the graph contains a large number of deletable edges, then there exists a cyclic decomposition of the graph that can be used to identify an irrelevant edge.[7] We prove a similar kind of result for p-$\kappa$-VCSS.

We develop a new tool called the *Wheel decomposition* for this purpose that helps us understand the structure of "nearly edge minimal" $\kappa$-vertex connected graphs. This is our main conceptual contribution. An intuitive description is as follows: It is a partition of the

[1] Formally, the input is a $\kappa$-vertex connected graph $G$ and an integer $t \geq 1$. The objective is to compute a minimum cost subset $F \subseteq V \times V$ such that $G + F$ is $(\kappa + t)$-vertex connected.

[2] Let us recall that in Parameterized Complexity, the input is a pair $(X, \ell)$ where $X$ is an instance of the problem and $\ell$ is an integer, called the *parameter*. The objective is to design a *Fixed Parameter Tractable (FPT) algorithm*, i.e. an algorithm that solves the problem in time $f(\ell) \cdot |X|^{\mathcal{O}(1)}$ where $f$ is a function of $\ell$ alone.

[3] They give FPT algorithms for $\lambda$-ECSS in both graphs and digraphs. Further, they extended their results to $\kappa$-VCSS in digraphs by reducing it to special instances of $\lambda$-ECSS.

[4] Here the $p$ in p-$\kappa$-VCSS denotes *parameterized*

[5] Here *non-uniform algorithm* refers to the complexity theory term, which is different from demands being uniform or non-uniform.

[6] i.e. one that is not present in some solution to the input instance and therefore remains in the graph when the edges of that solution are deleted.

[7] This is specifically required for odd values of $\lambda$ in undirected graphs. The other cases are much simpler.

edge set $E(G)$ of a graph $G$, with the parts arranged in a cyclic order. Any vertex either has edges in at most two consecutive parts, or else it has edges in every part of the partition.[8] Each of these parts, which are edge-subsets, describes a vertex cut in a natural way: the set of all those vertices that have an edge in this part and another edge somewhere outside it. In a Wheel decomposition, these vertex cuts are highly symmetric. For our results, we develop algorithmic tools to construct Wheel decompositions in instances of p-$\kappa$-VCSS and then identify irrelevant edges using them.

We believe that the Wheel decomposition is of independent interest. As we have observed earlier, vertex connectivity problems are often substantially more difficult than the corresponding edge-connectivity problems. One reason for this is the lack of structural results and tools for vertex connectivity as compared to edge connectivity. We believe that Wheel decompositions will be a useful tool in understanding vertex connectivity and resolving other open questions in the future.

**Related works.** As we mention above, our work has been most influenced by the work of Bang-Jensen et al. [1]; we however require several new ideas and methods to deal with vertex connectivity. Other related works gave FPT algorithms for Directed and Undirected Spanners [16, 17, 10], and 2-VCSS [12] in a similar setting. A recent work considered these problems parameterized by the solution size [9]. Additional results are known about connectivity augmentation problems, e.g. Strong Connectivity Augmentation [15], Edge connectivity Augmentation by One [21, 4] and Minimum Strong Spanning Subgraph [2].There is a vast amount of research on network design problems in approximation algorithms, too many to list comprehensively. We refer to the following surveys for an overview [14, 19, 22]. There has been recent interest in improving the approximation-factor for some specific simple cases of EC-SNDP, such as Weighted Tree Augmentation and Weighted Connectivity Augmentation by One). A sequence of works have finally led to breaching the approximation factor barrier 2 for both these problems [5, 24, 25]. Ideas and methods from the Parameterized algorithms for these problems also played a role in some of these results [5, 4].

## 2 Preliminaries and Notation

For a universe $W$ and a subset of elements $U \subseteq W$ we will denote the set $W \setminus U$ by $\overline{U}$. When doing set-operations where one of the sets is a singleton, e.g. $A \cup \{x\}$, we omit the curly-braces and just write $A \cup x$. For a graph $G$ and a subset of vertices $A \subseteq V(G)$, $G - A$ denotes the induced subgraph $G[V(G) \setminus A]$. Similarly, for a set of edges $B \subseteq E(G)$, $G - B$ denotes the subgraph with vertex set $V(G)$ and edge-set $E(G) \setminus B$. For a graph $G$ and a subset of vertex-pairs $B \subseteq V \times V$, $G + B$ denotes the graph with vertex set $V(G)$ and edge-set $E(G) \cup B$. Let $G = (V, E)$ be a graph and for an edge $e = uv \in E$ the **endpoints of e** are the vertices $u$ and $v$, and we have $V(e) = \{u, v\}$. For a vertex $u \in V$ let $\delta(u) \in E$ define the set of edges which have $u$ as an endpoint. We extend this notion to subsets of vertices, i.e. $\delta(X)$ denotes the set of edges with an endpoint in $X$. Further, for an edge $e = (u, v)$, $\delta(e)$ denotes the set $\delta(V(e))$. For a set of edges $E' \subset E$ and a vertex $v$ we will often denote that $\delta(v) \subseteq E'$ by writing $v \in E'$. Given a graph $G = (V, E)$, two vertices $s, t \in V$, and a path $P$ from $s$ to $t$ we denote the vertices of $P$ as $V(P)$ and $E(P)$ will denote the edges of $P$. Given two vertices $u, v \in V(P)$ the path $P[u, v]$ is the subpath of $P$ which goes from $u$ to $v$. Furthermore, $P]u, v[$ will be the induced path $P[u, v] \setminus \{u, v\}$.

[8] These two types of vertices can be thought of as the rim and the hub of a wheel.

An instance of a parameterized problem $\Pi$ consists of a main part $I$ and a parameter $l$, and it is denoted denoted $(I, l)$. A parameterized decision problem $\Pi$ admits a **fixed-parameter tractable (FPT)** if for every instance $(I, \ell) \in \Pi$ the problem admits an algorithm which can decide if there is an affirmative or negative answer to the problem and the algorithm has complexity $O(f(\ell)|I|^c)$ for some positive function $f$. The problem admits a *uniform FPT algorithm*, if there is an algorithm $\mathcal{A}$ that solves an instance $(I, \ell)$ of the problem in $O(f(\ell)|I|^c)$ time. And it admits a *non-uniform FPT algorithm* if for each value of $\ell$, there is an algorithm $\mathcal{A}_\ell$ that solves an instance $(I, \ell)$ in $O(f(l)|I|^c)$ time.

### Vertex-cuts and Separators

▶ **Definition 2.** *Given a set of edges $U \subseteq E$ the **vertex-cut** induced by $U$ is the minimal set of vertices denoted $\mathcal{S}(U) \subseteq V$ such that for every pair of edges $e \in U$ and $e' \in \overline{U}$ we have $V(e) \cap V(e') \subseteq \mathcal{S}(U)$.*

Note that, for every vertex $u \in \mathcal{S}(U)$ the sets $\delta(u) \cap U$ and $\delta(u) \cap \overline{U}$ are both not empty due to minimality of $U$. For two disjoint sets of edges $U, W \subseteq E$ we will use the notation $\mathcal{D}(U, W)$ to define those vertices in $V$ which are endpoints of edges in both $U$ and $W$. For two different graphs $G = (V, E)$ and $G' = (V, E')$, defined on the same set of vertices $V$, and a set of edges $U$ such that $U \subseteq E \cap E'$ we will use a subscript to indicate in which graph we consider the vertex-cut $\mathcal{S}(U)$. That is, $\mathcal{S}(U)_G$ will refer to a (uniquely determined) vertex-cut in $G$ while $\mathcal{S}(U)_{G'}$ will refer to a (uniquely determined) vertex-cut in $G'$. Moreover, with a slight abuse of notation for the sake of brevity, for a set of edges $W \subseteq E$ and the graph $G^* = (V, E \setminus W)$ we denote the vertex-cut $\mathcal{S}(U \setminus W)_{G^*}$ in $G^*$ as $\mathcal{S}(U)_{G^*}$. Note that, the underlying graph of a vertex-cut and the corresponding subset of edges are always clear from the context. Note that $\mathcal{S}(U)_{G^*} \subseteq \mathcal{S}(U)_G$. We will omit the subscript if there is only one graph or it is explicitly given in which graph the vertex-cut should be considered. Similarly, for sets of edges and sets of vertices a subscript will indicate which graph we refer to.

A set of vertices $Q \subseteq V$ in a graph $G = (V, E)$ is a **vertex-separator** if there exist two vertices $u, v \in V \setminus Q$ such that there is no path from $u$ to $v$ in $G - Q$. We will also call such a vertex-separator $Q$ a **$(u, v)$-separator** and say that $Q$ **separates** $u$ and $v$. For a minimal $(u, v)$-separator $Q$, let $R$ be the set of vertices in the same connected component as $u$ in $G - Q$ and $T = V \setminus (R \cup Q)$. Now let $U \subseteq E$ be the set of edges which have an endpoint in $R$ and observe that $Q = \mathcal{S}(U)$, that is, the vertex-cut $\mathcal{S}(U)$ is a minimal $(u, v)$-separator. This implies that $\delta(u) \subseteq U$ and $\delta(v) \subseteq \overline{U}$. Conversely, if there exists a vertex-cut $\mathcal{S}(U)$ such that for two vertices $u, v \in V$ it holds that $\delta(u) \subseteq U$ and $\delta(v) \in \overline{U}$ then there cannot be a path from $u$ to $v$ in $G - \mathcal{S}(U)$ as $\delta(v)$ will be disconnected from $\delta(u)$ in this graph. Hence $\mathcal{S}(U)$ must be a $(u, v)$-separator. Therefore, we have the following observation:

▶ **Observation 3.** *Let $G = (V, E)$ be a graph. For $U \subseteq E$, if there exist two vertices $u, v \in V$ such that $\delta(u) \subseteq U$ and $\delta(v) \in \overline{U}$, then $\mathcal{S}(U)$ is a $(u, v)$-vertex-separator. And if $Q$ is a minimal $(u, v)$-separator, then there is a subset of edges $U \subseteq E$ such that $Q = \mathcal{S}(U)$, $\delta(u) \subseteq U$ and $\delta(v) \subseteq \overline{U}$.*

We call a vertex-cut $\mathcal{S}(U)$ a **nearby vertex-separator with respect to** $e = uv$ if exacty one of the vertices $u$ and $v$ is contained in $\mathcal{S}(U)_G$, and $\mathcal{S}(U)_{G-e}$[9] is a $(u, v)$-separator in $G - e$. Figure 1 shows a nearby vertex-separator. By Definition 2, for every $x \in \mathcal{S}(U)_{G-e}$ it holds that $\delta(x)_{G-e}$ intersects $U_{G-e}$ and $\overline{U}_{G-e}$. Hence $\mathcal{S}(U)_G = \mathcal{S}(U)_{G-e} \cup v$ for $v \in V(e)$ which implies that $|\mathcal{S}(U)_G| = |\mathcal{S}(U)_{G-e}| + 1$.

[9] Recall that, for brevity we write $\mathcal{S}(U)_{G-e}$ to denote $\mathcal{S}(U \setminus \{e\})_{G-e}$.

▶ **Observation 4.** *For a graph $G = (V, E)$ and a nearby vertex-separator $\mathcal{S}(U)_G$ with respect to $e = uv$ it holds that $|\mathcal{S}(U)_G| = |\mathcal{S}(U)_{G-e}| + 1$ and $\mathcal{S}(U)_G = \mathcal{S}(U)_{G-e} \cup v$ for some $v \in V(e)$.*

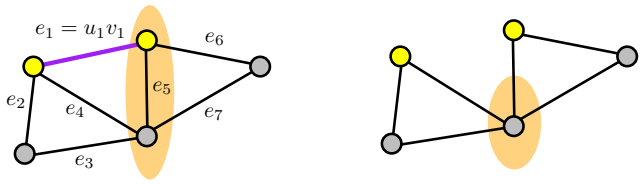

**Figure 1** $\mathcal{S}(U)$ is a near-vertex separator for $e_1$ where $U = \{e_1, e_2, e_3, e_4\}$.

▶ **Observation 5.** *A vertex-cut $\mathcal{S}(U)$ is a nearby vertex-separator with respect to $e = uv$ if and only if one of the following holds:*

- *$\delta(u) \setminus e \subseteq U$ and $\delta(v) \subseteq \overline{U}$ (or $\delta(u) \setminus e \subseteq \overline{U}$ and $\delta(v) \subseteq U$)*
- *$\delta(u) \subseteq U$ and $\delta(v) \setminus e \subseteq \overline{U}$ (or $\delta(u) \subseteq \overline{U}$ and $\delta(v) \setminus e \subseteq U$)*

We have the following results which follows directly from Menger's Theorem.

▶ **Lemma 6.** *Given a graph $G = (V, E)$ and two vertices $u, v \in V$ such that $uv \notin E$, it is possible to find a minimum $(u, v)$-separator $\mathcal{S}(U)$ in $O((|V| + |E|)^{O(1)})$ time.*

▶ **Corollary 7.** *Given a graph $G = (V, E)$ and an edge $e$, in $O((|V| + |E|)^{O(1)})$ time it is possible to find a minimum nearby vertex-separator with respect to $e$ or determine that no nearby vertex-separator with respect to $e$ exists.*

▶ **Theorem 8.** *The following statements are equivalent:*

- *The graph $G = (V, E)$ is $\kappa$-connected.*
- *$|V| \geq \kappa + 1$ and for every pair of vertices $u, v \in V$ such that $uv \notin E$ there are $\kappa$ internally disjoint paths from $u$ to $v$.*
- *$|V| \geq \kappa + 1$ and every vertex-separator has size at least $\kappa$.*

▶ **Lemma 9.** *Given a graph $G = (V, E)$, it is possible to determine if $G$ is $\kappa$-connected in $O(|G|^{O(1)})$ time .*

For vertex-cuts in general we have the following.

▶ **Lemma 10.** *The size of vertex-cuts is a submodular function, that is, given two edge-cuts $\mathcal{S}(U)$, $\mathcal{S}(W)$ we have $|\mathcal{S}(U \cap W)| + |\mathcal{S}(U \cup W)| \leq |\mathcal{S}(U)| + |\mathcal{S}(W)|$.*

### Deletable and Relevant Edges

For a p-$\kappa$-VCSS instance $(G = (V, E), \ell)$ where $G$ is a $\kappa$-vertex connected graph, we call a subset of edge $F \subseteq E$ **a solution** if $G = (V, E \setminus F)$ is $\kappa$-connected and $|F| \geq l$. To help distinguish between the edges which may be part of a solution and the edges which can definitely not be part of a solution we have the following definition:

▶ **Definition 11.** *An edge $e \in E$ is **deletable** if $G - e$ is $\kappa$-connected. If an edge is not deletable then it is **undeletable**.*

Clearly every edge of a solution $F \subseteq E$ is deletable in $G$. Let the set of deletable edges of $G$ be denoted $\mathsf{del}(\mathbf{G})$, and denote the remaining edges by $\mathsf{undel}(G)$. It means that for a solution $F \subseteq E$ we have $F \subseteq \mathsf{del}(G)$. Instead of working directly with deletable and undeletable edge we will be working with a subset with the property that $\mathcal{R} \subseteq \mathsf{del}(G)$, such that if there exists a solution $F$ then there also exists a solution $F' \subseteq \mathcal{R}$. The idea behind the algorithm is that we will either find a solution or shrink the set $\mathcal{R}$ until $\mathcal{R}$ is small enough that we can apply a brute force algorithm to determine if a solution exists or no solution exists.

▶ **Definition 12.** *A set $\mathcal{R} \subseteq \mathsf{del}(G)$ is a set of **relevant** edges if one of the following is true.*
- *There exists a solution $F \subseteq \mathcal{R}$.*
- *There exists no solution to the problem.*

Now we have the following relation between a deletable edge $e \in E$ and a nearby vertex-separators with respect to $e$.

▶ **Proposition 13.** *Given a graph $G = (V, E)$ and a deletable edge $e \in E$ it holds that every nearby vertex-separator with respect to $e$ in $G$ is of size at least $\kappa + 1$.*

## 3 Overview of the Algorithm

In this section we present an overview of our algorithm, that highlights the main ideas and techniques of this paper. Broadly we follow the approach of Bang-Jensen et al. [1], who studied the edge-connectivity version of the problem in both graphs and digraphs, and also the vertex-connectivity version in digraphs. However we develop some non-trivial new ideas and methods for vertex connectivity in undirected graphs. Due to limited space, the proofs and some technical details have been omitted from this extended abstract; they will be presented in the full version of the paper.

The starting point of our algorithm (similar to Bang-Jensen et al [1]) is the notion of a *deletable edge*. Let $\mathsf{del}(G)$ be the set of all deletable edges in $G$. Note that it is computable in polynomial time. It is clear that any solution $F$ to this instance is a subset of $\mathsf{del}(G)$. Here, by a *solution to* $(G, \ell)$ we mean a subset of $\ell$ edges, $F$, such that $G - F$ is $\kappa$-connected. Note that, if $|\mathsf{del}(G)|$ itself is upper-bounded, by say $49\kappa^2\ell^4$, then a simple brute-force algorithm can find a solution in the time $2^{\mathcal{O}(\kappa^2\ell^4)} \cdot n^{\mathcal{O}(1)}$. Therefore, we may assume that $|\mathsf{del}(G)| \geq 49\kappa^2\ell^4$.

Consider the effect of removing a deletable edge $e \in \mathsf{del}(G)$ from $G$. Observe that a number of edges in $\mathsf{del}(G)$ could become *undeletable* in $G - e$, i.e. removing any of these edges in $G - e$ will violate the $\kappa$-connectivity constraint. Let $\mathcal{I}_e^G = \mathsf{del}(G) \setminus \mathsf{del}(G - e)$ denote the set of all deletable edges in $G$ that become undeletable in $G - e$. We drop the superscript when the graph is clear from context. Now consider the following simple greedy algorithm based on the notion of deletable edges:

> If there is a deletable edge $e$ in the current instance $(G, \ell)$, find the one minimizing $|\mathcal{I}_e|$. Then recursively solve the instance $(G - e, \ell - 1)$ to obtain a solution $S'$ to it. Finally output the solution $S = S' \cup \{e\}$. Otherwise, output that there is no solution.

Observe that this algorithm succeeds only if in each sub-instance, the set $\mathcal{I}_e$ is not too large (e.g. $\mathcal{O}(\kappa^2\ell^3)$). In other words, only a bounded number of deletable edges should become undeletable in each recursive call. Then assuming that $\mathsf{del}(G)$ was sufficiently large (e.g. at least $\mathcal{O}(\kappa^2\ell^4)$) at the beginning, this greedy algorithm produces a solution to $(G, \ell)$ in polynomial time.

The remaining case is when there is a sub-instance $G'$ where, for any deletable edge $e' \in \mathsf{del}(G')$ $|\mathcal{I}_{e'}^{G'}| > 100\kappa^2\ell^3$, that is a large number of deletable edges become undeletable on removing $e'$ from $G'$. We pick such an edge $e' \in \mathsf{del}(G')$ and consider the pair $(G', e')$ and

analyze their structural properties. Our main technical result, simplified, is an algorithm $\mathcal{A}_{Irr}$ that given $G, G', e'$, where $G'$ is a $\kappa$-connected subgraph $G'$ of $G$ and $e' \in \mathsf{del}(G')$ such that $|\mathcal{I}_{e'}^{G'}| > 100\kappa^2\ell^2$, either finds a solution to $(G, \ell)$, or identifies a new irrelevant edge $e'' \in \mathcal{I}_{e'}^{G'}$ for the instance $(G, \ell)$. Here, an *irrelevant edge* refers to a deletable edge $e'' \in \mathsf{del}(G)$ such that there is a solution $F \subseteq \mathsf{del}(G) \setminus e''$. If we mark $e''$ as irrelevant, then it is treated just like an undeletable edge, and it remains in the graph.

The algorithm runs over many iterations, where in each iteration we either find a solution or find a new irrelevant edge. We maintain a set of *relevant* edges $\mathcal{R}$ which is initially $\mathsf{del}(G)$, and update it over a sequence of iterations until either a solution is found, or we have rule out the existence of a solution. Note that we ensure that $\mathcal{R}$ is always a subset of the deletable edges. Further, the definition of the set $\mathcal{I}_e$ now becomes $\mathcal{R} \setminus \mathsf{del}(G - e)$, since we are only interested in solutions formed with relevant edges. Therefore our updated algorithm for p-$\kappa$-VCSS is as follows:

> Let $(G, \ell)$ be the input instance of p-$\kappa$-VCSS, and let $\mathcal{R} \subseteq \mathsf{del}(G)$ be the set of relevant edges. We first apply the above greedy algorithm to $(G, \ell)$, and output a solution if one is found.
> Otherwise the above greedy algorithm fails to find a solution to $(G, \ell)$, therefore we find a sub-instance $G'$ and pick an arbitrary edge $e' \in \mathsf{del}(G')$ such that $\mathcal{I}_{e'}$ is large. Then, apply the algorithm $\mathcal{A}_{Irr}$ to $(G, G', e', \mathcal{R})$. It either finds a solution $F$ to $(G, \ell)$, or it finds a new irrelevant edge $e'' \in \mathcal{I}_{e'} \subseteq \mathcal{R}$ for $(G, \ell)$. In the first case, we output the solution found by $\mathcal{A}_{Irr}$. In the second case, start a new iteration on the instance $(G, \ell)$ with $\mathcal{R} - e''$ as the new set of relevant edges.

Observe that we have at most $|E|$ iterations of the above algorithm. Hence, the running time of the above algorithm is $(t_{\mathcal{A}_{Irr}} + 2) \cdot n^{\mathcal{O}(1)}$, where $t_{\mathcal{A}_{Irr}}$ denotes the running time of the algorithm $\mathcal{A}_{Irr}$. We prove that $t_{\mathcal{A}_{Irr}} = 2^{\mathcal{O}(\kappa^2\ell^4)} \cdot n^{\mathcal{O}(1)}$ where $n = |V|$.

Let us also address another special case of the problem that can be solved in polynomial time. It leads to a bound on the number of relevant edges incident on any single vertex. This is required for our implementation of $\mathcal{A}_{Irr}$. We begin by observing the following.

▶ **Observation 14.** *Given a $\kappa$-connected graph $G = (V, E)$, a set of relevant edges $\mathcal{R} \subseteq E$, and an edge $e = uv \in \mathcal{R}$. In $G - e$ every set of $\kappa$ internally disjoint paths from $u$ to $v$, $\mathcal{P} = \{P_1, P_2, \ldots, P_\kappa\}$, will use all of the irrelevant edges with respect to $e$, that is, $\mathcal{I}_e^G \subseteq \cup_{i \in \{1,\ldots,\kappa\}} E(P_i)$.*

▶ **Lemma 15.** *Given a $\kappa$-connected graph $G = (V, E)$ and a set of relevant edges $\mathcal{R}$. If there exists a vertex $u \in V$ such that $|\delta(u) \cap \mathcal{R}| \geq (\kappa + 1) \cdot l$, then a solution exists and it can be found in $O((|E| + |V|)^{O(1)})$ time.*

In the following subsections we give an overview of main ideas of the algorithm $\mathcal{A}_{Irr}$. For simplicity, we assume that $G = G'$, and we have an edge $e \in \mathcal{R} \subseteq \mathsf{del}(G)$ such that $|\mathcal{I}_e| > 100\kappa^2\ell^3$. In the general case, where $G'$ is a proper subgraph of $G$, our methods are identical with one extra step for handling the edges in $E(G) \setminus E(G')$. We construct a Wheel decomposition of the graph $G'$ and then we lift it back to $G$ (see Lemma 22).

### The Wheel Decomposition

The key conceptual idea behind the algorithm $\mathcal{A}_{Irr}$, is what we call the *Wheel decomposition* of a graph; the name is derived from the decomposition structure. See Figure 2.

▶ **Definition 16.** *Let $r \geq 3$ and $\alpha$ be integers. We say that $G$ admits an $\alpha$-wheel decomposition $(\mathcal{W}, r)$ if there is an edge partition $\mathcal{W} = \{X_0, X_1, \ldots, X_{r-1}\}$ of $E(G)$ into nonempty subsets, where the subsets are indexed cyclically, such that for every $i \in \{0, \ldots, r-1\}$ the following holds.*

1. $|\mathcal{S}(X_i)| = \alpha$
2. $\mathcal{S}(X_i) = \mathcal{D}(X_{i-1}, X_i) \cup \mathcal{D}(X_i, X_{i+1})$,
3. $|\mathcal{D}(X_{i-1}, X_i)| = |\mathcal{D}(X_i, X_{i+1})|$,
4. $\mathcal{D}(X_{i-1}, X_i) \cap \mathcal{D}(X_i, X_{i+1}) = \mathcal{S}(X_i) \cap \mathcal{S}(X_j)$ *for every* $j < i-1$ *and* $j > i+1$.

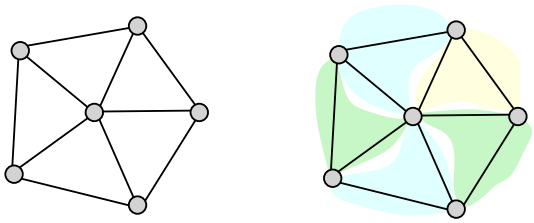

**Figure 2** A simple example of a Wheel decomposition of a graph; each part contains two edges and the center vertex is the only middle vertex of this wheel decomposition.

Observe that Property 4, ensures that for every vertex $v \in V(G)$ either $\delta(v)$ contains an edge from every part of $\mathcal{W}$, or from at most two consecutive parts of $\mathcal{W}$, where $X_{r-1}$ and $X_0$ are taken to be consecutive giving $\mathcal{W}$ a cyclic order. The vertices of the first kind, i.e. those that have an edge in every part of $\mathcal{W}$ are called the *middle vertices* of $\mathcal{W}$. We think of these vertices as the hub of a wheel whose ring is formed by the non-middle vertices of $\mathcal{W}$. Note the highly symmetrical properties of the vertex-cuts induced by the parts of $\mathcal{W}$. These are extensively applied in our proofs.

For the algorithm $\mathcal{A}_{Irr}$, we shall associate a $\kappa$-Wheel decomposition $\mathcal{W}$ with a subset of edges $E^+ \subseteq \mathcal{R}$. Recall that the input to this algorithm consists of a tuple $(G, \mathcal{R}, G', e')$, and in the simplified case that we are currently considering $G = G'$. Further, we have that $\mathcal{I}_{e'} = \mathcal{R} \setminus \mathsf{del}(G - e')$ contains at least $100\kappa^2\ell^3$ edges. We will compute a subset $E^+$ of $\mathcal{I}_e$, and use a Wheel decomposition to identify an irrelevant edge in $E^+$. Towards this we first recall the notion of a nearby vertex separator. We then have the following definition.

▶ **Definition 17.** *Let $\alpha$ be an integer. Let $G$ be a graph and let $E^+ = \{e_0, e_1, \cdots, e_{|U|-1}\} \subseteq E(G)$ be a subset of edges. We say that $G$ admits an* ***edge-restricted $\alpha$-wheel decomposition*** *$(\mathcal{W}, E^+)$ if there is an $\alpha$-wheel decomposition $(\mathcal{W}, |E^+|)$ such that for every $i \in \{0, \ldots, |E^+| - 1\}$;*

- $e_i \in X_i$,
- $\mathcal{S}(X_i)$ *and* $\mathcal{S}(X_{i+1})$ *are both nearby vertex-separators with respect to* $e_i$.

▶ **Observation 18.** *Let $G$ be a graph and let $E^+ = \{e_0, e_1, \ldots, e_{r-1}\} \subseteq \mathcal{R}$ be a subset of relevant edges. Let $(\mathcal{W}, E^+)$ be an edge-restricted $\alpha$-Wheel decomposition of $G$, for some integer $\alpha$, where $\mathcal{W} = \{X_0, X_1, \ldots, X_{r-1}\}$. Then for each edge $e_i = u_i v_i \in E^+$ such that $e_i \in X_i$, we have that $\delta(u_i) \subseteq X_i$ and $\delta(v_i) \setminus \{e_i\} \in X_{i+1}$. Here $X_r$ denotes the set $X_0$.*

The key idea is the fact that both $\mathcal{S}(X_i)$ and $\mathcal{S}(X_{i+1})$ are nearby vertex separators for $e_i$. This means that both $\mathcal{S}(X_{i+1})_{G-e_i}$ and $\mathcal{S}(X_i)_{G-e_i}$ are $u_i - v_i$ vertex separators. Hence $\delta(u_i) \setminus e_i \subseteq X_i \setminus e_i$ and $\delta(v_i) \setminus e_i \subseteq \overline{X_i}$. We can draw similar conclusions about $X_{i+1}$, and then arrive at these observations. It is immediate from Observation 18 that both endpoints of an edge $e_i \in E^+$ must be non-middle vertices of the Wheel decomposition $(\mathcal{W}, E^+)$. This

fact will be important in our proofs. However, we must also deal with another issue. Suppose that we have a $(\kappa+1)$-Wheel decomposition $(\mathcal{W}, E^+)$ and we wish to mark an edge $e_i \in E^+$ as irrelevant. To argue the correctness, we have to show that there is a solution that excludes $e_i$. Towards this, given some solution $F$ to $(G, \ell)$ that contains $e_i$, we construct another solution $F'$ that excludes $e_i$. The construction of $F'$ in our proofs must not only exclude $e_i$ but every edge in $E'_i = F \cap E(\mathcal{D}(X_i, X_{i+1})) \setminus Z$, where $Z$ denotes the set of middle vertices of the Wheel decomposition $(\mathcal{W}, E^+)$; this is a constraint of our arguments. These edges will be replaced by another set of edges contained in $E(\mathcal{D}(X_j, X_{j+1})) \setminus Z$ for some $j \neq i$. To describe the construction of $F'$ formally we require the following definition.

▶ **Definition 19.** *Given a $\kappa$-connected graph $G$, and a set of relevant edges $\mathcal{R} \subseteq E(G)$. If $G$ admits an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}, E^+)$ where $E^+ \subseteq \mathcal{R}$ then a* ***friendly set of edges for $e_i \in E^+$*** *is a set of edges $E_i \subseteq \mathcal{R}$ such that*

1. *$e_i \in E_i$,*
2. *every edge $e \in E_i$ has at least one of it's endpoints in $\mathcal{D}(X_i, X_{i+1})$ and none of the endpoints of $e$ are middle vertices,*
3. *$G - E_i$ is $\kappa$-connected,*

*and $E_i$ has the maximum cardinality among all edge subsets fulfilling these three criteria.*

Observe that a friendly set of edges $E_i$ for an edge $e_i \in E^+$ gives an upper-bound on the set $E'_i$ described above. It suggests that choosing $e_i$ that minimizes $|E_i|$ is the most likely candidate for a new irrelevant edge. The following lemma gives us a way of a computing friendly set of edges for a given wheel decomposition $(\mathcal{W}, E^+)$.

▶ **Lemma 20.** *Given a $\kappa$-connected graph $G$, a set of relevant edges $\mathcal{R}$, and an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}, E^+)$ of $G$ where $E^+ \subseteq \mathcal{R}$, it is possible to find a family of friendly sets $\mathcal{E} = \{E_i | i \in \{0, \ldots, |E^+|\}\}$ in $O(2^{O(d\cdot(\kappa+1))} \cdot |G|^{O(1)})$ time, where $d$ is the maximum number of relevant edges incident on a vertex $v \in V(G)$.*

Note that this lemma assumes that the number of relevant edges incident on any vertex is bounded by some number $d$. Here we require Lemma 15, where we have shown that if there were a vertex $v$ that had $(\kappa+1)\cdot\ell$ relevant edges incident on it, then we can compute a solution in polynomial time. Hence, we can assume that $d < (\kappa+1)\cdot\ell$, and therefore compute a friendly set of edges in $2^{\mathcal{O}((\kappa+1)^2\cdot l)} \cdot n^{\mathcal{O}(1)}$ time. This is suitable for an FPT algorithm.

With all these definitions and lemmas in hand, the process of identifying a new irrelevant edge in an instance $(G, \mathcal{R}, \ell)$ will be as follows. Using the steps described in the following sub-section, we will arrive at a subset of relevant edges $E^+ \subseteq \mathcal{R}$ containing more than $6\ell + \kappa + 2$ edges and an edge-restricted $(\kappa+1)$-Wheel decomposition $(\mathcal{W}, E^+)$ in polynomial time. Next, we will compute a friendly set of edges for every $e_i \in E^+$. Here we apply Lemma 20, along with the bound on the number of relevant edges incident to a vertex due to Lemma 15. This yields a friendly set of edges, $E_i$ for each edge in $e_i \in E^+$, in total time $2^{\mathcal{O}((\kappa+1)^2\cdot l)} \cdot n^{\mathcal{O}(1)}$. Finally, we mark the edge in $e_i \in E^+$ with the smallest friendly set of edges as irrelevant. The correctness of the last step is from the following lemma, which is one of our main technical results.

▶ **Lemma 21.** *Given a graph $G = (V, E)$, a set of relevant edges $\mathcal{R}$, an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}, E^+)$ of $G$ with $E^+ \subseteq \mathcal{R}$ where $|E^+| \geq 6l + \kappa + 2$, and a family of friendly sets $\mathcal{E}$ for the edges in $E^+$ such that $E_s \in \mathcal{E}$ has the minimum cardinality of all the sets in $\mathcal{E}$, it holds that $\mathcal{R} - e_s$ is a set of relevant edges in $G$.*

To prove this lemma we consider a hypothetical solution $F$ such that $e_s \in F$ and then we construct another solution $F'$ that excludes $e_s$. This then implies that $e_s$ is irrelevant. Let $\mathcal{W} = \{X_0, X_1, \ldots, X_{6\ell+\kappa+1}\}$. Since $|F| = \ell$, there must exist an index $i \in \{1, \ldots, 6\ell+\kappa+2\}$

such that for every $j \in \{-2, \ldots, 3\}$, $X_{i+j} \cap F = \emptyset$. Let $E'_s = F \cap \mathcal{D}(X_i, X_{i+1})$ and note that $e_s \in E'_s$. Let $F' = (F \setminus E'_s) \cup E_i$. We claim that $F'$ is also a solution. It is clear that $|F'| \geq |F|$ by our choice of $e_s$. To argue that $G - F'$ is $\kappa$-vertex connected, we give an argument based on (hypergraph) cut submodularity. While the actual argument is quite long and non-trivial, the essence of it is that if there were a $\kappa - 1$ cut in $G - F'$, then using submodularity we can trim it down to a $\kappa - 1$ cut that must exist in $G - F$. This is a contradiction since $F$ is a solution, i.e. $G - F$ is $\kappa$-connected. Here our arguments make extensive use of the highly symmetric properties of the cuts $\mathcal{S}(X_i)$.

The next lemma allows us to lift a Wheel decomposition from a subgraph $G'$ back to a graph $G$. This is required for the case where our simplifying assumption that $G' = G$ doesn't hold. In that case, $G = G' + F'$ and we have a Wheel decomposition in $G'$ that must be converted into a decomposition in $G$.

▶ **Lemma 22.** *Given a graph $G'$, a nonempty set of edges $F' \subseteq V(G') \times V(G')$, an edge-restricted $(\kappa + 1)$-wheel decomposition $(\mathcal{W}' = \{X'_0, X'_1, \cdots, X'_{|\mathcal{W}'|-1}\}, E' = \{e'_0, e'_1, \cdots, e'_{|\mathcal{W}|'-1}\})$ of $G'$ such that $|\mathcal{W}'| \geq 2 \cdot |F'| \cdot (r+1) + 1$ for an integer $r \geq 4$, it holds that in polynomial time it is possible to find an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}', E^+)$ of $G = G' + F'$ such that $|\mathcal{W}'| = r$ and $E^+ \subseteq E'$.*

The proof of this lemma essentially attempts to "merge" those parts $\{X'_i\}$ that are damaged by adding $F'$. The details are presented in the full-version.

### Wheel Decomposition for p-$\kappa$-VCSS

In this section we give an overview of the next part of the algorithm $\mathcal{A}_{Irr}$ that computes a Wheel decomposition with certain useful properties. The input is a $\kappa$-connected graph $G$ on $n$ vertices, an integer $\ell$ and a set of relevant edges $\mathcal{R}$ and an edge $e \in \mathcal{R}$ such that $\mathcal{I}_e = \mathcal{R} \setminus \mathsf{del}(G - e)$ contains at least $\kappa\ell \cdot 2(h+3)$ edges. Here $h \geq 3$ denotes the number of parts in our Wheel decomposition, and it is an integer whose value is roughly $O(\kappa\ell^2)$ in our final algorithm. We compute a edge-restricted Wheel decomposition $(\mathcal{W}, E^+)$ where $E^+ \subseteq \mathcal{I}_e$ using the following lemma, which is our second main technical result.

▶ **Lemma 23.** *Given a $\kappa$-connected graph $G = (V, E)$, an integer $h \geq 3$, an edge $e = uv \in \mathcal{R}$ where $\mathcal{R}$ is a relevant set of edges for $G$, such that $|\mathcal{I}_e| \geq \kappa \cdot \ell \cdot 2(h+3)$, in polynomial time $G$ it is possible to either:*

1. *find a set of edges $F \subseteq E$ such that $G - F$ is $\kappa$-connected and $|F| = \ell$, or*
2. *find a set $E^+ \subseteq \mathcal{I}_e$ such that $|E^+| = h$ and an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}, E^+)$ of $G$.*

Our proof of this lemma relies on several structural properties of $e$ and $\mathcal{I}_e$. In essence, we first identify a suitable subset of edges in $\mathcal{I}_e$ that can lead to the required Wheel decomposition, and then prove this fact. The first ingredient is the following. Let $e = uv$ and since $e \in \mathcal{R}$, the graph $G - e$ is $\kappa$-connected. Then we argue that for any system of $\kappa$ internally disjoint paths from $u$ to $v$ in $G - e$, $\mathcal{P}$, every edge in $\mathcal{I}_e$ occurs in one of the paths in $\mathcal{P}$. This is because if some edge $e' \in \mathcal{I}_e$ was excluded from $\mathcal{P}$, then one can show that $G - e - e'$ must also be $\kappa$-connected. From this statement we can conclude that one of the paths in $\mathcal{P}$ must have at least $|\mathcal{I}_e|/\kappa \geq \ell \cdot 2(h+3)$ edges from $\mathcal{I}_e$, and let $P \in \mathcal{P}$ be such a path. We say that this path $P$ satisfies the *intersection property* with respect to $e$. Observe that by a simple max-flow computation we can find this path $P$ in polynomial time. Let $\{e_1, e_2, \ldots, e_{\ell \cdot 2(h+3)}\} \subseteq E(P) \cap \mathcal{I}_e$ where the edges are in sequence of traversing $P$ from $u$ to $v$. Our objective is to show that a subset of these edges can lead us to the required Wheel decomposition.

Let $E' = \{e_i \mid i = 1 \mod 2(h+3)\}$, and let $r$ be the least integer such that $e_r \in E'$ and $G' = G - \{e_i \mid i = 1 \mod 2(h+3) \text{ and } i \leq r\}$ is *not* $\kappa$-connected. If $r \geq \ell + 1$, then clearly $\{e_i \mid i = 1 \mod 2(h+3) \text{ and } i < r\}$ is the required solution to $(G, \ell, \mathcal{R})$. Therefore, we assume $r \leq \ell$, and let $E'' = \{e_i \mid i = 1 \mod 2(h+3) \text{ and } i < r\}$. It is clear that $G - E''$ and $G - e_r$ are $\kappa$-connected, but $G' = G - E'' - e_r$ is not.

Let us fix a vertex-separator $\mathcal{S}(U')_{G'}$ of size less than $\kappa$ in $G'$, where $U' \subseteq E(G')$. It is clear that $\mathcal{S}(U')_{G'}$ separates the vertex pairs $u_r, v_r$ and $u_j, v_j$ where $e_r = u_r v_r$ and $e_j = u_j v_j \in E''$ for some $j < r$. Let us fix the largest such $j$. Note that $r - j \geq 2(h+3)$ and hence $r \geq 2(h+3)$. Let $E^* = \{e_j, e_r\} \cup \{e_{r+2i-2(h+2)} \mid 0 \leq i \leq h+1\}$. Finally, we define the edge subset $E^+$ which contains $h$ edges, that forms one half of our Wheel decomposition $(\mathcal{W}, E^+)$ as follows:

$$E^+ = E^* \setminus \{e_j, e_{r-2(h+2)}, e_{r-2}, e_r\}$$

We remark that the choice of $E^+$ may seem rather arbitrary, however it was chosen to encode several useful properties that are required for our proof. These properties are applied in the construction of the edge partition $\mathcal{W}$, which forms the other half of our decomposition.

For convenience, let us rename the edges in $E^*$ as $s_i \leftarrow e_{r+2i-2(h+2)}$ and further let $s = e_j$ and $t = e_r$. The following lemma is our next key ingredient, that computes a family of vertex cuts, defined via edge-subsets, corresponding to $E^*$. These cuts will be used to define $\mathcal{W}$ .

▶ **Lemma 24.** *Given a graph $G = (V, E)$, an edge $e = uv \in \mathcal{R}$ and a path $P$ between $u$ and $v$ fulfilling the intersection property such that $\mathcal{I}_e \cap P \neq \emptyset$, in polynomial time it is possible to find a family of cuts $\mathcal{C} = \{C_1, C_3 \cdots, C_{|\mathcal{I}_e \cap P|}\}$ such that for each $e_i \in \mathcal{I}_e \cap E(P)$,*

1. *$e_i \in C_i$, $e \in \overline{C_i}$, and $\mathcal{S}(C_i)$ is a nearby vertex-separator with respect to both $e_i$ and $e$.*
2. *$v_i$ is the only internal vertex of $P$ in $\mathcal{S}(C_i)$.*
3. *$|\mathcal{S}(C_i)| = \kappa + 1$,*
4. *For every $e_j = u_j v_j$ where $1 < j < i$, $\delta(u_j), \delta(v_j) \subseteq C_i$*
5. *For every $e_j = u_j v_j$ where $j \geq i + 2$, $\delta(u_j), \delta(v_j) \subseteq \overline{C_i}$*

*Further $C_i \subset C_j$ for any $j \geq i + 2$.*

Proving this lemma is not too difficult, although it requires working out some details. The idea is to start with a collection of arbitrary $\kappa$-cuts in $G - e$ containing an endpoint of these edges, and further exploiting the membership of $e_i$ in $\mathcal{I}_e$. These cuts are "untangled" using the submodularity of hypergraph cuts, to obtain that last containment property. Similar ideas were used by Bang-Jensen et al [1].

Applying the above lemma to $G, e$ and $P$ we obtain a collection of cuts, $\mathcal{C} = \{C_r, C_0, C_1, \ldots C_{h+1}, C_t\}$ corresponding to the edges in $E^* = \{s, s_0, s_1, \ldots, s_{h+1}, t\}$. Note that these cuts satisfy all the properties of the above lemma, and in particular $C_i \subset C_j$ for any $i < j$ in this collection. We can now define the edge-partition of our Wheel decomposition as follows:

$$\mathcal{W} = \{X_1 = E \setminus (C_h \cap \overline{C_1} \cap U'\} \cup \{X_i = C_i \cap \overline{C_{i-1}} \cap U' \mid 2 \leq i \leq h\}$$

Finally, to prove that $\mathcal{W}$ is indeed the required Wheel decomposition, we prove it's properties one by one. The main tool that we use is once again submodularity of cuts. In particular, from the definition of $\mathcal{W}$, some intutition can be derived. The cut induced by $U'$ is of size $\kappa - 1$ in $G'$. This cut splits each $C_i$ into two pieces, and further because of the containment property of $\mathcal{C}$, the parts $X_i$ are defined as the portion of $C_i \setminus C_{i-1}$ in $U'$. The part $X_1$ simply contains the remaining edges. The various symmetric properties of the cuts induced by each $X_i$ are consequences of the choice of $E^*$, via submodularity of cuts.

### Putting it all together: An algorithm for p-$\kappa$-VCSS

We collect all the previous results to arrive at the following algorithm for p-$\kappa$-VCSS:

1. If the induced graph $G' = (V, \mathcal{R})$ contains a vertex with degree at least $(\kappa+1)\cdot l$ then use the algorithm of Lemma 15 to find a solution and return it.
2. If $|\mathcal{R}| \leq 49\kappa^2 l^4$, then for every subset $F' \subseteq \mathcal{R}$ of size $l$ determine if $F'$ is a solution. If $F'$ is a solution, return $F'$ as a solution. If none of the subsets F' is a solution, return that no solution exists.
3. Choose an edge $f_i \in \mathcal{R}_i$, and let $\mathcal{I}_{f_i} = \mathcal{R}_i \setminus \mathsf{del}(G_i \setminus f_i)$:
   a. If $|\mathcal{I}_{f_i}| \geq \kappa \cdot l \cdot 2(2i\cdot(6l+\kappa+3)+4)$ then by Lemma 23
      i. we can either find a solution $F'$ for $G_i$ of size $l$, and return $F'$ as a solution,
      ii. or we can find a set $E^+ \subseteq \mathcal{I}_e$ such that $|E^+| = 2i\cdot(6l+\kappa+3)+1$ and an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}, E^+)$ for $G_i$.
         A. If $F \neq \emptyset$ then given $G_i$, $F$, and $(\mathcal{W}, E^+)$ by Lemma 22 find an edge-restricted $(\kappa+1)$-wheel decomposition $(\mathcal{W}', E')$ of $G = G_i + F$ such that $E' \subseteq E^+$ and $|E'| \geq 6l+\kappa+2$.
         B. Otherwise, if $F = \emptyset$ then set $(\mathcal{W}', E') = (\mathcal{W}, E^+)$ to be an edge-restricted $(\kappa+1)$-wheel decomposition of $G = G_i$.
         C. Given the set of relevant edges $\mathcal{R}$, and $(\mathcal{W}', E')$ use the algorithm from Lemma 20 to find the friendly sets for every edge $e_j \in E'$.
         D. Find the edge $e_j \in E'$ for which the corresponding friendly set $E_j$ has the smallest cardinality among all the friendly sets. Now set $\mathcal{R} := \mathcal{R} \setminus e_j$ and go to step 2. The correctness of this step follows from Lemma 21.
   b. Otherwise, set $G_{i+1} = G_i - f_i$, $\mathcal{R}_{i+1} = \mathcal{R} \cap \mathsf{del}(G_{i+1})$, and $F := F \cup f_i$. If $|F| \geq l$ return $F$ as a solution.

This algorithm proves Theorem 1. The correctness follows from the correctness of each lemma used in the above. For the running time, observe that Step 1 runs in polynomial time. The next steps are repeated at most $|E(G)|$ times, for each iteration, where we shrink the set of relevant edges $\mathcal{R}$ until Step 2 is finally applicable. Note that Step 2 runs in time $2^{\mathcal{O}(\kappa^2 \ell^4)} \cdot n^{\mathcal{O}(1)}$. One of Steps 3(a)i and 3(a)ii is run in each iteration, which is decided in polynomial time by Lemma 23. In the second case, we obtain a Wheel decomposition $(\mathcal{W}, E^+)$ in Step 3(a)iiC we spend $2^{\mathcal{O}((\kappa+1)^2\cdot l)} \cdot n^{\mathcal{O}(1)}$ time computing friendly sets of edges for $E^+$. We then mark an irrelevant step, and proceed to the next iteration. A straightforward calculation gives the claimed running time of the algorithm.

Due to space constraints, several proofs were omitted. Complete details may be found in the full version of the paper, in the appendix. Finally, we also thank anonymous reviewers for their suggestions on improving this paper.

# Lyndon Arrays in Sublinear Time

Technical University of Dortmund, Germany

## Abstract

A Lyndon word is a string that is lexicographically smaller than all of its non-trivial suffixes. For example, `airbus` is a Lyndon word, but `amtrak` is not a Lyndon word due to its suffix `ak`. The Lyndon array stores the length of the longest Lyndon prefix of each suffix of a string. For a length-$n$ string over a general ordered alphabet, the array can be computed in $\mathcal{O}(n)$ time (Bille et al., ICALP 2020). However, on a word-RAM of word-width $w \geq \log_2 n$, linear time is not optimal if the string is over integer alphabet $\{0, \ldots, \sigma\}$ with $\sigma \ll n$. In this case, the string can be stored in $\mathcal{O}(n \log \sigma)$ bits (or $\mathcal{O}(n/\log_\sigma n)$ words) of memory, and reading it takes only $\mathcal{O}(n/\log_\sigma n)$ time. We show that $\mathcal{O}(n/\log_\sigma n)$ time and words of space suffice to compute the succinct $2n$-bit version of the Lyndon array. The time is optimal for $w = \mathcal{O}(\log n)$. The algorithm uses precomputed lookup tables to perform significant parts of the computation in constant time. This is possible due to properties of periodic substrings, which we carefully analyze to achieve the desired result. We envision that the algorithm has applications in the computation of runs (maximal periodic substrings), where the Lyndon array plays a central role in both theoretically and practically fast algorithms.

## 1 Introduction

A Lyndon word is a string that is lexicographically smaller than all of its non-trivial suffixes. For example, `airbus` is a Lyndon word, but `amtrak` is not a Lyndon word due to its suffix `ak`. The Lyndon array stores the length of the longest Lyndon prefix of each suffix of a string (a precise definition follows later). In this article, we propose a new algorithm that computes the (succinct version of) the Lyndon array of a length-$n$ string over alphabet $\{0, \ldots, \sigma\}$ in $\mathcal{O}(n/\log_\sigma n)$ time and words of space on a word-RAM of word-width $w \geq \log_2 n$.

**Background and Applications.** Since their introduction in the field of combinatorics on words almost 70 years ago [32], Lyndon words have proven to be useful for designing efficient algorithms. The Lyndon factorization of a string uniquely decomposes it into lexicographically non-increasing Lyndon words [9, 15]. It can easily be obtained from the Lyndon array, and it has recently been used to capture overlaps between reads for next generation DNA sequencing [7, 8]. The closely related standard factorization $T = RS$ of a Lyndon word $T$ is uniquely defined by $S$, which is the longest proper Lyndon suffix, or equivalently the lexicographically smallest proper suffix of $T$. It is guaranteed that $R$ is also a Lyndon word [9]. By recursively factorizing $R$ and $S$ in the same manner until all segments are single symbols, we obtain the binary Lyndon tree. This tree can also be defined for a non-Lyndon word $T$, since prepending an infinitely small symbol makes any word Lyndon. The Lyndon tree encodes the same information as the Lyndon array (see, e.g., [13, 2]).

Hohlweg and Reutenauer [24] showed that the Lyndon factorization encodes the list of left-to-right suffix (lexicographical) minima of a string. Crochemore and Russo [13] showed that the Lyndon array (respectively the Lyndon tree) of a string encodes the left-to-right minima tree (respectively the Cartesian tree) of its inverse suffix array (the array that stores for each suffix its lexicographical rank among all the suffixes). This shows the close relation between the Lyndon array and the suffix array [33], one of the major data structures in string algorithmics, with countless applications in compression and indexing. Lyndon words and the Lyndon array have been used to efficiently compute the suffix array (e.g., [3, 5, 38]) and vice versa (e.g., [21, 31]). The Lyndon array can be computed from the suffix array in $\mathcal{O}(n)$ time; however, this requires a linearly-sortable alphabet (e.g., $\Sigma = \{0, \ldots, n^{\mathcal{O}(1)}\}$) due to the information-theoretic lower bound on comparison sorting. For general ordered alphabets, there is an $\mathcal{O}(n)$ time algorithm that computes the Lyndon array without the suffix array by exploiting combinatorial properties of Lyndon words [6] (see [16] for a simplified description). This algorithm can also be used to output a succinct $2n$-bit encoding of the Lyndon array, which is based on a balanced parentheses sequence of the tree structure of the Lyndon array.

The perhaps most important application of the Lyndon array is the computation of runs (maximal periodic substrings). Kolpakov and Kucherov showed that there are $\mathcal{O}(n)$ runs in a length-$n$ string, and conjectured that this upper bound can be improved to $n$ [29]. A series of results gradually improved the best known bound [40, 10, 11, 39]. Ultimately, the Lyndon array and its rich combinatorial properties were used to prove the conjecture [4], which also resulted in a remarkably simple proof. The Lyndon array is also one of the two main ingredients of a simple $\mathcal{O}(n)$ time algorithm for computing all the runs (see, e.g., [4, 13]). The second ingredient is a data structure for longest common extensions (LCEs), which answers queries of the type "Given $i, j$, what is the longest shared prefix between $T[i..n]$ and $T[j..n]$?". For linearly-sortable alphabets, an LCE data structure with constant query time can be constructed in $\mathcal{O}(n)$ time (e.g., [20]), which results in an $\mathcal{O}(n)$ time runs algorithm. It was conjectured that the same time can be achieved for general ordered alphabets [30], which resulted in a series of new LCE data structures aimed at these alphabets [30, 22, 12]. The first algorithm that achieves linear time [17] and hence proves the conjecture does not use an LCE data structure at all. Instead, it relies on the combinatorial structure of the Lyndon array to explicitly compute all the LCEs in overall linear time.

The existing $\mathcal{O}(n)$ time algorithms for the Lyndon array are optimal if the string is over a general ordered alphabet. However, they are not optimal on a word-RAM of word-width $w \geq \log_2 n$ if the alphabet is $\{0, \ldots, \sigma\}$ with $\sigma \ll n$. In this case, $\lfloor \log_\sigma n \rfloor$ symbols can be packed in a single word of memory, and hence they can be processed simultaneously. Word packing has lead to faster algorithms for many problems in string algorithmics. For example, $\mathcal{O}(n \log \sigma / \sqrt{\log n})$ time suffices to construct any of the following data structures for a packed string: compressed suffix arrays and trees with $\mathcal{O}(\log^\epsilon n)$ time operations [27]; an index that counts occurrences of a length-$m$ query pattern in $\mathcal{O}(m/\log_\sigma n + \log^\epsilon n)$ time [27]; the Burrows–Wheeler transform [26]; the wavelet tree [1, 35] with a fast practical implementation [25]. A novel LCE data structure by Kempa and Kociumaka can be constructed in even faster $\mathcal{O}(n/\log_\sigma n)$ time and answers queries in $\mathcal{O}(1)$ time [26].

**Our Contributions.** We show that the succinct $2n$ bit representation of the Lyndon array can be computed in $\mathcal{O}(n/\log_\sigma n)$ time and words of space on a word RAM of word-width $w \geq \log_2 n$. The time bound is optimal under the common assumption that the input size scales with the word-width, i.e., $w = \mathcal{O}(\log n)$. The algorithm uses the same ideas as previous $\mathcal{O}(n)$ time algorithms, but processes the string one word (rather than one position) at a time.

We accelerate the computation with lookup tables and the LCE data structure by Kempa and Kociumaka [26]. By carefully analyzing properties of periodic substrings, we are able to design the lookup tables in a way that minimizes the number of required LCE queries. The new algorithm will hopefully lead to a sublinear time algorithm for the computation of runs.

The remainder of the paper is structured as follows. In Section 2, we introduce basic definitions and notation, as well as a simple linear time algorithm for the succinct Lyndon array. This algorithm is the starting point of our new sublinear time algorithm, which we present in Section 3. It uses some auxiliary data structures, which we first use as a black box. In Sections 4 and 5, we show how to implement these data structures.

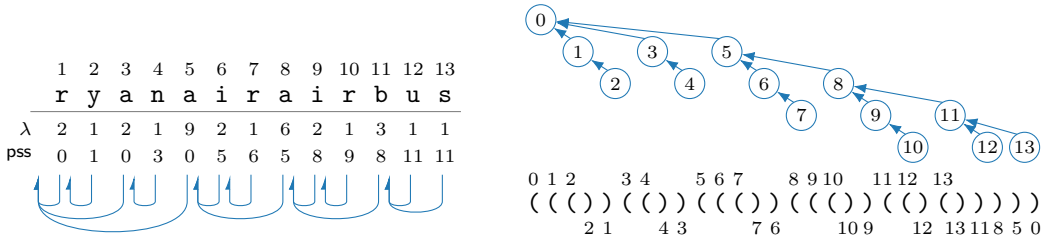
## 2 Preliminaries

**Strings and Computational Model.** For $i, j \in \mathbb{N}$, we write $[i, j] = (i-1, j] = [i, j+1) = (i-1, j+1)$ to denote the integer interval $\{i, i+1, \ldots, j\}$ (or the empty set if $i > j$). A string $T \in \Sigma^n$ is a sequence of $|T| = n$ symbols from some alphabet $\Sigma$. The empty string of length 0 is denoted by $\varepsilon$. For $i, j \in [1, n]$, we denote the $i^{\text{th}}$ symbol of the sequence by $T[i]$. The substring $T[i..j] = T(i-1..j] = T[i..j+1) = T(i-1..j+1)$ is the sequence of length $j-i+1$ that starts with the $i^{\text{th}}$ and ends with the $j^{\text{th}}$ symbol. For $j < i$ we define $T[i..j] = \varepsilon$. If $i \leq j$, then the longest common extension (LCE) at positions $i$ and $j$ is defined as $\text{LCE}(i, j) = \text{LCE}(j, i) = \max(\{\ell \in [0, n-j+1] \mid T[i..i+\ell) = T[j..j+\ell)\})$. Substrings $T[1..i]$ and $T[i..n]$ are respectively called prefix and suffix of $T$. A substring $T[i..j]$ is proper if $T[i..j] \neq T$, and non-trivial if it is proper and $T[i..j] \neq \varepsilon$. If the alphabet $\Sigma$ is totally ordered, then it induces a lexicographical order as follows. For strings $S \in \Sigma^m$ and $T \in \Sigma^n$, it holds $S \prec T$ (and we say that $S$ is lexicographically smaller than $T$) if and only if either $S$ is a prefix of $T$, or there is some $\ell \in [1, \min(m, n)]$ such that $S[1..\ell) = T[1..\ell)$ and $S[\ell] < T[\ell]$. We write $S \preceq T$ to denote that $T$ is not lexicographically smaller than $S$. A string $T[1..n]$ has period $p \in [1, n]$ if $T[1..n-p] = T[1+p..n]$. We then call $T[1..n-p]$ a border of $T$. The concatenation of two string $S$ and $T$ is denoted by $ST$. For $k \in \mathbb{N}^0$, the $k$-times concatenation (or $k$-power) of $T$ is denoted by $T^k$ (with $T^0 = \varepsilon$).

We work on a word RAM (see, e.g., [23]) with words of width $w \geq \log_2 n$ bits (where $n$ is the length of the input string). A string $T \in [0, \sigma)^n$ can be stored in packed representation, i.e., the binary representation of each symbol is stored in $\lceil \log_2 \sigma \rceil$ bits, and the entire string occupies $n \lceil \log_2 \sigma \rceil$ consecutive bits or $\mathcal{O}(n/\log_\sigma n)$ words of memory. (The number of bits can be improved to $\lceil n \log_2 \sigma \rceil + \mathcal{O}(\log^2 n)$ while retaining fast access [14, Theorem 1].) Primitive bitwise operations suffice to extract any substring of length $\mathcal{O}(\log_\sigma n)$ in constant time because such a substring fits in a constant number of words. Since a (sub-)string $S$ is a bit string of length $|S| \cdot \lceil \log_2 \sigma \rceil$, it can be interpreted as an integer in range $[1, 2^{|S| \cdot \lceil \log_2 \sigma \rceil}]$ (by reading the bit string as a binary number and adding one). We write $\mathsf{int}(S)$ to denote the integer value associated with $S$ (we also use this notations for bitvectors, as they are merely strings with $\sigma = 2$). In this model of computation, a data structure by Kempa and Kociumaka can be constructed in sublinear time and answers LCE queries (i.e., outputs the LCE of any two positions) in constant time.

▶ **Lemma 1** ([26, Theorem 5.4]). *Given a string $T \in [0, \sigma)^n$ in packed representation, LCE queries can be answered in $\mathcal{O}(1)$ time after an $\mathcal{O}(n/\log_\sigma n)$ time preprocessing.*

We do not use uninitialized memory or similar techniques, and hence the words of space used by the algorithm is upper bounded by the time spent (this includes Lemma 1). Therefore, we will not discuss any space complexities in the remainder of the paper, and instead only show the $\mathcal{O}(n/\log_\sigma n)$ time bound, which implies that $\mathcal{O}(n/\log_\sigma n)$ words of space suffice.



**(a)** Lyndon array $\lambda$ and PSS array pss. **(b)** The previous smaller suffix tree and its BPS.

**Figure 1** Data structures for the string `ryanairairbus`. Edges point to previous smaller suffixes.

**Lyndon Arrays.** A Lyndon word is a non-empty string $T[1..n]$ over a totally ordered alphabet that is lexicographically smaller than its non-trivial suffixes, i.e., $\forall i \in [2, n] : T \prec T[i..n]$.

▶ **Definition 2.** *Let $T[1..n]$ be a string over a totally ordered alphabet. The Lyndon array $\lambda[1..n]$ and the previous smaller suffix (PSS) array* pss$[1..n]$ *are defined $\forall i \in [1, n]$ by*

- $\lambda[i] = \max(\{\ell \in [1, n - i + 1] \mid T[i..i + \ell)$ *is a Lyndon word*$\})$, *and*
- pss$[i] = \max(\{j \in [1, i) \mid T[j..n] \prec T[i..n]\} \cup \{0\})$.

An example is provided in Figure 1a. We may interpret the PSS array as a rooted tree. The root is an artificial node with label 0. Every text position is a node, and for any position $i$, there is an edge from $i$ to its parent pss$[i]$. Each position is a child of a smaller position or the artificial root node, and hence it is easy to see that this indeed yields a tree with root 0. An example of this so-called *previous smaller suffix tree (PSS tree)* is provided in Figure 1b.

A balanced parentheses sequence (BPS) encodes the tree in $2n + 2$ bits (see, e.g., [36]), which can be described in the following constructive way. We write the sequence in an append-only manner. We perform a depth-first traversal of the tree, during which we visit the children of each node in increasing order. Whenever we walk down an edge from pss$[i]$ to $i$, we append the opening parenthesis of node $i$. Whenever we walk up an edge from $i$ to pss$[i]$, we write the closing parenthesis of node $i$. An example is provided in Figure 1b. If we assign preorder-numbers during this traversal, then node $i$ has preorder-number $i$ (see [19, Lemma 1] and [6]). Hence the $i^{\text{th}}$ opening parenthesis belongs to node $i$. In practice, the parentheses sequence is a bitvector, where 1-bits are opening parentheses, and 0-bits are closing ones. Bille et al. [6] showed that the PSS tree inherently encodes the Lyndon array because $\lambda[i]$ is exactly the size of the subtree rooted in node $i$. Hence we need to augment the parentheses sequence such that subtree-size$(i)$ can be answered in constant time. There are multiple support data structures that achieve this with $o(n)$ bits of additional space (see, e.g., [37]), but their current construction algorithms do not achieve sublinear time. However, we only require a small and simple subset of operations supported by these data structures (namely rank, select, and find-close). We plan to cover the efficient construction of support data structures for these operations in a future full version of the paper.

**Simple Construction Algorithm for the PSS Tree.** A simple algorithm computes the PSS tree in $\mathcal{O}(n)$ time, which will be the starting point for the $\mathcal{O}(n/\log_\sigma n)$ time algorithm in Section 3. Suppose that we have already computed the subtree induced by nodes $[0, i)$. Attaching node $i$ requires finding pss$[i]$. A strategy for this follows from the property that

**(a)** pss$[i]$ is one of the nodes on the already computed path from $i - 1$ to the root 0, and
**(b)** on this path, pss$[i]$ is the deepest node $j$ such that either $j = 0$ or $T[j..n] \prec T[i..n]$.

This observation has been used by previous results, and it has been proven, e.g., in [16, Lemma 6]. It implies an algorithm in which the positions are inserted into the tree one by one in left-to-right order. This is also the approach of Algorithm 1, which directly computes the BPS of the tree (see [6, Algorithm 1] for a more abstract version of this algorithm).

**Algorithm 1** Linear time construction of the PSS tree.

**Require:** Packed string $T \in [0, \sigma)^n$.
**Ensure:** BPS $\mathcal{B}$ of the PSS tree of $T$.

```
1:  B ← (                                   ▷ opening parenthesis of node 0
2:  Q ← stack that contains only 0
3:  for i = 1 to n do
4:      j ← Q.top()
5:      while j > 0 and T[i..n] ≺ T[j..n] do   ▷ evaluate with LCE data structure
6:          append ) to B                   ▷ closing parenthesis of node j
7:          Q.pop()
8:          j ← Q.top()
9:      append ( to B                       ▷ opening parenthesis of node i
10:     Q.push(i)
11: append |Q| times ) to B                 ▷ closing parentheses of nodes on path from n to 0
```

At the time at which the algorithm starts processing position $i$, the sequence $\mathcal{B}$ contains the prefix of the BPS that ends with the opening parenthesis of node $i-1$, and the stack $\mathcal{Q}$ contains exactly the nodes on the path from $i-1$ (topmost stack element) to the root 0 (bottommost stack element). A loop is used to find the topmost element $j$ on the stack that satisfies $j = 0$ or $T[j..n] \prec T[i..n]$ (lines 4–8). By properties (a) and (b), the final value of $j$ is the previous smaller suffix of $i$, which means that node $i$ will be attached as a child of $j$. Hence we pop the nodes on the path from $i-1$ to $j$ (but excluding $j$) from the stack, and then push $i$ on the stack (lines 7 and 10). As explained earlier, the BPS encodes a depth-first traversal of this tree. In terms of this traversal, we just moved from node $i-1$ up to node $j$, and then down to node $i$. Thus, we write one closing parenthesis for each step up (line 6), and then one opening parenthesis for moving down to node $i$ (line 9). After processing position $n$, we write the closing parentheses of the nodes on the path from $n$ to 0 (line 11).

The correctness follows from properties (a) and (b). Each line takes constant time, except for the lexicographical suffix comparison in line 5. It holds $T[i..n] \prec T[j..n]$ if and only if either $\text{LCE}(i,j) = n-i+1$ or $T[i+\text{LCE}(i,j)] < T[j+\text{LCE}(i,j)]$. Thus, the LCE data structure from Lemma 1 suffices to lexicographically compare suffixes in constant time (we use this technique repeatedly throughout the paper). The number of inner loop iterations is less than the number of closing parentheses, and hence the total time needed by the algorithm is $\mathcal{O}(n)$.

## 3 A Blockwise Algorithm for the PSS Tree

In this section, we modify Algorithm 1 such that instead of processing a single index at a time, it processes blocks of indices in each step. The block size $k = \left\lfloor \frac{\log_2 n}{8\lceil \log_2 \sigma \rceil} \right\rfloor$ is approximately one eighth of the number of symbols that fit into one word of memory, and hence there are $N = \lceil \frac{n}{k} \rceil = \Theta(n/\log_\sigma n)$ blocks. Let $B_1, \ldots, B_N$ with $\forall x \in [1, N] : B_x = (xk - k, xk]$ be the sequence of blocks (where without loss of generality we assume that $k$ divides $n$).

In the PSS tree, each block $B_x$ induces a forest that contains exactly the nodes that are members of the block. For any node $j \in B_x$, if $\mathsf{pss}[j] \in B_x$, then $\mathsf{pss}[j]$ is the parent of $j$ in the forest induced by $B_x$. Otherwise, $j$ is the root of a tree in the forest. We call these trees *small trees*, and their roots *small roots*. The small roots are exactly the left-to-right lexicographical minima of suffixes starting in $B_x$, i.e., $i \in B_x$ is a root if and only if $\forall i' \in B_x : i' < i \implies T[i'..n] \succ T[i..n]$. Just like in the PSS tree, we arrange the children of each node in increasing order. The BPS of the forest is the concatenation of the BPSs of its small trees in left-to-right order.

**High-Level Description of the Blockwise Algorithm.** We process the blocks one at a time in left-to-right order. At the time at which we process block $B_x$, we have already computed the partial PSS tree induced by all previous blocks, i.e., by $[0, xk - k]$. For $B_x$, we first obtain its induced PSS forest. Our goal is to attach the small roots (including their small trees) to the respective previous smaller suffixes, which lie on the path from $xk - k$ to 0 in the partial PSS tree. This is schematically shown in Figure 2a. Note that small roots further to the right will be attached further up in the path. This is because suffixes on the path are lexicographically decreasing towards the root, while the suffixes corresponding to small roots are lexicographically decreasing from left to right. Hence our task is to lexicographically *interleave* the path with the small roots. For an efficient implementation of this interleaving process, it is crucial that we maintain the path from $xk - k$ to 0 in a blockwise manner. Just like in Algorithm 1, we maintain a stack of the nodes on the path. However, each stack element is a pair $(y, \mathcal{L})$, where $y$ indicates that we consider block $B_y$, and $\mathcal{L}[1..k]$ is a bitvector indicating which of the positions in the block are relevant. For $j' \in [1, k]$, it holds $\mathcal{L}[j'] = 1$ if and only if $yk - k + j'$ lies on the path from $xk - k$ to 0. The stack then contains exactly the blocks with at least one 1-bit in the bitvector. This is visualized in Figure 2a.

## 3.1 Detailed Description of the Blockwise Algorithm

So far, we described the algorithm in terms of the PSS tree. However, we want to directly compute its BPS. After $\mathcal{O}(N)$ preprocessing time, we can obtain the BPS of the forest induced by any block in $\mathcal{O}(1)$ time. This follows directly from the lemma below.

▶ **Lemma 3.** *Let $T \in [0, \sigma)^n$ be a string in packed representation and let $\epsilon \in \mathbb{R}^+$. After $\mathcal{O}(n/\log_\sigma n)$ preprocessing time, the following type of query can be answered in $\mathcal{O}(1)$ time. Given a range $[i, i + \ell) \subseteq [1, n]$ of length $\ell \leq \frac{\log_2 n}{(2+\epsilon)\lceil \log_2 \sigma \rceil}$, output the BPS of the PSS forest induced by $[i, i + \ell)$, as well as a bitvector $\mathcal{R}[1..\ell]$ such that for $j \in [1, \ell]$ it holds $\mathcal{R}[j] = 1$ if and only if $i + j - 1$ is the root of a tree in the forest.*

The proof of the lemma is provided in Section 4. When we lexicographically interleave the suffixes, we will repeatedly encounter another type of query. Given a small root, we have to find its previous smaller suffix within a block on the stack. A solution for this is provided by the lemma below, which we prove in Section 5.

▶ **Lemma 4.** *Let $T \in [0, \sigma)^n$ be a string in packed representation and let $\epsilon \in \mathbb{R}^+$. After $\mathcal{O}(n/\log_\sigma n)$ preprocessing time, we can answer the following type of query in $\mathcal{O}(1)$ time. Given a position $i \in [1, n]$ and a non-empty interval $[j, j+\ell) \subseteq [1, n]$ of length $\ell \leq \frac{\log_2 n}{(5+\epsilon)\cdot\lceil \log_2 \sigma \rceil}$, find the position $j_{\max} = \max(\{j' \in [j, j + \ell) \mid T[j'..n] \prec T[i..n]\} \cup \{j - 1\})$.*

Now we have all the tools needed to describe the algorithm. We start with an empty stack $\mathcal{Q}$ and $\mathcal{B} = (,$ i.e., with the opening parenthesis of the artificial root node 0. Now we process the blocks $B_1, \ldots, B_N$ in left-to-right order. At the time at which we start processing

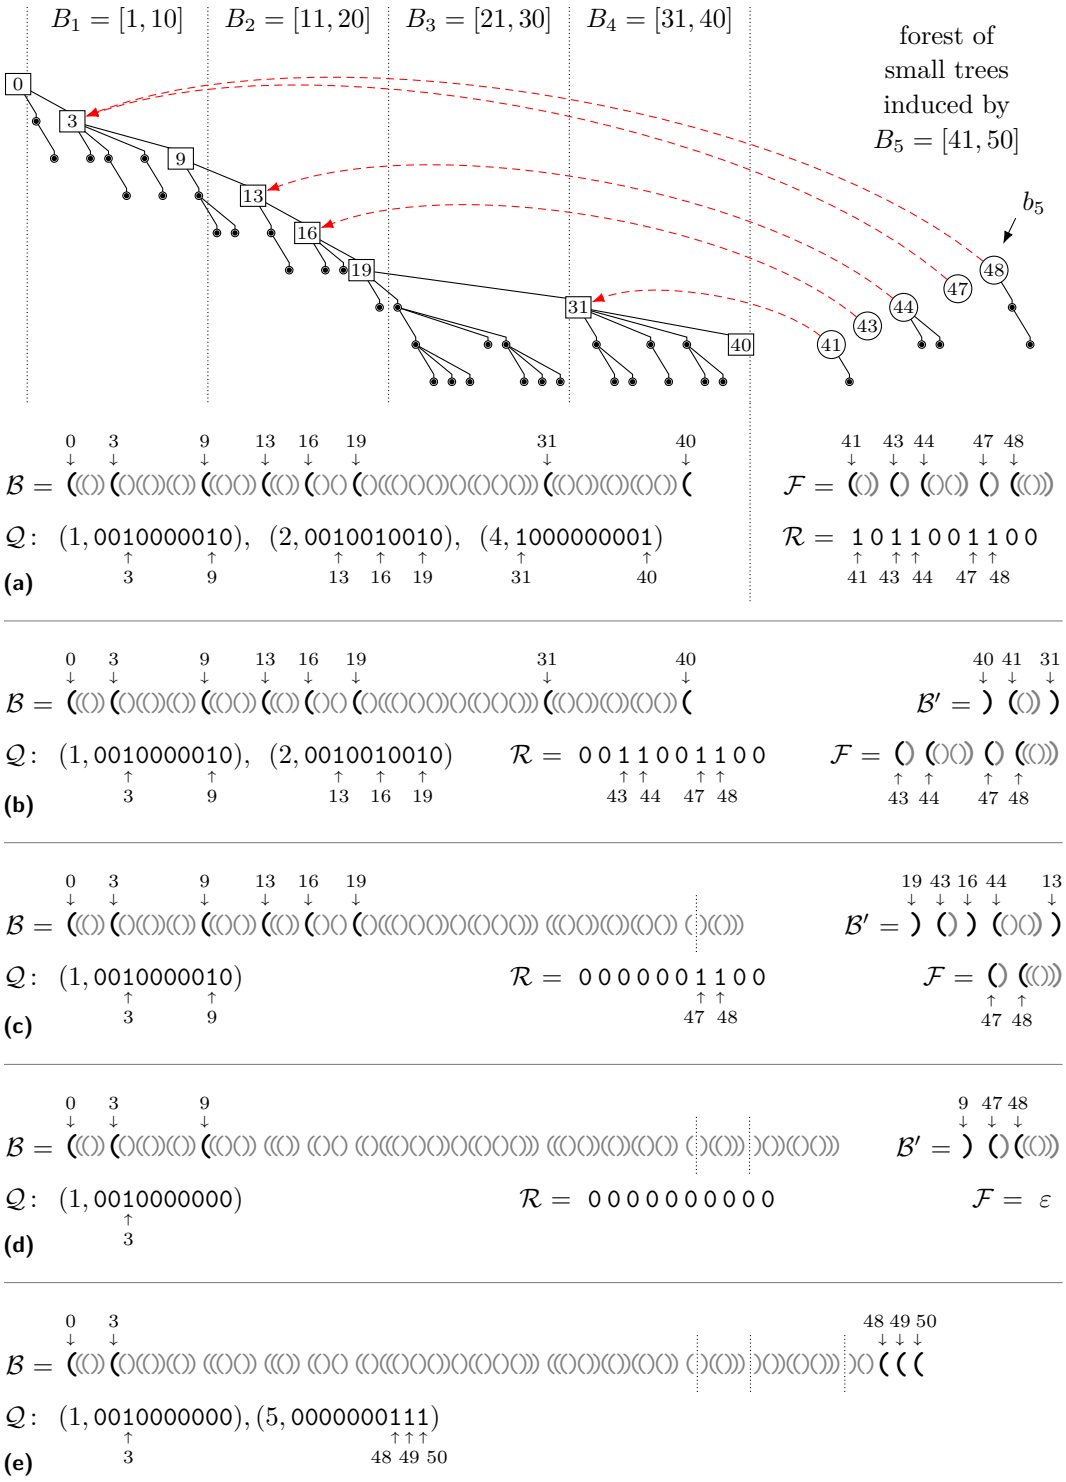


**Figure 2** Data structures during the execution of the blockwise algorithm with block size $k = 10$. While processing $B_5 = [41..50]$, the dashed edges will be inserted into the partial PSS tree induced by $[0..40]$. The drawings show the state of the relevant data structures before calling the subroutine during the first iteration of the main routine (a), and after calling the subroutine in the first (b), second (c), and third (d) iteration of the main routine. The state after finalizing $B_5$ is shown in (e).

$B_x$, the stack $\mathcal{Q}$ contains the nodes on the path from $xk-k$ to 0 in the blockwise manner described above, and $\mathcal{B}$ contains the prefix of the BPS of the PSS tree that ends with the opening parenthesis of node $xk-k$. We start by querying Lemma 3 with $B_x$ and obtain the BPS $\mathcal{F}$ of the forest induced by $B_x$, as well as the bitvector $\mathcal{R}$ indicating the small roots. We then find the rightmost 1-bit in $\mathcal{R}$ in constant time (there are only $2^k = \mathcal{O}(\sqrt[8]{n})$ possible values of $\mathcal{R}$, hence a lookup table for rightmost or leftmost 1-bits can be precomputed in $o(n/\log n)$ time). If this bit is at position $\mathcal{R}[b'_x]$, then $b_x = b'_x + xk - k$ is the rightmost small root in the forest induced by $B_x$. Note that $T[b_x..n]$ is the lexicographically smallest suffix starting in $B_x$. The state after this step is visualized in Figure 2a. Now we repeatedly run the interleaving main routine described below, during which we will alter $\mathcal{F}$, $\mathcal{R}$, $\mathcal{Q}$, and $\mathcal{B}$.

**Main Routine.** The goal of this routine is to interleave (the remaining small trees of) $B_x$ with the topmost block on the stack. If $\mathcal{F}$ is empty (which happens if and only if $\mathcal{R}$ contains only zeroes), then we have attached all small trees and the main routine terminates. Otherwise, if $\mathcal{Q}$ is empty, the remaining small trees need to be attached to the root of the PSS tree, and we append $\mathcal{F}$ to $\mathcal{B}$. This takes $\mathcal{O}(1)$ time and also terminates the main routine.

If neither $\mathcal{F}$ nor $\mathcal{Q}$ are empty, then we retrieve and pop the topmost pair $(y, \mathcal{L})$ from $\mathcal{Q}$. We use Lemma 4 to obtain $b_y = \max(\{j' \in B_y \mid T[j'..n] \prec T[b_x..n]\} \cup \{yk-k\})$, and the corresponding within-block offset $b'_y = b_y - yk + k$. If $\mathsf{pss}[b_x] \in B_y$ then $b_y = \mathsf{pss}[b_x]$, and all remaining small trees have to be attached to nodes from $B_y \cap [b_y, n]$. Since $b_x$ will be attached to $b_y$, none of the nodes from $B_y \cap (b_y, n]$ will remain on the stack. Hence we compute a bitvector $\mathcal{L}'[1..k]$ where for $j' \in [1,k]$ it holds $\mathcal{L}'[j'] = 1$ if and only if $\mathcal{L}[j'] = 1$ and $j' \leq b'_y$ (this takes constant time using bitwise operations). We then push $(y, \mathcal{L}')$ back onto the stack. If however $\mathsf{pss}[b_x] \notin B_y$, then $b_y = yk - k$ (the first position to the left of $B_y$) and $b_x$ will be attached to a node in a block left of $B_y$. This means that block $B_y$ will no longer be on the stack. Note that either way $\forall j' \in (b_y, b_x) : T[j'..n] \succ T[b_x..n]$.

Our next task is as follows. We have to attach some (possibly none, possibly all) of the remaining small trees to nodes in $B_y$. We reflect this change in $\mathcal{F}$ and $\mathcal{R}$ by removing the corresponding prefix of $\mathcal{F}$, and setting the corresponding bits in $\mathcal{R}$ to 0. Simultaneously, we extend $\mathcal{B}$ such that it contains the newly attached small trees, possibly interleaved with additional closing parentheses of nodes from $B_y$. This is realized by the following interleaving subroutine, which we run in a loop (and which will later be replaced by a single constant time table lookup). A sequence $\mathcal{B}'$ is used to buffer the parentheses that we will append to $\mathcal{B}$.

**Subroutine.** If either $\mathcal{L}$ or $\mathcal{R}$ consists only of 0-bits, we terminate the subroutine. Otherwise, we obtain the rightmost 1-bit of $\mathcal{L}$ (with a lookup table). If this bit is at position $\mathcal{L}[j']$, then the corresponding absolute position is $j = j' + yk - k$. If $j' = b'_y$ (which is equivalent to $j = b_y = \mathsf{pss}[b_x]$), then all remaining small trees need to be attached to $j$, and we append $\mathcal{F}$ to $\mathcal{B}'$. We replace $\mathcal{F}$ with $\varepsilon$ and $\mathcal{R}$ with an all-zero bitvector. This terminates the subroutine.

Otherwise (i.e., if $j' > b'_y$ or equivalently $j > b_y$), we obtain the leftmost 1-bit of $\mathcal{R}$ (with a lookup table). If this bit is at position $\mathcal{R}[i']$, then $i = i' + xk - k$ is the leftmost small root that we still have to attach. Now we have to determine if $T[i..n] \prec T[j..n]$. (This state is equivalent to reaching the head of the inner loop of Algorithm 1 with the current values of $i$ and $j$.) It holds $T[i..n] \prec T[j..n]$ if and only if $T[i..b_x) \preceq T[j..j + b_x - i)$. This is because $j + b_x - i \in (b_y, b_x)$, and hence we have already established that $T[b_x..n] \prec T[j + b_x - i..n]$. Thus, if $T[i..b_x) = T[j..j + b_x - i)$, it immediately follows that $T[i..n] \prec T[j..n]$. Note that $T[i..b_x)$ and $T[j..j + b_x - i)$ are substrings of $T(xk-k..xk]$ and $T(yk-k..yk+k]$ respectively, which will later be relevant for an efficient implementation. If $T[i..n] \prec T[j..n]$, then we

append ) to $\mathcal{B}'$ (this is the closing parenthesis of node $j$), and we assign $\mathcal{L}[j'] = 0$. If, however, $T[i..n] \succ T[j..n]$, then $\mathsf{pss}[i] = j$. In this case, we take the prefix of $\mathcal{F}$ that corresponds to the small tree rooted in $i$ (which is the shortest balanced prefix of $\mathcal{F}$), and append it to $\mathcal{B}'$. We remove this prefix from $\mathcal{F}$ and assign $\mathcal{R}[i'] = 0$. We then continue with the next iteration of the subroutine. After the subroutine terminates, we append $\mathcal{B}'$ to $\mathcal{B}$ and continue with the next iteration of the main routine. Figures 2b–2d shows the result of the subroutine in three consecutive iterations of the main routine.

**Finalizing the Block.** Once the main routine terminates for block $B_x$, we have attached all the small trees of $B_x$ to $\mathcal{B}$. The stack $\mathcal{Q}$ contains the blockwise representation of all the nodes on the path from $xk$ to 0, except for the ones in block $B_x$. Before we can continue with the next iteration of the main routine, we have to push $(x, \mathcal{L}'')$ on the stack, where the 1-bits in $\mathcal{L}''$ correspond to the nodes on the path from $xk$ to $b_x$. Note that this information can be obtained from the state of $\mathcal{F}$ at the beginning of the main routine iteration. Since $\mathcal{F}$ is a bitvector of length $2k$, a lookup table $W[1..2^{2k}]$ suffices to store the bitvector $\mathcal{L}''$ for each possible $\mathcal{F}$. The table has $\mathcal{O}(\sqrt[4]{n})$ entries and can be filled naively in $\mathcal{O}(\sqrt[4]{n} \cdot \mathrm{polylog}(n)) \subset \mathcal{O}(n/\log n)$ time. Once we need $\mathcal{L}''$, we simply lookup $W[\mathsf{int}(\mathcal{F})]$ in constant time. Finally, in order to continue, the last written parenthesis needs to be the opening parenthesis of $xk$. Hence we remove the at most $k$ trailing closing parentheses of $\mathcal{B}$ (in constant time, using another lookup table), and then continue by processing block $B_{x+1}$. Figure 2e shows the running example after finalizing the processed block.

After block $B_N$ has been processed, we finish the algorithm execution by appending the $2n + 2 - |\mathcal{B}|$ closing parentheses of the nodes on the path from $n$ to 0. This can be done in $\mathcal{O}(n/\log n)$ time by appending them one word (rather than one parenthesis) at a time.

## 3.2 Analyzing the Time Complexity

The initial and final processing of each block (i.e., computing $\mathcal{F}$, $\mathcal{R}$, $b_x$, and the pair $(x, \mathcal{L}'')$ to push on the stack) takes constant time. There are exactly $N$ terminal iterations of the main routine, i.e., iterations where either $\mathcal{F}$ or $\mathcal{Q}$ is empty. Each terminal iteration takes constant time. In each of the non-terminal iterations, we pop a pair $(y, \mathcal{L})$ from the stack. If we do not push an updated pair $(y, \mathcal{L}')$ back onto the stack, then block $B_y$ will never participate in the stack again, and hence this case occurs at most $N$ times. If, however, we do push an updated pair $(y, \mathcal{L}')$ back onto the stack, then during the same main routine iteration we will also attach all remaining small trees of $B_x$ to the partial PSS tree, which can also occur only $N$ times. Hence the total number of iterations of the main routine is $\mathcal{O}(N)$. In each non-terminal iteration of the main routine, we call the subroutine exactly once (even though a single call may lead to multiple iterations of the subroutine). Apart from this call, each iteration of the main routine takes constant time.

It remains to be shown how to implement the subroutine such that the $\mathcal{O}(N)$ calls take $\mathcal{O}(n/\log_\sigma n)$ time in total. A straightforward naive implementation takes $\mathcal{O}(\mathrm{poly}(k)) \subseteq \mathcal{O}(\mathrm{polylog}(n))$ time per call. Note that the subroutine only accesses the following information: $\mathcal{L}$, $b'_y$, $\mathcal{R}$ (which allows access to $b'_x$), $\mathcal{F}$, and substrings $T_y = T(yk - k..yk + k]$ and $T_x = T(xk - k..xk]$. Bitvectors $\mathcal{L}$ and $\mathcal{R}$ are of length $k$ bits each; $b'_y$ is an integer from $[0, k]$ and hence can be encoded in $\lceil \log_2(k+1) \rceil \leq \lfloor 0.99k \rfloor$ bits (for sufficiently large $k$); sequence $\mathcal{F}$ is of length at most $2k$ bits; strings $T_y$ and $T_x$ in packed representation require $2k \lceil \log_2 \sigma \rceil$ and $k \lceil \log_2 \sigma \rceil$ bits respectively. This motivates a lookup table

$$M[1..2^k][1..2^{\lfloor 0.99k \rfloor}][1..2^k][1..2^{2k}][1..2^{2k\lceil \log_2 \sigma \rceil}][1..2^{k\lceil \log_2 \sigma \rceil}].$$

In entry $M[\mathsf{int}(\mathcal{L})][b'_y][\mathsf{int}(\mathcal{R})][\mathsf{int}(\mathcal{F})][\mathsf{int}(T_y)][\mathsf{int}(T_x)]$, we store $\mathcal{B}'$ as well as the new values of $\mathcal{R}$ and $\mathcal{F}$ after running the subroutine. Note that $\mathcal{B}'$ is of length at most $3k$ because it contains at most all the parentheses from $\mathcal{F}$ and one closing parenthesis per 1-bit in $\mathcal{L}$. Hence the information stored in each table entry fits in a constant number of words, and can be retrieved in constant time. We fill the table in a lazy manner. Initially, we mark each entry as uninitialized. When accessing $M[\mathsf{int}(\mathcal{L})][b'_y][\mathsf{int}(\mathcal{R})][\mathsf{int}(\mathcal{F})][\mathsf{int}(T_y)][\mathsf{int}(T_x)]$, we check if this entry is marked. If it is, then we run the naive $\mathcal{O}(\mathrm{polylog}(n))$ time algorithm for the subroutine, store the result in the entry, and remove its marking. Otherwise, the entry already contains the values of $\mathcal{B}'$, $\mathcal{R}$, and $\mathcal{F}$ after running the subroutine, and we return them in constant time. The lookup table has at most $2^{7.99k\lceil\log_2\sigma\rceil} \leq 2^{\log_2 n \cdot 7.99/8} = n^{7.99/8}$ entries. Computing one entry takes $\mathcal{O}(\mathrm{polylog}(n))$ time. Thus, the entire time spent on filling the table (i.e., on running the subroutine naively) is $\mathcal{O}(n^{7.99/8} \cdot \mathrm{polylog}(n)) \subset \mathcal{O}(n/\log n)$. Additional $\mathcal{O}(n/\log_\sigma n)$ preprocessing time is needed for Lemmas 1, 3, and 4.

## 4 Proving Lemma 3

A key insight for the proof of Lemma 3 is that the lexicographical order of suffixes starting in a small range almost entirely depends on a short substring. This is formally expressed by the auxiliary lemma below.

▶ **Lemma 5.** *Let $T[1..n]$ be a string over a totally ordered alphabet, and let $[i, i+2\ell) \subseteq [1, n]$ be a non-empty interval of even length. Then at least one of the following properties holds:*

- $\forall x, y \in [i, i+\ell) : T[x..n] \prec T[y..n] \iff T[x..i+2\ell) \prec T[y..i+2\ell)$, *or*
- $\forall x, y \in [i, i+\ell) : T[x..n] \prec T[y..n] \iff T[x..i+2\ell)\# \prec T[y..i+2\ell)\#$,

  *where $\#$ is an infinitely large symbol, i.e., $\forall i' \in [1, n] : T[i'] < \#$.*

**Proof.** Let $\tilde{n} = i + 2\ell$. Assume that the lemma does not hold, then there are indices $x_1, x_2, y_1, y_2 \in [i, i+\ell)$ such that $T[x_1..n] \prec T[y_1..n]$ but $T[x_1..\tilde{n}) \succ T[y_1..\tilde{n})$, and $T[x_2..n] \prec T[y_2..n]$ but $T[x_2..\tilde{n})\# \succ T[y_2..\tilde{n})\#$. It is easy to see that this implies

$$\begin{aligned} T[y_1..\tilde{n}) &\prec T[x_1..\tilde{n}) \prec T[x_1..n] \prec T[y_1..n] = T[y_1..\tilde{n})T[\tilde{n}..n], \text{ and} \\ T[x_2..\tilde{n})\# &\succ T[y_2..\tilde{n})\# \succ T[y_2..n] \succ T[x_2..n] = T[x_2..\tilde{n})T[\tilde{n}..n]. \end{aligned}$$

Due to first condition, $T[y_1..\tilde{n})$ is a proper prefix of $T[x_1..\tilde{n})$ and it holds $x_1 < y_1$. Note that $T[y_1..\tilde{n})$ is therefore also a proper suffix (and hence a border) of $T[x_1..\tilde{n})$, and thus $T[x_1..\tilde{n})$ has period $p_1 = (y_1 - x_1)$. By the same reasoning, the second condition implies that $T[x_2..\tilde{n})$ is a border of $T[y_2..\tilde{n})$. Hence $y_2 < x_2$, and $T[y_2..\tilde{n})$ has period $p_2 = (x_2 - y_2)$. By combining these observations with the initial assumption, we obtain

$$\begin{aligned} T[y_1..\tilde{n})T[\tilde{n}-p_1..n] &= T[x_1..n] \prec T[y_1..n] = T[y_1..\tilde{n})T[\tilde{n}..n], \quad \text{and} \\ T[x_2..\tilde{n})T[\tilde{n}..n] &= T[x_2..n] \prec T[y_2..n] = T[x_2..\tilde{n})T[\tilde{n}-p_2..n]. \end{aligned}$$

The former implies $T[\tilde{n}-p_1..n] \prec T[\tilde{n}..n]$, the latter implies $T[\tilde{n}..n] \prec T[\tilde{n}-p_2..n]$. Hence

$$T[\tilde{n}-p_1..\tilde{n})T[\tilde{n}..n] \prec T[\tilde{n}..n] \prec T[\tilde{n}-p_2..\tilde{n})T[\tilde{n}..n].$$

Since $T[\max(x_1, y_2)..\tilde{n})$ is a suffix of both $T[x_1..\tilde{n})$ and $T[y_2..\tilde{n})$, it has periods $p_1$ and $p_2$. Note that $x_1 < i + \ell - p_1$ and $y_2 < i + \ell - p_2$, and hence $T[\max(x_1, y_2)..\tilde{n})$ is of length $\tilde{n} - \max(x_1, y_2) > \tilde{n} - i - \ell + \min(p_1, p_2) = \ell + \min(p_1, p_2) > p_1 + p_2$. Therefore, it follows from the periodicity lemma [18] that $T[\max(x_1, y_2)..\tilde{n})$ has period $p_0 = \gcd(p_1, p_2)$. Since

both $T[\tilde{n}-p_1..\tilde{n})$ and $T[\tilde{n}-p_2..\tilde{n})$ are suffixes of $T[\max(x_1,y_2)..\tilde{n})$, they also have period $p_0$. Let $\alpha = T[\tilde{n}-p_0..\tilde{n})$, $k_1 = p_1/p_0$ and $k_2 = p_2/p_0$. Then both $k_1$ and $k_2$ are positive integers, and it holds $T[\tilde{n}-p_1..\tilde{n}) = \alpha^{k_1}$ and $T[\tilde{n}-p_2..\tilde{n}) = \alpha^{k_2}$. Let $k_0$ be the largest integer (possibly 0) such that $T[\tilde{n}..n] = \alpha^{k_0}T[\tilde{n}+k_0p_0..n]$, and let $\beta = T[\tilde{n}+k_0p_0..n]$. Then $\alpha$ is not a prefix of $\beta$. The inequality above can be written as $\alpha^{k_1+k_0}\beta \prec \alpha^{k_0}\beta \prec \alpha^{k_2+k_0}\beta$. However, this is equivalent to $\alpha^{k_1}\beta \prec \beta \prec \alpha^{k_2}\beta$, which implies that $\alpha$ is a prefix of $\beta$. Due to this contradiction, the initial assumption must be false, and the lemma holds. ◀

Now we are ready to show Lemma 3, which is restated below.

▶ **Lemma 3.** *Let $T \in [0,\sigma)^n$ be a string in packed representation and let $\epsilon \in \mathbb{R}^+$. After $\mathcal{O}(n/\log_\sigma n)$ preprocessing time, the following type of query can be answered in $\mathcal{O}(1)$ time. Given a range $[i,i+\ell) \subseteq [1,n]$ of length $\ell \leq \frac{\log_2 n}{(2+\epsilon)\lceil\log_2\sigma\rceil}$, output the BPS of the PSS forest induced by $[i,i+\ell)$, as well as a bitvector $\mathcal{R}[1..\ell]$ such that for $j \in [1,\ell]$ it holds $\mathcal{R}[j] = 1$ if and only if $i+j-1$ is the root of a tree in the forest.*

**Proof.** The answer to any query $[i,i+\ell)$ is a parentheses sequence of length exactly $2\ell$ and a bitvector of length $\ell$. Hence it fits in a constant number of words. Let $\ell_{\max} = \left\lfloor \frac{\log_2 n}{(2+\epsilon)\cdot\lceil\log_2\sigma\rceil} \right\rfloor$. We precompute a 2D lookup table $E[1..2\ell_{\max}][1..\ell_{\max}]$ with the purpose of answering the subset of queries that satisfy $i+2\ell_{\max} > n$. For any such query $[i,i+\ell)$, it holds $n-i+1 \in [1,2\ell_{\max}]$, and we explicitly store its answer in $E[n-i+1][\ell]$. Since these queries only consider suffixes of length $\mathcal{O}(\log n)$, each of the $\mathcal{O}(\log^2 n)$ table entries can be computed naively in $\mathcal{O}(\text{polylog}(n))$ time.

We answer the remaining queries using the LCE data structure from Lemma 1 and additional lookup tables. For each possible value of $\ell$, we construct tables $A_\ell[1..2^{2\ell\lceil\log_2\sigma\rceil}]$ and $B_\ell[1..2^{2\ell\lceil\log_2\sigma\rceil}]$. For every string $S \in [0,\sigma)^{2\ell}$, we store at position $A_\ell[\mathsf{int}(S)]$ the BPS of the PSS forest of $S$ that is induced by $[1,\ell]$, as well as the bitvector that indicates the roots. At position $B_\ell[\mathsf{int}(S)]$, we store the BPS of the PSS forest of $S\#$ that is induced by $[1,\ell]$, as well as the bitvector that indicates the roots.

When answering query $[i,i+\ell)$, we first extract $T' = T[i,i+2\ell)$. Due to Lemma 5, the answer to the query is either $A_\ell[\mathsf{int}(T')]$ or $B_\ell[\mathsf{int}(T')]$. A table $C_\ell[1..2^{2\ell\lceil\log_2\sigma\rceil}]$ is used to decide which answer is correct. For every string $S \in [0,\sigma)^{2\ell}$, we store at position $C_\ell[\mathsf{int}(S)]$ an integer pair $(x,y) \in [1,\ell]^2$ such that $S[x..2\ell] \prec S[y..2\ell]$ and $S[x..2\ell]\# \succ S[y..2\ell]\#$ (or $x=y=1$ if such a pair does not exist). This is as a witness pair of suffixes for which $S$ and $S\#$ disagree on the lexicographical order. At query time, we lookup $(\hat{x},\hat{y}) = C_\ell[T']$. If $T[i+\hat{x}-1..n] \prec T[i+\hat{y}-1..n]$, then we return $A_\ell[\mathsf{int}(T')]$, and otherwise we return $B_\ell[\mathsf{int}(T')]$. The correctness follows from Lemma 5. Testing $T[i+\hat{x}-1..n] \prec T[i+\hat{y}-1..n]$ takes constant time with the LCE data structure from Lemma 1. Extracting $T'$ and performing table lookups also takes constant time because $T'$ fits in a single word of memory.

A single lookup table entry can be computed naively in $\mathcal{O}(\text{polylog}(n))$ time. There are $\mathcal{O}(\log n)$ tables, each storing at most $2^{2\ell_{\max}\lceil\log_2\sigma\rceil} \leq 2^{\log_2 n/(1+\epsilon/2)} = \sqrt[1+\epsilon/2]{n}$ entries. Thus, the precomputation of lookup tables takes $\mathcal{O}(\sqrt[1+\epsilon/2]{n}\cdot\text{polylog}(n))$ time, which is dominated by the $\mathcal{O}(n/\log_\sigma n)$ time needed to construct the LCE data structure. ◀

## 5 Proving Lemma 4

The proof of Lemma 4 relies on the properties of periodic substrings that are stated below.

▶ **Proposition 6.** *Let $\alpha$, $\beta$, and $\gamma$ be arbitrary strings. The following properties hold.*

1. *If $\alpha\beta \succ \beta$ and $\alpha\gamma \prec \gamma$ then $\beta \prec \gamma$.*
2. *If $\alpha\gamma \prec \gamma$ and $\alpha$ is not a prefix of $\gamma$, then $\forall x,y \in \mathbb{N}^0 : x > y \implies \alpha^x\beta \prec \alpha^y\gamma$.*

**Proof.** We start with (1). Let $k \in \mathbb{N}^0$ be the maximal value such that both $\beta = \alpha^k\beta'$ and $\gamma = \alpha^k\gamma'$ for some (possibly empty) strings $\beta'$ and $\gamma'$. If $\alpha^{k+1}\beta' \succ \alpha^k\beta'$ and $\alpha^{k+1}\gamma' \prec \alpha^k\gamma'$, then $\beta' \prec \alpha\beta'$ and $\alpha\gamma' \prec \gamma'$. Now assume that $\gamma' \preceq \beta'$, then $\alpha\gamma' \prec \gamma' \preceq \beta' \prec \alpha\beta'$. However, this implies that $\alpha$ is a prefix of both $\beta$ and $\gamma$, which contradicts the definition of $k$. Thus $\beta' \prec \gamma'$, which also implies $\beta = \alpha^k\beta' \prec \alpha^k\gamma' = \gamma$. For (2), consider any $x, y \in \mathbb{N}^0$ with $x > y$, and assume that $\alpha\gamma \prec \gamma$. Since $\alpha$ is not a prefix of $\gamma$, it follows from $\alpha\gamma \prec \gamma$ that $\alpha\delta \prec \gamma$ for every string $\delta$. Hence also $\alpha^{x-y}\beta \prec \gamma$, which implies $\alpha^x\beta = \alpha^y\alpha^{x-y}\beta \prec \alpha^y\gamma$. ◀

Now we are ready to show Lemma 4, which is restated below.

▶ **Lemma 4.** *Let $T \in [0,\sigma)^n$ be a string in packed representation and let $\epsilon \in \mathbb{R}^+$. After $\mathcal{O}(n/\log_\sigma n)$ preprocessing time, we can answer the following type of query in $\mathcal{O}(1)$ time. Given a position $i \in [1,n]$ and a non-empty interval $[j, j+\ell) \subseteq [1,n]$ of length $\ell \leq \frac{\log_2 n}{(5+\epsilon)\cdot\lceil\log_2\sigma\rceil}$, find the position $j_{\max} = \max(\{j' \in [j, j+\ell) \mid T[j'..n] \prec T[i..n]\} \cup \{j-1\})$.*

**Proof.** Similarly to what was done in Lemma 3, we spend $\mathcal{O}(\text{polylog}(n))$ time to precompute the answers to all queries that satisfy $j + 3\ell \geq n$ or $i + 2\ell \geq n$. For any of the remaining queries, we consider the set

$$C = \{j' \in [j, j+\ell) \mid T[j'..j'+2\ell) = T[i..i+2\ell)\} = \{c_1, c_2, \ldots, c_h\}$$

with $c_1 < c_2 < \cdots < c_h$. This set contains exactly the positions $j' \in [j, j+\ell)$ for which we cannot easily determine whether $T[j'..n] \prec T[i..n]$ by inspecting only a small number of symbols. Hence it captures the difficult part of answering a query, and we treat it separately from the rest. We answer the query using the following subsets of $[j, j+\ell)$:

- $D' = \{j' \in C \mid T[j'..n] \prec T[i..n]\}$ (the hard subset), and
- $D'' = \{j' \in [j, j+\ell) \setminus C \mid T[j'..n] \prec T[i..n]\}$ (the easy subset).

The result of the query is $j_{\max} = \max(j'_{\max}, j''_{\max})$, where $j'_{\max} = \max(D' \cup \{j-1\})$ and $j''_{\max} = \max(D'' \cup \{j-1\})$. We start with the significantly harder task of computing $j'_{\max}$. First, we outline the algorithmic approach and the combinatorial properties of the present substrings (without giving details of an efficient implementation). Later, we describe lookup tables that achieve the claimed preprocessing and query times.

**Periodicity of $T[i..i+2\ell)$ and $T[c_1..c_h+2\ell)$.** We show that, if $|C| \geq 2$, then there is some $p$ such that $T[c_1..c_h+2\ell)$ has period $p$, and $\forall x \in [1,h) : c_{x+1} - c_x = p$. This is similar to [34, Lemma 1] and [28, Lemma 2]. Assume that $|C| \geq 2$. For $x \in [1,h)$, let $p_x = c_{x+1} - c_x < \ell$. By design of $C$, it holds $T[c_x..c_x+2\ell-p_x) = T[c_{x+1}..c_{x+1}+2\ell-p_x) = T[c_x+p_x..c_x+2\ell)$. This means that $T[i..i+2\ell) = T[c_x..c_x+2\ell)$ has a border of length $2\ell - p_x$, and therefore it has period $p_x$. Let $p$ be the smallest period of $T[i..i+2\ell)$. If there was some $x \in [1,h)$ such that $p_x < p$, then $p$ would not be the smallest period of $T[i..i+2\ell)$. Hence $p_x \geq p$. Now we show that $\forall x \in [1,h) : p_x = p$. For the sake of contradiction, assume $p_x > p$. By definition of $C$, it holds $p_x < \ell$, which means that $T[c_x..c_x+2\ell)$ and $T[c_{x+1}..c_{x+1}+2\ell)$ overlap by $c_x + 2\ell - c_{x+1} = 2\ell - p_x > \ell > p$ symbols. Due to this overlap, and because the identical substrings $T[c_x..c_x+2\ell)$ and $T[c_{x+1}..c_{x+1}+2\ell)$ have period $p$, it is clear that also their union $T[c_x..c_{x+1}+2\ell)$ has period $p$. However, this implies $T[c_x..c_x+2\ell) = T[c_x+p..c_x+p+2\ell)$, which means that $c_x + p$ should be in $C$. Due to this contradiction, it holds $p_x = p$. It also follows that $T[c_1..c_h+2\ell)$ has period $p$.

**Computing $j'_{\max}$ from $c_1$, $c_h$, and $p$.** We will later introduce lookup tables that output $c_1$, $c_h$, and $p$ for any query in constant time. The tables might return that $c_1$ and $c_h$ do not exist (i.e., $|C| = 0$), in which case we report $j'_{\max} = j - 1$. Otherwise, it might be that $c_1 = c_h$ (i.e., $|C| = 1$). In this case, we report that $j'_{\max} = c_1$ if $T[i..n] \succ T[c_1..n]$ (using an LCE query for the comparison). Otherwise, we report $j'_{\max} = j - 1$. It remains to be shown how to compute $j'_{\max}$ if $c_1 \neq c_h$ (i.e., if $|C| \geq 2$, and the previously described periodicity exists).

We evaluate $T[i..n] \prec T[i + p..n]$ and $T[c_h..n] \prec [c_h + p..n]$ (using LCE queries). Due to the periodicity of $T[c_1..c_h + 2\ell)$, for $x \in [1, h)$ it holds $T[c_h..n] \prec T[c_h + p..n]$ if and only if

$$T[c_x..n] \;=\; T[i..i+p)^{k-x}T[c_h..n] \;\prec\; T[i..i+p)^{k-x}T[c_h+p..n] \;=\; T[c_{x+1}..n].$$

Hence either $T[c_1..n] \prec T[c_2..n] \prec \cdots \prec T[c_h..n]$ or $T[c_1..n] \succ T[c_2..n] \succ \cdots \succ T[c_h..n]$, and we already know which of the two applies. Depending on the outcome of the lexicographical comparisons, we report $j'_{\max}$ according to one of the following three cases.

**Case 1:** $T[c_1..n] \succ T[c_2..n] \succ \cdots \succ T[c_h..n]$.

For the computation of $j'_{\max}$, we are only interested in the rightmost $x \in [1, h]$ such that $T[i..n] \succ T[c_x..n]$. Since $T[c_h..n]$ is both rightmost and lexicographically minimal among all the possible $T[c_x..n]$, we simply use another LCE query to check if $T[i..n] \succ T[c_h..n]$. If yes, we report $j'_{\max} = c_h$. Otherwise, we report $j'_{\max} = j - 1$.

**Case 2:** $T[i..n] \succ T[i + p..n]$ and $T[c_1..n] \prec T[c_2..n] \prec \cdots \prec T[c_h..n]$.

Let $\alpha = T[i..i + p)$, $\beta = T[i + p..n]$, and $\gamma = T[c_2..n]$. The precondition of this case means that $\alpha\beta \succ \beta$ and $\alpha\gamma \prec \gamma$. Proposition 6.1 implies $\beta \prec \gamma$, and thus also $T[i..n] = \alpha\beta \prec \alpha\gamma = T[c_1..n] \prec T[c_2..n] \prec \cdots \prec T[c_h..n]$. Hence we report $j'_{\max} = j - 1$.

**Case 3:** $T[i..n] \prec T[i + p..n]$ and $T[c_1..n] \prec T[c_2..n] \prec \cdots \prec T[c_h..n]$.

Let $\alpha = T[i..i+p)$. We compute $r = \lfloor \textsc{lce}(i, i + p)/p \rfloor + 1$ and $s = \lfloor \textsc{lce}(c_1, c_1 + p)/p \rfloor + 1$, i.e., the respectively maximal integer powers with $T[i..n] = \alpha^r\beta$ and $T[c_1..n] = \alpha^s\gamma$, where $\beta = T[i + rp..n]$ and $\gamma = T[c_1 + sp..n]$. The precondition of this case means that $\alpha^s\gamma \prec \alpha^{s-1}\gamma$, and thus also $\alpha\gamma \prec \alpha$. Note that $\alpha$ is not a prefix of $\gamma$. Hence Proposition 6.2 implies that $\alpha^r\beta \prec \alpha^{s'}\gamma$ for any $s' < r$. Thus, for $x \in [1, h]$, if $s-x+1 < r$ then $T[i..n] = \alpha^r\beta \prec \alpha^{s-x+1}\gamma = T[c_x..n]$. Hence we only have to consider $x \leq s - r + 1$. On the other hand, the precondition of the case also implies $\alpha^r\beta \prec \alpha^{r-1}\beta$, and thus $\alpha\beta \prec \alpha$. Also, $\alpha$ is not a prefix of $\beta$. Hence Proposition 6.2 (with swapped roles of $\beta$ and $\gamma$) implies that $\alpha^r\beta \succ \alpha^{s'}\gamma$ for any $s' > r$. For $x \in [1, h]$, if $x \leq s - r$ then $T[i..n] = \alpha^r\beta \succ \alpha^{s-x+1}\gamma = T[c_x..n]$.
This motivates the following strategy. If $s - r + 1 < 1$, then there is no suitable choice of $x$ and we report $j'_{\max} = j - 1$. If $k \leq s - r$, then $T[i..n] \succ T[c_h..n]$ and we report $j'_{\max} = c_h$. We are left with the case where $s - r + 1 \in [1, h]$. If $T[i..n] \succ T[c_{s-r+1}..n]$, then we report $j'_{\max} = c_{s-r+1}$ (we use another LCE query to achieve constant time). If we still have not reported anything, then we report $j'_{\max} = c_{s-r}$ if and only if $s - r \in [1, h]$ (we have already established that $T[i..n] \succ T[c_{s-r}..n]$). If, however, $s - r \notin [1, h]$, then we report $j'_{\max} = j - 1$.

The three cases are exhaustive, and it takes constant time to determine which case applies. Regardless of the case, we report $j'_{\max}$ in constant time. We require the LCE data structure from Lemma 1, and hence the preprocessing time is $\mathcal{O}(n/\log_\sigma n)$.

**Lookup Tables for $c_1$, $c_h$, $p$, and $j''_{\max}$.** As described above, we can compute $j'_{\max}$ in constant time if we can determine $c_1$, $c_h$, and $p$ in constant time. Note that these values depend solely on the substrings $T[i..i+2\ell)$ and $T[j..j+3\ell)$. This also holds for $j''_{\max}$, which can be written as $j''_{\max} = \max(\{j' \in [j, j+\ell) \mid T[j'..j'+2\ell) \prec T[i..i+2\ell)\} \cup \{j-1\})$. For each possible value of $\ell$, we compute a lookup table $L_\ell[1..2^{2\ell\lceil\log_2\sigma\rceil}][1..2^{3\ell\lceil\log_2\sigma\rceil}]$. Let $S_1 \in [0,\sigma)^{2\ell}$ and $S_2 \in [0,\sigma)^{3\ell}$ be packed strings. In entry $L_\ell[\mathsf{int}(S_1)][\mathsf{int}(S_2)]$, we store the quadruple $\langle \hat{p}, \hat{c}_{\min}, \hat{c}_{\max}, \hat{y}_{\max}\rangle$, where

- $\hat{p}$ is the shortest period of $S_1$,
- $\hat{c}_{\min} = \min(\{x' \in [1,\ell] \mid S_2[x'..x'+2\ell) = S_1\} \cup \{\infty\})$,
- $\hat{c}_{\max} = \max(\{x' \in [1,\ell] \mid S_2[x'..x'+2\ell) = S_1\} \cup \{-\infty\})$,
- $\hat{y}_{\max} = \max(\{x' \in [1,\ell] \mid S_2[x'..x'+2\ell) \prec S_1\} \cup \{-\infty\})$.

A single entry $L_\ell[\mathsf{int}(S_1)][\mathsf{int}(S_2)]$ can be computed naively in $\mathcal{O}(\mathrm{poly}(\ell)) \subseteq \mathcal{O}(\mathrm{polylog}(n))$ time. Table $L_\ell$ has $2^{5\ell\lceil\log_2\sigma\rceil} \leq 2^{\log_2 n/(1+\epsilon/5)} = \sqrt[1+\epsilon/5]{n}$ entries, and there are $\mathcal{O}(\log n)$ tables. Thus, the entire preprocessing time is $\mathcal{O}(\sqrt[1+\epsilon/5]{n} \cdot \mathrm{polylog}(n)) \subset \mathcal{O}(n/\log_\sigma n)$. Whenever we have to answer a query $i$, $[j, j+\ell)$, we extract $T' = T[i..i+2\ell)$ and $T'' = T[j..j+3\ell)$ and lookup $\langle p, c_{\min}, c_{\max}, y_{\max}\rangle = L_\ell[\mathsf{int}(T')][\mathsf{int}(T'')]$. This takes constant time because $T'$ and $T''$ fit in a single word of memory. From the construction of $L_\ell$, it is clear that

- $p$ is the shortest period of $T[i..i+2\ell)$.
- If $c_{\min} \neq \infty$ then $c_1 = j + c_{\min} - 1$. Otherwise, $c_0$ does not exist.
- If $c_{\max} \neq -\infty$ then $c_h = j + c_{\max} - 1$. Otherwise, $c_h$ does not exist.
- If $y_{\max} \neq -\infty$ then $j''_{\max} = j + y_{\max} - 1$. Otherwise, $j''_{\max} = j - 1$.

Hence we can compute $j'_{\max}$ in constant time as described above, and output the query result $j_{\max} = \min(j'_{\max}, j''_{\max})$ in constant time. ◀

## Abstract

Wheeler nondeterministic finite automata (WNFAs) were introduced in (Gagie et al., TCS 2017) as a powerful generalization of prefix sorting from strings to labeled graphs. WNFAs admit optimal solutions to classic hard problems on labeled graphs and languages such as compression and regular expression matching. The problem of deciding whether a given NFA is Wheeler is known to be NP-complete (Gibney and Thankachan, ESA 2019). Recently, however, Alanko et al. (Information and Computation 2021) showed how to side-step this complexity by switching to *preorders*: letting $Q$ be the set of states and $\delta$ the set of transitions, they provided a $O(|\delta| \cdot |Q|^2)$-time algorithm computing a totally-ordered *partition* (i.e. equivalence relation) of the WNFA's states such that (1) equivalent states recognize the same regular language, and (2) the order of (the classes of) non-equivalent states is consistent with any Wheeler order, when one exists. As a result, the output is a preorder of the states as useful for pattern matching as standard Wheeler orders.

Further extensions of this line of work (Cotumaccio et al., SODA 2021 and DCC 2022) generalized these concepts to arbitrary NFAs by introducing *co-lex partial preorders*: in general, any NFA admits a partial preorder of its states reflecting the co-lexicographic order of their accepted strings; the smaller the width of such preorder is, the faster regular expression matching queries can be performed. To date, the fastest algorithm for computing the smallest-width partial preorder on NFAs runs in $O(|\delta|^2 + |Q|^{5/2})$ time (Cotumaccio, DCC 2022), while on DFAs the same task can be accomplished in $O(\min(|Q|^2 \log |Q|, |\delta| \cdot |Q|))$ time (Kim et al., CPM 2023).

In this paper, we provide much more efficient solutions to the co-lex order computation problem. Our results are achieved by extending a classic algorithm for the relational coarsest partition refinement problem of Paige and Tarjan to work with *ordered* partitions. More specifically, we provide a $O(|\delta| \log |Q|)$-time algorithm computing a co-lex total preorder when the input is a Wheeler NFA, and an algorithm with the same time complexity computing the smallest-width co-lex partial order of any DFA. In addition, we present implementations of our algorithms and show that they are very efficient also in practice.

## 1 Introduction

The classical *pattern matching* problem between two strings $S$ (the text) and $P$ (the pattern) over alphabet $\Sigma$ asks to find the substrings of $S$ matching $P$. Although many algorithms solving the *on-line* version of the problem exist, in many scenarios it is possible to pre-process $S$ *off-line* into an *index* to speed up subsequent pattern matching queries. As a matter of fact, a very successful line of research dating back to the invention of suffix trees [24] and culminating with the discovery of compressed data structures [20] showed that it is possible to represent $S$ in compact space while speeding up matching queries.

The *indexed pattern matching* problem can be generalized to collections of strings: in this case the pattern must be found as a substring in a string collection $\mathcal{S}$. A natural approach to solve this problem is to concatenate all strings in $\mathcal{S}$ into one string $S$ and re-use the well-optimized techniques for classical pattern matching. Even though there are many successful examples of indexes following this strategy [12, 14, 19], this approach suffers from high space consumption during index construction (the input is very large), and does not scale to a more general (and interesting) scenario: the case where $\mathcal{S}$ contains an *infinite* number of strings. A solution, addressing both issues, is to represent a (potentially infinite) collection of strings using a finite-state automaton with set of states $Q$ and transition function $\delta$. In this new scenario, the goal of pattern matching is to locate walks in the automaton (seen as a labeled graph) spelling the query pattern $P$. In bioinformatics, for example, genomic collections are represented using pangenome graphs: labeled graphs encoding nucleotide variations within the collection [5, 23]. Matching a DNA sequence over a pangenome graph allows one to discover the genetic variation in a population [22].

Unfortunately, both the off-line and on-line pattern matching problems are hard to solve on labeled graphs: Equi et al. [10, 11] showed that, conditioned on OVH [25], it is not possible to design a polynomial-time algorithm to index a labeled graph such that pattern matching queries can be answered in $O(|P| + |\delta|^{\alpha}|P|^{\beta})$ time, for any constants $\alpha < 1$ or $\beta < 1$.

A successful paradigm to cope with this hardness is to study sub-classes of graphs where the problem is easier. Along these lines, Gagie et al. [13] introduced the class of *Wheeler automata*: labeled graphs admitting a total order of their states (a *Wheeler order*) which respects the underlying alphabet's order and it is propagated through pairs of equally-labeled edges. Wheeler orders generalize prefix sorting (the machinery standing at the core of the most successful string indexes) to labeled graphs and as a consequence, an index over a Wheeler automaton supports pattern matching queries in near-optimal $O(|P| \log |\Sigma|)$ time.

Wheeler automata, however, have two important limitations. First, the classes of Wheeler automata and Wheeler languages (accepted by such automata) are quite restricted. For example, Wheeler automata cannot contain proper cycles labeled with a unary string, and

moreover, Wheeler languages are star-free [2]. Second, several natural problems related to Wheeler graphs are computationally hard. For example, the simple fact of deciding if an automaton is Wheeler is NP-complete, even when the automaton is acyclic [15].

Related to the first issue, the work [8] extended state-ordering to arbitrary automata by using the concept of *co-lex partial order*. By switching from total to partial orders, the authors showed that (i) every automaton can be (partially) sorted, and that (ii) the efficiency of pattern matching on the automaton depends on the *width* (maximum size of an antichain) of such partial order. Wheeler automata are the particular case in which there exists a total co-lex order (i.e., of width one), thus enabling near-optimal time pattern matching queries.

A way to circumvent the latter limitation (hardness of computing a Wheeler order) was proposed by Alanko et al. [2] by switching to *total preorders*: the authors showed a $O(|\delta| \cdot |Q|^2)$-time *partition refinement* algorithm, which outputs a totally-ordered partition of $Q$ such that (1) states in the same part recognize the same language, and (2) the order of the partition is consistent with *any* Wheeler order of $Q$. In other words, this ordered partition is a preorder of the states as useful for indexing as Wheeler orders. Recently, a similar solution was proposed by Chao et al. [4] to speed up the computation of Wheeler orders in practice; after a first polynomial-time partition refinement step, their tool runs an exponential-time solver to assign a Wheeler ordering within classes of equivalent states.

These strategies – partial orders and total preorders – were finally merged by Cotumaccio [6]. As in [8], the efficiency of pattern matching depends on the width of such a partial preorder. The author described a polynomial-time algorithm computing a *colex partial preorder* of smallest width over an arbitrary nondeterministic finite-state automaton (NFA) in $O(|\delta|^2 + |Q|^{5/2})$ time. Later, this running time was improved by Kim et al. [17] in the particular case of DFAs with two algorithms running in time $O(|Q|^2 \log |Q|)$ and $O(|\delta| \cdot |Q|)$, respectively, and one algorithm running in near-optimal time $O(|\delta| \log |Q|)$ on acyclic DFAs. Within the same running times, all the above-mentioned algorithms compute also a chain partition of minimum size $p$ of the partial preorder (by Dilworth's theorem [9], $p$ is equal to the order's width); such a chain partition is needed to build the index described in [6]. The index can be built in linear time given as input such a chain partition, uses $(\lceil \log |\Sigma| \rceil + \lceil \log p \rceil + 2) \cdot (1 + o(1))$ bits per edge, and answers pattern matching queries on the regular language accepted by the automaton in $O(p^2 \log(p \cdot |\Sigma|))$ time per pattern's character.

**Our contributions.** We consider two cases of colex orders: (1) total preorders on NFAs, and (2) partial orders of minimum width on DFAs. We provide algorithms running in time $O(|\delta| \log |Q|)$ for both cases, improving the state-of-the-art cubic and quadratic algorithms to near-optimal time.

Our solution to (1) is obtained by extending a classic algorithm for the relational coarsest partition refinement problem of Paige and Tarjan [21] to work with *ordered* partitions. Our algorithm starts from the ordered partition corresponding to the states' incoming labels and, similarly to [21], iteratively refines this partition by enforcing *forward-stability*: for any two parts $B$ (the "splitter") and $D$ (the "split") the image $\delta_a(B)$ of $B$ through the transition function (for any alphabet's character $a$) must either contain $D$ or be disjoint with $D$. If this condition is not satisfied, $D$ is split into three parts: states reached only from $B$, states reached only from $Q \setminus B$, and states reached from both. In addition to Paige and Tarjan's algorithm, we show how to sort these three parts consistently with the current partition's order. In fact, we show that our algorithm finds a total preorder on a class of automata being strictly larger than the Wheeler automata. We dub this class *quasi-Wheeler*, thereby extending the class of automata that can be indexed to support queries in near-optimal time.

▶ **Theorem 1.** *For an NFA $\mathcal{A} = (Q, \delta, s)$, we can compute a total preorder $\preceq$ in $O(|\delta| \log |Q|)$ time such that $\preceq$ corresponds to a Wheeler preorder if and only if $\mathcal{A}$ is quasi-Wheeler.*

Our solution to (2) relies on a further modification of the partition refinement algorithm. More specifically, we show that within the same time complexity, we can prune the automaton's transition function so that the resulting graph is a quasi-forest satisfying the following property: every state $u$ has only one incoming walk, whose label is co-lexicographically smallest (the *infimum*) among the labels of all walks ending at $u$ in the original DFA. Symmetrically, we compute a pruned automaton encoding the co-lexicographically largest strings (the *suprema*). We obtain our second result by plugging in the $O(|Q| \log |Q|)$-time algorithms of Kim et al. [17], which sort the infimum and suprema strings (suffix-doubling)[1] and then compute a minimum chain partition of the smallest-width co-lex order (interval graph coloring). Our result assumes that the DFA is input-consistent (all in-going transitions to a state are labeled with the same letter). This assumption is a common simplification in automata theory and it is not a limitation of our approach as every DFA can be easily transformed into an equivalent input-consistent DFA.

▶ **Theorem 2.** *For an input-consistent DFA $\mathcal{A} = (Q, \delta, s)$, we can compute a minimum chain partition of the smallest-width co-lex order in $O(|\delta| \log |Q|)$ time.*

We have implemented our partition refinement algorithms. We compared the implementation of our algorithm from Theorem 1 with a heuristic implementation from `WGT` [4] (their first polynomial time step) which, similarly to our algorithm, computes an ordered partition being consistent with any Wheeler order (although not the most refined – unlike the output of our algorithm). On random Wheeler NFAs generated with a tool from the same toolbox (`WGT`), our implementation outperforms the heuristic from `WGT` by more than two orders of magnitude. We also experimentally show that our algorithm from Theorem 2 can prune a pangenomic DFA with more than 50 million states in less than 6 minutes.

## 2 Notation and Preliminaries

For an integer $k \geq 1$, we let $[k] := \{1, \ldots, k\}$. Given a set $U$, a partition $\mathcal{P}$ of $U$ is a set of pairwise disjoint non-empty sets $\{U_1, \ldots, U_k\}$ whose union is $U$. We call $U_1, \ldots, U_k$ the *parts* of $\mathcal{P}$. If we, in addition, have a (total) order of the parts, we say that it is an *ordered partition* and denote it with $\langle U_1, \ldots, U_k \rangle$. For two (ordered) partitions $\mathcal{P}$ and $\mathcal{P}'$ of $U$, we say that $\mathcal{P}'$ is a *refinement* of $\mathcal{P}$ if every part of $\mathcal{P}'$ is contained in a part of $\mathcal{P}$, i.e., for every $U' \in \mathcal{P}'$ there is $U \in \mathcal{P}$ with $U' \subseteq U$. As a special case, a partition is a refinement of itself.

**Relations and Orders.** A *relation* $R$ over a set $U$ is a set of ordered pairs of elements from $U$, i.e., $R \subseteq U \times U$. We sometimes omit $U$ if it is clear from the context. For two elements $u, v$ from $U$, we usually write $uRv$ for $(u, v) \in R$.

A *strict partial order* over a set $U$ is a relation that satisfies irreflexivity, asymmetry, and transitivity. If, in addition, a strict partial order satisfies connectedness it is a *strict total order*. A *total preorder* over a set $U$ is a relation that satisfies transitivity, reflexivity, and connectedness (i.e., for all two distinct $u, v \in U$, $u$ is in relation with $v$ or $v$ is in relation with $u$). An *equivalence relation* over a set $U$ is a relation that satisfies reflexivity, symmetry,

[1] More precisely, it is a special case of the suffix doubling algorithm [17], which runs in the claimed time.

and transitivity. For an equivalence relation $\sim$, we use $[u]_\sim$ to denote the equivalence class of an element $u \in U$ with respect to $\sim$, i.e., $[u]_\sim := \{v \in U : u \sim v\}$. We denote with $U/_\sim$ the partition of $U$ consisting of all equivalence classes $[u]_\sim$ for $u \in U$. In this paper, we denote strict total orders with the symbols $\prec$ and $<$, total preorders with the symbols $\preceq$ and $\leq$, and equivalence relations with the symbols $\sim$ and $\approx$.

A total preorder $\preceq$ over $U$ induces an equivalence relation $\sim$ over $U$: For $u, v \in U$, define $u \sim v$ if and only if $u \preceq v$ and $v \preceq u$. Throughout the paper, $\sim$ will always refer to the equivalence induced by $\preceq$ (the order $\preceq$ will always be unambiguously defined). A total preorder $\preceq$, in addition, yields a strict total order $\prec$ on the elements of $U/_\sim$ as $[u]_\sim \prec [v]_\sim$ if and only if $u \preceq v$ and not $v \preceq u$. Throughout the paper $\prec$ will refer to the strict order induced by $\preceq$ (always unambiguously defined). A total preorder $\preceq$ over a set $U$ can thus be represented by a unique ordered partition $\langle U_1, \ldots, U_k \rangle$, where the parts $U_i$ represent the equivalence classes with respect to $\sim$ and their ordering represents the strict total order $\prec$.

**Non-Deterministic Finite Automata (NFAs).** Let $\Sigma$ denote a fixed finite and non-empty *alphabet* of *letters*. We assume that there is a strict total order $<$ on the alphabet $\Sigma$.

▶ **Definition 3** (NFA and DFA). *A* non-deterministic finite automaton (NFA) *over the alphabet $\Sigma$ is an ordered triple $\mathcal{A} = (Q, \delta, s)$, where $Q$ is the set of* states*, $\delta : Q \times \Sigma \to 2^Q$ is the* transition function*, and $s \in Q$ is the* source state*.*

*A* deterministic finite automaton (DFA) *over the alphabet $\Sigma$ is an NFA over $\Sigma$ such that $|\delta(v, a)| \leq 1$ for all $a \in \Sigma$ and $v \in V$.*

We note that the standard definition of NFAs includes also a set of final states. As we are not concerned with the accepting languages of automata in this work, we omit the final states from the definition. In what follows we consider the alphabet $\Sigma$ to be fixed and thus frequently refer to NFAs without specifying the alphabet. Given an NFA $\mathcal{A} = (Q, \delta, s)$, for a state $u \in Q$ and a letter $a \in \Sigma$, we use the shortcut $\delta_a(u)$ for $\delta(u, a)$, similarly $\delta_a^{-1}(u) = \{v \ : \ \delta(v, a) = u\}$. For a set $S \subseteq Q$, we let $\delta_a(S) := \bigcup_{u \in S} \delta_a(u)$ and $\delta_a^{-1}(S) := \bigcup_{u \in S} \delta_a^{-1}(u)$.

The set of finite strings over $\Sigma$, denoted by $\Sigma^*$, is the set of finite sequences of letters from $\Sigma$. We extend the transition function from letters to finite strings in the common way, i.e, for $\alpha \in \Sigma^*$ and $v \in Q$, we define $\delta_\alpha(v)$ recursively as follows. If $\alpha = \varepsilon$, we let $\delta_\alpha(v) = \{v\}$. Otherwise, if $\alpha = a\alpha'$ for some $a \in \Sigma$ and $\alpha' \in \Sigma^*$, we let $\delta_\alpha(v) = \bigcup_{w \in \delta_a(v)} \delta_{\alpha'}(w)$.

▶ **Definition 4** (Strings Reaching a State). *Given an NFA $\mathcal{A} = (Q, \delta, s)$, for a state $v \in Q$, the* set of strings reaching $v$ *is defined as $S_v = \{\alpha \in \Sigma^* : v \in \delta_\alpha(s)\}$.*

Equivalently, $S_v$ is the regular language recognized by state $v$. For simplicity, in this work we assume that NFAs satisfy the following two properties: (1) The source state has no in-going transitions, i.e., $S_s = \{\varepsilon\}$ and every other state is reachable from the source state, i.e., $|S_v| \geq 1$ for all $v \in Q \setminus \{s\}$. (2) The automaton is *input-consistent*, i.e., for every state $v \in Q \setminus \{s\}$ it holds that $\delta_a^{-1}(v)$ is non-empty for exactly one letter $a \in \Sigma$. It is easy to see that any automaton can be transformed into an equivalent one (in the sense of the recognized language) satisfying assumptions (1) and (2). Condition (1) yields that $|Q| \leq |\delta| + 1$. Condition (2) comes at the cost of increasing the number of states and transitions by a factor of at most $|\Sigma|$. We also assume that a given NFA contains at least one transition for every letter. We denote by $\lambda(v)$ the unique label of the in-going transitions of a state $v \in Q \setminus \{s\}$, while $\lambda(s) := \varepsilon$. We also extend this notation to sets of states, that is for a set of states $S$, we let $\lambda(S) := \{\lambda(v) : v \in S\}$ and if $\lambda(S) = \{a\}$, we write $\lambda(S) = a$.

**Forward-Stable Partitions.** Alanko et al. consider *forward-stable partitions* [2, Section 4.2].

▶ **Definition 5** (Forward-Stability). *Given an NFA $\mathcal{A} = (Q, \delta, s)$ and two sets of states $S, T \subseteq Q$, we say that $S$ is* forward-stable *with respect to $T$, if, for all $a \in \Sigma$, $S \subseteq \delta_a(T)$ or $S \cap \delta_a(T) = \emptyset$ holds. A partition $\mathcal{P}$ of $\mathcal{A}$'s states is* forward-stable for $\mathcal{A}$*, if, for any two parts $S, T \in \mathcal{P}$, it holds that $S$ is forward-stable with respect to $T$.*

A direct consequence of forward-stability is given in the following lemma, i.e., all states in the same part of a forward-stable partition are reached by the exact same set of strings.

▶ **Lemma 6.** *Let $\mathcal{P}$ be a forward-stable partition for an NFA $\mathcal{A} = (Q, \delta, s)$ and assume that $u, v \in P$ for some part $P \in \mathcal{P}$. Then, $S_u = S_v$.*

This property can be proven easily using the definition of forward-stability, see, e.g., [2, Lemma 4.7]. Furthermore, there is a straightforward relationship between forward-stability and bisimulation, see, e.g., the work of Kanellakis and Smolka [16] or Chapter 7.3 of the book by Katoen and Baier [3]. The *coarsest* forward-stable partition for an NFA $\mathcal{A}$, i.e., the forward-stable partition with fewest parts, is identical to the partition consisting of the equivalence classes with respect to the bisimilarity relation (the unique largest bisimulation) on $\mathcal{A}^{-1}$, the automaton obtained from $\mathcal{A}$ by reversing all its transitions. We include a proof of this fact in full version of this article. This also directly yields that there is a unique forward-stable partition. We note that a reverse statement of Lemma 6 may not necessarily hold even for the coarsest forward-stable partition. More precisely, states in different parts of the coarsest forward-stable partition may have the same set of strings reaching them, see the left automaton in Figure 1. In what follows, for an NFA $\mathcal{A} = (Q, \delta, s)$ and an equivalence relation $\sim$ on $Q$, we write $\mathcal{A}/_\sim$ for the quotient NFA (of $\mathcal{A}$ with respect to $\sim$) obtained by collapsing the equivalence classes into single states, see [2, Definition 8] for a formal definition.

**Wheeler NFAs and Quasi-Wheeler NFAs.** Wheeler NFAs [13] are a special class of NFAs that can be stored compactly and indexed efficiently as they can be endowed with a specific type of strict total order, the so-called *Wheeler order*.

▶ **Definition 7** (Wheeler NFA and Wheeler order). *Let $\mathcal{A} = (Q, \delta, s)$ be an NFA. We say that $\mathcal{A}$ is a* Wheeler NFA*, if there exists a* Wheeler order $\prec$ *of $Q$. A Wheeler order $\prec$ of $Q$ is a strict total order on $Q$ such that the source state precedes all other states, i.e., $s \prec v$ for all $v \in Q \setminus \{s\}$, and, for any pair $v \in \delta_a(u)$ and $v' \in \delta_{a'}(u')$:*

**(1)** *If $a < a'$, then $v \prec v'$.*

**(2)** *If $a = a'$, $u \prec u'$, and $v \neq v'$, then $v \prec v'$.*

Clearly, not every NFA is a Wheeler NFA and, even worse, recognizing if a given NFA is Wheeler is NP-complete (for alphabet size at least 2) as shown by Gibney and Thankachan [15]. We now introduce the following problem, called OrderWheeler: Given an arbitrary NFA $\mathcal{A} = (Q, \delta, s)$ as input, the task is to compute a strict total order $\prec$ of $Q$ with the property that $\prec$ is a Wheeler order if $\mathcal{A}$ is Wheeler. As a result of the NP-completeness of recognizing Wheeler NFAs previously mentioned, also OrderWheeler is NP-hard. This follows as checking whether a given order is indeed a Wheeler order can be done in linear time [1, Lemma 3.1]. This motivates introducing the following relaxed version of Wheeler NFAs.

▶ **Definition 8** (Wheeler preorders and quasi-Wheeler NFAs). *Let $\mathcal{A} = (Q, \delta, s)$ be an NFA. A Wheeler preorder $\preceq$ on $Q$ is a total preorder on $Q$ such that:*

- *The partition $Q/_\sim$, where $\sim$ is the equivalence relation induced by $\preceq$, is equal to the coarsest forward-stable partition of $\mathcal{A}$.*
- *The quotient automaton $\mathcal{A}/_\sim$ is a Wheeler NFA with the strict total order $\prec$ induced by $\preceq$ on the equivalence classes with respect to $\sim$.*

*We say that $\mathcal{A}$ is a* quasi-Wheeler NFA*, if there exists a* Wheeler preorder $\preceq$ *on $Q$.*

See the beginning of this section for the formal definition of $\sim$ and $\prec$. From the point of view of indexing, quasi-Wheeler NFAs are as useful as Wheeler NFAs: note that the quotient automaton $\mathcal{A}/_\sim$ in the definition above generates the same language as the original NFA $\mathcal{A}$ due to the properties of the forward-stable partition, see Lemma 6. However, $\mathcal{A}/_\sim$ is a Wheeler NFA and can thus be stored compactly and indexed efficiently. We next note that Corollary 4.11 in the paper by Alanko et al. [2] directly yields the following lemma.

▶ **Lemma 9.** *Let $\mathcal{A} = (Q, \delta, s)$ be a Wheeler NFA, then $\mathcal{A}$ is also a quasi-Wheeler NFA.*

Furthermore, the set of quasi-Wheeler NFAs is strictly larger than the set of Wheeler NFAs as there exist non-Wheeler NFAs $\mathcal{A}$ for which the quotient automaton $\mathcal{A}/_\sim$ is Wheeler, e.g., the NFA and its corresponding quotient NFA in the center and on the right of Figure 1.

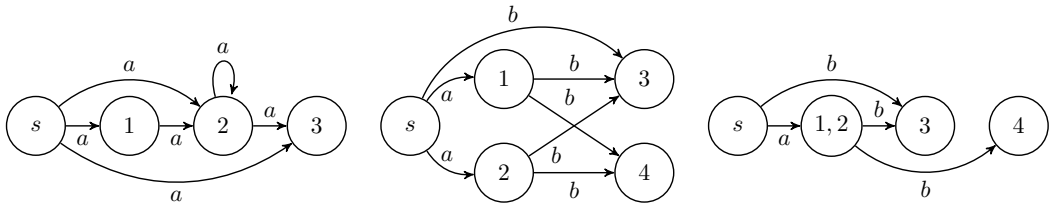

**Figure 1** Left: An NFA for which $\mathcal{P} = \langle\{s\}, \{1\}, \{2\}, \{3\}\rangle$ is the coarsest forward-stable partition, yet $S_2 = S_3$. Center: A non-Wheeler NFA (the two states 3 and 4 cannot be ordered) that is quasi-Wheeler as witnessed by the Wheeler preorder $\preceq$ corresponding to the ordered partition $\langle\{s\}, \{1, 2\}, \{3\}, \{4\}\rangle$. Right: Quotient automaton $\mathcal{A}/_\sim$, where $\mathcal{A}$ is the automaton in the middle and $\sim$ is the equivalence relation induced by the Wheeler preorder $\preceq$. Notice that $\mathcal{A}/_\sim$ is Wheeler with the strict total order $\prec$ induced by $\preceq$ on the equivalence classes with respect to $\sim$.

An important advantage of quasi-Wheeler NFAs over classical Wheeler NFAs is that the former can be recognized in polynomial time, which is implicit in the Forward Algorithm of Alanko et al. [2]. Indeed, the Forward Algorithm receives a Wheeler NFA as input and, in $O(|\delta||Q|^2)$ time, outputs a Wheeler order of the quotient automaton $\mathcal{A}/_\sim$, where $\sim$ is the equivalence relation induced by the returned partition. However, this algorithm actually solves a slightly more general problem, since their output partition is guaranteed to correspond to a Wheeler order of $\mathcal{A}/_\sim$ whenever $\mathcal{A}$ is quasi-Wheeler rather than Wheeler. In other words Alanko et al. gave a polynomial time algorithm for the following problem that we call PreOrderWheeler: Given an arbitrary NFA $\mathcal{A} = (Q, \delta, s)$, the task is to compute a total preorder $\preceq$ of $Q$ with the property that $\preceq$ is a Wheeler preorder if $\mathcal{A}$ is quasi-Wheeler. Their polynomial time algorithm for PreOrderWheeler, the *Forward Algorithm*, yields a polynomial-time recognition algorithm for quasi-Wheeler NFAs as follows: Given an arbitrary input NFA $\mathcal{A}$, run the Forward Algorithm to compute the Wheeler preorder $\preceq$ given by an ordering of the forward-stable partition. The output partition is guaranteed to be the coarsest forward-stable partition. Compute the quotient automaton with respect to this partition and check if it is Wheeler (in polynomial time by [1, Lemma 3.1]) when endowed with the induced strict total order $\prec$.

## 3 Partition Refinement for Wheeler Preorders of NFAs

In this section we provide an algorithm that solves PreOrderWheeler in $O(|\delta| \log |Q|)$ time. Recall that the Forward Algorithm of Alanko et al. [2] has running time $O(|\delta| \cdot |Q|^2)$. We achieve the nearly-linear time complexity by using the partition refinement framework of Paige and Tarjan [21]. It is in fact clear that this framework can be used to compute a forward-stable partition. Our notion of forward-stability corresponds to stability with respect to $|\Sigma|$ relations, defined as $E_a := \{(u, v) \in Q^2 : u \in \delta_a(v)\}$ for $a \in \Sigma$, in their terminology [21, Section 3]. Our main contribution here is to extend the framework so as to compute an *ordered* partition (and thus a preorder), while maintaining the nearly-linear running time.

We proceed with a description of the partition refinement algorithm by Paige and Tarjan. The algorithm maintains two partitions $\mathcal{P}$ and $\mathcal{X}$, here $\mathcal{P}$ is an input partition to be refined and $\mathcal{X}$ is such that (1) $\mathcal{P}$ is a refinement of $\mathcal{X}$ and (2) every part of $\mathcal{P}$ is stable with respect to every part of $\mathcal{X}$. Initially, $\mathcal{X}$ is the partition with a single part containing all elements. Until $\mathcal{P}$ becomes stable, i.e., every part of $\mathcal{P}$ is stable with respect to every part of $\mathcal{P}$, which is witnessed by the fact that $\mathcal{P} = \mathcal{X}$, the algorithm iteratively chooses a *compound part* $S$ from $\mathcal{X}$, i.e., a part form $\mathcal{X}$ that consists of multiple parts in $\mathcal{P}$. Then a "splitter" $B$ is chosen as one of the parts in $\mathcal{P}$ contained in $S$ and every part in $\mathcal{P}$ is refined using $B$ by doing a so-called "three-way split" that we detail in the next section. The idea behind the three-way split is essentially to make $\mathcal{P}$ stable with respect to $B$ and $S \setminus B$ at the same time. In fact, the choice of $B$ in the algorithm of Paige and Tarjan is crucial. It is fundamental to always choose a block $B$ such that $|B| \leq |S|/2$. This is the essential property that yields the nearly linear running time using the observation that every element is contained in at most logarithmically many splitters. This property on the size of $B$ is achieved in Paige and Tarjan's implementation by inspecting the first two elements of the list of all parts from $\mathcal{P}$ contained in $S$ and then choosing $B$ to be the smaller one (in size).

As it turns out, this choice of $B$ however interferes with maintaining the order of the parts such as to satisfy the properties of the Wheeler preorder. We solve this issue by choosing the smaller (in size) among the first and last block (in the sense of the ordered partition) contained in the first compound block (rather than the smaller out of the first two blocks, as in Paige and Tarjan's algorithm). This choice both guarantees that $|B| \leq |S|/2$ and enables us to maintain a consistent ordering between the parts resulting from a split step.

**Algorithm.** We proceed with a description of our algorithm. A pseudo-code formulation can be found in Algorithm 1. First, note that an input-consistent NFA has a natural partition of its states into the $|\Sigma|+1$ parts $\{Q_a\}_{a \in \Sigma \cup \{\varepsilon\}}$, where $Q_a := \{v \in Q : \lambda(v) = a\}$ for $a \in \Sigma \cup \{\varepsilon\}$. Property (1) of Wheeler orders already defines the ordering of these parts: any Wheeler preorder of the NFA's states has to satisfy that $u$ precedes $v$ if $u$'s in-coming letter is smaller than $v$'s. Hence, the ordering of the $|\Sigma|+1$ parts has to be $Q_\varepsilon, Q_{a_1}, \ldots Q_{a_k}$, where we assume that $\Sigma = \{a_1, \ldots, a_k\}$ with $a_1 < \ldots < a_k$. Following this observation, the ordered partition $\mathcal{P}$ in the algorithm is initialized to $\mathcal{P} := \langle Q_\varepsilon, Q_{a_1}, \ldots Q_{a_k} \rangle$.

As in the original partition refinement framework, the algorithm then keeps splitting the parts of the partition using so called *splitters* which are themselves parts in the partition. By splitting, we mean the operation of making all parts of the partition forward-stable with respect to the splitter. As in Paige and Tarjan's algorithm, to maintain the set of splitters, the algorithm also maintains another ordered partition $\mathcal{X}$ such that $\mathcal{P}$ is a refinement of $\mathcal{X}$. Initially $\mathcal{X}$ has a unique part that is equal to $Q$ and the algorithm will maintain the invariant that $\mathcal{P}$ is forward-stable with respect to each part from $\mathcal{X}$. As before, we call the

**Algorithm 1** Ordered Partition Refinement.

**Input** : NFA $\mathcal{A} = (Q, \delta, s)$
**Output** : Ordered Partition $\mathcal{P}$ of $Q$ that corresponds to Wheeler preorder if and only if $\mathcal{A}$ is quasi-Wheeler

```
// * initialization * //
```
$\mathcal{P} := \langle Q_\varepsilon, Q_{a_1}, ..., Q_{a_k} \rangle$, $\mathcal{X} := \langle Q \rangle$
**while** $\mathcal{X} \neq \mathcal{P}$ **do**
```
// * get splitter B * //
```
$S :=$ first block in $\mathcal{X}$ consisting of multiple blocks in $\mathcal{P}$
$B :=$ smaller of first and last block from $\mathcal{P}$ contained in $S$
```
// * variable B contains this block even if split *//
// * update X * //
```
**if** $B$ *is first block* **then** replace $S$ in $\mathcal{X}$ with $B, S \setminus B$ **else** with $S \setminus B, B$
```
// * split blocks in P using B * //
```
**for** $D \in \mathcal{P}$ **do**
```
// * split D * //
```
$D_1 := D \cap \delta_a(B)$, $D_2 := D \setminus D_1$, where $a = \lambda(D)$
$D_{11} := D_1 \cap \delta_a(S \setminus B)$, $D_{12} := D_1 \setminus D_{11}$
```
// * update P * //
```
**if** $B$ *first block* **then** replace $D$ in $\mathcal{P}$ with non-empty sets from $D_{12}, D_{11}, D_2$
**else** with non-empty sets from $D_2, D_{11}, D_{12}$
```
// * continue for behind newly inserted blocks in P * //
```
**return** $\mathcal{P}$

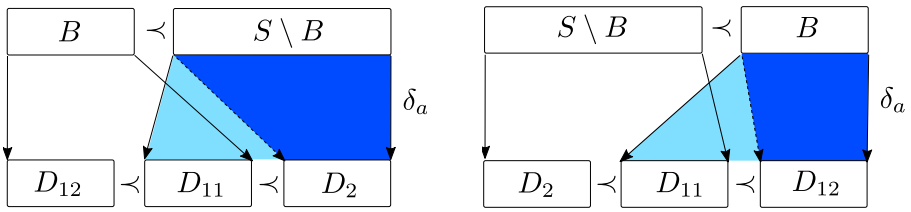

**Figure 2** The two cases of our "ordered" three-way split of $D$ into $D_2$, $D_{11}$ and $D_{12}$ using splitter $B$ contained in the compound part $S$. Here, $D_{11}$ is the part of $D$ that is reached both by $B$ and $S \setminus B$, $D_{12}$ is the part of $D$ reached by $B$ but not by $S \setminus B$, and $D_2$ is the part of $D$ reached by $S \setminus B$ but not by $B$. The size of the splitter $B$ is at most half of the size of the compound block $S$ containing $B$. On the left, $B$ is the first part in $S$ (in the ordered partition), on the right it is the last part. On the left, the order of $B, S \setminus B$ gets propagated forward, the resulting order within $D$ is $D_{12}, D_{11}, D_2$. On the right, the order of $S \setminus B, B$ gets propagated forward, the resulting order within $D$ is $D_2, D_{11}, D_{12}$. The two shades of blue indicate the pruning of edges explained in Section 4.

parts of $\mathcal{X}$ that contain more than a single part from $\mathcal{X}$ *compound parts*. The algorithm then iteratively takes the first (in the order of the ordered partition) compound block $S$ from $\mathcal{P}$ and defines the splitter $B$ as the smaller (in size) of the first and last (in the order of the ordered partition) block in $\mathcal{P}$ contained in $S$.

Once the splitter $B$ is defined, the algorithm aims to split each part $D$ of the partition $\mathcal{P}$ (including $B$ itself) using $B$. As we aim at making the partition forward-stable with respect to $B$ we would want to split $D$ into $D_1 := D \cap \delta_a(B)$ and $D_2 := D \setminus D_1$. To implement the three-way split, we however want to further refine $D$ by $S \setminus B$. Recall that $S$ was a part in $\mathcal{X}$ that contained $B$ and that $\mathcal{P}$ is already forward-stable with respect to $S$ by the invariant. The forward-stability of $D$ with respect to $S$ yields that all states in $D_2$ are reached by $S \setminus B$ and thus $D$ is decomposed into only three parts $D_{11} := D_1 \cap \delta_a(S \setminus B)$, $D_{12} := D_1 \setminus D_{11}$, and $D_2 := D \setminus D_1$ when splitting both with $B$ and $S \setminus B$. This three-way split can be implemented with work proportional to the number of edges leaving $B$ (rather than $B$ and $S \setminus B$). Together with the choice of $B$ being the smaller out of the first and the last block contained in $S$, this is the main property that allows to prove the nearly linear running time bound of the algorithm. The order in which the sets $D_{11}$, $D_{12}$, and $D_2$ are put in $\mathcal{P}$ replacing $D$ depends on whether $B$ was the first or the last block in $S$ and is chosen so as to satisfy property 2 of Wheeler orders. Intuitively, the order of $B$ and $S \setminus B$ is propagated forward to $D_{11}$, $D_{12}$, and $D_2$, see Figure 2 for an illustration of this "ordered" three-way split.

The algorithm keeps splitting the parts in $\mathcal{P}$ in this way until $\mathcal{X} = \mathcal{P}$, i.e., until there are no compound blocks left. Stopping at this point is correct by the invariant that the partition $\mathcal{P}$ is forward-stable with respect to each part from $\mathcal{X} = \mathcal{P}$, and, thus, forward-stable for $\mathcal{A}$.

**Analysis.** The following lemma states that the claimed invariant, that every part of $\mathcal{P}$ is forward-stable with respect to every part of $\mathcal{X}$, holds. This follows immediately from the same property of the framework by Paige and Tarjan (the proof of this lemma can be found in the full version).

▶ **Lemma 10.** *At the beginning of every iteration of the while loop in Algorithm 1, it holds that every part of the ordered partition $\mathcal{P}$ is forward-stable with respect to every part of $\mathcal{X}$.*

We will now prove the core technical result of this section: The ordered partition refinement algorithm in fact computes a partition that corresponds to a Wheeler preorder.

▶ **Lemma 11.** *Assume that Algorithm 1 is called on a quasi-Wheeler NFA $\mathcal{A} = (Q, s, \delta)$. Then, at any step of the algorithm, the partition $\mathcal{P} = \langle Q_1, \dots, Q_k \rangle$ agrees with every Wheeler order $\prec$ of the quotient automaton $\mathcal{A}' := \mathcal{A}/_{\mathcal{P}'}$, where $\mathcal{P}'$ denotes the coarsest forward-stable partition for $\mathcal{A}$. That is, if $i < j, u \in P_i, v \in P_j$ then $u \prec v$ for every Wheeler order $\prec$ of $\mathcal{A}'$.*

**Proof.** The initial partition $\mathcal{P} = \langle Q_\varepsilon, Q_{a_1}, \dots, Q_{a_k} \rangle$ agrees with any Wheeler order $\prec$ of $\mathcal{A}'$. We will show by induction over the number of steps of the while loop that this is the case in any step of the algorithm. Assume that this is true before some intermediate iteration and let us denote with $\mathcal{P}$ the ordered partition at that point. Now, let $S$ be the compound block and let $B$ be the splitter chosen in that iteration. Let us call $\mathcal{P}'$ the ordered partition after refining $\mathcal{P}$ with $B$ and $S \setminus B$, i.e., at the end of that iteration. We will prove that $\mathcal{P}'$ agrees with any Wheeler order $\prec$. As in the algorithm, for $D \in \mathcal{P}$, assume that $a = \lambda(D)$ and let $D_1 = D \cap \delta_a(B)$, $D_2 = D \setminus D_1$, and $D_{11} = D_1 \cap \delta_a(S \setminus B)$ and $D_{12} = D_1 \setminus D_{11}$. Now let $u, v \in D$. If $u$ and $v$ are contained in the same set out of the three sets $D_{12}, D_{11}, D_2$, nothing is to be shown. Hence, assume that $u$ and $v$ are in two different sets out of the three sets. There are three cases: (1) $u \in D_{11}$ and $v \in D_2$, (2) $u \in D_{12}$ and $v \in D_2$, and (3) $u \in D_{12}$ and $v \in D_{11}$. Notice first that in all three cases, there exists $x \in B$ with $u \in \delta_a(x)$. Now, recall that $D$ is stable with respect to $S$ due to Lemma 10 and thus there exists $y \in S \setminus B$ with $v \in \delta_a(y)$ in all three cases as well. Let us now first assume that $B$ is the first block in $S$ in line 5. Then, as $B$ precedes all blocks in $S \setminus B$ in $\mathcal{P}$ and $\mathcal{P}$ is consistent with any Wheeler

order of $\mathcal{A}'$, we have that $x \prec y$ for any Wheeler order of $\mathcal{A}'$. Then, property 2 of Wheeler orders implies that $u \prec v$ for any Wheeler order of $\mathcal{A}'$. In summary, as the algorithm replaces $D$ by $D_{12}, D_{11}, D_2$ in this case, we deduce that $\mathcal{P}'$ again agrees with each Wheeler order of $\mathcal{A}'$. If, instead $B$ is the last block in $S$ in line 5, then $B$ succeeds all blocks in $S \setminus B$ in $\mathcal{P}$ and thus we can analogously deduce $v \prec u$ from property 2 of Wheeler orders and as the algorithm replaces $D$ by $D_2, D_{11}, D_{12}$, we deduce that $\mathcal{P}'$ agrees with every Wheeler order of $\mathcal{A}'$ also in this case. ◀

It remains to argue that the ordered partition refinement algorithm in fact runs in the claimed running time bound of $O(|\delta| \log |Q|)$. The two main ingredients are as follows: (1) We always choose the smaller out of the first and the last part contained in $S$ as $B$ and thus $|B| \leq |S|/2$. As a result every state is in at most logarithmically many splitters. (2) We can implement the algorithm in such a way that the work done in a refinement step with splitter $B$ is proportional to the size of $B$ and the number of out-going transitions from $B$. This can be argued completely analogously as done by Paige and Tarjan. We prove our algorithm running time and describe the main data structure details in the full version. In summary, we obtain the following theorem.

▶ **Theorem 1.** *For an NFA $\mathcal{A} = (Q, \delta, s)$, we can compute a total preorder $\preceq$ in $O(|\delta| \log |Q|)$ time such that $\preceq$ corresponds to a Wheeler preorder if and only if $\mathcal{A}$ is quasi-Wheeler.*

## 4 Partition Refinement for Width-Optimal Co-lex Orders of DFAs

Cotumaccio and Prezza [8] propose a way of sidestepping the fact that there may not be a Wheeler order for a given NFA. They show how to index general NFAs using *partial orders*. For this purpose, they define co-lex orders for NFAs as follows.

▶ **Definition 12** (Co-lex Order). *Let $\mathcal{A} = (Q, \delta, s)$ be an NFA. A* co-lex order *for $\mathcal{A}$ is a strict partial order $\prec$ of $Q$ such that the source state precedes all other states, i.e., $s \prec v$ for all $v \in Q \setminus \{s\}$, and, for any pair $v \in \delta_a(u)$ and $v' \in \delta_{a'}(u')$:*
**(1)** *If $a < a'$, then $v \prec v'$.*
**(2)** *If $a = a'$, $v \prec v'$, and $u \neq u'$, then $u \prec u'$.*

The *width* of a strict partial order $\prec$ is defined as the size of the largest antichain, i.e. set of pairwise *incomparable* states, where two distinct states $u, v \in Q$ are said to be incomparable if neither $u \prec v$ nor $v \prec u$ holds. Finding a smallest-width co-lex order of $\mathcal{A}$ has been of particular interest for constructing efficient indexes for pattern matching on automata [8, 6, 7, 17]. We provide more context on co-lex orders in the full version. For DFAs, the following order is known to be the smallest-width co-lex order [8].

▶ **Definition 13.** *Let $\mathcal{A} = (Q, \delta, s)$ be a DFA. The relation $\prec_{\mathcal{A}}$ over $Q$ is defined as follows. For $u, v \in Q$, $u \prec_{\mathcal{A}} v$ holds if and only if $\alpha < \beta$ for all $\alpha \in S_u$ and $\beta \in S_v$.*

In the above definition, the alphabet order $<$ over $\Sigma$ is extended to the co-lexicographical order on strings. For the purpose of the co-lex order $\prec_{\mathcal{A}}$, a state $v \in Q$ can thus be represented solely using upper and lower bounds on $S_v$. In particular, for a state $v \in Q$, let $\inf S_v$ and $\sup S_v$ be the greatest lower bound (infimum) and the least upper bound (supremum) of $S_v$, respectively, which are possibly left-infinite strings. We refer the reader to the full version for a formal definition of these concepts. As shown by Kim et al. [17], the co-lex order $\prec_{\mathcal{A}}$ can be characterized using the co-lex order of $\mathrm{IS}_{\mathcal{A}} := \{\inf S_v : v \in Q\} \cup \{\sup S_v : v \in Q\}$.

▶ **Lemma 14** ([17, Theorem 10]). *Let $\mathcal{A} = (Q, \delta, s)$ be a DFA. Then, for any two distinct states $u, v \in Q$, $u \prec_{\mathcal{A}} v$ holds if and only if $\sup S_u \leq \inf S_v$.*

We note that, for the purpose of indexing, we also need a minimum chain partition of $\prec_{\mathcal{A}}$, i.e., a minimum-size partition of $Q$ such that the states in each part are totally ordered under $\prec_{\mathcal{A}}$. As shown by Kim et al. [17], such a chain partition can be computed in linear time via a greedy algorithm for the interval graph coloring problem, provided that the set $\mathrm{IS}_{\mathcal{A}}$ (implicitly defining an interval in co-lex order for each state) has been computed and sorted.

In this section, we give an algorithm for co-lex sorting the set $\mathrm{IS}_{\mathcal{A}}$ that runs in nearly-linear time $O(|\delta| \log |Q|)$ on any input-consistent DFA. This is a significant improvement with respect to the best previously-known algorithms that run in $O(|\delta| \cdot |Q|)$ and $O(|Q|^2 \log |Q|)$ time [17].

**Outline.** Given an input DFA $\mathcal{A} = (Q, \delta, s)$, we first compute a pruned automaton $\mathcal{A}^{\inf} = (Q, \delta^{\inf}, s)$ that *encodes* $\{\inf S_v : v \in Q\}$ in a sense that walking back starting at a state $v \in Q$ on the pruned transition $\delta^{\inf}$ yields its infimum string $\inf S_v$. Similarly, we compute a pruned automaton $\mathcal{A}^{\sup} = (Q, \delta^{\sup}, s)$ that encodes the supremum strings. As we will see, computing these sets takes $O(|\delta| \log |Q|)$ time each. On these two pruned automata, we compute the co-lex order of $\mathrm{IS}_{\mathcal{A}}$ in $O(|Q| \log |Q|)$ time in a similar way as done by Kim et al. [17], from which the smallest-width co-lex order of $\mathcal{A}$ (with a minimum chain partition) can be computed in linear time.

**Pruning Algorithm.** The algorithm is identical to Algorithm 1 with the only difference that we insert an additional pruning step, Algorithm 2, before Line 8 of the algorithm. See Figure 2 for an illustration: If a state in $D$ is reached from both $B$ and $S \setminus B$, we only keep the edges from the smaller (in the sense of the ordered partition) of the two. This corresponds to changing $\delta_a$ such that the blue portion of the figure shrinks to the dark blue one.

**Algorithm 2** Pruning Step for Algorithm 1 inserted before Line 8.

```
// * prune A * //
```
**if** *$B$ is the first block* **then** delete transitions from $S \setminus B$ to $D_1$ **else** from $B$ to $D_1$.

We inductively show that Algorithm 2 outputs a pruned automaton encoding the set of infima $I := \{\inf S_v : v \in Q\}$. For an integer $i \geq 1$, let $\delta^{(i)}$ be the pruned transition at the end of the $i$-th iteration of the while loop. Let us analogously denote with $\mathcal{X}^{(i)}$ and $\mathcal{P}^{(i)}$ the state of the ordered partitions $\mathcal{X}$ and $\mathcal{P}$ in the algorithm at the end of the $i$-th iteration. For convenience, we also define $\delta^{(0)} = \delta$, $\mathcal{X}^{(0)} = \langle Q \rangle$, and $\mathcal{P}^{(0)} = \langle Q_\varepsilon, Q_{a_1}, \ldots, Q_{a_k} \rangle$. Lemma 10 and the definition of the pruning step yield the following invariant on forward-stability.

▶ **Observation 15.** *At the end of every iteration $i$ of the while loop in Algorithm 1 when run together with the pruning step, it holds that every part of the ordered partition $\mathcal{P}^{(i)}$ is forward-stable with respect to every part in $\mathcal{X}^{(i)}$ in the automaton $\mathcal{A}^{(i)} = (Q, \delta^{(i)}, s)$.*

Intuitively speaking, the pruning step removes transitions that do not originate from the co-lexicographically smallest part in the sorted partition. Hence, we obtain the following lemma (the proof is deferred to the full version).

▶ **Lemma 16.** *Let $v \in Q$ be a state with $a = \lambda(v)$ and let $A, A' \in \mathcal{X}^{(i)}$ for some $i \geq 0$ be such that $v \in \delta_a^{(i)}(A) \cap \delta_a(A')$. Then either (i) $A = A'$ or (ii) $A$ precedes $A'$ in $\mathcal{X}^{(i)}$.*

Let $\mathcal{P}^*$ and $\delta^*$ be the ordered partition and the pruned transition, respectively, obtained at the end of the algorithm's execution. From Lemma 16, we can see that for every state $v \in Q \setminus \{s\}$, there exists a unique part $A \in \mathcal{P}^*$ such that $v \in \delta^*_{\lambda(v)}(A)$. Combining this with Observation 15, we obtain that a unique string can be obtained by walking backwards through the pruned transitions $\delta^*$. For $u \in Q$, let $\alpha^*_u$ be the longest (or possibly left-infinite) string that can be obtained in this way starting from $u$. Since every transition comes from a co-lex smallest part, we can obtain the following lemma (the proof is included in the full version).

▶ **Lemma 17.** *For every $u \in Q$, $\alpha^*_u = \inf S_u$.*

It is worth noting that some states possibly have more than one in-going transitions after the termination of the algorithm. Nevertheless, Lemma 17 still holds when we choose any of them and remove the others. From this observation, we can assume that every state (except the source state) in the pruned automaton $\mathcal{A}^{\inf}$ has exactly one in-going transition.

Similarly, we can compute the pruned automaton for the set of suprema $\{\sup S_v : v \in Q\}$. The only difference is that we start with the partition $\mathcal{P}'^{(0)} = \langle Q_{a_k}, \ldots, Q_{a_1}, Q_\varepsilon \rangle$ with the reversed order. It is simple to see the greatest string can be computed with this setting.

Regarding the time complexity, notice that the partition refinement algorithm iterates through the same partitions as if it were run on $\mathcal{A}^{\inf}$ in the first place. Additional time is taken for the pruning step for deleting transitions. This work can be done in $O(1)$ time per transition. Once a transition is deleted, it will never be considered in the rest of the execution and hence the additional work amortizes to $O(|\delta|)$. Consequently, the asymptotic time complexity of the partition refinement algorithm with pruning remains $O(|\delta| \log |Q|)$.

**Computing Co-Lex Order of $\mathrm{IS}_{\mathcal{A}}$.** Once the two pruned automata $\mathcal{A}^{\inf}$ and $\mathcal{A}^{\sup}$ are obtained, we can easily compute the co-lex order of $\mathrm{IS}_{\mathcal{A}}$ in $O(|Q| \log |Q|)$ time using the suffix doubling algorithm [17], which extends the well-known prefix-doubling algorithm [18]. Instead of accessing via integer indexes for the doubling procedure, each state keeps a pointer referring to another (possibly the same) state that is $2^k$ hops away along its backward walk. We describe all details of this algorithm in the full version. In summary, we conclude this section with the following theorem.

▶ **Theorem 2.** *For an input-consistent DFA $\mathcal{A} = (Q, \delta, s)$, we can compute a minimum chain partition of the smallest-width co-lex order in $O(|\delta| \log |Q|)$ time.*

## 5 Experimental results

We implemented our partition refinement algorithms in `C++` and made it available at `https://github.com/regindex/finite-automata-partition-refinement.git`. We compared the algorithm from Theorem 1 to the only (to the best of our knowledge) other available tool for computing a sorted partition consistent with any Wheeler order of the input NFA, the renaming heuristic from `WGT` [4]. For a fair comparison, we only run the first part of the `WGT` recognizer and remove the exponential time search that is used to subsequently compute a Wheeler order of the states ending up in equivalence classes.[2] We used the Wheeler graph generator included in `WGT` to generate 7 random input Wheeler NFAs with

[2] As observed empirically, the partition computed by `WGT` is in some cases coarser than the partition computed by our algorithm and is, thus, not necessarily forward-stable.

$|Q| \in \{5^6 \cdot 2^i : i = 0, \ldots, 6\}$ and $|\delta| = 3|Q|$ (we cannot generate much denser graphs since for Wheeler graphs $\delta = O(|\Sigma| \cdot |Q|)$ and here $|\Sigma| = 5$). Our experiments were run on a server with Intel(R) Xeon(R) W-2245 CPU @ 3.90GHz with 8 cores and 128 gigabytes of RAM running Ubuntu 18.04 LTS 64-bit.

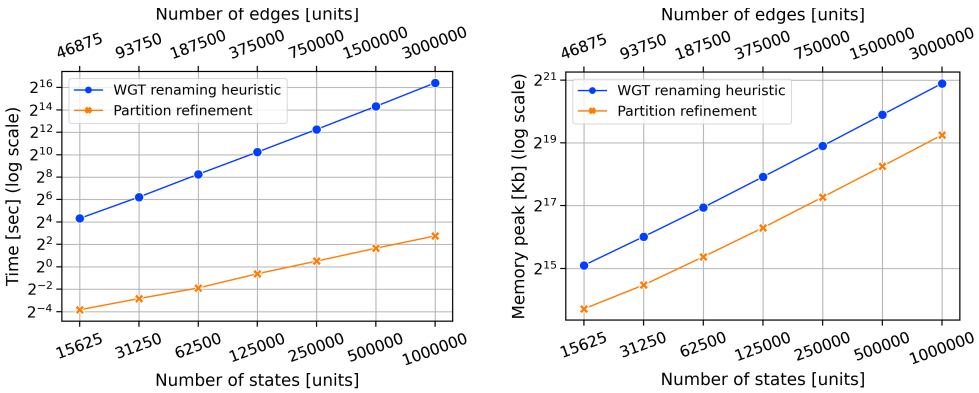

**Figure 3** CPU time (left) and memory peak (right) for sorting seven Wheeler NFAs using our partition refinement algorithm and the renaming heuristic contained in the `WGT` recognizer software. Datasets generated using `WGT` specifying seven different combinations of number of states and edges.

Figure 3 shows the running time and peak memory consumption of both implementations. As expected, our partition refinement implementation shows a slight super-linear behavior confirming the $O(|\delta| \cdot \log |Q|)$ worst-case running time of the algorithm. On the other hand, `WGT` shows a quadratic behavior, which is better than the cubic $O(|\delta| \cdot |Q|^2)$ bound for the Forward Algorithm of Alanko et. al [2], but between $\approx 100\times$ to $\approx 10000\times$ slower than our implementation. In terms of peak memory, both implementations behave linearly with respect to the automaton's size with a $3\times$ advantage in favor of our implementation. On the largest input instance containing one million states, our implementation computes the Wheeler preorder in about seven seconds. In a second experiment, we show that our implementation of the algorithm from Theorem 2 can prune a pangenomic DFA containing over 51 million states and 53 million edges in 355 seconds with a peak memory of 33.2 Gb.

## Abstract

We study the computational complexity of several polynomial-time-solvable graph problems parameterized by *vertex integrity*, a measure of a graph's vulnerability to vertex removal in terms of connectivity. Vertex integrity is the smallest number $\iota$ such that there is a set $S$ of $\iota' \leq \iota$ vertices such that every connected component of $G - S$ contains at most $\iota - \iota'$ vertices. It is known that the vertex integrity lies between the well-studied parameters *vertex cover number* and *tree-depth*. Our work follows similar studies for vertex cover number [Alon and Yuster, ESA 2007] and tree-depth [Iwata, Ogasawara, and Ohsaka, STACS 2018].

Alon and Yuster designed algorithms for graphs with small vertex cover number using fast matrix multiplications. We demonstrate that fast matrix multiplication can also be effectively used when parameterizing by vertex integrity $\iota$ by developing efficient algorithms for problems including an $O(\iota^{\omega-1}n)$-time algorithm for Maximum Matching and an $O(\iota^{(\omega-1)/2}n^2) \subseteq O(\iota^{0.687}n^2)$-time algorithm for All-Pairs Shortest Paths. These algorithms can be faster than previous algorithms parameterized by tree-depth, for which fast matrix multiplication is not known to be effective.

## 1 Introduction

Parameterized complexity provides a powerful framework for studying NP-hard problems. The main idea behind parameterized algorithms is to analyze the running time in terms of the input size $|I|$ as well as a parameter $k$, some measure of the input instance. A problem is *fixed-parameter tractable* or *FPT* for short, if it admits an *FPT algorithm*, an algorithm running in time $f(k) \cdot |I|^{O(1)}$ time, where $f$ is a function solely depending on $k$. In the past decade, a line of research dubbed "FPT in P" has emerged, where the goal is a more

refined parameterized analysis of polynomial-time-solvable problems [1, 5, 7, 13, 20, 25, 27]. Although the function $f$ usually has to be at least exponential when working with NP-hard problems, this is not true for problems in $P$. FPT algorithms where $f$ is a polynomial function are called *fully polynomial-time algorithms* and are of course desirable.

We study graph problems in this work. Let $n$ and $m$ be the number of vertices and edges, respectively. Also, let vc be the vertex cover number and td be the tree-depth (see Section 2 for definitions). Alon and Yuster [2] demonstrated that fast matrix multiplication can be used effectively for graphs with a (not necessarily small) vertex cover, developing algorithms for Maximum Matching and All-Pairs Shortest Paths (APSP) that run in $O(n^\omega)$ time (where $\omega < 2.372$ is the matrix multiplication exponent) even when $\mathrm{vc} = \Theta(n)$. More recently, Iwata et al. [26] proposed a divide-and-conquer framework in the design of fully polynomial-time algorithms parameterized by tree-depth. For instance, they showed that Maximum Matching can be solved in $O(m \cdot \mathrm{td})$ time.

In this work, we consider the parameter *vertex integrity*, a parameter that lies between vertex cover number and tree-depth. The vertex integrity $\iota$ of a graph $G$ is the smallest integer such that $G$ contains a set $S$ of $\iota' \leq \iota$ vertices whose deletion results in a graph whose connected components each have at most $\iota - \iota'$ vertices. Many problems can be solved in $O(nm)$ time and thus in $O(\iota n^2)$ time, since $m \in O(\iota n)$. As the relation $\mathrm{td} \leq \iota \leq \mathrm{vc}+1$ holds for any graph, an algorithm that runs in $O(m \cdot \mathrm{td})$ time (e.g., for Maximum Matching) also runs in time $O(\iota^2 n)$. These bounds become $O(n^3)$ when $\iota = \Theta(n)$. However, many problems can be solved in faster $O(n^\omega)$ time using fast matrix multiplication. We aim to close this gap by developing fully polynomial-time algorithms that run in $O(n^\omega)$ time even when $\iota = \Theta(n)$. Such algorithms are called *adaptive*, and are optimal unless there is an (unparameterized) algorithm that runs faster than $O(n^\omega)$ time. For many problems, the discovery of such an algorithm would be a breakthrough, given that these $O(n^\omega)$-time algorithms were developed decades ago and have not been improved since.

**Our approach.** Before describing our results, let us briefly discuss our approach (see Section 2 for details). Let $S$ be a *$k$-separator*, a vertex set of size at most $k' \leq k$ such that each connected component of $G - S$ has size $k - k'$. Throughout the paper, we will make the assumption that a $k$-separator is given as input. We remark that our algorithms do not require an (optimal) $\iota$-separator to compute the correct solution. However, the running times of our algorithm will depend on $k$ and to achieve the claimed running times, we require a $k$-separator with $k \in O(\iota)$. Although $G - S$ may have $O(n)$ connected components, we may assume that there are $\Theta(n/k)$ "components" (which are not necessarily connected; see Section 2 for details), each with $O(k)$ vertices. For every component $C$, we can use the $O(n^\omega)$-time algorithm to solve the instance on $G[C]$ or $G[S \cup C]$, which takes $O(k^\omega \cdot n/k) = O(k^{\omega-1} n)$ time. The next step is to combine solutions for $O(n/k)$ instances, which varies depending on the problem. For instance, this is trivial for the problem of finding a triangle, as a triangle must be contained in $S \cup C$ for some component $C$. For other problems, e.g., finding a maximum matching, this step requires a more sophisticated approach.

**Main results.** There are three main results in this work.

The first result concerns the problem of finding an induced copy of a graph $H$. Vassilevska Williams et al. [38] gave an $O(n^\omega)$-time algorithm that finds an induced copy of $H$ when $H$ is a graph on four vertices that is not a clique $K_4$ or its complement $\overline{K_4}$. Their randomized algorithm is based on computing the number of induced copies of $H$ modulo some integer $q$ which they show to be computable from $A^2$ in linear time, where $A$ is the adjacency matrix. We observe that the "essential" part of $A^2$ can be computed in $O(\iota^{\omega-1} n)$ time, leading to $O(\iota^{\omega-1} n)$-time algorithms.

Secondly, we develop an $O(\iota^{\omega-1}n)$-time algorithm for finding a maximum matching. We start by showing that whether a graph contains a perfect matching can be determined in $O(\iota^{\omega-1}n)$ time. Tutte [36] observed that the Tutte matrix is nonsingular if and only if the graph has a perfect matching. By the Schwartz-Zippel lemma, we can test its nonsingularity in randomized $O(n^\omega)$ time. We can thus test whether each component in $G-S$ has a perfect matching in $O(\iota^{\omega-1}n)$ time. However, there might be a vertex in $S$ that must be matched to a vertex in $G-S$. To handle these cases, we use *Schur complements*. The task of finding a maximum matching is more intricate. Lovász [30] generalized Tutte's observation by stating that the rank of the Tutte matrix (which can be computed in randomized $O(n^\omega)$ time) equals twice the size of a maximum matching. It was only decades later that $O(n^\omega)$-time algorithms for finding one were discovered. Mucha and Sankowski [31] and Harvey [24] gave such algorithms. We show how to adapt the latter to obtain an $O(\iota^{\omega-1}n)$-time algorithm for finding a maximum matching.

Lastly, we study APSP on unweighted graphs. Seidel [34] showed that APSP can be solved in $O(n^\omega \log n)$ time. Alon and Yuster [2] later developed an algorithm that runs in $O(\mathrm{vc}^{\omega-2}\, n^2)$ time (they actually provide a stronger bound using rectangular matrix multiplication). We show that APSP can be solved in $O(\iota^{\omega-2}n^2)$ time when the graph has constant diameter. We were not able to obtain an adaptive algorithm in general, but we give an $O(\iota^{(\omega-1)/2}n^2) \subseteq O(\iota^{0.687}n^2)$-time algorithm. When parameterizing by vc, we can effectively replace every vertex not in the vertex cover with edges of weight two connecting their neighbors. Thus, the $O(Wn^\omega)$-time algorithm [17, 35] for weighted APSP, where $W$ is the maximum weight, finds all pairwise distances between vertices in the vertex cover in $O(\mathrm{vc}^\omega)$ time. For vertex integrity, we show how to replace every component with edges of weight $O(\iota)$. To compute distances between pairs of vertices with at least one vertex not in the $k$-separator, we use the known subcubic-time algorithm for computing min-plus matrix multiplication for *bounded-difference matrices*, matrices in which the difference of two adjacent entries in a row is constant [10].

**Previous work on vertex integrity.** The notion of vertex integrity was introduced by Barefoot et al. [3]. The vertex integrity $\iota$ can be much smaller than $n$, e.g., it is known that $\iota \in O(n^{2/3})$ on $K_h$-minor free graphs [4]. The Vertex Integrity problem, i.e., computing an $\iota$-separator is NP-hard. A straightforward branching algorithm solves Vertex Integrity in $O(\iota^\iota \cdot n)$ time (see [15]). A greedy algorithm can find an $O(\iota^2)$-separator in linear time. There is also a polynomial-time algorithm that can find an $O(\iota \log \iota)$-separator [29]. FPT algorithms parameterized by vertex integrity gained increased attention recently [6, 15, 16, 22, 28]. In particular, see Gima et al. [22] for an extensive list of problems that are W[1]-hard for tree-depth but become FPT when parameterized by vertex integrity.

## 2 Preliminaries

We use standard notation from graph theory. Unless stated otherwise, all appearing graphs are undirected. Further, $V$ denotes the set of vertices in the graph, $E$ its set of edges, $n$ its number of vertices, and $m$ its number of edges. We denote an edge between two vertices $u$ and $v$ by $uv$. A *walk* of length $\ell$ is a sequence $v_1, \ldots, v_\ell$ of (not necessarily distinct) vertices such that $v_iv_{i+1} \in E$ for all $i \in [\ell-1]$, where $[j] := \{1, \ldots, j\}$ for any integer $j$. A walk whose vertices are all pairwise distinct is a *path*. The *adjacency matrix* of $G$ is the $V \times V$-matrix $A$ with $A[u,v] = 1$ if and only if $uv \in E$, and $A[u,v] = 0$ otherwise (where $A[u,v]$ is the entry of $A$ indexed by $u$ and $v$).

**Graph parameters.** For a graph $G$, the *vertex integrity* is the smallest integer $\iota$ such that $G$ contains a set $S$ (called *$\iota$-separator*) of $\iota' \leq \iota$ vertices whose deletion results in a graph whose connected components each have at most $\iota - \iota'$ vertices. The *vertex cover number* vc is the smallest cardinality of a vertex cover, a set that contains at least one endpoint of every edge. The *tree-depth* td is the smallest depth of a rooted forest $F$ with vertex set $V$ such that $G$ can be *embedded* in $F$, i.e., for every edge $xy$ in $G$, $x$ is an ancestor of $y$ or vice versa. The *feedback vertex number* is the smallest cardinality of a feedback vertex set, a set that contains at least one vertex of every cycle.

**Decomposition.** Here, we describe the decomposition with respect to a $k$-separator, which will be used throughout the paper. Let $S$ be a $k$-separator. Typically in our algorithms, we spend $O(k^\omega)$ time for every connected component in $G - S$. Since $G - S$ may have $\Omega(n)$ connected components, this would result in a running time of $O(k^\omega n)$, which is often worse than a more straightforward algorithm. Thus, we will do the following to bound the number of "components" by $O(n/k)$: Basically, we put together some connected components $C$ and construct a collection $\mathcal{T}$ of sets, each (except for possibly the last one) containing between $k$ and $2k-1$ vertices. More precisely, we start with $\mathcal{T} = \emptyset$ and process the connected components of $G - S$ one by one as follows. If every set $T \in \mathcal{T}$ has at least $k$ vertices, then add $\{C\}$ to $\mathcal{T}$, and otherwise replace the set $T \in \mathcal{T}$ with $|T| < k$ by $T \cup C$. Since every connected component $C$ has at most $k$ vertices, every set $T \in \mathcal{T}$ (except for possibly the last set which may be smaller) contains between $k$ and $2k-1$ vertices. Let $\mathcal{T} = \{T_1, \ldots, T_\nu\}$. It is easy to see that $\nu \leq n/k + 1$. In our algorithms, we will always assume that the decomposition $(S; T_1, \ldots, T_\nu)$ of $V$ is given. Note that given a $k$-separator, the decomposition can be computed in linear time.

**Basic operations in matrix multiplication time.** For $n \times n$-matrices $A, B$, one can compute the following in $O(n^\omega)$ time: (i) the product $AB$, (ii) the determinant $\det A$, (iii) the inverse $A^{-1}$, and (iv) a row/column basis of $A$ (see e.g., [9]). More generally, for a $k \times n$-matrix $A$ and an $n \times k$-matrix $B$, one can compute the product $AB$ in $O(k^{\omega-1}n)$ time by dividing $A$ and $B$ into $n/k$ blocks of size $k \times k$. The rank of $A$ can be computed using Gaussian elimination using $O(k^{\omega-1}n)$ arithmetic operations [8]. Throughout the paper, we will use a word RAM model with word size $O(\log n)$. If $\mathbb{F}$ is a field of size $\mathrm{poly}(n)$, we will assume that addition and multiplication take $O(1)$ time.

**Matrices and Matchings.** For a subset $X$ of rows and a subset $Y$ of columns, we denote by $A[X, Y]$ the restriction of the matrix $A$ to rows $X$ and columns $Y$. For a set $X$ of rows (or columns), we will use the shorthand $A[X]$ for $A[X, X]$. The $i$-th power of the adjacency matrix $A$ correspond to the number of walks of length $i$, i.e., $A^i[u, v]$ equals the number of $u$-$v$-walks of length $i$ in $G$.

Note that for any graph with a $k$-separator $S$ and decomposition $(S; T_1, \ldots, T_\nu)$ it holds that there is no edge between a vertex in $T_i$ and a vertex in $T_j$ for any $i \neq j$. We can therefore represent the adjacency matrix $A$ of the graph as follows.

$$A = \begin{array}{c} \\ S \\ \bar{S} \end{array} \begin{array}{c} \begin{array}{cc} S & \bar{S} \end{array} \\ \begin{bmatrix} \gamma & \beta \\ \beta^T & \alpha \end{bmatrix} \end{array}, \text{ for } \alpha = \begin{array}{c} \\ T_1 \\ \vdots \\ T_\nu \end{array} \begin{array}{c} \begin{array}{ccc} T_1 & \cdots & T_\nu \end{array} \\ \begin{bmatrix} \alpha_1 & \cdots & O \\ \vdots & \ddots & \vdots \\ O & \cdots & \alpha_\nu \end{bmatrix} \end{array} \text{ with } \beta = \begin{array}{c} \\ S \end{array} \begin{array}{c} \begin{array}{ccc} T_1 & \cdots & T_\nu \end{array} \\ \begin{bmatrix} \beta_1 & \cdots & \beta_\nu \end{bmatrix} \end{array}. \quad (1)$$

Here, $\bar{S} = T_1 \cup \cdots \cup T_\nu$ and the matrices $\alpha_i, \beta_i, \gamma$ all have size $O(k) \times O(k)$. Many of our algorithms will use this representation and exploit the sparseness when computing e.g., matrix multiplications and determinants.

We denote the (unique) finite field with $2^q$ many elements by $\mathrm{GF}(2^q)$. Note that this field has characteristic 2, i.e., $x + x = 0$ for every $x \in \mathrm{GF}(2^q)$. For a graph $G = (V, E)$, the Tutte matrix (also known as the skew adjacency matrix) $A$ whose rows and columns are indexed by $V = \{v_1, \ldots, v_n\}$ is defined by

$$A[u,v] = \begin{cases} +x_{uv} & \text{if } u = v_i, v = v_j \text{ with } i < j \text{ and } uv \in E(G) \\ -x_{uv} & \text{if } u = v_i, v = v_j \text{ with } j < i \text{ and } uv \in E(G) \\ 0 & \text{otherwise,} \end{cases}$$

where $x_{uv}$ is a variable associated with the edge $uv$. The Tutte matrix $A$ is *skew-symmetric*, i.e., $A = -A^T$. The Pfaffian of a skew-symmetric matrix $A$ indexed by $V$ is defined as

$$\mathrm{pf}(A) = \sum_{M \in \mathcal{M}} \sigma_M \prod_{uv \in M} A[u,v],$$

where $\mathcal{M}$ is the set of all perfect matchings of $(V, \binom{V}{2})$ and $\sigma_M \in \{\pm 1\}$ is the sign of $M$. We will assume that the field has characteristic 2 (implying $-1 = 1$), and thus the precise definition of $\sigma_M$ is not important for us. (This assumption is not essential to our algorithm but it will simplify the notation.)

The following are well-known facts about skew-symmetric matrices (see e.g., [23, 32]).

▶ **Lemma 1.** *For a skew-symmetric matrix $A$, we have $\det A = \mathrm{pf}(A)^2$.*

In particular, a skew-symmetric matrix $A$ is nonsingular if and only if $\mathrm{pf}(A) \neq 0$.

▶ **Lemma 2.** *For a skew-symmetric matrix $A$, if $X$ is a row (or column) basis, then $A[X]$ is nonsingular.*

The next is immediate from the definition of Pfaffians.

▶ **Lemma 3** (row expansion). *For a skew-symmetric matrix $A$ indexed by $V$ and $v \in V$ over a field of characteristic 2, we have $\mathrm{pf}(A) = \sum_{v' \in V \setminus \{v\}} A[v,v'] \cdot \mathrm{pf}(\widehat{A}_{v,v'})$, where $\widehat{A}_{v,v'}$ is the matrix where the rows and columns indexed by $v$ and $v'$ are deleted.*

Proofs of statements marked with $\star$ are omitted from the conference version and can be found in a full version of this paper.

## 3 Finding Subgraphs

In this section, we develop adaptive algorithms for finding four-vertex subgraphs. There are eleven non-isomorphic graphs with 4 vertices: the clique on four vertices ($K_4$) and its complement ($\overline{K_4}$), the diamond ($K_4 - e$) and its complement ($\overline{K_4 - e}$), the claw ($K_{1,3}$) and its complement ($\overline{K_{1,3}}$), the paw ($K_{1,3} + e$) and its complement ($\overline{K_{1,3} + e}$), the cycle on four vertices ($C_4$) and its complement ($\overline{C_4}$), and the path on four vertices ($P_4$) (which is its own complement). Note that $+e$ and $-e$ indicate the insertion of an edge or the deletion of any edge, respectively. A linear-time algorithm is known for detecting whether the input graph contains an induced $P_4$ [12]. For $K_4$ and $\overline{K_4}$, the currently fastest algorithm runs in $O(n^{3.257})$ [18, 21] and for all other graphs the best known algorithm is by Williams et al. [38] and runs in $O(n^\omega)$ time. Their approach can be summarized as follows.

- Let $G$ be an undirected graph and let $A$ be its adjacency matrix. Let $H = (V', E')$ be a four-vertex graph that is none of $K_4$, $\overline{K_4}$, $C_4$, $\overline{C_4}$. There is an integer $2 \leq q_H \leq 6$ such that if we can compute $A^2[u, v]$ for every edge $uv \in E(G)$ in time $t$, then we can compute the number of induced copies of $H$ in $G$ modulo $q_H$ in $O(n + m + t)$ time. See [38, Lemma 4.1] for details. (Some equations provided in [38] require $A^3[v]$ for every $v \in V$. However, this can be computed in $O(m)$ time if $A^2[u, v]$ is given for every edge $uv$.)
- Let $q \geq 2$ be an integer and let $G, H$ be two undirected graphs. Let $G'$ be an induced subgraph of $G$ obtained by independently deleting each vertex with probability $1/2$. If $G$ contains $H$ as an induced subgraph, then the number of induced copies of $H$ in $G'$ modulo $q$ is not 0 with probability at least $2^{-|V(H)|}$. (For our applications, $|V(H)| = 4$, so this probability is at least $1/16$.)

We show that when a $k$-separator is given, one can test in $O(k^{\omega-1}n)$ time whether there is an induced copy of $H$ for each four-vertex graph $H$ except for $K_4$ and $\overline{K_4}$. We start with all graphs except for $K_4$, $\overline{K_4}$, $C_4$, $\overline{C_4}$. Using the framework by Williams et al. [38], it suffices to show how to compute $A^2[u, v]$ for every edge $uv \in E(G)$. Clearly, it requires $\Omega(n^2)$ time to compute the square $A^2$. Our key observation is that the relevant part of $A^2$ can be computed in $O(k^{\omega-1} \cdot n)$ time. (Incidentally, $A^2$ can be computed in $O(k^{\omega-2}n^2)$ time; see Lemma 18.)

▶ **Lemma 4.** *Given a graph $G$ and a $k$-separator $S$, we can compute $A^2[u, v]$ for every edge $uv \in E(G)$ in $O(k^{\omega-1}n)$ time.*

**Proof.** We use the decomposition $(S; T_1, \ldots, T_\nu)$ described in Section 2 and suppose that the adjacency matrix $A$ has the form given in Equation (1). Note that

$$A^2 = \begin{array}{c} \\ S \\ T_1 \\ \vdots \\ T_\nu \end{array} \begin{array}{c} \begin{array}{cccc} S & T_1 & \cdots & T_\nu \end{array} \\ \begin{bmatrix} \zeta & \eta_1 & \cdots & \eta_\nu \\ \eta_1^T & \delta_1 & \cdots & - \\ \vdots & \vdots & \ddots & \vdots \\ \eta_\nu^T & - & \cdots & \delta_\nu \end{bmatrix} \end{array}, \text{ where } \begin{array}{l} \zeta = \gamma^2 + \beta\beta^T, \\ \eta_i = \gamma\beta_i + \beta_i\alpha_i, \text{ and} \\ \delta_i = \beta_i^T\beta_i + \alpha_i^2. \end{array}$$

Note that computing $\zeta$ takes $O(\nu \cdot k^\omega) = O(k^{\omega-1}n)$ time and computing each of the $O(\nu)$ submatrices $\eta_i$ or $\delta_i$ takes $O(k^\omega)$ time. The $-$ represents pairs where the corresponding vertices belong to different $T_i$ and are therefore non-adjacent. We thus do not need to compute these values. Thus, we can compute all relevant values in $O(k^{\omega-1}n)$ time. ◀

By Lemma 4, an induced copy of $H \notin \{K_4, \overline{K_4}, C_4, \overline{C_4}\}$ can be detected in $O(\iota^{\omega-1}n)$ time. We show next that $C_4$ and $\overline{C_4}$ can also be detected in $O(\iota^{\omega-1}n)$ time.

▶ **Proposition 5** (⋆). *Given a graph $G$, a $k$-separator, and a graph $H \in \{C_4, \overline{C_4}\}$, we can test whether $G$ contains $H$ as an induced subgraph in $O(k^{\omega-1}n)$ time.*

Thus, we obtain the following.

▶ **Proposition 6.** *Given a graph $G$, a $k$-separator, and a graph $H$ with four vertices that is not $K_4$ or $\overline{K_4}$, we can test whether $G$ contains an induced copy of $H$ in $O(k^{\omega-1}n)$ time.*

We can also find an induced copy with a constant overhead using a standard self-reduction.

▶ **Corollary 7** (⋆). *Given a graph, a $k$-separator, and a graph $H$ with four vertices that is not $K_4$ or $\overline{K_4}$, we can find an induced copy of $H$ in $O(k^{\omega-1}n)$ time if it exists.*

Finally, let us also remark on the detection of cliques $K_\ell$ and independent sets $\overline{K_\ell}$. Let $t_\ell(n)$ be the time complexity of finding $K_\ell$ (or $\overline{K_\ell}$) on an $n$-vertex graph. (It is known, for instance, that $t_4(n) \in O(n^{3.257})$ [18] using fast rectangular matrix multiplication [21].) Since any $K_\ell$ must fully be contained in $G[S \cup T_i]$ for some $i$, it can be detected in $O(t_\ell(\iota)/\iota \cdot n)$ time. For the detection of $\overline{K_\ell}$, note that if $n/\iota \geq \ell$, then there is an independent set of size $\ell$. Thus, we may assume that $n \leq \iota\ell$. For constant $\ell$, we can thus find $\overline{K_\ell}$ in $O(t_\ell(\iota))$ time.

In the full version of the paper, we also study the problem of finding short(est) cycles. In particular, we show that *girth*, i.e., the length of a shortest cycle, can be computed in $O(\iota^{\omega-1}n)$ time.

## 4 Matching

As mentioned in the introduction, Lovász [30] showed that the cardinality of a maximum matching can be determined in randomized $O(n^\omega)$ time. Several decades later, two algorithms have been developed to find a maximum matching [24, 31]. In this section, we show the following.

▶ **Theorem 8.** *Given a graph and a $k$-separator, we can find a maximum matching in randomized $O(k^{\omega-1}n)$ time.*

In the full version of the paper, we show that the existence of a perfect matching can be checked in $O(k^{\omega-1}n)$ time, where $k$ is the feedback vertex number of the input graph, that is, the minimum number of vertices to delete in order to turn the graph into a forest.

Tutte [36] showed that $G$ has a perfect matching if and only if its symbolic Tutte matrix $A$ is nonsingular. Lovász [30] later showed that the rank of $A$ equals twice the size of maximum matching. To avoid computation over a multivariate polynomial ring, we will assume that each variable $x_{uv}$ is instantiated with an element chosen from a finite field $\mathbb{F}$ uniformly at random. (We will assume that $|\mathbb{F}| = \mathrm{GF}(2^{c\lceil \log n \rceil})$ for a sufficiently large constant $c > 0$.) Since the determinant of the symbolic Tutte matrix has degree at most $n$, by the Schwartz–Zippel lemma [33, 39] (which states that a non-zero polynomial of total degree $d$ over a finite field $\mathbb{F}$ is, when evaluated at a uniformly randomly coordinate, non-zero with probability at least $1 - d/|\mathbb{F}|$), if $G$ has a perfect matching and $\mathbb{F}$ is of size at least $\delta n$, then $A$ is nonsingular with probability at least $1 - 1/\delta$.

Let $A$ be a block matrix $A = \begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix}$. If $\alpha$ is nonsingular, then the determinant of $A$ is $\det(A) = \det(\alpha) \cdot \det(C)$, where $C = \delta - \gamma\alpha^{-1}\beta$ is the Schur complement (see e.g., [32]). Thus, assuming that $\alpha$ is nonsingular, $A$ is nonsingular if and only if $\delta - \gamma\alpha^{-1}\beta$ is nonsingular. A simple application of the Schur complement yields the following.

▶ **Lemma 9.** *Consider a matrix $A$ of the following form. Then, provided that $\alpha$ is nonsingular, $A$ is nonsingular if and only if the following matrix $A'$ is nonsingular.*

$$A = \begin{bmatrix} \alpha & \beta & 0 \\ -\beta^T & \gamma & \zeta \\ 0 & -\zeta^T & \eta \end{bmatrix} \qquad A' = \begin{bmatrix} \gamma & \zeta \\ -\zeta^T & \eta \end{bmatrix} - \begin{bmatrix} -\beta^T \\ 0 \end{bmatrix} \alpha^{-1} \begin{bmatrix} \beta & 0 \end{bmatrix} = \begin{bmatrix} \gamma + \beta^T\alpha^{-1}\beta & \zeta \\ -\zeta^T & \eta \end{bmatrix}$$

**Harvey's algorithm.** There is a randomized $O(n^\omega)$-time algorithm to find a perfect matching in a graph (if one exists) due to Harvey [24]. We describe the algorithm outline here. The main idea is to delete edges as long as at least one perfect matching remains until we are left with a graph in which every vertex has exactly one neighbor. Here, deleting an edge

corresponds to setting the corresponding entries in the Tutte matrix to zero. Whether an edge is *deletable*, i.e., whether there remains a perfect matching after its deletion, can be determined in $O(1)$ time after computing the inverse of the Tutte matrix in a preprocessing step. This is essentially due to the fact that for a nonsingular matrix $A$ and column vectors $u$ and $v$, matrix $A + uv^T$ is nonsingular if and only if $1 + v^T A^{-1} u \neq 0$. When an edge is deleted, the inverse needs to be updated and the Sherman-Morrison-Woodbury formula (which is not relevant for us) is employed in Harvey's algorithm. However, it takes $O(n^2)$ time when this update is implemented naively. The crux of Harvey's algorithm lies in a recursive scheme that essentially allows to perform the update in $O(1)$ time. The algorithm uses a subroutine called DeleteEdgesCrossing, which takes two disjoint vertex sets $R$ and $S$ as input and iteratively deletes all deletable edges $uv$ with $u \in R$ and $v \in S$. This subroutine runs in $O(n^\omega)$ time and our algorithm will also use it.

## 4.1 Detecting a perfect matching

In this section, we will describe a randomized $O(k^{\omega-1}n)$-time algorithm to test whether a given graph with a $k$-separator $S$ contains a perfect matching. We assume that the Tutte matrix $A$ has the form of Equation (1) and that it is instantiated randomly from a field $\mathbb{F} = \mathrm{GF}(2^{c\lceil \log n \rceil})$. For each component $T_i$, we find a basis $T_i' \subseteq T_i$ of $A[T_i]$ in $O(k^\omega)$ time. Note that $A[T_i']$ is nonsingular by Lemma 2. Let $T_i^* = T_i \setminus T_i'$, $S_i = S_{i-1} \cup T_i^*$ for $S_0 = S$, and $S^* = S_\nu$. Note that if $G$ has a perfect matching $M$, then at least $|T_i^*|$ vertices of $T_i$ are matched to $S$. Thus, if $\sum_{i\in[\nu]} |T_i^*| > |S|$, we can conclude that there is no perfect matching. Otherwise, we have $|S^*| \leq 2k$. Now, consider for each component $T_i'$ the matrix

$$B_i = \begin{array}{c} \\ T_i' \\ S^* \\ V \setminus (S^* \cup \bigcup_{j\in[i-1]} T_j') \end{array} \begin{array}{c} \begin{array}{ccc} T_i' & S^* & V \setminus (S^* \cup \bigcup_{j\in[i-1]} T_j') \end{array} \\ \begin{bmatrix} \alpha_i & \beta_i & 0 \\ -\beta_i^T & \gamma_i & \zeta_i \\ 0 & -\zeta_i^T & \eta_i \end{bmatrix} \end{array},$$

where $\gamma_1 = \gamma$, $\gamma_{i+1} = \gamma_i + \beta_i^T \alpha_i^{-1} \beta_i$, and all entries except for $\gamma_i$ for $i > 1$ are identical to the corresponding entries of $A$. Note that $\alpha_i$ and $\beta_i$ may differ from $\alpha_i$ and $\beta_i$ in Equation (1), but if $T_j' = T_j$ for all $j \in [\nu]$, then $\alpha_i$ and $\beta_i$ here coincide with $\alpha_i$ and $\beta_i$ from Equation (1). Note that the matrix $B_1$ coincides with the Tutte matrix $A$. Hence, we only need to test whether $B_1$ is nonsingular. We do this by iteratively computing $B_{i+1}$ from $B_i$ in $O(k^\omega)$ time. For notational convenience, we will assume that there is an empty component $T_{\nu+1}'$. Since $\alpha_i = A[T_i']$ is nonsingular, by Lemma 9 the matrix $B_i$ is nonsingular if and only if $B_{i+1}$ is nonsingular. The nonsingularity of $B_{\nu+1} = \gamma_{\nu+1}$ can be tested in $O(k^\omega)$ time since it has size $O(k) \times O(k)$. Note that our algorithm takes $O(k^\omega)$ time for each $i \in [\nu + 1]$ and thus $O(\nu k^\omega) = O(k^{\omega-1}n)$ time overall. If $A$ is nonsingular, then our algorithm correctly concludes that there is a perfect matching. By the Schwartz–Zippel lemma, we know that if $G$ admits a perfect matching, then the probability that $A$ is nonsingular is at least $1 - n/|\mathbb{F}| \geq 1/2$. This leads to the following result.

▶ **Proposition 10.** *Given a graph and a $k$-separator, we can test whether it has a perfect matching in randomized $O(k^{\omega-1}n)$ time.*

In the full version of the paper, we show that whether there is a perfect matching can be checked in $O(k^{\omega-1}n)$ time, where $k$ is the feedback vertex number. We use a similar approach based on the Schur complement. The major difference is that computing $(A[V \setminus S])^{-1}$ would

require $\Omega(n^2)$ time ($A$ is the Tutte matrix and $S$ is a feedback vertex set). Instead, we compute $(A[V \setminus S])^{-1}A[S, V \setminus S]$ via dynamic programming in $O(kn)$ time. To that end, we first show that for entries with both coordinates in $S$ in the Tutte matrix, it suffices to use values in $\{0, 1\}$ instead of variables. This allows us to give a simple characterization of the entries of $(A[V \setminus S])^{-1}$ in terms of alternating paths. Our dynamic program uses a recurrence relation based on this.

▶ **Proposition 11** (⋆). *Deciding whether a given graph $G$ contains a perfect matching can be done in randomized $O(k^{\omega-1}n)$ time, where $k$ is the feedback vertex number of $G$.*

## 4.2 Finding a perfect matching

We next give an algorithm to find a perfect matching (if one exists). We will use the same notation as before and we will again assume that $\alpha_i$ is nonsingular for every $i \in [\nu]$. Note that if the submatrix $\gamma_1$ is also nonsingular, then it is easy to find a perfect matching since the corresponding submatrices $\gamma_1 = A[S^*]$ and $\alpha_i = A[T_i']$ are all nonsingular and therefore there exists a perfect matching in $G[S^*]$ and $G[T_i']$ for every $i \in [\nu]$. We can find these using one of the randomized $O(n^\omega)$-time algorithms [24, 31]. This procedure takes $O(k^\omega\nu) = O(k^{\omega-1}n)$ time. However, in general, we cannot assume that $\gamma_1$ is nonsingular.

To deal with the case that $\gamma_1$ is singular, we use Harvey's aforementioned algorithm. Our algorithm first computes $\gamma_i$ for each $i \in [\nu + 1]$. We then proceed inductively in decreasing order from $i = \nu+1$ to $i = 1$. Our algorithm finds a set $\widetilde{S}_i \subseteq \widetilde{S}_{i+1} \subseteq S^*$ (we set $\widetilde{S}_{\nu+1} = S^*$ for notational convenience) and a matching $M_i$ which saturates every vertex in $(\widetilde{S}_{i+1} \setminus \widetilde{S}_i) \cup T_i'$. The matching $M_i$ is the union of two matchings $M_i'$ and $M_i''$, where $M_i'$ is a perfect matching between $\widetilde{S}_{i+1} \setminus \widetilde{S}_i$ and $T_i' \setminus T_i''$ for $T_i'' \subseteq T_i'$ and $M_i''$ is a perfect matching in $G[T_i'']$ (see Lemmas 13 and 14).

We will maintain the invariant that $\gamma_i[\widetilde{S}_i]$ is nonsingular. For $i = \nu + 1$, we have that $\gamma_{\nu+1}[\widetilde{S}_{\nu+1}] = B_{\nu+1}$ is nonsingular. Moreover, if this invariant is maintained, then $\gamma_1[\widetilde{S}_1]$ is nonsingular and thus $G[\widetilde{S}_1]$ contains a perfect matching that can be combined with all previous $M_i$ to obtain a perfect matching for $G$. To find the set $\widetilde{S}_i$ for $i \in [\nu]$, consider the following submatrix $B_i'$ of $B_i$ whose rows and columns are indexed by $\widetilde{S}_{i+1} \cup T_i'$:

$$B_i' = \begin{bmatrix} \alpha_i & \beta_i[T_i', \widetilde{S}_{i+1}] \\ -\beta_i^T[\widetilde{S}_{i+1}, T_i'] & \gamma_i[\widetilde{S}_{i+1}] \end{bmatrix}.$$

Note that for a nonzero entry in $B_i'$, if one of the coordinates is in $T_i'$, then the corresponding edge exists in $G$ but this is not necessarily the case if both coordinates are in $\widetilde{S}_{i+1}$. We first show that $B_i'$ is nonsingular.

▶ **Lemma 12** (⋆). *For each $i \in [\nu]$, the matrix $B_i'$ is nonsingular.*

Since $B_i'$ is nonsingular, we can compute $(B_i')^{-1}$ and apply the subroutine DeleteEdges-Crossing of Harvey [24] on the bipartition $(\widetilde{S}_{i+1}, T_i')$ in $O(k^\omega)$ time. (This subroutine requires the inverse to be given.) Essentially, we "delete" (i.e., change to zero) all deletable entries with one coordinate in $\widetilde{S}_{i+1}$ and the other in $T_i'$. We then get a skew-symmetric matrix $C_i$ that is identical to $B_i'$ except that some entries in $C_i[\widetilde{S}_{i+1}, T_i']$ and $C_i[T_i', \widetilde{S}_{i+1}]$ are set to zero. Let $\widetilde{S}_i$ be those vertices $v \in \widetilde{S}_{i+1}$ such that $C_i[T_i', v]$ is a zero vector and $T_i''$ be those vertices $u \in T_i'$ such that $C_i[\widetilde{S}_{i+1}, v]$ is a zero vector. Each remaining nonzero entry in $C_i[\widetilde{S}_{i+1}, T_i']$ and $C_i[T_i', \widetilde{S}_{i+1}]$ is undeletable. We show that all edges corresponding to these entries form a perfect matching $M_i'$ between $\widetilde{S}_{i+1} \setminus \widetilde{S}_i$ and $T_i' \setminus T_i''$.

▶ **Lemma 13.** *The set* $M'_i = \{uv \mid C_i[u,v] \neq 0, u \in \widetilde{S}_{i+1} \setminus \widetilde{S}_i, v \in T'_i \setminus T''_i\}$ *is a matching in* $G$ *with high probability.*

**Proof.** For a vertex $u \in \widetilde{S}_{i+1} \setminus \widetilde{S}_i$, assume that there are two vertices $v, v'$ such that $C_i[u,v] \neq 0$ and $C_i[u,v'] \neq 0$. We show that this leads to a contradiction when the variables are treated as indeterminates. Let $\widehat{C_i}_{u,w}$ be the result of deleting the rows and columns indexed by $u$ and $w$ from $C_i$. By Lemma 3, we have

$$\operatorname{pf}(C_i) = C_i[u,v] \operatorname{pf}(\widehat{C_i}_{u,v}) + C_i[u,v'] \operatorname{pf}(\widehat{C_i}_{u,v'}) + p, \tag{2}$$

where $p = \sum_{w \in \widetilde{S}_{i+1} \cup T'_i,\, w \notin \{v,v'\}} C_i[u,w] \operatorname{pf}(\widehat{C_i}_{u,w})$.

By the assumption that deleting the corresponding edge $uv$ or $uv'$ (i.e., setting $x_{uv} = 0$ or $x_{uv'} = 0$) results in a singular matrix (this is due to Harvey's algorithm), we have

$$C_i[u,v] \operatorname{pf}(\widehat{C_i}_{u,v}) + p = 0 \text{ and } C_i[u,v'] \operatorname{pf}(\widehat{C_i}_{u,v'}) + p = 0.$$

We thus obtain $C_i[u,v] \operatorname{pf}(\widehat{C_i}_{u,v}) = C_i[u,v'] \operatorname{pf}(\widehat{C_i}_{u,v'}) = -p$. Note that $p \neq 0$, since otherwise $\operatorname{pf}(C_i) = -p = 0$ by Equation (2), which is a contradiction because $C_i$ is nonsingular by Harvey's algorithm. The left hand side $C_i[u,v] \operatorname{pf}(\widehat{C_i}_{u,v})$ is multiplied by a variable $C_i[u,v] = x_{u,v}$ but this variable does not appear on the right hand side $C_i[u,v'] \operatorname{pf}(\widehat{C}_{u,v'})$. Thus, $Q = C_i[u,v] \operatorname{pf}(\widehat{C_i}_{u,v}) - C_i[u,v'] \operatorname{pf}(\widehat{C_i}_{u,v'})$ is a polynomial that is not identically zero, which is a contradiction. We thus have exactly one vertex $v \in T'_i \setminus T''_i$ such that $C_i[u,v] \neq 0$. Since $Q$ has degree at most $n$, this evaluates to non-zero with high probability by the Schwartz–Zippel lemma. An analogous argument shows that for every $v \in T'_i \setminus T''_i$, there is exactly one $u \in \widetilde{S}_{i+1} \setminus \widetilde{S}_i$ such that $C_i[u,v] \neq 0$. Since every nonzero entry in $C_i[\widetilde{S}_{i+1}, T_i]$ corresponds to an edge in $G$, we are done. ◀

We can now show that our main invariant can be maintained with high probability.

▶ **Lemma 14** (⋆). *The matrices* $\gamma_i[\widetilde{S}_i]$ *and* $\alpha_i[T''_i]$ *are nonsingular with high probability.*

Concluding this section, we prove our main result.

▶ **Proposition 15** (⋆). *Given a graph with a perfect matching and a* $k$*-separator, we can find a perfect matching in* $O(k^{\omega-1}n)$ *time.*

In the full version of the paper, we prove Theorem 8, that is, we show how to find a maximum matching in $O(k^{\omega-1}n)$ time, when given a $k$-separator.

## 5 All-Pairs Shortest Paths

We study the well-known All-Pairs Shortest Paths problem (APSP) on unweighted graphs. APSP on unweighted graphs can be solved in $O(n^\omega)$-time using matrix multiplication [34]. In this section, we show an algorithm which is faster than $O(n^\omega)$ when $k$ is sufficiently small, that is, $k \in O(n^{0.541})$.

▶ **Theorem 16.** *Given an (unweighted undirected) graph and its* $k$*-separator, APSP can be solved in* $O(k^{(\omega-1)/2}n^2) \subseteq O(k^{0.687}n^2)$*-time.*

APSP is closely connected to the min-plus-product. In fact, solving APSP is subcubic equivalent to computing the min-plus product of two matrices [19]. The *min-plus product* $A \star B$ of a $p \times q$-matrix $A$ with a $q \times r$-matrices $B$ is the $p \times r$-matrix $C$

with $C[i,j] = \min_{k\in[q]} A[i,k] + B[k,j]$. While it is conjectured that there is no algorithm computing the min-plus product of two $n \times n$-matrices in $O(n^{3-\epsilon})$ time for any $\epsilon > 0$, there is a subcubic-time min-plus matrix multiplication algorithm for bounded-difference matrices, i.e., matrices in which the difference of two adjacent entries in a row is small [10]. Although the distance matrix $D$ (which contain pairwise distances) does not necessarily have bounded differences, for two adjacent vertices $u$ and $v$, the difference between $D[u,w]$ and $D[u,v]$ for any $w \in V$ is at most 1. The "standard" decomposition of $G - S$ into $T_1, \dots, T_\nu$ from Section 2 is not convenient in this case, since two vertices in $T_i$ may have distance $\Theta(n)$, e.g., when $T_i$ is not connected. Our algorithm first modifies the given graph so that we have bounded-difference distance matrices. The main idea is that, for a $k$-separator $S$, we can join connected components from $G - S$ by adding copies of vertices in $S$. We will also ensure that there is a Hamiltonian path through each component (this step is essentially also used by Deng et al. [14]). This ensures that if we rearrange the rows and columns according to the Hamiltonian path, then two consecutive rows correspond to adjacent vertices and the distances between either of them and some third vertex differ by at most one.

▶ **Lemma 17** ($\star$). *Given a graph $G$ and a $k$-separator $S$, we can compute in $O(n+m)$ time a graph $G'$ and its $O(k)$-separator $S'$ such that $G' - S'$ has connected components $T'_1, \dots, T'_\nu$ for $\nu' \in O(n/k)$, each of which has a Hamiltonian path $H_i$, and $|S'| = |T'_1| = \cdots = |T'_\nu|$. Moreover, given the distance matrix $D'$ for $G'$, one can compute the distance matrix $D$ of $G$ in $O(n^2)$ time.*

Using Lemma 17, we now show that APSP on unweighted graphs can be solved faster than $O(n^\omega)$ if the vertex integrity is sufficiently small and $\omega > 2$.

**Proof of Theorem 16.** If $k \geq n^{0.6}$, then $k^{(\omega-1)/2}n^2 > n^\omega$ and we apply the $O(n^\omega \log n)$-time algorithm [34]. Otherwise, $k \leq n^{0.6}$ and we use the following algorithm to solve APSP.

1. We apply Lemma 17, resulting in a graph $G$ and sets $S, T_1, \dots, T_\nu$.
2. For every $i$, we solve APSP on $G[S \cup T_i]$. Let $D_i = D'_i[T_i, S]$, where $D'_i$ is the distance matrix of $G[S \cup T_i]$.
3. We compute an edge-weighted graph $G_S$ where the vertex set is $S$, the edge set is $\binom{S}{2}$, and $w(uv) = 1$ if $uv \in E(G)$, and $w(uv) = \min_i D_i(uv)$ otherwise. We solve APSP on this weighted graph and call the resulting distance matrix $D_S$. As we show later, $D_S[u,v]$ is the distance from $u$ to $v$ in $G$.
4. For each $i, j \in [\nu]$, we compute $D^*_i := D_i \star D_S$. and $D^*_{i,j} := D^*_i \star D_j^T$.
5. Return a symmetric matrix $D^*$ where the upper triangular part of $D^*$ is defined by

$$D^*[u,v] = \begin{cases} D_S[u,v] & u,v \in S, \\ D^*_i[u,v] & u \in S \text{ and } v \in T_i, \\ \min\{D_i[u,v], D^*_{i,i}[u,v]\} & u,v \in T_i \text{ for some } i \in [\nu], \\ D^*_{i,j}[u,v] & u \in T_i \text{ and } v \in T_j \text{ for } i \neq j. \end{cases}$$

First we show the correctness of the algorithm. For $u, v \in S$, Step 3 guarantees that $D^*[u,v] = D_S[u,v]$ is the distance between $u$ and $v$ in the weighted graph $G_S$. As each edge $u'v'$ in $G_S$ corresponds to a path in $S \cup T_i$ of length $w(u'v')$ for some $i \in [\nu]$, it follows that each path in $G_S$ corresponds to a walk in $G$ of the same length. Thus, $D_S[u,v]$ is not smaller than a shortest $u$-$v$-path in $G$. On the other hand, let $P$ be a shortest $u$-$v$-path in $G$. Let $u = s_1, \dots, s_\ell = v$ be the vertices of $P$ in $S$ (in the order they appear in $P$). By construction, for each $i < \ell$, there are no vertices in $S$ between $s_i$ and $s_{i+1}$ in $P$. Hence, this subpath of $P$ is fully contained in $G[S \cup T_j]$ for some connected component $T_j$ and we

have $w(s_i, s_{i+1}) \leq \text{dist}_{G[S \cup T_j]}(s_i, s_{i+1})$. Consequently, we have that $P$ corresponds to a path in the weighted graph $G_S$ and $D_S(u, v)$ is not larger than the length of a shortest $u$-$v$-path in $G$. Thus, $D_S[u, v]$ equals the distance between $u$ and $v$ in $G$ and $D^*[u, v]$ has therefore been computed correctly.

Next, assume that $u \in T_i$ for some $i \in [\nu]$ and $v \in S$ (the case $u \in S$ and $v \in T_i$ is analogous). A shortest $u$-$v$-path then consists of a shortest $u$-$s$-path in $G[S \cup T_i]$ and a shortest $s$-$v$-path in $G$ for some $s \in S$ (since each vertex in $T_i$ only has neighbors in $T_i \cup S$). This implies $\text{dist}_G[u, v] = \min_{s \in S} D_i[u, s] + D_S[s, v] = D_i^*[u, v]$.

Next, assume that $u \in T_i$ and $v \in T_i$ for some $i \in [\nu]$. Then a shortest $u$-$v$-path either stays completely in $T_i$ or it decomposes into a shortest $u$-$s$-path in $G[S \cup T_i]$, followed by a shortest $s$-$s'$-path in $G$, and finally followed by a shortest $s'$-$v$-path in $G[S \cup T_i]$ for some $s, s' \in S$. In the first case, the distance between $u$ and $v$ equals to $D_i[u, v]$. In the second case, the distance between $u$ and $v$ equals

$$\min_{s,s' \in S} \text{dist}_{G[S \cup T_i]}(u, s) + \text{dist}_G(s, s') + \text{dist}_{G[S \cup T_i]}(s', v) = D_{i,i}^*[u, v].$$

Thus, $D^*[u, v]$ contains the distance between $u$ and $v$.

Finally, assume that $u \in T_i$ and $v \in T_j$ for some $i \neq j \in [\nu]$. A shortest $u$-$v$-path then decomposes into a shortest $u$-$s$-path in $G[S \cup T_i]$, followed by a shortest $s$-$s'$-path in $G$, and finally followed by a shortest $s'$-$v$-path in $G[S \cup T_j]$ for some $s, s' \in S$. Consequently, we have $\text{dist}(u, v) = \min_{s,s' \in S} D_i[u, s] + D_S[s, s'] + D_j[s', v] = D_{i,j}^*[u, v]$.

It remains to analyze the running time of the algorithm. Step 1 runs in linear time by Lemma 17. Step 2 solves APSP on $O(n/k)$ many instances, each with $O(k)$ vertices. As APSP on unweighted graphs with $k$ vertices can be solved in $O(k^\omega \log(k))$ time, Step 2 runs in $O(nk^{\omega-1} \log(k))$ time.

Step 3 first computes a weighted graph on $O(k)$ vertices. Each edge can be computed in $O(n/k)$ time. As there are $O(k^2)$ many edges, computing the graph takes $O(n \cdot k)$ time. Solving weighted APSP on this graph then can be done in $O(k^3)$ time [37]. As we assumed $k \leq n^{0.6}$, this step runs in $O(n^{1.8})$ time.

Step 4 computes for each pair $(i, j) \in [n/k]$ the min-plus product of $D_i$, $D_S$, and $D_j$. We will show that we can compute these min-plus products in $O(k^{(3+\omega)/2})$ time (which is faster than the state-of-the-art algorithm for computing arbitrary min-plus products). The trick is to use the fact that $D_i$ and $D_i^*$ have bounded difference and then use a result by Chi et al. [10] stating that the min-plus product of two matrices of dimension $n \times n$ can be computed in $O(n^{(3+\omega)/2}) \subseteq O(n^{2.687})$ time if one of the matrices has bounded difference. While it is not true a priori that $D_i$ and $D_i^*$ have bounded difference, we will order the rows according to the Hamiltonian path $H_i$. This ensures that two consecutive vertices are adjacent, which implies that consecutive entries in a row differ by at most one. Hence, each computation of the min-plus product can be done in $O(k^{(3+\omega)/2})$ time, as $|S| = |T_1| = \cdots = |T_\nu| = O(k)$ by Lemma 17. Overall, Step 4 runs in $O((n/k)^2 \cdot k^{(3+\omega)/2}) = O(n^2 \cdot k^{(\omega-1)/2})$ time.

Lastly, Step 5 runs in $O(n^2)$ time. The overall running time of $O(k^{(\omega-1)/2} \cdot n^2)$ follows from the observation that the running time for Step 4 dominates the running time of Steps 1, 2, 3, and 5 as $k \leq n$ and $\omega < 2.9$. ◀

**Adaptive algorithm for bounded diameter.** We give an adaptive algorithm for constant diameter. The crucial observation here is that we can compute the product of the adjacency matrix of a graph with any other matrix in $O(\iota^{\omega-2} n^2)$ time.

▶ **Lemma 18.** *Given a graph $G$ with adjacency matrix $A$, a $k$-separator $S$ for $G$, and an $n \times n$-matrix $M$, the matrices $AM$ and $MA$ can be computed in $O(k^{\omega-2} n^2)$ time.*

**Proof.** Suppose that the adjacency matrix has the form as described in Equation (1). Then,

$$AM = \begin{bmatrix} \gamma M[S,V] + \beta M[\overline{S},V] \\ \beta^T M[S,V] + \alpha M[\overline{S},V] \end{bmatrix}.$$

A closer inspection reveals that all the computation can be done in $O(k^{\omega-2}n^2)$ time: First observe that $\gamma M[S,V]$ can be computed in $O(k^{\omega-1}n)$ time. For the other terms, note that

$$\begin{aligned} \beta M[\overline{S},V] &= \begin{bmatrix} \beta M[\overline{S},S] & \beta M[\overline{S},T_1] & \dots & \beta M[\overline{S},T_\nu] \end{bmatrix}, \\ \beta^T M[S,V] &= \begin{bmatrix} \beta^T M[\overline{S},S] & \beta^T M[\overline{S},T_1] & \dots & \beta^T M[\overline{S},T_\nu] \end{bmatrix}, \\ \alpha M[\overline{S},V] &= \begin{bmatrix} \alpha_1 M[T_1,\overline{S}] & \alpha_2 M[T_2,\overline{S}] & \dots & \alpha_\nu M[T_\nu,\overline{S}] \end{bmatrix}^T. \end{aligned}$$

Since there are $O(n/k)$ submatrices and each takes $O(k^{\omega-1}n)$ time to compute, $AM$ can be computed in $O(k^{\omega-2}n^2)$ time. Note that $MA = (AM^T)^T$ can be computed analogously. ◀

We obtain our algorithm from the folklore observation that for any two vertices $u, v \in V$, there is a walk of length exactly length $d$ between $u$ and $v$ if and only if $A^d[u,v] \neq \emptyset$.

▶ **Proposition 19.** *Given a graph $G$ and a $k$-separator $S$, APSP can be solved in $O(dk^{\omega-2}n^2)$ time where $d$ is the diameter of $G$.*

**Proof.** Let $A$ be the adjacency matrix of $G$. We compute matrices $B^1, \dots, B^d \in \{0,1\}^{n \times n}$ recursively as follows. We start with $B^1 := A$. Matrix $B^{i+1}$ is computed by multiplying $B^i$ with $A$ and replacing all non-zero entries by 1. Note that $A^i[u,v] = 0$ if and only if $B^i[u,v] = 0$. Thus, the distance between two vertices $u \neq v$ is the minimum $i$ such that $B^i[u,v] \neq 0$. By Lemma 18, we can multiply any matrix with $A$ in $O(k^{\omega-2}n^2)$ time. Thus, we can compute $B^1, \dots, B^d$ in $O(dk^{\omega-2}n^2)$ time. ◀

Note that $d$ can be of order $\Omega(k^2)$ as the vertex integrity in a cycle with $n$ vertices is in $O(\sqrt{n})$ and its diameter is $\lfloor n/2 \rfloor$.

## 6 Conclusion

In this work, we investigated the parameter vertex integrity in search for more efficient algorithms in the FPT-in-P paradigm. We exhibited that for many problems, the structure of graphs with a small vertex integrity allows us to harness the power of fast matrix multiplication. In particular, we designed randomized $O(\iota^{\omega-1}n)$-time algorithms for finding a four-vertex subgraph (which is not a $K_4$ or a $\overline{K_4}$) and a maximum matching. We also showed that unweighted APSP can be solved in $O(\iota^{(\omega-1)/2}n^2)$ time using min-plus product of bounded-differences matrices, leaving open whether there is an $O(\iota^{\omega-2}n^2)$-time algorithm. More broadly, we wonder whether a similar approach using fast matrix multiplication can be used for graphs of bounded tree-depth or tree-width. Existing approaches (e.g. [11, 20, 26]) do not seem amenable to fast matrix multiplication.

## Abstract

The *min-diameter* of a directed graph $G$ is a measure of the largest distance between nodes. It is equal to the maximum min-distance $d_{\min}(u, v)$ across all pairs $u, v \in V(G)$, where $d_{\min}(u, v) = \min(d(u, v), d(v, u))$. Min-diameter approximation in directed graphs has attracted attention recently as an offshoot of the classical and well-studied diameter approximation problem.

Our work provides a $\frac{3}{2}$-approximation algorithm for min-diameter in DAGs running in time $O(m^{1.426}n^{0.288})$, and a faster almost-$\frac{3}{2}$-approximation variant which runs in time $O(m^{0.713}n)$. (An almost-$\alpha$-approximation algorithm determines the min-diameter to within a multiplicative factor of $\alpha$ plus constant additive error.) This is the first known algorithm to solve $\frac{3}{2}$-approximation for min-diameter in sparse DAGs in *truly subquadratic* time $O(m^{2-\epsilon})$ for $\epsilon > 0$; previously only a 2-approximation was known. By a conditional lower bound result of [Abboud et al, SODA 2016], a better than $\frac{3}{2}$-approximation can't be achieved in truly subquadratic time under the Strong Exponential Time Hypothesis (SETH), so our result is conditionally tight. We additionally obtain a new conditional lower bound for min-diameter approximation in general directed graphs, showing that under SETH, one cannot achieve an approximation factor below 2 in truly subquadratic time.

Our work also presents the first study of approximating bichromatic min-diameter, which is the maximum min-distance between oppositely colored vertices in a 2-colored graph. We show that SETH implies that in DAGs, a better than 2 approximation cannot be achieved in truly subquadratic time, and that in general graphs, an approximation within a factor below $\frac{5}{2}$ is similarly out of reach. We then obtain an $O(m)$-time algorithm which determines if bichromatic min-diameter is finite, and an almost-2-approximation algorithm for bichromatic min-diameter with runtime $\tilde{O}(\min(m^{4/3}n^{1/3}, m^{1/2}n^{3/2}))$.

## 1 Introduction

The *min-distance* between two vertices $x, y$ in a directed graph $G$ is the minimum of the one-way distances $d(x, y)$ and $d(y, x)$, and is written $d_{\min}(x, y)$. This notion of distance was introduced by Abboud, Vassilevska W., and Wang [2] in their study of diameter in directed graphs. Since the standard notion of distance in directed graphs is not symmetric,

[2] considered a number of symmetric distance functions: roundtrip distance, max-distance, and min-distance. The min-distance in particular, has since then been studied in a series of papers [13, 15, 11].

The min-distance is arguably the most natural notion of distance in directed acyclic graphs (DAGs), in which for every two vertices $x, y$, at most one of $d(x, y)$, $d(y, x)$ is finite. Min-distance is also applicable in potential real-world contexts: for example, if a patient needs to see a doctor as soon as possible, the doctor can visit the patient or vice versa.

The *min-diameter* of a directed graph $G$ is the maximum min-distance between any two vertices, or $\max_{x,y \in V(G)} d_{\min}(x, y)$. One can additionally define the *bichromatic min-diameter* in a graph $G$ with vertex set $V = A \sqcup B$ partitioned into "red" and "blue" vertices: the bichromatic min-diameter is the maximum min-distance between oppositely-colored vertices, or $\max_{a \in A, b \in B} d_{\min}(a, b)$. These are variants on the standard notions of diameter [1, 3, 6, 10, 12, 16, 24] and bichromatic diameter [5, 14], respectively.

One can compute min-diameter or bichromatic min-diameter – and for that matter All Pairs Shortest Paths (APSP), the shortest path distances $d(x, y)$ for all $x, y \in V$ – in an $n$-vertex $m$-edge graph in $O(mn + n^2 \log n)$ time, simply by running Dijkstra's algorithm from every vertex. In unweighted graphs, one can instead use BFS, giving an $O(mn)$ runtime.

One might ask whether, for either min-diameter or bichromatic min-diameter, a faster algorithm exists. However, just as for standard diameter and other diameter variants that have been studied [2, 14, 20], the Strong Exponential Time Hypothesis (SETH) [18, 9] suggests exact computation cannot be done in runtimes that are *truly subquadratic*, meaning $O(m^{2-\epsilon})$ for $\epsilon > 0$. SETH is one of the main hypotheses in Fine-Grained Complexity [22], and is among the most well-established hardness hypotheses for showing conditional lower bounds. It states that for every $\epsilon > 0$, there is an integer $k \geq 3$ so that $k$-SAT on $n$ variables cannot be solved in $O(2^{(1-\epsilon)n})$ time.

Since exact computation is conditionally hard, we resort to finding approximations. Since min-distance does not obey the triangle inequality, approximating min-diameter is especially challenging, in comparison to standard diameter or even roundtrip diameter or max-diameter. For this reason, much of the work on min-diameter has focused on DAGs.

## Min-Diameter

Abboud, Vassilevska W., and Wang [2] gave a 2-approximation for min-diameter in DAGs, running in $\tilde{O}(m)$ time.[1] Meanwhile, they showed that if one can obtain a $(\frac{3}{2}-\delta)$ approximation in $O(m^{2-\epsilon})$ time for min-diameter in DAGs (for $\varepsilon, \delta > 0$), then SETH is false. The results of [2] left a gap between the conditional lower bound of 3/2 and the upper bound of 2 for $O(m^{2-\epsilon})$ time algorithms for DAGs. (The lower bound is for $O((mn)^{1-\epsilon})$ time algorithms but since the instances are sparse, this is the same as $O(m^{2-\epsilon})$ time.)

Later work by Dalirrooyfard and Kaufmann [13] showed that in *dense* DAGs, one can beat the $mn$ barrier by obtaining an almost-$\frac{3}{2}$-approximation algorithm running in $O(n^{2.35})$ time. The conditional lower bound of [2] is for sparse DAGs, however, and the gap between upper and lower bounds has remained.

Our main result is to close this gap for sparse DAGs:

▶ **Theorem 1.** *There is an $O(m^{0.713}n)$ time algorithm that achieves a $(\frac{3}{2}, \frac{1}{2})$-approximation for min-diameter in any $m$-edge, $n$-node unweighted DAG.*

*Furthermore, there is an $O(m^{1.426}n^{0.288})$ time algorithm that achieves a $\frac{3}{2}$-approximation for min-diameter in any $m$-edge, $n$-node unweighted DAG.*

[1] The tilde hides polylogarithmic factors.

A $(c, a)$-approximation for a quantity $D$ is a quantity $D'$ such that $D \leq D' \leq cD + a$.

Similar to [13], we use hitting set and set intersection methods to certify distances. Our main new technique is to iteratively grow a central interval of vertices with convenient distance properties by checking that at least one of two neighboring vertex subsets, to its left and right, has the desired properties.

The algorithms use fast matrix multiplication. There are also combinatorial versions of the algorithms, with runtimes $O(m^{3/4}n)$ for the $(\frac{3}{2}, \frac{1}{2})$-approximation and $O(m^{5/4}n^{1/2})$ for the $\frac{3}{2}$-approximation.[2] These runtimess are still subquadratic for sparse graphs.

Our paper also considers the case of general directed graphs. Abboud, Vassilevska W., and Wang [2] showed that under SETH, any $O(m^{2-\varepsilon})$ time algorithm for $\varepsilon > 0$ for min-diameter can achieve at best a 2-approximation. This result only held for weighted graphs.

We give the first hardness result for unweighted graphs, extending the hardness of [2]:

▶ **Theorem 2.** *Under SETH, there can be no $O(m^{2-\varepsilon})$ time $(2-\delta)$-approximation algorithm for the min-diameter of an unweighted directed graph with $n$ vertices and $m = n^{1+o(1)}$ edges, for $\epsilon, \delta > 0$.*

Because our min-diameter approximation algorithms for DAGs obtain an approximation factor better than 2 in truly subquadratic time, this gives the first separation of hardness results for min-diameter approximation in the sparse cyclic versus acyclic cases.

This result, along with all other hardness results from SETH in this work, are via Orthogonal Vectors (OV) reductions. The OV problem is as follows: Given two sets $A, B$ each containing $n$ $d$-dimensional Boolean vectors, determine whether there are vectors $a \in A$ and $b \in B$ that are *orthogonal*, meaning $a \cdot b = 0$.

▶ **OV Conjecture** ([23]). *There is no constant $\epsilon > 0$ such that for any constant $c$ and $d = c \log n$, the OV problem can be solved by a randomized algorithm in time $O(n^{2-\epsilon})$.*

The OV Conjecture is implied by SETH [23]. OV-based sparse graph constructions have been commonly used to provide hardness results for diameter variants for the past decade, after having been first introduced by Roditty and Vassilevska W. in [20]. However, unlike previous OV-based constructions known to us, our construction is of a graph shaped as a cycle. If there are no orthogonal vectors then all vertices can reach one another via a single loop around the cycle, whereas if there are orthogonal vectors a path between them must loop nearly twice around the cycle, giving a min-diameter nearly twice as large.

As for upper bounds for general directed graphs, Dalirrooyfard et al. [15] gave for every integer $k \geq 2$, an $\tilde{O}(mn^{1/k})$ time $(4k-5)$-approximation algorithm for min-diameter. Most recently, Chechik and Zhang [11] achieved a 4-approximation in near-linear time. There is still a gap between the best approximation known in $O(m^{2-\varepsilon})$ time (3 by [15]) and the best hardness result for such algorithms (2 by this work for unweighted, and by [2] for weighted).

## Bichromatic Min-Diameter

A *bichromatic* version of diameter was considered by Dalirrooyfard et al. [14]. In a graph whose nodes are colored red and blue, the *bichromatic diameter* is the largest distance between two nodes of different colors. Dalirrooyfard et al. [14] gave algorithms and hardness for bichromatic diameter under the usual notion of distance.

[2] Combinatorial is here used to refer to an algorithm that does not rely on fast matrix multiplication.

Our work presents the first study of the notion of bichromatic min-diameter. As the min-diameter is the most natural diameter notion for DAGs, the bichromatic min-diameter is likewise a natural way to consider distances in DAGs whose vertices are two-colored.

We first give hardness for general directed graphs, suggesting that bichromatic min-diameter may be harder than regular min-diameter:

▶ **Theorem 3.** *Under SETH, there can be no $O(m^{2-\varepsilon})$ time $(\frac{5}{2}-\delta)$-approximation algorithm for bichromatic min-diameter in unweighted $n$-node, $m = n^{1+o(1)}$-edge graphs for $\epsilon, \delta > 0$.*

*Furthermore, under SETH, there can be no $O(m^{2-\varepsilon})$ time $(3-\delta)$-approximation algorithm for bichromatic min-diameter in graphs with $O(\log n)$ bit integer edge weights.*

It would be interesting if the $\tilde{O}(m\sqrt{n})$ 3-approximation algorithm for min-diameter of [15] can be extended to work for bichromatic min-diameter, as then one could get a tight result in the weighted case.

We next turn to bichromatic min-diameter in DAGs. We give an almost-2-approximation algorithm and show that it is essentially tight (up to the additive error) under SETH:

▶ **Theorem 4.** *Under SETH, there can be no $O(m^{2-\varepsilon})$ time $(2-\delta)$-approximation algorithm for bichromatic min-diameter in unweighted $n$-node, $m = n^{1+o(1)}$-edge DAGs, for $\epsilon, \delta > 0$.*

▶ **Theorem 5.** *There is an $\tilde{O}(m^{4/3}n^{1/3})$-time algorithm, which, given a DAG and maximum red-blue edge weight $M$, outputs a $(2, M)$-approximation of the bichromatic min-diameter.*

Finally, we present a linear-time algorithm which determines whether a directed graph has finite bichromatic min-diameter. The proof may be found in the full version of the paper [7].

▶ **Theorem 6.** *There is an $O(m)$ time algorithm which checks, for any weighted directed graph $G$, whether the bichromatic min-diameter is finite.*

## 1.1 Preliminaries

We assume the word-RAM model of computation with $O(\log n)$ bit words. All of our algorithms and reductions fall within this model.

Graphs in this work are directed and weakly connected.[3] Edge weights are polynomial in $n$.

The min-eccentricity of a vertex, $\epsilon(v)$, is given by $\max_{u \in V} d_{\min}(u, v)$.

For $v \in V$, the *distance-$D$ out-neighborhood* of $v$ is $N_D^{out}(v) = \{w \in V \setminus \{v\} \mid d(v, w) \leq D\}$. We define $N_D^{in}(v)$ correspondingly.

Given a DAG $G$ with topological ordering $\pi$ and vertex sets $S, T \subseteq V = V(G)$, we write $S <_\pi T$ if all vertices in $S$ appear to the left of all vertices in $T$. When $S$ or $T$ is equal to $\{x\}$ for some vertex $x$, we may omit the brackets. For vertices $s, t$, we write $s \leq_\pi t$ if $s <_\pi t$ or $s = t$. We define a closed subset (with respect to $\pi$) to be a subset $S$ such that for all $v \in V$, either $v \in S$, $v >_\pi S$, or $v <_\pi S$.

Given a DAG $G$ with topological ordering $\pi$, a vertex $v \in V$ and a set $S \subseteq V$, let $s_v \in S$ be the left-most vertex in $S$ such that $d(v, s) \leq D$, if such an $s_v$ exists. Then we define $N_{D,S}^{out}(v)$ to be the set of vertices $w$ such that $d(v, w) \leq D$ and, if $s_v$ exists, $w \leq_\pi s_v$. One can intuitively think of $N_{D,S}^{out}(v)$ as the set $N_D^{out}(v)$ of vertices at distance at most $D$ from $v$,

[3] If a graph is not weakly connected (which can be checked in $O(m + n)$ time), then it has infinite min-diameter, as well as infinite bichromatic min-diameter if its vertices are 2-colored.

but cut off after the first (left-most) time we hit $S$. We define $N^{in}_{D,S}(v)$ symmetrically. A set $S$ such that for all $v$, $|N^{out}_{d,S}(v)|, |N^{in}_{d',S}(v)| \leq k$, will be called a $(k,(d,d'))$-*neighborhood cover*. If $d = d'$ we refer to it as a $(k,d)$-neighborhood cover.

A *bichromatic DAG* $G$ is a DAG whose vertices are two-colored. An $(A,B)$-*separated DAG*, which we may also simply call a *separated DAG* is a DAG ordered according to some topological ordering $\pi$ with color sets $A, B$ such that $A <_\pi B$.

We sometimes omit $\pi$ when the choice of $\pi$ is clear.

Let $\omega(1,r,1)$ be the exponent of the runtime of multiplying $n \times n^r$ by $n^r \times n$ matrices. The square matrix multiplication exponent is $\omega = \omega(1,1,1) > 2.37286$ [4].

## 1.2 Techniques

In this section, we review two useful techniques. The first of these is the greedy set cover lemma. This lemma, and a related randomized version, have been commonly used in prior work on diameter variants ([3], [20], [8], [2], [13]). See [21] for a proof of the lemma.

▶ **Lemma 7.** *Let $p = O(n)$, and let $X_1, \ldots X_p \subseteq V$ have size $|X_i| \geq n^\epsilon$ for $\epsilon \in [0,1]$. In time $O(n^{1+\epsilon})$ one can construct a set $S \subseteq V$ of size $O(n^{1-\epsilon} \log n)$ such that $S \cap X_i \neq \varnothing$ for all $i \in [p]$.*

The following technique, previously used in [13], constructs a set cover of all sufficiently large balls of radius $d$.

▶ **Lemma 8.** *Given a topologically ordered DAG $G$ and parameters $d, d'$ and $k = n^\epsilon$ for $\epsilon \in [0,1]$, one can in time $O(nk^2)$ construct a $(k,(d,d'))$-neighborhood cover $S$ of size $O(\frac{n}{k} \log n)$, and also construct the sets $N^{out}_{d,S}(v)$, $N^{in}_{d',S}(v)$ for all $v \in V$.*

**Proof.** For each vertex $v$, if $|N^{out}_d(v)| < k$, we define $X^k_d(v) = N^{out}_d(v)$. Otherwise let $X^k_d(v)$ be the $k$ left-most vertices in $N^{out}_d(v)$. Similarly, we define the set $Y^k_{d'}(v)$: if $|N^{in}_{d'}(v)| < k$, then $Y^k_{d'}(v) = N^{in}_{d'}(v)$, and otherwise $Y^k_{d'}(v)$ is the $k$ right-most vertices in $N^{in}_{d'}(v)$.

We can compute $X^k_d(v)$ as follows: We initialize a set $S_0 = \varnothing$. While $|S_t| < k$, at step $t$, we consider the set $W = N^{out}(S_t \cup \{v\}) \cap N^{out}_d(v)$ of out-neighbors of $S_t \cup \{v\}$ that are at distance at most $d$ from $v$. If $W$ is nonempty, we let $w$ be its left-most element, and we construct $S_{t+1} = S \cup \{w\}$. If $W$ is empty, then $S_t = N^{out}_d(v) = X^k_d(v)$. If $|S_t| = k$, then $S_t$ contains the left-most $k$ vertices in $N^{out}_d(v)$. Thus, in either case, we will eventually construct $S_t = X^k_d(v)$. The key step in this construction process, namely finding $w$, can be done by maintaining a list containing the left-most neighbor of each vertex in $S_t$ such that the neighbor is of distance at most $d$ from $v$, and choosing the left-most vertex in the list at each step. At step $t$, this list has length at most $|S_t| < k$, and the total number of steps is at most $k$, so the construction can be done in $O(k^2)$ time.

We can construct $Y^k_{d'}(v)$ in $O(k^2)$ time similarly. Doing this for all $v \in V$ takes time $O(nk^2)$.

Lemma 7 gives us a set cover $S$ of size $O(\frac{n}{k} \log n)$ which intersects all sets $X^k_d(v), Y^k_{d'}(v)$ of size at least $k$. This takes time $O(nk)$. Then for each vertex $v$, we construct $N^{out}_{d,S}(v)$ as the set obtained from $X^k_d(v)$ by removing all vertices to the right of the left-most $s \in S \cap X^k_d(v)$. We construct $N^{in}_{d,S}(v)$ in a symmetric fashion. Since the sets $X^k_d(v), Y^k_{d'}(v)$ were of size at most $k$, the sets $N^{out}_{d,S}(v), N^{in}_{d',S}(v)$ are also of size at most $k$. ◀

# 2 Min-diameter approximation

In Section 2.1 we present a conditional lower bound showing that the OV Conjecture implies that no $(2-\delta)$-approximation algorithm for min-diameter in unweighted graphs can run in truly subquadratic time. Subsequently, in Section 2.2, we give an almost-$\frac{3}{2}$-approximation algorithm for min-diameter in unweighted DAGs which runs in truly subquadratic time.

## 2.1 Conditional lower bound in general graphs

We first present a conditional lower bound for approximating min-diameter in general graphs.

▶ **Theorem 9.** *If there are $\epsilon, \delta > 0$ such that there is an $O(m^{2-\epsilon})$-time $(2-\delta)$-approximation algorithm for min-diameter, then the OV Conjecture is false.*

**Proof.** Given $\delta > 0$, choose $t = \lceil \frac{2}{\delta} \rceil$ so that $2 - \delta < \frac{2t}{t+1}$. Let $A$ be an instance of single-set OV[4], that is, a set of $n \geq 2^t$ vectors in $\{0,1\}^{c_0 \log n}$ for a constant $c_0 > 0$. We will construct a graph $G_t$ with $O(tn)$ vertices, $\tilde{O}(tn)$ edges such that the min-diameter is $2t+1$ if $A$ contains a pair of orthogonal vectors, and $t+1$ otherwise. For each $i \in [t]$, we construct a set $A_i$ of $n$ vertices corresponding bijectively to the vectors in $A$. For each vector $a \in A$, let $a_i$ be the vertex in set $A_i$ corresponding to $a$. We also construct a set $I$ of "index" vertices $x_1, \ldots, x_{c \log n}$. In total we have $O(tn)$ vertices. We add an edge $a_1 \to x_j$ and an edge $x_j \to a_t$ whenever $a[j] = 1$. We also add edges $a_i \to a_{i-1}$ for each $i \in \{2, \ldots, t\}$. Finally, we add all possible edges $A_2 \to I$. In total we have $\tilde{O}(tn)$ edges. This graph $G_t$ may be constructed in $\tilde{O}(tn) = \tilde{O}(n)$ time.

We now check that if the OV instance is a YES instance, $G_t$ has at least min-diameter $2t+1$, and in the NO case, $G_t$ has min-diameter $t+1$.

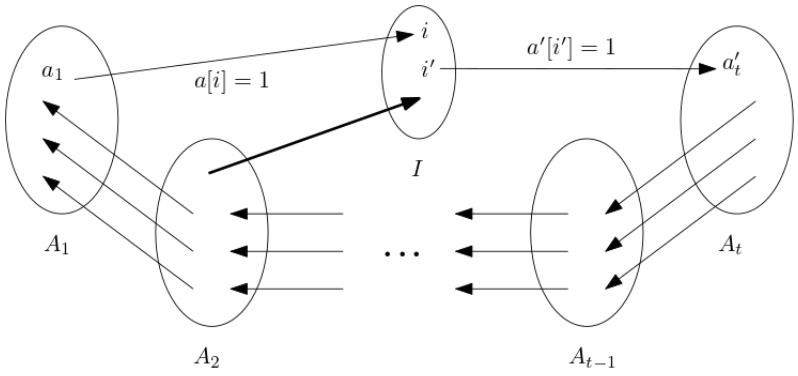

**Figure 1** The graph $G_t$. The thick edge denotes that all possible edges $A_2 \to I$ exist.

### YES case

Let $a, b \in A$ be orthogonal. Without loss of generality, $d_{\min}(a_1, b_1) = d(a_1, b_1)$. There is no $j$ such that $a[j] = b[j] = 1$, so there is no length-2 path from $a_1$ to $b_t$ via $I$. Since all edges between $A_i$ and $A_{i-1}$ are of the form $a_i \to a_{i-1}$, the first $t$ vertices on any $a_1 \to b_1$ path

[4] The OV Conjecture can be equivalently stated in terms of single-set OV (OV where $A = B$). Informally, the reduction is to construct $A'$ from $A$ by appending 10 to all vectors, and $B'$ from $B$ by appending 01 to all vectors. If $v_1, v_2 \in A' \cup B'$ are orthogonal, then we must have $v_1 \in A'$, $v_2 \in B'$ or vice versa.

must be of the form $a_1 \to x_j \to c_t \to \cdots \to c_2$ for some $j \in I, c \in A$ such that $a[j] = c[j] = 1$. We note that any path from $c_2$ to $b_1$ must traverse all sets of the cycle with the possible exception of $A_1$, so must be of length at least $t$. Then if $k$ is an index such that $b[k] = 1$, the path $c_2 \to x_k \to b_t \to \cdots \to b_1$ gives $d(c_2, b_1) = t + 1$. Thus, $d(a_1, b_1) = d_{\min}(a_1, b_1) \geq 2t + 1$. So $G_t$ has min-diameter at least $2t + 1$.

### NO case

Suppose that $A$ contains no pair of orthogonal vectors. For any $a_1, b_i$, there is some $j$ such that $a[j] = b[j] = 1$, so there is a path $a_1 \to x_j \to b_t \to \ldots b_i$ of length at most $t + 1$. Now, consider any vertices $a_i, b_{i'}$ with $2 \leq i \leq i'$. Let $j$ be an index such that $b[j] = 1$. There is a path $a_i \to \ldots a_2 \to x_j \to b_t \to \cdots \to b_{i'}$ which has length at most $t$. Furthermore, for any $a_1 \in A_1$, $x_j \in I$, $d(a_1, x_j) \leq t + 1$, since there is a path $a_1 \to x_k \to a_t \to \cdots \to a_2 \to x_j$ for some $k$ with $a[k] = 1$. Lastly, for any $a_i \in A_i$ with $i \geq 2$, and for any $x_j \in I$, there is a path $a_i \to \ldots a_2 \to x_j$ of length at most $t$. Hence, all pairs of vertices are at min-distance at most $t + 1$. ◀

## 2.2 A $(\frac{3}{2}, \frac{1}{2})$-approximation algorithm in unweighted DAGs

Unlike in general directed graphs, where $(2 - \delta)$-approximating min-diameter seems to be hard, in DAGs one can achieve an efficient $(\frac{3}{2}, \frac{1}{2})$-approximation and a (slightly less) efficient $\frac{3}{2}$-approximation. The $(\frac{3}{2}, \frac{1}{2})$ and the exact $\frac{3}{2}$ approximations have very similar proofs; we present the proof of the $(\frac{3}{2}, \frac{1}{2})$-approximation result here because the algorithm is faster and marginally simpler than in the exact $\frac{3}{2}$ case, whose proof can be found in the full version of the paper [7].

Our algorithm uses fast sparse matrix multiplication to compute set intersections. Its runtime involves the constants $\alpha = \max\{0 \leq r \leq 1 \mid \omega(1, r, 1) = 2\}$ and $\beta = \frac{\omega - 2}{1 - \alpha}$.

▶ **Theorem 10.** *There is an $\tilde{O}(m^{\frac{4\beta+2-2\alpha\beta}{5\beta+3-2\alpha\beta}} n)$-time algorithm achieving a $(\frac{3}{2}, \frac{1}{2})$-approximation for min-diameter in unweighted DAGs.*

Since $\alpha > 0.31389$ [17] and $\omega < 2.37286$ [4], we can use $\beta \simeq 0.5435$, giving the runtime $O(m^{0.713} n)$.

The algorithm starts by topologically sorting the DAG and fixing a neighborhood-size parameter $k$ (whose value will be determined later). It then performs two layers of recursion. The outer layer is a binary search over min-diameter estimates $D$: for each estimate $D$, it will either determine that $D$ is low or high, i.e. that $\texttt{min-diameter}(G) > D$ or $\texttt{min-diameter}(G) \leq \lceil \frac{3}{2} D \rceil$. The inner layer, in which the estimate $D$ is fixed, involves recursively splitting the graph in half according to the topological ordering. Then, in the core body of the algorithm, one of the following will occur:

- We find a pair of vertices with min-distance larger than $D$, in which case we end the recursion and report that $\texttt{min-diameter}(G) > D$.
- We verify that every min-distance between a vertex in the left half and a vertex in the right half is at most $\lceil 3D/2 \rceil$, and we recurse on the left and right halves of the graph.

The core body of the algorithm – which will be repeated recursively as the graph is repeatedly cut in half – is as follows:

First, using Lemma 8, we compute a $(k, (D/2, \lceil D/2 \rceil))$-neighborhood cover $S$ of size $O(\frac{n}{k} \log n)$ along with neighborhoods $N^{out}_{D/2,S}(v), N^{in}_{\lceil D/2 \rceil,S}(v)$ all of which have size at most $k$. Using BFS, we check that $d_{\min}(s, v) \leq D$ for all $s \in S, v \in V$. This step ensures that, for

every vertex with a "sufficiently large" (meaning, size-$k$) distance-$D/2$ out-neighborhood or distance-$\lceil D/2 \rceil$ in-neighborhood, some vertex in $S$ lies in that out- or in-neighborhood. In this sense, $S$ covers all of the large neighborhoods, which will be useful later.

We partition $V$ into $2\theta = n/k^2$ closed intervals, $V_1, \dots V_{2\theta}$. We let $L = V_1 \cup \cdots \cup V_\theta$ and $R = V_{\theta+1} \cup \cdots \cup V_{2\theta}$ be the left and right halves of $V$. We start in the middle and work outwards verifying that min-distances between vertices in $L$ and $R$ are at most $\lceil 3D/2 \rceil$.

At each inductive step, we consider two subsets of vertices $A = V_i$ and $B = V_j$ to the left and right of the "middle interval," which consists of the intervening subsets $V_{i+1} \cup \cdots \cup V_{j-1}$. Intuitively, one might picture the middle interval as a growing amoeba, which at each step engulfs one of $A$ or $B$. We will only add vertices to the middle interval once they have been "checked," so vertices from $A$ that are added to the middle interval have distance at most $3D/2$ to everything in $B$, and vice-versa. Eventually, either the algorithm will detect a min-distance greater than $D$ and report that `min-diameter(`$G$`)` $> D$, or the amoeba will have engulfed enough of the graph that it contains the entirety of one of the halves $L$ or $R$, meaning that all distances from vertices in $L$ to vertices in $R$ are at most $\lceil \frac{3}{2} D \rceil$.

In order to expand the middle interval we have to confirm that one of our two candidate subsets $A$ and $B$ has small distances to the opposite half of the graph. Performing a BFS from each vertex in $A$ or $B$ to confirm this directly would be too slow, so instead we present two subroutines to achieve this goal faster. Algorithm 2 checks that all min-distances between vertices $a \in A$ and $b \in B$ are at most $\lceil 3D/2 \rceil$. Algorithm 3 checks that either all vertices in $A$ have min-distance at most $\frac{3}{2}D$ to all vertices to the right of $B$, or that a symmetric property holds for all vertices in $B$. These algorithms will either detect that the min-diameter is more than $D$ or allow us to add one of $A$ or $B$ to the middle interval.

We first give a pseudocode description of the main algorithm, Algorithm 1, which will give context for the two subroutines, Algorithms 2 and 3, whose descriptions follow afterwards.

We will present the correctness and runtime analyses for the two subroutines, and then present the correctness proof and runtime analysis for the overall algorithm.

The first subroutine, Algorithm 2, checks distances between pairs of vertices in subsets $A, B$ by using the cover $S$ to hit large neighborhoods and using fast sparse rectangular matrix multiplication to efficiently check set intersections between small neighborhoods.

▶ **Theorem 11** ([19]). *If $M, M'$ are $p \times l$ matrices having at most $l$ nonzero entries, where $p^{1+\frac{\alpha}{2}} \le l \le p^{\frac{\omega+1}{2}}$, then in time $O(l^{\frac{2\beta}{\beta+1}} p^{\frac{2-\alpha\beta}{\beta+1}})$ one can compute the product $M^T M'$.*[5]

▶ **Lemma 12.** *Algorithm 2 produces the correct output in runtime $O(k^{4+\frac{2\beta-2\alpha\beta}{\beta+1}})$.*

**Proof.** We first show correctness. Assume the algorithm fails; then it fails inside the **foreach** loop at some pair $a, b$. Suppose for the sake of contradiction that $d_{\min}(a,b) \le D$. Let $x$ be a midpoint of the shortest path from $a$ to $b$, so $d(a,x) \le D/2$, $d(x,b) \le \lceil D/2 \rceil$. If $x \notin N^{out}_{D/2,S}(a)$ despite being distance $\le D/2$ from $a$, then $x$ must lie after the out-neighborhood of $a$ reaches the $(k, (D/2, \lceil D/2 \rceil))$-neighborhood cover $S$ and is cut off. That is, there is some $s \in N^{out}_{D/2}(a) \cap S$ to the left of $x$, and hence to the left of $b$. Thus the condition in line 9 holds, and we **continue** rather than **FAIL**, which is a contradiction. Similarly, if $x \notin N^{in}_{\lceil D/2 \rceil,S}(b)$ then the condition in line 7 holds, which is a contradiction. We conclude that $x \in N^{out}_{D/2,S}(a) \cap N^{in}_{\lceil D/2 \rceil,S}(b)$, in which case $M_{ab} \ge 1$, completing the contradiction. Thus, $d_{\min}(a,b) > D$, and so `min-diameter`$(G) > D$.

[5] To be precise, if we have $\alpha \ge a, \omega \le c$, we can define $b = \frac{c-2}{1-a}$, and then the theorem holds for any such pair $a, b$, used in place of $\alpha, \beta$.

**Algorithm 1** Full graph min-distance tester.

**Input:** DAG $G = (V, E)$, diameter guess $D$, parameters $k = m^{\frac{\beta+1}{5\beta+3-2\alpha\beta}}$ and $\theta = n/2k^2$.

**Output:** One of the following. Each output verifies a corresponding property of $G$.

| | | |
|---|---|---|
| **PASS** | $\Rightarrow$ | $\texttt{min-diameter}(G) \leq \lceil \frac{3}{2}D \rceil$ |
| **FAIL** | $\Rightarrow$ | $\texttt{min-diameter}(G) > D$ |

1 Topologically sort $G$;
2 Using Lemma 8 compute a $(k, (D/2, \lceil D/2 \rceil))$-neighborhood cover $S \subseteq V$. Run BFS to and from each vertex in $S$;
3 **if** $\exists s \in S$ *such that* $\epsilon(s) > D$ **then**
4  **FAIL**
5 Partition $V$ into consecutive closed intervals, $V_1, \ldots V_{2\theta}$, with $|V_i| = k^2$ for each $i$;
6 Initialize $i = \theta$ and $j = \theta + 1$;
7 **while** $i \geq 1$ **and** $j \leq 2\theta$ **do**
8  Run Algorithm 2 (all-pairs) on the pair $(V_i, V_j)$. If this fails, then **FAIL**;
9  Run Algorithm 3 (directional tester) on the pair $(V_i, V_j)$. If this fails, then **FAIL**;
10  **else if** *Algorithm 3 passes and returns* $V_i$ **then**
11  $i = i - 1$;
12  **else**
 /* Otherwise, Algorithm 3 passes and returns $V_j$. */
13  $j = j + 1$;
/* If this line is reached, all distances from $L$ to $R$ are at most $\lceil \frac{3}{2}D \rceil$. */
14 Recursively call this algorithm on $G[L]$ and $G[R]$. If either fails, **FAIL**. Else **PASS**;

Conversely, assume the algorithm passes. Then for each pair of vertices $a \in A, b \in B$, one of the conditions in lines 5, 7, or 9 must hold. If $M_{ab} \geq 1$, then there is some $x \in N^{out}_{D/2,S}(a) \cap N^{in}_{\lceil D/2 \rceil,S}(b)$, giving $d(a,b) \leq d(a,x) + d(x,b) \leq D/2 + \lceil D/2 \rceil \leq D+1$. Otherwise if $a <_\pi N^{in}_{\lceil D/2 \rceil,S}(b)$ and $N^{in}_{\lceil D/2 \rceil,S}(b) \cap S$ is nonempty, then there is some $s \in N^{in}_{\lceil D/2 \rceil,S}(b) \cap S$ with $s \geq_\pi a$. Thus $d(a,b) \leq d(a,s) + d(s,b) \leq D + \lceil D/2 \rceil \leq \lceil 3D/2 \rceil$. Similarly, if $b >_\pi N^{out}_{D/2,S}(a)$ and $N^{out}_{D/2,S}(a) \cap S$ is nonempty, then there is some $s \in N^{out}_{D/2}(a) \cap S$ with $s \leq_\pi b$. So $d(a,b) \leq d(a,s) + d(s,b) \leq D/2 + D \leq 3D/2$. We conclude that if the algorithm passes, then every pair $a \in A, b \in B$ satisfies $d(a,b) \leq \lceil 3D/2 \rceil$.

We conclude with runtime analysis. $M_a$ and $M_b$ are sparse $p \times n$ matrices with $O(pk) = O(k^3)$ entries, so may be treated as $p \times pk$ matrices. Using Theorem 11, the matrix multiplication takes time at most $O((pk)^{\frac{2\beta}{\beta+1}} p^{\frac{2-\alpha\beta}{\beta+1}}) = O(k^{4+\frac{2\beta-2\alpha\beta}{\beta+1}})$. The **foreach** loop takes $O(|A||B|) = O(k^4)$ time. ◀

▶ Remark 13. One can modify Algorithm 2 by computing set intersections of the sets $N^{out}_{D/2,S}(a)$, $N^{in}_{\lceil D/2 \rceil,S}(b)$ for $a \in A, b \in B$, by brute force in lieu of matrix multiplication. This gives a combinatorial version of Algorithm 2 which runs in time $\tilde{O}(p^2 k) = \tilde{O}(k^5)$.

Next we give the directional min-distance tester. A call to this subroutine will prove a min-distance bound of $3D/2$ from $A$ to everything past $B$, prove a bound of $\lceil 3D/2 \rceil$ from $B$ to everything before $A$, or find a pair of vertices with min-distance greater than $D$. The idea is to iterate over vertices $a$ in $A$; those with large $D/2$-neighborhoods get hit by $S$, and if some $a$ has a small $D/2$-neighborhood it can be used as a jumping-off set to show $B$ is close to everything past $A$.

**Algorithm 2** All-pairs min-distance tester.

**Input:** DAG $G = (V, E)$, topological ordering $\pi$, subsets $A <_\pi B \subseteq V$ with $|A| = |B| = p = O(k^2)$, diameter guess $D$, $(k, (D/2, \lceil D/2 \rceil))$-neighborhood cover $S \subseteq V$ such that $\epsilon(s) \leq D$ for all $s \in S$, and $N^{out}_{D/2,S}(a)$, $N^{in}_{\lceil D/2 \rceil,S}(b)$ for $a \in A, b \in B$.

**Output:** One of the following. Each output verifies a corresponding property of $G$.

| | | |
|---|---|---|
| **PASS** | $\Rightarrow$ | $d_{\min}(a,b) \leq \lceil \frac{3}{2} D \rceil$ for all in $a \in A$ and $b \in B$ |
| **FAIL** | $\Rightarrow$ | `min-diameter`$(G) > D$ |

1 Compute $M_A$, the matrix with columns given by indicator vectors of $N^{out}_{D/2,S}(a)$ for $a \in A$;
2 Compute $M_B$, the matrix with columns given by indicator vectors $N^{in}_{\lceil D/2 \rceil,S}(b)$ for $b \in B$;
3 Compute $M = M_A^T M_B$;
4 **foreach** $a \in A, b \in B$ **do**
5  **if** $M_{ab} \geq 1$ **then**
6  **continue**;
7  **else if** $a <_\pi N^{in}_{\lceil D/2 \rceil,S}(b)$ **and** $N^{in}_{\lceil D/2 \rceil,S}(b) \cap S \neq \emptyset$ **then**
8  **continue**;
9  **else if** $b >_\pi N^{out}_{D/2,S}(a)$ **and** $N^{out}_{D/2,S}(a) \cap S \neq \emptyset$ **then**
10  **continue**;
11  **else**
12  **FAIL**;
13 **PASS**;

▶ **Lemma 14.** *Algorithm 3 produces the correct output in runtime $O(mk)$.*

**Proof.** We first show correctness. If the algorithm fails, we must have found a vertex $u$ with $\epsilon(u) > D$, and thus `min-diameter`$(G) > D$.

If the algorithm returns $A$, then for each $a \in A$, there is some $s \in S \cap N^{out}_{D/2,S}(a)$ with $s$ appearing in $B$ or to its left. Thus for all $u >_\pi B$, we have $d(a,u) \leq d(a,s) + d(s,u) \leq D/2 + D = 3D/2$.

Otherwise, the algorithm returns $B$. Then the condition in line 2 must hold for some $a \in A$. Let $u <_\pi A$ and $b \in B$. Since we do not fail in line 5, we must have $d(a,b) \leq D$. Let $x$ be a midpoint of the shortest path from $a$ to $b$, so $d(a,x) \leq D/2$ and $d(x,b) \leq \lceil D/2 \rceil$. Since $N^{out}_{D/2,S}(a)$ is either not cut off by hitting $S$ or is cut off after $B$, we have $x \in N^{out}_{D/2,S}(a)$. Finally, since we do not fail in line 5, we must have $d(u,x) \leq D$. Concluding, $d(u,b) \leq d(u,x) + d(x,b) \leq D + \lceil D/2 \rceil \leq \lceil 3D/2 \rceil$. As $u, b$ were arbitrary, this completes the case.

We conclude with runtime analysis. The outer **foreach** loop repeats until we have covered every vertex in $A$ or the condition in line 2 is satisfied. Checking this condition takes time at most $O(k)$ for a total of $O(|A|k) = O(mk)$. If the condition is satisfied, we perform $1 + |N^{out}_{D/2,S}(a)|$ calls to BFS, for a total of $O(mk)$. The algorithm concludes before returning to the outer loop, so we may add these contributions for a total time of $O(mk)$. ◀

We can now complete the analysis of the overall algorithm.

▶ **Lemma 15.** *Algorithm 1 produces the correct output in runtime $\tilde{O}(m^{\frac{4\beta+2-2\alpha\beta}{5\beta+3-2\alpha\beta}} n)$.*

**Algorithm 3** Directional min-distance tester.

**Input:** DAG $G = (V, E)$, topological ordering $\pi$, closed subsets $A <_\pi B \subseteq V$, diameter guess $D$, parameter $k$, $(k, (D/2, \lceil D/2 \rceil))$-neighborhood cover $S \subseteq V$ with $\epsilon(s) \leq D$ for all $s \in S$, and neighborhoods $N^{out}_{D/2,S}(a)$ for all $a \in A$.

**Output:** One of the following. Each output verifies a corresponding property of $G$.

| | | |
|---|---|---|
| **PASS** and return $A$ | $\Rightarrow$ | $d(a, v) \leq \frac{3}{2}D$ for all $a \in A$ and $v >_\pi B$ |
| **PASS** and return $B$ | $\Rightarrow$ | $d(v, b) \leq \lceil \frac{3}{2}D \rceil$ for all $b \in B$ and $v <_\pi A$ |
| **FAIL** | $\Rightarrow$ | $\texttt{min-diameter}(G) > D$ |

```
1 foreach a ∈ A do
2     if N^out_{D/2,S}(a) ∩ S = ∅ or N^out_{D/2,S}(a) ∩ S >_π B then
3         foreach v ∈ {a} ∪ N^out_{D/2,S}(a) do
4             BFS to and from v;
5             if ε(v) > D then
6                 FAIL;
7         PASS and return B;
8 PASS and return A;
```

**Proof.** This algorithm fails only when some $s \in S$ has $\epsilon(s) > D$, when Algorithm 2 fails, or Algorithm 3 fails, all of which imply $\texttt{min-diameter}(G) > D$. We now show that in the event of a pass, $\texttt{min-diameter}(G) \leq \lceil 3D/2 \rceil$. It suffices to prove that if the algorithm reaches line 13 then all min-distances between vertices in $L$ and $R$ are at most $\lceil 3D/2 \rceil$.

Assume we are at the beginning of iteration $t$ of the **while** loop. Let $I_t = \bigcup_{i<\ell<j} V_\ell$ be the interval strictly between $V_i$ and $V_j$. We will show inductively that for all $x \in L$ and $y \in R$, where at least one of $x$ or $y$ is in the interval $I_t$, $d_{\min}(x, y) \leq \lceil 3D/2 \rceil$. When the loop terminates, $I_t$ must entirely contain either $L$ or $R$, which will prove that all min-distance between vertices in $L$ and $R$ are at most $\lceil 3D/2 \rceil$.

The base case is trivial, as $I_1$ is empty. Assume the claim holds for $t$. Without loss of generality, assume Algorithm 3 returns $V_i$, so that $I_{t+1} = I_t \cup V_i$. Let $x \in L, y \in R$ with at least one of $x$ or $y$ in $I_{t+1}$. If $x$ or $y$ is in $I_t$, then $d(x, y) \leq \lceil 3D/2 \rceil$ by induction. Otherwise, one must lie in $I_{t+1} \setminus I_t = V_i$, and since $V_i \subset L$, this vertex must be $x$. Then we have $y \in V_j$ or $y >_\pi V_j$. If $y \in V_j$, then since Algorithm 2 did not fail, we have $d(x, y) \leq 3D/2$. If $y >_\pi V_j$, then because Algorithm 3 returned $V_i$ we have $d(x, y) \leq \lceil 3D/2 \rceil$. This completes the induction and the proof of correctness.

$G$ can be topologically sorted in time $\tilde{O}(n)$. Lemma 8 constructs the set $S$ in time $O(nk^2)$. Running BFS to and from each vertex in $S$ takes time $\tilde{O}(mn/k)$. We run Algorithm 2 and Algorithm 3 each up to $2\theta = n/2k^2$ times. Since Algorithm 2 takes time $O(k^{4+\frac{2\beta-2\alpha\beta}{\beta+1}})$ and Algorithm 3 takes time $O(mk)$, the total runtime of a recursive step is therefore:

$$\tilde{O}(mn/k + nk^{2+\frac{2\beta-2\alpha\beta}{\beta+1}})$$

Setting $k = m^{\frac{\beta+1}{5\beta+3-2\alpha\beta}}$, we obtain $\tilde{O}(m^{\frac{4\beta+2-2\alpha\beta}{5\beta+3-2\alpha\beta}}n)$ for each recursive step. The recursion over the left and right halves of the graph then adds a logarithmic factor. ◀

**Proof of Theorem 10.** Binary searching over $D \in [n]$ using Algorithm 1 gives the desired algorithm. The additive $+1/2$ follows from the fact that $\lceil 3D/2 \rceil$ may equal $3D/2 + 1/2$. ◀

▶ Remark 16. Using the combinatorial version of Algorithm 2, one can obtain a combinatorial $(\frac{3}{2}, \frac{1}{2})$-approximation algorithm for min-diameter which runs in time $\tilde{O}(m^{3/4}n)$.

▶ **Theorem 17.** *There is a $\frac{3}{2}$-approximation algorithm for min-diameter in unweighted DAGs that runs in time $\tilde{O}(m^{\frac{8\beta+4-4\alpha\beta}{5\beta+3-2\alpha\beta}} n^{\frac{\beta+1}{5\beta+3-2\alpha\beta}})$.*

This runtime is at most $O(m^{1.426}n^{0.288})$. We note that there is also a combinatorial version of this algorithm which runs in time $\tilde{O}(m^{5/4}n^{1/2})$, and a version which runs in $\tilde{O}(m^{\frac{7\beta+3-3\alpha\beta}{5\beta+3-2\alpha\beta}} n^{\frac{2\beta+2-\alpha\beta}{5\beta+3-2\alpha\beta}})$ time, which is $O(m^{1.171}n^{0.543})$, when $m \leq n^{1.283}$. A proof of the theorem may be found in the full version of the paper [7].

# 3 Bichromatic min-diameter

We first present OV-based conditional lower bounds for bichromatic min-diameter approximations, both for general graphs and for DAGs. Then in Section 3.2, we give an almost-2-approximation algorithm for bichromatic min-diameter in DAGs.

## 3.1 Conditional lower bounds for bichromatic min-diameter

We present, in order of increasing strength of the bound, three conditional lower bounds for approximating bichromatic min-diameter: one for DAGs, one for unweighted directed graphs, and one of weighted directed graphs. The constructions proceed analogously to Theorem 9, and can be found in the full version of the paper [7].

▶ **Theorem 18.** *For any $\epsilon, \delta > 0$ if there is an $O(n^{2-\epsilon})$-time algorithm giving a $(2-\delta)$-approximation for bichromatic min-diameter in unweighted DAGs with $O(n)$ vertices and $O(n^{1+o(1)})$ edges, then the OV Conjecture is false.*

▶ **Theorem 19.** *For any $\epsilon, \delta > 0$, if there is an $O(n^{2-\epsilon})$-time algorithm giving a $(5/2-\delta)$-approximation for bichromatic min-diameter in unweighted graphs with $O(n)$ vertices and $O(n^{1+o(1)})$ edges, then the OV Conjecture is false.*

▶ **Theorem 20.** *For any $\epsilon, \delta > 0$, if there is an $O(n^{2-\epsilon})$-time algorithm giving a $(3-\delta)$-approximation for bichromatic min-diameter in weighted graphs with $O(n)$ vertices and $O(n^{1+o(1)})$ edges, then the OV Conjecture is false.*

## 3.2 Almost-2-approximation for bichromatic min-diameter in DAGs

We conclude by turning to upper bounds for bichromatic min-diameter.

▶ **Theorem 21.** *There is an $\tilde{O}(\min(m^{4/3}n^{1/3}, m^{1/2}n^{3/2}))$-time algorithm, which, given a DAG $G$ with maximum red-blue edge weight $M_0$, outputs an approximation $D_0$ such that $D \leq D_0 < 2D + M_0 \leq 3D$.*

We give a brief overview of the algorithm. The full details and proof of correctness can be found in the full version of the paper [7].

We first consider the simpler case when the DAG is *separated*, i.e. when in some topological ordering every red vertex is to the left of every blue vertex. As is typical, we proceed by a binary search; at each stage we have some guess $D$ for the bichromatic min-diameter and either verify the true bichromatic min-diameter is larger than $D$ or smaller than $2D$.

We begin by finding a hitting set for the red vertices with large *red outneighborhoods* (other red vertices at distance at most $D$). This is achieved via the standard sampling method (Lemma 8). By running a BFS from this hitting set, we can verify min-distances for all vertices hit in this way to the blue side are not large; it remains to control vertices with small red out-neighborhoods. This is handled separately for sparse and dense graphs.

For sparse graphs, we add an additional step of BFS for each vertex of high degree. By sparsity, this must be a small fraction of the vertices, so this has a controllable contribution to the total runtime. For any red vertex with a high-degree vertex in its red outneighborhood, this will again verify an upper bound on the min-distance to any blue vertex. At this stage, if any vertex is left, its red outneighborhood is composed of few vertices of low degree. Its *blue boundary*, the set of blue neighbors of vertices in its red outneighborhood, must therefore be small. Consider a single such vertex. Any path from it to a blue vertex must intersect its blue boundary. So its blue boundary must be a hitting set for blue in-neighborhoods of all of the blue vertices, or our red vertex would be unable to reach all blue vertices in distance $D$. BFSing from this small blue hitting set completes the algorithm.

For dense graphs, the BFS steps from every vertex of high degree and every vertex in a blue boundary become too costly. After eliminating vertices with large neighborhoods via the randomized hitting set, we compute blue in-neighborhoods for all remaining blue vertices and blue boundaries for all remaining red vertices, and conclude by running set intersection on these two lists of sets.

We then bootstrap this special case for separated DAGs into a complete proof, by recursively splitting the DAG into a "middle" (consisting of a separated DAG) along with left and right halves, and bounding min-distances between these different sections of the graph.

## Abstract

Dynamic programming on various graph decompositions is one of the most fundamental techniques used in parameterized complexity. Unfortunately, even if we consider concepts as simple as path or tree decompositions, such dynamic programming uses space that is exponential in the decomposition's width, and there are good reasons to believe that this is necessary. However, it has been shown that in graphs of low treedepth it is possible to design algorithms which achieve polynomial space complexity without requiring worse time complexity than their counterparts working on tree decompositions of bounded width. Here, *treedepth* is a graph parameter that, intuitively speaking, takes into account both the depth and the width of a tree decomposition of the graph, rather than the width alone.

Motivated by the above, we consider graphs that admit clique expressions with bounded depth and label count, or equivalently, graphs of low shrubdepth. Here, shrubdepth is a bounded-depth analogue of cliquewidth, in the same way as treedepth is a bounded-depth analogue of treewidth. We show that also in this setting, bounding the depth of the decomposition is a deciding factor for improving the space complexity. More precisely, we prove that on $n$-vertex graphs equipped with a tree-model (a decomposition notion underlying shrubdepth) of depth $d$ and using $k$ labels,

- Independent Set can be solved in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ using $\mathcal{O}(dk^2 \log n)$ space;
- Max Cut can be solved in time $n^{\mathcal{O}(dk)}$ using $\mathcal{O}(dk \log n)$ space; and
- Dominating Set can be solved in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ using $n^{\mathcal{O}(1)}$ space via a randomized algorithm.

We also establish a lower bound, conditional on a certain assumption about the complexity of Longest Common Subsequence, which shows that at least in the case of Independent Set the exponent of the parametric factor in the time complexity has to grow with $d$ if one wishes to keep the space complexity polynomial.

## 1 Introduction

**Treewidth and Treedepth.** Dynamic programming on graph decompositions is a fundamental method in the design of parameterized algorithms. Among various decomposition notions, *tree decompositions*, which underly the parameter *treewidth*, are perhaps the most widely used; see e.g. [9, 12] for an introduction. A tree decomposition of a graph $G$ of width $k$ provides a way to "sweep" $G$ while keeping track of at most $k+1$ "interface vertices" at a time. This can be used for dynamic programming: during the sweep, the algorithm maintains a set of representative partial solutions within the part already swept, one for each possible behavior of a partial solution on the interface vertices. Thus, the width of the decomposition is the key factor influencing the number of partial solutions that need to be stored.

In a vast majority of applications, this number of different partial solutions depends (at least) exponentially on the width $k$ of the decomposition, which often leads to time complexity of the form $f(k) \cdot n^{\mathcal{O}(1)}$ for an exponential function $f$. This should not be surprising, as most problems where this technique is used are NP-hard. Unfortunately, the space complexity – which often appears to be the true bottleneck in practice – is also exponential. There is a simple tradeoff trick, first observed by Lokshtanov et al. [29], which can often be used to reduce the space complexity to polynomial at the cost of increasing the time complexity. For instance, Independent Set can be solved in $2^k \cdot n^{\mathcal{O}(1)}$ time and using $2^k \cdot n^{\mathcal{O}(1)}$ space on an $n$-vertex graph equipped with a width-$k$ tree decomposition via dynamic programming [19]; combining this algorithm with a simple recursive Divide&Conquer scheme yields an algorithm with running time $2^{\mathcal{O}(k^2)} \cdot n^{\mathcal{O}(1)}$ and space complexity $n^{\mathcal{O}(1)}$.

Allender et al. [2] and then Pilipczuk and Wrochna [35] studied the question whether the loss on the time complexity is necessary if one wants to achieve polynomial space complexity in the context of dynamic programming on tree decompositions. While the formal formulation of their results is somewhat technical and complicated, the take-away message is the following: there are good complexity-theoretical reasons to believe that even in the simpler setting of path decompositions, one cannot achieve algorithms with polynomial space complexity whose running times asymptotically match the running times of their exponential-space counterparts. We refer to the works [2, 35] for further details.

However, starting with the work of Fürer and Yu [20], a long line of advances [25, 31, 32, 35] showed that bounding the *depth*, rather than the width, of a decomposition leads to the possibility of designing algorithms that are both time- and space-efficient. To this end, we consider the *treedepth* of a graph $G$, which is the least possible depth of an *elimination forest*: a forest $F$ on the vertex set of $G$ such that every two vertices adjacent in $G$ are in the

ancestor/descendant relation in $F$. An elimination forest of depth $d$ can be regarded as a tree decomposition of depth $d$, and thus treedepth is the bounded-depth analogue of treewidth. As shown in [20, 25, 32, 35], for many classic problems, including 3-Coloring, Independent Set, Dominating Set, and Hamiltonicity, it is possible to design algorithms with running time $2^{\mathcal{O}(d)} \cdot n^{\mathcal{O}(1)}$ and polynomial space complexity, assuming the graph is supplied with an elimination forest of depth $d$. In certain cases, the space complexity can even be as low as $\mathcal{O}(d + \log n)$ or $\mathcal{O}(d \log n)$ [35]. Typically, the main idea is to reformulate the classic bottom-up dynamic programming approach so that it can be replaced by a simple top-down recursion. This reformulation is by no means easy – it often involves a highly non-trivial use of algebraic transforms or other tools of algebraic flavor, such as inclusion-exclusion branching.

**Cliquewidth and Shrubdepth.** In this work, we are interested in the parameter *cliquewidth* and its low-depth counterpart: *shrubdepth*. While treewidth applies only to sparse graphs, cliquewidth is a notion of tree-likeness suited for dense graphs as well. The decompositions underlying cliquewidth are called *clique expressions* [8]. A clique expression is a term operating over *$k$-labelled graphs* – graphs where every vertex is assigned one of $k$ labels – and the allowed operations are: (i) apply any renaming function to the labels; (ii) make a complete bipartite graph between two given labels; and (iii) take the disjoint union of two $k$-labelled graphs. Then the cliquewidth of $G$ is the least number of labels using which (some labelling of) $G$ can be constructed. Similarly to treewidth, dynamic programming over clique expressions can be used to solve a wide range of problems, in particular all problems expressible in $\mathsf{MSO}_1$ logic, in FPT time when parameterized by cliquewidth. Furthermore, while several problems involving edge selection or edge counting, such as Hamiltonicity or Max Cut, remain W[1]-hard under the cliquewidth parameterization [16, 17], standard dynamic programming still allows us to solve them in XP time. In this sense, clique-width can be seen as the "least restrictive" general-purpose graph parameter which allows for efficient dynamic programming algorithms where the decompositions can also be computed efficiently [18]. Nevertheless, since the cliquewidth of a graph is at least as large as its linear cliquewidth, which in turn is as large as its pathwidth, the lower bounds of Allender et al. [2] and of Pilipczuk and Wrochna [35] carry over to the cliquewidth setting. Hence, reducing the space complexity to polynomial requires a sacrifice in the time complexity.

Shrubdepth, introduced by Ganian et al. [23], is a variant of cliquewidth where we stipulate the decomposition to have bounded depth. This necessitates altering the set of operations used in clique expressions in order to allow taking disjoint unions of multiple graphs as a single operation. In this context, we call the decompositions used for shrubdepth *$(d, k)$-tree-models*, where $d$ stands for the depth and $k$ for the number of labels used; a formal definition is provided in Section 2. Shrubdepth appears to be a notion of depth that is sound from the model-theoretic perspective, is FPT-time computable [21], and has become an important concept in the logic-based theory of well-structured dense graphs [13, 14, 22, 23, 33, 34].

Since shrubdepth is a bounded-depth analogue of cliquewidth in the same way as treedepth is a bounded-depth analogue of treewidth, it is natural to ask whether for graphs from classes of bounded shrubdepth, or more concretely, for graphs admitting $(d, k)$-tree-models where both $d$ and $k$ are considered parameters, one can design space-efficient FPT algorithms. Exploring this question is the topic of this work.

**Our contribution.** We consider three example problems: Independent Set, Max Cut, and Dominating Set. For each of them we show that on graphs supplied with $(d, k)$-tree-models where $d = \mathcal{O}(1)$, one can design space-efficient fixed-parameter algorithms whose

running times asymptotically match the running times of their exponential-space counterparts working on general clique expressions. While we focus on the three problems mentioned above for concreteness, we in fact provide a more general algebraic framework, inspired by the work on the treedepth parameterization [20, 25, 31, 32, 35], that can be applied to a wider range of problems. Once the depth $d$ is not considered a constant, the running times of our algorithms increase with $d$. To mitigate this concern, we give a conditional lower bound showing that this is likely to be necessary if one wishes to keep the space complexity polynomial.

Recall that standard dynamic programming solves the Independent Set problem in time $2^k \cdot n^{\mathcal{O}(1)}$ and space $2^k \cdot n^{\mathcal{O}(1)}$ on a graph constructed by a clique expression of width $k$ [19]. Our first contribution is to show that on graphs with $(d, k)$-tree-models, the space complexity can be reduced to as low as $\mathcal{O}(dk^2 \cdot \log n)$ at the cost of allowing time complexity $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$. In fact, we tackle the more general problem of computing the independent set polynomial.

▶ **Theorem 1.1.** *There is an algorithm which takes as input an $n$-vertex graph $G$ along with a $(d, k)$-tree model of $G$, runs in time $2^{\mathcal{O}(kd)} \cdot n^{\mathcal{O}(1)}$ and uses at most $\mathcal{O}(dk^2 \log n)$ space, and computes the independent set polynomial of $G$.*

The idea of the proof of Theorem 1.1 is to reorganize the computation of the standard bottom-up dynamic programming by applying the zeta-transform to the computed tables. This allows a radical simplification of the way a dynamic programming table for a node is computed from the tables of its children, so that the whole dynamic programming can be replaced by top-down recursion. Applying just this yields an algorithm with space polynomial in $n$. We reduce space to $\mathcal{O}(dk^2 \log n)$ by computing the result modulo several small primes, and using space-efficient Chinese remaindering. This is inspired by the algorithm for Dominating Set on graphs of small treedepth of Pilipczuk and Wrochna [35].

In fact, the technique used to prove Theorem 1.1 is much more general and can be used to tackle all coloring-like problems of local character. We formalize those under a single umbrella by solving the problem of counting List $H$-homomorphisms (for an arbitrary but fixed pattern graph $H$), for which we provide an algorithm with the same complexity guarantees as those of Theorem 1.1. The concrete problems captured by this framework include, e.g., Odd Cycle Transveral and $q$-Coloring for a fixed constant $q$ (details in the full version).

Next, we turn our attention to the Max Cut problem. This problem is W[1]-hard when parameterized by cliquewidth, but it admits a simple $n^{\mathcal{O}(k)}$-time algorithm on $n$-vertex graphs provided with clique expressions of width $k$ [17]. Our second contribution is a space-efficient counterpart of this result for graphs equipped with bounded-depth tree-models.

▶ **Theorem 1.2.** *There is an algorithm which takes as input an $n$-vertex graph $G$ along with a $(d, k)$-tree model of $G$, runs in time $n^{\mathcal{O}(dk)}$ and uses at most $\mathcal{O}(dk \log n)$ space, and solves the Max Cut problem on $G$.*

Upon closer inspection, the standard dynamic programming for Max Cut on clique expressions solves a Subset Sum-like problem whenever aggregating the dynamic programming tables of children to compute the table of their parent. We apply the approach of Kane [27] that was used to solve Unary Subset Sum in logarithmic space: we encode the aforementioned Subset Sum-like problem as computing the product of polynomials, and use Chinese remaindering to compute this product in a space-efficient way.

Finally, we consider the Dominating Set problem, for which we prove the following.

▶ **Theorem 1.3.** *There is a randomized algorithm which takes as input an $n$-vertex graph $G$ along with a $(d, k)$-tree model of $G$, runs in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ and uses at most $\mathcal{O}(dk^2 \log n + n \log n)$ space, and reports the minimum size of a dominating set in $G$ that is correct with probability at least $1/2$.*

Note that the algorithm of Theorem 1.3 is randomized and uses much more space than our previous algorithms: more than $n \log n$. The reason for this is that we use the inclusion-exclusion approach proposed very recently by Hegerfeld and Kratsch [26], which is able to count dominating sets only modulo 2. Consequently, while the parity of the number of dominating sets of certain size can be computed in space $\mathcal{O}(dk^2 \log n)$, to determine the existence of such dominating sets we use the Isolation Lemma and count the parity of the number of dominating sets of all possible weights. This introduces randomization and necessitates sampling – and storing – a weight function. At this point we do not know how to remove neither the randomization nor the super-linear space complexity in Theorem 1.3; we believe this is an excellent open problem.

Note that in all the algorithms presented above, the running times contain a factor $d$ in the exponent compared to the standard (exponential-space) dynamic programming on clique expressions. The following conditional lower bound shows that some additional dependency on the depth is indeed necessary; the relevant precise definitions are provided in Section 4.

▶ **Theorem 1.4.** *Suppose* Longest Common Subsequence *cannot be solved in time* $M^{f(r)}$ *and space* $f(r) \cdot M^{\mathcal{O}(1)}$ *for any computable function* $f$*, even if the length* $t$ *of the sought subsequence is bounded by* $\delta(N)$ *for any unbounded computable function* $\delta$*; here* $r$ *is the number of strings on input,* $N$ *is the common length of each string, and* $M$ *is the total bitsize of the instance. Then for every unbounded computable function* $\delta$*, there is no algorithm that solves the* Independent Set *problem in graphs supplied with* $(d, k)$*-tree-models satisfying* $d \leqslant \delta(k)$ *that would run in time* $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ *and simultaneously use* $n^{\mathcal{O}(1)}$ *space.*

The possibility of achieving time- and space-efficient algorithms for Longest Common Subsequence was also the base of conjectures formulated by Pilipczuk and Wrochna [35] for their lower bounds against time- and space-efficient algorithms on graphs of bounded pathwidth. The supposition made in Theorem 1.4 is a refined version of those conjectures that takes also the length of the sought subsequence into account. The reduction underlying Theorem 1.4 is loosely inspired by the constructions of [35], but requires new ideas due to the different setting of tree-models of low depth.

Finally, given that the above results point to a fundamental role of shrubdepth in terms of space complexity, it is natural to ask whether shrubdepth can also be used to obtain meaningful tractability results with respect to the "usual" notion of fixed-parameter tractability. We conclude our exposition by highlighting two examples of problems which are NP-hard on graphs of bounded cliquewidth (and even of bounded pathwidth) [7, 28], and yet which admit fixed-parameter algorithms when parameterized by the shrubdepth.

▶ **Theorem 1.5.** *Metric Dimension and Firefighter can be solved in fixed-parameter time on graphs supplied with* $(d, k)$*-tree-models, where* $d$ *and* $k$ *are considered the parameters.*

In this work some technical details have been omitted due to space constraints. We refer to the full version of the paper for all proofs [5].

## 2 Preliminaries

For a positive integer $k$, we denote by $[k] = \{1, \ldots, k\}$ and $[k]_0 = [k] \cup \{0\}$. For a function $f \colon A \to B$ and elements $a, b$ (not necessarily from $A \cup B$), the function $f[a \mapsto b] \colon A \cup \{a\} \to B \cup \{b\}$ is given by $f[a \mapsto b](x) = f(x)$ for $x \neq a$ and $f[a \mapsto b](a) = b$. We use standard graph terminology [11]. The full proofs of our results also require the use of algebraic tools – notably the cover product and the fast subset convolution machinery of Björklund et al. [6].

We use the same computational model as Pilipczuk and Wrochna [35], namely the RAM model where each operation takes time polynomially proportional to the number of bits of the input, and the space is measured in terms of bits. We say that an algorithm $A$ runs in time $t(n)$ and space $s(n)$ if, for every input of size $n$, the number of operations of $A$ is bounded by $t(n)$ and the auxiliary used space of $A$ has size bounded by $s(n)$ bits.

**Shrubdepth.** We first introduce the decomposition notion for shrubdepth: *tree-models*.

▶ **Definition 2.1.** *For $d, k \in \mathbb{N}$, a $(d,k)$-tree-model $(T, \mathcal{M}, \mathcal{R}, \lambda)$ of a graph $G$ is a rooted tree $T$ of depth $d$ together with a family of symmetric Boolean $k \times k$-matrices $\mathcal{M} = \{M_a\}_{a \in V(T)}$, a labeling function $\lambda\colon V(G) \to [k]$, and a family of renaming functions $\mathcal{R} = \{\rho_{ab}\}_{ab \in E(T)}$ with $\rho_{ab}\colon [k] \to [k]$ for all $ab \in E(T)$ such that:*

- *The leaves of $T$ are identified with vertices of $G$. For each node $a$ of $T$, we denote by $V_a \subseteq V(G)$ the leaves of $T$ that are descendants of $a$, and with $G_a = G[V_a]$ we denote the subgraph induced by these vertices.*
- *With each node $a$ of $T$ we associate a labeling function $\lambda_a : V_a \to [k]$ defined as follows. If $a$ is a leaf, then $\lambda_a(a) = \lambda(a)$. If $a$ is a non-leaf node, then for every child $b$ of $a$ and every vertex $v \in V_b$, we have $\lambda_a(v) = \rho_{ab}(\lambda_b(v))$.*
- *For every pair of vertices $(u, v)$ of $G$, let $a$ denote their least common ancestor in $T$. Then we have $uv \in E(G)$ if and only if $M_a[\lambda_a(u), \lambda_a(v)] = 1$.*

We introduce some notation. If $(T, \mathcal{M}, \mathcal{R}, \lambda)$ is a $(d,k)$-tree model of a graph $G$, then for every node $a$ of $T$ and every $i \in [k]$, let $V_a(i) = \lambda_a^{-1}(i)$ be the set of vertices labeled $i$ at $a$. Given a subset $X$ of $V_a$ and $i \in [k]$, let $X_a(i) = X \cap V_a(i)$ be the vertices of $X$ labeled $i$ at $a$.

We say that a class $\mathcal{C}$ of graphs has *shrubdepth $d$* if there exists $k \in \mathbb{N}$ such that every graph in $\mathcal{C}$ admits a $(d,k)$-tree-model. Thus, shrubdepth is a parameter of a graph class, rather than of a single graph; though there are functionally equivalent notions, such as *SC-depth* [23] or *rank-depth* [10], that are suited for the treatment of single graphs. We remark that in the original definition proposed by Ganian et al. [23], relabeling is not allowed; however, using either definition yields the same notion of shrubdepth. Moreover, throughout this work we abstract away from the computation of the tree-models themselves and assume that a $(d,k)$-tree-model of the considered graph is provided on input.

We note that a fixed-parameter algorithm for computing tree-models has been proposed by Gajarský and Kreutzer [21] (in the sense of Ganian et al. [23]). The approach of Gajarský and Kreutzer is essentially kernelization: they iteratively "peel off" isomorphic parts of the graph until the problem is reduced to a kernel of size bounded only in terms of $d$ and $k$. This kernel is then treated by any brute-force method. Consequently, a straightforward inspection of their algorithm [21] shows that it can be implemented with polynomial space; but not space of the form $(d+k)^{\mathcal{O}(1)} \cdot \log n$, due to the necessity of storing all the intermediate graphs in the kernelization process. We leave as an open question the computation of a $(d,k)$-tree model, for a given graph $G$, running in time $f(d,k) \cdot n^{\mathcal{O}(1)}$ and using space $(d+k)^{\mathcal{O}(1)} \cdot \log n$.

## 3 Space-Efficient Algorithms on Tree-Models

**Independent Set.** In this section, we provide a fixed-parameter algorithm computing the independent set polynomial of a graph in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ and using $\mathsf{poly}(d,k) \log n$ space, when given a $(d,k)$-tree model. In particular, given a $(d,k)$-tree model $(T, \mathcal{M}, \mathcal{R}, \lambda)$ of an $n$-vertex graph $G$, our algorithm will allow to compute the number of independent sets of size $p$ for each $p \in [n]$. For simplicity of representation, we start by describing an algorithm that uses $\mathsf{poly}(d,k,n)$ space and then show how a result by Pilipczuk and Wrochna [35] can be applied to decrease the space complexity to $\mathsf{poly}(d,k) \log n$.

In order to simplify forthcoming definitions/statements, let $a$ be an internal node of $T$ with $b_1, \ldots, b_t$ as children. For $S \subseteq [k]$, we denote by $q(a, S, p)$ the number of independent sets $I$ of size $p$ of $G_a$ such that $S = \{i \in [k] : I_a(i) \neq \emptyset\}$. Let us define the polynomial $\mathsf{IS}(a, S) = \sum_{p \in \mathbb{N}} q(a, S, p) \cdot x^p$. For the root $r$ of $T$, the number of independent sets of $G$ of size $p$ is then given by $\sum_{S \subseteq [k]} q(r, S, p)$ and the independent set polynomial of $G$ is $\sum_{S \subseteq [k]} \mathsf{IS}(r, S)$. Therefore, the problem boils down to the computation of $\mathsf{IS}(r, S)$ and its coefficients $q(r, S, p)$. A usual way to obtain a polynomial or logarithmic space algorithm is a top-down traversal of a rooted tree-like representation of the input – in our case, this will be the tree model. In this top-down traversal, the computation of coefficients $q(a, S, p)$ of $\mathsf{IS}(a, S)$ makes some requests to the coefficients $q(b_i, S_i, p_i)$ of $\mathsf{IS}(b_i, S_i)$ for each $i \in [t]$, for some integer $p_i$, and some set $S_i$ of labels of $G_{b_i}$ so that $\sum_{i \in [t]} p_i = p$ and $\bigcup_{i \in [t]} \rho_{ab_i}(S_i) = S$. Since there are exponentially many (in $t$) possible partitions of $p$ into $t$ integers and $t$ can be $\Theta(n)$, we must avoid running over all such integer partitions, and this will be done by the fast computation of a certain subset cover.

We will later show that if some independent set of $G_a$ contains vertices of labels $i$ and $j$ with $M_a[i, j] = 1$, then all these vertices come from the same child of $a$. In particular, the vertices of label $i$ (rsp. $j$) cannot come from multiple children of $a$. To implement this observation, after fixing a set $S$ of labels, for each label class in $S$ we "guess" (i.e., branch on) whether it will come from a single child of $a$ or from many. Such a guess is denoted by $\alpha \colon S \to \{1_=, 2_\geqslant\}$. So, the assignment $\alpha$ will allow us to control the absence of edges in the sought-after independent set. For a fixed $\alpha$, naively branching over all possibilities of assigning the labels of $S$ to the children of $a$ with respect to $\alpha$ would take time exponential in $t$, which could be as large as $\Theta(n)$. We will use inclusion-exclusion branching to speed-up the computations while retaining the space complexity. In some sense, we will first allow less restricted assignments of labels to the children of $a$, and then filter out the ones that result in non-independent sets using the construction of a certain auxiliary graph. The former will be implemented by using "less restricted" guesses $\beta \colon S \to \{1_=, 1_\geqslant\}$ where $1_\geqslant$ reflects that vertices of the corresponding label come from at least one child of $a$. Note that if the vertices of some label $i$ come from exactly one child of $a$, then such an independent set satisfies both $\beta(i) = 1_=$ and $\beta(i) = 1_\geqslant$. Although it might seem counterintuitive, this type of guesses will enable a fast computation of a certain subset cover. After that, we will be able to compute the number of independent sets satisfying guesses of type $\alpha \colon S \to \{1_=, 2_\geqslant\}$ by observing that independent sets where some label $i$ occurs in at least two children of $a$ can be obtained by counting those where label $i$ occurs in at least one child and subtracting those where this label occurs in exactly one child.

We now proceed to a formalization of the above. Let $S \subseteq \lambda_a(V_a)$ and $\alpha \colon S \to \{1_=, 2_\geqslant\}$ be fixed. Let $s_1, \ldots, s_{|\alpha^{-1}(2_\geqslant)|}$ be an arbitrary linear ordering of $\alpha^{-1}(2_\geqslant)$. To compute the number of independent sets that match our choice of $\alpha$, we proceed by iterating over $c \in \{0, \ldots, |\alpha^{-1}(2_\geqslant)|\}$, and we count independent sets where the labels in $\{s_1, \ldots, s_c\}$ occur exactly once, and the number of such sets where the labels occur at least once. Later, we will obtain the desired number of independent sets via carefully subtracting these two values. In particular, let $\gamma \colon \{s_1, \ldots, s_c\} \to \{1_=, 1_\geqslant\}$, and we denote by $q(a, S, \alpha, c, \gamma, p)$ the number of independent sets $I$ of size $p$ of $G_a$ such that

- for every label $i \notin S$, we have $I_a(i) = \emptyset$;
- for every label $i \in \{s_1, \ldots, s_c\}$ with $\gamma(i) = 1_=$, there exists a unique child $b_j$ of $a$ such that $I_a(i) \cap V_{b_j} \neq \emptyset$;
- for every label $i \in \{s_1, \ldots, s_c\}$ with $\gamma(i) = 1_\geqslant$, there exists at least one child $b_j$ of $a$ such that $I_a(i) \cap V_{b_j} \neq \emptyset$;

- for every label $i \in S \setminus \{s_1, \ldots, s_c\}$ with $\alpha(i) = 1_=$, there exists a unique child $b_j$ of $a$ such that $I_a(i) \cap V_{b_j} \neq \emptyset$;
- and for every label $i \in S \setminus \{s_1, \ldots, s_c\}$ with $\alpha(i) = 2_\geqslant$, there exist at least two children $b_{j_1}$ and $b_{j_2}$ of $a$ such that $I_a(i) \cap V_{b_{j_1}} \neq \emptyset$ and $I_a(i) \cap V_{b_{j_2}} \neq \emptyset$.

We now proceed with some observations that directly follow from the definitions.

▶ **Observation 3.1.** *We have* $q(a, S, p) = \sum_{\alpha \in \{1_=, 2_\geqslant\}^S, \gamma \in \{1_=, 1_\geqslant\}^\emptyset} q(a, S, \alpha, 0, \gamma, p)$ *for every* $S \subseteq \lambda_a(V_a)$ *and integer* $p$. *Also, for every* $\alpha \in \{1_=, 2_\geqslant\}^S$, *every* $c \in \{0, \ldots, |\alpha^{-1}(2_\geqslant)| - 1\}$ *and every* $\gamma \colon \{s_1, \ldots, s_c\} \to \{1_=, 1_\geqslant\}$, *we have* $q(a, S, \alpha, c, \gamma, p) = q(a, S, \alpha, c+1, \gamma[s_{c+1} \mapsto 1_\geqslant], p) - q(a, S, \alpha, c+1, \gamma[s_{c+1} \mapsto 1_=], p)$.

It remains then to show how to compute the value $q(a, S, \alpha, |\alpha^{-1}(2_\geqslant)|, \gamma, p)$ for every $\alpha \in \{1_=, 2_\geqslant\}^S$, every $\gamma \in \{1_=, 1_\geqslant\}^{\alpha^{-1}(2_\geqslant)}$, and every integer $p$. It is worth mentioning that if $\beta \colon S \to \{1_=, 1_\geqslant\}$ is such that $\beta^{-1}(1_=) = \alpha^{-1}(1_=) \cup \gamma^{-1}(1_=)$ and $\beta^{-1}(1_\geqslant) = \alpha^{-1}(2_\geqslant) \setminus \gamma^{-1}(1_=)$, then $q(a, S, \alpha, |\alpha^{-1}(1_\geqslant)|, \gamma, p)$ is exactly the number of independent sets $I$ of size $p$ of $G_a$ satisfying the following:

1. For every $i \in [k] \setminus S$, we have $I_a(i) = \emptyset$.
2. For every $i \in \beta^{-1}(1_=)$, there exists a unique index $j \in [t]$ such that $I_a(i) \cap V_{b_j} \neq \emptyset$.
3. For every $i \in \beta^{-1}(1_\geqslant)$, there exists a (not necessarily unique) index $j \in [t]$ such that $I_a(i) \cap V_{b_j} \neq \emptyset$.

We will therefore write $q(a, S, \beta, p)$ instead of $q(a, S, \alpha, |\alpha^{-1}(1_\geqslant)|, \gamma, p)$ and we define the polynomial $\mathsf{TIS}(a, S, \beta) \in \mathbb{Z}[x]$ (where "T" stands for "transformed") as $\mathsf{TIS}(a, S, \beta) = \sum_{p \in \mathbb{N}} q(a, S, \beta, p) \cdot x^p$. Recall that because we are computing $\mathsf{IS}(a, S)$ and $\mathsf{TIS}(a, S, \beta)$ in a top-down manner, some queries for $\mathsf{IS}(b_i, S_i)$ will be made during the computation. Before continuing in the computation of $\mathsf{TIS}(a, S, \beta)$, let us first explain how to request the polynomials $\mathsf{IS}(b_j, S_j)$ from each child $b_j$ of $a$. If $a$ is not the root, let $a^*$ be its parent in $T$, and we use $\mathsf{PIS}(a, S)$ (where "P" stands for "parent") to denote the polynomial $\mathsf{PIS}(a, S) = \sum_{p \in \mathbb{N}_0} q^\rho(a, S, p) x^p$ where $q^\rho(a, S, p) = \sum_{D \subseteq \lambda_a(V_a) \colon \rho_{a^* a}(D) = S} q(a, D, p)$ is the number of independent sets of $G_a$ of size $p$ that contain a vertex with label $i \in [k]$ (i.e., $I_{a*}(i) \neq \emptyset$) if and only if $i \in S$ holds, **where the labels are treated with respect to** $\lambda_{a^*}$. Then it holds that $\mathsf{PIS}(a, S) = \sum_{D \subseteq \lambda_a(V_a) \colon \rho_{a^* a}(D) = S} \mathsf{IS}(a, D)$ .

As our next step, we make some observations that will not only allow to restrict the $\beta$'s we will need in computing the polynomial $\mathsf{IS}(a, S)$ from the polynomials $\mathsf{TIS}(a, S, \beta)$, but will also motivate the forthcoming definitions. Recall that we have fixed $S \subseteq \lambda_a(V_a)$ and $\beta \colon S \to \{1_=, 1_\geqslant\}$, and in $\mathsf{IS}(a, S)$ and $\mathsf{TIS}(a, S, \alpha)$ we are only counting independent sets $I$ such that $I_a(i) \neq \emptyset$ if and only if $i \in S$.

▶ **Observation 3.2.** *If there exist* $i_1, i_2 \in S$ *such that* $M_a[i_1, i_2] = 1$, *then for any independent set* $I$ *counted in* $\mathsf{IS}(a, S)$, *there exists a unique* $j \in [t]$ *such that* $I_a(i_1) \cup I_a(i_2) \subseteq V_{b_j}$.

Recall that for every label $i \in \alpha^{-1}(2_\geqslant)$, each independent set $I$ contributing to the value $q(a, S, \alpha, 0, \gamma, p)$ has the property that there are distinct children $b_{j_1}$ and $b_{j_2}$ such that $I_a(i) \cap V_{b_{j_1}}$ and $I_a(i) \cap V_{b_{j_2}}$ are both non-empty. Then by Observation 3.2 for every $i_1 \in S$ it holds that if $\alpha(i_1) = 2_\geqslant$, then $M_a[i_1, i_2] = 0$ for all $i_2 \in S$. So if $\alpha$ does not satisfy this, the request $T(a, S, \alpha, 0, \gamma)$ can be directly answered with 0. Otherwise, since we use Observation 3.1 for recursive requests, the requests $\mathsf{TIS}(a, S, \beta)$ made all have the property that for each $i_1 \in S$ the following holds: if $\beta(i_1) = 1_\geqslant$, then $M_a[i_1, i_2] = 0$ for all $i_2 \in S$. We call such $\beta$'s *conflict-free* and we restrict ourselves to only conflict-free $\beta$'s. In other words, we may assume that if $i_1, i_2 \in S$ and $M_a[i_1, i_2] = 1$, then we have $\beta(i_1) = \beta(i_2) = 1_=$. Observation 3.2 implies that for such $i_1$ and $i_2$, each independent set $I$ counted in $\mathsf{TIS}(a, S, \beta)$

is such that $I_a(i_1) \cup I_a(i_2) \subseteq V_{b_j}$ for some child $b_j$ of $a$. Now, to capture this observation, we define an auxiliary graph $F^{a,\beta}$ as follows. The vertex set of $F^{a,\beta}$ is $\beta^{-1}(1_=)$ and there is an edge between vertices $i_1 \neq i_2$ if and only if $M_a[i_1, i_2] = 1$. Thus, by the above observation, if we consider a connected component $C$ of $F^{a,\beta}$, then in each independent set $I$ counted in $\mathsf{TIS}(a, S, \beta)$, all the vertices of $I$ with labels from $C$ come from a single child of $a$.

▶ **Observation 3.3.** *Let $C$ be a connected component of $F^{a,\beta}$. For every independent set $I$ counted in $\mathsf{TIS}(a, S, \beta)$, there exists a unique $j \in [t]$ such that $\bigcup_{i \in C} I_a(i) \subseteq V_{b_j}$.*

We proceed with some intuition on how we compute $\mathsf{TIS}(a, S, \beta)$ by requesting some $\mathsf{PIS}(b_j, S_j)$. Let $I$ be some independent set counted in $\mathsf{TIS}(a, S, \beta)$. This set contains vertices with labels from the set $S$, and the assignment $\beta$ determines whether there is exactly one or at least one child from which the vertices of a certain label come from. Moreover, by Observation 3.3, for two labels $i_1, i_2$ from the same connected component of $F^{a,\beta}$, the vertices with labels $i_1$ and $i_2$ in $I$ come from the same child of $a$. Hence, to count such independent sets, we have to consider all ways to assign labels from $S$ to subsets of children of $a$ such that the above properties are satisfied – namely, each connected component of $F^{a,\beta}$ is assigned to exactly one child while every label from $\beta^{-1}(1_\geqslant)$ is assigned to at least one child. Since the number of such assignments can be exponential in $n$, we employ the fast computation of a certain subset cover.

We now formalize this step. Let $\mathsf{cc}(F^{a,\beta})$ we denote the set of connected components of $F^{a,\beta}$. The universe $U^{a,\beta}$ (i.e., the set of objects we assign to the children of $a$) is defined as $U^{a,\beta} = \beta^{-1}(1_\geqslant) \cup \mathsf{cc}(F^{a,\beta})$. For every $j \in [t]$, we define a mapping $f_j^{a,\beta} \colon 2^{U^{a,\beta}} \to \mathbb{Z}[x, z]$ (i.e., to polynomials over $x$ and $z$) as follows: $f_j^{a,\beta}(X) = \mathsf{PIS}(b_j, \mathsf{flat}^{a,\beta}(X)) z^{|X \cap \mathsf{cc}(F^{a,\beta})|}$ where $\mathsf{flat}^{a,\beta} \colon 2^{U^{a,\beta}} \to 2^S$ intuitively performs a union over all the present labels – formally: $\mathsf{flat}^{a,\beta}(W) = (W \cap \beta^{-1}(1_\geqslant)) \cup \bigcup_{w \in W \cap \mathsf{cc}(F^{a,\beta})} w$. So if we fix the set $X$ of labels coming from the child $b_j$, then the (unique) coefficient in $f_j^{a,\beta}(X)$ reflects the number of independent sets of $G_{b_j}$ using exactly these labels (with respect to $\lambda_a$). The exponent of the formal variable $z$ is intended to store the number of connected components of $F^{a,\beta}$ assigned to $b_j$. This will later allow us to exclude from the computation those assignments of labels from $S$ to children of $a$ where the elements of some connected component of $F^{a,\beta}$ are assigned to multiple children of $a$. For every $j \in [t]$, we define a similar function $g_j^{a,\beta} \colon 2^S \to \mathbb{Z}[x, z]$ as follows:

$$g_j^{a,\beta}(Y) = \begin{cases} f_j^{a,\beta}(X) & \text{if } \mathsf{flat}^{a,\beta}(X) = Y \text{ for some } X \in 2^{U^{a,\beta}}, \\ 0 & \text{otherwise.} \end{cases}$$

Observe that the function $\mathsf{flat}^{a,\beta}$ is injective and hence $g_j^{a,\beta}$ is well-defined. The mapping $g_j^{a,\beta}$ filters out those assignments where some connected component of $F^{a,\beta}$ is "split".

▶ **Lemma 3.4.** *Let $(T, \mathcal{M}, \mathcal{R}, \lambda)$ be a $(d, k)$-tree model of an $n$-vertex graph $G$. Let $a$ be a non-leaf node of $T$ and let $b_1, \ldots, b_t$ be the children of $a$. For every $S \subseteq \lambda_a(V_a)$, and every conflict-free $\beta \colon S \to \{1_=, 1_\geqslant\}$, it holds that*

$$\mathsf{TIS}(a, S, \beta) = \left( \sum_{\substack{X_1, \ldots, X_t \subseteq [k] \colon \\ X_1 \cup \cdots \cup X_t = S}} \left( \prod_{j=1}^{t} g_j^{a,\beta}(X_j) \right) \right) \langle z^{|\mathsf{cc}(F^{a,\beta})|} \rangle,$$

*where for a polynomial $P = \sum_{u_1, u_2 \in \mathbb{N}_0} q_{u_1,u_2} x^{u_1} z^{u_2} \in \mathbb{Z}[x, z]$ the polynomial $P\langle z^{|\mathsf{cc}(F^{a,\beta})|} \rangle \in \mathbb{Z}[x]$ is defined as $P\langle z^{|\mathsf{cc}(F^{a,\beta})|} \rangle = \sum_{u_1 \in \mathbb{N}_0} q_{u_1, |\mathsf{cc}(F^{a,\beta})|} x^{u_1}$.*

Now we can apply a result by Björklund et al. [6] to accelerate the computation of $\mathsf{TIS}(a,S,\beta)$: It holds $\mathsf{TIS}(a,S,\beta) = \left(\sum_{Y\subseteq S}(-1)^{|S\setminus Y|}\prod_{j=1}^{t}\sum_{Z\subseteq Y} g_j(Z)\right)\langle z^{|\mathsf{cc}(F)|}\rangle$. We now have the equalities required for our algorithm to solve Independent Set parameterized by shrubdepth. By using these equalities directly, we would obtain an algorithm running in time $2^{\mathcal{O}(kd)}\cdot n^{\mathcal{O}(1)}$ and space $\mathcal{O}(dk^2n^2)$. However, the latter can be substantially improved by using a result of Pilipczuk and Wrochna [35] based on the Chinese remainder theorem:

▶ **Theorem 3.5** ([35]). *Let $P(x)=\sum_{i=0}^{n'} q_i x^i$ be a polynomial in one variable $x$ of degree at most $n'$ with integer coefficients satisfying $0\leqslant q_i\leqslant 2^{n'}$ for $i=0,\ldots,n'$. Suppose that given a prime number $p\leqslant 2n'+2$ and $s\in\mathbb{F}_p$, the value $P(s) \pmod p$ can be computed in time $T$ and space $S$. Then given $k\in\{0,...,n'\}$, the value $q_k$ can be computed in time $\mathcal{O}(T\cdot\mathsf{poly}(n'))$ and space $\mathcal{O}(S+\log n')$.*

With this, we can finally prove Theorem 1.1.

**Counting List-Homomorphisms.** We now explain how to apply the techniques from the above to a broader class of problems, namely all problems expressible as instantiations of the #-List-$H$-Homomorphism problem for a fixed pattern graph $H$ (which we will introduce in a moment). In this way, we cover problems such as Odd Cycle Transversal and $q$-Coloring, for a fixed $q$. Furthermore, the techniques will be useful for solving Dominating Set later.

Let $H$ be a fixed undirected graph (possibly with loops) and let $R\subseteq V(H)$ be a designated set of vertices. An instance of the $R$-Weighted #-List-$H$-Homomorphism problem consists of a graph $G$, a weight function $\omega\colon V(G)\to\mathbb{N}$, a list function $L\colon V(G)\to 2^{V(H)}$, a *cardinality* $C\in\mathbb{N}$ and a *total weight* $W\in\mathbb{N}$. The goal is to count the number of list $H$-homomorphisms of $G$ such that exactly $C$ vertices of $G$ are mapped to $R$ and their total weight in $\omega$ is $W$. More formally, we seek the value

$$\Big|\big\{\varphi\colon V(G)\to V(H)\ \Big|\ \forall v\in V(G)\colon\varphi(v)\in L(v),\forall uv\in E(G)\colon\varphi(u)\varphi(v)\in E(H),\\ |\varphi^{-1}(R)|=C,\text{ and }\omega(\varphi^{-1}(R))=W\big\}\Big|\ .$$

We say that such $\varphi$ has cardinality $C$ and weight $W$. For the "standard" #-List $H$-Homomorphism problem we would use $R=V(H)$, $C=W=|V(G)|$, and unit weights. We also have the following special cases of the $R$-Weighted #-List-$H$-Homomorphism problem. In all cases, we consider unit weights.

- To model Independent Set, the pattern graph $H$ consists of two vertices $\mathbf{u}$ and $\mathbf{v}$ and the edge set contains a loop at $\mathbf{v}$ and the edge $\mathbf{uv}$. The set $R$ consists of $\mathbf{u}$ only.
- Similarly, to model Odd Cycle Transversal, the pattern graph $H$ is a triangle on vertex set $\{\mathbf{u},\mathbf{v},\mathbf{w}\}$ with a loop added on $\mathbf{u}$. Again, we take $R=\{\mathbf{u}\}$.
- To model $q$-Coloring, we take $H$ to be the loopless clique on $q$ vertices, and $R=V(H)$.

While in all the cases described above we only use unit weights, we need to work with any weight function in our application to Dominating Set. We prove the following result.

▶ **Theorem 3.6.** *Fix a graph $H$ (possibly with loops) and $R\subseteq V(H)$. There is an algorithm which takes as input an $n$-vertex graph $G$ together with a weight function $\omega$ and a $(d,k)$-tree-model, runs in time $2^{\mathcal{O}(dk)}\cdot n^{\mathcal{O}(1)}\cdot(W^*)^{\mathcal{O}(1)}$ and uses space $\mathcal{O}(k^2d(\log n+\log W^*))$, and solves the $R$-Weighted #-List-$H$-Homomorphism in $G$, where $W^*$ denotes the maximum weight in $\omega$.*

**Max Cut.** In the classical Max Cut problem, we are given a graph $G$ and the task is to output $\max_{X \subseteq V(G)} |E(X, V(G) \setminus X)|$. Towards solving the problem, let us fix a graph $G$ and a $(d,k)$-tree model $(T, \mathcal{M}, \mathcal{R}, \lambda)$ of $G$. Recall that for every node $a$ of $T$, $i \in [k]$ and $X \subseteq V_a$, we denote by $X_a(i)$ the set of vertices in $X$ labeled $i$ at $a$, i.e., $X \cap \lambda_a^{-1}(i)$. Given a child $b$ of $a$, we let $V_{ab} = V_b$ and we denote by $V_{ab}(i)$ the set of vertices in $V_b$ labeled $i$ at $a$, *i.e.*, $V_b \cap V_a(i)$. By $X_{ab}(i)$ we denote the set $X \cap V_{ab}(i)$. Given $c \in \{a, ab\}$, we define the *c-signature* of $X \subseteq V_c$ – denoted by $\mathsf{sig}_c(X)$ – as the vector $(|X_c(1)|, |X_c(2)|, \ldots, |X_c(k)|)$. We let $\mathcal{S}(c)$ be the set of $c$-signatures of all the subsets of $V_c$, *i.e.*, $\mathcal{S}(c) := \{\mathsf{sig}_c(X) : X \subseteq V_c\}$. Observe that $|\mathcal{S}(c)| \in n^{\mathcal{O}(k)}$ holds. Also, for the children $b_1, \ldots, b_t$ of $a$, we define $\mathcal{S}(ab_1, \ldots, ab_t)$ as the set of all tuples $(s^1, \ldots, s^t)$ with $s^i \in \mathcal{S}(ab_i)$ for each $i \in [t]$. Given $s \in \mathcal{S}(c)$, we define $f_c(s)$ as the maximum of $|E(X, V_c \setminus X)|$ over all the subsets $X \subseteq V_c$ with $c$-signature $s$. To solve Max Cut on $G$, it suffices to compute $\max_{s \in \mathcal{S}(r)} f_r(s)$ where $r$ is the root of $T$.

Let $b$ be a child of $a$. We start explaining how to compute $f_{ab}(s)$ by making at most $n^{\mathcal{O}(k)}$ calls to the function $f_b$. Given $s' \in \mathcal{S}(b)$, we define $\rho_{ab}(s')$ as the vector $s = (s_1, \ldots, s_k) \in \mathcal{S}(ab)$ such that, for each $i \in [k]$, we have $s_i = \sum_{j \in \rho_{ab}^{-1}(i)} s'_j$. Observe that for every $X \subseteq V_b$, we have $\mathsf{sig}_{ab}(X) = \rho_{ab}(\mathsf{sig}_b(X))$. Consequently, for every $s \in \mathcal{S}(ab)$, $f_{ab}(s)$ is the maximum of $f_b(s')$ over the $b$-signatures $s' \in \mathcal{S}(b)$ such that $\rho_{ab}(s') = s$. It follows that we can compute $f_{ab}(s)$ with at most $n^{\mathcal{O}(k)}$ calls to the function $f_b$.

▶ **Observation 3.7.** *Given a node $a$ of $T$ with a child $b$ and $s \in \mathcal{S}(ab)$, we can compute $f_{ab}$ in space $\mathcal{O}(k \log(n))$ and time $n^{\mathcal{O}(k)}$ with $n^{\mathcal{O}(k)}$ oracle access to the function $f_b$.*

In order to simplify forthcoming statements, we fix a node $a$ of $T$ with children $b_1, \ldots, b_t$. Now, we explain how to compute $f_a(s)$ by making at most $n^{\mathcal{O}(k)}$ calls to the functions $f_{ab_1}, \ldots, f_{ab_t}$. The first step is to express $f_a(s)$ in terms of $f_{ab_1}, \ldots, f_{ab_t}$. We first describe $|E(X, V_a \setminus X)|$ in terms of $|E(X \cap V_{b_i}, V_{b_i} \setminus X)|$. We denote by $E(V_{b_1}, \ldots, V_{b_t})$ the set of edges of $G[V_a]$ whose endpoints lie in different $V_{b_i}$'s, i.e. $E(G[V_{b_1}, \ldots, V_{b_t}]) \setminus (E(G[V_{b_1}] \cup \cdots \cup E(G[V_{b_t}]))$. Given $X \subseteq V_a$, we denote by $E_a(X)$ the intersection of $E(X, V_a \setminus X)$ and $E(V_{b_1}, \ldots, V_{b_t})$. In simple words, $E_a(X)$ is the set of all cut-edges (i.e., between $X$ and $V_a \setminus X$) running between distinct children of $a$. For $i, j \in [k]$, we denote by $E_a(X, i, j)$ the subset of $E_a(X)$ consisting of the edges whose endpoints are labeled $i$ and $j$. We capture the size of $E_a(X, i, j)$ with the following notion. For every $c \in \{a, ab_1, \ldots, ab_t\}$, $s \in \mathcal{S}(c)$ and $i, j \in [k]$, we define

$$\#\mathsf{pairs}_c(s, i, j) := \begin{cases} s_i \cdot (|V_c(j)| - s_j) + s_j \cdot (|V_c(i)| - s_i) \text{ if } i \neq j, \\ s_i \cdot (|V_c(i)| - s_i) \text{ otherwise.} \end{cases}$$

It is not hard to check that, for every subset $X \subseteq V_a$ with $a$-signature $s$, $\#\mathsf{pairs}_a(s, i, j)$ is the size of $\mathsf{pairs}_a(X, i, j)$ being the set of pairs of distinct vertices in $V_a$ labeled $i$ and $j$ at $a$ such that exactly one of them is in $X$. Observe that when $M_a[i, j] = 1$, then $|E_a(X, i, j)|$ is the number of pairs in $\mathsf{pairs}_a(X, i, j)$ whose endpoints belong to different sets among $V_{b_1}, \ldots, V_{b_t}$. Moreover, given a child $b$ of $a$, the number of pairs in $\mathsf{pairs}_a(X, i, j)$ whose both endpoints belong to $V_b$ is exactly $\#\mathsf{pairs}_{ab}(\mathsf{sig}_{ab}(X), i, j)$. Thus when $M_a[i, j] = 1$, we have

$$|E_a(X, i, j)| = \#\mathsf{pairs}_a(\mathsf{sig}_a(X), i, j) - \sum_{i \in [t]} \#\mathsf{pairs}_{ab_i}(\mathsf{sig}_{ab_i}(X), i, j) \ . \tag{1}$$

We capture the size of $E_a(X)$ with the following notion. For every $c \in \{a, ab_1, \ldots, ab_t\}$, $s \in \mathcal{S}(c)$ and $(k \times k)$-matrix $M$, we define $m_c(s, M) := \sum_{\substack{i,j \in [k], i \leqslant j \\ M[i,j]=1}} \#\mathsf{pairs}_c(s, i, j)$. Note that $|E_a(X)| = \sum_{i,j \in [k] :\, i \leqslant j, M_a[i,j]=1} |E_a(X, i, j)|$. Hence, by Equation 1, we deduce that $|E_a(X)| = m_a(\mathsf{sig}_a(X), M_a) - \sum_{i \in [t]} m_{ab_i}(\mathsf{sig}_{ab_i}(X), M_a)$. Since $E(X, V_a \setminus X)$ is the disjoint union of $E_a(X)$ and the sets $E(X \cap V_{b_1}, V_{b_1} \setminus X), \ldots, E(X \cap V_{b_t}, V_{b_t} \setminus X)$ , we deduce:

▶ **Observation 3.8.** *For every $X \subseteq V_a$ we have*

$$|E(X, V_a \setminus X)| = m_a(\mathsf{sig}_a(X), M_a) + \sum_{i=1}^{t} \left( |E(X_i \cap V_{b_i}, V_{b_i} \setminus X_i)| - m_{ab_i}(\mathsf{sig}_{ab_i}(X_i), M_a) \right) .$$

We are ready to express $f_a(s)$ in terms of $f_{ab_1}, \ldots, f_{ab_t}$ and $m_a, m_{ab_1}, \ldots, m_{ab_t}$.

▶ **Lemma 3.9.** *For every $s \in \mathcal{S}(a)$, we have*

$$f_a(s) = m_a(s, M_a) + \max_{\substack{(s^1,\ldots,s^t) \in \mathcal{S}(ab_1,\ldots,ab_t) \\ s = s^1 + \cdots + s^t}} \left( \sum_{i=1}^{t} \left( f_{ab_i}(s^i) - m_{ab_i}(s^i, M_a) \right) \right) .$$

To compute $f_a(s)$ we use a twist of Kane's algorithm [27] for solving the $k$-DIMENSIONAL UNARY SUBSET SUM in Logspace.

**Dominating Set.** We now prove Theorem 1.3. Note that DOMINATING SET cannot be directly stated in terms of $H$-homomorphisms for roughly the following reason. For $H$-homomorphisms, the constraints are *universal*: every neighbor of a vertex with a certain state must have one of allowed states. For DOMINATING SET, there is an *existential* constraint: a vertex in state "dominated" must have at least one neighbor in the dominating set. Also, the state of a vertex might change from "undominated" to "dominated" during the algorithm. The techniques we used for $H$-homomorphisms cannot capture such properties.

The problem occurs for other parameters as well. One approach that circumvents the issue is informally called *inclusion-exclusion branching*, and was used by Pilipczuk and Wrochna [35] in the context of DOMINATING SET on graphs of low treedepth. Their dynamic programming uses the states *Taken* (i.e., in a dominating set), *Allowed* (i.e., possibly dominated), and *Forbidden* (i.e., not dominated). These states reflect that we are interested in vertex partitions into three groups such that there are no edges between *Taken* vertices and *Forbidden* vertices; these are constraints that can be modelled using $H$-homomorphisms for a three-vertex pattern graph $H$. Crucially, for a single vertex $v$, if we fix the states of the remaining vertices, the number of partitions in which $v$ is dominated is given by the number of partitions where $v$ is possibly dominated minus the number of partitions where it is not dominated, i.e., informally "*Dominated = Allowed - Forbidden*".

For technical reasons explained later, our algorithm uses the classic Isolation Lemma:

▶ **Theorem 3.10** (Isolation lemma, [30])**.** *Let $\mathcal{F} \subseteq 2^{[n]}$ be a non-empty set family over the universe $[n]$. For each $i \in [n]$, choose a weight $\omega(i) \in [2n]$ uniformly and independently at random. Then with probability at least $1/2$ there exists a unique set of minimum weight in $\mathcal{F}$.*

Consequently, we pick a weight function $\omega$ that assigns every vertex a weight from $1, \ldots, 2n$ uniformly and independently at random. Storing $\omega$ takes $\mathcal{O}(n \log n)$ space. The remainder of the algorithm uses only $\mathcal{O}(dk^2 \log n)$ space.

To implement the above idea, we let the graph $H$ have vertex set $\{\mathbf{T}, \mathbf{A}, \mathbf{F}\}$ standing for *Taken*, *Allowed*, and *Forbidden*. This graph $H$ has a loop at each vertex as well as the edges **TA** and **AF**. Further, let $R \coloneqq \{\mathbf{T}\}$. Following our approach for $H$-homomorphisms, for every set $S \subseteq \mathbf{States}$ with $\mathbf{States} \coloneqq \{(\mathbf{T}, 1), (\mathbf{F}, 1), \ldots, (\mathbf{T}, k), (\mathbf{F}, k)\}$, every cardinality $c \in [n]_0$, and every weight $w \in [2n^2]_0$, in time $2^{\mathcal{O}(dk)} \cdot n^{\mathcal{O}(1)}$ and space $\mathcal{O}(dk^2 \log n)$ (recall that here for the maximum weight $W^*$ we have $W^* \leqslant 2n$) we can compute the value $a_{S,c,w}$ being the number of ordered partitions $(\widehat{T}, \widehat{F}, \widehat{A})$ of $V(G)$ satisfying the following properties:

1. there are no edges between $\widehat{T}$ and $\widehat{F}$;
2. $|\widehat{T}| = c$ and $\omega(\widehat{T}) = w$; and
3. for every $i \in [k]$ and $I \in \{T, F\}$, we have $(\mathbf{I}, i) \in S$ iff $\widehat{I} \cap V(i) \neq \emptyset$.

Note that we do not care whether vertices of some label $i$ are mapped to $A$ or not.

After that, we aim to obtain the number of dominating sets of cardinality $c$ and weight $w$ from values $a_{S,c,w}$. For this we need to transform the "states" *Allowed* and *Forbidden* into *Dominated*. Above we have explained how this transformation works if we know the state of a single vertex. However, now the set $S$ only captures for every label $i$, which states occur on the vertices of label $i$. First, the vertices of this label might be mapped to different vertices of $H$. And even if we take the partitions where all vertices of label $i$ are possibly dominated and subtract the partitions where all these vertices are not dominated, then we obtain the partitions where *at least one vertex* with label $i$ is dominated. However, our goal is that *all vertices* of label $i$ are dominated. So the *Dominated = Allowed - Forbidden* equality is not directly applicable here.

Recently, Hegerfeld and Kratsch [26] showed that when working with label sets, this equality is in some sense still true modulo 2. On a high level, they show that if we fix a part $\widehat{T}$ of a partition satisfying the above properties, then any undominated vertex might be put to any of the sides $\widehat{A}$ and $\widehat{F}$. Thus, if $\widehat{T}$ is not a dominating set of $G$, then there is an even number of such partitions and they cancel out modulo 2.

We can apply the same transformation to obtain from $a_{S,c,w}$'s the number of dominating sets of size $c$ and weight $w$ modulo 2. Isolation lemma implies that with probability at least $1/2$ for some $w$ this number if non-zero if a dominating set of size $c$ exists.

▶ Question 3.11. Is there an algorithm for Dominating Set of $n$-vertex graphs provided with a $(d, k)$-tree-model that runs in time $2^{\mathcal{O}(kd)} \cdot n^{\mathcal{O}(1)}$ and uses $(d+k)^{\mathcal{O}(1)} \log n$ space?

## 4 The Lower Bound

In this section, we prove Theorem 1.4. This lower bound is based on a reasonable conjecture on the complexity of the problem Longest Common Subsequence (LCS).

An instance of LCS is a tuple $(N, t, \Sigma, s_1, \ldots, s_r)$ where $N$ and $t$ are positive integers, $\Sigma$ is an alphabet and $s_1, \ldots, s_r$ are $r$ strings over $\Sigma$ of length $N$. The goal is to decide whether there exists a string $s \in \Sigma^t$ of length $t$ appearing as a subsequence in each $s_i$. There is a standard dynamic programming algorithm for LCS that has time and space complexity $\mathcal{O}(N^r)$. Abboud et al. [1] proved that the existence of an algorithm with running time $\mathcal{O}(N^{r-\varepsilon})$ for any $\varepsilon > 0$ would contradict the Strong Exponential-Time Hypothesis. As observed by Elberfeld et al. [15], LCS parameterized by $r$ is complete for the class XNLP: parameterized problems solvable by a nondeterministic Turing machine using $f(k) \cdot n^{\mathcal{O}(1)}$ time and $f(k) \log n$ space, for a computable function $f$. The only known progress on the space complexity is due to Barsky et al. with an algorithm running in $\mathcal{O}(N^{r-1})$ space [3]. This motivated Pilipczuk and Wrochna to formulate the following conjecture [35].

▶ **Conjecture 4.1** ([35]). *There is no algorithm that solves the LCS problem in time $M^{f(r)}$ and using $f(r)M^{\mathcal{O}(1)}$ space for any computable function $f$, where $M$ is the total bitsize of the instance and $r$ is the number of input strings.*

Note that in particular, the existence of an algorithm with time and space complexity as in Conjecture 4.1 implies the existence of such algorithms for all problems in the class XNLP.

Our lower bound is based on the following stronger variant of Conjecture 4.1, in which we additionally assume that the sought substring is short.

▶ **Conjecture 4.2.** *For any unbounded and computable function $\delta$, Conjecture 4.1 holds even when $t \leqslant \delta(N)$.*

Let $(N, t, \Sigma, s_1, \ldots, s_r)$ be an instance of LCS. We assume, without loss of generality, that $N$ is a power of 2. We provide a reduction from $(N, t, \Sigma, s_1, \ldots, s_r)$ to an equivalent instance of Independent Set consisting of a graph $G$ with $(r + t + N)^{\mathcal{O}(1)}$ vertices which admits a $(d, k)$-tree-model where $d = \mathcal{O}(\log t)$ and $k = \mathcal{O}(r \log N)$. This implies Theorem 1.4 since for every unbounded and computable function $\delta$ there exists an unbounded and computable function $\delta'$ such that if $t \leqslant \delta'(N)$, then $d \leqslant \delta(k)$ for all sufficiently large $N, r \in \mathbb{N}$.

To outline the main idea of the reduction, let $s^\star$ be a potential common substring of $s_1, \ldots, s_r$ of length $t$. We use matchings to represent the binary encoding of the positions of the letters of $s^\star$ in each string.

For every string $s_p$ and $q \in [t]$, we define the **selection gadget** $\mathsf{S}_p^q$ which contains, for every $i \in [\log N]$, an edge called the *$i$-edge* of $\mathsf{S}_p^q$. One endpoint of this edge is called the *0-endpoint* and the other is called the *1-endpoint*; i.e., a selection gadget induces a matching on $\log N$ edges. This results in the following natural bijection between $[N]$ and the maximal independent sets of $\mathsf{S}_p^q$. For every $I \in [N]$, we denote by $\mathsf{S}_p^q | I$ the independent set that contains, for each $i \in [\log N]$, the $x$-endpoint of the $i$-edge of $\mathsf{S}_p^q$ where $x$ is the value of the $i$-th bit of the binary representation of $I - 1$ (we consider the first bit to be the most significant one and the $\log N$-th one the least significant). Then the vertices selected in $\mathsf{S}_p^q$ encode the position of the $q$-th letter of $s^\star$ in $s_p$.

We need to guarantee that the selected positions in the gadgets $\mathsf{S}_p^1, \ldots, \mathsf{S}_p^t$ are coherent, namely, for every $q \in [t]$, the position selected in $\mathsf{S}_p^q$ is strictly smaller than the one selected in $\mathsf{S}_p^{q+1}$. For this, we construct an **inferiority gadget** denoted by $\mathsf{Inf}(p, q)$ for every string $s_p$ and every $q \in [t-1]$. The idea behind it is to ensure that the only possibility for an independent set to contain at least $3 \log N$ vertices from $\mathsf{S}_p^q, \mathsf{S}_p^{q+1}$, and their inferiority gadget, is the following: there exist $I < J \in [N]$ such that the independent set contains $\mathsf{S}_p^q | I \cup \mathsf{S}_p^{q+1} | J$. The maximum solution size in the constructed instance of Independent Set – which is the sum of the independence number of each gadget – will guarantee that only such selections are possible. We refer to the full version of this paper for the construction of these inferiority gadgets and the arguments proving the following observation.

▶ **Observation 4.3.** *Let $p \in [r]$ and $q \in [t-1]$. The independence number of $\mathsf{Inf}(p, q)$ is $\log N$ and for every $I, J \in [N]$, we have $I < J$ iff there exists a set of $\log N$ vertices $S$ from $\mathsf{Inf}(p, q)$ such that the union of $S$, $\mathsf{S}_p^q | I$ and $\mathsf{S}_p^{q+1} | J$ induces an independent set.*

Next, we need to ensure that the $t$ positions chosen in $s_1, \ldots, s_r$ indeed correspond to a common subsequence, i.e., for every $q \in [t]$, the $q$-th chosen letter must be the same in every $s_1, \ldots, s_r$. For $p \in [r-1]$, let $\mathcal{M}_p$ denote the set of all ordered pairs $(I, J) \in [N]^2$ such that the $I$-th letter of $s_p$ and the $J$-th of $s_{p+1}$ are identical. For each $p \in [r-1]$ and $q \in [t]$, we create the *matching gadget* $\mathsf{Match}(p, q)$ as follows:

- For every pair $(I, J) \in \mathcal{M}_p$ and for each $p^\star \in \{p, p+1\}$, we create a copy $\mathsf{M}_{p^\star}^{p,q,I,J}$ of $\mathsf{S}_{p^\star}^q$ and for every $\ell \in [\log N]$ and $x \in \{0, 1\}$, we add an edge between the $x$-endpoint of the $\ell$-edge of $\mathsf{S}_{p^\star}^q$ and the $(1-x)$-endpoint of the $\ell$-edge of $\mathsf{M}_{p^\star}^{p,q,I,J}$.
- For every pair $(I, J) \in \mathcal{M}_p$, we add a new vertex $v_{p,I,J}^q$ adjacent to (1) all the vertices from $\mathsf{M}_p^{p,q,I,J}$ that are not in $\mathsf{M}_p^{p,q,I,J} | I$ and (2) all the vertices from $\mathsf{M}_{p+1}^{p,q,I,J}$ that are not in $\mathsf{M}_{p+1}^{p,q,I,J} | J$.

Finally, we turn $\{v^q_{p,I,J} : (I,J) \in \mathcal{M}_p\}$ into a clique. Observe that, for each $p^\star \in \{p, p+1\}$, an independent set $S$ contains $(|\mathcal{M}_p|+1)\log N$ vertices from $\mathsf{S}^q_{p^\star}$ and its copies $\mathsf{M}^{p,q,I,J}_{p^\star}$ if and only if there exists a value $I \in [N]$ such that $S$ contains $\mathsf{S}^q_{p^\star}|I$ and $\mathsf{M}^{p,q,I,J}_{p^\star}|I$ for each copy. This leads to the following observation.

▶ **Observation 4.4.** *Let $p \in [r-1]$ and $q \in [t]$. The independence number of $\mathsf{Match}(p,q)$ is $1 + 2 \cdot |\mathcal{M}_p| \cdot \log N$ and for every $I, J \in [N]$, we have $(I,J) \in \mathcal{M}_p$ iff there exists an independent set $S$ of $\mathsf{Match}(p,q)$ with $1 + 2|\mathcal{M}_p| \cdot \log N$ vertices such that the union of $S$, $\mathsf{S}^q_p|I$ and $\mathsf{S}^q_{p+1}|J$ is an independent set.*

This concludes the construction of the graph $G$. See Figure 1 below for an overview.

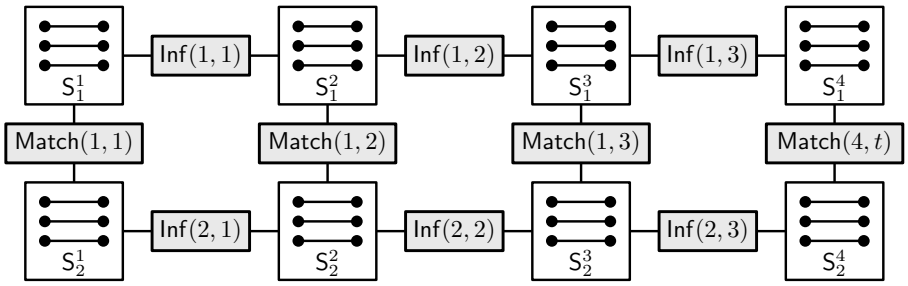

**Figure 1** Overview of the graph $G$ with $\log N = 3$, $r = 2$ and $t = 4$. There are some edges between two gadgets if and only if there are some edges between their vertices in $G$.

We prove correctness of the reduction in the following lemma which follows mostly from Observations 4.3 and 4.4.

▶ **Lemma 4.5.** *There exists an integer* goal *such that $G$ admits an independent set of size at least* goal *iff the strings $s_1, \ldots, s_r$ admit a common subsequence of length $t$.*

The next step is to construct a tree-model of $G$.

▶ **Lemma 4.6.** *We can compute in polynomial time a $(d,k)$-tree-model of $G$ where $d = 2\log t + 4$ and $k = 14r \log N - 3$.*

**Sketch of proof.** First, we prove that the union of the gadgets associated with a position $q \in [t]$ admits a simple tree-model. For every $q \in [t]$, we denote by $G^q$ the union of the selection gadgets $\mathsf{S}^q_p$ with $p \in [r]$ and the matching gadgets $\mathsf{Match}(p,q)$ with $p \in [r-1]$.

For each $q \in [t]$, we prove that $G^q$ admits a $(3,k)$-tree-model $(T^q, \mathcal{M}^q, \mathcal{R}^q, \lambda^q)$ where the tree $T^q$ is constructed as follows. We create the root $a^q$ of $T^q$ and we attach all the vertices in the selection gadgets $\mathsf{S}^q_p$ with $p \in [r]$ as leaves adjacent to $a^q$. Then, for every $p \in [r-1]$, we create a node $a^q_p$ adjacent to $a^q$ and for every $(I,J) \in \mathcal{M}_p$, we create a node $a^q_{p,I,J}$ adjacent to $a^q_p$. For each $(I,J) \in \mathcal{M}_p$, we make $a^q_{p,I,J}$ adjacent to the vertex $v^q_{p,I,J}$ and all the vertices in $\mathsf{M}^{p,q,I,J}_p$ and $\mathsf{M}^{p,q,I,J}_{p+1}$. Note that all the vertices in $\mathsf{Match}(p,q)$ are the leaves of the subtree rooted at $a^q_p$, and the leaves of $T^q$ are exactly the vertices in $G^q$. See Figure 2 for an illustration of $T^q$.

For every $q \in [t-1]$, we denote by $\mathsf{Inf}(q)$ the union of $\mathsf{Inf}(1,q), \ldots, \mathsf{Inf}(r,q)$. Moreover, for every interval $[x,y] \subseteq [t]$, we denote by $G^{x,y}$, the union of the graphs $G^q$ over $q \in [x,y]$, and the inferiority gadgets in $\mathsf{Inf}(q)$ over $q \in [x,y]$ such that $q+1 \in [x,y]$.

For every interval $[x,y]$, we prove by induction on $y-x$ that $G^{x,y}$ admits a $(2\log(y-x+1)+4, k)$-tree-model. In particular, it implies that $G^{1,t} = G$ admits a $(d,k)$-tree-model. It is also easy to see from our proof that this $(d,k)$-tree-model is computable in polynomial

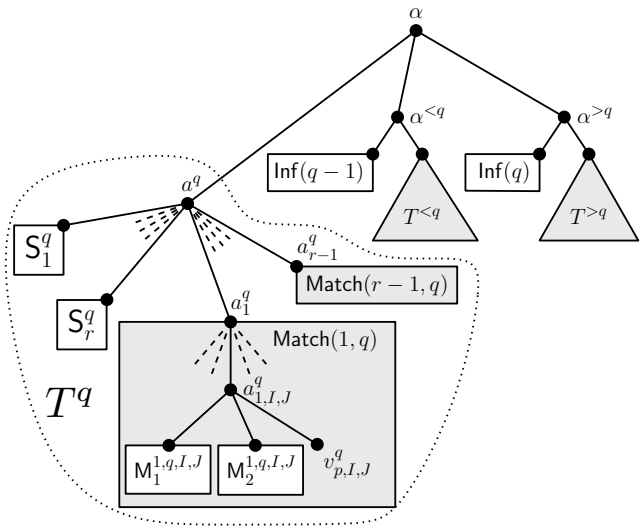

**Figure 2** Illustration of the tree $T$ and its subtree $T^q$ for the tree-model constructed in Lemma 4.6. An edge between a white filled rectangle labeled $\mathsf{X}$ and a node $a$ of the tree means that all the vertices in $\mathsf{X}$ are leaves adjacent to $a$.

time. For the base case of the induction, when $y = x$, we have $G^{x,y} = G^x$ and we have proved above that it admits a $(3, k)$-tree-model. When $x < y$, let $q = \lfloor (y - x)/2 \rfloor$. We use the induction hypothesis to obtain:

- A $(2\log(q - x) + 4, k)$-tree model $(T^{<q}, \mathcal{R}^{<q}, \mathcal{M}^{<q}, \lambda^{<q})$ for $G^{x,q-1}$.
- A $(2\log(y - q) + 4, k)$-tree-model $(T^{>q}, \mathcal{R}^{>q}, \mathcal{M}^{>q}, \lambda^{>q})$ for $G^{q+1,y}$.

Then, we construct a $(4 + 2\log(y - x + 1), k)$-tree-model $(T, \mathcal{R}, \mathcal{M}, \lambda)$ of $G^{x,y}$ from the tree-models of $G^{x,q-1}, G^{q+1,y}$, but also the $(3, k)$-tree-model $(T^q, \lambda^q, \mathcal{R}^q, \mathcal{M}^q)$ of $G^q$. To obtain $T$, we create the root $\alpha$ of $T$ and we make it adjacent to $a^q$, the root of $T^q$, and two new vertices: $\alpha^{<q}$ and $\alpha^{>q}$. We make $\alpha^{<q}$ adjacent to the root of $T^{<q}$ and to all the vertices in $\mathsf{Inf}(q-1)$. Symmetrically, we make $\alpha^{>q}$ adjacent to the root of $T^{>q}$ and to all the vertices in $\mathsf{Inf}(q)$. See Figure 2 for an illustration of $T$. ◀

## 5 Fixed-Parameter Algorithms for Metric Dimension and Firefighting

Theorem 1.5 – and in particular the fixed-parameter tractability of Metric Dimension and Firefighter parameterized by shrub-depth – can be obtained by combining known results about these problems [4, 24] with a bound on the maximum length of induced paths in graph classes of bounded shrubdepth [23, Theorem 3.7]. These results contrast the NP-hardness of both problems on graphs of bounded pathwidth [7, 28].

## Abstract

A minimal perfect hash function (MPHF) bijectively maps a set $S$ of objects to the first $|S|$ integers. It can be used as a building block in databases and data compression. RecSplit [Esposito et al., ALENEX'20] is currently the most space efficient practical minimal perfect hash function. It heavily relies on trying out hash functions in a brute force way.

We introduce *rotation fitting*, a new technique that makes the search more efficient by drastically reducing the number of tried hash functions. Additionally, we greatly improve the construction time of RecSplit by harnessing parallelism on the level of bits, vectors, cores, and GPUs.

In combination, the resulting improvements yield speedups up to 239 on an 8-core CPU and up to 5438 using a GPU. The original single-threaded RecSplit implementation needs 1.5 hours to construct an MPHF for 5 Million objects with 1.56 bits per object. On the GPU, we achieve the same space usage in just 5 seconds. Given that the speedups are larger than the increase in energy consumption, our implementation is more energy efficient than the original implementation.

## 1 Introduction

A *Perfect Hash Function* (PHF) is a hash function that does not have collisions, i.e., is injective, on a given set $S$ of objects. Evaluating the PHF on any object not in $S$ can return an arbitrary value. A *Minimal Perfect Hash Function* (MPHF) maps the objects in $S$ to the first

$n = |S|$ integers, so it is bijective. MPHFs are useful in many applications, for example, to implement hash tables with guaranteed constant access time [21]. By storing only fingerprints in the hash table cells [3, 15], we obtain an *approximate membership data structure*. Storing payload data in the cells, we obtain an updatable retrieval data structure [32]. Finally, the perfect hash function values can be used as small identifiers of the input objects [6], which are easier to handle and more space efficient than, for example, strings.

MPHFs can be very compact – the theoretically minimal space usage is 1.44 bits per object [2]. Currently, the most space-efficient practical MPHF is RecSplit [14]. It provides various trade-offs between the space consumption, construction time, and query time.

In this paper, we provide several improvements inside the RecSplit framework. We first describe RecSplit and other preliminaries in Section 2 and briefly review related work in Section 3. As a core step during construction, RecSplit tries out hash functions on a small set of objects until one hash function is a bijection. We introduce a new bijection search mechanism in Section 4, which reduces the search space of the brute force algorithm compared to the original method. *Rotation fitting* hashes the objects to two sets and tries to fit one set into the "holes" of the other set by rotating (cyclically shifting) it. As a positive side effect, this approach makes good use of bit parallelism.

We then parallelize RecSplit (with and without rotation fitting) using the vector parallelism available with *Single Instruction Multiple Data* (SIMD) instructions and the thread parallelism available with multicore CPUs and GPUs. Given that hash function construction here is mostly compute bound and can be done in parallel for a huge number of small subproblems, the GPU is an ideal hardware. Utilizing GPUs for evaluating hash functions is known from mining of cryptocurrencies with proof-of-work approach (e.g., Bitcoin). Our extensive evaluation in Section 6 shows speedups of up to 50 using SIMD, 239 when additionally using multi-threading with 16 threads, and 5438 using a GPU, compared to the original single-threaded implementation without rotation fitting. Because GPUs are so much faster at constructing MPHFs, they lead to a better energy efficiency than the CPU, as we show in the experiments. Finally, in Section 7, we summarize the results and give directions for future research.

**Our Contributions.** With *rotation fitting*, we introduce a new method for searching for bijections that can be used in RecSplit. We significantly accelerate the construction by four kinds of parallelism (bits, vectors, multicores, and GPU). Together, this accelerates RecSplit constructions by a factor up to 5438 and even makes its construction performance competitive to significantly less space efficient minimal perfect hash functions.

## 2 Preliminaries

In Section 2.1, we first shortly describe basic techniques needed by our implementation. We then continue with describing RecSplit in detail in Section 2.2. Finally, we describe SIMD in Section 2.3 and GPUs in Section 2.4.

### 2.1 Basics

**Words and Bit Vectors.** An important operation in RecSplit is `popcount`, which returns the number of 1-bits in a word. Given a bit vector, the $rank_1(x)$ operation returns the number of 1-bits before position $x$, and the $select_1(x)$ operation returns the position of the $x$-th 1-bit. The operation can be executed in constant time [10, 27] and has very fast and space-efficient implementations [28, 39]. An additional operation we need in this paper is $\text{rot}_k^i(x)$ which rotates (i.e., cyclically shifts) the $k$ least significant bits of $x$ by $i$ bit positions. This can be implemented in a bit parallel way using shifting and masking.

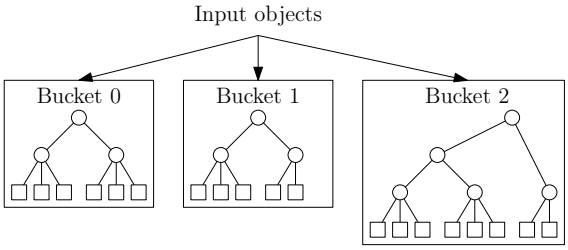

**Figure 1** Illustration of the overall RecSplit data structure. Circular nodes of the trees represent splittings, squares represent bijections.

**Golomb-Rice.** The Golomb code [24] is a variable length code that is optimal for geometric distributions. Golomb-Rice [38] is a faster special case, which is almost as space efficient. Given a parameter $\tau$ and the number $x$ to store, the $\tau$ least significant bits of $x$ form the *fixed part* which is stored directly. The remaining bits are encoded in unary, consisting of $\lfloor x/2^\tau \rfloor$ 0-bits and a final 1-bit. To access one element, we can get the lower bits from the array of fixed parts and the upper bits through two $select_1$ queries.

**Elias-Fano.** An Elias-Fano representation [13,16] can be used to store a monotonic sequence of integers $p_1, \ldots, p_k$ with $p_k \leq U$. Similar to Golomb-Rice codes, the least significant bits of each value are stored directly in the lower-bits array and can be accessed directly. The remaining most significant bits $u$ at index $i$ are encoded as a 1-bit in a bit vector at position $i + u$. This means that by executing a $select_1$ query on the upper bits and looking up the lower bits, we can restore any value in constant time. Using this representation, the sequence can be stored using $k(2 + \log(U/k))$ bits.

## 2.2 RecSplit

We now describe RecSplit [14], the MPHF that this paper is based on. Figure 1 illustrates the overall data structure. The first step of the construction is to apply an initial hash function on every object of the input to generate objects of uniform distribution. These objects are mapped to different buckets of expected size $b$, where $b$ is a tuning parameter.

**Splitting Trees.** In each bucket, RecSplit constructs an independent *splitting tree*. The tree partitions the objects into smaller and smaller sets until the individual sets have a small configurable size $\ell$. The splitting tree has a well-defined shape, depending only on the leaf size $\ell$ and the number of objects in the bucket. At each inner node, RecSplit tries random hash functions to find one that distributes the objects to the child nodes according to the tree structure. The number of child nodes of an inner node is called fanout. The fanout is optimized in such a way that the expected amount of work to find the splitting is roughly equal to the amount of work in all children combined. The fanouts of the two bottom-most levels are $\max\{2, \lceil 0.35\ell + 0.55 \rceil\}$ and $\max\{2, \lceil 0.21\ell + 0.9 \rceil\}$. In the terminology of the RecSplit paper, these levels are called *lower aggregation levels*. The levels above, also called *upper aggregation levels*, simply use a fanout of 2.

**Bijections.** The lowest level of the splitting tree is called *leaf level*. Each leaf, except for possibly the last, contains $\ell$ objects. This is small enough that it is feasible to search for a bijective mapping by trying random hash functions using brute force. The inner loop of the

bijection search applies a hash function modulo $\ell$ on each object. It converts the value to a bit by taking two to the power of it, and sets the corresponding bit in a bit vector of length $\ell$ using a logical `OR` operation. After hashing all objects, if the resulting bit vector has all its bits set to 1, it means that the hash function is a bijection on the leaf. If it is not, RecSplit tries the next hash function.

**Representation.** Because the splitting trees have a well-defined shape, it is enough to store the hash function identifier at each node in preorder. These numbers are encoded with Golomb-Rice code, where all unary parts and all binary parts of a tree are stored together. The optimal Golomb parameter $\tau$ is different based on the layer in the tree and can be pre-calculated. The encodings of all splitting trees from all buckets are concatenated in a single bit vector. An additional sequence with encoding based on Elias-Fano encodes both the prefix sums of the number of objects in each bucket and the positions where the encoding of each bucket starts.

**Query.** A RecSplit hash function can be evaluated by determining the bucket of an object and locating its encoding. The splitting tree in the bucket is traversed from the root to a leaf by applying the splitting hash function, which determines the child to descend into. Finding the encoding of a subtree is possible by executing a $select_1$ query on the upper bits of the Golomb-Rice coded hash function identifiers. During traversal, the number of objects stored in children left to the one descended into are accumulated. The final hash value is then the sum of the value of leaf bijection, the number of objects to the left in the splitting tree, and the total size of previous buckets.

The combination of brute force splitting and bijections is highly space efficient from an information-theoretical point of view – disregarding overheads due to encoding and metadata, optimal space consumption can be achieved. Consequently, as the leaf size $\ell$ gets larger, optimal space is approached [14].

## 2.3 SIMD

It is common, especially in perfect hashing, that the same operation needs to be executed on different data. This can be achieved with a simple loop, which means that the corresponding instructions must be decoded by the hardware for every element. This can be improved by using *Single Instruction, Multiple Data* (SIMD) [17]. A single instruction is used to apply the same operation on a *vector* of several elements. We refer to a single element within a SIMD vector as a *lane*. For example, a vector may contain 16 lanes with 32 bits each, i.e., the vector contains 512 bits overall. The exact set of operations depends on the concrete implementation of the SIMD model. On many Intel and AMD processors, SIMD operations are available through the Advanced Vector Extensions (AVX) [25]. AVX-512 [26] extends these operations to 512-bit vectors and is divided into many smaller subsets that offer additional operations. A subset that is useful for our implementation is AVX512VPOPCNTDQ, which provides `popcount` on 512-bit vectors with lanes of size 32 and 64 bits. The $\text{rot}_k^i$ function that cyclically shifts bits (see Section 2.1) can be implemented in parallel using SIMD.

## 2.4 GPUs

Graphics Processing Units (GPUs) are specialized processors initially designed for computer graphics applications. Over the last decades, GPUs evolved to general purpose processors for highly parallelizable tasks. We now describe the hardware and programming interface in the following paragraphs. To provide a grasp of the dimensions of a current GPU, we give metrics of the NVIDIA RTX 3090 [33], which is also used for our experiments (see Section 6).

**Compute Hardware.** A GPU consists of several streaming multiprocessors (SMs) (RTX 3090: 82). Each SM contains many arithmetic logic units (ALUs) to perform computations (RTX 3090: 64 integer ALUs). Several threads (RTX 3090: 32) operate in *lock-step*, i.e., they execute the same instruction at the same time. Such a bundle of threads is called *warp*. Threads are masked out for instructions they should not execute. This means that in loops, each thread in a warp has to iterate as many times as the thread with the largest number of iterations. To hide latencies, e.g., for memory access, each SM is oversubscribed with more threads than ALUs, and the GPU schedules the threads efficiently. Multiple warps of threads form a *thread block*. Thread blocks are guaranteed to reside on the same SM, which enables them to cooperate.

**Memory.** The *global memory* is the largest and slowest memory on the GPU (RTX 3090: 24 GB). When multiple threads of a warp access the memory simultaneously, the hardware serves the requests with as few memory transactions as possible. *Shared memory* is a fast memory placed on each SM. It is shared between the threads of the same thread block. On the RTX 3090, shared memory and L1 cache are allocated on the same memory areas. The data in shared memory is partitioned into 32 memory banks, and the $i$-th 32-bit word is stored in bank $i$ mod 32. When multiple threads simultaneously access different words within the same bank, the access operations have to be serialized.

**CUDA.** An efficient way to develop applications on NVIDIA GPUs is CUDA [34]. Functions which can be executed on the GPU are called *kernels*. Each kernel is executed on a *grid* of *thread blocks*. The grid size and the number of threads per block can be selected by the user. The user can create several *streams*. The kernels and data transfers launched into a specific stream are executed in order, but operations in different streams can arbitrarily overlap.

## 3 Related Work

Perfect Hashing is an active area of research [2, 7, 8, 9, 11, 20, 30, 31, 32, 37, 40]. Due to a lack of space, we only describe the most recent and fastest algorithms here. For a more detailed overview of recent methods, refer to Ref. [30]. To the best of our knowledge, there is no technique that constructs MPHFs on the GPU yet. Lefebvre and Hoppe [29] describe the GPU evaluation of MPHFs that were constructed on CPUs.

**FiPHa/BBHash.** A fast and simple approach to minimal perfect hashing uses fingerprinting and bumping [9, 31, 32]. BBHash [31] is a publicly available parallel implementation. The set $S$ of input objects is hashed using a hash function $h \to \beta n$ for a tuning parameter $\beta$. The set $S'$ of objects that have a collision is handled recursively. Consider the bit vector $b$ with $b[i] = 1$ iff $|\{s \in S : h(s) = i\}| = 1$. Then $rank_1(h(s))$ defines an MPHF on $S \setminus S'$. This approach needs at least $e$ bits per object (when $\beta = 1$) and provides efficient queries when about 4 or more bits per object are available (using larger values of $\beta$). An advantage is the very simple and easily parallelizable construction.

**PTHash.** PTHash [37] is based on FCH [20] which can be considered a predecessor of the hash-and-displace technique [2]. The objects are first distributed into different buckets using a hash function, but the distribution is not uniform. Specifically, about 60% of the objects are mapped to 30% of the buckets. The buckets are then processed in order of decreasing size. For each bucket, a hash function is searched such that each object can be placed in

the output domain without colliding with other objects that are already placed. The hash function identifiers are searched linearly and then stored in compressed form with several possible compression schemes. The proclaimed goal of PTHash is fast query times. Using an appropriate compression scheme, only a single memory access is required to find the hash value, and the remaining operations are simple hash function evaluations and arithmetic. Compared to the original implementation of RecSplit, PTHash consumes more space, but has faster queries and faster construction time. PTHash-HEM [36] is an implementation that first partitions the input and then constructs each partition independently in parallel.

**SicHash.** SicHash [30] is based on the simple idea to store the index of the hash function to be used in a retrieval data structure. It can capitalize on recent progress on fast and nearly space optimal retrieval [12]. Computing a valid index for all objects amounts to constructing a cuckoo hash table [19, 35]. In contrast to the brute force methods at the core of PTHash and RecSplit, this can be done in near linear time even on large tables. SicHash refines this basic approach using a mix of several fixed precision retrieval data structures and by using many small(ish) cuckoo hash tables rather than a single large table. Roughly, SicHash allows faster construction than PTHash while offering similar query time and space consumption.

## 4 Rotation Fitting

The general idea of RecSplit consists of two independent steps, bijections and splittings (see Section 2.2). In this section, we introduce a new method for searching for bijections in RecSplit's leaf nodes. As a reminder, given $m$ objects, we are looking for a way to quickly find a mapping of the objects to the first $m$ integers without any collisions. The original implementation tries out hash functions using brute force until one of them is a bijection.

*Rotation fitting* ensures that we need significantly fewer hash function evaluations. From the result of one evaluation, we derive additional candidates that are very fast to compute. Rotation fitting is efficient when $m \leq w$, where $w$ is the size of a machine word. We randomly distribute the objects into two sets $A$ and $B$ by using a 1-bit hash function. The 1-bit hash function is the same for all leaf nodes and does not ensure that $A$ and $B$ have the same size. Now we search for a hash function $h$ that gives a bijection on the leaf. Like in the original RecSplit implementation, we calculate the hash value of all objects in $A$ and set the respective bits in the word $a$ to 1. The function $h$ may be ruled out as a valid bijection by calculating the `popcount` of $a$. Analogously, the set $B$ is mapped to the word $b$ using the same hash function $h$. Let us now rotate (i.e., cyclically shift) the bits in $b$. If we can find a rotation value such that the 1-bits in $b$ fit exactly onto the 0-bits in $a$, we have found a bijection on the leaf. More formally, this is the case if there is an $r \in \{0, ..., m-1\}$, such that $a \,|\, \mathrm{rot}_m^r(b)$ has the $m$ least significant bits all set. In the extended version [5], we show that for large $m$ the probability of finding a bijection using rotation fitting is about $m$ times higher than the probability when using RecSplit's brute force approach.

To efficiently store $r$, we only try hash function identifiers which are multiples of $m$. This number plus $r$ is stored for each leaf. We can restore $r$ later by calculating modulo $m$ and restore the hash function index by rounding down to the next multiple of $m$. At query time, a rotation corresponds to an addition modulo $m$ to each object in the set $B$. The space overhead per object introduced by rotation fitting tends to 0 for large $m$ [5].

**Lookup Tables.** It is possible to avoid trying out all $m$ rotations by using a lookup table $t$. For all possible values of $a$, this table contains a rotation parameter $t[a]$ such that $\mathrm{rot}_m^{t[a]}(a)$ is minimal. If a value $x$ can be rotated to get the value $y$, then $\mathrm{rot}_m^{t[x]}(x) = \mathrm{rot}_m^{t[y]}(y)$. Let

$c = 2^m - 1$ be the word where the $m$ least significant bits are set. The value $\hat{b} = b \oplus c$ is $b$ with the $m$ least significant bits flipped. Note that $b$ can fill the holes in $a$ if and only if $\hat{b}$ can be rotated to match $a$. Thus, the necessary rotation of $b$ can be calculated as $r = (t[\hat{b}] - t[a]) \bmod m$ using two table lookups. Rotation $r$ is valid if $a|\text{rot}_m^r(b) = c$.

Because rotation is a very cheap operation, preliminary experiments show no improvement by lookup tables. Especially on GPUs, shared memory is a scarce resource and global memory is too slow. Our implementation therefore does not use lookup tables. Nonetheless, rotation fitting with lookup tables provides an asymptotic improvement of the running time by a factor of $m$. We also find the idea to normalize random permutations like this an interesting and novel concept. Applying this idea to other permutations is left for future research.

# 5 Parallelization

We describe the SIMD implementation in Section 5.1 and, on top of it, the multi-threaded implementation in Section 5.2. Finally, we describe the GPU implementation in Section 5.3.

## 5.1 SIMD

For the SIMD parallelization, we focus on the description of bijections and splittings, which (in most configurations) take most time of the construction. While we additionally accelerate the construction of the Elias-Fano data structure, the ideas are more straight forward and are omitted due to space constraints. The main idea of our SIMD parallelization is to try multiple hash function seeds simultaneously. Depending on the operation, we use SIMD lanes with a width of either 32 bits or 64 bits.

**Bijections.** For the bijections, each SIMD lane is responsible for trying one hash function. For this, we load consecutive hash function identifiers and the same input object to each lane of a SIMD vector, and evaluate the hash function. The resulting hash value in each lane is converted to a single bit by taking two to the power of it. After calculating the logical `OR` of these bits for all objects in the set, we check for a bijection by comparing each lane with a constant that has all $m$ lower bits set to 1. For rotation fitting, remember that the number we store as a seed is the hash function identification plus the rotation. This number should be as small as possible to avoid wasting space, so caution must be taken when trying out the rotations. If one lane finds a bijection, it might be possible that a higher rotation leads to a bijection on a lane with a smaller hash function index. Because this gives a smaller overall number to store, we always try all rotation values, even if a bijection is found.

**Splittings.** For the splittings, the original implementation uses small arrays of counters. Each counter contains the number of objects hashed to the respective split section. Instead, we use two different methods. For the *upper* aggregation levels with fanout 2, we use a single counter for the number of objects hashed to the left child. The number of objects in the right child can then be determined by subtraction. For all practical leaf sizes ($\ell \leq 24$), each counter of a valid *lower* level splitting fits into a single byte. Because an overflowing counter for one child would then just add 1 to the next counter, such overflows cannot make an invalid splitting look valid. When a seed for a valid splitting is found, we need to redistribute the objects. We now use SIMD to apply the same hash function to several objects at once, and store the results in an array. We then redistribute the objects without SIMD parallelism.

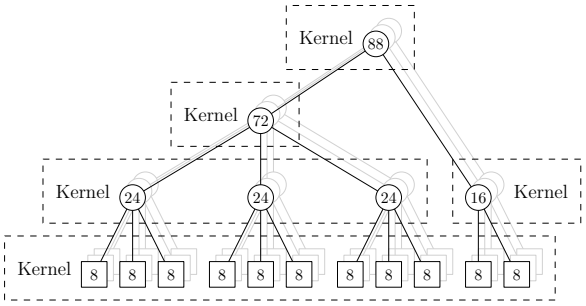

**Figure 2** Illustration of how all equally-shaped splitting trees are handled together on the GPU.

## 5.2 Multi-Threading

The original RecSplit implementation only uses a single thread. This leaves a lot of processing power unused since most modern processors contain multiple processing cores. As stated in the original RecSplit paper [14], parallelizing RecSplit is fairly easy because the buckets are completely independent of each other. First, we sort the input objects by their bucket index in parallel, and then determine the bucket borders. We then start several threads and assign a consecutive portion of the buckets to each thread. Because the number of buckets is large and the input objects are hashed to buckets uniformly, the load of all threads is reasonably balanced.

After a splitting or bijection is found, it must be stored in the Golomb-Rice coded sequence. To avoid synchronization, each thread uses its own local sequence and treats its input as if it was the complete input. This means it also stores the pointers to the start of each bucket encoding locally. After all threads are done, we sequentially concatenate the Golomb-Rice sequences and build the combined Elias-Fano data structure holding the prefix sum of bucket sizes and pointers to the bucket encodings.

## 5.3 GPU

In the GPU implementation, we first partition the objects to their buckets and partition the buckets by their respective size. We then use the GPU to determine the splittings and bijections within the buckets. Buckets with the same size have splitting trees with the same shape and can therefore be handled efficiently within the same set of kernel calls. This keeps the number of kernel calls small and is important for scalability. Using CUDA's streams, we additionally construct different bucket shapes concurrently, to utilize the GPU in case the number of buckets having a specific shape is small. For an overview, see Figure 2.

**Bijections.** All leaf nodes[1] of all trees with the same shape are constructed with a single kernel call. For each leaf node, we start one block of threads. First, the threads in each block cooperate to load all objects relevant for that leaf node into the shared memory. Similar to the SIMD implementation, where each lane tried a different hash function, now each thread tries a different hash function. After each hash function, the threads synchronize, check if a bijection was found and if it was, store the hash function index into global memory.

[1] All leaf nodes except possibly the last of each tree, which might have fewer objects.

**Splittings.** Like for the bijections, each splitting is handled by a thread block. The threads cooperate to load the objects into the shared memory and then each thread tries a different hash function index. For the two lowest aggregation levels, the thread blocks of all nodes in that level are started together using one kernel call (see Figure 2). Note that on these levels, the size of a node and the starting seed is constant. Therefore, the levels are very homogeneous. Conversely, the higher levels with fanout $s = 2$ are more heterogeneous. In particular, the number of objects on a specific level may be different for different nodes on the same level. Therefore, we launch individual kernels for each of those splittings, which contain the thread block for all trees with the same shape. We use multiplication and shifts to increment the counters of how many objects ended up in each lane. An alternative variant that stores counters in shared memory is slower in preliminary experiments, even when padding the counters to reduce the probability of bank conflicts. After a valid splitting is found, the threads in a block cooperate to reorder the objects in that node accordingly.

**Assembly.** Because the kernels are launched per level, the results are stored in BFS order. For the final data structure, we need to store them in preorder. The CPU unpacks the resulting seeds recursively and writes them to an encoded sequence.

## 6 Experiments

We first describe the experimental setup and general improvements. We then continue with a comparison of different techniques of our implementation before comparing the implementation with competitors from the literature. The code and scripts needed to reproduce our experiments are available on GitHub under the General Public License [22, 23].

**Experimental Setup.** We ran most of our experiments on an Intel i7 11700 processor with 8 cores (16 hardware threads (HT)) and a base clock speed of 2.5 GHz, supporting AVX-512. The machine runs Ubuntu 22.04 with Linux 5.15.0 and contains an NVIDIA RTX 3090 GPU. For additional experiments, we used a machine with an AMD EPYC 7702P processor with 64 cores (128 hardware threads) and a base clock speed of 2.0 GHz. The machine runs Ubuntu 20.04 with Linux 5.4.0 and supports only AVX2. Unless otherwise noted, all experiments were run on the Intel machine. We used the GNU C++ compiler version 11.2.0 with optimization flags `-O3 -march=native`. The SIMD implementation only supports x86 CPUs and is optimized towards AVX-512 using the Vector Class Library [18]. The GPU implementation uses CUDA 11. As a reminder, only the *construction* is using SIMD, multi-threading, and/or the GPU. The query implementation is identical for the SIMD and GPU implementation and almost equal to the original implementation [14]. We therefore did not compare the query performance of SIMD and GPU implementation.

For the comparison with competitors, we used strings of uniform random length $\in [10, 50]$ containing random characters except for the zero byte. Note that, as a first step, all competitors generate a *master hash code* (MHC) of each object using a high quality hash function. This makes the remaining computation largely independent of the input distribution. When only comparing different configurations of our own data structure, we used random 128-bit integers directly as MHC, which follows the approach of the original implementation [14].

### 6.1 Our Implementation

While the original implementation [14] uses std::sort to partition objects into buckets, we use IPS$^2$Ra [1]. For the less space efficient configurations ($\ell < 5, b < 100$), constructing the buckets is fast, so significant time is spent on sorting objects to buckets. For these

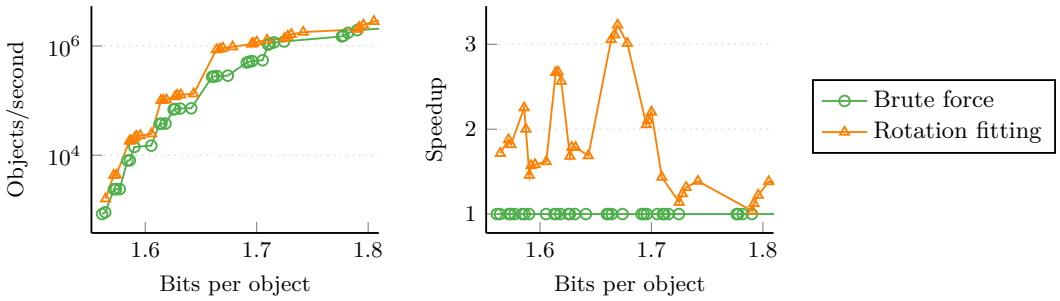

**Figure 3** Pareto front over the construction throughput of different variants of searching for bijections in the leaves. Single-threaded, non-vectorized measurements with $n = 5$ Million objects. The plot on the right gives speedups relative to the brute force method.[3]

configurations, IPS$^2$Ra both speeds up the sequential case and also enables sorting in parallel. For more space-efficient configurations ($\ell > 8$), the partitioning step needs less than 1% of the total construction time, both in the parallel and the sequential case. In this section, we compare against a slight adaption of the original implementation, using IPS$^2$Ra and supporting parallel construction.

**Rotation Fitting.** In order to compare rotation fitting with the brute force variant, we give a Pareto front[2] of space usage versus construction time in Figure 3. The construction time refers to the entire MPHF construction, including the time used for splittings. Rotation fitting is consistently faster, making the entire MPHF construction up to 3 times faster. The space overhead of rotation fitting becomes negligible for moderately large $\ell$ (see extended version [5]). Unless otherwise noted, all following experiments use rotation fitting.

**Dependence on Input Parameters.** In Figure 4, we plot the throughput of the SIMD, GPU and non-vectorized versions for different leaf sizes $\ell$ and bucket sizes $b$. For better comparability with the original paper [14], we include a wide range of configurations, even ones that are not very competitive. The SIMD version is consistently up to 4.5 times faster than the non-vectorized version and shows the same scaling behavior in $\ell$. The plot indicates that there is no configuration where one would prefer the non-vectorized version. While the GPU offers significant speedups for space efficient configurations, it performs not as good for the space inefficient configurations. A reason for this is data transfers to and from the GPU.

**Multi-Threading.** Table 1 shows that the parallel construction is up to 5 times faster on an 8-core machine. In the extended version [5], we give more detailed measurements of how different RecSplit configurations scale in the number of CPU threads. Rather unusual configurations with extremely small buckets ($b = 5$) do not scale as well, because they spend a lot of time partitioning the objects to buckets – even though we already use the highly optimized parallel sorter IPS$^2$Ra [1].

[2] A configuration is on the Pareto front if it is not dominated by any other configuration with respect to both construction time and space consumption.

[3] Note that giving speedups is non-trivial here because there might not be a configuration that achieves the same space usage that we could compare with. We therefore calculate the speedup relative to an interpolation of the next larger and next smaller data points. This is reasonable since RecSplit instances can be interpolated as well by hashing a certain fraction of objects into data structures with different configurations.

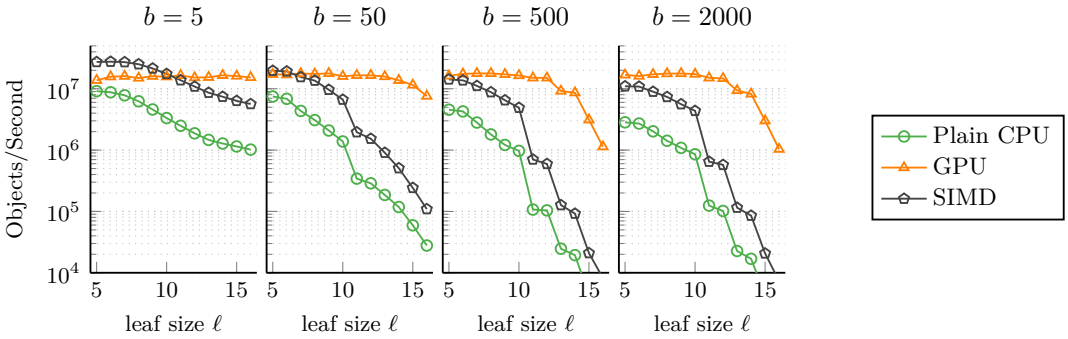

**Figure 4** Construction throughput with different hardware architectures based on different input parameters. $n = 5$ Million objects, 1 CPU thread.

**Overall Speedup.** Our rotation fitting technique leads to a speedup of up to 3 (see Figure 3) and SIMD parallelism improves the construction speed by up to a factor of 4.5 (see Figure 4). Multi-threading for highly space-efficient configurations shows a speedup of close to 5. Table 1 shows the overall improvement of our implementation on CPU and GPU when compared to the original RecSplit implementation. The original RecSplit paper says that MPHF construction at 1.56 bits per object is possible. This configuration with 5 Million objects takes about 1.5 hours using the original implementation. Our SIMD implementation achieves the same space usage in just 2 minutes on the CPU and 5 seconds on the GPU. Investing about 40 minutes of GPU time, our implementation achieves a space usage of only 1.495 bits per object. This is about 40% closer to the lower bound [2] of 1.44 bits, and simultaneously more than twice as fast as the original implementation.

**Energy Consumption.** Of course, directly comparing CPU and GPU implementations is unfair. A sensible metric to compare them is the energy consumption, which can be a major cost factor. Additionally, the energy consumption is not influenced by market prices. Table 2 gives energy consumption measurements for different configurations and hardware architectures. The energy consumption is homogeneous throughout most of the execution time, except for a short ramp-up in the beginning. We do not count the ramp-up to the energy consumption. Measurements are performed using a Voltcraft 870 Multimeter.

Even though SIMD instructions need slightly more power, the total energy consumption of constructing one MPHF is lower. The GPU, even though it needs significantly more power, is so much faster that the resulting energy usage is about 1000 times lower than the original single-threaded CPU implementation. For basic RecSplit, the AMD machine needs about 1.5 times more time than the Intel machine. This can be readily explained by a lower clock frequency. This performance gap grows to a factor 4.6 for sequential SIMDRecSplit. The likely main reason is that the AMD machines lacks the AVX-512 vector units of the Intel machine. Still, since both processors have two 256-bit AVX2 units per core, it seems that better performance might be achievable with careful tuning for the AMD architecture. On the contrary, the AMD machine shows good scalability so that the energy consumption when using the entire machine is only a factor 1.3 larger than on the Intel machine – despite the fact that our implementation was tuned for the Intel architecture.

**Table 1** Construction time of the GPU implementation compared to our multi-threaded adaption of the original RecSplit implementation. $n = 5$ Million objects (strong scaling). Construction times are given in $\mu$s/object. We do not report speedups for $\ell = 24$ because the CPU baseline takes too long for this configuration.

| Configuration | Method | Bijections | Threads | B/Obj | Constr. | Speedup |
|---|---|---|---|---|---|---|
| $\ell = 16, b = 2000$ | RecSplit [14] | Brute force | 1 | 1.560 | 1175.4 | 1 |
| | RecSplit | Brute force | 16 | 1.560 | 206.5 | 5 |
| | SIMDRecSplit | Rotation fitting | 1 | 1.560 | 138.0 | 8 |
| | SIMDRecSplit | Rotation fitting | 16 | 1.560 | 27.9 | 42 |
| | GPURecSplit | Brute force | GPU | 1.560 | 1.8 | 655 |
| | GPURecSplit | Rotation fitting | GPU | 1.560 | 1.0 | 1173 |
| $\ell = 18, b = 50$ | RecSplit [14] | Brute force | 1 | 1.707 | 2942.9 | 1 |
| | RecSplit | Brute force | 16 | 1.713 | 504.0 | 5 |
| | SIMDRecSplit | Rotation fitting | 1 | 1.709 | 58.3 | 50 |
| | SIMDRecSplit | Rotation fitting | 16 | 1.708 | 12.3 | 239 |
| | GPURecSplit | Brute force | GPU | 1.708 | 5.2 | 564 |
| | GPURecSplit | Rotation fitting | GPU | 1.709 | 0.5 | 5438 |
| $\ell = 24, b = 2000$ | GPURecSplit | Brute force | GPU | 1.496 | 2300.9 | — |
| | GPURecSplit | Rotation fitting | GPU | 1.496 | 467.9 | — |

## 6.2 Comparison with Competitors

We now compare our implementation to the sequential codes RecSplit [14], SicHash [30], and CHD [2] as well as the parallel codes PTHash [37], PTHash-HEM [36] and BBHash [31].

**Space usage trade-off.** Figure 5 shows a space versus construction time Pareto front for each approach. Looking at a single thread first, we make the surprising observation that SIMDRecSplit not only wins for the most space efficient configurations for which we designed it but, by far, dominates all the other methods also for less space-efficient cases. For parallel construction, SIMDRecSplit even strengthens its margin to the competing approaches.

**Construction Scaling.** Figure 6 compares scaling behavior of the parallel codes. We see that BBHash scales poorly while both PTHash-HEM and SIMDRecSplit scale well on the 8-core Intel machine. However, SIMDRecSplit scales better than PTHash-HEM on the 64-core AMD machine.

**Queries.** Table 3 shows that when looking at the query time, PTHash is a clear winner. While BBHash can achieve the same query speed and good construction speed, its space usage is large. SicHash has a query time close to PTHash's most compact representation, but is faster to construct and more space efficient. All RecSplit variants can achieve significantly lower space than other competitors but require considerably more query time. Our single-threaded SIMD implementation dominates most competitors with respect to both space and construction time. The use of rotations makes the queries about 10% slower than the original RecSplit implementation. The main goal of RecSplit is to achieve extremely small representation, and queries are not very fast to begin with, so this seems acceptable.

**Table 2** Energy consumption with $\ell = 18, b = 50$ and $n = 5$ Million objects. Energy consumption is both given as difference to the idle power, as well as total energy consumption of the whole system. For CPU-only measurements of the 8-core Intel machine, we dismount the GPU.

| | | | | Total system | | Δ to idle | |
|---|---|---|---|---|---|---|---|
| Machine | Method | Threads | Constr. Seconds | Power Watt | Energy Joule | Power Watt | Energy Joule |
| 8-core Intel | RecSplit [14] | 1 | 14 714.5 | 78 | 1 147 731 | 37 | 544 436 |
| | SIMDRecSplit | 1 | 291.5 | 87 | 25 360 | 46 | 13 409 |
| | SIMDRecSplit | 16 | 61.5 | 104 | 6 396 | 63 | 3 874 |
| | GPURecSplit | | 2.5 | 457 | 1 142 | 380 | 950 |
| 64-core AMD | RecSplit [14] | 1 | 21 620.8 | 223 | 4 821 438 | 91 | 1 967 492 |
| | SIMDRecSplit | 1 | 1 328.7 | 224 | 297 629 | 92 | 122 240 |
| | SIMDRecSplit | 128 | 23.6 | 364 | 8 590 | 232 | 5 475 |

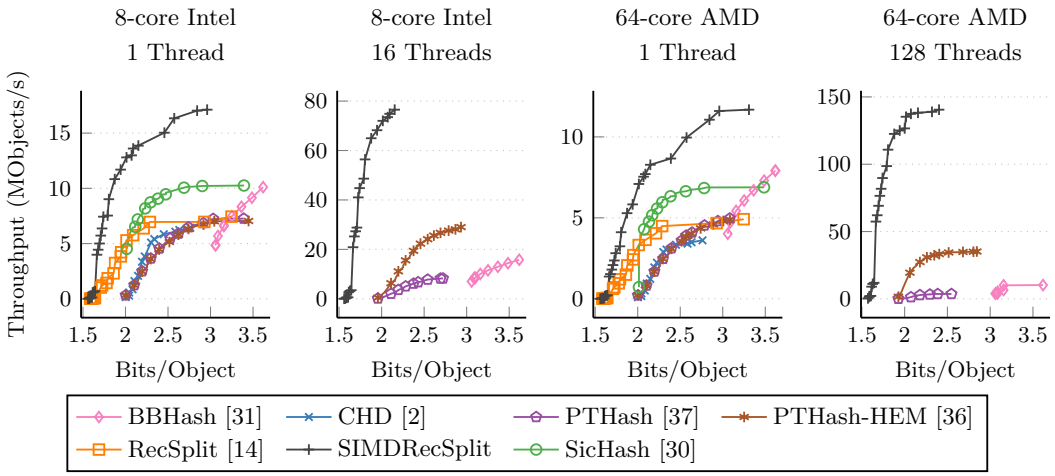

**Figure 5** Trade-off of construction time vs space usage. Weak scaling, $n/p = 10$ Million objects. For SicHash and PTHash, we plot all Pareto optimal data points but only show markers for every fourth point to increase readability. Therefore, the lines might bend on positions without markers.

## 7 Conclusion and Future Work

We have shown that by harnessing parallelism at all available levels – bits, vectors, cores, and GPUs – one can dramatically accelerate the construction of highly space efficient minimal perfect hash functions (MPHFs) using the brute force RecSplit approach [14]. This leads to speedups of up to 239 on SIMD and 5438 on the GPU and also dramatically reduces energy consumption. Surprisingly, this even turns out to be the fastest available approach for constructing less space-efficient MPHFs. This is not what we expected. Our initial hypothesis was that there would be a trade-off with asymptotically faster approaches winning for fewer requirements on space consumption. Our new technique *rotation fitting* reduces the work needed per tried hash function while adding a tiny bit of space requirement. The asymptotically "obvious" improvement of replacing $\ell$ rotations/checks by two table lookups are not productive on current architectures. So, brute force, simplicity (in the inner loops), and parallelism currently wins against any attempt at algorithmic sophistication.

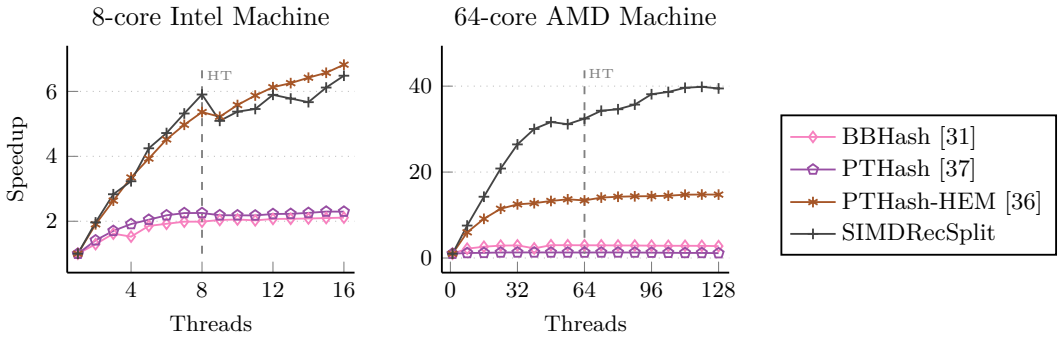

**Figure 6** Construction time speedups when using multiple threads $t$. Strong scaling, $n = 50$ Million. Speedups are given relative to each method's single threaded performance. For a comparison of absolute performance, refer to Figure 5. Configurations used are BBHash: $\gamma = 2.0$; PTHash/PTHash-HEM: $c = 6.0$, $\alpha = 0.95$, EF; SIMDRecSplit: $\ell = 10$, $b = 2000$.

**Table 3** Query and construction time of different competitor configurations on 10 Million objects.

| Method | Bits/Obj. | Constr./Obj. | Query/Obj. |
|---|---|---|---|
| BBHash [31], $\gamma$=5.0 | 6.871 | 50 ns | 36 ns |
| BBHash [31], $\gamma$=1.0 | 3.059 | 208 ns | 51 ns |
| PTHash [37], $c$=11.0, $\alpha$=0.88, D-D | 4.379 | 138 ns | 25 ns |
| PTHash [37], $c$=7.0, $\alpha$=0.99, C-C | 3.313 | 199 ns | 20 ns |
| PTHash [37], $c$=6.0, $\alpha$=0.99, EF | 2.345 | 248 ns | 35 ns |
| SicHash [30], $\alpha$=0.9, $p_1$=20, $p_2$=77 | 2.412 | 119 ns | 41 ns |
| SicHash [30], $\alpha$=0.97, $p_1$=44, $p_2$=30 | 2.081 | 172 ns | 40 ns |
| RecSplit [14], $\ell$=5, $b$=5 | 2.928 | 145 ns | 65 ns |
| RecSplit [14], $\ell$=8, $b$=100 | 1.793 | 709 ns | 75 ns |
| RecSplit [14], $\ell$=14, $b$=2000 | 1.584 | 126 534 ns | 96 ns |
| SIMDRecSplit, $\ell$=5, $b$=5 | 2.96 | 49 ns | 71 ns |
| SIMDRecSplit, $\ell$=8, $b$=100 | 1.806 | 107 ns | 80 ns |
| SIMDRecSplit, $\ell$=14, $b$=2000 | 1.585 | 11 742 ns | 110 ns |

Another attempt at sophistication that so far failed is to combine brute force RecSplit with the retrieval approach of SicHash [30]. The idea of this *ShockHash* approach is to allow retrieval of a single bit of information for each element. The brute force part then tries pairs of random hash functions until they define a pseudo-forest – a collection of components consisting of a tree plus one additional edge. While ShockHash seems to allow space efficient perfect hashing, initial experiments indicated that performance-wise ShockHash is also inferior to pure brute force (see the extended version [5] for details). More efficient implementations of ShockHash may change this picture in the future.

Also, rotation fitting could be generalized by splitting into more than two parts. The resulting search for several rotations gives more room for sophistications like search space pruning. Furthermore, the approach from rotation fitting to use a lookup table for normalizing bit patterns could be generalized to a richer set of mappings than just rotations.

Everything discussed so far is mainly concerned with construction time. However, an equally important problem is to improve query time. Traversing an aggressively compressed tree for each query is inherently more expensive than the simple constant time operations

needed in PTHash [37] or SicHash [30] but there should be more efficient ways to break down MPHF construction into small subproblems that can be solved with brute force. We believe that the techniques developed here will turn out to be useful in that respect.

Finally, we can look for generalizations of RecSplit for computing non-minimal PHFs which allows us to further reduce space consumption of the hash function itself. Better tuning of the SIMD variant for AMD or perhaps even a portable implementation that also works on ARM or RISC-V would be relevant for widespread application.

## Abstract

In this paper we study the threshold model of *geometric inhomogeneous random graphs* (GIRGs); a generative random graph model that is closely related to *hyperbolic random graphs* (HRGs). These models have been observed to capture complex real-world networks well with respect to the structural and algorithmic properties. Following comprehensive studies regarding their *connectivity*, i.e., which parts of the graphs are connected, we have a good understanding under which circumstances a *giant* component (containing a constant fraction of the graph) emerges.

While previous results are rather technical and challenging to work with, the goal of this paper is to provide more accessible proofs. At the same time we significantly improve the previously known probabilistic guarantees, showing that GIRGs contain a giant component with probability $1 - \exp(-\Omega(n^{(3-\tau)/2}))$ for graph size $n$ and a degree distribution with power-law exponent $\tau \in (2, 3)$. Based on that we additionally derive insights about the connectivity of certain induced subgraphs of GIRGs.

## 1 Introduction

Geometric inhomogeneous random graphs (GIRGs) are a generative graph model where vertices are weighted and placed in a geometric ground space and the probability for two of them to be adjacent depends on the product of their weights, as well as their distance [19]. In a sense the model combines the strengths of *inhomogeneous random graphs* [28] and *random geometric graphs* [26]. Introduced as a simplified and more general version of *hyperbolic random graphs* (HRGs) [23], GIRGs share crucial properties with complex real-world networks. Such networks are typically characterized by a *heterogeneous degree distribution* (with few high-degree vertices, while the majority of vertices has small degree), *high clustering* (vertices with common neighbors are likely adjacent themselves), and a *small diameter* (longest shortest path), and it has been shown that GIRGs and HRGs capture these properties well [17, 19, 25].

Beyond these structural properties, GIRGs have also been observed to be a good model for real-wold networks when it comes to the performance of graph algorithms [3]. This makes the GIRG framework relevant for algorithmic purposes in multiple ways. On the one hand, they are a useful tool in the context of average-case analysis, where they yield more

realistic instances than, e.g., the Erdős–Rényi model, while it is still sufficiently simple to be mathematically accessible [3, 7]. On the other hand, we can use GIRGs to generate an abundance of benchmark instances with varying properties, allowing us to perform thorough evaluations of algorithms even when real-world data is scarce [4, 5].

One of the most basic graph properties, which is also relevant from an algorithmic point of view, is *connectivity*, i.e., the question about what parts of a graph are connected via paths. For random graphs, the first question that typically arises in the context of connectivity revolves around the emergence of a so-called *giant component*, which is a connected component whose size is linear in the size of the graph. The existence of a giant has been researched on many related graph models like *Erdős–Rényi random graphs* [12, 13], *random geometric graphs* [2, 11, 26, 18], as well as on *Chung-Lu random graphs* that also capture inhomogeneous random graphs [1, 9, 10].

Unsurprisingly, being such a fundamental feature, connectivity has also been studied on GIRGs, and since HRGs are so closely related to them, we consider the corresponding results to be relevant here as well. For HRGs we know how the emergence of a giant depends on certain model properties that control the degrees of the resulting graph [6, 14]. We note that some analyses there are based on a coupling from HRGs to a continuum percolation model that exhibits a strong resemblance to GIRGs (see [14, Section 2] and [19, Part I, Section 3.5]). Beyond the giant we also have bounds on the size of the second largest component of HRGs [20]. For GIRGs it is known that a giant exists *asymptotically almost surely*, i.e., with probability $1 - o(1)$ [21], with another proof giving a certainty of $1 - n^{-\omega(1)}$ where $n$ denotes the number of vertices in the graph [19, Theorem 4.2]. We note that the specific function in the exponent has not been determined before.

In this paper, we answer this question, by showing that threshold GIRGs have a giant component with probability at least $1 - \exp(-\Omega(n^{(3-\tau)/2}))$. This improves the previous results in two ways. First, our proof is simpler and shorter than the technical existing proofs for HRGs [6, 14]. Secondly, our probability bound is substantially stronger compared to previous bounds obtained for GIRGs. Moreover, we note that our improved bound does not only hold for the full graph but also translates to subgraphs located in restricted regions of the ground space. The argument for this is inspired by a technique used for HRGs [14, Section 4] (though it is much simpler in our case).

Besides providing more accessible insights in the connectivity of GIRGs, we believe that our results, in particular those on subgraphs in restricted regions, can be helpful for algorithmic applications. For example in problems like *balanced connected partitioning* [8], one is interested in partitioning a graph into connected components of (roughly) equal size and in *component order connectivity* [16] the goal is to find a small separator that divides the graph into components of bounded size. There it is important, that the graph cannot only be separated into smaller pieces but that these pieces remain actually connected.

In the following, we give a brief overview of the basic concepts used in the paper (Section 2) before presenting our proofs regarding the emergence of a giant in GIRGs (Section 3).

## 2 Preliminaries

**Geometric Inhomogeneous Random Graphs.** Let $\mathbb{B}^d = [0,1]^d$ be the $d$-dimensional hypercube ($\mathbb{B}$ for "box") and let dist be the $L_\infty$ metric, i.e., for $x = (x_1, \dots, x_d) \in \mathbb{B}^d$ and $y = (y_1, \dots, y_d) \in \mathbb{B}^d$ we have $\text{dist}(x, y) = \max_{i \in [d]} |x_i - y_j|$.

A *geometric inhomogeneous random graph (GIRG)* $G = (V, E)$ with *ground space* $\mathbb{B}^d$ is obtained in three steps. The first step consists of a homogeneous Poisson point process on $\mathbb{B}^d$, with an intensity that yields $n$ points in expectation. Each point is then considered to

be a vertex in the graph. In the second step, each vertex $v$ is assigned a *weight* $w_v > 1$ that is sampled according to a Pareto distribution with exponent $\tau \in (2,3)$, i.e., $\Pr[w_v \leq w] = 1 - w^{-(\tau-1)}$. In the third step, any two vertices $u$ and $v$ are connected by an edge with a probability that depends on their distance and their weights. More precisely, there are two variants. In a *threshold GIRG*, $u$ and $v$ are adjacent if and only if

$$\operatorname{dist}(u,v) \leq \left(\frac{\lambda w_u w_v}{n}\right)^{1/d},$$

where the constant $\lambda > 0$ controls the expected average degree of the graph. We note that the relation between $\lambda$ and the corresponding average degree is not trivial and refer to [5, Section 4.3] for details. In the *temperate* variant we have an additional temperature parameter $T \in (0,1)$ and the probability for $u$ and $v$ to be adjacent is given by

$$\Pr[\{u,v\} \in E] = \min\left\{1, \left(\frac{\lambda w_u w_v}{n \cdot (\operatorname{dist}(u,v))^d}\right)^{1/T}\right\}.$$

The threshold variant is the limit of the temperature variant for $T \to 0$. We denote the resulting probability distribution of graphs with $\mathcal{G}(n, \mathbb{B}^d, \tau, \lambda, T)$ for general GIRGs (allowing temperatures in $T \in [0,1)$). When we just refer to the threshold case, we use $\mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$. We assume the parameters $d, \tau, \lambda$, and $T$ to be constant, i.e., independent of $n$.

**GIRG Variants.** In the literature, several variants of the GIRG model have been studied and we want to briefly discuss the choice we made here. Usually, GIRGs are considered with a torus $\mathbb{T}^d$ as ground space, i.e., the distance in the $i$th dimension, between $x$ and $y$ is $\min\{|x_i - y_i|, 1 - |x_i - y_i|\}$ instead of just $|x_i - y_i|$. The torus usually makes arguments easier as it eliminates the special case close to the boundary of $\mathbb{B}^d$. However, in our case, this is not relevant. Moreover, as distances in $\mathbb{T}^d$ are only smaller than in $\mathbb{B}^d$, all our results concerning the largest connected component directly translate to the case where $\mathbb{T}^d$ is the ground space.

Moreover, instead of sampling $n$ points uniformly at random in the ground space, we use a Poisson point process. This is a technique often used in geometric random graphs as it makes the number of vertices appearing in disjoint regions stochastically independent. This is a similar difference as the one between the Erdős–Rényi model $G(n,m)$ with a fixed number of edges $m$ and the Gilbert model $G(n,p)$ with a fixed probability $p$ for each individual edge to exist. While we generally advocate for using the Poisson variant of the GIRG model, we note that our result carries over to the uniform model.

**Poisson Point Process.** Let $R \subseteq \mathbb{B}^d$ be a region of the ground space with volume $a$. Then, the size of the vertex set $V(R)$, i.e., the number of vertices that are sampled in $R$ is a random variable following a Poisson distribution with expectation $\mu = an$. This in particular means that the probability for $R$ to contain no vertex is $\exp(-\mu)$.

We note that the Poisson point process we consider is a *marked* process, where each point sampled from $\mathbb{B}^d$ obtains a weight sampled from a weight space $\mathcal{W}$ as a mark. Due to the marking theorem, this is equivalent to considering an (inhomogeneous) Poisson point process of the product space $\mathbb{B}^d \times \mathcal{W}$, i.e., colloquially speaking, each point pops up with a position and a weight instead of initially only having a position and drawing the weight as an afterthought. This is also equivalent to just sampling the number of points $N$ following a Poisson distribution and viewing the positions and the weights as marks that are sampled subsequently for each of the $N$ points. Throughout the paper, we switch between these different perspectives without making this explicit.

**Lowest Weights Dominate.** We regularly consider weight ranges $[w_1, w_2]$ with $w_2 \geq c \cdot w_1$ for a constant $c > 1$. The probability for a $v$ to have weight in $[w_1, w_2]$ is dominated by $w_1$:

$$\Pr[w_v \in [w_1, w_2]] = w_1^{-(\tau-1)} - w_2^{-(\tau-1)} \geq w_1^{-(\tau-1)} \cdot \left(1 - c^{-(\tau-1)}\right) \in \Theta(\Pr[w_v \geq w_1]).$$

# 3 Existence of a Giant Component

We want to show that a threshold GIRG is highly likely to contain a connected component of linear size. Our argument goes roughly as follows. We first note that vertices with weight at least $\sqrt{n/\lambda}$ form a clique, which we call the *core* of the graph. For each non-core vertex, we can show that the probability that it has a path into the core is non-vanishing, i.e., it is lower bounded by a non-zero constant. This already shows that we get a connected graph of linear size in expectation.

To show concentration, i.e., that we get a large connected component with the claimed probability, we essentially need to show that the events for different low-weight vertices to connect to the core are sufficiently independent of each other. To this end, we subdivide the ground space into a grid of regular *cells* of side length $\Delta$. We call a cell *nice* if a linear number of its vertices connect to the core via paths not leaving the cell and then show that a cell is nice with non-vanishing probability. As this only considers paths within the cell, the different cells are independent. Thus, we get a series of independent coin flips, one for each cell. If a constant fraction of these coin flips succeeds, we have a connected component of linear size. Hence, if the number of cells is sufficiently large, we get concentration via a Chernoff bound. It follows that we essentially want to choose the cell width $\Delta$ to be as small as possible such that cells are still nice with non-vanishing probability.

In Section 3.1, we first show that every vertex has constant probability to have a path to the core. In fact, we show something slightly stronger, by considering not just any paths but so-called layer paths. Afterwards, we use this result in Section 3.2, to bound the probability for a cell to be nice. This then also informs us on how to choose the cell width $\Delta$ and thus on how many cells we obtain. With this, we can wrap up the argument in Section 3.3 by applying a Chernoff bound. Besides our main results, we there also mention immediate implications.

## 3.1 Layer Paths

We want to show that, for any individual vertex, the probability that it has a path to a vertex of the core is non-vanishing. For this, we define the $\ell$-th *layer* $V_\ell$ to be the set of vertices with weight in $[e^{\ell/2}, e^{(\ell+1)/2})$. Note that the upper and lower bounds are a constant factor apart and thus (as mentioned in Section 2) the probability for a vertex to have layer $\ell$ is asymptotically dominated by the lower bound, i.e., $\Pr[v \in V_\ell] \in \Theta(\Pr[w_v \geq e^{\ell/2}]) = \Theta(e^{-\ell(\tau-1)/2})$.

A path $(v_0, \dots, v_k)$ is a *layer path* if it goes from one layer to the next in every step, i.e., $v_i \in V_\ell$ implies $v_{i-1} \in V_{\ell-1}$ for every $i \in [k]$. Note that vertices in layer $\lceil \log(n/\lambda) \rceil$ have weight at least $\sqrt{n/\lambda}$ and thus belong to the core. Thus, the following lemma shows that each vertex has a layer path to the core with non-vanishing probability.

▶ **Lemma 1.** *Let $G \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$ be a threshold GIRG and let $v$ be a non-core vertex. The probability that there is a layer path from $v$ to layer $\lceil \log(n/\lambda) \rceil$ is non-vanishing.*

**Proof.** We bound the probability that such a layer path exists in three steps. First, we bound the probability that a vertex $u$ on layer $\ell$ has a neighbor in layer $\ell + 1$. In the second step, we consider the intersection of the events where this happens on all considered layers. Finally, we show that the resulting probability is non-vanishing.

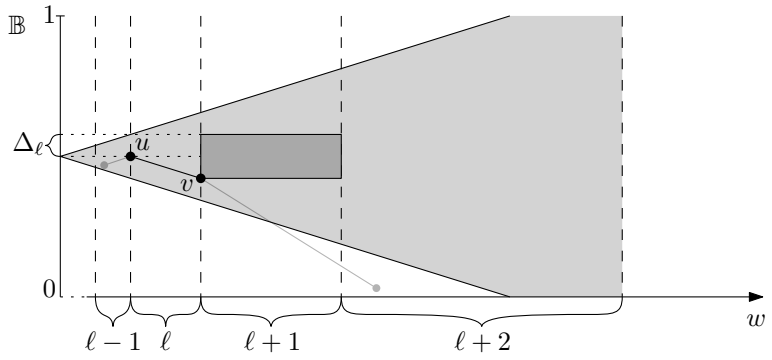

**Figure 1** Excerpt of a one-dimensional GIRG with the weights on the $x$-axis and the ground space $\mathbb{B}$ on the $y$-axis. A layer path spans from layer $\ell-1$ to $\ell+2$. The gray region is the neighborhood of vertex $u$. The dark-gray region contains all vertices in layer $\ell+1$ that have distance at most $\Delta_\ell$ to $u$.

For the first step, consider two vertices $u \in V_\ell$ and $v \in V_{\ell+1}$ in consecutive layers, as shown in Figure 1. Both their weights are at least $w = e^{\ell/2}$. Thus, they are definitely adjacent if their distance $\text{dist}(u,v)$ satisfies

$$\text{dist}(u,v) \leq \left(\frac{\lambda w^2}{n}\right)^{1/d} = \lambda^{1/d}\left(\frac{e^\ell}{n}\right)^{1/d} =: \Delta_\ell.$$

If vertex $u \in V_\ell$ is the current vertex from which we want to make the next step in a layer path, we are thus interested in the probability that there is a vertex $v$ that lies in layer $\ell+1$ with $\text{dist}(u,v) \leq \Delta_\ell$. Since these two events (being in layer $\ell+1$ and having sufficiently low distance) are independent, the probability that both happen is $\Pr[v \in V_{\ell+1}] \cdot \Pr[\text{dist}(u,v) \leq \Delta_\ell]$. As mentioned above, we have $\Pr[v \in V_{\ell+1}] \in \Theta(e^{-\ell(\tau-1)/2})$. Moreover, $\Pr[\text{dist}(u,v) \leq \Delta_\ell] \in \Theta(\Delta_\ell^d) = \Theta(e^\ell/n)$. Hence, we obtain

$$\Pr[v \in V_{\ell+1}] \cdot \Pr[\text{dist}(u,v) \leq \Delta_\ell] \in \Theta\left(e^{-\ell(\tau-1)/2} \cdot e^\ell/n\right) = \Theta\left(e^{\ell(3-\tau)/2}/n\right).$$

To conclude the first step of the proof, let $X_\ell$ be the number of vertices in layer $\ell+1$ with distance at most $\Delta_\ell$ to $u \in V_\ell$. By the above probability, we have $\mathbb{E}[X_\ell] = \Theta(e^{\ell(3-\tau)/2})$. We consider the event $X_\ell > 0$ and call it $A_\ell$. Note that $A_\ell$ implies that $u$ has at least one neighbor in the next layer. As $X_\ell$ follows a Poisson distribution, we get

$$\Pr[A_\ell] = 1 - \Pr[X_\ell = 0] = 1 - \exp(-\mathbb{E}[X_\ell]) = 1 - \exp\left(-\Theta\left(e^{\ell(3-\tau)/2}\right)\right).$$

In the second step of the proof, we now consider the intersection of all the independent events $A_0, A_1, \dots, A_{\lceil \log(n/\lambda)\rceil}$, which is sufficient for a layer path starting in layer 0 to exist. Note that a lower bound for the probability of this intersection also gives a lower bound for the existence of a layer path starting in any other layer. To show that this intersection occurs with non-vanishing probability, we utilize the fact that $\Pr[A_\ell]$ approaches 1 very quickly for increasing $\ell$. More precisely, we show that for a constant $c$, all subsequent events $A_\ell$ with $\ell \geq c$ are sufficiently likely, that we can simply take the union bound over their complements. Thus, we obtain

$$\Pr\left[\bigcap_{\ell=0}^{\lceil \log(n/\lambda)\rceil} A_\ell\right] = \Pr\left[\bigcap_{\ell=0}^{c-1} A_\ell\right] \cdot \Pr\left[\bigcap_{\ell=c}^{\lceil \log(n/\lambda)\rceil} A_\ell\right].$$

Clearly, the first factor is non-vanishing as it is the product of constantly many non-zero constants. For the second factor, we consider the complementary events and apply the union bound to obtain

$$\begin{aligned}\Pr\left[\bigcap_{\ell=c}^{\lceil\log(n/\lambda)\rceil} A_\ell\right] &= 1 - \Pr\left[\bigcup_{\ell=c}^{\lceil\log(n/\lambda)\rceil} A_\ell^C\right] \\ &\geq 1 - \sum_{\ell=c}^{\lceil\log(n/\lambda)\rceil} (1 - \Pr[A_\ell]) \\ &= 1 - \sum_{\ell=c}^{\lceil\log(n/\lambda)\rceil} \exp\left(-\Theta(e^{\ell(3-\tau)/2})\right).\end{aligned}$$

Since the sum converges, we can choose $c$ to be a sufficiently large constant such that the sum is bounded by any constant $\varepsilon > 0$. The above expression is thus at least $1 - \varepsilon$, which is non-vanishing. ◀

Observe that Lemma 1 already shows that the expected number of vertices with a layer path to the core is linear. Thus, the expected size of the connected component including the core vertices is linear. To show concentration, we separate the ground space into cells that are then considered independently.

## 3.2 A Coin Flip for Each Cell

We subdivide the ground space into a grid of regular cells of side length $\Delta$. We first show that the high-weight vertices of each cell are likely to induce a connected graph. This is useful as we can afterwards focus on vertices of lower weight. As edges between low-weight vertices are short, layer paths on these vertices can cover only a small distance and thus only few of them leave their cell, which makes different cells (mostly) independent.

▶ **Lemma 2.** *Let $G \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$ be threshold GIRG, let $C$ be a cell of side length $\Delta$, and let $w$ be a weight. Then, the graph induced by vertices in $C$ of weight at least $w$ is connected with probability at least*

$$1 - \frac{(2\Delta)^d}{\lambda w^2} \cdot \exp\left(-\frac{\lambda w^{3-\tau}}{2^d}\right) \cdot n.$$

**Proof.** We discretize the cell $C$ into sub-cells, such that vertices in adjacent sub-cells are adjacent themselves, as shown in Figure 2. Note that two vertices $u, v$ with weights $w_u, w_v \geq w$ are adjacent if their distance is bounded by

$$\operatorname{dist}(u, v) \leq \left(\frac{\lambda w^2}{n}\right)^{1/d}.$$

Thus, all vertices in adjacent sub-cells are guaranteed to be adjacent, if the side length of a sub-cell is

$$\Delta_w = \frac{1}{2}\left(\frac{\lambda w^2}{n}\right)^{1/d}.$$

Note that for very large $w$, we get $\Delta_w \geq \Delta$, in which case all vertices in $C$ are pairwise adjacent with probability 1. In the following, we therefore assume that $w$ is smaller. For a given sub-cell $C'$, we compute the probability for a given vertex $v$ to lie in $C'$ as

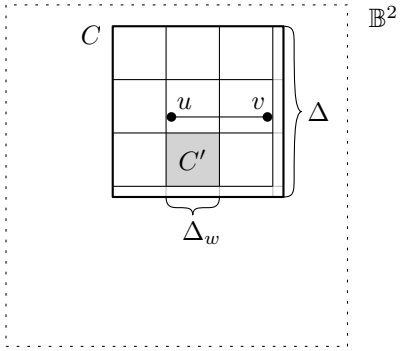

**Figure 2** The cell $C$ of width $\Delta$ is divided into sub-cells of width $\Delta_w$. The sub-cell $C'$ is completely contained in $C$. The vertices $u$ and $v$ are in adjacent sub-cells and are therefore adjacent themselves.

$$\Pr[v \in V(C')] = (\Delta_w)^d = \left(\frac{1}{2}\left(\frac{\lambda w^2}{n}\right)^{1/d}\right)^d = \frac{\lambda w^2}{2^d n}.$$

Additionally, the probability for $v$ to have weight at least $w_v \geq w$, is given by

$$\Pr[w_v \geq w] = 1 - \Pr[w_v \leq w] = w^{-(\tau-1)}.$$

Together, we obtain

$$\Pr[v \in V(C') \wedge w_v \geq w] = \Pr[v \in V(C')] \cdot \Pr[w_v \geq w] = \frac{\lambda w^2}{2^d n} \cdot w^{-(\tau-1)} = \frac{\lambda w^{3-\tau}}{2^d n}.$$

Consequently, the expected number of vertices of weight at least $w$ in $C'$ is

$$\mathbb{E}\left[|\{v \in V(C') \mid w_v \geq w\}|\right] = \frac{\lambda w^{3-\tau}}{2^d}.$$

Since the vertices are distributed according to a Poisson distribution, the probability for $C'$ to not contain any of these vertices is given by

$$\Pr[\{v \in V(C') \mid w_v \geq w\} = \emptyset] = \exp\left(-\frac{\lambda w^{3-\tau}}{2^d}\right).$$

Finally, we lower-bound the probability for the vertices of weight at least $w$ in our initial cell $C$ to induce a connected graph, by considering the probability that none of its sub-cells is empty. Note that we have

$$k = \left(\left\lfloor \frac{\Delta}{\Delta_w} \right\rfloor\right)^d$$

sub-cells $C'_1, \dots, C'_k$ that are *completely* contained in the cell $C$. Clearly, whether the remaining sub-cells (intersecting the boundary of $C$) are empty or not has no impact on the connectedness of the considered subgraph. The probability for all of the sub-cells $C'_1, \dots, C'_k$ to be non-empty can be simplified by applying union bound, which yields

$$\begin{aligned}\Pr[\forall C' \in \{C'_1, \dots, C'_k\} \colon V(C') \neq \emptyset] &= (1 - \Pr[V(C') = \emptyset])^k \\ &\geq 1 - k \cdot \Pr[V(C') = \emptyset] \\ &= 1 - \left(\left\lfloor \frac{\Delta}{\Delta_w} \right\rfloor\right)^d \cdot \exp\left(-\frac{\lambda w^{3-\tau}}{2^d}\right) \\ &\geq 1 - \Delta^d \cdot \frac{2^d n}{\lambda w^2} \cdot \exp\left(-\frac{\lambda w^{3-\tau}}{2^d}\right) \\ &= 1 - \frac{(2\Delta)^d}{\lambda w^2} \cdot \exp\left(-\frac{\lambda w^{3-\tau}}{2^d}\right) \cdot n. \end{aligned}$$

◀

The following lemma shows that we basically get an independent coin-flip with non-vanishing success probability for each cell to be nice. We want to point out three technical details of the lemma statement here. First, the lemma specifically considers the connected component containing a vertex of weight at least $\hat{w}$. We will later choose $\hat{w} = \sqrt{n/\lambda}$, i.e., this vertex is part of the core. As all core vertices form a clique, this makes sure that the components we get for the individual cells actually connect to one large component in the whole graph. Secondly, the lower bound on $\mu$, which is the expected number of vertices in the cell, given by $\mu = \Delta^d n$, requires that the cells are sufficiently large to contain a vertex of weight $\hat{w}$ with non-vanishing probability. Thirdly, the lower bound on $\hat{w}$ ensures that vertices with higher weight are likely connected by Lemma 2.

▶ **Lemma 3.** *Let $G \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$ be a threshold GIRG, let $\hat{w}$ be a weight, and let $C$ be a cell of side length $\Delta$ containing $\mu$ vertices in expectation. Then, with non-vanishing probability, the graph induced by the vertices in $C$ contains a vertex of weight at least $\hat{w}$ whose connected component has size $\Theta(\mu)$, if $\mu \geq \hat{w}^{\tau-1}$, $\mu \in \omega((\log n)^{2/(3-\tau)} \log\log(n)^d)$, and $\hat{w} \in \omega((\log n)^{1/(3-\tau)})$.*

**Proof.** The overall argument goes as follows. First, the lower bound on $\mu$ ensures that $C$ contains a vertex of weight $\hat{w}$ with non-vanishing probability. For a smaller weight $\overline{w} \leq \hat{w}$, we then apply Lemma 2 to get that all vertices of weight at least $\overline{w}$ form a connected component asymptotically almost surely. Afterwards, it remains to show that enough vertices of lower weight connect to a vertex of weight at least $\overline{w}$ via paths not leaving $C$. For the existence of these paths, we use Lemma 1. To show that most of them do not leave $C$, we use that the considered vertices have weight at most $\overline{w}$ and thus cannot deviate too much from the starting position.

Recall that the weight of a vertex is at least $\hat{w}$ with probability $\hat{w}^{-(\tau-1)}$. Thus, the expected number of vertices in cell $C$ with weight at least $\hat{w}$ is $\mu\hat{w}^{-(\tau-1)}$. Plugging in the bound $\mu \geq \hat{w}^{\tau-1}$, everything cancels and we obtain an expected value of 1. As the number of vertices in $C$ with weight above $\hat{w}$ follows a Poisson distribution, we get at least one such vertex with non-vanishing probability.

We set $\overline{w} = ((2^d/\lambda)\log n)^{1/(3-\tau)}$. Note that by the condition on $\hat{w}$ in the lemma statement, we have $\overline{w} \leq \hat{w}$ for sufficiently large $n$. Note further that $\overline{w}$ is chosen such that the exponent in the bound of Lemma 2 simplifies to $-\log n$. Thus by Lemma 2, the graph induced by the vertices of weight at least $\overline{w}$ in $C$ is connected with probability at least $1 - (2\Delta)^d/(\lambda\overline{w}^2)$. As $\Delta \leq 1$ and $\overline{w}$ is increasing with $n$, this goes to 1 for $n \to \infty$.

Consider a vertex of weight below $\overline{w}$. Then, by Lemma 1, it has a layer path to a vertex with weight at least $\overline{w}$ with non-vanishing probability. In the following, with *layer path* we always refer to a layer path that ends in the layer belonging to $\overline{w}$. Note that a layer path

has length at most $O(\log\log n)$. Also note that the largest weight we encounter is in $O(\overline{w})$ as the path stops in the layer belonging to weight $\overline{w}$ and the weights increase only by a constant factor between layers. It follows that, in each dimension, the distance between two consecutive vertices on a layer path is in $O((\overline{w}^2/n)^{1/d})$, as the vertices would not be connected otherwise. Thus, the overall deviation of a layer path from the starting point is upper bonded by $O((\overline{w}^2/n)^{1/d}\log\log n) = O\left(((\log n)^{2/(3-\tau)}\log\log(n)^d/n)^{1/d}\right)$. By the second lower bound on $\mu$, this is asymptotically less than $\Delta$. Thus, shrinking $C$ accordingly from all directions yields a subregion $C'$ that contains $\Theta(\mu)$ vertices in expectation such that any layer path that starts in $C'$ stays in $C$.

Instead of counting all vertices in $C'$ that have layer paths, we only count vertices in the first layer. This has the advantage, that the event that an individual vertex in the first layer has a layer path is independent of the number of vertices in the first layer (while it depends on the number of vertices in higher layers). First note that the number of vertices in the first level of $C'$ is a random variable following a Poisson distribution with expected value in $\Theta(\mu)$. Thus, there are $\Theta(\mu)$ such vertices with non-vanishing probability.

Now let $X \in [0,1]$ be the random variable that describes the fraction of vertices in the first layer that fail to have a layer path. By Lemma 1, the probability for an individual vertex to not have a layer path is a upper bounded constant $p < 1$ (i.e., the layer path exists with non-vanishing probability at least $1-p$). Thus, we get $\mathbb{E}[X] \leq p$. Markov's inequality then gives us $\Pr[X \geq c] \leq p/c$ and thus $\Pr[X < c] \geq 1 - p/c$. We can choose $c$ to be a constant with $p < c < 1$, which gives us a non-vanishing probability that a fraction of at least $1 - c > 0$ vertices have the desired layer path. Note that this holds independently of the number of vertices actually sampled in the first layer of $C'$.

To wrap up, consider the three events that there exists a vertex of weight at least $\hat{w}$, that there are $\Theta(\mu)$ vertices in the first layer of $C'$, and that a constant fraction of them have layer paths. Note that the three events are independent and each holds with non-vanishing probability. Thus, their intersection, which we denote with $A$, also holds with non-vanishing probability. Finally, the event $B$ that all vertices of weight at least $\overline{w}$ induce a connected graph holds asymptotically almost surely. Though $A$ and $B$ are not independent, we can apply the union bound to their complements to obtain that $A$ and $B$ together hold with non-vanishing probability. ◀

## 3.3 Large Components are Likely to Exist

To obtain the following theorem, it remains to apply a Chernoff bound to the coin flips obtained for each cell by Lemma 3.

▶ **Theorem 4.** *Let $G \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$ be a threshold GIRG. Then $G$ has a connected component of size $\Theta(n)$ with probability $1 - \exp\left(-\Omega(n^{(3-\tau)/2})\right)$.*

**Proof.** First note that the probability to have $\omega(n)$ vertices is exponentially small and thus we only have to show the lower bound on the size of the largest connected component. To apply Lemma 3, we choose the cell width $\Delta$ such that $\Delta^d n = \mu = \hat{w}^{\tau-1}$ where we set $\hat{w} = \sqrt{n/\lambda}$. With this, we obtain that the number of cells $k$ is

$$k \in \Theta\left(\frac{1}{\Delta^d}\right) = \Theta\left(\frac{n}{\hat{w}^{\tau-1}}\right) = \Theta\left(\frac{n}{\left(\sqrt{n/\lambda}\right)^{\tau-1}}\right) = \Theta\left(n^{\frac{3-\tau}{2}}\right).$$

Note that this bound is valid even if $\Delta$ does not divide the ground space evenly. Further note that the chosen $\Delta$ satisfies the conditions of Lemma 3, the graph induced by each cell contains a vertex from the core whose connected component has size $\Theta(\mu)$ with non-vanishing probability. If this holds for a constant fraction of cells, we get a giant component, as all vertices of weight at least $\hat{w}$ form a clique in $G$. Thus, we have $k$ independent coin flips, each succeeding with a probability of $p > 0$, and we are interested in the number of successes $X$. To show that $X \in \Theta(k)$ is highly likely, we can simply apply a Chernoff bound (see [24, Theorem 4.4]). For $\delta \geq 0$, we get

$$\Pr\left[X \leq (1-\delta)\mathbb{E}[X]\right] \leq \exp\left(-\frac{\delta^2}{2}\mathbb{E}[X]\right).$$

As $\mathbb{E}[X] \in \Theta(k)$, this implies $\Pr\left[X \in o(k)\right] \leq \exp\left(-\Omega(k)\right)$. Inserting $k$ yields the claim. ◀

As already mentioned in Section 2, this directly implies the following corollary.

▶ **Corollary 5.** *Theorem 4 also holds with the torus $\mathbb{T}$ as ground space.*

The following lemma states a well known property of GIRGs, see e.g. [19, Lemma 3.12] and [22, Definition 2.8]. For the sake of transparency, we give a simple proof based on the notation established throughout the paper.

▶ **Lemma 6** (folklore)**.** *Let $H \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda, T)$ be a GIRG and let $G$ be the subgraph induced by the vertices within a cell of side length $\Delta = (f(n)/n)^{1/d}$. Then $G \sim \mathcal{G}(f(n), \mathbb{B}^d, \tau, \lambda, T)$.*

**Proof.** Note that we basically consider two ways to generate a graph and claim that they give the same probability distribution over graphs. Intuitively, this can be seen by generating points with weights in the cell $[0, \Delta]^d$, scaling it to the full ground space $[0, 1]^d$, and making three observations. First, for the vertex positions, this is equivalent to directly sampling points in $[0, 1]^d$. Secondly, the weight distribution is independent of the number of vertices. Thirdly, the connection probabilities between vertices are the same in the scaled variant as they are in the cell. To make this more formal, draw $G$ as a subgraph of $H$ as stated in the lemma and draw $G' \sim \mathcal{G}(f(n), \mathbb{B}^d, \tau, \lambda, T)$. We show that $G$ and $G'$ follow the same distribution.

Recall that we consider the Poisson variant of the GIRG model, i.e., the vertices are the result of a Poisson point process in the product space $\mathbb{B}^d \times \mathcal{W}$. Thus, the vertex set of $G$ can be generated by first determining the number of points $n_G$ with positions in $[0, \Delta]^d$, which is a random variable following a Poisson distribution with expectation $n \cdot \Delta^d = f(n)$. Then, independently for each of the $n_G$ vertices, a position is drawn uniformly at random from $[0, \Delta]^d$ and a weight is drawn from $(1, \infty)$ with probability density function $(\tau - 1) \cdot w^{-\tau}$.

To generate $G'$, we can also first determine the number of points $n_{G'}$, which is also Poisson distributed with expectation $f(n)$. Thus, we can couple $n_G$ and $n_{G'}$ to have the same value and we assume a one-to-one correspondence between the vertices in $G$ and $G'$ in the following. For each vertex, the weight is again a random variable with density $(\tau - 1) \cdot w^{-\tau}$, which only depends on $\tau$. Thus, for each vertex, we can couple its weight in $G$ with its weight in $G'$ to assume them to be equal. The position in $G'$ is drawn uniformly from $[0, 1]^d$. Thus, we can couple the random variables for the positions in $G'$ with those in $G$ such that a vertex with position $x \in [0, \Delta]^d$ in $G$ has position $x/\Delta$ in $G'$. Note that this has the effect that all distances between vertices in $G'$ are scaled by a factor of $1/\Delta$ compared to the corresponding distance in $G$.

It remains to show that for every vertex pair $u, v$ the connection probability in $G$ is the same as in $G'$. Let $w_u$ and $w_v$ be the weight of $u$ and $v$ (which is the same for $G$ and $G'$ due to the coupling). Also, let $\text{dist}(u, v)$ be the distance between $u$ and $v$ in $G$ and let $\text{dist}'(u, v) = \text{dist}(u, v)/\Delta$ be their distance in $G'$. Then (for $T > 0$) the connection probability of $u$ and $v$ in $G$ is

$$\Pr[\{u, v\} \in E] = \min\left\{\left(\frac{\lambda w_u w_v}{n \,\text{dist}(u, v)^d}\right)^{1/T}, 1\right\}.$$

The two things that change for $G'$ is that $n$ is replaced by $f(n)$ and $\text{dist}(u, v)^d$ is replaced by $\text{dist}'(u, v)^d = (\text{dist}(u, v)/\Delta)^d = n/f(n) \cdot \text{dist}(u, v)^d$. The $f(n)$ cancels out, yielding the same connection probability for $G$ and $G'$. For $T = 0$, the argument works analogously. ◀

Together with Theorem 4 this yields the following corollary. We note that this also yields large connected components within cells that are too small to contain a core vertex. For such cells, we know that we get a large connected component but we do not know whether it connects to the giant of the whole graph. Clearly, the same statement holds with the torus $\mathbb{T}^d$ as ground space.

▶ **Corollary 7.** *Let $H \sim \mathcal{G}(n, \mathbb{B}^d, \tau, \lambda)$ be a threshold GIRG and let $G$ be the subgraph induced by the vertices within a cell of side length $\Delta = (f(n)/n)^{1/d}$. Then $G$ has a connected component of size $\Theta(f(n))$ with probability $1 - \exp\left(-\Omega(f(n)^{(3-\tau)/2})\right)$.*

## 4 Conclusion

Our proof for the emergence of a giant component in geometric inhomogeneous random graphs builds on three simple arguments. First, GIRGs are likely to contain a clique of high-weight vertices. Second, the remaining vertices are sufficiently likely to connect to this core via layer-paths, whose vertices have exponentially increasing weight. And, third, most of these paths exist sufficiently independently from each other.

We note that the same argumentation also works for the closely related hyperbolic random graph model, where the discretization into weight layers translates to a natural discretization of the underlying geometric space that was previously used to bound the diameter of HRGs [15].

Our resulting strong probability bound can be combined with a simple coupling argument to identify connected subgraphs of arbitrary size in certain subregions of the geometric ground space. In particular, when these subregions are the cells of a regular grid (as used several times throughout the paper), we obtain connected subgraphs of roughly equal size. We believe that this property can be utilized in the context of problems with connectivity constraints. For example, in the previously mentioned *balanced connected partitioning* problem [8, 27], the goal is to partition the vertices of a graph into a given number of sets of approximately equal size, such that their induced subgraphs are connected. Moreover, in *component order connectivity* [16] the aim is to find a minimum number of vertices such that after their removal each connected component has bounded size. We conjecture that our structural insights in Corollary 7 may prove useful in obtaining efficient algorithms for these problems on GIRGs and the networks they represent well.

# An Efficient Algorithm for Power Dominating Set

**Thomas Bläsius**
Karlsruhe Institute of Technology (KIT), Germany

**Max Göttlicher**
Karlsruhe Institute of Technology (KIT), Germany

## Abstract

The problem Power Dominating Set (PDS) is motivated by the placement of phasor measurement units to monitor electrical networks. It asks for a minimum set of vertices in a graph that observes all remaining vertices by exhaustively applying two observation rules. Our contribution is twofold. First, we determine the parameterized complexity of PDS by proving it is $W[P]$-complete when parameterized with respect to the solution size. We note that it was only known to be $W[2]$-hard before. Our second and main contribution is a new algorithm for PDS that efficiently solves practical instances.

Our algorithm consists of two complementary parts. The first is a set of reduction rules for PDS that can also be used in conjunction with previously existing algorithms. The second is an algorithm for solving the remaining kernel based on the implicit hitting set approach. Our evaluation on a set of power grid instances from the literature shows that our solver outperforms previous state-of-the-art solvers for PDS by more than one order of magnitude on average. Furthermore, our algorithm can solve previously unsolved instances of continental scale within a few minutes.

## 1 Introduction

Monitoring power voltages and currents in electric grids is vital for maintaining their stability and for cost-effective operation. The sensors required to obtain high-resolution measurements, so-called phasor measurement units, are expensive pieces of equipment. The goal to place as few of those sensors as possible to minimize cost is called the Power Dominating Set problem (PDS). It was first posed by Mili, Baldwin and Adapa. [16] and formalized by Baldwin et al. [2]. In its basic form, the problem asks whether the graph of a power grid can be observed by exhaustively applying two observation rules [7]: First, every sensor observes its vertex and all neighbors. Secondly, if a vertex is observed and has only one unobserved neighbor, that neighbor becomes observed, too.

PDS is unfortunately NP-complete [7, 11, 14], i.e., we cannot expect there to be an algorithm that performs reasonably on all inputs. Moreover, the problem remains hard for a wide range of different graph classes [7, 8, 11, 14, 20, 9, 15]. In terms of parameterized complexity, PDS is known to be $W[2]$-hard [9] when parameterized by solution size.

On the positive side, various approaches for solving PDS have been proposed. Theoretic results show that PDS can be solved in linear time in graphs with fixed tree-width [14, 9]. However, those algorithms have, to the best of our knowledge, never been implemented and are probably infeasible in practice due to their bad scaling with respect to the tree-width. Several exponential-time algorithms have been presented [7, 3] but those algorithms have not been implemented and evaluated either.

Practically feasible approaches using an MILP formulation have been proposed by Aazami [1]. This formulation was later improved upon by Brimkov, Mikesell, and Smith [6] and most recently Jovanovic and Voss [13]. A different approach is to reduce PDS to the hitting set problem [5, 18]. This approach is based on the observation that one can determine so-called *forts*, which are subsets of vertices that prevent propagation if none of them is selected. A set of vertices is a valid solution for PDS if and only if at least one vertex is selected for each fort, i.e., if it is a hitting set for the collection of all forts. Graphs may contain an exponential number of forts, so this hitting set instance is not computed explicitly. Instead, one can use the so-called *implicit hitting set* approach, where one starts with a subset of all forts, computes a hitting set for this subset, and then validates whether this is already a solution for the PDS instance. If not, one obtains at least one new fort that can be added to the set of considered forts. This is iterated until a solution is found. This implicit hitting set approach has been used for other problems, e.g., for MaxSAT [17] and TQBF [12]. For PDS, it has been introduced by Bozeman et al. [5]. The strategy of finding forts has been later improved by Smith and Hicks [18], providing the current state-of-the-art for solving PDS in practice.

Our contribution is threefold. First, we study the parameterized complexity of PDS parameterized by the solution size. Though it is known to be $W[2]$-hard [9], it was unknown whether PDS is also contained in $W[2]$. We show that PDS is $W[P]$-complete via a reduction from Weighted Circuit Satisfiability for circuits of arbitrary weft. This completely determines its parameterized complexity and in particular shows that it is not in $W[2]$ unless $W[2] = W[P]$. In our second contribution, we propose a set of reduction rules for pre-processing PDS instances. Our reduction rules aim to produce equivalent instances that are smaller and annotated with partial decisions, i.e., some vertices are marked as selected or as forbidden-to-select. Though these annotations lead to a more general problem than the basic PDS, we show that existing approaches for solving PDS can be easily adapted to solve the annotated instances. Moreover, we show that their performance greatly benefits from our reduction rules. Finally, our third contribution is an improved heuristic for finding forts for the implicit hitting set formulation. This improved heuristic together with our reduction rules beats the current state of the art solvers by more than one order of magnitude. Moreover, our approach can solve previously unsolved instances of continental scale.

The remainder of this paper is organized as follows. Section 2 provides an overview of the basic concepts and notation used throughout this paper. In Section 3, we show that PDS is $W[P]$-complete. Our reduction rules and the heuristic for extending the hitting set instance are presented in Section 4. Section 5 contains our experimental evaluation of the new method using a set of benchmark instances.

## 2 Preliminaries

**Graphs and Neighborhoods.** Let $G = (V, E)$ be an undirected graph with vertices $V$ and edges $E$. For $v \in V$, let $N(v) = \{u \in V \mid uv \in E\}$ be the *open neighborhood* of $v$. Similarly, $N[v] = N(V) \cup \{v\}$ is the *closed neighborhood* of $v$. Given a set $S \subseteq V$ we denote by $N(S)$ and $N[S]$ the union of all open and closed neighborhoods of the vertices in $S$.

**Power Dominating Set.** For a given graph $G$, the problem *Power Dominating Set (PDS)* is to find a minimum vertex set $S \subseteq V$ of *selected* vertices such that all vertices of the graph are observed. We call such set a *power dominating set*. The size of a minimum power dominating set of a given graph $G$ is called the *power dominating number* $\gamma_P(G)$. Whether a vertex is *observed* is determined by the following rules, which are applied iteratively. We note that for the second rule, vertices can be marked as *propagating*, i.e., the input of PDS is not just a graph but a graph together with a set of propagating vertices.

**Domination rule.** A vertex is observed if it is in the closed neighborhood of a selected vertex.

**Propagation rule.** Let $u \in V$ be a propagating vertex. If $u$ is observed and $v \in N(u)$ is the only neighbor of $u$ that is not yet observed, then $v$ becomes observed[1]. If the propagation rule is applied to an observed vertex $u$, we say it *propagates* its observation status.

The special case where we have no propagating vertices yields the well known *Dominating Set (DS)* problem. Moreover, the special case where all vertices are propagating is called *simple-PDS*. In addition to the above Dominating Set variants, we also consider the extension variant Dominating Set Extension. For DS-Extension, the input consists of the graph $G = (V, E)$, a set $X \subseteq V$ of *pre-selected* and a set $Y$ of *excluded* vertices; vertices in $V \setminus X \setminus Y$ are called *undecided*. DS-Extension asks whether there exists a solution $S \subset V$ such that $S$ includes all selected and excludes all excluded vertices, i.e., $X \subseteq S$ and $Y \cap S = \emptyset$. The problems PDS-Extension and simple-IPDS-Extension are defined analogously.

**Hitting Set.** Let $V$ be a set and let $\mathcal{F} \subseteq 2^V$ be a family of subsets. A set $H \subseteq V$ is a *hitting set* if it *hits* every set $F \in \mathcal{F}$, i.e., $F \cap H \neq \emptyset$ for all $F \in \mathcal{F}$. The problem *Hitting Set* is to find a hitting set of minimum size. Note that the extension variant of Hitting Set reduces to an instance of Hitting Set itself, as one can simply remove excluded elements and remove the sets containing pre-selected elements.

## 3 Power Dominating Set is $W[P]$-Complete

We prove $W[P]$-completeness via a chain of parameterized reductions from the Weighted Monotone Circuit Satisfiability (WMCS) problem. WMCS has a monotone Boolean circuit as input and asks whether it can be satisfied by setting at most $k$ inputs to true, where $k$ is the parameter. We assume familiarity with the $W$-hierarchy and parameterized reductions.We start by introducing a variant of the PDS problem that we use as an intermediate problem in our chain of reductions. For brevity, we only sketch an outline of the proof in this section; for the full proof see [4].

The input of the problem *Implicating Power Dominating Set (IPDS)* is an instance of PDS with the following additional information. First, edges of the graph $G = (V, E)$ can be marked as *booster edges*. Secondly, we are given a set of *implication arcs* $A \subseteq V \times V$. We interpret $A$ as a set of directed edges on $V$ but perceive them as separate from the graph $G$, i.e., they do not affect the neighborhood. In addition to the domination and propagation rule introduced in Section 2, we define the following to observation rules.

**Booster rule.** Let $uv \in E$ be a booster edge. If $u$ is observed, then $v$ becomes observed and vice versa.

**Implication rule.** Let $(u, v) \in A$ be an implication arc and let $u$ be observed. Then $v$ also becomes observed.

[1] The propagation rule is motivated by Kirchoff's law and Ohm's law in electric networks. Propagating vertices are also called *zero-injection vertices*. In electric networks, they refer to buses in substations that have no attached loads.

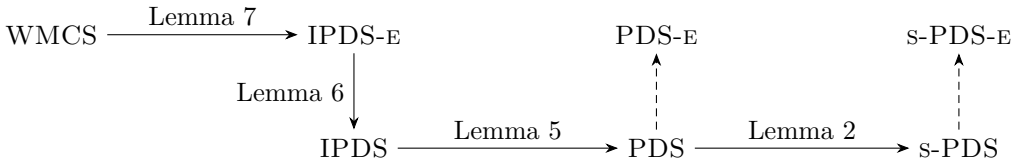

**Figure 1** Reduction steps to show that PDS and its variants are $W[P]$ hard. The solid arrows indicate our parameterized reductions described in this section. The hardness of the extension problems follows from the hardness of their basic problem, indicated by the dashed arrows.

We note that IPDS is a generalization of PDS in the sense that every PDS instances is an instance of IPDS with no booster edges and an empty set of implication arcs. The extension variant IPDS-Extension is defined analogously to PDS-Extension. Proving containment of IPDS-Extension in $W[P]$ is straight forward by giving an appropriate non-deterministic Turing machine. We note that the analogous statement has been observed before for PDS by Kneis et al. [14]. Note that this implies containment in $W[P]$ for all other problem variants we defined.

▶ **Lemma 1.** *Implicating Power Dominating Set Extension is in $W[P]$.*

As all other variants of the power dominating set problem we consider are special cases of IPDS-Extension, this also proves containment in $W[P]$ for the other variants.

**Power Dominating Set to Simple Power Dominating Set.** Our chain of reductions to prove $W[P]$-hardness is illustrated in Figure 1. We start with the reduction from PDS to Simple PDS, which is similar to the proof of $W[2]$ hardness of PDS [14, 9]. The core idea is to simulate a non-propagating vertex with a propagating vertex with an additional leaf attached.

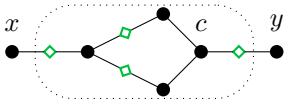
▶ **Lemma 2.** *There is a parameterized reduction from Power Dominating Set to Simple Power Dominating Set.*

**Proof Sketch.** Similar to the proof of $W[2]$ hardness of Power Dominating Set [14, 9], we can attach a leaf to each non-propagating vertex. Selecting the leaf as part of a solution is never optimal: one can instead choose its neighbor. Then, a vertex with an attached leaf can never propagate to any vertex except the leaf. ◀

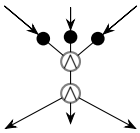
**Implicating Power Dominating Set to Power Dominating Set.** The reduction from IPDS to PDS, works in two steps. First, we show that we can eliminate implicating arcs by replacing each of them with the small gadget show in Figure 2a. Using another gadget, we eliminate booster edges in a similar way, yielding the reduction.

▶ **Lemma 3.** *Every instance of Implicating Power Dominating Set can be reduced to an equivalent instance with no implication arcs without changing the parameter.*

**Proof Sketch.** Given an IPDS-instance $G$, we replace all implication arcs $a = (x, y)$ with the gadget depicted in Figure 2a. To see why the gadget works as desired, consider the implication gadget and first assume that $x$ is observed. By applying the booster and the propagation rules, one can verify that all vertices introduced in the gadget and $y$ become observed. Conversely, if only $y$ is observed, $c$ becomes observed by the booster rule but cannot propagate due to its two unobserved neighbors. Thus, the gadget mimics the behavior of an implication arc. ◀



**(a)** Gadget simulating an implication arc from $x$ to $y$ using booster edges (marked with green diamonds).



**(b)** A gadget for simulating an `and` gate. The bottom $\wedge$-node is observed iff all input nodes are observed.

**Figure 2** Gadgets for implication arcs and `and` gates.

Our gadget for simulating booster edges requires adding a globally unique non-propagating vertex $b$ to which all such gadgets are connected. The gadget in turn replaces a booster edge between $x$ and $y$ with a new vertex $v_{xy}$ which is connected to $x$, $y$ and $b$. We enforce that $b$ is selected by attaching a leaf.

▶ **Lemma 4.** *Every IPDS-instances with booster edges can be reduced to an equivalent instance without booster edges.*

**Proof Sketch.** One can verify that the booster gadget works as intended as follows: by the domination rule, $b$ observes $v_{xy}$. If now either of $x$ or $y$ becomes observed, we can apply the propagation rule on $v_{xy}$, observing the other. Note that the inserted vertex $b$ is the same for all booster gadgets. ◀

▶ **Lemma 5.** *There is a parameterized reduction from* Implicating Power Dominating Set *to* Power Dominating Set.

**Extension to Non-Extension (for IPDS).** For the IPDS-Extension to IPDS, the core difficulty comes from enforcing the excluded vertices to not be selected. We already saw how to enforce the selection of vertices in the construction of the booster gadget. The basic idea for excluding vertices from the solution is to make the selection of certain vertices very expensive.

▶ **Lemma 6.** *There is a parameterized reduction from* Implicating Power Dominating Set Extension *to* Implicating Power Dominating Set.

**Proof Sketch (Vertex Exclusion).** Let $G = (V, E)$ be an IPDS-Extension-instance where the vertices $Y \subseteq V$ are excluded from a solution. We construct an equivalent instance without excluded vertices. We achieve this by creating a new graph $G'$, consisting of $|V| + 1$ copies of $G$ and a clique $C$ of $|V \setminus Y|$ non-propagating vertices. Each copy $G^{(i)}$ has a fresh set of vertices representing the vertices in $G$ and there is an edge between two vertices in a copy if there is an edge between their counterparts in $G$. There are no edges between vertices in different copies. The vertices in $C$ represent the vertices not excluded from a solution. For each vertex in $C$ we add edges to the closed neighborhoods of their counterparts in each of the copies.

Given a power dominating set $S$ of $G$, selecting the corresponding vertices in $C$ yields a power dominating set for $G'$. Conversely, the construction ensures that vertices selected in one of the copies never observe any vertices in another copy. Thus, and because all copies are identical, if a minimum power dominating set contains a vertex in one of the copies, it must contain a vertex in all other copies, too. Hence, a minimum power dominating set of size less then $|V|$ cannot contain any vertices outside $C$. As the vertices in $C$ correspond to the selectable vertices in $G$, we obtain a power dominating set of $G$. ◀

**WMCS to IPDS-Extension.** Finally, for the reduction from WMCS to IPDS-Extension, the core idea is to replace the arcs in the directed acyclic graph describing the circuit with implication arcs and to model `and`-gates as show in Figure 2b.

▶ **Lemma 7.** *There is a parameterized reduction from Weighted Monotone Circuit Satisfiability to Implicating Power Dominating Set Extension.*

**Proof Sketch.** We construct an equivalent IPDS-Extension-instance $G$ from a given monotone circuit $C = (V, E)$ as follows. In this construction, we interpret TRUE values in the circuit as a node being observed. We thus interpret all directed edges in the circuit as implication arcs and add further implication arcs from the output to every input. The input nodes become propagating vertices, all other vertices in $G$ are non-propagating. The `or`-gates are simulated by the implication rule without further adaptation.

To simulate the `and`-gates, we use the gadget in Figure 2b. We replace every `and`-gate $v$ by two new connected vertices $x$ and $y$ where all outgoing edges of $v$ are instead outgoing implication arcs of $y$. For every incoming edge of $v$ from $u$, we place a new proxy vertex $x_u$ and add an edge $x_u x$ and an implication arc $(u, x_u)$. Then, the gate output $y$ becomes observed by the propagation rule from $x$ if and only if all proxy vertices $x_u$ are observed, i.e. if all inputs of the `and`-gate are TRUE.

We need the implication arcs back from the output to the inputs to ensure all vertices become observed if the corresponding truth assignment is satisfying. ◀

▶ **Corollary 8.** *Power Dominating Set is W[P] complete.*

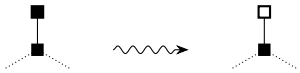
## 4 Solving Power Dominating Set

In this section, we give an algorithm for solving PDS-Extension. Our algorithm consists of different phases. In the first phase, we apply the reduction rules described in Section 4.1. Each rule either shrinks the graph or decides for a vertex that it should be pre-selected or excluded. We prove that the rules are safe, i.e., they yield equivalent instances. Afterwards, in Section 4.2 we split the instance into several components that can be solved independently. Finally, each of the subinstances is solved exactly using the implicit hitting set approach [5] with our improved strategy for finding new sets that need to be hit; see Section 4.3.

We note that these phases are somewhat modular in the sense that one could easily add further reduction rules or that one can replace the algorithm for solving the kernel in the final step. In our experiments in Section 5, we also use an MILP for this step. This MILP formulation is based on the formulation for PDS by Jovanovic and Voss [13] with the adjustments from [4, Appendix A]. Moreover, instead of solving the subinstances optimally, one can instead use a heuristic solver. The preceding application of our reduction rules and splitting into subinstances then helps to find better solutions rather than improving the running time of exact solvers. This is used in our experiments to find upper bounds on the power domination number before we have an exact solution.

### 4.1 Reduction Rules

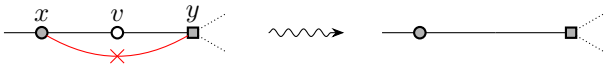
Many of our reduction rules are local in the sense that they transform one substructure into a different substructure. Most of our local reduction rules are illustrated in Figure 3. In the following, we specify additional reduction rules that are either non-local or otherwise difficult to illustrate. For more details and proofs of safeness, see [4, Appendix B].



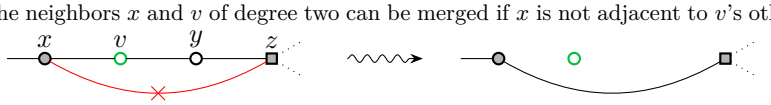
**(a)** `Deg1a`: If an undecided leaf is attached to a non-excluded vertex, the reduction rule excludes the leaf.

**(b)** `Deg1b`: Two cases of excluded leaves attached to a vertex. On the left, the parent vertex is propagating and becomes non-propagating. On the right, the parent vertex is non-propagating and becomes pre-selected. The attached leaf is removed in both cases.

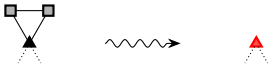
**(c)** `Deg2a`: A vertex $v$ of degree two can safely be excluded if it has an undecided neighbor.



**(d)** `Deg2b`: The neighbors $x$ and $v$ of degree two can be merged if $x$ is not adjacent to $v$'s other neighbor $y$.

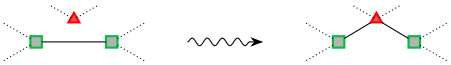


**(e)** `Deg2c`: If $v$ is observed and has two non-adjacent unobserved neighbors of degree two, $x$ and $y$, with $y$ being excluded, then we remove $y$ and the edge $xv$ and connect $x$ to the other neighbor $z$ of $y$.



**(f)** `Tri`: We pre-select the undecided and remove the two vertices of degree two in the triangle.

**(g)** `OnlyN`: If an excluded vertex is surrounded by non-propagating vertices, only one of which is not excluded, we pre-select the non-excluded vertex.



**(h)** `ObsE`: An edge with two observed endpoints is replaced by edges to an arbitrary pre-selected vertex. This leads to fewer applications of the propagation rule by replacing them with the domination rule. Together with `Deg1b`, `Deg2a` and `Deg2b` this also helps reduce the graph size.

**Figure 3** Illustrated overview of the local reduction rules. Round vertices ● are propagating, triangular vertices ▲ are non-propagating, square vertices ■ may be propagating or non-propagating. Hollow vertices □ are excluded from a solution, vertices filled black ■ are undecided, red triangular vertices ▲ are pre-selected. Vertices filled gray ■ may be undecided, excluded or pre-selected. Green vertices □ are observed but not pre-selected. The absence of an edge is indicated in red ⊣⊢.

▶ **Reduction** `ObsNP` (Observed Non-Propagating). *Let $v$ be an observed, non-propagating and excluded vertex. Then delete $v$.*

▶ **Reduction** `Isol` (Isolated). *Let $v$ be an undecided isolated vertex. Then pre-select $v$.*

For the next two reduction rules, we introduce the concept of *observation neighborhood*. For a set of vertices $U \subseteq V$ the observation neighborhood is the set of vertices that is observed when selecting $U$ in addition to all pre-selected vertices and applying the observation rules exhaustively. For convenience, we define the observation neighborhood of a single vertex $v$ to be the observation neighborhood of the single element set $\{v\}$.

▶ **Reduction** `Dom` (Domination). *If the closed neighborhood of some undecided vertex $w$ is contained in the observation neighborhood of some other undecided vertex $v$, exclude $w$.*

▶ **Reduction** `NecN` (Necessary Node). *Let $v$ be an undecided vertex. If the observation neighborhood of all undecided vertices except $v$ does not contain all vertices in $G$, select $v$.*

We note that Binkele-Raible and Fernau [3] already introduced reduction rules for their exponential-time algorithm. We do not use them in our algorithm as they are not generally applicable but rather require a specific situation. The only exception [3, "isolated"] is superseded by our reduction rules.

### 4.1.1 Order of Application

In a first step, use a depth first search and process the vertices in post-order to apply the rules `Deg1a`, `Deg1b`, and `Deg2a`. The order in which we process the vertices is important here, as it makes sure that attached paths are properly reduced. This is only relevant for this first application of the reduction rules and in later applications, we process the vertices and edges in arbitrary order. After this initial application, we iterate the following three steps until no reduction rules can be applied. (i) Iterate the application of the local reduction rules (`Deg1a`, `Deg1b`, `Deg2a`, `Deg2b`, `Tri`, `Deg2c`, `OnlyN`, `ObsNP`, `ObsE`) until no local reduction rule is applicable. (ii) Apply the non-local rule `Dom`. (iii) Apply the non-local rule `NecN`.

We note that applying `Dom` once to all vertices is exhaustive in the sense that it cannot be applied again immediately afterwards. It can, however, become applicable again after rerunning the other reduction rules. The same is true for `NecN`.

Our reasoning for this sequence of application is that the local rules are more efficient than the non-local ones. Thus, we first apply the cheap rules exhaustively before resorting to the expensive ones. Preliminary experiments showed that further tweaking the order of application has only minor effect on the kernel size and run time.

### 4.1.2 Implementation Notes

The naïve implementation of the reduction rules can be very slow, in particular for the non-local rules. The costly operation in those rules is the computation of the observation neighborhood. We thus use a specialized data structure that allows us to pre-select and deselect vertices in arbitrary order. Each time we pre-select a vertex, we also update the observed vertices and keep track of which vertex propagates to which other vertex. For de-selecting vertices, we only mark vertices as unobserved, that were directly or indirectly observed by the deselected vertex. Being able to select and deselect arbitrary vertices allows a straightforward implementation of the non-local rules.

## 4.2 Split into Subinstances

While the propagation rule may have non-local effects within the whole graph, propagation cannot pass through selected vertices. This is formalized by the following theorem.

▶ **Theorem 9.** *Let $G = (V, E)$ be the graph with pre-selected vertices $X \subseteq V$ and let $C_1, \ldots, C_\ell \subseteq V$ be the vertices in the connected components of the sub-graph of $G$ induced by $V \setminus X$. Further let $S_1, \ldots, S_\ell$ be minimum power dominating sets of the subgraphs induced by $N[C_1], \ldots, N[C_\ell]$. Then $S = S_1 \cup \cdots \cup S_\ell$ is a minimum power dominating set of $G$.*

These sub-problems can be identified in linear time using a depth-first search restarting at unexplored non-active nodes while ignoring outgoing edges of active nodes.

## 4.3 Solving the Kernel Via Implicit Hitting Set

We briefly describe the implicit hitting set approach. Compared to how Bozeman et al. [5] introduced it, we allow non-propagating vertices. However, this does not change any of the proofs and thus the approach directly translates to this slightly more general setting.

In a graph $G$, a *fort* is a non-empty subset of vertices $F \subseteq V(G)$ such that no propagating vertex outside $F$ is adjacent to precisely one vertex in $F$. A power dominating set must be a hitting set of the family of all *fort neighborhoods* in $G$, i.e., if $F$ is a fort and $S$ is a power dominating set, then $N[F] \cap S \neq \emptyset$. Conversely, if a hitting set for a family $\mathcal{F}$ of fort neighborhoods is not a power dominating set, then one can find an additional fort of $G$ whose neighborhood is not in $\mathcal{F}$.

This yields the following algorithm. Start with some set $\mathcal{F}$ of fort neighborhoods. Compute a minimum hitting set $H$ for $\mathcal{F}$. If $H$ is already a power dominating set, we have found the optimum. Otherwise, we construct at least one new fort neighborhood and add it to $\mathcal{F}$.

One core ingredient of this approach is the choice of which fort neighborhoods to add to $\mathcal{F}$. Previous approaches [18, 5] aimed at finding forts or fort neighborhoods that are as small as possible. The reasoning behind this is that the set of all fort neighborhoods can be exponentially large (even when restricted to those that are minimal with respect to inclusion) and thus it makes sense to add sets that are as restrictive as possible, hoping that only few sets suffice before the Hitting Set solution yields a PDS solution. However, finding forts of minimum size or minimum size fort neighborhoods is difficult while just finding any fort is easy. Moreover, if we add only few forts in every step, we have to potentially solve more Hitting Set instances. We thus propose to instead find multiple forts at once and to add them all to the Hitting Set instance. Our method of finding forts is based on the following lemma.

▶ **Lemma 10.** *Let $G = (V, E)$ be a graph and let $S \subseteq V$ be a set of selected vertices. Let further be $R$ the set of vertices observed by exhaustive application of the observation rules with respect to $S$. Then the set of unobserved vertices $V \setminus R$ is a fort.*

**Proof.** Assume $V \setminus R$ is not a fort. Then there exists a propagating vertex $v$ in $R$ that is adjacent to precisely one vertex $w$ in $V \setminus R$, i.e., $v$ has precisely one unobserved neighbor $w$. This constradicts the exhaustive application of the propagation rule and thus the set of unobserved vertices is a fort. ◀

By Lemma 10, whenever we have a candidate solution that does not yet observe all vertices, we obtain a new fort and can add its neighborhood to the Hitting Set instance $\mathcal{F}$. For the new forts, we have two objectives. First, we want the new fort neighborhood to actually provide new restrictions, i.e., it should not be already hit by the minimum hitting set $H$ of $\mathcal{F}$. This is achieved by making sure that the candidate solution $S$ is a superset of the hitting set $H$. Secondly, we want the resulting forts (i.e., the number of unobserved vertices) to be small. We achieve this heuristically by greedily considering large candidate solutions.

Specifically, we choose candidate solutions as follows. Recall, that we consider the extension problem, i.e., we have sets $X$ and $Y$ of pre-selected and excluded vertices, respectively. Moreover, let $H$ be a minimum hitting set of the current set of fort neighborhoods. Then $V$ is partitioned into the four sets $X$, $Y$, $H$, and $U = V \setminus H \setminus X \setminus Y$. Each candidate solution $S$ we consider is a superset of $H \cup X$ and a subset of $H \cup X \cup U$. We randomly order the vertices in $U = \{u_1, \dots, u_\ell\}$ and define a sequence $U_0, \dots, U_\ell \subseteq U$. We then consider the candidate solutions $S_i = H \cup X \cup U_i$ for $0 \leq i \leq \ell$. As we want to consider large candidate solutions, we start with $U_0 = U$, which clearly yields a solution as the instance would be invalid otherwise. We obtain the subset $U_i$ from $U_{i-1}$ as follows. If $S_{i-1}$ was a solution, i.e., there were no unobserved vertices, then $U_i = U_{i-1} \setminus \{u_i\}$. Otherwise, $U_i = U_{i-1} \cup \{u_{i-1}\} \setminus \{u_i\}$. Note that this makes sure that each candidate solution $S_i$ we consider is either a solution or barley not a solution as $S_i \cup \{u_i\}$ is a solution.

This gives us at least one and up to $\ell$ new fort neighborhoods. These are not directly added to the set $\mathcal{F}$. Instead, we first apply a simple local search to make sure that each fort is minimal with respect to inclusion. To this end, we iteratively re-select vertices from $U$ that had been removed before and check whether this still results in a non-empty fort.

We note that we only add sets to $\mathcal{F}$. Thus, we have to solve a sequence of increasing Hitting Set instances as a subroutine. To improve the performance of this, one can use lower bounds achieved in earlier iterations as lower bounds for later iterations (Hitting Set is monotone with respect to the addition of sets).

## 5 Experiments

The goal of this section is threefold. First, we evaluate the performance of our algorithm in comparison to two previous state-of-the-art approaches. Secondly, we give a more detailed view on the performance by analyzing how the upper and lower bounds found be the different algorithms converge to the optimal solution. Thirdly, we evaluate the impact of the different reduction rules.

**Experiment Setup.** We implemented our algorithm in C++ 20 and compiled it with clang 15.0.1 with the `-O3` optimization flag. Our source code will be made publicly available on publication. For the comparison with the previous state-of-the-art, we use the MILP formulation approach by Jovanovic and Voss [13]. In the following, we refer to this algorithm with `MILP`. The second solver by Smith and Hicks [18] and is based on the implicit hitting set approach. Unfortunately, their code is not publicly available, and the paper does not specify all implementation details. To make a fair (or rather generous) comparison, we initialized their set of forts with our fort heuristic, which, as far as we can judge, leads to better results than reported in the original publication [18]. We refer to this algorithm as `MFN` (abbreviation for *minimum fort neighborhood*). For the implicit hitting set approaches, we use an MILP formulation to solve the Hitting Set instances. All MILP instances are solved using Gurobi 9.5.2 [10].

The experiments were run on a machine running Ubuntu 22.04 with Linux 5.15. The machine has two Intel®Xeon®Gold 6144 CPUs clocked at 3.5 GHz with 8 single-thread cores and 192 GB of RAM.

We used a collection of instances shipped with pandapower [19]. We further use the Eastern, Western, Texas and US instances from the powersimdata set[2] [21] based on the US electric grids. We interpret the power grids as graphs were buses are vertices and power lines and transformers are edges. Buses without attached loads or generators yield propagating vertices. For experiments on the pandapower instances, we used a timeout of 2 h and repeated each experiment 5 times. On the powersimdata instances, we used a timeout of 10 h and only repeated the experiments using our solver. For repeated experiments, we report the median result.

**Performance Comparison.** We compare the performance of our solver to the `MILP` and `MFN` approach, each with and without preprocessing by the reduction rules. To assess the performance of our approach with reduction rules, we compute the speedup compared to the lowest run time of the previous approaches without reduction rules.

[2] `https://github.com/Breakthrough-Energy/PowerSimData`

**Table 1** Run times of different combinations of PDS solvers and reduction rules on the pandapower data set. Note that $|S|$ differs from the results reported in other literature. This is to be expected because we include non-propagating vertices from the input. Further observe that some run times are given in milli- or microseconds.

a) numbers here were obtained from our interpretation of the respective approach

Table 1 shows the run times of the solvers on the smaller pandapower instances. Preprocessing significantly reduced the running times of all solvers in most cases, especially for the larger instances. We found that our solver with reduction rules performs best in 17 out of 26 instances. In 3 further instances, our solver without reduction rules performed best and the version with reduction rules came second. In particular, our solver performs best on all instances of more than 300 vertices and all instances that took more than one millisecond to solve for any solvers. Even in the six instances where our solver was not the fastest, the other approaches could only compete when combined with the reduction rules.

For the larger powersimdata instances, neither MILP nor MFN were able to compute an optimal solution without using our reduction rules. Thus, for these instances, we only compare our solver with MFN+R and MILP+R. Table 2 shows the results. Observe that for Eastern, our algorithm finished after 16 min while MFN did not finish after more than 6 h, with a lower bound that was still more than 100 vertices below the optimal solution. Further observe that the number of fort neighborhoods $|\mathcal{F}|$ is lower for MFN. This is to be expected as minimizing their number is basically the main goal of MFN when finding new fort neighborhoods. However, this clearly does not show any benefit in the resulting run time.

**Table 2** Comparison between our algorithm and MFN on the larger powersimdata US instances preprocessed with our reduction rules. $n$ is the number of vertices, $|Z|$ is the number of non-propagating vertices an $|\mathcal{F}|$ is the size of the arising hitting set instance. For the solvers, we report the power dominating number $\gamma_P$ (or the best found lower bound) as well as the number of fort neighborhoods $\mathcal{F}$ and the run time.

| | Input | | Our Solver | | | MFN+R | | | MILP+R | |
|---|---|---|---|---|---|---|---|---|---|---|
| Instance | $n$ | $\|Z\|$ | $\gamma_P$ | $\|\mathcal{F}\|$ | $t$ (s) | $\gamma_P$ | $\|\mathcal{F}\|$ | $t$ (s) | $\gamma_P$ | $t$ (s) |
| Texas | 2000 | 376 | 411 | 838 | 0.98 | 411 | 659 | 17.73 | 411 | 1.81 |
| Western | 10024 | 4106 | 1825 | 2618 | 1.55 | 1825 | 2010 | 158.51 | 1825 | 2.16 |
| Eastern | 70047 | 30332 | 12895 | 27019 | 552.46 | >12789 | >15043 | >10 h | >12890 | >10 h |
| USA | 82071 | 34814 | 15131 | 30357 | 728.62 | >14124 | >16391 | >10 h | >15126 | >10 h |

**Lower and Upper Bounds.** We note that all three approaches find lower bounds while solving the instances. In case of the implicit hitting set approach, each time we solve the current Hitting Set instance, the solution size is a lower bound for a minimum power dominating set. This yields lower bounds for our approach as well as for MFN. Moreover, Gurobi also provides lower bounds for MILP. Additionally, Gurobi provides upper bounds. To also get upper bounds for the implicit hitting set approaches, we use the following greedy heuristic. Whenever we have computed a hitting set $H$ of the current fort neighborhoods, we greedily add vertices to $H$, preferably selecting vertices with many unobserved neighbors, until we have a power dominating set. Afterwards, we make sure that the resulting solution is minimal with respect to inclusion.

With this, we can observe how quickly the different algorithms converge towards the optimal solution. Figure 4 illustrates the behavior of the bounds with respect to the time for two of the four powersimdata instances. All three algorithms use our reduction rules (recall that neither MILP nor MFN were able to solve these instances without them). We clearly see that, with our approach, the gap between upper and lower bounds shrinks quickly, in particular compared to MFN. This validates our assumption that adding many – potentially larger – forts instead of a single minimum size one is highly beneficial. Recall that MFN can increase its lower bound only by at most 1 after finding a new hitting set while we can increase the lower by up to one for each undecided unhit vertex.

Interestingly, for MILP+R the gap between upper and lower bound closes much quicker than for MFN+R. In particular, for the largest USA instance, there is almost no gap left after little more than 100 s. Gurobi also found an optimal solution, but failed to prove the lower bound on its size within the timeout of 10 h. Thus, in cases where a good approximation is acceptable, MILP+R is not much worse than our approach.

**Reduction Rules.** To evaluate the effect of the reduction rules on the performance of our algorithm, we let it run on the pandapower instances with different subsets of reduction rules. Recall that we have several local reduction rules as well was the two non-local rules Dom and NecN. In addition to using all or no reduction rules, we consider the following subsets. Only local rules, only non-local rules, all local rules together with Dom, and all local rules together with NecN.

Figure 5a shows the median running time for each instance in the different settings. In most instances, the reductions could decrease the running time by an order of magnitude or more. Moreover, we can see that in most cases all reduction rules are relevant, i.e., we achieve the lowest run time when using all reduction rules and applying no reduction rules is usually slower than applying any of the rules.

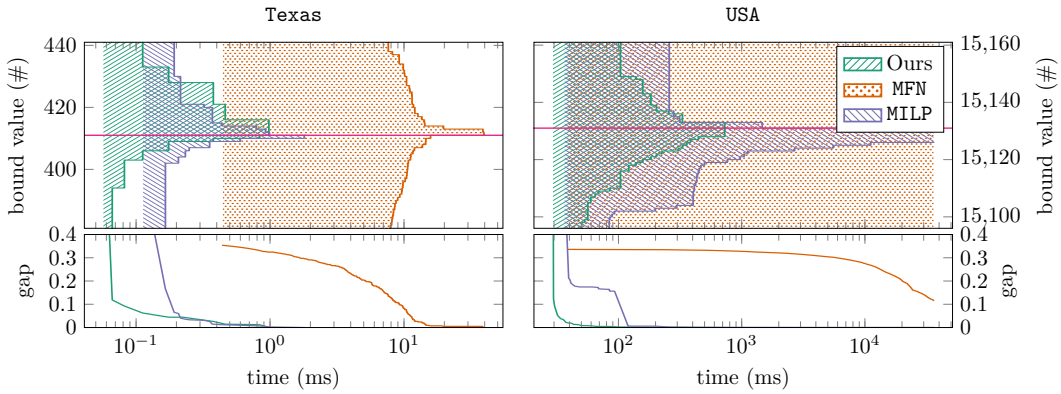

**Figure 4** Upper and lower bounds on the optimum value on the `Texas` and `USA` powersimdata instances with preprocessing by our reduction rules. We give the bounds reported by our solver and by `MFN`, both with added greedy upper bounds, as well as Gurobi for `MILP`. Lines and shaded areas each start at the time of the first respective bound. Note that the x axis uses a logarithmic scale.

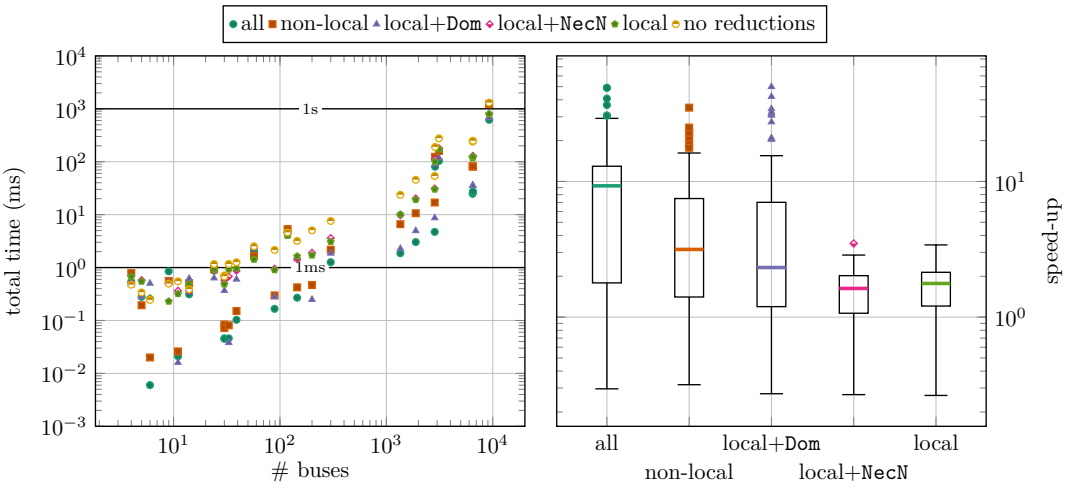
Figure 5b shows the speedup aggregated over all instances of using reduction rules compared to using no reduction rules for our solver. We can see that the median speedup is roughly one order of magnitude when applying all reduction rules. The most interesting observation here is that local+`NecN` does not give any improvement compared to just local. In fact, it is slightly slower. However, when combined with `Dom`, `NecN` gives a significant improvement.

## 6 Conclusion

We showed that PDS is $W[P]$-complete. This closes the gap in the study of its parameterized complexity. Our reduction uses an auxiliary problem, IPDS, to simulate arbitrary monotone circuits.

Our second contribution in this paper is a set of new reduction rules for PDS. The rules yield partially solved instances of PDS-Extension where some vertices are pre-selected for the power dominating set while other are forbidden from being included. Each rule shrinks the instance by removing vertices or edges, or pre-selects or excludes vertices from being selected. Our reduction rules can be used as a pre-processing step to significantly enhance the performance of existing solvers. Our third and last contribution is a new algorithm for solving PDS based on the implicit hitting set approach. The core of our algorithm is a new heuristic to find missing sets for the implicit hitting set instances. We evaluate the effectiveness of our reduction rules and the performance of our algorithm in experiments on a set of practical power grid instances from the literature. For comparison, we run the same experiments with two different approaches from the literature. The comparison shows clearly that our new heuristic for finding missing fort neighborhoods outperforms the previous approach. Our algorithm outperforms the reference solvers by more than one order of magnitude. Even when combining the other approaches with our reduction rules, our algorithm beats them on most instances. Furthermore, we can solve large instances of continental scale that could not be solved before. We found that our algorithm finds lower bounds on the power dominating number more quickly than Gurobi.

A major advantage of our fort heuristic is that it translates easily to other variants of PDS, as long as it is easy to verify which vertices are observed by a partial solution. Examples of such variant are the $k$-Power Dominating Set where propagation is possible



**(a)** Median running time on each instance with the different subsets of reduction rules.

**(b)** Aggregated speed-up of each set of reduction rules compared to our algorithm without reduction rules.

if a vertex has less than $k$ unobserved neighbors or $l$-Round Power Dominating Set where the number of propagation steps is limited. Other variants, such as Connected Power Dominating Set are less straightforward. It might be interesting to see if connectivity can be efficiently enforced in the implicit hitting set model.

Even though our algorithm shows a significant improvement over the state-of-the-art, there is still some potential for further engineering. Currently, our implementation of the reduction rules is optimized for a single execution as a pre-processing step. Further optimization might make them more efficient, especially when only few vertices have changed between rule applications. This might be useful in more accurate heuristics solutions on large instances or for use in a branching algorithm. Further fast high quality heuristics can provide good upper bounds on the solution size. Such a heuristic, combined with the lower bound provided by our algorithm, might prove optimality earlier, further reducing the run time. Also, other hitting set solvers beside Gurobi exist and our algorithm might benefit from using those instead.

## Abstract

In the dynamic approximate maximum bipartite matching problem we are given bipartite graph $G$ undergoing updates and our goal is to maintain a matching of $G$ which is large compared the maximum matching size $\mu(G)$. We define a dynamic matching algorithm to be $\alpha$ (respectively $(\alpha, \beta)$)-approximate if it maintains matching $M$ such that at all times $|M| \geq \mu(G) \cdot \alpha$ (respectively $|M| \geq \mu(G) \cdot \alpha - \beta$).

We present the first deterministic $(1-\varepsilon)$-approximate dynamic matching algorithm with $O(\text{poly}(\varepsilon^{-1}))$ amortized update time for graphs undergoing edge insertions. Previous solutions either required super-constant [Gupta FSTTCS'14, Bhattacharya-Kiss-Saranurak SODA'23] or exponential in $1/\varepsilon$ [Grandoni-Leonardi-Sankowski-Schwiegelshohn-Solomon SODA'19] update time. Our implementation is arguably simpler than the mentioned algorithms and its description is self contained. Moreover, we show that if we allow for additive $(1, \varepsilon \cdot n)$-approximation our algorithm seamlessly extends to also handle vertex deletions, on top of edge insertions. This makes our algorithm one of the few small update time algorithms for $(1-\varepsilon)$-approximate dynamic matching allowing for updates both increasing and decreasing the maximum matching size of $G$ in a fully dynamic manner.

Our algorithm relies on the weighted variant of the celebrated Edge-Degree-Constrained-Subgraph (EDCS) datastructure introduced by [Bernstein-Stein ICALP'15]. As far as we are aware we introduce the first application of the weighted-EDCS for arbitrarily dense graphs. We also present a significantly simplified proof for the approximation ratio of weighed-EDCS as a matching sparsifier compared to [Bernstein-Stein], as well as simple descriptions of a fractional matching and fractional vertex cover defined on top of the EDCS. Considering the wide range of applications EDCS has found in settings such as streaming, sub-linear, stochastic and more we hope our techniques will be of independent research interest outside of the dynamic setting.

# 1 Introduction

Matchings are fundamental objects of combinatorical optimization with a wide range of practical applications. The first polynomial time algorithm for finding a maximum matching was published by Kuhn[1] [39] in 1955 which ran in $O(n^4)$ time. A long line of papers have focused on improving this polynomial complexity. Notably Edmonds and Karp [30] showed the first $O(n^3)$ time algorithm for the problem which was later improved to $O(n^{2.5})$ [36]. Mucha and Sankowski [40] showed maximum matching can be solved in matrix multiplication time, that is in $O(n^\omega)$ where $\omega$ is currently around 2.38. In the very recent breakthrough result of Chen-Kyng-Liu-Peng-ProbstGutenberg-Sachdeva [29], they showed an $O(m^{1+o(1)})$ time algorithm for the maximum flow problem (which generalizes bipartite matching) providing the first near-linear time algorithm, essentially settling the problem in the sequential setting.

**Dynamic Model.** This paper focuses on the matching problem in the dynamic model where it has received extensive research attention in recent years, see e.g [1, 2, 10, 14, 17, 20, 22, 28, 41, 43, 45, 47] and many more. In this setting our task is to maintain a large matching as the graph undergoes updates. We will refer to updates being fully dynamic if they concern both insertions and deletions and partially dynamic if only one of the two is allowed. The objective is to minimize the time spent maintaining the output after each update. Throughout the paper we will always refer to update time in the amortized sense – averaged over the sequence of updates. In [45] Sankowski has shown the fist improvement for the fully dynamic maximum matching problem in terms of update time ($O(n^{1.45})$) compared to static recomputation after each update. Unfortunately, based on well accepted hardness conjectures no dynamic algorithm for the maximum matching problem may achieve update time sub-linear in $n$ [35]. Most works focused on the relaxed approximate version of the problem where the goal is to maintain a large matching in $G$ with respect to the maximum matching size $\mu(G)$. We will refer to matching algorithms as $\alpha$-approximate (respectively $(\alpha, \beta)$-approximate) if it maintains matching $M$ such that at all times $|M| \geq \mu(G) \cdot \alpha$ (respectively $|M| \geq \mu(G) \cdot \alpha - \beta$).

**Fully Dynamic Approximate Matching.** The holy grail of dynamic algorithm design is to achieve an update time of $O(\text{polylog}(n))$ or ideally even constant. For the fully dynamic approximate matching problem, a long line of research [6, 9, 18, 19, 21, 26, 42, 46] has lead to algorithms achieving $\approx \frac{1}{2}$-approximation with $O(\text{polylog}(n))$ and constant update time. No fully dynamic algorithm has been found achieving better than $\frac{1}{2}$-approximation in $O(\text{polylog}(n))$ update time for the problem, and this challenge appears to be one of the most celebrated problem within the dynamic matching literature. A set of interesting papers focused on $\approx \frac{2}{3}$-approximation in $\tilde{O}(\sqrt{n})$ update time [16, 17, 32, 38] and other approximation-ratio to polynomial-update-time trade-offs in the better-than-$\frac{1}{2}$-approximation regime were achieved by [10, 11, 44]. Note that through periodic recomputation of the matching (roughly every $\varepsilon\mu(G)$ updates) we can achieve fully dynamic $(1-\epsilon)$-approximation in $\tilde{O}(n)$ update time [34]. Very recently [12] has shown that $(1-\varepsilon)$-approximation is possible in slightly sublinear update time $O(n/\log^*(n)^{O(1)})$ suggesting that there might exist efficient non-trivial algorithms for the problem. Note that very recently [8, 25] have independently shown that if our goal is to maintain the *size* of the maximum matching (and not the edge-set) then sub-$\frac{1}{2}$ approximation is achievable in polylogarithmic update time.

[1] However, this result is usually attributed to Kőnig and Egerváry.

**Partially Dynamic Matching Algorithms.** For small approximation ratios, achieving poly-logarithmic update time for fully dynamic matching seems far out of reach with current techniques, or perhaps even impossible. Hence, a long line of papers have focused on maintaining a $(1-\varepsilon)$-approximate matching in partially dynamic graphs: either incremental (edge insertions) or decremental (edge deletions). The first $O(\text{poly}(\log(n), \varepsilon^{-1}))$ algorithm for maintaining a $(1-\varepsilon)$-approximate matching under edge insertions is due to Gupta [33], with amortized update time $O(\log^2(n)/\varepsilon^4)$. Their algorithm models the bipartite matching problem as a linear program, and uses the celebrated multiplicative-weights-updates framework. Generalizing the result of [33] recently Bhattacharya-Kiss-Saranurak [23] has shown that an arbitrarily close approximation to the solution of a linear program undergoing updates either relaxing or restricting (but not both) its solution polytope can be maintained in $O(\text{poly}(\log n, \varepsilon^{-1}))$ update time. Hence, the algorithm of [23] shows how to maintain a $(1-\varepsilon)$-approximate matching under either decremental or incremental updates with a unified approach. As both of these papers rely on static linear program solver sub-routines their update times inherently carry $\log(n)$ factors, and it seems implausible that these techniques can achieve constant update time independent of $n$.

The decremental algorithms of [15,37] focus on maintaining "evenly spread out" fractional matchings so that they are robust against edge-deletions. These algorithms rely on either maximum-flow computation or convex optimization sub-routines which similarly to LP-solvers carry $\log(n)$-factors into the update time.

The first constant time[2] partially dynamic matching algorithm is due to [31] who solve $(1-\varepsilon)$-approximate matching in incremental graphs with an update time of $(1/\varepsilon)^{O(1/\varepsilon)}$. Their solution relies on augmenting path elimination, a technique used commonly for the matching problem in the static setting. However, enumerating augmenting paths seems to inherently carry an exponential dependency on $1/\varepsilon$ due to the number of possible such paths present in the graph.

As far as we are aware partially dynamic $(1-\epsilon)$-approximate matching algorithms with update time independent of $n$ and faster than some exponential in $\epsilon$ are all restricted to a relaxed version of the problem where the graph may undergo vertex insertions/deletions. Such an algorithm can simply be obtained through straightforward periodic rebuilds (if we allow for additive $\epsilon \cdot n$ slack) or as shown by Zheng-Henzinger [48][3]. Hence, it we can observe the following apparent gap in the literature of partially dynamic matching algorithms:

▶ **Question 1.** *Can we maintain a $(1-\varepsilon)$-approximate maximum matching of a partially dynamic bipartite graph in $O(\text{poly}(\varepsilon^{-1}))$ update time?*

Based on the current landscape of the dynamic algorithms literature, achieving $(1-\varepsilon)$-approximation under fully dynamic updates in small update times seems to be far out of reach. Contrary to the extensive research effort, no fully dynamic algorithm with $\text{poly}(\log(n), \varepsilon^{-1})$ has been found for maintaining matchings with better than $\frac{1}{2}$-approximation. This apparent difficulty proposes the research of dynamic models somewhere between fully and partially dynamic updates. The previously mentioned paper by Zheng-Henzinger [48] implements a

[2] That is constant-time whenever $\varepsilon$ is constant, i.e. the update time should be independent of $n$.

[3] A very recent paper of Zheng-Henzinger [48] has initially claimed an algorithm which can maintain a $(1-\epsilon)$-approximate matching in $O(1/\varepsilon)$ update time under edge deletions. However, the authors have found a mistake in their paper and claim that their algorithm only works under specific vertex updates

$(1-\epsilon)$-approximate algorithm with $O(1/\varepsilon)$-update time which can support vertex insertions and deletions on separate sides of the bipartition. The existence of this new result proposes the following natural question:

▶ **Question 2.** *Under what kind of non-partially dynamic updates can we maintain a $(1-\varepsilon)$-approximate maximum matching of a bipartite graph?*

## 1.1 Our Contribution

In this paper we provide a positive answer to **Question 1** and make progress towards understanding **Question 2**. Our main result is the first $O(\text{poly}(1/\varepsilon))$ update time $(1-\varepsilon)$-approximate dynamic matching algorithm for bipartite graphs undergoing edge insertions:

▶ **Theorem 1.** *There exists a deterministic dynamic algorithm which for arbitrary small constant $\varepsilon > 0$ maintains a $(1-\varepsilon)$-approximate maximum matching of a bipartite graph undergoing edge insertions in total update time $O(n/\varepsilon^6 + m/\varepsilon^5)$.*

Previous algorithms for $(1-\varepsilon)$ approximate dynamic matching under edge updates required update times which were either super-constant [23, 33] or had an exponential dependency on $\varepsilon^{-1}$ [31]. Furthermore, our algorithm is arguably simpler then previous implementations and it is self contained (except for the static computation of $(1-\varepsilon)$-approximate maximum matchings) where as most dynamic matching algorithms either rely on heavy machinery from previous papers or use black-box tools like multiplicative weight updates or flow-subroutines.

We further show that if we allow for (additive) $(1, \varepsilon \cdot n)$-approximation[4] our algorithm seamlessly extends to a wider range of updates:

▶ **Theorem 2.** *There exists a deterministic dynamic algorithm which for arbitrary small constant $\varepsilon > 0$ maintains a $(1, \epsilon \cdot n)$-approximate maximum matching of a bipartite graph undergoing edge insertions and vertex deletions in total update time of $O(n/\varepsilon^8 + m/\varepsilon^5)$.*

In contrast to the similar update time result of [48] which allows for edge deletions and vertex insertions on one side of the bipartition our algorithm allows from arbitrary vertex deletions. Our algorithm maintains a $(1-\varepsilon)$-approximate maximum matching of the graph throughout updates which can both increase and decrease the maximum matching size of the graph. Hence, we hope our techniques provide useful insight towards fully dynamizing $(1-\varepsilon)$-approximate algorithms for the matching problem.

Our algorithm relies on the weighted variant of the celebrated Edge-Degree-Constrained-Subgraph (EDCS) matching sparsifier. The unweighted EDCS (first introduced by Bernstein-Stein [16]) has found applications in a number of different computational settings: streaming [3, 4, 13], stochastic, one way communication, fault tolerant [5], sub-linear [8, 12, 24, 25] and dynamic [8, 16, 17, 32, 38]. On the other hand the *weighted* EDCS variant which provides a tighter approximation has only found applications in small arboricity graphs [16]. Hence, we initiate the study of the weighted EDCS in dense graphs.

Furthermore, we show a significantly simplified proof for the approximation ratio of the weighted EDCS datastructure with respect to the maximum matching size. In our proof, we identify simple and explicit descriptions of a fractional matching and fractional vertex covers

[4] Recall that this means that we maintain a matching of size at least $\mu - \varepsilon n$, as opposed to $\mu - \varepsilon\mu$, where $\mu$ denotes the size of the maximum matching.

defined on top of the weighted EDCS, which might be of independent interest. Moreover, we show that the dependence on the slack parameter on the maximum degree of the weighted EDCS is exactly quadratic. This in sharp contrast to the unweighted EDCS where the same relationship have been proven to be linear [7]. While within the dynamic matching algorithm literature papers don't tend to focus on exact $\epsilon$ complexities but rather $n$ dependence, in models such as semi-streaming and distributed the $\epsilon$ dependency usually gains more focus. Our hard example (most likely) rules out applications of weighted EDCS in these models for obtaining sub $\epsilon^{-2}$ round/pass complexity algorithms. We hope that these observations will be of independent research interest due to the wide-spread popularity of the EDCS datastructure for solving matching problems.

## 1.2 Our Techniques

Assume $H$ is a multi-graph defined on the vertex set of $G$ and let $\deg_H(v)$ stand for the degree of vertex $v$ in $H$. We define the degree of an edge to be the sum of the degrees of its endpoints.[5]

▶ **Definition 3** (Weighted EDCS [16]). *Given a graph $G = (V, E)$, a multiset $H$ is called a weighted EDCS with parameter $\beta$ if*[a]*:*

**(i)** $\deg_H(u) + \deg_H(v) \leq \beta$ *for all edges* $(u, v) \in H$.

**(ii)** $\deg_H(u) + \deg_H(v) \geq \beta - 1$ *for all edges* $(u, v) \in E$.

If $H$ is not a weighted EDCS, we call an edge $e \in H$ *overfull* if it violates (i), and an edge $e \in E$ *underfull* if it violates (ii).

[a] Some authors use an additional parameter $\beta^- < \beta$ which replaces the "$\beta - 1$" in the degree-constraint. For our purposes, we will always have $\beta^- = \beta - 1$.

If $\beta = \Omega(\varepsilon^{-2})$ and $H$ is a $\beta$-WEDCS of $G$ then $\mu(H) \geq \mu(G) \cdot (1-\varepsilon)$ ( [16], Theorem 13). In order to derive our incremental result we show that a $\beta$-WEDCS can be efficiently maintained greedily under edge insertions. In turn we can efficiently maintain a $(1 - \epsilon)$-approximate matching within the support of $H$ through periodic recomputation.

Define a valid update of $H$ to be one of the following: (i) and edge $e \in H$ which is overfull with respect to $H$ gets deleted from $H$; and (ii) a copy of an edge $e \in E$ which is underfull with respect to $H$ is added to $H$. In Lemma 7 (slightly improving on the similar lemma's of [5, 13, 16]) we show that if $H$ is initialized as the empty graph and only undergoes valid updates, then it there are at most $O(\mu(G) \cdot \beta^2)$ many updates.

Fix some $\beta = \Theta(\varepsilon^{-2})$. Assume $G$ is initially empty and initialize $H$ to be an empty edge set (note that by definition initially $H$ is a $\beta$-WEDCS of $G$). Assume edge $e$ is inserted into $G$. If at this point $e$ is not underfull with respect to $H$ there is nothing to be done as $H$ remained a valid WEDCS of $G$. If $e$ is underfull with respect to $H$ we add copies of it to $H$ until it is not. This process of adding $e$ to $H$ has increased the edge degree of edges neighbouring $e$ in $H$ and some of them might have became overfull. To counteract this we iterate through the neighbours of $e$ in an arbitrary order and if we find an overfull edge $e'$ we remove it from $H$. This edge removal decreases the edge degrees in the neighbourhood of $e'$. To counteract this we recurse and look for underfull edges in the neighbourhood of

[5] Note that we are sticking to the notation weighted-EDCS instead of multi-EDCS to be in line with the naming convention of [16] which defined $H$ to be a weighted graph with integer edge weights.

$e'$. If such an edge $e''$ is found we add copies of it to $H$ until $e''$ is not underfull and repeat the same steps as if $e''$ was just inserted into $G$. This defines a natural recursive process for restoring the WEDCS properties after each edge insertion in a local and greedy way.

Whenever we have to explore the neighbourhood of an edge in $O(\Delta)$ time (where $\Delta$ is the max-degree) to either check for underfull or overfull edges we do so because $H$ underwent a valid update. By Lemma 7 this may only happen at most $O(\mu(G) \cdot \beta^2)$ times. Hence, naively the total work spent greedily fixing the WEDCS properties is $O(\mu(G) \cdot \Delta \cdot \beta^2)$. For some graphs this value might be significantly larger then $m$. In order to improve the update time to $O_\beta(m)$ we assign a counter $c_v$ to each vertex $v$ measuring the number of valid updates of $H$ the neighbourhood of $v$ has underwent. Once $c_v$ grows to $\Omega(\beta^2 \cdot \varepsilon^{-1})$ we mark $v$ dirty and ignore further edges inserted in the neighbourhood of $v$. By marking a single vertex dirty and ignoring some edges incident on it we may loose out only on a single edge of any maximum matching. However, whenever we mark a vertex dirty we can charge $\Omega(\beta^2 \cdot \varepsilon^{-1})$ valid updates of $H$ to that vertex. As there may be at most $O(\mu(G) \cdot \beta^2)$ valid updates of $H$ in total we may only mark $O(\mu(G) \cdot \varepsilon)$ vertices dirty hence we will only ignore an $O(\epsilon)$-fraction of any maximum matching within the graph through ignoring edges incident on dirty vertices. As we may scan the neighbourhood of vertex $v$ at most $O(\beta^2 \cdot \varepsilon^{-1}) = \text{poly}(\varepsilon^{-1})$ times until $v$ is marked dirty we ensure that each edge is explored $\text{poly}(\varepsilon^{-1})$ times guaranteeing a total running time of $O(m \cdot \text{poly}(\varepsilon^{-1}))$. Full details can be found in Section 3.

**Towards Full Dynamization.** The algorithm almost seamlessly adopts to vertex deletions if we allow for $(1, \varepsilon \cdot n)$-approximation[6]. Whenever a vertex gets deleted from the graph our WEDCS $H$ might be locally affected. This means that over the full run of the algorithm, $H$ may undergo further valid updates then the $O(\mu(G) \cdot \beta^2)$ bound provided by Lemma 7. A potential function based argument allows us to claim that each vertex deletion may increase the total number valid updates $H$ may undergo by $O(\beta^2)$. As each vertex may be deleted at most once this means that the total number of valid updates we might make to restore $H$ is $O(n \cdot \beta^2)$, each update requiring $O(\Delta)$ time if naively implemented. By marking vertices as dirty as before we can guarantee amortized $O(\text{poly}(1/\varepsilon))$ update time. However, now we must mark up to $\approx \varepsilon \cdot n$ vertices as dirty (as opposed to $\approx \varepsilon \cdot \mu(G)$ like before), which means we may miss out on $\varepsilon \cdot n$ edges of the maximum matching.

## 2 Preliminaries

**Matching Notation.** Let $N_E(v)$ stand for the edges neighbouring vertex $v$ in $E$. A fractional matching $f$ of a graph $G$ is an assignment of the edges of $G$ to values in the range $[0, 1]$ such that for all vertices $v \in V$ it holds that $\sum_{e \in N_E(v)} f_e \leq 1$. The *size* of a fractional matching is simply the sum of the fractional values over its edges. That is a maximum fractional matching is the solution to the linear program $\max\{\sum_{e \in E} f_e : \sum_{e \in N_E(v)} f_e \leq 1 \text{ for all } v \in V, f \geq 0\}$. A solution $x$ to the dual of this program $\min\{\sum_{v \in V} x_v : x_u + x_v \geq 1 \text{ for all } (u, v) \in E, x \geq 0\}$ is a fractional vertex cover.

[6] Readers may reasonable argue that the additive slack is not necessary as a number of vertex-sparsification techniques exist in literature allowing us to improve the approximation to purely multiplicative slack in the dynamic setting. Unfortunately, these techniques don't appear to be robust against vertex-wise updates.

Approximation with respect to a fractional matching is defined simmilarly as with respect to integral matchings. For a graph $G = (V, E)$ we use $\mu(G)$ to denote the size of the maximum matching in $G$. Likewise, we use $\mu^*(G)$ to denote the size of the maximum *fractional* matching. It is well-known that $\mu(G) \leq \mu^*(G) \leq \frac{3}{2}\mu(G)$ for any graph, and that $\mu^*(G) = \mu(G)$ in bipartite graphs.

▶ **Theorem 4** (Hopcroft-Karp [36]). *There exists a deterministic static algorithm which finds a $(1-\varepsilon)$-approximate maximum matching of a graph $G$ on $m$ edges in $O(m/\varepsilon)$ time.*

# 3 Incremental Approximate Matching

We start by showing our incremental fractional matching algorithm, and then show how to extend it (for bipartite graphs) to also maintain an integral matching.

## 3.1 Weighted EDCS & Fractional Matchings

In this section we show our algorithm to (almost[7]) maintain a weighted EDCS $H$ in an incremental graph. It is well-known that such an $H$ will be a $(1-\varepsilon)$-matching sparsifier on *bipartite* graphs, that is a "sparse" subgraph with $\mu(H) \geq (1-\varepsilon)\mu(G)$ [16].

As we show later in Section 5.1 (Theorem 13), we even known something stronger: there is an explicit fractional matching in $H$ of size at least $(1-\varepsilon)\mu^*(G)$, defined as

$$f_{(u,v)} = \min\left(\frac{1}{\deg_H(v)}, \frac{1}{\deg_H(u)}\right) \text{ on each } (u,v) \in H. \tag{1}$$

Note that [17] similarly (implicitly) defines a large fractional matching on the support of a weighted EDCS, however our construction and analysis are arguably simpler. This fractional matching is also valid for general (non-bipartite) graphs. Hence our incremental algorithm will also maintain this explicit $(1-\varepsilon)$-approximate fractional matching (even in non-bipartite graphs). Formally we prove the following theorem.

▶ **Theorem 5.** *For any $\varepsilon \in (0,1)$, there is an algorithm (Algorithm 1) that maintains a $(1-\varepsilon)$-approximate maximum* fractional *matching in an incremental graph in total update time $O(n/\varepsilon^6 + m/\varepsilon^5)$. Additionally, this fractional matching is always supported on a set of edges $H$ of size $|H| \leq \Theta(\mu(G)/\varepsilon^2)$ and maximum degree $O(1/\varepsilon^2)$.*

First we need two standard facts about weighted EDCS. For completeness, we prove these in Section 7. Lemma 7 has only been shown before for unweighted EDCS [5, 13, 16] and not weighted (but the arguments are very similar).

▶ **Lemma 6.** *In a $\beta$-WEDCS $H$, the maximum degree is at most $\beta$ and $|H| \leq \beta\mu^*(G)$.*

▶ **Lemma 7.** *If a multiset of edges $H$ is only ever changed by removing overfull edges and adding underfull edges, then there are at most $\beta^2\mu^*(G)$ such insertions/deletions to $H$.*

[7] As we will see later in this section, our sparsifier $H$ will be a weighted EDCS for $G \setminus R$, where $R$ is a subgraph of $G$ with very small maximum matching size $\mu(R) = O(\varepsilon\mu(G))$.

**Overview.** Our algorithm (see Algorithm 1) will maintain a weighted EDCS $H$ with $\beta = \Theta(1/\varepsilon^2)$. We also maintain the $(1-\varepsilon)$-approximate fractional matching $f$ as in Equation (1) and Theorem 13.

When we get an edge-insertions $(u, v)$, we need to reestablish the property that $H$ is an EDCS. If $(u, v)$ is underfull ($\deg_H(u) + \deg_H(v) < \beta - 1$), we add it (maybe multiple times) to $H$. This means that $\deg_H(u)$ (similarly $\deg_H(v)$) increases, which can potentially make some incident edge $(u, w) \in H$ overfull ($\deg_H(u) + \deg_H(w) > \beta$), so we must remove one such edge. This might in turn lead to some edge $(w, z) \in E$ being underfull (as now $\deg_H(w)$ decreased), so we add this edge to $H$. This process continues, so both from $u$ and $v$ we need to search for alternating paths of underfull and overfull edges (as is standard in EDCS-based algorithms). In total, Lemma 7 says there are $O(n/\varepsilon^4)$ updates to $H$ over the full run of the algorithm.

We note that searching for an *overfull* edge is cheap: the maximum degree in $H$ is just $O(\beta)$ (Lemma 6), so we can afford to, in $\Theta(1/\varepsilon^2)$ time, check all incident edges. However, searching for *underfull* edges is more expensive: this time we cannot afford to just go through all neighboring edges in $E$, as we no longer have a bound on the maximum degree.

To overcome this we use an amortization trick which allows us to ignore a vertex if we touched it too many times. There are only $\beta^2\mu^*(G)$ updates to $H$ in total (Lemma 7), so there will only be $\varepsilon\mu^*(G)$ many vertices incident to more than $2\beta^2/\varepsilon$ of these updates. Any edges incident to these "update-heavy" vertices we may ignore, as this may only decrease the maximum matching size by an $\varepsilon$ fraction. We thus only need to check each edge a total of $O(1/\varepsilon^5)$ times over the run of the algorithm, except when it is in $H$ already. Note that $H$ is no longer a weighted EDCS of $G = (V, E)$, but rather of $G' = (V, (E \setminus R) \cup H)$ where $R$ is this set of edges we ignored (with $\mu^*(R) \leq \varepsilon\mu^*(G)$).

**Algorithm 1** Incremental Weighted EDCS & Frasctional Matching.

```
// Initially E = H = ∅ and deg_H(v) = visits[v] = 0 for all v ∈ V.
// When an edge insertion e appears, add it to E and call FixEdge(e).

function FixEdge(e = (u, v))
    if deg_H(u) + deg_H(v) > β and (u, v) ∈ H then                  // overfull
        Remove (one copy of) the edge (u, v) from H
    if deg_H(u) + deg_H(v) < β − 1 then                             // underfull
        Add (one copy of) the edge (u, v) to H
    if the edge was added or removed then
        Update deg_H(u), deg_H(v), and the fractional matching accordingly
        FixVertex(u), FixVertex(v)

function FixVertex(v)
    visits[v] ← visits[v] + 1
    if visits[v] < 2β²/ε then
        for edge e ∈ E incident to v do
            FixEdge(e)
    else
        for edge e ∈ H incident to v do
            FixEdge(e)
```

**Running Time.** We analyse the total update time spent in different parts of our algorithm.

- We first note that `FixEdge` runs in constant time whenever it does not update $H$. It is called once for each edge-insertion (total $O(m)$ times), and also some number of times from `FixVertex`.
- Now consider the case when `FixEdge` does update $H$ (which happens at most $\beta^2\mu^*(G)$ times per Lemma 7). Now the algorithm uses $O(\beta)$ time for the update of the fractional matching and insertion/removal in $H$, in addition to exactly two calls to `FixVertex`. Except for these calls to `FixVertex`, over the run of the algorithm we hence spend a total of $O(\mu(G)\beta^3) = O(n/\varepsilon^6)$ time.
- By the previous point, we will call `FixVertex` at most $2\beta^2\mu^*(G)$ times. In each call, we either loop through all incident edges in $H$ or $E$. If we loop through $H$, we visit $\beta$ many edges (by Lemma 6). Either these `FixEdge` calls take constant time, or they are already accounted for in the previous point. In total, this thus accounts for another $O(\mu(G)\beta^3) = O(n/\varepsilon^6)$ running time.
- We account for the case when `FixVertex` loops through all incident edges in $E$ differently. Consider how often a specific edge $e$ appears in the for-loop at line 13. Each endpoint vertex of $e$ will reach this line at most $O(\beta^2/\varepsilon)$ times. Hence, in total for all edges, line 13 is run at most $O(m\beta^2/\varepsilon) = O(m/\varepsilon^5)$ times.

**Approximation Guarantee.** We now argue the approximation ratio. We will show that the fractional matching supported on $H$ is a $(1-2\varepsilon)$-approximation of maximum fractional matching in $G$. If one want a $(1-\varepsilon')$-approximation, then one can run the algorithm in the same asymptotic update time setting $\varepsilon = \varepsilon'/2$, and changing $\beta$ accordingly.

Define $R_V$ to be the set of "dirty"/"update-heavy" vertices: that is vertices $v$ for which `FixVertex(`$v$`)` has been called at least $2\beta^2/\varepsilon$ many times (i.e. $\mathsf{visits}[v] \geq 2\beta^2/\varepsilon$). By a counting argument $|R_V| \leq 2\beta^2\mu^*(G)/(2\beta^2/\varepsilon) = \varepsilon\mu^*(G)$, since by Lemma 7 in total there are only $\beta^2\mu^*(G)$ many updates to $H$, each issuing exactly two calls to `FixVertex`. If $R_E$ is the set of edges incident to $R_V$, then $\mu^*(R_E) \leq |R_V| \leq \varepsilon\mu^*(G)$ since $R_V$ is a vertex cover of $R_E$.

Define $G' = (V, E \setminus (R_E \setminus H))$. By the above, $\mu^*(G') \geq (1-\varepsilon)\mu^*(G)$. We will finish the proof by arguing that $H$ is a weighted EDCS of $G'$, and thus that our fractional matching is of value at least $(1-\varepsilon)\mu^*(G') \geq (1-\varepsilon)^2\mu^*(G) \geq (1-2\varepsilon)\mu^*(G)$. Whenever an edge is added or removed to $H$, we call `FixVertex` on its endpoints, and no other degrees $\deg_H$ have changes. Every time `FixVertex`$(v)$ is called for $v \notin R_V$, we make sure that all edges $e \in E$ incident to it satisfy the definition of an EDCS, and when `FixVertex(`$v$`)` is called for some $v \in R_v$, we check the edges incident to $H$. We note that when a vertex becomes "update-heavy" (added to $R_v$), then we do **not** immediately remove all incident edges from $H$ (as then we no longer have the same bound on the number of updates to $H$ since Lemma 7 no longer applies).

▶ Remark 8. We note that our algorithm runs in time $O(n\beta^3 + m\beta^2/\varepsilon)$, and a valid question is whether setting $\beta = \Theta(1/\varepsilon^2)$ is actually necessary? Recently it was shown that for unweighted EDCS $\beta = \Theta(1/\varepsilon)$ is enough [7]. However, for weighted EDCS the $\varepsilon^2$ dependency is indeed necessary, as we show by an example where this is asymptotically tight in Section 5.2 (Theorem 16).

## 3.2 Integral Matchings in Bipartite Graphs

In this section we argue how to extend our fractional matching algorithm (Theorem 5) to maintain an integral matching instead (for bipartite graphs), in the same asymptotic update time. We cannot use known dynamic rounding techniques [23, 47], since all these incur

polylog$(n)$ factors or require randomization, and we are aiming for update time independent of $n$. In fact, our technique is simple and combinatorial; and only relies on the standard Hopcroft-Karp algorithm for finding a $(1-\varepsilon)$-approximate matching in the static setting [36].

▶ **Theorem 1.** *There exists a deterministic dynamic algorithm which for arbitrary small constant $\varepsilon > 0$ maintains a $(1-\varepsilon)$-approximate maximum matching of a bipartite graph undergoing edge insertions in total update time $O(n/\varepsilon^6 + m/\varepsilon^5)$.*

▶ Remark 9. Before proving the above theorem, we briefly explain how to achieve a slightly less efficient version (amortized $O(1/\varepsilon^8)$ update time) by using the fully dynamic $(1-\varepsilon)$-approximate matching algorithm of Gupta-Peng [34] as a black box. The idea is to run the fully dynamic algorithm on our sparsifier – the weighted EDCS $H$. This way we maintain a matching $M$ of size $|M| \geq (1-\varepsilon)\mu(H) \geq (1-\varepsilon)^2\mu(G) \geq (1-2\varepsilon)\mu(G)$.

Gupta-Peng [34] state that their algorithm runs in $O(\sqrt{m}/\varepsilon^2)$ time per update. However, as previously pointed out by e.g. [16, Lemma 1], it is in fact more efficient when the max-degree $\Delta$ is low, in which case the update time is only $O(\Delta/\varepsilon^2)$. Since $H$ always has max-degree $\beta = \Theta(1/\varepsilon^2)$, we can maintain the integral matching $M$ in $O(1/\varepsilon^4)$ time *per update to* $H$. Over the run of the algorithm, we only perform $O(\mu(G)/\varepsilon^4)$ updates to $H$ (see Lemma 7), hence the total additional update time spent maintaining the integral matching will be $O(n/\varepsilon^8)$.

**Proof of Theorem 1.** To prove Theorem 1, we need a slightly more refined analysis than the one above. We still run our incremental algorithm (Algorithm 1 and Theorem 5) to maintain a weighted EDCS $H$ together with a fractional matching supported on $H$. Similarly to above, we additionally maintain an $(1-\varepsilon)$-approximate (integral) matching $M$ of $H$.

The main idea of the fully dynamic algorithm of Gupta-Peng [34] is to lazily recompute (in $O(|H|/\varepsilon)$ time via Hoproft-Karp Theorem 4) $M$ every $\approx \varepsilon\mu$ updates to $H$ (indeed, during this few updates, the matching size cannot change its value by more than $\varepsilon\mu$). There are two observations which helps us to do better:

- **(i)** The graph $G$ (but not the sparsifier $H$) is incremental, so $\mu(G)$ can only grow.
- **(ii)** We know a good estimate of $\mu(G)$, namely the size of our fractional matching. Denote by $\tilde{\mu}$ the value of the maintained fractional matching, so that $(1-\varepsilon)\mu(G) \leq \tilde{\mu} \leq \mu(G)$.

The above two observations mean that we only need to recompute the matching $M$ whenever $\mu(G)$ actually have increased significantly (namely by a $(1+\Theta(\varepsilon))$-factor), and not just every $\varepsilon\mu$ updates.

Formally, whenever $|M| \geq (1-\varepsilon)^2\tilde{\mu}$ we know that $M$ is still a $(1-3\varepsilon)$-approximation since then $|M| \geq (1-\varepsilon)^2\tilde{\mu} \geq (1-\varepsilon)^3\mu(G) \geq (1-3\varepsilon)\mu(G)$. Conversely, whenever $|M| < (1-\varepsilon)^2\tilde{\mu}$, we recompute $M$ in time $O(|H|/\varepsilon)$ (Theorem 4) so that it is a $(1-\varepsilon)$-approximation of the maximum matching in $H$ (and thus also a $(1-2\varepsilon)$-approximation of the maximum matching in $G$).

Let us now bound the total time spent recomputing $M$. Let $M_1, M_2, \ldots, M_t$ be the different approximate matchings we compute during the run of the algorithm. We first note that at the time when we compute $M_{i+1}$:

$$|M_i| \leq (1-\varepsilon)^2\tilde{\mu} \leq (1-\varepsilon)\left((1-\varepsilon)\mu(H)\right) \leq (1-\varepsilon)|M_{i+1}| \tag{2}$$

This in turn means that $|M_i| \leq (1-\varepsilon)^{t-i}\, n$ (since $|M_t| \leq n$), and hence that $\sum_{i=1}^{t} |M_i| \leq n\sum_{i=0}^{\infty}(1-\varepsilon)^i \leq n/\varepsilon$, by a geometric sum.

Finally we note that we spend $O(|M_i|/\varepsilon^3)$ time in order to compute $M_i$. Indeed, when we compute $M_i$, we did so in $O(|H|/\varepsilon)$ time, and $|H| = O(\mu(G)/\varepsilon^2)$ by Lemma 6. This means that in total, over the run of the algorithm, we spend $O(\sum |M_i|/\varepsilon^3) = O(n/\varepsilon^4)$ time

maintaining the integral matchings $M_i$. This is in addition to the time spent maintaining the weighted EDCS $H$ and the fractional matching (see Theorem 5). This concludes the proof of Theorem 1. ◀

## 4 Vertex Deletions

In this section we will observe that our algorithm can also handle vertex deletions (simultaneously to handling edge insertions) in similar total update time. However, this comes with one caveat: we instead get additive approximation error proportional to $\varepsilon n$ (that is we maintain a matching of size $\mu^*(G) - \varepsilon n$, instead of $\mu^*(G) - \varepsilon\mu^*(G)$ as before).

▶ **Theorem 10.** *For any $\varepsilon \in (0,1)$, there is an algorithm that maintains a* fractional *matching of size at least $\mu^*(G) - \varepsilon n$ in an graph $G$ undergoing edge insertions and vertex deletions. The total update time is $O(n/\varepsilon^6 + m/\varepsilon^5)$.*

**Proof.** The algorithm (Algorithm 1) remains the same as in Section 3.1. When a vertex is deleted, we simply remove all it's incident edges from $E$ and $H$, and call `FixVertex` on all neighboring vertices (in $H$) who now changed their degree. The only thing which changes in the analysis is the $\beta^2\mu^*(G)$-bound on the number of updates to $H$ (Lemma 7), which no longer applies. However, we can still get a weaker version of Lemma 7 with a $\beta^2 n$ total update bound instead:

▶ **Lemma 11.** *If a multiset of edges $H$ is only ever changed by (i) removing overfull edges, (ii) adding underfull edges, and (iii)* removing all edges incident to a vertex when no edges are underfull or overfull*, then there are at most $3\beta^2 n$ insertions/deletions to $H$.*

Given Lemma 11 (which we prove in Section 7), we see that the running time analysis of Algorithm 1 can remain exactly the same! In the approximation guarantee analysis, we now have more "update-heavy" vertices $|R_V| \leq 6\beta^2 n/(2\beta^2/\varepsilon) = 3\varepsilon n$, which is why we now can lose up to $O(n\varepsilon)$ edges from the matching. Otherwise, the approximation guarantee analysis remains the same, and so does the rest of the analysis of the algorithm. ◀

**Rounding in Bipartite Graphs.** Similar as in Section 3.2, we can round the fractional matching to an integral one in bipartite graphs, also while supporting edge-insertions and vertex-deletions simultaneously.

▶ **Theorem 2.** *There exists a deterministic dynamic algorithm which for arbitrary small constant $\varepsilon > 0$ maintains a $(1, \epsilon \cdot n)$-approximate maximum matching of a bipartite graph undergoing edge insertions and vertex deletions in total update time of $O(n/\varepsilon^8 + m/\varepsilon^5)$.*

**Proof.** Unlike in Section 3.2, we cannot argue that $\mu(G)$ is increasing when we have vertex deletions. So instead we resort to the Gupta-Peng [34] framework discussed in Remark 9 (together with Lemma 11), which has the additional cost of $O(n/\varepsilon^8)$ total update time to maintain an approximate integral matching on our sparsifier $H$. ◀

▶ Remark 12. We note that normal vertex-sparsification techniques (such as the one shown in [38] against oblivious adversaries) do not apply here in order to assume $n = \tilde{\Theta}(\mu(G))$ so that the additive error becomes multiplicative again. This is because vertex deletions in the original graph might become edge deletions in the vertex-sparsified graph. We also note that one can achieve similar guarantees of supporting vertex deletions with additive $\varepsilon n$ slack using *any* edge-incremental algorithm (also for non-bipartite graphs) as a black-box: see Section 6 for a discussion on how this can be done. The general approach in Section 6 will give worse dependency on $1/\varepsilon$ (for dense graphs), compared to Theorems 2 and 10 above.

# 5 Tight Bounds of the of Approximation Ratio of a Weighted EDCS

## 5.1 Explicit Fractional Matching

In this section, we give explicit formulas only based on the degrees in $H$, for a $(1-\varepsilon)$-approximate fractional matching. We prove this by also providing an explicit approximate fractional vertex cover, and showing that these satisfy approximate complimentary slackness. This also significantly simplifies the previous proof [16] that $H$ is $(1-\varepsilon)$-matching sparsifier in bipartite graphs.

▶ **Theorem 13.** *Suppose $H$ is a weighted EDCS of a graph $G$, with parameter $\beta \geq 25/\varepsilon^2$. Let $f_{(u,v)} = \min\{\frac{1}{\deg_H(v)}, \frac{1}{\deg_H(u)}\}$ for each[8] $(u,v) \in H$. Then $f$ is a $(1-\epsilon)$-approximate fractional matching of $G$.*

Define $r_v := \deg_H(v) - \frac{\beta-1}{2}$ for a vertex $v \in H$. We define the fractional matching $f$ as in the statement of the theorem, together with the fractional vertex cover $x$:

$$f_{(u,v)} = \min\left(\frac{1}{\deg_H(u)}, \frac{1}{\deg_H(v)}\right) \quad \text{for edge } (u,v) \in H \tag{3}$$

$$x_v = \begin{cases} \min(1, \frac{1}{2} + \frac{r_v^2}{\beta}) & \text{if } r_v \geq 0 \\ \max(0, \frac{1}{2} - \frac{r_v^2}{\beta}) & \text{if } r_v < 0 \end{cases} \tag{4}$$

It is now relatively straightforward (albeit a bit calculation-heavy) to argue that $f$ and $x$ are indeed feasible solutions and that they satisfy approximate complimentary slackness.

▷ Claim 14. Our $f$ is a fractional matching and our $x$ is a fractional vertex cover of $G$.

Proof. Our $f$ is feasible since no vertex $v$ is overloaded by the matching: at most $\deg_H(v)$ many incident edges to $v$ contribute at most $1/\deg_H(v)$ each.

To argue that $x$ is feasible, consider some edge $(u,v) \in E$. Without loss of generality we may assume that $\deg_H(v) \geq \deg_H(u)$ and $\deg_H(v) \geq \frac{\beta-1}{2}$, i.e. $r_v \geq r_u$ and $r_v \geq 0$ (since $\deg_H(u) + \deg_H(v) \geq \beta - 1$ as $H$ is a weighted EDCS). If $r_v^2 \geq \beta/2$, $x_v = 1$ so $(u,v)$ is covered. In the case $r_v^2 < \beta/2$, we instead have $x_v = \frac{1}{2} + \frac{r_v^2}{\beta}$. It is always the case that $x_u \geq \frac{1}{2} - \frac{r_u^2}{\beta}$. Additionally we note that $r_u + r_v \geq 0$ (so $r_u^2 \leq r_v^2$) since $\deg_H(u) + \deg_H(v) \geq \beta - 1$, so we conclude that $x_u + x_v \geq 1$, and hence that $(u,v)$ is covered. ◁

▷ Claim 15. The fractional matching $f$ and fractional vertex cover $x$ satisfy $(1 - \frac{3}{\sqrt{\beta}}, 1 + \frac{2}{\sqrt{\beta}} + \frac{2}{\beta})$-approximate complementary slackness[9]; in particular:

- **(i)** Whenever $f_{(u,v)} > 0$, then $x_u + x_v \leq 1 + \frac{2}{\sqrt{\beta}} + \frac{1}{\beta}$.
- **(ii)** Whenever $x_v > 0$, then $\sum_{u:(u,v)\in H} f_{(u,v)} \geq 1 - \frac{4}{\sqrt{\beta}}$.

Proof. We verify (i) and (ii).

- **(i)** Suppose $f_{(u,v)} > 0$, then $(u,v) \in H$, so $\deg_H(u) + \deg_H(v) \in \{\beta - 1, \beta\}$. This means that $0 \leq r_v + r_u \leq 1$. If both $r_v$ and $r_u$ are non-negative, we have that $x_u + x_v \leq 2(\frac{1}{2} + \frac{1^2}{\beta}) \leq 1 + \frac{2}{\beta}$. Now, without loss of generality $r_u < 0 \leq r_v$. In case

[8] We note that edges $e$ appearing multiple time in $H$ all contribute towards $f_e$: if $e$ appears $\phi_e$ times in $H$, the value of $f_e$ is naturally scaled by $\phi_e$.

[9] For completeness, we define the approximate complimentary slackness conditions in Section 7 and prove them in Lemma 20.

$r_u^2 \geq \beta/2$, we know $x_u = 0$ so $x_u + x_v \leq 1$. In the case when $r_u^2 < \beta/2$, we know $x_u = \frac{1}{2} + \frac{r_u^2}{\beta}$ and $x_v \leq \frac{1}{2} + \frac{r_v^2}{\beta}$. Since $r_u + r_v \leq 1$, we known that $r_v \leq |r_u| + 1$. Concluding:

$$x_v + x_u \leq 1 + \frac{(|r_u|+1)^2 - r_u^2}{\beta} = 1 + \frac{2|r_u|+1}{\beta} < 1 + \frac{2\sqrt{\beta}+1}{\beta} = 1 + \frac{2}{\sqrt{\beta}} + \frac{1}{\beta}.$$

**(ii)** Suppose $x_v > 0$. Hence $r_v > -\sqrt{\beta/2}$ (else $x_v = 0$), that is $\deg_H(v) > \frac{\beta-1}{2} - \sqrt{\beta/2}$. For any incident edge $(u,v) \in H$, we must have $\deg_H(v) + \deg_H(u) \leq \beta$, so $\deg_H(u) \leq \frac{\beta-1}{2} + (1 + \sqrt{\beta/2})$. Now, we see that we assign weight at least $1/(\frac{\beta-1}{2} + (1+\sqrt{\beta/2}))$ to the edge $(u,v)$ in $f$. Since this holds for all the $\deg_H(v) > \frac{\beta-1}{2} - \sqrt{\beta/2}$ incident edges we know that $v$ will in total receive, from the fractional matching $f$, at least:

$$\sum_{u:(u,v)\in H} f_{(u,v)} \geq \frac{\frac{\beta-1}{2} - \sqrt{\beta/2}}{\frac{\beta-1}{2} + 1 + \sqrt{\beta/2}} = 1 - \frac{\sqrt{8\beta}+2}{\beta + \sqrt{2\beta}+1} \geq 1 - \frac{3}{\sqrt{\beta}}.$$ ◀

**Proof of Theorem 13.** By the above claims and approximate complimentary slackness (see Lemma 20 in Section 7) we know that $(1 - \frac{3}{\sqrt{\beta}})|x| \leq (1 + \frac{2}{\sqrt{\beta}} + \frac{2}{\beta})|f|$. Since $(1 - \frac{3}{\sqrt{\beta}})/(1 + \frac{2}{\sqrt{\beta}} + \frac{2}{\beta}) > 1 - \frac{5}{\sqrt{\beta}}$, we get that $|f| \geq (1 - \frac{5}{\sqrt{\beta}})|x| \geq (1-\varepsilon)|x| \geq (1-\varepsilon)\mu^*(G)$ whenever $\beta \geq 25/\varepsilon^2$. ◀

## 5.2 Lower Bound

In this section we show that Theorem 13 is tight up to a constant, i.e. that one must set $\beta = \Theta(1/\varepsilon^2)$ in order to guarantee that a weighted EDCS preserves a $(1-\varepsilon)$-fraction of the matching. This might be a bit surprising, considering that for the *unweighted* EDCS, it is known that $\beta = \Theta(1/\varepsilon)$ suffices (to preserve a $(\frac{2}{3} - \varepsilon)$-approximation to the matching [7]).

▶ **Theorem 16.** *For any $\beta \geq 2$, there exists a (bipartite) graph $G$ together with a weighted EDCS $H$ for which $\mu(H) = (1 - \Theta(1/\sqrt{\beta}))\mu(G)$.*

We show our construction in Figure 1, and also describe it here formally in words. For simplicity, we will assume that $\beta = 2\gamma^2$ for some integer $\gamma$ (but it is not difficult to adapt the proof for when $\beta$ is not twice a square). In our construction, each edge appears at most once in $H$, and all edges $e \in H$ have $\deg_H(e) = \beta$; all edges $e \in E \setminus H$ have $\deg_H(e) = \beta - 1$.

Define the gadget $G_i = (S_i, L_i, E_i)$ to be a complete bipartite graph in which $|S_i| = \gamma^2 + i$ and $|L_i| = \gamma^2 - i$ ($S$ is for vertices with *small* degree, and $L$ for vertices with *large* degree). The subgraph $H$ will consist of many of these gadgets $G_i$, so we start by noting a few properties about them. Firstly, vertices in $L_i$ have degree $\frac{\beta}{2} + i$ while those in $S_i$ have degree $\frac{\beta}{2} - i$. This means that any edge in $(u,v) \in E_i$ has degree exactly $\deg_{G_i}(u) + \deg_{G_i}(v) = \beta$. We also note that the maximum matching inside $G_i$ is of size $|L_i| = \gamma^2 - i$.

**Subgraph $H$.** We begin by describing how the weighted EDCS $H$ looks like, and later we will define what additional edges are also in the full graph $G$. The subgraph $H$ will exactly consist of:

- One copy of $G_0$.
- Two copies each of $G_1, G_2, \ldots, G_{\gamma-1}$. Call the copies $G_i^{(1)}$ and $G_i^{(2)}$.
- $2\gamma$ copies of $G_\gamma$. Call the copies $G_\gamma^{(1,j)}$ and $G_\gamma^{(2,j)}$ for $j = 1, 2, \ldots, \gamma$.

▷ Claim 17. $\mu(H) = 4\gamma^3 - 4\gamma^2 + \gamma$.

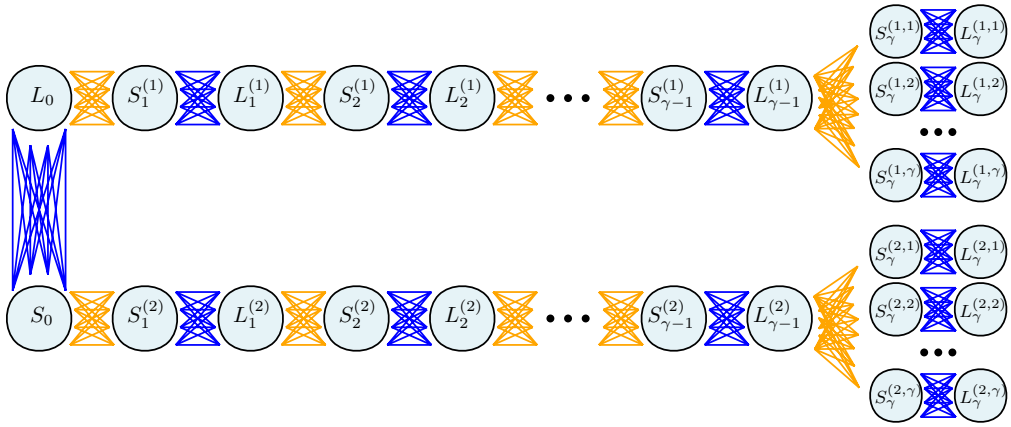

**Figure 1** The lower bound construction. The blue edges are part of $H$, while the yellow are not. We have $\gamma = \sqrt{\beta/2}$, and each set $S_i$, $L_i$ indicates an independent set of vertices of size $|S_i| = \gamma^2 + i$ and $|L_i| = \gamma^2 - i$ (so in $H$ they have degrees $\frac{\beta}{2} - i$ and $\frac{\beta}{2} + i$ respectively). The maximum matching in $H$ matches all vertices in $L_i$ to the corresponding $S_i$. The maximum matching in $G$ however, matches $L_i$ to $S_{i+1}$ (and $S_0$ to $S_1^{(2)}$), in addition to $L_\gamma$ which can also be matched to $S_\gamma$.

Proof. Since the maximum matching size in $G_i$ is $|L_i| = \gamma^2 - i$ we get:

$$\begin{aligned}\mu(H) &= |L_0| + 2\gamma|L_\gamma| + 2(|L_1| + |L_2| + \cdots + |L_{\gamma-1}|) \\ &= \gamma^2 + 2\gamma(\gamma^2 - \gamma) + 2\sum_{i=1}^{\gamma-1}(\gamma^2 - i) \\ &= 4\gamma^3 - 4\gamma^2 + \gamma\end{aligned}$$

◁

**Full graph $G$.** Now we describe the additional edges which are part of $G$ but not already in $H$ (see also Figure 1):

- For $k \in \{1, 2\}$, we connect $G_1^{(k)}, G_2^{(k)}, \ldots, G_{\gamma-1}^{(k)}$ in a chain as follows: every pair $(u, v)$ with $u \in L_i^{(k)}$ and $v \in S_{i+1}^{(k)}$ is an edge (so that the induced subgraph on these two sets of vertices forms a complete bipartite graph).
- At the end of these two chains, we connect all the gadgets $G_\gamma^{(k,j)}$ as follows: every pair $(u, v)$ with $u \in L_{\gamma-1}^{(k)}$ and $v \in S_\gamma^{(k,j)}$ for some $j$, is an edge.
- Finally we connect these two chains using $G_0 = (S_0, L_0, E_0)$ as follows: every pair $(u, v)$ with $u \in L_0$ and $v \in S_1^{(1)}$ is an edge; and every pair $(u, v)$ with $u \in S_0$ and $v \in S_1^{(2)}$ is an edge.

We note that $G$ is bipartite and all above edges have degree exactly $\deg_H(u) + \deg_H(v) = \beta - 1$, so indeed $H$ is a weighted EDCS of $G$.

▷ Claim 18. $\mu(G) \geq 4\gamma^3 - 3\gamma^2 + \gamma$.

Proof. We argue that a matching of this size exists in $G$. In fact the only edges of $H$ we will use as part of this matching are those in the gadgets $G_\gamma^{(k,j)}$.

- We pick a matching between $L_i^{(k)}$ and $S_{i+1}^{(k)}$ of size $|L_i^{(k)}| = \gamma - i$ for all $k \in \{1, 2\}$ and $i = 1, 2, \ldots, \gamma - 2$.
- In $G_\gamma^{(k,j)}$ we pick a matching of size $|L_\gamma^{(k,j)}| = \gamma^2 - \gamma$. Note that exactly $2\gamma$ vertices in $S_\gamma^{(k,j)}$ are left unmatched.

- Denote by $U^{(k)}$ the set of unmatched vertices in $S_\gamma^{(k,1)}, S_\gamma^{(k,2)}, \ldots, S_\gamma^{(k,\gamma)}$, for $k \in \{1,2\}$. Note that $|U^{(k)}| = 2\gamma^2$ and that $(L_{\gamma-1}^{(k)}, U^{(k)})$ forms a complete bipartite graph, so we pick a matching of size $|L_{\gamma-1}^{(k)}| = \gamma^2 - \gamma + 1$ from there.
- Finally we pick matchings between $L_0$ and $S_1^{(1)}$ (respectively $S_0$ and $S_1^{(2)}$) of size $|L_0| = \gamma$ (respectively $|S_0| = \gamma$).

In total we see that the above matching is exactly $|S_0| = \gamma$ larger than in Claim 17, which concludes the proof of the claim. ◁

**Approximation ratio.** To conclude the proof of Theorem 16, we see that $\mu(G) - \mu(H) = \gamma^2 \geq \frac{1}{4\gamma}\mu(G)$ whenever $\gamma \geq 1$. Hence $H$ preserves at most a $(1 - \frac{1}{4\gamma}) = (1 - \frac{1}{2\sqrt{2\beta}})$ fraction of the maximum matching of $G$.

## 6 Black-Box Vertex Deletions

Here we briefly explain how one can convert any incremental $(1-\varepsilon)$-approximate maximum matching algorithm to also support vertex deletions, if allowing additive $\varepsilon n$ approximation instead, in a black-box fashion. The reduction is simple and also works in general (non-bipartite) graphs. Hence, as an immediate application, we can get a $(1, \varepsilon n)$-approximate matching algorithm for general graphs undergoing both edge-insertions and vertex-deletions, with amortized $1/\varepsilon^{O(1/\varepsilon)}$ update time, if using the incremental algorithm of [31].

▶ **Lemma 19.** *Suppose $\mathcal{A}$ is an algorithm which maintains a $(1-\varepsilon/2)$-approximate maximum matching for a graph undergoing edge insertions, running in total time $T$. Then there exists an algorithm which maintains a $(1, \varepsilon n)$-approximate matching, in total time $O(T/\varepsilon)$, on a graph undergoing both edge insertions and vertex deletions.*

**Proof.** We run $\mathcal{A}$, and whenever we get a vertex deletion we ignore it and keep the vertex in the graph. In the outputted matching from the algorithm we remove any edges incident to deleted vertices. When $\varepsilon n/2$ vertices have been deleted, we actually delete them from the graph and rerun the algorithm from scratch (starting on the empty graph). This will only happen $\frac{2}{\varepsilon}$ times, which is the running time blow-up. At each point, the algorithm maintains a matching of size at least $\mu - (\varepsilon n/2 + \varepsilon n/2) = \mu - \varepsilon n$, since only one edge can be removed per deleted vertex still remaining in the graph. ◀

## 7 Omitted Proofs

### EDCS properties

▶ **Lemma 6.** *In a $\beta$-WEDCS $H$, the maximum degree is at most $\beta$ and $|H| \leq \beta\mu^*(G)$.*

**Proof.** If a vertex $u$ has $\deg_H(u) > \beta$, then any incident edge $(u,v) \in H$ is overfull: $\deg_H(u) + \deg_H(v) > \beta$, leading to a contradiction. Hence the maximum degree is at most $\beta$. Now we construct a fractional matching by assigning a weight of $1/\beta$ to every edge in $H$ (so an edge appearing with multiplicity $\phi$ in $H$ gets weight $\phi/\beta$). Clearly this is a feasible fractional matching of $G$, since no vertex is overloaded. On the other hand, the size of this fractional matching is $|H|/\beta$, implying that $|H| \leq \beta\mu^*(G)$. ◀

▶ **Lemma 7.** *If a multiset of edges $H$ is only ever changed by removing overfull edges and adding underfull edges, then there are at most $\beta^2\mu^*(G)$ such insertions/deletions to $H$.*

**Proof.** We use a potential function argument. Define

$$\Phi(H) := |H|(2\beta-1) - \sum_{(u,v)\in H} (\deg_H(v)+\deg_H(u)) = \sum_{(u,v)\in H} (2\beta-1-\deg_H(u)-\deg_H(v))$$

We note that if an edge $(u,v)$ appears multiple times in $H$, it appears multiple times in the above sum as well. We first note that $\Phi(\emptyset)=0$ and $\Phi(H) \leq \beta|H| \leq \beta^2\mu^*(G)$, by Lemma 6 and since $(2\beta-1-\deg_H(u)-\deg_H(v)) \leq \beta$ when $H$ is a valid EDCS. Now we verify that updates to $H$ increase the potential by at least 1:

- Insertion of an underfull edge $(u,v) \in E$.
  That is $\deg_H(u)+\deg_H(v) \leq \beta-2$ before adding the edge. The term $|H|(2\beta-1)$ will increase by $2\beta-1$. $\sum_{(u,v)\in H}(\deg_H(v)+\deg_H(u))$ will increase by at most $2\beta-2$, since one term of value $\deg_H(v)+\deg_H(v) \leq \beta-2+2$ (the $+2$ comes from $\deg_H(v)$ and $\deg_H(u)$ increasing by one when we add $(u,v)$ to $H$) is added, and at most $\beta-2$ other terms decrease in value by one.
- Deletion of an overfull edge $(u,v) \in H$.
  That is $\deg_H(u)+\deg_H(v) \geq \beta+1$ before removing the edge. The term $|H|(2\beta-1)$ will decrease by $2\beta-1$. $\sum_{(u,v)\in H}(\deg_H(v)+\deg_H(u))$ will decrease by at least $2\beta$, since one term of value $\deg_H(v)+\deg_H(v) \geq \beta+1-2$ (the $-2$ comes from $\deg_H(v)$ and $\deg_H(u)$ decreasing when we remove $(u,v)$) is erased, and at least $\beta+1$ other terms increase in value by one. ◀

▶ **Lemma 11.** *If a multiset of edges $H$ is only ever changed by (i) removing overfull edges, (ii) adding underfull edges, and (iii)* removing all edges incident to a vertex when no edges are underfull or overfull*, then there are at most $3\beta^2 n$ insertions/deletions to $H$.*

**Proof.** We continue the potential function argument from the proof of Lemma 7 above. When we delete, from $H$, all edges incident to some vertex $u$, we know that we deleted at most $\beta$ many edges from $H$ (as the degree of this vertex was at most $\beta$). For each such incident edge $(u,v)$, we bound how much its deletion could have decreased the potential function. The $|H|(2\beta-1)$ term decreased by exactly $2\beta-1$, and the $-\sum_{(u,v)\in H}(\deg_H(u)+\deg_H(v))$ term can only increase. So the total decrease in potential, over all up to $\beta$ incident edges which were deleted, is at most $2\beta^2-\beta$.

Since we can only delete up to $n$ vertices in total, and the potential is always bounded by $\beta^2\mu^*(G) \leq \beta^2 n$, it follows that the total increase in the potential function, over the run of the algorithm, is at most $3\beta^2 n - n\beta$ (and thus this many updates to $H$ from insertions/deletions of underfull/overfull edges). In total we deleted at most $n\beta$ edges in $H$ incident to deleted vertices, so the total number of updates to $H$ is thus bounded by $3\beta^2 n - \beta n + \beta n = 3\beta^2 n$. ◀

### Approximate Complimentary Slackness

▶ **Lemma 20.** *Suppose we have the primal linear program $\max\{c^T x : Ax \leq b, x \geq 0\}$, and its dual $\min\{b^T y : A^T y \geq c, y \geq 0\}$. We say that feasible primal solution $x$ and dual solution $y$ satisfy $(\alpha,\gamma)$-approximate complementary slackness (for $\alpha \leq 1 \leq \gamma$) if: (i) if $x_i = 0$ then $(A^T)_i y \leq \gamma c_i$, and (ii) if $y_j = 0$ then $(A)_j x \geq \alpha b_j$. When this is the case, then $\alpha b^T y \leq \gamma c^T x$ (i.e. $x$ and $y$ are $\frac{\gamma}{\alpha}$-approximate optimal).*

**Proof.** We see that $\gamma c^T x - \alpha b^T y = x^T(\gamma c - A^T y) + y^T(Ax - \alpha b)$. Now either $x_i = 0$ or $(\gamma c - A^T y)_i \geq 0$; and either $y_j = 0$ or $(Ax-\alpha b)_j \geq 0$. Hence $\gamma c^T x - \alpha b^T y \geq 0$. ◀

## Abstract

Dallard, Milanič, and Štorgel [arXiv '22] ask if, for every class excluding a fixed planar graph $H$ as an induced minor, Maximum Independent Set can be solved in polynomial time, and show that this is indeed the case when $H$ is any planar complete bipartite graph, or the 5-vertex clique minus one edge, or minus two disjoint edges. A positive answer would constitute a far-reaching generalization of the state-of-the-art, when we currently do not know if a polynomial-time algorithm exists when $H$ is the 7-vertex path. Relaxing tractability to the existence of a quasipolynomial-time algorithm, we know substantially more. Indeed, quasipolynomial-time algorithms were recently obtained for the $t$-vertex cycle, $C_t$ [Gartland et al., STOC '21], and the disjoint union of $t$ triangles, $tC_3$ [Bonamy et al., SODA '23].

We give, for every integer $t$, a polynomial-time algorithm running in $n^{O(t^5)}$ when $H$ is the friendship graph $K_1+tK_2$ ($t$ disjoint edges plus a vertex fully adjacent to them), and a quasipolynomial-time algorithm running in $n^{O(t^2 \log n)+f(t)}$, with $f$ a single-exponential function, when $H$ is $tC_3 \uplus C_4$ (the disjoint union of $t$ triangles and a 4-vertex cycle). The former generalizes the algorithm readily obtained from Alekseev's structural result on graphs excluding $tK_2$ as an induced subgraph [Alekseev, DAM '07], while the latter extends Bonamy et al.'s result.

## 1 Introduction

The Max Independent Set (MIS for short) problem asks, in its optimization form, for a largest *independent set* of its input graph $G$, i.e., a subset of pairwise non-adjacent vertices in $G$. In its decision form, the input is a graph $G$ and an integer $k$, and the question is whether $G$ admits an independent set of size at least $k$.

Besides the ubiquitous usefulness that such a fundamental problem has within combinatorial optimization, and notably in the areas of packing, scheduling, and coloring, MIS (or equivalently Maximum Clique, the same problem in the complement graph) has as wide a range of applications as possible, as evidenced for instance in map labeling [48], coding theory [17], spatial scheduling [26], genetic analysis [1], information retrieval [10], macromolecular docking [28], and sociometry [27] (also see Butenko's thesis [16]). It is thus unfortunate that this problem is not only hard to solve but also very reluctant to being approximated. Indeed, the decision version of MIS is NP-complete [29] and W[1]-complete [25], while its optimization version cannot be approximated within ratio $n^{1-\varepsilon}$ on $n$-vertex graphs, for any $\varepsilon > 0$, unless P=NP [35, 50].

In spite of this, theorists and practitioners have put a lot of effort in designing efficient algorithms for MIS. In parallel to generically solving MIS via integer programming, highly performant exact and heuristic MIS solvers have emerged in the recent years, based on diverse methods such as kernelization and evolutionary approaches [40], deep reinforcement learning [4], graph neural networks [44], and dataless training (where backpropagation is applied to a loss function based instead on the input) [9]. On the theory side, exact exponential algorithms have been developed for decades culminating in a running time below $1.2^n n^{O(1)}$ [49].

Another approach is to try and exploit the structure that the input graphs may have. Indeed, in all the aforementioned applications, inputs are not uniformly sampled over all $n$-vertex graphs: They instead bare some structural properties, and in some cases, might avoid some specific patterns. Graph theory[1] offers two main notions of *patterns* or containment: the natural and straightforward *subgraphs* (obtained by removing vertices and edges), and the deeper *minors* (further allowing to contract edges). Both notions come with an induced variant, when edge removals are disallowed, bringing the number of containment types to four. It is then sensible to determine the patterns $H$ whose absence makes MIS (more) tractable. It turns out that this question is completely settled for subgraphs and minors.

For the subgraph containment, the argument is the following. By the grid minor theorem [45], the class of graphs excluding $H$ as a subgraph has bounded treewidth if (and only if) all the connected components of $H$ are paths and subdivided *claws* (i.e., stars with three leaves); thus MIS can be solved in polynomial-time in this class, for instance by Courcelle's theorem [21]. If instead $H$ has a connected component which is not a path nor a subdivided claw, MIS remains NP-complete since such a class either contains all subcubic graphs or the $2|V(H)|$-subdivision of every graph, two families of graphs on which MIS is known to be NP-complete [5, 8, 43].

For minors, the dichotomy relies on the planarity of $H$. Indeed, if $H$ is planar, then the class of graphs excluding $H$ as a minor has bounded treewidth (again, mainly by the grid minor theorem), and MIS can be solved efficiently. If $H$ is non-planar, then the $H$-minor-free graphs include all planar graphs for which MIS is known to be NP-complete [30].

The question is more intriguing for the induced containments, and the *induced subgraph* case has received a lot of attention. While it is known for a long time that if $H$ is *not* the disjoint union of paths and subdivided claws, MIS remains NP-complete on graphs without $H$ as an induced subgraph [5, 43], it has been conjectured that MIS is otherwise polynomial-time solvable. This has been proven when $H$ is the 6-vertex path [34], a claw with exactly one edge subdivided [6, 41], or any disjoint union of claws [15]. The latter result extends a polynomial-time algorithm (essentially) due to Alekseev when $H$ is any disjoint

[1] We refer the reader to Section 2 for the relevant background in graph theory.

union of edges [7]. The author indeed proves that the total number of maximal independent sets is polynomially bounded. One can then enumerate all the maximal independent sets in polynomial time (following Alekseev's proof, or using the generic output-sensitive algorithm of Tsukiyama et al. [47]), and thus find a maximum independent set.

While we currently do not know of a polynomial-time algorithm when $H$ is the 7-vertex path, Gartland and Lokshtanov [31] have obtained a quasipolynomial-time algorithm when $H$ is $P_t$, the $t$-vertex path, for any positive integer $t$; also see [42]. Supporting the existence of at least a quasipolynomial-time algorithm when $H$ is $S_{i,j,k}$, the claw whose three edges are subdivided $i-1$, $j-1$, and $k-1$ times, respectively, a quasipolynomial-time approximation scheme (QPTAS) [20] and a polynomial-time algorithm among bounded-degree graphs [2] have been proposed. The parameterized complexity of MIS when excluding a fixed induced subgraph has been studied [12, 13, 22], but the mere statement of which $H$ make the problem fixed-parameter tractable (and which ones keep it W[1]-complete) is unclear [13].

We eventually arrive at the *induced minor* containment, the topic of the current paper. As for minors, the class of all graphs excluding a non-planar graph $H$ as an induced minor contains all planar graphs; hence MIS remains NP-complete in such a class. However we do not know of a *planar* graph $H$, for which MIS remains NP-complete on $H$-induced-minor-free graphs. This has led Dallard, Milanič, and Štorgel [23] to ask if such classes exist:

▶ **Question 1.** *Is it true that for every planar graph $H$, Max Independent Set can be solved in polynomial time in the class of graphs excluding $H$ as an induced minor?*

A first observation is that avoiding $H$ as an induced minor implies avoiding it as an induced subgraph. Thus Question 1 is settled for $P_6$, $S_{1,1,2}$, and $tS_{1,1,1}$ (where $tG$ denotes the disjoint of $t$ copies of $G$). The same authors [23] further obtain a polynomial-time algorithm when $H$ is $K_5^-$ (the 5-vertex clique minus an edge), $K_{2,t}$ (the bipartite complete graph with 2 vertices fully adjacent to $t$ vertices), and $W_4 = K_1 + C_4$ (a 4-vertex cycle $C_4$ with a fifth vertex fully adjacent to the cycle). All three cases were shown by bounding the so-called *tree-independence number* (i.e., treewidth where *bag size* is replaced by *independence number of the subgraph induced by the bag*) [23], in which case a polynomial-time algorithm can be derived for MIS using the corresponding tree-decompositions [24]. They also show that this is as far as this sole technique can go: $H$-induced-minor-free graphs have bounded *tree-independence number* if and only if $H$ is edgeless or an induced minor of $K_5^-$, $K_{2,t}$, or $W_4$ [23]. The framework of *potential maximal cliques* [14] and the *container method* has led to a polynomial-time algorithm when $H = C_5$ [3, 19].

Question 1 is a beautiful question and, if true, a very difficult one. Indeed, $H = P_7$, the 7-vertex path, is a very simple planar graph for which we currently do not know such a polynomial-time algorithm. A natural relaxation of Question 1 is to only request a quasipolynomial-time algorithm:

▶ **Question 2.** *Is it true that for every planar graph $H$, Max Independent Set can be solved in quasipolynomial time in the class of graphs excluding $H$ as an induced minor?*

We know somewhat more about Question 2. There is a quasipolynomial-time algorithm for MIS in $C_t$-induced-minor-free graphs [32], building upon the $H = P_t$ case. Recently, Bonamy et al. [11] present a quasipolynomial-time algorithm when $H$ is $tC_3$, i.e., the disjoint union of $t$ triangles. See Table 1 for a summary of the introduction.

Expecting an affirmative solution to Question 1 or Question 2 may seem optimistic. However, as far as precise running time is concerned, we do know that for every planar $H$, MIS is probably not as difficult in $H$-induced-minor-free graphs as it is in general graphs.

**Table 1** The complexity of Max Independent Set when $H$ is excluded as one of the four main types of patterns. "$\neg tS_{t,t,t}$" means that $H$ is not a subgraph of $tS_{t,t,t}$ for any $t$. Our results are framed.

| $H$ exluded as | subgraph | minor | induced subgraph | **induced minor** |
|---|---|---|---|---|
| in P | $tS_{t,t,t}$ | planar | $P_6$, $S_{1,1,2}$, $tS_{1,1,1}$ | $K_5^-$, $K_{2,t}$, $W_4$, $C_5$, $\boxed{K_1+tK_2}$ |
| known in QP | – | – | $P_t$ $(t \geqslant 7)$ | $C_t$ $(t \geqslant 6)$, $\boxed{tC_3 \uplus C_4}$ |
| NP-c | $\neg tS_{t,t,t}$ | non-planar | $\neg tS_{t,t,t}$ | non-planar |
| open P / NP-c | – | – | $P_7$, ... | $P_7$, $C_6$, ... |
| open QP / NP-c | – | – | $S_{1,1,3}$, $S_{1,2,2}$ ... | $C_4 \uplus C_4$, ... |

Indeed, Korhonen [39] describes a $2^{O(n/\log^c n)}$-time algorithm, for some constant $c > 0$, to solve MIS on $n$-vertex graphs excluding a fixed planar graph $H$ as an induced minor. Assuming the Exponential-Time Hypothesis [36], such a running time is impossible in general graphs [37].

**Our results.** We make some progress regarding Questions 1 and 2. Our first contribution is, for every positive integer $t$, a polynomial-time algorithm when $H$ is the *friendship graph* $K_1 + tK_2$ (also called *Dutch windmill graph* or *fan*), i.e., $t$ independent edges universally linked to a $2t + 1$-st vertex:

▶ **Theorem 1.** *For every positive integer $t$, Max Independent Set can be solved in polynomial-time $n^{O(t^5)}$ in $n$-vertex $K_1 + tK_2$-induced-minor-free graphs.*

This extends Alekseev's result [7] for graphs excluding $tK_2$ as an induced subgraph, or equivalently, as an induced minor. We indeed use this result to first derive a polynomial-time algorithm in subgraphs of $K_1 + tK_2$-induced-minor-free graphs $G$ induced by vertices from a bounded number of breadth-first search (BFS) layers of $G$.

We then consider the connected components of our input graph $G$ when deprived of a subset $X$ of vertices inducing $tK_2$ and, subject to that property, maximizing the order of the largest connected component in $G - X$. We show that, due to this careful selection of $X$, every component $C$ of $G - X$ admits an efficiently constructible path-decomposition $\mathcal{P}$ with *bounded adhesion* (i.e., any two distinct bags have a bounded intersection), each bag of which is contained in a bounded number of consecutive BFS layers of $C$. Hence MIS can be solved efficiently within a bag, by our opening step (see previous paragraph). This part is quite technical, but mostly to justify the existence of $\mathcal{P}$. The algorithm itself remains simple.

Theorem 1 is then obtained by exhaustively finding $X$ and guessing its intersection $X'$ with a maximum independent set of $G$, and performing dynamic programming on the connected components of $G - X$, deprived of $N(X')$. The dynamic-programming table is filled via the efficient algorithm when handling an induced subgraph contained in few BFS layers.

Our second contribution is a quasipolynomial-time algorithm when $H$ is, $tC_3 \uplus C_4$, the disjoint union of $t$ triangles and a 4-vertex cycle:

▶ **Theorem 2.** *For every positive integer $t$, Max Independent Set can be solved in quasipolynomial-time $n^{O(t^2 \log n)+f(t)}$ (where $f$ is single-exponential) in $tC_3 \uplus C_4$-induced-minor-free graphs.*

We first perform a quasipolynomial branching rule to get rid of holes of size at most 6 (i.e., induced cycles of length 4, 5, or 6). We then assume that the input graph $G$ is not $(t+2)C_3$-induced-minor-free, for otherwise we conclude with Bonamy et al.'s algorithm [11]. Thus $G$, being $tC_3 \uplus C_4$-induced-minor-free, has to admit $(t+2)C_3$ as an induced subgraph, i.e., a collection $T_1, \dots, T_{t+2}$ of $t+2$ pairwise vertex-disjoint and non-adjacent triangles. We define $S_{i,j}$, minimally separating $T_i$ and $T_j$ in the graph $G$ deprived of the neighborhoods of the other triangles $T_k$ (with $k \neq i, j$).

We show that each $S_{i,j}$ induces a clique. So does every intersection $N_{i,j}$ of the neighborhood of two distinct triangles $T_i, T_j$ of the collection (this is where getting rid of the holes of length at most 6 comes into play). We can therefore exhaustively guess the intersection of a maximum independent set with the union of the sets $S_{i,j}$ and $N_{i,j}$ (for every $i < j \in [t+2]$). We finally observe that $G' = G - \bigcup_{i \neq j \in [t+2]} (S_{i,j} \cup N_{i,j})$ is chordal, since the presence of a hole $H$ in $G'$ would imply the existence in $G$ of $t$ independent triangles in the non-neighborhood of $H$, a contradiction to the $tC_3 \uplus C_4$-induced-minor-freeness of $G$. We thus conclude by using a classic algorithm for MIS in chordal graphs [33, 46].

In Section 2 we introduce the relevant graph-theoretic background. In Section 3 we prove Theorem 1, and in Section 4 we prove Theorem 2.

## 2 Preliminaries

If $i \leqslant j$ are two integers, we denote by $[i, j]$ the set of integers $\{i, i+1, \dots, j-1, j\}$, and by $[i]$, the set $[1, i]$. We denote by $V(G)$ and $E(G)$ the set of vertices and edges of a graph $G$, respectively. We denote by $G_1 \simeq G_2$ the fact that the two graphs $G_1$ and $G_2$ are *isomorphic*, i.e., equal up to renaming their vertex set. For $S \subseteq V(G)$, the *subgraph of $G$ induced by $S$*, denoted $G[S]$, is obtained by removing from $G$ all the vertices that are not in $S$ (together with their incident edges). Then $G - S$ is a short-hand for $G[V(G) \setminus S]$. A graph $H$ is an *induced subgraph* of $G$ if there is an $S \subseteq V(G)$ such that $G[S] \simeq H$.

For $G$ a graph and a set $X \subseteq V(G)$, $E_G(X)$ (or simply $E(X)$) is a short-hand for $E(G[X])$. For $G$ a graph and $X, Y \subseteq V(G)$ two disjoint sets, $E_G(X, Y)$ denotes the set of edges of $E(G)$ with one endpoint in $X$ and the other endpoint in $Y$. We denote by $N_G(v)$ and $N_G[v]$, the open, respectively closed, neighborhood of $v$ in $G$. For $S \subseteq V(G)$, we set $N_G(S) := \bigcup_{v \in S} N_G(v) \setminus S$ and $N_G[S] := N_G(S) \cup S$. We may omit the subscript if $G$ is clear from the context. A *connected component* is a maximal connected induced subgraph.

Two cycles $C, C'$ are said to be *independent* if they are vertex-disjoint and there is no edge between $C$ and $C'$. A collection of cycles is *independent* if they are pairwise independent. Two vertex subsets $X, Y \subseteq V(G)$ *touch* if $X \cap Y \neq \emptyset$ or there is an edge $uv \in E(G)$ with $u \in X$ and $v \in Y$. Then two (or more) cycles are independent if and only if they do *not* touch. We say that $X, Y \subseteq V(G)$ *touch in* $Z$ if $X \cap Y \cap Z \neq \emptyset$ or there is an edge $uv \in E(G)$ with $u \in X \cap Z$ and $v \in Y \cap Z$, or equivalently, if $X \cap Z$ and $Y \cap Z$ touch.

A graph $H$ is an *induced minor* of a graph $G$ if $H$ can be obtained from $G$ by a sequence of vertex deletions and edge contractions. A *minor* is the same but also allows edge deletions. Equivalently an induced minor $H$ –with vertex set, say, $\{v_1, \dots, v_{V(H)}\}$– of $G$ can be defined as a vertex-partition $B_1, \dots, B_{|V(H)|}$ of an induced subgraph of $G$, such that every $G[B_i]$ is connected and $v_i v_j \in E(H)$ if and only if $E_G(B_i, B_j) \neq \emptyset$ (i.e., when the disjoint sets $B_i$ and $B_j$ touch). Observe indeed that contracting each $B_i$ into a single vertex (which is possible since each $B_i$ induces a connected subgraph) results in $H$. A graph $G$ (resp. a graph class) is said to be *$H$-induced-minor-free* if $H$ is not an induced minor of $G$ (resp. no graph of the class admits $H$ as an induced minor).

We denote by $C_\ell$ the $\ell$-vertex cycle, and by $K_\ell$, the $\ell$-vertex complete graph. A *hole* is an induced cycle of length at least four. A graph is *chordal* if it has no hole. For two disjoint sets $X, Y \subseteq V(G)$ in a graph $G$, an $(X,Y)$-*separator* is a (possibly empty) set $S \subseteq V(G) \setminus (X \cup Y)$ such that there is no path between $X$ and $Y$ in $G - S$. An $(X,Y)$-separator is *minimal* if no proper subset of it is itself an $(X,Y)$-separator.

The *disjoint union* $G_1 \uplus G_2$ of two graphs $G_1, G_2$ has vertex set $V(G_1) \uplus V(G_2)$ and edge set $E(G_1) \uplus E(G_2)$, where $V(G_1) \uplus V(G_2)$ presupposes that the vertex sets of $G_1$ and $G_2$ are disjoint. If $t \geqslant 2$ is an integer and $G$ a graph, $tG$ is the graph $G \uplus (t-1)G$, and $1G$ is simply $G$. The *join* $G_1 + G_2$ of two graphs $G_1, G_2$ has vertex set $V(G_1) \uplus V(G_2)$ and edge set $E(G_1) \uplus E(G_2) \uplus \{uv \ : \ u \in V(G_1), v \in V(G_2)\}$. In other words, the join of $G_1$ and $G_2$ is obtained from their disjoint union by adding all possible edges between $G_1$ and $G_2$.

A *breadth-first search* (BFS) *layering* in $G$ from a vertex $v \in V(G)$ (or from a connected set $S \subseteq V(G)$) is a partition of the remaining vertices into $L_1, L_2, \ldots$ such that every vertex of $L_i$ is at distance exactly $i$ from $v$ (or from $S$). Such an $L_i$ is called a *BFS layer* of $G$ (from $v$, or from $S$). Note that there cannot be an edge in $G$ between $L_i$ and $L_j$ if $|i-j| > 1$.

A *path-decomposition* of a graph $G$ is a list of vertex subsets $\mathcal{P} = (B_1, \ldots, B_h)$ such that

- $\bigcup_{1 \leqslant i \leqslant h} B_i = V(G)$,
- for every $e \in E(G)$, there is some $B_i$ that contains both endpoints of $e$, and
- whenever $v \in B_i \cap B_j$ with $i < j$, $v$ is also in all $B_k$ with $i < k < j$.

The sets $B_i$ (for $i \in [h]$) are called the *bags* of $\mathcal{P}$, and the sets $B_i \cap B_{i+1}$ (for $i \in [h-1]$) the *adhesions* of $\mathcal{P}$. Path-decomposition $\mathcal{P}$ has maximum adhesion $p$ if all of its adhesions have size at most $p$. Note that the adhesion $B_i \cap B_{i+1}$, if disjoint from $B_1 \cup B_h$, is a vertex cutset disconnecting $B_1$ from $B_h$.

## 3 Polynomial algorithm in $K_1 + tK_2$-induced-minor-free graphs

We first show how to solve Max Independent Set in $K_1 + tK_2$-induced-minor-free graphs of bounded diameter. More generally, we show the following.

▶ **Lemma 3.** *Let $t, h$ be fixed non-negative integers. Let $G$ be a $K_1 + tK_2$-induced-minor-free $n$-vertex graph, and $L_0 \subseteq V(G)$ such that $G[L_0]$ is connected. Let $L_i$, for any $i \in [h]$, be the subset of vertices of $G$ at distance exactly $i$ of $L_0$. Then, given as input $G$, $L_0$, and $S \subseteq \bigcup_{1 \leqslant i \leqslant h} L_i$, a maximum independent set of $H := G[S]$ can be computed in polynomial time $n^{(2t-1)h+O(1)}$.*

**Proof.** For every $j \in [h]$, $G[L_j]$ has no $tK_2$ induced subgraph (or equivalently, induced minor). Indeed, $G[\bigcup_{0 \leqslant i \leqslant j-1} L_i]$ is a connected graph, hence $\bigcup_{0 \leqslant i \leqslant j-1} L_i$ can be contracted to a single vertex, and every vertex in $L_j$ has at least one neighbor in $L_{j-1}$. Therefore a $tK_2$ induced subgraph in $G[L_j]$ would contradict the $K_1 + tK_2$-induced-minor-freeness of $G$.

Fix an arbitrary $S \subseteq \bigcup_{1 \leqslant i \leqslant h} L_i$, and consider the induced subgraph $H := G[S]$. In particular $H[L_j \cap S]$ has also no $tK_2$ induced subgraph, for every $j \in [h]$. Hence, by a classical result of Alekseev [7], $H[L_j \cap S]$ has at most $n^{2t-1}$ maximal independent sets, which can be listed in time $n^{2t+O(1)}$ [47].

We thus exhaustively list every $h$-tuple $(I_1, \ldots, I_h)$ where, for every $j \in [h]$, $I_j$ is a maximal independent set of $H[L_j \cap S]$, in time $n^{(2t-1)h+O(1)}$. Note that if there is an edge in $H$ between $L_i$ and $L_j$, then $|i-j| \leqslant 1$. As each $I_j$ (for $j \in [h]$) is an independent set, $H' = H[\bigcup_{j \in [h]} I_j]$ is a bipartite graph as witnessed by the bipartition $(I_1 \cup I_3 \cup \ldots, I_2 \cup I_4 \cup \ldots)$. A maximum independent set $I$ can thus be computed in polynomial time in $H'$. Indeed, by the Kőnig-Egerváry theorem [38], finding a maximum independent set in a bipartite graph boils down

to finding a maximum matching, which can be done in polynomial time (and now, even in almost linear time [18]) by solving a maximum flow problem. We output the largest independent set $I$ found among every run.

The correctness of the algorithm is based on the observation that a maximum independent set $I^\star$ of $H$ intersects every $L_i$ (for $i \in [h]$) in an independent set $J_i$, which by definition is contained in a maximal independent set $I_i$ of $H[L_i \cap S]$. In the run when every maximal independent set $I_i$ is a superset of $J_i$, we obtain an independent set with cardinality equal to that of $I^\star$. ◀

We say that $G$ is *reduced* if it does not contain degree-1 vertices. If $e = uv$ is an edge of $G$, let $G \setminus e$ (resp. $S \setminus e$, $S \cup e$, for some $S \subseteq V(G)$) be the induced subgraph $G[V(G) - \{u, v\}] = G - \{u, v\}$ (resp. the sets $S \setminus \{u, v\}$, $S \cup \{u, v\}$). More generally, for a collection $e_1 = u_1v_1, \ldots, e_k = u_kv_k$ of edges of $G$, we denote by $G \setminus \{e_1, \ldots, e_k\}$ the induced subgraph $G[V(G) - \{u_1, v_1, \ldots, u_k, v_k\}] = G - \{u_1, v_1, \ldots, u_k, v_k\}$.

▶ **Lemma 4.** *Let $G$ be a reduced connected $K_1 + tK_2$-induced-minor-free graph containing $tK_2$ as an induced subgraph. Let $X \subseteq V(G)$ maximize the order of a largest component of $G' := G - X$, among those sets $X$ such that $G[X] \simeq tK_2$. Then for any $e \in E(G' - N_G(X))$ contained in a connected component $C$ of $G'$,*

1. *$C \setminus e$ is disconnected, and*
2. *each connected component of $C \setminus e$ contains a vertex in $N_G(X)$.*

**Proof.** As $G$ is reduced, every vertex of $X$ has degree at least two (in $G$). Thus $G'$ cannot be connected, for otherwise, contracting in $G$ the set $V(G')$ to a single vertex would form a $K_1 + tK_2$ induced minor. We thus know that $G'$ has at least two connected components.

Let $C'$ be a largest connected component of $G'$. Since $G$ is connected, there exists a shortest path $P$ in $G$ from $V(C')$ to $V(G') \setminus V(C')$. Say, that $P$ ends in the connected component $C \neq C'$ of $G'$. Path $P$ has to have some internal vertices in $X$, but since $G[X] \simeq tK_2$, it follows that there is an edge $e^*$ in $E(X)$ (but not necessarily in $P$) intersecting both $N_G(V(C))$ and $N_G(V(C'))$.

For every edge $e \in E(G' - N_G(X))$ in component $C$ (which is possibly equal to $C'$), $C \setminus e$ is disconnected. Indeed, for the sake of contradiction, suppose that $C \setminus e$ is connected, and consider $X' := (X \setminus e^*) \cup e$. By assumption, $G[X'] \simeq tK_2$. Furthermore, the connected component of $G - X'$ containing $e^*$ is strictly larger than $C'$, as it contains $(V(C') \setminus e) \cup e^*$ and intersects $V(C) \setminus e$, which are two disjoint sets. This contradicts the maximality of $X$, and establishes the first item.

We now prove the second item, also by contradiction. Suppose that there is a connected component $D$ of $C \setminus e$ that does not contain a vertex in $N_G(X)$. We will reach a contradiction by showing that $D$ contains an edge $e'$ not intersecting $N_G(X)$, and such that $D \setminus e'$ is connected (and conclude in light of the previous paragraph).

Let $L_i \subseteq V(D)$ be the *$i$-th neighborhood of $e$* in $D$, i.e., the vertices at distance $i$ of one endpoint of $e$, and at least $i$ of the other endpoint. We consider the *last layer* $L_k$, i.e., such that $L_k \neq \emptyset$ and $L_{k+1} = \emptyset$. If $L_k$ contains an edge $e'$, then removing the endpoints of this edge does not disconnect $D$ (and hence $C$) since each vertex in $L_k$ has a neighbor in $L_{k-1}$ (with the convention that $L_0$ consists of the endpoints of $e$) and $G[L_0 \cup L_1 \cup \cdots \cup L_{k-1}]$ is connected.

If $L_k$ does not contain an edge, then each vertex in $L_k$ has two neighbors in $L_{k-1}$. This is because $G$ is reduced, and by assumption that no vertex of $D$ has a neighbor in $X$. Hence, removing the endpoints of any edge $e'$ incident to a vertex in $L_k$ does not disconnect $D$ (nor $C$), since each vertex in $L_k$ has at least one neighbor in $L_{k-1}$ which is not an endpoint of $e'$. In either case, $e'$ is an edge of $C - N_G(X)$ that does not disconnect $C$, which we showed is not possible. ◀

We now prove the main technical result of the section.

▶ **Proposition 5.** *Let $G$ be a reduced connected $n$-vertex $K_1 + tK_2$-induced-minor-free graph containing $tK_2$ as an induced subgraph. Let $X \subseteq V(G)$ maximize the order of a largest component of $G' := G - X$, among those sets $X$ such that $G[X] \simeq tK_2$. Then for every connected component $C$ of $G'$, a path-decomposition $\mathcal{P}$ of $C$ such that*

- *every bag of $\mathcal{P}$ is contained in $O(t^4)$ consecutive BFS layers of $C$, and*
- *every adhesion of $\mathcal{P}$ is of size at most $2t^2$,*

*can be computed in time $n^{O(1)}$.*

**Proof.** Let $v$ be a vertex in $N_G(X) \cap V(C)$ and, for any positive integer $s$, let $L_s$ be the set of vertices at distance $s$ from $v$ in $C$. Let $q$ be the largest distance between $v$ and a vertex of $C$. We set $f(t) := (t^2+1)(6t^2+2) = O(t^4)$. We will show that, for every $s \in [q - f(t)]$, there is a vertex cutset of size at most $2t^2$ separating $L_s$ from $L_{s+f(t)-1}$, and use that fact for $s = 1, f(t)+1, 2f(t)+1, \ldots$ to build the path-decomposition $\mathcal{P}$.

We show that any sufficiently long induced path (such as a shortest path from $L_s$ to $L_{s+f(t)-1}$) has some edges with both endpoints in $V(C) \setminus N_G(X)$.

▷ Claim 6. Any induced path $P$ in $C$ contains less than $3t^2$ vertices in $N_G(X)$.

Proof. If there are $3t^2$ vertices on $P$ with a neighbor in $X$, then there are at least $3t$ vertices $w_1, \ldots, w_{3t}$ on $P$ that are neighbors of a fixed edge $e \in E(X)$. For each $i \in [t]$, contract every edge of $P$ between $w_{3i-2}$ and $w_{3i-1}$ but one, say $e_i$. Contract $e$, and call $z$ the resulting vertex. The vertex $z$ and the $t$ edges $e_i$ contradict the fact that $G$ is $K_1 + tK_2$-induced-minor-free. ◁

For an edge $e \in E(C)$ we denote by $\mathrm{dist}(e, v)$ the length of a shortest path in $C$ from an endpoint of $e$ to $v$. We build a collection of paths $Q_i$ of $C$, and edges $e_i \in E(Q_i)$, for $i = 1, 2, \ldots$, while they are well-defined, in the following way.

Let $s \in [q - f(t)]$ and $Q_1$ be a shortest path from $L_s$ to $L_{s+f(t)-1}$ in $C$. Let $e_1 \in E(Q_1)$ minimize $e \mapsto \mathrm{dist}(e, v)$, among those edges of $Q_1$ with both endpoints in $V(C) \setminus N_G(X)$. By Claim 6 there are less than $6t^2$ edges on $Q_1$ with an endpoint in $N_G(X)$, hence $\mathrm{dist}(e_1, v) \leqslant s + 6t^2$. We denote by $Q_1'$ the maximal subpath of $Q_1$ starting in $L_s$ and not containing an endpoint of $e_1$ (that is, stopping just before reaching an endpoint of $e_1$). Note that $Q_1$ is possibly empty. For the next iteration, we work in $C \setminus e_1$ (recall that this stands for $C$ deprived of the two endpoints of $e_1$).

We now describe in general the $i$-th iteration for $i \geqslant 2$. Let $Q_i$ be a shortest path from $L_s$ to $L_{s+f(t)-1}$ in $C \setminus \{e_1, e_2, \ldots, e_{i-1}\}$. Let $e_i$ be the first edge of $Q_i$ (when starting from $L_s$) such that $\mathrm{dist}(e_i, v) \geqslant \mathrm{dist}(e_{i-1}, v) + 2$ and $e_i$ has no endpoint in $N_G(X)$. Note that by Claim 6, $\mathrm{dist}(e_i, v) \leqslant \mathrm{dist}(e_{i-1}, v) + 2 + 6t^2$. Let $Q_i'$ be the maximal subpath of $Q_i$ starting in $L_s$ and not containing an endpoint of $e_i$. See Figure 1.

Let $e_1, \ldots, e_k$ be the obtained collection of edges. In principle, the while loop stops when one of the following two conditions holds:

- **(i)** $L_s$ is disconnected from $L_{s+f(t)-1}$ in $C \setminus \{e_1, \ldots, e_k\}$, or
- **(ii)** there is no edge $e_{k+1} \in E(Q_{k+1})$ such that $\mathrm{dist}(e_{k+1}, v) \geqslant \mathrm{dist}(e_k, v) + 2$ and $e_{k+1}$ has no endpoint in $N_G(X)$.

▷ Claim 7. If case $(ii)$ holds, then $k > t^2$.

Proof. Remark first that for any $i$ we have $\mathrm{dist}(e_i, v) \leqslant s + i(6t^2+2) - 2$. Next, we claim that as long as $\mathrm{dist}(e_i, v) + 2 + 6t^2 \leqslant s + f(t) - 1$, and case $(i)$ does not occur, the construction of $e_{i+1}$ can not fail, since $Q_{i+1}$ exists, and there are at least $6t^2$ edges $e$ in $Q_{i+1}$ satisfying $\mathrm{dist}(e, v) \geqslant \mathrm{dist}(e_i, v)$. Thus if case $(ii)$ occurs, it must be that $(k+1)(6t^2+2) - 2 > f(t) - 1$, hence $k > t^2$ since $f(t) = (t^2+1)(6t^2+2)$. ◁

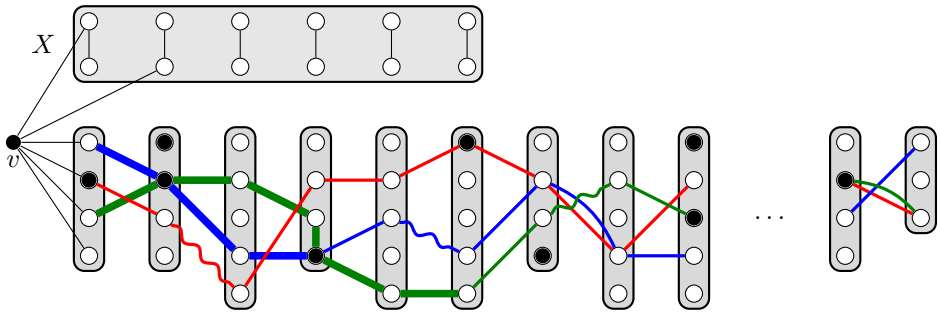

**Figure 1** Illustration of $X$ (for $t = 6$) and the first (i.e., with $s = 1$) $f(t)$ layers (from left to right) of the connected component $C$ of $G - X$ rooted at $v$. Vertices of $C$ with a neighbor in $X$ are filled. We represented the first three iterations: $Q_1, e_1$ (in red), $Q_2, e_2$ (in blue), $Q_3, e_3$ (in dark green). Not to clutter the figure, we do not represent all the edges, and we code the different labels: edges $e_i$ are squiggly, and subpaths $Q'_i$ are thicker.

▷ Claim 8. It holds that $k \leqslant t^2$.

Proof. Assume for the sake of contradiction that $k \geqslant t^2 + 1$. By Lemma 4 (using both items), for each $i \in [k]$ there exists a vertex $v_i \in V(C) \cap N_G(X)$ disconnected from $v$ in $C \setminus e_i$. Since $k \geqslant t^2 + 1$, there are $t + 1$ vertices $v_{a_1}, \ldots, v_{a_{t+1}}$, with $a_1 < a_2 < \ldots < a_t$, all adjacent to an endpoint of the same fixed edge $e \in E(X)$. Let $C'$ be the component containing $v$ in $C \setminus \{e_{a_1}, \ldots, e_{a_t}\}$, and let us contract (in $G$) the set $V(C')$ to a single vertex, say $w$. We will now show that vertex $w$ is adjacent to an endpoint of $e$.

By construction, the edge $e_{a_{t+1}}$ is reachable from $v$ in $C \setminus \{e_{a_1}, e_{a_2}, \ldots, e_{a_t}\}$, hence $e_{a_{t+1}} \in E(C')$. Let $P'$ be a path in $C'$ from $v$ to an endpoint of $e_{a_{t+1}}$. Every path in $C$ from $v$ to $v_{a_{t+1}}$ goes through at least one endpoint of $e_{a_{t+1}}$, by definition of $v_{a_{t+1}}$. Let us consider a shortest path in $C$ from $v$ to $v_{a_{t+1}}$, i.e., intersecting each layer at most once. Consider a suffix $P''$ of this path starting at an endpoint of $e_{a_{t+1}}$ and ending at $v_{a_{t+1}}$. By the previous remark, $P''$ cannot contain an edge among $\{e_{a_1}, e_{a_2}, \ldots, e_{a_t}\}$, since these edges are in layers with strictly smaller indices than the endpoints of $e_{a_{t+1}}$. Thus $P' \cup P''$ (possibly combined with $e_{a_{t+1}}$) connects $v$ to $v_{a_{t+1}}$ in $C \setminus \{e_{a_1}, e_{a_2}, \ldots, e_{a_t}\}$. Therefore, the contracted vertex $w$ *contains* $v_{a_{t+1}}$; the latter being adjacent to an endpoint $e$.

Observe also that, for every $i \in [t]$, each subpath $Q'_{a_i}$ is contained in $C'$. Vertex $w$ is adjacent to an endpoint $u_{a_i}$ of $e_{a_i}$, for every $i \in [t]$. Let $C_{a_i}$ be the vertex set of the connected component of $C \setminus e_{a_i}$ containing $v_{a_i}$. Let $R_{a_i}$ be a path from $u_{a_i}$ to $v_{a_i}$ in the subgraph of $G$ induced by $C_{a_i}$ plus the endpoints of $e_{a_i}$. For each $i \in [t]$, if $R_{a_i}$ has at least two edges, contract the edge $wu_{a_i}$, and all the edges of $R_{a_i}$ but the last two; the last one being $f_{a_i} = y_{a_i} v_{a_i}$. Finally contract $e$, and the edge between $e$ and $w$. We call the resulting vertex $z$.

We claim that $z$ and the edges $f_{a_i}$ make a $K_1 + tK_2$ induced minor in $G$. One can see that $z$ is adjacent to $v_{a_i}$ via $e \in E(X)$, and to $y_{a_i}$ via $w$ and the path $R_{a_i}$. We shall justify that the edges $f_{a_i}$ form an induced matching in $G$. Indeed, suppose some $f_{a_i}$ and $f_{a_j}$ touch with $i \neq j \in [t]$. Then in $C \setminus e_{a_i}$, there is a path from $v$ to $v_{a_i}$ via $Q'_j$, a contradiction. ◁

By Claims 7 and 8, case (*ii*) is impossible, and the $2k \leqslant 2t^2$ endpoints of $e_1, \ldots, e_k$ form a vertex cutset disconnecting $L_s$ from $L_{s+f(t)-1}$. We can now build the path-decomposition $\mathcal{P}$. Recall that the BFS search from $v$ gives rise to $q$ layers, $L_1, \ldots, L_q$ (outside $\{v\}$).

For $j \in [\lfloor q/f(t) \rfloor]$, let $S_j$ be the vertex cutset of size at most $2t^2$ (and obtained as detailed above) disconnecting $L_{(j-1)f(t)+1}$ from $L_{jf(t)}$. We denote by $L_{s \to s'}$ the set $\bigcup_{s \leqslant h \leqslant s'} L_h$.

- Let $B_1 \subseteq V(C)$ consist of $v$, $S_1$, plus all the vertices of connected components of $C[L_{1\to f(t)}] - S_1$ that do not intersect $L_{f(t)}$.
- For $j$ going from 2 to $\lfloor q/f(t) \rfloor - 1$, let $B_j \subseteq V(C)$ consist of $S_j \cup S_{j+1}$ plus the vertices not already present in one of $B_1, \ldots, B_{j-1}$ of all the connected components of

$$C[L_{(j-1)f(t)+1\to(j+1)f(t)}] - (S_j \cup S_{j+1})$$

  that do not intersect $L_{(j+1)f(t)}$.
- Let finally $B_{\lfloor q/f(t)\rfloor} \subseteq V(C)$ consist of $S_{\lfloor q/f(t)\rfloor}$ plus the vertices of all the connected components of $C[L_{(\lfloor q/f(t)\rfloor-1)f(t)+1\to q}] - S_{\lfloor q/f(t)\rfloor}$ that intersect $L_q$.

Let $\mathcal{P}$ be the path-decomposition $(B_1, B_2, \ldots, B_{\lfloor q/f(t)\rfloor})$. $\mathcal{P}$ is indeed a path-decomposition of $C$, since our process entirely covers $V(C)$, and by virtue of $S_j$ separating $L_{(j-1)f(t)+1}$ from $L_{jf(t)}$. By construction,

- every bag intersects at most $2f(t) = O(t^4)$ layers of BFS from vertex $v$, and
- for every $j \in [\lfloor q/f(t)\rfloor - 1]$, $B_j \cap B_{j+1} = S_j$, so every adhesion has size at most $2t^2$.

Finally note that once $X$ is found, one can find the path-decomposition $\mathcal{P}$ of $C$ in time $n^{O(1)}$, since this only involves computing (at most $n$) shortest paths. ◀

We can now wrap up, using Proposition 5 and Lemma 3.

▶ **Theorem 1.** *For every positive integer $t$, Max Independent Set can be solved in polynomial-time $n^{O(t^5)}$ in $n$-vertex $K_1 + tK_2$-induced-minor-free graphs.*

**Proof.** Let $G$ be our $K_1 + tK_2$-induced-minor-free $n$-vertex input graph. As including vertices of degree 1 in the independent set is a safe reduction rule, we can assume that $G$ is reduced. By dealing with the possibly several connected components of $G$ separately, we can further assume that $G$ is connected. If $G$ has no $tK_2$ as an induced subgraph, we conclude by invoking Alekseev's result [7, 47]. Thus we also assume that $G$ has such an induced subgraph. In time $n^{O(t)}$ we find $X \subseteq V(G)$ that maximizes the order of a largest component of $G' := G - X$, among those sets $X$ such that $G[X] \simeq tK_2$.

We exhaustively guess the intersection $X'$ of a fixed maximum independent set of $G$ with the set $X$, with an extra multiplicative factor of $2^{2t}$. We are now left with solving MIS separately in $C' := C - N_G(X')$ for each connected component $C$ of $G'$. By Proposition 5, we obtain in time $n^{O(1)}$ a path-decomposition $\mathcal{P} = (B_1, \ldots, B_p)$ of $C'$, such that

- every $B_i$ (for $i \in [p]$) is contained in $O(t^4)$ consecutive BFS layers *of* $C$, and
- every adhesion $A_i := B_i \cap B_{i+1}$ (for $i \in [p-1]$) is of size at most $2t^2$.

Indeed, removing $N_G(X')$ from $C$ (and its path-decomposition) preserves those properties.

Let us define $A_0, A_p$ to be empty. We proceed to the following dynamic programming. For $i \in [0, p]$, and for any $S \subseteq A_i$, $T[i, S]$ is meant to eventually contain an independent set $I$ of $C'[\bigcup_{1\leqslant j\leqslant i} B_j]$ of maximum cardinality among those such that $I \cap B_i = S$. We set $T[0, \emptyset] = \emptyset$, and observe that it is the only entry of the form $T[0, \cdot]$.

We fill this table by increasing value of $i = 1, 2, \ldots, p$. Assume that all entries of the form $T[i', \cdot]$ are properly filled for $i' < i$. For every $S \subseteq A_i$, $T[i, S]$ is filled in the following way. For every $S' \subseteq A_{i-1}$, if $S \cup S'$ is an independent set, we compute, by Lemma 3 (with $L_1, \ldots, L_h$ being the $O(t^4)$ consecutive BFS layers *of* $C$ containing $B_i$, and $L_0$ being the connected set, *in* $C$, formed by the union of all the previous layers), a maximum independent set $I_i$ in $C'[B_i] - N[S \cup S']$ in time $n^{O(ht)} = n^{O(t^5)}$. We finally set $T[i, S] = T[i-1, S'] \cup I_i \cup S$ for a run that maximizes the cardinality of $T[i-1, S'] \cup I_i$.

It takes time $p \cdot 2^{O(t^2)} \cdot n^{O(t^5)} = n^{O(t^5)}$ to completely fill $T$. Eventually $T[p, \emptyset]$ contains a maximum independent set of $C'$. We return the union of $X'$ and of the maximum independent sets of $C'$ found for each connected component $C$ of $G'$. The overall running time is $n^{O(t^5)}$. ◀

## 4 Quasipolynomial algorithm in $tC_3 \uplus C_4$-induced-minor-free graphs

We first show that the existence of a short hole allows for a quasipolynomial-time branching rule in $tC_3 \uplus C_4$-induced-minor-free graphs. By branching rule, we mean here a Turing reduction to (quasipolynomially many) subinstances with no short holes.

▶ **Lemma 9.** *Let $G$ be an $n$-vertex $tC_3 \uplus C_4$-induced-minor-free graph, and let $\ell \geqslant 4$ be a fixed integer. While there is a hole $H$ of length at most $\ell$ and a $tC_3$ as an induced subgraph in $G$, Max Independent Set admits a quasipolynomial branching rule, running in $n^{O_\ell(t \log n)}$.*

**Proof.** Let $C(G) := \{X \in \binom{V(G)}{3t} : G[X] \simeq tC_3\}$ be the collection of vertex subsets inducing $t$ disjoint triangles, and assume $\mu(G) := |C(G)| > 0$, and $H$ is a hole of $G$ of length at most $\ell$. As $G$ is $tC_3 \uplus C_4$-induced-minor-free, $N[V(H)]$ intersects every $X \in C(G)$. In particular, there is a vertex $v \in V(H)$ such that $N[v]$ intersects at least a $1/\ell$ fraction of the $X \in C(G)$.

We branch on two options: either we take $v$ in an (initially empty) solution, and remove its closed neighborhood from $G$, or we remove $v$ from $G$ (without adding it to the solution). With the former choice, the measure $\mu$ drops by at least a $1/\ell$ fraction (and the number of vertices of $G$ decreases by at least 1), and with the latter choice, the number of vertices drops by 1. This branching is exhaustive. We simply need to argue about its running time.

Note that each option can be done at most $n$ times, while the first option cannot be done more than $\log_\ell(n^{3t}) = O_\ell(t \log n)$ times. Hence the branching tree has at most $\binom{n}{\log_\ell(n^{3t})} = n^{O_\ell(t \log n)}$ leaves. ◀

The previous lemma permits us to get rid of short holes, which turns out useful in some corner case.

▶ **Theorem 2.** *For every positive integer $t$, Max Independent Set can be solved in quasipolynomial-time $n^{O(t^2 \log n)+f(t)}$ (where $f$ is single-exponential) in $tC_3 \uplus C_4$-induced-minor-free graphs.*

**Proof.** We apply the quasipolynomial branching rule of Lemma 9 with $\ell = 6$, until the input $n$-vertex graph $G$ no longer has holes of length at most 6, or $tC_3$ induced subgraph.

In time $n^{O(t)}$, we exhaustively look for a collection of pairwise vertex-disjoint and non-adjacent triangles $T_1, T_2, \ldots, T_{t+2}$ in $G$. If such a collection does not exist, $G$ is $(t+2)C_3$-induced-minor-free. Indeed, the absence of $(t+2)C_3$ as an induced subgraph implies that at least one of the $(t+2)$ independent cycles realizing a $(t+2)C_3$ induced minor is of length at least four. This is ruled out by the assumption that $G$ is $tC_3 \uplus C_4$-induced-minor-free. (Note here that only $(t+1)$ independent cycles would suffice.)

We can thus assume that a collection $T_1, T_2, \ldots, T_{t+2}$ exists, for otherwise, we can conclude with the quasipolynomial-time algorithm, running in $n^{O(t^2 \log n)+f(t)}$ (where $f$ is single-exponential), of Bonamy et al. [11] for Max Independent Set in graphs with a bounded number of independent cycles (here, $(t+2)C_3$-induced-minor-free). In turn, as $G$ contains $tC_3$ (even $(t+2)C_3$) as in induced subgraph, we can, in light of the first paragraph, further assume that all the cycles of $G$ have length either 3 or at least 7. We refer the reader to Figure 2 for a visual summary of the next two paragraphs.

For every pair $T_i, T_j$ (with $i < j \in [t+2]$), consider the subgraph $G_{i,j} := G - \bigcup_{k \in [t+2] \setminus \{i,j\}} N(T_k)$. We claim that $G_{i,j}$ is chordal. Indeed, since $G_{i,j}$ is disjoint from the neighborhood of $\bigcup_{k \in [t+2] \setminus \{i,j\}} T_k$, a hole $H$ in $G$ would form a $tC_3 \uplus C_4$-induced-minor together with $\{T_k : k \in [t+2] \setminus \{i,j\}\}$. Let now $S_{i,j}$ be a minimal $(T_i, T_j)$-separator in $G_{i,j}$. A classical argument then shows that $S_{i,j}$ is a clique: suppose for the sake of contradiction that $u, v \in S_{i,j}$ are distinct and non-adjacent. Let $X_i, X_j$ be the two components of $G_{i,j} - S_{i,j}$

containing $T_i, T_j$. By minimality of $S_{i,j}$, each of $u, v$ is adjacent to both $X_i$ and $X_j$. Thus we can find two induced $uv$-paths, whose internal vertices are in $X_i$ and $X_j$ respectively. The union of these paths is a hole $H$ in $G_{i,j}$.

Let $N_{i,j}$ be the set $N(T_i) \cap N(T_j)$ for each pair $i < j \in [t+2]$. Observe that the sets $N_{i,j}$ need not be disjoint, and that when $T_i$ and $T_j$ are at distance at least 3 apart, $N_{i,j}$ is empty. We notice that $N_{i,j}$ is a clique, for otherwise we can exhibit an induced cycle of length 4, 5, or 6 in $G$ (hence a hole of length at most 6).

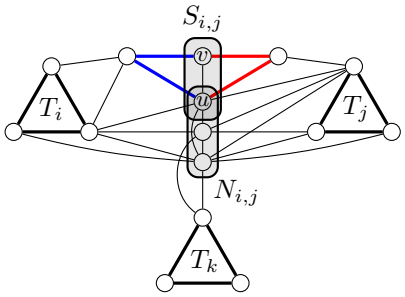

**Figure 2** Illustration of the sets $S_{i,j}$ and $N_{i,j}$, and the two $uv$-paths through the two components, in red and blue. If $uv$ were a non-edge, these paths would form a hole in the non-neighborhood of the other triangles $T_k$, contradicting $tC_3 \uplus C_4$-minor-freeness. The absence of hole of length at most 6 implies that $N_{i,j}$ is also a clique.

We claim that $G' := G - (\bigcup_{i<j\in[t+2]} S_{i,j} \cup N_{i,j})$ is chordal. Indeed assume there is a hole $H'$ in $G'$. The $tC_3 \uplus C_4$-induced-minor-freeness implies that $H'$ intersects at least two sets $N[T_i]$ and $N[T_j]$. Thus there exists a subpath $P$ of $H'$ whose endpoints are in two distinct $N(T_i)$ and $N(T_j)$. By choosing $P$ minimal, we can furthermore assume that no internal vertex of $P$ lies in some $N[T_k]$ with $k \notin \{i, j\}$. Since $G'$ does not include any vertex of $\bigcup_{i'<j'\in[t+2]} N_{i',j'}$, the endpoints of $P$ are not in some $N[T_k]$ with $k \notin \{i, j\}$ either. Therefore, the path $P$ contradicts that $S_{i,j}$ separates $T_i$ and $T_j$ in $G - \bigcup_{k\in[t+2]\setminus\{i,j\}} N(T_k)$.

We can now describe the rest of the algorithm after the collection $T_1, T_2, \ldots, T_{t+2}$ is found. We greedily compute the minimal separators $S_{i,j}$. We exhaustively try every subset $S \subseteq \bigcup_{i<j\in[t+2]} S_{i,j} \cup N_{i,j}$ that is an independent set. Such a set $S$ contains at most one vertex in each $S_{i,j}$ and each $N_{i,j}$, as we have established that each $S_{i,j}$ and each $N_{i,j}$ form a clique. Hence there are $n^{O(t^2)}$ such sets $S$. For each $S$, we compute a maximum independent set $I$ in the *chordal* graph $G - (N[S] \cup \bigcup_{i<j\in[t+2]} S_{i,j} \cup N_{i,j})$ in linear time (see [33, 46]). We finally output the set $S \cup I$ maximizing $|S \cup I|$. Note that the overall running time is $n^{O(t^2 \log n)+f(t)}$. ◀

## 5 Conclusion

We provided a polynomial-time algorithm for Maximum Independent Set on graphs excluding the friendship graph as an induced minor and a quasipolynomial-time algorithm on graphs excluding a disjoint union of $t$ triangles and a 4-cycle as an induced minor. As mentioned in the introduction, it is of interest to study on which other classes of graphs exluding some fixed planar graph $H$ as an induced minor MIS can be solved in (quasi)polynomial-time. If $H$ is a subgraph of the friendship graph or of the wheel, some of our methods developed for $K_1 + tK_2$ might extend.

For disjoint unions of cycles, the first open case is when $H$ is $C_4 \uplus C_4$. Our treatment for $H = tC_3 \uplus C_4$ does not (easily) extend to this case. It is thus likely that new methods have to be found. Obtaining a quasipolynomial-time algorithm when $H = tC_t$ for any integer $t$ is a first challenging milestone in the study of MIS on $H$-induced-minor-free graphs.

## Abstract

We revisit the classic 0-1-Knapsack problem, in which we are given $n$ items with their weights and profits as well as a weight budget $W$, and the goal is to find a subset of items of total weight at most $W$ that maximizes the total profit. We study pseudopolynomial-time algorithms parameterized by the largest profit of any item $p_{\max}$, and the largest weight of any item $w_{\max}$. Our main result are algorithms for 0-1-Knapsack running in time $\widetilde{O}(nw_{\max}p_{\max}^{2/3})$ and $\widetilde{O}(np_{\max}w_{\max}^{2/3})$, improving upon an algorithm in time $O(np_{\max}w_{\max})$ by Pisinger [J. Algorithms '99]. In the regime $p_{\max} \approx w_{\max} \approx n$ (and $W \approx \mathrm{OPT} \approx n^2$) our algorithms are the first to break the cubic barrier $n^3$.

To obtain our result, we give an efficient algorithm to compute the min-plus convolution of *near-convex* functions. More precisely, we say that a function $f\colon [n] \mapsto \mathbf{Z}$ is $\Delta$-near convex with $\Delta \geq 1$, if there is a convex function $\breve{f}$ such that $\breve{f}(i) \leq f(i) \leq \breve{f}(i) + \Delta$ for every $i$. We design an algorithm computing the min-plus convolution of two $\Delta$-near convex functions in time $\widetilde{O}(n\Delta)$. This tool can replace the usage of the *prediction technique* of Bateni, Hajiaghayi, Seddighin and Stein [STOC '18] in all applications we are aware of, and we believe it has wider applicability.

## 1 Introduction

In the 0-1-Knapsack problem, we are given a set of $n$ items $\mathcal{I} = \{ (p_1, w_1), \dots, (p_n, w_n) \}$, where item $i$ has a profit $p_i \in \mathbf{N}$ and a weight $w_i \in \mathbf{N}$, as well as a weight budget $W \in \mathbf{N}$. The goal is to compute $\mathrm{OPT} := \max \sum_{i=1}^n p_i x_i$ subject to the contraints $\sum_{i=1}^n w_i x_i \leq W$ and $x \in \{0,1\}^n$. This classic and fundamental problem in computer science and operations research has been studied for decades (see e.g. [29] for a book on the topic and related problems). Knapsack is weakly NP-hard, and the textbook dynamic programming algorithm due to Bellman [5] solves it in time $O(n \cdot \min\{W, \mathrm{OPT}\})$.

Recent works have studied the fine-grained complexity of Knapsack and related problems, where the goal is to give best-possible pseudopolynomial-time algorithms with respect to different parameters, see Table 1 and [7, 27, 12, 2, 15, 22, 30, 23, 26]. In this work we study the complexity of 0-1-Knapsack in terms of two natural parameters: the largest weight among the items denoted by $w_{\max}$, and the largest profit denoted by $p_{\max}$. Note that we can assume

without loss of generality that $w_{\max} \leq W$ and $p_{\max} \leq \mathrm{OPT}$. Therefore, a small polynomial dependence on these parameters can lead to faster algorithms compared to the standard dynamic programming algorithm on certain instances.

This parameterization has been studied by several previous works, see Table 1. To compare these running times, note that since any feasible solution includes at most all items, we can assume without loss of generality that $W \leq nw_{\max}$ and $\mathrm{OPT} \leq np_{\max}$. Note that when $p_{\max} \approx w_{\max} \approx n$ (and $W \approx \mathrm{OPT} \approx n^2$), all known algorithms require time $\Omega(n^3)$. In particular, in this regime the algorithm in time $O(nw_{\max}p_{\max})$ of Pisinger from '99 [34] is still the best known. In this paper we *overcome this cubic barrier*:

▶ **Theorem 1.** *There is a randomized algorithm for 0-1-Knapsack that runs in time*[1] $\widetilde{O}((p_{\max}W)^{2/3}(nw_{\max})^{1/3} + nw_{\max})$ *and succeeds with high probability. Using the bound* $W \leq nw_{\max}$*, this running time is at most* $\widetilde{O}(n\, w_{\max}\, p_{\max}^{2/3})$.

Symmetrically, we obtain the following:

▶ **Theorem 2.** *There is a randomized algorithm for 0-1-Knapsack that runs in time* $\widetilde{O}((w_{\max}\mathrm{OPT})^{2/3}(np_{\max})^{1/3} + np_{\max})$ *and succeeds with high probability. Using the bound* $\mathrm{OPT} \leq np_{\max}$*, this running time is at most* $\widetilde{O}(n\, p_{\max}\, w_{\max}^{2/3})$.

**Table 1** Pseudopolynomial-time algorithms for 0-1 Knapsack.

**Min-Plus Convolution.** Given functions $f, g\colon [\,n\,] \mapsto \mathbf{Z}$, their min-plus convolution is the function $h\colon [\,2n\,] \mapsto \mathbf{Z}$ defined as $h(x) = \min_{x'} f(x') + g(x - x')$ for $x \in [\,2n\,]$. This can be trivially computed in time $O(n^2)$, and the best known algorithm for it runs in time $n^2/2^{\Omega(\sqrt{\log n})}$ [6, 36, 17]. The lack of faster algorithms has led to the *Min-Plus Convolution Hypothesis*, which postulates that there is no truly subquadratic algorithm for this problem [20, 32]. Despite this hypothesis, there are structured instances of min-plus convolution that can be solved faster [1, 4, 13, 16, 18]. These improvements have been *key to obtain the Knapsack algorithms listed in Table 1* (the only exception being Bellman's and Pisinger's algorithms [5, 34]):

[1] We use $\widetilde{O}(\cdot)$ to supress polylogarithmic factors in the input size and the largest input number.

- When one of the functions is convex, their min-plus convolution can be computed in time $O(n)$ using the SMAWK algorithm [1]. This has been used for Knapsack indirectly[2] by Kellerer and Pferschy [28], and explicitly by Axiotis and Tzamos [3] and Polak, Rohwedder and Węgrzycki [35].
- When the functions are monotone and have bounded entries, their min-plus convolution can be computed in time $\widetilde{O}(n^{1.5})$ by an algorithm due to Chi, Duan, Xie and Zhang [18]. This has been used for Knapsack by Bringmann and Cassis [8].
- Bateni, Hajiaghayi, Seddighin and Stein [4] introduced the *prediction technique* to show that the min-plus convolution of certain instances arising from Knapsack can be computed efficiently. More precisely, let $h$ be the min-plus convolution of two given functions $f, g\colon [n] \mapsto \mathbf{Z}$. They show that if one is given $n$ intervals $[x_i \mathinner{..} y_i]$ for $i \in [n]$ satisfying (i) $|h(i+j) - (f(i)+g(j))| \leq \Delta$ for every $i \in [n]$ and $j \in [x_i \mathinner{..} y_i]$, (ii) for every output $h(k)$ there exists at least one $i$ such that $f(i) + g(k-i) = h(k)$ and $k - i \in [x_i \mathinner{..} y_i]$ and (iii) $0 \leq x_i, y_i < n$ for all intervals and $x_i \leq x_j, y_i \leq y_j$ for all $i < j$; then $h$ can be computed in time $\widetilde{O}(n \cdot \Delta)$. They showed that this is applicable in the context of Knapsack.

Our Theorems 1 and 2 fall into the same category of improvements, as we design an efficient algorithm for a new class of structured instances of min-plus convolution, namely *near convex* functions: We say that $f\colon [n] \mapsto \mathbf{Z}$ is $\Delta$-near convex, if there is a convex function $\breve{f}\colon [n] \mapsto \mathbf{Q}$ such that $\breve{f}(i) \leq f(i) \leq \breve{f}(i) + \Delta$ for all $i \in [n]$. Our theorem reads as follows:

▶ **Theorem 3** (Near Convex MinPlus Convolution). *Let $f\colon [n] \mapsto [-U \mathinner{..} U]$, and $g\colon [m] \mapsto [-U \mathinner{..} U]$ be given as inputs where $n, m, U \in \mathbf{N}$. Let $\Delta \geq 1$ such that both $f$ and $g$ are $\Delta$-near convex. Then the min-plus convolution of $f$ and $g$ can be computed in time $\widetilde{O}((n+m) \cdot \Delta)$.*

We view our Theorem 3 as a replacement for the prediction technique by Bateni et al. [4]. Indeed, all uses of the prediction technique exploit near-convexity to ensure its preconditions, and thus all uses that we are aware of can be replaced by our Theorem 3. Since the prediction technique is both difficult to state and difficult to apply, we view our Theorem 3 as replacing the prediction technique by an *easily applicable tool with a concise statement*. Moreover, Theorem 3 provides a new tool for structured instances of min-plus convolution, which we use in this paper to make progress on 0-1-Knapsack, and which we believe has wider applicability.

**Our Techniques.** Our approach to prove Theorem 3 is as follows. Let $f, g\colon [n] \mapsto \mathbf{Z}$ be the input functions, and let $h$ be their min-plus convolution, which we aim to compute. First we observe that we can obtain the convex approximations $\breve{f}, \breve{g}$ witnessing the $\Delta$-near convexity of $f$ and $g$, and compute their min-plus convolution $\breve{h}$ efficiently. By exploiting $\breve{h}$ and the convexity of $\breve{f}$ and $\breve{g}$, we identify a structured set $R \subseteq [n]^2$ with the property that any $(i,j) \in [n]^2 \setminus R$ satisfies $f(i) + g(j) > h(j)$. Then, we give a simple recursive algorithm to cover $R$ with a collection $\mathcal{C}$ of disjoint dyadic boxes $I \times J$ , where $(I, J) \in \mathcal{C}$ satisfies $I, J \subseteq [n]$ and $I \times J \subseteq R$. Thus, we can infer $h$ by computing the *sumset* $A := \{(i, f(i)) \mid i \in I\} + \{(j, g(j)) \mid j \in J\}$ and taking $h(k) = \min\{y \mid (k, y) \in A\}$ for every $(I, J) \in \mathcal{C}$. To do this efficiently we observe that inside $I$ and $J$, the functions $f[I]$ and $g[J]$ are close to linear functions with the same slope up to an additive error of $\pm O(\Delta)$ (which follows from their $\Delta$-near convexity). This implies that their sumset is small; more

[2] Kellerer and Pferschy did not use SMAWK, but gave a different algorithm for computing the min-plus convolution of these instances in time $O(n \log n)$.

precisely it has size $O((|I|+|J|)\Delta)$. Finally, we make use of known tools that can compute a sumset in time proportional to its size. The idea of identifying a covering with small sumsets to efficiently compute the min-plus convolution is inspired by Chan and Lewenstein's [16] algorithm for bounded monotone sequences (in which they do not use convexity in any form). Our algorithm shares some similarities with the prediction technique by Bateni et al. [4]. In particular, the covering by dyadic boxes where functions are near-linear resembles the way in which they exploit the intervals $[\,x_i\,..\,y_i\,]$ required by their algorithm.

To obtain Theorems 1 and 2, we follow the *partition and convolve* paradigm that has been used in many recent algorithms for Subset Sum and Knapsack, see e.g. [7, 4, 8, 26, 14, 31, 21, 11]. Specifically, we randomly split the items into $q$ groups. In each group, we use the standard dynamic programming algorithm to compute for each weight $i$, the maximum profit $f(i)$ attainable with weight at most $i$ using items from that group. Then we combine the functions $f$ over all groups by min-plus convolution. The crucial observation is that due to the random splitting we only need to compute the values $f(i)$ in a small weight interval.

**Further Related Work.** Cygan et al. [20] and Künnemann et al. [32] showed that under the Min-Plus Convolution Hypothesis, there is no truly subquadratic algorithm for Knapsack on instances with $w_{\max}, W = \Theta(n)$ and $p_{\max}, \mathrm{OPT} = \Omega(n^2)$, and symmetrically, on instances with $p_{\max}, \mathrm{OPT} = \Theta(n)$ and $w_{\max}, W = \Omega(n^2)$. This implies that Bellman's dynamic programming algorithm is conditionally optimal in these settings.

Pseudopolynomial-time algorithms parameterized by $p_{\max}$ and $w_{\max}$ have also been studied for the closely related Unbounded Knapsack problem. Here, the setup is the same as for 0-1 Knapsack but now a solution might include an arbitrary number of copies of each item. Chan and He [15] gave an algorithm for this problem in time $\widetilde{O}(n \cdot \min\{\, p_{\max}, w_{\max}\,\})$, which is optimal under the Min-Plus Convolution Hypothesis. Bringmann and Cassis [8] gave an algorithm in time $\widetilde{O}(n + (p_{\max}+w_{\max})^{1.5})$ which is better when $w_{\max} \approx p_{\max} \approx n$.

**Outline.** The paper is organized as follows. In Section 2 we give some formal preliminaries and establish some notation. In Section 3 we give our algorithm for Knapsack proving Theorems 1 and 2, assuming Theorem 3. In Section 4 we will then give our algorithm for min-plus convolution, proving Theorem 3.

## 2 Preliminaries

We write $\mathbf{N} = \{\,0, 1, 2, \dots\,\}$. For $t \in \mathbf{N}$, we define $[\,t\,] := \{\,0, 1, \dots, t\,\}$. Let $A \in \mathbf{Z}^{n+1}$ be an integer sequence, i.e., $A[i] \in \mathbf{Z}$ for $i \in [\,n\,]$. Sometimes we will refer to such a sequence as a *function* $A\colon [\,n\,] \mapsto \mathbf{Z}$. With this in mind, we use the notation $-A$ to denote the entry-wise negation of $A$. Given $a, b \in \mathbf{R}$ with $a \le b$, we define $[\,a\,..\,b\,] := \{\,\max(0, \lfloor a \rfloor), \max(0, \lfloor a \rfloor)+1, \dots, \lceil b \rceil - 1, \lceil b \rceil\,\}$. The non-standard rounding and capping at 0 in the definition of $[\,a\,..\,b\,]$ is useful to index a subsequence $A[\,a\,..\,b\,]$ when $a$ and $b$ might not be non-negative integers.

The max-plus convolution of two sequences $A[\,0\,..\,n\,] \in \mathbf{Z}^{n+1}, B[\,0\,..\,m\,] \in \mathbf{Z}^{m+1}$, denoted by $\textsc{MaxConv}(A, B)$, is a sequence of length $n+m+1$ where for each $k \in [\,n+m\,]$ we have $\textsc{MaxConv}(A,B)[k] := \max_{i+j=k} A[i] + B[j]$. The min-plus convolution $\textsc{MinConv}(A, B)$ is defined analogously, but replacing max by a min. Note that by negating the entries of the sequences, these two operations are equivalent.

▶ **Fact 4.** *For any $A \in \mathbf{Z}^{n+1}, B \in \mathbf{Z}^{m+1}$, we have $\textsc{MaxConv}(A,B) = -\textsc{MinConv}(-A,-B)$.*

We will use the following handy notation: Given sequences $A[0\,..\,n], B[0\,..\,n]$ and intervals $I, J \subseteq [n]$ and $K \subseteq [2n]$, we denote by $C[K] := \textsc{MaxConv}(A[I], B[J])$ the computation of $C[k] := \max\{A[i] + B[j] \colon i \in I, j \in J, i + j = k\}$ for each $k \in K$.

We say that a function $f \colon [n] \mapsto \mathbf{Q}$ is *convex* if $f(i) - f(i-1) \leq f(i+1) - f(i)$ holds for every $i \in [1\,..\,n-1]$. We say that $f$ is *concave* if $-f$ is convex.

▶ **Definition 5** (Near Convex and Near Concave Functions). *For $\Delta \geq 0$, we say that a function $f \colon [n] \mapsto \mathbf{Z}$ is $\Delta$-near convex, if there is a convex function $\breve{f} \colon [n] \mapsto \mathbf{Q}$ such that $\breve{f}(i) \leq f(i) \leq \breve{f}(i) + \Delta$. We say that $f$ is $\Delta$-near concave if $-f$ is $\Delta$-near convex.*

If the input consists of $N$ numbers in $[-U\,..\,U]$, we denote $\widetilde{O}(T) = \bigcup_{c \geq 0} O(T \log^c(NU))$.

## 3 Faster 0-1 Knapsack Algorithm

In this section we prove Theorem 1. Let $(\mathcal{I}, W)$ be a 0-1 Knapsack instance. Throughout, we denote the number of items by $n := |\mathcal{I}|$. We identify the item set $\mathcal{I}$ with $\{1, \ldots, n\}$. We represent a *solution* to the knapsack instance (i.e., a subset of $\mathcal{I}$), by an indicator vector $x \in \{0,1\}^n$. For a subset of the items $\mathcal{J} \subseteq \mathcal{I}$, we put $w_{\mathcal{J}}(x) := \sum_{i \in \mathcal{J}} w_i x_i$ and $p_{\mathcal{J}}(x) := \sum_{i \in \mathcal{J}} p_i x_i$. We define the profit sequence $\mathcal{P}_{\mathcal{I}}[\cdot]$, where for each $j \in \mathbf{N}$ we have

$$\mathcal{P}_{\mathcal{I}}[j] = \max\{\, p_{\mathcal{I}}(x) \mid x \in \{0,1\}^n, w_{\mathcal{I}}(x) \leq j \,\}.$$

Observe that $\mathcal{P}_{\mathcal{I}}$ is monotone non-decreasing, and that $\mathrm{OPT} = \mathcal{P}_{\mathcal{I}}[W]$. The textbook way to compute $\mathcal{P}_{\mathcal{I}}[0\,..\,j]$ is to use dynamic programming:

▶ **Fact 6.** *For any $j \in \mathbf{N}$ the sequence $\mathcal{P}_{\mathcal{I}}[0\,..\,j]$ can be computed in time $O(nj)$.*

Before presenting the algorithm, we make two simple observations about the given Knapsack instance $(\mathcal{I}, W)$. First, by ignoring items with weight larger than the capacity $W$, we can assume without loss of generality that $w_{\max} \leq W$. Now every single item is a feasible solution, so we have $p_{\max} \leq \mathrm{OPT}$. Second, observe that if $W \geq n \cdot w_{\max}$, then the instance is trivial since we can pack all items. Thus, we can assume without loss of generality that $W \leq n \cdot w_{\max}$. Moreover, since any feasible solution consists of at most all the $n$ items, it follows that $\mathrm{OPT} \leq n \cdot p_{\max}$.

### The Algorithm

We now describe the algorithm. Set parameters $q := \min\{(n/p_{\max})^{2/3}(W/w_{\max})^{1/3}, W/w_{\max}\}$ rounded down to the closest power of 2, $\Delta := w_{\max} W/q$ and $\eta := 11 \log n$. For each $\ell \in [\log q]$ we define the interval $J^\ell := [\frac{W}{q} 2^\ell - \sqrt{\Delta 2^\ell}\eta\,..\,\frac{W}{q} 2^\ell + \sqrt{\Delta 2^\ell}\eta]$.

We start by splitting the items $\mathcal{I}$ into $q$ groups $\mathcal{I}_1^0, \ldots, \mathcal{I}_q^0$ uniformly at random. The idea will be to compute an array $C_j^0$ associated to each $\mathcal{I}_j^0$, and then combine them in a *tree-like* fashion. A crucial aspect for the running time is that we only compute $|J^\ell|$ entries of each array $C_j^\ell$. In detail, we proceed as follows:

**Base Case.** For each $\mathcal{I}_j^0$, we use Fact 6 to compute $\mathcal{P}_{\mathcal{I}_j^0}[0\,..\,\frac{W}{q} + \sqrt{\Delta}\eta]$ and define the subarray $C_j^0[J^0] := \mathcal{P}_{\mathcal{I}_j^0}[J^0]$.

**Combination.** Iterate over the *levels* $\ell = 1, \ldots \log(q)$. For $j \in [1\,..\,q/2^\ell]$ we set $\mathcal{I}_j^\ell := \mathcal{I}_{2j-1}^{\ell-1} \cup \mathcal{I}_{2j}^{\ell-1}$. Then, compute the subarray $C_j^\ell[J^\ell]$ by taking the relevant entries of the max-plus convolution of $C_{2j-1}^{\ell-1}[J^{\ell-1}]$ and $C_{2j}^{\ell-1}[J^{\ell-1}]$.

**Returning the answer.** (Note that when $\ell = \log(q)$, it holds that $\mathcal{I}_1^{\log q} = \mathcal{I}$.) We return the value $C_1^{\log q}[W]$. See Algorithm 1 for the pseudocode.

**Algorithm 1** Knapsack Algorithm. Given a set of items $\mathcal{I}$ and a weight budget $W$, the algorithm computes the maximum attainable profit.

$q \leftarrow \min\{ (n/p_{\max})^{2/3}(W/w_{\max})^{1/3}, W/w_{\max} \}$ rounded down to the closest power of 2
$\Delta \leftarrow w_{\max}W/q$
$\eta \leftarrow 11 \log n$
$\mathcal{I}_1^0, \dots, \mathcal{I}_q^0 \leftarrow$ random partitioning of $\mathcal{I}$ into $q$ groups
**for** $i = 1 \dots q$ **do**
    Compute $\mathcal{P}_{\mathcal{I}_j^0}[\,0\,..\,\frac{W}{q} + \sqrt{\Delta}\eta\,]$ using standard dynamic programming (Fact 6)
    $J^0 \leftarrow [\,\frac{W}{q} - \sqrt{\Delta}\eta\,..\,\frac{W}{q} + \sqrt{\Delta}\eta\,]$
    $C_j^0[J^0] \leftarrow \mathcal{P}_{\mathcal{I}_j^0}[J^0]$
**for** $\ell = 1 \dots \log(q)$ **do**
    $J^\ell \leftarrow [\,\frac{W}{q}2^\ell - \sqrt{\Delta 2^\ell}\eta\,..\,\frac{W}{q}2^\ell + \sqrt{\Delta 2^\ell}\eta\,]$
    **for** $j = 1, \dots, q/2^\ell$ **do**
        $\mathcal{I}_j^\ell \leftarrow \mathcal{I}_{2j-1}^{\ell-1} \cup \mathcal{I}_{2j}^{\ell-1}$
        Compute $C_j^\ell[J^\ell] \leftarrow \textsc{MaxConv}(C_{2j-1}^{\ell-1}[J^{\ell-1}], C_{2j}^{\ell-1}[J^{\ell-1}])$ using Theorem 3
**return** $C_1^{\log q}[W]$

## Correctness

We start by analyzing the correctness of the algorithm. The following lemma shows that the weight of any solution restricted to one of the sets $\mathcal{I}_j^\ell$ is concentrated around its expectation.

▶ **Lemma 7** (Concentration, proof deferred to the full version). *Let $x \in \{0,1\}^n$ be a solution to the given Knapsack instance. Fix a level $\ell \in [\,0\,..\,\log q\,]$ and $j \in [\,1\,..\,q/2^\ell\,]$. Then, with probability at least $1 - 1/n^4$ it holds that:*

$$\left| w_{\mathcal{I}_j^\ell}(x) - \frac{w_{\mathcal{I}}(x) \cdot 2^\ell}{q} \right| \leq \sqrt{\Delta 2^\ell} \cdot 10 \log n.$$

Using Lemma 7, we can argue that at level $\ell$ it suffices to compute a subarray of length $\widetilde{O}(\sqrt{\Delta 2^\ell})$ around $W2^\ell/q$. The following lemma makes this precise:

▶ **Lemma 8** (Proof deferred to the full version). *Let $x \in \{0,1\}^n$ be a solution to the given Knapsack instance satisfying $w_{\mathcal{I}}(x) \in [\,W - w_{\max}\,..\,W\,]$. With probability at least $1 - 1/n^2$, for all levels $\ell \in [\,0\,..\,\log q\,]$ and all $j \in [\,1\,..\,q/2^\ell\,]$ it holds that:*

- $w_{\mathcal{I}_j^\ell}(x) \in J^\ell = [\,\frac{W}{q}2^\ell - \sqrt{\Delta 2^\ell}\eta\,..\,\frac{W}{q}2^\ell + \sqrt{\Delta 2^\ell}\eta\,]$, *and*
- $C_j^\ell[w_{\mathcal{I}_j^\ell}(x)] \geq p_{\mathcal{I}_j^\ell}(x)$.

▶ **Lemma 9** (Correctness of Algorithm 1). *Let $x^* \in \{0,1\}^n$ be an optimal solution to the given Knapsack instance. Then, for every $i \in [\,w_{\mathcal{I}}(x^*)\,..\,W\,]$, it holds that $C_1^{\log q}[i] = \mathcal{P}_{\mathcal{I}}[i]$ with probability at least $1 - 1/n^2$.*

**Proof.** We can check in linear time $O(n)$ whether the optimal solution consists of all items, in which case the instance is trivial. Thus, we can assume without loss of generality that $x^*$ does not include all items. In particular, $x^*$ leaves at least one item out and therefore its weight satisfies $w_{\mathcal{I}}(x^*) \in [\,W - w_{\max}\,..\,W\,]$. By Lemma 8, it holds that $C_1^{\log q}[w_{\mathcal{I}}(x^*)] \geq p_{\mathcal{I}}(x^*) = \mathcal{P}_{\mathcal{I}}[w_{\mathcal{I}}(x^*)]$ with probability at least $1 - 1/n^2$. From now on we condition on this event. We will use the following auxiliary claim:

▷ Claim 10. The sequence $C_1^{\log q}[J^{\log q}]$ is monotone non-decreasing, and satisfies $C_1^{\log q}[i] \leq \mathcal{P}_{\mathcal{I}}[i]$ for all $i \in J^{\log q}$.

Proof. First we argue monotonicity by induction. Note that in the base case $\ell = 0$, the sequence $C_j^0[J^0] = \mathcal{P}_{\mathcal{I}_j^0}[J^0]$ is monotone non-decreasing due to the definition of $\mathcal{P}_{\mathcal{I}_j^0}$. For level $\ell > 0$, the sequence $C_j^\ell$ is computed by taking the max-plus convolution of sequences of level $\ell - 1$. The result follows by observing that the max-plus convolution of two monotone non-decreasing sequences is monotone non-decreasing.

The second part of the claim follows since (inductively) every entry $C_1^{\log q}[i]$ for $i \in J^{\log q}$ corresponds to the profit of a subset of items of $\mathcal{I}$ of weight at most $i$. ◁

Since $x^*$ is an optimal solution, it holds that $\mathcal{P}_{\mathcal{I}}[i] = p_{\mathcal{I}}(x^*)$ for all $i \in [\, w_{\mathcal{I}}(x^*) \,..\, W\,]$. Thus Claim 10 yields that $C_1^{\log q}[i] = \mathcal{P}_{\mathcal{I}}[i]$ for all $i \in [\, w_{\mathcal{I}}(x^*) \,..\, W\,]$, completing the proof. ◀

## Running Time

Now we analyze the running time of Algorithm 1. The key speedup comes from the computation in Algorithm 1, where we use Theorem 3 to perform the max-plus convolution. Since Theorem 3 is phrased in terms of min-plus convolution of near-convex functions, we will use the following corollary:

▶ **Corollary 11.** *Let $f\colon [\,n\,] \mapsto [\,-U \,..\, U\,]$ and $g\colon [\,m\,] \mapsto [\,-U \,..\, U\,]$ be given as inputs, where $U \in \mathbf{N}$. Let $\Delta \geq 1$ be such that both $f$ and $g$ are $\Delta$-near concave. Then, $\textsc{MaxConv}(f, g)$ can be computed in time $\widetilde{O}((n+m)\Delta)$*

**Proof.** Noting that $-f$ and $-g$ are $\Delta$-near convex (Definition 5), the result follows from Theorem 3 and Fact 4. ◀

▶ **Lemma 12** (Near Concavity, proof deferred to the full version)**.** *For every level $\ell \in [\,1 \,..\, q\,]$ and every $j \in [\,1 \,..\, q/2^\ell\,]$, it holds that $C_j^\ell[J^\ell]$ is $p_{\max}$-near concave.*

▶ **Lemma 13.** *Fix a level $\ell \in [\,1 \,..\, q\,]$ and an iteration $j \in [\,1 \,..\, q/2^\ell\,]$. The computation of $C_j^\ell$ in Algorithm 1 takes time $\widetilde{O}(p_{\max}\sqrt{\Delta 2^\ell})$*

**Proof.** By Lemma 12, the sequences $C_{2j-1}^{\ell-1}[J^{\ell-1}], C_{2j}^{\ell-1}[J^{\ell-1}]$ are $p_{\max}$-near concave. Thus, by Corollary 11, their max-plus convolution can be computed in time $\widetilde{O}(p_{\max}|J^\ell|) = \widetilde{O}(p_{\max}\sqrt{\Delta 2^\ell})$, where we used $\eta = \widetilde{O}(1)$. ◀

▶ **Lemma 14** (Running Time of Algorithm 1)**.** *Algorithm 1 runs in time*

$$\widetilde{O}((p_{\max}W)^{2/3}(nw_{\max})^{1/3} + nw_{\max}).$$

**Proof.** Recall that $q = \min\{\, (n/p_{\max})^{2/3}(W/w_{\max})^{1/3}, W/w_{\max}\,\}$ (up to a factor of 2). Since $W \leq nw_{\max}$, we have that $q \leq n$. Moreover, since we assume without loss of generality that $w_{\max} \leq n$, note that $q < 1$ if and only if $q = (n/p_{\max})^{2/3}(W/w_{\max})^{1/3} < 1$. This implies that $p_{\max} > n\sqrt{W/w_{\max}}$. But in this case, the claimed running time is $\Omega(nW)$, so the standard $O(nW)$ dynamic programming algorithm (Fact 6) already achieves our time bound. Thus, we can assume without loss of generality that $1 \leq q \leq n$, i.e., $q$ is a valid choice for the number of groups in which we split the item set $\mathcal{I}$.

We start bounding the running time of the base case, i.e., the computation of the arrays $C_j^0$ for $j \in [\,1\,..\,q\,]$ in Algorithm 1. By Fact 6, and the definition $\Delta = w_{\max}W/q$ this takes time

$$O\left(\sum_{j=1}^{q} |\mathcal{I}_j^0|(\tfrac{W}{q} + \sqrt{\Delta}\eta)\right) = O\left(n(\tfrac{W}{q} + \sqrt{\Delta}\eta)\right) = \widetilde{O}\left(n\tfrac{W}{q} + n\sqrt{\tfrac{w_{\max}W}{q}}\right). \tag{1}$$

Now we bound the time of the combination step done in Algorithms 1–1. At level $\ell \in [\,1\,..\,q\,]$ and iteration $j \in [\,1\,..\,q/2^\ell\,]$ the execution of Algorithm 1 takes time $\widetilde{O}(p_{\max}\sqrt{\Delta 2^\ell})$ by Lemma 13. Thus, we can bound the overall time as

$$\sum_{\ell=1}^{\log q}\sum_{j=1}^{q/2^\ell} \widetilde{O}(p_{\max}\sqrt{\Delta 2^\ell}) = \sum_{\ell=1}^{\log q} \frac{q}{2^\ell}\widetilde{O}\left(p_{\max}\sqrt{\tfrac{w_{\max}W}{q}2^\ell}\right) = \sum_{\ell=1}^{\log q} \widetilde{O}\left(p_{\max}\sqrt{\tfrac{qw_{\max}W}{2^\ell}}\right),$$

since this is a geometric series, it is bounded by the first term $\widetilde{O}(p_{\max}\sqrt{qw_{\max}W})$. Combining this with (1), we obtain overall time

$$\widetilde{O}\left(p_{\max}\sqrt{qw_{\max}W} + n\tfrac{W}{q} + n\sqrt{\tfrac{w_{\max}W}{q}}\right).$$

Recalling that $q = \Theta(\min\{\,(n/p_{\max})^{2/3}(W/w_{\max})^{1/3}, W/w_{\max}\,\})$, we obtain overall time

$$\widetilde{O}((p_{\max}W)^{2/3}(nw_{\max})^{1/3} + nw_{\max} + (p_{\max}W)^{1/3}(nw_{\max})^{2/3}).$$

Finally, using that $\sqrt{xy} \le (x+y)/2$ for all $x, y \ge 0$, we have that

$$\begin{aligned}(p_{\max}W)^{1/3}(nw_{\max})^{2/3} &= \sqrt{(p_{\max}W)^{2/3}(nw_{\max})^{1/3}nw_{\max}} \\ &\le O((p_{\max}W)^{2/3}(nw_{\max})^{1/3} + nw_{\max}).\end{aligned}$$

Thus, the overall running time is $\widetilde{O}((p_{\max}W)^{2/3}(nw_{\max})^{1/3} + nw_{\max})$, as claimed. ◀

**Proof of Theorem 1.** Run Algorithm 1. By Lemma 9, we obtain that $\mathcal{I}_1^{\log q}[W] = \mathrm{OPT}$ with probability at least $1 - 1/n^2$, which proves correctness. The running time is immediate from Lemma 14. Observe that we can obtain success probability $1 - 1/n^c$ for any constant $c \ge 2$ by repeating the algorithm $c/2$ times. Finally, note that Algorithm 1 only computes the optimal profit of the given instance. In the full version of the paper we describe how to reconstruct the set of items in an optimal solution with no overhead in the running time. ◀

**Proof Sketch of Theorem 2.** Our presentation focused on proving Theorem 1. The proof of the symmetric variant stated in Theorem 2 is very similar, thus we only sketch the required changes. Essentially, we need to exchange profits with weights everywhere, which in turn means exchanging max-plus convolutions by min-plus convolutions. In more detail: Instead of working with the profit sequence $\mathcal{P}_\mathcal{I}$, we work with the weight sequence $\mathcal{W}_\mathcal{I}$, where the entry $\mathcal{W}_\mathcal{I}[j]$ stores the minimum weight of a solution with profit at least $j$. We do not know OPT, but we can compute an approximation $\tilde{V}$ satisfying $\tilde{V} - p_{\max} \le \mathrm{OPT} \le \tilde{V}$ in linear time (see e.g. [29, Theorem 2.5.4]). In the algorithm, we exchange all ocurrences of $w_{\max}$ by $p_{\max}$ and all ocurrences of $W$ by $\tilde{V}$. With these changes, the functions $C_j^\ell$ are now $w_{\max}$-near convex (instead of $p_{\max}$-near concave) so we use Theorem 3 directly instead of Corollary 11. In this way, we obtain the array $C_1^{\log q}[\,\tilde{V} - p_{\max}\,..\,\tilde{V}\,] = \mathcal{W}_\mathcal{I}[\,\tilde{V} - p_{\max}\,..\,\tilde{V}\,]$. Then, we can infer OPT as the largest $i \in [\,\tilde{V} - p_{\max}\,..\,\tilde{V}\,]$ such that $\mathcal{W}_\mathcal{I}[i] \le W$. ◀

# 4 MinPlus Convolution for Near-Convex Sequences

In this section we prove Theorem 3.

▶ **Theorem 3** (Near Convex MinPlus Convolution). *Let $f\colon [n] \mapsto [-U\,..\,U]$, and $g\colon [m] \mapsto [-U\,..\,U]$ be given as inputs where $n, m, U \in \mathbf{N}$. Let $\Delta \geq 1$ such that both $f$ and $g$ are $\Delta$-near convex. Then the min-plus convolution of $f$ and $g$ can be computed in time $\widetilde{O}((n+m)\cdot\Delta)$.*

## 4.1 Preparations

Throughout this section, fix the functions $f\colon [n] \mapsto [-U\,..\,U], g\colon [m] \mapsto [-U\,..\,U]$. Recall that we say that $f\colon [n] \mapsto \mathbf{Z}$ is $\Delta_f$-near convex, if there is a convex function $\breve{f}\colon [n] \mapsto \mathbf{Q}$ such that $\breve{f}(i) \leq f(i) \leq \breve{f}(i) + \Delta_f$ for all $i \in [n]$ (see Definition 5). First observe that the lower convex hull of the points $\{ (i, f(i)) \mid i \in [n] \}$ gives the pointwise maximal convex function $\breve{f}$ with $\breve{f} \leq f$. This can be computed in time $O(n)$ by Graham's scan [25], since the points are already sorted by $x$-coordinate. Then, we can infer $\Delta_f = \max\{ 1, \max_{i\in[n]} f(i) - \breve{f}(i) \}$. Thus, from now on we assume that we know $\breve{f}, \Delta_f, \breve{g}, \Delta_g$. Set $\Delta := \max\{ \Delta_f, \Delta_g \}$. Let $\breve{h} := \textsc{MinConv}(\breve{f}, \breve{g})$ and $h := \textsc{MinConv}(f, g)$. The goal is to compute $h$.

We start by introducing some notation. We call $(i, j) \in [n] \times [m]$ a *point*. We visualize a point $(i, j)$ as lying on the $i$-th row and $j$-th column of an $n \times m$ grid, where $(0, 0)$ is on the bottom-left corner and $(n, m)$ on the top right corner. A point $(i, j)$ lies on *diagonal* $i + j$. For any $\delta \geq 0$, a point $(i, j)$ is *$\delta$-relevant* if $\breve{f}(i) + \breve{g}(j) \leq \breve{h}(i + j) + \delta$. We denote by $R_\delta$ the set of all $\delta$-relevant points.

Points that are 0-relevant are important because of the following observation: We call $i$ a *witness* for $\breve{h}(k)$ if $\breve{f}(i) + \breve{g}(k - i) = \breve{h}(k)$. Thus, observe that $i$ is a witness for $\breve{h}(k)$ if and only if $(i, k - i)$ is a 0-relevant point.

The importance of $2\Delta$-relevant points is captured by the following lemma:

▶ **Lemma 15.** *If $(i, j) \notin R_{2\Delta}$ then $f(i) + g(j) > h(i + j)$.*

That is, points that are not $2\Delta$-relevant can be ignored for the purpose of computing $h$.

**Proof.** Since $(i, j)$ is not $2\Delta$-relevant, it holds that $f(i) + g(j) \geq \breve{f}(i) + \breve{g}(j) > \breve{h}(i + j) + 2\Delta$. Let $k := i + j$, and let $i^*$ be a witness for $\breve{h}(k)$, i.e., $\breve{f}(i^*) + \breve{g}(k - i^*) = \breve{h}(k)$. Then,

$$h(k) \leq f(i^*) + g(k - i^*) \leq \breve{f}(i^*) + \Delta + \breve{g}(k - i^*) + \Delta = \breve{h}(k) + 2\Delta < f(i) + g(j). \qquad \blacktriangleleft$$

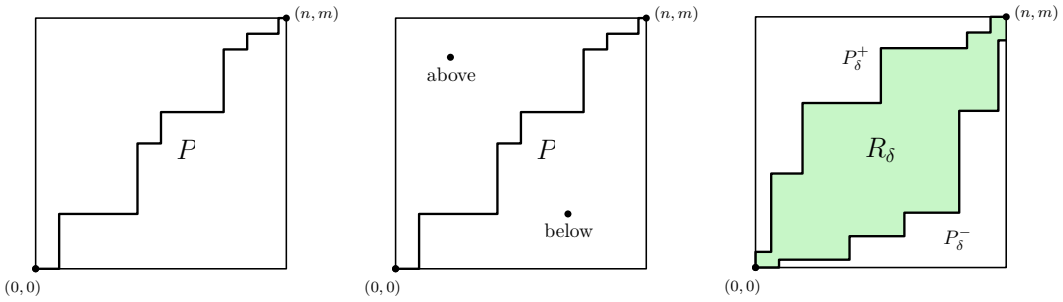
We say that a set of points $P$ is a *monotone path* if for every $k \in [n + m]$ $P$ contains exactly one point $(i_k, j_k)$ on diagonal $k$, and we have $(i_{k+1}, j_{k+1}) \in \{ (i_k + 1, j_k), (i_k, j_k + 1) \}$ for every $k \in [n + m - 1]$, see Figure 1a for an illustration. For any $\delta > 0$, we let

$$P_\delta^+ := \{ (i, k - i) \mid k \in [n + m], i \in [n] \text{ is maximal s.t. } (i, k - i) \text{ is } \delta\text{-relevant} \},$$
$$P_\delta^- := \{ (i, k - i) \mid k \in [n + m], i \in [n] \text{ is minimal s.t. } (i, k - i) \text{ is } \delta\text{-relevant} \}.$$

The next two lemmas show that $P_\delta^+, P_\delta^-$ are monotone paths and that $P_\delta^+, P_\delta^-$ form the boundary of $R_\delta$, see Figure 1c for an illustration. This establishes structure of $R_\delta$ that we will be exploit later.

▶ **Lemma 16** (Monotone Paths, proof deferred to the full version). *For any $\delta \geq 0$, $P_\delta^-, P_\delta^+$ are monotone paths.*

Let $(i, j)$ be a point and $P$ a monotone path. Let $(a, b) \in P$ be the unique point on the same diagonal as $(i, j)$, i.e., $a + b = i + j$. We say that $(i, j)$ is *below* $P$ if $i < a$, *above* $P$ if $i > a$, and *on* $P$ if $i = a$, see Figure 1b for an illustration.



**(a)** A monotone path $P$. **(b)** Points above and below $P$. **(c)** $R_\delta$ is between $P_\delta^+$ and $P_\delta^-$.

**Figure 1** Visualizations for concepts used in Section 4.

▶ **Lemma 17.** *For any $\delta \geq 0$, $R_\delta$ consists of all points $(i, j)$ that are on or below $P_\delta^+$ and on or above $P_\delta^-$.*

**Proof.** Fix $k \in [\, n + m \,]$ and let $(i^+, k - i^+), (i^-, k - i^-)$ be the point on diagonal $k$ in $P_\delta^+$ and $P_\delta^-$, respectively. Consider any $(i, j) \in R_\delta$ on diagonal $k$. By maximality of $i^+$ we have $i \leq i^+$, and similarly $i \geq i^-$ by the minimality of $i^-$. Thus, no point in $R_\delta$ is above $P_\delta^+$ or below $P_\delta^-$. It remains to show that for any $i^- \leq i \leq i^+$ we have $(i, k - i) \in R_\delta$. Note that the function $r(i) := \breve{f}(i) + \breve{g}(k - i)$ is convex (since it is the sum of convex functions). Since $(i^+, k - i^+)$ is $\delta$-relevant, we have $r(i^+) \leq \breve{h}(k) + \delta$. Similarly, since $(i^-, k - i^-)$ is $\delta$-relevant, we have $r(i^-) \leq \breve{h}(k) + \delta$. By convexity of $r$, we obtain that $r(i) \leq \breve{h}(k) + \delta$ for all $i^- \leq i \leq i^+$. Hence, we conclude that for each $i^- \leq i \leq i^+$ we have $(i, k - i) \in R_\delta$. ◀

Finally, we need some background on *sumsets*. Given $A, B \subseteq [\, -U \,..\, U \,]^2$ where $U \in \mathbf{N}$, we define $A + B = \{\, a + b \mid a \in A, b \in B \,\}$ as their sumset, where the addition $a + b$ is done componentwise. The naive way to compute $A + B$ takes time $O(|A| \cdot |B|)$. For our application, we want to compute the sumset in time near linear in its size $|A + B|$. For this end, we will use the following tool to compute *sparse non-negative convolution*. Given vectors $P, Q \in \mathbf{N}^n$, their *convolution* $P \star Q \in \mathbf{N}^{2n-1}$ is defined coordinate-wise by $(P \star Q)[k] = \sum_{i+j=k} P[i] \cdot Q[j]$.

▶ **Theorem 18** (Deterministic Sparse Convolution [10])**.** *There is a deterministic algorithm to compute the convolution of two nonnegative vectors $A, B \in \mathbf{N}^n$ in time $O(t \operatorname{polylog}(n\Delta))$, where $t$ is the number of non-zero entries in $A \star B$ and $\Delta$ is the largest entry in $A$ and $B$.*

See also [9] for improvements in the log-factors at the cost of randomization and [19, 33, 24] for prior randomized algorithms with similar guarantees.

▶ **Corollary 19** (Output Sensitive Sumset Computation)**.** *Given $A, B \subseteq [\, -U \,..\, U \,]^2$, with $|A + B| \leq N$, $A + B$ can be computed in time $\widetilde{O}(N)$.*

**Proof.** Let $A' := \{\, (x+U) \cdot 5U + (y+U) \mid (x, y) \in A \,\}$ and similarly, let $B' := \{\, (x+U) \cdot 5U + (y+U) \mid (x, y) \in B \,\}$. Observe that this is a one-to-one embedding of $A, B \subseteq [\, -U \,..\, U \,]^2$ into $A', B' \subseteq [\, \Theta(U^2) \,]$. Moreover, one can check that given $C' := A' + B'$ we can infer $C := A + B$ (the choice of $5U$ prevents any interactions between coordinates when summing them up).

Thus, it suffices to compute $A' + B'$. To this end, construct their indicator vectors $P_{A'}, P_{B'} \in \mathbf{N}^{\Theta(U^2)}$ and compute the convolution $P_{C'} = P_{A'} \star P_{B'}$. The non-zero entries in $P_{C'}$ correspond to the elements of $A' + B'$. By Theorem 18, this runs in time $O(|A' + B'| \operatorname{polylog}(N, U)) = \widetilde{O}(N)$. ◀

## 4.2 Algorithm

We are ready to describe our algorithm. Recall that we have access to the functions $f, \breve{f}, g, \breve{g}$ and the value $\Delta = \max\{\Delta_f, \Delta_g\}$.

**Computing $\breve{h} = \textsf{MinConv}(\breve{f}, \breve{g})$.** Consider the pseudocode given in Algorithm 2.

**Algorithm 2** Given convex functions $\breve{f}\colon [n] \mapsto \mathbf{Q}, \breve{g}\colon [m] \mapsto \mathbf{Q}$, the algorithm computes $\breve{h} = \textsc{MinConv}(\breve{f}, \breve{g})$.

1: $i_0^* \leftarrow 0, \breve{h}(0) \leftarrow \breve{f}(0) + \breve{g}(0)$
2: **for** $k = 1, \ldots, n+m$ **do**
3: $\quad i_k^* \leftarrow \operatorname{argmin}\{\breve{f}(i) + \breve{g}(k-i) + \frac{i}{2n} \mid i \in \{i_{k-1}^*, i_{k-1}^* + 1\} \cap [n]\}$
4: $\quad \breve{h}(k) \leftarrow \breve{f}(i_k^*) + \breve{g}(k - i_k^*)$

▶ **Lemma 20.** *Algorithm 2 computes $\breve{h} = \textsc{MinConv}(\breve{f}, \breve{g})$ in time $O(n+m)$.*

**Proof.** The running time is immediate. To see correctness, focus on $i_k^*$ for $k \in [n+m]$ as computed in Algorithm 2. We claim that the path $P_0^-$ equals $\{(i_k^*, k - i_k^*) \mid k \in [n+m]\}$. That is, we want to argue that $i_k^*$ is the minimum witness of $\breve{h}(k)$ for each $k \in [n+m]$. Indeed, by Lemma 16, $P_0^-$ is a monotone path. Thus, $i_k^* \in \{i_{k-1}^*, i_{k-1}^* + 1\}$. Observe that in Algorithm 2 we pick $i_k^*$ as the minimizer of $\breve{f}(i) + \breve{g}(k-i) + \frac{i}{2n}$ where $i \in \{i_{k-1}^*, i_{k-1}^* + 1\}$. Therefore, the algorithm correctly computes $i_k^*$ (the additive term $i/(2n)$ ensures that we choose the minimal $i$). Since $i_k^*$ is a minimum witness of $\breve{h}(k)$, the algorithm correctly computes $\breve{h}(k)$ for all $k \in [n+m]$. ◀

We remark that $\textsc{MinConv}(\breve{f}, \breve{g})$ could be computed using the SMAWK algorithm [1]. The reason we give a direct algorithm, is that we will need the witness path $P_0^-$ as computed by Algorithm 2.

**Computing $h = \textsf{MinConv}(f, g)$.** Recall that $f\colon [n] \mapsto \mathbf{Z}$ and $g\colon [m] \mapsto \mathbf{Z}$. As a final simplification, we argue that we can assume without loss of generality that $n = m$, and $n+1$ is a power of 2. To this end, let $N$ be the smallest power of 2 greater than $\max\{n, m\}$. We pad the functions to length $N$ by setting $f(n+j) := 2j \cdot W$ for $j \in [1\,..\,N-1-n]$ and $g(m+j) := 2j \cdot W$ for $j \in [1\,..\,N-1-m]$, where $W$ is an integer larger than $\max_{i \in [n]} f(i) + \max_{j \in [m]} g(j)$. Observe that the entries $h(0), \ldots, h(n+m)$ of the result $h = \textsc{MinConv}(f, g)$ are unchanged (due to the choice of sufficiently large $W$), so we can read off the original result from the result of the padded functions. Moreover, observe that the padding does not change the parameters $\Delta_f$ and $\Delta_g$.

Now we can describe the algorithm. After running Algorithm 2 we can assume that we have computed $\breve{h}$ and the witness path $P_0^- = \{(i_k^*, k - i_k^*) \mid k \in [n+m]\}$. We will make use of the following subroutines:

- $\textsc{Relevant}(i, j)$: returns $\breve{f}(i) + \breve{g}(j) \le \breve{h}(i+j) + 2\Delta$.
- $\textsc{BelowWitnessPath}(i, j)$: returns $i < i_{i+j}^*$
- $\textsc{AboveWitnessPath}(i, j)$: returns $i > i_{i+j}^*$

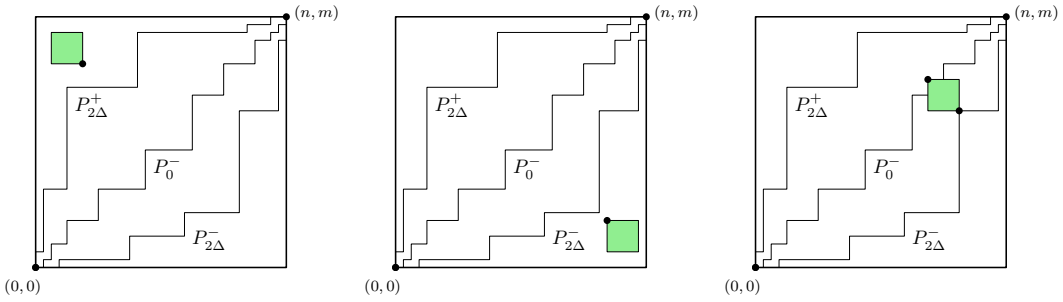
Now we can compute $h = \textsc{MinConv}(f, g)$ by calling $\textsc{RecMinConv}([0\,..\,n], [0\,..\,m])$. See Algorithm 3 for the pseudocode.

**Algorithm 3** Given intervals $I = [\, i_A \,..\, i_B \,], J = [\, j_A \,..\, j_B \,]$, the algorithm computes the contribution of $f[I]$ and $g[J]$ to $\textsc{MinConv}(f, g)$.

```
1:  procedure RecMinConv(I = [ i_A .. i_B ], J = [ j_A .. j_B ])
2:      if AboveWitnessPath(i_A, j_B) and NotRelevant(i_A, j_B) then        ▷ Case 1
3:          return h̃(k) = ∞ for all k ∈ [ i_A + j_A .. i_B + j_B ]
4:      if BelowWitnessPath(i_A, j_B) and NotRelevant(i_B, j_A) then        ▷ Case 2
5:          return h̃(k) = ∞ for all k ∈ [ i_A + j_A .. i_B + j_B ]
6:      if Relevant(i_A, j_B) and Relevant(i_B, j_A) then                   ▷ Case 3
7:          Compute C ← { (i, f(i)) | i ∈ I } + { (j, g(j)) | j ∈ J } using Corollary 19
8:          Infer h̃(k) ← min{ y | (k, y) ∈ C } for all k ∈ [ i_A + j_A .. i_B + j_B ]
9:          return h̃
10:     else                                                                ▷ Case 4
11:         Split I into two intervals I_1, I_2 of equal length, similarly split J into J_1, J_2
12:         Recursively compute g̃_{i,j} ← RecMinConv(I_i, J_j) for i, j ∈ { 1, 2 }
13:         return the pointwise minimum of the functions g̃_{i,j} for i, j ∈ { 1, 2 }
```

Algorithm 3 recursively computes the contribution of $f[\, i_A \,..\, i_B \,]$ and $g[\, j_A \,..\, j_B \,]$ to $h = \textsc{MinConv}(f, g)$. We next discuss its four cases; see Figure 2 for illustrations of Cases 1-3. If $(i_A, j_B)$ is above the witness path $P_0^-$ and is not $2\Delta$-relevant (Case 1), then as we argue below no point in $I \times J$ contributes to the output $h$, so in this case we return a dummy function (which is $+\infty$ everywhere). Case 2 is symmetric, where $(i_B, j_A)$ is above $P_0^-$ and not $2\Delta$-relevant, and we again return a dummy function. Case 3 applies when $(i_A, j_B)$ and $(i_B, j_A)$ are both $2\Delta$-relevant. In this case, we explicitly compute $\tilde{h} = \textsc{MinConv}(f[\, i_A \,..\, i_B \,], g[\, j_A \,..\, j_B \,])$ by computing the sumset $C = \{ (i, f(i)) \mid i \in I \} + \{ (j, g(j)) \mid j \in J \}$ and infering $\tilde{h}(k)$ as the minimum $y$ such that $(k, y) \in C$, which by definition of the sumset equals the minimum $f(i) + g(j)$ such that $i \in I, j \in J$ and $i + j = k$. Note that this step can be done for all $k \in [\, i_A + j_A \,..\, i_B + j_B \,]$ in total time $O(|C|)$ by once scanning over all elements of $C$.

Finally, if none of the above cases apply, then we split both intervals $I$ and $J$ into equal halves and recurse on all 4 combinations of halves. We combine them by taking the pointwise minimum of all computed functions. This case is essentially brute force.



**(a)** Case 1. **(b)** Case 2. **(c)** Case 3.

**Figure 2** Visualization of Cases 1-3. The green box represents the current subproblem.

**Correctness.** We start by analyzing the correctness of the algorithm.

▶ **Lemma 21** (Correctness of Algorithm 3). *$\textsc{RecMinConv}([\, 0 \,..\, n \,], [\, 0 \,..\, m \,])$ (Algorithm 3) correctly computes $h = \textsc{MinConv}(f, g)$.*

**Proof.** Let $k \in [\, n+m \,]$ and consider a point $(i^*, j^*)$ in diagonal $k$ such that $f(i^*) + g(j^*) = h(k)$, i.e., a witness for $h(k)$. We argue that some recursive call computes $f(i^*) + g(j^*)$. This is clear in Case 4, as $(i^*, j^*)$ is covered by one recursive subproblem. It is also clear in Case 3, since then $f(i^*) + g(j^*)$ is explicitly computed.

To finish correctness, we argue that $(i^*, j^*)$ can never be in a subproblem to which Case 1 or 2 applies. Recall that Case 1 applies to a subproblem $I = [\, i_A \,..\, i_B \,], J = [\, j_A \,..\, j_B \,]$ if $(i_A, j_B)$ is above $P_0^-$ and $(i_A, j_B)$ is not $2\Delta$-relevant. Since $(i_A, j_B)$ is not $2\Delta$-relevant, by Lemma 17 $(i_A, j_B)$ must be above $P_{2\Delta}^+$ or below $P_{2\Delta}^-$. Since $(i_A, j_B)$ is above $P_0^-$, it can only be above $P_{2\Delta}^+$. Since $(i_A, j_B)$ is the lower right corner of $I \times J$, it follows that all points in $I \times J$ are above $P_{2\Delta}^+$. Thus, by Lemma 17 all points in $I \times J$ are not $2\Delta$-relevant. If we assume for the sake of contradiction that $(i^*, j^*) \in I \times J$, then Lemma 15 implies $f(i^*) + g(j^*) > h(k)$, contradicting the choice of $(i^*, j^*)$ as a witness for $h(k)$. Hence, $(i^*, j^*)$ can never be in a Case 1 subproblem. Case 2 is symmetric. This finishes the correctness proof. ◀

**Running Time.** Next, we analyze the running time. The key insight is that in relevant regions both functions are essentially linear, with the same slope (see Lemma 22). This implies that the sumset computed in Case 3 is small (see Lemma 23), so it can be computed efficiently using Corollary 19. In the following two lemmas, let $I = [\, i_A \,..\, i_B \,] \subseteq [\, n \,]$ and $J = [\, j_A \,..\, j_B \,] \subseteq [\, m \,]$ be intervals of the same length $|I| = |J|$.

▶ **Lemma 22** (Near Linearity, proof deferred to the full version). *If $I \times J \subseteq R_{2\Delta}$ then there are $a, b, c \in \mathbf{R}$ such that $|f(i) - (a \cdot i + b)| \leq 2\Delta$ for all $i \in I$ and $|g(j) - (a \cdot j + c)| \leq 2\Delta$ for all $j \in J$.*

▶ **Lemma 23** (Relevant Regions have Small Sumsets). *If $I \times J \subseteq R_{2\Delta}$ then the sumset $\{\, (i, f(i)) \mid i \in I \,\} + \{\, (j, f(j)) \mid j \in J \,\}$ has size $O(\Delta \cdot (|I| + |J|))$.*

**Proof.** By Lemma 22, for any $(i, j) \in I \times J$ with $i + j = k$ we have

$$f(i) + g(j) = (a \cdot i + b) + (a \cdot j + c) \pm O(\Delta) = a \cdot k + b + c \pm O(\Delta).$$

Thus, for each of the $|I| + |J| - 1$ $x$-coordinates (i.e., choices of $i + j$), there are $O(\Delta)$ different $y$-coordinates (i.e., values $f(i) + g(j)$) in the sumset. ◀

▶ **Lemma 24** (Running Time of Algorithm 3). *RecMinConv$([\, 0 \,..\, n \,], [\, 0 \,..\, m \,])$ (Algorithm 3) runs in time $\widetilde{O}(n\Delta)$.*

**Proof.** We first analyze the running time of one recursive subproblem, ignoring the cost of recursive calls. Note that in Cases 1 and 2 it suffices to return a dummy value, i.e., we do not need to iterate over $k \in [\, i_A + j_A \,..\, i_B + j_B \,]$ to explitly return $\tilde{h}(k) = \infty$. Thus, Cases 1 and 2 run in time $O(1)$. We charge this time to the parent of the current subproblem, which is a Case 4-subproblem.

Consider Case 4. Ignoring the cost of the recursive subproblems, Case 4 runs in time $O(1)$, which also covers the charging from children which fall in Cases 1 and 2.

Consider Case 3, and let $s := i_B - i_A + 1 = j_B - j_A + 1$ be the current side length. By Lemma 23, the sumset computed in Algorithm 3 has size $O(\Delta s)$. Thus, it can be computed in time $\widetilde{O}(\Delta s)$ using Corollary 19, and the function $\tilde{h}$ can be inferred from it in time $O(\Delta s)$.

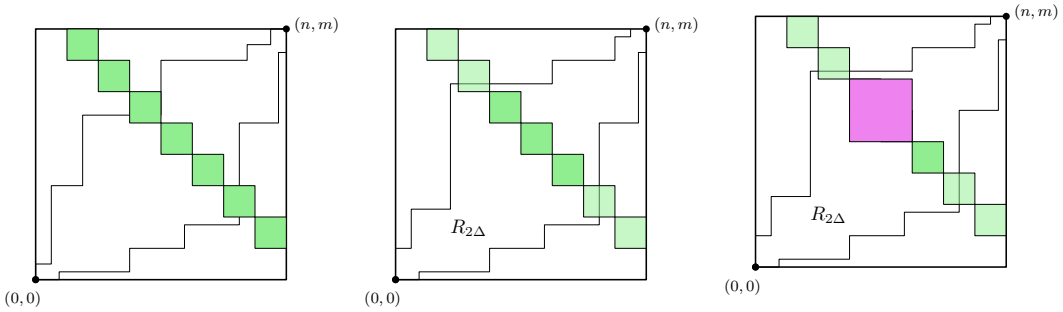
Now we bound the total running time across subproblems. Fix a side length $s$ and consider all possible subproblems of side length $s$, i.e., all boxes

$$B_{x,y}^s := [\, x \cdot s \,..\, x \cdot s + s - 1 \,] \times [\, y \cdot s \,..\, y \cdot s + s - 1 \,], \text{ where } x, y \in [\, n/s \,].$$

Consider a diagonal $D_{s,d} := \{ B^s_{x,x+d} \mid x \in [n/s] \}$ of these boxes, see Figure 3a. Note that a box in $D_{s,d}$ that lies fully above $P^+_\Delta$ corresponds to a Case 1-subproblem. A box in $D_{s,d}$ that lies fully below corresponds to a Case 2-subproblem. A box that is below or on $P^+_{2\Delta}$ and above or on $P^-_{2\Delta}$ corresponds to a Case 3-subproblem. The remaining boxes intersect $P^+_{2\Delta}$ or $P^-_{2\Delta}$ and correspond to Case 4.

Note that by monotonicity of $P^+_{2\Delta}, P^-_{2\Delta}$, at most two boxes in $D_{s,d}$ are intersected by $P^+_{2\Delta}$ or $P^-_{2\Delta}$ and thus at most two boxes in $D_{s,d}$ can appear as Case 4-subproblems. Thus, Case 4 incurs time $O(1)$ per diagonal. We argue that among the boxes in $D_{s,d}$, at most two can appear as Case 3-subproblems. Indeed, if these would be at least three such boxes, then the parent of the middle box would also be between $P^+_{2\Delta}$ and $P^-_{2\Delta}$, and thus the parent would already be a Case 3-subproblem, see Figures 3b and 3c. Thus, the middle box would not get split, and it would not become a recursive subproblem. Hence per diagonal $D_{s,d}$, Case 3 incurs time $\widetilde{O}(\Delta s)$ for each of at most two boxes.

It remains to sum up over all side lengths $1 \leq s \leq n$ where $s = 2^\ell$ is a power of 2 (recall that at each recursive level we split the side length in two equal parts), and over all $O(n/s)$ diagonals $d$, to obtain total time $\sum_{\ell=1}^{\log n} O(n/2^\ell) \cdot \widetilde{O}(\Delta 2^\ell) = \widetilde{O}(\Delta n)$. Note that the sum over $\ell$ only adds another log-factor, which is hidden by the $\widetilde{O}$-notation. ◀



**(a)** A diagonal of boxes $D_{s,d}$.

**(b)** Three boxes inside $R_{2\Delta}$.

**(c)** The parent box is already contained in $R_{2\Delta}$.

**Figure 3** Visualizations for the proof of Lemma 24.

# Funnelselect: Cache-Oblivious Multiple Selection

**Gerth Stølting Brodal**
Aarhus University, Denmark

**Sebastian Wild**
University of Liverpool, UK

## Abstract

We present the algorithm *funnelselect*, the first optimal randomized cache-oblivious algorithm for the multiple-selection problem. The algorithm takes as input an unsorted array of $N$ elements and $q$ query ranks $r_1 < \cdots < r_q$, and returns in sorted order the $q$ input elements of rank $r_1, \ldots, r_q$, respectively. The algorithm uses expected and with high probability $O\left(\sum_{i=1}^{q+1} \frac{\Delta_i}{B} \cdot \log_{M/B} \frac{N}{\Delta_i} + \frac{N}{B}\right)$ I/Os, where $B$ is the external memory block size, $M \geq B^{1+\varepsilon}$ is the internal memory size, for some constant $\varepsilon > 0$, and $\Delta_i = r_i - r_{i-1}$ (assuming $r_0 = 0$ and $r_{q+1} = N + 1$). This is the best possible I/O bound in the cache-oblivious and external memory models. The result is achieved by reversing the computation of the cache-oblivious sorting algorithm funnelsort by Frigo, Leiserson, Prokop and Ramachandran [FOCS 1999], using randomly selected pivots for distributing elements, and pruning computations that with high probability are not expected to contain any query ranks.

## 1 Introduction

We present the first optimal randomized cache-oblivious algorithm for the multiple-selection problem. Our result combines ideas from the cache-oblivious sorting algorithm funnelsort with existing multiple-selection algorithms. Many existing time- and comparison-optimal multiple-selection algorithms are already cache oblivious, but they are not optimal with respect to the number of I/Os performed when analyzed in the cache-oblivious model.

Let us start with a brief history of the multiple-selection problem. In 1961, Hoare presented the classic randomized sorting algorithm *quicksort*, published as Algorithm 64 in the Algorithms column of the Communications of the ACM [15]. Quicksort makes essential use of the randomized algorithm *partition* (Algorithm 63 [14]), that picks a random element, denoted a *pivot*, and partitions the elements into those smaller and larger than the pivot. By recursing on each subproblem, quicksort sorts an input of size $N$ in expected $O(N \lg N)$ time and comparisons[1]. Hoare observed that if we are only interested in finding the $r$th smallest element in the input, denoted the element of *rank* $r$, we do not need to sort the input completely. By pruning recursive calls in quicksort not relevant for finding the $r$th smallest element, the resulting algorithm *find* (Algorithm 65 [16]) achieves expected $O(N)$ time. Chambers [7] generalized this idea to finding $q$ elements of $q$ given ranks $1 \leq r_1 < r_2 < \cdots < r_q \leq N$, in the following denoted the *multiple-selection* problem, by just skipping all recursive problems not containing any query rank. The expected running time is $O(N \lg q)$, but Prodinger [19] proved a tighter expected bound of $O(\mathcal{B} + N)$, where $\mathcal{B} = \sum_{i=1}^{q+1} \Delta_i \lg \frac{N}{\Delta_i}$ with $\Delta_i = r_i - r_{i-1}$, for $1 \leq i \leq q+1$, assuming $r_0 = 0$ and $r_{q+1} = N+1$.

[1] lg denotes the binary logarithm.

We call $\mathcal{B}$ the *entropy* of the multiple-selection query [3]. Dobkin and Munro [8] achieved matching asymptotic bounds for the worst-base time in the comparison model by using a deterministic linear-time (single) selection algorithm [4, 20] for the partitioning steps.

## 1.1 Model of Computation

In this paper we study the multiple-selection problem in a hierarchical-memory model, where we have an infinite external memory and an internal memory of capacity $M$ elements, and where data is transferred between the internal and external memory in blocks of $B$ consecutive elements. A block transfer is called an *I/O* (input/output operation). The I/O cost of an algorithm is the number of I/Os it performs. Aggarwal and Vitter [1] introduced this as the *external-memory model* and proved that sorting in this model requires $\Theta\big(\frac{N}{B}\log_{M/B}\frac{N}{B}\big)$ I/Os. The upper bound is, e.g., achieved by $M/B$-way mergesort and distributionsort algorithms, where the algorithms exploit knowledge of the parameters $M$ and $B$.

Frigo *et al.* [12, 13] introduced the *cache-oblivious model*, that essentially is the same as the external-memory model, except that algorithms *do not know* $M$ and $B$, and I/Os are assumed to be performed automatically by an optimal paging algorithm. As a consequence, cache-oblivious algorithms also adapt to multi-level memory hierarchies (under certain conditions [13]). The same paper introduced the cache-oblivious sorting algorithm *funnelsort* achieving the optimal external-memory I/O bound, assuming a *"tall-cache"*, $M = \Omega(B^2)$. Brodal and Fagerberg [6] observed that under the weaker tall-cache assumption $M \geq B^{1+\varepsilon}$, for a constant $\varepsilon > 0$, the optimal I/O bound increases by a factor $\Theta(1/\varepsilon)$.

Multiple selection was studied in external-memory by Hu *et al.* [17] and Barbay *et al.* [3]. The algorithms have an I/O cost of $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$, where $\mathcal{B}_{\mathrm{I/O}} = \frac{\mathcal{B}}{B\lg(M/B)}$. A matching lower bound was sketched in [3] as a reduction from sorting, assuming the multiple-selection algorithm partitions the input elements into the gaps between the queried elements (most algorithms actually solve this problem, that Chambers denoted *partial sorting*). Hu *et al.* [17] considered the case where the queried elements can be returned in arbitrary order without partial sorting, and showed that without a tall-cache assumption, this problem can actually be solved asymptotically faster for a small number of queries $q$.

## 1.2 Results

Our first result is a lower bound for the external-memory multiple-selection problem (and not only for the partial-sorting problem as in the lower bound of Barbay *et al.* [3]).

▶ **Theorem 1** (Lower bound). *External-memory multiple selection in expectation requires* $\Omega(\mathcal{B}_{\mathrm{I/O}}) - O\big(\frac{N}{B}\log_{M/B} B\big)$ *I/Os.*

Note that an external-memory lower bound is also a cache-oblivious lower bound (for any online paging strategy), and that under a tall-cache assumption $M \geq B^{1+\varepsilon}$, for a constant $\varepsilon > 0$, the last term $O\big(\frac{N}{B}\log_{M/B} B\big) = O\big(\frac{1}{\varepsilon}\cdot\frac{N}{B}\big)$. The result is obtained by combining the comparison lower bound for the multiple-selection problem by Dobkin and Munro [8] with the general reduction technique of Arge *et al.* [2], that can derive an I/O-decision-tree lower bound from a comparison-decision-tree lower bound.

Our second result is the cache-oblivious algorithm funnelselect.

▶ **Theorem 2** (Funnelselect upper bound). *There exists a randomized cache-oblivious algorithm solving the multiple-selection problem using* $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ *I/Os in expectation and with high probability.*

At the high level, the result is obtained by the standard approach of recursively partitioning by pivots and pruning computations not containing any query ranks. To achieve good I/O performance in the cache-oblivious model we pipeline the partitioning by essentially reversing the computations done by funnelsort, and replace each merging node by a partitioning node. Since we do not know the ranks of the pivots during the partitioning, we pick the pivots carefully from a random sample such that a concentration bound guarantees approximate ranks of the pivots, so we can truncate computations that with high probability do not contain any query ranks. Table 1 summarizes known and the new results.

## 1.3 Preliminaries and Notation

Throughout the paper we assume that the input to a multiple-selection algorithm are two arrays $S$ and $R$, where $S$ is an unsorted array of $N$ elements from a totally ordered universe, and $R$ is a sorted array $r_1, \ldots, r_q$ of $q$ distinct query ranks, where $1 \leq r_1 < \cdots < r_q \leq N$. Our task is to report an array of the $q$ order statistics $S_{(r_1)}, \ldots, S_{(r_q)}$, where $S_{(r)}$ is the $r$th smallest element in $S$, i.e., the element at index $r$ in an array storing $S$ after sorting it. If $x$ is an element and $S$ a set, we let $x < S$ denote that $x < y$ for all $y$ in $S$. Unless stated otherwise, we assume that all elements in $S$ are distinct.

## 1.4 Outline of Paper

In Section 2 we prove the I/O lower bound for multiple selection stated in Theorem 1. In Section 3 we present internal-memory and external-memory algorithms as a warm-up for the cache-oblivious algorithm in Section 4 achieving Theorem 2. In Section 5 we analyze the algorithm. In Section 6, we discuss how to extend the algorithm to partially sort the input, and in Section 7, we discuss how to deal with equal elements. Section 8 concludes with open problems.

# 2 Lower Bound

In this section we prove Theorem 1. Dobkin and Munro [8, Theorem 1] observed that the comparisons done by a comparison-based multiple-selection algorithm must classify the remaining elements into "*gaps*" between the selected elements, and by sorting each of these

gaps with $\Delta_i - 1$ elements using $\Delta_i \lg \Delta_i - O(\Delta_i)$ additional comparisons, one can sort the input. Together with the $N \lg N - O(N)$ lower bound on comparison based sorting, we have

$$\#\text{comparisons for multiple selection} + \sum_{i=1}^{q+1}(\Delta_i \lg \Delta_i - O(\Delta_i)) \;\geq\; N \lg N - O(N)\,,$$

implying a lower bound of $\mathcal{B} - O(N)$ on the number of comparisons for multiple selection, where $\mathcal{B} = \sum_{i=1}^{q+1} \Delta_i \lg\left(\frac{N}{\Delta_i}\right)$. This holds for worst, average, and expected case.

To prove I/O lower bounds on external-memory algorithms, Arge *et al.* [2] presented a general reduction that converts a comparison lower bound into an I/O lower bound, by converting an I/O-decision tree $T$ to a standard comparison decision tree $T_c$. An I/O-decision tree consists of unary I/O-nodes moving $B$ elements between internal and external memory, and comparison nodes between two elements in internal memory. Their lower bound reduction [2, Corollary 5] relates for any input $x$, the number of I/Os in $T$, $\#\text{I/Os}_T(x)$, to the number of comparisons in $T_c$, $\#\text{comparisons}_{T_c}(x)$, as

$$\#\text{comparisons}_{T_c}(x) \;\leq\; N \lg B + \#\text{I/Os}_T(x) \cdot B\left(3 + \lg \frac{M-B}{B}\right). \tag{1}$$

Since the reduction relates comparisons and I/Os for each input instance, the reduction can be used to show worst-case, average-case, and expected-case lower bounds.

Plugging the $\mathcal{B} - O(N)$ comparison lower bound into eq. (1) we get

$$\sum_{i=1}^{q+1} \Delta_i \lg \frac{N}{\Delta_i} - O(N) \;\leq\; N \lg B + \#\text{I/Os} \cdot B\left(3 + \lg \frac{M-B}{B}\right),$$

implying the following I/O lower bound for multiple selection:

$$\#\text{I/Os} \;\geq\; \frac{1}{1 + \frac{3}{\lg(M/B)}} \cdot \mathcal{B}_{\text{I/O}} - O\left(\frac{N}{B} \log_{M/B} B\right) \;=\; \Omega(\mathcal{B}_{\text{I/O}}) - O\left(\frac{N}{B} \log_{M/B} B\right),$$

for $M \geq 2B$ and $\mathcal{B}_{\text{I/O}} = \sum_{i=1}^{q+1} \frac{\Delta_i}{B} \log_{M/B} \frac{N}{\Delta_i} = \frac{\mathcal{B}}{B \lg(M/B)}$. This concludes the proof of Theorem 1.

Aggarwal and Vitter [1, Theorem 3.1] proved that comparison-based external-memory sorting requires $\Omega\left(\frac{N}{B} \cdot \log_{M/B} \frac{N}{B}\right)$ I/Os. This lower bound also applies to sorting in the cache-oblivious model. Brodal and Fagerberg [6, Corollary 2] showed that for a cache-oblivious sorting algorithm to be asymptotically optimal for all choices of $M$ and $B$, a "tall-cache" assumption $M \geq B^{1+\varepsilon}$ is *necessary*. Since we can sort $N$ elements using a multiple-selection algorithm by querying all ranks $1, \ldots, N$, a tall-cache assumption is also necessary for matching bounds for multiple selection in the cache-oblivious model.

## 3 Internal-Memory and External-Memory Multiple Selection

In this section we consider simple internal-memory and external-memory (cache-conscious) algorithms for multiple selection as a warm-up for our cache-oblivous algorithm in Section 4, which borrows ideas from both algorithms.

### 3.1 Internal Memory

A simple recursive internal-memory algorithm is MultiSelect (Algorithm 1). This is essentially Chamber's algorithm from 1971 [7], except for the choice of pivot. If there are no query ranks in $R$, nothing needs to be reported. Otherwise, pick a pivot $P$ from $S$, partition

**Algorithm 1** Internal-memory multiple selection.

```
1: procedure MultiSelect(S[1..N], R[1..q])
2:     if R ≠ ∅ then
3:         P ← median of S (pivot)
4:         Partition S into S_1 < P < S_2
5:         r̄ ← |S_1| + 1 (the rank of P in S)
6:         Partition R into R_1 < r̄ < R_2
7:         MultiSelect(S_1, R_1)
8:         if r̄ ∈ R then
9:             Report P
10:        MultiSelect(S_2, {r − r̄ | r ∈ R_2})
```

**Algorithm 2** External-memory multiple selection (multi-way generalization of MultiSelect).

```
1: procedure MultiSelect_I/O(S[1..N], R[1..q])
2:     if R ≠ ∅ then
3:         Find k̄ − 1 ≤ k − 1 pivots P_1 < ··· < P_{k̄−1} in S
4:         Partition S into S_1, ..., S_k̄ s.t. P_{i−1} < S_i < P_i (P_0 = −∞, P_k̄ = +∞)
5:         r̄_i ← i + |S_1| + ··· + |S_i| (the rank of P_i in S)
6:         Partition R into R_1, ..., R_k̄ s.t. r̄_{i−1} < R_i < r̄_i (r̄_0 = 0, r̄_k̄ = N + 1)
7:         for i = 1, ..., k̄ do
8:             MultiSelect_I/O(S_i, {r − r̄_{i−1} | r ∈ R_i})
9:             if r̄_i ∈ R then
10:                Report P_i
```

$S \setminus \{P\}$ into $S_1$ and $S_2$, such that $S_1 < P < S_2$, compute the rank $\bar{r}$ of the pivot $P$ in $S$, partition $R \setminus \{\bar{r}\}$ into $R_1$ and $R_2$, such that $R_1 < \bar{r} < R_2$, and recurse on the subproblems $(S_1, R_1)$ and $(S_2, R_2)$. The pivot $P$ is output before the second recursion if $\bar{r}$ is a query rank in $R$ (so elements are reported in increasing rank order). This intuitively corresponds to a distributionsort/quicksort, where we truncate recursive calls not containing any query ranks in $R$.

In Algorithm 1, $P$ is the exact median of $S$, but we could also have used an approximate median, or a randomly sampled pivot. Chamber's original algorithm uses a random element from $S$. Finding the pivot can be done using the deterministic linear-time median finding algorithms by Blum *et al.* [4] or the randomized algorithms by Hoare [16] or Floyd and Rivest [11]. Prodinger [19] proved that selecting a random pivot leads to expected overall $O(\mathcal{B} + N)$ time. Kaligosi *et al.* [18, Section 2] proved that Algorithm 1 achieves $O(\mathcal{B} + N)$ worst-case time, if a linear time median selection algorithm is used.

Algorithm MultiSelect is cache oblivious, since it is designed independently of the memory parameter $B$ and $M$. All the above median algorithms are based on repeatedly scanning arrays and (analyzed in the cache-oblivious model) require $O(N/B)$ I/Os worst-case and expected, respectively. Since the additional work of MultiSelect can be implemented by repeatedly scanning arrays allocated on a stack, the I/O cost of the algorithm equals the internal computation time divided by the external-memory block size, i.e., $O(\mathcal{B}/B)$ I/Os. Our cache-oblivious algorithm from Section 4 improves upon this I/O cost by a factor $\Theta\big(\lg \frac{M}{B}\big)$.

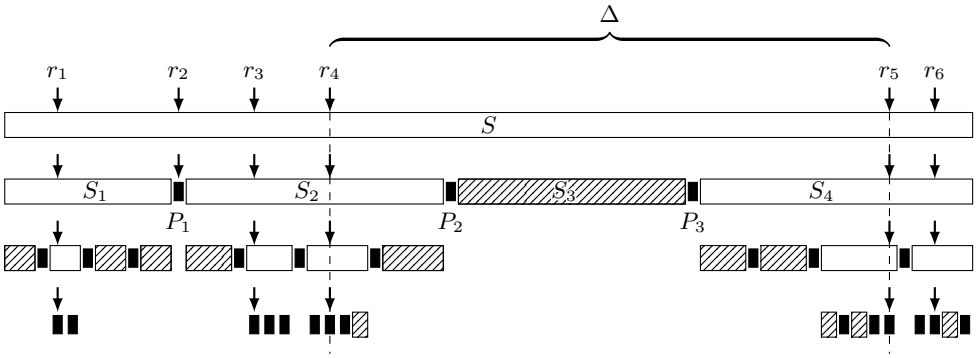

**Figure 1** Recursion for MultiSelect$_{I/O}$ with six query ranks and $k = 4$. Black squares are pivots, arrows show rank queries, and shaded areas are skipped subproblems with no query ranks.

## 3.2 External Memory

A generalization of MultiSelect better suited for external memory is to replace the binary partitioning by a multi-way partitioning. For a parameter $k \geq 2$, we assume the set $S$ is partitioned into $\bar{k} \leq k$ subsets around $\bar{k} - 1$ pivots, where each set has size $O(|S|/k)$. The resulting algorithm is shown as MultiSelect$_{I/O}$ in Algorithm 2. Figure 1 shows a recursion for MultiSelect$_{I/O}$ on an example with six query ranks. If all sets $S_i$ defined by the pivots have size at most $\alpha|S|$, where $1/k \leq \alpha < 1$, we denote the partitioning a $(k, \alpha)$-*partitioning*. The algorithm MultiSelect (with exact medians) is the special case of MultiSelect$_{I/O}$, where we use a $\left(2, \frac{1}{2}\right)$-partitioning.

There are several $(k, O(1/k))$-partitioning schemes described in the literature, e.g., a $(k, 1.5/k)$-partitioning method with $k = \sqrt{M/B}$ by Aggarwal and Vitter [1]. Here we describe a simpler $(k, 2/k)$-partitioning that incrementally inserts the $N$ elements of $S$ into buckets defined by a monotonically growing set of pivots, that also works for $k = \Theta(M/B)$. Initially there is one empty bucket and no pivot. Whenever a bucket reaches size $> 2N/k$ (i.e., the size is $1 + \lfloor 2N/k \rfloor$), the median of the bucket is selected as a new pivot, and the bucket is split around the pivot into two buckets with the elements smaller than and larger than the new pivot, respectively. Each new bucket has size at least $\lfloor N/k \rfloor$. Therefore, the total number of buckets created is at most $k$ and each bucket contains at most $2N/k$ elements.

Crucial for the I/O effectiveness of this partitioning is that one memory block from each bucket is in memory while scanning $S$ and distributing elements to buckets, i.e., $k \leq c\frac{M}{B}$ for a suitable constant $0 < c < 1$. Since each bucket can be split using $O(N/(kB))$ I/Os using the deterministic selection algorithm from [4], the total cost for creating a $(k, 2/k)$-partitioning of $S$ is $O(N/B)$ I/Os, provided $k \leq c\frac{M}{B}$. A binary search to find the bucket for an element requires $\leq \lceil \lg(k-1) \rceil$ comparisons with pivots, i.e., in total $O(N \lg k)$ comparisons for distributing to buckets. Since each of the at most $k - 1$ bucket splits requires $O(N/k)$ comparisons [4], creating a $(k, 2k)$-partitioning requires $O(N \lg k)$ comparisons.

## 3.3 Analysis

We now analyze the comparison and I/O cost of MultiSelect$_{I/O}$. Assume creating a $(k, \alpha)$-partitioning has an (abstract) cost of $C \cdot N$, where $C = C(k, \alpha, M, B)$ does not depend on $N$. For example, when counting comparisons we have $C = \Theta(\lg k)$. The total cost of MultiSelect$_{I/O}$ is the sum of the costs of all partitioning steps, i.e., $C$ times the sum of the sizes of all the subsets partitioned by the algorithm (the white rectangles in Figure 1).

Consider any fixed gap $\Delta$ between two query ranks. We assume that the right query rank (but not the left) is part of the gap, so that all elements of $S$ belong to exactly one gap. At each level of the recursion, the gap $\Delta$ intersects at most two subproblems that need to be partitioned, namely the subproblems containing the query ranks at the boundary of $\Delta$ (illustrated by the dashed lines in Figure 1). Since subproblems at depth $d$ of the recursion have size at most $\alpha^d N$, the total cost we need to charge within gap $\Delta$ is at most $C$ times

$$\sum_{d=0}^{\infty} \min(\Delta, 2\alpha^d N) \;\leq\; \Delta \left\lfloor \log_{1/\alpha} \frac{2N}{\Delta} \right\rfloor + \Delta \sum_{i=0}^{\infty} \alpha^i \;\leq\; \Delta \log_{1/\alpha} \frac{2N}{\Delta} + \frac{\Delta}{1-\alpha} \,.$$

Here we use that $2\alpha^d N$ is geometrically decreasing and $\Delta = 2\alpha^d N$ implies $d = \log_{1/\alpha} \frac{2N}{\Delta}$, i.e., in the sum, $\Delta$ is the term for the first $\lfloor \log_{1/\alpha} \frac{2N}{\Delta} \rfloor$ levels, whereas the remaining terms are geometrically decreasing, starting with at most $\Delta$. Summing over all gaps we obtain total cost at most

$$C \cdot \left( \sum_{i=1}^{q+1} \Delta_i \log_{1/\alpha} \frac{2N}{\Delta_i} + \frac{N}{1-\alpha} \right) . \tag{2}$$

Recall that MultiSelect is the special case of MultiSelect$_{\mathrm{I/O}}$ with $k = 2$ and $\alpha = 1/2$. For comparisons, we have $C = O(1)$ per processed element in partitioning. By eq. (2), the total number of comparisons in MultiSelect is $O(\mathcal{B} + N)$. For MultiSelect$_{\mathrm{I/O}}$ we have $k = cM/B$ and $\alpha = 2/k$, and a cost of $C = O(1/B)$ I/Os per processed element, so by eq. (2), MultiSelect$_{\mathrm{I/O}}$ has a total cost of $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ I/Os. Alternatively, using the multiway partitioning method of Aggarwal and Vitter [1] with $k = \sqrt{M/B}$, $\alpha = 1.5/k$, and cost $C = O(1/B)$ for I/Os, we also get a total cost of $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ I/Os from eq. (2).

## 4 Cache-Oblivious Multiple Selection

In this section we present our cache-oblivious multiple-selection algorithm FunnelSelect (Algorithm 4). We first recall funnels for merging (Section 4.1) and then show that they can be used for partitioning (Section 4.2). FunnelSelect performs a single round of such a funnel-based partitioning, splitting the input into $k$ parts of expected size $\Theta(N/k)$ using $k-1$ pivots, where $k = \Theta(N^{1/d})$ and $d = \max\{1 + 2/\varepsilon, 3\}$ under the tall-cache assumption $M \geq B^{1+\varepsilon}$. We then deal with each of the $k$ parts with a non-empty set of rank queries by fully sorting it and returning the sought ranks.

However, to stay within the allowed I/O bound, we have to truncate partitioning, namely whenever neither side of the split is likely to contain a query rank (Section 4.4). To boost the probability of "guessing correctly" which buckets query ranks fall into, we also have to choose pivots judiciously (Section 4.3). Section 5 then proves Theorem 2.

### 4.1 Funnelsort

Since our cache-oblivious multiple-selection algorithm is heavily based on ideas from the optimal cache-oblivious sorting algorithm funnelsort by Frigo *et al.* [12, Section 4], we briefly recall funnelsort and in particular its $k$-merger construction here.[2] Funnelsort uses

[2] It should be noted that the cache-oblivious distributionsort algorithm in [12, Section 5] is a significantly different approach than the one taken by funnelsort and our algorithm, even though our algorithm highly resembles a classic internal-memory distributionsort algorithm.

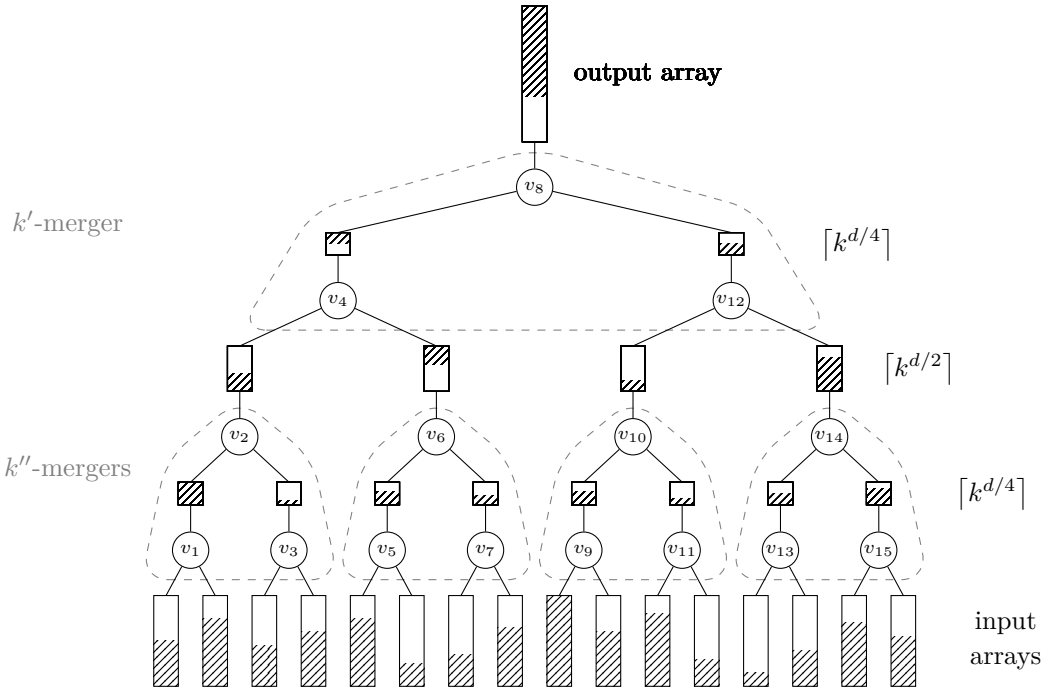

**Figure 2** A $k$-merger in funnelsort for $k = 16$ input arrays. Content in the buffers is shaded; elements are added to the bottom of buffers and consumed from the top of buffers. The figure shows the situation where $v_6$ is in the process of filling its output buffer, after being recursively called from $v_4$ during its merging, which in turn has been called by $v_8$ during its merging. Buffer sizes for the three internal levels are shown next to the buffers.

$O(\frac{N}{B} \log_{M/B} \frac{N}{B})$ I/Os, assuming the tall-cache assumption $M \geq B^2$. Brodal and Fagerberg [5, Lemma 1] presented a lazy version of funnelsort, achieving the same I/O bound under the weaker tall-cache assumption $M \geq B^{1+\varepsilon}$, for any constant $\varepsilon > 0$. Funnelsort sorts an array of $N$ elements by an outer recursion that partitions the input into $k$ arrays each of size at most $\lceil N/k \rceil$, sorts these subarrays recursively, and then merges these arrays using a $k$-way construction named a *$k$-merger*. The parameter $k$ depends on the tall-cache assumption (via $\varepsilon$) and the input size $N$: $k = 2^{\lceil \lg(N)/d \rceil} = \Theta(N^{1/d})$ for $d = 1 + 2/\varepsilon$.

A $k$-merger (see Figure 2) consists of a perfectly balanced binary tree of height $\lg k$ of binary *merger-nodes*, where each tree edge contains a buffer that is a sorted array of elements. Each merger-node consumes elements from two child buffers and feeds into its parent output buffer. When invoking a merger-node $v$, the node $v$ fills its output buffer by merging the content of its input buffers until either the output buffer is full or one of the input buffers is exhausted. If the input buffer of a child $w$ is exhausted, we recursively invoke $w$ to fill its output buffer; then $v$ continues to fill its output buffer.

The I/O efficiency of funnelsort hinges entirely on a judicious choice of buffer sizes. The buffers connecting the middle levels of binary mergers (between level $\lceil \lg(k)/2 \rceil$ and one below) can hold $\lceil k^{d/2} \rceil$ elements each. The construction is recursively applied to a $k' = 2^{\lceil \lg(k)/2 \rceil} \approx \sqrt{k}$-merger forming the top $\lceil \lg(k)/2 \rceil$ levels and the $k'$ children each of which is a $k'' = 2^{\lfloor \lg(k)/2 \rfloor} \approx \sqrt{k}$-merger below the middle buffers; following a van-Emde-Boas layout of the binary tree and recursively allocating buffers consecutively in memory in that order.

## 4.2 Funnels for Partitioning

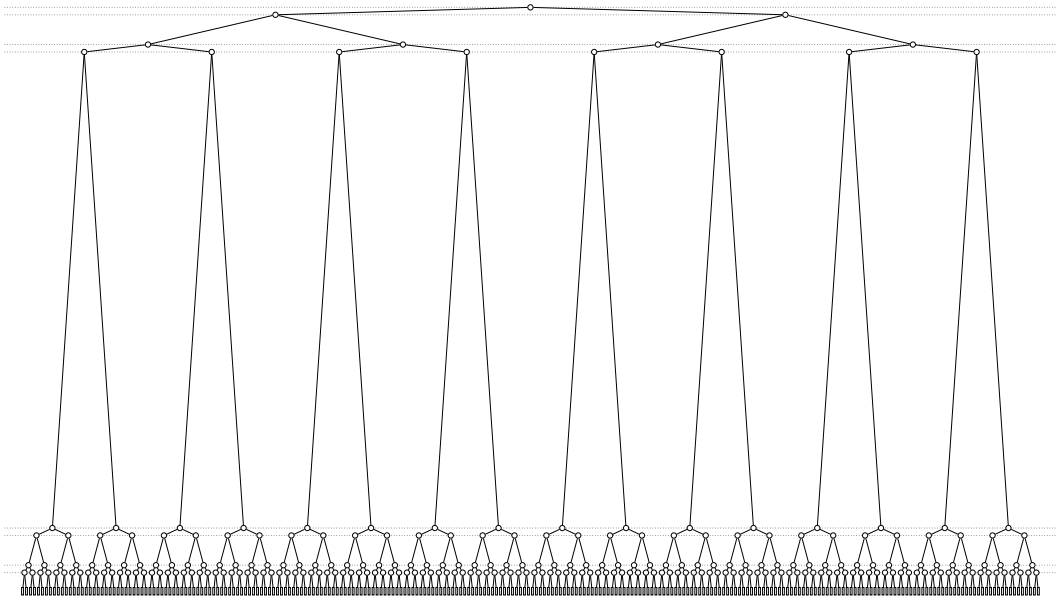

**Figure 3** A 256-partitioner; splitter nodes are shown as circles (as in Figure 2); buffers are only shown as edges, but with the vertical length of the edges to scale with the buffer sizes for $d = 2$. (Buffer sizes by level are 4, 16, 4, 256, 4, 16, 4).

A key innovation of this paper is the *k-partitioner*, which uses funnels *in reverse*: instead of merging $k$ runs, we push elements down the funnel while partitioning them around $k-1$ pivots into $k$ buckets. We use the same internal buffer sizes for a $k$-partitioner as in a $k$-merger; each buffer is organized as a queue and maintains an element count. The $k$ output buffers at the bottom of a $k$-partitioner are conceptually unbounded (never full). Note that in partitioning, we always know the number $N$ of elements and can allocate output buffers as linked lists of blocks of size $\Theta(N/k)$. Calling Partition (Algorithm 3) on a node $v$ partitions elements around $v$'s pivot and passes them to one of $v$'s children, recursively emptying these whenever they become full. FunnelPartition starts with all elements in the root's input buffer and then calls Partition on the root. After that, Flush recursively empties any remaining nonempty buffers.

Figure 2 can be read *mutatis mutandi* as a $k$-partitioner instead of a $k$-merger: Each node $v_i$ stores a pivot $P_i$ and Partition pushes elements towards the leaves. Buffers are consumed from the bottom and filled at the top of the hatched area. Figure 2 shows an overall Partition call at $v_8$, where first $v_4$ and then $v_6$ had run full; currently $v_6$ is moving elements from its parent buffer to its child buffers. Note that buffer sizes in Figure 2 are not drawn to scale; Figure 3 gives a more truthful representation.

The main property of $k$-partitioners is given in Lemma 3 below. It is similar to [6, Lemma 1], but we give a self-contained proof here.

▶ **Lemma 3** (Funnel lemma). *There exists a constant $c \geq 1$ so that the following holds. Let $d \geq 2$ be a constant. The size of a $k$-partitioner (excluding its output buffers) is bounded by $c \cdot k^{(d+1)/2}$. Assume $d \geq 2$ is such that $B^{1+\varepsilon} \leq M/3$ where $\varepsilon = 2/(d-1)$. Partitioning $N \geq k^d$ elements with FunnelPartition around $k-1$ pivots uses $N \lg(k)$ comparisons and incurs $O\big(\frac{N}{B}(\log_M(k)+1)+k\big)$ I/Os.*

**Algorithm 3** Operations on $k$-partitioners. The *full*() method returns whether a buffer has capacity for further elements. The *clear*() method removes all current elements from a buffer.

```
1:  procedure FunnelPartition(S[1..N], P[1..k − 1])
2:      Sort P
3:      Build k-partitioner, using P as pivots (assigned in in-order to nodes)
4:      r ← root node of k-partitioner
5:      Partition(r, S)
6:      Flush(r)
7:      Return k-partitioner output buffers

8:  procedure Partition(v, S[1..N])
9:      for x ∈ S do
10:         if x ≤ v.pivot then
11:             if v.leftBuffer.full() then
12:                 Partition(v.left, v.leftBuffer)
13:             v.leftBuffer.append(x)
14:         else
15:             if v.rightBuffer.full() then
16:                 Partition(v.right, v.rightBuffer)
17:             v.rightBuffer.append(x)
18:     S.clear()

19: procedure Flush(v)
20:     if v ≠ null then
21:         Partition(v.left, v.leftBuffer)
22:         Flush(v.left)
23:         Partition(v.right, v.rightBuffer)
24:         Flush(v.right)
```

**Proof.** Let $h = \lg(k)$; by definition of $k$, we have $h \in \mathbb{N}$. The space usage is given recursively by $s(k) = k' \cdot \lceil k^{d/2} \rceil + s(k') + k' \cdot s(k'')$; where $k' = 2^{\lceil h/2 \rceil}$ and $k'' = 2^{\lfloor h/2 \rfloor}$ are the number of leaves in the top funnel and the bottom funnels, respectively. Assuming $k = 2^{2^i}$ for $i \in \mathbb{N}$, this simplifies to $s(k) = k^{(d+1)/2} + (k^{1/2} + 1)s(k^{1/2})$, which satisfies $s(k) \leq S(k)$ where we set $S(k) = ck^{(d+1)/2}$ for a constant $c \geq 1$ that depends on initial conditions; if we use $s(4) = 2 \cdot 4^{d/2} + 3$ (space for the buffers and the 3 pivots), $c \geq 2.2$ suffices. The bound $s(k) \leq S(k)$ indeed remains valid even when $h$ is not a power of 2.

For the analysis of the I/O bound, let $M$ and $B$ with $B^{(d+1)/(d-1)} \leq M/3$ ("tall-cache assumption") be given. We follow the recursive construction of the funnel until a $\hat{k}$-partitioner $\hat{F}$ satisfies $S(\hat{k}) \leq M/3$, i.e., its it fits entirely into (a third of the) internal memory. For that choice, by the tall-cache assumption, the whole $\hat{k}$-partitioner and one block per child and parent buffer fit into internal memory: $S(\hat{k}) + (\hat{k} + 1)B \leq M$.

Call the edges/buffers connecting $\hat{F}$ to its parent and children *large* (if they exist). For the analysis, imagine removing all large edges; this leaves us with disconnected *base trees*, which in the $k$-partitioner are connected only by the large edges. Note that between any two levels, either none or all edges are large. However, unless $k = 2^{2^i}$, the height $\hat{h} = \lg(\hat{k})$ of a base tree can vary between $\underline{h} = \lg(M/(3c))/(d + 1)$ and $\overline{h} = 2\underline{h}$.

Now consider a call to PARTITION at the root of a base tree $\hat{F}$ with $\hat{k}$ leaves. Over the course of (recursively) pushing elements down through $\hat{F}$, we incur I/Os for loading the buffers and pivots of $\hat{F}$. Since base trees fit entirely into internal memory, unless there is another call triggered on a child base tree upon a full (large) buffer, we will only load buffers inside the $\hat{k}$-partitioner into memory once, at a total cost of $O(S(\hat{k})/B)$ I/Os; we also need to bring one block for each parent and child buffer into memory, using $O(\hat{k})$ I/Os. We now distinguish two cases.

Case (1): If $\hat{k} = k$, i.e., $\hat{F}$ is the entire $k$-partitioner. Since $\hat{F}$ (as well as one block per input and output buffer) fits into internal memory, we only need to load it once, at a cost of $O(S(k)/B + k)$ I/Os. This is $O(k^{(d+1)/2}/B + k) = O(k^d/B + k) = O(N/B + k) = O(N/B(\log_M(k) + 1) + k)$ as claimed.

Case (2): Otherwise, $\hat{k} < k$. We will argue that the following potential scheme pays for all I/Os costs: Whenever an element is inserted into a large buffer, it releases $\Theta(1/B)$ potential.

We first show that charging all elements for this released potential yields the desired bound. Between any two large buffers, one partitioning phase moves an element at least $\underline{h}$ levels down the tree. Overall, the $N$ elements need to travel at most $h = \lg(k)$ levels down, hence each element can be inserted at most $\lceil h/\underline{h} \rceil = O(\log_M(k) + 1)$ times into a large buffer, giving an overall potential of $O\big(\frac{N}{B}(\log_M(k) + 1)\big) = O\big(\frac{N}{B}(\log_M(k) + 1) + k\big)$ as claimed.

It remains to prove that the released potential exceeds the incurred I/O cost. First observe that we initially have to load each $\hat{F}$ when it is first used; likewise, we have to potentially load each $\hat{F}$ an additional time during the final FLUSH calls. These two load events sum to $O(S(k)/B + k)$ I/Os, which is $O(N/B + k)$ (as in case (1) above). Additionally, at any point in time during a PARTITION call on $\hat{F}$, we can get recursive PARTITION calls on $\hat{F}$'s child base trees in case their buffer becomes full; such a recursive call can evict $\hat{F}$ from the internal memory, and it has to be loaded before PARTITION resumes on $\hat{F}$, causing additional I/Os. We cannot say *when* these evictions will happen, but every eviction of $\hat{F}$ implies that a batch of $\beta$ elements have been pushed down from $\hat{F}$'s input buffer to a child's buffer, where $\beta$ is the size of the buffers below $\hat{F}$. By the recursive funnel construction, $\beta = \Omega(\hat{k}^d)$, so we must have seen a total release of $\Theta(\beta/B) = \Omega(\hat{k}^d/B)$ in potential. Since $\hat{k}$ is the first value with $S(\hat{k}) \leq M/3$, we have $S(2\hat{k}^2) > M/3$, which implies, $M = O(\hat{k}^{d+1})$. By the tall-cache assumption, this implies $B = O(M^{(d-1)/(d+1)}) = O\big((\hat{k}^{(d+1)})^{(d-1)/(d+1)}\big) = O(\hat{k}^{d-1})$, so $\hat{k} = O(\hat{k}^d/B)$. Hence, the cost of loading $\hat{F}$ again after an eviction of $O(S(\hat{k})/B + \hat{k}) = O(\hat{k}^d/B)$ I/Os is covered by a release in potential. ◀

On a conceptual level, a $k$-partitioner can be thought of as a cache-oblivious gadget for repeatedly partitioning with (variable) fan-out in $\Omega(M^{1/(d+1)}) \cap O(M^{2/(d+1)})$ that, when applied to $\Omega(M^{d/(d+1)})$ elements, uses $O(1/B)$ I/Os per element and partitioning round. This results from the bounds on $\hat{k}$ in base trees in the proof above.

## 4.3 Selecting Pivots

For funnelselect, we choose pivots $P_1, \ldots, P_{k-1}$ as follows; see also Figure 4: We first sample each element in the input $S$ with probability $p = 1/\lg N$. The resulting sample $\bar{S}$ is sorted. Finally we select the pivots as the ideal pivots in the sample, using the (expected) sample size $pN$: the $i$th pivot $P_i$ is the $\lfloor 1 + ipN/k \rfloor$th smallest element of $\bar{S}$. If $\bar{S}$ is too small, i.e., if $|\bar{S}| < \lfloor (k-1)pN/k \rfloor$ or $|\bar{S}| > 2pN$, we declare the pivot selection *failed* and repeat the sampling process.

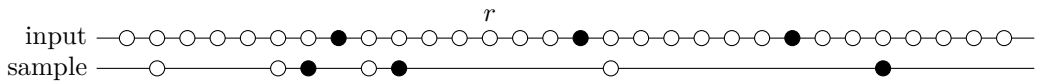

**Figure 4** Using sampling to select $k-1$ pivots for a $k$-way partitioning of the input, when $k=4$ and $N=30$. The expected sample size was 9 elements, but only 7 were actually sampled. Top shows the sorted input and $k-1$ ideal pivots, whereas the bottom shows similarly $k-1$ ideal pivots for a sample of the input points. Note the input of rank $r$ is in the 2nd block of white nodes defined by the ideal pivots, but would be in the 3rd block defined by the actual pivots from the sample.

In Lemma 6 we prove that all pivots are expected "close" to the ideal pivots in $S$. We call the $i$th pivot $P_i$ "$\xi$-bad" if its rank is more than $\xi$ away from its ideal rank, more formally

$$P_i \text{ is "}\xi\text{-bad"} \quad \text{if and only if} \quad \big|S \cap (-\infty, P_i]\big| \notin \big[\lfloor 1 + iN/k \rfloor - \xi\,,\, \lfloor 1 + iN/k \rfloor + \xi\big]\,.$$

We will call $P_i$ *bad* if it is $\xi$-bad; otherwise it is *good*. We call a pivot selection "bad" if any of the pivots is bad, and "good" otherwise. We select $\xi = \lceil N^{1/2+\delta} \rceil$ for a small constant $\delta$, where $0 < \delta < 1/6$. Since we assume $d \geq 3$, $k = \Theta\big(N^{1/d}\big)$ implies $N/k = \Omega\big(N^{2/3}\big)$, and $\xi < \frac{1}{2}N/k$ for sufficiently large $N$. We get the following fact:

▶ **Fact 4** (Good pivots). *If $\xi < \frac{1}{2}N/k$ and all pivots are good,*

**(a)** *no bucket $S_i$ contains more than $N/k + 2\xi \leq 2N/k$ elements, and*

**(b)** *a query for a rank $r$ will fall into one of at most two buckets: the $\lceil (r-\xi)/N \cdot k \rceil$th or the $\lceil (r+\xi)/N \cdot k \rceil$th bucket.*

Our analysis makes iterated use of the following Chernoff bound.

▶ **Lemma 5** ([10, Theorem 1.1]). *If $X_1, \ldots, X_n$ are independent random variables in $[0,1]$, and $X = X_1 + \cdots + X_n$, then for all $t > 0$ we have*

$$\Pr[X < \mathbb{E}[X] - t],\ \Pr[X > \mathbb{E}[X] + t] \quad \leq \quad e^{-2t^2/n}\,.$$

▶ **Lemma 6.** *The probability that $P_i$ is $\xi$-bad is bounded by $2\exp\big(-2\xi^2 p^2/N\big)$.*

**Proof.** $P_i$ is bad if its rank in $S$ is too small ("small bad") or too big ("big bad"). We first consider too small ranks. By choice, there are $ipN/k$ elements in $\bar{S}$ smaller than $P_i$; if $P_i$ has small-bad rank, all of these elements must be of rank $< iN/k - \xi$ in $S$. That means, from these $iN/k - \xi - 1$ smallest elements in $S$, we have chosen at least $ipN/k$ into $\bar{S}$. Since each choice is done independently with probability $p = 1/\lg N$, the number chosen for the sample is $X \stackrel{\mathcal{D}}{=} \mathrm{Bin}(iN/k - \xi - 1, p)$, a random variable with binomial distribution and expectation $\mathbb{E}[X] = p(iN/k - \xi - 1)$. We have

$$\begin{aligned}\mathbb{P}[P_i \text{ "small bad"}] \quad &\leq \quad \mathbb{P}[X \geq piN/k] \quad \leq \quad \mathbb{P}[X > \mathbb{E}[X] + p\xi] \\ &\underset{\text{Lemma 5}}{\leq} \exp\left(-2\frac{(p\xi)^2}{iN/k - \xi - 1}\right) \quad \leq \quad \exp\left(-\frac{2\xi^2 p^2}{N}\right).\end{aligned}$$

For the "big-bad" case, we must have chosen at most $ipN/k$ elements from the $iN/k + \xi + 1$ smallest elements in $S$ into $\bar{S}$. With $X' \stackrel{\mathcal{D}}{=} \mathrm{Bin}(iN/k + \xi + 1, p)$, we obtain

$$\mathbb{P}[P_i \text{ "big bad"}] \quad \leq \quad \mathbb{P}[X' \leq piN/k] \quad \leq \quad \mathbb{P}[X' < \mathbb{E}[X'] - p\xi] \quad \leq \quad \exp\left(-\frac{2\xi^2 p^2}{N}\right).$$

By the union bound, $P_i$ is bad with probability at most $2\exp\big(-2\xi^2 p^2/N\big)$. ◀

▶ **Lemma 7.** *The probability that the sample is too small to choose $k-1$ pivots is bounded by* $\exp\big(-2(pN/k-1)^2/N\big)$.

**Proof.** For the sample to be too small, we must have selected at most $(k-1)pN/k$ elements into the sample. Since $|\bar{S}| \stackrel{D}{=} \mathrm{Bin}(N,p)$, we have by Lemma 5

$$\mathbb{P}[\bar{S} \text{ too small}] \;=\; \mathbb{P}[|\bar{S}| \le \mathbb{E}[|\bar{S}|] - pN/k] \;\le\; \exp\left(-2\frac{(pN/k-1)^2}{N}\right). \qquad \blacktriangleleft$$

▶ **Corollary 8.** *With high probability, the pivot choice is well-defined and all $k-1$ pivots of one sampling round are good.*

**Proof.** By Lemmas 6 and 7 and the union bound, the probability that the sample is too small to choose our pivots or that any $P_i$ is bad is at most

$$2(k-1)\exp\big(-2\xi^2p^2/N\big) + \exp\big(-2(pN/k-1)^2/N\big) \;\le\; 2k\exp\big(-\Omega\big(N^{2\delta}/\lg^2 N\big)\big).$$

The inequality follows from $p = 1/\lg(N)$, $\xi = \Omega\big(N^{1/2+\delta}\big)$, $N/k = \Omega\big(N^{2/3}\big)$, and $\delta < 1/6$. This probability tends to 0 with speed superpolynomial in $N$. $\blacktriangleleft$

## 4.4 Truncated Partitioning

The algorithms from Section 3 achieve optimal cost from simply not recursing on subproblems not containing any query rank; after partitioning, it is obvious which subproblems are "query free". In a cache-oblivious algorithm, we have to truncate partitioning *inside* the $k$-partitioner.

After $k$-partitioning the input, elements are split into $k$ buckets; let us denote these buckets by $S_1, \ldots, S_k$. By Fact 4(b), when pivots are good, a query rank $r$ will fall in one of two buckets: one in $S(r) = \{S_{\lceil (r-\xi)/N\cdot k\rceil}, S_{\lceil (r+\xi)/N\cdot k\rceil}\}$. Buckets in the set $QF = \{S_1,\ldots,S_k\} \setminus \bigcup_{r\in R} S(r)$ do not contain any query ranks whenever pivots are good; we call these buckets *"expected query-free"*. Note that this is a property solely of $R$ and $k$ and hence $QF$ can be determined by scanning $R$ before partitioning commences.

When constructing the $k$-partitioner $F$, we check in a depth-first traversal whether all leaves below a binary partitioning node $v$ are in $QF$; if so, we remove $v$ and rewire its parent to send elements directly to an output buffer instead of $v$'s input buffer. The sizes of buffers between partitioning nodes and the Partition methods remain unchanged. By generating the output buffers for the leaves of $F$ consecutive in memory, before all internal buffers and reserving $2N/k$ space for each, this truncation operation simply changes one pointer.

## 4.5 Funnelselect

The overall algorithm FunnelSelect is shown in Algorithm 4. It applies one round of truncated $k$-partitioning as described above. For each of the resulting buckets, we then simply invoke an existing I/O-optimal cache-oblivious sorting algorithm and report the sought ranks. This can be done as a stack-based computation, so that no extra I/Os are paid for reporting elements, but instead they are reported while they are in main memory anyways from sorting.

# 5 Analysis

▶ **Theorem 9.** *Algorithm FunnelSelect is cache oblivious and uses $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ I/Os to report $q$ query ranks $r_1 < \cdots < r_q$ from an unsorted array of $N$ elements. With high probability it does not fail.*

**Algorithm 4** Our overall cache-oblivious multiple-selection algorithm.

```
1: procedure FunnelSelect(S[1..N], R[1..q], δ)
2:     p ← 1/lg N
3:     k ← 2^⌈lg(N)/d⌉
4:     ξ ← ⌈N^{1/2+δ}⌉
5:     Scan S, copy each element into the sample S̄ i.i.d. with prob. p
6:     if |S̄| ≤ (k−1)pN/k ∨ |S̄| < (1/2)Np ∨ |S̄| > 2Np then
7:         return Fail
8:     Sort S̄
9:     for i = 1, ..., k−1 do
10:        P_i ← S̄[⌊1 + ipN/k⌋] (select pivots from S̄)
11:    Construct k-partitioner F using pivots P_1, ..., P_{k−1}; let S_1, ..., S_k be its leaf buckets
12:    for r ∈ R do
13:        b_1 ← ⌈(r − ξ)/N · k⌉ and b_2 ← ⌈(r + ξ)/N · k⌉
14:        Mark leaf buckets S_{b_1} and S_{b_2} as expected query free
15:    for node v in bottom-up traversal of F do
16:        if both of v's children are marked expected query free then
17:            Mark v as expected query free
18:            Delete v's children
19:    for node v in preorder traversal of F do
20:        if v marked expected query free then
21:            Declare v's parent an expected query free output buffer
22:            Delete v
23:    Partition(F.root, S)
24:    Flush(F.root)
25:    L_1, ..., L_{k̂} ← leaf buckets in F
26:    ℓ ← 0
27:    for i = 1, ..., k̂ do
28:        R′ ← R ∩ (ℓ, ℓ + |L_i|]
29:        if R′ ≠ ∅ then
30:            if L_i marked expected query free ∨ |L_i| > 2N/k then
31:                return Fail
32:            else
33:                Sort L_i using an I/O-optimal cache-oblivious sorting algorithm.
34:                for r ∈ R′ do
35:                    Report L_i[r − ℓ]
36:        ℓ ← ℓ + |L_i|
```

**Proof.** Let us first deal with failures. We let the algorithm fail if $|\bar{S}|$ is smaller than $\frac{1}{2}Np$ or larger than $2Np$. From Lemma 5, with high probability, this does not happen. The only other cause for failure are bad pivots; by Corollary 8 with high probability, this also does not happen.

For the I/O cost, we consider the different steps in turn. The I/O cost for computing the pivots consists of $O(N/B)$ I/Os to scan the input to construct the sample $\bar{S}$ of size at most $\bar{N} = 2N/\lg N$. To sort the sample, we can use standard top-down mergesort, yielding $O(\bar{N}/B \cdot \lg(\bar{N}/M)) = O(N/B)$ I/Os for sorting $\bar{S}$ and $O(N/B)$ I/Os to extract the pivots from $\bar{S}$. In total selecting the pivots requires $O(N/B)$ I/Os.

The buffers of $F$ can be built sequentially, using $O(k^{(d+1)/2}/B) = O(N^{(d+1)/2d}/B) = O(N/B)$ I/Os (Lemma 3). Preparing the leaf buffers additionally touches $k = O(N^{1/d})$ positions; if $N^{1/d} > N/B$, then $B > N^{(d-1)/d}$ and by the tall-cache assumption, $M \geq B^{(d+1)/(d-1)} > N^{(d+1)/d}$, so the entire input fits in internal memory and the $k$ accesses are cached. The same applies for truncating the $k$-partitioner; anything touching $O(k)$ random positions incurs $O(N/B)$ I/Os. Marking leaves and nodes as expected query-free can be done by scanning $R$ (which is sorted), hence we use $O(q/B) = O(N/B)$ I/Os.

The key step is the $k$-partitioner. As in the proof of Lemma 3, we define $\hat{k}$ as the level in the recursive construction of the partitioner where the $\hat{k}$-partitioner first fits into internal memory. We overestimate the actual cost by always assuming the smallest $\hat{k} = (M/3c)^{1/(d+1)}$. As shown there, the $k$-partitioner has up to constant factors the same I/O cost as a repeated $\hat{k}$-way external-memory partitioning: $O(1/B)$ I/Os per element and $\hat{k}$-way split. This remains true when truncating the same subtrees in both algorithms. We can hence bound the cost of funnel partitioning as in Section 3 by charging the lengths of segments that are split further (white rectangles in Figure 1) to individual gaps $\Delta$. For MultiSelect$_{\mathrm{I/O}}$, charging a gap $\Delta$ on each level either $\Delta$ or the 2 segments containing its endpoints, whichever is less, was sufficient to cover all partitioning costs. For FunnelSelect, due to marking (up to) two leaf buckets as not query-free for the endpoints, we can have up to 4 segments on any level that still require partitioning. The rest of the analysis is the same, though, and with $C = O(1/B)$, $k = \hat{k}$, and $\alpha = 2/\hat{k}$, we obtain an upper bound of

$$C \cdot \left( \sum_{i=1}^{q+1} \Delta_i \log_{1/\alpha} \frac{4N}{\Delta_i} + \frac{N}{1-\alpha} \right) \quad = \quad O(\mathcal{B}_{\mathrm{I/O}} + N/B)$$

I/Os for partitioning.

The last part of the algorithm, solving subinstances of multiple selection within leaf buckets, could be solved recursively, but as we now show, fully sorting such buckets also fits our desired I/O bound. This improves the failure probability as sorting can be deterministic. A subproblem $L_i$ to recurse on is never declared query-free and hence moves all the $\lg k$ levels down the $k$-partitioner. For $N' = |L_i|$, $L_i$ hence contributes $\Theta\big(\frac{N'}{B} \log_M k\big) = \Theta\big(\frac{N'}{B} \log_{M/B} N\big)$ I/Os to the partitioning cost, since $k = \Theta\big(N^{1/d}\big)$ and under our tall-cache assumption $\lg \frac{M}{B} = \Theta(\lg M)$. This is an upper bound on the I/O cost of sorting $N'$ elements. Any I/O-efficient cache-oblivious sorting method (such as funnelsort) hence suffices for overall $O(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B})$ I/Os. ◀

▶ **Corollary 10.** *There exists a randomized cache-oblivious algorithm solving the multiple-selection problem using expected and with high probability $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ I/Os.*

**Proof.** FunnelSelect is formulated as a Monte-Carlo algorithm with worst-case time matching our expected-case time, but which can Fail occasionally. Repeating any failed execution turns it into a Las-Vegas algorithm with $O\big(\mathcal{B}_{\mathrm{I/O}} + \frac{N}{B}\big)$ expected I/Os; since the failure probability is superpolynomially small, we obtain the same bound with high probability. ◀

## 6 Partial Sorting

In internal memory, multiple selection would usually rearrange the input in place so that after the call to the multiple-selection algorithm, the sought elements are at indices $r_1, \ldots, r_q$. One would then not even return these elements explicitly. In external memory, this variant is less desirable, as one would have to pay $q$ I/Os for accessing the elements by index later. Hence

we defined the multiple-selection problem to return the elements of given ranks. However, it can be useful to also obtain the input partitioned around these returned values. Since all our multiple-selection algorithms conceptually follow an inorder traversal of a recursion tree and report sought elements (in sorted order) when they are identified, it is easy to augment the algorithms to produce a partitioned copy of the input array along the way. For funnelselect, we just have to make sure that output buckets are allocated sequentially in memory from left to right. That way we can output all elements falling between two returned pivots.

## 7 Allowing Identical Elements

In the previous sections we assumed elements to be distinct. A generic way to allow identical elements in the algorithms is by letting the algorithms process pairs $(x, i)$, where $x$ is the $i$th element in the array $S$, and break comparison ties between identical elements by comparing by their input position. This ensures all elements are considered distinct.

The drawback is that the computations need to process and store all these input positions. To avoid this overhead, one needs to address the problem directly by the individual algorithms. In the algorithms one needs to handle that multiple elements can be equal to the pivots. In the partitioning steps one needs to keep track of the number of elements equal to the pivots and only partition the elements not equal to pivots. Finally, one need to use this information gathered to handle that a pivot can span a range of ranks and be the answer to multiple query ranks.

## 8 Conclusion and Open Problems

We presented the first cache-oblivious multiple-selection algorithm that achieves the optimal I/O cost even when taking the (entropy of the) ranks to select into account.

A natural open problem is to find a *deterministic* cache-oblivious multiple-selection algorithm that achieves the same I/O bound as our randomized algorithm. Another interesting direction to explore is the "online" version of multiple selection studied in [3], where the ranks are given one after the other in arbitrary order and the algorithm has to produce the element of a given rank before the next rank is revealed. Investigating the practical performance of funnelselect is another route to pursue.

## Abstract

Given a point set $P$ in the Euclidean plane and a parameter $t$, we define an *oriented $t$-spanner* as an oriented subgraph of the complete bi-directed graph such that for every pair of points, the shortest cycle in $G$ through those points is at most a factor $t$ longer than the shortest oriented cycle in the complete bi-directed graph. We investigate the problem of computing sparse graphs with small oriented dilation.

As we can show that minimising oriented dilation for a given number of edges is NP-hard in the plane, we first consider one-dimensional point sets. While obtaining a 1-spanner in this setting is straightforward, already for five points such a spanner has no plane embedding with the leftmost and rightmost point on the outer face. This leads to restricting to oriented graphs with a one-page book embedding on the one-dimensional point set. For this case we present a dynamic program to compute the graph of minimum oriented dilation that runs in $\mathcal{O}(n^8)$ time for $n$ points, and a greedy algorithm that computes a 5-spanner in $\mathcal{O}(n \log n)$ time.

Expanding these results finally gives us a result for two-dimensional point sets: we prove that for convex point sets the greedy triangulation results in an oriented $\mathcal{O}(1)$-spanner.

## 1 Introduction

Computing geometric spanners is an extensively studied problem [5, 20]. Directed geometric spanners have also been considered [1]. Given a point set $P \subset \mathbb{R}^d$ and a parameter $t$, a *directed $t$-spanner* $G = (P, E)$ is a subgraph of the complete bi-directed geometric graph on $P$ such that for every pair of points $p, p'$, the shortest path in $G$ is at most a factor $t$ longer than the shortest path in the complete graph, that is, $|p - p'|$. The *dilation* of $G$ then is the smallest such $t$. Formally, $t = \max\left\{ \frac{|d_G(p,p')|}{|p-p'|} \;\middle|\; p, p' \in P \right\}$, where $d_G(p, p')$ denotes the *shortest path from $p$ to $p'$ in $G$*.

(Directed) geometric spanners have a wide range of applications, ranging from wireless ad-hoc networks [7, 21] to robot motion planning [12] and the analysis of road networks [2, 14]. In all of these applications one might want to avoid adding the edge $(v, u)$ if the edge $(u, v)$ was included: in ad-hoc networks this may reduce interference, in motion planning it may reduce congestion and simplify collision avoidance, in road networks this corresponds to one-way

roads or tracks, which may be necessary because of space limitations, and in communication networks one could require two neighbouring devices not to exchange data by the same (bi-directional) direct connection, for example, in two-way authentication.

This motivates our study of *oriented graphs* as spanners, i.e. directed spanners $G = (P, E)$ where $(p, p') \in E$ implies $(p', p) \notin E$. With this restriction, if the edge $(p, p')$ is added, the dilation in the other direction is never 1. Even worse, given a set $P$ of three points, where $p$ and $p'$ are very close to each other and $p''$ is far away from both, any oriented graph will have arbitrarily high dilation for either $(p, p')$ or $(p', p)$ (see Figure 1). Therefore, considering the dilation for an oriented graph as $t = \max\{\frac{|d_G(p,p')|}{|p-p'|} \mid p, p' \in P\}$ would not tell us much about the quality of the spanner. To obtain meaningful results, we define *oriented dilation*.

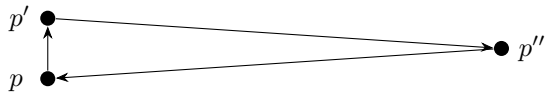

**Figure 1** If $p$ and $p'$ are very close to each other and $p''$ is far away from both, any oriented graph will have arbitrarily high (directed) dilation.

By $C_G(p, p')$ we denote the *shortest oriented cycle* containing the points $p$ and $p'$ in an oriented graph $G$. The *optimal oriented cycle* $\Delta(p, p')$ for two points $p, p' \in P$ is the shortest oriented cycle containing $p$ and $p'$ in the complete graph on $P$. Notice, $\Delta(p, p')$ is the triangle $\Delta_{pp'p''}$ with $p'' = \underset{p^* \in P \setminus \{p,p'\}}{\arg\min} \big(|p - p^*| + |p^* - p'|\big)$.

▶ **Definition 1** (oriented dilation). *Given a point set $P$ and an oriented graph $G$ on $P$, the* oriented dilation of two points $p, p' \in P$ *is defined as*

$$\mathrm{odil}(p, p') = \frac{|C_G(p, p')|}{|\Delta(p, p')|}.$$

*The dilation $t$ of an oriented graph is defined as $t = \max\{\mathrm{odil}(p, p') \mid \forall p, p' \in P\}$.*

An oriented graph with dilation at most $t$ is called an *oriented $t$-spanner*. We frequently contrast our results to known results on undirected geometric spanners, and refer to the known results by using the adjective *undirected*. Our new measure for oriented graphs is similar to the definition of dilation in round trip spanners [9, 10] that has been considered in the setting of (non-geometric) directed graph spanners; but round trip spanners require a starting graph, and using the complete bi-directed geometric graph would not give meaningful results.

In this paper, we initiate the study of oriented spanners. As is common for spanners, our general goal is to obtain *sparse* spanners, i.e. with linear number of edges. The goal can be achieved by bounding the number of edges explicitly or by restricting to a class of sparse graphs like plane graphs [5]. We refer to a spanner as a *minimum (oriented) spanner* if it minimises $t$ under the given restriction.

It is known that computing a minimum undirected spanner with at most $n - 1$ edges, i.e. a minimum dilation tree, is NP-hard [15]. The corresponding question for oriented spanners asks for the *minimum dilation cycle*. We prove this problem to be NP-hard in Section 3.1.

The problem of computing the minimum undirected spanner restricted to the class of plane straight-line graphs is called the *minimum dilation triangulation* problem; its hardness is still open [14, 15], but it is conjectured to be NP-hard [6]. As this undirected problem can be emulated in the oriented setting by suitable vertex gadgets, it is unlikely that finding a *minimum plane straight-line (oriented) spanner* can be done efficiently.

Therefore, in Section 2, we start with one-dimensional point sets. For such a point set $P$ with $n$ points, we can give a minimum spanner with $3n-6$ edges. However, if we are interested in a one-dimensional result analogous to minimum plane spanners, this spanner is not suitable: it has no plane embedding with leftmost and rightmost point on the outer face. Therefore, we restrict our attention to a graph class that is closer to the plane case for two-dimensional point sets: one-page book embeddings.

We show how to compute a $t$-spanner which is a one-page plane book embedding for a one-dimensional point set in Section 2.2. We prove that with a greedy algorithm, we can always generate such a $t$-spanner with $t \leq 5$ in $\mathcal{O}(n \log n)$ time. An optimal one-page plane spanner can be computed in $\mathcal{O}(n^8)$ time (Theorem 11).

As the resulting spanner is outerplanar, this particular class of graphs is also motivated by the problem of finding a minimum plane spanner for points in convex position. Using these results, in Section 3.2, we show that suitably orienting the greedy triangulation leads to oriented $\mathcal{O}(1)$-spanners for two-dimensional point sets in convex position (Theorem 16). For general (non-convex) point sets, there are examples where all orientations of the greedy triangulation have large dilation.

The greedy triangulation fulfils the $\alpha$-diamond-property [11], and all triangulations with this property are undirected $\mathcal{O}(1)$-spanners. This raises the question whether all triangulations fulfilling this property are also oriented $\mathcal{O}(1)$-spanners for convex point sets. In Section 3.3 we answer this question negatively.

**Table 1** Overview of the results of the paper.

| Point set | Spanner type | Dilation | Time complexity | Reference |
|---|---|---|---|---|
| 2-dim. | unrestricted | minimum | NP-hard | Theorem 14 |
| 2-dim. | unrestricted | $\leq 2$ | $\mathcal{O}(n^2)$ | Proposition 13 |
| 2-dim. | plane | minimum | Min.Dil. Triangulation | Observation 15 |
| 2-dim. convex | plane | $\mathcal{O}(1)$ | $\mathcal{O}(n \log n)$ | Theorem 16 |
| 1-dim. | unrestricted | 1 | $\mathcal{O}(n)$ | Corollary 3 |
| 1-dim. | 2-page-plane | $\leq 2$ | $\mathcal{O}(n)$ | Proposition 4 |
| 1-dim. | 1-page-plane | minimum | $\mathcal{O}(n^8)$ | Theorem 11 |
| 1-dim. | 1-page-plane | $\leq 5$ | $\mathcal{O}(n \log n)$ | Theorem 10 |

## 2 One-Dimensional Point Sets

We first focus on points in one dimension. We will always draw points on a horizontal line with the minimum point leftmost, and the maximum point rightmost. We observe that in one dimension only the dilation of a linear number of candidate pairs needs to be checked.

▶ **Lemma*** **2.** *Let $P$ be a one-dimensional point set of $n$ points. The oriented dilation $t$ of an oriented graph $G$ on $P$ is*

$$t = \max\{\mathrm{odil}(p_i, p_{i+2}), \mathrm{odil}(p_j, p_{j+3}) \mid 1 \leq i \leq n-2, 1 \leq j \leq n-3\}.$$

This observation directly leads to an oriented 1-spanner with $3n-6$ edges for every one-dimensional point set.

The proofs of results marked by $*$ are given in a long version of this paper.

▶ **Corollary 3** (oriented 1-spanner). *For every one-dimensional point set $P$, $G = (P, E)$ with*

$$E = \{(p_i, p_{i+1}), (p_{j+2}, p_j), (p_{k+3}, p_k) \mid 1 \leq i \leq n-1, 1 \leq j \leq n-2, 1 \leq k \leq n-3\}$$

*is an oriented 1-spanner for $P$ (see Figure 2).*

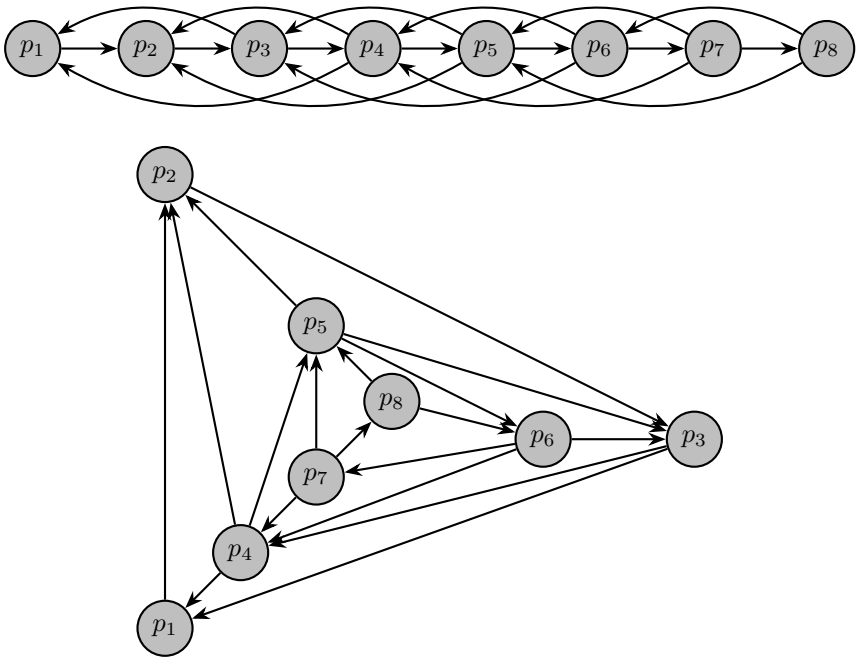

**Figure 2** One-dimensional oriented 1-spanner and its plane embedding in the Euclidean space.

In two dimensions, plane (straight-line) spanners are of particular interest. The natural one-dimensional analogue to plane straight-line graphs are one- and two-page book embeddings [3, 8, 13, 22].

A *one-page book embedding* of a graph corresponds to an embedding of the vertices as points on a line with the edges drawn without crossings as circular arcs above the line. In a *two-page book embedding* an edge may be drawn as an arc above or below the line. In such a (one- or two-page) book embedding, for consecutive points on the line, we may draw their edge straight on the line. We call a graph *one-page plane* (respectively *two-page plane*) if it has a one-page (respectively two-page) book embedding.

In particular, one-page plane graphs are outerplanar graphs and correspond to plane straight-line graphs if we embed the points on a (slightly) convex arc instead of on a line. Two-page plane graphs are a subclass of planar graphs, while any planar graph has a four-page book embedding [22].

As we argue next, the 1-spanner of Corollary 3 is not two-page plane (and therefore also not one-page plane). This follows from a stronger statement: the graph has no plane embedding with the first and last point on the outer face. Suppose the graph would have such an embedding. The graph has $3n - 6$ edges, but no edge between the first and the last point for $n > 4$. Thus, we could add this edge while maintaining planarity, which contradicts the fact that a planar graph has at most $3n - 6$ edges. Interestingly, the 1-spanner is planar. We construct a stack triangulation by adding points from left to right. The first three points form a triangle. Then, we inductively add the next point into the triangle formed by the previous three points. See Figure 2.

## 2.1 Two-Page Plane Spanners

As argued above, the 1-spanner given in Corollary 3 is not two-page plane (and thus not one-page plane). Moreover, by Lemma 2, no two-page plane 1-spanner can exist. However, we can give a two-page plane 2-spanner for every one-dimensional point set:

▶ **Proposition*** **4** (two-page plane 2-spanner)**.** *For every one-dimensional point set $P$, the graph $G = (P, E)$ with $E = \{(p_i, p_{i+1}), (p_{j+2}, p_j) \mid 1 \leq i \leq n-1, 1 \leq j \leq n-2\}$ (see Figure 3) is a two-page plane oriented 2-spanner for $P$.*

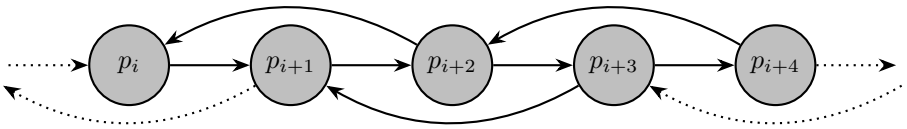

**Figure 3** Part of $G = (P, E)$ with $E = \{(p_i, p_{i+1}), (p_{j+2}, p_j) \mid 1 \leq i \leq n-1, 1 \leq j \leq n-2\}$.

## 2.2 One-Page Plane Spanners

The 2-spanner given by Proposition 4 is two-page plane, but not one-page plane. As noted above, one-page plane graphs on one-dimensional point sets correspond to plane straight-line graphs if we interpret the point set as being convex. We thus place particular focus on one-plane plane graphs, since they are not only of interest in their own right but also aid us in finding oriented plane spanners in two-dimensions.

By *maximal one-page plane*, we mean a one-page plane graph $G = (P, E)$ such that for every edge $e \notin E$, the graph $G' = (P, E \cup \{e\})$ is not one-page plane. We call the edge set $\{(p_i, p_{i+1}) \mid 1 \leq i \leq n-1\}$ the *baseline*. A directed edge $(p_j, p_i)$ with $i < j$ is a *back edge*.

We refer to an oriented one-page plane graph that includes a baseline and all other edges are back edges as a one-page-plane-baseline graph, for short 1-*PPB graph*. Lemma 5 shows that a 1-PPB graph has smaller dilation than an oriented graph with the same edge set but another orientation. Without loss of generality, we consider only 1-PPB graphs instead of one-page plane graphs in general.

▶ **Lemma*** **5.** *Let $G = (P, E)$ be a one-page plane oriented $t$-spanner for a one-dimensional point set $P$. Let $E'$ be an edge set where the edges are incident to the same vertices as $E$, but the orientation may be different. If we orientate such that $G' = (P, E')$ is a 1-PPB graph, then the dilation of $G'$ is at most $t$.*

▶ **Lemma*** **6.** *Let $P$ be a one-dimensional point set of $n$ points. The oriented dilation $t$ of a 1-PPB graph for $P$ is*

$$t = \max\{\mathrm{odil}(p_i, p_{i+2}) \mid 1 \leq i \leq n-2\}.$$

Lemma 6 holds for every 1-PPB graph, even if it is not maximal. Proposition 4 shows that Lemma 6 does not hold for non-one-page plane graphs.

Due to one-page planarity, for a point set $P$ with $|P| > 3$, every graph $G$ contains a tuple $p_i, p_{i+2} \in P$ where $C_G(p_i, p_{i+2}) \neq \Delta(p_i, p_{i+2})$. Combining this with Lemma 6, we get:

▶ **Corollary 7.** *There is no one-page plane 1-spanner for any point set $P$ with $|P| > 3$.*

However, there are point sets with a one-page plane almost 1-spanner. Let $G = (P, E)$ be a graph with $|P| = 5$, $E = \{(p_i, p_{i+1}) \mid 1 \leq i \leq n-1\} \cup \{(p_3, p_1), (p_5, p_3)\}$ and the distances $p_2 - p_1 = p_5 - p_4 = \varepsilon$ and $p_3 - p_2 = p_4 - p_3 = 1$ (see Figure 4). It holds that $t = \text{odil}(p_2, p_4) = \frac{2+2\varepsilon}{2}$. For an arbitrary small $\varepsilon$, $G$ is a one-page plane almost 1-spanner.

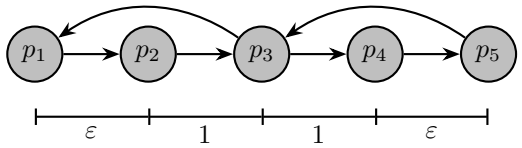

**Figure 4** 1-PPB almost 1-spanner.

▶ **Observation*** **8.** *There are one-dimensional point sets where no one-page plane oriented $t$-spanner exists for $t < 2$.*

We construct a 1-PPB spanner by starting with the base line and greedily adding back edges sorted by length from shortest to longest if they do not cross any of the edges already added. The following leads to a simple, greedy algorithm for constructing this graph: The first edge that we need to add is the shortest edge between two points with exactly one point in between. Imagine deleting the point that was in between. Then again, we need to add the shortest edge with exactly one point in between and so on, until only two points are left. By maintaining the points in a linked list and the relevant distances in a priority queue, this leads to a run time of $\mathcal{O}(n \log n)$.

To bound the dilation of the resulting graph, we need the concept of a *blocker*.

▶ **Definition 9** (blocker). *Let $E$ be the greedily computed back edge set. Because the resulted graph $G = (P, E \cup \{(p_i, p_{i+1}) \mid 1 \leq i \leq n-1\})$ is maximal, $(p_j, p_i) \notin E$ for $i + 2 \leq j$ implies there is a shorter edge in $E$ which intersects with $(p_j, p_i)$. (The greedy algorithm added this edge first and discarded $(p_j, p_i)$ in a later iteration of the loop.) For the shortest edge intersecting $(p_j, p_i)$, we say it* blocks *$(p_j, p_i)$. The edge can* be blocked by *$(p_k, p_m)$ with $k > j$ and $i < m < j$ or $(p_m, p_{k'})$ with $k' < i$ and $i < m < j$ (see Figure 5).*

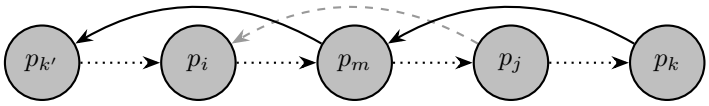

**Figure 5** $(p_j, p_i)$ can be blocked by $(p_k, p_m)$ or $(p_m, p_{k'})$ with $i < m < j$, $k > j$ and $k' < i$.

▶ **Theorem*** **10** (one-page plane 5-spanner). *Given a one-dimensional point set $P$ of size $n$, a one-page plane oriented 5-spanner can be constructed in $\mathcal{O}(n \log n)$ time.*

The full proof is given in the full version, but, since the proof of correctness for the greedy two-dimensional algorithm (see Section 3.2) works similarly, we give a proof sketch here.

**Proof sketch.** Due to Lemma 6, it is sufficient to bound the dilation $\text{odil}(p_i, p_{i+2})$ of tuples $p_i, p_{i+2}$ with one point in-between. Let $(b_1, p_{i+1})$ be the blocker of the optimal edge $(p_{i+2}, p_i)$ (blue). There could be a "sequence of blockers" $b_1, \ldots, b_{j+1}$, such that $(b_k, p_{i+1})$ blocks $(b_{k-1}, p_i)$ for $2 \leq k \leq j + 1$ (green), see Figure 6.

Combining this with a lower bound on the distance of a tuple $b_{i-2}, b_i$ for $3 \leq i \leq j+1$ (violet), we show that there are only two blockers $b_j$ and $b_{j+1}$, whose the distance to $p_{i+1}$ is larger than $p_{i+1} - p_i$. There are two cases for the shortest oriented cycle $C_G(p_i, p_{i+2})$. For $(b_{j+1}, p_i) \in E$ holds $\operatorname{odil}(p_i, p_{i+2}) = 4$. The worst-case is that $(b_{j+1}, p_i) \notin E$ is blocked by some edge $(p_{i+1}, p_l)$ with $l < i$ (red). Then the dilation is

$$\operatorname{odil}(p_i, p_{i+2}) = \frac{(b_1 - p_l) \cdot 2}{(p_{i+2} - p_i) \cdot 2} \leq \frac{b_1 - p_{i+1} + p_{i+1} - p_l}{p_{i+2} - p_i} \leq \frac{p_{i+2} - p_i + 4 \cdot (p_{i+1} - p_i)}{p_{i+2} - p_i} = 5.$$

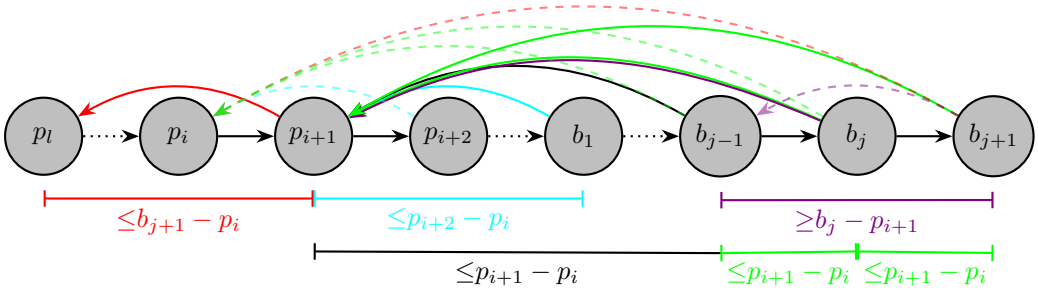

**Figure 6** Blockers in the proof of Theorem 10.

Figure 7 shows a point set $P$ and its greedily constructed spanner $G$. The oriented dilation of $G$ is $t = \frac{5-7\varepsilon}{1+\varepsilon}$. Thus, $G$ is a 5-spanner for $P$.

However, Figure 8 shows a $t$-spanner with $t = \frac{2-2\varepsilon}{1+\varepsilon} < 2$ for the same point set. Therefore, the greedy algorithm does not return the minimum spanner for every given one-dimensional point set.

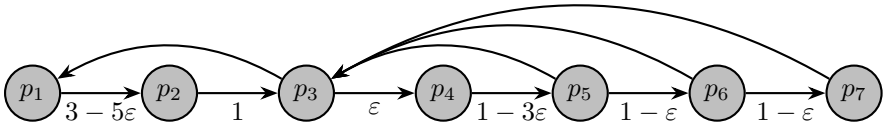

**Figure 7** Example of a greedily constructed spanner, its dilation is $t = \operatorname{odil}(p_2, p_4) = \frac{5-7\varepsilon}{1+\varepsilon} < 5$.

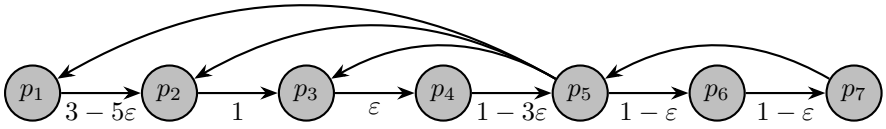

**Figure 8** A spanner on the point set of Figure 7 with dilation $t = \operatorname{odil}(p_2, p_4) = \frac{2-2\varepsilon}{1+\varepsilon} < 2$.

The minimum dilation of a 1-PPB spanner for a one-dimensional point set is larger than 1 (Observation 8), unlike non-plane oriented spanners (Corollary 3). Algorithm 1 computes in $\mathcal{O}(n^8)$ time a minimum 1-PPB spanner for a given point set. The dynamic program is based on the following idea. By Lemma 6, it holds that $t = \max\{t', t'', \operatorname{odil}(p_{k-1}, p_{k+1})\}$, where $t'$ is the minimum dilation for $\{p_1, \ldots, p_k\}$ and $t''$ is the minimum dilation for $\{p_k, \ldots, p_n\}$. Due to one-page-planarity, if $(p_r, p_l) \in E$, it holds that $(p_j, p_i) \notin E$ for $l < i < r < j$ and $i < l < j < r$. We test all candidates for a split point $p_k$. By adding the edges $(p_n, p_k)$

and $(p_k, p_1)$, we can compute the optimal edge set for $\{p_1, \ldots, p_k\}$ and $\{p_k, \ldots, p_n\}$ (almost) independently. (We need the parameters $l'$ and $r'$ which represent the only edges needed to consider $\text{odil}(p_{k-1}, p_{k+1})$.)

▶ **Theorem*** **11** (Optimal 1-PPB). *Given a one-dimensional point set $P$ of size $n$, the minimum one-page plane oriented spanner for $P$ can be calculated in $\mathcal{O}(n^8)$ time.*

## 3 Two-Dimensional Point Sets

In the one-dimensional case, we have seen that a 1-spanner exists for every point set, though it is not plane. In two dimensions, the complete bi-directed graph is always a directed 1-spanner. This is not the case for oriented dilation. There we have point sets where no 1-spanner exists, even more, no 1.46-spanner exists:

▶ **Observation*** **12.** *There are two-dimensional point sets for which no oriented $t$-spanner exists for $t < 2\sqrt{3} - 2 \approx 1.46$.*

While an oriented complete graph does not lead to a 1-spanner, it does yield a 2-spanner:

▶ **Proposition*** **13.** *For every point set an oriented 2-spanner can be constructed by orienting a complete graph.*

## 3.1 Hardness

We now have shown that although a 1-spanner does not exist for every two-dimensional point set, we get a 2-spanner via the oriented complete graph. However, this leads to a graph with $\frac{1}{2}n \cdot (n-1)$ edges, so this graph is neither sparse nor plane.

We will see that computing a sparse minimum oriented spanner is NP-hard:

▶ **Theorem*** **14.** *Given a two-dimensional set $P$ of $n$ points and the parameters $t$ and $m'$, it is NP-hard to decide if there is an oriented $t$-spanner $G = (P, E)$ with $|E| \leq m'$.*

For computing a minimum *plane* oriented spanner, i.e. a minimum oriented dilation triangulation, hardness remains open. In the undirected setting this question is a long-standing open problem [6, 14, 15]. To our knowledge, it is not even known whether a PTAS for this problem exists, and for several related open problems there is no FPTAS [15], unless $P = NP$. We show the following relative hardness result.

▶ **Observation 15.** *An FPTAS for minimum plane oriented spanner would imply an FPTAS for minimum dilation triangulation.*

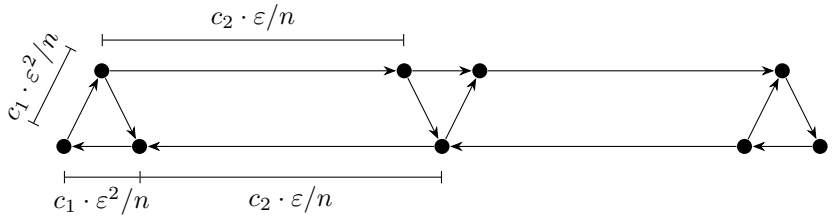

**Figure 9** By replacing each point with this construction, we can reduce the minimum dilation triangulation problem to the minimum plane oriented spanner problem.

We sketch a reduction from the minimum dilation triangulation problem. Suppose we are given a set $P$ of $n$ points. The idea is to replace every point with the gadget depicted in Figure 9. The gadget consists of $3 \cdot \lceil \frac{4n}{3} \rceil$ points, positioned along a line in small triangles. Since the triangles are small relative to the distance between the triangles, we obtain an oriented dilation of less than $(1 + c\varepsilon)$ within the gadget by connecting the gadget points as in the figure, where $c > 0$ is a constant that we can choose by suitably picking $c_1$ and $c_2$.

The gadget leaves us with room for two edges to every one of $n$ points, one in each direction, without disturbing planarity. Therefore, minimising the oriented dilation in this setting while requiring planarity should pick the edges that correspond to those in the minimum dilation triangulation, except if they are $\varepsilon$-close.

## 3.2 Greedy Triangulation

Given the relative hardness of computing minimum plane oriented spanners, we next investigate the question of whether plane oriented $\mathcal{O}(1)$-spanners exist. In the undirected setting, prominent examples for plane constant dilation spanners are the Delaunay triangulation and the greedy triangulation. Our main result on oriented spanners in two dimensions is that the greedy triangulation is an $\mathcal{O}(1)$-spanner for convex point sets (i.e. point sets for which the points lay in convex position).

The *greedy triangulation* of a point set is the triangulation obtained by considering all pairs of points by increasing distance, and by adding the straight-line edge if it does not intersect any of the edges already added. The greedy triangulation can be computed in linear time from the Delaunay triangulation [18], and in linear time for a convex point set if the order of the points along the convex hull is given [19].

It is known that the dilation of the undirected greedy triangulation is bounded by a constant. This follows from the fact that the greedy triangulation fulfils the $\alpha$-diamond-property [11]. The currently best upper bound on the dilation $t$ of such a triangulation is $t \leq \frac{8(\pi-\alpha)^2}{\alpha^2 \sin^2(\alpha/4)}$ with a lower bound on $\alpha$ of $\pi/6$ for the greedy triangulation [4].

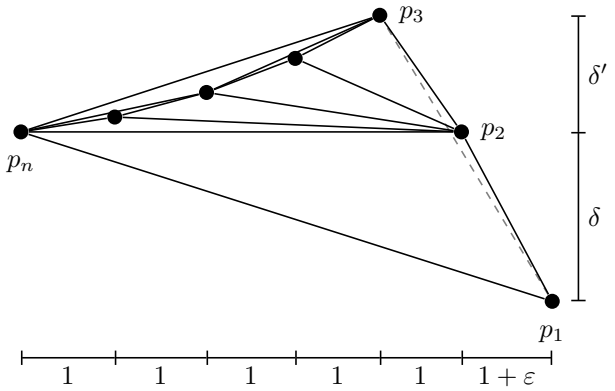

**Figure 10** Greedy triangulation for a non-convex point set. It is is also a minimum weight triangulation.

We first observe that restricting to convex point sets is necessary to obtain constant dilation from orienting the greedy triangulation. For this, consider the greedy triangulation $T = (P, E)$ on the following non-convex point set $P = \{p_1, \ldots, p_n\}$. As shown in Figure 10, we place the points $\{p_3, \ldots, p_n\}$ on a very flat parabola. By arbitrarily decreasing the $y$-distances $\delta, \delta' > 0$, we reduce the construction to an almost one-dimensional problem. The $x$-distance of each consecutive point pair $p_i, p_{i+1}$ is 1 for $2 \leq i < n$. We place $p_1$ slightly right of $p_2$ such that the $x$-distance is $1 + \varepsilon$ for a small $\varepsilon > 0$. Therefore, the $x$-distance of $p_1$ to $p_i$ is $\varepsilon$-larger than $x$-distance of $p_2$ to $p_{i+1}$ for $3 \leq i < n$. By this, the greedy triangulation added $(p_2, p_{i+1}) \in E$ and discarded $(p_1, p_i) \notin E$ for $3 \leq i < n$. Further, we place $p_1$ slightly below $p_2$ so that, due to planarity, $p_1$ is only adjacent to $p_2$ and $p_n$. Since $p_1$ has degree 2, for any orientation of $T$, every shortest oriented cycle containing $p_1$ contains the subpath $p_n, p_1, p_2$ or vice versa. From this construction, it follows that $\mathrm{odil}(p_1, p_3) \geq \frac{n+\varepsilon}{2+\varepsilon}$, regardless of the orientation of $T$. Therefore, every orientation of greedy triangulation has oriented dilation $\Omega(n)$.

In contrast, for convex point sets, the greedy triangulation results in a $\mathcal{O}(1)$-spanner. For this, we use a *consistent* orientation of the edges. This means each face of an oriented triangulation is confined by an oriented cycle. If such an orientation exists for a given triangulation, we call it an *orientable triangulation*. Since the dual graph of a triangulation of a convex point set is a tree, it is orientable.

▶ **Theorem 16.** *By orienting the greedy triangulation of a convex two-dimensional point set $P$ consistently, we get a plane oriented $\mathcal{O}(1)$-spanner for $P$.*

**Proof.** Let $T = (P, E)$ be the greedy triangulation of $P$ and $G = (P, \overrightarrow{E})$ its consistent orientation (which is unique up to reversing all edges). Note that $T$ is an undirected graph, whereas $G$ is directed. To improve readability, undirected edges are written with curly

brackets and directed edges with round brackets. Due to $\alpha$-diamond property, the undirected dilation of any greedy triangulation can be bounded by a constant. Let $t_g$ be the (smallest such) constant.

We distinguish between i) $\{p, p'\}$ is in $E$ or ii) not.

For i), we prove that there is a path from $p$ to $p'$ in $T - \{p, p'\}$ of length in $\mathcal{O}(|\Delta(p, p')|)$, where $\Delta(p, p')$ is a smallest triangle in the complete graph incident to $p$ and $p'$. By that, we bound the length of the shortest oriented cycle $C_G(p, p')$.

Let $q \in P$ be the third point incident to $\Delta(p, p')$. Let $\Pi$ be the undirected path from $p$ to $q$ in $T$ with first edge $\{p, q'\}$, w.l.o.g. $q' \neq p'$. (If $q' = p'$, then the proof would be the same with switched roles for $p$ and $p'$.)

If $\{q', p'\} \in E$, then $\Delta_{pq'p'} \in E$. Regardless of the orientation of $\{p, q'\}$, we can bound $|C_G(p, p')| \leq |\Delta_{pq'p'}| \leq 2 \cdot t_g \cdot |\Delta(p, p')|$. However, $\{q', p'\}$ could be blocked by another edge. Since $P$ is convex and $T$ is planar, this edge is incident to $p$. Analogous to Theorem 10, we show that there could be a "sequence of blockers" (see Definition 9), but that there is path from $p$ to $q$ of length $\mathcal{O}(|p - q|)$.

Let $b_{j+2c}$ be such that $\{q', b_{j+2c}\} \in E$ and $\{q', b_{j+2c}\}$ blocks $\{q', p'\}$. Let the points $b_1, \ldots, b_{j+2c}$ be ordered such that $\{p, b_i\} \in E$ is the shortest edge that blocks $\{q', b_{i-1}\}$ with $b_0 = p'$ (see Figure 11a).

The following inequalities hold for these blockers:

$$|p - b_i| \leq |q' - b_{i-1}|, \tag{1}$$

$$|p - b_i| \leq |p - b_k| \text{ for } 1 \leq i < k \leq j + 2c, \text{ and} \tag{2}$$

$$|p - b_{i-1}| \leq |b_{i-2} - b_i| \text{ for } 3 \leq i \leq j + 2c. \tag{3}$$

Equation 2 is true, because otherwise $\{p, b_k\}$ would block $\{q', b_{i-1}\}$ instead of $\{p, b_i\}$.

Equation 3 is explained as follows: due to convexity and planarity, $\{p, b_{i+1}\} \in E$ implies $\{b_i, b_{i+2}\} \notin E$. This means the greedy algorithm added $\{p, b_{i+1}\}$ and discarded $\{b_i, b_{i+2}\}$ in later iteration (see Figure 11b).

Let $\gamma$ be an arbitrary constant. We call an edge *long* if its length is larger than $|q' - p| \cdot \gamma$. Because of Equation 2, once an edge $\{p, b_i\}$ is long, every edge $\{p, b_k\}$ is also long, for $1 \leq i < k \leq j + 2c$. Let $b_j$ be the point such that $\{p, b_j\}$ is the *last short* blocker, i.e.

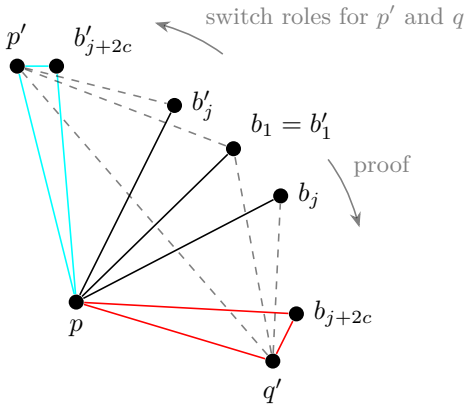
$$|p - b_j| \leq |q' - p| \cdot \gamma \text{ and} \tag{4}$$

$$|p - b_k| > |q' - p| \cdot \gamma \text{ for all } j + 1 \leq k \leq j + 2c. \tag{5}$$

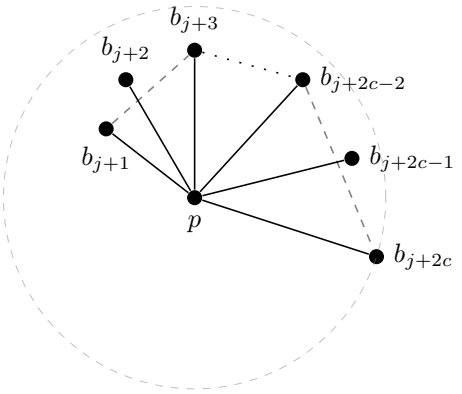
By this, the length of the last blocker $\{p, b_{j+2c}\}$ depends on $\gamma$ and $c$:

$$\begin{aligned} |p - b_{j+2c}| &\overset{\text{eq. 1}}{\leq} |q' - b_{j+2c-1}| \overset{\substack{\text{triangle}\\\text{inequality}}}{\leq} |q' - p| + |p - b_{j+2c-1}| \\ &\overset{\text{eq. 1}}{\leq} |q' - p| + |q' - b_{j+2c-2}| \overset{\substack{\text{triangle}\\\text{inequality}}}{\leq} \ldots \leq 2c \cdot |q' - p| + |p - b_j| \\ &\overset{\text{eq. 4}}{\leq} |q' - p| \cdot (2c + \gamma). \end{aligned} \tag{6}$$

Due to convexity, the points $b_{j+1}, \ldots, b_{j+2c}$ must be contained in the circle with centre $p$ and radius $|p - b_{j+2c}|$ (see Figure 11b). Therefore, their pairwise distances are bounded by its circumference. Upper and lower bounding the sum of the pairwise distances of tuples $b_{j+i}, b_{j+i+2}$ for $1 \leq i \leq 2c - 2$, it follows $c$ is bounded by a function dependent on $\gamma$:



**(a)** Regardless of the orientation, $|C_G(p,p')| \leq |\Delta_{pp'b'_{j+2c}}| + |\Delta_{pq'b_{j+2c}}|$.



**(b)** The points $b_{j+1}, \ldots, b_{j+2c}$ lie in the circle with centre $p$ and radius $|p - b_{j+2c}|$.

**Figure 11** Visualisation of the central proof steps of case i) in Theorem 16.

$$2c \cdot \gamma \cdot |q' - p| \overset{\text{eq. 5}}{<} \sum_{i=2}^{2c-1} |p - b_{j+i}| \overset{\text{eq. 3}}{\leq} \sum_{i=1}^{2c-2} |b_{j+i} - b_{j+i+2}| \overset{\text{eq. 6}}{\leq} 2\pi(2c+\gamma) \cdot |q' - p|$$
$$\iff \quad c < \pi \cdot \frac{\gamma - 1}{\gamma - 2\pi}.$$

For $\gamma = \mathcal{O}(1)$, it holds that $c = \mathcal{O}(1)$. Thus, the length of the last blocker $\{p, b_{j+2c}\}$ is bounded by a constant times $|p - q'|$.

This proof can be repeated with switched roles for $p'$ and $q$. Then, the points $b'_1, \ldots, b'_{j+2c}$ are ordered such that $\{p, b'_i\}$ blocks $\{p', b_{i-1}\}$ with $b_0 = q'$ (Figure 11a).

By definition of the point set $b_1, \ldots, b_{j+2c}$ (respectively $b'_1, \ldots, b'_{j+2c}$), it holds that $\{q', b_{j+2c}\} \in E$ and $\{p', b'_{j+2c}\} \in E$. Regardless of the orientation, the length of the shortest oriented cycle is bounded by $|C_G(p,p')| \leq |\Delta_{pq'b_{j+2c}}| + |\Delta_{pp'b'_{j+2c}}|$. This permits a constant dilation for the case $\{p, p'\} \in E$ as

$$\begin{aligned}
\operatorname{odil}(p,p') = \frac{|C_G(p,p')|}{|\Delta(p,p')|} &\leq \frac{|\Delta_{pq'b_{j+2c}}| + |\Delta_{pp'b'_{j+2c}}|}{|\Delta_{pp'q}|} \\
&\leq \max\left\{ \frac{|\Delta_{pq'b_{j+2c}}|}{|\Delta_{pp'q}|}, \frac{|\Delta_{pp'b'_{j+2c}}|}{|\Delta_{pp'q}|} \right\} \overset{\text{wlog}}{=} \frac{|p-q'| + |q'-b_{j+2c}| + |b_{j+2c}-p|}{|\Delta_{pp'q}|} \\
&\overset{\text{triangle inequality}}{\leq} \frac{2\cdot|p-q'| + 2\cdot|p-b_{j+2c}|}{|\Delta_{pp'q}|} \\
&\overset{\text{eq. 6}}{\leq} \frac{2\cdot|p-q'| + 2\cdot|p-q'|\cdot(2c+\gamma)}{|\Delta_{pp'q}|} = \frac{|p-q'|\cdot(4c+2\gamma+2)}{|p-p'|+|p'-q|+|q-p|} \\
&\overset{\alpha\text{-diamond-property}}{\leq} \frac{t_g\cdot|p-q|\cdot(4c+2\gamma+2)}{|\Delta_{pp'q}|} \leq t_g\cdot(4c+2\gamma+2) = \mathcal{O}(1).
\end{aligned}$$

For ii) $\{p, p'\} \notin E$, due to $\alpha$-diamond property, there is an undirected path $\Pi$ from $p$ to $p'$ in $T$ of length $|\Pi| \leq t_g \cdot |p - p'|$. Applying case i) gives factor $\lambda = \mathcal{O}(1)$ for each path edge $\{q', q''\} \in \Pi$. The dilation for the case $\{p, p'\} \notin E$ is bounded by

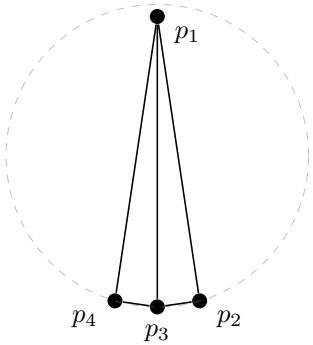


**Figure 12** Delaunay triangulation for convex point set. It is also a minimum dilation triangulation.

$$\text{odil}(p,p') = \frac{|C_G(p,p')|}{|\Delta(p,p')|} \leq \frac{\sum_{\{q',q''\}\in\Pi} |C_G(q',q'')|}{|\Delta(p,p')|}$$
$$\overset{\text{case i)}}{\leq} \frac{\lambda\cdot|\Pi|}{|\Delta(p,p')|} \leq \frac{\lambda\cdot t_g\cdot|p-p'|}{|\Delta(p,p')|} = \lambda\cdot t_g = \mathcal{O}(1). \qquad \blacktriangleleft$$

## 3.3 Other Triangulations

As the greedy triangulation leads to a plane oriented $\mathcal{O}(1)$-spanner for convex point sets, the question arises whether the $\alpha$-diamond property implies the existence of oriented spanners.

We already have seen that this is not the case for the greedy triangulation on general point sets. Likewise, the minimum weight triangulation has the $\alpha$-diamond property [17] but does not yield an $\mathcal{O}(1)$-spanner in general. This can be seen by the same example as for the greedy triangulation in Figure 10. By essentially the same argument, the minimum weight triangulation will have the same edges incident to $p_1$, which results in an oriented dilation of $\Omega(n)$. Whether the minimum weight triangulation is an oriented $\mathcal{O}(1)$-spanner for convex point sets, we leave as an open problem.

For the Delaunay triangulation the situation is even worse. The Delaunay triangulation has the $\alpha$-diamond property [16] and is the basis for many undirected plane spanner constructions [5]. However, for $n \geq 4$ its oriented dilation can be arbitrary large, no matter how we orient its edges, even for convex point sets.

Figure 12 shows the Delaunay triangulation $T = (P, E)$ of a convex point set of size 4. The shortest cycle $C_G(p_2, p_4)$ contains $p_1$, for any orientation of $T$. We can place $p_2, p_3, p_4$ arbitrarily close to each other without decreasing the radius of the circle through them. By placing $p_1$ in the circle and sufficiently far away from $p_2, p_3$ and $p_4$, the oriented dilation $\text{odil}(p_2, p_4) \geq \frac{|C_G(p_2,p_4)|}{|\Delta_{p_2p_3p_4}|}$ can be made arbitrary large. The example can be modified to include more points without changing $\text{odil}(p_2, p_4)$.

Finally, we consider orienting the undirected minimum dilation triangulation. However, essentially the same example as for the Delaunay triangulation shows that there are convex point sets for which any orientation has arbitrarily large oriented dilation. In Figure 12, consider the case in which we have fixed all positions except for the $y$-coordinates of $p_2$ and $p_4$. Let $y_0$ be the $y$-coordinate of $p_3$, and let $y_0 + \varepsilon$ be the $y$-coordinate of $p_2$ and $p_4$. By decreasing $\varepsilon > 0$, we can make sure that the minimum dilation triangulation chooses the same diagonal as the Delaunay triangulation, since the undirected dilation between $p_2$ and $p_4$ by the path through $p_3$ becomes arbitrarily close to 1. However, as in the Delaunay triangulation, the oriented dilation between $p_2$ and $p_4$ can be made arbitrarily large.

Thus, the quest for a triangulation of small oriented dilation for non-convex point sets remains open.

## 4 Conclusion and Outlook

Motivated by applications of geometric spanners, we introduced the concept of oriented geometric spanners. We provided a wide range of extremal and algorithmic results for oriented spanners in one and two dimensions.

Intriguingly, orienting the greedy triangulation yields a plane $\mathcal{O}(1)$-spanner for point sets in convex position, but not for general point sets. Furthermore, other natural triangulations like the Delaunay and the minimum weight triangulation do not lead to plane constant dilation spanners.

This raises the question of whether a plane constant dilation spanner exists and can be computed efficiently. If this is not possible, what is the lowest dilation that we can guarantee? Until now, even showing whether the greedy triangulation yields an $\mathcal{O}(n)$-spanner remains open.

As the concept of oriented spanners is newly introduced, it opens up many new avenues of research, for example:

- We know that the minimum one-page plane oriented spanner achieves a dilation of at most 5 (since this is the bound for the greedy algorithms) and that there are point sets where it has a dilation of 2. What is its worst-case dilation $2 \leq t \leq 5$? Can we compute it faster?
- We constructed a two-page plane oriented 2-spanner for any one-dimensional point set. Is 2 a tight upper bound on the dilation of a minimum two-page plane spanner? Is there an efficient algorithm to compute such a spanner?
- For two-dimensional point sets, the question of bounding minimum oriented dilation already arises without restricting to plane graphs. What is the worst-case dilation $2\sqrt{3} - 2 \leq t \leq 2$ of the minimum dilation oriented complete graph?
- Given an undirected geometric graph, can we efficiently compute an orientation minimising the dilation? For which graph classes is this possible?
- While undirected dilation compares the shortest path from $p$ to $p'$ in $G$ with the edge between them in the complete graph $K_n$, oriented dilation compares the shortest oriented cycle through $p$ to $p'$ in $G$ to the shortest triangle in $K_n$. An analogous measure in undirected graphs, *cyclic dilation*, would compare the shortest simple cycle in $G$ to the shortest triangle in $K_n$. Can we efficiently compute sparse graphs, in particular triangulations, of low cyclic dilation? Another measure of interest would be *detour dilation*, which compares the shortest path not using the edge $\{p, p'\}$ in $G$ (i.e. the shortest path in $G - \{p, p'\}$) with the triangle in $K_n$. Low detour dilation is a necessary condition for low oriented dilation, and actually at the core of our analysis of the greedy triangulation. Is there a triangulation with constant detour dilation? Can it be oriented to obtain constant oriented dilation?
- In the applications mentioned, it is desirable to reduce the number of bi-directional edges but it may not be necessary to avoid them completely. This opens up a whole new set of questions on the trade-off between directed dilation and the number of bi-directional edges. For instance, given a parameter $t$, compute the directed $t$-spanner with as few bi-directional edges as possible (and no bound on the number of oriented edges). Or, given a plane graph with certain edges marked as *one-way*, compute the orientation of these edges that minimises the directed dilation (while all other edges are bi-directional). For which families of graphs can this be done efficiently? For which is this problem NP-hard?

# Online Coalition Formation Under Random Arrival or Coalition Dissolution

**Martin Bullinger**

Technical University of Munich, Germany

## Abstract

Coalition formation considers the question of how to partition a set of $n$ agents into disjoint coalitions according to their preferences. We consider a cardinal utility model with additively separable aggregation of preferences and study the online variant of coalition formation, where the agents arrive in sequence and whenever an agent arrives, they have to be assigned to a coalition immediately. The goal is to maximize social welfare. In a purely deterministic model, the greedy algorithm, where an agent is assigned to the coalition with the largest gain, is known to achieve an optimal competitive ratio, which heavily relies on the range of utilities.

We complement this result by considering two related models. First, we study a model where agents arrive in a random order. We find that the competitive ratio of the greedy algorithm is $\Theta\left(\frac{1}{n^2}\right)$, whereas an alternative algorithm, which is based on alternating between waiting and greedy phases, can achieve a competitive ratio of $\Theta\left(\frac{1}{n}\right)$. Second, we relax the irrevocability of decisions by allowing to dissolve coalitions into singleton coalitions, presenting a matching-based algorithm that once again achieves a competitive ratio of $\Theta\left(\frac{1}{n}\right)$. Hence, compared to the base model, we present two ways to achieve a competitive ratio that precisely gets rid of utility dependencies. Our results also give novel insights in weighted online matching.

## 1 Introduction

Coalition formation is a vibrant topic in multi-agent systems. The goal is to partition a set of $n$ agents into disjoint coalitions. We consider the framework of hedonic games, where the agents have preferences for the coalitions they are part of by disregarding externalities [18]. More specifically, we assume that each agent has cardinal utilities for each other agent and that utilities for coalitions are aggregated in an additively separable way by taking sums [7].

Most of the hedonic games literature considers an offline setting, where a fully specified instance is given. By contrast, in many real-life situations, such as the formation of teams in a company, the agents are not all present in the beginning but rather join an ongoing coalition formation process over time. With this motivation in mind, Flammini et al. [22] proposed an online version of hedonic games, where agents arrive one by one. Upon arrival, an agent reveals their preferences for coalitions containing the agents present thus far, and has to be added immediately and irrevocably to an existing coalition (or to a new singleton coalition).

Flammini et al. [22] seek to find algorithms that have high social welfare in a worst-case analysis against an adaptive adversary that is allowed to select an arbitrary instance and an arbitrary arrival order of the agents. The performance of an algorithm is measured with respect to its competitive ratio, that is, the worst-case ratio of the social welfare of the computed solution compared to the social welfare of the optimal offline solution. Their main result is that the greedy algorithm, which adds every agent to the best possible coalition upon arrival, has the optimal competitive ratio of $\Theta\left(\frac{1}{n}\frac{U_{min}}{U_{max}}\right)$, where $U_{max}$ and $U_{min}$ are the maximum and minimum absolute value of a non-zero single-agent utility in the adversarial instance, respectively.[1] In other words, for a fixed number of agents the competitive ratio is infinite if the maximum or minimum utility is not bounded.

Arguably, unbounded utilities give a lot of power to an adversary. The following example by Flammini et al. [22] exploits this. Consider the situation where the first two arriving agents have a mutual utility of 1. If an algorithm adds the second agent to the coalition of the first agent, then the adaptive adversary can set the utility of 1 as the minimum utility and add agents with large positive and negative utilities that bring no gain to this coalition. Hence, the welfare of the large positive utilities is lost, and the algorithm performs badly. Otherwise, if an algorithm puts the second agent into a singleton coalition, then the adversary can set the utility of other arriving agents to 0, and the loss of the welfare of the single positive edge leads to an unbounded competitive ratio.

As a consequence, we want to see whether we can perform better if the adversary has less power in two related models. First, we consider a model where the adversary is still capable of fixing a bad instance. However, agents arrive in a random order according to a permutation of the agents selected uniformly at random. We show that the greedy algorithm achieves a competitive ratio of $\Theta\left(\frac{1}{n^2}\right)$. Moreover, we present an alternative algorithm with a competitive ratio of $\Theta\left(\frac{1}{n}\right)$, which is based on alternating between waiting and greedy phases.

Second, we allow an algorithm to dissolve a coalition into singleton coalitions to revert bad previous decisions. We present a $\frac{1}{6}$-competitive online matching algorithm, which can be used to achieve a competitive ratio of $\Theta\left(\frac{1}{n}\right)$ for online coalition formation. Hence, compared to the deterministic model, we present a novel algorithm, whose competitive ratio gets precisely rid of utility dependencies. We conclude by showing boundaries for optimal algorithms in both settings. Moreover, we discuss why the worst-case analysis for our presented algorithm does not generalize for any algorithm.

## 2 Related Work

Hedonic games originated from economic theory [18] more than four decades ago. However, their broad consideration only started about two decades later [3, 7, 16]. In particular, Bogomolnaia and Jackson [7] introduced additively separable hedonic games (ASHGs), which are since then an ongoing subject of study. A large part of the research on ASHGs focuses on the computational complexity of stability measures [2, 9, 13, 17, 22, 23, 29, 30], but some more recent studies also consider economic efficiency in the sense of Pareto optimality [12, 19], popularity [8], or strategyproofness [21]. In general, maximizing social welfare is NP-hard, even if utilities are symmetric and only attain the values $-1$ and 1 [2]. Moreover, even though Bullinger [12] presents a polynomial-time algorithm to compute Pareto-optimal partitions for symmetric ASHG, the partitions computed by this algorithm can have negative social welfare. All of the literature discussed thus far considers ASHG in an offline setting.

[1] Flammini et al. [22] simplify the exposition by scaling the utilities such that $U_{min}$ is always 1.

The online variant only came under scrutiny very recently and has been researched far less. Flammini et al. [22] introduce the problem and focus on deterministic algorithms with guarantees to social welfare. Strictly speaking, they consider a variant of games equivalent to ASHGs, where utilities are scaled by a factor of 2. In particular, they consider games restricted by a maximum coalition size or maximum number of coalitions.

Moreover, there is a recent stream of research on dynamic models of coalition formation [4, 10, 15]. Instead of agents arriving over time, there exists an initial partition, which is altered over discrete time steps based on deviations of agents. Some of this literature explicitly deals with ASHGs or close variants [5, 6, 9, 14].

From the online algorithms literature, most related to our work is the online matching problem, which was first considered in the seminal paper by Karp et al. [27] considering online bipartite matching. In this work, an unweighted, bipartite graph is given, and the agents of one side appear online. The goal is to find a matching of maximum cardinality. Karp et al. [27] introduce the famous ranking algorithm, which achieves a competitive ratio of $1 - \frac{1}{e}$. An overview of this research is presented in the very recent book chapter by Huang and Tröbst [25].

Our model of online coalition formation can be viewed as a generalization of the setting by Karp et al. [27], with the following modifications: (i) there are edge weights, (ii) all vertices arrive online, (iii) the underlying graph is not necessarily bipartite, and (iv) coalitions can be arbitrary subsets of agents. While condition (iv) is specific to coalition formation, conditions (i)-(iii) have been studied in the literature, albeit, to the best of our knowledge, not in the combination of all three. Feldman et al. [20] consider condition (i), i.e., a bipartite setting with edge weights, where one side of the vertices arrives online. They show that the natural greedy algorithm is $\frac{1}{2}$-competitive, and they provide an algorithm matching the competitive ratio of $1 - \frac{1}{e}$ from Karp et al. [27]. An important condition in this setting is *free disposal*, which essentially requires that a previous matching can be dissolved upon the arrival of a better option. Wang and Wong [31] consider condition (ii), i.e., online bipartite matching where both sides arrive online. They can beat the greedy algorithm by a primal-dual algorithm achieving a competitive ratio of $0.532 < 1 - \frac{1}{e}$. Finally, Huang et al. [24] consider the conjunction of conditions (ii) and (iii), i.e., fully online (non-bipartite) matching. They extend the ranking algorithm to this setting and show that it is 0.5211-competitive. Both Wang and Wong [31] and Huang et al. [24] show that a competitive ratio of $1 - \frac{1}{e}$ is impossible to achieve in their respective settings. Interestingly, the competitive ratio of $1 - \frac{1}{e}$ can be beaten in the random arrival model [26, 28].

## 3 Preliminaries

In this section, we present our model. For an integer $i \in \mathbb{N}$, we define $[i] := \{1, \dots, i\}$. Additionally, for any set $N$, define $\binom{N}{2} := \{e \subseteq N \colon |e| = 2\}$.

### 3.1 Additively Separable Hedonic Games

Let $N$ be a finite set of $n$ *agents*. Any subset of $N$ is called a *coalition*. We denote the set of all possible coalitions containing agent $i \in N$ by $\mathcal{N}_i = \{C \subseteq N \colon i \in C\}$. A *coalition structure* (or *partition*) is a partition of the agents. Given an agent $i \in N$ and a partition $\pi$, let $\pi(i)$ denote the coalition of $i$, i.e., the unique coalition $C \in \pi$ with $i \in C$.

A *hedonic game* is a pair $(N, \succsim)$ consisting of a set $N$ of agents and a preference profile $\succsim = (\succsim_i)_{i \in N}$, where $\succsim_i$ is a weak order over $\mathcal{N}_i$ that represents the preferences of agent $i$. A hedonic game is called an *additively separable hedonic game* (ASHG) if there exists a

complete, undirected, and weighted graph $G = (N, E, w)$ with edge set $E = \binom{N}{2}$ and weight function $w\colon E \to \mathbb{Q}$, such that, for every agent $i \in N$ and every pair of coalitions $C, C' \in \mathcal{N}_i$, it holds that $C \gtrsim_i C'$ if and only if $\sum_{j\in C} w(\{i,j\}) \geq \sum_{j\in C'} w(\{i,j\})$ [7].[2] We then speak of the ASHG *given by* $G$. We abbreviate $w(i,j) = w(\{i,j\})$. Moreover, since we only consider complete graphs, we shorten notation and write $G = (N, w)$, where $w\colon \binom{N}{2} \to \mathbb{Q}$, instead of $G = (N, E, w)$ to fully specify an underlying graph. For an agent $i \in N$ and a coalition $C \in \mathcal{N}_i$ or a partition $\pi$, we define the *utility* of $i$ for $C$ or $\pi$ by $u_i(C) := \sum_{j\in C} w(i,j)$ and $u_i(\pi) := u_i(\pi(i))$, respectively.

Additionally, we extend the weight function to sets of edges $F \subseteq \binom{N}{2}$ by $w(F) := \sum_{e\in F} w(e)$. A *matching* is a coalition structure $\pi$ such that, for all $C \in \pi$, it holds that $|C| \leq 2$. A matching $\pi$ is represented by its edge set $M(\pi) := \{C \in \pi\colon |C| = 2\} \subseteq \binom{N}{2}$. We then write $w(\pi) := w(M(\pi))$ for the weight of matching $\pi$.

## 3.2 Online Coalition Formation

In this section, we introduce our model of online coalition formation and appropriate objectives. Consider an ASHG given by $G = (N, w)$. Given a subset of agents $N' \subseteq N$, let $G[N']$ denote the subgraph induced by agent set $N'$. Moreover, given a partition $\pi$ of $N$ and a subset of agents $N' \subseteq N$, we define $\pi[N']$ as the *partition restricted to* $N'$ as $\pi[N'] := \{C \cap N'\colon C \in \pi, C \cap N' \neq \emptyset\}$. Specifically, if $N' = N \setminus \{i\}$ for some agent $i \in N$, we write $\pi - i$ instead of $\pi[N']$.

In an online setting, previous decisions influence the capabilities of an algorithm to form a partition in the next step. Given a partition $\pi$ and an agent $i$ not covered by $\pi$, let $\mathcal{A}(\pi, i)$ denote the set of *available partitions*, when the tentative partition is $\pi$ and the newly arriving agent is $i$. As a default, we assume the standard setting where $\mathcal{A}(\pi, i) = \mathcal{A}^S(\pi, i) := \{\pi'\colon \pi' - i = \pi\}$. We also consider algorithms that have the capability to dissolve a coalition completely. We say that an algorithm acts under *free dissolution* if $\mathcal{A}(\pi, i) = \mathcal{A}^D(\pi, i) := \mathcal{A}^S(\pi, i) \cup \bigcup_{C\in\pi, j\in C}\{(\pi \setminus \{C\}) \cup \{\{i,j\}\} \cup \{\{k\}\colon k \in C \setminus \{j\}\}\}$. Free dissolution is the natural extension of free disposal by Feldman et al. [20] in the domain of matching adapted to coalitions of size larger than 2. In addition, we define $\Sigma(N) := \{\sigma\colon [|N|] \to N \text{ bijective}\}$ as the set of all *orders* of the agent set $N$.

An instance of an *online coalition formation problem* is a tuple $(G, \sigma)$, where $G = (N, w)$ defines an ASHG and $\sigma \in \Sigma(N)$. An *online coalition formation algorithm* for instance $(G, \sigma)$ gets as input the sequence $G_1, \ldots, G_n$, where, for every $i \in [n]$, $G_i = G[\{\sigma(1), \ldots, \sigma(i)\}]$. Then, for every $i \in [n]$, the algorithm produces a partition $\pi_i$ of $\{\sigma(1), \ldots, \sigma(i)\}$ such that the algorithm has only access to $G_i$ and for $i \geq 2$, it holds that $\pi_i \in \mathcal{A}(\pi_{i-1}, \sigma(i))$.

The output of the algorithm is the partition $\pi_n$. Given an online coalition formation algorithm $ALG$, let $ALG(G, \sigma)$ be its output for instance $(G, \sigma)$.

In other words, the algorithm iteratively builds a partition such that, whenever an agent arrives, the only knowledge is the game restricted to the present agents, and the algorithm has to irrevocably assign the new agent to an existing coalition or start a new coalition (or, under free dissolution, dissolve any coalition before making its decision). If an online coalition formation algorithm creates a matching in any step, we speak of an *online matching algorithm*.

Our benchmark algorithm is the greedy algorithm as introduced by Flammini et al. [22].

[2] Since our focus will be on social welfare, the consideration of *undirected* graphs is without loss of generality because the social welfare of a partition is invariant under the symmetrization $w^S(\{x,y\}) = \frac{1}{2}(w_x(y) + w_y(x))$ given directed edges with weights $w_i(j)$.

▶ **Definition 1** (Greedy algorithm). *On input* $(G, \sigma)$*, in the* $i$*th step,* $i \geq 2$*, the* greedy algorithm *(GDY) forms* $\pi_i = \arg\max_{\pi \in \mathcal{A}(\pi_{i-1}, \sigma(i))} \mathcal{SW}(\pi)$ *if there exists* $\pi \in \mathcal{A}(\pi_{i-1}, \sigma(i))$ *with* $\mathcal{SW}(\pi) > \mathcal{SW}(\pi_{i-1})$*, and* $\pi_i = \pi_{i-1} \cup \{\{\sigma(i)\}\}$*, otherwise.*

Hence, *GDY* assigns each arriving agent to the available coalition such that the increase in social welfare is maximized, or creates a new singleton coalition if no increase is possible.

## 3.3 Competitive Analysis

The competitive analysis needs a quantifiable objective and we follow Flammini et al. [22] by considering social welfare. The *social welfare* of a partition $\pi$ is defined as $\mathcal{SW}(\pi) = \sum_{i \in N} u_i(\pi)$. A partition $\pi$ is said to be *welfare-optimal* if, for every partition $\pi'$, it holds that $\mathcal{SW}(\pi) \geq \mathcal{SW}(\pi')$. Given a hedonic game $G$, let $\pi^*(G)$ be a welfare-optimal partition. We say that an online coalition formation algorithm $ALG$ is *c-competitive*[3] if

$$\inf_{G} \min_{\sigma \in \Sigma(N)} \frac{\mathcal{SW}(ALG(G, \sigma))}{\mathcal{SW}(\pi^*(G))} \geq c.$$

Equivalently, this means that, for all instances $(G, \sigma)$, it holds that $\mathcal{SW}(ALG(G, \sigma)) \geq c\,\mathcal{SW}(\pi^*(G))$. The *competitive ratio* of an algorithm $ALG$, denoted by $c_{ALG}$, is the maximum $c$ such that $ALG$ is $c$-competitive. Note that the competitive ratio is always at most 1.

In addition, we consider online coalition formation with a random arrival order, where we assume that the arrival order is selected uniformly at random. In the random arrival model, the competitive ratio of an algorithm $ALG$ is defined as

$$\inf_{G} \frac{\mathbb{E}_\sigma\left[\mathcal{SW}(ALG(G, \sigma))\right]}{\mathcal{SW}(\pi^*(G))} \geq c.$$

There, the expectation is over the uniform selection of an arrival order $\sigma$ from $\Sigma(N)$. Note that if $\pi$ is a matching, then $w(\pi) = \frac{1}{2}\mathcal{SW}(\pi)$. Hence, in the competitive analysis of online matching algorithms, we can as well consider the weight of matchings instead of their social welfare.

# 4 Random Arrival Model

In this section, we analyze algorithms aiming at achieving a high social welfare in the random arrival model. Interestingly, while in the deterministic arrival model, the specific utility values affect the competitive ratio of the greedy algorithm (and any other algorithm) [22], in the random arrival model, the dependency is solely on the number of agents. For our analysis of algorithms in this section we use the notation $x \prec^\sigma y$ to say that $\sigma^{-1}(x) < \sigma^{-1}(y)$ for $x, y \in N$ and an arrival order $\sigma$.

▶ **Theorem 2.** *The competitive ratio of GDY for ASHGs under a random arrival order satisfies* $\Theta\left(\frac{1}{n^2}\right)$.

**Proof.** First, we show that the competitive ratio of *GDY* satisfies $O\left(\frac{1}{n^2}\right)$ by providing an example where it performs "bad". Let $\epsilon > 0$ and consider the ASHG given by $G^\epsilon = (N, w^\epsilon)$ depicted in Figure 1. The agent set is $N = X \cup Y \cup \{a, b\}$, where $|X| = |Y| = m$. Utilities

[3] Here, we use the convention that $\frac{0}{0} = 1$ and $\frac{x}{0} = 0$ for any $x \in \mathbb{Q}_{<0}$. Also, note that Flammini et al. [22] define the competitive ratio in the inverse way such that it is always at least 1. Here, we prefer the more common definition in the online matching literature.

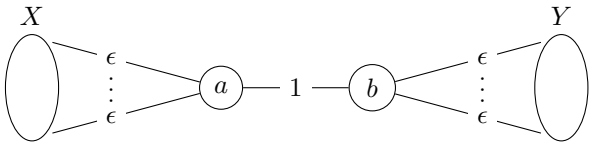

**Figure 1** The example contains $n = 2m + 2$ agents. There are $m$ agents in each of the sets $X$ and $Y$. The utility between $a$ and any agent in $X$ and $b$ and any agent in $Y$ is $\epsilon$. All omitted edges represent utilities of $-1$.

are given by $w^\epsilon(a,b) = 1$, $w^\epsilon(a,x) = w^\epsilon(b,y) = \epsilon$ for $x \in X$ and $y \in Y$, and all other weights are $-1$. Clearly, for sufficiently small $\epsilon$, the optimal solution has a value of 2 (with $\{a,b\}$ the only non-singleton coalition). By inspecting the limit case for $\epsilon$ tending to 0, the value of the greedy algorithm (and therefore also its competitive ratio) is at most twice the probability of forming $\{a,b\}$, i.e.,

$$\begin{aligned} c_{GDY} &= \inf_G \frac{\mathbb{E}_\sigma\left[\mathcal{SW}(GDY(G,\sigma))\right]}{\mathcal{SW}(\pi^*(G))} \leq \inf_{\epsilon>0} \frac{\mathbb{E}_\sigma\left[\mathcal{SW}(GDY(G^\epsilon,\sigma))\right]}{2} \\ &\leq \mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma)). \end{aligned}$$

We compute

$$\begin{aligned} \mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma)) &= \mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma) \mid a \prec^\sigma b)\mathbb{P}_\sigma(a \prec^\sigma b) \\ &\quad + \mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma) \mid b \prec^\sigma a)\mathbb{P}_\sigma(b \prec^\sigma a) \\ &= 2\mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma) \mid a \prec^\sigma b)\mathbb{P}_\sigma(a \prec^\sigma b). \end{aligned}$$

The second equality follows by symmetry. Next, we sum over all possible arrival positions of $b$ by summing over the number of alternatives that arrive before $b$ in addition to $a$. Note that if more than $m$ agents arrive before $b$, excluding $a$, then, by the pigeonhole principle, some $x \in X$ arrives before $b$ and forms a coalition with $a$. This prevents the coalition $\{a,b\}$ from forming so all terms of the sum for $i > m$ are 0. Conditioned on $a$ arriving before $b$, the coalition $\{a,b\}$ forms if and only if all $i$ agents arriving before $b$ are from $Y$ since those agents will not form a coalition with $a$. We derive[4]

$$\begin{aligned} c_{GDY} &\leq 2\sum_{i=0}^{m} \mathbb{P}_\sigma(\{a,b\} \in GDY(G^\epsilon,\sigma) \mid a \prec^\sigma b, \sigma^{-1}(b) = i+2) \\ &\qquad \cdot \mathbb{P}_\sigma(a \prec^\sigma b \mid \sigma^{-1}(b) = i+2)\mathbb{P}_\sigma(\sigma^{-1}(b) = i+2) \\ &= 2\sum_{i=0}^{m} \mathbb{P}_\sigma(\{d\colon d \prec^\sigma b\} \setminus \{a\} \subseteq Y \mid a \prec^\sigma b, \sigma^{-1}(b) = i+2) \\ &\qquad \cdot \mathbb{P}_\sigma(a \prec^\sigma b \mid \sigma^{-1}(b) = i+2)\mathbb{P}_\sigma(\sigma^{-1}(b) = i+2). \end{aligned}$$

We compute all individual terms in the previous sum. First, the probability that the $i$ agents arriving before $b$ are all from $Y$ is $\mathbb{P}_\sigma(\{d\colon d \prec^\sigma b\} \setminus \{a\} \subseteq Y \mid a \prec^\sigma b, \sigma^{-1}(b) = i+2) = \frac{\binom{m}{i}}{\binom{2m}{i}}$, i.e., the number of possibilities to draw $i$ agents from $Y$ divided by the number of possibilities to draw $i$ agents from $Y \cup X$.

[4] For the first inequality, note that it holds that $\mathbb{P}(A \mid B)\mathbb{P}(B) = \mathbb{P}(A,B) = \sum_C \mathbb{P}(A,B,C) = \sum_C \mathbb{P}(A \mid B,C)\mathbb{P}(B,C) = \sum_C \mathbb{P}(A \mid B,C)\mathbb{P}(B \mid C)\mathbb{P}(C)$ for arbitrary events $A$, $B$, and $C$ and probability measures $\mathbb{P}$.

Second, the probability that $a$ arrives before $b$ when $b$ arrives in position $i+2$ is $\mathbb{P}_\sigma(a \prec^\sigma b \mid \sigma^{-1}(b) = i+2) = \frac{i+1}{2m+1}$ because we have $i+1$ chances to draw $a$ among the remaining $2m+1$ alternatives. Finally, due to the random arrival order, the probability that agent $b$ arrives in a certain fixed position is $\mathbb{P}_\sigma(\sigma^{-1}(b) = i+2) = \frac{1}{2m+2}$. Together, we obtain

$$c_{GDY} \leq 2\sum_{i=0}^{m} \frac{\binom{m}{i}}{\binom{2m}{i}} \frac{i+1}{2m+1}\frac{1}{2m+2} = \frac{2}{m^2+3m+2} \in O\left(\frac{1}{m^2}\right) = O\left(\frac{1}{n^2}\right).$$

Next, we show that the competitive ratio of $GDY$ satisfies $\Omega\left(\frac{1}{n^2}\right)$. Consider an arbitrary ASHG given by $G = (N, w)$ and let $E^+(G) = \left\{e \in \binom{N}{2} \colon w(e) > 0\right\}$ be the set of agent pairs with positive weights. Then, the welfare-optimal partition $\pi^*(G)$ satisfies $\mathcal{SW}(\pi^*(G)) \leq 2\sum_{e\in E^+(G)} w(e)$. Furthermore, the social welfare of $GDY$ is at least twice the utility between the first arriving pair of agents from $E^+(G)$. Indeed, until the arrival of a pair of agents with positive utility, every agent is assigned to a singleton coalition. Thus, since every pair in $E^+(G)$ has equal probability to be the first such pair, the expected social welfare of $GDY$ is at least the average, i.e., $\mathbb{E}_\sigma[\mathcal{SW}(GDY(G,\sigma))] \geq \frac{\sum_{e\in E^+(G)} 2w(e)}{|E^+(G)|}$ and the competitive ratio is then at least

$$c_{GDY} = \inf_G \frac{\mathbb{E}_\sigma[\mathcal{SW}(GDY(G,\sigma))]}{\mathcal{SW}(\pi^*(G))} \geq \inf_G \frac{\frac{\sum_{e\in E^+(G)} 2w(e)}{|E^+(G)|}}{2\sum_{e\in E^+(G)} w(e)} = \inf_G \frac{1}{|E^+(G)|} \in \Omega\left(\frac{1}{n^2}\right).$$

Altogether, we have shown that $c_{GDY}$ is of order $\Theta\left(\frac{1}{n^2}\right)$. ◀

The natural question is whether we can obtain better algorithms than the greedy algorithm. A simple attempt to achieve a better algorithm is to make use of randomization. The performance of the greedy algorithm was bounded because in the worst case, the value of greedy is equal to the average weight of a positive edge. However, we can easily achieve the average weight of a random matching, improving the performance to $1/n$. For simplicity, we assume first that $n$ is even and known to the algorithm in advance. We first analyze a simple online matching algorithm.

▶ **Definition 3** (Random matching algorithm). *The* random matching algorithm *(RMA) leaves the first $\frac{n}{2}$ agents unmatched. Then, we select a bijection $\phi\colon \left[\frac{n}{2}\right] \to \left[\frac{n}{2}\right]$ uniformly at random. For $1 \leq i \leq \frac{n}{2}$, if the weight between the $\left(\frac{n}{2}+i\right)$th agent and the $\phi(i)$th agent is positive, then these are matched. Otherwise, the $\left(\frac{n}{2}+i\right)$th remains unmatched.*

We determine the competitive ratio of *RMA*.

▶ **Proposition 4.** *RMA has a competitive ratio of $\Theta\left(\frac{1}{n}\right)$ for matching instances under a random arrival order when $n$ is known.*

**Proof.** Consider an instance given by $G = (N, w)$ such that there exists agents $a, b \in N$ with $w(a, b) = 1$, and $w(x, y) = 0$ if $\{x, y\} \neq \{a, b\}$. Then, the maximum weight matching has weight 1, but *RMA* has only a chance of

$$\frac{\binom{2}{1}\binom{n-2}{\frac{n}{2}-1}}{\binom{n}{\frac{n}{2}}} \cdot \frac{1}{n} = \frac{n}{2(n-1)} \cdot \frac{1}{n} = \Theta\left(\frac{1}{n}\right),$$

to have $a$ and $b$ in the same coalition. There, the first part of the product is the chance that $a$ and $b$ appear in different stages of the algorithm, and the factor of $1/n$ is the probability that they are matched conditioned on them arriving in different stages. Hence, the competitive ratio of *RMA* satisfies $O\left(\frac{1}{n}\right)$.

On the other hand, in an execution of *RMA*, every positive edge has a probability of $\frac{n}{2(n-1)} \cdot \frac{1}{n}$ to contribute to the computed matching. Let $E^+ = \left\{e \in \binom{N}{2} \colon w(e) > 0\right\}$. Hence, $\mathbb{E}_\sigma[RMA(G,\sigma)] = \sum_{e \in E^+} \frac{n}{2(n-1)} \cdot \frac{1}{n} w(e) \geq \frac{1}{2n} w(E^+)$. Since any matching is of weight at most $w(E^+)$, we conclude that

$$c_{RMA} \geq \frac{1}{2n} = \Omega\left(\frac{1}{n}\right). \qquad \blacktriangleleft$$

Our next goal is to derandomize this algorithm while maintaining the same competitive ratio. A natural way to do this is to have the first half of the agents form singleton coalitions, and the second half of the agents join the best available coalition. This yields a deterministic algorithm achieving a competitive ratio of $\frac{1}{n}$. First, we maintain the assumption that $n$ is even and known to the algorithm beforehand. However, after we have analyzed this algorithm, we will show that we can drop this additional assumption and that a variation of the algorithm still achieves the same competitive ratio asymptotically.

▶ **Definition 5** (Waiting greedy algorithm)**.** *The* waiting greedy algorithm *(WGDY) places the first $\frac{n}{2}$ agents in singleton coalitions. Then, for the remaining $\frac{n}{2}$ agents, it assigns coalitions greedily.*

The upper bound of the performance of *WGDY* is again attained by the game depicted in Figure 1. The analysis is more involved and relies on investigating the distribution of the agents in the second phase. We defer the complete proof to the full version and restrict attention to the lower bound. The full version also contains all other missing proofs.

▶ **Theorem 6.** *The competitive ratio of WGDY for ASHGs under a random arrival and known and even $n$ is $\Theta\left(\frac{1}{n}\right)$.*

**Proof of lower bound.** We show that $WGDY \in \Omega\left(\frac{1}{n}\right)$. Consider an arbitrary ASHG given by $G = (N, w)$. Let $\Pi(n) = \left\{(A,B) \colon A \cup B = N, |A| = |B| = \frac{n}{2}\right\}$ be the set of partitions of the agent set $N$ into two equally-sized subsets.

Let $(A,B) \in \Pi(n)$. Define $E^+(A,B) = \left\{e = \{a,b\} \in \binom{N}{2} \colon w(e) > 0, a \in A, b \in B\right\}$. We claim that if the agents in $A$ and $B$ arrive in the first and second stage, respectively, then the weight of the obtained partition is at least $\frac{1}{n} w(E^+(A,B))$. Let $P_{A,B}$ denote the event that the partition $(A,B)$ realizes.

Consider an arbitrary agent $b \in B$. Let $a_1(b), \ldots, a_{r(b)}(b) \in A$ be the agents in $A$ such that $\{b, a_i(b)\} \in E^+(A,B)$, where $r(b) \in \mathbb{N}$ is their number. Assume that $w(a_1(b), b) \geq w(a_2(b), b) \geq \cdots \geq w(a_{r(b)}(b), b)$. Let $i \in [r(b)]$. In the event $P_{A,B}$, an agent $b \in B$ arrives as the $(\frac{n}{2} + i)$th agent (i.e., the $i$th agent within $B$) with a probability of $\frac{2}{n}$. Moreover, when $b$ arrives as the $(\frac{n}{2} + i)$th agent, then at most $i - 1$ coalitions have formed so far, and therefore some agent in $\{a_1(b), \ldots, a_i(b)\}$ is still in a singleton coalition. Hence, the increase in weight caused by $b$ is at least the weight of forming a singleton coalition with the worst partner in $\{a_1(b), \ldots, a_i(b)\}$, that is, $w(a_i(b), b)$. Let $I_b$ be the random variable denoting the gain in social welfare caused by the arrival of $b$.

Hence, in the event $P_{A,B}$, the attained expected social welfare satisfies

$$\begin{aligned}
\mathbb{E}_\sigma[\mathcal{SW}(\mathit{WGDY}(G,\sigma)) \mid P_{A,B}] &\geq \sum_{b\in B} \mathbb{E}_\sigma[I_b \mid P_{A,B}] \\
&= \sum_{b\in B}\sum_{i=1}^{r(b)} \mathbb{E}_\sigma\left[I_b \mid P_{A,B}, \sigma^{-1}(b) = \frac{n}{2}+i\right] \mathbb{P}_\sigma\left(\sigma^{-1}(b) = \frac{n}{2}+i \mid P_{A,B}\right) \\
&= \sum_{b\in B}\sum_{i=1}^{r(b)} \mathbb{E}_\sigma\left[I_b \mid P_{A,B}, \sigma^{-1}(b) = \frac{n}{2}+i\right] \frac{2}{n} \\
&\geq \sum_{b\in B}\sum_{i=1}^{r(b)} w(a_i(b),b)\frac{2}{n} = \frac{2}{n}\sum_{b\in B}\sum_{e\in E^+(A,B)\colon b\in e} w(e) = \frac{2}{n}w(E^+(A,B)).
\end{aligned}$$

Hence, the expected social welfare of the partition computed by *WGDY* is

$$\mathbb{E}_\sigma\left[\mathcal{SW}(\mathit{WGDY}(G,\sigma))\right] \geq \frac{1}{|\Pi(n)|}\sum_{(A,B)\in\Pi(n)} \frac{2}{n} w\left(E^+(A,B)\right) \geq \frac{1}{2}\frac{2}{n} w\left(E^+\right). \tag{1}$$

In the first inequality, we have used that each partition in $\Pi(n)$ is realized with equal probability, and in the second inequality, we have used that an edge in $E^+ = \left\{e \in \binom{N}{2}\colon w(e) > 0\right\}$ is in $E^+(A,B)$ for at least half of the partitions in $\Pi$. The latter holds because there are $n^2/4$ edges between $A$ and $B$ and $n(n-1)/2$ edges in total.

Additionally, the social welfare of any partition is at most $2w(E^+)$. Combining this with Equation (1), we obtain

$$c_{\mathit{WGDY}} \geq \frac{\frac{w(E^+)}{n}}{2w(E^+)} = \frac{1}{2n} \in \Omega\left(\frac{1}{n}\right). \qquad \blacktriangleleft$$

Next, we show that we can still use a variant of this algorithm even if we do not know $n$. The idea is to run *WGDY* on an exponentially growing number of agents repeatedly, possibly not finishing the last iteration.

▶ **Definition 7** (Iterated waiting algorithm). *The* iterated waiting algorithm *(IWA) alternates between placing $2^i$ agents in singleton coalitions and then assigning $2^i$ agents to coalitions with the previous $2^i$ agents greedily. The parameter is set to $i = 0$ at the start and is increased by 1 after $2^{i+1}$ agents arrive.*

The lower bound in the analysis follows, because *IWA* completes an execution of *WGDY* for a sufficiently large number of agents. For the upper bound, we can once again use the game in Figure 1. The analysis is even more involved as in Theorem 6 because we need to consider dependencies of the distributions of the agents between the phases of *IWA*.

▶ **Theorem 8.** *IWA has a competitive ratio of $c \in \Theta\left(\frac{1}{n}\right)$.*

## 5 Deterministic Model under Free Dissolution

In this section, we consider the model with deterministic arrivals under free dissolution. For bipartite online matching instances, where one side of the agents is present offline, Feldman et al. [20] show that *GDY*, i.e., transitioning to best coalitions within $\mathcal{A}^D(\pi,i)$ achieves a competitive ratio of $\frac{1}{2}$. However, if all vertices arrive online, then *GDY* does not even achieve a constant competitive ratio.

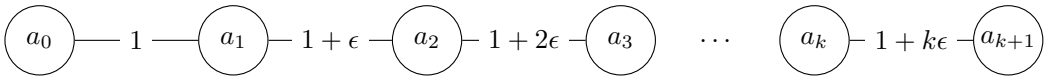

**Figure 2** Family of instances for upper bound of the competitive ratio of *GDY* for matching instances under free dissolution.

▶ **Proposition 9.** *In the deterministic model with free dissolution, GDY has a competitive ratio of* $\Theta(\frac{1}{n})$ *in the matching domain.*

**Proof.** First, note that *GDY* will definitely match a pair of agents with the highest possible weight $W_{\max}$. Moreover, every matching has weight at most $\frac{n}{2}W_{\max}$, and therefore $c_{GDY} \in \Omega(\frac{1}{n})$.

For the upper bound, consider the family of instances depicted in Figure 2. Let $\epsilon > 0$ and $k \in \mathbb{N}$ even. Consider $G^{k,\epsilon} = (N^{k,\epsilon}, w^{k,\epsilon})$ where $N^{k,\epsilon} = \{a_i \colon 0 \leq i \leq k+1$ and, for $i \in [k+1]$, $w^{k,\epsilon}(a_{i-1}, a_i) = 1 + (i-1)\epsilon$. All other weights are set to 0. Let the arrival order be $(a_0, a_1, \ldots, a_k, a_{k+1})$. Let $M^*(G^{k,\epsilon})$ be the maximum weight matching for the instance given by $G^{k,\epsilon}$.

Then, $M^*(G^{k,\epsilon}) = \left\{\{a_{2i}, a_{2i+1}\} \colon 0 \leq i \leq \frac{k}{2}\right\}$ and *GDY* outputs the matching $\{\{a_k, a_{k+1}\}\}$. Hence,

$$\inf_{\epsilon>0} \frac{\mathcal{SW}(GDY(G^{k,\epsilon}, \sigma^k))}{\mathcal{SW}(M^*(G^{k,\epsilon}, \sigma^k))} = \inf_{\epsilon>0} \frac{1+k\epsilon}{\frac{k}{2} + \frac{1}{4}k(k+2)\epsilon} = \frac{2}{k} \in \Theta\left(\frac{1}{n}\right). \qquad \blacktriangleleft$$

The non-zero edges in the construction of the previous proposition even induce *bipartite* graphs, and it is therefore essential for the result by Feldman et al. [20] that one side of the agents is present offline. Proposition 9 indicates that even achieving a constant competitive ratio is a non-trivial task for an online matching algorithm for weighted graphs. In fact, as we will see in Section 6, the usual result of achieving a competitive ratio of $1/2$ with some algorithm [27, 20, 31] is impossible. Still, we can modify the greedy algorithm to achieve a constant competitive ratio.

▶ **Definition 10** (Dissolution threshold algorithm)**.** *Given a matching* $\pi$ *and a newly arriving vertex* $i$*, the* dissolution threshold algorithm *(DTA) is the greedy algorithm for the available matchings* $\mathcal{A}(\pi, i) = \{(\pi - j) \cup \{\{i, j\}\} \colon \{j\} \in \pi\} \cup \{(\pi \setminus \{C\}) \cup \{\{i, j\}, \{k\}\} \colon C = \{j, k\} \in \pi, w(i, j) \geq 2w(j, k)\}$.

In words, *DTA* only dissolves a matched pair if the weight of the new edge compared to the weight of the dissolved edge is larger by at least a factor of 2.

▶ **Theorem 11.** *In the deterministic model with free dissolution, DTA has a competitive ratio of* $\frac{1}{6}$ *in the matching domain.*

**Proof.** We show first that $c_{DTA} \leq \frac{1}{6}$. To this end, we define a family of instances $(G^{k,\epsilon})_{k\geq 1, \epsilon > 0}$ with a sufficiently large gap between the social welfare of the algorithmic and optimal solutions. The construction is depicted in Figure 3.

Let $G^k = (N^k, w^k)$ where $N^k = \{a_i, b_i \colon 0 \leq i \leq k+1\}$. The edge weights are given by $w(a_i, b_i) = 2^{i+1} - \epsilon$ for $0 \leq i \leq k$, $w(a_{k+1}, b_{k+1}) = 2^{k+1} - \epsilon$, and $w(a_i, a_{i+1}) = 2^i$ for $0 \leq i \leq k$. All other weights are set to 0. The arrival order $\sigma^k$ is $(a_0, a_1, b_0, a_2, b_1, \ldots, a_{k+1}, b_k, b_{k+1})$.

Consider an execution of *DTA* for $(G^{k,\epsilon}, \sigma^k)$. It is easy to see that $DTA(G^{k,\epsilon}, \sigma^k) = \{\{a_k, a_{k+1}\}\}$, hence $\mathcal{SW}(DTA(G^{k,\epsilon})) = 2^k$. On the other hand, the maximum weight matching for $G^{k,\epsilon}$ (and sufficiently small $\epsilon$) is $M^*(G^{k,\epsilon}) = \{\{a_i, b_i\} \colon 0 \leq i \leq k+1\}$ with $\mathcal{SW}(M^*(G^{k,\epsilon})) = 2^{k+1} + 2^{k+2} - 2 - (k+2)\epsilon$. Hence,

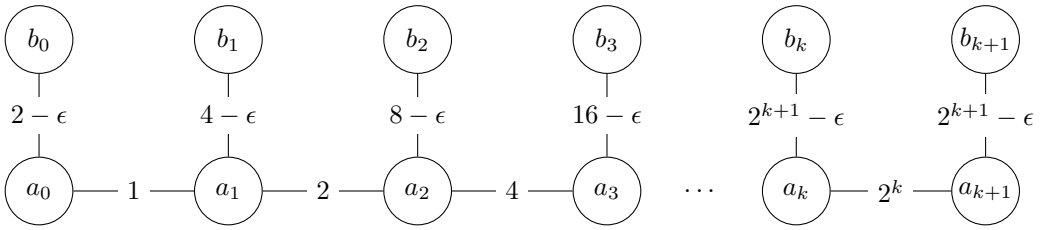

**Figure 3** Family of instances for tightness of competitive ratio in Theorem 11.

$$c_{DTA} = \inf_{G,\sigma} \frac{\mathcal{SW}(DTA(G,\sigma))}{\mathcal{SW}(M^*(G,\sigma))} \leq \inf_{k\geq 1,\epsilon>0} \frac{\mathcal{SW}(DTA(G^{k,\epsilon},\sigma^k))}{\mathcal{SW}(M^*(G^{k,\epsilon}))}$$
$$= \inf_{k\geq 1,\epsilon>0} \frac{2^k}{2^{k+1}+2^{k+2}-2-(k+2)\epsilon} = \frac{1}{6}.$$

Next, we show that $c_{DTA} \geq \frac{1}{6}$. Let $M$ be the matching produced by $DTA$ and let $M^*$ be a maximum weight matching. Without loss of generality, we may assume that all edges in $M^*$ have positive weight. Further let $F \subseteq E$ be the set of edges that were formed by $DTA$ at some point, i.e., $F$ consists of the edges in $M$ as well as all edges that have been dissolved. The key idea is to consider the relation induced by the replacement of edges. More precisely, given two edges $e, e' \in F$, we say that $e$ *dominates* $e'$ with respect to replacement, written as $e \succ_R e'$, if there exists a chain of edges $e_0, \dots, e_j$ such that $e_0 = e'$, $e_j = e$ and for $i \in [j]$, the formation of $e_i$ has lead to the dissolution of $e_{i-1}$. Note that $M$ consists precisely of the maximal elements in $F$ with respect to $\succ_R$.

We define a function $\mu\colon M^* \to 2^F$ as follows. Let $m = \{a, b\} \in M^*$ and assume that $b$ arrives after $a$. For a set of edges $F' \subseteq F$, we define $\max_{\succ_R}(F') = \{f \in F' \colon \nexists f' \in F \text{ with } f' \succ_R f\}$.

If, at the arrival of $b$, $a$ is already matched with $c$ and $2w(a,c) > w(a,b)$, then $\mu(m) = \max_{\succ_R}\{f \in F \colon f \succsim_R \{a,c\}, a \in f\}$. If, at the arrival of $b$, $a$ is already matched with $c$ and $2w(a,c) \leq w(a,b)$, then $b$ is matched with some $d$ and we define $\mu(m) = \max_{\succ_R}(\{f \in F \colon f \succsim_R \{a,c\}, a \in f\} \cup \{f \in F \colon f \succsim_R \{b,d\}, b \in f\})$. If at the arrival of $b$, $a$ is unmatched, then $b$ is matched with some $d$ and we define $\mu(m) = \max_{\succ_R}\{f \in F \colon f \succsim_R \{b,d\}, b \in f\}$. Note that $\mu$ always maps to a non-empty set. Indeed, if $a$ is unmatched or matched to an agent $c$ with $2w(a,c) \leq w(a,b)$, then $b$ will certainly be matched because matching with $a$ is an eligible option. Note that $\mu$ is a set-valued function, but for all $m \in M^*$, it holds that $|\mu(m)| \leq 2$. Moreover, the only case where $\mu(m)$ contains two edges is if we are in the second case and the edge $\{a,b\}$ is not created.

Bounding the weight of $M^*$ proceeds in three steps. First, we bound the weights of edges in $M^*$ by their image set in $F$. Then, we show that each edge in $F$ is only in the image of few edges. Lastly, we bound the weight accumulated by edges dominated with respect to $\succ_R$.

To illustrate the proof, it is useful to consider the example in Figure 3 from the first part of the proof. There, $F = \{\{a_i, a_{i+1}\} \colon 0 \leq i \leq k\}$. Moreover, the maximum weight matching is $M^* = \{\{a_i, b_i\} \colon 0 \leq i \leq k+1\}$. For $0 \leq i \leq k$ we have $\mu(\{a_i, b_i\}) = \{\{a_i, a_{i+1}\}\}$ according to the first case in the definition of $\mu$. In addition, $\mu(\{a_{k+1}, b_{k+1}\}) = \{\{a_k, a_{k+1}\}\}$, also according to the first case in the definition of $\mu$.

▷ Claim 12. For all $m \in M^*$, it holds that $w(m) \leq 2w(\mu(m))$.

Proof. Let $m = \{a, b\} \in M^*$ and assume that $b$ arrives after $a$. Assume first that, at the arrival of $b$, $a$ is already matched with $c$ and $2w(a, c) > w(a, b)$. Then, for every edge $f \in F$ with $f \succsim_R \{a, c\}$ and $a \in f$, there exists a sequence of edges $e_0, \dots, e_j$ such that $e_0 = e$, $e_j = f$ and for $i \in [j]$, $e_i$ has replaced $e_{i-1}$. Hence, $w(e) = w(e_0) \leq w(e_1) \leq \cdots \leq w(e_j) = w(f)$. It follows that $w(m) < 2w(a, c) \leq 2w(\mu(m))$.

Assume next that, at the arrival of $b$, $a$ is already matched with $c$ and $2w(a, c) \leq w(a, b)$. Then, $b$ will be matched with an agent $d$ such that $w(b, d) \geq w(a, b) - w(a, c)$. As in the first case, $w(a, c) \leq w(\max_{\succ_R}\{f \in F \colon f \succsim_R \{a, c\}, a \in f\})$ and $w(b, d) \leq w(\max_{\succ_R}\{f \in F \colon f \succsim_R \{b, d\}, b \in f\})$.

If $d \in \{a, c\}$, then $\{a, b\} \precsim_R f$ for all $f \in \mu(m)$ and $w(m) = w(a, b) \leq w(\mu(m))$. Otherwise, i.e., if $d \neq a$ and $d \neq c$, then $\{a, c\} \cap \{b, d\} = \emptyset$ and therefore also $\max_{\succ_R}\{f \in F \colon f \succsim_R \{a, c\}, a \in f\} \neq \max_{\succ_R}\{f \in F \colon f \succsim_R \{b, d\}, b \in f\}$. Hence, $w(m) \leq w(b, d) + w(a, c) \leq w(\mu(m))$.

Finally, assume that $a$ is unmatched. Then, $b$ will be matched with an agent $d$ such that $w(b, d) \geq w(a, b)$. As before, $w(b, d) \leq w(\max_{\succ_R}\{f \in F \colon f \succsim_R \{b, d\}, b \in f\})$, and we conclude $w(m) \leq w(b, d) \leq w(\mu(m)) \leq 2w(\mu(m))$. This completes the proof of the claim. ◁

Next we bound the number of edges that map to the same edge. Given an edge $e \in F$, define $\mu^{-1}(e) := \{m \in M^* \colon \mu(m) = e\}$.

▷ Claim 13. If $e \in M$, then $|\mu^{-1}(e)| \leq 2$. If $e \in F \setminus M$, then $|\mu^{-1}(e)| \leq 1$.

Proof. By definition of $\mu$, for every $m \in M^*$ and $m' \in \mu(m)$, $m' \cap m \neq \emptyset$. Let $e \in F$. Since $M^*$ is a matching, there can be at most one edge in $M^*$ with a non-empty intersection with each of the two endpoints of $e$. Hence, $|\mu^{-1}(e)| \leq 2$ and the first part of the claim holds.

Now, let $e = \{a, b\} \in F \setminus M$ and assume for contraction that there exist edges $m, m' \in M^*$ with $m \neq m'$, $e \cap m = \{a\}$, $e \cap m' = \{b\}$, and $e \in \mu(m) \cap \mu(m')$. Since, $e \notin M$, the edge $e$ was replaced during the algorithm by another edge $e'$. By definition of *DTA*, it holds that $e \cap e' \neq \emptyset$, say $e \cap e' = \{a\}$. Moreover, $e' \succ_R e$, contradicting that $e \in \mu(m)$. Hence, $|\mu^{-1}(e)| \leq 1$. ◁

It remains to bound the weight of replaced edges. For this, we introduce the following notation. For $e \in M$, define $F_e = \{e' \in F \colon e \succ_R e'\}$.

▷ Claim 14. For all $e \in M$, it holds that $w(F_e) \leq w(e)$.

Proof. Let $e \in M$. Since each edge can only replace a single other edge, $F_e$ is of the form $\{e_1, \dots, e_j\}$ for some $j \geq 0$ such that, for all $i \in [j-1]$, $e_i$ has replaced $e_{i+1}$, and $e$ has replaced $e_1$. Moreover, since a replacement only happens upon a sufficiently large weight improvement, we know that, for all $i \in [j-1]$, $w(e_i) \geq 2w(e_{i+1})$, and $w(e) \geq 2w(e_1)$. Hence, for all $i \in [j]$, it holds that $w(e_i) \leq 2^{-i}w(e)$. Hence, $w(F_e) = \sum_{i=1}^{j} w(e_i) \leq w(e)\sum_{i=1}^{j} 2^{-i} \leq w(e)$. ◁

Combining all three claims, we compute

$$w(M^*) = \sum_{m \in M^*} w(m) \overset{\text{Claim 12}}{\leq} \sum_{m \in M^*} 2w(\mu(m)) \overset{\text{Claim 13}}{\leq} 4\sum_{e \in M} w(e) + 2\sum_{e \in F \setminus M} w(e)$$
$$\overset{\text{Claim 14}}{\leq} 4\sum_{e \in M} w(e) + 2\sum_{e \in M} w(e) = 6w(M).$$ ◀

The next two lemmas let us apply *DTA* as an online coalition formation algorithm.

▶ **Lemma 15.** *Let $G = (N, w)$ be a complete weighted graph and $M^*$ a maximum weight matching of $G$. Then, $w(M^*) \geq \frac{1}{n} w(E^+)$, where $E^+ = \left\{e \in \binom{N}{2} : w(e) > 0\right\}$.*

▶ **Lemma 16.** *Let $ALG$ be a $c$-competitive algorithm for online matching. Then, $ALG$ is $\frac{c}{n}$-competitive for online coalition formation.*

**Proof.** Let $(G, \sigma)$ be an arbitrary instance of online coalition formation. Let $M^*$ be a maximum weight matching for the underlying weighted graph $G$, and let $\pi^*$ be a partition maximizing social welfare. Let $E^+ = \{e \in E : w(e) > 0\}$ be the set of positive edges. Then,

$$\mathcal{SW}(ALG(G, \sigma)) \geq c\, 2\, w(M^*) \geq c\, 2\, \frac{1}{n}\, w(E^+) \geq \frac{c}{n}\, \mathcal{SW}(\pi^*).$$

The first inequality holds because $ALG$ is a $c$-competitive algorithm in the matching domain. The second inequality follows from Lemma 15. The last inequality holds because twice the sum of positive edges is an upper bound for the social welfare of any partition. ◀

As a consequence, we can apply $DTA$ in the coalition formation domain to obtain a $\Theta(1/n)$-competitive algorithm under free dissolution.

▶ **Corollary 17.** *$DTA$ is $\frac{1}{6n}$-competitive for coalition formation in the deterministic model under free dissolution.*

## 6 Boundaries for Optimal Algorithms

In both of our models, we have found algorithms with a competitive ratio of $\Theta\left(\frac{1}{n}\right)$. This raises the question, whether it is possible to achieve even better algorithms, for instance, with a constant competitive ratio. While we leave the ultimate answer to this question open, in this section, we give some insight why the optimal algorithm may be hard to find. We start with upper bounds for the performance of any algorithm in our two settings.

▶ **Proposition 18.** *In the random arrival model, no online coalition formation algorithm achieves a competitive ratio of more than $\frac{1}{2}$.*

**Proof.** Let $ALG$ be any online coalition formation algorithm. Assume for contradiction that $ALG$ is $c$-competitive for some $c > \frac{1}{2}$.

First, note that for any $x > 0$, if the edge between the first two agents has a weight of $x$, then $ALG$ has to form a coalition of size 2. Otherwise, the competitive ratio is 0 in the instance where just these two agents arrive.

Now, we define a family of instances similar to the instance in Figure 1, with the difference that the agents in the sets $X$ and $Y$ also have positive utilities. Let $\epsilon > 0$ be a sufficiently small number and $k$ be a positive integer. Consider the ASHG given by $G^{k,\epsilon} = (N^{k,\epsilon}, w^{k,\epsilon})$, where $N^{k,\epsilon} = \{a, b\} \cup X \cup Y$ with $|X| = |Y| = k$. Hence, there are a total of $n = 2k+2$ agents. Utilities are given as $w^{k,\epsilon}(a, b) = 1$, $w^{k,\epsilon}(a, x_1) = w^{k,\epsilon}(b, y_1) = w^{k,\epsilon}(x_1, x_2) = w^{k,\epsilon}(y_1, y_2) = \epsilon$ for $x_1, x_2 \in X$ and $y_1, y_2 \in Y$. All other utilities are $-1$.

For $\epsilon$ sufficiently small, the social welfare is approximately maximized if the only non-singleton coalition is $\{a, b\}$, yielding a social welfare of 2.

Consider a random arrival order $\sigma$. If the first pair of agents are both from $X \cup \{a\} \times Y$ or $Y \cup \{b\} \times X$, then $\mathcal{SW}(ALG, \sigma) \leq n^2 \epsilon$.

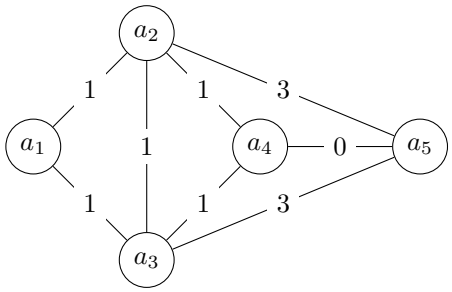

**Figure 4** Instance for online coalition formation algorithm with free dissolution. The two missing edges have a weight of $w(a_1, a_4) = w(a_1, a_5) = -12$.

In all other cases, i.e., for the other $2(k+1)^2$ possibilities for the first two agents, the social welfare is at most 2. Hence,

$$c_{ALG} \leq \inf_{k>0} \inf_{\epsilon>0} \frac{1}{2}\mathbb{E}_\sigma \left[\mathcal{SW}(ALG(G^{k,\epsilon}, \sigma))\right] \leq \inf_{k>0} \inf_{\epsilon>0} \frac{1}{2} \frac{4(k+1)^2 + 2(k+1)kn^2\epsilon}{(2k+2)(2k+1)}$$
$$= \inf_{k>0} \inf_{\epsilon>0} \frac{k+1}{2k+1} + \frac{kn^2}{2(2k+1)}\epsilon = \inf_{k>0} \frac{k+1}{2k+1} = \frac{1}{2}.$$

The infimum is attained in the limit for $k$ to infinity. ◀

▶ **Proposition 19.** *In the deterministic arrival model, no online coalition formation algorithm achieves a competitive ratio of more than $\frac{1}{3}$ under free dissolution.*

**Proof.** Let $ALG$ be any online coalition formation algorithm with free dissolution. Assume for contradiction that $ALG$ is $c$-competitive for some $c > \frac{1}{3}$.

Consider the ASHG given by $G = (N, w)$ depicted in Figure 4. The agents arrive in the order $(a_1, a_2, a_3, a_4, a_5)$. Since the algorithm is $c$-competitive for $c > \frac{1}{3}$, it has to maintain a coalition structure that has a social welfare of strictly more than $\frac{1}{3}$ of the current maximum social welfare. As a consequence the algorithm is forced to form the partitions $\{\{a_1, a_2\}\}, \{\{a_1, a_2, a_3\}\}$, and $\{\{a_1, a_2, a_3\}, \{a_4\}\}$ after $a_2$, $a_3$, and $a_4$ arrive, respectively. If the algorithm forms a different partition at any of these steps, then it achieves a social welfare of at most $\frac{1}{3}$ of the current maximum social welfare. Thus, the adversary can stop and then $c_{ALG} \leq \frac{1}{3}$, a contradiction.

Finally, agent $a_5$ arrives. In the ASHG given by $G$, the maximum social welfare of 18 is achieved by the partition $\pi^* = \{\{a_1\}, \{a_2, a_3, a_4, a_5\}\}$. However, the partition before $a_5$ arrives is $\{\{a_1, a_2, a_3\}, \{a_4\}\}$. It is easy to see that the highest social welfare that can be achieved with free dissolution is 6. This contradicts the assumption that $c_{ALG} > \frac{1}{3}$. ◀

A similar bound holds for the online matching setting. As we have already discussed in Section 5, our next result is a surprising contrast to the usual possibility of achieving a competitive ratio of 1/2 in many related settings [27, 20, 31]. Interestingly, once again, our construction only uses bipartite instances. Hence, the crucial property why we cannot achieve a better competitive ratio is that *all* agents arrive online.

▶ **Proposition 20.** *In the deterministic arrival model, no online matching algorithm achieves a competitive ratio of more than $\psi$ under free dissolution, where $\psi := \frac{2}{3+\sqrt{5}} \approx 0.382$.*

**Proof.** Let $ALG$ be any online coalition formation algorithm with free dissolution. Let $\psi = \frac{2}{3+\sqrt{5}}$ and assume for contradiction that $ALG$ is $c$-competitive for some $c > \psi$.

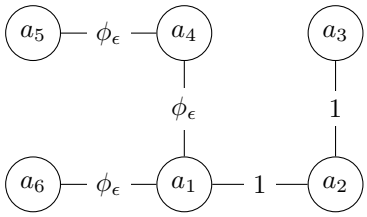

**Figure 5** Instance for online matching algorithm with free dissolution. We have $\phi_\epsilon = \frac{1+\sqrt{5}}{2} + \epsilon$ and the missing edges have weight 0. The figure depicts the case in the proof where $b = a_1$.

We provide an adversarial strategy along the game depicted in Figure 5. Since the algorithm is $c$-competitive, it has to maintain a coalition structure that has a social welfare of strictly more than a $c$-fraction of the current maximum social welfare.

First, two agents $a_1$ and $a_2$ arrive with $w(a_1, a_2) = 1$. Hence, $ALG$ has to form the edge $\{a_1, a_2\}$. Now, an agent $a_3$ arrives with $w(a_1, a_3) = 0$ and $w(a_2, a_3) = 1$. Then, $ALG$ only maintains a matching of positive weight if it leaves $a_3$ unmatched, or if it dissolves $\{a_1, a_2\}$ and forms $\{a_2, a_3\}$. Since the resulting situation is completely symmetric, we assume without loss of generality that $ALG$ leaves $a_3$ unmatched.

Let $\epsilon > 0$ and consider the constant $\phi_\epsilon := \frac{1+\sqrt{5}}{2} + \epsilon$.[5] Next, an agent $a_4$ arrives with $w(a_1, a_4) = \phi_\epsilon$ and $w(a_2, a_4) = w(a_3, a_4) = 0$. Now, $ALG$ only maintains a matching of positive weight if it leaves $a_4$ unmatched, or if it dissolves $\{a_1, a_2\}$ and forms $\{a_1, a_4\}$. In the former case, $ALG$ creates a matching of weight 1, while the maximum weight matching is $M_1 = \{\{a_1, a_4\}, \{a_2, a_3\}\}$ with $w(M_1) = 1 + \phi_\epsilon$. This implies that $c_{ALG} \leq \frac{1}{1+\phi_\epsilon} = \frac{1}{1+\frac{1+\sqrt{5}}{2}+\epsilon} < \frac{1}{1+\frac{1+\sqrt{5}}{2}} = \frac{2}{3+\sqrt{5}} = \psi < c$, a contradiction. Hence, $ALG$ has to dissolve $\{a_1, a_2\}$ and form $\{a_1, a_4\}$.

Next, an agent $a_5$ arrives with $w(a_4, a_5) = \phi_\epsilon$ and $w(a_1, a_5) = w(a_2, a_5) = w(a_3, a_5) = 0$. Similar to the situation after the arrival of the third agent, $ALG$ has to leave $a_4$ unmatched, or to dissolve $\{a_1, a_4\}$ and form $\{a_4, a_5\}$. Let $b \in \{a_1, a_5\}$, such that $ALG$ creates the matching $\{\{a_4, b\}\}$.

Now, an agent $a_6$ arrives with $w(b, a_6) = \phi_\epsilon$ and $w(x, a_6) = 0$ for all $x \in \{a_i \colon i \in [5]\} \setminus \{b\}$. Hence, $ALG$ will achieve a matching of weight at most $\phi_\epsilon$. For $b' \in \{a_1, a_4\}$ with $b' \neq b$, consider the matching $M_2 = \{\{a_2, a_3\}, \{b, a_6\}, \{b', a_4\}\}$. Then, $w(M_2) = 1 + 2\phi_\epsilon$. Hence,

$$c_{ALG} \leq \lim_{\epsilon \to 0} \frac{\phi_\epsilon}{1 + 2\phi_\epsilon} = \frac{\frac{1+\sqrt{5}}{2}}{1 + 1 + \sqrt{5}} = \frac{1 + \sqrt{5}}{2(2 + \sqrt{5})} = \frac{2}{3 + \sqrt{5}} = \psi < c.$$

This is our final contradiction, and hence such an algorithm cannot exist. ◀

Finally, we want to discuss general obstacles for finding classes of instances on which all algorithms perform poorly. Interestingly, the performance of $GDY$, $WGDY$, and $IWA$ is bounded by the same class of instances, namely the instances depicted in Figure 1. This raises the question whether this instance is a general worst-case instance. Our next result shows that this is not the case, unless there exists an algorithm that achieves a constant competitive ratio whenever the number of agents is known. Indeed, if there exists some highly valuable edge, then we can make use of an optimal stopping algorithm to achieve a good competitive ratio. To this end, we show how to apply the odds algorithm [11]. The details are discussed in the full version.

[5] To maintain games with rational weights, we can restrict attention to those $\epsilon$ where $\phi_\epsilon$ is rational.

▶ **Proposition 21.** *Let $I$ be a set of ASHGs and $\lambda \in (0, 1]$ a constant such that for each ASHG in $I$ given by $G = (N, w)$, the maximum weight edge $e_{\max}$ has a weight $w(e_{\max}) \geq \lambda \cdot \pi^*(G)$, where $\pi^*(G)$ maximizes social welfare. Then, there exists an online coalition formation algorithm $ALG$ with $c_{ALG} \in \Theta(1)$ on $I$ in the random arrival model with known $n$.*

## 7 Conclusion

We have considered two models of online coalition formation that both facilitate the existence of good algorithms compared to a deterministic arrival model. First, we have diminished the power of the adversary by considering a random arrival of agents. Second, we have increased the capabilities of an algorithm by allowing coalition dissolution. Both models allow for algorithms that achieve a competitive ratio of $\Theta(\frac{1}{n})$. Interestingly, this precisely gets rid of weight dependencies of the best algorithm in the deterministic model.

In both approaches, matchings play an important role. In the random arrival model, we present an algorithm whose output dominates the weight of a randomly created matching. Hence, matchings occur implicitly in the analysis of the algorithm. Under free dissolution, our coalition formation algorithm is itself a matching algorithm. The key challenge is to achieve a constant competitive ratio for online matching under the most general model, where all agents arrive online, and input graphs are weighted and possibly non-bipartite. The idea of our algorithm is to enhance the greedy algorithm by adding a threshold for the improvement in social welfare whenever dissolving a coalition (or edge).

Our work offers several promising directions for future research. First, while we have some indication that it is hard to obtain algorithms with a competitive ratio better than $\Theta(\frac{1}{n})$, we leave open the question whether there are algorithms obtaining a constant competitive ratio. Moreover, it would be interesting to find the optimal online matching algorithm for a fully online model with weighted non-bipartite input instances. Finally, there are many other classes of coalition formation games, such as fractional hedonic games [1] or ordinal classes of hedonic games. Considering a random arrival model or coalition dissolution for these games might lead to intriguing discoveries.

## Abstract

We study the problem of $k$-means clustering in the space of straight-line segments in $\mathbb{R}^2$ under the Hausdorff distance. For this problem, we give a $(1+\epsilon)$-approximation algorithm that, for an input of $n$ segments, for any fixed $k$, and with constant success probability, runs in time $O(n + \varepsilon^{-O(k)} + \varepsilon^{-O(k)} \cdot \log^{O(k)}(\varepsilon^{-1}))$. The algorithm has two main ingredients. Firstly, we express the $k$-means objective in our metric space as a sum of algebraic functions and use the optimization technique of Vigneron [40] to approximate its minimum. Secondly, we reduce the input size by computing a small size coreset using the sensitivity-based sampling framework by Feldman and Langberg [21, 22]. Our results can be extended to polylines of constant complexity with a running time of $O(n + \varepsilon^{-O(k)})$.

## 1 Introduction

The *$k$-means* clustering problem is as follows: Given a point set in a metric space, find a set of points, called *centers*, such that the sum of the squared distances from each input point to its closest center is minimized (over all possible choices of centers). It is a fundamental algorithmic problem with a ubiquitous role in data analysis in numerous application domains. As such, it has been studied extensively in geometric and general metric spaces, under various constraints on the objective and the choice of centers, and with a focus on complexity lower and upper bounds and the quality of the (approximate) solution [1, 2, 3, 8, 9, 11, 12, 13, 14, 15, 16, 17, 18, 21, 22, 25, 28, 31, 34].

In geometric settings, almost all previous work involves clustering points in some low- or high-dimensional Euclidean space. Notable exceptions include the work on $k$-means clustering for lines with point centers [32], and the works on *$k$-center* [5] and *$k$-median* [6, 10, 19, 37] clustering for polygonal curves with respect to the Fréchet distance; for $k$-center, one seeks to minimize the maximum distance to the closest center, while for $k$-median, one seeks to minimize just the sum of the distances (instead of the sum of the squares) to the closest centers. In this paper, we consider the $k$-means problem in the space of segments and of polylines of constant complexity in the plane with respect to the Hausdorff distance.

## 1.1 Formalization of the problem

Let $(\mathcal{S}, d_H)$ be the metric space of closed straight-line segments in $\mathbb{R}^2$, where $d_H$ is the Hausdorff distance. Given a set $S$ of $n$ weighted segments, where each $s \in S$ has an associated positive weight $w_s \in \mathbb{R}_{>0}$, and for any $k$ segments $s_1, \ldots, s_k$ playing the role of "centers" of the clusters, we define the objective function

$$\text{cost}_S(\{s_1, \ldots, s_k\}) \;:=\; \sum_{s \in S} w_s \cdot \min\{d_H^2(s_1, s), \ldots, d_H^2(s_k, s)\}$$

and define the $k$-means problem as the problem of finding a minimizer, i.e., a set of segments $S^* = \{s_1^*, \ldots, s_k^*\}$ that minimizes the above cost. Note here that quite often we deal with *unweighted* input segments. However, for technical reasons (made clear later in our discussion) in order to incorporate coresets in our algorithm, we have to consider the more general case of weighted segments. Also note that we study the *continuous* version of the problem, where the solution segments can come from anywhere in $(\mathcal{S}, d_H)$. This is harder than the so-called *discrete* version, where the solution segments have to be selected among the input segments.

We also consider the $k$-means problem for polylines, each with a bounded number of segments, under the Hausdorff distance, where the definition of the problem is analogous.

We remark here on an interesting connection to the older and closely related concept of the *Fréchet mean* [24]. This is a generalization of the classic notion of mean or average to any abstract metric space. For a finite point set $P$ in a metric space $(\mathcal{M}, d)$, a Fréchet mean is any minimizer of the so-called *Fréchet variance* $\text{cost}_P(q) \;:=\; \sum_{p \in P} d^2(q, p)$, taken over all $q \in \mathcal{M}$. For Euclidean spaces, the Fréchet mean is the usual arithmetic mean. (Other usual means can be recovered as Fréchet means by considering other distances.) The Fréchet mean is a well-studied concept in Statistics and in Riemannian spaces, where sometimes it is known as Karcher mean, see [38] for a general, comprehensive treatment. Computing a Fréchet-mean is precisely the 1-means clustering problem while the $k$-means is the generalization where the cost of each cluster is given by the functional defining the Fréchet mean.

## 1.2 Results

Our main result is a $(1+\varepsilon)$-approximation algorithm for the $k$-means problem in $(\mathcal{S}, d_H)$. The algorithm runs in $O\left(\left(n + \varepsilon^{-16k+4-\eta} + \varepsilon^{-12k-3}\log^{4k+1}(\varepsilon^{-1})\right)(\log(1/\delta))\right)$ time, for any fixed $k$, any $\eta > 0$, and with success probability at least $1-\delta$ (the constant hidden in the $O$-notation depends on $\eta$ and $k$).

There are two main ingredients in our algorithm. For the first one, described in Section 2, we express the $k$-means objective in the space $(\mathcal{S}, d_H)$ as a sum of algebraic functions of constant description complexity. This algebraic approach allows us to use the optimization technique of Vigneron [40] for approximating the minimum. This is, to the best of our knowledge, the first application of this technique in the context of clustering. While this technique is very expensive when applied directly to the entire set of input segments, we can decrease the running time dramatically by combining it with coresets. This is the second ingredient of our algorithm, described in Sections 3 and 4 namely, we use the sensitivity framework of Feldman and Langberg [21, 22] to compute a small coreset of the input and then we apply the former algebraic approach to the coreset.

We then extend this result to polylines of description complexity at most $\ell = O(1)$; this is given in Section 5. In this context, each input polyline and each solution polyline has at most $\ell$ segments, but we may put in the solution polylines that are not part of the input. The running time becomes $O\left(\left(n + \varepsilon^{-O(k\ell)}\right)\log(1/\delta)\right)$.

As a side-result, in the full version of this paper, we consider the Fréchet mean (or 1-means) problem in a concrete example with two perpendicular segments that intersect at their centers. We show that even in this simple setting the set of Fréchet means is surprisingly complex. The optimum is attained in a 3-dimensional subset of the 4-dimensional parameter space needed to model the space of candidate segments. This example also prompts to the benefit of looking into an algebraic approach for the general setting.

## 1.3 Related work

For general metric spaces, $k$-means (as well as $k$-median) clustering is APX-hard (when $k$ is part of the input) [15, 26]. Several polynomial-time, constant factor approximation algorithms are known for both the continuous and discrete versions of the problem [1, 8]. For the discrete version, there even exist algorithms that achieve factors arbitrarily close to the lower bound [26] and run in FPT-time with respect to $k$ and the approximation error $\varepsilon$ [17].

The Euclidean $k$-means, where the input is a set of points in $\mathbb{R}^d$, is NP-hard for $d = 2$ [34] and APX-hard when $d = \omega(\log n)$ [2]. The problem admits EPTASs with respect to $k$ and $\varepsilon$ [31] and with respect to $d$ and $\varepsilon$ [11, 13].

As for the Fréchet mean, it has been considered for persistence diagrams [36, 39], point sets on the unit circle [7], and in the space of graphs [23, 30, 35], to name a few metric spaces far from the Euclidean setting.

## 1.4 Definitions and notation

For each point $p \in \mathbb{R}^2$, we use $x(p)$ and $y(p)$ for its two coordinates. Thus, $p = (x(p), y(p))$. For any two points $p, q \in \mathbb{R}^2$, we denote by $pq$ the segment with endpoints $p$ and $q$, and by $|pq|$ the Euclidean distance between them: $|pq|^2 = (x(p) - x(q))^2 + (y(p) - y(q))^2$. For simplicity we assume that all input segments have positive length.

Recall that the Hausdorff distance $d_H(A, B)$ between any two compact subsets $A, B \subset \mathbb{R}^2$ is defined by

$$d_H(A, B) = \max\Big\{\max_{a\in A}\min_{b\in B}|ab|,\ \max_{b\in B}\min_{a\in A}|ab|\Big\}.$$

Define $\delta(a, B) = \min_{b\in B}|ab|$ for the (directed) distance from a point $a$ to a closed set $B$. It is well known and easy to see that for any two segments $s_1 = a_1b_1$ and $s_2 = a_2b_2$ in $\mathcal{S}$

$$d_H(s_1, s_2) = \max\{\delta(a_1, s_2), \delta(b_1, s_2), \delta(a_2, s_1), \delta(b_2, s_1)\}. \tag{1}$$

# 2 An algebraic approach to $k$-means in $(\mathcal{S}, d_H)$

We use the following adaptation of the definition of a *nice* family of functions by Vigneron [40, Section 2.1]. Let $\mathcal{F} = \{f_i : \mathbb{R}^d \to \mathbb{R} \mid i \in I\}$ be a finite family of functions, where $I$ is some index set. We say that $\mathcal{F}$ is *nice* if there exists a constant $\lambda > d > 0$ such that:

- each $f_i \in \mathcal{F}$ is nonnegative and bounded;
- for each $f_i \in \mathcal{F}$, there exists a semialgebraic set $\operatorname{supp}(f_i) \subseteq \mathbb{R}^d$ and an algebraic function $g_i$ of degree at most $\lambda$ with $f_i(x) = g_i(x)$ for $x \in \operatorname{supp}(f_i)$ and $f_i(x) = 0$ for $x \notin \operatorname{supp}(f_i)$;
- for each $f_i \in \mathcal{F}$, the semialgebraic set $\operatorname{supp}(f_i) \subseteq \mathbb{R}^d$ is a boolean combination of at most $\lambda$ subsets of $\mathbb{R}^d$, each of them defined by an polynomial inequality of degree at most $\lambda$;
- for each $f_i \in \mathcal{F}$, the restriction of $f_i$ to $\operatorname{supp}(f_i)$ is continuous.

Note that the definition allows that the sets $\mathrm{supp}(f_i)$ are open, closed or mixed. It also allows that $f_i$ is discontinuous in $\mathbb{R}^d \setminus \mathrm{supp}(f_i)$, which may include the boundary of $\mathrm{supp}(f_i)$ in some cases.

Our use of this concept will be through the following result for computing an approximation to the minimum of the function $\sum_i f_i$.

▶ **Theorem 1** (Adaptation of Theorem 3.4 in Vigneron [40]). *Assume that $\varepsilon \in (0,1)$. Let $\mathcal{F} = \{f_i : \mathbb{R}^d \to \mathbb{R} \mid i \in I\}$ be a nice family of $m$ functions. Define $g = \sum_{i\in I} f_i$ and assume that $\min_{x\in\mathbb{R}^d} g(x)$ exists. Then we can compute a point $x'_\varepsilon \in \mathbb{R}^d$ such that $g(x'_\varepsilon) \leq (1+\varepsilon)\min_{x\in\mathbb{R}^d} g(x)$ in time $O(m^{2d-2+\eta} + (m/\varepsilon)^{d+1}\log^{d+1}(m/\varepsilon))$ for any $\eta > 0$.*[1] *The constant hidden in the $O$-notation depends on $\eta$ and on $d$.*

Let us first consider the simpler case of two segments and how their Hausdorff distance is defined. We parameterize a segment $ab$ as the point $(x(a), y(a), x(b), y(b))$ in $\mathbb{R}^4$. Note that in this parameterization we have the artifact that the segments $ab$ and $ba$ give different points in $\mathbb{R}^4$.

Let $\ell_{ab}$ be the line supporting a segment $ab$. For a point $p$, the distance $\delta(p, ab)$ is given by one of the three terms $|pa|$, $|pb|$, or $\delta(p, \ell_{ab})$. For a point $q \in \mathbb{R}^2$ and a segment $ab$, let $\ell_\perp(q, ab)$ be the line perpendicular to $\ell_{ab}$ through $q$. The lines $\ell_\perp(a, ab)$ and $\ell_\perp(b, ab)$ partition the plane into three 2-dimensional faces (Figure 1) with closures

$$\begin{aligned}
\sigma(ab) &= \text{the closed slab between } \ell_\perp(a, ab) \text{ and } \ell_\perp(b, ab),\\
\tau(a, ab) &= \text{the closed halfspace defined by } \ell_\perp(a, ab) \text{ that does not contain } b,\\
\tau(b, ab) &= \text{the closed halfspace defined by } \ell_\perp(b, ab) \text{ that does not contain } a.
\end{aligned}$$

We then have

$$\delta(p, ab) \;=\; \begin{cases} |pa| & \text{if } p \in \tau(a, ab),\\ |pb| & \text{if } p \in \tau(b, ab),\\ \delta(p, \ell_{ab}) & \text{if } p \in \sigma(ab). \end{cases}$$

From Equation (1), we conclude that, for any two segments $ab$ and $a'b'$, the distance $d_H(ab, a'b')$ is given by one of the functions in the family

$$\mathcal{F}(ab, a'b') \;:=\; \big\{|aa'|,\ |ab'|,\ |ba'|,\ |bb'|,\ \delta(a, \ell_{a'b'}),\ \delta(b, \ell_{a'b'}),\ \delta(a', \ell_{ab}),\ \delta(b', \ell_{ab})\big\}.$$

We next argue that all the expressions involved are algebraic. A point $p$ lies on the line $\ell_\perp(a, ab)$ if and only the scalar product of the vectors $\vec{ap}$ and $\vec{ab}$ is zero. This is equivalent to $\big(x(p), y(p), x(a), y(a), x(b), y(b)\big)$ being a zero of the algebraic (actually polynomial) function

$$\psi(x, y, x_a, y_a, x_b, y_b) := (x - x_a)(x_b - x_a) + (y - y_a)(y_b - y_a).$$

The sign of this expression also tells us which side of $\ell_\perp(a, ab)$ the point $p$ lies on. Note that this function is linear in $x$ and $y$, while it is quadratic in $x_a$ and $y_a$. Symmetrically, the sign of $\psi\big(x(p), y(p), x(b), y(b), x(a), y(a)\big)$ tells us which side of $\ell_\perp(b, ab)$ point $p$ lies on.

In the following, we will treat the segment $a'b'$ as variable, identified with $\mathbb{R}^4$, while the segment $ab$ will be fixed. We will show that the space $\mathbb{R}^4$ can be decomposed into cells such that, within a cell, the distance $d_H(ab, a'b')$ is defined always by the same function from

[1] As noted in Vigneron [40], one needs to assume either the Real-RAM model of computation (which is standard in computational geometry) or a model where we can choose the precision of the intermediate computations, and then the computational complexity of the algorithm depends on the desired precision.

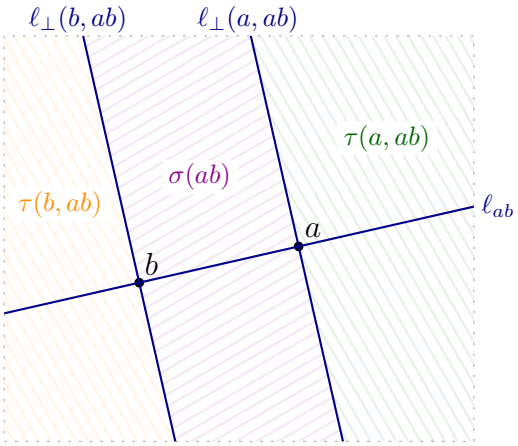

**Figure 1** The regions $\sigma(ab)$, $\tau(a, ab)$ and $\tau(b, ab)$.

$\mathcal{F}(ab, a'b')$. Such a decomposition is given by the eight algebraic hypersurfaces describing the conditions

$$a' \in \ell_\perp(a, ab),\ b' \in \ell_\perp(a, ab),\ a' \in \ell_\perp(b, ab),\ b' \in \ell_\perp(b, ab),$$
$$a \in \ell_\perp(a', a'b'),\ b \in \ell_\perp(a', a'b'),\ a \in \ell_\perp(b', a'b'),\ b \in \ell_\perp(b', a'b'),$$

together with a set of hypersurfaces, "bisectors", each defined by the set of points where two appropriate functions from $\mathcal{F}(ab, a'b')$ meet; this will become clear shortly. Finally, we note that each function in $\mathcal{F}(ab, a'b')$ is algebraic of constant degree; for example, elementary algebra shows that

$$\delta^2(a', \ell_{ab}) = \frac{\Big(\big(x(b) - x(a)\big)\big(y(a) - y(a')\big) - \big(x(a) - x(a')\big)\big(y(b) - y(a)\big)\Big)^2}{\big(x(a) - x(b)\big)^2 + \big(y(a) - y(b)\big)^2}.$$

We parameterize the space of (sequences of) $k$ segments $a_1b_1, \ldots, a_kb_k$ (the $k$ candidate cluster centers) by the point

$$\big(x(a_1), y(a_1), x(b_1), y(b_1), \ldots, x(a_k), y(a_k), x(b_k), y(b_k)\big) \in \mathbb{R}^{4k}.$$

Similarly, each $z \in \mathbb{R}^{4k}$ defines a $k$-tuple of segments with $s_1(z) = a_1(z)b_1(z), \ldots, s_k(z) = a_k(z)b_k(z)$ by taking the inverse of the parameterization.

▶ **Theorem 2.** *Let $k$ be a fixed, positive integer and let $s$ be a segment in the plane. In $O(1)$ time we can construct a nice family $\mathcal{F}_s = \{f : \mathbb{R}^{4k} \to \mathbb{R}\}$ of $O(1)$ functions such that*

$$\forall z \in \mathbb{R}^{4k} : \quad \sum_{f \in \mathcal{F}_s} f(z) = \min_{i \in [k]} d_H^2(s, s_i(z)).$$

**Proof.** Let $s = ab$ be the fixed segment. For each index $i \in [k]$, we consider the set $\Sigma(i)$ of 8 hypersurfaces in $\mathbb{R}^{4k}$, each of them given by one of the following conditions

$$a_i \in \ell_\perp(a, ab),\ b_i \in \ell_\perp(a, ab),\ a_i \in \ell_\perp(b, ab),\ b_i \in \ell_\perp(b, ab),$$
$$a \in \ell_\perp(a_i, a_ib_i),\ b \in \ell_\perp(a_i, a_ib_i),\ a \in \ell_\perp(b_i, a_ib_i),\ b \in \ell_\perp(b_i, a_ib_i).$$

Note that here $x(a)$, $y(a)$, $x(b)$ and $y(b)$ are input data while $x(a_i)$, $y(a_i)$, $x(b_i)$ and $y(b_i)$ are variables defining coordinates in the parameter space $\mathbb{R}^{4k}$.

Set $\Sigma := \cup_{i\in[k]}\Sigma(i)$ and let $\mathcal{A}_\Sigma$ be the arrangement in $\mathbb{R}^{4k}$ defined by $\Sigma$. From the foregoing discussion, we have the following property: for each cell $c$ of $\mathcal{A}_\Sigma$ and each index $i \in [k]$, the set of functions $\mathcal{F}(s, a_ib_i)$ stays the same and each of the distances $\delta(a, a_ib_i), \delta(b, a_ib_i), \delta(a_i, ab)$, and $\delta(b_i, ab)$, is given by the same function from $\mathcal{F}(s, a_ib_i)$. Thus, for all $z \in c$, the distance $d_H(s, s_i(z))$ is described by the maximum among the same four functions from $\mathcal{F}(s, a_ib_i)$.

In order to make clear that only the coordinates of $a_i$ and $b_i$ are relevant in the functions in $\mathcal{F}(s, a_ib_i)$, we change the notation to $\mathcal{G}_i$ and take each function $g$ of $\mathcal{G}_i$ to map from $\mathbb{R}^{4k}$ to $\mathbb{R}$. Formally, for each function $f \in \mathcal{F}(s, a_ib_i)$ we put into $\mathcal{G}_i$ the function $g(z) := f(ab, s_i(z))$.

We next define a set $\Lambda$ of algebraic hypersurfaces in $\mathbb{R}^{4k}$ playing the role of "bisectors". For each $i, j \in [k]$ with $i \le j$, we define $\Lambda(i, j)$ as the hypersurfaces given by equating each function of $\mathcal{G}_i$ to each function of $\mathcal{G}_j$. Note that each hypersurface is defined by a polynomial equality of degree at most 6. Since $\mathcal{G}_i$ has 8 functions for each $i \in [k]$, the set $\Lambda(i, j)$ has at most $8^2 = 64$ hypersurfaces (it is 32 for $\Lambda(i, i)$).

Set $\Lambda := \cup_{i\in[k]} \cup_{j\in[k],i\le j} \Lambda(i, j)$ and let $\mathcal{A}_\Lambda$ be the arrangement in $\mathbb{R}^{4k}$ induced by $\Lambda$. For each cell $c \in \mathcal{A}_\Lambda$ the sign of each function $g(z) - g'(z)$ remains constant for $g \in \mathcal{G}_i$, $g' \in \mathcal{G}_j$ and $z \in c$.

Finally, let $\mathcal{A}$ be the arrangement in $\mathbb{R}^{4k}$ induced by the hypersurfaces in $\Sigma \cup \Lambda$. Note that this is a refinement of $\mathcal{A}_\Sigma$ and $\mathcal{A}_\Lambda$, meaning that each cell of $\mathcal{A}$ is contained in a cell of $\mathcal{A}_\Sigma$ and a cell of $\mathcal{A}_\Lambda$.

Consider a cell $c \in \mathcal{A}$. Since $c$ is contained in a cell of $\mathcal{A}_\Sigma$, for each $i \in [k]$, each function in the set $\Delta_i(c) = \{\delta(a, s_i(z)), \delta(b, s_i(z)), \delta(a_i(z), ab)$, and $\delta(b_i(z), ab)\}$ is given by the same function of $\mathcal{G}_i$ for all $z \in c$. Moreover, since $c$ is contained in a cell of $\mathcal{A}_\Lambda$, for every two distinct functions $\delta, \delta' \in \Delta_i(c)$ the sign of $\delta - \delta'$ is constant for all $z \in c$. From these two facts we conclude that, for each $i \in [k]$, there is some function $g_{c,i}(z) \in \mathcal{G}_i$ such that $d_H(s, s_i(z)) = g_{c,i}(z)$ for all $z \in c$. This function can be easily determined in $O(1)$ time per cell by evaluating each function in $\Delta_i(c)$ at some arbitrary point in $c$.

Similarly, since $c$ is contained in a cell of $\mathcal{A}_\Lambda$, we have that for each distinct $i, j \in [k]$ the sign of

$$d_H(s, s_i(z)) - d_H(s, s_j(z)) \;=\; g_{c,i}(z) - g_{c,j}(z)$$

is constant for all $z \in c$. This implies that, for each cell $c \in \mathcal{A}$, there exists some index $\iota(c) \in [k]$ with the following property:

$$\forall j \in [k],\ z \in c: \quad d_H(s, s_{\iota(c)}(z)) \le d_H(s, s_j(z)).$$

In other words, the segment $s_{\iota(c)}(z)$ is a closest one to $s$ among $s_1(z), \ldots, s_k(z)$ and moreover the distance $d_H(s, s_{\iota(c)}(z))$ is given by a single function $g_{c,\iota(c)}$ from $\mathcal{G}_{\iota(c)}$. Thus, for each $z \in c$ it holds $\min_{i\in[k]} d_H(s, s_i(z)) = g_{c,\iota(c)}(z)$. As before, the function $g_{c,\iota(c)}(z)$ can be determined in $O(k)$ time per cell by evaluating each $d_H(s, s_i(z))$ at some arbitrary point in $c$.

For any set $A$, let $1_A$ be the function with $1_A(x) = 1$ if $x \in A$ and $1_A(x) = 0$ if $x \notin A$. For each cell $c \in \mathcal{A}$, define the function $h_c : \mathbb{R}^{4k} \to \mathbb{R}$ by $h_c(z) = 1_c(z) \cdot g^2_{c,\iota(c)}(z)$. Finally, set $\mathcal{F}_s := \{h_c \mid c \in \mathcal{A}\}$. We can then express the function

$$z \in \mathbb{R}^{4k} \mapsto \min_{i\in[k]} d^2_H(s, s_i(z))$$

as

$$\min_{i\in[k]} d^2_H(s, s_i(z)) \;=\; \sum_{c\in\mathcal{A}} 1_c(z)\, g^2_{c,\iota(c)}(z) \;=\; \sum_{c\in\mathcal{A}} h_c(z) \;=\; \sum_{h\in\mathcal{F}_s} h(z).$$

Since $\Sigma \cup \Lambda$ has $O(k^2) = O(1)$ hypersurfaces, the arrangement $\mathcal{A}$ has $O(O(k^2)^{4k}) = O(1)$ cells, each of them described by $O(k^2) = O(1)$ algebraic inequalities of constant description complexity and the family of functions $\mathcal{F}_s$ has the desired properties, where the constant $\lambda$ used to define the niceness is $O(k^{8k})$. Constructing $\mathcal{A}$ (i.e., with algebraic descriptions for each cell) takes $O(O(k^2)^{4k+1} 6^{O((4k)^4)}) = O(1)$ [4, Chapter 16]. The family $\mathcal{F}_s$ can be constructed in this time as well. ◀

We can now apply Theorem 1 combining all the functions $\mathcal{F}_s$ for $s \in S$ and compute a set of $k$ segments whose cost approximates that of an optimal set of segments.

▶ **Theorem 3.** *Let $k$ a fixed, positive integer and let $\varepsilon \in (0,1)$. Let $S$ be a family of $n$ segments in the plane with positive weights. We can compute $k$ segments $s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}$ in $\mathbb{R}^2$ such that*

$$\text{cost}_S(\{s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}\}) \;\leq\; (1+\varepsilon) \min\Big\{\text{cost}_S(\{s_1, \ldots, s_k\}) \mid s_1, \ldots, s_k \text{ segments}\Big\}$$

*in time $O(n^{8k-2+\eta} + (n/\varepsilon)^{4k+1} \log^{4k+1}(n/\varepsilon))$, for any $\eta > 0$. The constant hidden in the $O$-notation depends on $\eta$ and on $k$.*

**Proof.** For each segment $s \in S$ we compute the family $\mathcal{F}_s$ of Theorem 2. This takes $O(n) \cdot O(1) = O(n)$ time in total. To account for the weight $w_s > 0$ of the segment $s$, we replace in $\mathcal{F}_s$ each function $f \in \mathcal{F}_s$ with $w_s \cdot f$. Define $\mathcal{F} := \cup_{s \in S} \mathcal{F}_s$ and the function $g := \sum_{f \in \mathcal{F}} f$. Note that $\mathcal{F}$ is a family of $O(1) \cdot O(n) = O(n)$ nice functions and

$$\forall z \in \mathbb{R}^{4k} : \quad g(z) \;=\; \sum_{s \in S} \sum_{f \in \mathcal{F}_s} f(z) \;=\; \sum_{s \in S} w_s \cdot \min_{i \in [k]} d_H(s, s_i(z))^2 \;=\; \text{cost}_S(\{s_1(z), \ldots, s_k(z)\}).$$

We can then use Theorem 1 to find in time $O(|\mathcal{F}|^{2 \cdot 4k-2+\eta} + (|\mathcal{F}|/\varepsilon)^{4k+1} \log^{4k+1}(|\mathcal{F}|/\varepsilon))$, for any $\eta > 0$, a point $z'_\varepsilon \in \mathbb{R}^{4k}$ such that

$$g(z'_\varepsilon) \;\leq\; (1+\varepsilon) \min_{z \in \mathbb{R}^{4k}} \text{cost}_S(\{s_1(z), \ldots, s_k(z)\}).$$

The point $z'_\varepsilon \in \mathbb{R}^{4k}$ defines the segments $s_{1,\varepsilon} := s_1(z'_\varepsilon), \ldots, s_{k,\varepsilon} := s_k(z'_\varepsilon)$. As $s_1(z), \ldots, s_k(z)$ goes over all $k$ tuples of segments when $z$ iterates over all $\mathbb{R}^{4k}$, we have

$$\min_{z \in \mathbb{R}^{4k}} \text{cost}_S(\{s_1(z), \ldots, s_k(z)\}) \;=\; \min_{s_1, \ldots, s_k} \text{cost}_S(\{s_1, \ldots, s_k\}).$$

We conclude that

$$\text{cost}_S(\{s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}\} \;=\; g(z'_\varepsilon) \;\leq\; (1+\varepsilon) \min_{s_1, \ldots, s_k} \text{cost}_S(\{s_1, \ldots, s_k\}).$$ ◀

## 3 A coreset for $k$-means in $(\mathcal{S}, d_H)$

We use the sensitivity framework of Feldman and Langberg [21, 22]. Let $F$ be a finite set of functions, each of them mapping from $\mathbb{R}^d$ to $\mathbb{R}_{\geq 0}$. The *sensitivity* of $f \in F$ with respect to $F$ is

$$\sigma(f, F) \;:=\; \sup_{z \in \mathbb{R}^d} \frac{f(z)}{\sum_{g \in F} g(z)}.$$

We also consider the following range space

$$\text{range}_{\geq}(F) \;:=\; \Big(F, \big\{\{f \in F \mid f(z) \geq r\} \mid z \in \mathbb{R}^d,\; r \in [0, \infty)\big\}\Big).$$

We will use the following theorem from [22], which we state here adapted to our needs.

▶ **Theorem 4** (Adaptation of Theorem 31 in Feldman et al. [22]). *Let $F$ be a set of $n$ functions from $\mathbb{R}^d$ to $[0,\infty)$ with the following properties:*

- *For each choice of weights $w_f > 0$ for $f \in F$, the range space $\text{range}_{\geq}(\{w_f \cdot f \mid f \in F\})$ has bounded VC-dimension.*
- *For each $f \in F$ we are given a value $\tilde{\sigma}(f)$ such that*

$$\tilde{\sigma}(f) \geq \frac{1}{|F|} \quad \text{and} \quad \tilde{\sigma}(f) \geq \sigma(f,F).$$

*Set $\tilde{\Sigma}(F) := \sum_{f\in F} \tilde{\sigma}(f)$. Let $\delta, \varepsilon$ be real values in $(0,1/2)$. In time $O(|F|)$ we can compute a subset $C \subseteq F$ of*

$$O\left(\frac{\tilde{\Sigma}(F)}{\varepsilon^2}\left(\log \tilde{\Sigma}(F) + \log\frac{1}{\delta}\right)\right)$$

*weighted functions and weights $u_f > 0$ for each $f \in C$ such that, with probability at least $1-\delta$:*

$$\forall z \in \mathbb{R}^d: \quad \left|\sum_{f\in F} f(z) - \sum_{f\in C} u_f \cdot f(z)\right| \leq \varepsilon \sum_{f\in F} f(z).$$

For each input segment $s \in S$, we define the function $f_s : \mathbb{R}^{4k} \to \mathbb{R}_{\geq 0}$ with

$$f_s(z) := \min\{d_H^2(s,s_1(z)),\ldots,d_H^2(s,s_k(z))\} = \left(\min\{d_H(s,s_1(z)),\ldots,d_H(s,s_k(z))\}\right)^2.$$

Here, the segments $s_1(z),\ldots,s_k(z)$ are the same that were used in the parameterization before Theorem 2. Set $F = \{f_s \mid s \in S\}$. In order to use the above theorem, we need appropriate sensitivity upper bounds $\tilde{\sigma}(f_s)$ for each $f_s \in F$ and a bound on the total sensitivity $\tilde{\Sigma}(F)$. Let $\text{opt}_k(S)$ be the cost of an optimal set of segments for $k$-means, i.e., $\text{opt}_k(S) = \min_{s_1,\ldots,s_k} \text{cost}_S(\{s_1,\ldots,s_k\})$.

▶ **Lemma 5.** *Let $s'_1\ldots,s'_{k'}$ be a bicriteria $(\alpha,\beta)$-approximation for $k$-means, that is, $k' \leq \beta k$ and $\text{cost}_S(\{s'_1,\ldots,s'_{k'}\}) \leq \alpha \cdot \text{opt}_k(S)$, where $\alpha,\beta \geq 1$. For each $i \in [k']$, let $S'_i$ be the segments of $S$ closer to $s'_i$ than to any other segment $s'_j$, $j \in [k'] \setminus \{i\}$; ties are solved arbitrarily so that $S'_1,\ldots,S'_{k'}$ is a partition of $S$. For each segment $s \in S$, let $\iota(s) \in [k']$ be such that $s \in S'_{\iota(s)}$. Define for each $s \in S$ the value*

$$\tilde{\sigma}(f_s) := \frac{32\alpha}{|S'_{\iota(s)}|} + \frac{16\alpha \cdot d_H^2(s,s'_{\iota(s)})}{\sum_{s'\in S'_{\iota(s)}} d_H^2(s',s'_{\iota(s)})} = \frac{32\alpha}{|S'_{\iota(s)}|} + \frac{16\alpha \cdot d_H^2(s,s'_{\iota(s)})}{\text{cost}_{S'_{\iota(s)}}(s'_{\iota(s)})}.$$

*Then $\tilde{\sigma}(f_s) \geq \sigma(f_s,F)$ and $\tilde{\sigma}(f_s) \geq \frac{1}{|F|}$.*

(The proof of the above lemma is technical and can be found in the full version of this paper.)

Finally, note that for the sensitivities $\tilde{\sigma}(f_s)$ defined in Lemma 5, we have the total sensitivity

$$\begin{aligned}
\tilde{\Sigma}(F) &= \sum_{s\in S} \tilde{\sigma}(f_s) = \sum_{s\in S}\left(\frac{32\alpha}{|S'_{\iota(s)}|} + \frac{16\alpha \cdot d_H^2(s,s'_{\iota(s)})}{\text{cost}_{S'_{\iota(s)}}(s'_{\iota(s)})}\right) \\
&= \sum_{i\in[k']}\left(\sum_{s\in S'_i}\frac{32\alpha}{|S'_i|} + \sum_{s\in S'_i}\frac{16\alpha \cdot d_H^2(s,s'_i)}{\text{cost}_{S'_i}(s'_i)}\right) = \sum_{i\in[k']}(32\alpha+16\alpha) \\
&= O(\beta\alpha k).
\end{aligned}$$

Next, we bound the VC-dimension of the range space associated with the input segments.

▶ **Lemma 6.** *Assume that we have a weight $w_s > 0$ for each $s \in S$ and consider the set of functions $F_w = \{w_s \cdot f_s \mid s \in S\}$. The range space* $\text{range}_{\geq}(F_w)$ *has VC-dimension* $O(1)$.

**Proof.** First note that the range space $\text{range}_{\geq}(F_w)$ is equivalent to the range space $(S, R)$, where the ranges are

$$\begin{aligned} R &= \big\{\{s \in S \mid (w_s \cdot f_s)(z) \geq r\} \mid z \in \mathbb{R}^{4k},\ r \in [0,\infty)\big\} \\ &= \big\{\{s \in S \mid w_s \cdot \min\{d_H^2(s, s_1(z)) \ldots, d_H^2(s, s_k(z))\} \geq r\} \mid z \in \mathbb{R}^{4k},\ r \in [0,\infty)\big\} \\ &= \big\{\{s \in S \mid \forall i \in [k] :\ \sqrt{w_s} \cdot d_H(s, s_i(z)) \geq \sqrt{r}\} \mid z \in \mathbb{R}^{4k},\ r \in [0,\infty)\big\}. \end{aligned}$$

Setting $w'_s = \sqrt{w_s}$ for each $s \in S$ and $r' = \sqrt{r}$, we get that the ranges are

$$R = \big\{\{s \in S \mid \forall i \in [k] :\ w'_s \cdot d_H(s, s_i(z)) \geq r'\} \mid z \in \mathbb{R}^{4k},\ r' \in [0,\infty)\big\}.$$

For each segment $s \in S$, consider the hypersurface $\lambda_s$ in $\mathbb{R}^{4k+1}$ given by the graph of the function $z \in \mathbb{R}^{4k} \mapsto w'_s \cdot d_H(s, s_i(z))$. This is $\lambda_s \equiv \big\{\big(z, w'_s \cdot d_H(s, s_i(z))\big) \in \mathbb{R}^{4k} \times \mathbb{R} \mid z \in \mathbb{R}^{4k}\big\}$. As it has been discussed and used in Section 2 when defining the set $\mathcal{F}(ab, a'b')$, the hypersurface $\lambda_s$ is contained in the union of 8 *algebraic* hypersurfaces of bounded degree, each of them being the graph of a function. Let $\Lambda_s$ be the set of those 8 algebraic hypersurfaces for the segment $s \in S$.

Set $\Lambda := \cup_{s \in S} \Lambda_s$ and let $\mathcal{A}$ be the arrangement in $\mathbb{R}^{4k+1}$ induced by $\Lambda$. Each point $(z, r') \in \mathbb{R}^{4k} \times \mathbb{R}$ gives a range to $R$, and two points in the same cell of $\mathcal{A}$ give exactly the same range to $R$ because, for each $s \in S$, the surface $\lambda_s$ is above, below or on all the points of the cell. It may happen that points in different cells of $\mathcal{A}$ give the same range, as one still has to check the condition $\forall i \in [k] :\ w'_s \cdot d_H(s, s_i(z)) \geq r'$. In any case, the number of cells in $\mathcal{A}$ is an upper bound to the number of ranges in $R$, which is exactly the number of ranges in $\text{range}_{\geq}(F_w)$.

Classical results in Real Algebraic Geometry imply that $\mathcal{A}$ has $|\Lambda|^{O(k)}$ cells; see for example [4, Chapter 7] or [33, Section 6.2]. This implies that the so-called shattering dimension of $\text{range}_{\geq}(F_w)$ is $O(k) = O(1)$. (See for example Har-Peled [27, Chapter 5] for the concept and the next property.) Since a range space has bounded shattering dimension if and only if it has bounded VC-dimension this implies that the VC-dimension of $\text{range}_{\geq}(F_w)$ is $O(1)$. The approach we have used is essentially an application of the methodology discussed by Matoušek [33, Section 10.3].

Note that in this proof we have not tried to optimize the bound on the VC-dimension because we assume $k$ is constant. Perhaps a better bound follows from adapting the result of Driemel at al. [20] to the case of weights. ◀

We can now apply Theorem 4 on $F$ to obtain the coreset.

▶ **Theorem 7.** *Assume that $k$ is a fixed positive integer. Let $\delta, \varepsilon$ be real values in $(0, 1/2)$. For any set $S$ of $n$ unweighted segments in the plane, we can compute in time $O(n \log(1/\delta))$ a subset $T \subseteq S$ of*

$$O\left(\varepsilon^{-2} \log \frac{1}{\delta}\right)$$

*segments and weights $u_s > 0$ for each $s \in T$ such that, with probability at least $1 - \delta$:*

$$\forall \text{ segments } s_1, \ldots, s_k :\ |\text{cost}_S(\{s_1, \ldots, s_k\}) - \text{cost}_T(\{s_1, \ldots, s_k\})| \leq \varepsilon \cdot \text{cost}_S(\{s_1, \ldots, s_k\}).$$

**Proof.** We first compute a bicriteria $(\alpha = O(1), \beta = O(1))$-approximation for $k$-means on $S$ by using the algorithm of Chen [9, Theorem A.4], which in turn is a modification of the algorithm by Indyk [29]. For a probability of error $\delta' = \delta/2$, the algorithm takes $O(n \log(1/\delta')) =$

$O(n\log(1/\delta))$ time and succeeds with probability at least $1-\delta'$ in finding a set $s_1,\ldots,s_{k'}$ of $k'=O(k)$ segments such that $\mathrm{cost}_S(\{s_1,\ldots,s_{k'}\}) \le O(1)\cdot\mathrm{cost}_S(\{s_1,\ldots,s_k\})$. Note that the algorithm of Chen is for the discrete version of $k$-means, where the centers under consideration must be a subset of $S$. However, it is well-known that the triangle inequality implies that this is a factor 4 off for the continuous $k$-means version. This factor 4 is then subsumed by the $O(1)$ approximation factor.

Let $F=\{f_s \mid s\in S\}$. We use the bicriteria approximation for the sensitivity upper bounds $\tilde{\sigma}(f_s)$, for each $f_s\in F$, as defined in Lemma 5. As discussed after Lemma 5, the total sensitivity $\tilde{\Sigma}(F)$ is $O(1)$ and, by Lemma 6, the VC-dimension of $\mathrm{range}_{\ge}(F)$ is $O(1)$. The result then follows using Theorem 4 with probability of error $\delta'=\delta/2$. The size of the set $C\subseteq F$ selected by Theorem 4 is $O(\tilde{\Sigma}(F)\varepsilon^{-2}(\log\tilde{\Sigma}(F)+\log(1/\delta'))=O(\varepsilon^{-2}\log(1/\delta))$, and each function $f\in C$ has a given weight $u_f>0$. We set $T=\{s\in S\mid f_s\in C\}$ and, for each segment $s\in T$, we define the weight $w_s:=u_{f_s}$.

With probability at least $1-\delta'$ we have

$$\forall z\in\mathbb{R}^{4k}: \quad \left|\sum_{f\in F} f(z) - \sum_{f\in C} u_f\cdot f(z)\right| \le \varepsilon\sum_{f\in F} f(z),$$

which can be rewritten as

$$\forall z\in\mathbb{R}^{4k}: \quad \left|\sum_{s\in S} f_s(z) - \sum_{s\in T} w_s\cdot f_s(z)\right| \le \varepsilon\sum_{s\in S} f_s(z).$$

Since $f_s(z)=\min\{d_H^2(s,s_1(z)),\ldots,d_H^2(s,s_k(z))\}$ and $s_1(z),\ldots,s_k(z)$ goes over all $k$ tuples of candidate segments when $z$ iterates over all $\mathbb{R}^{4k}$, the last statement is equivalent to

$$\forall \text{ segments } s_1,\ldots,s_k: \ |\mathrm{cost}_S(\{s_1,\ldots,s_k\})-\mathrm{cost}_T(\{s_1,\ldots,s_k\})| \le \varepsilon\cdot\mathrm{cost}_S(\{s_1,\ldots,s_k\}).$$

The algorithm may fail only if the bicriteria approximation of Chen fails or if the application of Theorem 4 fails, and each of them separately fails with probability at most $\delta/2$. ◀

## 4 Putting it all together

Let $S$ be a set of $n$ segments in the plane without weights. We first set a fixed probability of error $\delta=1/2$, which means that the terms $\log(1/\delta)$ become $O(1)$. We keep using $\varepsilon\in(0,1/2)$ as a parameter.

We first compute a weighted coreset $T\subseteq S$ with $|T|=O(\varepsilon^{-2}))$ elements in $O(n)$ time as described in Theorem 7; for each segment $s\in T$ we have a weight $w_s>0$. If $S^*=\{s_1^*,\ldots,s_k^*\}$ is an optimal set of segments for $S$, then from Theorem 7 we have that $\mathrm{cost}_T(S^*)\le(1+\varepsilon)\cdot\mathrm{cost}_S(S^*)$ with probability at least $1/2$.

We apply the $(1+\varepsilon)$-approximation algorithm of Theorem 3 on $T$, taking into account the weights of the segments. As $|T|=O(\varepsilon^{-2})$ the algorithm runs in time

$$O\left((\varepsilon^{-2})^{8k-2+\eta}+(\varepsilon^{-3})^{4k+1}\log^{4k+1}(\varepsilon^{-3})\right) = O\left(\varepsilon^{-16k+4-\eta}+\varepsilon^{-12k-3}\log^{4k+1}(\varepsilon^{-1})\right)$$

for any $\eta>0$. When $k=1$, the second summand dominates. When $k\ge 2$ and $\varepsilon$ is below some constant $\varepsilon_0$, the first summand dominates.

Let $T^* = \{t_1^*, \ldots, t_k^*\}$ be an optimal set of segments for $k$-means of the weighted set $T$. The algorithm of Theorem 3 has then provided a set $S_\varepsilon = \{s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}\}$ of $k$ segments for which $\text{cost}_T(S_\varepsilon) \leq (1+\varepsilon) \cdot \text{cost}_T(T^*)$. Note that for the set $S_\varepsilon$ we also get from Theorem 7 that $(1-\varepsilon) \cdot \text{cost}_S(S_\varepsilon) \leq \text{cost}_T(S_\varepsilon)$. Since $\text{cost}_T(T^*) \leq \text{cost}_T(S^*)$, we conclude that

$$\begin{aligned}(1-\varepsilon) \cdot \text{cost}_S(S_\varepsilon) \;&\leq\; \text{cost}_T(S_\varepsilon) \;\leq\; (1+\varepsilon) \cdot \text{cost}_T(T^*) \;\leq\; (1+\varepsilon) \cdot \text{cost}_T(S^*) \\ &\leq\; (1+\varepsilon)^2 \cdot \text{cost}_S(S^*)\end{aligned}$$

or

$$\text{cost}_S(S_\varepsilon) \;\leq\; \frac{(1+\varepsilon)^2}{(1-\varepsilon)} \cdot \text{cost}_S(S^*) \;=\; (1+O(\varepsilon)) \cdot \text{cost}_S(S^*).$$

Setting $\varepsilon = \Theta(\varepsilon')$ appropriately, we get a $(1+\varepsilon')$-approximation for any desired $\varepsilon'$.

By independently repeating the algorithm $O(\log(1/\delta))$ times and taking the best among the solutions, we can reduce the probability of error to any given value $\delta$. Because $k = O(1)$, evaluating each candidate solution with respect to the whole set of segments takes $O(n)$ time. We summarize in the following.

▶ **Theorem 8.** *Let $k$ a fixed, positive integer and let $\delta, \varepsilon \in (0, 1/2)$. Let $S$ be a family of $n$ unweighted segments in the plane. We can compute $k$ segments $s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}$ in $\mathbb{R}^2$ such that, with probability at least $1-\delta$,*

$$\text{cost}_S(\{s_{1,\varepsilon}, \ldots, s_{k,\varepsilon}\}) \;\leq\; (1+\varepsilon) \min_{s_1,\ldots,s_k} \text{cost}_S(\{s_1, \ldots, s_k\})$$

*in time $O\left(\left(n + \varepsilon^{-16k+4-\eta} + \varepsilon^{-12k-3} \log^{4k+1}(\varepsilon^{-1})\right)(\log(1/\delta))\right)$, for any $\eta > 0$.*

For $k = 1$, the running time is $O\left(\left(n + \varepsilon^{-15} \log^5(\varepsilon^{-1})\right)(\log(1/\delta))\right)$, while for $k \geq 2$ the running time is $O\left(\left(n + \varepsilon^{-16k+4-\eta}\right)(\log(1/\delta))\right)$ for any $\eta > 0$.

## 5 Extension to polylines

In this section we briefly discuss the extension of our result to the case of polylines of bounded complexity. To reduce the number of parameters, we assume that each polyline has at most $\ell$ segments and we search the $k$-means among polylines that have at most $\ell$ segments. (We can also handle the case where the input and the target centers have different complexities.) To simplify the discussion, we assume that each input polyline has exactly $\ell$ segments. We further assume that $\ell = O(1)$.

We regard each polyline $\pi$ as the union of segments and note that the distance between the polyline $\pi$ with segments $s_1, \ldots, s_\ell$ and the polyline $\pi'$ with segments $s'_1, \ldots, s'_\ell$ is

$$d_H(\pi, \pi') \;=\; \max\left\{\max_{i\in[\ell]} \min_{j\in[\ell]} d_H(s_i, s'_j),\; \max_{j\in[\ell]} \min_{i\in[\ell]} d_H(s'_j, s_i)\right\}.$$

Therefore the distance between any two polylines is described as a max-min combination of $O(\ell^2) = O(1)$ values.

A polyline with $\ell$ segments is parameterized by $2(\ell+1)$ real values. Therefore, a sequence of $k$ polylines with $\ell$ segments each is parameterized by a point in $\mathbb{R}^\kappa$ for $\kappa = 2k(\ell+1)$. (Before, for segments, we had $\kappa = 4k$.) Each $z \in \mathbb{R}^\kappa$ defines $k$ polylines $\pi_1(z), \ldots, \pi_k(z)$, each consisting of $\ell$ segments.

Let $\Pi$ be a set of polylines in the plane, each with $\ell$ segments. For each $\pi \in \Pi$, we define the function $f_\pi : \mathbb{R}^\kappa \to \mathbb{R}$ by

$$f_\pi(z) := \min\{d_H^2(\pi, \pi_1(z)), \ldots, d_H^2(\pi, \pi_k(z))\} = \big(\min\{d_H(\pi, \pi_1(z)), \ldots, d_H(\pi, \pi_k(z))\}\big)^2$$

and then define the set of functions $F = \{f_\pi \mid \pi \in \Pi\}$.

We first note that the VC-dimension of the range space $\text{range}_{\geq}(F_w)$ is $O(1)$, where $F_w$ is obtained from $F$ by scaling each $f_\pi \in F$ with a different scalar $w_\pi > 0$. The proof of Lemma 6 readily applies to this case as it only relies on the description complexity of $d_H(\pi, \pi_i(z))$ being constant, and each patch of the description being an algebraic function.

Next we note that we can use the bicriteria $(\alpha = O(1), \beta = O(1))$-approximation for $k$-means of Chen, as we did in the proof of Theorem 7. Indeed, this algorithm only requires that we can compute the distance between any two input objects, which we can do in constant time. The rest of the proof of Theorem 7 goes unchanged because Lemma 5 and Theorem 4 do not make any assumption related to segments beyond the VC-dimension. We thus obtain with probability at least $1/2$ a coreset $\tilde{\Pi}$ of $O(\varepsilon^{-2})$ input polylines, each of them with a positive weight $w_\pi$.

It remains to adapt Theorem 3 to the setting of polylines. As we have done in Theorem 2, for each polyline $\pi$ we can compute a family $\mathcal{F}_\pi$ of nice functions such that

$$f_\pi(z) = \sum_{f \in \mathcal{F}_\pi} f(z) = \min_{i \in [k]} d_H^2(\pi, \pi_i(z)) \quad \text{for all } z \in \mathbb{R}^\kappa.$$

Indeed, as we did in the proof of Theorem 2, we can break the parameter space $\mathbb{R}^\kappa$ using $O(k^2\ell^2) = O(1)$ algebraic hypersurfaces into $O(1)$ cells such that, within each cell, the max-max-min expression defining $d_H(\pi, \pi_i(z))$ is always the same algebraic expression. We can then apply Theorem 1 to the family of nice functions $\cup_{\pi \in \tilde{\Pi}} \mathcal{F}_\pi$, where each function in $\mathcal{F}_\pi$ has been scales with the corresponding weight $w_\pi$. Thus, we have an application of Theorem 1 in $\mathbb{R}^\kappa$ for $O(\varepsilon^{-2})$ functions. The running time is, for any $\eta > 0$,

$$\begin{aligned} O((\varepsilon^{-2})^{2\kappa-2+\eta} + (\varepsilon^{-3})^{\kappa+1} \log^{\kappa+1}(\varepsilon^{-3})) &= O(\varepsilon^{-4\kappa+4+\eta} + \varepsilon^{-3\kappa-3} \log^{\kappa+1}(\varepsilon^{-1})) \\ &= O(\varepsilon^{-O(k\ell)}). \end{aligned}$$

Like before, we can make $O(\log(1/\delta))$ independent repetitions to decrease the probability of failure to $\delta$. We summarize below.

▶ **Theorem 9.** *Let $k$ and $\ell$ be fixed, positive integers and let $\delta, \varepsilon \in (0, 1/2)$ be parameters. Let $\Pi$ be a family of $n$ unweighted polylines in the plane, each with at most $\ell$ segments. We can compute $k$ polylines $\pi_{1,\varepsilon}, \ldots, \pi_{k,\varepsilon}$ in $\mathbb{R}^2$, each with at most $\ell$ segments, such that, with probability at least $1 - \delta$,*

$$\text{cost}_\Pi(\{\pi_{1,\varepsilon}, \ldots, \pi_{k,\varepsilon}\}) \leq (1+\varepsilon) \min_{\pi_1, \ldots, \pi_k} \text{cost}_\Pi(\{\pi_1, \ldots, \pi_k\})$$

*in time $O\left(\left(n + \varepsilon^{-O(k\ell)}\right)(\log(1/\delta))\right)$.*

## Abstract

Effective resistances are ubiquitous in graph algorithms and network analysis. For an undirected graph $G$, its effective resistance $R_G(s,t)$ between two vertices $s$ and $t$ is defined as the equivalent resistance between $s$ and $t$ if $G$ is thought of as an electrical network with unit resistance on each edge. If we use $L_G$ to denote the Laplacian matrix of $G$ and $L_G^\dagger$ to denote its pseudo-inverse, we have $R_G(s,t) = (\mathbf{1}_s - \mathbf{1}_t)^\top L^\dagger (\mathbf{1}_s - \mathbf{1}_t)$ such that classical Laplacian solvers [46] provide almost-linear time algorithms to approximate $R_G(s,t)$.

In this work, we study *sublinear* time algorithms to approximate the effective resistance of an *adjacent pair* $s$ and $t$. We consider the classical adjacency list model [41] for local algorithms. While recent works [4, 40, 31] have provided sublinear time algorithms for *expander graphs*, we prove several lower bounds for *general graphs* of $n$ vertices and $m$ edges:

1. It needs $\Omega(n)$ queries to obtain 1.01-approximations of the effective resistance of an adjacent pair $s$ and $t$, even for graphs of degree at most 3 except $s$ and $t$.
2. For graphs of degree at most $d$ and any parameter $\ell$, it needs $\Omega(m/\ell)$ queries to obtain $c\cdot\min\{d,\ell\}$-approximations where $c > 0$ is a universal constant.

Moreover, we supplement the first lower bound by providing a sublinear time $(1+\epsilon)$-approximation algorithm for graphs of *degree 2* except the pair $s$ and $t$.

One of our technical ingredients is to bound the expansion of a graph in terms of the smallest non-trivial eigenvalue of its Laplacian matrix after removing edges. We discover a new lower bound on the eigenvalues of perturbed graphs (resp. perturbed matrices) by incorporating the effective resistance of the removed edge (resp. the leverage scores of the removed rows), which may be of independent interest.

# 1 Introduction

Effective resistance of a graph is a fundamental quantity to measure the similarity between two vertices. Given an unweighted graph $G$ and two vertices $s$ and $t$, the $s$-$t$ effective resistance, denoted by $R_G(s,t)$, is defined as the electrical distance between $s$ and $t$ when $G$ represents an electrical circuit with each edge $e$ a resistor with electrical resistance 1. Together with the related concept electrical flows, effective resistances have played important roles in advancing the development of graph algorithms. They have been utilized for computing and approximating maximum flow [10, 34], generating random spanning tree [35, 43], designing faster algorithms for multicommodity flow [28], and graph sparsification [45, 15]. In addition, effective resistances have also found applications in machine learning and social network analysis. For example, it has been used for graph convolutional networks [2], for measuring the similarity of vertices in social networks [30, 40] and measuring robustness of networks [19].

Let $L_G$ denote the Laplacian matrix of $G$ and $L_G^\dagger$ denote its pseudo-inverse. Then the $s$-$t$ effective resistance admits an elegant expression $R_G(s,t) = (\mathbf{1}_s - \mathbf{1}_t)^\top \cdot L_G^\dagger \cdot (\mathbf{1}_s - \mathbf{1}_t)$ where $\mathbf{1}_u \in \mathbb{R}^n$ denotes the indicator vector at vertex $u$. Hence classical Laplacian solvers [46, 13] provide *almost-linear* time algorithms to approximate $R_G(s,t)$.

It has recently received increasing interest of designing *sublinear-time* (or local) algorithms for estimating effective resistances. In this setting, we are given query access to a graph and any specified vertex pair $s$ and $t$, our goal is to find a good approximation of the $s$-$t$ effective resistance, by making as few queries as possible. Such algorithms are particularly motivated by the ubiquitousness of modern massive graphs, on which traditional polynomial-time algorithms are no longer feasible. Andoni et al. [4] gave an algorithm that $(1+\epsilon)$-approximates $R_G(s,t)$ in $O(\frac{1}{\epsilon^2}\mathsf{poly}\log\frac{1}{\epsilon})$ time for $d$-regular expander graphs. Peng et al. [40] then generalized this algorithm to unbounded-degree expander graphs with an additive error $\epsilon$ and similar query complexity. Li and Sachdeva [31] then gave one algorithm that $(1+\epsilon)$-approximates the $s$-$t$ effective resistance in $O(\frac{\mathsf{poly}(\log n)}{\epsilon})$ time on expander graphs (which is implicit in the proof of Theorem 3.1 in [31]). However, the question of whether it is possible to obtain sublinear-time estimation for effective resistances on non-expander or general graphs remains largely open.

Besides the aforementioned sublinear-time algorithms for effective resistances on expander graphs, one can observe an $\Omega(n)$-query lower bound for approximating the effective resistance of *non-adjacent* pair $s$ and $t$. Indeed, consider an $n$-vertex path, on which the $s$-$t$ effective resistance is equivalent to the $s$-$t$ shortest path length. Intuitively, for the latter problem, any algorithm with a constant approximation ratio needs to well estimate the number of edges on the path from $s$ to $t$, which takes $\Omega(n)$ queries in the worst case.

In this paper, we consider the power and limitations of sublinear-time algorithms for $s$-$t$ effective resistance such that $s$ and $t$ are *adjacent*, i.e., $(s,t) \in E(G)$. The adjacency case is already interesting in many applications. For example, in the seminal work on graph sparsification [45], it suffices to have good estimations of the effective resistances between the endpoints of edges, i.e., the adjacent pairs. It is also known that the effective resistance multiplied by the edge weight is equal to the probability that the edge belongs to a randomly generated spanning tree (see e.g. [18]), which has found applications in random spanning tree generation.

On the other hand, for an adjacency pair, the lower bound from the previous discussion does not hold any more, as for any pair $s$ and $t$ such that $(s,t) \in E$, their effective resistance is exactly 1 on a path. A priori, it could be true that a $(1+\epsilon)$-approximation of the $s$-$t$ effective resistance for an adjacent pair can be found in sublinear time.

Now we state our results on sublinear-time algorithms for estimating the effective resistances. We will focus on unit-weighted graphs and the adjacency list model [41], in which the local algorithms can perform degree, neighbor queries and also sample vertices uniformly at random.

**Strong Lower Bounds.** First, we provide a strong lower bound for graphs of degree at most 3 except the given pair $s$ and $t$. For convenience, for a parameter $C > 1$, we say that value $a$ is a $C$-approximation of value $b$ if $a \in [b/C, b]$. In the following, we always assume that the given pair $s$ and $t$ are *adjacent*, i.e., $(s,t) \in E$.

▶ **Theorem 1.** *There are infinitely many $n$ and graphs of $n$ vertices such that any local algorithm with success probability 0.6 and approximation ratio 1.01 on $R_G(s,t)$ needs $\Omega(n)$ queries. This holds even for graphs whose vertices are of degree at most 3 except the adjacent pair $s$ and $t$.*

Next, observe that the trivial algorithm outputting 1 directly gives an approximation factor $\frac{2}{1/d(s)+1/d(t)}$ where $d(s)$ and $d(t)$ are the degrees of the adjacent pair $s$ and $t$. This is because $R_G(s,t) \geq \frac{1/d(s)+1/d(t)}{2}$ from the spectral graph theory [33]. This factor equals $d$ if the graph is regular and is between $\min\{d(s), d(t)\}$ and $2\min\{d(s), d(t)\}$ in general. If we consider large approximation factors instead of the $(1+\epsilon)$-approximation shown in Theorem 1, a natural question is can we design sublinear time algorithms that improve upon this trivial approximation ratio $\frac{2}{1/d(s)+1/d(t)}$? Our next theorem shows that it would take $\Omega(n)$ queries to improve this ratio significantly.

▶ **Theorem 2.** *There exist a universal constant $c > 0$ and infinitely many $n$ such that given any $d \geq 4$ and any $\ell \geq 4$, for graphs of $n$ vertices and degree at most $d$, any local algorithm to approximate $R_G(s,t)$ with success probability 0.6 and approximation ratio $1 + c \cdot \min\{d, \ell\}$ needs $\Omega(nd/\ell)$ queries.*

If we set $\ell = d$, this indicates that it takes $\Omega(n)$ queries to obtain an approximation ratio $o(d)$ for $d$-regular graphs since $m = nd/2$. In contrast, the corresponding trivial approximation ratio for adjacent pairs on $d$-regular graphs is $d$. If we fix $\ell$ and consider graphs with sufficiently large degree $d > \ell$, Theorem 2 also gives a trade-off between the query complexity and approximation ratio. Next we remark that we could incorporate additive errors into the lower bounds of Theorem 1 and Theorem 2. This is because these two bounds consider the task of distinguishing between graphs with $R_G(s,t) = 1$ and graphs with $R_G(s,t) < 1$.

On the other hand, for graphs of degree at most 2 except the given pair $s$ and $t$, we provide a $(1+\epsilon)$-approximation algorithm of sublinear time in Section 5.

**Total effective resistance.** Another important measure of a network is the total effective resistance, which is defined as $R_{tot}(G) = \sum_{u<v} R_G(u,v)$ and is also known as the Kirchhoff index of a graph (see e.g. [20, 19, 30] for numerous applications of $R_{tot}(G)$). Because of the elegant expression $R_{tot}(G) = n \cdot \sum_{i>1} \frac{1}{\lambda_i(L_G)}$ where the sum is over all non-trivial eigenvalues of the Laplacian of $G$, one may wonder whether there is a simpler approximation algorithm for the total effective resistance or not. However, we show that even for simple graphs with degree 2, any algorithm with approximation ratio $< 2$ needs $\Omega(n)$ queries.

▶ **Theorem 3.** *For any $n$ and any $\ell > 1$, any local algorithm for computing the total effective resistance with success probability 0.6 and approximation ratio $\ell$ needs $\Omega(n)$ queries. In particular, this holds even for $\ell = 2 - o(1)$ and graphs of degree at most 2.*

**Eigenvalues of graph perturbation.** One technical ingredient in the proof of Theorem 1 is to show that an expander graph is still an expander after removing one edge. A natural approach would be to compare the smallest non-trivial eigenvalue of the Laplacian of the perturbed graph to the corresponding one of the original graph. Since deleting one edge in $G$ does not change its edge expansion too much, one may use Cheeger's inequality (with other properties) to lower bound the new eigenvalue in terms of the original one. However, our key technical lemma provides a more direct bound by incorporating the effective resistance of the moved edge.

▶ **Lemma 4.** *Given a graph $G = (V, E)$ with $n$ vertices, let $\lambda_1(G) \leq \cdots \leq \lambda_n(G)$ be the eigenvalues of its Laplacian $L_G$. Given any edge $(u, v)$ in $G$, let $G' = \big(V, E \setminus \{(u, v)\}\big)$ be the graph obtained from $G$ by removing the edge $(u, v)$ and let $\lambda_1(G') \leq \ldots \leq \lambda_n(G')$ be the eigenvalues of its Laplacian $L_{G'}$. Then it holds that*

$$\forall i \in [n], \lambda_i(G') \geq \big(1 - R_G(u, v)\big) \cdot \lambda_i(G).$$

This lemma shows that after removing edge $(u, v)$ in an expander $G$ with $R_G(u, v)$ strictly less than 1, $G$ is still an expander. We remark that this requirement on the effective resistance $R_G(u, v)$ is necessary. Because there exists an expander graph $G$ with edges of effective resistance 1 and vertices of degree 1 (see Claim 10 in Section 3), one can not delete an arbitrary edge in $G$ while maintaining the expansion property.

We could consider the general problem of bounding the eigenvalues of a matrix after removing a few rows. Specifically, given a matrix $A \in \mathbb{R}^{m \times n}$ and $k$ distinct rows $\mathbf{a}_{\ell_1}, \ldots, \mathbf{a}_{\ell_k}$, the question is to compare all eigenvalues of $(A')^\top A'$, where $A' \in \mathbb{R}^{(m-k) \times n}$ removes row $\mathbf{a}_{\ell_1}, \ldots, \mathbf{a}_{\ell_k}$ from $A$, to the eigenvalues of $A^\top A$. Since $(A')^\top A' \preceq A^\top A$, each eigenvalue $\lambda_i\big((A')^\top A'\big) \leq \lambda_i\big(A^\top A\big)$. We give a lower bound for every $\lambda_i\big((A')^\top A'\big)$ by incorporating the leverage scores of those rows.

The (statistical) leverage scores of a matrix $A \in \mathbb{R}^{m \times n}$ provide a nonuniform importance sampling distribution over the $m$ rows of $A$, which plays a crucial role in randomized matrix algorithms (see [47] for a list of applications). For each row $\mathbf{a}_i$ in $A$, its leverage score $\tau_i$ is defined to be $\mathbf{a}_i^\top \cdot (A^\top A)^\dagger \cdot \mathbf{a}_i$. In fact, the leverage scores of a matrix are the analogues of the effective resistances of a graph [16]. More formally, let $B \in \mathbb{R}^{m \times n}$ denote the edge-incidence matrix of a graph $G$ as follows: Each edge $(u, v)$ of $G$ gives a row $\mathbf{1}_u - \mathbf{1}_v$ in $B$. Furthermore, the Laplacian matrix $L$ of $G$ equals $B^\top B$. If a row of $B$ corresponds to edge $(u, v)$, its leverage score $(\mathbf{1}_u - \mathbf{1}_v)^\top \cdot (B^\top B)^\dagger \cdot (\mathbf{1}_u - \mathbf{1}_v) = (\mathbf{1}_u - \mathbf{1}_v)^\top \cdot L^\dagger \cdot (\mathbf{1}_u - \mathbf{1}_v)$ turns out to be the effective resistance of $(u, v)$ in $G$.

Now we state Lemma 5 for the general problem. So Lemma 4 is a direct corollary of Lemma 5 by setting $A$ to the incidence matrix of $G$ as discussed above.

▶ **Lemma 5.** *Given a matrix $A \in \mathbb{R}^{m \times n}$, let $\lambda_1 \leq \cdots \leq \lambda_n$ be the eigenvalues of $A^\top A$. Moreover, for each $\ell \in [m]$, let $\mathbf{a}_\ell$ be row $\ell$ of $A$ and $\tau_\ell = \mathbf{a}_\ell^\top (A^\top A)^\dagger \mathbf{a}_\ell$ be its leverage score.*

*For any $k$ distinct indices $\ell_1, \ldots, \ell_k \in [m]$, let $A' \in \mathbb{R}^{(m-k) \times n}$ be the matrix obtained from $A$ by removing the corresponding $k$ rows $\mathbf{a}_{\ell_1}, \ldots, \mathbf{a}_{\ell_k}$; and let $\lambda'_1 \leq \cdots \leq \lambda'_n$ be the eigenvalues of $(A')^\top A'$. It holds that*

$$\forall i \in [n], \lambda'_i \in \big[(1 - \tau_{\ell_1} - \tau_{\ell_2} - \cdots - \tau_{\ell_k}) \cdot \lambda_i, \lambda_i\big].$$

## 1.1 Related Work

Previous research has studied the problem of how to quickly compute and approximate the effective resistances in the regime of polynomial-time algorithms, as such algorithms can be used as a crucial subroutine for other graph algorithms. For example, for any two vertices $s$

and $t$ in a $n$-vertex $m$-edge graph, one can $(1+\epsilon)$-approximate the $s$-$t$ effective resistance in $\tilde{O}(m+n\epsilon^{-2})$ [18] and $\tilde{O}(m\log(1/\epsilon))$ [13] time, respectively. To $(1\pm\epsilon)$-approximate the effective resistances between $s$ given pairs, Chu et al. [11] provided an algorithm in time $O(m^{1+o(1)}+(n+s)n^{o(1)}\cdot\epsilon^{-1.5})$. There are also algorithms that find $(1+\epsilon)$-approximations to the effective resistance between every pair of vertices in $\tilde{O}(n^2/\epsilon)$ time [27]. In order to exactly compute the $s$-$t$ or all-pairs effective resistance, the current fastest algorithms run in times $O(n^\omega)$ (by using the fastest matrix inversion algorithm [8, 24]), where $\omega<2.373$ is the matrix multiplication exponent [3]. Faster algorithms are known for planar graphs by using the nested dissection method [32].

There exists a line of works on how to efficiently maintain the effective resistances *dynamically* [42, 1, 21, 22, 17, 9], i.e., if the graph undergoes edge insertions and/or deletions, and the goal is to support the update operations and query for the effective resistances as quickly as possible, rather than having to recompute it from scratch each time.

For the total effective resistance, Ghosh et al. [20] studied algorithms for allocating edge weights on a given graph in order to minimize the total effective resistance. Li and Zhang [30] used Kirchhoff index (i.e., total effective resistance) as the measure of edge centrality in weighted networks and gave efficient algorithms for the measure.

Matrix perturbation considers the eigenvalues (singular values) of $A$ after adding a matrix $E$ of the same order. Various bounds on the error of matrix perturbation, such as absolute errors and relative errors, has been studied. We refer to the survey [26] and the reference therein for a complete overview. Even though Lemma 5 is an instantiation of Theorem 2.8 in [26] with (statistical) leverage scores, we provide two simpler proofs in this work which are more intuitive. Also, different perturbation bounds in terms of the leverage scores were provided in [25, 23].

Leverage scores, analogue to effective resistances of graphs, have wide applications in randomized matrix algorithms and large-scale data algorithms. The most notable property is that sampling the rows of a matrix $A$ via its leverage scores gives an efficient construction of the subspace embedding of $A$ [45]. This fact is extremely useful in designing ultra-efficient algorithms for linear regression and low rank approximations [12]. We refer to the survey [47] for a list of applications. Since bounding eigenvalues are sufficient for $\ell_2$-subspace embeddings, there is a line of research on the connection between eigenvalues and leverage scores, such as spectral sparsifications [45, 5].

Sublinear-time algorithms for the related graph problems has also been investigated. For example, Lee [29] gave an algorithm for producing a probabilistic $(\epsilon,\delta)$-spectral sparsifier with $O(n\log n/\epsilon^2)$ edges in $\tilde{O}(n/\epsilon^2\delta)$ time for unweighted undirected graph. Note that its running time is sublinear if the number of edges in the graph is large enough. For spectral approximations in sublinear time, various approximation guarantees have been studied in [14, 39, 7].

**Organization.** In Section 2, we provide the basic definitions and notations of this work. Next we discuss about eigenvalues of perturbed matrices and graphs in Section 3. Then we prove the lower bounds of Theorem 1 in Section 4. Finally, we discuss the approximation algorithm for degree-2 graphs in Section 5. Due to the space constraint, we leave the proof of Theorem 2 and 3 to the full version of this paper in arXiv.

## 2 Preliminaries

For any integer $k\geq 1$, let $[k]:=\{1,\cdots,k\}$. We use $a=b\pm c$ to denote $a\in[b-c,b+c]$ and $\mathbf{1}$ to denote the all 1 vector.

**Basic definitions from graph theory.** In this work, we only consider undirected graphs with unit weights on each edge. Given an undirected graph $G = (V, E)$ with $n := |V|$ vertices and $m := |E|$ edges, let $A_G \in \mathbb{R}^{n\times n}$ denote the adjacency matrix of $G$ and $D_G \in \mathbb{R}^{n\times n}$ denote its degree diagonal matrix. We use $L_G \in \mathbb{R}^{n\times n}$ to denote its Laplacian, i.e., $L_G = D_G - A_G$. Also, we use $V(G)$ and $E(G)$ to denote the vertex set and edge set of a graph $G$.

In this work, we use $\tilde{L}_G$ to denote the normalized Laplacian of $G$, i.e., $\tilde{L}_G := D_G^{-1/2} \cdot L_G \cdot D_G^{-1/2}$. When the graph is clear, we hide the notation $G$. Also, we use $V(G)$ and $E(G)$ to denote the vertex and edge set of $G$. Moreover, we use $d$ to denote the maximum degree of $G$. For a vertex $u$, let $d(u)$ denote its degree in $G$ and $\mathbf{1}_u \in \mathbb{R}^n$ denote the indicator vector of $u$, i.e., $\mathbf{1}_u(v) = 1$ if $v = u$ and 0 otherwise.

Now we define the adjacency list model for sublinear time graph algorithms [41]. There are three types of operations in constant time:

1. degree query: the algorithm queries the degree of a fixed vertex $v \in V$;
2. neighbor query: the algorithm queries the $i$-th neighbor of vertex $v$ given $v$ and $i$;
3. uniform sampling: the algorithm receives a random vertex in $V$.

**Basic definitions about matrices and expander graphs.** We use $\psi$, $\phi$, and bold letter $\mathbf{a}$ to denote vectors and $\|\cdot\|$ to denote their $L_2$ (Euclidean) norms. For a vector $\mathbf{a} \in \mathbb{R}^V$ and a subset $U \subset V$, let $\mathbf{a}(U)$ denote the vector in $\mathbb{R}^U$ which contains the corresponding entries in $U$. So $\mathbf{a}(i)$ denotes the $i$-th entry of $\mathbf{a}$.

Given a symmetric matrix $A$, we always use $\lambda_1(A) \le \lambda_2(A) \le \cdots \le \lambda_n(A)$ to denote its eigenvalues in the non-decreasing order. Furthermore, let its eigendecomposition be $A = \sum_i \lambda_i(A) \cdot \psi_i \psi_i^T$ where $\psi_i$ is the eigenvector corresponding to the eigenvalue $\lambda_i(A)$.

We say $G$ is an expander if the second smallest eigenvalue $\lambda_2(\tilde{L})$ of $\tilde{L}$ is at least $c_1$, for some universal $c_1 > 0$. This is equivalent to $\lambda_2(L_G) \ge c_2$ for some $c_2 > 0$ when the degree of $G$ is bounded. We will use Ramanujan graphs [36, 38] of degree 3 and near-Ramanujan graphs for every degree $d \ge 4$ [37]. The guarantee of a Ramanujan graph $G$ of regular degree $d$ is that $\lambda_2(L_G) \ge d - 2\sqrt{d-1}$. For near-Ramanujan graphs, we only need $\lambda_2(L_G) \ge d - 2.01\sqrt{d-1}$.

**Basic definitions about effective resistances.** Then we define the Moore-Penrose pseudo-inverse and effective resistances. For a symmetric matrix $M \in \mathbb{R}^{n\times n}$ whose eigendecomposition is $M = \sum_i \lambda_i \psi_i \psi_i^T$, its Moore-Penrose pseudo-inverse $M^\dagger = \sum_{i:\lambda_i \neq 0} \frac{1}{\lambda_i} \psi_i \psi_i^T$.

▶ **Definition 6** (Effective Resistances). *Given a graph $G = (V, E)$, for any two vertices $s, t \in V$, the $s - t$ effective resistance is defined as $R_G(s, t) := (\mathbf{1}_s - \mathbf{1}_t)^\top \cdot L_G^\dagger \cdot (\mathbf{1}_s - \mathbf{1}_t)$. Moreover, the total effective resistance of $G$ is defined as $R_{tot}(G) = \sum_{i<j} R_G(i, j)$.*

In this work, we will extensively use the following facts about effective resistances (see [33, 44] for their proofs).

▶ **Lemma 7.** *Given a graph $G = (V, E)$, the effective resistances in $G$ satisfy the following properties:*

1. $\sum_{(u,v)\in E} R_G(u, v) = n - 1$ *and* $R_{tot}(G) = n \cdot \sum_{i=2,\ldots,n} \frac{1}{\lambda_i(L_G)}$.
2. $2m \cdot R_G(u, v) = \kappa_G(u, v)$, *where $\kappa_G(i, j)$ is the* commute time *of a simple random walk from vertex $i$ to $j$ in $G$, i.e., the expected number of steps in a random walk starting at $i$, after vertex $j$ is visited and then vertex $i$ is reached again.*
3. $\frac{1}{2}\left(\frac{1}{d(u)} + \frac{1}{d(v)}\right) \le R_G(u, v) \le \left(1/\lambda_2(\widetilde{L}_G)\right) \cdot \left(\frac{1}{d(u)} + \frac{1}{d(v)}\right)$ *where $\lambda_2(\widetilde{L}_G)$ is the 2nd smallest eigenvalue of the normalized Laplacian $\widetilde{L}_G$.*

4. *Given any $(s,t)$, consider all functions $\phi \in \mathbb{R}^V$ such that $\phi(s)=1$ and $\phi(t)=0$, then*

$$R_G(s,t) = \frac{1}{\min\limits_{\phi\in\mathbb{R}^V:\phi(s)=1,\phi(t)=0} \sum_{(u,v)\in E}(\phi(u)-\phi(v))^2}.$$

   *In fact, the minimum value above is acheived when $\phi$ is harmonic, namely the unique solution satisfying $\phi(s)=1, \phi(t)=0$, and $\phi(v)=\frac{1}{d(v)}\sum_{(u,v)\in E}\phi(u)$ for $v\in V\setminus\{s,t\}$. An equivalent definition is $R_G(s,t)=\max\limits_{\phi\in\mathbb{R}^n:\phi\perp\mathbf{1}}\frac{\langle \mathbf{1}_s-\mathbf{1}_t,\phi\rangle^2}{\phi^\top\cdot L_G\cdot\phi}$. In particular, the leverage score $\tau_\ell$ of row $\mathbf{a}_\ell$ in $A$ also equals $\tau_\ell=\max\limits_{\phi\in\mathbb{R}^n}\frac{\langle \mathbf{a}_\ell,\phi\rangle^2}{\|A\cdot\phi\|_2^2}$.*
5. *Let $\mathcal{T}(G)$ denote all spanning trees in $G$. Let us pick $T\in\mathcal{T}$ uniformly at random. Then $R_G(u,v)$ is the probability $(u,v)$ is in $T$, i.e., $R_G(u,v)=\Pr_{T\sim\mathcal{T}(G)}[(u,v)\in T]$.*

Note that the first equation $\sum_{(u,v)\in E} R_G(u,v)=n-1$ in Lemma 7 considers the summation over all edges in $E$ where the total effective resistance is the summation over all pairs.

## 3 Eigenvalues of Perturbed Graphs and Matrices

We discuss Lemma 4 and Lemma 5 in this section. We give two different proofs for Lemma 5 such that Lemma 4 is a direct corollary by setting $A$ to be the incidence matrix. Then we show expander graphs with edges of effective resistance 1 to illustrate that we have to remove edges with $R_G(u,v)<1$ to keep the perturbed graph as an expander in Lemma 4.

We restate Lemma 5 again. One remark is that both bounds could be tight in Lemma 5. For example, consider the case $A^\top A=I$ whose $\tau_\ell=\|\mathbf{a}_\ell\|_2^2$ for all $\ell$ and $\lambda_i\equiv 1$ for all $i$. Then after removing any $\mathbf{a}_\ell$ (hence $k=1$), $(A')^\top A'=I-\mathbf{a}_\ell\cdot\mathbf{a}_\ell^\top$ has $\lambda_1'=1-\|\mathbf{a}_\ell\|_2^2$ with eigenvector $\frac{\mathbf{a}_\ell}{\|\mathbf{a}_\ell\|_2}$. So $\lambda_1'$ matches the lower bound $(1-\tau_\ell)\cdot\lambda_1$; and all the rest eigenvalues of $(A')^\top A'$ are 1, the same as those of $A^\top A$.

▶ **Lemma 5.** *Given a matrix $A\in\mathbb{R}^{m\times n}$, let $\lambda_1\le\cdots\le\lambda_n$ be the eigenvalues of $A^\top A$. Moreover, for each $\ell\in[m]$, let $\mathbf{a}_\ell$ be row $\ell$ of $A$ and $\tau_\ell=\mathbf{a}_\ell^\top(A^\top A)^\dagger\mathbf{a}_\ell$ be its leverage score.*

*For any $k$ distinct indices $\ell_1,\ldots,\ell_k\in[m]$, let $A'\in\mathbb{R}^{(m-k)\times n}$ be the matrix obtained from $A$ by removing the corresponding $k$ rows $\mathbf{a}_{\ell_1},\ldots,\mathbf{a}_{\ell_k}$; and let $\lambda_1'\le\cdots\le\lambda_n'$ be the eigenvalues of $(A')^\top A'$. It holds that*

$$\forall i\in[n], \lambda_i'\in\left[(1-\tau_{\ell_1}-\tau_{\ell_2}-\cdots-\tau_{\ell_k})\cdot\lambda_i,\lambda_i\right].$$

The first proof is based on the characteristic polynomial of $A^\top A$, which is motivated by the potential function method of classical work [5]. One ingredient in this proof is the matrix determinant lemma [5].

▶ **Lemma 8.** *If $A$ is nonsingular and $v$ is a vector, then $det(A+vv^\top)=\det(A)\cdot(1+v^\top A^{-1}v)$.*

**Proof of Lemma 5.** For ease of exposition, we start with $k=1$. Namely, we remove one row $\mathbf{a}_\ell$ from $A$ to obtain $A'$. Consider the characteristic polynomial of $(A')^\top A'$:

$$\begin{aligned} det(xI-(A')^\top A') &= det(xI-A^\top A+\mathbf{a}_\ell\mathbf{a}_\ell^\top)\\ &= det\left((xI-A^\top A)\cdot\left(I+(xI-A^\top A)^\dagger\mathbf{a}_\ell\mathbf{a}_\ell^\top\right)\right)\\ &= det\left(xI-A^\top A\right)\cdot det\left(I+(xI-A^\top A)^\dagger\mathbf{a}_\ell\mathbf{a}_\ell^\top\right). \end{aligned}$$

Let $\psi_i$ be the corresponding eigenvector of $\lambda_i$ in $A$ such that $(xI-A^\top A)^\dagger\mathbf{a}_\ell\mathbf{a}_\ell^\top=\left(\sum\limits_{i\in[n]:\lambda_i\neq x}\frac{1}{x-\lambda_i}\psi_i\psi_i^\top\right)\mathbf{a}_\ell\mathbf{a}_\ell^\top$. Then we apply the matrix determinant lemma (Lemma 8) to $det\left(I+(xI-A^\top A)^\dagger\mathbf{a}_\ell\mathbf{a}_\ell^\top\right)$ such that

$$det(xI-(A')^\top A') = det(xI-A^\top A)\cdot\left(1+\mathbf{a}_\ell^\top\cdot\sum_{i=1}^{n}\frac{1}{x-\lambda_i}\psi_i\psi_i^\top\cdot\mathbf{a}_\ell\right)$$
$$= det(xI-A^\top A)\cdot\left(1-\sum_{i=1}^{n}\frac{1}{\lambda_i-x}\langle\psi_i,\mathbf{a}_\ell\rangle^2\right).$$

Let $\lambda'_1,\lambda'_2,\cdots,\lambda'_n$ be the roots of $det(xI-(A')^\top A')$. Similar to the argument in [5]: If $\langle\psi_i,\mathbf{a}_\ell\rangle=0$, then $\lambda_i$ is a root of $det(xI-A^\top A)$, i.e., $\lambda'_i=\lambda_i$. Otherwise, $\lambda'_i\in(\lambda_{i-1},\lambda_i)$ satisfies $\sum_{j=1}^{n}\frac{1}{\lambda_j-\lambda'_i}\langle\psi,\mathbf{a}_\ell\rangle^2=1$. This is because $\lim_{x\to\lambda_{i-1}+}\sum_{i=1}^{n}\frac{1}{\lambda_i-x}\langle\psi_i,\mathbf{a}_\ell\rangle^2=-\infty$ and $\lim_{x\to\lambda_i-}\sum_{i=1}^{n}\frac{1}{\lambda_i-x}\langle\psi_i,\mathbf{a}_\ell\rangle^2=+\infty$. For the 2nd case, we show $\lambda'_i\geq(1-\tau_\ell)\lambda_i$.

Let the function $p(x):=\sum_{j=1}^{n}\frac{1}{\lambda_j-x}\langle\psi_j,\mathbf{a}_\ell\rangle^2$. If $\lambda_{i-1}\geq(1-\tau_\ell)\lambda_i$, then we have proved $\lambda'_i>(1-\tau_\ell)\lambda_i$. Otherwise we show $\lambda'_i>(1-\tau_\ell)\lambda_i$ by considering $p(x)$ in the continuous interval $\big[(1-\tau_\ell)\lambda_i,\lambda_i\big)$.

$$p\Big((1-\tau_\ell)\lambda_i\Big)=\sum_{j=1}^{n}\frac{1}{\lambda_j-(1-\tau_\ell)\lambda_i}\langle\psi,\mathbf{a}_\ell\rangle^2$$
$$\leq\sum_{j=i}^{n}\frac{1}{\lambda_j-(1-\tau_\ell)\lambda_i}\langle\psi,\mathbf{a}_\ell\rangle^2$$
(Since $\lambda_1<\cdots<\lambda_{i-1}<(1-\tau_\ell)\lambda_i$ from the assumption, their corresponding terms are negative.)
$$\leq\sum_{j=i}^{n}\frac{1}{\lambda_j-(1-\tau_\ell)\lambda_j}\langle\psi,\mathbf{a}_\ell\rangle^2=\frac{1}{\tau_\ell}\sum_{j=i}^{n}\frac{1}{\lambda_j}\langle\psi,\mathbf{a}_\ell\rangle^2$$

From the definition, $\tau_\ell=\mathbf{a}_\ell^\top(A^\top A)^\dagger\mathbf{a}_\ell=\mathbf{a}_\ell^\top\left(\sum_{i=1}^{n}\frac{1}{\lambda_i}\psi_i\psi_i^\top\right)\mathbf{a}_\ell=\sum_{i=1}^{n}\frac{1}{\lambda_i}\langle\psi_i,\mathbf{a}_\ell\rangle^2$. So $p\big((1-\tau_\ell)\lambda_i\big)\leq 1$.

On the other hand, $\lim_{x\to\lambda_i-}\sum_{i=1}^{n}\frac{1}{\lambda_i-x}\langle\psi_i,\mathbf{a}_\ell\rangle^2=+\infty$. So $p\big((1-\tau_\ell)\lambda_i\big)\leq 1$ and $p(\lambda_i-\epsilon)>1$ infer that there exists a $x\in[(1-\tau_\ell)\lambda_i,\lambda_i)$ such that $p(x)=1$, which also means that $det(xI-(A')^\top A')$ has a root $\lambda'_i\in[(1-\tau_\ell)\lambda_i,\lambda_i)$.

Next we prove $\lambda'_i\geq(1-\tau_{\ell_1}-\cdots-\tau_{\ell_k})\lambda_i$ by induction on $k$. The above calculation proves the base case of $k=1$.

For the inductive step, let $\tilde{A}$ denote the matrix after removing $\mathbf{a}_{\ell_1},\ldots,\mathbf{a}_{\ell_q}$ and $A'$ denote the matrix by removing one more edge $a_{\ell_{q+1}}$. By the induction hypothesis, $\lambda_i(\tilde{A})\in\left[\big(1-\sum_{j=1}^{q}\tau_{\ell_j}\big)\cdot\lambda_i,\lambda_i\right]$ and $(1-\sum_{j=1}^{q}\tau_{\ell_j})\cdot A^\top A\preceq\tilde{A}^\top\tilde{A}$. This implies $(\tilde{A}^\top\tilde{A})^\dagger\preceq(1-\sum_{j=1}^{q}\tau_{\ell_j})^{-1}\cdot(A^\top A)^\dagger$,

$$\tilde{\tau}_{\ell_{q+1}}=\mathbf{a}_{\ell_{q+1}}^\top(\tilde{A}^\top\tilde{A})^\dagger\mathbf{a}_{\ell_{q+1}}\leq\left(1-\sum_{j=1}^{q}\tau_{\ell_j}\right)^{-1}\mathbf{a}_{\ell_{q+1}}^\top(A^\top A)^\dagger\mathbf{a}_{\ell_{q+1}}=\left(1-\sum_{j=1}^{q}\tau_{\ell_j}\right)^{-1}\tau_{\ell_{q+1}}.$$

Using the perturbation bound for $k=1$ on $\tilde{A}$ and $A'$,

$$\lambda_i(A')\in\big[(1-\tilde{\tau}_{\ell_{q+1}})\lambda_i(\tilde{A}),\lambda_i(\tilde{A})\big]$$
$$\subseteq\left[\left(1-\left(1-\sum_{j=1}^{q}\tau_{\ell_j}\right)^{-1}\tau_{\ell_{q+1}}\right)\left(1-\sum_{j=1}^{q}\tau_{\ell_j}\right)\lambda_i,\lambda_i\right]=\left[\left(1-\sum_{j=1}^{q+1}\tau_{\ell_j}\right)\lambda_i,\lambda_i\right].\quad\blacktriangleleft$$

Next we present the 2nd proof, which is based on Property 4 of the leverage score in Lemma 7. One advantage of this proof is that it works directly on multiple edges.

**Proof of Lemma 5.** We will apply the Courant-Fischer theorem below, which shows $\lambda'_i = \min_{\substack{S\subset\mathbb{R}^n,\\ dim(S)=i}} \max_{\phi\in S} \frac{\phi^\top (A')^\top A'\phi}{\phi^\top\phi}$.

▶ **Lemma 9** (Courant-Fischer-Weyl theorem)**.** *Let $H$ be an $n\times n$ Hermitian matrix with eigenvalues $\lambda_1(H)\le\lambda_2(H)\le\cdots\le\lambda_n(H)$, then*

$$\lambda_k(H) = \min_{\substack{S\subset\mathbb{R}^n,\\ dim(S)=k}} \max_{x\in S} \frac{x^\top Hx}{x^\top x} \qquad \textit{and} \qquad \max_{\substack{S\subset\mathbb{R}^n,\\ dim(S)=n-k+1}} \min_{x\in S} \frac{x^\top Hx}{x^\top x}.$$

We compare the Rayleigh quotient $\frac{\phi^\top (A')^\top A'\phi}{\phi^\top\phi}$ with $\frac{\phi^\top A^\top A\phi}{\phi^\top\phi}$:

$$\frac{\phi^\top (A')^\top A'\phi}{\phi^\top\phi} = \frac{\|A'\phi\|_2^2}{\|\phi\|_2^2} = \frac{\|A\phi\|_2^2 - \sum_{j=1}^{k}\left(a_{\ell_j}^\top\phi\right)^2}{\|\phi\|_2^2} = \frac{\|A\phi\|_2^2}{\|\phi\|_2^2}\cdot\left[1-\sum_{j=1}^{k}\frac{\left(a_{\ell_j}^\top\phi\right)^2}{\|A\phi\|_2^2}\right].$$

Since $\tau_\ell = \max_{\phi\in\mathbb{R}^n}\frac{\left(a_\ell^\top\phi\right)^2}{\|A\phi\|_2^2}$ from Property 4 of Lemma 7, $1-\sum_{j=1}^{k}\frac{\left(a_{\ell_j}^\top\phi\right)^2}{\|A\phi\|_2^2}\ge 1-\sum_{j=1}^{k}\tau_{\ell_j}$.

Using Lemma 9 again,

$$\lambda'_i = \min_{\substack{S\subset\mathbb{R}^n,\\ dim(S)=i}}\max_{\phi\in S}\frac{\|A\phi\|_2^2}{\|\phi\|_2^2}\left[1-\sum_{j=1}^{k}\frac{\left(a_{\ell_j}^\top\phi\right)^2}{\|A\phi\|_2^2}\right] \ge \left(1-\sum_{j=1}^{k}\tau_{\ell_j}\right)\min_{\substack{S\subset\mathbb{R}^n,\\ dim(S)=i}}\max_{\phi\in S}\frac{\|A\phi\|_2^2}{\|\phi\|_2^2} = (1-\sum_{j=1}^{k}\tau_{\ell_j})\lambda_i.$$

As $1-\sum_{j=1}^{k}\frac{\left(a_{\ell_j}^\top\phi\right)^2}{\|A\phi\|_2^2}\le 1$, we can get $\lambda'_i\le\lambda_i$ in a similar way. Combining the two inequalities, $\lambda'_i\in[(1-\sum_{j=1}^{k}\tau_{\ell_j})\lambda_i,\lambda_i]$. ◀

We remark that Lemma 5 is also an instantiation of Theorem 2.8 in [26] with leverage scores. However, we believe the above two proofs shed more insights on the structure of perturbed matrices and are simplier (without Weyl's interlacing inequality). But for completeness, we provide that proof in the full version.

Next we show that there exist edges in expander graphs with unit effective resistance.

▷ Claim 10. For any $c_0>0$ and infinitely many $n$, there exists an expander graph $G$ of constant degree such that

1. The smallest non-trivial eigenvalue of its Laplacian is at least $c_0$;
2. There exists an edge $e$ in $G$ with effective resistance 1.

Hence, after removing $e$, $\lambda_2(L_{G'})=0$ in the perturbed graph $G'$ such that $G'$ is no longer an expander.

Proof. Given an expander $G'=(V',E')$ with constant degree and $\lambda_2(L_G)=\Omega(1)$, we add an extra vertex of degree 1 to it. More formally, let $V'=\{1,\ldots,n-1\}$ and $G=(V,E)=(V'\cup\{n\},E'\cup\{(n-1,n)\})$. Then $R_G(n-1,n)=1$. We will show $\lambda_2\left(L_{G'}\right)=\Omega(1)$ such that $G'$ is also an expander (its degree is still a constant). So $L_G(i,j)=L_{G'}(i,j)$ except $i\in\{n-1,n\}$ and $j\in\{n-1,n\}$ where those four entries have $L_G(n-1,n-1)=L_{G'}(n-1,n-1)+1, L_G(n-1,n)=L_G(n,n-1)=-1$, and $L_G(n,n)=1$.

By the Courant-Fischer Theorem, $\lambda_2(L_G) = \min_{\phi \perp \mathbf{1}, \|\phi\|_2 = 1} \phi^\top L_G \phi$. Then we prove $\phi^\top L_G \phi = \Omega(1)$ for all $\phi$ with $\phi \perp \mathbf{1}$ and $\|\phi\|_2 = 1$ by considering $\phi(n)$ in two cases.

If $|\phi(n)| \geq 0.8$, then $|\phi(n-1)| \leq 0.6$ because $\|\phi\|_2 = 1$. So $\phi^\top L_G \phi = \sum_{(u,v)\in E} (\phi(u) - \phi(v))^2 \geq (\phi(n) - \phi(n-1))^2 \geq 0.04$.

Otherwise $|\phi(n)| < 0.8$. For convenience, we assume $\phi(n) \in [0, 0.8)$. Let $\phi([n-1]) \in \mathbb{R}^{[n-1]}$ denotes the sub-vector on $V'$ and $\mathbf{1}([n-1])$ denotes the all 1-vector on $V'$. Then $\|\phi([n-1])\| \geq 0.6$ and

$$\phi^\top L_G \phi = \sum_{(u,v)\in E} (\phi(u) - \phi(v))^2 \geq \sum_{(u,v)\in E'} (\phi(u) - \phi(v))^2 = \phi([n-1])^\top \cdot L_{G'} \cdot \phi([n-1]).$$

Since $L_{G'}$ has an eigenvalue 0 with eigenvector $\mathbf{1}([n-1])$, we consider $\phi([n-1])$ after orthonormalization: $\phi([n-1]) - \frac{\langle \phi([n-1]), \mathbf{1}([n-1])\rangle}{n-1} \cdot \mathbf{1}([n-1])$.

Note that $\langle \phi, \mathbf{1}\rangle = 0$ implies $\langle \phi([n-1]), \mathbf{1}([n-1])\rangle = -\phi(n)$. We calculate its $L_2$ norm after orthonormalization as

$$\begin{aligned}
&\left\| \phi([n-1]) - \frac{\langle \phi([n-1]), \mathbf{1}([n-1])\rangle}{n-1} \cdot \mathbf{1}([n-1]) \right\|^2 \\
&= \left\| \phi([n-1]) + \frac{\phi(n)}{n-1} \cdot \mathbf{1}([n-1]) \right\|^2 \\
&= \|\phi([n-1])\|^2 + \left\| \frac{\phi(n)}{n-1} \cdot \mathbf{1}([n-1]) \right\|^2 + \frac{2\phi(n)}{n-1} \cdot \langle \phi([n-1]), \mathbf{1}([n-1])\rangle \\
&\geq \|\phi([n-1])\|^2 - \frac{2\phi(n)}{n-1} \cdot \phi(n) \geq 0.36 - \frac{2}{n-1} \geq 0.3.
\end{aligned}$$

So $\phi^\top L_G \phi \geq \lambda_2(L_{G'}) \cdot \left\| \phi([n-1]) - \frac{\langle \phi([n-1]), \mathbf{1}([n-1])\rangle}{n-1} \cdot \mathbf{1}([n-1]) \right\|^2 = \Omega(1)$.

From all discussion above, $\lambda_2(L_G) = \Omega(1)$. Since $G$ has a constant degree, $\lambda_2(\tilde{L}_G) \geq \lambda_2(L_G)/d(G) = \Omega(1)$, which means $G$ is also an expander. ◁

## 4 Lower Bound for Degree 3

In this section, we prove the lower bound for graphs with degrees at most 3 (except the given pair $s$ and $t$). Recall the statement of Theorem 1 in Section 1.

▶ **Theorem 1.** *There are infinitely many $n$ and graphs of $n$ vertices such that any local algorithm with success probability 0.6 and approximation ratio 1.01 on $R_G(s,t)$ needs $\Omega(n)$ queries. This holds even for graphs whose vertices are of degree at most 3 except the adjacent pair $s$ and $t$.*

One ingredient in the proof is Lemma 4, which bounds the expansion of a perturbed graph $G'$ obtained from removing one edge $e$ of the original graph $G$, in terms of the eigenvalues of the Laplacian of $G$ and the effective resistance $R_G(e)$.

In the rest of this section, we finish the proof of Theorem 1. The high level idea is to consider a graph $G$ of degree 3 (see Figure 2 for an illustration) constituted by two disjoint expanders $H_s$ and $H_t$ with one extra edge between $s$ and $t$ in these two expanders separately.

Then we produce a random graph $G'$ as follows (see Figure 1 for an illustration): remove one random edge $(u, u')$ in $H_s$ and another one $(v, v')$ in $H_t$ separately; then add two edges $(u, v)$ and $(u', v')$ to $G'$.

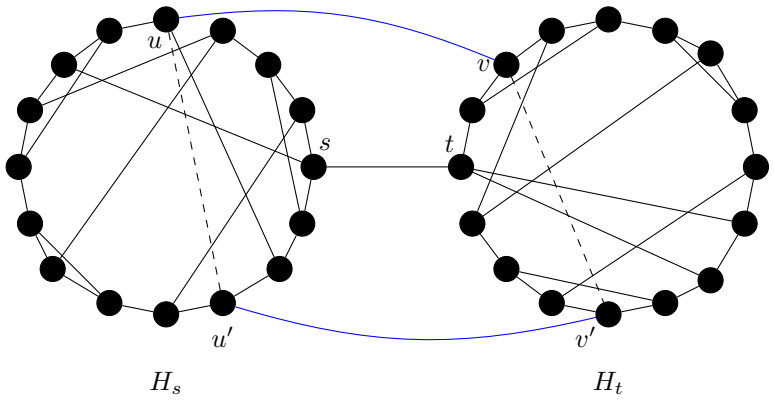

**Figure 1** $G'$ after modification.

So the number of vertices in $G$ and $G'$ are the same; moreover all vertices have the same degrees. Thus the only way to distinguish between $G$ and $G'$ is to figure out whether any of these four edges $(u, u'), (v, v'), (u, v), (u', v')$ is in the graph or not. Since there are $3n/2$ edges, this needs $\Omega(n)$ queries. Finally we bound $R_{G'}(s, t)$ (and the approximation ratio) via Lemma 4.

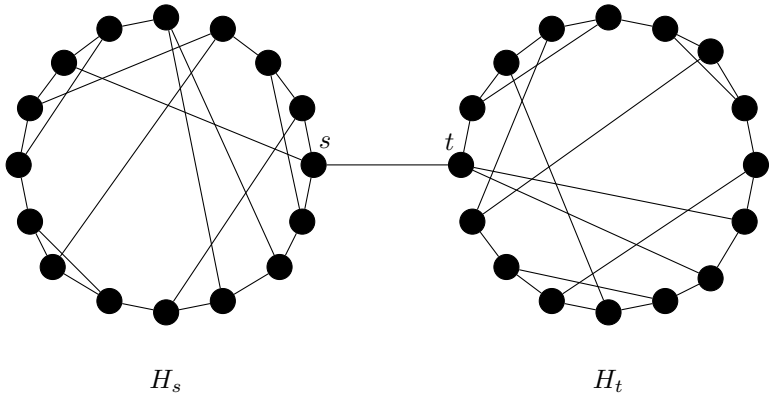

**Figure 2** Construction of $G$ with two expanders $H_s$ and $H_t$.

**Proof of Theorem 1.** We provide a distribution $\mathcal{G}$ of graphs with $n$ vertices and degree at most 3 (except $s$ and $t$). Then by Yao's minimax principle, we only need to consider deterministic algorithms of $q_n$ neighbor queries and 1.01-approximation ratio whose success probability is at least 0.6 over $\mathcal{G}$. Our goal is to prove $q_n = \Omega(n)$.

Consider any $n$ such that there exists a 3-regular Ramanujan graph $H$ of size $n/2$ [36, 38]. Then we construct $G$ with the given pair $(s, t)$ as follows:

1. Take two vertex-disjoint copies of $H$, denoted by $H_s$ and $H_t$, such that $H_s$ contains vertex $s$ and $H_t$ contains vertex $t$.
2. Define the vertex set $V(G)$ of $G$ to be the union of the vertex sets of $H_s$ and $H_t$.
3. Define the edge set $E(G)$ of $G$ to be the union of $(s, t)$, the edge set $E(H_s)$ of $H_s$ and the edge set $E(H_t)$ of $H_t$.

Note that the effective resistance $R_G(s, t) = 1$ in $G$.

Next, we construct a random graph $G'$ based on $G$. Let $E_{s,3/4}$ be the set of edges in $H_s$ with effective resistance at most 3/4, i.e., $E_{s,3/4} = \{(u,v) \in E(H_s) | R_G(u,v) \leq 3/4\}$ and we define $E_{t,3/4}$ analogously. We use the following claim to lower bound the sizes of these two sets whose proof is deferred to Section 4.1.

▷ Claim 11. It holds that $|E_{s,3/4}| \geq n/12$ and $|E_{t,3/4}| \geq n/12$.

We give the construction of $G'$ which is almost identical to $G$ except four edges.

1. Choose one edge $(u,u')$ uniformly at random from $E_{s,3/4}$ and remove it from $G$. Similarly, remove another random edge $(v,v') \in E_{t,3/4}$. For convenience, let $H'_s$ be the subgraph of $H_s$ obtained by removing $(u,u')$ from $H_s$ and $H'_t$ be the subgraph obtained by removing $(v,v')$ from $H'_t$.
2. Add $(u,v)$ and $(u',v')$ to $G'$.

By our choices of $(u,u') \in E_{s,3/4}$ and $(v,v') \in E_{t,3/4}$, $H'_s$ and $H'_t$ are still expander graphs from Lemma 4. Based on this property, we show the effective resistance between $s$ and $t$ in $G'$ is strictly less than 1 in Claim 12, whose proof is deferred to Section 4.1.

▷ Claim 12. It holds that $R_{G'}(s,t) \leq 0.99$.

Now we fix a deterministic algorithm $A$ with approximation ratio at most 1.01 and consider the underlying distribution $\mathcal{G}$, which is $G$ or $G'$ with probability 1/2 separately. Observe that whenever $A$ succeeds, $A$ is able to distinguish between $G$ and $G'$, since the ratio between $R_G(s,t) = 1$ and $R_{G'}(s,t) \leq 0.99$ is more than 1.01. For convenience, let us modify $A$ so that its output is an assertion about whether the input graph is $G$ or $G'$. By Yao's minimax principle, it holds that

$$0.6 \leq \Pr_{\mathcal{G}}[A \text{ succeeds}] = \frac{\Pr[A(G) = G]}{2} + \frac{\Pr[A(G') = G']}{2}. \tag{1}$$

Next we consider all neighbor queries made by $A$ when the underlying graph is $G$. Since $A$ and $G$ are fixed, say $A$ makes $q_n$ fixed neighbor queries on $G$. If $G'$ and $G$ provide the same answers on these neighbor queries, $A$ fails to distinguish them. But $G'$ is obtained from $G$ by removing one random edge in $E_{s,3/4}$ and another one in $E_{t,3/4}$ separately. Hence at most $q_n$ edges in $E_{s,3/4}$ will be queried; and similarly for $E_{t,3/4}$. So we bound

$$\begin{aligned}\Pr[A(G') = G'] &\leq \Pr[A(G) = G'] + \Pr[\text{One neighbor query returns different values}] \\ &\leq 1 - \Pr[A(G) = G] + q_n/|E_{s,3/4}| + q_n/|E_{t,3/4}|.\end{aligned}$$

Plugging this into (1) with the two bounds in Claim 11, we obtain $q_n \geq 0.1 \cdot \frac{n}{12}$. ◀

We remark that replacing $H$ by an expander of degree $[m/n]$ would give a lower bound $\Omega(m)$ instead of $\Omega(n)$, but this result is covered by Theorem 2 with $\ell = 1$.

## 4.1 Proofs of Claim 11 and Claim 12

We now give the proof of Claim 11.

Proof of Claim 11. Recall that $E_{s,3/4} = \{(u,v) \in E(H_s) | R_G(u,v) \leq 3/4\}$. First, for any edge $(u,v)$ in $H_s$, $R_{H_s}(u,v) = R_G(u,v)$. Since $(s,t)$ is the unique edge between $H_s$ and $H_t$, the set of spanning trees $\mathcal{T}(G)$ is generated by picking one spanning tree $T_1 \in \mathcal{T}(H_s)$ and one $T_2 \in \mathcal{T}(H_t)$ then connecting them by $\{(s,t)\}$. Then by Property 5 of Lemma 7, $R_{H_s}(u,v) = R_G(u,v)$. Thus, $E_{s,3/4} = \{(u,v) \in E(H_s) | R_{H_s}(u,v) \leq 3/4\}$.

From Property 1 of Lemma 7, $\sum_{(u,v)\in E(H_s)} R_{H_s}(u,v) = \frac{n}{2}-1$. By the definition of $E_{s,3/4}$, we have $|E(H_s)\backslash E_{s,3/4}|\cdot\frac{3}{4} \le \sum_{(u,v)\in E(H_s)\backslash E_{s,3/4}} R_{H_s}(u,v) \le \sum_{(u,v)\in E(H_s)} R_{H_s}(u,v) = \frac{n}{2}-1$, which implies that $|E(H_s)\setminus E_{s,3/4}| \le \frac{n/2-1}{3/4}$.

Since $|E(H_s)| = \frac{n}{2}\cdot\frac{3}{2}$, it holds that $|E_{s,3/4}| \ge \frac{n}{2}\cdot\frac{3}{2} - \frac{n/2-1}{3/4} \ge n/12$. ◁

While it is possible to use the Cayley graph construction of Ramanujan graphs to obtain a better bound, we did not attempt to optimize those constants in this work. Then we finish the proof of Claim 12.

Proof of Claim 12. Recall that $H'_s$ and $H'_t$ are subgraphs in $G'$ obtained by removing $(u,u')$ in $H_s$ and $(v,v')$ in $H_t$ separately. We show that the 2nd eigenvalue of $L_{H'_s}$ has $\lambda_2(L_{H'_s}) \ge \frac{3-2\sqrt{2}}{4}$. As a Ramanujan graph $H_s$, $\lambda_2(L_{H_s}) \ge 3-2\sqrt{2}$. Then we apply Lemma 4 to $\lambda_2$: since $R_{H_s}(u,u') = R_G(u,u') \le 3/4$ (from the proof of Claim 11), $\lambda_2(L_{H'_s}) \ge \lambda_2(L_{H_s})\cdot(1 - R_{H_s}(u,u')) \ge \frac{3-2\sqrt{2}}{4}$.

As removing other edges doesn't decrease the effective resistance of $(s,t)$, we ignore $(u',v')$ to give a upper bound of $R_{G'}(s,t)$. Consider another path $s-u-v-t$, we have

$$\begin{aligned} R_{H'_s}(s,u) &= (\mathbf{1}_s-\mathbf{1}_u)^\top L^\dagger_{H'_s}(\mathbf{1}_s-\mathbf{1}_u) \\ &\le \lambda_n(L^\dagger_{H'_s})\cdot\|\mathbf{1}_s-\mathbf{1}_u\|_2^2 = \frac{1}{\lambda_2(L_{H'_s})}\cdot\|\mathbf{1}_s-\mathbf{1}_u\|_2^2 = \frac{4}{3-2\sqrt{2}}\cdot 2 = 24+16\sqrt{2}; \end{aligned}$$

and the same bound holds for $R_{H'_t}(v,t)$. Since $(s,t)$ and the path passing by $s-u-v-t$ are in parallel, we have $R_{G'}(s,t) \le \frac{1}{1+\frac{1}{R_{H'_s}(s,u)+1+R_{H'_t}(v,t)}} \le 0.99$.

More formally, $1/R_{G'}(s,t) = \min_{\phi\in\mathbb{R}^V:\phi(s)=1,\phi(t)=0} \sum_{(a,b)\in E}(\phi(a)-\phi(b))^2$ from Property 4 of Lemma 7. Since $\phi(s)$ and $\phi(t)$ are fixed,

$$\min_{\phi\in\mathbb{R}^V:\phi(s)=1,\phi(t)=0} \sum_{(a,b)\in E}(\phi(a)-\phi(b))^2 = 1 + \min_{\phi\in\mathbb{R}^V:\phi(s)=1,\phi(t)=0} \sum_{(a,b)\in E(G')\backslash(s,t)}(\phi(a)-\phi(b))^2.$$

Because there is only one path $s-u-v-t$ between $s$ and $t$ in $G'$ if we ignore the two edges $(s,t)$ and $(u',v')$, we simplify the 2nd term as follows.

$$\begin{aligned} &\min_{\phi\in\mathbb{R}^V:\phi(s)=1,\phi(t)=0} \sum_{(a,b)\in E(G')\backslash(s,t)}(\phi(a)-\phi(b))^2 \\ &= \min_{\phi(u),\phi(v)\in\mathbb{R}}\left[(\phi(u)-\phi(v))^2 + \min_{\phi(s)=1}\sum_{(a,b)\in E(H'_s)}(\phi(a)-\phi(b))^2 + \min_{\phi(t)=0}\sum_{(a,b)\in E(H'_t)}(\phi(a)-\phi(b))^2\right] \\ &= \min_{\phi(u),\phi(v)\in\mathbb{R}}\left[(\phi(u)-\phi(v))^2 + \frac{(1-\phi(u))^2}{R_{H'_s}(s,u)} + \frac{\phi(v)^2}{R_{H'_t}(v,t)}\right] = \frac{1}{1+R_{H'_s}(s,u)+R_{H'_t}(v,t)}, \end{aligned}$$

where the second equation follows from Property 4 of Lemma 7 and the last equation holds when $\phi^*(u) = \frac{1+R_{H'_t}(v,t)}{1+R_{H'_s}(s,u)+R_{H'_t}(v,t)}$ and $\phi^*(v) = \frac{R_{H'_t}(v,t)}{1+R_{H'_s}(s,u)+R_{H'_t}(v,t)}$. ◁

## 5 Approximation Algorithm for Degree 2

In Section 4, we proved a lower bound for degree-3 graphs (except $s$ and $t$). Now we give an approximation algorithm to solve the case of degree 2 in sublinear time. Since all vertices are of degree 2 except $s$ and $t$, essentially, $G$ is constituted by several disjoint paths (some of them are disconnected) between $s$ and $t$.

▶ **Theorem 13.** *Given any $\epsilon < 0.1$, for any graph with degree at most 2 except the adjacent pair $s$ and $t$, there is a local algorithm such that with probability 0.99, it outputs a $(1+\epsilon)$-approximation of $R_G(s,t)$ in time $O\left(\min\{d(s)^2, d(t)^2\} \cdot \log^2 n \cdot \log\log n \cdot \epsilon^{-2}\right)$.*

Note that as long as $\min\{d(s), d(t)\}$ is not too large, the running time in the above theorem is sublinear for any constant $\epsilon > 0$. In the rest of this section, we finish the proof of Theorem 13. In fact, our algorithm could output an additive-error approximation $\tilde{R}_G(s,t)$ in time $O\left(\min\{d(s), d(t)\} \cdot \log^2 n \cdot \log\log n \cdot \delta^{-1} \cdot \epsilon^{-1}\right)$ such that $\tilde{R}_G(s,t) = (1\pm\epsilon)\cdot R_G(s,t) + \delta$. Since $R_G(s,t) \geq \frac{2}{1/d(s)+1/d(t)} \geq 1/\min\{d(s), d(t)\}$ from Property 3 of Lemma 7, $\tilde{R}_G(s,t)$ is a $(1+2\epsilon)$-approximation if we choose $\delta = \epsilon/\min\{d(s), d(t)\}$. This choice of $\delta$ gives the running time in Theorem 13. Then we show the additive-error approximation.

First of all, by the following claim (whose proof is deferred to the full version), we focus on the approximation of $\rho := 1/R_G(s,t)$ instead of the approximation of $R_G(s,t)$.

▷ Claim 14. If $\tilde{\rho} = (1\pm\epsilon)\cdot\rho \pm \delta$ for $\epsilon < 0.1$, $\delta < 0.1$, and $\rho \geq 1$, we always have that $1/\tilde{\rho}$ is a $(1+2\epsilon, 2\delta)$-approximation of $1/\rho$.

We remark that $\rho \geq 1$ for adjacent pairs. But for any non-adjacent pair $s$ and $t$, our algorithm gives an additive-error approximation on their conductance $1/R_G(s,t)$.

Because all vertices except $s$ and $t$ are of degree 2, $G$ is constituted by several *disjoint* paths (some are disconnected) between $s$ and $t$. For convenience, we assume $d(s) \leq d(t)$ and consider each edge from $s$ as a path. In this proof, we define its length $\ell_i = +\infty$ if it is disconnected; otherwise $\ell_i$ is the exact length of that path from $s$ to $t$. Since $R_G(s,t) = \frac{1}{\sum_i 1/\ell_i}$, our goal becomes to approximate $1/R_G(s,t) = \rho = \sum_i 1/\ell_i$. In Algorithm 1, we describe the additive-error approximation algorithm motivated by the chaining argument whose idea is to sample longer paths with smaller probability. Its guarantee is

$$\tilde{\rho} = (1\pm\epsilon)\cdot\rho \pm \delta \qquad \text{for the output } \tilde{\rho} = 1/\tilde{R}_G(s,t) \text{ and } \rho = 1/R_G(s,t), \tag{2}$$

which gives the additive error approximation $\tilde{R}_G(s,t) = (1\pm 2\epsilon)\cdot R_G(s,t) \pm 2\delta$ by Claim 14.

**Algorithm 1** Algorithm for estimating effective resistance with additive error.

**function** AdditiveApproximationEffectiveResistance($G, \epsilon, \delta, s, t$)
  If $d(s) > d(t)$ then swap $s$ and $t$
  $\tilde{\rho} \leftarrow 0, p_0 \leftarrow 1$
  $a \leftarrow \dfrac{20\log n \cdot \log\log n}{\epsilon\delta}$
  **for** $k$ **in** $[0, \cdots, \log n]$ **do**
    **for** each path $i$ from $s$ **do**
      With prob. $p_k$, take at most $2^{k+1}\cdot a$ steps in path $i$ to find out its length $\ell_i$
      if it reaches $t$ and $\ell_i > 2^k \cdot a$, then $\tilde{\rho} \leftarrow \tilde{\rho} + 1/(p_k \cdot \ell_i)$
    $p_k \leftarrow p_{k-1}/2$
  **return** $1/\tilde{\rho}$ as the effective resistance (and $\tilde{\rho}$ as the conductance)

In the rest of this section, we prove the correctness of Algorithm 1. We remark that $p_k = 2^{-k}$ in this section. Let us consider its expected time. For a path of length $\ell_i$, if $j = \lfloor \log_2 \ell_i/a \rfloor$, the number of expected steps on this path is at most

$$p_0\cdot 2a + p_1\cdot 4a + \cdots + p_j\cdot 2^j a + p_{j+1}\cdot\ell_i + \cdots + p_{\log n}\cdot\ell_i = 2a\cdot j + \ell_i\cdot(p_{j+1}+\cdots+p_{\log n}) = O(a\cdot\log n).$$

Since we can start from either $s$ or $t$, the expected time is $O(\min\{d(s), d(t)\}\cdot a\cdot\log n)$.

Next we show the approximation guarantee in (2). For all paths whose lengths are at most $2a$, the algorithm gets the exact conductance $1/\ell_i$ of them. The rest paths are divided into $\log n$ groups $G_1, \ldots, G_{\log n}$. The paths in group $G_k$ have lengths between $(2^k \cdot a, 2^{k+1} \cdot a]$. Assuming path $i$ is in group $k$, we define the random variable $X_i$ for estimating $1/\ell_i$: With probability $p_k$, $X_i = \frac{1}{p_k \ell_i} - \frac{1}{\ell_i}$; otherwise, $X_i = -\frac{1}{\ell_i}$. So $\mathbb{E}\, X_i = 0$ and $\mathsf{Var} X_i = \frac{1-p_k}{p_k \cdot \ell_i^2} \le \frac{1}{p_k \cdot \ell_i^2}$. And the result of Algorithm 1 is $\tilde{\rho} = \sum \frac{1}{\ell_i} + X_i = \rho + \sum X_i$.

Now, we calculate the approximation of group $G_k$ by Bernstein's inequality. There are two cases of $G_k$, i.e., $\sum_{G_k} \frac{1}{\ell_i} > b$ and $\sum_{G_k} \frac{1}{\ell_i} \le b$ for a threshold value $b = \frac{\delta}{\epsilon \cdot \log n}$.

▶ **Lemma 15** (Bernstein's inequality [6]). *Let $X_1, \cdots, X_n$ be independent zero-mean random variables. Suppose that $|X_i| \le M$ almost surely, for all $i$. Then, for all positive $t$,* $\Pr\left[\left|\sum_{i=1}^{n} X_i\right| \ge t\right] \le 2\exp\left[-\frac{1}{4} \cdot \min\left\{t^2 \Big/ \sum_{i=1}^{n} \mathbb{E}\, X_i^2, t/M\right\}\right]$.

In the previous case, $(\sum_{G_k} \frac{1}{\ell_i})^2 / \sum_{G_k} \frac{1}{\ell_i^2} \ge \frac{(|G_k| \cdot \min_{G_k} \ell_i)^2}{|G_k| \cdot (\max_{G_k} \ell_i)^2} \ge |G_k|/4 \ge 2^{k-2} \cdot ab$. The first inequality comes from $\max_{G_k} \ell_i < 2 \min_{G_k} \ell_i$. And the last step is implied by $b < \sum_{G_k} \frac{1}{\ell_i} < |G_k|/(2^k \cdot a)$ since each $\ell_i > 2^k \cdot a$ in $G_k$.

Then $\sum_{G_k} \mathbb{E}\, X_i^2 \le \sum_{G_k} \frac{1}{p_k \ell_i^2} \le \frac{4}{ab} (\sum_{G_k} \frac{1}{\ell_i})^2$, and $|X_i| \le \frac{2^k - 1}{2^k \cdot a} \le \frac{1}{a}$ for all $i \in G_k$. From the above discussion, Bernstein's inequality infers that for $t = \epsilon \sum_{G_k} \frac{1}{\ell_i}$,

$$\Pr\left[\left|\sum_{G_k} X_i\right| \ge \epsilon \sum_{G_k} \frac{1}{\ell_i}\right] \le 2\exp\left[-\frac{1}{4} \min\left\{\frac{ab\epsilon^2}{4}, a\epsilon \sum_{G_k} \frac{1}{\ell_i}\right\}\right] \le 2\exp\left[-\frac{1}{4} \min\left\{\frac{ab\epsilon^2}{4}, ab\epsilon\right\}\right].$$

The second step is by the assumption $\sum_{G_k} \frac{1}{\ell_i} > b$.

In the latter case, $\sum_{G_k} \mathbb{E}\, X_i^2 \le \sum_{G_k} \frac{1}{p_k \ell_i^2} \le \sum_{G_k} \frac{1}{a \cdot \ell_i} \le \frac{b}{a}$ with $\ell_i \ge 2^k \cdot a$ and $\sum_{G_k} \frac{1}{\ell_i} \le b$. So

$$\Pr\left[\left|\sum_{G_k} X_i\right| \ge \frac{\delta}{\log n}\right] \le 2\exp\left[-\frac{1}{4} \min\left\{\frac{a\delta^2}{b \log^2 n}, \frac{a\delta}{\log n}\right\}\right].$$

Take a union bound for all $G_k$ with $b = \frac{\delta}{\epsilon \cdot \log n}$, $\Pr\left[\left|\sum_{i \in [d]} X_i\right| \ge \epsilon \cdot \sum_{i \in [d]} \frac{1}{\ell_i} + \delta\right]$ is at most $2\log n \cdot \exp\left[-\frac{1}{4} \min\left\{\frac{a\delta\epsilon}{4 \log n}, \frac{a\delta}{\log n}\right\}\right] + 2\log n \cdot \exp\left[-\frac{1}{4} \min\left\{\frac{a\delta\epsilon}{\log n}, \frac{a\delta}{\log n}\right\}\right] \le 4 \log n \cdot \exp\left[-\frac{a\delta\epsilon}{16 \log n}\right]$. When $a = \frac{20 \log n \cdot \log\log n}{\epsilon\delta}$, $\tilde{\rho}$ is a $(1+\epsilon, \delta)$-approximation of $\rho$ with probability 0.99.

## Abstract

We present new min-max relations in digraphs between the number of paths satisfying certain conditions and the order of the corresponding cuts. We define these objects in order to capture, in the context of solving the half-integral linkage problem, the essential properties needed for reaching a large bramble of congestion two (or any other constant) from the terminal set. This strategy has been used ad-hoc in several articles, usually with lengthy technical proofs, and our objective is to abstract it to make it applicable in a simpler and unified way. We provide two proofs of the min-max relations, one consisting in applying Menger's Theorem on appropriately defined auxiliary digraphs, and an alternative simpler one using matroids, however with worse polynomial running time.

As an application, we manage to simplify and improve several results of Edwards et al. [ESA 2017] and of Giannopoulou et al. [SODA 2022] about finding half-integral linkages in digraphs. Concerning the former, besides being simpler, our proof provides an almost optimal bound on the strong connectivity of a digraph for it to be half-integrally feasible under the presence of a large bramble of congestion two (or equivalently, if the directed tree-width is large, which is the hard case). Concerning the latter, our proof uses brambles as rerouting objects instead of cylindrical grids, hence yielding much better bounds and being somehow independent of a particular topology.

We hope that our min-max relations will find further applications as, in our opinion, they are simple, robust, and versatile to be easily applicable to different types of routing problems in digraphs.

## 1 Introduction

In combinatorial optimization, a *min-max relation* establishes the equality between two quantities, one naturally associated with *minimizing* the size of an object satisfying some conditions, and the other one associated with *maximizing* the size of another object. Within graph theory, famous such min-max relations include Kőnig's Theorem [15] stating the equality between the sizes of a maximum matching and a minimum vertex cover in a bipartite graph or, more relevant to this article, Menger's Theorem [18] stating, in its simplest form, the equality between the maximum number of pairwise internally disjoint paths between two vertices, and the minimum size of a vertex set disconnecting them. Typically, min-max relations come along with polynomial-time algorithms to find the corresponding objects, making them extremely useful from the algorithmic point of view.

In this article we focus on directed graphs, or *digraphs* for short, and our results are motivated by the complexity of problems related to finding *directed disjoint paths* between given terminals. More precisely, in the $k$-Directed Disjoint Paths problem ($k$-DDP for short), we are given a digraph $G$ and $k$ pairs of vertices $s_i, t_i, i \in [k]$, and the objective is to decide whether $G$ contains $k$ pairwise disjoint paths connecting $s_i$ to $t_i$ for $i \in [k]$. A solution to this problem is usually called a *linkage* in the literature. Here we note that disjoint paths is equivalent to paths which are vertex-disjoint.

Unfortunately, Fortune et al. [9] proved that the $k$-DDP problem is NP-complete already for $k = 2$, and Thomassen [20] strengthened this result by showing that it remains so even if the input digraph is $p$-strongly connected (see Section 2 for the definition) for any integer $p \geq 1$. Thus, in order to obtain positive algorithmic results, research has focused on either restricting the input digraphs (for instance, to being acyclic [19] or, more generally, to having bounded directed tree-width [12]), or on considering relaxations of the problem. Concerning the latter, a natural candidate is to relax the disjointness condition of the paths, and allow for *congestion* in the vertices. Namely, for an integer $c \geq 2$, an input of the $k$-Directed $c$-Congested Disjoint Paths problem ($(k, c)$-DDP for short) is the same as in the $k$-DDP, but now we allow each vertex of $G$ to occur in at most $c$ out of the $k$ paths connecting the terminals. In the particular case $c = 2$, a solution to this problem is usually called a *half-integral linkage* in the literature.

Despite a considerable number of attempts, it is still open whether the $(k, c)$-DDP problem can be solved in polynomial time for every fixed value of $c \geq 2$ and $k > c$ (note that if $k \leq c$, then the problem can be easily solvable in polynomial time just by verifying the connectivity between each pair of terminals). A positive answer for the case $c = 2$ has been recently conjectured by Giannopoulou et al. [11]. Again, in order to obtain positive results, several restrictions and variations of the problem have been considered, such as considering several parameterizations [2, 16], restricting the input graph to have high connectivity [8], or considering an *asymmetric* version of the $(k, c)$-DDP problem [11, 13, 14], where the input is as in $(k, c)$-DDP, but the goal is to either certify that it is a no-instance of $k$-DDP (without congestion) or a yes-instance of $(k, c)$-DDP. This asymmetric version has been solved in polynomial time for every fixed $k$ (i.e., showing that it is in XP; see Section 2) for distinct values of $c$ in a series of articles, namely for $c = 4$ by Kawarabayashi et al. [13], for $c = 3$ by Kawarabayashi and Kreutzer [14], and for $c = 2$ by Giannopoulou et al. [11].

The main motivation of this article stems from the techniques used in the latter two approaches mentioned above. In a nutshell, the main strategy used in [8, 11, 13, 14] is the following. First, one computes whether the directed tree-width of the input graph is bounded by an appropriate function of $k$, the number of terminal pairs. This can be done in time XP

in $k$ by the results of Johnson et al. [12], or even in time FPT by the results of Campos et al. [4] (see also [3, Theorem 9.4.4]). If the directed tree-width is bounded by a function of $k$, one solves the problem in time XP by using standard programming techniques from Johnson et al. [12] (cf. Proposition 3). If not, one exploits the fact that large directed tree-width implies the existence of large "structures" that can be used to carry out the routing of the desired paths. Typically, such a structure is a *bramble*, as for example in [8], or a *cylindrical grid*, as for example in [11, 14], making use of the celebrated Directed Grid Theorem of Kawarabayashi and Kreutzer [14] (see also [4] for recent improvements). For the sake of exposition, assume henceforth that the desired structure is a bramble, but the strategy is essentially the same with a cylindrical grid.

A bramble in a digraph $D$ is a set $\mathcal{B}$ of strongly connected subgraphs of $G$ that pairwise either intersect or have edges in both directions. The *order* of a bramble $\mathcal{B}$ is the smallest size of a vertex set of $G$ that intersects all its elements, and its *congestion* is the maximum number of times that a vertex of $G$ appears in the elements of $\mathcal{B}$. It is known that large directed treewidth implies the existence of a bramble of large order and of congestion $c \geq 2$. For $c = 2$, a proof about how to find such a bramble in polynomial time (with degree not depending on $k$), provided that a certificate for large directed tree-width is given, can be found in [8] (see also [17] for improved bounds for brambles of higher congestion). Assume for simplicity that $c = 2$, let $\mathcal{B}$ be such a bramble, and let $S$ and $T$ be the sets of sources and sinks, respectively, of the corresponding problem. The idea is that if one can find a set $\mathscr{P}^S$ of disjoint paths from $S$ to appropriate elements of $\mathcal{B}$, and a set $\mathscr{P}^T$ of disjoint paths from appropriate elements of $\mathcal{B}$ to $T$ (regardless of the ordering of the vertices of $S$ and $T$), then we are done. Indeed, once the paths starting in $S$ reach $\mathcal{B}$, one can use the connectivity properties of the bramble to "shuffle" the paths appropriately as required by the terminals, and then follow the paths from $\mathcal{B}$ to $T$. The fact that the bramble has congestion two, and that the paths in $\mathscr{P}^S$, as well as those in $\mathscr{P}^T$, are pairwise disjoint, together with a good choice for the destination and starting points of the those paths, implies that every vertex of $G$ occurs in at most two of the resulting paths.

Otherwise, if such sets of paths $\mathscr{P}^S$ and $\mathscr{P}^T$ do *not* exist, the approach consists in using a Menger-like min-max duality to obtain an appropriate *separator* (or *cut*) between the terminals and the bramble of size bounded by a function of $c$ and $k$, and make some progress toward the resolution of the problem, for instance by splitting into subproblems of lower complexity. The ways to define and to exploit such a separator depend on every particular application, and this ad-hoc subroutine is usually one of the most technically involved parts of the resulting algorithms [8, 11, 13, 14].

**Our results and techniques.** Motivated by the inherent common essential strategy in the above articles, we aim at finding the crucial general ingredient that can be applied in order to define and find the corresponding separators. To this end, we introduce new objects that abstract the existence of the aforementioned desired paths $\mathscr{P}^S$ and $\mathscr{P}^T$ between the terminals and the bramble. These objects are what we call *D-paths*, *T-paths* and *R-paths*. The inspiration for D-paths and T-paths is what we believe to be the common essential strategies used by Edwards et al. [8] and Giannopoulou et al. [10]. We remark that a particular set of T-paths is directly constructed in [10], particularly inside the proof of [10, Theorem 9.1]. The presence of D-paths and T-paths in [8] is more subtle in the construction of a long algorithm and a collection of non-trivial proofs. In fact, they are not explicitly built due to constraints in their techniques, but our initial results for this paper included simplifying and improving the proofs in [8] using D-paths and T-paths. Once the new proofs were obtained,

we noticed that they could be further improved by a new object which we call R-paths. It must be noted that this paper includes results for D-paths, T-paths, and R-paths but we only show applications for R-paths. The reason for this is twofold. First, T-paths have stronger properties than R-paths which might be useful for solving different problems, and D-paths are needed in the proof of the duality of T-paths. And second, these three objects are similar to the point of having similar proofs for their min-max formulas and algorithms, and showing these variations incurs little additional effort. The formal definitions of these special types of paths can be found in Section 3.

All three types of paths are associated with a defining partition $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ sharing some properties and differing in others. For all three, it holds that any two paths in a same part $\mathcal{P}_i$ are disjoint, and it is possible that two paths in distinct parts share vertices. In the context of the $(k, c)$-DDP problem, the main difference between D-paths, T-paths, and R-paths lies in how we want to reach (or, by applying a simple trick of reversing the edges of the digraph, be reached from) the elements of a bramble $\mathcal{B}$ in the given digraph. In D-paths we ask that all paths end in distinct vertices of a given $B \subseteq V(G)$. In T-paths we ask that all paths end in distinct vertices of the bramble, and that the set containing all last vertices of the T-paths forms a *partial transversal* (see Section 2 for the definition) of $\mathcal{B}$. In R-paths we ask that all R-paths end in elements of $\mathcal{B}$ and that there is a "matching-like" association between the last vertices of the paths and elements of $\mathcal{B}$ containing these vertices.

For each type of paths we define an associated notion of *cut* and its corresponding *order* (see e.g. Definition 10). These cuts are respectively called *D-cuts*, *T-cuts*, and *R-cuts*. We show that each of these special types of paths and cuts satisfies a Menger-like min-max duality, that is, that the maximum number of paths equals the minimum order of a cut (cf. Theorems 11, 13, and 15). Moreover, the corresponding objects attaining the equality can be found in polynomial time. The proofs of these min-max relations basically consist in applying Menger's Theorem [18] in appropriately defined auxiliary graphs. We provide alternative simpler proofs of these equalities using intersections and unions of matroids, namely gammoids and transversal matroids. Even if the resulting polynomial-time algorithms using matroids have worse running time than the ones that we obtain by applying Menger's Theorem [18], and that using the deep theory of matroids somehow sheds less light on interpreting the actual behavior of the considered objects, we think that it is interesting to observe that the paths and cuts that we define are in fact matroids with nice properties.

The main application we provide for R-paths/cuts in this article is in the proof of Theorem 16, which is an improved version of [10, Theorem 9.1] both in the requested order of the structure and by relying on brambles instead of cylindrical grids. Informally, Theorem 16 says that given a digraph $G$, ordered sets $S, T \subseteq V(G)$, and a large (depending on the congestion $c$ and on the size $k$ of $S$ and $T$) bramble of congestion $c$, we can either find a large set of R-paths from $S$ to the bramble and from the bramble to $T$, which in turn are used to appropriately connect the pairs $s_i \in S, t_i \in T$, or find a separator of size at most $k-1$ intersecting every path from $S$ to a large subset of the bramble, or every path from a large subset of the bramble to $T$. Additionally, if the bramble is given, one of the outputs can be obtained in polynomial time, computing either the paths or one of the separators.

Since in $k$-strong digraphs the separators are never found, Theorem 16 immediately implies an improved version of a result by Edwards et al. [8]. Namely, in [8, Theorem 11] the authors show that, when restricted to $(36k^3 + 2k)$-strong digraphs, every instance of $(k, 2)$-DDP where the input digraph contains a large (depending on $k$) bramble of congestion two is positive and a solution can be found in polynomial time. When compared to theirs, our result is an improvement in the following ways. First, it allows us to solve $(k, c)$-DDP for any

$c \geq 2$ in the larger class of $k$-strong digraphs instead of being restricted to $(36k^3 + 2k)$-strong digraphs as in [8]. This bound on the strong connectivity of the digraph is almost best possible according to [8, Theorem 2], unless $\mathsf{P} = \mathsf{NP}$ (note that an $\mathsf{XP}$ algorithm in $(k-d)$-strong digraphs, for some constant $d$, may still be possible). Second, we show how to find the desired paths using a bramble of congestion $c$ and size at least $2k(c \cdot k - c + 2) + c(k-1)$, which is equal to $4k^2 + 2k - 2$ when $c = 2$, instead of the size $188k^3$ required in [8]. Finally, our proof is much simpler and shorter than the proof presented in [8]. A main reason of this simplification is that we can replace the seven properties of the paths requested in [8, Lemma 12] by $\mathsf{R}$-paths. It is worth mentioning that our algorithm reuses the procedure of Edwards et al. [8] to find a large bramble of congestion two in digraphs of large directed tree-width (cf. Corollary 8).

We remark that it is also possible to improve the result by Edwards et al. [8] from $(36k^3 + 2k)$-strong digraphs to $k$-strong digraphs by replacing part of their proof, namely [8, Theorem 11], by the result of Giannopoulou et al. [10, Theorem 9.1]. The trade-off is that the latter relies on the stronger structure of a cylindrical grid (and such grids do contain brambles of congestion two [8]) instead of brambles. A fundamental difference stands on the fact that, given a certificate of large directed tree-width, one can produce a bramble of congestion two in polynomial time, while finding a cylindrical grid still requires $\mathsf{FPT}$ time parameterized by the order of the certificate [4]. Our result using $\mathsf{R}$-paths keeps the best of both worlds: we are able to drop the request on the strong connectivity of the digraph to $k$ while relying only on brambles as the routing structures.

Our second application deals with the asymmetric version of the $(k, c)$-DDP problem discussed in the introduction. By using our min-max relations, we manage to simplify and improve one of the main results of Giannopoulou et al. [11] for the case $c = 2$. Instead of using the Directed Grid Theorem [14] to reroute the paths through a cylindrical grid, we reroute them through a bramble of congestion two in a very easy manner after a careful choice of the paths reaching and leaving the bramble, which is done by applying the duality between $\mathsf{R}$-paths and $\mathsf{R}$-cuts. Namely, we can replace [10, Theorem 9.1] (this is the full version of [11]) entirely by Theorem 16 and mostly keep the remaining part of their proof to obtain an improved version of their $\mathsf{XP}$ algorithm for the asymmetric version of $(k, 2)$-DDP.

We hope that our min-max relations will find further applications in the future as, in our opinion, they are quite simple, robust, and versatile to be easily applicable to different types of routing problems in digraphs. A natural candidate is the $(k, c)$-DDP problem for any choice of fixed values of $c \geq 2$ and $k > c$, which has remained elusive for some time.

**Organization.** In Section 2 we present some preliminaries. In Section 3 we state and discuss our new Menger-like statements for paths in digraphs. The applications of our results are presented in Section 4. Due to space limitations, the proofs of the results marked with "$(\star)$" can be found in the full version of this paper, available at `https://arxiv.org/abs/2306.16134`.

## 2 Preliminaries

Due to space limitations, in this section we provide only the most important or non-standard preliminaries, and additional ones can be found in the full version of this paper, namely basic definitions of digraphs and matroids.

We refer the reader to [5, 7] for background on parameterized complexity, and we define here only the most basic definitions. A *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$. For an instance $I = (x, k) \in \Sigma^* \times \mathbb{N}$, $k$ is called the *parameter*. A parameterized problem $L$ is

*fixed-parameter tractable* (FPT) if there exists an algorithm $\mathcal{A}$, a computable function $f$, and a constant $c$ such that given an instance $I = (x, k)$, $\mathcal{A}$ (called an FPT *algorithm*) correctly decides whether $I \in L$ in time bounded by $f(k) \cdot |I|^c$. For instance, the Vertex Cover problem parameterized by the size of the solution is FPT. A parameterized problem $L$ is in XP if there exists an algorithm $\mathcal{A}$ and two computable functions $f$ and $g$ such that given an instance $I = (x, k)$, $\mathcal{A}$ (called an XP *algorithm*) correctly decides whether $I \in L$ in time bounded by $f(k) \cdot |I|^{g(k)}$. For instance, the Clique problem parameterized by the size of the solution is in XP.

Within parameterized problems, the class W[1] may be seen as the parameterized equivalent to the class NP of classical decision problems. Without entering into details, a parameterized problem being W[1]-*hard* can be seen as a strong evidence that this problem is *not* FPT. The canonical example of W[1]-hard problem is Clique parameterized by the size of the solution.

If $\mathcal{B}$ is a collection of sets, for conciseness we use $\bigcup\mathcal{B}$ to denote the set $\bigcup_{A\in\mathcal{B}} A$. For a positive integer $k$, we denote by $[k]$ the set $\{1, \ldots, k\}$. For a sequence of sets $\mathcal{B} = (B_1, \ldots, B_k)$, a *transversal* of $\mathcal{B}$ is a set $\{b_1, \ldots, b_k\}$ such that $b_i \in B_i$ for all $i \in [k]$. Here we remark that the terms in $\mathcal{B}$ need not be distinct but the elements in a transversal $\{b_1, \ldots, b_k\}$ are distinct. For a set of indices $J$, we use $(B_j \mid j \in J)$ to denote the sequence of sets indexed by $J$ so we can use $\mathcal{B} = (B_j \mid j \in [k])$. A *subsequence* of $\mathcal{B}$ is a sequence $(B_j \mid j \in J)$ for $J \subseteq [k]$. A *partial transversal* of $\mathcal{B}$ is a transversal of some subsequence of $\mathcal{B}$. For convenience, we extend all notation regarding transversals and partial transversals to collections of sets.

If $P$ is a path in a digraph $G$, we denote by $\mathsf{s}^-(P)$ and $\mathsf{s}^+(P)$ the first and last vertices of $P$, respectively. Every vertex of $P$ other than $\mathsf{s}^-(P)$ and $\mathsf{s}^+(P)$ is an *internal* vertex. For $A, B \in V(G)$, we say that $P$ is an $A \to B$ *path* if $\mathsf{s}^-(P) \in A$ and $\mathsf{s}^+(P) \in B$. For $A, B \subseteq V(G)$ an $(A, B)$-*separator* is a set $X \subseteq V(G)$ such that there are no $A \to B$ paths in $G \setminus X$.

Let $\mathcal{P}$ be a collection of paths in $G$. We use $\mathsf{s}^-(\mathcal{P})$ to denote $\bigcup_{P\in\mathcal{P}} \mathsf{s}^-(P)$ and $\mathsf{s}^+(\mathcal{P})$ to denote $\bigcup_{P\in\mathcal{P}} \mathsf{s}^+(P)$. For conciseness, we say henceforth that the paths in $\mathcal{P}$ are *disjoint* if they are pairwise vertex-disjoint. For $A, B \in V(G)$, we say that $\mathcal{P}$ is a collection of $A \to B$ paths if $\mathsf{s}^-(\mathcal{P}) \subseteq A$ and $\mathsf{s}^+(\mathcal{P}) \subseteq B$. For the remaining of this article and unless stated otherwise, $n$ is used to denote the number of vertices of the input digraph of the problem under consideration.

▶ **Theorem 1** (Menger's Theorem [18]). *Let $G$ be a digraph and $A, B \subseteq V(D)$. The maximum size of a collection of disjoint $A \to B$ paths is equal to the minimum size of an $(A, B)$-separator. Furthermore, a maximum size collection of paths and a minimum size separator can be found in time $\mathcal{O}(n^2)$.*

A digraph $G$ is *strongly connected* if for every $u, v \in V(G)$ there are paths from $u$ to $v$ and from $v$ to $u$ in $G$. A *separator* of $G$ is a set $X \subseteq V(G)$ such that $G \setminus X$ has a single vertex or is *not* strongly connected. If $G$ has at least $k + 1$ vertices and $k$ is the minimum size of a separator of $G$, we say that $G$ is $k$-*strongly connected* (or $k$-*strong* for short). A *strongly connected component* (or *strong component* for short) of a digraph $G$ is a maximal induced subgraph of $G$ that is strongly connected.

The *directed tree-width* of digraphs was introduced by Johnson et al. [12] as a directed analogue of tree-width of undirected graphs. Informally, the directed tree-width $\mathsf{dtw}(G)$ of a digraph $G$ measures how close $G$ can be approximated by a DAG, and the formal definition immediately implies that $\mathsf{dtw}(G) = 0$ if and only if $G$ is an acyclic digraph (DAG). Directed tree-width and arboreal decompositions are not explicitly used in this article and thus we refer the reader to [12] for the formal definitions. Here it suffices to mention a few known results. In the same paper where they introduced directed tree-width, Johnson et al. [12] showed that $k$-DDP can be solved in XP time with parameters $k + \mathsf{dtw}(G)$.

▶ **Proposition 2** (Johnson et al. [12]). *The $k$-DDP problem is solvable in time $n^{\mathcal{O}(k+\mathsf{dtw}(G))}$.*

Notice that every instance of the $(k,c)$-DDP problem with $c \geq k$ is trivially solvable in polynomial time by simply checking for connectivity between each pair $(s_i, t_i)$. Thus we can always assume that $c < k$. It is easy to reduce the congested version to the disjoint version of DDP: it suffices to generate a new instance by making $c$ copies of each vertex $v$ of the input digraph, each of them with the same in- and out-neighborhood as $v$. A formal proof of this statement was given by Amiri et al. [1]. Hence it follows that $(k,c)$-DDP is also XP with parameters $k$ and $\mathsf{dtw}(G)$. A direct proof of this statement is also possible by applying the same framework used to prove Proposition 2, although such a proof is not given in [12]. A similar proof for a congested version of a DDP-like problem is given by Sau and Lopes in [16]. In any case, the following holds.

▶ **Proposition 3.** *The $(k,c)$-DDP problem is solvable in time $(c \cdot n)^{\mathcal{O}(c(k+\mathsf{dtw}(G)))}$.*

For both the $k$-DDP and $(k,c)$-DDP problems, (a small variation of) the result of Slivkins [19] implies that the XP time is unlikely to be improvable to FPT, even when restricted to DAGs (although the result in [19] concerns the *edge*-disjoint version of $k$-DDP, it easily implies W[1]-hardness of the disjoint version by noticing that the line digraph of a DAG is also a DAG).

As it is the case with tree-width, Johnson et al. [12] also introduced a dual notion for directed tree-width in the form of *havens*. However, although the duality in the undirected case is sharp, in the directed case it is only approximate: they showed that the directed tree-width of a digraph $G$ is within a constant factor (more precisely, a factor three) from the maximum order of a haven of $G$. Since havens and (strict) *brambles* are interchangeable in digraphs whilst paying only a constant factor for the transformation (see [6, Chapter 6] for example), we skip the definition of the former and focus only on the latter.

▶ **Definition 4** (Brambles in digraphs). *A* bramble $\mathcal{B} = \{B_1, \ldots, B_\ell\}$ *in a digraph $G$ is a collection of strong subgraphs of $G$ such that if $B, B' \in \mathcal{B}$ then $V(B) \cap V(B') \neq \emptyset$ or there are edges in $G$ from $V(B)$ to $V(B')$ and from $V(B')$ to $V(B)$. We say that the elements of $\mathcal{B}$ are the* bags *of $\mathcal{B}$. A* hitting set *of a bramble $\mathcal{B}$ is a set $C \subseteq V(G)$ such that $C \cap V(B) \neq \emptyset$ for all $B \in \mathcal{B}$. The* order *of a bramble $\mathcal{B}$, denoted by $\mathsf{ord}(\mathcal{B})$, is the minimum size of a hitting set of $\mathcal{B}$. A bramble $\mathcal{B}$ is said to be* strict *if for all pairs $B, B' \in \mathcal{B}$ it holds that $V(B) \cap V(B') \neq \emptyset$. For an integer $c \geq 1$ we say that $\mathcal{B}$ has* congestion *$c$ if every vertex of $G$ appears in at most $c$ bags of $\mathcal{B}$.*

See Figure 1 for an example of a bramble. Notice that if $\mathcal{B}$ is a bramble of congestion $c$ for some constant $c$, its *order* increases together with its *size*; i.e., $|\mathcal{B}|$. More precisely, since every vertex of the host digraph can hit at most $c$ elements of $\mathcal{B}$ it holds that $\mathsf{ord}(\mathcal{B}) \geq \lceil |\mathcal{B}|/c \rceil$. If $\mathcal{B}' \subseteq \mathcal{B}$ then we may say that $\mathcal{B}'$ is a *subbramble* of $\mathcal{B}$.

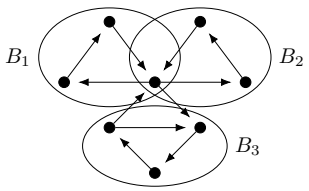

**Figure 1** Example of a bramble $\{B_1, B_2, B_3\}$ of order two.

Johnson et al. [12] gave an algorithm that, given a digraph $G$, either correctly decides that $\mathsf{dtw}(G) \leq 3k-2$ (also yielding an arboreal decomposition of $G$) or produces a bramble of order $\lfloor k/2 \rfloor$. This was later improved to an FPT algorithm by Campos et al. [4]. Although the authors do not explicitly say that the produced bramble is strict, it is easy to verify that this is the case in their proof, and the same holds for the proof of [12].

▶ **Proposition 5** (Campos et al. [4]). *Let $G$ be a digraph and $t$ be a non-negative integer. There is an algorithm running in time $2^{\mathcal{O}(t \log t)} \cdot n^{\mathcal{O}(1)}$ that either produces an arboreal decomposition of $G$ of width at most $3t-2$ or finds a strict bramble of order $t$ in $G$.*

Brambles of constant congestion are a key structure used to solve instances of $(k,c)$-DDP in $f(k)$-strong digraphs in the approach by Edwards et al. [8], as discussed in Section 4. In particular, they use the following result, originally proved by Kawarabayashi and Kreutzer [14] where an XP algorithm is given, and then improved by Campos et al. [4] with an FPT algorithm and a better dependency on $k$. We refer the reader to [4, 14] for the definition of well-linked sets, and we remark that, for convenience, we present the statement of the following result in a slightly different way than in the original article.

▶ **Proposition 6** (Campos et al. [4]). *Let $g(k) = (t+1)(\lfloor t/2 \rfloor + 1) - 1$ and $G$ be a digraph with directed tree-width at least $3g(t)-1$. There is an algorithm running in time $2^{\mathcal{O}(t^2 \log t)} \cdot n^{\mathcal{O}(1)}$ that finds in $G$ a bramble $\mathcal{B}$ of order $g(t)$, a path $P$ that intersects every bag of $\mathcal{B}$, and a well-linked set $X$ of size $t$ such that $X \subseteq V(P)$.*

▶ **Proposition 7** (Edwards et al. [8]). *There exists a function $f : \mathbb{N} \to \mathbb{N}$ satisfying the following. Let $G$ be a digraph and $t \geq 1$ be an integer. Let $P$ be a path in $G$ and $X \subseteq V(P)$ be a well-linked set with $|X| \geq f(t)$. Then $G$ contains a bramble $\mathcal{B}$ of congestion two and size $t$ and, given $G, P$, and $X$, we can find $\mathcal{B}$ in polynomial time.*

Pipelining Propositions 5–7 we obtain the following.

▶ **Corollary 8.** *There is a function $f : \mathbb{N} \to \mathbb{N}$ and an FPT algorithm with parameter $t$ that, given a digraph $G$ and an integer $t \geq 1$, either correctly decides that the directed tree-width of $G$ is at most $f(t)$ or finds a bramble $\mathcal{B}$ of congestion two and size $t$ in $G$.*

## 3 New Menger-like statements for paths and cuts in digraphs

In this section we present the definition and the min-max formulas associated with each pair D-paths/D-cuts, T-paths/T-cuts, and R-paths/R-cuts. Since all three types of paths share some properties (in fact, the major distinction between them is in how they reach their destinations), it is convenient to adopt the following notations.

▶ **Definition 9** (Digraph-source sequences and respecting paths). *For an integer $\ell \geq 1$, a* digraph-source sequence *of* size $\ell$ *is a pair $(\mathcal{F}, \mathcal{S})$ such that $\mathcal{F} = (G_1, \ldots, G_\ell)$ is a sequence of digraphs and $\mathcal{S} = (S_1, \ldots, S_\ell)$ is a sequence of subsets of vertices with $S_i \subseteq V(G_i)$ for $i \in [\ell]$. We say that a set of paths $\mathscr{P}$* respects *$(\mathcal{F}, \mathcal{S})$ or, alternatively, is $(\mathcal{F}, \mathcal{S})$*-respecting *if there is a partition $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ of $\mathscr{P}$ such that*
**(a)** *for $i \in [\ell]$, $\mathcal{P}_i$ is a set of disjoints paths in $G_i$, and*
**(b)** *for $i \in [\ell]$, $\mathsf{s}^-(\mathcal{P}_i) \in S_i$.*
*In this case, we say that $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ is a* defining partition *of $\mathscr{P}$.*

Thus in any set of $(\mathcal{F}, \mathcal{S})$-respecting paths, any two paths can intersect only if they belong to distinct parts of the defining partition.

To provide some intuition within the context of the $(k, c)$-DDP problem, in the next three definitions one can think of the sequence $(S_1, \ldots, S_\ell)$ as being formed by many copies of $S$ followed by many copies of $T$. Notice that any set of $(\mathcal{F}, \mathcal{S})$-respecting paths includes paths *leaving* $T$, which seems counter-intuitive when considering the goal of solving instances of $(k, c)$-DDP. We remark this can be easily addressed by associating, with each copy of $T$ in the sequence $\mathcal{S}$, the digraph $G^{\mathsf{rev}}$ obtained by reversing the orientation of every edge of $G$.

**D-paths and D-cuts.** Within the context of this paper, D-paths and D-cuts are used as a tool to prove our results regarding T-paths and T-cuts. In this scenario, one should think of the set $B$ in the following definition as the set of vertices of a highly connected structure that is intended to be used to appropriately connect the last vertices of paths from $S$ to the first vertices of paths from $T$.

▶ **Definition 10** (D-paths and D-cuts). *For an integer $\ell \geq 1$, let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence with $\mathcal{F} = (G_1, \ldots, G_\ell)$, $\mathcal{S} = (S_1, \ldots, S_\ell)$, and $B \subseteq \bigcup_{i=1}^{\ell} V(G_i)$. With respect to $B$, we say that a set of $(\mathcal{F}, \mathcal{S})$-respecting paths $\mathscr{P}$ with defining partition $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ is a set of* D-paths *if*

**(1)** *for all distinct $P, P' \in \mathscr{P}$ it holds that $\mathsf{s}^+(P) \neq \mathsf{s}^+(P')$, and*

**(2a)** $\mathsf{s}^+(\mathscr{P}) \subseteq B$.

*A* D-cut *is a sequence $\mathcal{X} = (X_0, \ldots, X_\ell)$ with $X_0 \subseteq B$ such that, for $i \in [\ell]$, the set $X_i \subseteq V(G_i)$ is an $(S_i, B \setminus X_0)$-separator in $G_i$. The* order *of a D-cut $X$ is $\mathsf{ord}(\mathcal{X}) = |X_0| + \sum_{i=1}^{\ell} |X_i|$.*

Thus, in the definition of D-paths we ask each collection of paths associated with each $\mathcal{P}_i$ to be pairwise disjoint in $G_i$, and the paths from distinct parts $\mathcal{P}_i, \mathcal{P}_j$ may share vertices in $\bigcup_{i=1}^{\ell} V(G_i)$ other than the last vertices of the paths. The "D" in the name stands for "disjoint". For the min-max formula, we prove the following.

▶ **Theorem 11** ($\star$). *Let $(\mathcal{F}, \mathcal{S})$ be digraph-source sequence of size $\ell$ with $\mathcal{F} = (G_1, \ldots, G_\ell)$, and let $B \subseteq \bigcup_{i=1}^{\ell} V(G_i)$. With respect to $\mathcal{F}, \mathcal{S}$, and $B$, the maximum number of D-paths is equal to the minimum order of a D-cut. Additionally, a D-cut of minimum order and a maximum collection of D-paths can be found in time $\mathcal{O}((\ell \cdot n^* + |\mathcal{B}|)^2)$ where $n^* = \max_{i \in [\ell]}(|V(G_i)|)$.*

**T-paths and T-cuts.** For the sake of intuition, in the next definition one should think of $\mathcal{B}$ as a bramble. Informally, and given a digraph $G$, we use T-paths and T-cuts to find a large collection of paths from a given ordered $S \subseteq V(G)$ to the bags of a subbramble $\mathcal{B}^S \subseteq \mathcal{B}$, and from the bags of another subbramble $\mathcal{B}^T \subseteq \mathcal{B}$ to $T$ (we can achieve this orientation for these paths by reversing the orientation of the edges of $G$), while ensuring that every vertex outside of $\mathcal{B}$ appears in at most two of those paths, and that all elements of $\mathcal{B}^S \cup \mathcal{B}^T$ are pairwise distinct. The first property can be achieved by simply applying Menger's Theorem (cf. Theorem 1) twice. However, by doing this, we can end with a set of paths all ending on the same bag of $\mathcal{B}$. This scenario is far from ideal, since at some point the goal is to use the strong connectivity of $G[B \cup B']$ for every $B, B' \in \mathcal{B}$ to appropriately connect the ending vertices of the paths from $S$ to the starting vertices of the paths to $T$, while maintaining the property that every vertex appears in at most two (or $c$, in the general case) of those paths. If a unique bag $B$ contains all starting and ending vertices of the paths, then connecting those vertices while maintaining such properties may be as hard as finding a solution to an instance of $(k, c)$-DDP in the strong digraph $G[B]$, or downright impossible to do.

Therefore, in the proofs applying similar techniques, as seen in the works by Edwards et al. [8] and by Giannopoulou et al. [10], there is considerable effort into finding paths with "good properties" that can be used to connected the paths inside of $\mathcal{B}$ (or inside of a

cylindrical grid in the case of [10]), and these properties always include, as far as we know, that the paths end or start in distinct bags of $\mathcal{B}$ (or distinct sections of the cylindrical grid). In particular, [8, Lemma 16] includes a set of seven properties over a set of paths that we can substitute by T-paths to achieve better results in a simpler manner.

We can prove the same results using R-paths and R-cuts, which are simpler than T-paths and T-cuts. We include the proofs for the two latter objects for potential applications in which the extra properties of T-paths and T-cuts may become handy.

▶ **Definition 12** (T-paths and T-cuts). *For an integer $\ell \geq 1$, let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence with $\mathcal{F} = (G_1, \ldots, G_\ell)$ and $\mathcal{S} = (S_1, \ldots, S_\ell)$, and $\mathcal{B}$ be a family of subsets of $\bigcup_{i=1}^{\ell} V(G_i)$. With respect to $\mathcal{B}$, we say that a set of $(\mathcal{F}, \mathcal{S})$-respecting paths $\mathscr{P}$ with defining partition $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ is a set of* T-paths *if*
**(1)** *for all distinct $P, P' \in \mathscr{P}$ it holds that $\mathsf{s}^+(P) \neq \mathsf{s}^+(P')$, and*
**(2b)** *the set $\mathsf{s}^+(\mathscr{P})$ is a partial transversal of $\mathcal{B}$.*
*A* T-cut *is a pair $(\mathcal{B}', \mathcal{X})$ with $\mathcal{B}' \subseteq \mathcal{B}$ and such that $\mathcal{X}$ is a D-cut with respect to $\mathcal{F}, \mathcal{S}$, and $\bigcup\mathcal{B}'$. The* order *of a T-cut $(\mathcal{B}', X)$ is $\mathsf{ord}(\mathcal{B}', X) = |\mathcal{B} \setminus \mathcal{B}'| + \mathsf{ord}(\mathcal{X})$.*

For convenience, we keep only one set of parenthesis, writing $\mathsf{ord}(\mathcal{B}', \mathcal{X})$ instead of $\mathsf{ord}((\mathcal{B}', \mathcal{X}))$.

Notice that conditions **(1)** in the definition of T-paths is the same as in the definition of D-paths. Thus the difference between D-paths and T-paths is that in the former we ask the paths to end in distinct vertices of $B$, while in the latter we ask the endpoints of the paths to form a partial transversal of $\mathcal{B}$. This implies that those endpoints are distinct, and that each of them is associated with a unique element of $\mathcal{B}$. The "T" in the name stands for "transversal". See Figure 2 for an example of a transversal of a collection of sets.

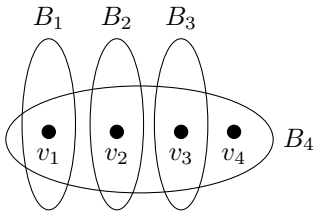

**Figure 2** Example of a transversal of the collection $\{B_1, B_2, B_3, B_4\}$. For $i \in [4]$ the vertex $v_i$ is associated with the set $B_i$.

For the T-paths/T-cuts duality, we prove the following.

▶ **Theorem 13** (⋆). *Let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence of size $\ell$ with $\mathcal{F} = (G_1, \ldots, G_\ell)$, and let $\mathcal{B}$ be a collection of subsets of $\bigcup_{i=1}^{\ell} V(G_i)$. With respect to $\mathcal{F}, \mathcal{S}$, and $\mathcal{B}$, the maximum number of T-paths is equal to the minimum order of a T-cut. Additionally, a T-cut of minimum order and a maximum collection of T-paths can be found in time $\mathcal{O}((\ell \cdot n^* + |\mathcal{B}|)^2)$, where $n^* = \max_{i \in [\ell]}(|V(G_i)|)$.*

**R-paths and R-cuts.** The intuition for R-paths is similar to the one for T-paths, as is the motivation to use these objects in the context of $(k, c)$-DDP and similar problems. The difference between them is that, if $\mathscr{P}$ is a set of T-paths, then all vertices of the form $\mathsf{s}^+(P)$, where $P \in \mathscr{P}$, are distinct. In R-paths this only holds when considering paths inside of the same part of its defining partition. More precisely, given a partition $\mathcal{P}$ of a set of R-paths as defined below, $\mathsf{s}^+(P)$ and $\mathsf{s}^+(P')$ are guaranteed to be disjoint only when $P$ and $P'$ are in distinct parts of $\mathcal{P}$. In Section 4 we show that this relaxation poses no problem for the application of R-paths/R-cuts we show in this article.

▶ **Definition 14** (R-paths and R-cuts). *For $\ell \geq 1$, let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence with $\mathcal{F} = (G_1, \ldots, G_\ell)$ and $\mathcal{S} = (S_1, \ldots, S_\ell)$, and $\mathcal{B}$ be a family of subsets of $\bigcup_{i=1}^{\ell} V(G_i)$. With respect to $\mathcal{B}$, we say that a set of $(\mathcal{F}, \mathcal{S})$-respecting paths $\mathscr{P}$ with defining partition $\mathcal{P}_1, \ldots, \mathcal{P}_\ell$ is a set of* R-paths *if*

**(1c)** *for some family $\mathcal{B}^* \subseteq \mathcal{B}$ there is a bijective mapping $h : \mathscr{P} \to \mathcal{B}^*$ such that $h(P) = B$ implies $\mathsf{s}^+(P) \in B$.*

*An* R-cut *is a pair $(\mathcal{B}', \mathcal{X})$ where $\mathcal{B}' \subseteq \mathcal{B}$ and $\mathcal{X}$ is a sequence $(X_1, \ldots, X_\ell)$ such that each $X_i \in \mathcal{X}$ is an $(S_i, \bigcup \mathcal{B}')$-separator in $G_i$. The* order *of an R-cut $(\mathcal{B}', \mathcal{X})$ is $\mathsf{ord}(\mathcal{B}', \mathcal{X}) = |\mathcal{B} \setminus \mathcal{B}'| + \sum_{i=1}^{\ell} |X_i|$.*

We remark that the only difference between R-paths and T-paths is that, in the latter, condition **(1)** ensures that all vertices forming the partial transversal of $\mathcal{B}$ are distinct. The "R" in the name stands for "representatives". For the duality, we prove the following.

▶ **Theorem 15** (⋆). *Given a digraph-source sequence $(\mathcal{F}, \mathcal{S})$ of size $\ell$ and a set $B \subseteq \bigcup_{i=1}^{\ell} V(G_i)$ then, with respect to $\mathcal{F}, \mathcal{S}$, and $B$, the maximum number of R-paths is equal to the minimum order of an R-cut. Additionally, an R-cut of minimum order and a maximum collection of R-paths can be found in $\mathcal{O}((k \cdot n^* + |\mathcal{B}|)^2)$ where $n^* = \max_{i \in [\ell]}(|V(G_i)|)$.*

Observe that the right side of the pair forming an R-cut cannot be simply a set of vertices $X$ because, for example, a vertex $v \in X$ can be in two distinct $G_i$ and $G_j$ and be part of the separator in $G_i$ but *not* part of the separator in $G_j$. In this case $v$ would be counted twice in the order of the R-cut, but it is only used in one separator. Also notice that when $|\mathcal{B}|$ is larger than the allowed budget to construct an R-cut, every R-cut of appropriate order must identify some separator in some $G_i$, i.e., $\mathcal{X} \neq \emptyset$. In fact, there are only two options for the size of $\mathcal{X}$: either $\mathcal{B}' = \emptyset$ and hence $\mathcal{X} = \emptyset$, or $\mathcal{B}' \neq \emptyset$ and $|\mathcal{X}| = \ell$. In the latter case, it is possible that some $X_i \in \mathcal{X}$ are empty. In Lemma 19 we exploit this fact to show how to either find in a digraph $G$ a large collection of R-paths from a set $S$ to the vertices appearing in the elements of some sufficiently large collection $\mathcal{B}$ (corresponding to a bramble), or a small separator intersecting every path from $S$ to all such vertices.

## 4 Applications

In this section we show how to exploit the duality between R-paths and R-cuts to improve on results by Edwards et al. [8] and Giannopoulou et al. [11]. The following is the main result that we prove, and then we use it to improve on results by [8, 11].

▶ **Theorem 16.** *Let $k, c$ be integers with $k, c \geq 2$ and $g(k, c) = 2k(c \cdot k - c + 2) + c(k - 1)$. Let $G$ be a digraph, assume that we are given the bags of a bramble $\mathcal{B}$ of congestion $c$ and size at least $g(k, c)$, and $S, T \subseteq V(G)$ with $S = \{s_1, \ldots, s_k\}$ and $T = \{t_1, \ldots, t_k\}$. Then in time $\mathcal{O}(k^4 \cdot n^2)$ one can either*

1. *find a $\mathcal{B}^* \subseteq \mathcal{B}$ with $|\mathcal{B}^*| \geq g(k, c) - c(k-1)$ and an $(S, \bigcup \mathcal{B}^*)$-separator $X_S$ with $|X_S| \leq k-1$ that is disjoint from all bags of $\mathcal{B}^*$, or*
2. *find a $\mathcal{B}^* \subseteq \mathcal{B}$ with $|\mathcal{B}^*| \geq g(k, c) - c(k-1)$ and an $(\bigcup \mathcal{B}^*, T)$-separator $X_T$ with $|X_T| \leq k-1$ that is disjoint from all bags of $\mathcal{B}^*$, or*
3. *find a set of paths $\{P_1, \ldots, P_k\}$ in $G$ such that each $P_i$ with $i \in [k]$ is a path from $s_i$ to $t_i$ and each vertex of $G$ appears in at most $c$ of these paths.*

Theorem 16 yields an XP algorithm with parameter $k$ for the $(k, c)$-DDP problem in $k$-strong digraphs, as we proceed to discuss. First, we remark that the XP time is only required when a large bramble of congestion at most $c$ is not provided. If this is the case, we

first look at the directed tree-width of $G$, which can be approximated in FPT time applying Proposition 5. If $\mathsf{dtw}(G) \leq f(k)$ for some computable function $f$, then we solve the problem applying Proposition 3. Otherwise, we apply the machinery by Edwards et al. [8] pipelining Propositions 6 and 7 to obtain a large bramble of congestion two in digraphs of large directed tree-width, and use Theorem 16 to find a solution in polynomial time, which we show to always be possible. When assuming that the input digraph is $k$-strong, only the third output of Theorem 16 is possible, and therefore as a direct consequence of Theorem 16 we obtain the following.

▶ **Theorem 17.** *Let $G$ be a $k$-strong digraph and $\mathcal{B}$ be a bramble of congestion $c \geq 2$ with $|\mathcal{B}| \geq 2k(c \cdot k - c + 2) + c(k-1)$. Then for any ordered sets $S, T \subseteq V(G)$ both of size $k$, the instance $(G, S, T)$ of $(k,c)$-DDP with $c \geq 2$ is positive and a solution can be found in time $\mathcal{O}(k^4 \cdot n^2)$.*

As mentioned in the introduction, our result improves over the result of Edwards et al. [8] by relaxing the strong connectivity of the input digraph from $36k^3 + 2k$ to $k$ (and this bound is close to the best possible unless P = NP), by needing a smaller bramble (from size $188k^3$ to $4k^2 + 2k - 2$ when $c = 2$), and because the proof is simpler and shorter. Finally, applying Corollary 8, Proposition 3, and Theorem 17 (thus again using Proposition 7 by [8]) we immediately obtain the following.

▶ **Corollary 18.** *For every integer $c \geq 2$, the $(k,c)$-DDP problem is solvable in XP time with parameter $k$ in $k$-strong digraphs.*

As a tool to prove Theorem 16, we first show how we can take many copies of digraphs $G$ and $G'$, say $\ell$ copies of each, to either find $2\ell \cdot k$ R-paths to a given collection $\mathcal{B}$ of sufficiently large size, or find an appropriate separator of size at most $k-1$ in $G$ or in $G'$.

▶ **Lemma 19.** *Let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence where $\mathcal{F}$ contains $\ell$ copies of a digraph $G_S$ and $\ell$ copies of a digraph $G_T$, in this order, and $\mathcal{S}$ contains $\ell$ copies of a set $S \subseteq V(G_S)$ and $\ell$ copies of a set $T \subseteq V(G_T)$, in this order, where $|S| = |T| = k$. Finally, let $\mathcal{B}$ be a collection of subsets of $V(G)$ with $|\mathcal{B}| \geq 2\ell \cdot k$. Then either there is a set of R-paths with respect to $\mathcal{F}, \mathcal{S}$, and $\mathcal{B}$ of size at least $2\ell \cdot k$, or for some non-empty $\mathcal{B}' \subsetneq \mathcal{B}$ there is an R-cut $(\mathcal{B}', \mathcal{X})$ of order at most $2\ell \cdot k - 1$ such that $\mathcal{X}$ contains $\ell$ copies of an $(S, \bigcup \mathcal{B}')$-separator $X_S$ followed by $\ell$ copies of an an $(T, \bigcup \mathcal{B})$-separator $X_T$ with $|X_S| + |X_T| \leq 2k - 1$.*

**Proof.** Assume that the maximum size of a set of R-paths with respect to $\mathcal{F}, \mathcal{S}$, and $\mathcal{B}$ is at most $2\ell \cdot k - 1$. Then by Theorem 15 there is a minimum R-cut $Y = (\mathcal{B}', \mathcal{X}')$ of order at most $2\ell \cdot k - 1$.

Since $|\mathcal{B}| \geq 2\ell \cdot k$ we conclude that $\mathcal{B}' \neq \emptyset$ and thus $|\mathcal{X}'| = 2\ell$. (we refer the reader to the discussion in the end of the first part of Section 3). Hence by the choice of $\mathcal{F}$ and $\mathcal{S}$ and the definition of R-cuts, we can construct an R-cut $(\mathcal{B}', \mathcal{X})$ with the same order as $Y$ by simply including in $\mathcal{X}$ exactly $\ell$ copies of the $(S, \bigcup \mathcal{B}')$-separator $X_S$ contained in $\mathcal{X}'$, and $\ell$ copies of the $(T, \bigcup \mathcal{B}')$-separator $X_T$ contained in $\mathcal{X}'$. Thus the newly generated R-cut satisfies $|\mathcal{B} \setminus \mathcal{B}'| + \ell(|X_S| + |X_T|) = \mathsf{ord}(\mathcal{B}', \mathcal{X}) = \mathsf{ord}(\mathcal{B}', \mathcal{X}') \leq 2\ell k - 1$. This immediately implies that $|X_S| + |X_T| \leq 2k - 1$ and the result follows. ◀

Now the plan is to apply twice the duality between R-paths and R-cuts. In the first application, we consider the digraph-source sequence formed by $2k(c \cdot k - c + 1)$ copies of $G_S = G$ and then exactly as many copies of $G_T = G^{\mathsf{rev}}$, and the same number of copies of $S$ and $T$, also in this order. If we do not find a set of $2k(c \cdot k - c + 1)$ R-paths to the bags of the

bramble, then we apply Lemma 19 and find an R-cut $(\mathcal{B}', \mathcal{X})$ of small order and a separator of size at most $k-1$ in $G_S$ or $G_T$. Since the given bramble has congestion $c$, we show that we can stop with output **1** or **2** of Theorem 16 by taking the bramble $\mathcal{B}^*$ containing all bags of $\mathcal{B}$ that are disjoint from the small separator. This holds because no bag of $\mathcal{B}^*$ can be in the "wrong side" of the separator. That is, if for instance there is an $S \to A$ path $P$ avoiding the separator $X_S$ of size at most $k-1$ in $G_S$, then every bag of $\mathcal{B}^*$ must be in $\mathcal{B} \setminus \mathcal{B}'$ since otherwise one can construct a path in $G_S \setminus X_S$ from $S$ to a bag of $\mathcal{B}'$ by using $P$ and the connectivity properties of the bramble. In this case, we also arrive at a contradiction since the size of $\mathcal{B}^*$ is too large to be contained in the R-cut.

If the R-paths are found, then we refine the digraph by carefully choosing edges to delete from $G$ in such a way that, from a second application of the duality between R-paths and R-cuts, we are guaranteed to find $2k$ R-paths that can be used to construct the $\{s_i\} \to \{t_i\}$ paths while maintaining the congestion under control. In the refined digraph, we keep the R-paths found in the first iteration and delete edges leaving vertices of the bramble appearing in bags that were not used as destinations for the R-paths. We apply Lemma 19 in this digraph and show that the only possible outcome is that the R-paths are found. Otherwise, there is an R-cut of order at most $2k-1$ and hence there is a $\mathcal{B}'' \subseteq \mathcal{B}$ that contains at least one bag $A$ that is not in the R-cut and is disjoint from the separator, say $X'_S$, of size at most $k-1$ that is part of the R-cut. Now the size of $X'_S$ implies that there is a path from $S$ to a bag disjoint from $X'_S$ avoiding the separator, and thus we can reach $A$ from $S$ avoiding $X'_S$. Finally, the refined digraph allows us to associate each vertex of the bramble used by a path in $\{P_1, \ldots, P_k\}$ with a bag of the bramble, depending on where the vertex appears in the path, in such a way that no vertex is associated twice with the same bag by two distinct paths. Together with the bound on the congestion of the bramble, this immediately implies that every vertex of the digraph appears in at most $c$ paths of the set $\{P_1, \ldots, P_k\}$.

**Proof of Theorem 16.** Let $G$, $S$, $T$, and $\mathcal{B}$ be as in the statement of the theorem. Define $G_S = G$ and $G_T = G^{\mathsf{rev}}$ and let $(\mathcal{F}, \mathcal{S})$ be a digraph-source sequence with $\mathcal{F}$ containing, in order, $c \cdot k - c + 1$ copies of $G_S$ followed by $c \cdot k - c + 1$ copies of $G_T$, and $\mathcal{S}$ containing, in order, the same number of copies of $S$ followed by exactly as many copies of $T$. Now, applying Lemma 19 with respect to $\mathcal{F}, \mathcal{S}, \mathcal{B}$, and $\ell = c \cdot k - c + 1$, we conclude that either there are $2k(c \cdot k - c + 1)$ R-paths or, for some $\mathcal{B}' \subseteq \mathcal{B}$ there is an R-cut $(\mathcal{B}', \mathcal{X})$ where $\mathcal{X}$ contains $\ell$ copies of an $(S, \bigcup \mathcal{B}')$-separator $X_S$ and $\ell$ copies of an an $(S, \bigcup \mathcal{B}')$-separator $X_T$ with $|X_S| + |X_T| \leq 2k - 1$. We first consider the case where the separators are obtained. Thus $|X_S| \leq k-1$ or $|X_T| \leq k-1$. Since both cases are symmetric (the $T \to X_T$ paths become $X_T \to T$ paths when we restore the orientation of the edges of $G_T$), we suppose without loss of generality that $|X_S| \leq k-1$.

Let $\mathcal{B}^*$ contain all bags of $\mathcal{B}$ that are disjoint from $X_S$. Since $\mathcal{B}$ has congestion $c$ we conclude that $|\mathcal{B}^*| \geq g(k,c) - c(k-1)$. We show that no vertex appearing in a bag of $\mathcal{B}^*$ is reachable from $S$ in $G_S \setminus X_S$. By contradiction, assume that there is an $S \to A$ path $P$ in $G_S \setminus X_S$ for some $A \in \mathcal{B}^*$. If there is $A' \in \mathcal{B}^* \cap \mathcal{B}'$ then we can use the strong connectivity of $G_S[A \cup A']$ and the path $P$ to construct an $S \to A'$ path in $G_S \setminus X_S$, contradicting the choice of $X_S$. Thus in this case $\mathcal{B}^*$ must be entirely contained in $\mathcal{B} \setminus \mathcal{B}'$. Again we obtain a contradiction since $2k(c \cdot k - c + 2) \leq |\mathcal{B}^*| \leq |\mathcal{B} \setminus \mathcal{B}'| \leq \mathsf{ord}(\mathcal{B}', \mathcal{X}) < 2k(c \cdot k - c + 1)$. In other words, the existence of path from $S$ to a vertex in a bag of $\mathcal{B}^*$ avoiding $X_S$ implies that every bag of $\mathcal{B}^*$ is reachable from $S$ in $G_S \setminus X_S$ and thus such path cannot exist since $\mathcal{B}^*$ is too large to be contained in any R-cut of order less than $2k(c \cdot k - c + 1)$. We conclude that no bag $A \in \mathcal{B}^*$ is reachable from $S$ in $G_S \setminus X_S$, and and output **1** of the theorem follows. Symmetrically, output **2** of the theorem follows if $|X_T| \leq k-1$.

Assume now that a set of R-paths $\mathscr{P}$ of size at least $2k(c \cdot k - c + 1)$ is found. Let $\mathcal{B}^1 \subseteq \mathcal{B}$ and let $h : \mathscr{P} \to \mathcal{B}^1$ be the bijective mapping as in **(1c)** of Definition 14. Thus $h(p) = B$ implies that $\mathsf{s}^+(P) \in B$. Since $|S| = |T| = k$, we can split $\mathscr{P}$ into two sets of equal size $\mathscr{P}^S$ and $\mathscr{P}^T$, where every path in $\mathscr{P}^S$ is a path leaving $S$ in $G_S$ and every path in $\mathscr{P}^T$ is a path leaving $T$ in $G_T$. We define $\mathcal{B}_S = \{h(P) \in \mathcal{B}^1 \mid P \in \mathscr{P}^S\}$ and $\mathcal{B}_T = \{h(P) \in \mathcal{B}^1 \mid P \in \mathscr{P}^T\}$. The next step is to refine $\mathscr{P}$ to make it *minimal with respect to* $\mathcal{B}$. That is, we say that $\mathscr{P}$ is $\mathcal{B}$-*minimal* if no path of $\mathscr{P}$ contains an internal vertex that is in a bag $\mathcal{B} \setminus (\mathcal{B}_S \cup \mathcal{B}_T)$. In other words, when following a path $P \in \mathscr{P}$ from the first to the last vertex, if we find an internal vertex $v$ in a bag $B$ that is not in $\mathcal{B}_S$ nor in $\mathcal{B}_T$, we swap $P$ in $\mathscr{P}$ by its subpath ending in $v$ and update $\mathcal{B}_S$ or $\mathcal{B}_T$ accordingly. Clearly, condition **(1c)** of Definition 14 still hold with respect to the new choice of $\mathscr{P}$, and therefore from now on we assume that $\mathscr{P}$ is $\mathcal{B}$-minimal. This property is important later to bound the maximum number of times that a vertex can appear in the $S \to T$ paths we construct.

Next, we reduce $G_S$ and $G_T$ to digraphs that are still well connected to $\mathcal{B}$, thus ensuring that we can find a large set of R-paths in the new digraphs, in which we can maintain control over how many times a vertex can appear in the $S \to T$ paths we construct from these new R-paths. To this end, define

$$V_S = \bigcup_{P \in \mathscr{P}^S} (V(P) \setminus \{\mathsf{s}^+(P)\}) \cup \bigcup_{A \in \mathcal{B}_S} A \quad \text{and} \quad V_T = \bigcup_{P \in \mathscr{P}^T} (V(P) \setminus \{\mathsf{s}^+(P)\}) \cup \bigcup_{A \in \mathcal{B}_T} A. \tag{1}$$

Finally, we construct the digraphs $G'_S$ and $G'_T$ starting from $G_S$ and $G_T$, respectively, applying the following two rules:

- For every $v \in V(G_S)$, if $v \in (\bigcup \mathcal{B}) \setminus V_S$ then we delete from $G'_S$ every edge leaving $v$.
- For every $v \in V(G_T)$, if $v \in (\bigcup \mathcal{B}) \setminus V_T$ then we delete from $G'_T$ every edge leaving $v$.

Consider the digraph-source sequence $(\{G'_S, G'_T\}, \{S, T\})$ and let $\mathcal{B}' = \mathcal{B} \setminus (\mathcal{B}_S \cup \mathcal{B}_T)$, and notice that $\mathcal{B}'$ may not be a bramble in $G'_S$ nor in $G'_T$. Clearly $|\mathcal{B}'| \geq g(k,c) - 2k(c \cdot k - c + 1) = c(k-1) + 2k > 2k$. We apply Lemma 19 with respect to $\{G'_S, G'_T\}, \{S, T\}$ (and thus $\ell = 1$), and $\mathcal{B}'$, to either obtain a set of R-paths $\mathscr{P}'$ of size at least $2k$ or an R-cut $(\mathcal{B}'', \{X'_S, X'_T\})$ with order at most $2k-1$ where $|X'_S| + |X'_T| \leq 2k-1$ and $\mathcal{B}'' \neq \emptyset$. We claim that only the first output is possible. By contradiction, assume that the R-cut and the separators were obtained and, without loss of generality, that $|X_S| \leq k-1$. First notice that the upper bound on the order of the R-cut implies that $|\mathcal{B}'' \setminus \mathcal{B}'| \geq c(k-1) + 1$. Since $|X_S| \leq k-1$ this implies that there is at least one bag $A' \in \mathcal{B}''$ that is disjoint from $X_S$ and not included in R-cut.

Now, set $q = 2(c \cdot k - c + 1)$ and let $\mathcal{P}_1, \ldots, \mathcal{P}_q$ be the defining partition of $\mathscr{P}$. That is, for every $i \in [q]$, the part $\mathcal{P}_i$ is a set of $k$ disjoint paths in the $i$-th digraph of $\mathcal{F}$ (this is possible since $|S| = |T| = k$ and hence $\mathscr{P}$ cannot contain more than $k$ disjoint paths in any digraph in $\mathcal{F}$). Thus exactly $q/2$ parts $\mathcal{P}_i$ contain only paths starting in $S$. Now the size of $X_S$ allows it to intersect at most $c(k-1)$ bags of $\mathcal{B}$, and thus for some $\mathcal{P}_i$ no bag in $\mathcal{B}_i = \{A \in \mathcal{B}_S \mid P \in \mathcal{P}_i \text{ and } \mathsf{s}^+(P) \in A\}$ is intersected by $X'_S$. Since $|X'_S| \leq k-1$, there is a $P \in \mathcal{P}_i$ from $S$ to a bag $A \in \mathcal{B}_i$ that is not intersected by $X'_S$. By the choice of $G'_S$ this path also exists in this digraph and, since $\mathsf{s}^+(P) \in A$ and $A \in \mathcal{B}_S$, every edge of $G_S$ leaving every vertex in $A$ is kept in $G'_S$ and thus $G'_S[A]$ is strong. Now, as $\mathcal{B}$ is a bramble, we can construct a path from $S$ to $A'$ (remember that $A' \in \mathcal{B}''$ and $A' \cap X_S = \emptyset$) by following the path $P$ and then taking a path from $\mathsf{s}^+(P)$ to $A'$ in $G'_S[A \cup A']$, which in turn is guaranteed to exist since either $A \cap A' \neq \emptyset$ or there is an edge from $A$ to $A'$ in $G'_S$. This contradicts our assumption that $(\mathcal{B}'', \{X'_S, X'_T\})$ is an R-cut and the claim follows.

Assume now that a set $\mathscr{P}'$ of $2k$ R-paths is obtained. Therefore, there are disjoint paths $\{Q_1^S, \ldots, Q_k^S\}$ leaving $S$ and disjoint paths $\{Q'_1, \ldots, Q'_k\}$ leaving $T$ in $\mathscr{P}$. By recovering the orientation of the edges of $G'_T$ (we remind the reader that $G_T = G^{\mathsf{rev}}$), we construct paths $\{Q_1^T, \ldots, Q_k^T\}$ *reaching* $T$ in $G$ and, by renaming the paths if needed, we assume that, for $i \in [k]$, each $Q_i^S$ is a path starting in $s_i$ and each $Q_i^T$ is a path ending in $t_i$. Moreover, by condition **(1c)** in the definition of R-paths (see Definition 14), each $\mathsf{s}^+(Q_i^S)$ is associated with a unique bag $A_i \in \mathcal{B}$ and each $\mathsf{s}^-(Q_i^T)$ is associated with a unique bag $A'_i \in \mathcal{B}$, such that all bags $A_1, \ldots, A_k, A'_1, \ldots, A'_k$ are distinct. Hence, since $\mathcal{B}$ is a bramble, it follows that for every $i \in [k]$ we can find a shortest path $Q_i$ from $\mathsf{s}^+(Q_i^S)$ to $\mathsf{s}^-(Q_i^T)$ in the strong digraph $G[A_i \cup A'_i]$. Finally, we construct the desired paths $\{P_1, \ldots, P_k\}$, such that each $P_i$ with $i \in [k]$ is a path from $s_i$ to $t_i$, by appending $Q_i$ to $Q_i^S$ and then $Q_i^T$ to the resulting path. Notice that this construction may result in a walk instead of a path, but every walk can be easily shortened into a path $P_i$.

We now claim that every vertex of $G$ appears in at most $c$ paths of the collection $\{P_1, \ldots, P_k\}$. First, notice that since the paths $\{Q_1^S, \ldots, Q_k^S\}$ are disjoint and the paths $\{Q_1^T, \ldots, Q_k^T\}$ are disjoint as well, any vertex not appearing in any bag of $\mathcal{B}$ can appear in at most two paths of $\{P_1, \ldots, P_k\}$. Assume now that $v$ is a vertex appearing in some bag of $\mathcal{B}$. Depending on where $v$ is located in the paths $Q_i^S$, $Q_i^T$, and $Q_i$, we associate $v$ with a bag of $\mathcal{B}$. Since $\mathcal{B}$ has congestion $c$, this immediately validates the claim and the result follows. We remind the reader of our assumption that $\mathscr{P}$ is $\mathcal{B}$-minimal, and look again at Equation 1. If $v$ is in $V_S$ because $v$ is in path $P \in \mathscr{P}^S \cup \mathscr{P}^T$ and $v \neq \mathsf{s}^+(P)$, then we say that $v$ is a *type* 1 vertex. Otherwise, we say that $v$ is a *type* 2 vertex.

For $i \in [k]$, if $v$ is a internal vertex of some $Q_i^S$, then $v \in V^S$ and is either a type 1 or a type 2 vertex. If $v$ is of type 1, then $v$ is an internal vertex of some path $P \in \mathscr{P}^S$ and $v \neq \mathsf{s}^+(P)$. Since $\mathcal{P}$ is $\mathcal{B}$-minimal, this implies that $v$ is in some destination bag of $\mathcal{B}_S$ and we associate $v$ with this bag. If $v$ is of type 2, then $v$ is not an internal vertex of any path in $\mathscr{P}^S$ and is in some bag of $\mathcal{B}_S$. We associate $v$ with this bag. Since the paths $\{Q_1^S, \ldots, Q_k^S\}$ are disjoint, $v$ appears only in one of those paths and thus no other $Q_j^S$ can associate $v$ with another bag of $\mathcal{B}$. The analysis is similar if $v$ is an internal vertex of some $Q_j^T$. Notice that it is possible that $v$ is in both $Q_i^S$ and $Q_j^T$ and, in this case, those two paths associate $v$ with two distinct bags of $\mathcal{B}_S$ and $\mathcal{B}_T$, respectively.

Now let $\mathcal{B}^2 \subseteq \mathcal{B}'$ and let $h' : \mathscr{P} \to \mathcal{B}^2$ be a bijective mapping as in **(1c)** of Definition 14. If $v$ is a vertex of some $P_i$ from $\mathsf{s}^+(Q_i^S)$ to $\mathsf{s}^-(Q_i^T)$ then we associate $v$ with $h'(Q_i^S)$ if $v \in h'(Q_i^S)$, and we associated $v$ with $h'(Q_i^T)$ if $v \in h'(Q_i^T)$.

Now, for $i, j \in [k]$, every path of the form $Q_i^S$, $Q_i^T$, or $P_i$ associates each of its vertex inside of the bramble with a unique bag of $\mathcal{B}$, each vertex associated with some bag appears in $V(Q_i^S) \setminus \{\mathsf{s}^+(Q_i^S)\}$, $V(Q_i^T) \setminus \{\mathsf{s}^-(Q_i^T)\}$, or $V(Q_i)$, no two distinct $Q_i^S, Q_j^T$ associate a vertex $v$ with the same bag, and the same holds with relation to distinct pairs of paths of the form $Q_i, Q_j$ and $Q_i^T, Q_j^T$. We remark that while it is possible that some $v$ appears in both $Q_i^S$ and $Q_i^T$, this does not pose an issue since in this case $v$ is associated with a pair of distinct bags $B \in \mathcal{B}_S$ and $B' \in \mathcal{B}_T$ by $Q_i^S$ and $Q_i^T$, respectively. Since $\mathcal{B}$ has congestion $c$, it follows that every vertex is associated with at most $c$ bags, which implies that every vertex is in at most $c$ paths of $\{P_1, \ldots, P_k\}$, and the result follows.

The bound on the running time follows by Theorem 15 and by observing that a set of R-paths can be made $\mathcal{B}$-minimal in time $\mathcal{O}(c \cdot k^2 \cdot n^2)$ ◀

**Application to the asymmetric version of $(k, c)$-DDP.** Theorem 16 is a direct translation of Giannopoulou et al. [10, Theorem 9.1] to our setting. As mentioned in the introduction, we can prove a weaker version of Theorem 17 by replacing Theorem 16 by [10, Theorem 9.1].

In comparison with the result by Edwards et al. [8], with this approach we can drop the bound on the strong connectivity of the digraph from $(36k^3 + 2k)$ to $k$, and the trade-off is that in this case we have to rely on the topology of *cylindrical grids* to connect the paths, instead of a bramble of congestion $c$. Although it is true that every digraph with large directed tree-width contains a large cylindrical grid [14], and that such a grid can be found in FPT time [4], to find a cylindrical grid of order $k$ the directed tree-width of the digraph has to increase much more than it is needed to find a bramble of congestion two (although both dependencies still consist of a non-elementary tower of exponentials). Additionally, we remark that if the goal is to solve the $(k, c)$-DDP problem with $c \geq 8$, then as stated in Theorem 17 a bramble of congestion eight suffices, and a polynomial dependency on how large the directed tree-width of a digraph must be to guarantee the existence of a large bramble of congestion eight was shown by Masarík et al. [17].

On the other hand, Theorem 16 improves upon [10, Theorem 9.1] in both its statement, since we use brambles instead of cylindrical grids, and in simplicity. Indeed, brambles of bounded congestion seem to be a weaker structure than cylindrical grids, since it possible to extract such brambles with order $t$ from a cylindrical grid of order at least $2t$ (see [8, Lemma 9]), and the bound on how large the directed tree-width of a digraph has to be to guarantee the existence of such a bramble with size $t$ is, in many cases (see [17] for instance) and as far as we know also in the general case, substantially better than what is needed to find a cylindrical grid with the same order. Additionally, the algorithm to find cylindrical grids runs in FPT time [4] given a certificate of large directed tree-width and, in contrast, a large bramble of congestion two can be found in polynomial time when such certificates are provided, as stated in Proposition 7. Finally, we only ask the bramble to have order $2k(c \cdot k - c + 2) + c(k - 1)$ (which equals $4k^2 + 2k - 2$ when $c = 2$) instead of order $k(6k^2 + 2k + 3)$ for the cylindrical grid in [10, Theorem 9.1], where the goal is to compute solutions for $(k, 2)$-DDP. Their proof relies on the topology of cylindrical grids to connect the paths inside of this structure, after some careful selection on how to reach it from $S$ and leave it to reach $T$. In our proof of Theorem 16, it is very simple to connect the paths inside the bramble. Indeed, after applying twice the duality between R-paths and R-cuts, for each $i \in [k]$ we simply connect the ending vertex of the path from $s_i$ to the bramble containing the starting vertex of the path from the bramble to $t_i$, using the strong connectivity of the digraph induced by $B \cup B'$, where $B$ is the bag associated with $s_i$ and $B'$ the bag associated with $t_i$.

Their result [10, Theorem 9.1] is one of the cornerstones in their algorithm to solve the asymmetric version of $(k, 2)$-DDP. Recall that, given ordered sets of terminals $\{s_1, \ldots, s_k\}$ and $\{t_1, \ldots, t_k\}$, the goal in this asymmetric version is to either produce a collection of paths from each $s_i$ to the corresponding $t_i$ such that every vertex is in at most two paths of the collection, or conclude that there is no collection of disjoint $\{s_i\} \to \{t_i\}$ paths. In the first case, we say that we have constructed a *half-integral linkage*. In the second case, we say that we have a no-instance. At any point of their dynamic programming algorithm, if one of the subproblems they define deals with an instance in which there is no small separator intersecting all paths from $S$ to the grid or from the grid to $T$, then they apply [10, Theorem 9.1] to find a solution to the instance. If a separator is found, then they generate two easier instances, one of bounded directed tree-width, and one with fewer number of terminals. Intuitively, the same holds true if we substitute [10, Theorem 9.1] by our Theorem 16. In the full version of this paper, we give an informal sketch of why this is indeed the case.

# Enumerating Maximal Induced Subgraphs

**Yixin Cao**
Department of Computing, Hong Kong Polytechnic University, Hong Kong, China

## Abstract

Given a graph $G$, the maximal induced subgraphs problem asks to enumerate all maximal induced subgraphs of $G$ that belong to a certain hereditary graph class. While its optimization version, known as the minimum vertex deletion problem in literature, has been intensively studied, enumeration algorithms were only known for a few simple graph classes, e.g., independent sets, cliques, and forests, until very recently [Conte and Uno, STOC 2019]. There is also a connected variation of this problem, where one is concerned with only those induced subgraphs that are connected. We introduce two new approaches, which enable us to develop algorithms that solve both variations for a number of important graph classes. A general technique that has been proven very powerful in enumeration algorithms is to build a solution map, i.e., a multiple digraph on all the solutions of the problem, and the key of this approach is to make the solution map strongly connected, so that a simple traversal of the solution map solves the problem. First, we introduce retaliation-free paths to certify strong connectedness of the solution map we build. Second, generalizing the idea of Cohen, Kimelfeld, and Sagiv [JCSS 2008], we introduce an apparently very restricted version of the maximal (connected) induced subgraphs problem, and show that it is equivalent to the original problem in terms of solvability in incremental polynomial time. Moreover, we give reductions between the two variations, so that it suffices to solve one of the variations for each class we study. Our work also leads to direct and simpler proofs of several important known results.

## 1 Introduction

A vertex deletion problem asks to transform a given graph into a graph in a certain graph class $\mathcal{P}$ by deleting vertices. Many classic optimization problems belong to the family of vertex deletion problems, and their algorithms and complexity have been intensively studied. More often than not, the graph class is *hereditary*, i.e., closed under taking induced subgraphs. Examples include complete graphs, edgeless graphs, acyclic graphs, bipartite graphs, planar graphs, and perfect graphs. For a hereditary graph class, this problem is either NP-hard or trivial [40]. An equivalent formulation of a vertex deletion problem toward $\mathcal{P}$ is to ask for a maximum induced subgraph that belongs to $\mathcal{P}$. A plethora of algorithms, including approximation [42, 14, 12, 51, 36, 1], exact [30, 29], and parameterized [10, 15, 14, 12, 36, 1, 2], have been proposed for both formulations.

Yet another approach toward this problem is to enumerate, or generate or list, inclusion-wise *maximal* induced subgraphs that belong to the graph class $\mathcal{P}$, hence called the *maximal induced $\mathcal{P}$ subgraphs* problem. Trivially, one can always use an enumeration algorithm to solve the optimization version of the same problem. A classical example of nontrivial use is to color a graph by enumerating its maximal independent sets [38, 27, 9, 6]. Indeed, the enumeration of maximal independent sets and the enumeration of maximal cliques are practically the same, and both are well-studied classic problems [3, 17, 43]. They were also used in finding

connected vertex covers and edge dominating sets [28]. In general, the maximal induced $\mathcal{P}$ subgraphs problem is motivated by the intrinsic difficulty in formulating a combinatorial optimization problem: there are always factors that are ill characterized or even omitted in the formulation [26, 44].[1] This is particularly the case for vertex deletion problems, of which the primary applications are the processing of noisy data, where modifications to a graph are meant to exclude outliers or to fix noise.

Motivations of maximal induced $\mathcal{P}$ subgraphs problems also come from database theory [18], where one is usually concerned with only induced $\mathcal{P}$ subgraphs that are connected. Of any hereditary graph class $\mathcal{P}$, we can define a subclass by allowing only connected graphs in $\mathcal{P}$. With very few exceptions, this naturally defined class is not hereditary, and hence this variation, called the *maximal connected induced $\mathcal{P}$ subgraphs* problem, poses different challenges. Indeed, as we will see, it is somewhat more difficult than the original one.

Let $n$ denote the number of vertices in the input graph, and by a solution we mean a maximal vertex set that induces a subgraph in $\mathcal{P}$. Since there might be an exponential number (on $n$) of *solutions*, care needs to be taken when we talk about the running time of an enumeration algorithm. For example, in a graph consisting of disjoint triangles, there are $3^{n/3}$ maximal independent sets. Johnson et al. [37] defined three complexity classes for enumeration algorithms, namely, polynomial total time (polynomial in $n$ and the total number of solutions), incremental polynomial time (for all $s$, the time to output the first $s$ solutions is polynomial in $n$ and $s$), and polynomial delay (the time to output the first solution and the time between two consecutive solutions are both polynomial in $n$). Both maximal independent sets and maximal cliques can be enumerated with polynomial delay, and so are maximal bicliques (complete bipartite graphs) [23, 33] and maximal forests [45]. See the survey [48] and the recent results [21, 19].

## 2 Our contributions

Our algorithms are summarized below.

▶ **Theorem 1.** *The maximal induced $\mathcal{P}$ subgraphs problem and its connected variation can be solved with polynomial delay when $\mathcal{P}$ is one of the following graph classes: interval graphs, trivially perfect graphs, split graphs, complete split graphs, pseudo-split graphs, threshold graphs, cluster graphs, complete bipartite graphs, complete $p$-partite graphs, and $d$-degree-bounded graphs.*

▶ **Theorem 2.** *The maximal induced $\mathcal{P}$ subgraphs problem and its connected variation can be solved in incremental polynomial time when $\mathcal{P}$ is one of the following graph classes: wheel-free graphs, unit interval graphs, block graphs, 3-leaf powers, basic 4-leaf powers, and any graph class that can be characterized by a finite set of forbidden induced subgraphs.*

Since a connected cluster graph is a clique, the result for the maximal connected induced cluster subgraphs problem is already known. Also, for a graph class that can be characterized by a finite set of forbidden induced subgraphs, algorithms for the maximal induced $\mathcal{P}$ subgraphs problem, but not its connected variation, can be derived from Eiter and Gottlob [24] (see the discussion in Section 2.6).

## 2.1 Solution maps and retaliation-free paths

In a seminal work, Schwikowski and Speckenmeyer [45] proposed an algorithm for enumerating maximal induced forests, as well as its directed variation, enumerating maximal induced directed acyclic subgraphs. They introduced a successor function, which, given a solution, returns a nonempty multi-set of other solutions of $G$. In so doing they *implicitly* built a multiple digraph $\mathcal{M}(G)$ whose nodes are the solutions, and there are arc(s) from node $S_1$ to node $S_2$ if $S_2$ is one of the successors of $S_1$. The key properties of $\mathcal{M}(G)$ are (1) the successor function can be calculated in polynomial time; and (2) $\mathcal{M}(G)$ is strongly connected. As a result, traversing $\mathcal{M}(G)$ from any node, we can visit all the solutions in time polynomial in $n$ and linear on the number of solutions. With a standard bookkeeping mechanism, we can easily implement it with polynomial delay. We call the multiple digraph on the solutions of an enumeration problem its *solution map*. Gély et al. [33] later rediscovered this idea, and used it to re-analyze enumeration algorithms for maximal cliques and maximal bicliques. Solution maps are actually very general and powerful. Conte et al. [21, 19] built solution maps to solve the maximal (connected) induced $\mathcal{P}$ subgraphs problem for several important graph classes. In particular, they solved the connected variation for forests, and directed acyclic graphs. (They also designed algorithms for enumerating maximal subgraphs, a direction that we will not pursue in the present paper, and other non-graphic problems.)

To solve an enumeration problem with a solution map consists in defining the successor function and proving that the implied solution map $\mathcal{M}$ is strongly connected. All the mentioned algorithms follow the same general scheme, although the details are quite problem specific. For convenience, we may assume that the solutions are subsets of some ground set $U$; for the maximal (connected) induced $\mathcal{P}$ subgraphs problem, $U$ is the vertex set of the input graph.

**Successors of a solution $S$:** For each $v \in U \setminus S$, define a sub-instance restricted to $S \cup \{v\}$, and find a set of solutions of this sub-instance. The union of these $|U \setminus S|$ sets makes the successors of $S$.

**Strong connectedness:** For each solution $S^*$, define a specific metric and show that every other solution $S$ has a successor "closer" to $S^*$ than $S$ with respect to this metric.

Since a solution $S'$ can be a successor of $S$ by virtue of two different elements in $U \setminus S$, the solution map is a multiple digraph. The simplest metric is arguably the lexicographical order. If we number the elements such that those in $S^*$ are the smallest, then $S^*$ is the smallest among all solutions, and hence it suffices to show that each solution $S$ has a lexicographically smaller successor. The existence of a path from $S$ to $S^*$ in $\mathcal{M}$, hence the strong connectedness of $\mathcal{M}$, will then follow from the finiteness of the ground set $U$. Other metrics have also been used in literature [45, 18, 21, 19]

The requirement that every other solution has a *direct* successor that is closer to $S^*$, with respect to the metric decided by $S^*$, is not always easy to achieve. For example, such successor functions have been claimed for unit interval graphs and interval graphs, but both turned out to be incorrect. For the connectedness of a solution map, after all, we are only concerned with the reachability: whether a solution can reach $S^*$ instead of how long it takes to do so. (Indeed, in "the most ideal case," the solution map can be a simple directed cycle, in which the distance of a pair of solutions can be the number of solutions minus one.)

We introduce retaliation-free paths to certify strong connectedness of a solution map. Suppose that we are using the lexicographic metric. In our framework, it is possible that all the successors of a solution $S$ are lexicographically larger than $S$. Thus, the strong connectedness of our solution maps is not readily guaranteed, and we proceed as follows. Let $s$ be the smallest element in $S^* \setminus S$. If any successor of $S$ contains $[1..s]$, then it is

lexicographically smaller than $S$ and we are done. Otherwise, we look for a solution $S'$ that contains $[1..s]$ and is reachable from $S_0 = S$ by a nontrivial path $S_0 S_1 \cdots S'$. It is better to view this path as a transforming procedure. In the first step, we choose a successor $S_1$ of $S$ containing $s$; we call $s$ the *gainer*, and elements in $[1..s] \setminus S_1$ the *victims* of $s$. We then try to add the victims of $s$ back, with the guarantee that none of them unseats $s$, an action which we call *retaliation*. A victim $r$ of $s$ may become a gainer in a later step, hence introducing further victims. In this case, we put other victims of $s$ on hold, and try to restore the victims of $r$. Now we need to make sure both $r$ and $s$ are safe. Thus, we consider the gainer–victim relationship transitive. Such a path of solutions in $\mathcal{M}$ is called *retaliation-free*; see, e.g., Figure 1. A retaliation-free path terminates only when it reaches $S^*$. Therefore, it suffices to show that it does terminate. (After we reach a solution containing $[1..s]$, the element $s$ is no longer a gainer, and may be removed as a victim for adding a later element. The path from $S$ to $S^*$ we produced as such can have a length super-polynomial in $n$.)

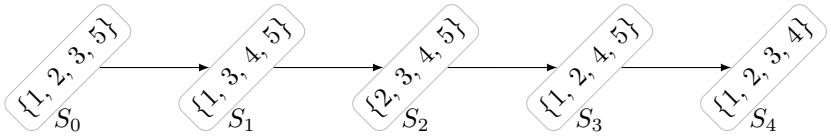

**Figure 1** A path from $S_0$ to $S_4 = S^*$ in a solution map. Here $U = \{1, 2, 3, 4, 5\}$, and its elements are numbered such that those in $S^*$ have the smallest numbers. In the first step ($S_0 \to S_1$), element 4 is the gainer and element 2 is the victim, which becomes the gainer of the second step ($S_1 \to S_2$), with victim 1. The last two steps have no victims.

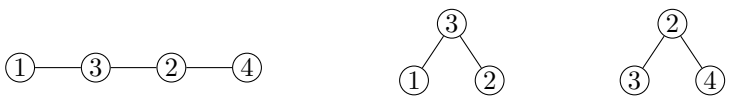
▶ **Theorem 3** (Informal). *Let $\mathcal{M}$ be the solution map of an enumeration problem, and let $S^*$ be a specific solution. Every retaliation-free path in $\mathcal{M}$ with respect to $S^*$ terminates at $S^*$.*

We use Theorem 3 to develop enumeration algorithms for the maximal (connected) induced trivially perfect subgraphs problem and the maximal (connected) induced interval subgraphs problem, both running with polynomial delay. The two problems are paradigmatic for the use of this technique. The main structures we use for interval graphs are the clique paths, which are linear, while for trivially perfect graphs, we work on their generating forests, which are hierarchical.

A trivially perfect graph $G$ can be represented as a forest $F$, called its generating forest, such that two vertices $u$ and $v$ are adjacent in $G$ if and only if one of them is an ancestor of the other in $F$ [49, 50]. It is simpler if we consider the connected variation, where generating forests are trees. For the purpose of transforming a solution $S$ to another solution $S^*$, we transform a generating tree $T$ of $G[S]$ to a generating tree $T^*$ of $G[S^*]$. A main obstacle is that two vertices in $S \cap S^*$ may have different ancestor–descendant relationship in $T$ and $T^*$; see, e.g., vertices 2 and 3 in Figure 2.

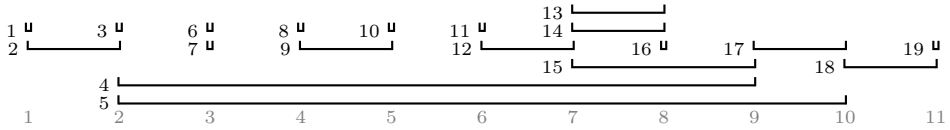


**(a)** $G$. **(b)** $G[S^*] = T^*$. **(c)** $G[S] = T$.

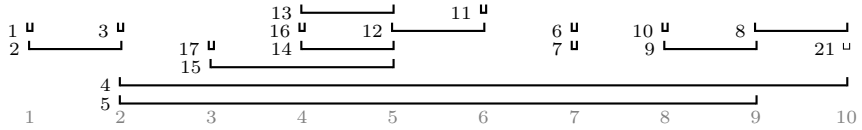
**Figure 2** A graph $G$ and its only two maximal connected induced trivially perfect subgraphs.

We add the vertices in $S^* \setminus S$ bottom-up, i.e., children before parents. Let $v$ be the smallest vertex in $S^* \setminus S$ in the post-order of $T^*$; note that all the $T^*$-descendants of $v$ are in $S$. It is easy to add $v$ if $v$ is a leaf of $T^*$ (because all its $T^*$-ancestors have larger numbers than $v$) or if $v$ has a single child $v'$ in $T^*$ (because $v$ and $v'$ are true twins in $G[S^*]$). The nontrivial case is when $v$ has multiple $T^*$-children. Since we can only make a polynomial number of solutions to be successors of $S$, it is very likely that none of the successors keep all the $T^*$-children of $v$. We observe that as long as we keep two $T^*$-children of $v$, then the relationship between $T^*$-descendants of $v$ and $T^*$-ancestors of $v$ will be correctly maintained. We afford to lose other children of $v$ and their descendants as victims of this step, because they can be added back easily: all the operations for adding these victims back are under $v$, hence isolated from other parts.

Interval graphs are a very important and well-studied graph class [8, 32, 34, 35], and the interval vertex deletion problem receives a lot of attention [7, 14, 11, 2]. The maximal cliques of an interval graph can be arranged in a linear manner, called a clique path [32]. A natural idea is to take a clique path for $G[S^*]$ and number the vertices from left to right; see, e.g., Figure 3(a). Then for another solution $S$, we try to add the smallest vertex in $S^* \setminus S$. However, for solution $S$ shown in Figure 3(b), there is no obvious way to add vertex 18 to $S$, without removing a smaller vertex. The reason is that intervals for vertices 6–17 are organized in very different ways in the two clique paths. For a reader familiar with the recognition of interval graphs, the issue is essentially the same as recognizing interval graphs by graph searches, scanning the vertices from one end to the other end [13]. Note that $\{8, 9, 10\}$ is a *module* (a subset of vertices that have the same neighborhood outside this subset) of $G[S^*]$ and switching the positions of vertices 8 and 10 gives another valid representation of $G[S^*]$. On the other hand, the set $\{6, \ldots, 17\}$ is not a module of $G[S^*]$, and its orientation is fixed from the right by 18. Since this fact can only be deduced after seeing vertex 18, it is not available if one scans from the left. The algorithm in [13] tries to detect and keep track of the orientation of such vertex sets via multiple-sweep searches. For our problem, we allow some vertices in $\{6, \ldots, 17\}$ to fall victims to vertex 18. Afterward, we restore the victims *from right to left*: we process them in a different direction because vertex 18 is the anchor of this set.



**(a)** $S^*$.



**(b)** $S$.

**Figure 3** Two maximal connected induced interval subgraphs of some graph $G$ (other vertices are immaterial and omitted). Gray numbers at the bottom indicate the indices of the maximal cliques.

## 2.2 Algorithms in incremental polynomial time

In each of the mentioned algorithms, the successor function has to be handcrafted. For example, our successor function for interval graphs does not work for unit interval graphs. Nor can the successor function of [21, 19] for chordal graphs be applied to interval graphs.[2] In the following we aim for general approaches that can be applied with little efforts.

There is nothing inherent in solution maps about polynomial delay, though all of the mentioned algorithms based on solution maps are of this type. The running time of such an algorithm is determined by the successor function, which is almost always determined by the number of successors a solution can have. If the number is polynomial in $n$, then the algorithm has polynomial delay. If we allow the number to be polynomial in both $n$ and the number of solutions, then it needs polynomial total time. One "weakness" of the approach based on solution maps is the lack of a simple way to develop algorithms in incremental polynomial time, save those simple classes [18]. We obviate this concern with the following observation.

▶ **Theorem 4.** *For any hereditary graph class $\mathcal{P}$, the maximal (connected) induced $\mathcal{P}$ subgraphs problem can be solved in polynomial total time if and only if it can be solved in incremental polynomial time.*

For the maximal induced $\mathcal{P}$ subgraphs problem, the statement follows from the classical result of Bioch and Ibaraki [5]; see discussions in Section 2.6. As far as we can check, the statement for the connected variation was not previously known. (This explains why Cohen et al. [18] had to prove the statement separately.) Theorem 4 enables us to use solution maps transparently in developing algorithms for enumerating maximal (connected) induced $\mathcal{P}$ subgraphs in incremental polynomial time. There is strong evidence that a similar claim on general enumeration problems does not hold [46, 16].

## 2.3 Restricted versions

Lawler et al. [39] introduced the *input-restricted version* of an enumeration problem: there exists an element $x \in U$ such that $U \setminus \{x\}$ is a solution. This special problem arises naturally in several design paradigms for enumeration problems, e.g., the design of successor functions, and the reverse search technique [4]. Cohen et al. [18] proved that the maximal (connected) induced $\mathcal{P}$ subgraphs problem can be solved with polynomial delay when its input-restricted version can be solved in polynomial time. Moreover, the original problem can be solved in incremental polynomial time if and only if its input-restricted version can. They also proved a similar statement for polynomial total time, which is rendered redundant by Theorem 4. Thus, this ostensibly simpler version is the core of the maximal (connected) induced $\mathcal{P}$ subgraphs problem in terms of solvability in incremental polynomial time.

Since the appearance of [18], there have been attempts at extending its core idea. A "natural" way seems to be defining a restricted version that is equipped with a special set of more than one vertex; i.e., $G - Z$ is in $\mathcal{P}$ for some set $Z$ of $t$ vertices, where $t > 1$. However,

[2] An early version of [19] mistakenly claimed that their algorithm for the maximal induced chordal subgraphs problem also applies to interval graphs. Roughly speaking, what they did is to reconstruct a perfect elimination ordering of a desired solution $S^*$ from a solution $S$. As long as the newly added vertex is simplicial, the resulting graph is chordal. But it is not always an interval graph. The tent graph (adding three edges to connect the even-number vertices of a 6-cycle) is a counterexample. In the solution map they built, the only successor of $V(G) \setminus \{v\}$, where $v$ is any degree-2 vertex of $G$, is $G$ itself, which is not an interval graph. It is quite nontrivial, if possible at all, to adapt this approach to interval graphs.

the extra $t-1$ vertices in the set $Z$ turn out to be not helpful. Consider, for instance, $\mathcal{P}$ being the forests. For a graph $G$ and any $t$, we can make a new graph $H$ by introducing $t-1$ copies of disjoint triangles to $G$, and then $H$ satisfies the new definition if and only if $G$ is input-restricted. Therefore, this special version does not have any property that is not already in the input-restricted version, hence not easier to solve than the latter.

This negative example does not suggest a dead end, and there is a natural generation that does work. We may view the input-restricted version as an enumeration problem by itself, and try to build a solution map to solve it. Then in designing the successor function, in the sub-instance restricted to $S \cup \{v\}$, aside from the vertex $x$ we had, we are bestowed with another vertex $v$ such that the removal of either of $x$ and $v$ leaves a subgraph in $\mathcal{P}$. We are thus inspired to define the *$t$-restricted version* of the maximal induced $\mathcal{P}$ subgraphs problem:

> There exists a set $Z$ of $t$ vertices in $G$ such that $G - z$ is in $\mathcal{P}$ for *every* $z \in Z$.

It is equivalent to that *every* induced subgraph of $G$ that is not in $\mathcal{P}$ contains *all* vertices in $Z$. This requirement is far stronger than $G - Z$ being in $\mathcal{P}$, though equivalent when $t = 1$. We are able to show that even this far more restricted version is still equivalent to the original problem in terms of enumerability in incremental polynomial time. We remark that our proofs, based on solution maps, are significantly simpler than those on the input-restricted version [18], which can now be viewed as the 1-restricted version. With the benefit of hindsight, we can see that all the results of [18] can be easily interpreted using solution maps, with simpler proofs.

▶ **Theorem 5.** *Let $\mathcal{P}$ be a hereditary graph class. The maximal (connected) induced $\mathcal{P}$ subgraphs problem can be solved in incremental polynomial time if and only if there exists a positive integer $t$ such that its $t$-restricted version can be solved in polynomial total time.*

The strong requirement stipulated in defining the $t$-restricted version makes it significantly easier than the original problem. All the algorithms in Theorem 2 are obtained by reducing these problems to their $t$-restricted versions. Of these results, we would like to draw special attention to those on wheel-free graphs, though this graph class in its own sense may seem to be less interesting compared to others we study. Lokshtanov [41] proved that the vertex deletion problem toward wheel-free graphs is W[2]-hard with respect to standard parameterization, hence very unlikely fixed-parameter tractable. This suggests that the complexity of the maximal induced $\mathcal{P}$ subgraphs problem can be quite different from its optimization counterpart.

Theorem 5 also implies, among others, the following result on graph classes that can be characterized by a finite set $\mathcal{F}$ of forbidden induced subgraphs. Indeed, with $t$ being the maximum order of graphs in $\mathcal{F}$, the $t$-restricted version of the maximal (connected) induced $\mathcal{F}$-free subgraphs problem is trivial. Eiter and Gottlob [24] have proved this result for the maximal induced $\mathcal{F}$-free subgraphs problem, but their proof does not apply to the connected variation; see discussions in Section 2.6.

▶ **Corollary 6.** *Let $\mathcal{F}$ be a finite set of graphs. The maximal (connected) induced $\mathcal{F}$-free subgraphs problem can be solved in incremental polynomial time.*

We note that the vertex deletion problem to $\mathcal{F}$-free graphs for finite $\mathcal{F}$ has been well studied. In particular, they are fixed-parameter tractable [10] and admit constant-approximation [42].

## 2.4 Reductions between the two variations

Since we are dealing with both the maximal induced $\mathcal{P}$ subgraphs problem and its connected variation, it is really irksome if we have to develop two algorithms for each class. Although Cohen et al. [18] and Conte et al. [21, 19] dealt with both variations, they stopped at noting that with one of them solved, a slight modification would be able to solve the other. These modifications have to be done, however, case by case.

The main issue of the connected variation is that the set of connected graphs in a hereditary graph class $\mathcal{P}$, viewed as a graph class in its own regard, is mostly not hereditary. If there are two nonadjacent vertices in any connected graph $G$ in $\mathcal{P}$, then the edgeless graph on two vertices is an induced subgraph of $G$, hence in $\mathcal{P}$. Therefore, the class of connected graphs in $\mathcal{P}$ remains hereditary only when $\mathcal{P}$ is the class of cluster graphs, in which the connected ones are the complete graphs, and the class of edgeless graphs. A connected edgeless graph has precisely one vertex, and this seems to be the only class on which the connected variation, which is trivial, is the easier between the two variations. For a hereditary graph class $\mathcal{P}$, and a graph $G$, let us use $N_1$ and $N_2$ to denote, respectively, the number of maximal induced $\mathcal{P}$ subgraphs and the number of maximal connected induced $\mathcal{P}$ subgraphs of $G$. It is not difficult to see that $N_1/N_2$ can be an exponential number on $n$, while $N_2/N_1$ can never be more than $n$. In the trivial case when $\mathcal{P}$ is edgeless, $N_2$ is precisely $n$, while $N_1$ can be $3^{n/3}$. For a nontrivial example, the graph consisting of $n/4$ disjoint 4-cycles has $2^{n/2}$ maximal induced forests, while only $n$ maximal induced trees. This example applies to interval graphs, chordal graphs, and many others. Therefore, it is very unlikely we can use an enumeration algorithm for the maximal induced $\mathcal{P}$ subgraphs problem to solve its connected variation.

The other direction is promising. Two simple observations help here. First, if we can add vertices to a graph without making new forbidden induced subgraphs, then it does not change the number of maximal induced $\mathcal{P}$ subgraphs, though each of them gets more vertices. Second, if the extra vertices make all the maximal induced $\mathcal{P}$ subgraphs connected, then by enumerating all maximal connected induced $\mathcal{P}$ subgraphs of the new graph, we obtain effortlessly all maximal induced $\mathcal{P}$ subgraphs of the original graph. This idea works when $\mathcal{P}$ is closed under adding universal vertices, examples of which include interval graphs, chordal graphs, etc. A less trivial reduction can be devised for several other graph classes, e.g., wheel-free graphs and triangle-free graphs. These reductions focus us on the connected variation of the problems only, instead of working on both.

Via Theorem 5, we are able to establish a more interesting connection. Although the condition in the statement looks rather technical, it is satisfied by many natural graph classes: apart from those in Theorem 2, another notable example is planar graphs. As for the $t$-restricted version of both variations, there are only a polynomial number of solutions that are not a proper superset of $Z$, and they are easy to handle. Therefore, the focus is on those solutions containing all vertices in $Z$. We observe that under the connectivity condition, in every maximal induced $\mathcal{P}$ subgraph of $G$ that contains all vertices in $Z$, all the vertices in $Z$ are always in the same component. As a result, there is a one-to-one mapping between such solutions for these two variations.

▶ **Theorem 7.** *Let $c$ be a constant. Let $\mathcal{F}$ be a set of graphs such that every graph in $\mathcal{F}$ of order $c$ or above is biconnected. The maximal induced $\mathcal{F}$-free subgraphs problem can be solved in incremental polynomial time if and only if its connected variation can be solved in incremental polynomial time.*

## 2.5 Characterizing the easy classes

We try to better understand maximal (connected) induced $\mathcal{P}$ subgraphs problems that can be solved with polynomial delay by considering its input-restricted version. We say that a graph class $\mathcal{P}$ has the *CKS property*, after the initials of the authors of [18], if the input-restricted version of the maximal (connected) induced $\mathcal{P}$ subgraphs problem can be solved in time polynomial only in $n$. Since it is straightforward to see that the class of edgeless graphs (independent sets), the class of complete graphs (cliques), and the class of complete bipartite graphs (bicliques) have the CKS property, the polynomial-delay algorithms for them can be immediately explained by this general result. On the other hand, the polynomial-delay algorithms of [45] and [21, 19], and our polynomial-delay algorithms for the maximal (connected) induced interval subgraphs problem and for the maximal (connected) induced trivially perfect subgraphs problem cannot be derived from this observation. As we will see, none of these graph classes has the CKS property.

It turns out that star forests, forests in which every tree is a star, play a crucial role in characterizing graph classes with the CKS property. Therefore, to find those graph classes with the CKS property, it suffices to consider those forbidding both a star forest and the complement of a star forest.

▶ **Theorem 8.** *Let $\mathcal{F}$ be a nonempty set of graphs. If the class of $\mathcal{F}$-free graphs has the CKS property, then $\mathcal{F}$ contains at least one star forest and the complement of at least one star forest.*

Unfortunately, this condition is not sufficient, and many graph classes satisfy this condition but do not have the CKS property. Moreover, it is possible that a class $\mathcal{P}$ of graphs has the CKS property but a proper subclass of $\mathcal{P}$ does not. This fact makes a full characterization of graph classes with the CKS property more difficult.

## 2.6 Related work

Let us put our work into context. The aforementioned characterization of a hereditary graph class by a set $\mathcal{F}$ of forbidden induced subgraphs provides another perspective to view the maximal induced $\mathcal{P}$ subgraphs problem, but not its connected variation in general. A subset $S$ of vertices is a solution if and only if $V(G) \setminus S$ intersects all *forbidden sets* of $G$, i.e., a minimal set $X$ of vertices such that $G[X] \in \mathcal{F}$. If we list all the forbidden sets of $G$ as a set system, then the problem becomes enumerating *minimal* vertex sets that intersect each of the forbidden sets. This brings us to the well-studied problem of enumerating minimal hitting sets of a set system. A set system is also known as a *hypergraph*, and the problem is called *hypergraph transversal* in literature. Some important general results on enumeration of maximal induced $\mathcal{P}$ subgraphs, e.g., the algorithm for graph classes characterized by a finite number of forbidden induced subgraphs, were first proved in this setting [24]. Reducing to the hypergraph transversal problem was also a common approach used by many earlier heuristic enumeration algorithms, for maximal independent sets and for maximal forests. A graph may have an exponential number of simple cycles, and thus the maximal induced forests problem and its associated hypergraph transversal problem have significantly different input sizes: the latter, including the number of elements and the number of forbidden sets, may be exponential on the former. This can happen for all graph classes $\mathcal{P}$ that have an infinite number of forbidden induced subgraphs. Deciding whether a graph belongs to such a class $\mathcal{P}$ may be NP-hard, and hence the maximal induced $\mathcal{P}$ subgraphs problem cannot be solved in polynomial total time, though it is still possible for the corresponding hypergraph

transversal problem, with all the forbidden sets given. Thus, we have to exclude from our study those graph classes that cannot be recognized in polynomial time. For a graph class that can be recognized in polynomial time, the maximal (connected) induced $\mathcal{P}$ subgraphs problem is in EnumP, the counterpart of NP for enumeration [16]. (One may consider the oracle model, where whether a graph is in the class is answered by an oracle in $O(1)$ time, but this paper will not take this direction.)

The (minimal) hitting sets of a hypergraph $H$ define another hypergraph $H'$, and it is an easy exercise to verify that each set in $H$ is a (minimal) hitting set of $H'$. The hypergraph transversal problem has a decision version: given a pair of hypergraphs on the same set of elements, decide whether one consists of exactly the minimal hitting sets of the other. Bioch and Ibaraki [5] showed that the hypergraph traversal problem can be solved in polynomial total time if and only if it can be solved in incremental polynomial time, by showing that this is the case precisely if the decision version can be solved in polynomial time. Note that under certain complexity assumptions, these two complexity classes for enumeration problems are not equal in general [46, 16].

The results of [5] were actually developed in the setting of monotone Boolean functions. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *monotone* if $x \leq y$ always implies $f(x) \leq f(y)$. The *identification* problem is to find all minimal true vectors *and* all maximal false vectors of $f$. It is easy to see that the maximal induced $\mathcal{P}$ subgraphs problem is a special case of it. Let $G$ be a graph on $n$ vertices, for any subset $X \subseteq V(G)$, we use $x$ to denote the characteristic vector of $X$, i.e., an $n$-dimension Boolean vector with 1 at the $i$th position if and only if $v_i \in X$, and set $f(x) = 0$ if and only if $G[X] \in \mathcal{P}$. Then minimal forbidden sets and the vertex sets of maximal induced $\mathcal{P}$ subgraphs of $G$ correspond to minimal true vectors and maximal false vectors of $f$, respectively. In this terminology, the maximal induced $\mathcal{P}$ subgraphs problem asks for maximal false vectors only, hence different in the output size. (Moreover, the identification problem is usually asked in the oracle model.) The decision version of the identification problem, known as dualization of monotone Boolean functions, is equivalent to the hypergraph traversal problem, and its incarnations can be found in database systems, artificial intelligence, and game theory. Fredman and Khachiyan [31] proved that dualization of monotone Boolean functions, hence hypergraph traversal, can be solved in quasi-polynomial time. It has been open for nearly four decades whether this problem can be solved in polynomial time; see the survey of Eiter et al. [25].

The main motivation of studying the connected variation is its practical applications in database theory, where several important problems can be modeled as enumerating maximal connected induced $\mathcal{P}$ subgraphs. We refer to Cohen et al. [18] and references therein for the background. Since this variation cannot be directly cast into hypergraphs or monotone Boolean functions, fewer results on it have been known in literature [18, 21, 19], and they had to be dealt with separately.

We are exclusively concerned with maximal (connected) induced $\mathcal{P}$ subgraphs. There is also research on enumerating all induced $\mathcal{P}$ subgraphs and enumerating all maximum induced $\mathcal{P}$ subgraphs. The first is usually very easy, if not completely trivial, while the latter has to be very hard: after all, finding a single maximum induced subgraph in a nontrivial and hereditary graph class is already NP-hard [40]. Yet another, probably more practical, approach is to list top $k$ solutions, or solutions of costs at most (or at least) $k$. This is frequently studied in the framework of parameterized computation. There is work using the input size as the sole measure for the running time of enumeration algorithms, e.g., [47]. In summary, efforts toward a systematic understanding of enumeration are gaining momentum [22].

Our final remark is on the space usage. A naïve implementation of our main approaches needs to keep track of all the solutions, hence takes exponential space. How to reduce the space is the major open problem in this area, and positive results are few but growing. Using reverse search, Conte et al. [20] showed how to strengthen polynomial-delay algorithms of [18] to use only polynomial space. Conte et al. [21, 19] also managed to reduce some of their algorithms to polynomial space.

## Abstract

We consider variants of the classic Multiway Cut problem. Multiway Cut asks to partition a graph $G$ into $k$ parts so as to separate $k$ given terminals. Recently, Chandrasekaran and Wang (ESA 2021) introduced $\ell_p$-norm Multiway Cut, a generalization of the problem, in which the goal is to minimize the $\ell_p$ norm of the edge boundaries of $k$ parts. We provide an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation algorithm for this problem, improving upon the approximation guarantee of $O(\log^{3/2} n \log^{1/2} k)$ due to Chandrasekaran and Wang.

We also introduce and study Norm Multiway Cut, a further generalization of Multiway Cut. We assume that we are given access to an oracle, which answers certain queries about the norm. We present an $O(\log^{1/2} n \log^{7/2} k)$ approximation algorithm with a weaker oracle and an $O(\log^{1/2} n \log^{5/2} k)$ approximation algorithm with a stronger oracle. Additionally, we show that without any oracle access, there is no $n^{1/4-\varepsilon}$ approximation algorithm for every $\varepsilon > 0$ assuming the Hypergraph Dense-vs-Random Conjecture.

## 1 Introduction

In this paper, we consider a variant of the classic combinatorial optimization problem, Minimum Multiway Cut. Given an undirected graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_{\geq 0}$ and $k$ terminals $t_1, \ldots, t_k \in V$, the Minimum Multiway Cut problem asks to partition graph $G$ into $k$ parts $P_1, \ldots, P_k$ so that $P_i$ contains terminal $t_i$. The Multiway Cut objective is to minimize the number or total weight of cut edges. For $k = 2$, the problem is equivalent to the minimum $st$-Cut problem. Dahlhaus, Johnson, Papadimitriou, Seymour, and Yannakakis proved that it is NP-complete and APX-hard for every $k > 2$ [9]. They also gave a simple combinatorial $(2 - 2/k)$-approximation algorithm. Later Călinescu, Karloff, and Rabani [7] showed how to obtain a $3/2$ approximation using linear programming. This

result was improved in a series of papers by Karger, Klein, Stein, Thorup, and Young [11], Buchbinder, Naor and Schwartz [5], and Sharma and Vondrák [13] (see also [6]). The currently best known approximation factor is 1.2965 [13]. The best known LP integrality gap and Unique Games Conjecture hardness is 1.20016 due to Bérczi, Chandrasekaran, Király, and Madan [4] (see also [2, 10, 12]).

In 2004, Svitkina and Tardos [14] introduced the Min-Max Multiway Cut problem. In this problem, as before, we need to partition graph $G$ into $k$ parts $P_1, \ldots, P_k$ so that each $P_i$ contains one terminal $t_i$. However, the objective function is different: Min-Max Multiway Cut asks to minimize the maximum of edge boundaries of sets $P_i$ i.e., minimize $\max_i \delta(P_i)$, where $\delta(P_i)$ is the total weight of edges crossing the cut $(P_i, V \setminus P_i)$. Svitkina and Tardos [14] gave an $O(\log^3 n)$ approximation algorithm for the problem. Later, Bansal, Feige, Krauthgamer, Makarychev, Nagarajan, Naor, and Schwartz [3] provided an $O(\sqrt{\log n \log k})$-approximation algorithm. Also, Ahmadi, Khuller, and Saha [1] studied a related Min-Max Multicut problem.

Recently, Chandrasekaran and Wang [8] proposed a common generalization of the Min Multiway Cut and Min-Max Multiway Cut problems, which they called Minimum $\ell_p$-norm Multiway Cut. This problem asks to minimize the $\ell_p$ norm of the edge boundaries of parts $P_1, \ldots, P_k$. In other words, the objective is to

$$\textbf{minimize: } \Big(\sum_{i=1}^{k} \delta(P_i)^p\Big)^{1/p}.$$

Note that this problem is equivalent to Min Multiway Cut when $p = 1$ and to Min-Max Multiway Cut when $p = \infty$. Chandrasekaran and Wang [8] gave an $O(\log^{3/2} n \log^{1/2} k)$ approximation for the problem. Further, they proved that the problem is NP-hard for every $p \geq 1$ and $k \geq 4$. Moreover, it does not admit an $O(k^{1-1/p-\varepsilon})$-approximation for every $\varepsilon > 0$ assuming the Small Set-Expansion Conjecture; a natural convex program for the problem has the intgerality gap of $\Omega(k^{1-1/p})$.

In this paper, we provide an improved $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation algorithm. We note that for $p = \infty$, our approximation guarantee matches the approximation of the algorithm due to Bansal et al. [3].[1] For $p = 2$, our approximation guarantee is $O(\log^{1/2} n \log k)$, which is $\Theta(\log n/\sqrt{\log k})$ times better than the approximation guarantee of the algorithm due to Chandrasekaran and Wang [8]. We also consider variants of Multiway Cut with norms other than the $\ell_p$ norm.

## 1.1 Our Results

We now formally state our results. First, we present an approximation algorithm for the $\ell_p$-norm Multiway Cut problem. We show that our algorithm achieves an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for every $p > 1$.

▶ **Theorem 1.** *There exists a polynomial-time randomized algorithm that given a graph with $n$ vertices, $k$ terminals, and $p > 1$, finds an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for $\ell_p$-norm Multiway Cut with high probability.*

Further, we provide approximation algorithms for Norm Multiway Cut with an arbitrary monotonic norm, a further generalization of $\ell_p$-norm Multiway Cut. The monotonic norm is defined as follows.

[1] Our algorithm is stated only for the case where $p$ is finite. However, we can solve an instance with $p = \infty$ by running the algorithm with $p = \log k$. Since $\|\cdot\|_{\log k}$ is within a constant factor of $\|\cdot\|_\infty$ for vectors in $\mathbb{R}^k$, this approach yields an $O(\sqrt{\log n} \log^{1/2+1/\log k} k) = O(\sqrt{\log n \log k})$-approximation.

▶ **Definition 2.** *A norm $\|\cdot\|$ on $\mathbb{R}^d$ is monotonic if for any $x, y \in \mathbb{R}^d$ with $|x_i| \le |y_i|$ for all $i \in [d]$, it holds $\|x\| \le \|y\|$.*

We consider two oracles to the monotonic norm used in the Norm Multiway Cut: (1) minimization oracle; (2) ordering oracle. For a set $A \subseteq [d]$, let $\mathbb{1}_A \in \{0,1\}^d$ denote the indicator vector of $A$, i.e., the $i$-th coordinate $(\mathbb{1}_A)_i = 1$ if $i \in A$; otherwise, $(\mathbb{1}_A)_i = 0$.

▶ **Definition 3.** *Given a monotonic norm $\|\cdot\|$ on $\mathbb{R}^d$, for any $i \in [d]$, the minimization oracle efficiently finds a set $A_i \subseteq [d]$ that minimizes the norm of indicator vectors among all subsets with size $i$, i.e.*

$$A_i = \operatorname*{arg\,min}_{A \subseteq [n], |A| = i} \|\mathbb{1}_A\|.$$

▶ **Definition 4.** *Given a monotonic norm $\|\cdot\|$ on $\mathbb{R}^d$, for any vector $x \in \mathbb{R}^d$, the ordering oracle efficiently finds an ordering of the vector $x$ that minimizes the norm, i.e.*

$$\pi_x = \operatorname*{arg\,min}_{\pi \in S_d} \|x^\pi\|,$$

*where $x^\pi$ denotes the ordering of $x$ regarding the permutation $\pi$.*

Assuming that they are given access to either a "minimization oracle" or a stronger "ordering oracle", our algorithms give $O(\log^{1/2} n \log^{7/2} k)$ and $O(\log^{1/2} n \log^{5/2} k)$ approximation, respectively. We remark that the oracles only answer queries about the norm and, in particular, there is an ordering oracle for the $\ell_p$-norm, weighted $\ell_p$-norm, and many other natural norms. Thus, our result implies an $O(\log^{1/2} n \log^{5/2} k)$ approximation for *weighted* $\ell_p$-norm Multiway Cut. We prove the following theorems in the full version of the paper.

▶ **Theorem 5.** *There exists a polynomial-time algorithm that for every monotonic norm with a minimization oracle, given a graph with $n$ vertices and $k$ terminals, finds an $O(\log^{1/2} n \log^{7/2} k)$ approximation for the Norm Multiway Cut with high probability.*

▶ **Theorem 6.** *There exists a polynomial-time algorithm that for every monotonic norm with an ordering oracle, given a graph with $n$ vertices and $k$ terminals, finds an $O(\log^{1/2} n \log^{5/2} k)$ approximation for the Norm Multiway Cut with high probability.*

Finally, we show that the problem becomes very hard if we are not given access to a norm minimization oracle. The proof is given in the full version of the paper.

▶ **Theorem 7.** *Consider the Norm Multiway Cut problem with a monotonic norm. Assume that the norm is given by a formula (in particular, we can easily compute the value of the norm; however, we are not given a minimization oracle for it). Then, assuming the Hypergraph Dense-vs-Random Conjecture, there is no polynomial-time algorithm for Norm Multiway Cut with approximation factor $\alpha(n) \le n^{1/4-\varepsilon}$ for every $\varepsilon > 0$.*

## 1.2 Proof Overview

We first describe our algorithm for the $\ell_p$-norm Multiway Cut. Our algorithm consists of three procedures: (1) covering procedure, (2) uncrossing procedure, and (3) aggregation procedure.

In the covering procedure, we generate a collection of subsets of the vertex set, $\mathcal{S} = \{S_1, S_2, \cdots, S_m\}$. We generate these sets iteratively by using a bi-criteria approximation algorithm for Unbalanced Terminal Cut by Bansal et al. [3] and a multiplicative weight

update method. See Section 2.1 and Algorithm 1 for details. Each set in $\mathcal{S}$ contains at most one terminal. These sets are not disjoint. While, these sets cover the entire graph, which means the union of all sets in $\mathcal{S}$ contains all vertices. The number of sets in $\mathcal{S}$ is at most $O(k \log n)$. We show that the $\ell_p$ norm and $\ell_1$ norm of the edge boundaries of sets in $\mathcal{S}$ is at most $O(\log^{1/p} n \cdot \alpha)\,\mathrm{OPT}$ and $O(\log n \cdot k^{1-1/p} \cdot \alpha)\,\mathrm{OPT}$ respectively, where $\alpha = \sqrt{\log n \log k}$ and OPT is the cost of the optimal solution. This covering procedure follows the approach by Bansal et al. [3] for Min-Max Multiway Cut. Chandrasekaran and Wang [8] also use a similar covering procedure for $\ell_p$-norm Multiway Cut. Their algorithm finds a cover $\mathcal{S}$ that satisfies the above properties except for the $\ell_1$ norm bound. We get this $\ell_1$ norm bound on the edge boundaries of sets in $\mathcal{S}$ by picking proper measure constraints for the Unbalanced Terminal Cut algorithm. This $\ell_1$ norm bound is important in the aggregation procedure to get an improved approximation.

Note that the sets in $\mathcal{S}$ are not disjoint. We use the uncrossing procedure to create a partition of the graph with at most $O(k \log k)$ sets. Our uncrossing procedure first sample $O(k \log k)$ sets from $\mathcal{S}$ uniformly at random. Then, we run an iterative uncrossing process given by Bansal et al. [3] over sampled sets until all sets are disjoint and have small boundaries. We show that all sampled sets cover almost the entire graph. The set of uncovered vertices does not contain terminals and has a small boundary with high probability. Next, we use the aggregation procedure to merge these $O(k \log k)$ sets into a $k$ partition. We assign $k$ sets containing one terminal to $k$ parts. For other sets without terminals, we assign them to $k$ parts almost uniformly such that each part has almost the same $\ell_1$ norm over assigned sets. After the uncrossing procedure, the $\ell_p$ norm and $\ell_1$ norm of edge boundaries is at most $O(\log^{1/p} k \cdot \alpha)\,\mathrm{OPT}$ and $O(k^{1-1/p} \cdot \alpha)\,\mathrm{OPT}$ respectively. We upper bound the sets containing one terminal and the sets with the largest edge boundary in each part by the above $\ell_p$ norm bound. For the remaining sets, by the $\ell_1$ norm bound and the uniform assignment, we upper bound the $\ell_p$ norm for these sets by $O(\alpha)\,\mathrm{OPT}$. Chandrasekaran and Wang [8] achieve an $O(\log n \cdot \alpha)$ where the $O(\log n)$ factor is due to their aggregation procedure. We use the $\ell_1$ norm bound in the covering procedure and a new aggregation procedure to reduce $O(\log n)$ extra factor to $O(\log^{1/p} n)$. We use the sampling in the uncrossing procedure to further reduce the extra factor from $O(\log^{1/p} n)$ to $O(\log^{1/p} k)$.

We now describe our algorithm for Norm Multiway Cut. We use the same framework with covering, uncrossing, and aggregation procedures. While, unlike the $\ell_p$ norm, the general monotonic norm may not be permutation invariant. For each terminal, we first compute a minimum cut that separates this terminal from other terminals. Then, we can remove all terminals and assign the remaining vertices freely among $k$ parts. We mainly use a bucketing idea to modify our algorithm. We partition $k$ coordinates into $\log_2 k$ buckets with exponentially increasing size $2^i$ such that the coordinates with large boundaries in the optimal solution are assigned to small buckets. Differing from the previous covering procedure, the new covering procedure uses the Unbalanced Terminal Cut algorithm with parameters related to each bucket. The cover $\mathcal{S}$ contains $O(2^i \log n \log k)$ sets in each bucket $i$. The boundary of every set in each bucket is relatively small, at most $O(\alpha)$ times the boundary of the optimal part in this bucket. We then run the uncrossing and aggregation procedure to create a multiway cut. We still sample each set in $\mathcal{S}$ with probability $\log_2 k / \log_2 n$. Thus, we have $O(2^i \log^2 k)$ sets in each bucket $i$ after the uncrossing procedure. For bucket $0 \le i \le \log_2 k$, we find a set of $2^i$ coordinates $I_i \in [k]$ that minimizes the norm of the indicator vector through the minimization oracle. We then assign $O(2^i \log^2 k)$ sets in each bucket to coordinates in $I_i$ such that each coordinate has $O(\log^2 k)$ sets in bucket $i$. Thus, we achieve an $O(\log^2 k \cdot \alpha)$ approximation for each bucket. Since these sets of coordinates $I_i$ may overlap, we lose an

additional $O(\log k)$ factor for $\log_2 k$ buckets. Suppose we have a stronger oracle that finds the best ordering for any given vector that minimizes the norm. Then, we provide an assignment for each bucket to avoid the large overlapping among buckets. Therefore, we avoid the extra $O(\log k)$ factor loss due to the overlapping.

## 2 $\ell_p$-norm Multiway Cut

In this section, we present our algorithm for $\ell_p$-norm Multiway Cut. We prove the following theorem. Our algorithm consists of three parts: covering procedure, uncrossing procedure, and aggregation procedure. We describe and analyze the covering procedure in Section 2.1, the uncrossing and aggregation procedures in Section 2.2.

▶ **Theorem 1.** *There exists a polynomial-time randomized algorithm that given a graph with $n$ vertices and $k$ terminals, and $p > 1$, finds an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for the $\ell_p$-norm Multiway Cut with high probability.*

### 2.1 Covering Procedure

We first present and analyze a covering procedure in our algorithm. The covering procedure takes a undirected graph $G = (V, E)$ with edge weights $w : E \to \mathbb{R}_{\geq 0}$ and $k$ terminals $T = \{t_1, \dots, t_k\} \subset V$ as input and outputs a collection of sets $\mathcal{S} = \{S_1, \dots, S_m\}$ where $S_i \subset V$ for all $i$. All sets $S_i \in \mathcal{S}$ covers the entire graph, $\bigcup_{i=1}^m S_i = V$. Each set $S_i \in \mathcal{S}$ contains at most one terminal. For each subset $S \subseteq V$, we use $\partial(S) = E(S, V \setminus S)$ to denote all edges crossing the cut $(S, V \setminus S)$. We use $\delta(S) = \sum_{e \in \partial(S)} w(e)$ to denote the edge boundary of set $S$, which is the total weight of all edges crossing $(S, V \setminus S)$. We prove the following upper bounds on the $\ell_1$-norm and $\ell_p$-norm of the edge boundaries of these sets in $\mathcal{S}$, which is crucial for our approximation guarantee.

▶ **Lemma 8.** *Given a graph $G = (V, E)$ with $n$ vertices and $k$ terminals $T \subset V$, the covering procedure shown in Algorithm 1 returns $m = O(k \log n)$ sets $\mathcal{S} = \{S_1, \dots, S_m\}$ that satisfies*

1. $|S_i \cap T| \leq 1$ *for all* $i \in [m]$,
2. $\bigcup_{i=1}^m S_i = V$,
3. $\sum_{t=1}^m \delta(S_t)^p \leq \log n \cdot O(\alpha^p) \cdot \mathrm{OPT}^p$,
4. $\sum_{t=1}^m \delta(S_t) \leq \log n \cdot O(\alpha) \cdot k^{1-1/p} \cdot \mathrm{OPT}$,

*where $\alpha = \sqrt{\log n \log k}$ and* OPT *is the objective value of the optimal $\ell_p$-norm Multiway Cut.*

Our algorithm relies on an intermediate problem, Unbalanced Terminal Cut that we introduce now.

▶ **Definition 9** (Unbalanced Terminal Cut)**.** *The input to this problem is a tuple $\langle G, w, \mu, \rho, T \rangle$, where $G = (V, E)$ is a graph with edge weights $w : E \to \mathbb{R}_{\geq 0}$, a measure $\mu : V \to \mathbb{R}_{\geq 0}$, a parameter $\rho \in (0, 1]$, and a set of terminals $T$. The goal is to find $S \subseteq V$ of minimum cost $\delta(S)$ satisfying:*

1. $|S \cap T| \leq 1$,
2. $\mu(S) \geq \rho \cdot \mu(V)$.

Bansal, Feige, Krauthgamer, Makarychev, Nagarajan, Naor, and Schwartz [3] gave a bi-criteria approximation algorithm for Unbalanced Terminal Cut that we state in the following theorem.

**Algorithm 1** Covering Procedure.

Set $t = 1$, and $\mu_1(v) = 1$ for all $v \in V$. Let $\mathcal{S} = \varnothing$.
**while** $\sum_{v \in V} \mu_t(v) \geq \frac{1}{n}$ **do**
  Let $P_i^*$ be a set as stated in Lemma 14.
  Guess $\mu_t(P_i^*)$.
  Let $S_t \subseteq V$ be the solution for Unbalanced Terminal Cut instance $\langle G, w, \mu_t, \max\{\frac{1}{2k}, \frac{\mu_t(P_i^*)}{\mu_t(V)}\}, T\rangle$.
  Let $\mathcal{S} = \mathcal{S} \cup \{S_t\}$.
  **for** $v \in V$ **do**
    Set $\mu_{t+1}(v) = \begin{cases} \mu_t(v)/2, & \text{if } v \in S_t, \\ \mu_t(v), & \text{if } v \notin S_t. \end{cases}$
  Set $t = t + 1$
**return** $\mathcal{S}$.

▶ **Theorem 10.** *There exists a polynomial-time algorithm that given an instance $\langle G, w, \mu, \rho, T\rangle$ of Unbalanced Terminal Cut, finds a set $S \subseteq V$ satisfying $|S \cap T| \leq 1$, $\mu(S) \geq \Omega(\rho) \cdot \mu(V)$, and $\delta(S) \leq \alpha \cdot \mathrm{OPT}_{\langle G,w,\mu,\rho,T\rangle}$ where $\alpha = O\left(\sqrt{\log n \log 1/\rho}\right)$.*

Our covering procedure relies on the multiplicative weights update method and is inspired by the algorithm in [3]. It initializes the measure of each vertex to one. At each iteration $t$, the algorithm guesses the measure $\mu_t(P_i^*)$ of a particular set $P_i^*$ in an optimal solution and computes $S_t$ of measure $\mu_t(S_t) \approx \mu_t(P_i^*)$ using the Unbalanced Terminal Cut algorithm in Theorem 10. The existence of such a $P_i^*$ is shown in Lemma 14. Once $S_t$ is computed, the algorithm decreases the measure of the vertices covered by $S_t$ by a factor of 2. The algorithm terminates when the total measure of vertices is less than $1/n$.

We guess $\mu_t(P_i^*)$ as follows: For any set $S \subseteq V$, its measure $\mu_t(S)$ lies in the range $[\mu_t(u), n \cdot \mu_t(u)]$, where $u = \arg\max_{v \in S} \mu_t(v)$ is the heaviest vertex in $S$. Thus $\mu_t(P_i^*)$ can be well approximated by the set $A = \left\{2^i \cdot \mu_t(v) : v \in V, i = 0, \ldots, \lfloor \log_2 n \rfloor\right\}$ of size $O(n \log n)$. For each candidate $a \in A$ we compute a set $S(a)$ using the Unbalanced Terminal Cut algorithm with a parameter $a$ and choose $S_t = \arg\min_{a \in A} \delta(S(a))$ with the smallest cost. We give a pseudo-code for this algorithm in Algorithm 1. We remark that one can think of this algorithm as of multiplicative weight update algorithm for solving a covering LP with constraints from Lemma 8.

We then analyze this covering algorithm in Algorithm 1. Let $\mathcal{S} = \{S_1, \cdots, S_m\}$ denote the collection of $m$ sets output by Algorithm 1. By Theorem 10, every set $S_i$ contains at most one terminal. First, for any fixed vertex $v \in V$, we give a lower bound on the number of sets containing $v$.

▷ Claim 11. For a vertex $v \in V$, let $N_v = |\{S_t |\ v \in S_t\}|$ denote the number of sets containing $v$. Then $N_v \geq \Omega(\log n)$.

Proof. Recall that initially $\mu_1(v) = 1$ and after iteration $m$ its measure becomes $\mu_{m+1}(v) = \left(\frac{1}{2}\right)^{N_v}$. Due to the stopping condition of our algorithm we have $\mu_{m+1}(V) < \frac{1}{n}$. Thus, $\frac{1}{2^{N_v}} < \frac{1}{n}$ and the claim follows. ◁

Next, we bound the number of sets in $\mathcal{S}$. In the following claim we give an upper bound on the total normalized measure of the sets produced by our algorithm.

▷ Claim 12. $\sum_{t=1}^{m} \frac{\mu_t(S_t)}{\mu_t(V)} \leq 4 \ln n + 1$.

Proof. Observe that the total measure at iteration $t$ can be described as follows:

$$\mu_t(V) = \mu_{t-1}(V) - \frac{\mu_{t-1}(S_{t-1})}{2} = \mu_{t-1}(V) \cdot \left(1 - \frac{\mu_{t-1}(S_{t-1})}{2\mu_{t-1}(V)}\right).$$

Since $\mu_m(V) \geq \frac{1}{n}$, we have

$$\frac{1}{n} \leq \mu_m(V) = \mu_1(V) \cdot \prod_{t=1}^{m-1} \left(1 - \frac{\mu_t(S_t)}{2\mu_t(V)}\right) \leq n \cdot \prod_{t=1}^{m-1} e^{-\frac{\mu_t(S_t)}{2\mu_t(V)}} = n \cdot e^{-\frac{1}{2}\cdot\sum_{t=1}^{m-1}\frac{\mu_t(S_t)}{\mu_t(V)}},$$

which implies $\sum_{t=1}^{m-1} \frac{\mu_t(S_t)}{\mu_t(V)} \leq 4\ln n$. Since $\frac{\mu_m(S_m)}{\mu_m(V)} \leq 1$, we get the desired result. ◁

We obtain an upper-bound on the number of sets in $\mathcal{S}$ which immediately follows from Claim 12 and the fact that $\mu_t(S_t) \geq \Omega(1/k)\mu_t(V)$ for all $t$.

▶ **Corollary 13.** *The cover $\mathcal{S}$ returned by Algorithm 1 contains $m = O(k \log n)$ sets.*

We prove the existence of a set in an optimal solution with large measure and small cut value.

▶ **Lemma 14.** *Let $\mathcal{P}^* = (P_1^*, \dots, P_k^*)$ be an optimal solution to an $\ell_p$-norm Multiway Cut instance and let* OPT *denote the $\ell_p$-norm of $\mathcal{P}^*$. For any measure $\mu : V \to \mathbb{R}_{\geq 0}$ on vertices such that $\mu(V) \neq 0$, there exists an $i \in [k]$ such that the following three conditions hold:*

1. $\delta(P_i^*)^p \leq 5 \cdot \mathrm{OPT}^p \cdot \frac{\mu(P_i^*)}{\mu(V)}$
2. $\delta(P_i^*) \leq 5k^{1-1/p} \cdot \mathrm{OPT} \cdot \frac{\mu(P_i^*)}{\mu(V)}$
3. $\mu(P_i^*) \geq \frac{\mu(V)}{2k}$

**Proof.** Let

$$J = \{j \in [k] : \delta(P_j^*)^p \leq 5 \cdot \mathrm{OPT}^p \cdot {}^{\mu(P_j^*)}\!/_{\mu(V)}, \delta(P_j^*) \leq 5k^{1-1/p} \cdot \mathrm{OPT} \cdot {}^{\mu(P_j^*)}\!/_{\mu(V)}\}$$

be the indices of sets in $\mathcal{P}^*$ that satisfies conditions 1 and 2 in Lemma 14. It is sufficient to show that $\sum_{j\in[k]\setminus J} \mu(P_j^*) < \mu(V)/2$. If $\sum_{j\in[k]\setminus J} \mu(P_j^*) < \mu(V)/2$, then there exists a $j \in J$ such that $\mu(P_j^*) \geq {}^{\mu(V)}\!/_{2k}$, which implies this set $P_j^*$ satisfies all three conditions.

We now show that $\sum_{j\in[k]\setminus J} \mu(P_j^*) < \mu(V)/2$. Let $\bar{J}_1 = \{j \in [k] \setminus J : \delta(P_j^*)^p > 5 \cdot \mathrm{OPT}^p \cdot {}^{\mu(P_j^*)}\!/_{\mu(V)}\}$ be the indices of sets $P_j^*$ that does not satisfy condition 1. Let $\bar{J}_2 = \{j \in [k] \setminus J : \delta(P_j^*) > 5k^{1-1/p} \cdot \mathrm{OPT} \cdot {}^{\mu(P_j^*)}\!/_{\mu(V)}\}$ be the indices of sets $P_j^*$ that does not satisfy condition 2. Note that $[k] \setminus J = \bar{J}_1 \cup \bar{J}_2$. Then, we have

$$\begin{aligned}
\sum_{j\in[k]\setminus J} \mu(P_j^*) &\leq \sum_{j\in\bar{J}_1} \mu(P_j^*) + \sum_{j\in\bar{J}_2} \mu(P_j^*) \\
&\leq \sum_{j\in\bar{J}_1} \mu(V) \cdot \frac{\delta(P_j^*)^p}{5\,\mathrm{OPT}^p} + \sum_{j\in\bar{J}_2} \mu(V) \cdot \frac{\delta(P_j^*)}{5k^{1-1/p}\,\mathrm{OPT}} \\
&\leq \mu(V) \cdot \sum_{j\in[k]} \left(\frac{\delta(P_j^*)^p}{5\,\mathrm{OPT}^p} + \frac{\delta(P_j^*)}{5k^{1-1/p}\,\mathrm{OPT}}\right).
\end{aligned}$$

Since $\mathcal{P}^*$ is a partition with an optimal cost, we have

$$\sum_{i=1}^{k} \delta(P_i^*)^p = \mathrm{OPT}^p.$$

Similarly, we have

$$k^{-1/p} \cdot \mathrm{OPT} = \left( \sum_{i=1}^{k} \frac{1}{k} \cdot \delta(P_i^*)^p \right)^{1/p} \geq \frac{1}{k} \sum_{i=1}^{k} \delta(P_i^*),$$

where the inequality follows from Jensen's inequality. Thus, we have

$$\sum_{j \in [k] \setminus J} \mu(P_j^*) \leq \mu(V) \cdot \sum_{j \in [k]} \frac{\delta(P_j^*)^p}{5\,\mathrm{OPT}^p} + \frac{\delta(P_j^*)}{5k^{1-1/p}\,\mathrm{OPT}} \leq \mu(V) \cdot \frac{2}{5} < \frac{\mu(V)}{2}. \qquad \blacktriangleleft$$

We now prove the main lemma in this section. Specifically, we give two upper-bounds on the $\ell_1$-norm and $\ell_p$-norm of the cut values of the sets produced by the covering procedure in Algorithm 1, respectively.

**Proof of Lemma 8.** We already show the number of sets in $\mathcal{S}$ is at most $m = O(k \log n)$ in Corollary 13. By Theorem 10 and Claim 11, we have every $S_i$ contains at most one terminal and all sets in $\mathcal{S}$ covers the entire graph. Thus, it is sufficient to prove the two bounds on the $\ell_1$-norm and $\ell_p$-norm of the cut values of the sets in $\mathcal{S}$ as shown in Conditions 3 and 4 in the lemma.

Due to Lemma 14 at each iteration $t$, there exists a set $P_i^*$ in an optimal solution with a measure $\mu_t(P_i^*) \geq \frac{\mu_t(V)}{2k}$ such that

$$\delta(P_i^*) \leq 5 \cdot \min \left\{ \left( \frac{\mu_t(P_i^*)}{\mu_t(V)} \right)^{1/p}, k^{1-1/p} \cdot \frac{\mu_t(P_i^*)}{\mu_t(V)} \right\} \cdot \mathrm{OPT}\,.$$

Thus, at each iteration $t$ of Algorithm 1, we have

$$\delta(S_t) \leq O(\alpha) \cdot \min \left\{ \left( \frac{\mu_t(P_i^*)}{\mu_t(V)} \right)^{1/p}, k^{1-1/p} \cdot \frac{\mu_t(P_i^*)}{\mu_t(V)} \right\} \cdot \mathrm{OPT}\,.$$

Note that each set $S_t$ is computed by the Unbalanced Terminal Cut algorithm in Theorem 10. Thus, we have $\mu_t(S_t) \geq \Omega(\mu_t(P_i^*))$. Since $\mu_t(S_t) \geq \Omega(\mu_t(P_i^*))$ holds, we obtain (1) $\delta(S_t)^p \leq O(\alpha^p) \cdot \mathrm{OPT}^p \cdot \frac{\mu_t(S_t)}{\mu_t(V)}$; and (2) $\delta(S_t) \leq O(\alpha) \cdot k^{1-1/p} \cdot \mathrm{OPT} \cdot \frac{\mu_t(S_t)}{\mu_t(V)}$. These provide

$$\sum_{t=1}^{m} \delta(S_t)^p \leq O(\alpha^p) \cdot \mathrm{OPT}^p \cdot \sum_{t=1}^{m} \frac{\mu_t(S_t)}{\mu_t(V)},$$
$$\sum_{t=1}^{m} \delta(S_t) \leq O(\alpha) \cdot k^{1-1/p} \cdot \mathrm{OPT} \cdot \sum_{t=1}^{m} \frac{\mu_t(S_t)}{\mu_t(V)}.$$

By Claim 12, we have $\sum_{t=1}^{m} \frac{\mu_t(S_t)}{\mu_t(V)} = O(\log n)$. Then, we get the desired upper bounds on $\sum_{t=1}^{m} \delta(S_t)^p$ and $\sum_{t=1}^{m} \delta(S_t)$. $\blacktriangleleft$

## 2.2 Uncrossing and Aggregation Procedures

In this section, we provide procedures that transform the cover of the graph $\mathcal{S}$ produced by the covering procedure into a partition of the graph $\mathcal{P} = \{P_1, P_2, \ldots, P_k\}$. Each set $P_i$ in $\mathcal{P}$ contains exactly one terminal in $T$. With a positive probability, this solution is an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for the $\ell_p$-Norm Multiway Cut.

▶ **Theorem 15.** *Given a graph $G = (V, E)$ and $k$ terminals $T \subset V$, there exists a polynomial-time algorithm that returns a partition of the graph $\mathcal{P} = \{P_1, P_2 \ldots, P_k\}$ such that with probability at least $3/4 - 1/k$*

1. $|P_i \cap T| = 1$ *for all* $i \in [k]$,
2. $\left(\sum_{i=1}^{k} \delta(P_i)^p\right)^{1/p} \leq O(\log^{1/2} n \log^{1/2+1/p} k) \cdot \mathrm{OPT}$.

Note that the sets in the cover $\mathcal{S}$ are not disjoint. We first use the uncrossing procedure to generate a $m' = O(k \log k)$ partition of the graph $\mathcal{P}' = \{P'_1, P'_2, \ldots, P'_{m'}\}$ from the cover $\mathcal{S}$ produced by the covering procedure. We sample $O(k \log k)$ sets from $\mathcal{S}$ uniformly at random. These sampled sets cover a large fraction of the graph. Then, we generate disjoint sets from these sampled sets by using the uncrossing step in [3]. The uncrossing procedure is shown in Algorithm 2. We then merge these sets in $\mathcal{P}'$ to get a $k$-partition $\mathcal{P}$ using the aggregation procedure in Algorithm 3.

In the aggregation procedure, we assign all sets in $\mathcal{P}'$ into $k$ parts to get a $k$-partition. Since $\mathcal{P}' = \{P'_1, P'_2, \ldots, P'_{m'}\}$ is a partition of the graph and each set $P'_i$ contains at most one terminal, there are exactly $k$ sets containing one terminal in $\mathcal{P}'$. Suppose $P'_1, P'_2, \cdots, P'_k$ are these sets containing one terminal. We initially assign these sets $P'_1, P'_2, \cdots, P'_k$ to $k$ parts $P_1, P_2, \ldots, P_k$. Let $\mathcal{Q} = \mathcal{P}' \setminus \{P_1, P_2, \cdots, P_k\}$ be the sets in $\mathcal{P}'$ that does not contain any terminals. We assign all sets in $\mathcal{Q}$ into $k$ parts in a round-robin approach. We sort the sets in $\mathcal{Q}$ by the cut values in descending order and denote it by $\mathcal{Q} = \{Q_1, Q_2, \ldots, Q_{m'-k}\}$. We then partition all sets in $\mathcal{Q}$ into $k$ buckets $\mathcal{Q}_1, \ldots, \mathcal{Q}_k$ as follows. Consider every $k$ consecutive sets $\{Q_{jk+1}, Q_{jk+2}, \cdots, Q_{(j+1)k}\}$ in $\mathcal{Q}$ for $0 \leq j \leq \lfloor m'-k/k \rfloor$. If $jk + i > n$ for $j = \lfloor m'-k/k \rfloor$ and some $i \in [k]$, then let $Q_{jk+i} = \varnothing$. For every $i \in [k]$, we assign the set $Q_{jk+i}$ to the bucket $\mathcal{Q}_i$. Finally, we assign each bucket $\mathcal{Q}_i$ to part $P_i$ and set $P_i = P_i \cup (\bigcup_{Q_j \in \mathcal{Q}_i} Q_j)$.

**Algorithm 2** Uncrossing Procedure.

Sample $m'' - 1 = 12k \ln k$ sets $\mathcal{S}' = (S'_1, S'_2, \ldots, S'_{m''-1})$ from $\mathcal{S}$ uniformly at random.
Sort sets in $\mathcal{S}'$ in a random order.
Set $P'_i = S'_i \setminus \cup_{j<i} S'_j$ for all $i = 1, 2 \ldots, m'' - 1$.
**while** there exists a set $P'_i$ such that $\delta(P'_i) > 2\delta(S'_i)$ **do**
  Set $P'_i = S'_i$ and for all $j \neq i$, $P'_j = P'_j \setminus S'_i$.
Set the set $P'_{m''} = V \setminus \cup_{i=1}^{m''-1} P'_i$.
**return** all non-empty sets $P'_i$.

**Algorithm 3** Aggregation Procedure.

Set $\mathcal{P} = \{P'_i \in \mathcal{P}' : P'_i \cap T \neq \varnothing\} = \{P_1, P_2, \ldots, P_k\}$.
Set $\mathcal{Q} = \mathcal{P}' \setminus \mathcal{P}$.
Sort the sets in $\mathcal{Q} = \{Q_1, \ldots, Q_{m'-k}\}$ by the cut value in descending order.
Partition the sets in $\mathcal{Q}$ into $k$ buckets $\mathcal{Q}_1, \cdots, \mathcal{Q}_k$, where

$$\mathcal{Q}_i = \{Q_j \in \mathcal{Q} : (j-1) \mod k = i - 1\}.$$

Set $P_i = (\bigcup_{Q_j \in \mathcal{Q}_i} Q_j) \cup P_i$ for all $i = 1, \ldots, k$.
**return** all sets $P_1, P_2, \ldots, P_k$.

We first prove the following lemma on the partition $\mathcal{P}'$ returned by the uncrossing procedure.

▶ **Lemma 16.** *Let $\mathcal{S}$ denote the collection of sets produced by the covering procedure for a graph $G = (V, E)$ and $k$ terminals $T$. Given $\mathcal{S}$ as input, the uncrossing procedure as shown in Algorithm 2 generates a $m' = O(k \log k)$ partition of the graph $\mathcal{P}' = \{P'_1, P'_2, \ldots, P'_{m'}\}$ such that with probability at least $3/4 - 1/k$*

1. $|P'_i \cap T| \leq 1$ *for all* $i \in [m']$,
2. $\sum_{i=1}^{m'} \delta(P'_i)^p \leq O(\log k \cdot \alpha^p) \cdot \mathrm{OPT}^p$,
3. $\sum_{i=1}^{m'} \delta(P'_i) \leq O(k^{1-1/p} \cdot \alpha) \cdot \mathrm{OPT}$,

*where $\alpha = \sqrt{\log n \log k}$.*

**Proof.** We consider all sets $P'_1, P'_2, \ldots, P'_{m''}$ generated in the uncrossing procedure (Algorithm 2), including those empty sets that are not returned. If the set $P'_i$ is empty, we take $\delta(P'_i) = 0$. It is easy to see that these sets $P'_1, P'_2, \ldots, P'_{m''}$ are disjoint, and $\bigcup_{i=1}^{m''} P'_i = V$.

We first show that Algorithm 2 terminates in polynomial time. In graph $G$, we assume that the ratio between the largest non-infinite edge weight $w_{max}$ and the smallest non-zero edge weight $w_{min}$ is at most $w_{max}/w_{min} \leq n^2/\varepsilon$ for a small constant $\varepsilon > 0$. If the graph does not satisfy this assumption, then we transform it into an instance satisfying this condition as follows. We guess the largest weight of the cut edge in the optimal solution, denoted by $W$. There are at most $O(n^2)$ different edge weights. Then, we construct a new graph $G'$ with the same vertex set $V$ and edge set $E$. For every edge $e \in E$, we assign its weight $w'(e)$ in $G'$ to be $w(e)$ if $\varepsilon W/n^2 \leq w(e) \leq W$, $w'(e) = 0$ if $w(e) < \varepsilon W/n^2$, and $w'(e) = \infty$ if $w(e) \geq W$. Thus, the new graph $G'$ satisfies the assumption that $w_{max}/w_{min} \leq n^2/\varepsilon$. Let $\mathrm{OPT}'$ be the optimal value of $\ell_p$ multiway cut on graph $G'$. We know that $\mathrm{OPT}' \leq \mathrm{OPT}$ since the optimal multiway cut on graph $G$ has a smaller value on graph $G'$. Suppose we find an $\alpha$-approximation for $\ell_p$ multiway cut on graph $G'$. Then, the same partition on the original graph $G$ has an objective value at most $\alpha \cdot \mathrm{OPT}' + \varepsilon W \leq (\alpha + \varepsilon)\,\mathrm{OPT}$. Hence, this $\alpha$-approximation solution on $G'$ provides an $(\alpha + \varepsilon)$-approximation on $G$.

Consider any iteration of Algorithm 2. Let $P'_i$ be the partition of $V$ before the current uncrossing iteration. Suppose we pick a set $P'_i$ such that $\delta(P'_i) > 2\delta(S'_i)$. For any two subsets $A, B \subseteq V$, we use $\delta(A, B)$ to denote the total weight of edges crossing $A$ and $B$. Then, we have the $\ell_1$-norm of the cut values after this iteration is

$$\begin{aligned}
\delta(S'_i) + \sum_{j \neq i} \delta(P'_j \setminus S'_i) &\leq \delta(S'_i) + \sum_{j \neq i} \delta(P'_j) - \delta(P'_j, S'_i \setminus P'_j) + \delta(S'_i, P'_j \setminus S'_i) \\
&\leq \delta(S'_i) - \delta(P'_i) + \delta(S'_i) + \sum_{j \neq i} \delta(P'_j) \\
&\leq 2\delta(S'_i) - 2\delta(P'_i) + \sum_j \delta(P'_j) \leq \sum_j \delta(P'_j) - 2w_{min},
\end{aligned}$$

where the last inequality is due to $\delta(P'_i) > 2\delta(S'_i)$ and the minimum non-zero edge weight is $w_{min}$. Thus, the $\ell_1$-norm of the cut values decreases by $2w_{min}$ after each iteration. Since the largest $\ell_1$-norm of the cut values is at most $w_{max}n^2$, the total number of iterations is polynomial in $n$.

We then show that the partition returned by Algorithm 2 satisfies two conditions in the Lemma. We first show that each set $P'_i$ contains at most one terminal. Note that for every $i = 1, 2, \ldots, m'' - 1$, the set $P'_i$ is a subset of $S'_i \in \mathcal{S}$. By Lemma 8, we have

$|P'_i \cap T| \le |S'_i \cap T| \le 1$ for all $i = 1, 2, \ldots, m'' - 1$. By Claim 11, every vertex $u \in V$ is covered by at least $\log_2 n$ sets in $\mathcal{S}$. By Corollary 13, the cover $\mathcal{S}$ contains at most $6k \log_2 n$ sets. Thus, a random set in $\mathcal{S}$ covers $u$ with probability at least $1/6k$. For each vertex $u \in V$, the probability that $u$ is not covered by any set in $\mathcal{S}'$ is at most

$$\mathbb{P}\{u \notin \cup_{i=1}^{m''-1} S'_i\} \le \left(1 - \frac{1}{6k}\right)^{12k \ln k} \le \frac{1}{k^2}. \tag{1}$$

By the union bound over all terminals, all terminals are covered by $\mathcal{S}'$ with probability at least $1 - 1/k$. Thus, the set $P'_{m''}$ contains no terminal with probability at least $1 - 1/k$.

We now bound the $\ell_1$-norm of the cut values of sets $P'_1, P'_2, \ldots, P'_{m''}$. The first two steps in Algorithm 2 can be implemented equivalently by sorting sets in $\mathcal{S}$ in a random order and picking the first $m'' - 1 = 12k \ln k$ sets as $\mathcal{S}'$. Let $S_1, S_2, \ldots, S_m$ be the sets in $\mathcal{S}$ in a random order. Let $\tilde{P}_i = S'_i \setminus \cup_{j<i} S'_j$ for $i = 1, 2, \ldots, m$. Then, for any $i = 1, 2, \ldots, m'' - 1$, the set $\tilde{P}_i$ corresponds to the set $P'_i$ before running the while loop in Algorithm 2.

We first bound the expected $\ell_1$-norm of the cut values of sets $\tilde{P}_1, \tilde{P}_2, \ldots, \tilde{P}_{m''-1}$. Note that we have

$$\sum_{i=1}^{m''-1} \delta(\tilde{P}_i) \le \sum_{i=1}^{m} \delta(\tilde{P}_i).$$

We assign each cut edges $(u, v) \in \partial \tilde{P}_i$ into the following two types: (1) edge $(u, v)$ is cut by a set $\tilde{P}_j$ for $j < i$; (2) edge $(u, v)$ is first cut by the set $\tilde{P}_i$. Let $E_i$ be the set of cut edges that first cut by the set $\tilde{P}_i$. Let $w(E_i) = \sum_{e \in E_i} w(e)$ be the total weight of edges in $E_i$. Each cut edge is counted twice in $\sum_{i=1}^{m} \delta(\tilde{P}_i)$, while each cut edge is counted exactly once in $\sum_{i=1}^{m} w(E_i)$. Thus, we have

$$\sum_{i=1}^{m} \delta(\tilde{P}_i) = 2 \sum_{i=1}^{m} w(E_i).$$

Note that $E_i \subseteq \partial S_i$ is a subset of edges cut by $S_i$. Each edge $(u, v) \in \partial S_i$ is a cut edge in $E_i$ after uncrossing if and only if $S_i$ is the first set among all sets that contain node $u$ or node $v$ in the uncrossing sequence. Suppose $S_i$ only contains node $u$. Then, the probability that $(u, v)$ is contained in $E_i$ is at most the probability that $S_i$ is the first set among all the sets that contain node $u$ in the uncrossing sequence. If a set in $\mathcal{S}$ that contains node $v$ is before set $S_i$, then this edge $(u, v)$ is not count in $E_i$. By Claim 11, we have

$$\mathbb{P}\{(u, v) \in E_i\} \le \mathbb{P}\{S_i \text{ is the first set that contains } u\} \le \frac{1}{\log_2 n}.$$

Therefore, we have the expected $\ell_1$-norm of the cut values of sets $\tilde{P}_1, \tilde{P}_2, \ldots, \tilde{P}_m$ is at most

$$\begin{aligned}\mathbf{E}\left[\sum_{i=1}^{m} \delta(\tilde{P}_i)\right] &= 2 \sum_{i=1}^{m} \mathbf{E}[w(E_i)] = 2 \sum_{i=1}^{m} \sum_{e \in \partial S_i} w(e) \cdot \mathbb{P}\{e \in E_i\} \\ &\le \frac{2}{\log_2 n} \sum_{i=1}^{m} \delta(S_i) \le k^{1-1/p} \cdot O(\alpha) \cdot \mathrm{OPT},\end{aligned}$$

where the last inequality is from Lemma 8. At every iteration of the while loop, the $\ell_1$-norm of the cut values of sets $P'_1, P'_2, \cdots, P'_{m''-1}$ only decreases. Thus, we have

$$\mathbf{E}\left[\sum_{i=1}^{m''-1} \delta(P'_i)\right] \le \mathbf{E}\left[\sum_{i=1}^{m''-1} \delta(\tilde{P}_i)\right] \le k^{1-1/p} \cdot O(\alpha) \cdot \mathrm{OPT}\,.$$

Thus, the expected $\ell_1$-norm of the cut values of sets $P'_1, P'_2, \ldots, P'_{m''}$ is

$$\mathbf{E}\left[\sum_{i=1}^{m''} \delta(P'_i)\right] \leq 2 \cdot \mathbf{E}\left[\sum_{i=1}^{m''-1} \delta(P'_i)\right] \leq k^{1-1/p} \cdot O(\alpha) \cdot \mathrm{OPT}\,.$$

To bound the $\ell_p$-norm of edge boundaries, we then bound the edge boundary of the last set $P'_{m''}$. We only consider the subsampling process in the uncrossing procedure. We sample $O(k \log k)$ sets from the cover $\mathcal{S}$ uniformly at random. Consider every edge $(u, v)$ in the boundary of sets in cover $\mathcal{S}$. If this edge $(u, v)$ is a cut edge crossing $P'_{m''}$ and $v \in P'_{m''}$, then one of the sets $S_i \in \mathcal{S}$ that contains node $u$ is sampled and node $v$ is not covered by sampled sets. Each set $S_i \in \mathcal{S}$ is sampled with probability $O(\log k / \log n)$. Suppose the set $S_i \in \mathcal{S}$ cuts this edge $(u, v)$ and contains node $u$. Similar to Equation (1), the probability that node $v \in P'_{m''}$ conditioned on $S_i \in \mathcal{S}'$ is at most $2/k^2$. Thus, we have

$$\begin{aligned}
\mathbf{E}[\delta(P'_{m''})] &= \mathbf{E}\left[w\left\{(u,v) \in \bigcup_{i=1}^{m''-1} \partial S'_i : u \notin P'_{m''} \text{ and } v \in P'_{m''}\right\}\right] \\
&\leq \sum_{i=1}^{m} \sum_{(u,v)\in\partial S_i} w(u,v) \cdot \mathbb{P}\{u \in S_i, S_i \in \mathcal{S}', v \in P'_{m''}\} \\
&\leq O\left(\frac{1}{k^2} \cdot \frac{\log k}{\log n}\right) \cdot \sum_{i=1}^{m} \delta(S_i) \leq O(\alpha) \cdot \mathrm{OPT},
\end{aligned}$$

where the last inequality is due to condition 4 in Lemma 8.

After the while loop, we have $\delta(P'_i) \leq 2\delta(S'_i)$ for all $i = 1, 2, \ldots, m''-1$. Since $\mathbf{E}[\delta(P'_{m''})] \leq O(\alpha) \cdot \mathrm{OPT}$, by Markov's Inequality, we have with probability at least $7/8$ that $\delta(P'_{m''}) \leq O(\alpha) \cdot \mathrm{OPT}$. Since we subsample a fraction $O(\log k / \log n)$ of sets in the cover $S$ uniformly at random, we have

$$\mathbf{E}\left[\sum_{i=1}^{m''-1} \delta(S'_i)^p\right] \leq O\left(\frac{\log k}{\log n}\right) \sum_{i=1}^{m} \delta(S_i)^p.$$

When $\delta(P'_{m''}) \leq O(\alpha) \cdot \mathrm{OPT}$, we have

$$\begin{aligned}
\mathbf{E}\left[\sum_{i=1}^{m''} \delta(P'_i)^p\right] &\leq 2^p \cdot \mathbf{E}\left[\sum_{i=1}^{m''-1} \delta(S'_i)^p\right] + \mathbf{E}\delta(P'_{m''})^p \\
&\leq 2^p \cdot O\left(\frac{\log k}{\log n}\right) \sum_{i=1}^{m} \delta(S_i)^p + O(\alpha^p) \cdot \mathrm{OPT}^p \leq O(\log k \cdot \alpha^p) \cdot \mathrm{OPT}^p,
\end{aligned}$$

where the third inequality is from the condition 3 in Lemma 8. Therefore, we have the conditions 2 and 3 in this lemma hold in expectation with probability at least $7/8$. By Markov's Inequality, we have the conditions 2 and 3 in the lemma hold simultaneously with probability at least $3/4$. Since the condition 1 hold with probability at least $1 - 1/k$, we have all conditions hold with probability at least $3/4 - 1/k$. ◀

Next, we analyze the aggregation procedure, which merges these sets to get a $k$ partition of the graph.

**Proof of Theorem 15.** By Lemma 16, the partition $P'_1, P'_2, \ldots, P'_{m'}$ returned by the uncrossing procedure (Algorithm 2) satisfies the following three conditions with probability at least $3/4 - 1/k$:

1. $|P'_i \cap T| \le 1$ for all $i \in [m']$,
2. $\sum_{i=1}^{m'} \delta(P'_i)^p \le O(\log k \cdot \alpha^p) \cdot \mathrm{OPT}^p$,
3. $\sum_{i=1}^{m'} \delta(P'_i) \le O(k^{1-1/p} \cdot \alpha) \cdot \mathrm{OPT}$.

We now assume the partition $\mathcal{P}' = \{P'_1, P'_2, \dots, P'_{m'}\}$ given by the uncrossing procedure satisfies these three conditions. Then, we use the aggregation procedure as shown in Algorithm 3 on this partition $\mathcal{P}' = \{P'_1, P'_2, \dots, P'_{m'}\}$ to get a $k$-partition $\mathcal{P} = \{P_1, P_2, \cdots, P_k\}$. Since each part $P_i$ has exactly one set $P'_i$ containing one terminal, we have $|P_i \cup T| = 1$ for all $i \in [k]$.

We now bound the $\ell_p$-norm of the cut values. Let $Q'_i = \bigcup_{j>k, Q_j \in \mathcal{Q}_i} Q_j$ be the union of sets in bucket $\mathcal{Q}_i$ excluding the set with the largest cut in that bucket. Thus, we have each part $P_i = Q'_i \cup Q_i \cup P'_i$ for all $i \in [k]$. By the triangle inequality, we have

$$\left(\sum_{i=1}^{k} \delta(P_i)^p\right)^{1/p} \le \left(\sum_{i=1}^{k} \delta(Q'_i)^p\right)^{1/p} + \left(\sum_{i=1}^{k} \delta(Q_i)^p\right)^{1/p} + \left(\sum_{i=1}^{k} \delta(P'_i)^p\right)^{1/p}.$$

By Lemma 16, the $\ell_p$-norm of the cut values of sets $P'_1, P'_2, \dots, P'_k$ is

$$\left(\sum_{i=1}^{k} \delta(P'_i)^p\right)^{1/p} \le O(\log^{1/p} k \cdot \alpha) \cdot \mathrm{OPT}\,.$$

Similarly, we have the $\ell_p$-norm of the cut values of sets $Q_1, Q_2, \dots, Q_k$ is

$$\left(\sum_{i=1}^{k} \delta(Q_i)^p\right)^{1/p} \le O(\log^{1/p} k \cdot \alpha) \cdot \mathrm{OPT}\,.$$

We then bound the $\ell_p$-norm of the cut values of sets $Q'_1, Q'_2, \dots, Q'_k$. We first bound the cut value of each set $Q'_i$. Since $Q_i$ are sorted by the cut value in descending order, we have

$$\delta(Q'_i) \le \sum_{j>k, Q_j \in \mathcal{Q}_i} \delta(Q_j) \le \sum_{Q_j \in \mathcal{Q}_k} \delta(Q_j) \le \frac{1}{k} \sum_{Q_j \in \mathcal{Q}} \delta(Q_j),$$

where the second inequality is due to $\delta(Q_{i+zk}) \le \delta(Q_{zk})$ for $z \ge 1$ and the third inequality is because $\mathcal{Q}_k$ contains the smallest cut set for every $k$ consecutive sets. By Lemma 16, we have

$$\delta(Q'_i) \le \frac{1}{k} \cdot \sum_{Q_j \in \mathcal{Q}} \delta(Q_j) \le O(k^{-1/p} \cdot \alpha) \cdot \mathrm{OPT}\,.$$

Therefore, we have $\ell_p$-norm of the cut values of sets $Q'_1, Q'_2, \dots, Q'_k$ is at most

$$\left(\sum_{i=1}^{k} \delta(Q'_i)^p\right)^{1/p} \le \left(k \cdot O(k^{-1} \cdot \alpha^p) \cdot \mathrm{OPT}^p\right)^{1/p} = O(\alpha) \cdot \mathrm{OPT}\,.$$

Combining three parts, we get the conclusion. ◀

By Theorem 15, given a graph with $n$ vertices and $k$ terminals, our algorithm finds an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for the $\ell_p$-Norm Multiway Cut with probability at least $3/4 - 1/k$. We can repeat this algorithm $O(\log 1/\varepsilon)$ times to find an $O(\log^{1/2} n \log^{1/2+1/p} k)$ approximation for the $\ell_p$-Norm Multiway Cut with probability at least $1 - \varepsilon$, which proves Theorem 1.

## Abstract

We prove the following result about approximating the maximum independent set in a graph. Informally, we show that any approximation algorithm with a "non-trivial" approximation ratio (as a function of the number of vertices of the input graph $G$) can be turned into an approximation algorithm achieving almost the same ratio, albeit as a function of the treewidth of $G$. More formally, we prove that for any function $f$, the existence of a polynomial time $(n/f(n))$-approximation algorithm yields the existence of a polynomial time $O(\mathsf{tw} \cdot \log f(\mathsf{tw})/f(\mathsf{tw}))$-approximation algorithm, where $n$ and $\mathsf{tw}$ denote the number of vertices and the width of a given tree decomposition of the input graph. By pipelining our result with the state-of-the-art $O(n \cdot (\log \log n)^2/\log^3 n)$-approximation algorithm by Feige (2004), this implies an $O(\mathsf{tw} \cdot (\log \log \mathsf{tw})^3/\log^3 \mathsf{tw})$-approximation algorithm.

## 1 Introduction

An independent set of a graph is a subset of pairwise non-adjacent vertices. The Maximum Independent Set problem, which asks to find an independent set of maximum cardinality of a given input graph on $n$ vertices, has been among the most fundamental optimization problems that appeared in many research areas of computer science and has been a canonical problem of study in algorithms.

In the field of *approximation algorithms*, the problem is notoriously hard: It has no $O(n/2^{\log^{3/4} n})$-approximation algorithm running in polynomial time unless $NP$ can be solved in randomized quasi-polynomial time by the work of Khot and Ponnuswami [15] (building on earlier work by among others Håstad [14]). The best known polynomial time approximation algorithm is an $\tilde{O}(n/\log^3 n)$-approximation by Feige [9], which is almost twenty years old; here the $\tilde{O}$-notation hides factors polynomial in $\log\log n$.

Besides measuring the approximation ratio as a function of $n$, two other directions have been suggested in the literature. One of the directions is to measure the ratio as a function of the maximum degree $d$ of the input graph. The first improvement over the naive greedy $(d+1)$-approximation to $o(d)$ was given by Halldorsson and Radhakrishnan [12] in 1994. After this, several improvements to this approximation were made [1, 11, 13], culminating in the currently best $\tilde{O}(d/\log^{1.5} d)$-approximation by Bansal, Gupta, and Guruganesh [4] with an almost matching lower bound of $\Omega(d/\log^2 d)$ under the Unique Games Conjecture (UGC) by Austrin, Khot, and Safra [2]; here the $\tilde{O}$-notation hides factors polynomial in $\log\log d$.

Another direction is to measure the approximation ratio as a function of the *treewidth* of the input graph. Here, a simple greedy algorithm that is based on the fact that graph of treewidth $\mathsf{tw}$ are $\mathsf{tw}$-degenerate (see Lemma 2.5) achieves an approximation ratio of $(\mathsf{tw}+1)$. This was improved by Czumaj, Halldórsson, Lingas, and Nilsson [7] in 2005, who gave a $(\mathsf{tw}/\log n)$-approximation algorithm when a tree decomposition of width $\mathsf{tw}$ is given with the input graph. Their algorithm is quite elegant and follows easily from the observation that one can greedily partition the vertices of the graph into sets $V_1, \ldots, V_r$ such that the treewidth of $G[V_i]$ is at most $\mathsf{tw}/r$. Combined with dynamic programming for independent set on graphs of bounded treewidth, this gives a $2^{\mathsf{tw}/r} n^{O(1)}$ time $r$-approximation for any $r$, and therefore runs in polynomial time when we set $r = \mathsf{tw}/\log n$, resulting in the $(\mathsf{tw}/\log n)$-approximation algorithm.

Contrary to the degree-direction of approximating independent set, there has been no progress in the two other directions measuring the approximation ratio as a function on the number of vertices or the treewidth since the milestone results of Feige [9] and Czumaj et al. [7]. It is easy to show that one cannot improve the result of Czumaj et al. [7] to a polynomial time $(\mathsf{tw}/(f(\mathsf{tw})\log n))$-approximation for any diverging positive function $f$, assuming the Exponential Time Hypothesis (ETH). In particular, given an input graph $G$ on $n_0$ vertices we can create a graph $G'$ on $n = 2^{n_0/f(n_0)}$ vertices by adding $n - n_0$ vertices of degree 0. Then $G'$ has treewidth $n_0$ and the assumed algorithm is a $n^{O(1)} = 2^{o(n_0)}$-time $r$-approximation for $r = n_0/(f(n_0)\log n) = 1$, which violates the lower bound that Maximum Independent Set cannot be solved exactly in $2^{o(n_0)}$ time on graphs with $n_0$ vertices, assuming ETH (see e.g. for an equivalent lower bound for Vertex Cover [6, Theorem 14.6] ) .

This ETH lower bound naturally brings us to the question of what is the best approximation ratio in terms of treewidth only. In this paper, we essentially resolve this question by relating the approximation ratio parameterized by treewidth tightly to the approximation ratio parameterized by $n$.

Formally, as our main result we prove the following theorem:

▶ **Theorem 1.1.** *Let $f : \mathbb{N} \to \mathbb{N}$ be a function such that there exists an $\frac{n}{f(n)}$-approximation algorithm for Maximum Independent Set, where $n$ is the number of vertices of the input graph*[1]*. Then there exists an $O\left(\frac{\mathsf{tw} \cdot \log f(\mathsf{tw})}{f(\mathsf{tw})}\right)$-approximation algorithm for Maximum Independent Set, where $\mathsf{tw}$ is the width of a given tree decomposition of the input graph.*

Let $\gamma(n)$ be the approximability function of Maximum Independent Set for $n$-vertex graph (i.e., the function for which $O(\gamma(n))$-approximation exists and $o(\gamma(n))$-approximation is hard). As mentioned before, the current state of the art has provided the lower and upper bounds $\gamma(n) = \Omega(n/2^{\log^{3/4} n})$ [15, 14] and $\gamma(n) = \tilde{O}(n/\log^3 n)$ respectively [9]. Similarly, one can consider Maximum Independent Set parameterized by $\mathsf{tw}$ and define $\tau(\mathsf{tw})$ as the approximability function of Maximum Independent Set on the setting when a tree decomposition of width $\mathsf{tw}$ is given. Our result implies that the approximability functions $\gamma$ and $\tau$ are essentially the same function, so this closes the treewidth-direction of Maximum Independent Set approximation.

We find this phenomenon rather surprising. For some other parameters, such relations do not hold, e.g., when we consider the degree parameter $d$ of the input graph, the approximability function of Maximum Independent Set is $\Omega(d/\log^2 d)$ assuming UGC [2], while the $\tilde{O}(n/\log^3 n)$-approximation of Feige [9] exists.

Combining Theorem 1.1 with the result of Feige [9], we obtain the following corollary.

▶ **Corollary 1.2.** *There exists an $O\left(\frac{\mathsf{tw} \cdot (\log\log \mathsf{tw})^3}{\log^3 \mathsf{tw}}\right)$-approximation algorithm for Maximum Independent Set, where $\mathsf{tw}$ is the width of a given tree decomposition of the input graph.*

This improves over the result of Czumaj et al. [7] when $\log^{1/3} n = o\left(\frac{\log \mathsf{tw}}{\log\log \mathsf{tw}}\right)$, i.e., when $\mathsf{tw}$ is larger than $\exp(\tilde{\Omega}(\log^{1/3} n))$. It is better than the algorithm of Feige [9] whenever $\mathsf{tw} = o(n/\log\log n)$, so overall it improves the state-of-the-art in the range of parameters

$$\exp(\tilde{\Omega}(\log^{1/3} n)) \leq \mathsf{tw} \leq o(n/\log\log n).$$

These results assume that the tree decomposition is given as part of the input. To remove this assumption, we can use the algorithm of Feige et al. [10] to $O(\sqrt{\log \mathsf{tw}})$-approximate treewidth. In particular, their algorithm combined with Corollary 1.2 yields the following corollary in the setting when a tree decomposition is not assumed as a part of the input.

▶ **Corollary 1.3.** *There exists an $O\left(\frac{\mathsf{tw} \cdot (\log\log \mathsf{tw})^3}{\log^{2.5} \mathsf{tw}}\right)$-approximation algorithm for Maximum Independent Set, where $\mathsf{tw}$ is the treewidth of the input graph.*

## Techniques

On a high level, our technique behind Theorem 1.1 is as follows: First we delete a set of vertices of size at most $\mathsf{OPT}/2$ from the graph so that each of the remaining components can be partitioned into subinstances with pathwidth at most $\mathsf{tw}$ and subinstances with tree decompositions of width $O(\mathsf{tw})$ and depth $O(\log f(\mathsf{tw}))$. For the subinstances of small pathwidth, we partition the vertices into $O(\log f(\mathsf{tw}))$ levels based on in how many bags of the path decomposition they occur. Similarly, for the subinstances with $O(\log f(\mathsf{tw}))$-depth tree decompositions, we partition the vertices in levels based on the depth of the highest bag of the tree decomposition they occur in. In both subinstances we argue that all vertices of

[1] We make mild assumptions on the properties of $f$, which are detailed in Section 2. Any "reasonable" function $f$ satisfies these assumptions.

all but one level can be removed, in order to make the vertices in the remaining level behave well in the decomposition, after which the remaining level can be chopped into components of size roughly $O(\mathsf{tw})$ such that the size of maximum independent again does not decrease significantly.

Although some aspects of our approach are natural, we are not aware of arguments modifying the tree decomposition as we did here in the previous literature; we expect these arguments may have more applications for designing approximation algorithms for other $NP$-hard problem parameterized by treewidth similar to Theorem 1.1.

### Organization

The paper is organized as follows. We give preliminaries in Section 2. A major ingredient of Theorem 1.1 will be an approximation algorithm for Maximum Independent Set parameterized by pathwidth, which we will be presented in Section 3. Then, the approximation algorithm for Maximum Independent Set parameterized by treewidth will be presented in Section 4. This will use the pathwidth case as a black box. We then conclude and present open problems in Section 5.

## 2 Preliminaries

### Basic notation

We refer to [8] for standard graph terminology. We use the standard notation – $\alpha(G)$ – to denote the independence number, i.e., the size of a maximum independendent set, of graph $G$. Throughout, for a natural number $i$ we denote the set $\{1, \ldots, i\}$ by $[i]$, and for two natural numbers $i \leq j$ we denote the set $\{i, i+1, \ldots, j\}$ by $[i, j]$. We use log to denote the base-2 logarithm.

### Tree decompositions

Given a graph $G$, a tree decomposition of $G$ consists of a tree $T$, where each node $t \in V(T)$ is associated with a subset $B_t \subseteq V(G)$ of vertices called a bag, such that

1. $\bigcup_{t \in V(T)} B_t = V(G)$
2. For every edge $uv \in E(G)$, there must be some node $t$ such that $\{u, v\} \subseteq B_t$.
3. For every vertex $v \in V(G)$, the bags $\{t : v \in B_t\}$ are connected in $T$.

The **width** of a tree decomposition is $\max_{t \in V(T)} |B_t| - 1$. The **treewidth** of $G$ (denoted by $\mathsf{tw}(G)$) is the minimum number $k$, such that $G$ has a tree decomposition of width $k$. When the input graph is clear from the context, we simply write $\mathsf{tw}$ to denote the treewidth of $G$.

A rooted tree decomposition is a tree decomposition where one node is assigned to be the root of the tree $T$. We use standard rooted-tree definitions when talking about rooted tree decomposition. The depth of a rooted tree decomposition is the depth of the tree $T$, i.e., the length of the longest root-leaf path.

A rooted tree decomposition $T$ is called **nice** if it satisfies that

- Every node of $T$ has at most 2 children.
- If a node $t$ has two children $t'$ and $t''$, then $t$ is called a join node and $B_t = B_{t'} = B_{t''}$.
- If a node $t$ has one child $t'$, then either:
  1. $B_t \subset B_{t'}$ and $|B_{t'}| = |B_t| + 1$, in which case $t$ is a forget node, or
  2. $B_{t'} \subset B_t$ and $|B_t| = |B_{t'}| + 1$, in which case $t$ is an introduce node.
- If a node $t$ has no children we call it a leaf node.

It is well-known that any tree decomposition can be turned into a nice tree decomposition.

▶ **Lemma 2.1** ([16]). *For every graph $G$ on $n$ vertices, given a tree decomposition $T'$ of width $\omega$, there is a nice tree decomposition $T$ with at most $4 \cdot n$ nodes and width $\omega$ that can be computed in polynomial time.*

It is possible to also assume the following additional property without loss of generality.

▶ **Lemma 2.2.** *Given a tree decomposition $T'$ of width $\omega$, there exists a nice tree decomposition of width $\omega$ and at most $4n$ nodes, that can be computed in polynomial time, such that for each leaf node $t \in V(T)$, there exists a vertex $v \in B_t$ that appears in exactly one bag, i.e., the bag $B_t$ itself.*

**Proof.** We use Lemma 2.1 to compute a nice tree decomposition $T$. If there exists a leaf node $t \in V(T)$ that does not contain such a vertex, we delete $t$ from $T$. Notice that all the properties of a tree decomposition continue to hold after such a deletion. However, if after this deletion the former parent $s$ of $t$ in $T$ is not a leaf, $s$ was a join node which now has a child with the same bag as $s$ which violates niceness. To repair this we can simply contract the edge between $s$ and its remaining child in $T$. It is straightforward to verify that after this $T$ remains nice. We can iterate the above, strictly decreasing the number of nodes of $T$, until $T$ has the desired property. ◀

We will use the following well-known lemma of Bodlaender and Hagerup [5] to turn a tree decomposition into a logarithmic-depth tree decomposition, while increasing the width only by a factor of three.

▶ **Lemma 2.3** ([5, Lemma 2.2]). *Given a tree decomposition of a graph $G$ of width $\omega$ and having $\gamma$ nodes, we can compute in polynomial time a rooted tree decomposition of $G$ of depth $O(\log \gamma)$ and width at most $3\omega + 2$.*

### Path decompositions

A path decomposition is a tree decomposition where the tree $T$ is a path. The **pathwidth** of $G$ is the minimum number $k$, such that $G$ has a path decomposition of width $k$. It is denoted by $\mathsf{pw}(G)$. A nice path decomposition is a nice tree decomposition where $T$ is a path, and the root is assigned to a degree-1 node, i.e., at one end of the path. Note that there are no join-nodes in a nice path decomposition.

We observe that any path decomposition can be turned into a nice path decomposition with $2n$ nodes.

▶ **Lemma 2.4.** *For every graph $G$ on $n$ vertices, given a path decomposition $P'$ of width $\omega$, there is a nice path decomposition $P$ with $2n$ nodes and width $\omega$, that can be computed in polynomial time.*

**Proof.** By introducing vertices one at a time and forgetting vertices one at a time we obtain a nice path decomposition where the bag of the first node is empty, the bag of the last node is empty, and on each edge exactly one vertex is either introduced or forgotten, and therefore the path decomposition has exactly $2n$ edges and $2n + 1$ nodes. We can remove the first bag that is empty to get a path decomposition with exactly $2n$ nodes. ◀

### Maximum independent set approximation

Given a function $r$ that maps graphs to numbers greater than 1, an $r$-approximation algorithm for Maximum Independent Set takes as input a graph $G$ and outputs in polynomial time an independent set in $G$ of size at least $\frac{\alpha(G)}{r(G)}$. We usually denote any occurrence of $|V(G)|$ in $r$ by $n$.

Let us now detail our assumptions on the function $f$ in Theorem 1.1. We assume that the approximation ratio $n/f(n)$ of the given approximation algorithm is a non-decreasing function on $n$. This assumption is reasonable because if $n/f(n)$ would be decreasing at some point, we could improve the approximation ratio by adding universal vertices to the graph; note that adding universal vertices does not change the optimal solution, but increases $n$. This also implies that the function $f(n)$ grows at most linearly in $n$. We assume that for arbitrary fixed constant $c \geq 1$, it holds that $f(c \cdot n) \in O(f(n))$. We also assume that the function $f$ can not decrease too much when $n$ grows, in particular, we assume that for arbitrary fixed constant $c \geq 1$ it holds that $f(c \cdot n) \in \Omega(f(n))$.

Moreover, we will use a basic result about finding independent sets whose size depends on the treewidth of the graph. Recall that a graph $G$ is $d$-degenerate if there is always a vertex of degree at most $d$ in any induced subgraph of $G$. It is known that every graph $G$ is $\mathsf{tw}(G)$-degenerate: Simply consider the vertex that is contained at a leaf bag and no other bag of a tree decomposition $T$ of any induced subgraph of $G$ as given by Lemma 2.2. This vertex has degree at most $\mathsf{tw}(G)$. Therefore, we obtain a following trivial algorithm for approximating Maximum Independent Set parameterized by treewidth.

▶ **Lemma 2.5.** *There is a polynomial time algorithm that given a graph $G$ on $n$ vertices finds an independent set of size at least $n/(\mathsf{tw}(G)+1)$.*

**Proof.** Iteratively assign a vertex of minimum degree to the independent set and delete its neighbors. By the aforementioned degeneracy argument, at each iteration at most $\mathsf{tw}(G)+1$ vertices are deleted, so the number of iterations and the size of the found independent set is at least $n/(\mathsf{tw}(G)+1)$. ◀

Note that the algorithm of Lemma 2.5 does not need a tree decomposition as an input.

## 3 Approximation parameterized by pathwidth

In this section, we prove a version of Theorem 1.1 where instead of a tree decomposition, the input graph is given together with a path decomposition. This will be an important ingredient for proving Theorem 1.1. In particular, this section is devoted to the proof of the following lemma.

▶ **Lemma 3.1.** *Let $f : \mathbb{N} \to \mathbb{N}$ be a function such that there exists an $\frac{n}{f(n)}$-approximation algorithm for Maximum Independent Set, where $n$ is the number of vertices of the input graph, and $f$ satisfies the assumptions outlined in Section 2. Then there exists an $O\left(\frac{\mathsf{pw}\cdot\log f(\mathsf{pw})}{f(\mathsf{pw})}\right)$-approximation algorithm for Maximum Independent Set, where $\mathsf{pw}$ is the width of a given path decomposition of the input graph.*

Throughout this section we will use $G$ to denote the input graph and $\mathsf{pw}$ to denote the width of the given path decomposition of $G$. We denote by $k = \mathsf{pw}+1$ the maximum size of a bag in the given decomposition. Note that by our assumptions on the function $f$, it holds that $f(k) = \Theta(f(\mathsf{pw}))$.

Let us denote $\mathsf{OPT} = \alpha(G)$. If $\mathsf{OPT} < \frac{n}{f(k)}$, then Lemma 2.5 gives us a solution of size at least

$$\frac{n}{\mathsf{tw}(G)+1} \geq \mathsf{OPT} \cdot \frac{f(k)}{\mathsf{tw}(G)+1},$$

i.e., an $O(\mathsf{tw}(G)/f(k))$-approximation, which would give the desired result by the facts that $\mathsf{tw}(G) \leq \mathsf{pw}$ and $f(k) = \Omega(f(\mathsf{pw}))$. Therefore, in the rest of this section we will assume that $\mathsf{OPT} \geq \frac{n}{f(k)}$.

Let $P$ be the given path decomposition of $G$. By Lemma 2.4, we can assume without loss of generality that $P$ is a nice path decomposition and has exactly $2n$ bags, which we will denote by $B_1, \ldots, B_{2n}$ in the order they occur in the path. For each $v \in V(G)$, we define the **length** of $v$ to be the number of bags in $P$ that contain $v$, and denote the length of $v$ by $\ell(v)$. In particular,

$$\ell(v) = |\{i \in [1, 2n] \colon v \in B_i\}|.$$

Then, we partition $V(G)$ into $2 + \lceil \log f(k) \rceil$ sets based on the lengths of the vertices:

$$\begin{aligned} V_0 &= \{v \colon \ell(v) < 2k\} \\ V_i &= \{v \colon \ell(v) \in [k \cdot 2^i, k \cdot 2^{i+1})\}, && 1 \leq i \leq \lceil \log f(k) \rceil \\ V' &= \{v \colon \ell(v) \geq 4k \cdot 2^{\lceil \log f(k) \rceil}\} \end{aligned}$$

Note that $(V_0, V_1, \ldots, V_{\lceil \log f(k) \rceil}, V')$ is indeed a partition of $V(G)$. We first show that the set $V'$, which consists of the longest vertices, can only contribute to at most half of the optimal solution.

▶ **Lemma 3.2.** *It holds that* $|V'| \leq \mathsf{OPT}/2$.

**Proof.** First, notice that $\sum_{v \in V(G)} \ell(v) \leq 2nk$. This is because $P$ has $2n$ bags, each vertex appears in $\ell(v)$ bags of $P$, and each bag of $P$ can have at most $k$ vertices appearing in it. Now, because for vertices $v \in V'$ we have $\ell(v) \geq 4k \cdot 2^{\lceil \log f(k) \rceil} \geq 4k \cdot f(k)$ the vertices in $V'$ contribute at least $\sum_{v \in V'} \ell(v) \geq 4k \cdot f(k) \cdot |V'|$ to the sum. Therefore, it holds that

$$|V'| \leq \frac{2nk}{4k \cdot f(k)} \leq \frac{n}{2 \cdot f(k)} \leq \mathsf{OPT}/2,$$

as desired. ◀

Lemma 3.2 implies that at least half of any maximum independent set in $G$ must be in the subgraph $G[V_0 \cup V_1 \cup \ldots \cup V_{\lceil \log f(k) \rceil}]$. In the rest of this section, we will focus on the following lemma.

▶ **Lemma 3.3.** *For each* $i \in [0, \lceil \log f(k) \rceil]$*, there is a* $O(k/f(k))$*-approximation algorithm for Maximum Independent Set in* $G[V_i]$.

It is easy to see how Lemma 3.3 implies Lemma 3.1. For each such $G[V_i]$, we invoke Lemma 3.3 to obtain a $O(k/f(k))$-approximate solution $S_i \subseteq V_i$. Our algorithm returns the set $S_i$ with the largest cardinality. Since there are at most $O(\log f(k))$ such sets, by Lemma 3.2 there must be some integer $i^*$ for which $\alpha(G[V_{i^*}]) \geq \Omega(\mathsf{OPT}/\log f(k))$. Therefore, the returned set must have size at least

$$\frac{\Omega(\mathsf{OPT}/\log f(k))}{O(k/f(k))} = \mathsf{OPT} \cdot \Omega\left(\frac{f(k)}{k \cdot \log f(k)}\right) = \mathsf{OPT} \cdot \Omega\left(\frac{f(\mathsf{pw})}{\mathsf{pw} \cdot \log f(\mathsf{pw})}\right).$$

Therefore, to finish the proof of Lemma 3.1, it remains to prove Lemma 3.3.

**Proof of Lemma 3.3.** Recall that the bags of $P$ are denoted by $B_1, B_2, \ldots, B_{2n}$ where $B_h$ is the $h$-th bag in the order from left to right. Let $L = \max_{v \in V_i} \ell(v)$ denote the maximum length of a vertex $v \in V_i$. Recall that by our definition of $V_i$, it holds that if $i = 0$, then $L < 2k$, and if $i > 0$, then all vertices in $V_i$ have length between $L/2$ and $L$. We partition the set $V_i$ into sets $X_r$ and $Y_r$ as follows.

- For each $r \in [1, \lfloor 2n/(2L) \rfloor]$, we define $X_r = B_{2Lr} \cap V_i$. These sets contain the vertices of $V_i$ that appear in bags $B_{2L}, B_{4L}, \ldots$ and the vertices in $B_{2Lr}$ can never occur in the same bag as the vertices in $B_{2Lr'}$, for any $r \neq r'$, since all vertices in $V_i$ have length at most $L$. Let $X = \bigcup_r X_r$.
- Denote the remaining vertices by $Y = V_i \setminus X$. We further partition $Y$ into sets $Y_r$ for $r \in [1, \lceil 2n/(2L) \rceil]$, where $Y_r$ contains the vertices $v \in Y$ that occur only in the bags $B_j$ in the interval $j \in [2L(r-1)+1, 2Lr-1]$.

It follows from definitions that $X \cup Y = V_i$. See Figure 1 for an illustration.

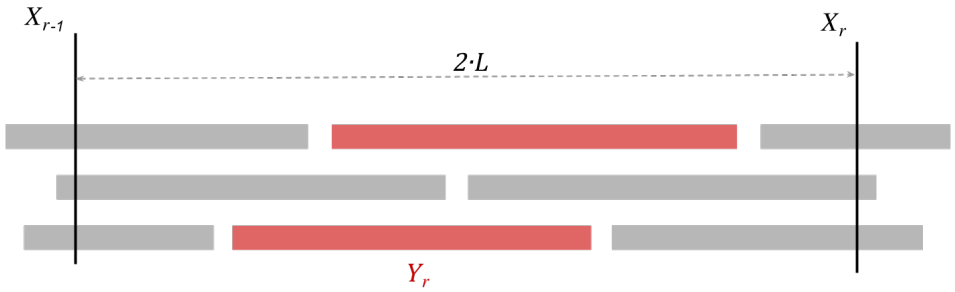

**Figure 1** $X_r$ is the set of vertices in $V_i$ that are in the $(2Lr)$-th bag. $Y_r$ (in red) is the set of vertices in $V_i$ that start after $X_{r-1}$ and end before $X_r$.

We prove the following claim.

▷ Claim 3.4. For all $r \in \mathbb{N}$, both sets $X_r$ and $Y_r$ have size at most $4k$.

Proof of claim. For the set $X_r$, there is nothing to prove since each bag contains at most $k$ vertices. Let us consider the set $Y_r$. First, we observe that because vertices of $Y_r$ occur only in the bags $B_{2L(r-1)+1}, \ldots, B_{2Lr-1}$, we have that

$$\sum_{v \in Y_r} \ell(v) \leq k \cdot 2L, \tag{1}$$

by the argument that each bag can contribute to the length of at most $k$ vertices. Then, we consider two cases: $i > 0$ and $i = 0$.

In the case when $i > 0$, we know that each vertex $v \in Y_r$ has length at least $\ell(v) \geq L/2$. Together with Equation (1), this implies that $|Y_r| \leq 4k$.

In the case when $i = 0$, we have $L \leq 2k$, but we do not have the lower bound on the length of vertices in $V_0$. In this case, we use the property that $P$ is a nice path decomposition of $G$. We know that the paths of vertices in $Y_r$ appear only in the bags $B_{2L(r-1)+1}, \ldots, B_{2Lr-1}$ of $P$. There are $2L - 1$ such bags, and because $P$ is nice, each bag either introduces a single vertex in $Y_r \cup X_r$ or forgets a single vertex in $X_{r-1} \cup Y_r$. Since all vertices of $Y_r$ must be introduced in these bags, but there are only $2L - 1$ such bags, this implies that $|Y_r| \leq 2L - 1 \leq 4k$. ◁

Finally, notice that because there are no bags that contain vertices from both $Y_r$ and $Y_{r'}$ for $r \neq r'$, there are no edges between $Y_r$ and $Y_{r'}$ for $r \neq r'$. Also, since $X_{r-1}$ and $X_r$ have $2L-1$ bags between them and the maximum length of a vertex is $L$, it follows that no vertex from $X_{r-1}$ occurs in a bag together with a vertex in $X_r$, and therefore there are no edges between $X_r$ and $X_{r'}$ for $r \neq r'$. Therefore, a union of independent sets in $Y_1, \ldots, Y_{\lceil 2n/(2L) \rceil}$ is an independent set in $Y$, and a union of independent sets in $X_1, \ldots, X_{\lfloor 2n/(2L) \rfloor}$ is an independent set in $X$.

As each graph $G[X_r]$ and $G[Y_r]$ has at most $4k$ vertices, we use the given $\frac{n}{f(n)}$-approximation algorithm to $\frac{4k}{f(4k)}$-approximate maximum independent set in all of the graphs $G[X_r]$ and $G[Y_r]$. We denote by $X^*$ the union of the results in the graphs $G[X_r]$ and by $Y^*$ the union of the results in the graphs $G[Y_r]$. Note that by previous arguments, $\alpha(G[X]) = \sum_r \alpha(G[X_r])$ and $\alpha(G[Y]) = \sum_r \alpha(G[Y_r])$, and therefore $X^*$ is a $\frac{4k}{f(4k)}$-approximation for independent set in $G[X]$ and $Y^*$ is a $\frac{4k}{f(4k)}$-approximation for independent set in $G[Y]$. Now, we observe that because $V_i = X \cup Y$, either $\alpha(G[X]) \geq \alpha(G[V_i])/2$ or $\alpha(G[Y]) \geq \alpha(G[V_i])/2$, and therefore the larger of $X^*$ and $Y^*$ is a $\frac{8k}{f(4k)}$-approximation for independent set in $G[V_i]$. Note that $\frac{8k}{f(4k)} = O(k/f(k))$, which is the desired approximation ratio. ◀

## 4 Approximation parameterized by treewidth

In this section, we finish the proof of Theorem 1.1. For the convenience of the reader, let us re-state Theorem 1.1 here.

▶ **Theorem 1.1.** *Let $f : \mathbb{N} \to \mathbb{N}$ be a function such that there exists an $\frac{n}{f(n)}$-approximation algorithm for Maximum Independent Set, where $n$ is the number of vertices of the input graph*[2]*. Then there exists an $O\left(\frac{\mathsf{tw} \cdot \log f(\mathsf{tw})}{f(\mathsf{tw})}\right)$-approximation algorithm for Maximum Independent Set, where $\mathsf{tw}$ is the width of a given tree decomposition of the input graph.*

Throughout this section we will use $G$ to denote the input graph and $\mathsf{tw}$ to denote the width of the given tree decomposition of $G$. We denote by $k = \mathsf{tw} + 1$ the maximum size of a bag in the given tree decomposition. Recall that $f(k) = \Theta(f(\mathsf{tw}))$.

Let $T$ be the given tree decomposition of $G$. By Lemma 2.2 we assume that $T$ is nice, and moreover that for each leaf node $t$ of $T$ there exists a vertex $v \in B_t$ that occurs only in the bag $B_t$. Let $\mathsf{OPT}$ denote the size of a maximum independent set in $G$. Similarly to the pathwidth case in Section 3, by using Lemma 2.5 we can assume in the rest of this section that $\mathsf{OPT} \geq \frac{n}{f(k)}$.

Let $\mathcal{L} \subseteq V(T)$ be the set of all leaf nodes of $T$. If the number of leaf nodes is at least $|\mathcal{L}| \geq \frac{\mathsf{OPT} \cdot f(k)}{k}$, then the unique vertices in these leaf bags already give us an independent set with the desired approximation factor. Therefore, in the rest of this section we will also assume that $|\mathcal{L}| < \frac{\mathsf{OPT} \cdot f(k)}{k}$. With this assumption, we can invoke the following lemma with $\ell = 2f(k)$.

▶ **Lemma 4.1.** *There exists a set $X \subseteq V(G)$ of size $|X| \leq k \cdot \frac{|\mathcal{L}|}{\ell}$ such that for each connected component of $G - X$ there is a rooted tree decomposition of width at most $k-1$ that has at most $\ell$ leaf nodes. Such a set $X$ and the tree decompositions of the components can be computed in polynomial time.*

[2] We make mild assumptions on the properties of $f$, which are detailed in Section 2. Any "reasonable" function $f$ satisfies these assumptions.

**Proof.** We prove the lemma constructively starting with $X = \emptyset$ and the tree decomposition $T$ of the entire graph. We also maintain a set of tree decompositions $\mathcal{C}$ of connected components of $G - X$. We iteratively remove vertices from the graph $G$ based on the structure of $T$ as follows.

Initially, we define the set of tree decompositions we will return as $\mathcal{C} = \emptyset$, and we initially assign $T' = T$ as the tree decomposition from which we will "chop off" pieces with at most $\ell$ leaf nodes into $\mathcal{C}$. As long as $T'$ has more than $\ell$ leaves, let $t^*$ be a node of $T'$ such that there are at least $\ell$ leaf nodes in the subtree $T^*$ of $T'$ rooted at $t^*$ and no descendant of $t^*$ has the same property. We add the vertices of $B_{t^*}$ to $X$ and delete them from the graph and all bags of $T'$. This separates the vertices in the bags in $T^*$ from the vertices in the bags of the rest of $T'$ and since no descendant of $t^*$ had more than $\ell$ leaves, all connected components of $T^* - t^*$ have at most $\ell$ leaves.

We remove $T^*$ from $T'$, and add all connected components of $T^* - t^*$ into $\mathcal{C}$. This completes the iteration. When the process stops, vertices in $G$ are either deleted (because they belonged to $B_{t^*}$ in some iteration) or appear in some tree decomposition that was added to $\mathcal{C}$.

By construction, each connected component of $G - X$ has a tree decomposition that is given by a connected component in $\mathcal{C}$. Each of these has fewer than $\ell$ leaves and did not increase in width compared to $T$.

With these observations, the following claim finishes the proof of the lemma.

▷ Claim 4.2. It holds that $|X| \leq k \cdot \frac{|\mathcal{C}|}{\ell}$.

Proof of claim. In each iteration of the algorithm, the number of leaves of $T'$ decreases by at least $\ell$, because $T^*$ has more than $\ell$ leaves. Hence, this process terminates after at most $\frac{|\mathcal{C}|}{\ell}$ iterations. Each such iteration adds a subset of a bag of $T$ to $X$ (which contains at most $k$ vertices). Therefore, the total number of deleted vertices is at most $k \cdot \frac{|\mathcal{C}|}{\ell}$. ◁

◀

We then assume to have $X$ as in the statement of Lemma 4.1 with $\ell = 2 \cdot f(k)$, and for each connected component $C$ of $G - X$ a tree decomposition $T^C$ of width at most $k - 1$ with at most $2f(k)$ leaves. For a connected component $C$ of $G - X$, let $S_C$ denote a fixed maximum independent set in $C$. Since $|X| \leq k \cdot \frac{|\mathcal{C}|}{2f(k)} \leq \mathsf{OPT}/2$, we know that the sum of $|S_C|$ over all connected components $C$ of $G - X$ is at least $\mathsf{OPT}/2$.

We can distinguish two cases for a single connected component $C$ of $G - X$ based on whether a majority of $S_C$ appears in bags of nodes of degree at least 3 in $T^C$ or not. Formally, let $Q$ denote the set of vertices that appear in the bags of nodes of degree at least 3 in $T^C$, i.e., $Q = \bigcup_{t \text{ has degree} > 2 \text{ in } T^C} B_t$. For each component $C$ one of the following two alternatives holds:

1. $|S_C \setminus Q| > |S_C|/2$, or
2. $|S_C \cap Q| \geq |S_C|/2$.

For handling the first case we can observe an easy pathwidth bound for $C - Q$, which allows us to apply Lemma 3.1.

▶ **Lemma 4.3.** *A path decomposition of $C - Q$ of width at most $k - 1$ can be computed in polynomial time given the tree decomposition $T^C$.*

**Proof.** A path decomposition witnessing this can easily be obtained from $T^C$ by deleting all nodes with degree at least 3 as well as vertices in their bags from the decomposition, resulting in a disjoint union of paths all of whose bags are of size at most $k$. These paths can be concatenated in arbitrary order. ◀

For the second case we next give a lemma that splits up each $C[Q]$ into $O(\log f(k))$ many disjoint subgraphs in which every connected component has at most $O(k)$ vertices.

▶ **Lemma 4.4.** *$C[Q]$ can be divided into $\ell \leq O(\log f(k))$ subgraphs $H_1, \ldots, H_\ell$, such that $V(C[Q]) = \dot{\bigcup}_{i\in[\ell]} V(H_i)$, and for any $i \in [\ell]$, each connected component of $H_i$ has at most $6k$ vertices. Such $H_1, \ldots, H_\ell$ can be computed in polynomial time.*

**Proof.** Consider the tree decomposition $T^C$ of $C$ obtained according to Lemma 4.1. In particular, such a tree has at most $2f(k)$ leaves and therefore at most $2f(k) - 1$ nodes with degree at least 3.

We can replace each path between two nodes $u$ and $v$ of degree at least 3 in $T^C$ by two edges incident to a shared new node whose bag consists of the union $B_u \cup B_v$ of the bags of $u$ and $v$. In this way we obtain a tree decomposition of $C[Q]$ with at most $4 \cdot f(k)$ nodes and width at most $2k - 1$.

For this tree decomposition we invoke Lemma 2.3 to obtain a tree decomposition $T^J$ of $C[Q]$ with width at most $6k - 1$ and depth $\ell \in O(\log f(k))$. Now, we partition the vertices in $C[Q]$ into $H_1, \ldots, H_\ell$ where $H_i$ contains all vertices $v$ such that the distance between the root of $T^J$ and the highest bag in which $v$ appears is exactly $i - 1$.

By definition all $V(H_i)$ are pairwise disjoint and because $T^J$ is a tree decomposition of $C[Q]$, the union of all $V(H_i)$ covers $V(C[Q])$. Moreover each connected component of any $H_i$ is by construction a subset of some bag of $T_J$ and thus has at most $6k$ vertices as desired. ◀

With the previous lemmas in hand, we are now ready to finish the proof of Theorem 1.1 as follows.

**Proof of Theorem 1.1.** We begin by invoking Lemma 4.1. Let $\mathcal{C}$ be the set of connected components in $G - X$.

For the next few paragraphs consider an arbitrary but fixed single connected component $C \in \mathcal{C}$. We first use Lemma 4.3 to invoke Lemma 3.1 on $C - Q$ to obtain an independent set $S_C^J$ in $C - Q$ of size at least $\Omega\left(\frac{f(k)}{k \cdot \log f(k)}\right) \cdot \alpha(C - Q)$.

Independently we invoke Lemma 4.4 and on each of the returned graphs $H_i$ the assumed $\frac{n}{f(n)}$-approximation for $n$-vertex graphs on each of its connected components. Due to their small component size for each $H_i$ this results in an independent set $S_{H_i}$ of size at least $\Omega\left(\frac{f(k)}{k}\right) \cdot \alpha(H_i)$. Because the graphs $H_i$ vertex-partition $C[Q]$ and there are only $O(\log f(k))$ many $H_i$, returning an $S_{H_i}$ with maximum size yields an $O(k \log f(k)/f(k))$-approximate solution for Maximum Independent Set on $C[Q]$.

We know that either

1. $\alpha(C - Q) \geq \alpha(C)/2$, or
2. $\alpha(C[Q]) \geq \alpha(C)/2$.

Overall this implies that returning the larger of $S_C^J$ and the maximum-size $S_{H_i}$ yields an $O\left(\frac{k \log f(k)}{f(k)}\right)$-approximate solution for Maximum Independent Set on $C$. We denote the returned independent set by $S_C$.

Our final output is the union of all $S_C$. Because all $C$ are pairwise independent, the union of $S_C$ is an independent set in $G$. Moreover, because $\sum_{C\in\mathcal{C}} \alpha(C) \geq \mathsf{OPT}/2$ and because of the above approximation guarantee for each $S_C$, we obtain the overall desired approximation guarantee. ◀

## 5 Conclusion and open problems

In this paper we essentially settled the polynomial time approximability of Maximum Independent Set when parameterized by treewidth. The most relevant open problem is to extend our approach to give the improved time-approximation tradeoff result in Czumaj et al. [7]. The current best known algorithm gives an $r$-approximation in $2^{\mathsf{tw}/r}n^{O(1)}$ time. With fine-tuning of the parameters and using the recent exponential-time approximation result of Bansal et. al. [3], we believe our techniques could give an improved running time of $2^{o(\mathsf{tw}/r)}$ when $r$ is sufficiently high, e.g., $r = \log^{\Omega(1)} \mathsf{tw}$.

For us, the most interesting question is perhaps when $r$ is tiny. Can we get a 2-approximation algorithm that runs in time $2^{(1/2-\epsilon)\mathsf{tw}}n^{O(1)}$? Can we prove some concrete lower bound in this regime? While the Gap-ETH lower bound $2^{\mathsf{tw}/\mathsf{poly}(r)}$ (for sufficiently large $r$) is immediate from [3], such techniques do not rule out anything when $r$ is a small constant.

A different possible direction for future research would be to formulate approximation algorithms in terms of treewidth only for the more general Maximum Weight Induced Subgraph problem studied by Czumaj et al. [7].

Heidelberg University, Germany

## Abstract

Local clustering aims to identify a cluster within a given graph that includes a designated seed node or a significant portion of a group of seed nodes. This cluster should be well-characterized, i.e., it has a high number of internal edges and a low number of external edges. In this work, we propose `SOCIAL`, a novel algorithm for local motif clustering which optimizes for motif conductance based on a local hypergraph model representation of the problem and an adapted version of the max-flow quotient-cut improvement algorithm (`MQI`). In our experiments with the triangle motif, `SOCIAL` produces local clusters with an average motif conductance 1.7% lower than the state-of-the-art, while being up to multiple orders of magnitude faster.

## 1 Introduction

Graphs are a fundamental tool for representing complex systems and relationships in a wide range of contexts. They can be used to model everything from data dependencies and social networks to web links and email interactions. With the massive expansion of data in recent years, many real-world graphs have grown to enormous sizes, making it challenging to analyze them. In particular, many applications only require analyzing a small, localized portion of a graph rather than the entire graph, which is the case for community-detection on Web [12] and social [21] networks as well as structure-discovery in bioinformatics [47] networks, among others. Those real-world applications are usually preceded by or modeled as a *local clustering* problem. Local clustering aims at identifying a specific cluster within a given graph that includes a designated seed node or a portion of a group of seed nodes, and is *well-characterized*, i.e., it consists of many internal edges and few external edges. More specifically, the quality of a community can be quantified by specific metrics such as *conductance* [22]. Since minimizing conductance is NP-hard [48], approximate and heuristic approaches are used in practice. Given the nature and scale of the problem, these approaches should ideally require time and memory dependent only on the size of the found cluster.

The local clustering problem has been investigated both theoretically [1] and experimentally [29], and has been solved using a wide variety of techniques, including statistical [9, 24], numerical [30, 32], and combinatorial [35, 15] methods. While traditional approaches to local

clustering typically consider the edge distribution when evaluating the quality of a local community, novel methods [49, 50, 33, 34, 7] have shifted focus to finding local communities based on the distribution of *motifs*, higher-order structures within the graph. These works provide empirical evidence that this approach, which can be called *local motif clustering*, is effective at detecting high-quality local communities. Nevertheless, since this local clustering perspective is relatively new, there are still many opportunities to improve upon current approaches and discover more efficient algorithms for finding high-quality solutions.

**Contribution.** In this work, we propose a novel algorithm for local motif clustering which optimizes for motif conductance by combining the strongly local hypergraph model from Chhabra et al. [7] with an adapted version of the fast and effective algorithm *max-flow quotient-cut improvement* (`MQI`) [26]. Our algorithm `SOCIAL`, which stands for *faSter mOtif Clustering vIa mAximum fLows*, starts by building a hypergraph model which is an exact representation for the motif-distribution around the seed node on the original graph [7]. Using this model, we create a flow model in which certain cuts correspond one-to-one with sub-sets of the initial cluster that include the seed node and have lower motif conductance than that of the whole cluster. We then use a push-relabel algorithm to either find such a cut and repeat the process recursively, or to prove that the current cluster is optimal among all its sub-clusters containing the seed node. In our experiments with the triangle motif, `SOCIAL` produces communities with a motif conductance value that is 1.7% lower than the state-of-the-art on average, while also being up to multiple orders of magnitude faster.

## 2 Preliminaries

**Graphs.** Let $G = (V = \{0, \ldots, n-1\}, E)$ be an *undirected graph* with no multiple or self edges allowed, such that $n = |V|$ and $m = |E|$. Let $c : V \to \mathbb{R}_{\geq 0}$ be a node-weight function, and let $\omega : E \to \mathbb{R}_{>0}$ be an edge-weight function. We generalize $c$ and $\omega$ functions to sets, such that $c(V') = \sum_{v \in V'} c(v)$ and $\omega(E') = \sum_{e \in E'} \omega(e)$. Let $N(v) = \{u : \{v, u\} \in E\}$ be the *open neighborhood* of $v$, and let $N[v] = N(v) \cup \{v\}$ be the *closed neighborhood* of $v$. We generalize the notations $N(.)$ and $N[.]$ to sets, such that $N(V') = \cup_{v \in V'} N(v)$ and $N[V'] = \cup_{v \in V'} N[v]$. A graph $G' = (V', E')$ is said to be a *subgraph* of $G = (V, E)$ if $V' \subseteq V$ and $E' \subseteq E \cap (V' \times V')$. When $E' = E \cap (V' \times V')$, $G'$ is the subgraph *induced* in $G$ by $V'$. Let $\overline{V'} = V \setminus V'$ be the *complement* of a set $V' \subseteq V$ of nodes. Let a *motif* $\mu$ be a connected graph. *Enumerating* the motifs $\mu$ in a graph $G$ consists of building the collection $M$ of all occurrences of $\mu$ as a subgraph of $G$. Let $d(v)$ be the *degree* of node $v$ and $\Delta$ be the maximum degree of $G$. Let $d_\omega(v)$ be the *weighted degree* of a node $v$ and $\Delta_\omega$ be the maximum weighted degree of $G$. Let $d_\mu(v)$ be the *motif degree* of a node $v$, i.e., the number of motifs $\mu \in M$ which contain $v$. We generalize the notations $d(.)$, $d_\omega(.)$, and $d_\mu(.)$ to sets, such that the *volume* of $V'$ is $d(V') = \sum_{v \in V'} d(v)$, the *weighted volume* of $V'$ is $d_\omega(V') = \sum_{v \in V'} d_\omega(v)$, and the *motif volume* of $V'$ is $d_\mu(V') = \sum_{v \in V'} d_\mu(v)$. Let a *spanning forest* of $G$ be an acyclic subgraph of $G$ containing all its nodes. Let the *arboricity* of $G$ be the minimum amount of spanning forests of $G$ necessary to cover all its edges.

**Local Motif Clustering.** In the *local graph clustering* problem, a graph $G = (V, E)$ and a seed node $u \in V$ are taken as input and the goal is to detect a *well-characterized cluster* (or *community*) $C \subset V$ containing $u$. A high-quality cluster $C$ usually contains nodes that are densely connected to one another and sparsely connected to $\overline{C}$. There are many functions to quantify the quality of a cluster, such as *modularity* [5] and *conductance* [22].

The conductance metric is defined as $\phi(C) = |E'|/\min(d(C), d(\overline{C}))$, where $E' = E \cap (C \times \overline{C})$ is the set of edges shared by a cluster $C$ and its complement. *Local motif graph clustering* is a generalization of local graph clustering where a motif $\mu$ is taken as an additional input and the computed cluster optimizes a clustering metric based on $\mu$. In particular, the *motif conductance* $\phi_\mu(C)$ of a cluster $C$ is defined by Benson et al. [4] as a generalization of the conductance in the following way: $\phi_\mu(C) = |M'|/min(d_\mu(C), d_\mu(\overline{C}))$, where $M'$ are all the motifs $\mu$ which contain at least one node in $C$ and one node in $\overline{C}$. Note that, if the motif under consideration is simply an edge, then $|M'|$ is the edge-cut and $\phi_\mu(C) = \phi(C)$.

**Hypergraphs.** Let $H = (\mathcal{V} = \{0, \ldots, \mathfrak{n}-1\}, \mathcal{E})$ be an *undirected hypergraph* with no multiple or self hyperedges allowed, with $\mathfrak{n} = |\mathcal{V}|$ *nodes* and $\mathfrak{m} = |\mathcal{E}|$ *hyperedges* (or *nets*). A net is defined as a subset of $\mathcal{V}$. The nodes that compose a net are called *pins*. Let $c : \mathcal{V} \to \mathbb{R}_{\geq 0}$ be a node-weight function, and let $\omega : \mathcal{E} \to \mathbb{R}_{>0}$ be a net-weight function. We generalize $c$ and $\omega$ functions to sets, such that $c(\mathcal{V}') = \sum_{v \in \mathcal{V}'} c(v)$ and $\omega(\mathcal{E}') = \sum_{e \in \mathcal{E}'} \omega(e)$. A node $v \in \mathcal{V}$ is *incident* to a net $e \in \mathcal{E}$ if $v \in e$. Let $\mathcal{I}(v)$ be the set of incident nets of $v$, let $d(v) := |\mathcal{I}(v)|$ be the *degree* of $v$, and let $d_\omega(v) := \omega(\mathcal{I}(v))$ be the *weighted degree* of $v$. We generalize the notations $d(.)$ and $d_\omega(.)$ to sets, such that the *volume* of $\mathcal{V}'$ is $d(\mathcal{V}') = \sum_{v \in \mathcal{V}'} d(v)$ and the *weighted volume* of $\mathcal{V}'$ is $d_\omega(\mathcal{V}') = \sum_{v \in \mathcal{V}'} d_\omega(v)$. Two nodes are *adjacent* if they are incident to the same net. Let the number of pins $|e|$ in a net $e$ be the *size* of $e$. We define the *contraction* operator as $/$ such that $H/\mathcal{V}'$, with $\mathcal{V}' \subseteq \mathcal{V}$, is the hypergraph obtained by contracting the nodes from $\mathcal{V}'$ of $H$. This contraction consists of substituting all the nodes in $\mathcal{V}'$ by a single representative node $x$, removing nets totally contained in $\mathcal{V}'$, and substituting all the pins in $\mathcal{V}'$ by a single pin $x$ in each of the remaining nets. Given a cluster $\mathcal{V}' \subseteq \mathcal{V}$, the *cut* or *cut-net* $cut(\mathcal{V}')$ of $\mathcal{V}'$ consists of the total weight of the nets crossing the cluster, i.e., $cut(\mathcal{V}') = \sum_{e \in \mathcal{E}'} \omega(\mathcal{E}')$, in which $\mathcal{E}' := \left\{e \in \mathcal{E} : e \cap \mathcal{V}' \neq \emptyset, e \cap \overline{\mathcal{V}'} \neq \emptyset\right\}$.

**Flows.** Let $\mathcal{N} = (V, E)$ be a directed flow network. A directed flow network has one source node $s \in V$, one sink node $t \in V$, and a set of remaining nodes $V \setminus \{s, t\}$. All edges $e = (u, v)$ in a directed flow network are directed and associated with a nonnegative capacity $cap(u, v)$. An s-t flow is a function $f : V \times V \to \mathbb{R}_{>0}$ which satisfies a *capacity* constraint, i. e., $f(u, v) \leq cap(u, v)$, a *symmetry* constraint, i. e., $\forall u, v \in V : f(u, v) = -f(v, u)$, and a *flow conservation* constraint, i. e., $\forall u \in V \setminus \{s, t\} : \sum_{v \in V} f(u, v) = 0$. An edge $(u, v)$ is called *saturated* if $cap(u, v) = f(u, v)$; The total amount of flow moved from $s$ to $t$ is defined as the *value* $|f|$ of $f$ and is computed as follows: $|f| = \sum_{u \in V} f(u, t) = \sum_{v \in V} f(s, v)$. A given s-t flow $f$ in $\mathcal{N}$ is *maximum* if, for any s-t flow $f'$ in $\mathcal{N}$, $|f'| \leq |f|$. Let $\mathcal{N}_f = (V, E_f)$ be the *residual graph* associated with a given flow $f$ on $\mathcal{N}$, such that $E_f = \{(u, v) \in V \times V : cap(u, v) - f(u, v) > 0\}$. According to the Max-Flow Min-Cut Theorem [13], the value $|f|$ of a maximum s-t flow $f$ on $\mathcal{N}$ equals the weight of a minimum s-t cut on $\mathcal{N}$, i. e., a 2-way partition of $\mathcal{N}$ where edge weights equal edge capacities, $s$ and $t$ are in distinct blocks, and the total weight of the cut edges is minimum. To find the sink side of the minimum cut associated with a maximum flow in $\mathcal{N}$, a reverse breadth-first search can be performed on $\mathcal{N}$ starting at the sink node $t$.

**Push-Relabel.** For each node $u$ in a directed flow network $\mathcal{N}$, let $d(u)$ be its potential and $exc(u) = \sum_{v \in V}(f(v, u) - f(u, v))$ be its *excess*. A node $u$ is called *active* if $exc(u) > 0$. An edge $(u, v)$ is called *admissible* if $cap(u, v) - f(u, v) > 0$ and $d(u) = d(v) + 1$. The push-relabel [16] algorithm builds a maximum flow by computing a succession of *preflows*, i. e., flows where the flow conservation constraint is relaxed and replaced by $\forall u \in V \setminus \{s, t\} : exc(u) \geq 0$. In the initial preflow, all out-edges of $s$ are saturated, $\forall u \in V \setminus \{s\} : d(u) = 0$, and $d(s) = |V|$.

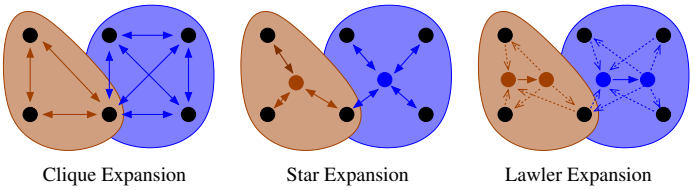

**Figure 1** Net expansion techniques. Nodes and nets of the hypergraph are respectively represented by black circles and colored areas around them. Artificial nodes and edges are respectively represented by circles and arrows with same color as the corresponding net. Bidirectional arrows represent edges in both directions. Solid and dashed edges have finite and infinite weight, respectively.

The initial preflow is evolved via operations *push*, i. e., sending as much flow as possible from an active node through an admissible edge, and *relabel*, i. e., increasing the potential of a node until it becomes active. Preflows induce minimum sink-side cuts, so a maximum flow and a minimum cut are obtained once no node is active.

**Flows on Hypergraphs.** A common technique to solve flow problems on hypergraphs consists of transforming them in directed graphs and then applying traditional graph-based techniques on them. Among the existing transformations [46, 27], we highlight *clique expansion*, *star expansion*, and *Lawler expansion*. In the *clique expansion*, each net is represented by a clique, i.e., a set of edges connecting each pair of its pins in both directions. In this approach, the weight of each edge is equal to weight of the corresponding net $e$ divided by $|e| - 1$ and parallel edges are substituted by a single edge whose weight is the sum of the weights of the removed edges. In the *star expansion*, each net is represented by an auxiliary artificial node connected to its pins by edges in both directions. In this expansion, the edges have the same weight as the corresponding net. In the *Lawler expansion*, each net $e$ is represented by two auxiliary artificial nodes $w_1$ and $w_1$ and a collection of edges. In particular, there is a directed edge $(w_1, w_2)$ which has the same weight as the corresponding net. Additionally, each pin of the corresponding net has an out-edge to $w_1$ and an in-edge from $w_2$, each of them with weight infinity. The three transformation approaches are exemplified in Figure 1.

## 2.1 Related Work

Motif-based clustering has been widely studied in the literature, with works such as [3, 49, 25, 36, 44] partitioning all the nodes of a graph into clusters based on motifs. We also address the topic of clustering based on motifs, but our focus is on identifying clusters in the immediate vicinity of a specific seed node, rather than on the entire graph. Several works [24, 30, 32, 11, 42] propose local clustering algorithms on graphs, but they do not focus on optimizing for motif-based metrics like our work. Instead, they use metrics based on edges, like conductance and modularity. Multiple works [45, 14, 20, 31] propose local clustering algorithms on hypergraphs. These algorithms are not designed for local graph clustering based on motifs, but for local hypergraph clustering. In one of them [45], the authors utilize a hypergraph extension of `FlowImprove` [2], which is itself an extension of the `MQI` [26] technique. Similarly, we also extend `MQI` to hypergraphs, then we use it as one of the steps of our algorithm `SOCIAL`. In this section, we review previous work on local graph clustering based on motifs, which is the focus of our work.

Rohe and Qin [38] propose a local clustering algorithm based on triangle motifs. Their algorithm starts by initializing a cluster containing only the seed node, and iteratively grows this cluster. Particularly, the algorithm greedily inserts nodes contained in at least a

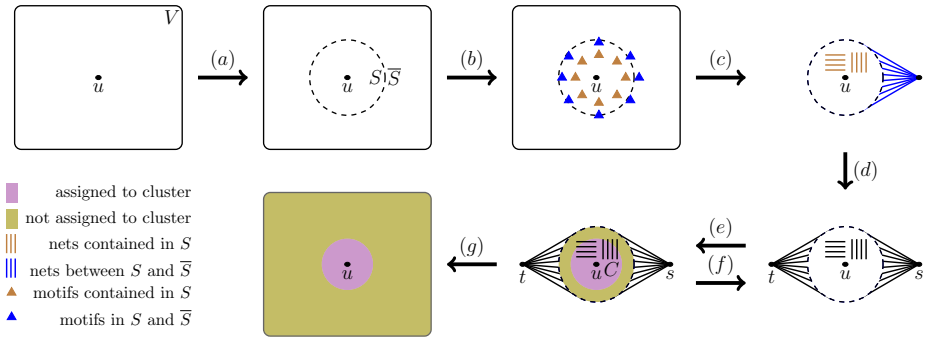

**Figure 2** Illustration of the phases of SOCIAL. (a) Given a seed node $u$ and a graph $G$, a ball $S$ around $u$ is selected. (b) Motif occurrences of $\mu$ with at least a node in $S$ are enumerated. (c) The hypergraph model $H_\mu$ is built by converting motifs into nets and contracting $\overline{S}$ into a single node. The ball $S$ is taken as the initial cluster $C_0$. (d) The flow model $\mathcal{N}$ is built based on $C_0$ in $H_\mu$. (e) A cluster $C \subseteq C_0$ containing $u$ is found using maximum flows. (f) While $C \subset C_0$, the model $\mathcal{N}$ is rebuilt based on $C$, which is taken as the initial cluster $C_0$. (g) When eventually $C = S$, $C$ is converted in a local cluster around the seed node in $G$.

predefined amount of cut triangles. Huang et al. [19] recover local communities containing a seed node in online and dynamic setups based on higher-order graph structures named Trusses [10]. They define the $k$-truss of a graph as its largest subgraph whose edges are all contained in at least $(k-2)$ triangle motifs, hence trusses are a graph structure based on the frequency of triangles. The authors use indexes to search for $k$-truss communities in time proportional to the size of the recovered community.

Yin et al. [49] propose MAPPR, a local motif clustering algorithm based on the Approximate Personalized PageRank (APPR) method. In a preprocessing phase, MAPPR enumerates the motif of interest in the entire input graph and constructs a weighted graph $W$, in which edges only exist between nodes that appear in at least one instance of the motif, and their edge weight is equal to the number of occurrences of the motif containing these two endpoints. Afterward, MAPPR uses an adapted version of the APPR method to find local communities in the weighted graph constructed in the preprocessing phase. MAPPR is able to extract local communities from directed input graphs, something that cannot be done using APPR alone.

Zhang et al. [50] propose LCD-Motif, an algorithm that addresses the local motif clustering problem using a modified version of the spectral method. LCD-Motif has two main differences in comparison to the traditional spectral motif clustering method. First, instead of computing singular vectors, the algorithm performs random walks to identify potential members of the searched cluster. They use the span of a few dimensions of vectors, obtained through random walks, as an approximation for the local motif spectra. Second, instead of using $k$-means for clustering, LCD-Motif searches for the minimum 0-norm vector within the previously mentioned span, which must contain the seed nodes in its support vector.

Meng et al. [33] propose FuzLhocd, a local motif clustering algorithm that uses fuzzy arithmetic to optimize a modified version of modularity. Given a seed node, FuzLhocd starts by detecting probable core nodes of the targeted local community using fuzzy membership. After identifying the probable core nodes of the target local community using fuzzy membership, the algorithm expands these nodes using another fuzzy membership to form a cluster.

Zhou et al. [51] propose HOSPLOC, a local motif clustering algorithm that uses a motif-based random walk to compute a distribution vector, which is then truncated and used in a vector-based partitioning method. The algorithm begins by approximately estimating the

distribution vector through a motif-based random walk. To further refine the computation and focus on the local region, HOSPLOC sets all small vector entries to 0. After this preprocessing step, the algorithm applies a vector-based partitioning method [43] on the resulting distribution vector in order to identify a local cluster.

Shang et al. [41] propose HSEI, a local motif clustering algorithm that uses motif and edge information to grow a cluster from a seed node. The algorithm begins by creating an initial cluster consisting of only the seed node. It then adds nodes to the cluster from the seed's neighborhood, selecting them based on their motif degree. The cluster is expanded using a motif-based extension of the modularity function.

Chhabra et al. [7] propose an algorithm to solve the local motif clustering problem using powerful (hyper)graph partitioning tools [39, 40, 17, 18]. Their algorithm first uses a breadth-first search to select a ball containing the seed node and nearby nodes. Next, they enumerate motif occurrences within the ball and build a (hyper)graph model which allows them to compute the motif conductance of any cluster within the ball. They then partition their model into two blocks using a high-quality (hyper)graph partitioning algorithm, and refine the solution for motif conductance.

# 3 Local Motif Clustering via Maximum Flows

We now present our algorithm SOCIAL, then we discuss its algorithmic components.

## 3.1 Overall Strategy

Given a graph $G = (V, E)$, a seed node $u$, and a motif $\mu$, our strategy for local clustering is based on the following phases. First, we select a set $S \subseteq V$ containing $u$ and close-by nodes. From now on, we refer to this set $S$ as a *ball around* $u$. Second, we enumerate the collection $M$ of occurrences of the motif $\mu$ which contain at least one node in $S$. Third, we build a hypergraph model $H_\mu$ in such a way that the motif-conductance of any cluster $C \subseteq S$ in $G$ can be computed directly in $H_\mu$. Fourth, we set $C_0 = S$ as our initial cluster and use it to build our MQI-based [26] flow model $\mathcal{N}$ from the hypergraph model $H_\mu$. Fifth, we use $\mathcal{N}$ to either find a new cluster $C \subset C_0$ containing $u$ with strictly smaller motif conductance than $C_0$ or prove that such cluster does not exist. While $C \subset C_0$ is found, we take it as our new initial cluster, rebuild $\mathcal{N}$, and repeat the previous phase. When eventually no such strict sub-set is found, the best obtained cluster is directly translated back to $G$ as a local cluster around the seed node. Figure 2 provides a comprehensive illustration of the consecutive phases of SOCIAL. Note that there is no guarantee of finding the best overall cluster including $u$ strictly contained in $S$. Instead, we find a succession of clusters with strictly decreasing cardinality and motif conductance until a local optimum is reached. To better explore the vicinity of $u$ in $G$ and overcome the fact we only find clusters inside $S$, we repeat the overall strategy $\alpha$ times with different balls $S$. Our overall algorithm including the mentioned repetitions is outlined in Algorithm 1.

## 3.2 Hypergraph Model

We follow the same procedure as Chhabra et al. [7] to construct the hypergraph model $H_\mu$. To ensure a thorough understanding of our overall algorithm, we provide a summary of the phases involved, i.e., finding a ball around the seed node, enumerating motifs within it, and finally constructing the hypergraph model $H_\mu$.

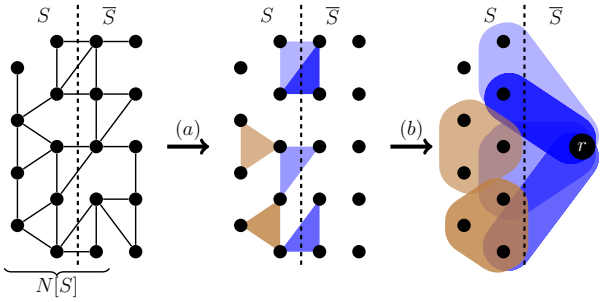

**Figure 3** Example of motif-enumeration and model-construction phases for the triangle motif. In the left, the nodes of $G$ are split into sets $S$ and $\overline{S}$. In the center, motifs containing nodes in $S$ are enumerated. In the right, $H_\mu$ is built by converting motifs in nets and contracting $\overline{S}$ into a node $r$.

**Algorithm 1** Local Motif Clustering via Max Flows.

**Input** graph $G = (V, E)$; seed node $u \in V$; motif $\mu$
**Output** cluster $C^* \subseteq V$

$C^* \leftarrow \emptyset$
**for** $i = 1, \ldots, \alpha$ **do**
  Select ball $S$ around $u$
  $M \leftarrow$ Enumerate motifs in $S$
  Build hypergraph model $H_\mu$ based on $S$ and $M$
  $C \leftarrow S$
  **do**
    $C_0 \leftarrow C$
    Build flow model $\mathcal{N}$ based on $C_0$ in $H_\mu$
    Solve $\mathcal{N}$ to obtain cluster $C \subseteq C_0$ including $u$
  **while** $C \subset C_0$
  **if** $C^* = \emptyset \vee \phi_\mu(C) < \phi_\mu(C^*)$ **then**
    $C^* \leftarrow C$
Convert $C^*$ into a local motif cluster in $G$

**Ball around the Seed Node.** Our approach to select a ball $S$ is a fixed-depth breadth-first search (BFS) rooted on $u$. More specifically, we compute the first $\ell$ layers of the BFS tree rooted on $u$, then we include all its nodes in $S$. For each of the $\alpha$ repetitions of the overall algorithm, we use different amounts $\ell$ of layers for a better algorithm exploration. Two special cases are handled by `SOCIAL`, namely a ball $S$ that is either too small or disconnected from $\overline{S}$. We avoid the first special case by ensuring that $S$ contains 100 or more nodes in at least one repetition of our overall algorithm. More specifically, in case this condition is not automatically met, then we accomplish it in the last repetition by growing additional layers in our partial BFS tree while it contains fewer than 100 nodes. The number 100 is based on the findings of Leskovec et al. [29], which show that most well characterized communities from real-world graphs have a relatively small size, in the order of magnitude of 100 nodes. If the second exceptional case happens, it means that the whole BFS tree rooted on the seed node has at most $\ell$ layers. In this case, we simply stop the algorithm and return the entire ball $S$, which corresponds to an optimal community with motif conductance 0 provided that there is at least one motif in $S$ and another one in $\overline{S}$. The number $\alpha$ of repetitions as well as the amount $\ell$ of layers used in each repetition are tuning parameters.

**Motif Enumeration.** Although enumerating a general motif on some graph is NP-hard [37], there are efficient heuristics to do it such as the one proposed by Kimmig et al. [23]. Nevertheless, simpler motifs such as small paths, cycles, and cliques can be trivially enumerated in

polynomial time. We focus our enumeration phase on the triangle motif. We implement the simple and exact algorithm proposed by Chiba and Nishizeki [8] to enumerate the collection $M$ of occurrences of the motif $\mu$ which contain at least one node in $S$. Roughly speaking, this algorithm works by intersecting the neighborhoods of adjacent nodes. For each node $v$, the algorithm starts by marking its neighbors with degree smaller than or equal to its own degree. For each of these specific neighbors of $v$, it then scans its neighborhood and enumerates new triangles as soon as marked nodes are found. The running time of this algorithm is $O(ma)$, where $a$ is the arboricity of the graph. We apply this enumeration algorithm only on the subgraph induced in $G$ by $N[S]$, which is enough to find all triangles containing at least one node in $S$, as exemplified by transformation (a) in Figure 3. Assuming a constant-bounded arboricity, the overall cost of our motif-enumeration phase for triangles is $O\big(|N[S] \times N[S]) \cap E|\big)$.

**Hypergraph Model.** The hypergraph model $H_\mu$ is finally built in two conceptual operations. First, define a hypergraph containing $V$ as nodes and a set $\mathcal{E}$ of nets such that, for each motif in $M$, $\mathcal{E}$ has a net with pins equal to the endpoints of this motif. Then, we contract together all nodes in $\overline{S}$ into a single node $r$ and substitute parallel nets by a single net whose weight is equal to the summed weights of the removed parallel nets. More formally, we define the hypergraph version of our model as $H_\mu = (S \cup \{r\}, \mathcal{E})$ where the set $\mathcal{E}$ of nets contains one net $e$ associated with each motif occurrence $G' = (V', E') \in M$ such that $e = V'$ if $V' \subseteq S$, and $e = V' \cap S \cup \{r\}$ otherwise. In the former case the net has weight 1, in the latter case the net has weight equal to the amount of motif occurrences in $M$ represented by it. Since node weights in $H_\mu$ are irrelevant for `SOCIAL`, the involved theorems, and the motif conductance metric, we make all node weights unitary in $H_\mu$. In practice, the model $H_\mu$ can be built by instantiating the nodes in $S \cup \{r\}$ and the nets in $\mathcal{E}$. Assuming that the number of nodes in $\mu$ is a constant, our model is built in time $O(|S| + |M|)$ and uses memory $O(|S| + |M|)$. The construction of $H_\mu$ is illustrated in transformation (c) of Figure 2 and demonstrated for a particular example in transformation (b) of Figure 3. Theorem 1 shows that the motif conductance in $G$ of any cluster $C \subseteq S$ can be directly computed from $H_\mu$ assuming $d_\mu(S) \leq d_\mu(\overline{S})$. The assumption $d_\mu(S) \leq d_\mu(\overline{S})$ is fair in practice since the ball $S$ computed via BFS tends to be considerably smaller than $\overline{S}$ for huge sparse networks. Enumerating the motifs in $\overline{S}$ is not reasonable for a local clustering algorithm, but we did verify that our assumption holds during all our experiments.

▶ **Theorem 1** (Theorem 3.2 from [7]). *The motif conductance $\phi_\mu(C)$ of a cluster $C \subseteq S$ in the original graph $G$ can be calculated directly in the hypergraph model $H_\mu$ using the ratio of its cut-net $cut(C)$ to its weighted volume $d_w(C)$, assuming that the motif enumeration step is exact and $d_\mu(S) \leq d_\mu(\overline{S})$.*

## 3.3 Flow Model

In this section, we describe the process of constructing our `MQI`-based flow model $\mathcal{N}$ using the hypergraph model $H_\mu$ and an initial cluster $C_0 \subseteq S$ which contains the seed node $u$. There are three possible implementations of $\mathcal{N}$ based on the three already explained techniques to represent hypergraphs using graphs, namely *clique expansion*, *star expansion*, and *Lawler expansion* (see Figure 1). We show a bijective correspondence between certain s-t cuts in $\mathcal{N}$ and clusters $C \subseteq C_0$ in $G$ that include the seed node $u$ and have motif conductance less than that of $C_0$. We start by converting our hypergraph model $H_\mu$ in a directed graph using the chosen net expansion technique. Second, we find a corresponding cluster $C'_0$

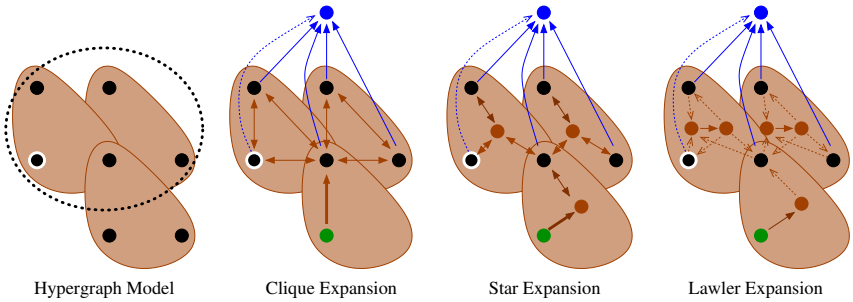

**Figure 4** Flow model $\mathcal{N}$ given a hypergraph model $H_\mu$ and an initial cluster $C_0$. Nodes and nets of $H_\mu$ are respectively represented by black circles and brown areas around them. The seed node $u$ is circled in white and the initial cluster $C_0$ is surrounded by a dotted ellipse. Auxiliary artificial nodes and edges used in each net-expansion are respectively represented by brown circles and arrows. Bidirectional arrows represent pairs of edges in both directions. The seed node $s$, the sink node $t$, and the in-edges of $t$ are respectively represented by a green circle, a blue circle, and blue arrows. Solid and dashed arrows respectively represent edges with finite and infinite weight.

for $C_0$ in the created graph. For the *clique expansion*, $C'_0 = C_0$ since this transformation does not create artificial nodes. For the *star expansion*, $C'_0$ consists of $C_0$ and also the auxiliary artificial nodes connected to at least one node in $C_0$. For the *Lawler expansion*, $C'_0$ consists of $C_0$, the auxiliary artificial nodes $w_1$ having in-edges only from nodes in $C_0$, and the auxiliary artificial nodes $w_2$ having out-edges to at least one node in $C_0$. Third, we contract $\overline{C'_0}$ to a single *source* node $s$ and then remove all its in-edges. Fourth, we multiply the weight of all the remaining edges by $d_{\mathcal{W}}(C_0)$, i.e., the weighted volume of $C_0$ in $H_\mu$. Fifth, we introduce a sink node $t$ and include in-edges to it from each of the nodes $v \in C_0 \setminus \{u\}$, such that the weight of $(v,t)$ is set to $cut(C_0)d_{\mathcal{W}}(v)$, i.e., the cut-net of $C_0$ in $H_\mu$ multiplied by the weighted degree of $v$ in $H_\mu$. Finally, we include an edge $(u,t)$ from the seed node to the sink and set its weight to infinity. Our flow network model $\mathcal{N}$ is concluded by setting edge capacities to match edge weights. Figure 4 shows the three possible configurations of our flow model $\mathcal{N}$ for a given hypergraph model $H_\mu$ and an initial cluster $C_0$.

We now analyze the theoretical guarantees provided by the defined flow model $\mathcal{N}$. Theorem 2 shows that there is a set $C \subset C_0$ in $G$ including the seed node $u$ with motif conductance smaller than that of $C_0$ if, and only if, the value of the maximum flow on $\mathcal{N}$ is less than $cut(C_0)d_{\mathcal{W}}(C_0)$, which is the weight of the trivial cut $(\{s\}, V(\mathcal{N}) \setminus \{s\})$. Due to space constraints, we put the proof of Theorem 2 in our public technical report [6]. In the proof, we show that such improved cluster $C$ consists of the sink side of the minimum cut associated with the maximum flow. This cluster can be directly obtained with a reverse breadth-first search on $\mathcal{N}$ starting at the sink node. For an even stronger claim, see our public technical report [6]. Assumptions (a) and (b) in Theorem 2 are the same used in Theorem 1, which were previously shown to be reasonable in practice. Note that the claim is only valid for motifs with three nodes for clique and star expansion models, while it is valid in general for the Lawler expansion model.

▶ **Theorem 2.** *There is a set $C \subset C_0$ in $G$ including the seed node $u$ with motif conductance smaller than that of $C_0$ if, and only if, the maximum flow on $\mathcal{N}$ is less than $cut(C_0)d_{\mathcal{W}}(C_0)$ under the following assumptions:*

**a)** *the motif enumeration phase is exact;*

**b)** *$d_\mu(S) \leq d_\mu(\overline{S})$ in $G$;*

**c)** *in case $\mathcal{N}$ is based on clique expansion or star expansion, the motif $\mu$ has three nodes;*

SOCIAL utilizes a push-relabel approach to iteratively search for a maximum s-t flow in the model $\mathcal{N}$. If the found maximum flow is strictly smaller than $cut(C_0)\mathrm{d}_{\mathfrak{W}}(C_0)$, then we can directly find a minimum cut with the same weight as it and, consequently, a cluster $C \subset C_0$ containing the seed node $u$ that has a strictly smaller motif conductance value $\phi_\mu(C)$ than that of $C_0$ in $G$. If such a cut is found, the algorithm repeats the process recursively setting the identified sub-cluster $C$ as the new initial cluster, i.e., it constructs a new flow model based on $H_\mu$ and the initial cluster and uses the push-relabel algorithm to continue searching for sub-clusters with even lower motif conductance values. If, on the other hand, the maximum flow is not strictly smaller than $cut(C_0)\mathrm{d}_{\mathfrak{W}}(C_0)$, it means that the current cluster $C_0$ is optimal among all of its sub-clusters containing the seed node $u$, and the algorithm terminates for the given ball $S$.

## 4 Experimental Evaluation

**Methodology.** We implemented SOCIAL in C++. We compiled our program using gcc 11.2 with full optimization turned on (-O3 flag). All our experiments are based on the triangle motif, i.e., the undirected clique of size three. Since this motif has three nodes, Theorem 2 is valid for all net expansion techniques. Therefore, we focus our experiments on the clique expansion technique, which is more efficient than the other techniques because it does not utilize any auxiliary artificial nodes and uses the minimum amount of auxiliary artificial edges. We use the following parameters for SOCIAL: $\alpha = 3$, $\ell \in \{1, 2, 3\}$. We do not utilize more than 3 BFS layers because otherwise the ball around the seed node could become too large in densely connected areas of a graph. Nevertheless, as explained in Section 3.2, SOCIAL might occasionally use more than 3 BFS layers to ensure that the ball includes a minimum of 100 nodes, if the seed node under consideration is located in a sparse portion of the graph. We ensure the integrity of our results by using the same motif-conductance evaluator function for all tested algorithms. In our experiments, we have used a machine with a sixty-four-core AMD EPYC 7702P processor running at 2.0 GHz, 1 TB of main memory, 32 MB of L2-Cache, and 256 MB of L3-Cache. We measure running time, motif-conductance, and/or size of the computed cluster. For each graph, we pick 50 random seed nodes and use all of them as input for each algorithm. When averaging running time or cluster size over multiple instances, we use the geometric mean in order to give every instance the same influence on the *final score*. When averaging motif conductance over multiple instances, the final score is computed via arithmetic mean. This is a necessary averaging strategy since motif conductance can be zero, which makes the geometric mean infeasible to compute. We also use *performance profiles* which relate the running time (resp. motif conductance) of a group of algorithms to the fastest (resp. best) one on a per-instance basis. Their x-axis shows a factor $\tau$ while their y-axis shows the percentage of instances for which algorithm $A$ has up to $\tau$ times the running time (resp. motif conductance) of the fastest (resp. best) algorithm.

**Table 2** Average comparison against state-of-the-art. Times are given in seconds.

**Instances.** The graphs used in our experiments are the same ones used by Yin et al. [49] and Chhabra et al. [7] and the seed nodes used in our experiments are the same used in [7]. Specifically, we use real graphs from the SNAP Network Dataset Collection [28]. Prior to our experiments, we removed parallel edges, self-loops, and directions of edges and assigning unitary weight to all nodes and edges. Basic properties of the graphs under consideration can be found in Table 1.

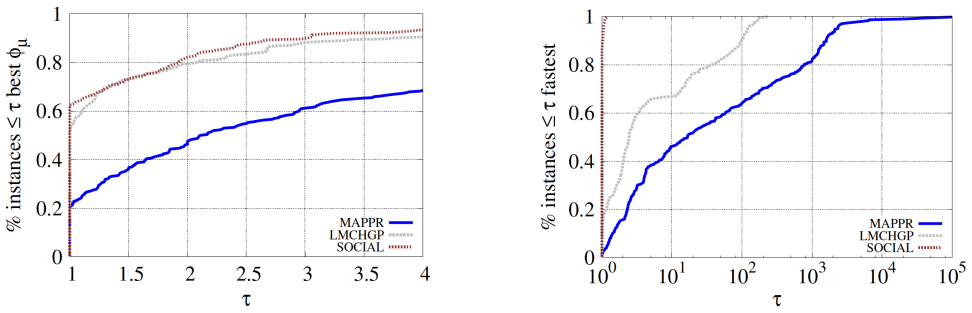
**Competitors.** We experimentally compare our SOCIAL against the state-of-the-art competitors, namely MAPPR [49] and the algorithm proposed by Chhabra et al. [7]. For conciseness, we refer to the latter one from now on as LMCHGP, an acronym for *local motif clustering via (hyper)graph partitioning*. We also ran preliminary experiments with HOSPLOC [51]. However, the algorithm is very slow even for small graphs and not scalable as their algorithm works using an adjacency matrix and hence needs $\Omega(n^2)$ space and time. Moverover, experiments done in their paper are on graphs that are multiple orders of magnitude smaller than the graphs used in our evaluation. Hence, we are not able to run the algorithm on the scale of the instances used in this work. We were not able to explicitly compare against LCD-Motif [50] since their code is not available (neither public, nor privately[1]) and the data presented in the respective paper does not warrant explicit comparisons (e.g. seed nodes are typically not presented in the papers). However, we try to make implicit comparisons in Section 4.1.

We compare our results against the globally best cluster computed for each seed node by MAPPR using its standard parameters ($\alpha = 0.98$, $\epsilon = 10^{-4}$) and by LMCHGP using the configuration with best overall results in [7] (graph model, label propagation, $\alpha = 3$, $\ell \in \{1, 2, 3\}$, and $\beta = 80$). Unless mentioned otherwise, experiments presented here involve all graphs from Table 1.

## 4.1 Results

The performance profile plots shown in Figures 5a and 5b, compare LMCHGP [7] and MAPPR [49] against SOCIAL. In Table 2, we show average results for each graph in our Test Set as well as average results overall. As shown in Figure 5a, SOCIAL obtains the best or equal motif conductance value for 62% of the instances, while LMCHGP and MAPPR respectively obtain the best or equal motif conductance for 49% and 19% of the instances. This result can be explained with two observations. First, SOCIAL explores the solution space considerably better than MAPPR, since we build our model multiple times, while MAPPR simply uses the APPR algorithm. Second, SOCIAL is based on a flow approach which directly optimizes for motif conductance, whereas LMCHGP is based on a (hyper)graph partitioning algorithm which

[1] Personal communication with the authors



**(a)** Motif conductance. **(b)** Running time.

**Figure 5** Performance profiles for motif conductance and running time considering all instances, i.e., 50 random seed nodes for each graph in Table 1. In the running time plot, the `SOCIAL` curve is roughly coincident with the y-axis.

is repeated multiple times to compensate for its design to minimize the number of cut motifs rather than motif conductance. In Table 2, `SOCIAL` outperforms `LMCHGP` for 4 of the 6 graphs and overall, and outperforms `MAPPR` for all graphs and overall. Overall, `SOCIAL` computes clusters with motif conductance 0.178 while `LMCHGP` and `MAPPR` compute clusters with motif conductance 0.181 and 0.500, respectively.

As exhibited in Figure 5b, `SOCIAL` is the fastest one for 87% of the instances, while `LMCHGP` and `MAPPR` are the fastest ones for 12% and 1% of the instances, respectively. Furthermore, the running time of `SOCIAL` is within a factor 1.18 of the running times of the fastest competitors for all instances. `SOCIAL` is respectively up to 237 and 144 063 times faster than `LMCHGP` and `MAPPR` while being a factor 5.4 and 34.1 faster than them on average. The reason for `MAPPR` being considerably slower than the other algorithms is that it must enumerate motifs across the entire graph, while `SOCIAL` and `LMCHGP` only require enumeration of motifs in a ball around the seed node. The reduced but still substantial difference in running time between `SOCIAL` and `LMCHGP` is a result of `LMCHGP`'s repeated partitioning of each ball around the seed node, while `SOCIAL` employs a flow model to greedily improve the motif conductance metric until a local optimum cluster is obtained. In Table 2, `SOCIAL` outperforms `LMCHGP` and `MAPPR` on average in terms of running time for every single graph and overall.

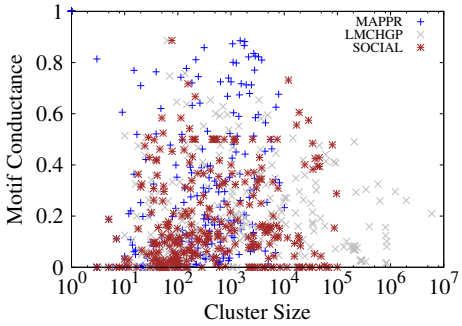


**Figure 6** Motif conductance vs cluster size.

For a more intuitive analysis of the quality of our results, Figure 6 plots motif conductance versus cluster size for all communities computed by the three algorithms. Observe that the communities found by SOCIAL are densely localized in the lower left area of the chart, which is the region with smaller motif conductance and smaller cluster size. On the other hand, communities computed by MAPPR are often in the upper area of the chart and communities computed by LMCHGP are often in the right area of the chart.

**Additional Comparisons.** As we mention above, we were not able to run comparisons against LCD-Motif [50] explicitly since their code is not available (neither publicly, nor privately) and the data presented in the respective papers does not warrant explicit comparisions (e.g., seed nodes are typically not presented in papers, and in this case instances are directed rather than undirected). Here, we make an attempt at implicit comparisons. Zhang et al. [50] (Table 4 therein) compare motif conductance against MAPPR on three directed instances (cit-HepPh, Slashdot, StanfordWeb) and report an geometric mean improvement of 54% in motif conductance for the triangle motif. As SOCIAL works for undirected instances, we have build undirected version of those graphs and run SOCIAL as well as MAPPR for the triangle motif. The geometric mean improvement we obtain over MAPPR is 223% which is significantly larger than the improvement of Zhang et al. [50] over MAPPR. Also note that in our experiments from Table 2, the geometric mean improvement (using the average motif conductance values) of SOCIAL over MAPPR in motif conductance is 219%.

## 5 Conclusion

In this work, we propose SOCIAL, a fast flow-based algorithm to solve the local motif clustering problem in graphs. Given a seed node, our SOCIAL selects a ball of nodes around it, which is taken as an initial cluster and used to build an exact hypergraph model where nets represent motifs. Using this model and the initial cluster, we create a flow model in which the value of the maximum s-t flow is directly related to the presence of sub-sets of the initial cluster that contain the seed node and have lower motif conductance than the initial cluster as a whole. Utilizing a push-relabel algorithm, SOCIAL either identifies a sub-cluster containing the seed node with improved motif conductance and repeats the process recursively by considering it as the initial cluster, or demonstrates that the current initial cluster is the best among all its sub-clusters that include the seed node.

In our experiments with the triangle motif, we found that SOCIAL produces communities with an average motif conductance better than the state-of-the-art, while running up to orders of magnitude faster on average. For future work, we intend to conduct experiments with larger motifs and use the Lawler-expansion version of our flow model, since it is the only one whose quality guarantee holds true for larger motifs. Laslty, we intend to add parallelization to improve the speed on large instances further.

# Primal-Dual Schemes for Online Matching in Bounded Degree Graphs

**Ilan Reuven Cohen**
Bar-Ilan University, Ramat Gan, Israel

**Binghui Peng**
Columbia University, New York, NY, USA

## Abstract

We explore various generalizations of the online matching problem in a bipartite graph $G$ as the b-matching problem [8], the allocation problem [5], and the AdWords problem [13] in a beyond-worst-case setting. Specifically, we assume that $G$ is a $(k, d)$-bounded degree graph, introduced by Naor and Wajc [14]. Such graphs model natural properties on the degrees of advertisers and queries in the allocation and AdWords problems. While previous work only considers the scenario where $k \geq d$, we consider the interesting intermediate regime of $k \leq d$ and prove a tight competitive ratio as a function of $k, d$ (under the small-bid assumption) of $\tau(k, d) = 1 - (1 - k/d) \cdot (1 - 1/d)^{d-k}$ for the $b$-matching and allocation problems. We exploit primal-dual schemes [6, 3] to design and analyze the corresponding tight upper and lower bounds. Finally, we show a separation between the allocation and AdWords problems. We demonstrate that $\tau(k, d)$ competitiveness is impossible for the AdWords problem even in $(k, d)$-bounded degree graphs.

## 1 Introduction

Ad auctions have emerged as a powerful tool for online advertisers seeking to reach targeted audiences through search engines and other digital platforms. Therefore, there has been much interest in optimizing their revenue generation in recent years. In an ad auction, advertisers bid on specific keywords or phrases relevant to their products or services. When users query search engines, in addition to the algorithmic search results, it also displays sponsored ads that match the ad auctions. These ads are rapidly sold or assigned to potential buyers (advertisers). In their seminal work, Mehta et al. [13] developed a model for optimizing the allocation of ad auctions, building upon the concept of online bipartite matching of Karp et al. [10]. There are $n$ bidders, where each bidder $i \in \{1, \ldots, n\}$, has a known daily budget $B(i)$. Ad auctions arrive online, one at a time, and each bidder $i$ provides a bid $b(i, j)$ for buying the product $j$ (displaying the ad). Once the bids are received, the seller's algorithm must allocate the ad to one of the interested bidders, and this decision is irrevocable. The seller's objective is to maximize the total revenue accumulated from the ad auctions. To accomplish this, Mehta et al. [13] proposed a (tight) deterministic algorithm, which is $(1 - 1/e)$-competitive in cases where the budget of each bidder is relatively larger than the bids. This is a realistic assumption in the ad auction scenario.

Consequently, a loss of $1/e$ can equate to billions of dollars in potential revenue loss each year. In addition, the $1 - 1/e$ hardness result of Karp et al. [10] for online matching is prevalent in all the problem extensions. Therefore, researchers have been inspired to pursue a more comprehensive theoretical understanding that extends beyond the worst-case scenarios.

One line of research considers stochastic arrival models, which include random order arrival and iid arrival models. In the random order model, a fixed input graph is prepared in advance, and the online vertices are randomly arranged. On the other hand, the iid arrival model involves drawing online vertices from a known or unknown distribution. With these arrival models, researchers were able to demonstrate results that outperform the $1 - 1/e$ competitive ratio in both online matching and vertex-weighted matching, as demonstrated by various sources [4, 7, 9, 11, 12].

In this work, we consider a different line of research, which assumes structural properties commonly encountered in ad allocation instances used for targeted advertising. Such properties were first identified and formalized by Naor and Wajc [14]. We assume that $G$ is a bipartite $(k, d)$-bounded-degree graph (for brevity's sake, we use the term $(k, d)$-graphs).

Specifically, we assume that advertisers are interested in a large number of ad slots (i.e. $\sum_j b(i, j) \geq k \cdot B(i)$ for all $i$) and every ad slot is of interest to a relatively small number of advertisers (i.e. $|N(j)| = |\{i : b(i, j) > 0\}| \leq d$ for all $j$).

This structural assumption is relatively natural for ad allocation graphs. First, ad campaigns often target relatively small, specific population segments, resulting in users belonging to fairly few segments. When coupled with the limited number of active campaigns, this creates a limited pool of ads that may be shown to a particular user, justifying the assumption of a small degree for ad slots. Second, advertisers generally aim to target large population segments. However, they often allocate insufficient budget to display ads to all users within a segment. This leads to the high-degree assumption on the offline side since every page view by a specific, targeted user corresponds to a vertex in the graph.

**Related work.** Buchbinder et al. [5] developed a primal-dual algorithm for AdWords that attains a competitive ratio of $(1-1/c)(1-R_{\max})$, where $c = (1+R_{\max})^{1/R_{\max}}$. As $R_{\max} \to 0$, the competitiveness tends to $1 - 1/e$. Buchbinder et al. also examined a setting where the degree of each incoming query was upper bounded by $d$ (i.e., $(1, d)$-graph) and produced an algorithm with a competitive ratio of nearly $1 - (1 - 1/d)^d$ for the AdWords with equal bids per advertiser (a.k.a, the allocation problem). Azar et al. [3] showed that this ratio is the best possible, also for randomized algorithms. The expression $1 - (1 - 1/d)^d$ is always greater than $1 - 1/e$ but approaches the latter as $d$ increases. Naor and Wajc [14] introduced the $(k, d)$-graphs class and applied it to the AdWords problem and online bipartite matching. For $k \geq d$, they developed deterministic online algorithms achieving a competitive ratio of $1 - (1 - 1/d)^k$ for online bipartite matching and its vertex-weighted extension, where all edges connected to an offline vertex $i$ have the same weight. They also showed that this ratio holds for AdWords with equal bids per advertiser, where each advertiser has the same bid for all relevant keywords. The ratio of $1 - (1 - 1/d)^k$ is the best possible for online bipartite matching and the vertex-weighted extension if $k \geq d$. For AdWords with arbitrary bids, Naor and Wajc provided an algorithm with a competitive ratio of $(1 - R_{\max})(1 - (1 - 1/d)^k)$. They also demonstrated that if $k \geq d$, the best possible competitiveness is upper-bounded by $(1 - R_{\max})(1 - (1 - 1/d)^k/R_{\max})$. As $k/d$ increases, the expression $1 - (1 - 1/d)^k$ tends to 1, and for $k \simeq d$ it approaches $1 - 1/e$.

A recent work [2], studied the online $b$-matching problem in $(k, d)$-graphs for $k \geq d$. In this scenario, each vertex $a$ located on the left-hand side of the bipartite graph represents a server with a capacity of $b_a$, which implies that it can be matched with up to $b_a$ incoming

requests that appear as right-hand side vertices. The objective is to maximize the size of the generated matching. Their results also hold for the vertex-weighted problem extension and, thus, for AdWords and auction problems in which each bidder issues individual, equally valued bids. They designed deterministic online algorithms for optimal competitiveness, for $k \geq d$ instances. Later, in [1], they showed a non-trivial extension for the AdWords problem, i.e., bids of arbitrary value. Specifically, they showed an algorithm for the general AdWords problem that achieves competitiveness arbitrarily close to 1 for $k \geq d$ using the small-bids assumption.

**Our Contributions.** We examine the interesting scenarios of $(k, d)$-graphs where $k \leq d$. First, we study the $b$-matching problem for $k \in \mathbb{N}$. Our algorithm is based on a fractional algorithm for $b$-matching. In Section 3, we provide a fractional algorithm with a competitive ratio of $\tau(k, d)$, where $\tau(k, d) = 1 - \frac{d-k}{d}\left(1 - \frac{1}{d}\right)^{d-k}$. The algorithm is based on two steps; The first ensures that each offline vertex's fractional load at the end of the algorithm is at least $k/d$, while the second step uses the water-level algorithm to allocate the remaining volume. We analyze the algorithm using the primal-dual scheme and a carefully chosen potential function, $f^{(k,d)}$. Second, we prove that the bound $\tau(k, d)$ is tight. We use the primal-dual techniques from [3] to analyze a class of $(k, d)$-graphs where any online algorithm is at most $\tau(k, d)$-competitive.

Next, for arbitrary $k \in \mathbb{R}_+$, let $\alpha = k/d \leq 1$, we prove that for AdWords in the equally-valued bids case, it is possible to achieve almost $\tau(\alpha)$-competitive values (under the small bid assumption), where $\tau(\alpha) = 1 - (1 - \alpha) \cdot e^{\alpha - 1}$. It is evident that $\lim_{d \to \infty, k = \alpha \cdot d} \tau(k, d) = \tau(\alpha)$. Figure 1 presents a comparison of the bound of $\tau(k, d)$ as a function of $\alpha = k/d$ and $d$. The algorithm uses a similar approach to our fractional matching algorithm on $(k, d)$-graph and uses a 'smoother' potential function $f^{(\alpha)}$ as a function only of $\alpha$. We round the fractional algorithm outputs using the algorithm of [5].

Finally, we prove that achieving a $\tau(\alpha)$-competitive algorithm for the AdWords problem for bids of arbitrary value is impossible. To do that, we significantly extend the lower bounds of [3], which essentially uses a single scenario, to a multi-scenario instance; we show that the primal-dual techniques can be adapted to analyze the multi-scenario. Subsequently, we prove an improved upper bound by carefully choosing such a multi-scenario instance.

## 2 Preliminaries

### The AdWords problem

The online ad auctions problem comprises a group of $L = \{1, \ldots, n\} = [n]$ buyers, where bidder $i$ has a daily budget of $B(i)$. In the online setting, a group of $R = [m]$ products arrives one by one, and each buyer $i$ places a bid $b(i, j)$ for each product $j$. The objective is to allocate the products to buyers to maximize the seller's revenue. The allocation can be

| Primal: | Dual: |
|---|---|
| $\max \sum_{j \in R} \sum_{i \in N(j)} b(i,j) \cdot x_{i,j}$ | $\min \sum_{i \in L} B(i) \cdot y_i + \sum_{j \in R} z_j$ |
| $\sum_{j \in N(i)} b(i,j) \cdot x_{i,j} \leq B(i), \ \forall i \in L \quad (y_i)$ | $b(i,j) \cdot y_i + z_j \geq b(i,j), \quad \forall i,j \quad (x_{i,j})$ |
| $\sum_{i \in N(j)} x_{i,j} \leq 1, \quad \forall j \in R \quad (z_j)$ | $y_i \geq 0, \quad \forall i \in L$ |
| $x_{i,j} \geq 0, \quad \forall i,j$ | $z_j \geq 0, \quad \forall j \in R$ |

**Figure 2** The fractional AdWords problem (the primal) and the corresponding dual problem.

integral, where a product goes to a single buyer, or fractional, where products can be divided among several buyers. However, the sum of the fractions cannot exceed 1 for each product. The revenue received from a buyer $i$ is the minimum between the sum of the costs of the products allocated to the buyer (times the allocated fraction) and the buyer's total budget. The problem can be formulated as a linear programming problem where the variable $x_{i,j}$ denote the fraction of product $j$ allocated to buyer $i$. The objective is to maximize the total seller revenue, and the constraints guarantee that the sum of fractions for each product does not exceed 1 and each buyer's budget is not exceeded. See Figure 2 for the corresponding fractional Linear Program and its dual.

▶ **Definition 1** ($(k,d)$-bounded graph [14]). *A bipartite graph $G = (L, R, E)$ is $(k,d)$-bounded if each left vertex $i \in L$ has a degree $d(i) \geq k$, and every right vertex $j \in R$ has a degree $d(j) \leq d$. For ad allocations, we replace $d(i) \geq k$ with the property $\sum_j b(i,j) \geq k \cdot B(i)$.*

**Rounding the fractional solution.** For the AdWords problem with equal bids per advertiser, in [5], they presented an algorithm that rounds the online fractional solution, such that if each product's bid price is small compared to the total bidder budget (the small bid assumption), then this rounding phase only reduces the revenue by a factor of $1 - o(1)$ compared to the fractional solution revenue. Formally, let $b_{\max} = \max_j b(j)$ denote the maximum bid price, and $B_{\min} = \min_i B(i)$.

▶ **Theorem** (Theorem 5.4 in [5]). *There exists a deterministic online rounding algorithm, where the integral allocation algorithm's revenue is at least $1 - o(1)$ times the revenue of the fractional solution, provided that:* $(1 + b_{\max})\sqrt{\frac{\ln 2n}{B_{\min}}} = o(1)$

## 3 Matching on bounded-degree graphs

In this section, we prove the tight bounds for online fractional bipartite matching on bounded-degree graphs.

### The b-matching problem

Consider a bipartite graph $G = (L \cup R, E)$, where $L$ represents servers and $R$ represents requests. The set of servers, $L$, is known beforehand, and each server $i \in L$ has an individual capacity $B(i)$, indicating that it can be matched with up to $B(i)$ requests. Requests arrive online, one by one, and when a new request $j \in R$ arrives, its incident edges are revealed, and

it must be immediately and irreversibly matched to an eligible server, provided one exists. The objective is to maximize the number of matching edges. According to the AdWords formulation, we have $b(i,j) = 1$ if $(i,j) \in E$ and 0 otherwise.

A fractional version of the bipartite matching problems allows for every node $j \in R$ to be allocated partially with nodes $i \in N(j)$ in fractions $x_{i,j}$. We study the case where $G$ is a $(k,d)$-graph. Let $\tau(k,d) = 1 - \frac{d-k}{d}\left(1 - \frac{1}{d}\right)^{d-k}$.

▶ **Theorem 2.** *For the fractional online b-matching problem in $(k,d)$-graphs, where $k \leq d$ and $k, d \in \mathbb{N}_+$, there exists a $\tau(k,d)$-competitive algorithm.*

In Section 4, we prove the result is tight for any $(k,d)$ graph. Note that we may apply the rounding algorithm of [5] (Theorem 5.4) to the $b$-matching problem.

## 3.1 The Two-Step-Water-Level algorithm

For a vertex $i \in L$, denote the level of vertex $i$ as $\ell(i) = \frac{\sum_{j \in N(i)} x_{ij}}{B(i)}$. Note that, for $(k,d)$-graphs, a naive online algorithm can ensure that the level of any $i \in L$ at the end of the algorithm is $k/d$. This is achieved by assigning each online vertex a $1/d$ fraction to each neighbor. Since the degree of any $j \in R$ is at most $d$, the algorithm is feasible. In addition, since for any vertex $i \in L$, the degree is at least $k \cdot B(i)$, its level at the end of the algorithm will be $k/d$. Accordingly, our algorithm consists of two steps. For the allocation of an online vertex $j \in R$, the first step fractionally allocates the vertex's volume to vertices in $i \in N(j)$ such that their degree is less or equal to $k \cdot B(i)$. As a result of this step, a level of at least $k/d$ is guaranteed at the end of the algorithm's run for all $i \in L$. The second step runs the water-level algorithm, continuously raising the level on the current set of minimum-level vertices in $N(j)$ on the remainder of the vertex $j$ volume. We use the notations $d^j(i)$ and $\ell^j(i)$ for the degree and level of vertex $i$ after vertex $j$'s arrival, respectively. Given a function $f^{(k,d)} : [0,1] \to [0,1]$, which we will describe later, the algorithm also maintains a solution to the dual variables.

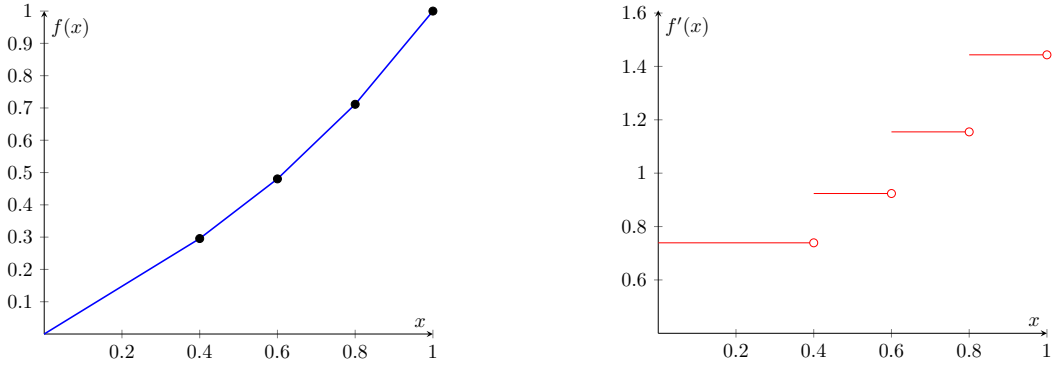
**Algorithm 1** The **Two-Step-Water-Level** algorithm.

Upon the arrival of a new vertex $j \in R$:

1. For each vertex $i \in N(j)$, such that $d^j(i) \leq k \cdot B(i)$
   Increase (if necessary) the level of $i$ to $d^j(i)/d$
2. Using the leftover volume:
   Increase the level of vertices in $N(j)$ using the water-level algorithm
3. Update the dual variables, let $\ell(j) = \min_{i \in N(j)} \ell^j(i)$ and $\hat{\ell}(j) = \max(k/d, \ell(j))$.
   Set $y_i = f^{(k,d)}(\ell(i))$, for $i \in N(j)$
   Set $z_j = 1 - f^{(k,d)}(\hat{\ell}(j))$

## 3.2 The algorithm's feasibility

We will prove that for a proper $f^{(k,d)}$,(for brevity's sake, we use $f$ for $f^{(k,d)}$ for the rest of the section) the primal and dual solutions of the **Two-Step-Water-Level** (TSWL) algorithm are feasible.



**(a)** $f(x)$. **(b)** $f'(x)$.

**Figure 3** The function $f^{(k,d)}(x)$ for $k = 2$ and $d = 5$.

▶ **Lemma 3.** *Given a function $f : [0,1] \to [0,1]$, where $f$ is a monotone non-decreasing function, the primal and dual solutions of the TSWL Algorithm are feasible at the end of the algorithm.*

**Proof.** First, we will show that the algorithm does not over-allocate online vertex $j$ in step 1. We assume that the algorithm is feasible until the arrival of vertex $j$. For any vertex $i \in N(j)$, its degree increases by 1, and by the algorithm definition, its level prior to the assignment of vertex $i$ is at least $\frac{d^j(i)-1}{d}$. Therefore, for any such $i$, $x_{ij}$ after the first step is at most $\frac{d^j(i)}{d} - \frac{d^j(i)-1}{d} = \frac{1}{d}$, and by the definition of $(k,d)$-graphs, $|N(j)| \leq d$. Therefore, vertex $j$ fractional allocation at step 1 is at most $|N(j)| \cdot \frac{1}{d} \leq 1$. By the definition of step 1, and since $G$ is $(k,d)$-graph, at the end of the sequence, the level of any vertex $i \in L$ is at least $k/d$.

To prove that the dual is feasible, we need to verify for $i \in N(j)$ that $y_i + z_j \geq 1$ $(b(i,j) = 1)$. If $\ell(j) \geq k/d$, then

$$y_i + z_j = f(\ell(i)) + 1 - f(\ell(j)) \geq f(\ell^j(i)) + 1 - f(\ell(j)) \geq 1,$$

where the first inequality is since $\ell(i) \geq \ell^j(i)$ and $f$ is a monotone, non-decreasing function, and the second inequality is because, by definition, $\ell^j(i) \geq \ell(j)$. If $\ell(j) < k/d$, by definition $\hat{\ell}(j) = k/d$, then we have

$$y_i + z_j = f(\ell(i)) + 1 - f(\hat{\ell}(j)) \geq f(k/d) + 1 - f(k/d) \geq 1,$$

the first inequality is since the level of any vertex $i \in L$ at least $k/d$ and the end of the algorithm, and since $f$ is a monotone, non-decreasing function. ◀

## 3.3 The potential function

For a function $f$, we denote $f'_+(x)(f'_-(x))$ the right (left) derivative of $f$ at point $x$.

▶ **Lemma 4.** *For any $k \leq d, k \in \mathbb{N}_+$ there exists $f^{(k,d)} = f : [0,1] \to [0,1]$, such that*

- *$f, f'$ are monotone, non-decreasing functions.*
- *$f(0) = 0, f(1) = 1$.*
- *$1 - f\left(\frac{d-i}{d}\right) + f'_-\left(\frac{d-i}{d}\right) = \frac{1}{\tau(k,d)}$, for $i \in \{0, \ldots, d-k\}$.*

**Proof.** Let $\beta = 1/\tau(k,d)$. We define $f[0,1] \to [0,1]$ as a piece-wise linear function.

$$f'_+\left(\frac{d-i+1}{d}\right) = f'_-\left(\frac{d-i}{d}\right) = \beta \cdot \left(\frac{d-1}{d}\right)^i, \quad \text{for } i \in \{0,\dots,d-k-1\},$$

and

$$f'_+(0) = f'_-\left(\frac{k}{d}\right) = \beta \cdot \left(\frac{d-1}{d}\right)^{d-k}.$$

By definition, $f'$ is a monotone, non-decreasing function, and since $f'(x) > 0$, $f$ is a monotone, increasing function. We set $f(0) = 0$, we have

$$\begin{aligned} f(1) &= f(0) + \frac{k}{d} \cdot f'_-\left(\frac{k}{d}\right) + \frac{1}{d} \cdot \sum_{i=0}^{d-k-1} f'_-\left(\frac{d-i}{d}\right) \\ &= 0 + \frac{k}{d} \cdot \beta \cdot \left(\frac{d-1}{d}\right)^{d-k} + \frac{1}{d} \cdot \sum_{i=0}^{d-k-1} \beta \cdot \left(\frac{d-1}{d}\right)^i \\ &= \beta \cdot \left(\frac{k}{d} \cdot \left(\frac{d-1}{d}\right)^{d-k} + 1 - \left(\frac{d-1}{d}\right)^{d-k}\right) = 1 \end{aligned}$$

Finally, we show by induction that for $i \in \{0,\dots,d-k\}$, we have $1 - f\left(\frac{d-i}{d}\right) + f'_-\left(\frac{d-i}{d}\right) = \beta$. For $i = 0$:

$$1 - f\left(\frac{d-i}{d}\right) + f'_-\left(\frac{d-i}{d}\right) = 1 - 1 + \beta \cdot \left(\frac{d-1}{d}\right)^0 = \beta$$

and for $i \in \{1,\dots,d-k\}$:

$$\begin{aligned} &1 - f\left(\frac{d-i-1}{d}\right) + f'_-\left(\frac{d-i-1}{d}\right) \\ &= 1 - f\left(\frac{d-i}{d}\right) + \frac{1}{d} \cdot f'_-\left(\frac{d-i}{d}\right) + \frac{d-1}{d} \cdot f'_-\left(\frac{d-i}{d}\right) \\ &= 1 - f\left(\frac{d-i}{d}\right) + f'_-\left(\frac{d-i}{d}\right) = \beta. \end{aligned}$$

◀

## 3.4 The algorithm's competitive ratio

We are now able to complete the proof of Theorem 2. By demonstrating that the value of the primal is at least $\tau(k,d) = \frac{1}{\beta}$ times the value of the dual solution, we conclude by the weak duality that the TSWL is $\tau(k,d)$-competitive.

We prove it by bounding the ratio of the increment of the primal and the dual objectives for every arrival of a vertex $j \in R$. We denote $\Delta P(\Delta D)$ as the primal (dual) value increment. Moreover, $\Delta D = \Delta L + \Delta R$, where $\Delta L(\Delta R)$ refers to the increment from the left side (right side). Now, we have the following key lemma:

▶ **Lemma 5.** *For every arrival of a vertex $j \in R$, we have $\Delta D \le \beta \cdot \Delta P$.*

**Proof.** Given a vertex $j \in R$, let $t = \ell(j) \cdot d$ and $t^\star = \lceil t \rceil$. We divide it into three cases:

**Case 1:** $\Delta P < 1$. Here, $t = d$ and vertex $j$'s neighbors have been fully matched, i.e., $\ell(i) = 1$ for all $i \in N(j)$. Then we would set $\Delta R = z_u = 1 - f(1) = 0$, thus we and $\Delta L \le f'_-(1) \cdot \Delta P$ since $f'$ in monotone, non-decreasing, therefore:

$$\Delta D = \Delta L + \Delta R \le f'_-(1) \cdot \Delta P + 0 = f'_-(1) \cdot \Delta P = \beta \cdot \Delta P$$

**Case 2:** $\Delta P = 1$ and $t > k$. In this case, we know that $z_j = 1 - f(t/d)$. Next, let $V_1$ be the increment volume for $j$'s neighbors between $t^\star - 1$ and $t^\star$. And Let $V_2 = 1 - V_1$, i.e., the total volume of the increment for $j$'s neighbors below $t^\star - 1$. We have

$$\begin{aligned}
\Delta L &\leq V_1 \cdot f'_-(\frac{t^\star}{d}) + V_2 \cdot f'_-(\frac{t^\star - 1}{d}) \\
&= V_1 \cdot f'_-(\frac{t^\star}{d}) + V_2 \cdot \frac{d-1}{d} \cdot f'_-(\frac{t^\star}{d}) \\
&= \frac{d-1}{d} \cdot f'_-(\frac{t^\star}{d}) + \frac{1}{d} \cdot V_1 \cdot f'_-(\frac{t^\star}{d}) \\
&\leq \frac{d-1}{d} \cdot f'_-(\frac{t^\star}{d}) + \frac{1}{d} \cdot (t - t^\star + 1) \cdot f'_-(\frac{t^\star}{d}) \\
&= f'_-(\frac{t^\star}{d}) + \frac{1}{d} \cdot (t - t^\star) \cdot f'_-(\frac{t^\star}{d})
\end{aligned}$$

where the first inequality is because $f'$ in a monotone, non-decreasing function, and the last inequality holds since we know that (note that $j \in R$, therefore $d(j) \leq d$)

$$V_1 \leq \left(\frac{t}{d} - \frac{t^\star - 1}{d}\right) \cdot d(j) \leq \left(\frac{t}{d} - \frac{t^\star - 1}{d}\right) \cdot d = t - t^\star + 1$$

And, by $f$'s definition:

$$\Delta R = 1 - f(\frac{t}{d}) = 1 - f(\frac{t^\star}{d}) - (\frac{t}{d} - \frac{t^\star}{d}) \cdot f'_-(\frac{t^\star}{d}) = 1 - f(\frac{t^\star}{d}) - \frac{1}{d} \cdot (t - t^\star) \cdot f'_-(\frac{t^\star}{d}).$$

Therefore,

$$\Delta D = \Delta R + \Delta L \leq 1 - f(\frac{t^\star}{d}) + f'_-(\frac{t^\star}{d}) = \beta.$$

**Case 3:** $\Delta P = 1$ and $t \leq k$. By the algorithm definition, $\Delta R = z_j = 1 - f(k/d)$, and $\Delta L = f'_-(k/d)$. Thus, we have

$$\Delta D = \Delta R + \Delta L = 1 - f(\frac{k}{d}) + f'_-(\frac{k}{d}) = \beta.$$ ◀

## 4 Upper Bounds for fractional matching

In this section, we provide an instance indicating that $\tau(k, d)$ is the best possible competitive ratio that can be achieved by any online algorithm.

▶ **Theorem 6.** *For fractional online matching in $(k, d)$-graphs, no online algorithm can be better than $\tau(k, d)$-competitive. This upper bound also holds for randomized algorithms.*

**Proof.** The hard instance is inspired by [3]. More concretely, we construct a parameterized family of primal linear programs based on a candidate collection of input sequences for proving the lower bound, where the objective function corresponds to optimizing the competitive ratio. Given $d, k$, our instance is a bipartite graph $G(L, R, E)$, where the number of vertices is $n = |L| = |R|$. Given a deterministic online fractional algorithm, the adversary sequence has $d$ phases in total. Wherein in the first $k$ phases, the adversary divides $L$ into $n/d$ groups, each containing $d$ vertices, and introduces a single online vertex adjacent to each group. This guarantees $d(i) \geq k$ for all $i \in L$ and that the offline can match $k$ vertices from each group. Accordingly, the adversary sets $L_{k+1} \subset L$ by dropping each group's

$k$-lowest load vertices (according to the online algorithm assignment). Next, in phase $t \in \{k+1, \ldots, d-1\} = [k+1, d-1]$, the adversary divides $L_t$ into $|L_t|/d$ groups and introduces a single online vertex adjacent to each group. The adversary defines $L_{t+1} \subset L_t$ by dropping the lowest load vertex from each group. In the last phase, for each vertex $i \in L_d$, the adversary introduces an online adjacent vertex.

Formally, the adversary defines for each phase $t \in [d]$, $L_t \subseteq L$, where all the new edges in phase $t$ would be connected only to $L_t$, and the adversarial would set $L_d \subseteq L_{d-1} \subseteq \cdots \subseteq L_1 = L$. Moreover, the adversary groups each set $L_t$ into $|L_t|/d$ disjoint groups, each of size $d$, denoted as $L_{t,s}$, for $s \in [|L_t|/d]$. In phase $t \in [d-1]$, $|L_t|/d$ online vertices arrive, and the $s^{th}$ ($s \in [|L_t|/d]$) vertex has edges to the offline vertices in the group $L_{t,s}$. For $t \in [k]$, $L_t = L$, and the adversary uses the same (arbitrary) grouping, i.e., $L_{t_1,s} = L_{t_2,s}$ for $t_1, t_2 \in [k]$, $s \in [n/d]$. According to the online algorithm assignment, the adversary sets $L_{k+1}$. Specifically, for $s \in [n/d]$, let $L^e_{k,s} \subset L_{k,s}$ the subset of the $k$-lowest load vertices in $L_{k,s}$ after phase $k$ and $L^m_{k,s} = L_{k,s} \setminus L^e_{k,s}$ (the subset of the $(d-k)$-highest load vertices in $L_{k,s}$). We define $L_{k+1} = \cup_{s=1}^{n/d} L^m_{k,s}$. note that,$|L_{k+1}| = (1 - k/d)\,|L_k|$. Similarly, the adversary sets $L_{t+1}$, for $t \in [k+1, d-1]$ as follow: For $s \in \frac{|L_t|}{d}$, let $L^e_{k,s} \subset L_{k,j}$ be the subset containing the lowest total load vertex in $L_{t,s}$ after phase $t$ and $L^m_{t,s} = L_{t,s} \setminus L^e_{t,s}$. We define $L_{t+1} = \cup_{s=1}^{|L_t|/d} L^m_{t,s}$. Note that, $|L_{t+1}| = (1 - 1/d)\,|L_t|$ for $t \in [k+1, d-1]$. Finally, in phase $d$, for each vertex $i \in L_d$, the adversary introduces an online adjacent vertex. We set $n$ as a large constant, ensuring that $|L_t|$ for $t \in [d]$ is a multiple of $d$.

Clearly, the optimal matching size is $n$ since it matches online vertices of phases $t \in [k]$ to the vertices $L^e_{k,s}$ (for $s \in [n/d]$), and for $t \in [k+1, d-1]$ match the $s$'th online vertex of phase $t$ to the vertex in $L^e_{t,s}$. The rest of the $L_d$ vertices are matched in the last phase.

## 4.1 The primal linear program

We would use $x^m_k(x^e_k)$ as the average load assigned in phases $[k]$ on vertices in $L^m_{k,s}(L^e_{k,s})$ for $s \in [n/d]$. Similarly, for $t \in [k+1, d-1]$ we use $x^m_t(x^k_t)$ as the average load assigned in phase $t$ to vertices in $L^m_{t,s}(L^e_{t,s})$. For $t \in [k+1, d-1]$, we use $u^m_t(u^e_k)$ as the average total load assigned before phase $t$ to vertices in $L^m_{t,s}(L^e_{t,s})$, and $u^m_d$ as the average total load assigned before phase $d$ to $L_d$.

$$\textbf{max } \tfrac{|L_k|}{d}((d-k)x^m_k + k \cdot x^e_k) + \sum_{t=k+1}^{d-1} \frac{|L_t|}{d}(x^e_t + (d-1)x^m_t) + |L_d|(1 - u^m_d)$$

$$(d-k) \cdot x^m_k + k \cdot x^e_k \le k \qquad (v_k)$$

$$(d-1) \cdot x^m_t + x^e_t \le 1 \qquad \forall t \in [k+1, d-1], \quad (v_t)$$

$$x^e_k \le x^m_k \qquad (m_k)$$

$$x^e_t + u^e_t \le x^m_t + u^m_t \qquad \forall t \in [k+1, d-1], \quad (m_t)$$

$$d \cdot x^m_k \le (d-1) \cdot u^m_{k+1} + u^e_{k+1} \qquad (c_k)$$

$$d \cdot (x^m_t + u^m_t) \le (d-1) \cdot u^m_{t+1} + u^e_{t+1} \qquad \forall t \in [k+1, d-2], \quad (c_t)$$

$$d \cdot (x^m_{d-1} + u^m_{d-1}) \le d \cdot u^m_d \qquad (c_{d-1})$$

$$x^m_t, u^m_t, x^e_t, u^e_t \ge 0 \qquad \forall t \in [k, d]$$

Constraint $v_k$ implies that the total volume in vertices in $L^m_k$ (note, $\frac{|L^m_k|}{|L_k|} = \frac{d-k}{d}$) plus the total volume of vertices in $L^e_k$ (note, $\frac{|L^e_k|}{|L_k|} = \frac{k}{d}$) does not exceed the total volume in the first $k$ phases. Constraint $v_t$ for $t \in [k+1, d-1]$ implies that the total volume of vertices

in $L_t^m$ (note, $\frac{|L_t^m|}{|L_t|} = \frac{d-1}{d}$) plus the total volume of vertices in $L_t^e$ (note, $\frac{|L_t^e|}{|L_t|} = \frac{1}{d}$) does not exceed the total volume assigned in those phases. Constraints $m_t$ for $t \in [k, d-1]$ preserve the monotonicity property, i.e., the average total load of vertices in $L_{t,s}^m$ is higher than the average total load of vertices in $L_{e,s}^m$, by the groups' definition. Constraints $c_t$ for $t \in [k, d-1]$ preserve the total volume of $L_t^m$ after phase $t$ as the total volume of $L_{t+1}$ prior to phase $t+1$. Finally, the objective function captures the fractional volume assigned on $L$.

## 4.2 The dual linear program

The dual of the linear program is:

$$\begin{aligned}
&\textbf{min}\; k \cdot v_k + \sum_{t=k}^{d-1} v_t + |L_d| \\
&(d-k) \cdot v_k - m_k + d \cdot c_k \geq n \cdot (1 - k/d) && (x_k^m)\\
&k \cdot v_k + m_k \geq \frac{n \cdot k}{d} && (x_k^e)\\
&(d-1) \cdot v_t - m_t + d \cdot c_t \geq n \cdot (1 - k/d) \cdot (1 - 1/d)^{t-k} \qquad \forall t \in [k+1, d-1], && (x_t^m)\\
&v_t + m_t \geq \frac{n}{d} \cdot (1 - k/d) \cdot (1 - 1/d)^{t-k-1} \qquad \forall t \in [k+1, d-1], && (x_t^m)\\
&-m_t - (d-1) \cdot c_{t-1} + d \cdot c_t \geq 0 \qquad \forall t \in [k+1, d-1], && (u_t^m)\\
&m_t - c_{t-1} \geq 0 \qquad \forall t \in [k+1, d-1], && (u_t^e)\\
&-d \cdot c_{d-1} \geq -n \cdot (1 - k/d) \cdot (1 - 1/d)^{d-k-1} && (u_d^m)
\end{aligned}$$

## 4.3 Constructing the dual solution

By assuming the constraints are tight, we have by constraint $(u_d^m)$: $c_{d-1} = \frac{n}{d} \cdot (1 - 1/d)^{d-k-1}$, by summing constraints $(u_t^m)$ and $(u_t^e)$ for all $t \in [k+1, d-1]$: $c_t = c_{t-1}$, and, therefore,

$$c_t = \frac{n}{d} \cdot (1 - 1/d)^{d-k-1}, \text{ for all } t \in [k, d-1].$$

By summing constraints $(x_k^m)$ and $(x_k^e)$ for all $t \in [k+1, d-1]$: $d \cdot v_k + d \cdot c_k = n$, therefore:

$$v_k = n \cdot \frac{1 - d \cdot c_k}{d} = \frac{n}{d} \cdot \left(1 - (1 - k/d) \cdot (1 - 1/d)^{d-k-1}\right).$$

By summing constraints $(x_t^m)$ and $(x_k^e)$ for all $t \in [k+1, d-1]$, we have: $d \cdot v_t + d \cdot c_t = n \cdot (1 - k/d) \cdot (1 - 1/d)^{t-k-1}$, therefore:

$$v_t = \frac{n}{d} \cdot (1 - k/d) \cdot (1 - 1/d)^{d-k-1} \left((1 - 1/d)^{t-d} - 1\right), \text{ for all } t \in [k+1, d-1].$$

Finally, by constraint $x_k^e$, $m_k = \frac{n \cdot k}{d} - k \cdot v_k$, and by constraint $x_t^m$, $m_t = \frac{n}{d} \cdot (1 - k/d) \cdot (1 - 1/d)^{t-k-1} - v_t$. It is easy to verify that the dual is feasible. The value of the dual objective function:

$$\begin{aligned}
k \cdot v_k + \sum_{t=k+1}^{d-1} v_t + |L_d| &= \frac{n \cdot k}{d} \cdot \left(1 - (1 - k/d) \cdot (1 - 1/d)^{d-k-1}\right) \\
&\quad + \sum_{t=k+1}^{d-1} \frac{n}{d} \cdot (1 - k/d) \cdot (1 - 1/d)^{d-k-1} \left((1 - 1/d)^{t-d} - 1\right) \\
&\quad + n \cdot (1 - k/d) \cdot (1 - 1/d)^{d-k-1} \\
&= n \cdot \tau(k, d)
\end{aligned}$$

Therefore, there is a feasible solution for the dual, with the value $n \cdot \tau(k,d)$. By weak duality, and since the primal captures the objective of the online algorithm, any online algorithm will fractionally match at most $n \cdot \tau(k,d)$ vertices. Finally, since by our construction, the optimal value is $n$, any online is at most $\tau(k,d)$ competitive as required. See discussion in [3] for applying the lower bound also on randomized algorithms. ◀

# 5 Allocation problem

We improve the competitive ratio for the *allocation problem* on $(k,d)$-graphs for $k \leq d$.

## The allocation problem

In the allocation problem, a seller is interested in selling products to a group of buyers $L = [n]$, where buyer $i \in L$ has a budget $B(i)$, and $R$ is a set of products the seller introduces one by one. Each product $j \in R$ has a fixed price $b(j)$. Upon the arrival of a product, the buyers announce to the seller whether they are interested in buying the current product for the set price. The seller then decides (instantly) which of the interested buyers to sell the product to. Using the AdWords formulation, we have $b(i,j) \in \{0, b(j)\}$ for all $i$.

For $k \geq d$, there exists a trivial online fractional solution. Assume $k \leq d$ and let $\alpha = k/d$ and $\tau(\alpha) = 1 - (1-\alpha) \cdot e^{\alpha - 1}$, we will show that there exists a $\tau(\alpha)$-competitive fractional online algorithm.

▶ **Theorem 7.** *For the fractional online allocation problem in $(k,d)$-graphs, where $\alpha = k/d$, there exists a $\tau(\alpha)$-competitive algorithm.*

Note that the upper bound of Section 4 also holds for the allocation problem; hence, the result is tight. The algorithm and analysis are similar to the upper bound in Section 4, except we use a smooth potential function $f^{(\alpha)}$.

Let $\alpha = k/d$, $\tau(\alpha) = 1 - (1-\alpha) \cdot e^{\alpha-1}$, and for a fixed alpha, set $\beta = 1/\tau(\alpha)$, and define $g(x) = 1 + \beta \cdot (\exp(x-1) - 1)$, and $f^{(\alpha)}$,

$$f^{(\alpha)}(x) = \begin{cases} g(x) & \text{for } x \in [\alpha, 1] \\ \frac{x \cdot g(\alpha)}{\alpha} & \text{for } x \in [0, \alpha), \end{cases}$$

▶ **Lemma 8.** *For $f = f^{(\alpha)}$:*

- $f(0) = 0$, $f(1) = 1$.
- *$f$ and $f'$ are continuous functions in the segment $[0,1]$, and $f, f'$ are monotone non-decreasing functions.*
- *For $x \in [\alpha, 1]$ we have $1 - f(x) + f'(x) = \beta$*

**Proof.** Clearly, $f(x), f'(x)$ are continuous functions in the segments $[0,\alpha), (\alpha, 1]$. In addition, $f_-(\alpha) = g(\alpha) = f_+(\alpha)$, so $f$ is a continuous function and

$$\begin{aligned} f'_+(\alpha) &= g'(\alpha) = \beta \cdot \exp(\alpha - 1) \\ &= \frac{\beta \cdot \alpha \exp(\alpha-1)}{\alpha} = \frac{\beta \cdot (1/\beta - 1 + \exp(\alpha-1))}{\alpha} = \frac{1 + \beta \cdot (\exp(\alpha-1) - 1)}{\alpha} \\ &= \frac{g(\alpha)}{\alpha} = f'_-(\alpha), \end{aligned}$$

therefore, $f'$ is continuous as well. And $f'(x) > 0$ for $x \in [0,1]$. Moreover, $f''(x) = 0$ for $x \in [0,\alpha]$ and $f''(x) = \exp(x-1)/\beta \geq 0$; hence, $f'$ is monotone non-decreasing. $f(0) = 0 \cdot g(\alpha)/\alpha = 0$, and $f(1) = g(1) = 1 + \beta \cdot (\exp(1-1) - 1) = 1$. Finally, for $x \in [\alpha, 1]$

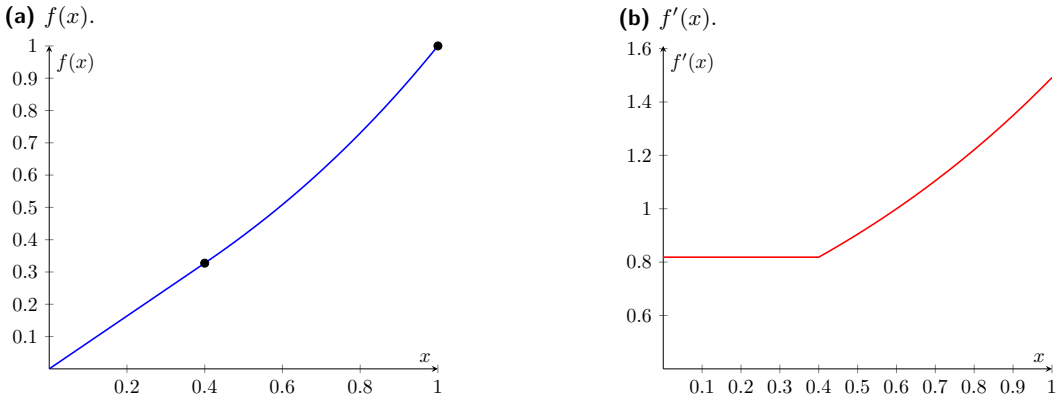


**Figure 4** The functions $f^{(\alpha)}$ and $f'^{(\alpha)}$, for $\alpha = 0.4$.

$$1 - f(x) + f'(x) = 1 - g(x) - g'(x)$$
$$= 1 - (1 + \beta \cdot (\exp(x-1) - 1)) + \beta \cdot \exp(x-1) = \beta. \quad \blacktriangleleft$$

## 5.1 The Two-Step-Water-Level Allocation algorithm

For $i \in L$, let $N(i)$ be the set of products that buyer $i$ is interested in. Let $T(i) = \frac{\sum_{j \in N(i)} b(j)}{B(i)}$ be the ratio between the sum of prices in which buyer $i$ is interested, to its budget, and let $G(i) = \sum_{j \in N(i)} b(j) \cdot x_{i,j}$ be the total gain of bidder $i$, the level of buyer $i \in L$, defined as $\ell(i) = \frac{G(i)}{B(i)}$. Accordingly, we define the degree and level after the arrival of product $j$, as $T^j(i) = \sum_{t \in N(i), t \leq j} b(t)$, and $\ell^j(i) = \frac{G^j(i)}{B(i)}$, where $G^j(i) = \sum_{t \in N(i), t \leq j} b(t) \cdot x_{i,t}$.

**Algorithm 2** The **Two-Step-Water-Level Allocation** algorithm.

Upon the arrival of a new product $j \in R$:

1. For each buyer $i \in N(j)$, such that $T^j(i) \leq k$
   Increase (if necessary) $G^j(i)$, the gain of buyer $i$, to $T^j(i)/d$
2. Using the leftover volume of product $j$:
   Increase the gain of bidders in $N(j)$ using the water-level algorithm (according to the buyer's level)
3. Update the dual variables, let $\ell(j) = \min_{i \in N(j)} \ell^j(i)$ and $\hat{\ell}(j) = \max(k/d, \ell(j))$.
   Set $y_i = f^{(\alpha)}(\ell(i))$, for $i \in N(j)$
   Set $z_j = 1 - f^{(\alpha)}(\hat{\ell}(j))$

## 5.2 The algorithm's feasibility

First, we will prove that for a proper $f^{(\alpha)}$ (for brevity's sake, we use $f$ for $f^{(\alpha)}$ for the rest of the section), the primal and the dual solutions of **Two-Step-Water-Level Allocation algorithm** (TSWLA) are feasible.

▶ **Lemma 9.** *Given a function $f : [0,1] \to [0,1]$, where $f$ is monotone, non-decreasing the primal and dual solutions of the TSWLA algorithm are feasible at the end of the algorithm.*

**Proof.** First, we will show that the algorithm does not over-allocate product $j$ in step 1. We assume that the algorithm is feasible until the arrival of product $j$, and we bound the value of $x_{i,j}$ after step 1, and we will show that $x_{i,j} \leq 1/d$, for all $i \in N(j)$. For $i \in N(j)$, by our assumption that the algorithm is feasible until the arrival of product $j$, its level before the arrival of $j$ is at least $\frac{T^j(i)-b(j)/B(i)}{d}$, by rearranging the terms $x_{i,j} \leq \frac{1}{d}$. Second, $\sum_{i \in N(j)} x_{i,j} \leq \frac{|N(j)|}{d} \leq 1$, by $d$'s definition. In the second step, the water level algorithm never increases the level above one, and, therefore, $G(i) \leq B(i)$ for all $i \in L$. We will show that for any monotone, non-decreasing function $f : [0,1] \to [0,1]$, the dual is feasible at the end of the algorithm's run. We have for all $i \in L$, $\ell(i) \geq \frac{\min(T(i),k)}{d} \geq k/d$, where the last inequality is by $k$'s definition. The dual constraints: If $\ell(j) \leq k/d$, for $i \in N(j)$, we have

$$b(j) \cdot y_i + z_j = b(j) \cdot f(\ell(i)) + b(j) \cdot (1 - f(k/d)) \geq b(j),$$

since $\ell(i) \geq k/d$ for all $i \in L$ at the end of the algorithm and $f$ is monotone, non-decreasing. If $\ell(j) > k/d$, we have,

$$b(j) \cdot y_i + z_j \geq b(j) \cdot f(\ell^j(i)) + b(j) \cdot (1 - f(\hat{\ell}(j))) \geq b(j),$$

where the first inequality is because $\ell(i)$ only increases, and $f$ is monotone, non-decreasing. ◀

## 5.3 Algorithm's competitive ratio

We are now able to complete the proof of Theorem 7. By proving that the value of the Primal is at least the $\tau(\alpha) = \frac{1}{\beta}$ times the value of the dual solution, then, by weak duality, we will conclude the TSWLA is $\tau(\alpha)$-competitive as required.

We prove it by bounding the ratio of the increment of the primal and the dual for every arrival. We denote $\Delta P(\Delta D)$ to denote the increment for the primal (dual) variable. Moreover, $\Delta D = \Delta L + \Delta R$, where $\Delta L(\Delta R)$ refers to the increment from the left side (right side). Now, we have the following key lemma:

▶ **Lemma 10.** *For every arrival of a product $j \in R$, we have $\Delta D \leq \Delta P \cdot \beta$.*

**Proof.** At every step $t$, we have $\Delta R = z_t$, $\Delta L = \sum_{i \in N(j)} \Delta L_i$, where $\Delta L_i = B(i) \cdot (y_i^j - y_i^{j-1})$

We note that, $\frac{d\Delta P_i}{dx_{i,j}} = b(j)$. Therefore, $\Delta P = b(j) \cdot \sum_{i \in N(j)} x_{i,j}$.

$$\frac{d\Delta L_i}{dx_{i,j}} = B(i) \cdot \frac{dy_i}{dx_{i,j}} = B(i) \cdot \frac{b(j)}{B(i)} \cdot f'(\ell(i)) \leq b(j) \cdot f'(\ell^j(i)) = b(j) \cdot f'(\hat{\ell}(j))$$

where the inequality is because $f'$ is a monotone non-decreasing function, and the last equality is since $f'(x) = f'(\alpha)$ for $x \in [0, \alpha]$.

Therefore, we have $\Delta L \leq b(j) \cdot f'(\hat{\ell}(j)) \sum_{i \in N(u)} x_{i,j}$
